INTRODUCTION

The kidney of vertebrates plays a major role in the homeostasis of the extracellular fluid. Despite large changes in water and salt intake, the kidney is able to maintain the extracellular osmolarity and volume within very narrow margins. Such fine control requires specific factors or hormones. In 1952, Simpson and Tait identified aldosterone as the most potent Na^+-retaining factor in mammals. When the Na^+-retaining activity of the newly identified steroid hormone was compared to that of cortisol (or corticosterone), aldosterone was found to be 3000-fold more potent *in vivo*. Aldosterone differs from cortisol (or corticosterone) by the presence of an aldehyde group in position 18 on the second ring. Thus, an apparently minimal change in the structure of the steroid confers on the molecule a strikingly different biological activity (see review in [1]). During the evolution of vertebrates, aldosterone appeared about 300 million years ago with amphibians, which were the first vertebrates to adapt to a dry, terrestrial environment.[2] The three most important and conserved functions of aldosterone are to promote Na^+ reabsorption and K^+ and H^+ secretion across certain "tight" epithelia – that is, epithelia which display a high transepithelial electrical resistance and an amiloride-sensitive, electrogenic Na^+ transport. In mammals, such epithelia are found in the distal part of the nephron, the bladder, the distal part of the intestine (mainly the surface epithelium of distal colon and rectum), and the ducts of exocrine glands (salivary, mammary, and sweat glands). In the mammalian kidney, the Na^+ and K^+ responses are localized in the segment-specific cells of the aldosterone-sensitive distal nephron (ASDN), while acid secretion is mediated via intercalated cells. The main goal of this chapter is to provide an overview on the renal tubular sites that respond to aldosterone, and to highlight the underlying cellular and molecular mechanisms by which aldosterone controls sodium, potassium, and extracellular fluid homeostasis. The chapter is revised and updated from its previous version established by our colleagues François Verrey, Edith Hummler, Laurent Schild, and Bernard Rossier that appeared in the fourth edition of this book.

The Aldosterone Sensitive Distal Nephron (ASDN)

Each day, the glomeruli of the human kidney filter about 1.5 kg of NaCl out of the blood into the primary urine. However, usually less than 1% of the filtered NaCl is finally excreted. Thus, most of it is reabsorbed along the renal tubular system, which is composed by serial arrangement of the proximal tubule (PCT and PST), the thin limb (TL), the thick ascending limb (TAL), the distal convoluted tubule (DCT), the connecting tubule (CNT), and the collecting duct (CD) (Figure 35.1). While the bulk of Na^+ reabsorption occurs in the proximal tubule (PT) and the TAL, the final regulation of Na^+ excretion takes place in the so-called Aldosterone-Sensitive Distal Nephron (ASDN) which extends from the late portion of the DCT (also called DCT-2) to the end of the collecting duct (IMCD) in the renal papilla.[3] The three ASDN segments differ in their histotopographical localization and epithelial structure. The DCT and CNT are located in the cortical labyrinth, while the CD extends from the

medullary rays in the renal cortex down to the renal medulla until its opening on the tip of the renal papilla. DCT cells have an apical localized cell nucleus and numerous mitochondria that are densely stuffed into the interdigitating basolateral membrane infoldings. The CNT cells are usually less tall than the DCT cells, have less mitochondria and a basal membranous labyrinth that is predominantly formed by membrane infoldings. The CCD cells are even smaller, and are characterized by a basal thin rim of mitochondria-free membrane infoldings. The medullary CD is formed by cuboidal cells that have few cell organelles (Figure 35.1). Membrane infoldings and mitochondrial density progressively decrease from DCT to CCD, in parallel with a reduction in the abundance and activity of the Na^+,K^+-ATPase,[4] suggesting different ion transport rates along the ASDN. In fact, recordings of transepithelial Na^+ fluxes in isolated rabbit CNTs[5,6] and rat CCDs,[7,8] indicate at least a 10-fold higher Na^+ transport rate in the CNT than in the CCD (600–120 versus 0.2 to 24 pmoles Na^+/min/mm). The rates of Na^+ transport in OMCD and IMCD are generally low,[9] but Na^+ channels are also expressed in the OMCD and IMCD, and can be activated, at least to some extent, by aldosterone.[10]

Although the sequence of tubule portions appears to be quite similar in mammals, subtle species differences in the structural and functional organization of the ASDN have to be taken into account if functional data from different nephron portions and species are compared.[11] For example, rabbits have morphologically well-defined sharp transitions from DCT to CNT and from CNT to CD, while the segment transitions in rats, mice, and humans are gradual. These morphological differences are reflected by the distribution pattern of ion- and water-transporting proteins. In rabbits, the sharp transitions from DCT to CNT and from CNT to CCD coincide with the immediate replacement of the DCT-specific NaCl co-transporter (NCC) by the epithelial Na^+ channel (ENaC), and the abrupt onset of aquaporin-2 (AQP2) expression.[12] In contrast, in rats, mice, and humans NCC and ENaC overlap in the late DCT (DCT2), and AQP2 extends into the connecting tubule.[11,13]

Despite the above-mentioned segmental and species differences, all ASDN cells in common express high levels of the mineralocorticoid receptor (MR), the glucocorticoid receptor (GR), the enzyme 11-beta-hydroxysteroid-dehydrogenase type 2 (11β-HSD2), and the epithelial Na^+ channel (ENaC)[3] (Figure 35.2). The MR and the GR are hormone-activated transcription factors that can bind both mineralocorticoid and glucocorticoid hormones, although with different affinities. While the MR is a high-affinity receptor (K_d for

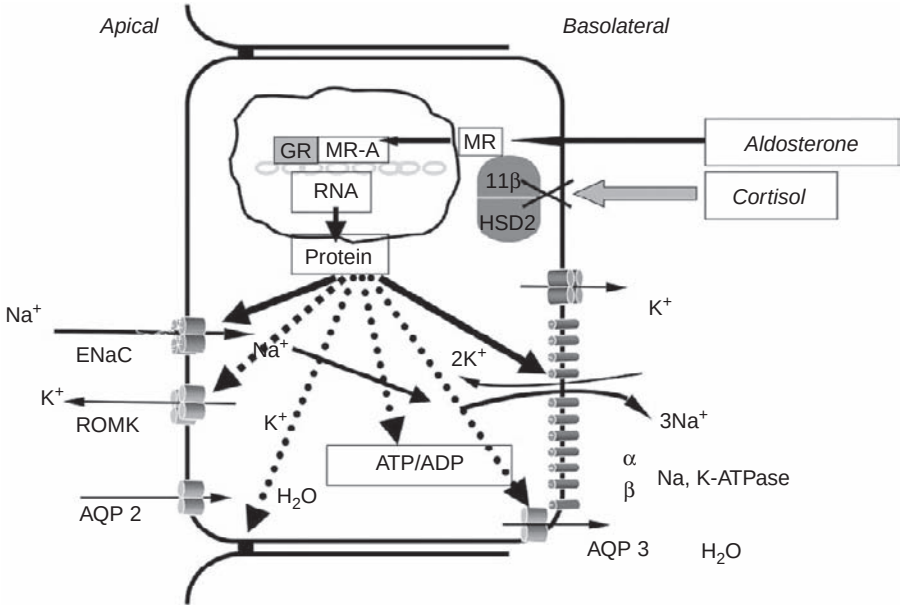

FIGURE 35.2 **Model of the mechanism of aldosterone action in an epithelial target cell.** Aldosterone crosses the plasma membrane and binds to its high affinity mineralocorticoid receptor (MR) and/or the low affinity glucocorticoid receptor (GR). Cortisol is metabolized by the 11βHSD-2 into inactive metabolites with a very low affinity for MR and GR. The complex translocates to the nucleus, where it undergoes interaction with promoter regions of target genes, activating or repressing their transcriptional activity. Induced or repressed proteins mediate an increase in transepithelial sodium transport by the activation of pre-existing transport proteins (ENaC, Na,K-ATPase), and a further accumulation of transport proteins and other elements of the sodium transport machinery. Possible effects on ROMK, tight junction proteins, mitochondria, and water transport proteins (AQP 3) are indicated with dotted arrows. *(From Verrey, F., Hummler, E., Schild, L., and Rossier, B. C. (2008). Mineralocorticoid action in the aldosterone-sensitive distal nephron. In "Seldin and Giebisch's The Kidney," Vol. 1, 4th edn., 889–924. Elsevier Inc.)*

aldosterone and cortisol in the range from 0.5 to 3 nM), the GR has a more than 10 times lower affinity for these steroids (K_d in the range from 20 to 65 nM).[14] The corticosteroid levels in the plasma (cortisol in humans and corticosterone in rats) are usually far above these K_d values, and exceed the plasma concentrations of aldosterone 100–1000-fold. Under these conditions, mineralocorticoid specificity is thought to be conferred to the ASDN cells by their high expression of 11β-HSD2 that rapidly hydrolyzes the physiological corticosteroids to inactive metabolites.[15] Upon hormone binding, the receptors are thought to homo- or heterodimerize and to translocate to the cell nucleus, where they modulate a transcriptional program that modulates the expression of ENaC, the Na^+,K^+-ATPase, and of regulatory proteins that control the activity of these Na^+-reabsorbing proteins.

Na^+ transport across the ASDN cells occurs in two steps. Na^+ uptake from the lumen into the cells is mediated by ENaC, while Na^+ exit across the basolateral plasma membrane depends on the Na^+,K^+-ATPase. The activity of ENaC and the Na^+,K^+-ATPase is electrogenic, and generates a transepithelial electrochemical gradient that drives paracellular Cl^- reabsorption and transcellular K^+ secretion. The apical K^+ secretion is thought to occur via secretory K^+ channels such as the renal outer medulla K^+ channel (ROMK) and the flow-dependent maxi-K (BK) channel.[16–19] Immunohistochemical studies revealed that ROMK is highly abundant in the DCT, CNT, and CD cells,[20,21] where it becomes activated and redistributed to the apical plasma membrane in response to an increased dietary K^+ intake.[22] Likewise, a high-K^+ diet appears to stimulate the BK channel. In rabbits, it increases the mRNA expression of the α-, β2-, and β4-subunits,[23] and in rats it elevates the electrical activity in CCD cells.[24] In contrast to ROMK, the BK channel is not only present in the segment-specific ASDN cells, but also in intercalated cells.[17] Intercalated cells may not only secrete but also reabsorb K^+ via their apical H^+,K^+-ATPase.[25] Thereby, intercalated cells may help to modulate the interdependence of ENaC-mediated Na^+ reabsorption and K^+ secretion via apical K^+ channels. A close link between the function of intercalated and segment-specific ASDN cells is also indicated by the fact that, in all species investigated so far, the appearance of intercalated cells in the early ASDN coincides precisely with the onset of functional ENaC expression.[11] Moreover, several recent studies on various rodent models further supported the idea of a functional cooperation between ASDN and intercalated cells. The ASDN has at least two types of intercalated

cells.[26,27] The acid-secreting type-A intercalated cells have the vacuolar H^+-ATPase in the apical plasma membrane and the Cl^-/HCO_3^- anion exchanger AE1 in the basolateral plasma membrane, whereas the bicarbonate-excreting type-B intercalated cells have the H^+-ATPase in the basolateral plasma membrane, and are characterized by the abundance of the Cl^-/HCO_3^- exchanger pendrin in the apical membrane, which may contribute to a combined transcellular reabsorption of Na^+ (via ENaC) and Cl^- (via pendrin). In fact, experiments in pendrin-deficient mice indicated that bicarbonate secretion via the type-B intercalated cells is necessary for normal ENaC expression and activity.[28,29] Consistent with this view, the mice are prone to develop arterial hypotension when placed on an NaCl-deficient diet, and they are protected from hypertension under mineralocorticoid treatment.[30,31] Pendrin may not only cooperate with ENaC, but also with the Na^+-dependent chloride-bicarbonate exchanger SLC4A8,[32] which may account for the previously reported thiazide-sensitive NaCl reabsorption in the renal collecting system. Experiments in SLC4A8- and NCC-deficient mice indicated that about 40–70% of collecting duct Na^+-absorption involve SLC4A8.[32] Similar to ENaC, the thiazide-sensitive electroneutral Na^+ reabsorption, as well as SLC4A8, appear to be stimulated by aldosterone.[27] Na^+ reabsorption via ENaC may not only interfere with K^+, H^+, and Cl^- handling of the ASDN cells, but also with transepithelial water reabsorption. The ENaC activity generates an osmotic gradient that likely favors the vasopressin-dependent transepithelial water reabsorption via the water channels AQP2 in the apical and AQP3 and AQP4 in the basolateral plasma membrane of the segment-specific ASDN cells. Although there are some indications that aldosterone directly controls the expression and activity of ROMK,[33–35] BK,[36] pendrin,[31,37] SLC4A8,[32] AQP2,[38,39] and AQP3,[40] the functional significance of these regulations compared with the indirect effects mediated via enhanced activity of ENaC and Na^+,K^+-ATPase are still unclear. Nevertheless, the various cell types and ion transport pathways with manifold possible interactions likely contribute significantly to the complexity of ion handling along the ASDN which may allow adaptation of urinary ion excretion precisely to homeostatic needs. Details on the regulation of K^+ channels, pendrin, SLC4A8, and aquaporins are given in several excellent recent reviews.[16,17,26,27,37,41–43]

Aldosterone Action in Non-ASDN Cells

A huge variety of studies have been aimed at localizing MR and GR along the mammalian nephron. Ligand-binding studies and RNAase protection assays on microdissected nephron portions, as well as autoradiography, *in situ* hybridization and immunohistochemistry on kidney sections, revealed a very high abundance of MR and GR along the classical ASDN.[44] Moreover, these studies indicated that the MR, the GR, and 11β-HSD2 are expressed in nephron segments and cell types that are considered not to be classical targets for aldosterone, including glomerular mesangial cells, podocytes, and proximal tubules (reviewed in [15]). Using a set of highly specific MR antibodies,[45] Ackerman et al. recently confirmed that the MR is expressed along the entire distal tubule, including the TAL and the entire DCT.[46] MR expression in the TAL is in line with studies describing a profound stimulatory effect of aldosterone on TAL Na^+ transport,[47] but contrasts with other reports that did not reveal any effect of the mineralocorticoid on the expression and activity of the Na^+,K^+-ATPase and K^+ transport in the TAL of adrenalectomized rabbits and rats, respectively.[48–50] Likewise, there is considerable evidence that aldosterone stimulates NaCl co-transport in the DCT. Velazquez et al. demonstrated that adrenalectomy lowers the electroneutral Na^+ transport activity (corresponding to NCC activity) in the DCT, and that this effect can be fully restored to normal when aldosterone and/or glucocorticoids are replaced.[51] Consistent with a stimulatory role of aldosterone on the DCT, immunoblotting and immunohistochemistry on rat kidneys showed that dietary Na^+ restriction, which stimulates endogenous aldosterone production, as well as exogenous aldosterone application, increases the abundance and phosphorylation of NCC in the DCT.[52–56] Frindt and Palmer used *in vivo* cell surface biotinylation to show in the rat that dietary Na^+ restriction does also increase the cell surface abundance of NCC.[57] Conversely, dietary Na^+-loading removes NCC from the plasma membrane, indicating that aldosterone may affect the trafficking of NCC as well.[58] Interestingly, the increase in NCC protein abundance and phosphorylation was significantly lower when MR was blocked by spironolactone.[53,59] Although the effect of spironolactone points to an MR-mediated transcriptional response, changes in plasma aldosterone do not appear to directly affect NCC mRNA expression, indicating that mineralocorticoids elicit their effects on NCC abundance via enhanced translation and/or reduced degradation of the protein.[55] In fact, there is increasing evidence that NCC protein abundance might be controlled by ubiquitylation, and hence by altered protein stability.[60–63] Aldosterone is also known to stimulate renal H^+ excretion. The intercalated cells in the ASDN play an important role for renal acid–base handling. However, so far it is unclear whether aldosterone directly affects renal acid

secretion via activation of the H^+-ATPase in intercalated cells or indirectly via activation of ENaC-dependent Na^+ transport in principal cells, which increases the electrochemical driving force for H^+secretion by intercalated cells. Functional studies on isolated collecting ducts indicated that aldosterone rapidly stimulates intercalated cells via non-genomic pathways that may involve PKC and PKA signaling,[64] and perhaps require the vasopressin V1 receptor.[65] Nevertheless, it is uncertain whether the observed effects depend on a yet-unknown putative membrane-bound corticosteroid-binding receptor or the classical MR. Although expression of the MR in intercalated cells was long disputed, a recent immunohistochemical study established rather strong expression of the MR, not only in the ASDN segment-specific cells, but also in all subtypes of intercalated cells.[46] However, this study did also provide evidence that the rather low expression levels of the 11β-HSD2 in TAL, early DCT, and intercalated cells, makes it unlikely that aldosterone has significant direct genomic effects on these cell types in the physiological context of several-fold higher plasma levels of corticosterone than aldosterone. Nevertheless, mineralocorticoid-selectivity might be conferred to the MR also in an 11β-HSD2-independent way by a functional preference of the receptor to aldosterone, as indicated in cell culture assays[66] and *in vivo* experiments.[67] Moreover, MR expression in TAL, early DCT, and intercalated cells may become relevant in patients with pharmacological (e.g., by spironolactone) or genetic (i.e., PHA-1) MR inactivation. Under these conditions, the loss of MR function in these cells may contribute to the salt-losing phenotype with hyperkalemia and metabolic acidosis.[68]

SODIUM TRANSPORT REGULATION BY ALDOSTERONE: PHYSIOLOGICAL AND BIOPHYSICAL MECHANISMS

Epithelial Na^+ transport is a two-step process that comprises: (1) facilitated transport – driven by an electrochemical potential difference – across the apical membrane (from urine to cell); and (2) active transport – driven by metabolic energy – across the basolateral membrane (from cell to interstitium).[69] In the ASDN, the apical-membrane entry step is mediated by Na^+-selective amiloride-sensitive ion channels,[70] while the exit step is catalyzed by Na^+, K^+-ATPase, the ouabain-sensitive Na^+ pump.[71,72] The aldosterone-dependent electrogenic transepithelial Na^+ transport has been studied in a great variety of *in vitro*, *ex vivo*, and *in vivo* models.[73,74] The different models revealed different baseline and maximal transport rates in response to aldosterone. In the *toad urinary bladder*, "basal" transport rates, measured by the short-circuit current method, are around 5–10 $\mu A/cm^2$[75] and aldosterone produces a 2- to 5-fold increase in transport. In the *rat colon*, basal transport rates through amiloride-sensitive channels are very low, while tissues stimulated *in vivo* by adrenal steroids can have rates of 500–1000 $\mu A/cm^2$.[76] *Isolated, perfused rat cortical collecting ducts* express no measurable net Na^+ fluxes when the animals are maintained on normal diets. When animals are placed on a low-Na^+ diet (to elevate endogenous aldosterone levels) or injected with mineralocorticoids, Na^+ reabsorption is as high as 30 pmoles/min-mm, which corresponds to ~100 $\mu A/cm^2$.[7,8] These values match well the amiloride-sensitive current measured by cell attached patches of mouse CCD cells.[77]

Aldosterone and the Epithelial Sodium Channel ENaC

The apical entry of Na^+ involves the low conductance, highly selective (Na^+ over K^+), and amiloride-sensitive epithelial Na^+ channel[78,79] (ENaC). ENaC was cloned from rat distal colon by functional expression in *Xenopus* oocytes. The channel is composed of three homologous subunits denoted α-, β-, and γ-EnaC, which share 30 to 40% identity at the level of their amino acid sequences. In addition to these three well-characterized ENaC subunits, a fourth EnaC subunit, δ-ENaC, has been cloned from a human kidney cDNA library.[80] However, this subunit has been described so far only in humans, and its relevance for transepithelial Na^+ reabsorption in the ASDN is unclear. When the three classical α-, β-, and γ-ENaC subunits are co-expressed in *Xenopus laevis* oocytes, the subunits form a channel with functional characteristics similar to the channel identified by Palmer in the rat CCD, with a low 5 pS conductance (for Na^+), a high selectivity ratio of Na^+ over K^+ (>20), and a high sensitivity for amiloride with a K_i in the submicromolar range. In the *Xenopus* oocyte expression system, the co-expression of all three ENaC subunits is required for maximal cell surface abundance and activity of the channel.[81] The subunit stoichiometry of the active channel is not finally resolved. Various technical approaches suggested models with four, eight or nine subunits.[82] Recently, the crystal structure of the closely related acid-sensing ion channel isoform $ASIC1_A$ has been reported, and points to a trimeric oligomerization of the channel.[83,84] However, this trimeric model still awaits further confirmation by establishing the crystal structure of ENaC itself.

ENaC is expressed in several organs including the kidney, the colon, the salivary and sweat glands.

ENaC-mediated Na^+ transport helps to adjust Na^+ excretion in the urine, feces, and sweat. In lung and airways, ENaC activity is important for alveolar liquid clearance and regulation of mucous fluidity. In the taste buds of the tongue, ENaC is likely involved in salt tasting, whereas ENaC expression in the eye and inner ear may help to control the ionic composition of the aqueous humor and the endolymph, respectively.[82] In the kidney the distribution of ENaC is fully compatible with its involvement in aldosterone-dependent Na^+ transport. Morphological and functional studies on rodent and human kidneys[11,13] clearly showed that the ENaC subunits are highly abundant along the entire ASDN, starting in the late DCT (DCT2), and extending through the CNT down to the medullary CD. In the ASDN cells, increased plasma aldosterone levels induced either by dietary Na^+ restriction or by exogenous application appear to stimulate ENaC mainly by three mechanisms. First, aldosterone increases the abundance of the α-ENaC mRNA and protein, without much affecting the mRNAs encoding for the β- and γ-subunits.[85–87] In contrast, the β- and γ-subunit mRNAs are upregulated in the colon by aldosterone, while the α-subunit mRNA is expressed constitutively.[85,86,88] Second, aldosterone induces the appearance of low molecular weight forms of α- and γ-ENaC, which are thought to represent proteolytically activated channel subunits.[89–91] Recently, Frindt and co-workers performed cell surface biotinylation experiments on rat kidneys perfused with biotin *in situ*. These experiments showed that feeding a low-Na^+ diet or the infusion of aldosterone for one week increases the cell surface pool of cleaved α- and γ-ENaC, but not β-ENaC subunits at the cell surface.[92] Third, aldosterone causes a redistribution of ENaC channel subunits from intracellular storage compartments to the apical plasma membrane. In fact, the subcellular localization of ENaC along the axis of the ASDN changes drastically with altered plasma aldosterone levels in response to altered dietary Na^+ intake.[90,93] In rodents kept under a high dietary Na^+ intake with low plasma aldosterone levels, ENaC subunits are barely detectable at the luminal membrane, and are found almost exclusively at intracellular sites. On a standard dietary Na^+ intake with moderate plasma aldosterone levels, ENaC subunits are traceable at the luminal membrane in the late DCT and the early CNT, but in downstream segments (i.e., late CNT and CD), particularly β- and γ-ENaC are found almost exclusively at intracellular sites.[93] Only the α-EnaC-subunit was reported to have a more pronounced apical localization and can be found at the apical plasma membrane in CNT and CD.[94] In response to dietary Na^+ restriction, the apical abundance of ENaC subunits drastically increases due to a translocation of channel subunits from intracellular compartments to the apical plasma membrane.[59,90,93,95,96] Nevertheless, the axial gradient for apical ENaC prevails, and the apical localization of ENaC subunits remains more prominent in early ASDN than in late ASDN.[12,97] The activation and apical translocation of ENaC occurs rapidly (within hours), suggesting that they are relevant for the renal adaptation to day-to-day variations of Na^+ intake.[3,89,98] Likewise, injection of aldosterone in adrenalectomized rats induces a rapid (within 2 hours) induction of α-ENaC-subunit expression along the ASDN which is followed by a translocation of all three ENaC subunits to the apical plasma membrane (Figure 35.3). Again, the apical shift occurs predominantly in the early and not in the late ASDN, although the induction of α-ENaC was seen to be similar along the entire segment.[3] Based on previous studies in *Xenopus laevis* A6 cells, it has been proposed that the induction of α-ENaC might be a prerequisite for full assembly of ENaC in the ER and its subsequent delivery to the cell surface.[99] However, in the kidney *in vivo* the induction of α-ENaC protein by aldosterone is rather small[90] and, at least in the CCD, not necessarily followed by an apical redistribution of all three ENaC subunits.[3] Moreover, apical targeting of ENaC apparently occurs even without previous α-ENaC induction.[100] Likewise, when ENaC activity was assessed as whole-cell amiloride-sensitive current, ENaC activity in rat CCD was drastically increased within 15 hours of salt restriction, and thus in a timeframe in which no changes in the abundance of ENaC mRNA or protein could be detected.[89] Thus, the induction of α-ENaC alone cannot account for the apical targeting of ENaC. Other co-stimulatory factors are needed. One of these factors was proposed to be the serum- and glucocorticoid-regulated kinase (Sgk1). Sgk1 is a member of the PKB/Akt family of serine/threonine kinases, and is rapidly induced by aldosterone in ASDN model epithelia *in vitro*, as well as in the kidney *in vivo*.[3,101–103] Likewise, prolonged dietary Na^+ restriction increases Sgk1 mRNA expression in the kidney.[104] Co-expression of ENaC with Sgk1 in heterologous expression systems profoundly increases ENaC-mediated Na^+-currents, most likely by an accelerated insertion-rate of ENaC into the plasma membrane.[105] Consistently, the induction of Sgk1 by aldosterone precedes the apical translocation of ENaC in ASDN cells *in vitro* and Sgk1-deficient mice (Table 35.1) show mild urinary Na^+-wasting that becomes aggravated on dietary Na^+ restriction.[106] At least part of the effects of Sgk1 on ENaC cell surface abundance is mediated by an Sgk1-dependent phosphorylation of the ubiquitin-protein ligase Nedd4-2. Nedd4-2 phosphorylation blocks the interaction of this ligase with the C-terminus of ENaC subunits, and thereby presumably prevents

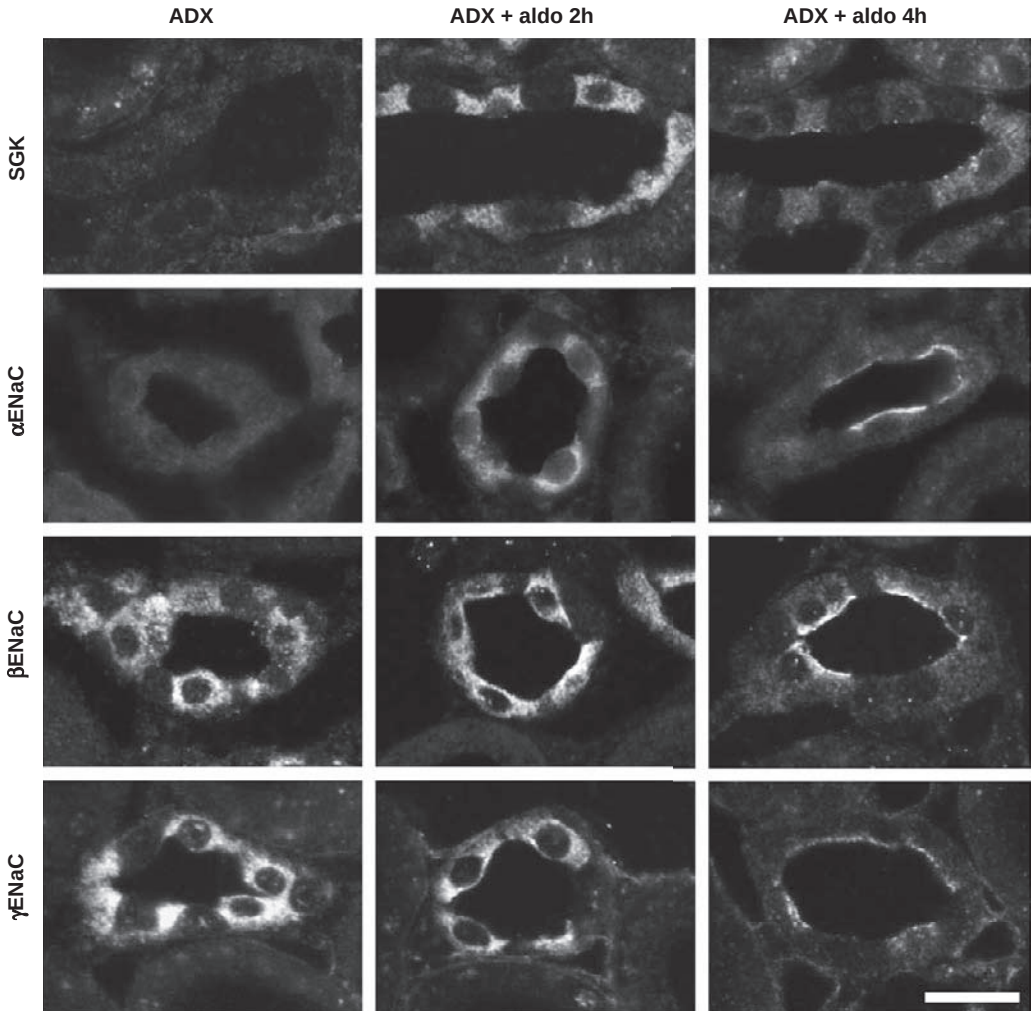

FIGURE 35.3 **CNT profiles in kidney from ADX rats, 2 and 4 hours after aldosterone injection.** Immunofluorescence with rabbit antisera against α-, β-, and γ-ENaC, and the serum-and-glucocorticoid-induced kinase (SGK1) on cryostat sections is shown. Unstained cells in the CNT epithelium are intercalated cells. Aldosterone induces a rapid induction of SGK1 and α-ENaC (at 2 hours) that precedes the apical translocation of all three ENaC subunits from intracellular sites towards the apical plasma membrane (at 4 hours). *(Adapted from Loffing, J., et al. (2001).[3])*

Nedd4-2-induced ubiquitylation and subsequent endocytosis and degradation of ENaC subunits.[107–109] Interestingly, immunohistochemical studies showed that the Nedd4-2 abundance increases along the ASDN, which is inverse to the axial gradient of apical ENaC abundance, and further supports the idea that Nedd4-2 is a negative regulator of ENaC cell surface abundance.[110]

Patch-clamp studies corroborated the immunohistochemically traceable axial gradient of the apical localization of ENaC.[111] The ASDN segments isolated from rats kept on a standard lab chow exhibited no amiloride-sensitive currents at the single channel level, whereas CNTs and CDs isolated from rats with elevated plasma aldosterone levels revealed significant single channel ENaC currents (Figure 35.4). Mice appear to have sizeable ENaC whole-cell currents already on a standard diet, which further increase when animals are kept on low dietary Na^+ intake.[112] In general, amiloride-sensitive currents decrease in the following order: CNT > initial CD > CD.[113] These findings on apical ENaC localization and activity are consistent with previous studies on microperfused rat tubules,[7] and on isolated rabbit tubules[5] that established several times higher Na^+ transport rates in early ASDN (i.e., DCT and CNT) than in further downstream ASDN segments (i.e., CD). The axial gradient of ENaC also parallels the progressive decrease of the basolateral Na^+,K^+-ATPase activity along the ASDN.[4] Taken together, these data clearly indicate that the aldosterone-dependent adaptation of renal Na^+ excretion to dietary Na^+ intake occurs through ENaC, predominantly in the early ASDN, while the late ASDN gets recruited only under high plasma

TABLE 35.1 Transgenic Mouse Models Used to Elucidate Mechanisms of Aldosterone-Dependent Sodium/Potassium Transport

Strain	Phenotype	References

γ-ENaC − / −	Severe PHA-1	135

aldosterone levels. Using whole-cell current data, and considering the anatomical length of the two segments, Frindt and Palmer estimated that the Na^+ transport capacity of the CNT is at least 10 times higher than that of the CD.[113]

The importance of the early ASDN versus late ASDN for the maintenance of Na^+ balance was highlighted by the development of a mouse model with targeted inactivation of α-ENaC in the collecting duct.[95] These mice survive well and are able to maintain Na^+ and K^+ balance, even when challenged by salt restriction or K^+-loading (Figure 35.5a). Moreover, these mice show a normal urinary acidification in response to furosemide and thiazide treatment,[114] suggesting that functional expression of ENaC in the CNT is sufficient for maintaining ion homeostasis. In contrast, mice with targeted inactivation of α-ENaC in CD and CNT show symptoms of renal salt-wasting (Figure 35.5b). Already under control conditions, the mice have significantly higher urinary Na^+ excretion and increased plasma aldosterone levels. With dietary Na^+ restriction, the mice start to decompensate and exhibited at day 15 a more than 12% reduction in body weight and exceedingly high plasma aldosterone levels (~20,000 pg/ml in knockout

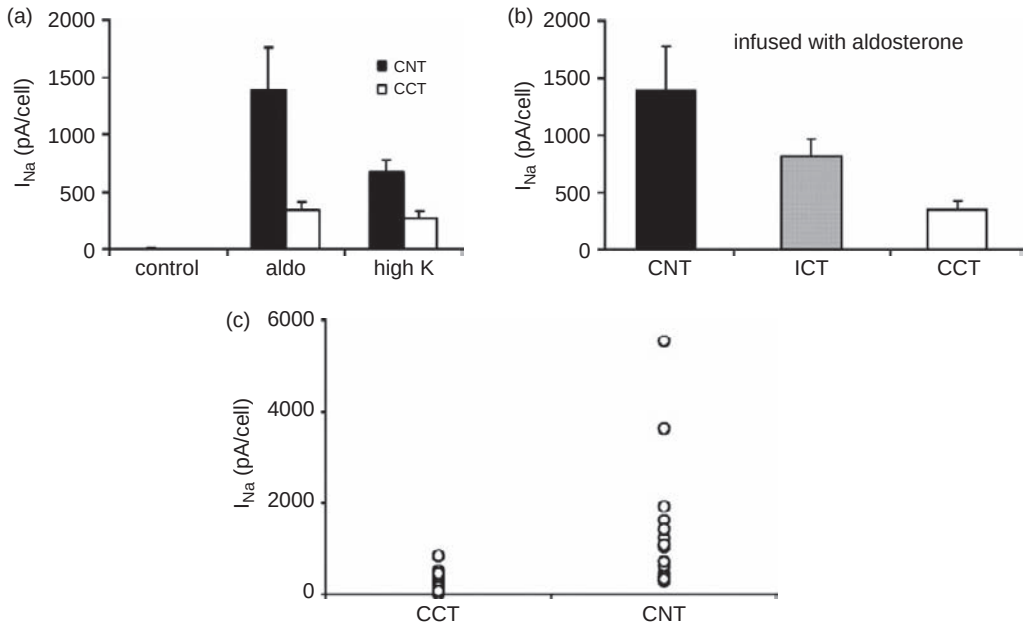

FIGURE 35.4 **Sodium transport in CNT and principal cells of the ASDN (I_{Na}).** (a) I_{Na} in CNT and cortical collecting tubule (CCT) of control rats fed a normal (control) diet, aldosterone treated rats fed a normal diet or rats fed a high-K diet. (b) I_{Na} in cells of CNT, initial collecting tubule (ICT), and CCT of aldosterone-treated rats. (c) Individual values of I_{Na} in CCT and CNT cells of aldosterone-treated rats. *(From Frindt, G., and Palmer, L.G. (2004).[113])*

mice versus ~1200 pg/ml in control mice). Moreover, the mice show hyperkalemia, that worsens with dietary K^+-loading. Furthermore, the mice are polyuric, consistent with the idea that ENaC is important not only for renal Na^+ and K^+ handling, but also for the control of water reabsorption.[115]

Similar to this CNT and CD α-ENaC knockout model, mice with targeted deletion of the MR in the CD and CNT, but intact MR expression and ENaC regulation in early CNT and DCT2, show impaired Na^+ balance (Figure 35.6). Although these mice develop normally under a standard diet, they continuously lose body weight and show signs of severe extracellular volume contraction under a low-Na^+ diet.[116] These studies did also show that the MR is crucial for the increased expression of αENaC and apical targeting of all three ENaC subunits in response to dietary Na^+ restriction. Interestingly, these observations in mice with genetic deletion of the MR contrast with findings in rodents with pharmacological inhibition of the MR. In rats, blockade of the MR by spironolactone does not prevent the apical translocation of ENaC in response to dietary Na^+ restriction.[100] Likewise, the combined inhibition of the MR and GR by spironolactone and RU486 does not block the induction of αENaC and ENaC trafficking induced by aldosterone-infusion.[117] Together with the observation that the severe symptoms of pseudohypoaldosteronism in MR-deficient mice can be improved by glucocorticoid treatment,[118] and that mice with CNT/CD-specific MR-deficiency have a milder phenotype than mice with CNT/CD-specific deletion of αENaC, the data point to some redundancies in the MR and GR-dependent signaling pathways that control ENaC function.

ENaC-Related Genetic Diseases Underline Pathophysiological Relevance

The discovery that rare monogenic diseases caused by mutations in the genes encoding the ENaC subunits cause defects in the control of Na^+ balance and blood pressure provided direct evidence for the implication of this channel in these processes.[119] Remarkably, these diseases represent on the one hand, a gain-of-function phenotype (Liddle's syndrome), and on the other hand a loss-of-function disease (pseudohypoaldosteronism type I or PHAI).

LIDDLE'S SYNDROME

Liddle's syndrome is a rare disorder (pseudoaldosteronism) described first by G. W. Liddle in a family in which multiple siblings had early onset of severe hypertension associated with hypokalemia.[120] Urinary excretion of aldosterone was low in these patients, and no effects of spironolactone on blood pressure could be demonstrated. By contrast, administration of the Na^+ channel-blocker triamterene, together with restriction of salt intake, tended to normalize blood pressure. These clinical features suggested that hypertension was due to excessive aldosterone-independent Na^+ reabsorption in the distal nephron, due to the constitutive

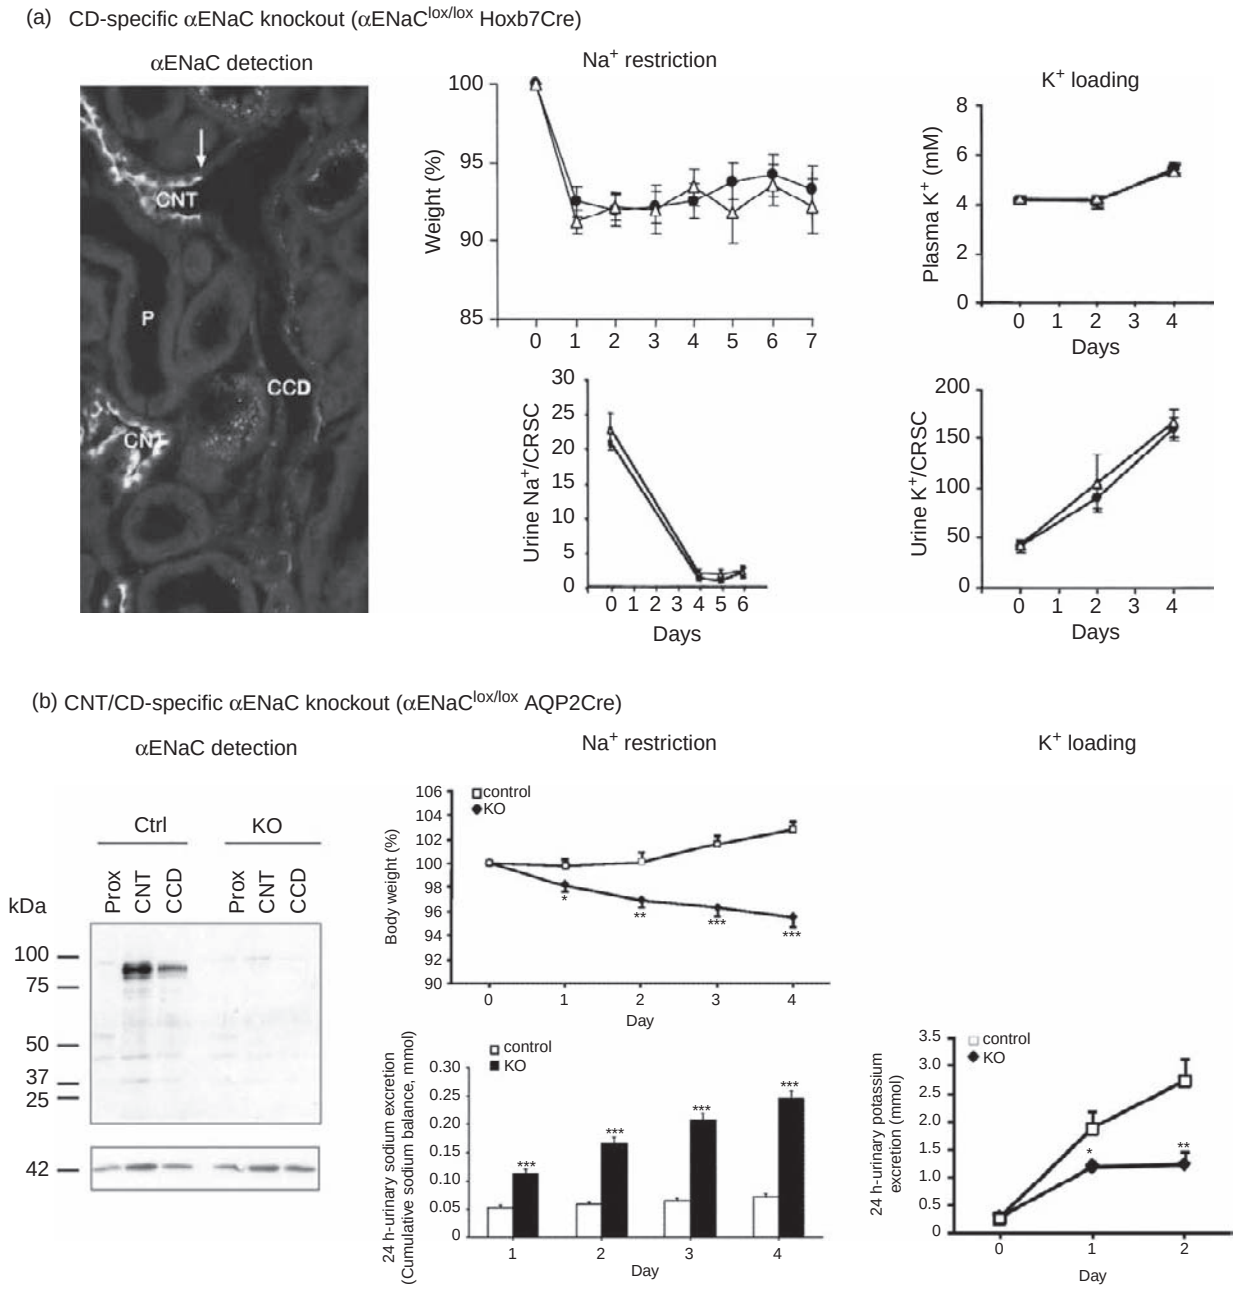

FIGURE 35.5 **Different phenotype of mice with targeted deletion of α-ENaC in the CD only (a) or in the CD and CD (b).** Left panels (a) and (B): Detection of α-ENaC by immunohistochemistry (a) or immunoblotting (b) confirms the efficient deletion of α-ENaC in the targeted segments in the mouse models. Middle panels (a) and (b): On dietary Na^+ restriction, $MR^{lox/lox}$ Hoxb7Cre mice do not lose more body weight than control mice, while $MR^{lox/lox}$ AQP2Cre mice lose more body weight than controls. Moreover, $MR^{lox/lox}$ AQP2Cre mice do not retain Na^+ from the urine as efficently as control mice. Right panels (a) and (b): $MR^{lox/lox}$ Hoxb7Cre mice tolerate dietary K^+-loading without any differences from control mice with respect to plasma K^+ levels and fractional urinary K^+ excretion. In contrast, $MR^{lox/lox}$ AQP2Cre mice become hyperkalemic (Serum K^+ 7.7 ± 0.8 mM vs. 5.2 ± 0.2 mM in controls) and excrete less K^+ with their urine than control mice. *(Adapted from (a) Rubera, I., et al. (2003).[95]; and (b) from Christensen, B. M., et al. (2010)[115].)*

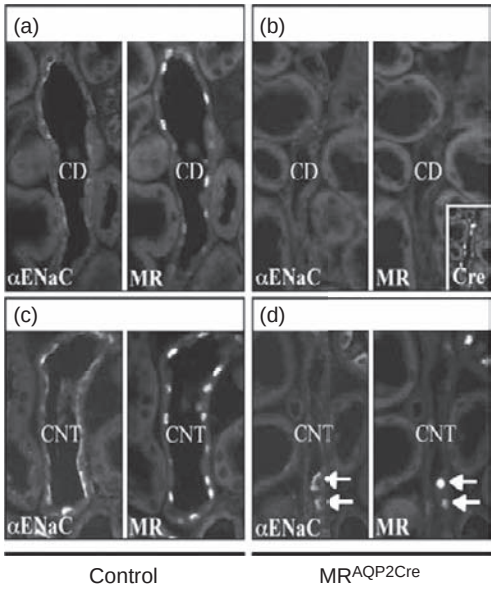
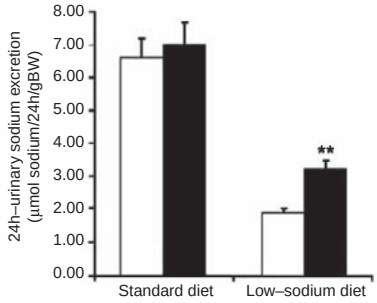
activation of ENaC. Despite the low plasma aldosterone in these patients, they still responded to aldosterone injections by further decreasing their renal Na^+ excretion.

The pedigree of the original kindred described by Liddle was in the meantime extended, clearly demonstrating the autosomal dominant inheritance of the disease.[121] A candidate gene approach was used to





Diet	Plasma Aldosterone (pg/ml)	
	Controls	$MR^{AQP2Cre}$
Standard	430 ± 82 (7)	5195 ± 701 (11)[b]
Low-sodium (3 d)	1083 ± 154 (10)[c]	10500 ± 990 (9)[b,c]
Low-sodium (10 d)	3167 ± 423 (3)[c]	19719 ± 1667 (8)[b,c]

FIGURE 35.6 **Renal sodium wasting in transgenic mice with CNT- and CD-specific deletion of the MR (MR^{AQPcre} mice).** (a)–(d) Immunofluorescent detection of α-ENaC and MR in collecting ducts (CD) and connecting tubules (CNT) of control mice and of MR^{AQPcre} mice kept for 10 days on a low-NaCl diet. Deletion of the MR goes along with a loss of detectable α-ENaC levels. In only a few CNT cells with inefficient MR-targeting, does α-ENaC remain detectable at the cell surface (arrows). Insert in panel (b) shows expression of the Cre recombinase in the CCD of the transgenic mouse. While the rate of urinary Na^+ excretion does not differ between the groups on a standard diet, MR^{AQPcre} mice cannot lower their urinary Na^+ excretion as efficiently as control mice when kept for 9 days on dietary Na^+ restriction (white bars: control mice; black bars: MR^{AQPcre} mice). Consistent with mild pseudohypoaldosteronism type 1, MR^{AQPcre} mice have higher plasma aldosterone levels than control mice on standard and low-sodium diets. *(Adapted from Ronzaud, C., et al. (2007).[116])*

identify mutations causing this rare Mendelian form of hypertension.[122] Complete linkage of the Liddle's syndrome to a locus encoding the β-subunit of ENaC, and analysis of the β gene revealed various mutations in the cytoplasmic C-terminus: deletion or frameshift mutations leading to truncation of a major portion of the C-terminus; and missense mutations in a highly-conserved proline-rich domain.[122–124] A deletion of the C-terminus in the γ-subunit has also been identified as a cause of Liddle's syndrome, whereas no mutations in the α-subunit have been linked to this disorder.[125] Expression of these β- and γ-ENaC variants, together with α-subunits in the *Xenopus* oocyte system, revealed a significant increase in ENaC channel activity at the cell surface, consistent with the initial postulate that these hyperactive channel mutants lead to an excessive Na^+ reabsorption and hypertension.[126]

To elucidate the causal relationship between dietary salt intake, genetically-determined salt handling by the kidney, and hypertension, a mouse model for Liddle's syndrome was developed by introducing the R566stop mutation at the β-ENaC allele ("knockin" strategy).[127] Interestingly, with a normal-salt diet, mice carrying the β-ENaC mutated L/L allele remain normotensive, despite evidence of hypervolemia and increased Na^+ reabsorption in the large intestine. Moreover, plasma pH, Na^+, K^+, Cl^- or HCO_3^- concentrations were not significantly affected.[127] However, these mice manifested the classical Liddle's phenotype with higher blood pressure, metabolic alkalosis, and hypokalemia, accompanied by cardiac and renal hypertrophy in response to a high-salt diet. Moreover, evidence for impaired ENaC internalization was demonstrated *in vivo*, as the increase in urinary Na^+ excretion upon short time (6–12 hours) salt repletion following 1 week of a low-salt diet is significantly delayed in Liddle mice, despite the presence of lower circulating aldosterone concentrations.[128] Isolated perfused CCDs from Liddle mice exhibit higher transepithelial potential differences, and confluent primary cultures of CCDs microdissected from their kidneys exhibit significant lower transepithelial electrical resistance and higher negative potential differences, consistent with an overall increased ENaC activity.[128] Interestingly, mineralocorticoid upregulation of ENaC expression and function is still maintained in Liddle mice that show a remarkable high sensitivity to aldosterone *in vitro*[129] and *in vivo*.[77] Renal CD cells from Liddle mice exhibit hyperactive apical vasopressin-regulated CFTR Cl^- conductance that could contribute to the enhanced NaCl reabsorption observed in the distal nephron of patients with Liddle's syndrome. In

summary, in the Liddle mouse, dysfunction of ENaC in the kidney is demonstrated before onset of arterial hypertension that argues in favor of the kidney hypothesis proposed by Liddle.[120]

PSEUDOHYPOALDOSTERONISM TYPE 1

Pseudohypoaldosteronism type 1 (PHA-1) is characterized by dehydration, hyponatremia, hyperkalemia and metabolic acidosis, despite elevated plasma aldosterone concentration and plasma renin activity. The association of renal Na^+-wasting, hyperkalemia, and failure to respond to mineralocorticoids suggest a defective Na^+ reabsorption in the distal nephron. There are two forms of PHA-1, an inherited recessive disease characterized by a culminant clinical presentation in the neonatal period persisting in adulthood,[130] and an autosomal dominant or sporadic form which is milder and remits with age.[68] Genetic investigations of kindred with the recessive PHA-1 revealed deletion or missense mutations in each of the three ENaC subunits, resulting in decreased channel function when expressed in Xenopus oocytes. Linkage of PHA-1 to loss-of-function ENaC variants further supports the critical role ENaC in aldosterone regulation of Na^+ reabsorption.

Constitutive gene inactivation studies for all three subunits of ENaC (α-, β-, and γ-, encoded by *Scnn1a*, *Scnnn1b*, and *Scnn1g*, respectively) revealed a crucial role for each subunit in the survival of the animal (see for review [131]). Constitutive inactivation of the mouse αENaC gene locus leads to severe respiratory distress with neonatal death, demonstrating the crucial role of ENaC in lung liquid clearance at birth.[132] The αENaC knockout neonates died so rapidly from their lung phenotype that they did not manifest any electrolyte disturbances. However, mice with a genetic rescue by reintroducing the αENaC-subunit under the control of a heterologous (cytomegalovirus) promoter demonstrated the importance of precise regulation of ENaC in the kidney.[133] The transgenic rescued mice had sufficient basal Na^+ absorptive capacity to clear lung liquid and survive the early neonatal period, but developed a severe PHA-1 like phenotype with renal salt-wasting, metabolic acidosis, high aldosterone levels, growth retardation, and increased early mortality.[134] In contrast to the αENaC knockout mice, mice with constitutive inactivation of βENaC and γENaC revealed severe early renal dysfunction.[135,136] Urinary Na^+-wasting, K^+ retention, and increased plasma aldosterone concentrations go along with failure to thrive and early postnatal deaths (see for review [137,138]). It seems that low residual ENaC activity in these mice is sufficient to circumvent the neonatal lung phenotype, consistent with the assumption that αβ- and αγ-subunit combinations can establish some ENaC activity in airway epithelia. Inactivation of the γ-ENaC-subunit in mice resulted in early death (at 36 hours after birth) of the mice, mainly due to disturbed total body electrolyte balance.[135] In the course of generating a mouse model for Liddle's syndrome by the insertion of a stop codon corresponding to residue R566 in human β-ENaC, together with the selection marker neomycin, mice were obtained with a partial disruption of the β-ENaC gene locus (β-ENaCm/m).[139] Under a normal-salt diet, these mice show a mild PHA-1 phenotype with reduced ENaC activity and elevated plasma aldosterone levels, but develop an acute PHA-1 with continuous weight loss, hyperkalemia, and decreased blood pressure when kept under a low-salt diet.

In summary, although the onset and severity of PHA-1 symptoms vary in these models, the renal phenotype of these mice corresponds well to the human PHA-1 phenotype (with salt-wasting, hyperkalemia, and metabolic acidosis), revealing the important implication of ENaC in Na^+, K^+ homeostasis.

Aldosterone and K^+ Secretion

The ASDN of mammals also plays a critical role in the maintenance of K^+ homeostasis. In this nephron segment, Na^+ reabsorption through ENaC is electrically coupled with K^+ secretion: increasing the Na^+ influx depolarizes the apical membrane and increases the driving force for K^+ secretion into the lumen, and *vice versa* (see Figure 35.2). Pathophysiological conditions where Na^+ absorption is increased in the ASDN (hyperaldosteronism, pseudoaldosteronism) are associated with hypokalemia; conversely, ENaC loss-of-function in PHA-1 results in a loss of Na^+ absorption in the ASDN and hyperkalemia (see above). Consistently, mice with constitutive inactivation of β- and γ-ENaC show renal Na^+-wasting and elevated plasma aldosterone level that goes along with renal K^+ retention and hyperkalemia.[135,136] While mice lacking the α-ENaC subunit die soon after birth due to respiratory insufficiency related to impaired alveolar fluid clearance,[132] mice with targeted inactivation of α-ENaC in the CNT and CD survive, and show not only renal salt-wasting, but also hyperkalemia,[115] further confirming the critical role of ENaC for Na^+ and K^+ homeostasis.

The K^+ secretion in the ASDN is mediated by a K^+ conductive pathway in the apical membrane of principal cells. Small conductance inwardly rectifying K^+ channels, termed SK channels, account for most of the apical conductance of principal cells.[140–142] These SK channels have been identified at the molecular level and are the product of the ROMK channel gene. Moreover, the large, Ca^{2+}-activated K^+ channel (BK), present in intercalated and/or principal cells, is thought to contribute to K^+ secretion along the ASDN.[17]

Experiments in mice deficient for either ROMK or the α-subunit of BK suggest that the channels may compensate for each other.[143,144] The functional role and the regulation of these channels in the kidney have been the topic of several recent reviews,[16,18,19,145] and are also extensively addressed in a separate chapter in this book. Therefore, we will here only briefly touch the possible impact of aldosterone on renal K^+ secretion via these channels.

High dietary K^+ intake and elevated plasma K^+ concentrations increase aldosterone secretion by the zona glomerulosa of the adrenal gland and stimulate urinary K^+ excretion. This raises the question of whether aldosterone has a primary effect on K^+ secretion, via genomic effects on principal cells of the ASDN. However, although some studies indicated that aldosterone may directly affect the activity of the renal secretory K^+ channels,[33–36] there is no strong evidence that aldosterone at physiological concentrations increases the apical K^+ conductance of principal cells in the CCD *in vivo*.[146] In fact, rats fed with a low-Na^+ diet have a high plasma level of aldosterone and show a large increase in the density of active ENaC channels in the apical membrane of principal cells, but the density of ROMK channels remains unchanged.[147] Recently, Fodstad and co-workers described that the established mouse CCD cell line (mCCD(cl1)) expresses ROMK mRNA and a robust Ba^{2+}- and tertiapin-Q sensitive K^+ conductance in the apical membrane.[148] Overnight exposure to 100 nM aldosterone did not significantly change the K^+ conductance, but it increased the amiloride-sensitive Na^+ transport. Surprisingly, in this cell model the mRNA levels of all ROMK isoforms measured by qRT-PCR were even decreased by 15–45%, further supporting the idea that aldosterone does not directly stimulate ROMK.

Nevertheless, a high dietary K^+ intake increases both the activity of ENaC and of ROMK (Figure 35.4). Interestingly, the kaliuretic response to dietary K^+ occurs very rapidly, and even before plasma K^+ and aldosterone levels are elevated. Moreover, renal kaliuresis can be clearly dissociated from renal Na^+ handling (for review see [145,149]). In a recent study, Frindt and Palmer addressed the question of whether the concomitant activation of ENaC is required for enhanced urinary K^+ excretion. Rats were kept on different K^+ diets, and then infused via osmotic minipumps with a constant dose of amiloride which was supposed to block more than 98% of Na^+ transport through ENaC. Measurements of urinary K^+ excretion indicated that on a control diet (0.6% KCl), distal nephron K^+ secretion completely depends on ENaC, while on a high-K^+ diet (10% KCl) an increasing fraction of K^+ excretion is independent of Na^+ channels.[150]

Taken together, the current evidence suggests that the activation of ENaC by aldosterone is sufficient to increase the driving force for K^+ secretion, leading to an increase in kaliuresis, without upregulating K^+ channels. In contrast, a high-K^+ diet increases the density of active ROMK channels, suggesting the presence of kaliuretic factors that control K^+ secretion, independently of aldosterone.[145,149]

Aldosterone and the Na^+,K^+-ATPase

For efficient transepithelial sodium reabsorption, apical Na^+ entry via ENaC has to be matched by Na^+ extrusion across the basolateral plasma membrane via the Na^+,K^+-ATPase. Consistently, the activity of the Na^+,K^+-ATPase is also regulated by aldosterone (for a review see [151,152]). Briefly, it was already shown 30 years ago that aldosterone induced augmentation of Na^+,K^+-ATPase in the CCD of adrenalectomized rats after 1 to 3 hours of aldosterone infusion.[153,154] In non-adrenalectomized animals, aldosterone also induced the Na^+ pump, but the response was delayed and observable between 2 days and 1 week.[48] In the rabbit CCD, Sansom and O'Neil observed a doubling in the basolateral membrane conductance after 24 hours of the mineralocorticoid DOCA (deoxycorticosterone acetate) treatment, which could be accounted for by a rise in basolateral K^+ and Cl^- conductance.[155] Moreover, morphometric studies revealed a significant increase in the basal side surface area of the rabbit CCD principal cells, which can be correlated with an increase in single cell capacitance.[156,157] However, these changes in cell surface area could only partially account for the increase in basolateral membrane conductance. It is not clear in these cases whether the mineralocorticoid-induced increase in basolateral membrane conductance is a direct effect of the hormone or secondary to an increase in Na^+ entry into the cell.

As discussed in,[151] it is likely that the early effects involve activation and/or translocation to the basolateral membrane of pre-existing Na^+,K^+-ATPases, whereas the late effects are caused by *de novo* synthesis of the Na^+,K^+-ATPase. Indeed, it has been shown both in adrenalectomized rats and in mpkCCD_{cl4} cells that infusion or treatment for 2 to 3 hours with aldosterone strongly increases the cell surface abundance of Na^+,K^+-ATPase, whereas the total cellular pool was only affected later.[152,158,159] It was shown by the same researchers that Sgk1 is able to increase the cell surface expression of Na^+,K^+-ATPase,[160] providing a potential mechanism of how aldosterone may regulate the pump. However, it remains open if the kinase regulates Na^+,K^+-ATPase by direct phosphorylation or not.

Hence, aldosterone is able to modify Na^+,K^+-ATPase activity by increasing the number of Na^+,K^+-ATPase at the basolateral membrane, likely by translocating pre-existing pumps to the surface (short-term regulation), and by increasing the *de novo*

synthesis of Na^+,K^+-ATPases. Moreover, aldosterone is also able to increase the basolateral membrane surface. The cellular and molecular mechanisms that are involved in this regulation are only vaguely known, and may involve Sgk1.

SODIUM TRANSPORT REGULATION BY ALDOSTERONE: CELLULAR AND MOLECULAR MECHANISMS

Non-Genomic Actions of Aldosterone

Aldosterone, similar to many other steroid hormones, has two fundamentally different mechanisms of action, namely rapid, non-genomic effects that are different from the classical and delayed genomic effects, involving MR and GR and the induction of a complex translational/transcriptional response.[161,162] The non-genomic effects of aldosterone on intracellular signaling pathways have been demonstrated in a variety of animal and human cell types, including those localized in the classical mineralocorticoid target organs.[161,162] These effects are characterized by short latencies of seconds or minutes, and do not involve changes in gene expression mediated by the transcriptional role of the MR.[163] They may involve MR itself and being sensitive to MR antagonists such as spironolactone or eplerenone or being independent of MR. The existence of an alternative receptor with high affinity for aldosterone has been postulated, which may be membrane-bound or representing a signaling molecule within the cell. Recently it has been shown that aldosterone signals independently of MR through GPR-30, an intracellular G-protein-coupled receptor localized in the endoplasmic reticulum, leading to extracellular related kinase (ERK) activation and apoptosis, and to myosin light chain phosphorylation.[164,165] It will be important to determine the role of GPR-30 in the ASDN, where its presence has been reported.[166]

The non-genomic effects involve the activation of protein kinase pathways, including mitogen activated protein (MAP) kinases, protein kinase D1 (PKD1), and protein kinase C (PKC).[162] Interestingly, PKCα (a PKC isoform) directly binds *in vitro* aldosterone via its C2 domain, leading to its autophosphorylation. Hence, PKCα may represent an intracellular aldosterone receptor distinct from the classical MR. PKC signaling is an illustrative example of cross-talk between non-genomic and genomic pathways, as demonstrated in cultured rat cortical collecting duct cells, in which transepithelial Na^+ transport may be stimulated in the early phase by PKCα and independent of MR, whereas the late phase requires genomic action via MR.[167] Also involved in short non-genomic activation of ENaC may be PKD1 that appears to regulate subcellular localization of αENaC in M1 CCD cells.[168] Together, the number of different non-genomic effects of aldosterone that have been described, the lack of physiological targets in many cases, as well as the potentially diverse modes of action, do not allow us to draw a unifying conclusion. However, it is likely that non-genomic actions and genomic actions of aldosterone interfere in some instances with each other for the control of physiological functions.

Genomic Actions of Aldosterone

Mineralocorticoid Receptor (MR) and Glucocorticoid Receptor (GR)

As discussed above, both MR and GR act as aldosterone receptors, having different affinities to aldosterone. MR is the high-affinity type 1 receptor (K_d approximately 0.5 to 2 nmol/l), and GR is the low-affinity type 2 receptor (K_d approximately 14 to 60 nmol/l).[169] On the other hand, the glucocorticosteroid hormone cortisol (corticosterone in rodents) binds to MR with high affinity similar to that of aldosterone, and with a higher affinity to GR.[14,170] Cell-specific hormone and receptor specificity-conferring mechanisms discussed below are necessary to explain the differences in the response to mineralocorticoids and glucocorticoids at the systemic and organ levels.[161,171,172] It is important to note that the precise role of these two receptors (MR versus GR), the extent of their functional overlap, and the role of specificity-conferring mechanism are not fully-understood, and the analysis of MR/GR-modified animals may help to clarify these issues.

The clinical importance of the MRs was demonstrated in patients carrying mutations in the gene leading to an autosomal dominant form of pseudohypoaldosteronism, a disease that remits with age.[68] Moreover, various heterozygous loss-of-function mutations in the human MR (hMR) gene have been identified and characterized, including frameshift, nonsense, and missense mutations, and gene deletions.[173,174] In contrast, a constitutive active mutation in MR (S810L) has been found in patients with an early-onset hypertension that is markedly exacerbated in females during pregnancy.[175] This mutation alters the receptor specificity, and renders progesterone and other steroids lacking 21-hydroxyl groups, normally MR antagonists, to potent agonists of the receptor. Biochemical studies revealed that the S810L mutation induces a change in the receptor conformation, which increases the steroid−receptor complex stability, contributing to the agonistic action.[176,177]

MR and GR belong to the nuclear receptor superfamily that includes other steroid hormone receptors,

including the thyroid hormone, retinoic acid, vitamin D. These nuclear receptors are modulary proteins harboring different conserved domains.[178] The N-terminal domain is the less conserved among nuclear receptors, both in size and sequence, and represents in the case of MR almost half of the protein. This region contains a ligand-independent activation function, which is important for interaction with transcriptional co-regulators, and for intramolecular interactions with the ligand-binding domain (LBD) that lies at the C-terminus.[14,172] This latter domain is complex, as it harbors regions involved in formation of the ligand-binding pocket, interaction with heat shock proteins, dimerization, and a ligand-dependent activation function, which interacts with transcriptional co-regulators. The centrally located DNA-binding domain (DBD) is the most conserved region of the receptor. It folds into two zinc fingers, in which one zinc atom is tetra-coordinated by four cysteines. The core DBD contains two α-helices; the first one, or recognition helix, binds to the major groove of DNA making contacts with specific bases. This domain also contains segments involved in receptor homo- and heterodimerization. Putative nuclear localization signals are localized in the C-terminal part of the DBD and the beginning of the hinge region. Acting as enhancers or repressors of transcription, steroid receptors target specific DNA sequences; these hormone-responsive elements (HREs) then confer inducibility/repressibility to the genes by the corresponding hormone.[172]

In the absence of a ligand, the corticosteroid receptors and possibly all other members of the steroid receptor gene family are primarily localized in the cytosol and associated to a heat shock protein complex, which includes Hsp90, Hsp70, p23, p48, FK-binding protein 51, 52, 59 immunophilins or cyclophillin 40[171,179] (Figure 35.7). This maintains the receptors in an inactive, but ligand binding-competent and stable conformation. Recently it was suggested that this complex also binds via FKB52 to the motor protein dynein, promoting MR translocation into the nucleus.[180] Thereby, the classical concept that MR dissociates from the complex in order to translocate through the nuclear pore was challenged by showing that MR-Hsp90 cross-linked complexes accumulate in the nucleus in an aldosterone-dependent fashion (Figure 35.7). Hsp90 also stabilizes the MR, as inhibition of Hsp90 with the geldanamycin analog 17-AAG (17-Allylamino-17-demethoxygeldanamycin) promotes rapid ubiquitylation by the CHIP (carboxyl terminus of Hsc70-interacting protein) ubiquitin-protein ligase and consequent proteasomal degradation.[181] It was suggested that treatment with 17-AAG may represent an interesting and alternative pharmacological tool to interfere with MR activation. Activation of the receptor by the binding of an agonist or some antagonists results in receptor dimerization. After nuclear translocation, the dimerized receptors will bind to the corresponding hormone-responsive elements and alter the transcription of target gene(s), as do classical sequence-specific transcription factors.[171]

Once activated and translocated to the nucleus, MR and GR associate with and recruit a complex co-activator and co-repressor machinery, involving numerous proteins[171,179] (Figure 35.7). In the case of MR, these include the transcription co-activators SRC-1, SRC-1e, and PGC-1, the histone acetylase CBP/p300, the helicase RHA, and the Pol II elongation factor ELL. The latter one represents an MR-specific transcriptional co-regulator of MR. Similar complexes are also recruited by the GR.[182] Moreover, co-repressors of the steroid receptors are recruited as well. They include SMRT and NCoR, the apoptosis-controlling DAXX and the sumo ligase PIAS that has been shown to sumoylate MR, causing inhibition of transcription activation of MR.[179] Besides sumoylation, both MR and GR become modified by numerous post-translational modifications (PTMs). These modifications involve phosphorylation, ubiquitylation, and acetylation at various sites. For many of these PTMs the functional consequences have not yet been clearly established, nor have the specific sites been determined.

There are, beside aldosterone, other high-affinity ligands for MR which do not produce the same effects, including progesterone, spironolactone, and other antagonists.[183,184] The working hypothesis to explain this specific differential response is the following: (1) agonists bind to and produce a conformational change which fully activates the receptor and elicits the maximal biologic response; (2) partial agonists fully occupy the receptor, but afford incomplete activation and thus a partial response; and (3) antagonists fully occupy the receptor, but are not able to induce a conformational change necessary for binding to target DNA and transactivation.[185] In the latter case it is assumed that MR (or GR), upon antagonist binding, translocates into the nucleus and recruit instead of the transactivation a transrepression machinery, including the co-repressors described above.[172,186]

Specific aldosterone binding, immunochemical staining, and messenger RNA detection have identified MR in classical mineralocorticoid target tissues such as kidney, gut, and sweat glands, and also in skin, brain, pituitary, and heart.[171,172] In kidney, aldosterone appears to control Na^+ reabsorption across the entire distal nephron from DCT to the IMCD. Indeed, presence of MR and GR protein in the distal nephron has been demonstrated.[46] Both MR and GR are expressed in the TAL, DCT, CNT, CD, and in intercalated cells.[46] The GR is found additionally in proximal tubule cells. In the study by Ackermann et al.,[46] the concept of ligand-dependent translocation into the nucleus of GR and MR

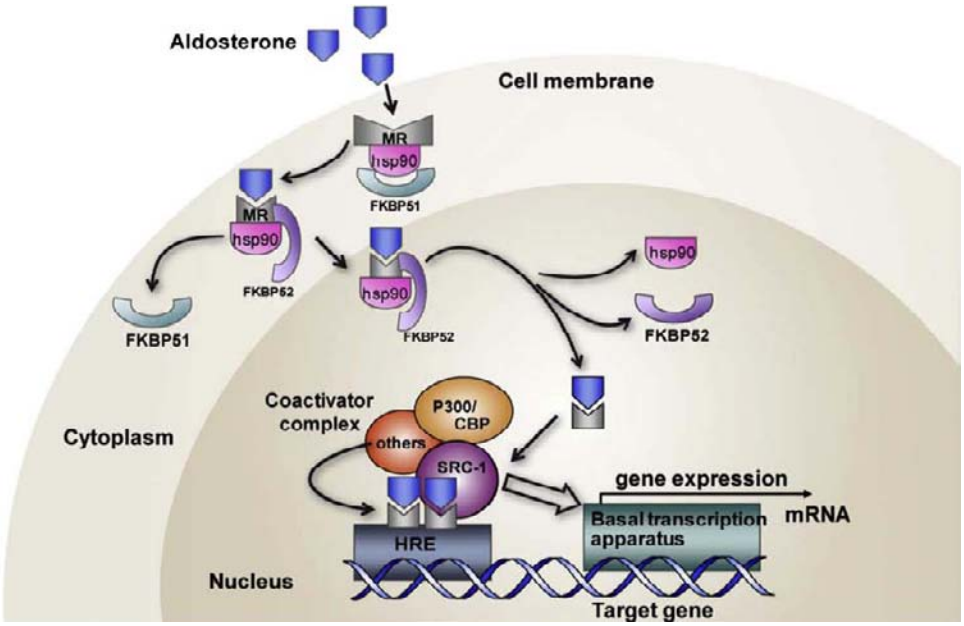


FIGURE 35.7 **Model of MR transcriptional activation.** In the non-stimulated state, MR is localized to the cytosol, where it is compexed to a number of proteins, including Hsp90, FKB51, FKB52, and other proteins. Upon binding to aldosterone, FKB51 dissociates, and MR/Hsp90/FKB52 translocate into the nucleus. There the complex dissociates, and MR will associate with a co-activator complex including SRC-1/P300/CBP and other proteins, and stimulate a complex transcriptional response. *(Reproduced with permission from Yang, J., and Fuller, P. J., (2012).[179])*

was nicely confirmed, although important differences between GR and MR were revealed (see below).

KO and Transgenic Mouse Models of MR and GR

Several mouse models have been generated to study the role of the MR and the GR for ENaC regulation and the control of ion homeostasis (Table 35.1). Mice in which the mineralocorticoid receptor (MR) was inactivated developed severe symptoms of pseudohypoaldosteronism with failure to thrive, weight loss, severe Na^+ and water loss, and highly stimulated renin–angiotensin system.[187] At day 10 after birth, these $MR^{-/-}$ mice die, since they are not able to compensate for Na^+ loss. Interestingly, amiloride-sensitive Na^+ reabsorption is reduced, but the abundance of the mRNAs encoding ENaC and Na^+,K^+-ATPase is unchanged in the kidney, indicating that regulation of Na^+ reabsorption via MR may not be achieved by transcriptional control of ENaC and Na^+,K^+-ATPase. In $MR^{-/-}$ mice, expression of the renin–angiotensin–aldosterone system (RAAS) is highly stimulated. The changes in mRNA levels of the components of the RAAS in 8-day-old $MR^{-/-}$ mice were not apparent in the heterozygous $MR^{+/-}$ mice. However, these animals have an increased urinary Na^+ loss, three-fold increase in Na^+ fractional excretion, and a modest compensatory stimulation of the circulating RAAS, revealed by a three-fold increase in renin, angiotensin II, and aldosterone levels compared with those in $MR^{+/+}$. This suggests a modest neonatal Na^+ loss, compatible with survival in the $MR^{+/-}$ mice. This mild Na^+ loss exhibited by these heterozygous mice is similar to the phenotype observed in patients with autosomal dominant pseudohypoaldosteronism type I.[68] In patients with a heterozygous defect in the MR gene, a modest form of neonatal renal salt-wasting, with hyperkalemia and acidosis, was observed. The disease remits with age, indicating the crucial importance of aldosterone-dependent Na^+ reabsorption in the postnatal period, and its decreasing role with age.[188] Daily injections of β methasone, a synthetic glucocorticoid, from day 5 after birth onward prolonged the survival of $MR^{-/-}$ mice, suggesting that an activated GR can partially but not completely compensate for the loss of MR function.[188] Daily subcutaneous injections of NaCl from day 5 after birth until weaning and continued oral NaCl supply lead to the survival of MR knockout mice.[189] This NaCl rescue proves that neonatal MR knockout mice die because they are not able to compensate for their renal Na^+ loss. Injections of isotonic NaCl solution enabled the animals to live through a critical phase of life, after which they adapt their salt and water intake to their persisting renal salt-wasting. Mice in which tissue-specific deletion of the MR has been achieved in the late CNT and CD by Cre recombinase under the control of the AQP2 promotor (either constitutive or inducible by tamoxifen), develop normally and show unchanged Na^+ balance under standard conditions and highly elevated aldosterone levels. When kept under low Na^+ diet, mice

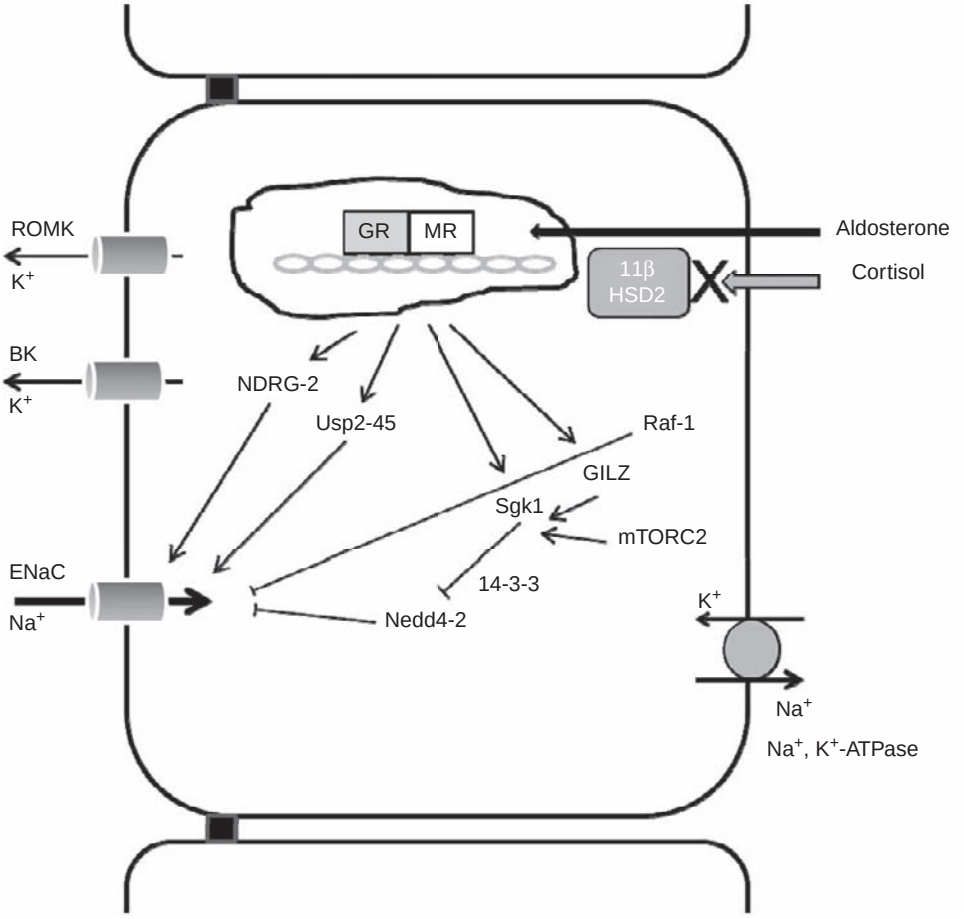

FIGURE 35.8 **Model of the aldosterone-signaling cascade in the principal cells of CD/CCD.** Upon binding of MR to the promotor regions of aldosterone-induced proteins (e.g., Sgk1, Usp2-45, NDRG-2, GILZ, 14-3-3β), transcription/translation leads to increased levels of these proteins. Sgk1, which is part of the ERC complex (comprising also Nedd4-2, GILZ and Raf-1), is activated by PI-3 kinase/mTORC2, stabilized by GILZ, and phosphorylates the ubiquitin-protein ligase Nedd4-2 on specific sites. 14-3-3β binds to these sites and interferes with binding and ubiquitylation of ENaC by Nedd4-2, causing reduced internalization and degradation of ENaC.

lose bodyweight due to Na^+ and water loss. The data indicate that the loss of MR in the late CNT and CD can be compensated by increased aldosterone levels, likely causing an increased MR-dependent Na^+ reabsorption in the DCT 2 and early CNT and/or activation of MR-independent sodium-retaining mechanisms in late CNT and CD.[116,190]

Constitutive hMR overexpression in all MR-expressing tissues, notably the kidney and heart, led to both renal and mild cardiac alterations compatible with hypokalemic nephropathies, despite normal K^+ serum levels.[191]

Inactivation of the GR *in vivo* resulted in perinatal death due to respiratory failure.[192] Lung maturation was severely retarded and RNA encoding ENaC was diminished, which may cause insufficient fluid clearance of the lung at birth. That the GR may play a role in the control of Na^+ handling along the ASDN can be deduced from the observation that mice with a conditional overexpression of the human GR in the CD show some signs of enhanced ENaC activation with renal Na^+ retention.[193] However, mice with targeted deletion of the GR in the entire distal nephron do not reveal any overt phenotype, suggesting that the MR can largely compensate for the loss of the GR along the ASDN.[194]

11β-HSD2 and Molecular Determinants of Mechanisms Conferring Specificity

Aldosterone is present at low concentration in the extracellular fluid (in the order of 10^{-10}–10^{-8} mol/l). It can diffuse (or eventually be transported) through the plasma membrane of all cells, but may encounter a specific receptor only in target cells. The free MR and GR are localized mostly in the cytosol.[46] At the cellular level, the action of aldosterone is initiated by its binding to the MR, and under certain conditions also to the GR. However, the major glucocorticoid in humans is cortisol; in the plasma, 95% is bound to plasma proteins, in particular to the corticosteroid-binding globulin (CBG).[195] In comparison, the plasma level of aldosterone, the main mineralocorticoid hormone, is much lower (two orders

of magnitude) than that of cortisol or corticosterone. Thus, the glucocorticoids, which have a similar high affinity for the MR as aldosterone, would be expected to occupy the high-affinity type I sites of MR. Indeed, even the "effective" free concentration of aldosterone, which in contrast to the natural glucocorticoids has no specific carrier plasma protein, is lower than that of glucocorticoids. However, glucocorticoids do normally not occupy MR or GR at a significant extent in aldosterone target epithelia. As described below, this is essentially due to the expression of a crucial protection mechanism represented by the 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which catalyzes the conversion of the active 11-hydroxycorticosteroids (cortisol and corticosterone) to 11-oxocorticosteroids (cortisone or 11-dehydrocorticosterone) that have a much lower affinity for the corticosteroid receptors.[15,196] Consequently, this mechanism allows aldosterone to occupy MR but also GR. Along the ASDN, 11β-HSD2 and MR may not only share the cellular, but also the subcellular localization. The 11β-HSD2 is thought to be restricted to the endoplasmic reticulum[197] that spans as a membranous labyrinth throughout almost the entire cytoplasm of the cells. In the non-activated state, MR may localize in direct vicinity to the 11β-HSD2, either outside or even inside the ER.[198] This close co-localization likely contributes to the efficient protection from cortisol activation. The crucial role of 11β-HSD2 for preventing the occupation of the MR by endogenous glucocorticoids is underlined by the fact that mutations of its gene or inhibition of its function by licorice (glycyrrhenetic acid) produces a syndrome of apparent mineralocorticoid excess (AME) with salt retention, arterial hypertension, and hypokalemic alkalosis.[196] Genetic inactivation of 11β-HSD2s in the mouse confirmed the crucial role of the enzyme in the protection of the MR (and GR) from circulating glucocorticoids, and allowed further study of the molecular and cellular mechanisms leading to the characteristic pathophysiology of AME.[199] About 50% of the 11β-HSD2 knockout mice die early after birth, showing muscle weakness, reduced suckling, intestinal ileus, and possible cardiac arrest, which are all likely due to the severe hypokalemia.[200] Also, the surviving knockouts exhibit hypokalemia with hypochloremia, hypotonic polyuria, and marked arterial hypertension. They further show striking histological changes, with marked hyperplasia and hypertrophy of the distal nephron, consistent with persistent MR activation, leading to the AME disease phenotype with severe electrolyte imbalances.[199] The structural changes to the ASDN cells might be irreversible, and hence may explain why suppression of endogenous glucocorticoid production does not always reverse the phenotype in AME patients.[200,201]

The utmost importance of 11β-HSD2 for the regulation of the renal corticosteroid receptors was also demonstrated by immunohistochemical studies on rat kidneys.[46] In the 11β-HSD2-positive cells of the ASDN, the MR and GR were found to be localized to the cell nuclei under control conditions. Under a high dietary Na^+ intake, when aldosterone plasma levels are low, the GR but not the MR was removed from the cell nuclei. The differential response was suggested to be the result of the different affinities of both receptors to corticosteroids. In the presence of low plasma aldosterone levels, the activity of the 11β-HSD2 is likely high enough to lower the intracellular corticosterone levels sufficiently to protect the low-affinity GR, but not the high-affinity MR, from glucocorticoid-binding and nuclear translocation. Consistently in adrenalectomized rats (having no endogenous gluco- and mineralocorticoids), any nuclear localization of the MR and GR was lacking. Infusion of low dose of corticosterone translocated the MR to the cell nucleus of all distal tubules cells, but the GR only translocated in those cells that have little or no 11β-HSD2 expression. Only when corticosterone was infused at high level, were both MR and GR located to the cell nuclei in all ASDN cells. These findings were interpreted to indicate that the 11β-HSD2 protects primarily the GR, and not the MR, from activation and translocation to the cell nuclei in the ASDN cells.[46] The separate regulation of MR and GR trafficking may allow for a differential control of MR and GR homo- and heterodimerization, which might be decisive for the induced and/or repressed transcriptional program,[44] and hence may contribute to the complexity of corticosteroid effects along the ASDN.

Other Specificity-Conferring Mechanisms

Two distinct molecular mechanisms are widely accepted to define the actions of nuclear receptors on gene expression: (1) the classic mechanisms involving transactivation and transrepression via interaction with cognate DNA-binding sites (e.g., HREs); and (2) mechanisms of transcription interference and synergy mediated by protein−protein interactions between corticosteroid receptors and other transacting factors. Transcriptional synergy, functionally defined as a more-than-additive increase in gene transcription conferred by multiple transacting factors or multiple linked cis-acting DNA response elements, can result from cooperative binding of transacting factors to linked enhancers, cooperative recruitment of transcription initiation complexes, and regulation of sequential steps in transcription initiation.[183] The relevance of the distinct properties of synergy of MR and GR is highlighted by the fact that in the MR, the N-terminal domain NTD and the ligand-binding domain (LBD) do interact in an aldosterone-dependent manner. This interaction is not observed in the GR, and

is antagonized by the antagonists spironolactone and eplerenone, and surprisingly, by cortisol.[172] The precise regions involved in this interaction are not known. However, the N-terminal region of MR contains so-called synergy control (SC) motifs whose disruption selectively increased MR activity at GRE multimers.[202] Possibly of relevance, the SCs correspond also to sites that are modified by sumoylation. Although mutations of the sumoylation sites do not interfere with the NTD/LBD interaction, direct and distinguishable inhibitory roles for SUMO isoforms in the control of transcriptional synergy have been demonstrated,[203] although the mechanistic basis for SUMO1 synergy inhibition remains to be determined (see for review[172,204]).

In addition to the major role played by the prereceptor protective mechanisms, the nature of the cellular responses to aldosterone or glucocorticoid is determined to a large extent by the type and the state of the target cell. Indeed, the set of genes regulated by a given activated receptor is cell-specific. This is due to the fact that much more than a single regulatory protein has to bind to a gene to activate its transcription. An intracellular receptor can activate a gene only if an appropriate cell type-specific combination of other gene regulatory proteins is expressed. This opens the possibility of interaction at several levels. As mentioned above, protein−protein interactions play a central role in the establishment of pre-initiation complexes. Thus, the structural differences of the MR and GR, in particular at the level of their amino-terminal domains, certainly allow them to undergo receptor-specific interactions. These interactions, in turn, might selectively modulate the transregulatory action of the receptors, independent of their common DNA-binding properties. Considerable efforts have been made to identify ligand-specific interacting and/or transactivation proteins. RNA helicase A (RHA) has been found to mediate transactivation of MR only in the presence of aldosterone, but not of cortisol; it was speculated that the NTD/LBD interaction may be affected.[172] On the other hand, differential expression and regional distribution of steroid receptor co-activators SRC-1 and SRC-2 in brain and pituitary have been found, and two splice variants of the steroid receptor co-activator-1 (SRC-1), 1a and 1e, can differ significantly in certain cell populations.[205,206] Thus, each cell might have its specific pattern of co-activators which might be involved in cell-specific responses to corticosteroids in a promoter- and ligand-dependent way. Finally, PTMs may also modify the transcriptional effects of MR. Recently it has been shown that cyclin-dependent kinase 5 does modify the MR transcriptional response. However, it is not known to date if aldosterone and cortisol induce different modifications of MR, which might contribute to the differential effects of the two corticosteroids.[172]

How Does Transcriptional Regulation Lead to Transport Regulation?

This question has interested many scientists over the last five decades. Until recently, the epithelial Na^+ channel (ENaC) and the Na^+ pump (Na^+,K^+-ATPase) were recognized as the two main transport proteins mediating Na^+ reabsorption in the ASDN, although the thiazide-sensitive Na^+,Cl^--co-transporter NCC may also be involved (see discussion above). Here we will focus on ENaC and the pump, which were primarily investigated in this context. Starting at the level of Na^+ transport effectors, this approach has permitted definition of different phases of aldosterone action: an early phase, characterized by an activation of pre-existing proteins; and a late phase, during which new structural proteins are accumulated. Another approach to the mechanism of aldosterone action starts from the transcriptional event, with the identification of aldosterone-regulated gene products.[207,208] These are then further investigated at the level of their potential involvement in the physiological action of the hormone. Using new powerful techniques to analyze differential gene expression, aldosterone-regulated gene products were identified, as discussed below. It is believed that there are still many important aldosterone-regulated gene products that remain to be identified.

ENaC Activation: Transcriptional Induction and Regulation

Aldosterone directly controls ENaC transcription at the level of the α-subunit gene.[209] The mRNA of this subunit was correspondingly shown to increase in the ASDN of adrenalectomized rats within 2 hours of aldosterone treatment, and on long-term treatment.[3,210] This effect can account for the accumulation of the α-subunit in ASDN cells that was also observed within 2 hours of aldosterone treatment and in the long-term.[3,90] Interestingly, at the protein level aldosterone not only increases the amount of α-ENaC, but also induces a cleavage of γ-ENaC.[90]

Although the induction of αENaC and the apical translocation of all three ENaC-subunits are well visible 2 and 4 hours after aldosterone treatment, transepithelial Na^+ reabsorption and K^+ secretion start earlier, being measurable already within 30 min of treatment.[211] Thus, the early aldosterone response must also involve the activation of pre-existing but previously silent channels. In this regard, ubiquitylation of ENaC (i.e., the modification with ubiquitin[212]) is an

important aldosterone-regulated mechanism that has been shown to control channel surface expression and function.[213] Indeed, experiments have indicated that the ubiquitin-protein ligase Nedd4-2 ubiquitylates ENaC on Lys residues in the NH_2-terminal tails of ENaC-subunits.[214–217] The enzyme binds to PY motifs of the COOH-terminal tails of β- and γ-ENaC via WW protein–protein interaction domains,[214,215,218] and ubiquitylates the channel.[217] Interestingly, missense mutations causing deletion of the PY motifs in β- and γ-ENaC characteristic of Liddle's syndrome lead to an increase in cell surface ENaC expression, and also to an increase in its open probability (P_o), a condition leading to Na^+ retention, low K^+, and hypertension.[119,137,219] The control of ENaC by ubiquitylation appears to be regulated at several levels. First, dietary Na^+, likely via aldosterone action, controls Nedd4-2 expression in the ASDN. A high-salt diet increases Nedd4-2 expression, whereas a low-salt diet decreases it,[110] likely by interfering with excess Na^+ uptake via ENaC. Second, aldosterone has been shown to induce the expression of Sgk1 kinase[220] and the deubiquitylating enzyme Usp2-45.[221,222] In the former case, Sgk1 phosphorylates Nedd4-2, creating a binding site for 14-3-3 proteins.[107,216] By binding to Nedd4-2, 14-3-3 proteins mask the ENaC interacting motif of Nedd4-2, and thus prevent ENaC ubiquitylation and downregulation. This short cascade represents the first direct link between the aldosterone-regulated transcriptional activity of the MR and the function of ENaC that was demonstrated[220,223] (Figure 35.8). Besides acting via Nedd4-2, Sgk1 has been shown to act in concert via other mechanisms: (1) it may phosphorylate a consensus phosphorylation site on the C-terminus of α-ENaC close to the second transmembrane domain.[224] It is noteworthy, though, that this site is not conserved in *Xenopus laevis* ENaC, indicating that this mode of regulation has evolved lately in evolution; (2) it relieves the transcriptional repression by Dot1a-Af9 of the channel subunit,[225] consequently stimulating aldosterone-induced transcription of α-ENaC.

Usp2-45 was identified in a microarray screen of aldosterone early induced transcripts of the CCD.[221] This deubiquitylating enzyme was then shown to deubiquitylate ENaC, to interact both with ENaC and Nedd4-2, and to promote ENaC activity, activation by cleavage and cell surface expression.[226–228] The *in vivo* physiological relevance of Usp2-45 in ENaC regulation, however, remains to be demonstrated. Moreover, it is important to note that the Sgk1-Nedd4-2 pathway is not the only link between aldosterone and ENaC function. This has been indicated by results of experiments performed with mpkCCD cells expressing Liddle's-type ENaC that cannot bind Nedd4-2 and still responds to aldosterone, as did mutant mice expressing an ENaC β-subunit with the Liddle's mutation.[77,129]

Several mouse models deficient for Nedd4-2[60,229–231] and Sgk1[106,232,233] have been created (Table 35.1). Nedd4-2 knockout models have a relatively mild renal phenotype. They show normal Na^+ and K^+ balance, normal[229] or decreased[60] aldosterone, and salt-sensitive hypertension (Figure 35.9). They display increased ENaC protein levels, and in at least one model there were significantly increased NCC levels.[60] Therefore it is likely that Nedd4-2 is not only involved in ENaC regulation, but also in regulation of NCC. Two Nedd4-2 KO models have been shown to have a lung phenotype, with defective ENaC regulation.[230,231] The Sgk1 knockout mice generated by Wulff et al. and Fejes-Toth et al. are total knockouts, whereas the third model by Faresse et al. is an inducible, nephron-specific inactivation of Sgk1. They all display normal Na^+ and K^+ balance when kept under normal-salt diet, but have higher aldosterone levels, indicating a problem in the handling of Na^+ and K^+ (Figure 35.10). Under a low-salt diet, the knockout mice were unable to sufficiently upregulate NaCl reabsorption, despite excessive elevation of plasma aldosterone concentrations, and reduced and maintained apical ENaC translocation.[106,233] Intriguingly, although I_{Na} (measured by whole cell patch-clamping in the CD) was elevated, the proteolytic processing of γENaC is reduced in Sgk1 KO mice, even under conditions were aldosterone is induced.[232] These findings suggest that Sgk1 is required for processing of ENaC, but is not necessary for aldosterone-induced ENaC activation. The Sgk1 knockout models also revealed that Sgk1 is not only involved in ENaC regulation, but also controls the expression of NCC.[232,233] This control of NCC by Sgk1 appears to involve different regulatory pathways, and may act via Nedd4-2 phosphorylation[60,233] or via WNK kinases.[234–237]

Nedd4-2 has been associated through genome-wide studies with essential hypertension (for a recent review see [238]). On the other hand, the contribution of Sgk1 and Usp2-45 to hypertension has remained uncertain.[239–241]

The major part of the ENaC protein faces the extracellular milieu like a receptor, and evidence has accumulated during recent years that furin-mediated cleavage within the extracellular loop appears to be part of the maturation process of α- and γ-ENaC.[242] Yet luminal protease-mediated ENaC activation systems have also been suggested to play an important regulatory role in the function of ENaC. Originally this hypothesis was formulated from the model kidney cell line A6, when a cDNA that encodes a protease that activates ENaC by increasing its P_o was identified.[243] This channel-activating protease (CAP-1) and related

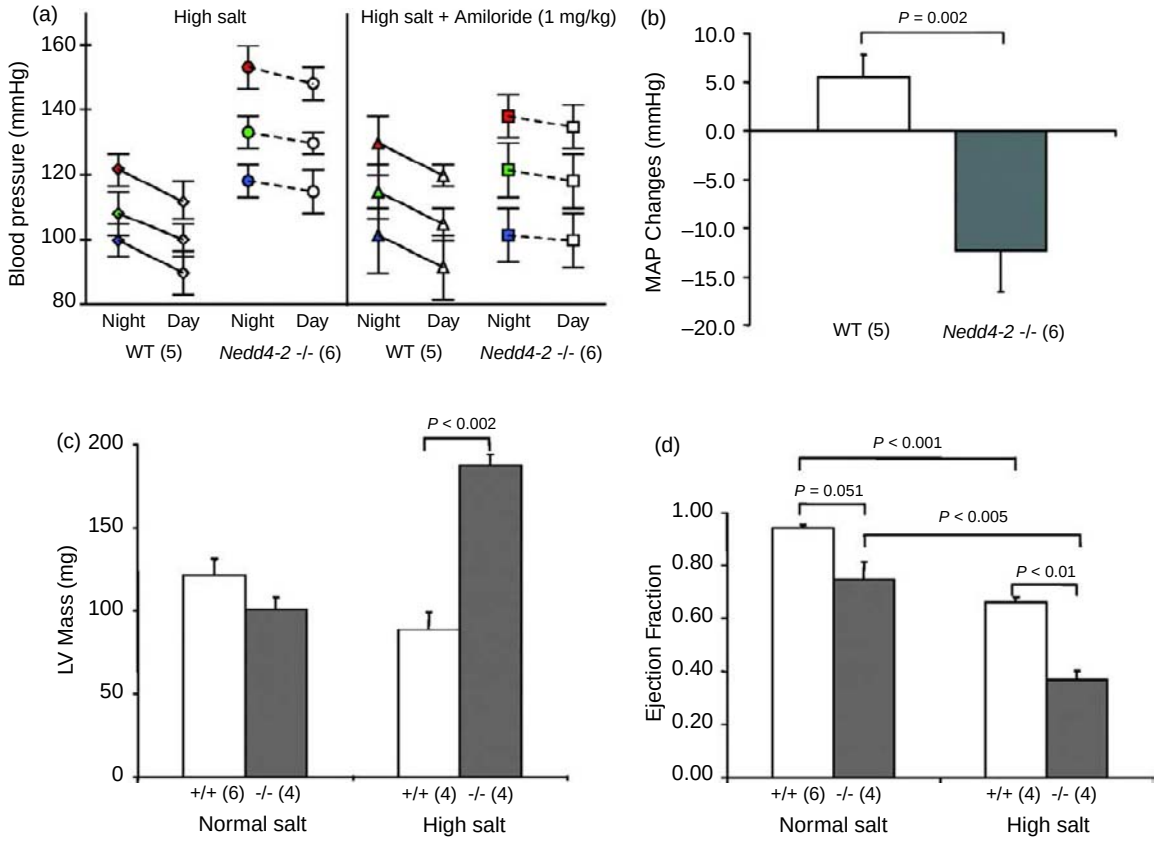

FIGURE 35.9 **Salt-sensitive arterial hypertension, cardiac hypertrophy, and reduced cardiac function in Nedd4-2$^{-/-}$ mice.** Top: Arterial blood pressure (bp) was recorded continuously by radiotelemetry in wild-type (WT) and Nedd4-2$^{-/-}$ mice that were kept for at least two weeks on a high-salt diet (Systolic bp: red symbols; diastolic bp: blue symbols; mean Bp: green symbols). Subsequent daily injections of amiloride for 12 days lowered arterial blood pressure in Nedd4-2$^{-/-}$, but not in WT mice (a), which was most evident when mean arterial pressure (MAP) values before and after amiloride treatment were plotted (b). Bottom: Left ventricular (LV) mass and cardiac ejection fraction in Nedd4-2$^{+/+}$ and Nedd4-2$^{-/-}$ mice kept for 8 to 10 months on normal or a high-salt diet. Heart weights and cardiac ejection fraction were determined by postmortem gravimetry and intravital echocardiography, respectively. *(Adapted from Shi, P. P., et al. (2008).*[229]*)*

proteases have been shown to be highly-expressed in ENaC expressing tissues, like kidney and intestine, in which protease inhibitors have also been shown to decrease Na^+ channel activity (for a review see [244]). The finding that proteolytic events modulate ENaC activity from the extracellular side is supported by the observation made in different cell lines that the application of protease inhibitors decreases, and the addition of proteases increases, Na^+ channel activity. As of yet, the actual mechanism by which this pathway leads to channel activation has not been elucidated. One report suggests that this ENaC-activating mechanism is induced by aldosterone. It was observed that urinary CAP1/prostasin was augmented by aldosterone in rats and humans.[245] Interestingly, proteolysis of ENaC by furin/extracellular proteases may be regulated by ubiquitylation of Nedd4-2. Indeed, it has been shown in transfected cells that ENaC channels with Liddle's mutations (inactivation of PY-motifs, the binding motifs for Nedd4-2) display a higher degree of proteolytic cleavage,[246] similar to co-expression of the deubiquitylating enzyme Usp2-45.[226,227] In view of the fact that proteases have been shown to primarily affect P_o, these observations may explain the observed effect of Liddle's mutations on both cell surface expression and P_o.[219] These observations have to be confirmed *in vivo*. It is noteworthy, however, that in Sgk1 knockout mice, the proteolytic processing of γ-ENaC appears to be defective, compatible with the role of Sgk1 in Nedd4-2-dependent ENaC regulation.[232]

ENaC has also been found to be regulated by lipid-based signaling pathways involving phosphoinositides, such as phosphatidylinositol 4,5-biphosphate (PIP_2), and phosphatidylinositol 3,4,5-triphosphate (PIP_3).[247] PIP_2 is required for ENaC-gating, and is likely to bind directly to the channel. It is important to note that $P2Y_2$ receptors interfere with ENaC activity by stimulating the metabolism of PIP_2. Evidence for such regulation is

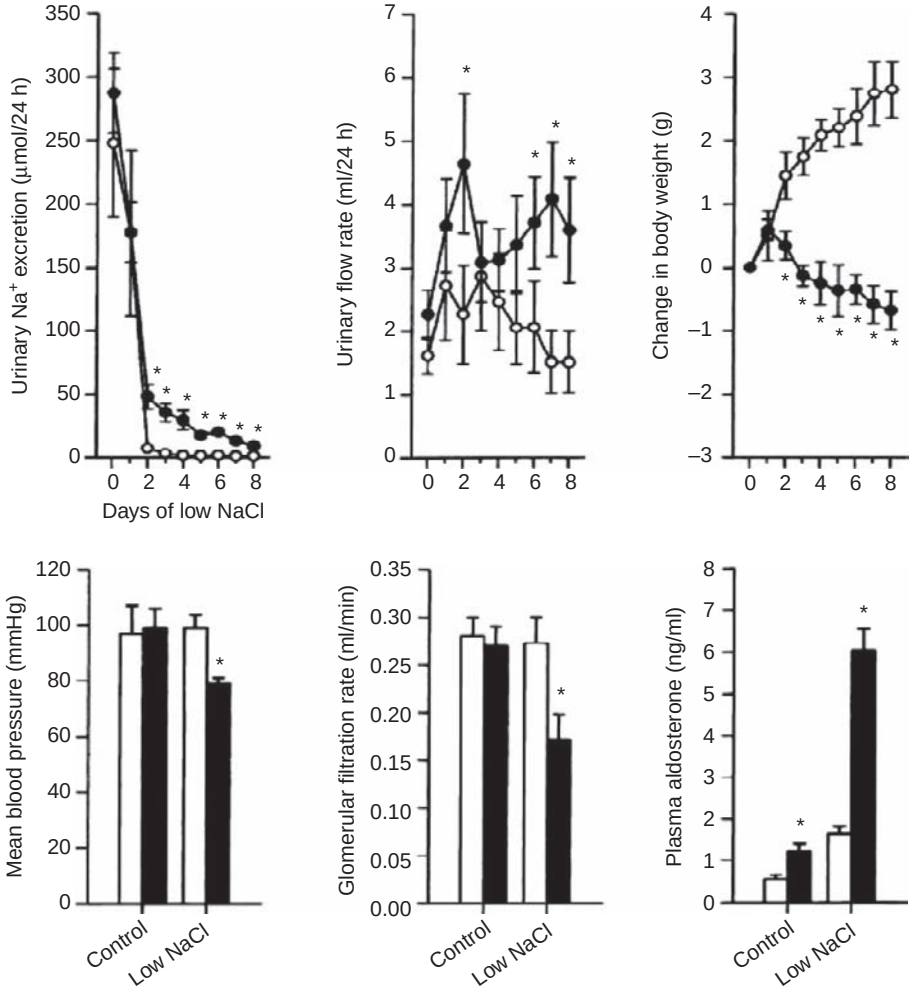

FIGURE 35.10 **Deficient adaptive response to low-Na intake in Sgk1$^{-/-}$ mice.** (Top) Urinary excretion of Na^+ and water, and change in body weight in response to a low-NaCl diet assessed in metabolic cages. (Bottom) Mean arterial blood pressure, glomerular filtration rate, and plasma aldosterone concentration in mice on the control diet and after feeding 3 days of a low-NaCl diet. Filled circles and bars indicate Sgk1$^{+/+}$ mice, open circles and bars indicate Sgk1$^{-/-}$ mice (*p 0.05 vs Sgk1$^{+/+}$mice). *(Adapted from Wulff, P., et al. (2002).[106])*

provided by $P2Y_2$ receptor null mice that are hypertensive with increased ENaC activity.[248] PIP_3 is thought to affect ENaC by several mechanisms: (1) PIP_3 may directly increase the P_o of ENaC expressed in CHO cells, and the aldosterone-induced protein K-Ras[249,250] may act by localizing the PIP_3-producing enzyme phosphatidylinositol-3OH kinase PI3-K close to the channel[251,252]; (2) PI-3K and PIP_3 may acutely stimulate ENaC open probability, likely by direct binding to ENaC[247,253]; (3) another important role for PIP_3 in this context is its role as activator of the PDK kinases (e.g., mSIN1/mTORC2 complex) that in turn activate aldosterone-inducible Sgk1.[220,254] As discussed above, Sgk1 positively affects ENaC by the inhibition of the ubiquitin-protein ligase Nedd4-2, and eventually also by direct phosphorylation of α-ENaC.[220]

Identification of Aldosterone-Regulated RNAs by Gene Expression Profiling

The aim of this section is to mention additional aldosterone-regulated gene products that support the pleiotropic action of aldosterone. Some of these gene products were identified because they were considered as candidates for aldosterone regulation, and therefore the impact of the hormone on their expression was directly tested. Others were identified in the context of screening procedures for aldosterone-regulated mRNAs.[208] This was the case for the two gene products discussed above, Sgk1 and Usp2-45.[222]

Besides ENaC and Na^+,K^+-ATPase, three gene products clearly involved in NaCl reabsorption were identified due to their role in controlling the ion balance in the ASDN. First, two epithelial transporters were shown to be upregulated *in vivo* by mineralocorticoids in the long-term: the thiazide-sensitive Na^+,Cl^--co-transporter NCC of DCT segment-specific cells; and the Cl^-/HCO_3-exchanger pendrin expressed in type B-intercalated cells.[31,52] Both transporters participate at the NaCl reabsorption, and might be upregulated by indirect mechanisms. The third candidate involved in NaCl transport and shown to be induced by aldosterone is the regulatory protein WNK1. This latter effect was shown in a cell culture model to be mediated rapidly by activated MR.[255] It will be interesting to verify

the *in vivo* regulation of WNK1, the role of which appears to be the control of the balance between partially overlapping Na^+, K^+, and Cl^- reabsorption.[256,257] The EGF receptor is an additional regulatory protein, the expression of which was shown in kidney cells to be induced by aldosterone. Interestingly, this receptor has been implicated in the signaling of non-genomic actions of aldosterone, and might play a role in the pathological actions of aldosterone.[258]

Progressively, molecular biology methods have become available that have started to allow the identification of regulated gene products. First, the group of Garty cloned a cDNA-encoding CHIF, a protein that is induced by aldosterone in the colon and belongs to the FXYD family of small Na^+,K^+-ATPase regulatory proteins.[259–261] Interestingly, CHIF is also localized to the distal part of the ASDN, and increases the apparent affinity of the Na^+,K^+-ATPase for Na^+.[262,263] CHIF-deficient mice have a rather mild phenotype pointing to some defects in renal and colonic Na^+ and K^+ transport when stressed by low-Na^+ or high-K^+ intake. The findings were consistent with a dysregulation of the Na^+-K^+-ATPase as the common denominator.[264]

Moreover, Spindler and colleagues used a differential display PCR approach to compare cDNA fragments generated from RNA of control and aldosterone-treated A6 epithelia.[249] They showed that only a small proportion of the mRNA ($<0.5\%$) was significantly regulated within the lag period of aldosterone action, and hence potentially involved in its early effect. One of the regulated gene products was a splice variant of a *Xenopus* K-*ras*. Functional experiments in *Xenopus* oocytes showed that this small G-protein activates ENaC at the cell surface.[250] The connection of K-*Ras* with PIP_3-mediated ENaC activation has been described above.

Another aldosterone-regulated gene product that has been identified by subtractive hybridization is NDRG2.[265] When co-expressed with ENaC, it has been shown to potentiate ENaC activity.[266] Moreover, it is a potential target of Sgk1.[267] Its potential physiological role in the context of Na^+ transport remains to be established.

Some gene screens were performed by SAGE (Serial Analysis of Gene Expression) or gene array analysis on kidney-derived cultured cells.[208] The major limitation of these studies was the large number of genes normally repressed *in vivo* that are expressed in cultured cells, some of which are sensitive to corticosteroids. Nonetheless, some interesting gene products were identified. One of them is the strongly upregulated GILZ, a gene product identified in mpkCCD cells by SAGE analysis.[268] Its induction has been verified in kidney, but its functional role has not yet been unraveled.[269] Interestingly, GILZ has been shown recently to be part of the ENaC regulatory complex (ERC), which also comprises the ENaC inhibitory proteins Raf-1 and Nedd4-2, as well as Sgk1.[270] In this context, GILZ is able to regulate ENaC via Sgk1 stabilization by decreasing its endoplasmic reticulum-mediated degradation.[271] Moreover, GILZ deficient mice show subtle deficiencies in water and Na^+ handling.[272]

In IMCD-3 cells, a series of aldosterone-regulated gene products (1 hour treatment) was identified. Sgk1 was one of the most highly-regulated ones. Moreover, genes involved in circadian rhythm were identified, and it was then shown that the circadian rhythm plays an essential role in ion and water homeostasis, and that Per1, part of the basic circadian regulatory machinery, is involved in α-ENaC regulation.[273–275] It will be timely to obtain a more complete list of the gene products regulated by aldosterone in target cells. It can be envisaged that most of them participate in signaling cascades, directly affecting the function of the cellular machinery for Na^+ reabsorption and K^+ secretion.

CONCLUSION

Since the identification of aldosterone as a major hormone that controls extracellular Na^+, K^+ and fluid homeostasis, tremendous progress has been made in the identification of the cellular and molecular mechanisms by which this hormone mediates its actions, in particular in the kidney. Structural and functional studies allowed us to define the renal tubule segments forming the aldosterone-sensitive distal nephron (ASDN) and to address their contribution to the adaptation of the kidneys to varying functional needs. The main receptors (e.g., MR, GR), specificity conferring mechanisms (e.g., 11-α-HSD2), and effectors (e.g., ENaC, NCC, and Na^+,K^+-ATPase) have been cloned and studied in various *in vitro* and *in vivo* settings. Rare human genetic diseases related to mutations in these proteins were unraveled, and mouse models mimicking the human phenotypes have been generated. Together, these studies further underlined the utmost importance of the ASDN for ion homeostasis and blood pressure control. However, we have just started to identify the homeostatic signals and mechanisms that ensure the efficient cooperation of the different ASDN segments and cell types, which ensure an independent regulation of renal Na^+, K^+, proton, and fluid excretion. Co-expression of the MR, the GR, and additional alternative receptors in the same ASDN cells may add significantly to the complexity of genomic and non-genomic corticosteroid actions along the ASDN. The mild phenotype of Sgk1, Nedd4-2, and CHIF deficient mice points to a rather extensive and redundant signaling cascade. The rapid advancement

of molecular and physiological techniques, together with the increasing availability of genetic mouse models with conditional deletion or overexpression of the receptors and certain regulatory molecules will allow us to further unravel the complex control of the aldosterone-dependent control of renal ion homeostasis. As even subtle dysfunction within the underlying regulatory cascades may already predispose to human diseases such as salt-sensitive hypertension, further research is needed.

Acknowledgment

We are grateful to Drs. Edith Hummler, Bernard Rossier, Laurent Schild, and François Verrey for having established with the previous edition(s) of this chapter a solid base to build on. Moreover, we thank Drs. Dominique Loffing-Cueni, Caroline Ronzaud, and Nourdine Faresse for critically reading the manuscript. We also thank Mr. Jean-Claude Broillet for having established the Reference Databank.

Inherited Disorders of Renal Salt Homeostasis: Insights from Molecular Genetics Studies

Ute I. Scholl and Richard P. Lifton

Departments of Genetics and Internal Medicine, Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, USA

INTRODUCTION

Approaches to Identify Genes and Mutations that Contribute to Human Disease

The regulation of blood pressure is fantastically complex, with contributions from the brain, heart, vasculature, adrenal, and kidney. In the face of such complexity, it has been very difficult to identify the rate-limiting steps in the determination of long-term blood pressure from physiologic analysis alone. In this setting, human genetics has proven highly informative, because the finding of mutations in specific genes that result in significant effects on blood pressure can establish a causal link between specific genes, their biochemical pathways, and blood pressure.[1]

There are a number of approaches to the discovery of human disease genes. One approach is to search for rare mutations with large effects on the trait. In the most extreme form these are so-called Mendelian traits, in which the presence of rare mutations produces a distinctive trait, and the transmission of that trait can be followed through families based on the clinical features. These traits generally follow a few simple patterns of inheritance. Autosomal dominant traits are produced by the inheritance of one mutated copy of a gene. As a result, such traits are commonly transmitted from an affected parent to half of their offspring, and multigenerational pedigrees with many affected subjects can sometimes be found. Dominant mutations can either be gain-of-function – in which the mutant gene has function not present in the normal gene – or less often loss of biochemical function, with a large effect produced by a 50% reduction in gene dosage. Dominant mutations that drastically impair reproductive fitness are commonly found as *de novo* mutations; new mutations found in affected index cases that are absent in their biological parents. Autosomal recessive traits require the inheritance of mutations in the genes on both chromosomes. Typical recessive pedigrees show affected subjects among a single sibship in a family, with parents being clinically unaffected and one in four of their offspring being affected. The mutations that cause autosomal recessive traits typically result in loss of biochemical function. Mutations on the X-chromosome produce distinctive patterns of transmission, since males have only one copy of this chromosome. As a result, these traits are never transmitted from affected fathers to their sons, and loss-of-function traits are found far more frequently among males than females. Other patterns of Mendelian transmission are much less frequent.

The development of complete genetic maps of the human genome identified extensive variations in DNA sequence, allowing the comparison of the inheritance of every segment of every chromosome to the inheritance of the Mendelian trait in families. With sufficient numbers of informative individuals and families, the chromosomal location of disease genes can be mapped, and genes in the linked interval can be searched for mutations. The finding of independent mutations that show specificity for the trait, and which significantly segregate with the trait in pedigrees, provides evidence that a gene responsible for the trait has been identified.

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00036-7

To date, genes and their corresponding mutations that underlie more than 3000 human disease traits have been identified by this approach. The strength of Mendelian genetics has been that the identified mutations directly identify the gene whose function is altered, and is causal to the trait. A second strength is that because the effect size is typically very large, robust inferences about the effect of implicated genes on the trait are possible.

A second general approach to genetic analysis is genetic association. This approach has historically sought to determine whether specific common variants are found with significantly different frequency among cohorts of patients contrasting for specific phenotypes. Early efforts typically used candidate gene approaches, and commonly produced false-positive results. The development of dense maps containing millions of common variants called single nucleotide polymorphisms (SNPs) across the human genome, coupled with the ability to genotype these inexpensively, has led to large-scale genome-wide association studies (GWAS). These studies have allowed careful matching of genetic backgrounds of cases and controls, as well as rigorous statistical thresholds for significance. More than 1200 robust associations of common sequence variations with disease have been established using this approach. Strengths of the approach are the ability to find effects that are common in the population. These have been highly informative in diseases for which Mendelian forms have not been found. Weaknesses are that the common variants are most often not in genes, and consequently identifying the genes whose expression might be altered can be difficult to establish. Also, effect sizes are typically very small, changing disease risk by ~20%. As a result, new biological inferences are frequently difficult to immediately discern from these studies. Nonetheless, these studies can provide leads for diseases that have not yielded productive results from Mendelian studies.

Most recently, the ability to inexpensively sequence whole genomes or whole exomes (all the exons of protein-coding genes) has provided new opportunities for disease gene discovery. Classes of Mendelian traits that were previously intractable, such as diseases caused predominantly by *de novo* mutations, can now be solved. Moreover, one can anticipate that searches for rare variants with moderate effect size – less than typical Mendelian traits, but much larger than GWAS signals – are likely to be discovered by sequencing large cohorts of cases and controls.

Insight into Human Blood Pressure Variation from Genetic Studies

In the past 20 years, molecular genetic studies of rare Mendelian diseases featuring extreme forms of hyper- and hypotension have greatly contributed to our understanding of renal salt handling, and its role in blood pressure regulation.[1] Despite the complexity of blood pressure regulation, which is influenced by diverse mechanisms including the neuronal, cardiovascular, and endocrine systems, many if not all of the genes thus far identified ultimately directly or indirectly affect renal salt reabsorption. Specifically, genes whose products increase renal salt reabsorption cause hypertension, while genes diminishing renal salt reabsorption result in hypovolemia, and sometimes life-threatening hypotension. Increased salt reabsorption is accompanied by water reabsorption to maintain normal concentrations of Na^+, leading to increased intravascular volume, increased venous blood return to the heart, and increased cardiac output via the Frank–Starling mechanism. Blood pressure then rises according to Ohm's law. These findings have implicated renal salt handling as a key element of long-term blood pressure homeostasis.

Nonetheless, hemodynamic patterns among hypertensive patients, even among those with primary increases in renal salt homeostasis, show increased systemic vascular resistance (SVR) with normal cardiac output. An explanation for this has been provided by Hall and Guyton, who have shown that tissues regulate their perfusion by increasing or decreasing vascular resistance according to metabolic demand. Dogs given aldosterone initially show expanded intravascular volume and increased cardiac output, but within weeks evolve to a state of high SVR and normal cardiac output.[2] These findings establish that one cannot infer the initiating cause of hypertension from steady-state hemodynamic profiles.

Overview of Renal Salt Homeostasis

The kidneys filter about 180 liters of plasma per day, containing ~1.5 kg of salt; ~99.5% of the filtered salt load must be reabsorbed on a typical Western diet to maintain sodium homeostasis (Figure 36.1). The bulk of this reabsorption (50–60%) occurs in the proximal tubule, driven by the basolateral Na^+/K^+-ATPase and apical Na^+/H^+ exchanger, as well as co-transporters that couple uptake of glucose, amino acids, and other solutes to the favorable gradient for Na^+ reabsorption. Approximately 30% of the filtered load is reabsorbed in the thick ascending limb of Henle (TAL) via the $Na^+/K^+/2Cl^-$ co-transporter NKCC2, the target of loop diuretics, and ~7–10% in the distal convoluted tubule (DCT) via the thiazide-sensitive Na-Cl co-transporter NCC. The fine-tuning of renal salt reabsorption (~2–5%) occurs in the connecting tubule (CNT) and cortical collecting duct (CCD), and is predominantly mediated by the epithelial sodium channel

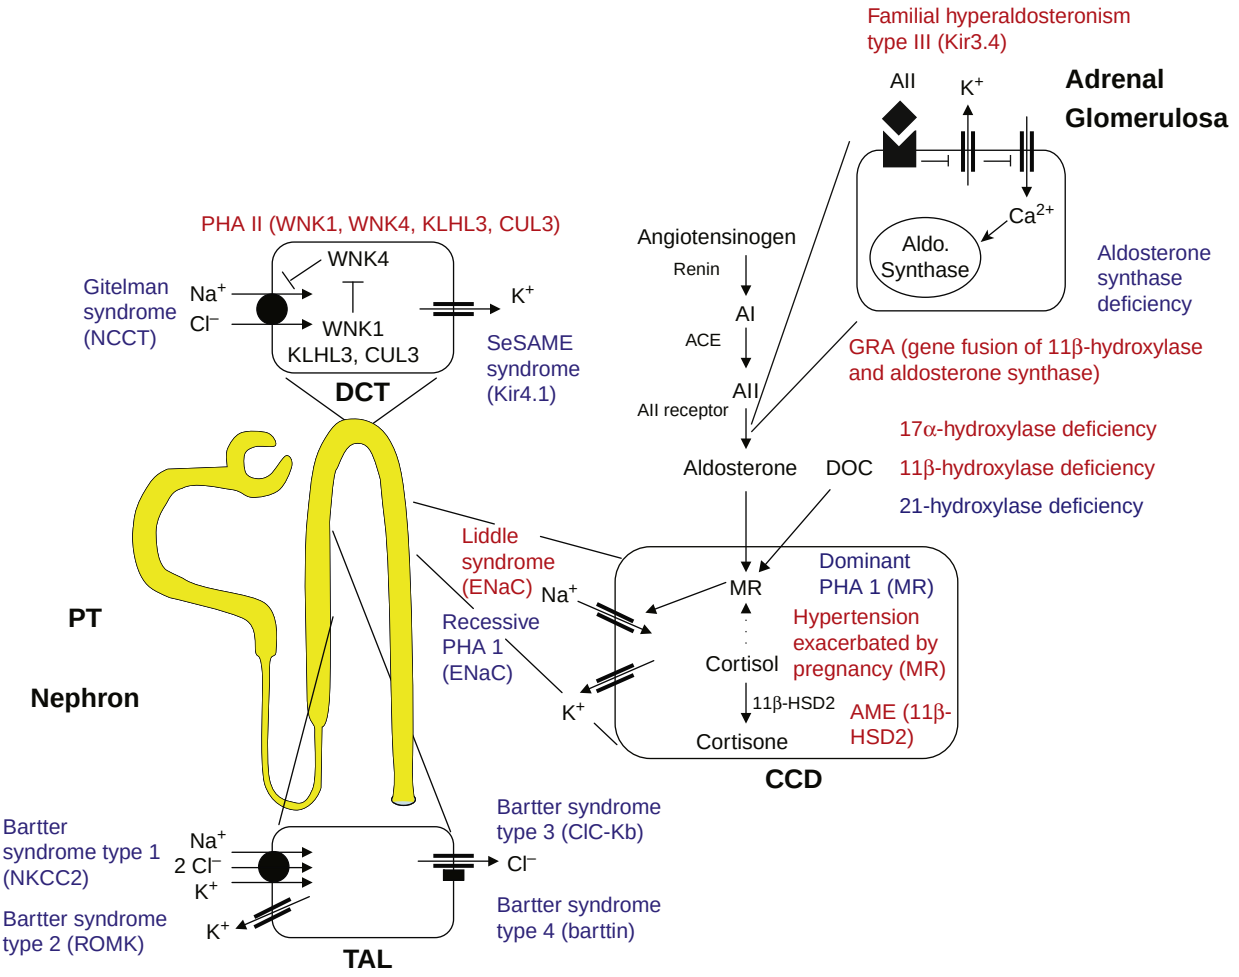

FIGURE 36.1 **Diagram of the nephron and the renin–angiotensin–aldosterone system.** Shown are key molecular pathways mutated in Mendelian forms of hypertension (red) and hypotension (blue). [1]).*

(ENaC), the target of the potassium-sparing diuretic amiloride. Many of the tubular channels, transporters, and regulators involved in these processes of salt reabsorption are affected by loss- and/or gain-of-function mutations that will be discussed in this chapter.

A major regulatory pathway that modulates renal salt reabsorption is the renin–angotensin–aldosterone system (Figure 36.1). In response to intravascular volume depletion or reduced delivery of salt to the thick ascending limb of Henle, the juxtaglomerular apparatus of the kidney secretes the active form of the aspartyl protease renin. Active renin cleaves angiotensinogen that is produced by the liver and constitutively circulates in the blood; this cleavage produces the decapeptide angiotensin I (AI), which is then cleaved by the angiotensin-converting enzyme (ACE), resulting in the octapeptide angiotensin II (AII). Angiotensin II binds to a specific G-protein-coupled receptor in adrenal glomerulosa (the type 1 angiotensin II receptor or AT1 receptor). This binding results in the activation of signaling cascades leading to adrenal glomerulosa membrane depolarization, activation of voltage-gated calcium channels, calcium influx, and increased synthesis of the steroid hormone aldosterone. Aldosterone, an effector of this pathway, communicates a signal for increased salt reabsorption to the kidney: it binds to the mineralocorticoid receptor (MR), a nuclear hormone receptor located in cells of the DCT, CNT, and principal cells of the CCD (the so-called aldosterone-sensitive distal nephron), leading to increased salt reabsorption via ENaC, and also the NCC (see above). The renin–angiotensin–aldosterone (RAA) pathway is not only

mutated in genetic disorders of salt homeostasis, but is also the target of multiple pharmacologic approaches in the treatment of hypertension, including renin inhibitors, ACE inhibitors, angiotensin receptor blockers, and aldosterone antagonists.

This chapter covers the genetic disorders that modulate blood pressure by altering renal salt reabsorption, as well as the insights into physiological mechanisms of blood pressure regulation derived from these discoveries.

GENETIC DISORDERS CAUSING HYPERTENSION

Mendelian forms of hypertension are rare among the general hypertensive population. Clues to the deduction that a patient may have an underlying Mendelian cause of hypertension generally come from the age of onset, the family history, and distinctive biochemical features. Hypertension is very uncommon in the first decade of life, and unusual before the age of 18; however, this is a typical finding among subjects with Mendelian hypertension. Consequently, Mendelian diseases should be considered in patients with early onset hypertension, and should be ruled out if there is also a family history of early onset hypertension. Other diseases that can cause hypertension in young subjects, such as structural renal defects and other causes of renal insufficiency, should be ruled out as well. Hypertension can be very severe, but this is not invariably the case. Biochemical findings that are most helpful in pointing to a diagnosis are plasma renin activity, aldosterone levels (best measured in 24 hour urine specimens), and serum/plasma electrolyte values. It is important to note that patients with aldosteronism need not have hypokalemia, and the absence of this finding should not be taken to exclude a disorder caused by increased aldosterone or increased activity of the mineralocorticoid receptor. An algorithm that is helpful in the evaluation of these patients is shown in Figure 36.2.

Disorders of the Renin–Angiotensin–Aldosterone System

Mutations that Increase Activation of the Mineralocorticoid Receptor

A number of genes have been identified in which mutation results in hypertension due to increased activation of the mineralocorticoid receptor (MR). These include diseases caused by mutations that lead to renin-independent production of aldosterone, as well as diseases in which steroids other than aldosterone can activate MR.

MUTATIONS RESULTING IN INCREASED ALDOSTERONE SECRETION

GLUCOCORTICOID-REMEDIABLE ALDOSTERONISM (FAMILIAL HYPERALDOSTERONISM TYPE I) Glucocorticoid-Remediable Aldosteronism (GRA) is an autosomal dominant disease featuring hypertension with inappropriate aldosterone secretion despite suppression of the renin–angiotensin system.[3] Patients typically present with hypertension in the first two decades of life, and are found to have elevated

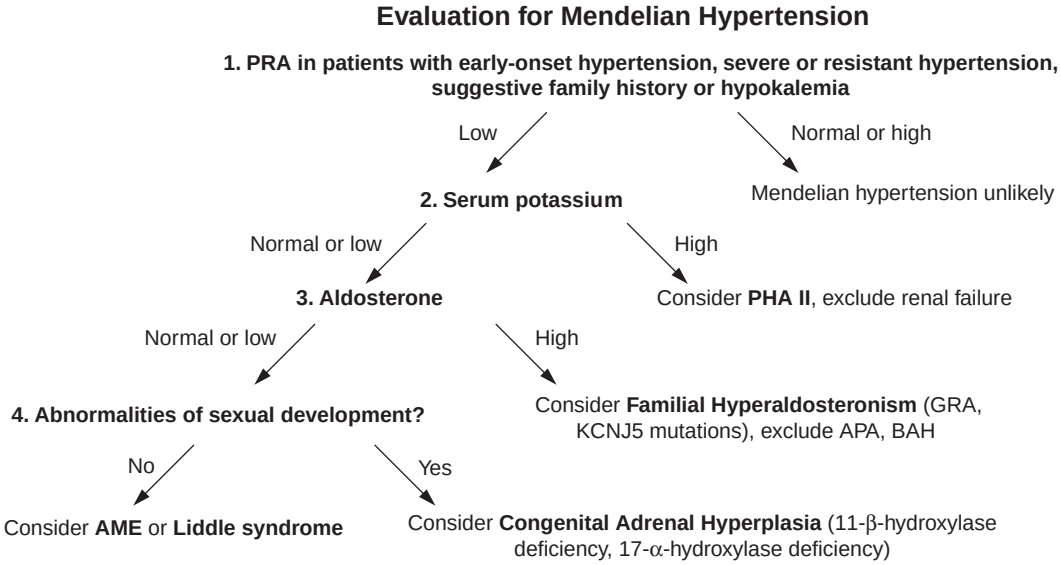

FIGURE 36.2 **A diagnostic approach to Mendelian hypertension.** (PRA: plasma renin activity; PHAII: pseudohypoaldosteronism type II; GRA: glucocorticoid remediable aldosteronism; APA: aldosterone-producing adenoma; BAH: bilateral adrenal hyperplasia; AME: apparent mineralocorticoid excess.)

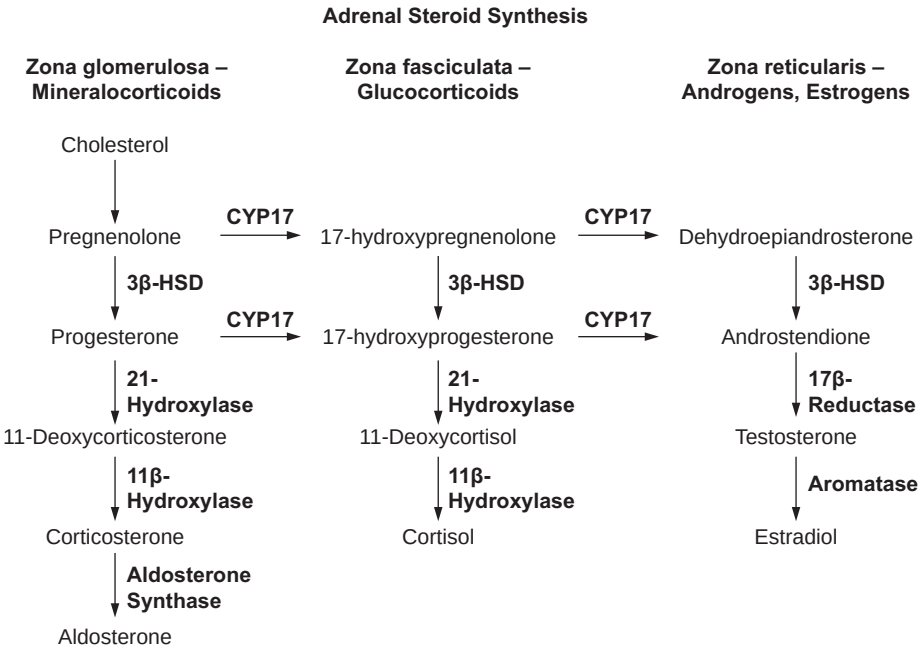

FIGURE 36.3 **Adrenal steroid synthesis.** Hormone synthesis in the adrenal cortex occurs in distinct compartments: aldosterone is synthesized in the outermost zona glomerulosa; cortisol in adrenal fasciculata; and sexual steroids in the innermost zona reticularis. Enzymes required for biosynthesis are noted (3β-HSD: 3β-hydroxysteroid dehydrogenase).

aldosterone secretion despite suppressed plasma renin activity, indicating autonomous production of aldosterone. Hypertension is often severe, and affected subjects are at a markedly increased risk of cerebral hemorrhage at young ages.[4] Hypokalemia and metabolic alkalosis are variable associated findings.[5,6] Consistent with autosomal dominant transmission, the family history is usually positive, with one parent and about half of siblings and offspring having early diagnosis of hypertension, and there is a frequent history of early cerebral hemorrhage.

Unlike normal individuals, aldosterone secretion in GRA shows sustained increase with administration of the cortisol secretagogue ACTH. Moreover, affected subjects produce so-called hybrid steroids, 18-hydroxy- and 18-oxocortisol, which are present in negligible amounts in normal subjects. These hybrid steroids have hydroxylation at C-17, characteristic of metabolism by 17-alpha hydroxylase (CYP17 gene) in the adrenal fasciculata, and oxidation at C-18, characteristic of metabolism by aldosterone synthase, which is normally confined to the adrenal glomerulosa[7,8] (Figure 36.3). Suppression of cortisol secretion from the adrenal gland by administration of exogenous glucocorticoids also causes rapid and sustained suppression of aldosterone secretion, a finding that does not occur in normal individuals.[3] These features suggest that aldosterone in GRA is produced in the adrenal fasciculata under the control of ACTH, rather than in adrenal glomerulosa under the control of the normal secretagogue angiotensin II (Ang II).

Analysis of linkage in a large GRA kindred demonstrated complete linkage of early hypertension to

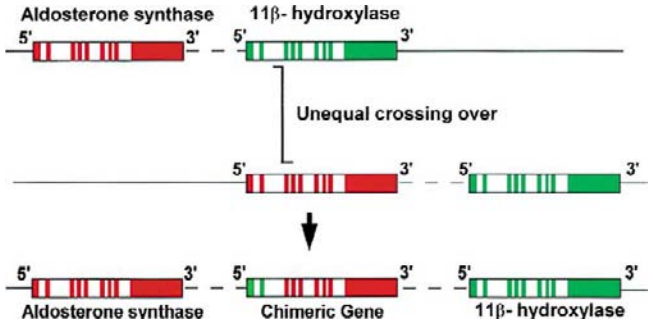

FIGURE 36.4 **Unequal crossing-over recombination between aldosterone synthase and 11-β hydroxylase causes GRA.** Shown is the segment of chromosome 8 that contains the two highly homologous genes. Unequal crossing-over between these two genes produces a chromosome with normal copies of aldosterone synthase and 11-β hydroxylase, and a third chimeric gene between them that fuses 5′ regulatory sequences from 11-β hydroxylase to coding sequences of aldosterone synthase, conferring aldosterone synthase function on the encoded gene product *(reproduced with permission from ref. [1]).*

chromosome 8q, which contains the gene aldosterone synthase (CYP11B2) and the closely related gene steroid 11-β hydroxylase (CYP11B1). These two genes recently evolved from a common ancestor, and are highly similar at the DNA sequence level. Patients with GRA prove uniformly to have mutations that result from unequal crossing-over recombination between these two homologous genes (Figure 36.4). This recombination event produces two mutant chromosomes, one with normal copies of aldosterone synthase and 11-β hydroxylase, and a third chimeric gene between them that fuses 5′ regulatory sequences from 11-β hydroxylase to coding sequences of aldosterone

synthase.[9,10] This is the mutation uniformly found in patients with GRA. The other mutant chromosome has no normal gene, and only a single hybrid gene that fuses 5′ sequences from aldosterone synthase to a coding sequence that produces 11-β hydroxylase enzymatic activity. This mutation is found in some patients with 11-β hydroxylase deficiency. These events occur in pre-meiotic germ cell development, hence only one is transmitted to a zygote. All of these recombination events seen in GRA occur upstream of exon 5,[10] with the result that the hybrid genes in patients with GRA include the two amino acids in exons 5 and 6 that are critical for the resulting enzyme having aldosterone synthase rather than 11-β hydroxylase activity.[11] These hybrid genes bear the 5′ regulatory elements of 11-β hydroxylase, and are consequently expressed in adrenal fasciculata under the control of ACTH, but encode aldosterone synthase enzymatic activity. As a consequence, aldosterone secretion in these patients is constitutive, driven by ACTH and the maintenance of normal cortisol levels. The renin−angiotensin system is suppressed, but this fails to turn off aldosterone production. These mutations thus account for the ectopic production of aldosterone in adrenal fasciculata and its control by ACTH, and explain the resulting hypertension.

GRA should be suspected by the finding of hypertension in young individuals with elevated aldosterone level (best measured in 24 hour urine samples), despite suppressed plasma renin activity, particularly if there is a history of early hypertension among first degree relatives. Hypokalemia and metabolic alkalosis are common but by no means invariant, and the absence of these findings should not be used to exclude the diagnosis.[5] Molecular genetic testing by either Southern blotting[9] or PCR[12] provides a sensitive and specific means for establishing the diagnosis. Because of the autosomal dominant transmission, there are frequently many affected members among extended families of index cases, and case finding can be performed by sequential sampling, testing all first degree relatives of affected subjects, then all first degree relatives of positive cases in subsequent rounds. Sampling in these families is likely to prevent morbidity and mortality from uncontrolled hypertension and early cerebral hemorrhage. Because of the availability of genetic screening, determination of urinary levels of hybrid steroids or dexamethasone suppression test is no longer recommended.[13] Of note, family screening has demonstrated that not all individuals carrying the gene fusion are hypertensive,[14] and first degree relatives of patients with confirmed GRA should be genetically screened even in the absence of hypertension.[15]

Treatment options for GRA include use of mineralocorticoid receptor antagonists (spironolactone or eplerenone), amiloride or triamterene (which inhibit the epithelial sodium channel that drives both hypertension and hypokalemic alkalosis in GRA). Exogenous glucocorticoids can be used to shut down aldosterone production from the adrenal fasciculata. Careful attention to dosage in children is essential to maintain normal growth and to avoid glucocorticoid side-effects. Potassium-wasting diuretics such as hydrochlorothiazide and furosemide should be used with caution, because of the risk of severe hypokalemia.[13,15]

ALDOSTERONE-PRODUCING ADRENAL ADENOMA AND FAMILIAL HYPERALDOSTERONISM DUE TO KCNJ5 MUTATIONS Aldosterone-producing adenoma, also known as Conn's syndrome,[16] is a common cause of severe hypertension, found in about 5% of patients in hypertension referral clinics worldwide, and in about half of patients diagnosed with primary aldosteronism.[17] Patients typically present with worsening hypertension, and are found to have elevated serum and 24 hour urinary aldosterone levels in conjunction with suppressed plasma renin activity, consistent with these tumors having renin-independent aldosterone secretion. Hypokalemia and metabolic alkalosis are frequent, but not invariant findings. The finding of an adrenal mass by CT scan with increased aldosterone levels in ipsilateral adrenal vein plasma is considered diagnostic, and removal of these tumors corrects or improves blood pressure in the large majority of patients.[13]

Exome sequencing of four aldosterone-producing adrenal adenomas (APAs) and matched blood DNA enabled identification of somatic mutations in the tumors.[18] The results showed a low somatic mutation rate, with only 2−5 somatic mutations per tumor. Surprisingly, the K^+ channel encoded by KCNJ5 was mutated in two of these tumors. Examination of this channel in 22 tumors identified somatic KCNJ5 mutations in 8 tumors, and either of the same two mutations were found in all, substituting arginine for glycine at position 151 or arginine for leucine at position 168. These two positions lie in or abut the highly conserved K^+ channel selectivity filter that enables these channels to allow passage of K^+ but not other ions through the channel pore.[19,20] Electrophysiologic studies demonstrated that these mutations cause markedly increased Na^+ conductance of the mutant channel, sufficient to depolarize the cell.

These findings explain the pathogenesis of APA in these tumors. The normal adrenal glomerulosa cell is hyperpolarized owing to constitutively open K^+ channels.[21,22] Angiotensin II signaling results in closure of these channels,[23,24] resulting in depolarization and activation of voltage-gated calcium channels, which raises

intracellular calcium. Hyperkalemia produces the same results, potentially via increased frequency of depolarizing membrane potential oscillations.[25] Increased intracellular Ca^{2+} is the acute signal for increased expression of aldosterone synthase and other rate-limiting steps in aldosterone biosynthesis. Chronic signaling provides the stimulus for increased cell replication.[26] Thus, these single mutations can explain both the cell-autonomous aldosterone secretion and cell proliferation that are the hallmarks of these benign tumors.

Subsequent work has confirmed these findings. The study of 287 tumors by Björklund et al. found the G151R or L168R mutations in 47% of APAs, and a markedly higher prevalence of these mutations among women with APA (63%) than men (22%). Only one additional mutation (E145Q) was found in two cases.[26a] Similar findings were observed by Boulkroun et al., who found either of these two mutations in 34% of all APAs with a similar bias for female subjects.[27] These tumors are more prevalent among younger individuals, and tend to be slightly larger compared to non-KCNJ5-mutant tumors.

In addition to these mutations causing APAs, they also account for a rare inherited form of primary aldosteronism. In 2008, Geller et al. reported a father and two daughters with a new familial form of severe early-onset hypertension due to primary aldosteronism.[28] Hypertension in these patients was diagnosed between the ages of 4 and 7 years; it was resistant to aggressive antihypertensive therapy, including spironolactone and amiloride. There was massive adrenocortical hyperplasia. Hybrid steroids 18-oxocortisol and 18-hydroxycortisol were elevated, however, in clear contrast to patients with GRA, there was a significant increase in aldosterone levels upon dexamethasone administration, and affected subjects did not have the gene fusion characteristic of GRA. Due to unrelenting hypertension, all three subjects underwent bilateral adrenalectomy in childhood, demonstrating massive adrenal hyperplasia (with paired adrenal weights up to 81 g, normal is less than 12 g) and diffuse hyperplasia of the zona fasciculata by light microscopy (with transitional zone morphology by electron microscopy). Screening of candidate genes revealed no pathogenic mutations.

Affected members of this family proved to have a T158A mutation in KCNJ5 which also modified channel selectivity, resulting in Na^+ conductance.[18] In this case, since the mutation is present in every cell, rather than acquired somatically by a single cell, every cell in the adrenal glomerulosa is receiving the signal for aldosterone production and cell proliferation, accounting for the massive adrenal hyperplasia and severe aldosteronism at young ages. This Mendelian form of disease provides strong evidence that these single mutations are sufficient for cell proliferation and constitutive aldosterone secretion.

Subsequent studies have identified additional families with early severe aldosteronism and mutations in KCNJ5. Most interestingly, these include two different mutations at the same amino acid – G151 – that result in markedly different phenotypes. One of these inherited mutations is G151R, the same mutation found as a somatic mutation in APA. Patients with inherited G151R[29] mutations develop massive adrenocortical hyperplasia, have difficult-to-control hypertension, and virtually invariably come to bilateral adrenalectomy for control of hypertension, similar to the T158A mutation described above. The other mutation is G151E. Patients with this mutation also present with early hypertension and aldosteronism; however, they do not develop adrenal hyperplasia, are typically responsive to antihypertensive therapy, and do not come to adrenalectomy.[29–31] Most interestingly, the milder human phenotype resulting from G151E is associated with a much more severe electrophysiologic phenotype. G151E results in dramatically greater Na^+ conductance than G151R. The consequence of this is markedly increased sodium-dependent lethality. This suggests a model in which cells expressing the G151E mutation differentiate from a stem cell pool, produce aldosterone as they are born, but die rapidly, preventing development of hyperplasia. Their continuous renewal from a stem cell pool provides a long-term source for excessive aldosterone production, and a milder hypertension than in subjects with the G151R mutation.

This phenotype of primary aldosteronism without adrenal hyperplasia due to KCNJ5 mutation is as yet unique to the G151E mutation, while massive adrenal hyperplasia requiring adrenalectomy has also been reported with another KCNJ5 mutation, I157S.[32]

While KCNJ5 mutations unequivocally explain the pathogenesis of a large fraction of APAs and a rare form of familial hypertension, the role of the wild-type channel in human adrenal function is less clear. Its activation by dopamine, an inhibitor of aldosterone secretion,[18,33] suggests that the normal role of this channel might be to hyperpolarize cells, contributing to inhibition of aldosterone secretion.

Primary aldosteronism due to mutations in aldosterone synthase and KCNJ5 both produce constitutive secretion of aldosterone and hypertension. Patients with KCNJ5 mutations tend to present in the first several years of life with severe hypertension, while those with GRA are more frequently, though not exclusively, diagnosed later in the first or second decade. Consistent with greater disease severity among KCNJ5 families and impaired reproductive fitness, no families

with more than four affected members have been reported to date, while a number of large, multigenerational families with more than 20 members with GRA have been studied.

MUTATIONS CAUSING IMPAIRED CORTISOL BIOSYNTHESIS AND INCREASED MINERALOCORTICOIDS

CONGENITAL ADRENAL HYPERPLASIA DUE TO 11-β-HYDROXYLASE DEFICIENCY Congenital adrenal hyperplasia (CAH) is a recessive disease, featuring cortisol deficiency caused by inherited defects of enzymes required for cortisol biosynthesis in the adrenal gland. Affected patients have increased ACTH levels due to impaired feedback inhibition, which stimulates excessive production of steroids proximal to the impaired step in cortisol biosynthesis. Precursor steroids can have androgenic effects, and female patients may present with virilization. In the most common form of CAH (21-hydroxylase deficiency), impaired synthesis of mineralocorticoids leads to salt-wasting (see below), while other defects can result in accumulation of precursors which have mineralocorticoid effects, leading to hypertension.

The most common form of congenital adrenal hyperplasia associated with hypertension is 11-β-hydroxylase deficiency[34] (Figure 36.3). Affected females may present with ambiguous genitalia at birth or with menstrual irregularities and hirsutism in adolescence or adulthood, while male subjects may present with penile enlargement or precocious puberty. Hypertension and hypokalemia are variable associated features, and are thought to occur due to the accumulation of 11-deoxycorticosterone, a moderately potent mineralocorticoid. However, there is no clear correlation between 11-deoxycorticosterone levels, the degree of virilization and the presence of hypertension. Renin and aldosterone are typically low.[35–37]

In most cases, 11-β-hydroxylase deficiency is caused by recessive point mutations that cause loss-of-function of CYP11B1, although loss-of-function mutations due to the reciprocal product of unequal crossing-over between aldosterone synthase and 11-β-hydroxylase found in GRA (see above) can also produce loss-of-function mutations (in this case there is a chromosome that only expresses 11-β hydroxylase in adrenal glomerulosa).[38]

11-β-hydroxylase deficiency should be suspected in female infants with ambiguous genitalia and male infants with penile enlargement. In the late onset form, hirsutism and menstrual irregularities in female patients and precocious puberty in boys may be the only signs of presentation. The abnormal hormone profile, in particular the finding of elevated basal and ACTH-stimulated 11-deoxycortisol concentrations, is diagnostic. Treatment with exogenous glucocorticoids suppresses ACTH secretion and the accumulation of precursor steroids. Precursor steroids should be monitored, and glucocorticoid dosage has to be carefully adjusted to avoid growth inhibition in children and exogenous Cushing's syndrome. Persistent hypertension may require additional treatment with aldosterone antagonists or amiloride.

CONGENITAL ADRENAL HYPERPLASIA DUE TO 17-α-HYDROXYLASE DEFICIENCY 17-α-hydroxylase deficiency[39] is a rare cause of congenital adrenal hyperplasia. Patients typically present in adolescence with lack of pubertal development. Genetic females have primary amenorrhea and do not develop secondary sexual characteristics; genetic males typically have complete pseudohermaphroditism with female external genitalia and intra-abdominal testes, although ambiguous genitalia have been reported. Hypertension is a common finding, and may be associated with hypokalemia.[40]

17-α-hydroxylase deficiency is caused by mutations in CYP17.[41] The encoded enzyme is expressed in adrenal gland and gonads, and has both 17-hydroxylase and 17,20-lyase activities (Figure 36.3). Most patients with CYP17 mutations thus have combined deficiencies of both enzymatic functions, although isolated deficiency of 17,20-lyase activity has been reported.[42] Hydroxylation at carbon 17 of the steroid nucleus is required for cortisol production, and in its absence normal activation of the glucocorticoid receptor is not achieved. In addition, 17,20-lyase activity is needed for the generation of androgen and estrogen precursors from cortisol precursors.

Patients with CYP17 mutations consequently have cortisol deficiency leading to elevated ACTH levels, as well as androgen and estrogen deficiency, accounting for sexual infantilism and pseudohermaphroditism. Hypertension is caused by activation of the mineralocorticoid receptor (MR) due to increased levels of 11-deoxysteroids (corticosterone, 11-deoxycorticosterone, and 18-hydroxy-deoxycorticosterone), similar to the mechanism of hypertension in 11-β-hydroxylase deficiency. As a result, renin and aldosterone are typically suppressed.

The diagnosis is based on the clinical presentation and characteristic hormone profile, and treatment relies on replacement of glucocorticoids and sex steroids, the latter starting in adolescence.

Mutations that Impair Conversion of Cortisol to Cortisone: Syndrome of Apparent Mineralocorticoid Excess

The syndrome of apparent mineralocorticoid excess (AME)[43] is an autosomal recessive disease featuring severe hypertension presenting in the first decade of

life. It is associated with suppression of both the renin–angiotensin system and aldosterone secretion. Hypokalemia and metabolic alkalosis are common associated findings. The hypertension can be mitigated with antagonists of the mineralocorticoid receptor, which suggested the presence of a new circulating mineralocorticoid; however, such a molecule was not found. Instead, a defect in cortisol metabolism was identified in affected patients, causing reduced conversion of cortisol to cortisone, with a consequently increased half-life of cortisol.[44]

How this defect in cortisol metabolism resulted in hypertension remained unclear until the cloning and subsequent purification of the mineralocorticoid receptor (MR).[45] *In vitro*, cortisol binds and activates MR as well as aldosterone does,[46] while cortisol is normally a weak mineralocorticoid *in vivo*. This discrepancy is explained by the presence in many aldosterone-responsive cells of an enzyme, steroid 11-β hydroxysteroid dehydrogenase type 2 (11βHSD2), that "protects" MR from cortisol by converting cortisol to cortisone. Cortisone has negligible ability to activate MR. The finding of homozygous loss-of-function mutations in 11βHSD2 in AME provided proof of the relevance of this mechanism *in vivo*.[47] These findings fully explain the pathophysiology of AME, and are confirmed by the recapitulation of AME in mice deficient for 11βHSD2.[48]

AME should be suspected in young individuals with hypertension, suppressed PRA, and low aldosterone levels. AME shares these clinical features with Liddle syndrome (see below); however, Liddle syndrome is autosomal dominant, and affected subjects consequently commonly have one parent with early severe hypertension, and may have other relatives in earlier generations or other branches of the pedigree with similar findings. In contrast, AME is suggested by the absence of disease in earlier generations and the presence of parental consanguinity. The diagnosis of AME can typically be made by genetic testing involving sequencing of 11βHSD2. Abnormal cortisol:cortisone ratios can also establish the diagnosis.[49]

Inhibitors of the mineralocorticoid receptor, such as spironolactone or eplerenone, or inhibitors of the epithelial sodium channel, such as amiloride or triamterene, are treatment options in AME. Eplerenone has recently been suggested for prevention of strokes even in the absence of hypertension; however, the utility of this approach is not established.[50]

Intriguingly, exuberant ingestion of natural licorice produces a clinically similar syndrome owing to the effects of a metabolite of glycyrrhetinic acid – derived from glycyrrhizic acid in licorice – which inhibits 11βHSD2.[51] Carbenoxolone, a drug once used for peptic/gastric ulcer disease, has similar effects.

In the presence of 11βHSD2, elevated levels of cortisol are required to achieve activation of the mineralocorticoid receptor (by exceeding the capacity of 11βHSD2 to metabolize cortisol).[1] Hypertension can therefore occur in states of glucocorticoid excess, such as ectopic ACTH syndrome, Cushing's disease due to a pituitary tumor, iatrogenic Cushing's syndrome or cortisol-producing adenomas.

Mutations in the Mineralocorticoid Receptor

HYPERTENSION EXACERBATED IN PREGNANCY

As discussed above, binding of aldosterone to the mineralocorticoid receptor causes increased renal salt reabsorption by raising the activity of the epithelial sodium channel ENaC, which results in elevated blood pressure. Geller and colleagues identified an as-yet unique family with early onset of typically severe hypertension associated with suppressed PRA, negligible aldosterone levels, and variable hypokalemia and alkalosis; this trait segregated as an autosomal dominant trait in a large extended family.[52,53] A striking clinical feature among affected women was marked exacerbation of hypertension in pregnancy, requiring early delivery for poorly controlled hypertension and marked hypokalemia. Analysis of linkage in this large kindred localized the disease gene to the segment of chromosome 4 that harbors the mineralocorticoid receptor. This gene proved to have a novel missense mutation in the ligand-binding domain, S810L, which precisely co-segregated with the disease phenotype in the kindred.

The clinical features suggested that this mutation results in an activated receptor, despite the absence of aldosterone. *In vitro* studies demonstrated that this is the case: the mutant receptor shows partial constitutive activity in the absence of ligand. In addition, however, the mutation altered the specificity of the receptor such that some steroids lacking 21-hydroxyl groups, which normally fail to activate MR, are now potent agonists. One of these new agonists is progesterone, a steroid whose level increases dramatically in pregnancy. Cortisone is another molecule that can more weakly activate the mutant receptor, suggesting that this cortisol metabolite may play a constitutive role. The crystal structure of the mutant mineralocorticoid receptor was solved,[54] suggesting that progesterone-induced MR S810L activation is caused by a network of contacts at the A-ring, created by L810.

Mutations that Cause Hypertension without Activation of MR

Mineralocorticoids impart their renal effects by modulating the expression and activity of ion

transporters and channels. Mutations in several genes have been identified that cause hypertension without activation of MR.

LIDDLE SYNDROME Liddle syndrome[55] is an autosomal dominant trait featuring hypertension with variable hypokalemia and alkalosis. While these features recapitulate the phenotype of the diseases with mineralocorticoid excess discussed above, there are no circulating mineralocorticoids in patients with Liddle syndrome. Hypertension is responsive to treatment with blockers of the epithelial sodium channel ENaC (amiloride or triamterene), but not to spironolactone.

Genetic studies identified rare mutations in subunits of ENaC as the cause of Liddle syndrome[56,57] (Figures 36.5 and 36.6). ENaC is composed of subunits encoded by three homologous genes, alpha, beta, and gamma[58]; each has cytoplasmic amino and carboxy termini, and traverses the plasma membrane twice.[59] Virtually all mutations that cause Liddle syndrome eliminate a sequence required for removal of the channel from the cell surface by clathrin-coated pit-mediated endocytosis. This internalization sequence, PPPXY (where X is variable among different ENaC subunits) is present in the carboxy terminus of each subunit. Disease causing mutations introduce premature termination codons after the second transmembrane domain and before the PPPXY sequence, or alternatively produce missense mutations at one of the cognate positions of the internalization motif.[56,57,60] These mutations result in reduced clearance and prolonged half-life of the channel at the cell surface[61–63] (Figure 36.6). Nedd4 was subsequently identified as having domains that specifically bind the PPPXY domains in ENaC, and contribute to its clearance from the cell surface.[64] This protein contains ubiquitin-ligase domains, suggesting that ubiquitination and subsequent degradation plays a role in ENaC regulation. The likely candidate for this regulation in human kidney is Nedd4-2.[65] Together, these findings suggest that mutations in ENaC in Liddle syndrome impair binding of Nedd4 to the mutant channel, and prevent ubiquitination and degradation. In addition to the mutations deleting or altering the PY motif, a mutation in the extracellular domain of γ-ENaC has been reported as causing an increased open probability of the channel.[66] Consistent with these genetic findings, renal transplantation can cure the hypertension of Liddle syndrome.[67]

A mouse model of Liddle syndrome[68] does not develop hypertension or hypokalemic alkalosis on a standard diet, despite increased ENaC activity. However, a Liddle phenotype develops when these animals are fed a high-salt diet.

Liddle syndrome should be suspected in patients with early hypertension and suppressed PRA and aldosterone levels; hypokalemia and metabolic alkalosis are supportive, but not essential findings. As discussed above, these features are shared with AME. A family history of hypertension consistent with

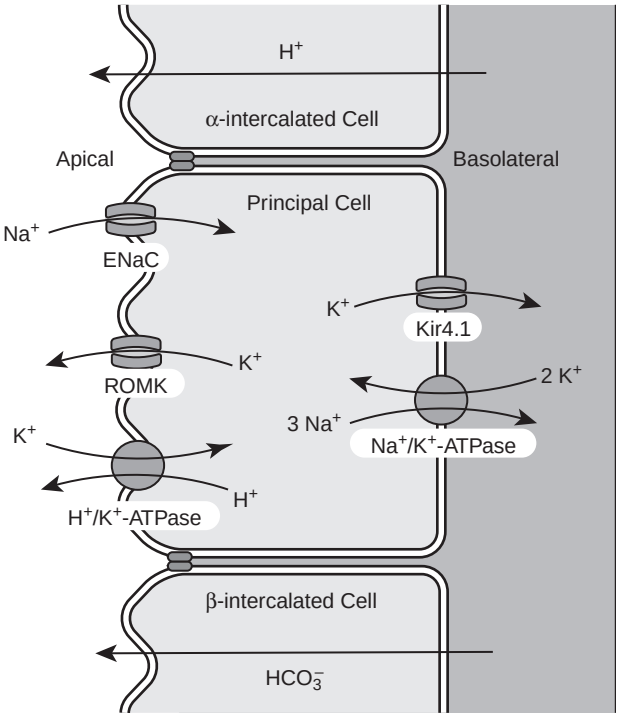

FIGURE 36.5 **Salt reabsorption in the cortical collecting duct.** Na^+ reabsorption in the principal cells of the cortical collecting duct is dependent on aldosterone and happens via ENaC. The resulting lumen-negative potential promotes K^+ secretion via ROMK and H^+ secretion.

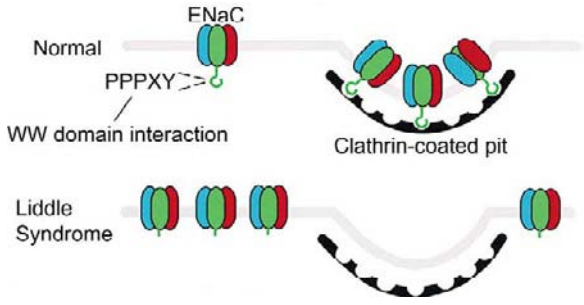

FIGURE 36.6 **Increased surface expression of the epithelial sodium channel ENaC causes Liddle syndrome.** The β- and γ-subunits of the channel contain a PPPXY motif in the cytoplasmic C-terminus. In normal individuals, binding of Nedd4-2 (not shown) leads to internalization in clathrin-coated pits. Channels are then either degraded or recycled back to the membrane. ENaC lacking the PPPXY motif in Liddle syndrome does not interact with Nedd4-2, and as a result is retained at the membrane. This causes increased Na^+ reabsorption and hypertension in affected individuals *(reproduced with permission from ref. [1]).*

autosomal dominant transmission, however, is suggestive of Liddle syndrome. Genetic testing is recommended. Treatment with amiloride or triamterene can correct hypertension and hypokalemia.

THE SYNDROME OF HYPERTENSION WITH HYPERKALEMIA (PSEUDOHYPOALDOSTERONISM TYPE II) Aldosterone is secreted in two distinct physiologic conditions: volume depletion and hyperkalemia. Restoration of normal intravascular volume in the former condition requires increased salt and water reabsorption, while K^+ secretion must be increased in the latter state. How the kidney achieves these alternative results has been obscure. Classical explanations have suggested that this is a result of alterations in fluid flow and/or delivery of salt to the distal nephron. The notion that this is an incomplete explanation comes from a disease in which the kidney appears to be unable to use aldosterone to direct K^+ secretion, but instead constitutively activates salt reabsorption. This disease, referred to as pseudohypoaldosteronism type II (also known as syndrome of hyperkalemia with hypertension, Gordon syndrome) invariably features hyperkalemia, and has variable levels of hypertension and distal renal tubular acidosis. Aldosterone levels are normal to slightly elevated, and plasma renin activity is suppressed. Serum K^+ levels are virtually always greater than 5.0 mM without therapy, and can be greater than 7.0 mM. The disease was first described in 1964 by Paver and Pauline, who reported a 15-year-old boy with blood pressure 180/120 mmHg, serum potassium 7.0–8.2 mM, but normal glomerular filtration, and suppressed PRA and normal aldosterone.[69] Since early descriptions, the disease has been recognized to be familial, initially described as an autosomal dominant trait.[70–72]

Subsequent studies have demonstrated that K^+ cannot be corrected by supplemental aldosterone; however, both hypertension and hyperkalemia can be corrected by elimination of chloride intake or by low doses of thiazide diuretics.[70,73] These findings have suggested that increased activity of the thiazide-sensitive Na-Cl co-transporter may play a role in this disease.

Analysis of genetic linkage in families followed by molecular studies identified mutations in two members of a novel family of serine-threonine kinases, PRKWNK1 and PRKWNK4, as causes of PHAII[74] (Figure 36.7). Mutations in WNK4 were novel missense mutations that predominantly clustered in a short acidic domain of unknown function in the protein. Mutations in WNK1 were large deletions of 20,000 to 40,000 base pairs in the first intron of WNK1 that caused increased expression of WNK1 mRNA. These genes were both found to be expressed

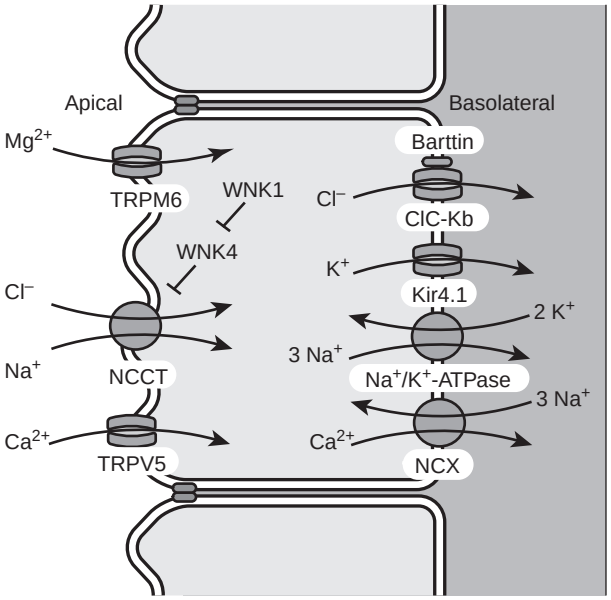

FIGURE 36.7 Salt reabsorption in the distal convoluted tubule. Salt reabsorption is driven by the activity of the Na^+/K^+-ATPase on the basolateral suface. K^+ entering the cell via the sodium pump recirculates through Kir4.1 ("pump leak coupling"). NaCl enters the cell via NCCT following the favorable Na^+ gradient, and Cl^- exits via basolateral ClC-Kb channels. The basolateral NCX transporter uses the Na^+ gradient for Ca^{2+} reabsorption. Ca^{2+} enters on the apical site via the TRPV5 channel. On the apical surface, Mg^{2+} enters the cell via TRPM6. The molecular identity of a putative basolateral Mg^{2+} transporter is unknown. NCCT activity is regulated by the WNK1 and WNK4 protein kinases.

in the distal convoluted tubule and collecting duct of the kidney.

At the time of this discovery, the normal and disease-related functions of WNK1 and WNK4 were entirely unknown. Much subsequent work has been done to determine the roles these WNK kinases play in physiology.[74–82] It appears that both play a role in coordinating the functions of diverse electrolyte flux pathways, and that a key function in the kidney is to regulate the balance between Na-Cl reabsorption and K^+ secretion. The WNK kinases regulate ion transport by several mechanisms, among them phosphorylation via intermediary kinases (SPAK, OSR1, and SGK1), and regulation of protein trafficking.[81]

Early studies addressed the role of WNK4 in the regulation of NCCT using the oocyte expression system.[75,83] Co-expression of NCCT with WT-WNK4 resulted in inhibition of thiazide-sensitive Na^+ uptake due to reduced surface expression. This effect was completely abrogated when a mutation seen in PHA II (Q562E) or kinase-dead WNK4 was used, suggesting that NCCT inhibition is lost in patients with PHA II, causing hypertension. Subsequent studies in mammalian cells suggested that this inhibitory WNK4 effect is

mediated by suppression of membrane delivery via lysosomal accumulation.[84]

Co-expression with WNK4 also dramatically reduces ROMK activity in oocytes,[76] by interaction with an endocytic scaffold protein, intersectin.[85] However, in contrast to the effect on NCCT, PHA II-mutant WNK4 produces increased inhibition of ROMK, accounting for hyperkalemia in PHA II. While WT WNK4 led to a modest increase of paracellular chloride permeability in MDCK cells, this effect was greatly augmented in PHA II-mutant WNK4, which may contribute to the chloride retention observed in PHA II.[77,78] In addition, WNK4 inhibited ENaC activity in oocytes, and this inhibition was relieved by PHA II mutations.[86] The inhibitory effect of WNK4 on ENaC and ROMK appears to require phosphorylation of WNK4 by SGK1, a kinase which translates aldosterone effects in the kidney.[87]

Similar studies as for WNK4 were performed for WNK1. While a direct effect of WNK1 on NCCT was not identified, a long isoform of WNK1 (L-WNK1) inhibits WNK4 (which inhibits NCCT, see above), and a kidney-specific isoform (KS-WNK1) inhibits L-WNK1.[75] In addition, L-WNK1 inhibits ROMK, an effect reversed by KS-WNK1 and synergistic with, but not dependent on, the WNK4 effect on ROMK[88]; L-WNK1 also activates ENaC.[89] Finally, similar to WNK4, WNK1 increases paracellular chloride flux.[90] ATII, which is produced in volume depletion, appears to be an upstream regulator of WNK4, attenuating its inhibitory effect on NCCT and thus stimulating salt reabsorption via NCCT. In contrast, the inhibitory effect of WNK4 of ROMK is retained. These findings suggest that PHA II mutations mimic a state of volume depletion with increased angiotensin II levels.[91]

Regulation of several additional proteins (e.g., TRP channels, SLC26A6) by WNK1 and WNK4 kinases has been reported, and studies of the related kinase WNK3 has revealed a role in regulation of NKCC, as well as KCC co-transporters.[92]

Taken together, *in vitro* studies suggest a key role of the WNK kinases in a functional switch among three states governing the balance between salt reabsorption and K^+ secretion. In a basal equilibrium state, both NaCl reabsorption and K^+ secretion are inhibited by the WNK kinases. In the setting of low intravascular volume, AII signaling inhibits WNK4's inhibition of NCC, but increases inhibition of ROMK; this effect is mimicked by PHA II mutations, accounting for constitutive NaCl reabsorption and hyperkalemia seen in affected patients. In a third state, hyperkalemia leads to increased aldosterone production by the adrenal gland and, potentially via SGK, to increased ROMK activity and increased ENaC activity, with sustained inhibition of electroneutral salt reabsorption via NCCT.[80]

Animal models have confirmed the role of WNK1 and WNK4 in generating hyperkalemia and hypertension. A transgenic mouse model carrying an additional copy of PHA II-mutant WNK4 shows hypertension, hyperkalemia, and hypercalciuria and, in addition, increased mass of the distal convoluted tubule and increased NCCT expression. In contrast, an additional copy of WT WNK4 leads to decreased DCT mass and reduced NCCT abundance.[79] A knockout mouse model of WNK4 displays a phenotype similar to Gitelman syndrome (see below), with increased plasma renin activity, and decreased NCC activity.[93] Deletion of the first WNK1 intron as found in PHA II in mice leads to ubiquitous ectopic KS-WNK1 expression, as well as overexpression of L-WNK1 in the DCT,[94] which explains increased activity of NCCT through alleviation of WNK4 inhibition.

Importantly, mutations in WNK1 and WNK4 explained only about 15% of families with PHA II. Exome sequencing of unrelated PHA II cases led to the identification of two additional genes for PHA II, which together account for nearly all of the remaining cases.[95,96] These two genes are partners in a ubiquitin ligase complex. Cullin 3 (CUL3) is a scaffold that serves to assemble a complex containing a RING E-3 ubiquitin ligase and one of many BTB domain-containing proteins that target specific proteins for ubiquitination. One of these BTB domain proteins is Kelch-like 3 (KLHL3). KLHL3 has a C-terminal BTB domain, and an N-terminal kelch domain, a six-bladed propeller that is likely used to bind and target proteins for ubiquitination. Surprisingly, different families showed either autosomal dominant or autosomal recessive transmission of mutations in KLHL3. Recessive mutations are distributed throughout the protein, and include typical loss-of-function mutations such as premature termination mutations. In contrast, dominant mutations cluster at positions in the kelch domain that are clustered at parts of the domain inferred to be involved in target binding. Because these dominant mutations produce a phenotype very similar to that caused by homozygous loss-of-function mutations in KLHL3, the dominant mutations likely have a dominant-negative effect.

The mutations in CUL3 that cause PHA II all cause skipping of exon 9, resulting in an in-frame deletion of 57 amino acids between the BTB-binding and RING-binding domains. These mutations are all dominant, and nearly all appear to be *de novo* mutations. Because these mutations phenocopy recessive loss-of-function mutations in KLHL3, it is inferred that these CUL3 mutations selectively prevent ubiquitination at targets bound by KLHL3. While CUL3 is ubiquitously expressed, KLHL3 is selectively expressed in the distal nephron.

Comparison of the phenotypes of patients with mutations in these different genes reveals strong genotype–phenotype correlations. Patients with CUL3 mutations have the most severe hyperkalemia, are nearly always hypertensive at young ages, and commonly have acidosis. Patients with recessive and dominant KLHL3 mutations have intermediate phenotypic severity, and those with WNK1 and WNK4 mutations often have only hyperkalemia without hypertension at early ages, and do not uniformly develop hypertension at later ages. The molecular mechanisms that link mutations in KLHL3 and CUL3 to PHA II are presently unknown; however, it is highly likely that these mutations will intersect with the WNK/NCC/ROMK pathway.

GENETIC DISORDERS CAUSING RENAL SALT LOSS

Several Mendelian disorders can cause renal salt loss, leading to signs and symptoms ranging from mild polyuria and salt craving to life-threatening hypotension and shock. A diagnostic approach to these diseases is suggested in Figure 36.8.

Disorders of the Renin–Angiotensin–Aldosterone System

Mutations Affecting Circulating Mineralocorticoid Levels

MUTATIONS RESULTING IN CONGENITAL HYPOALDOSTERONISM

Congenital hyper-reninemic hypoaldosteronism is a rare autosomal recessive disorder.[97,98] Affected patients present in infancy with salt-wasting, leading to severe dehydration, failure to thrive and growth retardation, as well as hyponatremia and hyperkalemia. Aldosterone is low despite elevated renin. These features are a clinical mirror image of the states of primary aldosteronism described above.

Genetic studies identified mutations in the aldosterone synthase gene (CYP11B2) as the cause of congenital hypoaldosteronism.[99,100] Aldosterone synthase catalyzes both 18-hydroxylation of corticosterone, and the subsequent conversion of the 18-hydroxyl group to an aldehyde (Figure 36.3). Several mutations, including nonsense, missense, and frameshift mutations, affect the 18-hydroxylase activity of the enzyme; as a result, levels of 18-hydroxycorticosterone are low in these patients. In other cases, specific missense mutations can abolish 18-oxidase activity, while 18-hydroxylase activity remains intact or is only slightly reduced. These patients consequently have elevated levels of 18-hydroxycortisone.[99]

Not all patients with hyper-reninemic hypoaldosteronism, however, have mutations at the CYP11B2 locus. Kayes-Wandover et al.[101] described four unrelated kindreds (two consanguineous) without evidence of such mutations; linkage to the CYP11B2 locus could be excluded in the two consanguineous families, suggesting genetic heterogeneity. The underlying gene defect of this disorder, termed familial hyper-reninemic hypoaldosteronism type 2, remains to be established.

CONGENITAL ADRENAL HYPERPLASIA DUE TO STEROID 21-HYDROXYLASE DEFICIENCY

Steroid 21-hydroxylase deficiency is an autosomal recessive disease. It accounts for the vast majority of the cases of congenital adrenal hyperplasia (CAH), and is one of the most common Mendelian diseases.

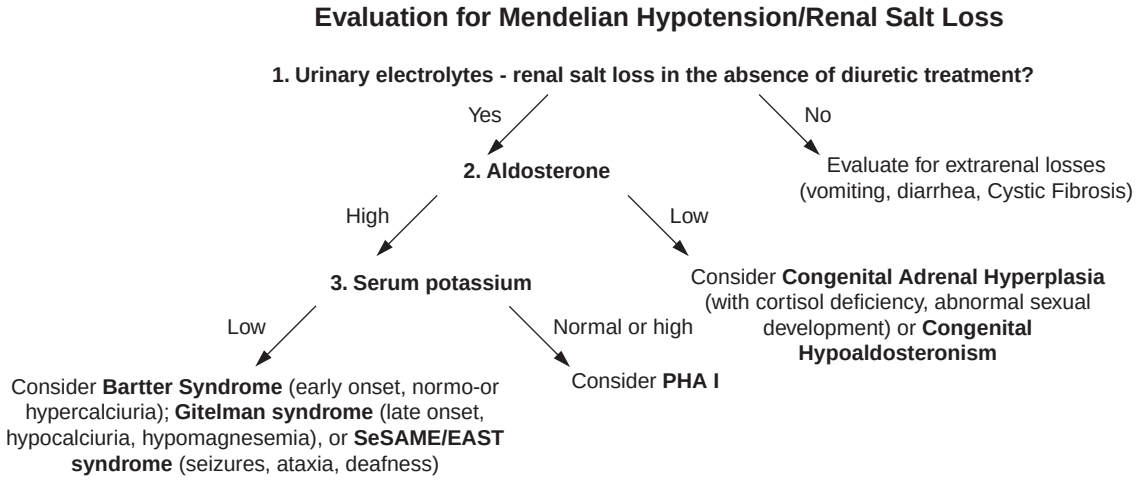

FIGURE 36.8 **A diagnostic approach to Mendelian hypotension and renal salt loss.** (PHA I: pseudohypoaldosteronism type I.)

21-hydroxylase catalyzes the 21-hydroxylation of progesterone, and is a required step in the biosynthesis of both cortisol and aldosterone (Figure 36.3).

Three subforms of the disease are recognized: patients with the salt-losing form of classic CAH are severely affected and present at birth or in infancy with cortisol and mineralocorticoid deficiency; females typically have ambiguous genitalia and virilization. In the simple virilizing form of classic CAH, high ACTH levels are sufficient to produce adequate levels of glucocorticoids and mineralocorticoids at the expense of increased adrenal androgen synthesis, resulting in virilization. Finally, patients with the late-onset or non-classic form may present in childhood, adolescence or even adulthood with premature pubarche and accelerated bone age; female patients develop hirsutism, infertility or irregular menstrual cycles.

The salt-losing form of classic CAH has an estimated incidence of ~1/23,000 live births, and is due to mutations in 21-hydroxylase (CYP21A gene) in almost all cases.[102] Girls with this condition present as neonates with masculinization. Salt-losing adrenal crisis, with vomiting, dehydration, hypotension, hypoglycemia, and electrolyte abnormalities (hyponatremia and hyperkalemia) typically occurs in the first or second week of life, and these can be the only presenting symptoms in boys. When untreated, adrenal crisis can lead to shock, cardiac arrhythmia, and neonatal death.[103]

CYP21A mutations causing salt-losing CAH often arise from unequal crossing-over between the functional CYP21A gene and a non-functional pseudogene located in close proximity[104]; the mutated enzyme typically shows complete loss-of-function. 21-hydroxylase deficiency is recognized clinically in patients with ambiguous genitalia or adrenal crisis, or in newborn screening programs; the diagnosis is based on elevated levels of 17-hydroxyprogesterone. Genetic testing is available, and can be supplemental for prenatal diagnosis, genetic counseling or ambiguous cases. Prenatal therapy with exogenous glucocorticoids can prevent or ameliorate virilization in female children, but is only recommended in a research setting due to potential side-effects.[105] If the child is known to be at risk, treatment is started as early as the mother knows she is pregnant, and stopped if the child is found to be male or unaffected by prenatal screening. Treatment after birth includes glucocorticoid and mineralocorticoid replacement, as well as salt supplementation in infants, and potentially feminizing surgery.[105]

RARE CAUSES OF SALT-WASTING CONGENITAL ADRENAL HYPERPLASIA

Very rare causes of salt-wasting congenital adrenal hyperplasia include 3-β-HSD 2 deficiency[106] and StAR deficiency[107] in lipoid adrenal hyperplasia. In both diseases, severe adrenal insufficiency with deficiency of gluco- and mineralocorticoids occurs at neonatal age or in infancy; genetically male patients typically have abnormalities of sexual development at birth, with female external genitalia in StAR deficiency.

Mutations in Genes Expressed in the Kidney that Cause Salt-Wasting

PSEUDOHYPOALDOSTERONISM TYPE I

Pseudohypoaldosteronism Type I (PHA I) is a rare genetic syndrome whose features include renal salt-wasting, hyperkalemia, hyponatremia, and metabolic acidosis despite elevated renin and aldosterone levels.[52,108] The disease presents as either an autosomal dominant or autosomal recessive trait. The recessive form appears to be uniformly severe, and requires life-long salt supplementation. The dominant form is clinically more variable at birth, and typically largely resolves after the first years of life with the ability to self-select a high-salt diet.

AUTOSOMAL RECESSIVE PSEUDOHYPOALDOSTERONISM TYPE I (PHAI) Infants with autosomal recessive PHA I frequently present with life-threatening episodes of hypovolemia, sometimes leading to neonatal death. Affected subjects have marked renal salt-wasting and striking hyperkalemia (as high as 12 mM), and renal tubular acidosis despite drastic elevations of PRA and aldosterone. There is also salt-wasting from salivary and sweat glands, as well as the colon. These patients require life-long sodium supplementation and often chronic treatment with resin-binding agents for hyperkalemia. Frequent pulmonary infections somewhat reminiscent of cystic fibrosis have been reported in some patients,[109] and markedly increased ciliary clearance of lung water has been reported.[110]

Genetic studies led to identification of recessive loss-of-function mutations in the alpha, beta or gamma subunits of the epithelial Na^+ channel (ENaC) in virtually all affected subjects.[111,112] Functional studies in *Xenopus* oocytes confirmed loss of channel activity. In summary, these findings demonstrated that mutations in all ENaC subunits can cause PHA I. All the features of this disease are explained by loss of ENaC function. Loss of ENaC function results in dramatic salt-wasting, leading to activation of the renin–angiotensin system; however, because ENaC is absent, this fails to adequately augment salt reabsorption in the kidney. Impaired salt absorption in the colon may also contribute to disease severity. K^+ and H^+ secretion are also markedly impaired, owing to loss the lumen-negative

potential resulting from loss of ENaC, causing hyperkalemia and acidosis.

These findings have been confirmed in animal studies. Mice deficient for the β- and γ-subunits show a phenotype characteristic of PHA I, with early death due to Na^+-wasting and K^+ retention,[113,114] and a PHA I-like phenotype is observed in α-ENaC knockout mice with transgenic expression of rat α-ENaC for rescue.[115] α-ENaC knockout mice show early postnatal demise with a mean survival of 24 hours postnatally due to respiratory distress,[116] suggesting a role of the mouse channel in pulmonary liquid clearance after birth that is apparently not observed at birth in humans but is found later in life.[110,117]

AUTOSOMAL DOMINANT PHA I Autosomal dominant PHA I has a milder phenotype that typically largely resolves in the early years of life. Patients may be asymptomatic or can present with renal salt-wasting and mild-to-moderate hyperkalemia and acidosis.[118,119] NaCl supplementation can typically be discontinued after early childhood, as the disease remits with age. Geller et al.[118] identified heterozygous mutations in the mineralocorticoid receptor gene in five kindreds with autosomal dominant PHA I. All mutations were inferred to be loss-of-function, inferred to cause diminished ENaC activity, with resulting salt loss. Since Na^+ reabsorption via ENaC is required for the lumen-negative potential that drives K^+ and H^+ secretion in the cortical collecting duct, diminished ENaC activity can cause hyperkalemic acidosis in these kindreds. The improvement with age is consistent with a decreasing requirement for aldosterone action in older children, presumably due to increasing salt intake and a self-selected high-salt diet after infancy. Adult carriers show no abnormalities of serum and urinary electrolytes or blood pressure, but consistently demonstrate markedly elevated serum aldosterone levels, consistent with homeostasis being achieved by compensating for the reduced level of MR by increased aldosterone levels.[119]

A case of autosomal recessive PHA I due to mutations in the mineralocorticoid receptor was recently reported – a newborn with very severe PHA I who was compound heterozygous for S166X and W806X deletions.[120] Within her family, carriers of the S166X mutation had typical autosomal dominant PHA I, while carriers of the W806X mutation were clinically asymptomatic, but had elevated renin and aldosterone levels.

A mouse model of PHA 1 shows increased renin and aldosterone, but develops normally in the heterozygous state. The homozygous knockout is lethal,[121] but can be rescued by subcutaneous NaCl injection before weaning.[122]

Mutations Affecting Renal Ion Channels, Transporters and their Regulators

Thick Ascending Limb of Henle

BARTTER SYNDROME

Bartter syndrome is a rare autosomal recessive disorder.[123] Patients may present at various ages with a variety of signs and symptoms. Renal salt-wasting is the key underlying primary problem, causing polyuria and subsequent polydipsia. In severe cases, patients present antenatally with polyhydramnios[124] (due to intrauterine polyuria), and affected subjects are often born prematurely. Renal salt-wasting, typically severe, leads to volume depletion, activation of the renin–angiotensin–aldosterone system and subsequent hypokalemic alkalosis; growth and mental development are impaired in some patients.[125] Hypercalciuria and nephrocalcinosis[126] are frequently found and can cause end-stage renal disease; deafness has been observed in a subset of patients.[127]

Early physiologic studies localized defective salt reabsorption in patients with Bartter syndrome to the loop of Henle[128] (Figure 36.9), and the finding of elevated levels of prostaglandins enabled treatment with inhibitors of prostaglandin synthesis.[129–131] The spectrum of clinical presentations and the underlying

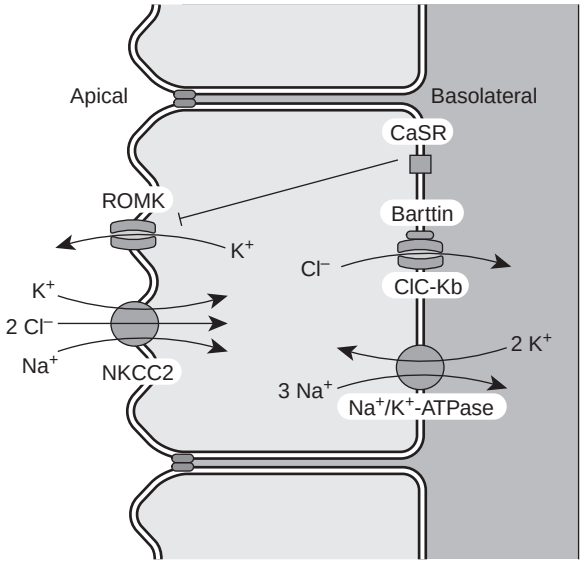

FIGURE 36.9 **Salt reabsorption in the thick ascending limb of Henle's loop.** Salt reabsorption is driven by the activity of the Na^+/K^+-ATPase on the basolateral suface. Na^+, Cl^-, and K^+ enter the cell on the apical surface via NKCC2 following the favorable gradient established by the sodium pump. While K^+ recirculates through ROMK, Cl^- is reabsorbed on the basolateral surface via ClC-Kb and its accessory subunit barttin. ROMK is inhibited by the calcium-sensing receptor (CaSR).

pathophysiology of this disorder was elucidated by the identification of the underlying genetic defects.

MUTATIONS IN NKCC2 CAUSE BARTTER SYNDROME TYPE I Recessive loss-of-function mutations in NKCC2, the bumetanide-sensitive Na-K-2Cl co-transporter (product of the SLC12A1 gene) were identified among a subset of patients with Bartter syndrome[132] (now Bartter syndrome type I). Affected index cases had all been born prematurely with polyhydramnios, and presented as neonates with hypokalemia and hyper-reninemic hyperaldosteronism; all had hypercalciuria. These clinical findings were consistent with the observation that pharmacologic inhibitors of NKCC2 produce similar electrolyte abnormalities. Loss of Na-Cl reabsorption in the TAL leads to massive salt-wasting, with activation of the renin–angiotensin system, and defense of intravascular volume by increased ENaC activity, which causes increased K^+ loss via increased lumen-negative potential in the connecting tubule and collecting duct. NCKK2 activity leads to reabsorption of two Cl^- and one Na^+ ions; the K^+ that enters across the apical membrane returns to the lumen via the K^+ channel ROMK. This results in a lumen-positive potential, which provides the electrical driving force for paracellluar calcium and magnesium reabsorption in the TAL. It is thus not surprising that loss of NKCC2 function results in hypercalciuria. Surprisingly, however, Mg^{2+} levels remain normal with little renal Mg^{2+} loss, suggesting compensation in other nephron segments. A knockout mouse model of NKCC2[133] generally recapitulated the features of Bartter syndrome (salt loss, dehydration, failure to thrive, response to treatment with indomethacin, and hypercalciuria).

MUTATIONS IN ROMK CAUSE BARTTER SYNDROME TYPE II Following the discovery of mutations in NKCC2, Simon et al. identified nine additional kindreds with Bartter syndrome without mutations in NKCC2, and excluded genetic linkage to this locus in several, providing strong evidence of genetic heterogeneity and indicating that additional loci accounted for many cases of Bartter syndrome.[134]

In the TAL, NKCC2 mediates apical sodium, potassium, and chloride influx using the favorable sodium gradient established by the basolateral Na^+/K^+-ATPase. Because luminal K^+ levels are low in the TAL compared to Na^+ and Cl^-, a role for the apical "recycling" of K^+ was speculated to be important for normal salt reabsorption in the TAL.[135,136] This was proven to be true by the finding of recessive loss-of-function mutations in the renal outer medullary K^+ channel (ROMK, product of the KCNJ1 gene), the apical K^+ channel of the TAL, in a subset of patients with Bartter syndrome (now referred to as Bartter syndrome type II).[134] These findings not only identified ROMK as a second disease locus in Bartter syndrome, but also established a key role of this apical potassium channel in renal salt reabsorption. Interestingly, ROMK is not only expressed in the thick ascending limb, but also in the cortical collecting duct, where it mediates apical potassium secretion (see above) driven by the lumen-negative potential established by reabsorption of Na^+ via ENaC. As found by Simon et al.,[134] and further elaborated by Peters et al.[137] and Finer et al.,[138] due to this defect in apical potassium secretion, serum potassium levels in patients with mutations in ROMK are significantly higher than in patients with NKCC2 mutations. Moreover, these patients typically present with hyperkalemia at birth. The development of relatively mild hypokalemia later in life indicates the presence of an alternative potassium-secreting channel with delayed maturation, likely the BK potassium channel.[139,140] A mouse model of Bartter syndrome with mutation in ROMK generally recapitulates the human phenotype.[141]

These findings define ROMK as a very promising target for the development of saluretic or antihypertensive agents with an adverse effect profile preferable over that of the common loop diuretics, limiting hypokalemia; such agents are currently under development.

MUTATIONS IN CLCNKB CAUSE BARTTER SYNDROME TYPE III Screening of 66 Bartter syndrome kindreds found mutations in NKCC2 and ROMK in only 22 kindreds.[142] This suggested the presence of at least one additional disease gene, supported by exclusion of linkage to either of the known genes by homozygosity mapping in 10 of 11 consanguineous kindreds. In the model of channels and transporters mediating salt reabsorption in the TAL outlined above, sodium enters via NKCC2 and exits via the Na^+/K^+-ATPase, while K^+ enters the cell via NKCC2 and returns to the lumen via ROMK. However, for net NaCl reabsorption, a basolateral exit pathway for chloride entering via NKCC2 is required. This exit had been suggested to be mediated by the chloride channels ClC-K1 and ClC-K2 in rat kidney[143,144] and their human homologs ClC-Ka (CLCNKA gene) and ClC-Kb (CLCNKB gene).[145] These two genes are closely linked, with CLCNKA located at 5′ of CLCNKB. Genetic analysis revealed linkage to this chromosome interval among Bartter syndrome families without mutation in NKCC2 and ROMK. Further analysis revealed deletions, missense, splice site, and premature termination mutations in the CLCNKB gene in affected members of 17 kindreds. Several of the deletions arose via unequal crossing-over between CLCNKB and CLCNKA. No point mutations were identified in the CLCNKA gene.

In contrast to the findings in patients with NKCC2 and ROMK mutations, hypercalciuria was variable, and none of the kindreds initially reported demonstrated nephrocalcinosis. Strikingly, there is a wide range of presentations in these patients, from severe volume depletion in the neonatal period to late-onset presentation. Hypomagnesemia[146] (see below) has been described in a few of these kindreds, but not to the extent generally seen in Gitelman syndrome. A possible explanation for this overlapping phenotype may be found in the expression of ClC-Kb, which is not restricted to the thick ascending limb of Henle, but extends into the distal convoluted tubule; the milder phenotype in some kindreds may be due to residual function of the mutant channel or partially compensating activity of the ClC-Ka channel in the thick ascending limb.

MUTATIONS IN BSND OR COMBINED MUTATIONS IN CLCNKA AND CLCNKB CAUSE BARTTER SYNDROME WITH SENSORINEURAL DEAFNESS (TYPE IV) Patients with Bartter syndrome type IV[127] typically present early with polyhydramnios and prematurity, as well as polyuria and renal saltloss after birth. This subtype is clinically distinguished from other forms of Bartter syndrome by the presence of sensorineural deafness. Genetic studies[147,148] led to the identification of a novel gene, named BSND (Bartter syndrome with sensorineural deafness), which had recessive loss-of-function mutations in 11 kindreds with this phenotype.[148] The novel disease gene and its product, named barttin, were found to be expressed in human and mouse kidney, as well as stria vascularis of the cochlea and dark cells of the vestibular organ. In stria vascularis, a set of channels and transporters highly similar to that mediating salt reabsorption in the thick ascending limb is responsible for potassium secretion into the endolymph and generation of the endocochlear potential, effects that are essential for normal hearing. Barttin was found to be an accessory subunit of ClC-Ka and ClC-Kb chloride channels required for surface insertion of the channel.[149] Most BSND missense mutations reduced current compared to WT when co-expressed with the chloride channels. Barttin co-localized with ClC-K channels on the basolateral surface of thin and thick ascending limb of Henle and more distal segments, including intercalated cells of the cortical collecting duct. The more severe renal phenotype of patients with BSND mutations compared to patients with CLCNKB mutation is likely caused by an additional effect on the ClC-Ka channel. In the inner ear, ClC-Ka can compensate for loss of ClC-Kb function in patients with CLCNKB mutations, while mutations in BSND abrogate basolateral chloride conductance in this epithelium, leading to sensorineural deafness. Accordingly, combined CLCNKA and CLCNKB mutations can cause Bartter syndrome and sensorineural deafness[150,151]; a condition sometimes referred to as Bartter syndrome type IVb. Isolated mutations in CLCNKA have not been described so far; a knockout ClC-K1 mouse model has diabetes insipidus,[152] which may clinically be less apparent than the salt loss observed with CLCNKB mutations. A constitutional BSND knockout mouse model manifests severe dehydration and early postnatal lethality, while inner-ear-specific disruption causes profound congenital hearing loss and subtle vestibular symptoms.[153]

MUTATIONS IN THE CALCIUM-SENSING RECEPTOR CAUSE BARTTER SYNDROME TYPE V The calcium-sensing receptor (CaSR) is a G-protein-coupled receptor, which, by sensing extracellular calcium, regulates both PTH secretion from the parathyroid and renal calcium reabsorption. Activating mutations in CaSR cause the syndrome of autosomal dominant hypoparathyroidism,[154] characterized by hypocalcemia, hypomagnesemia, and low serum PTH. A small number of these patients demonstrate features of Bartter syndrome (hyper-reninemic hyperaldosteronism and hypokalemia due to volume depletion),[155,156] potentially due to inhibition of apical ROMK channels[157] and inhibition of paracellular Na^+, Ca^{2+}, and Mg^{2+} reabsorption in the thick ascending limb. Although this disease clearly differs from Bartter syndrome, and the primary manifestation is hypocalcemia rather than salt loss, it is sometimes referred to as Bartter syndrome type V.

In summary, the identification of the genes mutated in subsets of Bartter syndrome has suggested a detailed classification, including clinically relevant features such as transient hyperkalemia in patients with Bartter syndrome type II that had not been recognized previously. This classification is now preferred over the the traditional distinction of "hyperprostaglandin E syndrome" in patients with early onset, severe salt loss, and increased urinary prostaglandin production, and "classic Bartter syndrome" with later onset and milder phenotype.[158]

The clinical diagnosis of Bartter syndrome is based on the presence of renal salt loss in infancy or childhood (high urinary chloride excretion in the absence of diuretic treatment), hyperaldosteronism, and hypokalemic alkalosis in the absence of hypertension. Urinary calcium is typically elevated, but can be normal in some patients with Cl^- channel mutations. Serum Mg^{2+} may be normal or slightly low, but does not typically reach the extremely low values seen in Gitelman syndrome (see below). Other causes of hypokalemia, such as vomiting and treatment with diuretics, should be excluded. Genetic testing is available.

Genotype–phenotype correlations can suggest the underlying mutant gene from the clinical presentation. Patients with ROMK mutations are distinguished by typically having hyperkalemia in the neonatal period, and evolve to hypokalemia that is less severe than that seen in other patients. Patients with CLCNKB mutations are least likely to have hypercalciuria and nephrocalcinosis, and account for most patients with mild disease, as can be seen with a few particular mutations.[159] Patients with sensorineural deafness have either BSND or combined CLCNKA/CLCNKB mutations. Patients without these distinguishing features are enriched for NKCC2 mutations.

Prostaglandin synthesis inhibitors (NSAIDs) are an important part of the therapeutic regimen in Bartter syndrome. While the exact mechanism of increased prostaglandin synthesis in these patients remains unclear, prostaglandin E2 can exacerbate renal salt-wasting.[160] Monitoring for nephrotoxicity and gastrointestinal side-effects is important. Severe volume depletion requires intravenous fluids, and a life-long high-salt diet is encouraged. Potassium supplementation is often needed, and magnesium supplementation is occasionally also needed. Potassium-sparing diuretics to limit renal K^+ loss can be used if necessary; however, these must be used with caution as they will exacerbate renal salt loss in these patients. Therapy with growth hormone can be considered in patients with growth retardation. As expected for a genetic disease affecting the kidney, renal transplantation is curative. Transplantation is usually limited to patients who proceed to end-stage renal failure, although preemptive transplantation has been reported.[161]

Salt-Wasting Due to Mutations Affecting Salt Reabsorption in the Distal Convoluted Tubule

GITELMAN SYNDROME

Gitelman syndrome is an autosomal recessive disorder. The clinical features typically include renal salt-wasting, elevated levels of PRA and aldosterone, hypokalemia, metabolic alkalosis, hypomagnesemia, and hypocalciuria.[162,163] The clinical distinction from Bartter syndrome is usually obvious. While Bartter syndrome patients typically present in the first year of life (mean age 0.8 years), often with severe volume depletion, Gitelman patients typically present later (mean age 10.5 years) with symptoms that are less obviously due to volume depletion, but often related to hypokalemia and/or hypomagnesemia. The urinary calcium: creatinine ratio in Bartter syndrome is typically ≥ 0.4 mmol/mmol, hypocalciuria is characteristic of Gitelman syndrome (ratio ≤ 0.1 mmol/mmol). Mean plasma magnesium is considerably lower in Gitelman patients (mean 0.54 mmol/L versus 0.82 mmol/L in Bartter syndrome), and seizures or tetanic episodes have been described in several cases.[163] While adult patients with Bartter syndrome are very uncommon, adult Gitelman syndrome patients are not rare, and women with Gitelman syndrome successfully complete pregnancy in many cases.

Clinical studies localized salt loss in Gitelman syndrome to the distal convoluted tubule (Figure 36.7), and demonstrated a reduced response to intravenous administration of a thiazide diuretic.[164] The thiazide-sensitive carrier, NCC, had been cloned from flounder bladder and rat kidney,[165,166] but not from human. To study NCC as a disease gene in Gitelman syndrome, Simon et al.[167] cloned and characterized the human gene; they isolated DNA from members of 12 kindreds with Gitelman syndrome and genotyped markers spanning the NCC locus, demonstrating linkage of Gitelman syndrome and NCC. Affected kindred members all had mutations in NCC, including splice site mutations and premature termination codons. The findings demonstrated that Gitelman syndrome is caused by mutations in NCCT. Many additional patients and mutations have been reported since; for example Ji et al. found 91 different mutations in 246 alleles among 123 patients with Gitelman syndrome.[168] In a single large kindred comprising more than 200 subjects segregating mutations in NCC, virtually complete penetrance of hypokalemia, alkalosis, and hypocalciuria was seen among subjects with two mutant NCC alleles, and these subjects had lower blood pressure than others in the pedigree, despite consuming significantly more salt.[206] Heterozygotes were intermediate in salt consumption and blood pressure.

While Gitelman syndrome is a much milder disease than Bartter syndrome, these patients are not asymptomatic – common complaints include salt craving, musculoskeletal symptoms such as cramps, muscular weakness, and aches, as well as fatigue, generalized weakness, polydipsia, and polyuria.[169]

The finding of mutations in NCC clearly explains renal salt loss in patients with Gitelman syndrome – apical NaCl entry in DCT is impaired, leading to reduced salt reabsorption with concomitant water loss, activation of the renin–angiotensin–aldosterone system and upregulation of ENaC activity in the collecting duct. This again accounts for hypokalemic alkalosis in these patients. It is less clear, however, why these patients develop hypomagnesemia and hypocalciuria, similar to patients treated with thiazide diuretics. Hypocalciuria has been attributed to increased proximal calcium reabsorption[170]; however, the exact physiologic mechanism of this effect is still a matter of debate. Hypomagnesemia was linked to decreased expression of the apical TRPM6 channel in DCT,[171] which mediates magnesium reabsorption and is mutated in another

rare Mendelian syndrome, hypomagnesemia with secondary hypocalcemia. This may be due to the decreased mass of the distal convoluted tubule observed with NCC deficiency or thiazide treatment.[172,173]

The above results from human studies have been confirmed in a knockout mouse model of NCCT[172] featuring hypomagnesemia and hypocalciuria. While hypokalemia and hyperaldosteronism were absent on a normal rodent diet, a marked reduction in plasma potassium occured upon low-potassium diet, and was accompanied by polyuria, polydipsia, and hyperaldosteronism.[174]

Although genetic testing is available, the diagnosis of Gitelman syndrome can be made reliably in typical cases in adolescents and adults on the basis of elevated PRA and aldosterone with hypokalemic alkalosis, hypomagnesemia, hypocalciuria, and evidence of renal salt loss in the absence of diuretic treatment or abuse. Because this clinical picture is virtually identical to that seen with use of thiazide diuretics, affected patients are often suspected of surreptitiously taking these medications. Genetic studies can be helpful in this situation.

Therapeutic options include electrolyte supplements (although magnesium supplementation can be particularly challenging) and potassium-sparing diuretics, although the latter can worsen volume depletion. Treatment with NSAIDs is generally not recommended, because these patients typically do not show elevated prostaglandin production.

SeSAME/EAST SYNDROME

A novel autosomal-recessive genetic disorder featuring renal salt loss was recently independently described as SeSAME (seizures, sensorineural deafness, ataxia, mental retardation, and electrolyte imbalance)[175] and EAST (epilepsy, ataxia, sensorineural deafness, tubulopathy)[176] syndrome. The renal features of this disorder resemble Gitelman syndrome, with persistent hypokalemic alkalosis due to activation of the renin–angiotensin–aldosterone system and variable hypomagnesemia, as well as hypocalciuria. Patients typically present in infancy with recurrent seizures; brain MRI is normal. More severe sensorineural hearing loss may be apparent in neonatal screening, while milder cases may go unnoticed until late childhood. Speech and motor delay are associated features, and may in part be due to ataxia. Genome-wide linkage analysis in three informative kindreds demonstrated complete linkage of SeSAME to a single segment on chromosome 1q23, and the Kir4.1 inward rectifier potassium channel (encoded by the *KCNJ10* gene) was identified as a candidate gene within the interval. Kir4.1 is expressed in kidney, inner ear, and brain; a knockout mouse model shows seizures, sensorineural deafness, and ataxia.[177–179] Screening of five affected subjects from four kindreds revealed homozygous or compound heterozygous mutations that segregated with the disease; this included a nonsense mutation and five missense mutations at conserved residues, which were inferred to be loss-of-function.[175] Similar findings were reported by Böckenhauer et al.[176] in two consanguineous families. In addition, they demonstrated electrophysiologic loss of channel function in mutant channels, and confirmed expression of Kir4.1 in the distal convoluted tubule, connecting tubule, and early cortical collecting duct. Analysis of the previously established knockout mouse model revealed polyuria, elevated urinary sodium concentration, and low urinary calcium concentration.

Seizures in patients with KCNJ10 mutations are likely due to loss of the channel's function in "spatial buffering",[180,181] i.e., glial uptake of excess potassium ions released during neuronal activity, followed by release at domains with low extracellular potassium concentration, a process that normally prevents neuronal hyperexcitability. Likewise, deafness is accounted for by expression of the channel in the stria vascularis, where it is essential for the generation of the endocochlear potential.[182]

The renal abnormalities in SeSAME/EAST syndrome are likely due to loss of basolateral potassium recycling which is required for maximal activity of the sodium pump ("pump leak coupling"[183]). Na^+/K^+-ATPase activity, which drives NaCl reabsorption via NCC, increases K^+ entry, which is inferred to be mitigated by return across the basolateral membrane via Kir4.1 activity. In the absence of this function, the accumulation of potassium in the cell limits Na^+/K^+-ATPase activity, and hence NaCl reabsorption in the DCT, and is inferred to cause hypomagnesemia and hypocalciuria due to impaired NCC function, analogous to Gitelman syndrome (see above). Subsequent studies have identified several additional families with SeSAME/EAST syndrome.[184–186] The diagnosis of this syndrome is based on the unique clinical findings. Genetic testing is available.

Treatment options include anticonvulsives and hearing aids to prevent further language delay. Potassium and, where required, magnesium supplementation and potassium-sparing diuretics are used to treat the electrolyte abnormalities in SESAME/EAST syndrome.

GENETIC STUDIES OF ESSENTIAL HYPERTENSION IN THE GENERAL POPULATION

The above considerations largely focus on rare genetic diseases with extreme phenotypes. The identification of the underlying defects had made an

invaluable contribution to our current concept of renal salt handling, and to the identification of novel physiological pathways. The results of these studies unequivocally link increased renal salt reabsorption to hypertension, and renal salt loss to sometimes life-threatening hypotension.

While Mendelian diseases of blood pressure homeostasis are extremely rare, hypertension affects more than one billion people worldwide[187] and contributes to more than seven million deaths each year.[188,189] However, despite the early recognition from twin and family studies that blood pressure is influenced by genetic mechanisms,[190,191] with ~60% heritability of hypertension,[192] the genes involved are still largely unknown.

The genetic contribution to common diseases could, in theory, be based on common genetic variants (defined by an allelic frequency of more than 5%). Such variants are identified in genome-wide association studies (GWAS), where a large number of polymorphic markers is genotyped in affected subjects and controls to identify those associated with the disease. Many large GWAS studies on hypertension have been reported,[193,194] with the most recent large meta-analysis evaluating 2.5 million single nucleotide polymorphisms (SNPs) in 69,395 individuals, with replication in up to 133,661 individuals, all of European ancestry.[15] The authors identified 29 independent SNPs at 28 loci that were significantly associated with systolic blood pressure (SBP), diastolic blood pressure (DBP) or both. However, these variants are typically of very small effect size, less than 1 mmHg on systolic blood pressure, and the 29 SNPs reported collectively account for only 0.9% of the phenotypic variance for SBP and DBP. Even including an estimated another 116 variants with similar effect size that did not achieve statistical significance, only ~2.2% of the variance could be explained.

These considerations suggest that only a small fraction of heritability of blood pressure in the general population is explained by common variants, and raise the possibility that a greater fraction of heritability is based on rare variants with larger effect size. Such hypothetical variants are not amenable to analysis by GWAS due to their small allelic frequency. However, their proposed larger effect could well be due to alterations in similar pathways as in Mendelian diseases of blood pressure regulation, i.e., genes involved in renal salt homeostasis. To test this hypothesis, Ji et al. resequenced three target genes, encoding NCC, NKCC2, and ROMK implicated in Bartter and Gitelman syndrome, respectively (see above) in 3125 members of the Framingham Heart Study population (1985 unrelated subjects and 1140 kindred members), all with careful and systematic blood pressure measurements at regular intervals.[168] From the frequency of the homozygous recessive state for Gitelman and Bartter syndrome, it was expected that heterozygous loss-of-function mutations should be present in about 1–2% of the population. Sequencing of these three genes in this cohort identified 23 subjects with 10 mutations that were previously known loss-of-function mutations or null alleles. Another 19 variants in 25 subjects were found at positions that are completely conserved from flies and worms to humans, strongly suggesting that these are functionally significant. Importantly, these functional mutations are all rare in the population, with allele frequencies less than 1 in 2000. Blood pressure in carriers of mutations in any of the three genes was significantly reduced at ages 40, 50, and 60 years compared to either non-carrier members of the cohort or non-carrier siblings, with a mean 9 mmHg reduction in systolic blood pressure at age 60. Mutation carriers were significantly protected from hypertension (59% risk reduction compared to non-carriers at age 60).

The development of next generation sequencing techniques and the dropping cost of this technology now enables genome-wide and unbiased analysis of rare variants by means of whole genome sequencing or, for reasons of cost effectiveness, whole exome sequencing, in large cohorts. It is expected that ongoing studies will provide new insights into the contribution of rare variants to blood pressure homeostasis, although large sample sizes will be required.[195]

NEW INSIGHTS INTO BASIC PHYSIOLOGY, PREVENTION, AND THERAPEUTICS FROM GENETIC STUDIES

The molecular genetic studies described above have collectively made a number of tangible contributions to our understanding of electrolyte homeostasis and blood pressure regulation. One element in renal physiology that was difficult to predict *a priori* was the physiologic consequence of eliminating specific transport pathways. For example, it was known that ENaC mediates the reabsorption of only a few percent of the filtered sodium load, and clinically used inhibitors of this channel have modest effects on salt balance and blood pressure. It consequently came as a surprise that genetic deficiency of any of the ENaC subunits results in profound renal salt-wasting with severe hyperkalemia and acidosis.[111,112] Affected subjects are extremely ill from birth onward, and typically require massive salt supplementation as well as treatment for hyperkalemia. These findings indicate that ENaC is constitutively active in the absence of an activated renin–angiotensin system, and is required for

maintenance of normal salt balance; its absence cannot be reasonably compensated by increasing the activity of other nephron segments. These findings also left no doubt that ENaC activity is absolutely required for normal K^+ and H^+ ion secretion, since severe hyperkalemia and acidosis results in the absence of ENaC activity. In contrast, loss of activity of the target for thiazide diuretics, NCC, has a far more subtle effect on salt balance, despite the fact that NCC normally accounts for reabsorption of a far greater fraction of the filtered salt load.[167] Similarly, the effects of loss of ROMK on net salt and K^+ balance were quite unpredictable from physiologic studies alone.[134] Would loss of ROMK produce hyperkalemia owing to its normal role in K^+ secretion in the distal nephron or hypokalemia due to K^+-wasting from the TAL? The finding that loss of ROMK results in dramatic salt-wasting but only mild hypokalemia, much less severe than that seen with loss of NKCC2, suggests that inhibitors of ROMK might be of particular clinical benefit as antihypertensive diuretic agents.

Second, this work has firmly established the key role of altered renal salt balance in the determination of long-term blood pressure in humans. All mutations that increase salt reabsorption raise blood pressure, while those that reduce salt reabsorption lower blood pressure. Despite diverse effects on K^+, pH, Mg^{2+}, and Ca^{2+} handling, the vector for salt reabsorption dictates the direction of blood pressure. This has implications for control of blood pressure in the general population (see below). These findings underscore the observation that other known sufficient causes of hypertension also modulate renal salt handling. Renovascular hypertension caused by stenosis of one or both renal arteries decreases renal blood flow and thereby causes activation of the RAA system and increased renal salt reabsorption; renal blood flow is likewise reduced in aortic coarctation and pheochromocytoma, again leading to increased renal renin secretion. The same final common pathway is activated by primary aldosteronism with increased aldosterone production from the adrenal gland and by licorice intoxication. Finally, in ESRD, the kidney is unable to eliminate excess volume, leading to hypertension.

Third, this work has uncovered entirely new physiology that was not previously anticipated. Specifically, the role of the WNK kinases in the regulation of the balance between salt reabsorption and K^+ secretion, revealed by genetic studies,[74] has identified a new layer of regulatory physiology in which these kinases are orchestrating the activity of diverse flux pathways to allow appropriate responses to diverse environmental perturbations. Moreover, the realization of the yin and yang relationship between Na-Cl reabsorption and K^+ secretion produced by the WNK kinase pathway provides an explanation for the long-recognized blood pressure-lowering effect of increased dietary potassium—increased K^+ secretion must occur at the expense of reduced Na-Cl reabsorption, accounting for the observed reduction in blood pressure.[196–199] The recent identification of the CUL3-KLHL3 ubiquitin ligase pathway[95,96] will extend this developing paradigm in the coming years.

Perhaps the most important implication of this work is the recognition that modulation of salt balance can modulate blood pressure across the entire spectrum seen in the human population. For example, genetic loss of ENaC function results in life-threatening hypotension, while gain of ENaC function results in early and often severe hypertension. The finding that modulation of activity of single genes in this pathway can dial blood pressure across the entire spectrum seen in the human population reveals the power of this system. These findings provide the basic science foundation that suggests that reduction of dietary salt intake might be beneficial in lowering blood pressure in the general population. This idea has been supported by recent studies showing that even a modest 25% reduction in dietary salt results in clinically significant blood pressure reduction, and that larger reductions in salt intake have proportionately larger effects.[196,200] Goldman and colleagues[201] have estimated that such a 25% reduction in dietary salt intake would be expected to dramatically reduce the number of strokes, myocardial infarctions, all cause deaths, and healthcare costs. The Institute of Medicine has released a study suggesting that such a 25% reduction in salt intake could be approached by reducing salt in processed foods and restaurant meals.[202] Programs to reduce dietary salt have been implemented in a number of countries worldwide.

These insights also have implications for the control of hypertension among patients with end-stage renal disease (ESRD), who have a particularly high prevalence of hypertension. Interestingly, a retrospective cross-sectional study in patients on hemodialysis suggested that a traditional treatment protocol lowering "dry weight" (weight at the end of dialysis) until optimal blood pressure is achieved and limiting dietary salt intake to 5–6 g per day may lead to similar control of hypertension as treatment with antihypertensive drugs, yet better outcome in terms of left ventricular (LV) hypertrophy, LV function, and intradialytic hypotension.[203] Other studies demonstrated that longer, slower dialysis to remove more salt and volume enabled drastic reduction in the prevalence of hypertension.[204,205]

Lastly, these findings provide insight into the potential for new antihypertensive diuretic agents and rational combination therapy. It is striking that patients

genetically deficient for the thiazide target (NCC) dramatically increase their dietary salt intake.[206] This suggests that activation of the renin–angiotensin system secondary to salt-wasting contributes to the drive to eat more salt as an adaptive response to volume depletion. Thus, the effects of diuretics are inherently blunted without blockade of compensatory activation of the renin–angotensin system.

The effects of loss-of-function mutations in specific genes provide an excellent proxy for both the magnitude of effect that could be achieved by pharmacologic inhibition of a target, as well as insight into potential mechanism-based adverse effects. It is interesting that loss of the thiazide target, NCC, has a modest effect on blood pressure compared to the effect of loss-of-function mutation in many other genes in the salt reabsorption pathway. The largest loss-of-function effects on blood pressure are seen with targets in the thick ascending limb and collecting duct. Among these, hyper- and hypokalemia are quite severe with most targets, including hypokalemia with mutations in NKCC2, CLCNKB, and BSND, and severe hyperkalemia with loss-of-function mutations in ENaC. These findings might limit the ability to push inhibition at these targets to high enough levels to achieve desired blood pressure lowering. In contrast, ROMK, which produces salt-wasting similar to that seen with mutations in NKCC2, the target of furosemide, produces much less hypokalemia, suggesting that one might achieve very large reductions in salt balance with little effect on K^+. Moreover, heterozygotes for ROMK mutations show significant reductions in blood pressure,[168] suggesting that graded effects can be achieved with dose modification. These findings suggest that ROMK inhibitors, plus inhibition of the renin–angiotensin system, could provide greater blood pressure lowering with fewer side-effects than current treatment regimens, and that ROMK inhibitors may also be of benefit in congestive heart failure. This speculation will require substantial empiric validation to determine the potential value of such agents.

Natriuretic Hormones

David L. Vesely

University of South Florida Cardiac Hormone Center, and James A. Haley Veterans Medical Center, Tampa, FL, USA

INTRODUCTION

Cardiac, Renal, Intestinal, and Adrenal Hormones which Enhance Sodium Excretion

Hormones which enhance sodium excretion, i.e., natriuretic peptide hormones, are very important for the maintenance of extracellu/lar fluid volume within a narrow range, despite wide variations in dietary sodium intake. This regulation occurs through a complex interplay of the antinatriuretic renin–angiotensin–aldosterone system and the antinatriuretic renal sympathetic system, which help to conserve sodium when sodium intake is low, and the natriuretic hormones, which enhance sodium excretion whenever sodium excess occurs. Several of the cardiac natriuretic hormones (Figure 37.1) directly inhibit aldosterone secretion[14,46,124,195,214,354,375] and/or indirectly inhibit aldosterone secretion by inhibiting renin release from the kidney to help regulate extracellular fluid volume.[39,104,149,197,214,404] This chapter will concentrate on the natriuretic hormones (cardiac, intestinal, renal, and adrenal) in normal renal physiology, their synthesis, secretion, biologic effects, pathophysiological changes with hypertension and renal diseases, and potential for treating diseases such as acute renal failure.

HISTORY OF ATRIAL (CARDIAC) NATRIURETIC PEPTIDE HORMONES

In 1628, Harvey[147] first correctly described the heart as a pump or a muscular organ that contracts in rhythm, pushing blood first to the lungs for oxygenation and then through the peripheral vascular system, bringing oxygen and nutrients to every cell in the body. It was another 350 years before the heart was established as an endocrine gland with its main physiologic targets being the kidney and vasculature.[366] The history of experimentation leading to defining the cardiac natriuretic peptide hormonal system (the first of the natriuretic hormonal systems) has followed two pathways: anatomical and physiological.

History of Cardiac Hormones: Anatomical Studies

Atrial Granule Structure

Shortly before Henry and colleagues[150] reported their observation that balloon distention of atria caused a diuresis, in 1955 Kisch,[188] utilizing electron microscopy, described dense granules that were located in the atria, but not in the ventricles of mammals. The presence of these dense granules in the cytoplasm of atrial cardiac myocytes, but not in the ventricles of the heart, was rapidly confirmed by others utilizing electron microscopy.[28,156,268] Jamieson and Palade[164] demonstrated that such granules are present in cardiocytes of the atria of all mammals, including humans, and were the first, in 1964, to suggest that these granules resemble other granules that release polypeptide hormones.[164] These granules are usually adjacent to one or occasionally both poles of the nucleus, and are interspersed among the voluminous elements of the Golgi complex and within close proximity to the mitochondria,[164] and are influenced by salt intake reduction.[218,269]

Ultrastructural cytochemistry has shown that these granules consist of proteins.[151] They incorporate both [^{3}H]-leucine and [^{3}H]-fructose in a pattern identical to other endocrine-secreting cells, with protein synthesis

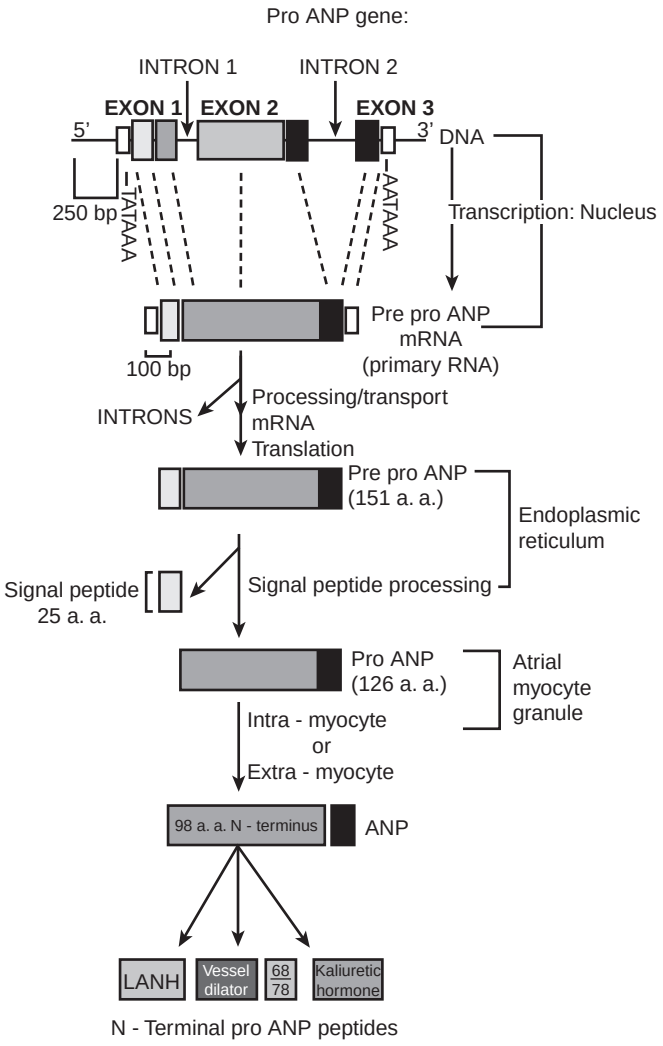

FIGURE 37.1 **Structure of the atrial natriuretic peptide prohormone (proANP) gene.** Four peptide hormones (e.g., atrial natriuretic peptide (ANP), long-acting natriuretic peptide (LANP), vessel dilator, and kaliuretic peptide) are synthesized by this gene. Each of these peptide hormones have biological effects, such as natriuresis and diuresis, mediated via the kidney[24,72,73,124,126,201,329,350,376,437] (a.a.: amino acids; LANH: long-acting natriuretic hormone (a different nomenclature for LANP). *(With permission, from ref. [366].)*

occurring in the Golgi complex.[155] The ultrastructural features of the specific granules of different species are similar, in that they display an amorphous core and a limiting membrane, and generally measure 300–500 nm.[68,70,164] The size and number of these granules vary among species, and generally are inversely related to size. Thus, atrial myocytes from large animals such as cows contain fewer and smaller granules than myocytes from small rodents such as rats.[70] In the rat there are up to 600 spherical, electron-opaque granules per cell.[70,164]

Atrial Extracts and Natriuresis

In 1922, Banting and Best[20] utilized what is now considered a classic endocrinological technique in their discovery of insulin. They pulverized pancreas with buffer, filtered the crude tissue extract, and found that it produced hypoglycemia in an experimental dog.[20] In 1981, deBold and colleagues,[69] utilizing a similar approach, infused the supernatants of extracts of rat cardiac atria and rat ventricles into other rats, and found that the rat atria extracts, but not the extracts from the rat ventricles, caused dramatic diuresis and natriuresis, with urine flow increasing 10-fold, and sodium and chloride excretion increasing 30-fold. This simple but elegant experiment led to the discovery of atrial peptides that have the most potent endogenous natriuretic activity of any substance yet described.[349] Atrial natriuretic peptide(s) isolated from these atrial extracts has been found to be a two-fold stronger natriuretic producing agent than furosemide (Lasix®, which is one of the most potent natriuretic producing drugs utilized in clinical medicine today.)[349] Other investigators quickly confirmed this natriuretic action,[110] as well as the ability of atrial extracts to cause vasodilation.[63,419] It was rapidly demonstrated that these effects were at least partially due to a peptide(s).[70,349] Further investigation revealed that the atrial extracts have significantly more natriuresis and diuresis than pure synthetic ANP, suggesting that other peptide hormones with natriuretic properties were in these atrial extracts.[75,123,140]

History of Cardiac Hormones: Physiological Studies

Association of Heart and Renal Function

In 1847, Harthshorne suggested that the heart possessed volume receptors capable of sensing the "fullness of bloodstream" induced by whole-body immersion, which he clearly recognized had a diuretic effect.[146] This observation received little further notice until 1935, when John Peters of Yale University made the same proposal that "the fullness of the bloodstream may provoke the diuretic response on the part of the kidney".[262] This concept then received experimental verification when it was shown that expansion of blood volume increases urine flow.[29,118,263,264,441] Peters also suggested that the diuretic response was secondary to the ability of the heart, or something very near the heart, to "sense the fullness of the bloodstream".[262]

Balloon Distention of Atria

Experimental evidence of an association between cardiac atria and renal function was provided in

1956 by Henry et al.,[150] who observed that balloon distention of the left atrium in anesthetized dogs was associated with an increase in urine flow. Because the renal response to left atrial distention could not be elicited after the cervical vagi had been cooled to block nerve conduction, Henry and colleagues[150,151] concluded that stretch receptors in the left atrium must be present. This finding was later extended to the right atrium.[117] In their reports, Henry et al.[150,151] noted the diuresis, but did not investigate whether it was associated with increased salt excretion (natriuresis). It is well-established now, however, that balloon distention of the cardiac atria causes natriuresis as well as diuresis.[121,123,213] Evidence that animals with denervated hearts or denervated kidneys may also respond to an atrial pressure increase to produce diuresis[209] suggests a hormonal pathway between the heart and the kidney. At least part of this hormonal pathway involves hormones made in the heart.

The "Third Factor"

With respect to a possible hormonal agent causing natriuresis and diuresis, de Wardener and colleagues[73] demonstrated in 1961 that saline infusion produced an increase in urine flow and sodium excretion in anesthetized dogs independent of changes in glomerular filtration rate (GFR), which was decreased, and even in the presence of high circulating levels of aldosterone. These experiments gave rise to the popular concept of an unidentified "third factor," a term coined by Levinsky and Lalone.[206] The other two factors were aldosterone and GFR-affected sodium excretion. The search for this third factor soon focused on a possible hormonal mediator that came to be known as "natriuretic hormone." Although this mediator (or mediators) from plasma or urine of volume-expanded humans or animals that causes natriuresis when injected into animals[37] was never chemically identified, the evidence points toward this third factor having a peptide structure(s), because acid hydrolysis characteristically inactivated this substance.[149] The "third factor" that was sought for decades now appears to be a family of peptide hormones termed "atrial natriuretic peptides" (ANPs), so named since they are found in their highest concentrations in the atria of the heart, have natriuretic properties, and are peptides. The third factor(s) also has the ability to inhibit Na^+,K^+-ATPase in the kidney.[149] Some of the natriuretic peptide hormones synthesized in the heart fill all of the criteria of being the "third factor(s)." Atrial natriuretic peptide (ANP) does not inhibit Na^+,K^+-ATPase,[51,139,270] so it would not fulfill the criteria of being the "third factor." Three of the other peptide hormones synthesized by the ANP prohormone gene (Figure 37.1), namely long-acting natriuretic peptide, vessel dilator, and kaliuretic peptide, however, do inhibit renal Na^+, K^+-ATPase[51,139] and fill all of the criteria of being the "third factor(s)" that researchers have sought since the 1960s.

Family of Cardiac Natriuretic Peptide Hormones

At first it was thought that a single peptide was found in atrial extracts, but further investigation revealed a sophisticated endocrine system in the atria (and other tissues including the kidney) in which the atrial natriuretic peptide (ANP) prohormone gene synthesized four peptide hormones[23,368,369,370] (Figure 37.1), and two other genes were present, as reviewed below. The three other peptide hormones synthesized by the ANP prohormone gene – long-acting natriuretic peptide, vessel dilator, and kaliuretic peptide – were first demonstrated to have biologic effects in 1987,[389] and one of their mechanisms of action, via intracellular messenger cyclic GMP, was also elucidated in 1987.[373] Fifth and sixth members of the natriuretic peptide family were identified in 1988, i.e., brain natriuretic peptide (BNP) isolated from a porcine brain cDNA library,[332] and urodilatin, a peptide formed by differential processing of ANP prohormone in the kidney, which was first found in opossum urine.[205,240,315] A seventh member of this family was identified in 1990 in brain tissue and termed C-type natriuretic peptide (CNP).[333] A possible eighth member, DNP, was first described in 1992 from the venom of the green mamba snake.[316]

FAMILY OF CARDIAC NATRIURETIC HORMONES: SYNTHESIS OF THREE PROHORMONES

This family of cardiac peptide hormones has been designated atrial natriuretic peptides (ANPs), also known as atrial natriuretic hormones (ANHs). These peptide hormones are synthesized by three different genes,[94,116,205,216,240,290,426] and then stored as three different prohormones (126 amino acid (a.a.) ANP, 108 a.a. BNP, and 103 a.a. CNP prohormones).[205,366] In healthy adults, the main site of ANP prohormone synthesis is the atrial myocyte with its mRNA being 30–50-fold higher in the atria than that observed in the ventricle,[114] but it is also synthesized in a variety of other tissues including the kidney.[114,393] The different organs that synthesize the ANPs in the approximate order that they contribute to the synthesis of ANPs are listed in Table 37.1.

TABLE 37.1 Site of Synthesis, Molecular Weight, and Hemodynamic and Natriuretic Properties of Natriuretic Peptides

	Molecular Weight (kDa)	Site of Synthesis	MAP	Diuresis	Natriuresis
LANP	3508	Atria, ventricle, GI, lung, kidney, brain, adrenal	↓	↑	↑
Vessel dilator	3878	Atria, ventricle, GI, lung, kidney, brain, adrenal	↓	↑	↑

CARDIAC PEPTIDE HORMONES ORIGINATING FROM ATRIAL NATRIURETIC PEPTIDE PROHORMONE

Within the 126 a.a. ANP prohormone encoded by a single gene are four peptide hormones (Figure 37.1) with blood pressure lowering, natriuretic, diuretic, and/or kaliuretic (i.e., potassium excreting) properties in both animals[24,77,78,140,141,220,389,405,433,434] and humans.[379–382] These peptide hormones, numbered by their a.a. sequences beginning at the N-terminal end of the ANP prohormone, consist of the first 30 a.a. of the prohormone (proANP 1–30, long-acting natriuretic peptide [LANP]); a.a. 31–67 (proANP 31–67, vessel dilator); a.a. 79–98 (proANP 79–98, kaliuretic peptide); and a.a. 99–126 (ANP) (Figure 37.1). These peptide hormones which were each discovered before BNP and CNP were named for their most prominent biologic effects rather than the tissue they were first found in, because these peptides are synthesized in many tissues.[114,369,393] Brain natriuretic peptide, so named because it was first found in porcine brain cDNA, for example, is actually present in the heart in 10-fold higher concentrations than in the brain.[52,140,212,344] Each of the four peptide hormones from the ANP prohormone circulate in healthy humans, with LANP and vessel dilator concentrations in plasma being 15–20-fold higher than ANP and 100-fold higher than BNP.[18,72,102,103,160,391,420,421]

BNP and CNP Prohormones

The BNP and CNP genes, on the other hand, appear to synthesize only one peptide hormone each within their respective prohormones, that is, BNP and CNP.[22,93,116,199,200,428] The pro BNP gene and its regulation are reviewed in the section on BNP prohormone gene. The biologic effects of BNP and CNP are reviewed in sections on BNP, "Biologic Effects" and CNP, "Circulating Concentrations and Biologic Effects."

ORIGINATION OF PEPTIDE HORMONES FROM PROHORMONES

More than one peptide hormone originating from the same prohormone is common with respect to the synthesis of hormones.[366] Adrenocorticotropin (ACTH), for example, is derived from a prohormone that contains four known peptide hormones.[366] α-MSH, which has natriuretic properties,[157,158] originates from this same prohormone. ACTH, similar to vessel dilator, originates from the middle of its prohormone. The middle of their respective prohormones is the most common origin of hormones with calcitonin, glucagon, vasoactive intestinal peptide, gastrin, cholecystokinin, and substance P, as well as ACTH and vessel dilator.[366] Several hormones, such as vasopressin (antidiuretic hormone (ADH)), oxytocin, pancreatic polypeptide, angiotensin, and gastrin-releasing peptide, originate from the N-terminus of their respective prohormones,[366] as does long-acting natriuretic peptide (proANF 1–30). The origin of hormones from the C-terminus of their respective prohormones like ANP, BNP, and CNP is less common, with somatostatin, inhibin, and parathyroid hormone (PTH) being the only known C-terminal prohormone-derived peptides.[366] In the case of PTH, 84 of the 90 a.a. in its

prohormone are considered to be the C-terminal "active" hormone; thus, it is not a small C-terminal-derived prohormone peptide, but rather nearly the intact PTH prohormone that serves as the actual peptide hormone.

MOLECULAR BIOLOGY OF THE CARDIAC NATRIURETIC HORMONAL SYSTEM

ProANP Gene

The gene encoding the synthesis of atrial natriuretic peptide prohormone (proANP) consists of three exon (coding) sequences separatedby two intron (intervening) sequences which encode for a mature mRNA transcript approximately 900 bases long[135,171,172,244,251,275,321,440] (Figure 37.1). Translation of human ANP prohormone mRNA results in a 151 a.a. preprohormone.[135,244,251,321] Exon 1 encodes the 5′-untranslated region, the hydrophobic signal peptide (leader segment), and the first 16 a.a. of the ANP prohormone (first 16 a.a. of long-acting natriuretic peptide).[133,135,244,251,321] The signal peptide, which is important for the translocation of the precursor peptide from the ribosome into the rough endoplasmic reticulum,[244,249] is cleaved from the preprohormone (151 a.a.) in the endoplasmic reticulum (Figure 37.1). The resulting 126 a.a. prohormone is the storage form for the four atrial natriuretic peptide hormones in tissues and the major constituent of the atrial granules.[27,135,244,251] The first 16 a.a. of this prohormone encoded by exon 1 are, after proteolytic processing of the ANP prohormone, also the first 16 a.a. of long-acting natriuretic peptide (LANP) (Figure 37.1). Exon 3 encodes for the terminal tyrosine (a.a. 126 of the ANP prohormone) in humans, and terminal three a.a. (Try-Arg-Arg) in rat, rabbit, cow, and mouse.[133,135,244,251,321] Deletion of this terminal tyrosine residue encoded by exon 3 does slightly affect the binding of ANP, but does not appear to contribute to biologic activity, as there is no apparent decrease in biologic activity when this terminal tyrosine is not present.[313] Exon 2 encodes for the rest of the prohormone (a.a. 17−125 in humans).[135,244,251,321]

There is considerable homology in the proANP gene among species, particularly in the encoding and 5′ flanking sequences.[93,251,406] The proANP gene has many features common to all eukaryotic genes,[27,33,242,276,382] including a TATTA box (T=thymine; A=adenine), intervening sequences bounded by GT-AG splicing signals (G=guanine), and a consensus sequence found in promoted regions. An interesting feature of the human proANP gene is a consensus sequence for a putative glucocorticoid hormone regulatory element in the second intron.[115,260,321]

The amino acid sequence of the whole ANP prohormone synthesized by the above gene is strikingly homologous among many species with differences clustered at the extreme carboxy terminal end of the prohormone, i.e., where ANP is formed.[15,120,148,173,175,183,202,216,242,244,251,252,406,450] In each species, the C-terminus is distinguished from the rest of the prohormone by forming a 17 a.a. ring structure via the joining by a disulfide bond between two cysteine residues (105 and 121 of the prohormone), as schematically shown in Figure 37.2. The ring structure originally was believed to be absolutely necessary for biologic activity,[64,152] but linear forms (same amino acids in linear form) without a ring structure have since been shown also to have biologic activity.[30] For full natriuretic and vasorelaxant activity, the Phe-Arg-Tyr (a.a. 124−126) at the COOH-terminus[64] and a.a. 99−104 of the NH_2-terminus of ANP are necessary.[34] In the dog, it appears that deletion of a.a. 99−102 of prohormone does not affect natriuresis, but deletion of a.a. 103 and 104 decreases natriuretic activity 10-fold.[34] Twenty of 30 a.a. in long-acting natriuretic peptide (Figure 37.2) are exactly the same in the five above species, and another six of the remaining 10 amino acids are exactly the same in four out of the five species.[15,93,94,119,321] Only three a.a. (33, 42, and 43 of the prohormone) are not the same in vessel dilator (Figure 37.2) in the majority of the five species.[119,174,251,321,406] Kaliuretic peptide has a highly-conserved sequence among the aforementioned five species, with 16 of its 20 a.a. (Figure 37.2) being the same in all five.[15,93,94,119,174,321]

BNP

This extraordinary conservation among species of LANP, vessel dilator, and kaliuretic peptide is not observed in the BNP prohormone, where there is a marked difference in amino acid sequence homology among species.[93,113,199,290,332]

Tissue-Specific Expression of ProANP Gene

In healthy adult animals and humans, the atrial myocyte is the main site of the ANP prohormone synthesis, but it is also synthesized in a variety of other tissues.[114,128,129,271,273] ProANP gene expression is 30−50 times higher in the atria of the heart than in extra-atrial tissues.[114] The expression of this gene has been found in kidney, gastrointestinal tract (antrum of stomach, small and large intestine), lung, aorta, central nervous system, anterior pituitary, and hypothalamus.[114,128,129,272,273] An example of where the

FIGURE 37.2 **Amino acid sequences of the natriuretic peptides.** Each of the sequences are human sequences except for *Dendroaspis* natriuretic peptide (DNP), whose sequence is only known in the snake. The brackets illustrate the location of cysteine bridges that help to form a ring structure in a number of these peptides (BNP: brain natriuretic peptide; CNP: C-type natriuretic peptide). *(With permission, from ref. [370.])*

proANP gene synthesized peptides localized in the kidney is illustrated in Figure 37.3.

Mechanisms of Action of Gene Products (i.e., Cardiac Hormones and Urodilatin) of ProANP Gene

Part of the intracellular mechanism of action(s) of the four peptide hormones encoded by the proANP gene is that after they bind to their specific receptors they enhance membrane-bound guanylyl cyclase to cause an increase in the intracellular messenger cyclic GMP[50,409,429](Figure 37.4). Cyclic GMP then stimulates a cyclic GMP-dependent, protein kinase that phosphorylates protein(s) in the cell, producing physiologic effects (Figure 37.4). Cyclic GMP mediates the vasodilation of each of the cardiac hormones.[250,373,419] The receptors for ANP that mediate ANPs biologic effects (e.g., ANP-A and -B receptors) are interesting, in that they contain guanylyl cyclase and a protein kinase in the receptors themselves[82,194,369](Figure 37.5). The NPR-A receptor has a 441 a.a. extracellular portion that binds ANP which, in turn, activates the catalytic portion of guanylyl cyclase in the cell (Figure 37.5). The protein kinase in this receptor has an inhibitory influence on guanylyl cyclase until this receptor is activated by ANP or BNP.[82,369] There is a 21 a.a. portion of this receptor which attaches this receptor to the membrane (Figure 37.5). The natriuresis secondary to the ANP is thought to also be mediated by cyclic GMP.[34] Vessel dilator, LANP, and kaliuretic peptide's mechanisms of action of producing a natriuresis is via enhancing the synthesis of prostaglandin E_2, which in turn inhibits Na^+-K^+-ATPase in the kidney,[51,139] which ANP does not do.[45,51,270] Vessel dilator and kaliuretic peptide's homodynamic effects via vasodilation of blood vessels are, however, mediated by cyclic GNP.

PROCESSING OF ATRIAL NATRIURETIC PEPTIDE PROHORMONE IN KIDNEY

ANP prohormone processing is different in the kidney compared to other tissues, resulting in an additional four a.a. added to the N-terminus of ANP (proANP 95–126, urodilatin (Figure 37.2)), a peptide first identified in opossum urine.[315] Thus, in the kidney, the identical four a.a. from the C-terminus of kaliuretic peptide are added to ANP to form the peptide urodilatin (Figure 37.2). At first, urodilatin was thought not to circulate,[231,315] and that it was not a

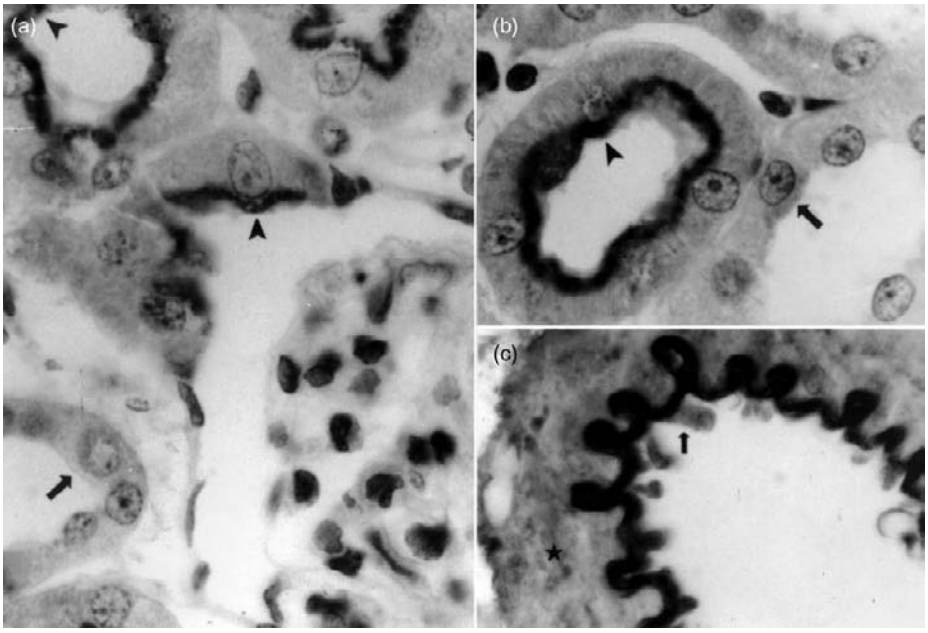

FIGURE 37.3 Vessel dilator immunoperoxidase staining in the rat kidney reveals strong staining of the sub-brush border of proximal convoluted tubules (arrowheads in a and b), including a proximal tubule in (a) originating directly from the top left portion of the glomerulus. The interstitial artery (c) had strong proANF (31–67) staining of the elastica with moderate staining of endothelial cells (arrow) and media (*). The distal tubules and collecting ducts (arrows in a and b) had weak staining with no demonstrable staining in some of the collecting ducts cells (Magnification× 940). *(With permission, from ref. [281].)*

hormone. To be defined as a hormone, a given protein has to be synthesized in a tissue or organ, circulate in the bloodstream, and have biologic effects in another tissue or organ.[366] With a very sensitive radioimmunoassay, it appears that urodilatin does circulate, but in such low concentrations (9–12 pg/ml) that it may not be physiologically relevant.[392] Since urodilatin constitutes less than 1% of the circulating natriuretic hormones, its physiologic importance as a circulating hormone is very limited, with over 99% of the physiologic natriuretic effects being from the other natriuretic hormones. Urodilatin, however, may have paracrine functions, and may mediate the effects of one of the other natriuretic hormones (ANP).[392] Infusion of ANP increases the circulating concentration of urodilatin, suggesting that some ANP effects may be mediated by urodilatin.[392] Infusion of long-acting natriuretic peptide, vessel dilator, and kaliuretic peptide, on the other hand, do not affect the circulating concentration of urodilatin in healthy humans.[392]

REGULATION OF ATRIAL NATRIURETIC PEPTIDE PROHORMONE GENE

Enhancement of ProANP Gene Expression

Stretch

Mechanical stretch, or more specifically tension, delivered across the atrial wall is a potent activator of proANP gene expression and/or secretion.[74,76,408] In animals, an increase of sodium intake results in an increased release of the ANP prohormone peptides.[78,80,403]

Thyroid Hormones

Thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) increase proANP gene expression.[13,198] The increase in proANP mRNA in hypothyroidism when treated with thyroid hormone is paralleled by the increase in circulating concentrations of the gene products of this synthesis – vessel dilator, LANP, and ANP – in persons with hypothyroidism treated with thyroid hormone.[400]

The changes in proANP mRNA in both hypothyroidism and hyperthyroidism parallel very closely the circulating concentrations of vessel dilator, LANP, and ANP in humans, which are decreased in hypothyroidism and increased in hyperthyroidism.[400,438,439] When the hyperthyroid subjects were treated with the antithyroid drug propylthiouracil (PTU) the circulating concentrations of LANP, vessel dilator, and ANP decreased 50% after one week of treatment, with a simultaneous 50% decrease in serum triiodothyronine (T_3) levels.[400]

Glucocorticoids

Dexamethasone, at a dose of 1 mg/day, increases proANP mRNA levels in both atria and ventricles of the rat approximately two-fold.[115] There is negative feedback between cortisol and the gene products of proANP gene expression in that the cardiac hormones vessel dilator, LANP, kaliuretic hormone, and ANP decrease the circulating concentration of

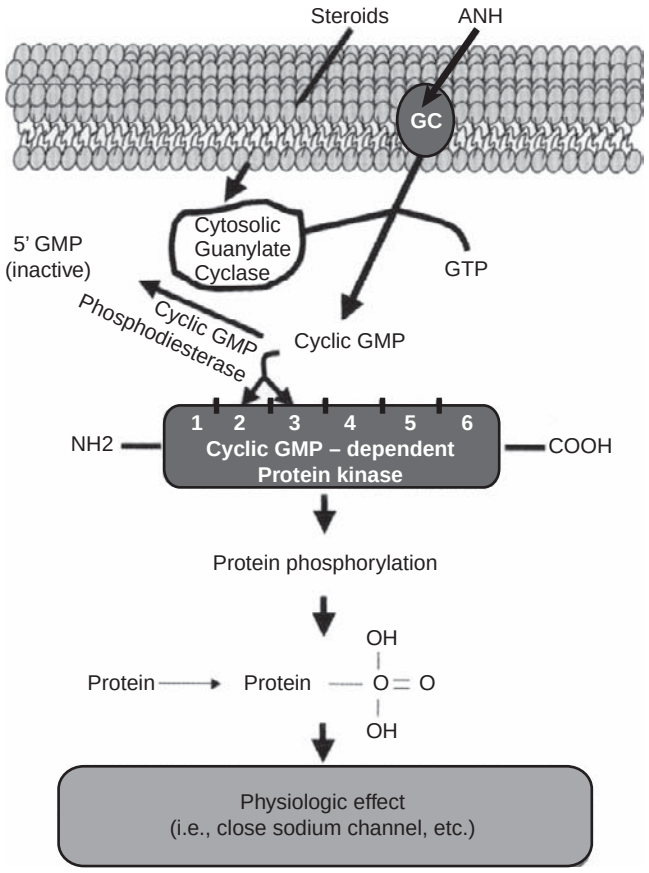

FIGURE 37.4 **Atrial natriuretic hormone (ANH) stimulates a membrane-bound guanylate cyclase.** Steroid hormones, on the other hand, diffuse through the cell to enhance the activity of a cytosolic guanylate cyclase. When either membrane-bound or soluble guanylate cyclase is activated, the intracellular messenger, cyclic 3′5′-guanosine monophosphate (cyclic GMP) is generated from guanosine triphosphate (GTP). Cyclic GMP then stimulates cyclic GMP-dependent protein kinase, which, in turn, phosphorylates proteins within the cell producing a biologic effect. Cyclic GMP is metabolized to an inactive 5′-GMP within the cell by cyclic GMP phosphodiesterase. *(With permission, from ref. [366].)*

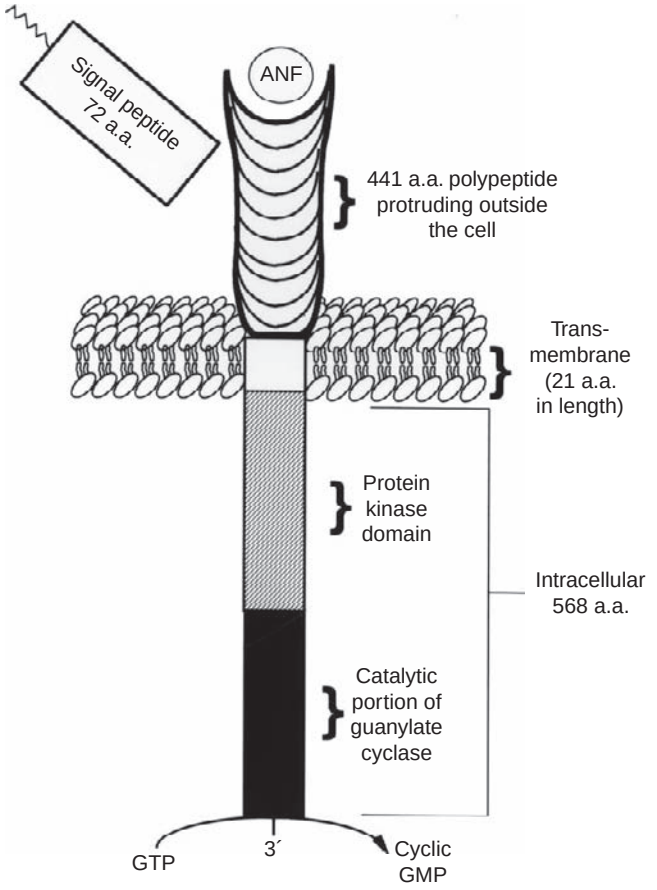

FIGURE 37.5 **Structure of atrial natriuretic peptide (ANP or NPR)-A (active) receptor.** The 441 amino acid (a.a.) extracellular portion of the receptor binds ANP, which activates the catalytic prrtion of guanylate cyclase within the cell. The protein kinase within this receptor has an inhibitory influence on guanylate cyclase until the receptor is activated by ANP. *(With permission, from ref. [366].)*

cortisol.[398] This decrease in cortisol is due, at least in part, to these cardiac hormones decreasing the circulating concentration of the hypothalamic peptide corticotrophin-releasing hormone (CRH), with a resultant decrease in ACTH, which stimulates the production of cortisol.[398]

Mineralocorticoids

Administration of mineralocorticoids to animals causes transient fluid and sodium retention. Despite continued administration of a mineralocorticoid, animals return to sodium balance within a few days, a phenomenon termed "mineralocorticoid escape." To investigate the role of ANP in mineralocorticoid escape, Ballerman et al.[19] administered DOCA to rats in sodium balance, and found plasma ANP levels and atrial proANP mRNA content increased in rats retaining sodium in response to DOCA. After "escape" from the mineralocorticoid-induced sodium retention, plasma ANP levels returned to baseline and relative atrial proANP mRNA content remained moderately elevated.[19] This increase in proANP mRNA probably resulted from the secondary cardiovascular effects of the steroids (e.g., increased intravascular volume), rather than from a direct effect of the mineralocorticoids on the ANP-secreting cell, as DOCA has no direct effect on proANP mRNA in ANP-expressing neonatal cardiocytes.[113,115]

Vasoconstrictive Peptides

Several vasoconstrictive peptides, including endothelin, norepinephrine, and angiotensin II, stimulate

proANP transcription and secretion.[290,294,295] The cardiac hormones, in turn, affect endothelin in a negative-feedback manner.[376]

Calcium

Primary cultures of neonatal rat cardiocytes exposed for 24 hours to 2 mM $CaCl_2$ in the culture media increase proANP messenger RNA three-fold, and increase secretion of ANP prohormone into the media three-fold.[201] When these cardiocytes were treated with the calcium channel-blocking agents diltiazem, nifedipine or verapamil, both proANP synthesis and secretion decreased to 25–40% of control values.[201]

TRANSGENIC KNOCKOUT AND/OR MICE OVEREXPRESSING ATRIAL NATRIURETIC PEPTIDE PROHORMONE GENE

Transgenic mice with an 11 base-pair deletion in exon 2 of the proANP gene (Figure 37.1) have increased blood pressure in homologous ($^{-/-}$) mice of 8–23 mmHg compared to wild-type ($^{+/+}$) mice.[168] Exon 2 of the proANP gene encodes for vessel dilator, kaliuretic peptide, and ANP (Figure 37.2). Exon 2 homozygote mutants have no circulating ANP, and they become hypertensive when fed a standard diet.[168] Heterozygotes ($^{+/-}$) with this base pair deletion in exon 2 are salt-sensitive and become hypertensive (systolic blood pressure increases 27 mmHg) on a high-salt (8%) diet.[168] Mice that overexpress the proANP gene, on the other hand, become hypotensive.[331]

HUMAN DISEASES WITH UPREGULATION OF ATRIAL NATRIURETIC PEPTIDE PROHORMONE GENE

Cerebrovascular Disease (Stroke and Hypertension)

A genetic linkage study followed 22,071 male physicians, all of whom had no history of stroke, from 1982 to 1999.[293] DNA extracted from peripheral white blood cells of those individuals who had a subsequent stroke revealed that, when compared to those without strokes, these individuals had a molecular variant in exon 1 of the proANP gene that was associated with a two-fold ($p < 0.01$) increased risk of stroke.[293] The individuals who had cerebrovascular accident (stroke) had significantly ($p < 0.001$) higher systolic and diastolic blood pressures than the persons who did not have a stroke.[293] This molecular variant of the proANP gene was found to be an independent risk factor (in addition to hypertension) for a cerebrovascular accident. This molecular variant was found to be responsible for a valine-to-methionine transposition in long-acting natriuretic peptide (LANP), i.e., the only peptide hormone synthesized by exon 1.[366] (Exon 1 does not encode for ANP.) In the 16 a.a. of LANP encoded by exon 1 there is only one valine, which is at position 7 of LANP (Figure 37.2).[370] Residue #7 (amino acid #7 of the ANP prohormone) is highly-conserved among different species.[15,93,94,119,321] In this human study there was no defect in the structure or expression of the proBNP gene.[293] In humans, blood pressure and the cardiac hormones correlate throughout the 24-hour period in a circadian relationship.[329,330] There is evidence to suggest that long-acting natriuretic peptide reflects salt sensitivity in hypertension-prone individuals, even before they develop hypertension.[228]

LANP and Stroke

Long-acting natriuretic peptide (LANP) has potent vasodilatory properties in both animals[389] and humans.[381,382] Antisera to LANP (to block the biologic activity of this peptide hormone) results in a significant increase in mean arterial pressure from 112 ± 12 mmHg to 131 ± 9 mmHg in normotensive animals, and exacerbates hypertension in spontaneously hypertensive rats (SHR) from 140 ± 10 mmHg to 159 ± 9 mmHg.[79] These antisera data indicate an important physiological role for long-acting natriuretic peptide in the regulation of arterial pressure.[79] In the brain of stroke-prone rats, the expression ANP prohormone gene (which synthesizes LANP) is significantly reduced.[291] There were no mutations in the BNP gene, and no differences in BNP gene expression between stroke-prone and stroke-resistant animals.[291,292]

Further evidence of the importance of the peptide hormones synthesized by the ANP prohormone gene derives from studies in mice with the ANP prohormone gene knocked-out: all develop salt-sensitive hypertension within one week leading to stroke.[168] The BNP gene does not upregulate to prevent hypertension and/or stroke when the proANP gene is knocked-out.[168] Downregulation of the proANP gene in the brain in stroke-prone SHRs has further been found to co-segregate with the occurrence of early strokes in their F_2 descendants.[291]

Natriuretic Peptide Hormones and Hypertension

The original hypothesis for hypertension was that there was a defect in the production of the

blood pressure-lowering cardiac hormones.[12,334] Experimental evidence revealed that, rather than being decreased, these blood pressure lowering cardiac hormones are elevated in the circulation in an apparent attempt to overcome the elevated blood pressure.[12,227,334,371] ANP increases in essential hypertension[12,334] and in persons with pheochromocytomas.[371] The hypertension associated with pheochromocytomas is characterized by increased circulating concentrations of vessel dilator and long-acting natriuretic peptide (LANP), as well as ANP.[372] Each of these blood pressure lowering hormones increase further with surgical manipulation-induced increases in blood pressure, and then these peptides return to normal after surgical removal of the pheochromocytomas and lowering of blood pressure.[371,372] The hypertension of obesity also is associated with increased circulating concentrations of ANP which decreases into the normal range with weight reduction-induced decrease in high blood pressure.[227]

In pregnancy, cardiac hormones increase in each trimester with the plasma volume expansion which accompanies a normal pregnancy.[229] ANP, vessel dilator, and LANP increase dramatically with the hypertension of pre-eclampsia, compared to their circulating concentrations in healthy pregnant women.[230] If one knocks-out the ANP prohormone gene that synthesizes the four cardiac hormones (Figure 37.1), within one week the animals develop salt-sensitive hypertension[168] while, on the other hand, transgenic mice overexpressing the ANP prohormone gene develop hypotension.[331] In addition to directly vasodilating vasculature, kaliuretic peptide and ANP inhibit the release of the potent vasoconstrictive peptide endothelin which is produced by the vascular endothelium.[376]

Congestive Heart Failure

In congestive heart failure (CHF), proANP gene expression is upregulated.[83,274,350] The increase in proANP gene expression is, however, not in the atria of the heart, but rather in the ventricle of the heart.[83,273,274,350] In persons with CHF, there is no defect in the production of the peptides from the ANP prohormone, but rather each are increased in the bloodstream in an attempt by the heart to overcome abnormal sodium and water retention by releasing more of these peptides that cause sodium and water excretion.[379,380,420] Vessel dilator and LANP increase in direct proportion to the severity of CHF, as classified by the New York Heart Association (NYHA).[420] The ANP-clearance receptor pathway is not linked to the avid sodium retention and/or to the renal ANP resistance observed in CHF.[32]

Cirrhosis with Ascites

Another salt- and water-retaining state, cirrhosis with ascites, is characterized by increased circulating concentration of the cardiac hormones, and with a 4.1-fold ventricular (but not atrial) increased steady-state proANP messenger RNA.[273] Although the liver expresses proANP messenger RNA, there is no upregulation of proANP gene expression in the liver when ascites develops.[272] Rather, the upregulation of this gene is only in the ventricle of the heart.[272]

LOCALIZATION OF ATRIAL NATRIURETIC PEPTIDE PROHORMONE GENE ON CHROMOSOMES

The proANP gene is located on the distal short arm of chromosome 1 in band 1P36 in humans and on chromosome 4 in mice.[366]

BRAIN NATRIURETIC PEPTIDE PROHORMONE GENE

The BNP gene is comprised of three exons separated by two introns, similar to the proANP gene in Figure 37.1.[113,345] Regulation of the BNP gene is controlled at the transcriptional level by several cis-acting regulatory elements in the proximal promoter, and the transcription factors that associate with them.[26,44,138,345] The cardiac specific transcription factor GATA 4 plays a major role directing basal activity of the BNP gene promoter.[44,138] GATA 4 is a nuclear mediator of mechanical stretch-activated BNP gene,[266] and might function as a central integrator of regulatory activity controlled by other transcription factors, such as GATA 6,[44] the neuron restricted silencer element-binding factor,[249] and YY1 the embryonic development protein.[26] Several of these factors interact synergistically with GATA 4, in both a physical and a functional sense, to stimulate BNP gene transcription.[44,249] Both the proANP and proBNP genes are activated in cardiac hypertrophy.[113,138] The GATA 4 transcription factor activates the proANP gene, as well as the proBNP gene.[113,138,266]

In healthy animals, cardiac BNP mRNA is mainly of atrial origin, that is, 10−50-fold more abundant than in ventricles.[52,140,212,344] In early left ventricular (LV) dysfunction, BNP mRNA markedly increases in the left atrium, but remains below or just barely at the level of detection in the ventricles.[212] The majority of investigations have found no increase in BNP mRNA in the ventricles in congestive heart failure,[140,212] which is exactly the opposite of ANP prohormone gene expression

which increases in the ventricle but not in the atria in sodium and water-retaining states.[83,274,350] Likewise, with streptotocin-induced diabetes BNP mRNA doubles in atria, without any change in ventricular myocardium BNP mRNA.[52] BNP gene knockout mice do not develop hypertension or hypertrophy[343] as ANP prohormone knockout mice do.[168] BNP knockout mice exhibit cardiac fibrosis as the only known effect of the BNP gene being knocked-out.[343] These knockout studies suggest that regulation of blood pressure is contributed to by the cardiac hormones synthesized by the proANP gene, but not by BNP.

SECRETION OF CARDIAC NATRIURETIC PEPTIDES

The main physiological stimulus to secretion of these peptide hormones to control blood volume appears to be an increase in pressure in the atria.[74,76,264,294,295,408] An increase of 4 to 6 mmHg in the atria releases the four cardiac hormones from the ANP prohormone.[76] These peptide hormones, in turn, decrease the volume returning to the heart secondary to their causing a diuresis and natriuresis.[76,220,405] Rapid heart rates at 125 beats/min and higher release the cardiac hormones into the circulation.[247] Both atrial and ventricular arrhythmias with heart rates of 125 beats/min and higher release these peptide hormones and increase the circulating concentrations of these cardiac hormones in humans.[246] Hypoxia and a variety of humoral factors (endothelin, glucocorticoids, acetylcholine, adrenergic agonists) have been suggested as contributing to release, but the majority of these humoral factors' effects are to increase the ANP prohormone gene synthesis, as outlined previously, rather than release *per se*.[294,295] With respect to hyperosmolarity, the threshold for ANP release is as low as 10 mOsmol/kg H_2O and this is regulated by a cross-talk between sarcolemmal L-type Ca^2 channel and the sarcoplasmic Ca^2 release.[167] ANP, vessel dilator, LANP, and kaliuretic peptide have a feedback mechanism whereby they inhibit their own and each other's release.[381] CNP also inhibits ANP release.[203]

BIOLOGIC EFFECTS OF THE CARDIAC NATRIURETIC HORMONES AND THEIR MECHANISMS OF ACTION

ANP

Vasodilation

The original report by deBold et al.[69] where crude atrial extracts cause diuresis and natriuresis also indicated that these extracts could decrease mean arterial pressure. Crude atrial extracts were then shown to possess vasorelaxant activity in isolated aortic segments.[5,63,111] When synthetic ANP became available, it was demonstrated that the pure form of ANP could also cause vasodilation *in vitro*.[112,191,312,374,419] Both crude[5] and synthetic[107] ANP decrease total peripheral resistance. Large central arteries (aorta and renal) relax, whereas more distal (ear and basilar) arteries are refractory to nanomalor concentrations of ANP.[283,366] Pulmonary, femoral, and iliac arteries are intermediate in their response to ANP.[366] One exception to small arteries not responding well upon the addition of ANP is the carotid arteries, which respond well.[283] In general, veins do not appear to vasodilate with the addition of ANP as well as arteries do, but ANP has been shown to relax peripheral veins in addition to aortic rings.[312]

ANP produces a dose-dependent reduction in systemic blood pressure in humans.[413] The immediate blood pressure lowering of 5.5 mmHg in 2 minutes with 100 μg ANP intravenously has been associated with a sensation of facial flushing in four of six human subjects, suggesting acute vasodilation of skin.[366] ANP elicits greater blood pressure-lowering properties in spontaneously hypertensive rats than in normotensive rats.[366] A greater response in hypertensive versus normotensive subjects is also true for most, if not all, antihypertensive agents.

MECHANISM OF ANP-INDUCED VASODILATION

The vasodilation observed with ANP is endothelium-independent.[317,373,419] It is mediated by cyclic GMP, which is increased after enhancement of membrane-bound guanylyl cyclase by ANP.[250,373,419] Cyclic GMP itself has been demonstrated to cause vasodilation.[282,317,419] The vasorelaxation with ANP appears to be independent of calcium[373,419] and cyclic AMP, with no change in cyclic AMP occurring during the same period of time that cyclic GMP increases.[373,419] With respect to calcium, ANP can increase cyclic GMP and cause vasodilation with no calcium in the incubation media,[250,373,409,419] but possible shifts of calcium already in the vasculature are still being debated. The ANP-induced relaxation of contracted vasculature is not blocked by adrenergic antagonists,[111] cholinergic antagonists[111] or indomethacin,[111] the latter suggesting that this vasodilation is not mediated by prostaglandins.

Natriuresis

ANP-induced natriuresis[8,105,259,327] appears to have a dependence on renal vasodilation, since ligation of the renal artery eliminates ANP-induced natriuresis.[328]

ANP has been shown to directly increase renal blood flow in dogs.[39] Redistribution of renal blood flow to the proximal[144] and distal[181] tubules has been reported as contributing to the natriuretic effects. The proximal tubule contains guanylyl cyclase, and cyclic GMP produced by this enzyme increases amiloride-sensitive ^{22}Na uptake in the phosphorylated brush border membranes of the proximal tubule, suggesting that the ANP intracellular mediator, cyclic GMP, directly stimulates the Na−H antiporter in the proximal tubule.[134]

ANP and Site of Action in Kidney

The renal actions of ANP are complex. Hemodynamic effects of pharmacologic doses of exogenous ANP constrict efferent and dilate afferent arterioles[219]; the resultant increase in glomerular capillary hydrostatic pressure could increase the glomerular filtration rate (GFR).[56,105] Physiologic doses of ANP, however, do not increase GFR.[105,259,327] The circulating physiological concentration of ANP is below the concentration of ANP that has been found necessary to increase GFR.[259,327] Early micropuncture and microcatheterization studies suggested a late distal nephron site of action, but functional studies of ANP in the inner medullary collecting duct (IMCD) indicate that it is a major target site of ANP action in the tubule.[433,435] Binding studies indicated specific binding sites for ANP on IMCD cells.[366] ANP increases cGMP accumulation in isolated cells from this segment in a concentration-dependent manner.[433] ANP also inhibits oxygen consumption in IMCD cells, indicative of inhibition of sodium transport.[435] This inhibition occurs through a cGMP-mediated effect on an amiloride-sensitive sodium channel.[433,435]

A proximal tubular site of action has been suggested from studies showing that ANP inhibits angiotensin II-stimulated proximal sodium reabsorption at very low concentrations (as low as 10^{-12} mol/L).[109,145] In the cortical collecting ducts, ANP inhibits tubular water transport by antagonizing the action of vasopressin.[81] ANP has been localized by immunoperoxidase and immunofluorescence methods to the sub-brush border of the pars convuluta and pars recta proximal tubule, as well as the distal tubule.[281,297] These studies indicate that ANP may have widespread actions on tubular function.

ANP Inhibits the Renin–Aldosterone System

Atrial natriuretic peptide has been found to be a potent *in vivo* and *in vitro* inhibitor of aldosterone secretion via a direct effect on aldosterone secretion from the zona glomerular cells of adrenal cortex,[14,46,124,195,214,354,375] and indirectly through inhibition of renin release from the juxtaglomerular cells of the kidney.[39,104,149,197,214,404] The mechanism of the inhibition of renin release by ANP appears to involve cyclic GMP, as this inhibition is duplicated by permeable analogs of cyclic GMP.[149,197]

Cardiac Peptide Hormones: LANP, Vessel Dilator, and Kaliuretic Peptide

Vasodilation

LANP, vessel dilator, and kaliuretic peptide cause vasodilation of vasculature that is endothelium-independent,[373] and similar to ANP endothelium-independent vasodilation of vasculature.[317,374,419] The amount of vasodilation *in vitro* with these cardiac peptide hormones is similar to that observed with addition of ANP.[373] When infused over 2 hours at the same 100 ng/kg of body weight/per minute concentration, vessel dilator and ANP were found to decrease blood pressure from an average of 145 to 124 mmHg ($p<0.05$), and from 143 to 123 mmHg ($p<0.05$), respectively.[220] Long-acting natriuretic peptide lowered blood pressure from a mean of 138 to 122 mmHg ($p<0.05$), whereas kaliuretic peptide decreased blood pressure from a mean of 155 to 138 mmHg ($p<0.05$).[220] Blood pressure did not change in the control animals throughout the 120-minute pre-experimental period or during the 120-minute experimental period.[220] Similar to ANP, the mechanism of vasodilating vasculature for these hormones is mediated by cyclic GMP.[373] The enhancement of guanylyl cyclase by the cardiac hormones is calcium-independent in vasculature.[373]

Cardiac Hormones: LANP, Vessel Dilator, and Kaliuretic Peptide

Natriuresis Mechanism of Action

Comparison of the relative natriuretic and diuretic potencies of the same dose in 100 ng/kg of body weight per minute of vessel dilator, revealed that LANP and ANP have significant natriuretic properties in healthy humans, but kaliuretic peptide enhancement of the urinary sodium excretion rate was not significant.[382] The natriuretic properties of vessel dilator are especially impressive in light of the fact that ANP has been found to be a more potent natriuretic and diuretic agent than furosemide,[349] and that vessel dilator has equally potent natriuretic effects[376,380,382] and circulates normally at a 17-fold higher concentration than ANP and 100-fold higher than BNP.[72,102,103,113,126,145,160,390,391,420] This 17-fold higher circulating concentration is found both during unstimulated conditions and with release secondary to

physiological stimuli, such as head-out water immersion where the atria are stretched releasing these peptides.[390,391] Vessel dilator's biologic effects also last significantly longer than ANP (greater than 6 hours versus 30 minutes).[376,380,382] Vessel dilator and ANP, with nearly equal abilities to enhance sodium excretion, are markedly different, however, with respect to potassium excretion.[382] Vessel dilator is the only one of the four cardiac peptide hormones from the ANP prohormone that does not significantly enhance potassium excretion.[220,382] This potassium-sparing effect of vessel dilator makes it distinctly different from ANP, LANP, and kaliuretic peptide. Kaliuretic peptide does not significantly enhance the fractional excretion of sodium (FE_{Na}), but it is the only natriuretic peptide that significantly enhances the fractional excretion of potassium (FE_k) in healthy humans. (Fractional excretion of sodium or potassium is the percentage of glomerular-filtered sodium or potassium that is excreted into the urine.[382])

The natriuretic effects of long-acting natriuretic peptide, kaliuretic peptide, and vessel dilator have different mechanism(s) of action from ANP, in that they inhibit renal Na^+,K^+-ATPase secondary to their ability to enhance the synthesis of prostaglandin E_2,[51,139] which ANP does not do.[51,139,270] ANP, BNP, and CNP effects in the kidney are thought to be mediated by cyclic GMP.[34,140,294,368]

Cardiac Hormones: Localization within the Kidney

Immunohistochemical studies have localized vessel dilator (Figure 37.3) and long-acting natriuretic peptide as well as ANP to the sub-brush border of the pars convuluta and pars recta of the proximal tubules of animal[281] and human[297] kidneys. Immunofluorescent studies reveal that each of these peptides has a strong inclination for the perinuclear region in both the proximal and distal tubules.[281,297]

LANP, Vessel Dilator, and Kaliuretic Peptide: Renin–Aldosterone System

Kaliuretic hormone and long-acting natriuretic peptide (LANP) are potent inhibitors of the circulating concentrations of aldosterone in healthy humans.[375] Kaliuretic peptide and LANP effects on decreasing plasma aldosterone levels last for at least 3 hours after their infusions have stopped, while ANP no longer has any effect on plasma aldosterone concentrations within 30 minutes of infusion cessation.[375] Vessel dilator does not appear to have direct effects on aldosterone synthesis, but is a potent inhibitor (66%) of plasma renin activity.[404] Thus, the four cardiac hormones from the ANP prohormone gene act as endogenous antagonists of the vasoconstrictor and salt-and-water-retaining systems (e.g., the renin–angiotensin–aldosterone system, vasopressin,[81] and endothelin[351,376]) in the body's defense against blood pressure elevation and plasma volume expansion via direct vasodilator, diuretic, and natriuretic properties. These four cardiac hormones' multiple biologic effects are illustrated in Figure 37.6. It is important to note in this illustration with respect to the kidney, that these peptide hormones also increase protein excretion (albumin, B2 microglobulin)[226,394,395] and phosphate reabsorption,[144] as well as cause a natriuresis and diuresis.

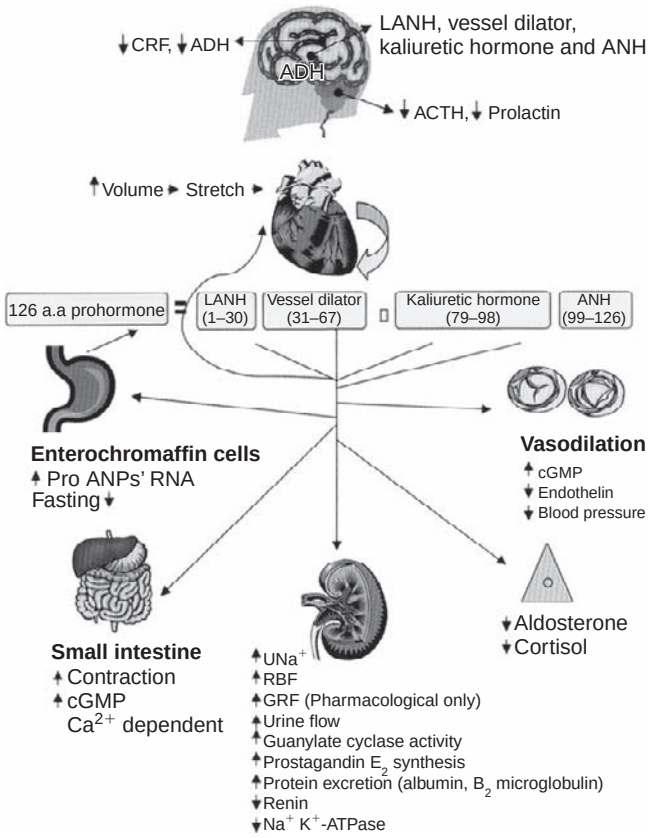

FIGURE 37.6 **Long-acting natriuretic hormone (LANH or LANP), vessel dilator, kaliuretic hormone, and atrial natriuretic hormone (ANH or ANP) are released with increased volume, which causes stretching of the atrium of the heart.** The biological effects of these peptide hormones include vasodilation mediated via enhancing guanylate cyclase activity with a resultant increase in the intracellular messenger cyclic GMP and inhibiting the vasoconstrictive peptide endothelin. ANPs cause a natriuresis mediated (except for ANH) by their enhancing the synthesis of prostaglandin E2, which, in turn, inhibits renal Na^+,K^+-ATPase. These peptide hormones also reduce circulating cortisol, aldosterone, and/or plasma renin activity. ANPs decrease corticotrophin-releasing factor (CRF) and antiduretic hormone (ADH) from the hypothalamus as well as decrease the circulating concentration of adenocorticotropin (ACTH) and prolactin from the anterior pituitary. They increase protein excretion by the kidney.[394,395] *(With permission, from ref. [369].)*

Kidney Hormone: Urodilatin

Vasodilation

Urodilatin has vasodilatory effects similar to those of ANP.[309,315] This would be expected, since the ANP prohormone post-translational processing in the kidney results in an additional four a.a. from kaliuretic peptide being added to the N-terminus of ANP (proANP 95–126, urodilatin)[205,240,315] (Figure 37.2). The rest of the amino acids in urodilatin are identical, and in the same sequence as those in ANP (Figure 37.2). Urodilatin and ANP have identical ring structures formed with cysteine-to-cysteine bonding (Figure 37.2). The four a.a. added to form urodilatin are the same four a.a. present in the C-terminus of kaliuretic peptide in other tissues, but in the kidney the ANP prohormone is cleaved between a.a. 94 and 95 rather than between a.a. 98 and 99 to form urodilatin.[315] Urodilatin is not formed in the heart or in other tissues except the kidney.[205] Urodilatin at first was thought not to be a hormone, in that it was thought that it did not circulate,[315] but sensitive assays revealed that it circulates at very low concentrations (9–12 pg/ml).[392] Infusion of ANP increases the circulating concentration of urodilatin, suggesting that some ANP effects may be mediated by urodilatin.[392] Infusion of long-acting natriuretic peptide, vessel dilator, and kaliuretic peptide, on the other hand, do not affect the circulating concentration of urodilatin in healthy humans.[392]

Urodilatin: Natriuresis

Urodilatin has natriuretic and diuretic effects similar to ANP,[309] and since it has an identical amino acid sequence and ring structure as ANP one would expect it to bind to the same receptors and have similar biologic effects as ANP. It does bind to the same receptor and has similar biologic effects as ANP.

Localization of Urodilatin in Kidney

Immunohistochemical studies have localized urodilatin to the distal tubule with no evidence of urodilatin in the proximal tubule.[281] ANP messenger-RNA studies have confirmed that the ANP prohormone is synthesized in the kidney.[137] The amount of the ANP prohormone present in the kidney, however, is only 1/190th of that produced in the atria of the heart.[274] These studies taken together suggest that since urodilatin is found mainly in the distal nephron,[137,281,288] and since it is part of the ANP prohormone,[278,315,369] synthesis of the ANP prohormone may take place in the distal nephron.[137,281,288] The ANP prohormone gene is present and can be expressed in the kidney.[137,274] This gene is upregulated within the kidney in early renal failure in diabetic animals,[324] and in the remnant kidney of rats with 5/6 reduced renal mass.[347] Within the kidney, in addition to urodilatin, the ANP prohormone gene synthesizes LANP, vessel dilator, and a shortened form of kaliuretic peptide, but not ANP *per se*.[130,369]

Urodilatin and Renin–Aldosterone System

Urodilatin does not affect renin or aldosterone concentrations.[88]

BNP and CNP

BNP: Biologic Effects

Brain natriuretic peptide (BNP) is a 32 a.a. peptide in humans (45 a.a. in rat) with similar diuretic and natriuretic effects and a short half-life as ANP[332] (Figure 37.2). BNP half-life is 100-fold shorter than the half-lives of vessel dilator and LANP.[4,199,332,333,366] BNP has remarkable sequence homology to ANP with only four a.a. being different in the 17 a.a. ring structure formed by a disulfide bond common to both peptides[199,200,290,294,332] (Figure 37.2). Although BNP was named[332] for where it was first isolated (porcine brain), the main source of its synthesis and secretion is the heart (10-fold greater than brain)[65,140,199,205,294,344] (Table 37.1). As with ANP, the highest levels of BNP are found in the atria of the heart.[140,344] BNP levels in the atria, however, are less than 1% of ANP levels.[344] The immunoreactive level of BNP in the ventricles is only 1% of BNP concentration in the atria; in brief, 99% of BNP is found in the atria.[344] BNP, however, has been termed a "ventricular" peptide, based on ventricular BNP mRNA levels being similar to those in the atria with ventricles being much larger than the atria,[240] but as above, 99% of BNP is in the atria rather than the ventricles.[344]

The 108 a.a. BNP prohormone is processed in the heart to yield a biologic functioning BNP consisting of a.a. 77–108 of the BNP prohormone (in humans) and a biologically inactive N-terminus of the BNP prohormone (a.a. 1–76 of prohormone), both of which circulate.[199] BNP circulating concentration is less than 20% of ANP.[140] The sequence homology of BNP differs appreciably across species (both in size and a.a. sequence).[93,199,240,344] The major circulating form varies substantially among species, being 26, 45, and 32 a.a. in pig, rat, and human, respectively.[113,199] The marked sequence variability of BNP explains in part variations in its biologic activity in different species. The peptide hormones from the ANP prohormone, on the other hand, have remarkable homology across different species.[15,93,94,116,120,321] Mice overexpressing the BNP gene, where the circulating concentration of BNP is 10- to 100-fold higher than in healthy mice, have less glomerular hypertrophy and mesangial expansion with

intraglomerular cells than healthy mice 16 weeks after both received renal ablation.[179] This mouse model of subtotal renal ablation, however, also has significantly increased ANP concentrations,[254,303,378] which may also have contributed to the effects attributed to BNP in the BNP-gene overexpressing mice.[179]

CNP: Circulating Concentrations and Biologic Effects

C-type natriuretic peptide (CNP) is a 22 a.a. peptide with remarkable similarity to ANP and BNP in its amino acid sequence, but lacks the carboxy-terminal tail of ANP and BNP[21,22,333] (Figure 37.2). CNP was found originally in the brain, but more recent studies suggest that it is also present in the heart[176] and kidney.[222,223,342] The amount of CNP in the heart, however, is very low and only small amounts are present in plasma.[176] Two CNP molecules, 22 and 53 a.a. in length, have been identified in plasma.[22,55] Each is derived from a single CNP prohormone, with the 22 a.a. form contained in the carboxy-terminal portion of the 53 a.a. form. The 22 a.a. form predominates in plasma, and is more potent than the 53 a.a. form in humans.[21,22,55,333] The plasma concentration of CNP is very low, with some authors reporting that CNP is not normally detectable but becomes detectable only in renal failure[304] and congestive heart failure.[176] CNP is present in the human kidney.[223,342] CNP has been found to have little effect on renal vasoconstriction.[430] Although CNP has been reported to have natriuretic effects in some animals, when infused in humans at physiological concentrations and in concentrations that reached four- to ten-fold above those observed in disease states, CNP did not affect renal function.[21] Thus, in healthy humans CNP had no effect on renal hemodynamics, systemic hemodynamics, intrarenal sodium handling, sodium excretion or plasma levels of renin and aldosterone.[21] Even when CNP was increased 60-fold in human plasma there were no significant hemodynamic or natriuretic effects.[159] The authors of this study concluded that it is unlikely that CNP has any endocrine role in circulatory physiology.[159] There is one study in humans where infusion of CNP to increase CNP plasma levels 550-fold above normal caused a 1.5-fold increase in urine volume and sodium excretion.[161] With this very high plasma concentration of CNP, both ANP and BNP also increased 2.4-fold,[161] which may have been the cause of the natriuresis and diuresis observed that was not observed in any other study with CNP.[21,159] Each of these studies suggests that CNP does not contribute physiologically to any natriuresis or diuresis in healthy humans.[21,159,161] The main site of CNP synthesis is vascular endothelium, and CNP acts as a paracrine endothelium-derived hyperpolarizing factor (EDHF) via activation of NPR-C receptor and the opening of a G-protein-gated inwardly rectifying K channel (GIRK) in mesenteric resistance arteries to mediate vasodilation.[47] In conduit vessels, on the other hand, CNP induces relaxation via a cyclic GMP-dependent mechanism.[47]

Adrenal Natriuretic Peptides, Adrenomedullin and Proadrenomedullin N-Terminal 20 Peptide: Biologic Effects

Adrenomedullin (ADM), a 52 a.a. peptide with one intramolecular disulfide bond (Figure 37.2) originally isolated from an extract of a pheochromocytoma,[189] also has a range of biologic properties similar to the cardiac hormones, but these properties are less pronounced than those of the cardiac hormones[170,189,190,301] (Table 37.1). Infusion of ADM lowers blood pressure and produces diuresis and natriuresis.[170,189,301] Adrenomedullin causes a long-lasting hypotension accompanied by increased heart rate as a side-effect.[257] ANP, but not LANP, vessel dilator or kaliuretic hormone, increases the circulating concentration of adrenomedullin three- to four-fold, suggesting that some of the reported effects of ANP may be mediated via adrenomedullin.[374] However, the natriuresis and diuresis secondary to ANP were much larger than has ever been observed with adrenomedullin,[374] suggesting that ADM does not mediate all of the natriuretic and diuretic effects of ANP. Adrenomedullin is a larger peptide than any of the cardiac hormones, with its main site of synthesis being in the adrenal (Table 37.1), but isolated renal cells also have the ability to synthesize adrenomedullin secondary to stimulation by vasopressin via V2 receptors.[301,306] Since vasopressin (antidiuretic hormone, ADH) inhibits a diuresis these findings are opposed to findings that ADM causes a diuresis.[170,189,301] Adrenomedullin is part of a peptide family that shares structural similarity with calcitonin gene-related peptides and amylin, which share biologic effects and some cross-reactivity between receptors.[89,301,305] The adrenomedullin prohormone at its N-terminal end contains another biologically active peptide with vasodilating properties known as proadrenomedullin N-terminal 20 peptide (PAMP).[90,302] Whether more PAMP or adrenomedullin is produced depends on alternate splicing of its prohormone by the enzyme peptidylglycine C-amidating monoxygenase.[53,170,190,301,302] Adrenomedullin exerts its actions through G-protein-coupled membrane receptors linked to adenylyl cyclase, resulting in an increase in cellular cyclic AMP[301] as opposed to the cardiac hormones (ANP, BNP, LANP, vessel dilator, and kaliuretic peptide) whose second messenger is cyclic GMP.[373,409,419] Proadrenomedullin is thought not to act via either

cyclic AMP or cyclic GMP, but rather via potassium channels, which eventually exert a presympathetic inhibition of sympathetic nerves innervating blood vessels.[302]

Dendroaspis Natriuretic Peptide: Biologic Effects

Dendroaspis natriuretic peptide (DNP) is the newest of the natriuretic peptides (Figure 37.2). This peptide was isolated from the venom of the green mamba snake *Dendroaspis angusticeps*.[316] This venom also contains several polypeptide toxins that block cholinergic receptors to cause paralysis.[316] DNP-like peptide has been reported to be present in human plasma and in heart atria.[310] In plasma, DNP concentration is very low at 6 pg/ml, which is 0.5% of the circulating cardiac hormones.[310] This peptide has a 17 a.a. disulfide ring structure similar to ANP, BNP, and CNP (Figure 37.2), and causes a natriuresis and diuresis in dogs.[210] Infusion of DNP does not cause any significant change in the circulating levels of ANP, BNP, or CNP.[210]

Richards et al.[286] have questioned whether DNP actually exists in humans and mammals, since it has not been characterized by high-pressure liquid chromatography linked to immunoassay, followed by purification and analysis to establish the human amino acid sequence, as has been done with the aforementioned cardiac hormones. The gene for DNP has not been cloned in the snake or in any mammal as has been done for each of the other natriuretic peptides.[286] Richards et al.[286] suggest that DNP may be "snake BNP," since BNP varies markedly in amino acid sequence among species (and the BNP sequence in this snake is unknown). The peptides from the ANP prohormone are markedly conserved among species,[15,93,94,116,119,321] and one would not suspect that DNP is one of these peptides as their amino acid sequences are markedly different from DNP. Further experimentation with the studies discussed previously suggested by Richards et al.[286] should give one more insight with respect to this peptide.

Guanylin, Lymphoguanylin, Renoguanylin, and Uroguanylin: Biologic Effects

Guanylin, a 15 a.a. peptide,[62] isolated from rat intestine, and uroguanylin, a 16 a.a. peptide originally isolated from opossum urine,[99,143] are peptides which are structurally and functionally similar to bacterial heat-stable enterotoxins produced by strains of pathogenic *Escherichia coli* intestinal bacteria.[82] Traveler's diarrhea is the result of these enterotoxins interacting with a membrane-bound guanylyl cyclase-C (GC-C receptor) on the luminal surface of enterocytes.[82] The resulting increase in cyclic GMP phosphorylates the cystic fibrosis transmembrane conductance regulator (CFTR), leading to an efflux of chloride into the intestinal lumen.[287] Cyclic GMP in the intestine inhibits Na^+ absorption mediated by apical Na^+/H^+ exchange, and activates protein kinase G II.[326] Guanylin and uroguanylin, which have similar structures to this enterotoxin, have a similar mechanism of action in the intestine via the same GC-C receptor.[100,101] These peptides have been identified in the intestine in different locations, with guanylin in the colon but not the proximal intestine, and uroguanylin expressed in the proximal intestine but not in the colon.[91,97,99,142] These intestinal peptides have natriuretic properties.[62,99] The observation of renal expression of guanylin and uroguanylin mRNA[62,99] suggests renal synthesis and a local paracrine action of these peptides in a manner analogous to the ANP prohormone gene products. Wang et al.[412] showed that intravenous and intraluminal administration of uroguanylin in the kidney affects tubuloglomerular feedback, but it failed to cause a natriuresis and diuresis in rats at up to 100 nmol/kg/h intravenously, which was less than other supraphysiologic concentrations used previously[41,136] to cause a natriuresis. The uroguanylin dose used by Wang et al.[412] was still, however, a pharmacologic dose which resulted in higher uroguanylin concentrations in rat blood and urine than physiological concentrations which are in the femtomolar range.[106] Rats fed a high-salt diet had higher uroguanylin and cGMP concentrations in the urine; however, the plasma concentration of uroguanylin was not increased, which argues against uroguanylin being an endocrine hormone in the kidney.[106]

Renoguanylin is a peptide hormone similar to guanylin and uroguanylin that has, thus far, been only found in Japanese eels.[432] In the eel it has been proposed that renoguanylin may be involved in osmol regulation, but this has not been proven at present.[432] Renoguanylin was not as prominent in the kidney and intestine of the eel as guanylin and uroguanylin.[432] Renoguanylin has not been found in mammals or humans and may be unique to the Japanese eel and fish.[432] Lymphoguanylin is a 109 a.a polypeptide expressed in spleen and lymphoid tissues of opossum.[98] The 109 a.a polypeptide shares 84% and 40% of its residues with prouroguanylin and proguanylin, respectively.[98] Lymphoguanylin is less potent than uroguanylin or guanylin in intestinal bioassay, and has reduced efficacy for activation of OK-GC receptor in the kidney.[98] 100 μM of lymphoguanylin stimulates cGMP production in renal cells only five-fold, compared to 206-fold with uroguanylin and 88-fold with guanylin.[98] A serine-7 analog of lymphoguanylin has

natriuretic properties in *ex vivo* rat kidneys and increases cyclic GMP 1000-fold more than the native lymphoguanylin.[96]

The inactive precursor of uroguanylin, i.e., prouroguanylin, is delivered to the kidney as an unprocessed propeptide,[277] and is processed to its active natriuretic form exclusively within the renal tubules.[277] The proximal convoluted tubule is thought to be the target for the uroguanylin natriuretic response.[87] Renal uroguanylin messenger RNA expression is also highest in proximal tubules, while guanylin is expressed mainly in the collecting ducts.[271] Salt-loading (1% NaCl in drinking water) for three days increases uroguanylin mRNA expression by 1.8-fold, but has no effect on guanylin expression.[271] The synthesis of these peptides by renal tubule epithelium may contribute to local control of renal function and adaptation to dietary salt.[271]

Both guanylin and uroguanylin elicit natriuretic responses from the kidney.[40,95,136] Both guanylin and uroguanylin exist in conformationally distinct A and B type topoisomers.[222,238,239] Topoisomer uroguanylin B has natriuretic activity in the kidney,[239] while the uroguanylin A in high concentration antagonizes the natriuretic action of the B form.[239] Uroguanylin knockout mice have an impaired ability to excrete an enteral load of NaCl, primarily due to an inappropriate increase in renal Na^+ reabsorption.[211] Further, there appears to be an interaction between guanylin, uroguanylin, and the cardiac hormone natriuretic peptide system, in that pretreatment with ANP (0.03 nM) enhances guanylin and uroguanylin's natriuretic activity when ANP is present in low dose.[304] When pharmacological doses of ANP or urodilatin are utilized they clearly inhibit uroguanylin-induced natriuresis.[304]

The GC-C receptor with which the heat-stable enterotoxin, uroguanylin, and guanylin interact in the intestine was cloned from intestinal cDNA libraries.[82] It exhibits 55% identity to NPR-A and NPR-B receptors in the catalytic region, 39% identity in the protein kinase domain, but only 10% identity in the extracellular region.[82] Within the kidneys, heat-stable enterotoxin, uroguanylin, and guanylin bind chiefly to apical membranes of proximal tubule cells,[91,100] also a site of CFTR expression.[60]

Two different guanylyl cyclase signaling receptors have been identified, one in kidney (OK-GC) and one in the intestine (GC-C), that are activated by the guanylin peptides.[101] Uroguanylin and guanylin regulate transport in mouse renal cortical collecting ducts independent of guanylyl cyclase C receptor,[325] and in guanylyl cyclase C-receptor deficient mice renal effects are retained,[325] strongly suggesting that GC-C is not the mediator of uroguanylin or guanylin effects in the kidney.

ANP Prohormone System and Expression in Gastrointestinal Tract

Almost 37 years ago it was noted that an oral load of sodium resulted in a natriuresis that was greater than the same amount of sodium chloride given intravenously, suggesting that the gastrointestinal tract monitors and responds to oral sodium-load.[204] Guanylin and uroguanylin may respond to this oral sodium-load in the colon and proximal intestine, respectively, but the stomach is an earlier monitor of this sodium-load. Immunoreactive cardiac hormones, ANP prohormone, and mRNA are present in the proximal stomach and antrum.[84,128,129,132] ANP prohormone gene expression and gene products LANP and ANP have been localized to the enterochromaffin cells in the lower portion of antropyloric glands of the stomach.[129] Fasting for 72 hours in adult rats results in a significant ($p < 0.05$) decrease in the levels of ANP prohormone messenger RNA, and a decrease in immunoreactive long-acting natriuretic peptide and ANP to <33% of that of fed rats.[129] In humans, food intake increases the excretion of LANP, vessel dilator, and ANP into the urine, suggesting an interaction between the cardiac hormones synthesized in the gastrointestinal tract and the kidneys.[384] A fluid load of Coca-Cola© rapidly (in 15 minutes) decreases the excretion of LANP, vessel dilator, and ANP into the urine, allowing more of these peptides which cause a diuresis to be present to respond to the fluid load.[384] In the stomach, cholinergic neurons inhibit, and pituitary adenylate cyclase-activating polypeptide neurons stimulate, ANP secretion, suggesting that there is also neuronal control of their secretion from the stomach.[127] ANPs are present not only in the stomach, but throughout the gastrointestinal tract (small intestine) and colon,[122,393,407] as opposed to guanylin and uroguanylin, which are present only in specific portions of the gastrointestinal tract.[91,97,99,142] Guanylyl cyclases A and B, which ANP, BNP, and CNP interact with, are present in the gastrointestinal tract,[280] as well as guanylyl cyclase-C which guanylin and uroguanylin enhance.[100] ANPs also appear to have effects within the gastrointestinal track itself.[17] ANP increases the spontaneous phasic contractions of longitudinal music two- to four-fold over a concentration range of 10 pm to 1000 mM, which was associated with a three-fold increase in cyclic GMP.[17] Vessel dilator and LANP also increase these spontaneous place contractions, which are additive with ANP.[17] The ANPs appear to act as neurotransmitters in the gastrointestinal tract to move water and feces through the gastrointestinal tract via increased force of contraction of the longitudinal muscles[17] until feces reaches the anal sphincter which ANP has been shown to relax to expel the contents of the gastrointestinal tract.[17,63]

Melanocyte-Stimulating Hormones

Melanocyte-stimulating hormones (MSHs) are small peptides of three different primary sequences (α-, β-, and γ-MSH), derived from the precursor prohormone pro-opiomelanocortin (POMC), which also gives rise to ACTH. Thus, MSHs, like ANPs, are from a prohormone containing four peptide hormones when proteolytically processed.[157,158] Each of the MSH peptides is natriuretic when infused in experimental animals.[49,157,158,253] The mechanisms of action of the MSHs are different from those of the cardiac hormones, in that MSH works via intracellular cyclic AMP rather than cyclic GMP.[388] The MSH-induced natriuresis does not appear to be a direct effect on the kidney, but rather via an interaction with renal nerves to inhibit sodium reabsorption, as prior renal denervation completely prevents the natriuresis secondary to MSH.[49]

Ouabain-Like Factors

Ouabain-like factors (factors that circulate and by definition inhibit Na^+,K^+-ATPase) have been sought for decades. Utilizing a very sensitive radioimmunoassay to ouabain, E. P. Gomez-Sanchez et al. determined that ouabain itself does not circulate in human or rat plasma, as a peak corresponding to ouabain was not found on high pressure liquid chromatography.[125] In most samples, they found only very low levels of an ouabain-like substance was present.[125] As outlined previously, vessel dilator, long-acting natriuretic peptide, and kaliuretic peptide are circulating peptide hormones[72,102,103,160,391,420,421] that inhibit the ouabain site on renal $Na^+ - K^+$-ATPase.[51,139] ANP does not inhibit renal $Na^+ - K^+$-ATPase,[51,139,270] and therefore would not be the "third factor" or an ouabain-like factor. Since the other three peptide hormones fulfill all the characteristic of the "third factor," they may actually be the "ouabain-like factors" that have been sought. Since LANP, vessel dilator, and kaliuretic peptide circulate at 100-fold higher levels than this substance, the volume-expanded substance(s) that do the majority of inhibiting of Na^+-K^+-ATPase at the ouabain site on the Na^+-K^+-ATPase are LANP, vessel dilator, and kaliuretic peptide, rather than some substance structurally similar to ouabain which, if it circulates, is present in extremely low levels in the circulation.[125]

NATRIURETIC PEPTIDE RECEPTORS A, B, AND C

Atrial natriuretic peptides, after moving via the circulation to their respective target tissues, mediate their action(s) at the cellular level by first binding to high-affinity specific receptors on the cell surface (Figure 37.4), which results in the intracellular generation of cyclic GMP via activation of the enzyme guanylyl cyclase which resides in the cytosolic domain of these membrane receptors as an integral part of these receptors.[50,82,194] Guanylyl cyclase (also termed guanylate cyclase) catalyzes the formation of the intracellular messenger cyclic 3′,5′-guanosine monophosphate (cyclic GMP).[373,409,419]

The area in the kidney with the most ANP-binding sites is the glomeruli, followed by proximal tubules and then inner medullary collecting ducts.[194] With respect to ANP, BNP, and CNP receptors, cDNA cloning has shown three types of natriuretic peptide receptors (NPR): NPR-A; NPR-B; and NPR-C.[50,82,194,199,240] Only NPR-A and NPR-B exhibit the intracellular guanylyl cyclase (GC) catalytic domain (Figure 37.4), whereas the third receptor, NPR-C, contains no guanylyl cyclase domain.[82,194,240] NPR-A and NPR-B, which bind ANP, BNP, and CNP, are structurally similar and contain a ligand-binding extracellular domain,[194] a protein kinase-like domain, and a guanylyl cyclase domain[50,82,194] (Figure 37.4). Upon ligand biding, a change in receptor conformation allows cytosolic factors to interact with the kinase-like domain, leading to activation of guanylyl cyclase and the consequent generation of cGMP, the second messenger of the cardiac hormones. The NPR-A receptor binds ANP, BNP, CNP, and urodilatin with a rank order of selectivity being ANP = urodilatin > BNP > CNP.[50,82,194,240] The order is reversed for NPR-B receptor (CNP >> ANP > BNP). NPR-B is structurally similar to the NPR-A receptor, with 74% homology at the cytoplasmic domain, but only 44% homology in the extracellular-binding domain, which may explain the difference in ligand specificities of the two guanylyl cyclase receptors.[50,194]

NPR-A mRNA is expressed mainly in the kidney, in the glomeruli, renal vasculature, proximal tubules, and in the IMCD.[19,50,194] The distribution of NPR-B overlaps to some extent with that of the NPR-A, and is found in the kidney, vasculature, and brain. In vascular endothelium and smooth muscle, NPR-B is more abundant than NPR-A. Compared to the NPR-A receptor, low levels of the NPR-B receptor are present in the kidney.[34,221]

Number of ANP Receptors per Cell

The number of ANP receptors per cell varies with the cell type.[19,71,152] Smooth muscle vasculature appears to be the target cell most richly endowed with ANP receptors.[152] The reported number of receptors in

vascular smooth muscle cells has ranged from 18,400 binding sites per cell to 500,000.[366] Comparison of a variety of cultured cells revealed 310,000, 80,000, 50,000, 14,000, and 3,000 sites per cell for vascular smooth muscle, lung fibroblasts, adrenal cortex, aortic endothelial cells, and Leydig cells of the testis, respectively.[366] Twelve thousand ANP-binding sites per cell have been found in kidney glomerular mesangial cells; markedly less than in other vascular areas, but the receptors in the mesangial cells exhibited as high affinity as other vascular areas for ANP.[19]

Inverse Relationship of Change in Number of ANP Receptors with Circulating ANP Concentrations

The number of ANP receptors varies with fluid status, and inversely with the circulating ANP concentration.[366] Deprivation of water decreases the circulating ANP concentration and augments receptor number in both kidney and adrenal gland.[366] Rats fed a low-salt diet for 2 weeks exhibit "upregulation" of glomerular ANP receptor density, whereas animals fed a high-salt diet have a decreased receptor density.[366] The decrease in total ANP receptors, at least after salt-loading, is due exclusively to a decrease in the NPR-C receptor, rather than the NPR-A receptor.[366]

Structure of NPR-A Receptor

The structure of the NPR-A receptor is illustrated in Figure 37.5. This structure was elucidated using complimentary DNA (cDNA) encoding a 115 kDa human natriuretic peptide receptor (NPR)-active (A or functional) receptor that possesses guanylyl cyclase activity.[50,82,194] The NPRA receptor has 1029 a.a., a 32 a.a. signal sequence followed by at 441 a.a. extracellular domain (i.e., projecting from the cell).[50,82,194] This extracellular portion of the NPR-A receptor is 33% homologous to the 60 kDa NPR-C receptor.[82,194] This extracellular portion of the receptor is the binding site for ANP, BNP, and CNP. A 21 a.a. transmembrane portion of the receptor "anchors" the receptor to the membrane. Inside the cell (intracellular domain) there is a 568 a.a. cytoplasmic portion of the receptor with homology (23%) to the protein kinase family (protein kinase domain) being next to the membrane,[50,82,194] followed by a large guanylyl cyclase catalytic portion of the receptor (Figure 37.5) that is 42% homologous to cytoplasmic guanylyl cyclase.[50,82,194] The kinase domain binds ATP, but lacks true kinase activity. Rather, it functions to inhibit the guanylyl cyclase domain. If the kinase domain is "knocked-out," guanylyl cyclase continuously functions. The molecular weight of this receptor is 114,426.[50]

The guanylyl cyclase portion of human and rat NPR-A receptors are 90% identical throughout their sequences.[50,82] The similar amino acid sequence between the NPR-C receptor[82,194,240] and the extracellular portion of the NPR-A receptor reflect a common function shared between them – they both bind ANP, BNP, and CNP.

NPR-C (Clearance) Receptor

Cross-linking studies revealed that in addition to the high molecular weight receptors for ANP, BNP, and CNP there was also a low molecular weight 60 kDa receptor that appeared to be a subunit of the high molecular weight receptor.[82,194,240] This 60 kDa receptor was found not to contain guanylyl cyclase or to mediate any of the known effects of ANP, such as natriuresis or diuresis.[82,194,215]

Structure of NPR Clearance Receptor

The NPR-C receptor is similar structurally outside the cell to the NPR-A receptor, with 496 a.a. compared to the 441 a.a. projecting from the cell for the NPR-A receptor.[82,194,215] They have a similar single short transmembrane-spanning region, but where the two receptors markedly differ is inside the cell. The NPR-C receptor has only a very short 37 a.a. tail into the cytoplasm of the cell as compared to the large 568 a.a. portion in the cell for the NPR-A receptor.[50,82,194,215] Neither the protein kinase domain nor the guanylyl cyclase catalytic site is present in the NPR-C receptor. That the NPR-C receptor is not linked to a second messenger system explains its inability to cause vasodilation, diuresis or natriuresis.[50,82,194,215] The order of binding to the NPR-C receptor is ANP > CNP > BNP. The NPR-C receptor is the most abundant receptor of the natriuretic receptors, accounting for more than 95% of the total receptor population, and is located at high density in kidney, vascular endothelium, smooth muscle cells, and the heart.[82,194,215]

Vessel Dilator and LANP Receptors

Vessel dilator and long-acting natriuretic peptide do not bind to the NPR-A, B or C receptors, but rather have their own specific receptors.[365,372,378,397] Vessel dilator, LANP, and kaliuretic peptide, on the other hand, are linear peptide hormones, and one would not expect binding to the above NPR-A, -B, and -C receptors which require a ring structure for binding[50,82,194,215,240] which ANP, BNP, and CNP have.[372,378]

LANP Receptor

Long-acting natriuretic peptide (LANP), as well as ANP, binds specifically to smooth muscle membranes,[378] placental membranes,[365] distal nephrons,[397] proximal tubules,[397] and renal cortical and medullary membranes.[397] ANP and vessel dilator inhibit ^{125}I-labeled LANP-binding somewhat at concentrations above which these peptide hormones are known to circulate, i.e., 10^{-6} M for ANP and 10^{-7} M for vessel dilator. Scatchard analysis of the LANP-binding data resulted in a straight line,[378] suggesting that these smooth muscle cells contain a single class of high-affinity binding sites for LANP with an equilibrium dissociation constant (K_d) of 0.11 nM. The binding capacity (maximal binding, B_{max}) for LANP was 2.57 fmol/10^6 cells, and the number of binding sites was calculated to be 1548 per cell.[378]

Vessel Dilator Receptor

Vessel dilator also binds specifically to smooth muscle membranes,[378] proximal tubules,[397] distal nephrons,[397] placental membranes,[365] and renal cortical and medullary membranes[397] at a site distinct from the binding of ANP to membranes. The binding of this peptide hormone could be inhibited by concentrations (10^{-4} to 10^{-7} M) of ANP, LANP, insulin, and ACTH, which are far in excess of their respective circulating concentrations.[378] Scatchard analysis of the vessel dilator-binding data resulted in a straight line,[378] suggesting that smooth muscles contain a single class of high-affinity binding sites for vessel dilator with an equilibrium dissociation constant (K_d) of 4 nM. B_{max} for vessel dilator was 59.9 fmol/10^6 cells, and the number of binding sites was calculated to be 36,087 per cell.[378]

DEGRADATION OF NATRIURETIC PEPTIDES BY KIDNEY

The inactivation of the ANP, BNP, and CNP occurs via two pathways: binding to clearance receptors and enzymatic degradation. The clearance receptor (NPR-C)[32,50,82,194,240] clears ANP, BNP, and CNP through receptor-mediated uptake, internalization, and lysosomal hydrolysis with rapid and efficient recycling of internalized receptors to the cell surface. Enzymatic degradation of ANP, BNP, and CNP takes place in the lung, liver, and kidney, and the main enzyme responsible for this degradation is neutral endopeptidase (NEP-24.11).[34,411] NEP, originally referred to as enkephalinase because of its ability to degrade opioid peptides in the brain, was subsequently shown to be identical to a well-characterized zinc metallopeptidase present in the kidney.[411] This zinc metalloproteinase hydrolyzes internal peptide bonds of polypeptides, rather than those adjacent to their N- or C-terminal ends. NEP has a ubiquitous tissue distribution and multiple functions, sharing structural similarities with various metallopeptidases, including aminopeptidase ACE, and carboxypeptidases A, B, and E.[411] NEP is most abundant in the brush borders of the proximal tubules of the kidney, where it rapidly degrades filtered ANP, thus preventing ANP from reaching more distal luminal receptors.[411] In the case of ANP, NEP-24.11 cleaves the Cys^{105}–Phe^{106} bond to disrupt the ring structure and inactivate the peptide. NEP 24.11 is a nonspecific enzyme that also cleaves enkephalins, endothelin, substance P, kinins, neurotensin, insulin B chain, angiotensin, calcitonin gene-related peptide, and adrenomedullin, as well as ANP, BNP, and CNP. With respect to ANPs in humans,[411] ANP and CNP are preferred substrates for NEP as opposed to BNP with the Cys–Phe bond of human BNP being relatively insensitive to enzymatic cleavage.[411]

INFLUENCE OF ACUTE RENAL FAILURE ON CIRCULATING CONCENTRATION OF CARDIAC HORMONES

Each of the cardiac hormones from the ANP prohormone (vessel dilator, ANP, LANP, and kaliuretic peptide),[12,18,48,56,103,160,193,243,300,395,396,420,421] BNP,[39,43,58,108,199,200] and CNP[22,159,161,348] increase in the circulation (mainly from the heart ventricle[83,115,271]) in salt- and water-retaining states such as renal failure and congestive heart failure, compared to their concentrations in healthy individuals, in an apparent attempt to overcome the salt and water retention via their natriuretic and diuretic properties.[379,380] The disease state associated with the highest circulating concentrations of the cardiac natriuretic peptides is renal failure.[102,103,307,417,421] One would suspect that cardiac natriuretic peptides are higher in renal failure versus Class IV New York Heart Association congestive heart failure patients, because of the added pathophysiology of decreased degradation of these peptides with the decreased functioning renal parenchyma.[421] Franz et al.,[103] however, have shown that there is an increased excretion of the cardiac natriuretic peptides in renal failure, and that the increase in vessel dilator excretion occurs even before serum creatinine levels begin to rise. The circulating concentrations of the cardiac hormones in chronic renal failure appear to reflect volume status.[193,236,284,422] Despite increased circulating concentrations of cardiac hormones in sodium-retaining disease states, the kidney retains sodium and is hyporesponsive to ANP, LANP, and BNP.[35,199,277,352,379] The mechanism for the attenuated

renal response to these natriuretic peptides is multifactoral and includes renal hypoperfusion, activation of the renin–angiotensin–aldosterone and the sympathetic nervous systems.[34,140,235]

Influence of Renal Failure on other Natriuretic Peptides

Adrenomedullin,[90,305,346] guanylin,[187] and uroguanylin[185,186] increase in renal failure and/or experimental nephrotic syndrome.

HEMODIALYSIS

Cardiac Hormones Synthesized by ANP Prohormone Gene

The circulating concentrations of the cardiac hormones have been suggested as possible indicators of when to perform dialysis in persons with chronic renal failure.[193,236,284,307,422] Other data, however, suggest that ANPs are not useful to predict when hemodialysis is necessary.[29] Hemodialysis lowers the circulating concentration of cardiac hormones by 34%–42%, with the amount of decrease appearing to be related to volume status of the patients.[193,417,422] Hemodialysis does not return the levels of ANP to those of healthy adults,[193,416,417,422] and it does not reduce circulating concentrations of vessel dilator and LANP.[422] Part of the reason for the difference in hemodialysis effects on the cardiac hormones is that less than 1.5% of vessel dilator and LANP cross the dialysis membrane, compared to 15% to 25% of ANP crossing hemodialysis membranes.[422] Hemodialysis using cellulose-triacetate dialyzers reduces plasma levels of these peptides in acute renal failure more than hemodialysis therapy with polysulfone dialyzers.[102]

BNP

Hemodialysis has been reported both to lower,[200] and to have no effect on circulating BNP levels.[49] Before dialysis in persons with chronic renal failure (CRF), plasma BNP levels have no relationship to serum creatinine or mean blood pressure.[192] In CRF patients whose plasma BNP levels decrease with dialysis, this decrease correlates with the degree of postural blood pressure drop, but there is no correlation with the fall in serum creatinine.[200] In none of the studies of BNP and dialysis[39,58,192,200] has BNP ever returned its circulating concentration to that of healthy individuals. With volume repletion after hemodialysis there is an exaggerated release of ANP, but changes in BNP are small and without any correlation with either atrial or ventricular volume.[58]

Adrenomedullin and Proadrenomedullin N-Terminal 20 Peptide

Both adrenomedullin and proadrenomedullin N-terminal 20 peptide (PAMP) increase in chronic renal failure.[90,305,346] Hemodialysis decreases these peptides to near-control levels, with PAMP being 2.17 ± 0.18 fmol/ml versus 1.64 ± 0.12 fmol/ml for controls.[346]

Guanylin and Uroguanylin

Both guanylin and uroguanylin are increased in persons with impaired renal function.[168,169] Hemodialysis with EVAL membranes decreases guanylin concentrations after one hour of dialysis, but the plasma levels after hemodialysis with PC membranes show no change.[187]

RENAL TRANSPLANTATION

Successful transplantation of functioning kidneys decreases the markedly elevated circulating levels of cardiac hormones in persons with acute renal failure to those of healthy individuals.[265,279] Nonfunctioning renal allografts continue to have elevated circulating concentrations of the cardiac hormones.[265,279] Post renal transplant, it takes seven days for ANP and 10 days for vessel dilator to return to normal.[265] This suggests that the allograft kidney does not fully function immediately with respect to clearing these peptides. The half-life of ANP in healthy persons is only 2.5–3.5 minutes.[4,366] If the transplanted kidneys began to function immediately, one would have expected the circulating concentration of ANP to have decreased to the normal range within 24 hours (360 half-lives). Vessel dilator has a 20-fold longer half-life compared to that of ANP,[4,366] which may explain why it takes three more days for this peptide hormone to normalize in the circulation after successful renal transplantation. If one gives ANP (via infusion) at the time of renal transplant, this does not appear to have any beneficial effect on the outcome of the renal allograft.[303] It is important to note that the elevated circulating cardiac hormones in heart failure also normalize with successful heart transplantation.[416]

ATRIAL NATRIURETIC PEPTIDE PROHORMONE GENE EXPRESSION IN INVERTEBRATES AND PLANTS

In addition to proANP gene being present in mammals and vertebrates, where lower vertebrates such as

the frog have an identical proANP gene,[296] blue crabs and oysters have been demonstrated to have the proANP gene in their hearts.[273,367] The proANP gene in oysters and blue crabs can be upregulated by increasing salinity in the external environment, such as when the animal moves from freshwater to seawater.[273,402] This change in environmental salinity also modulates end-product concentrations of this gene expression, that is, the cardiac hormones.[256] Environmental salinity also modulates ANP in the teleost fish *Gila atraria*.[415] Seawater trout have higher concentrations of ANP, vessel dilator, and LANP than freshwater trout to help them maintain volume homeostasis in a higher salt environment.[59] Even the most primitive heart in the animal kingdom contains the atrial natriuretic peptide hormonal system.[386] Diving is a modulator of ANP in lower animals, with diving increasing ANP in freshwater diving turtles[16] similar to whole body immersion in humans.[390,391,396]

Although a gene in the animal kingdom expressing a peptide hormonal system in plants had never been demonstrated previously, there is now evidence for a proANP-like gene in plants.[401] Southern blots of English ivy (*Hedera helix*) genomic DNA revealed that the proANP gene sequence was present in its roots, stems, and leaves.[401] In plants, ANPs enhance the flow of water up stems to flowers and leaves, a process that is at least partially due to increasing the rate of transpiration (loss of water from the leaves) via opening the stomatal pores in leaves.[367,387] These peptides are present even in *Euglena*, a single-cell, flagellated, chlorophyll-containing plant without leaves, stems or roots.[387] The oldest existing trees on Earth, the *Metasequoia*, which exist only in China, contain the ANP prohormone and ANP.[427] These peptide hormones are also found in single-cell animals, such as paramecium.[385] In single cell organisms, these peptides appear to help maintain the internal volume of the cell.[385] The demonstration of the proANP gene sequences and expression of the ANP-like gene in plants suggests that plants and animals may have evolved much more similarly than previously thought.[387]

PROTECTIVE AND THERAPEUTIC EFFECTS OF CARDIAC AND RENAL HORMONES IN ACUTE RENAL FAILURE

ANP and Urodilatin

Animals

Acute renal failure (ARF) develops in 2–5% of all patients admitted to tertiary care hospitals.[154,423] The underlying cause is a renal insult (acute tubular necrosis) in 60% of patients.[154,423] When dialysis was introduced in the mid-1940s, the mortality resulting from severe ARF was approximately 50%.[154] This poor prognosis has not improved, with mortality now in the 40–80% range in oliguric ARF.[9,31,66,153,154,308,423] The occurrence of ARF in the hospital increases the relative risk of dying by 6.2-fold, and the length of hospitalization by 10 days.[277]

Several of the cardiac hormones have been investigated as possible treatment(s) for ARF. Atrial natriuretic peptide (ANP) had encouraging results in early studies of ARF in animals.[57,208] The infusion of ANP[57,208,219,236,240,245,254,278,308,322,378,379] or urodilatin[232,314,323] in rat models of ischemic ARF attenuated renal tissue damage and preserved glomerular filtration rate. Nakamoto et al.[241] and Shaw et al.[322] were able to shorten the course of renal artery cross-clamping-induced ARF in rats with ANP. Conger et al.[57] found marked improvement in GFR in a rat renal artery-clamp model when ANP-III (0.2 μg/kg/min) was given intravenously immediately after clamp release in combination with dopamine sufficient to maintain mean arterial pressure above 100 mmHg. In the rat, ANP had no effect on GFR when given intravenously, but did have a GFR effect when given directly into the renal artery for four hours.[322] The inability of ANP to increase GFR when given intravenously could be restored if dopamine was given simultaneously.[57] In the dog, the improvement in renal perfusion only lasted for a short period after a 180-minute infusion of ANP.[245] When ANP was given by intra-aortic bolus on days 1 and 2 after the above infusion, there was no significant improvement in renal perfusion on those days.[245] Thus, in animals the improvement in renal failure with ANP was only of short duration and depended upon whether ANP was given intravenously or directly into the artery.[57,245,322]

Humans

The administration of 0.2 μg of ANP/kg of body weight^{-1}/min^{-1} for 24 hours to humans with ARF revealed that ANP did not cause significant improvement, and did not reduce the need for dialysis or reduce mortality.[7,207] ANP infusions were associated with decreased survival in the nonoliguric ARF subjects (75% of subjects).[7] The usefulness of ANP for treatment is hampered by its short half-life of 2.5 minutes,[4,366] and by its very short duration of action.[57,208,214,220,278,382] Of 504 ARF patients treated with ANP, 46% developed hypotension, which would further limit its usefulness in ARF.[7] Urodilatin has also been associated with severe hypotension and bradycardia, when given as a potential treatment of congestive heart failure.[184] ANP is now considered more harmful than helpful with respect to the treatment of acute renal failure.[35] When ANP was given before and

during radiocontrast study in 247 patients with chronic renal failure, no beneficial effect was found.[196] Urodilatin has been suggested as a possible treatment of renal failure,[231,314,315] but in double-blind phase II trials in acute renal failure patients, urodilatin has been found to have no beneficial effect.[232]

Vessel Dilator

Vessel dilator appears to be the cardiac hormone with the most promising therapeutic potential in ARF. Vessel dilator ($0.3\,\mu g/kg^{-1}/min^{-1}$ via intraperitoneal pump) decreases blood urea nitrogen (BUN) and serum creatinine from 162 ± 4 mg/dl and 8.17 ± 0.5 mg/dl, respectively, to 53 ± 17 mg/dl and 0.98 ± 0.12 mg/dl in acute renal failure animals, where ARF was established for 2 days (after vascular clamping) before vessel dilator was given.[54] At day 6 of ARF, mortality decreased to 14% with vessel dilator from 88% without vessel dilator.[54] The ARF animals that did not receive vessel dilator had moderate (25%–75% of all tubules involved) to severe (>75% of all tubules necrotic) acute tubular necrosis by day 8 after their ischemic event (Figure 37.7b). As shown in Figure 37.7b, the nuclei in the tubules of these animals were almost completely destroyed, and the tubules were filled with sludge. The destruction of the tubules included both the proximal and distal tubules, with the proximal tubules being more severely affected (Figure 37.7b). The glomerulus of the ARF animals was spared compared to the renal tubules, with glomerulus appearing to be normal in the ARF animals (Figure 37.7a and 37.7b).

The addition of vessel dilator after renal failure had been present for two days resulted in a marked improvement in the renal histology (Figure 37.7c), with scores ranging from 0 (no tubular necrosis) to 1+ (<5% of the tubules involved).[54] The nuclei of the ischemic tubules regenerated secondary to vessel dilator (Figure 37.7c). When the kidneys were examined at day 8 of renal failure, the brush borders of the proximal tubules of the ARF animals treated with vessel dilator were present (Figure 37.7c), which was similar to the proximal tubules of healthy animals (Figure 37.7a). In the ARF animals not treated with vessel dilator, the brush borders of the tubules were destroyed (Figure 37.7b). The glomeruli of vessel dilator-treated ARF animals also appeared normal (Figure 37.7c). It is important to note that the animals treated with vessel dilator who had a significant increase in survival had nonoliguric renal failure.[54] As noted previously, nonoliguric renal failure subjects treated with ANP had a decreased survival and it was the nonoliguric renal failure subjects who did not respond to ANP.[7] Vessel dilator, LANP, and kaliuretic peptide, as opposed to ANP, BNP, and urodilatin, have never caused a hypotensive episode when given to either healthy animals or humans[220,381,382] or when given to humans with sodium and water retention.[243,379,380]

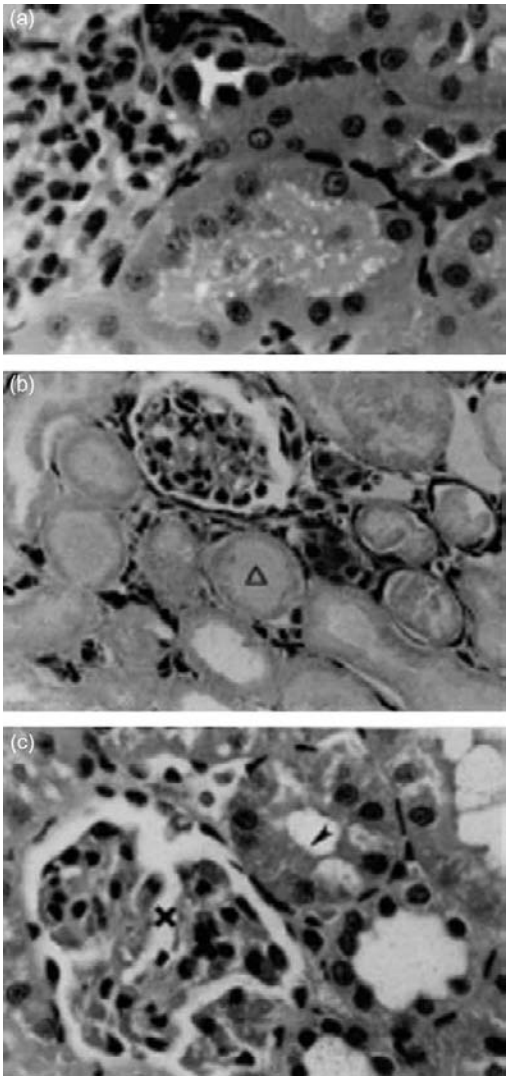

FIGURE 37.7 **Renal histology of healthy Sprague–Dawley rat.** (a) with intact proximal tubular brush border (arrowhead). (b) ARF rat at day 8 with marked tubular necrosis (open triangle) and without intact brush border present (>75% of tubules are necrotic). The glomerulus (x) appears to be normal. (c) ARF rat treated with vessel dilator from days 2 to 5 of ARF with kidney examined after day 8 of ARF reveals brush border to be present in proximal tubule (arrowhead). No tubules are necrotic in this ARF animal treated with vessel dilator. The glomerulus (x) is intact (Magnification of hematoxylin and eosin: ×426 (a) and (c); and ×320 (b); ARF: acute renal failure). *(With permission, from ref. [54].)*

The ability of vessel dilator to reverse ischemic ARF is consistent with the important concept that the pathophysiology of ischemic ARF is due to a sublethal and reversible injury to renal tubular cells.[31,234] Part of the improvement by vessel dilator may be due to its ability to cause intrarenal vasodilation, as it is a strong vasodilator.[389] The reason why vessel dilator has greater beneficial effects than ANP, BNP, CNP, and urodilatin in acute renal failure appears due, at least in part, to its ability to cause the endogenous synthesis of renoprotective prostaglandin E_2 (PGE_2)[6,180,414] which ANP, BNP, CNP, and urodilatin do not do.[51,139]

A suggestion that PGE_2 is renoprotective (by maintaining glomerular hemodynamics) is reinforced by the observation that cyclooxygenase inhibitors in congestive heart failure and volume depletion states augment the reduction in RBF and GFR.[92,410] There is a dramatic decrease with prostaglandins in the outer medulla perfusion following ischemic injury,[178] a region of renal tissue which normally operates "on the verge of ischemia".[36] Prostaglandins have a favorable effect on blood flow distribution to this region.[237] In addition, prostaglandins have distinct cytoprotective effects and improve microvascular permeability in ischemic ARF.[42,180] Prostaglandins are not stored in the kidney, but rather have to be synthesized acutely secondary to a stimulating agent such as vessel dilator[51,139] in order for prostaglandins to have a positive beneficial effect in renal failure.

Adrenomedullin

There is evidence that ADM is renoprotective in Dahl salt-sensitive rats, in that when perfused for seven days the glomerular injury score is 54% less ($p < 0.05$) than in untreated Dahl salt-sensitive rats.[248] The adrenomedullin treated salt-sensitive rats, however, had considerably more ($p < 0.01$) glomerular sclerosis and anteriolar sclerosis and atrophic tubules after treatment than the control Dahl salt-resistant rats.[248]

BNP

BNP has not been investigated as a treatment of acute renal failure, but one would expect that BNP, similar to ANP, will have blunted or no effects in ARF compared to its effects in healthy animals.[7,207,245]

CNP

CNP increases in the circulation in ARF,[348] but its effects in acute renal failure are unknown. As discussed above, CNP has no natriuretic effects in healthy humans.[21,47,161]

DNP

DNP has been evaluated in persons with end-stage renal disease on dialysis and was found not to correlate ($p = 0.62$) with echocardiographic left ventricular mass index (LVMI), while ANP and BNP did correlate with LVMI of these end-stage renal patients.[43] DNP has not been investigated with respect to its possible therapeutic effects in renal failure.

TREATMENT OF OTHER DISEASES WITH ABNORMAL BLOOD VOLUME

Congestive Heart Failure

As part of the adaptive response to the pathophysiology of congestive heart failure, cardiac hormones increase in circulation.[32,38,83,108,176,177,273,350,368,379,380,418] The rationale for treatment of the pathophysiology of CHF with cardiac hormones (which are already increased in the circulation) is based upon other hormonal systems, where if one gives pharmacological rather than physiological concentrations of a hormone one often can overcome a defect in the target organ with respect to a particular hormone. In congestive heart failure, the pathophysiology with respect to atrial natriuretic peptides appears to be in the target organ(s) – the kidney has a diminished response to some of the atrial peptides – rather than the heart not producing enough of the respective hormones.[366] When ANP was investigated for possible treatment of CHF pathophysiology, it was found to have a markedly attenuated natriuretic response.[56,104,255,318] High-dose administration of ANP produces little or no diuresis or natriuresis in humans with CHF.[56] Synthetic brain natriuretic peptide (Nesteride®) in CHF individuals causes a small increase in urine volume (90 ± 38 versus 67 ± 27 ml/hr).[217] There is no significant natriuresis[3] or diuresis[166,233] with Nesteride® infusion in humans with CHF. In CHF animals, BNP has had no significant natriuretic or diuretic effects.[199] BNP can cause significant hypotension, however, in CHF subjects[3,233] with an incidence of 27% reported with 0.06 μg/kg/min dose.[233] Urodilatin infusion in CHF animals, likewise, causes significantly less natriuresis and diuresis compared to healthy animals.[1]

Vessel dilator, when given intravenously for 60 minutes to NYHA Class III CHF subjects, increases urine flow two- to 13-fold, which is still increased three hours after its infusion is stopped.[380] In CHF subjects, vessel dilator infusion enhances sodium excretion levels three- to four-fold, and the fractional excretion of sodium (FE_{Na}) six-fold, which are still

significantly ($p < 0.01$) elevated 3 hours later.[380] Vessel dilator simultaneously decreases systemic vascular resistance 24%, pulmonary vascular resistance 25%, pulmonary capillary wedge pressure 33%, and central venous pressure 27%, while simultaneously increasing cardiac output 34%, cardiac index 35%, and stroke volume index 24% in individuals with CHF.[380] There were no side-effects with infusion of vessel dilator in CHF subjects, and specifically none of the CHF subjects became hypotensive as with BNP and ANP.[380] The natriuretic and diuretic effects of vessel dilator to help reverse the pathophysiology of CHF are as potent (not decreased or blunted) in persons with CHF as those observed in healthy persons.[380]

Long-acting natriuretic peptide (LANP) maximally increases urine flow and natriuresis only two-fold in persons with CHF[379] compared to four- to five-fold increase in urine flow and three- to eight-fold increase in natriuresis in healthy individuals.[382]

ANTIPROLIFERATIVE AND ANTI-CANCER PROPERTIES OF CARDIAC NATRIURETIC HORMONES

In blood vessels, ANP inhibits smooth muscle cell proliferation (hyperplasia) as well as smooth muscle cell growth (hypertrophy).[2,162,163,431] Atrial natriuretic peptide has growth-regulatory properties in a variety of other tissues including brain, bone, myocytes, red blood cell precursors, and endothelial cells.[10,11,143,169,261,431] In the kidney, ANP causes antimitogenic and antiproliferative effects in glomerular mesangial cells via inhibiting DNA synthesis.[10,11,169] The newest discovered property of the cardiac hormones, urodilatin, CNP, and DNP is their ability to inhibit the growth of cancers *in vitro* and *in vivo*.[361,362,377] The first cancer studied both *in vitro* and *in vivo* was human pancreatic adenocarcinomas, which have the lowest five-year survival rate of all common cancers.[267,424] The five-year survival rate of persons with adenocarcinoma of the pancreas is 1%.[267,424] The median survival is four months.[267,424] Current cancer chemotherapy and surgery prolong survival by a few months, but the abovementioned survival rates are for persons treated with surgery and/or currently available cancer chemotherapeutic agents.[267,424]

The four cardiac hormones from the ANP prohormone (Figure 37.1) decrease the number, i.e., eliminate up to 97% of human pancreatic, kidney, prostate, colon, breast, and ovarian adenocarcinoma cells,[131,355,356,357,361,362] angiosarcoma of the heart cells,[363] melanomas,[358] medullary thyroid carcinomas,[85] glioblastomas of brain,[359] as well as small-cell,[364] and squamous cell lung carcinoma cells[360] within 24 hours. There was a 97.4%, 87%, 88%, and 89% ($p < 0.001$ for each) decrease (i.e., elimination) of human prostate adenocarcinoma cells secondary to vessel dilator, long-acting natriuretic peptide, kaliuretic peptide, and ANP, respectively, within 24 hours at their 1 mM concentrations, without any proliferation in the three days following this decrease.[355] When utilized with these four cardiac hormones respective antibodies, their ability to decrease the number of prostate cancer cells was completely blocked, indicating that their effects were specific, i.e., not due to some other hormone or substance.[355] Atrial natriuretic peptide reduces the number of hepatoblastoma cells in culture.[285]

BRAIN NATRIURETIC PEPTIDE AND C-NATRIURETIC HAVE LESS SIGNIFICANT ANTI-CANCER EFFECTS

Dose–response investigations indicate that brain natriuretic peptide (BNP) has no anti-cancer effects at any concentration.[131,355–357,364] The addition of BNP for 24 hour results in a 1%, 2%, and 4% (all non-significant) decrease in renal carcinoma cell numbers at its 1, 10, and 100 μM concentrations.[356] C-natriuretic peptide (CNP) has anti-cancer effects, but only at 100-fold higher concentrations than that observed for the four cardiac hormones synthesized by the proANP gene.[356,364] With exposure to CNP for 24 hours there was a 1% (n.s.), 7% (n.s.), and 10% ($p = 0.04$) decrease in renal carcinoma cell numbers at its 1, 10, and 100 μM concentrations.[356] Similar results were found at 48, 72, and 96 hours exposure to BNP and CNP.[356]

THE KIDNEY HORMONE URODILATIN ALSO HAS ANTI-CANCER EFFECTS

One might expect that urodilatin may have anti-cancer effects, as this peptide has identical a.a. to ANP and identical a.a. to the four terminal a.a. of kaliuretic peptide, both of which have anti-cancer effects. Urodilatin decreases the number of renal carcinoma cells by 66% at its 100 μM concentration, while ANP and kaliuretic peptide with the same amino acids at this same concentration eliminated 70% and 74% of the renal carcinoma cells in 24 hours.[356] Urodilatin, vessel dilator, LANP, kaliuretic peptide, and ANP each at their 1 μM concentrations inhibit DNA synthesis when incubated with the human renal carcinoma cells for 24 hours by 65%, 84%, 70%, 74%, and 77%, respectively ($p < 0.001$).[356]

CARDIAC NATRIURETIC HORMONES ELIMINATE UP TO 80% OF HUMAN PANCREATIC ADENOCARCINOMAS *IN VIVO*

When the four cardiac hormones from the proANP gene each at 3 nM min^{-1} kg^{-1} body weight were infused subcutaneously for 28 days in athymic mice bearing human pancreatic adenocarcinomas, ANP eliminated 80% of the human pancreatic cancers.[383] Vessel dilator, LANP, and kaliuretic peptide eliminated the primary pancreatic cancers in 33%, 20%, and 14% of their respective treatment groups.[383] In none of the animals in which the pancreatic adenocarcinomas were eliminated in the primary site did a single animal ever have a recurrence in the primary site during its normal lifespan.[383] One ANP-treated animal developed a metastatic lesion, and this lesion was eliminated with treatment with vessel dilator.[383] Even in the treated animals which did not have total elimination of their human pancreatic adenocarcinoma, their tumor volume decreased to less than 10% (and with vessel dilator to less than 2%) of that of the untreated animals both during treatment and in a 12-month follow-up period.[383]

CARDIAC HORMONES ELIMINATE TWO-THIRDS OF HUMAN BREAST CANCERS *IN VIVO* WITHOUT ANY SURGERY

It was estimated that in 2009 there were 194,280 new cases of breast cancer and 40,610 deaths from breast cancer in the United States.[165] Breast cancer is the second leading cause of death from cancer in women, and the leading cause of death in women aged 40 to 55 in the United States.[258] Breast cancer is the leading cause of cancer death in women worldwide.[258] The number of new cases of breast cancer worldwide was estimated to be 1.05 million, with 370,000 deaths in 2000.[258]

Vessel dilator, LANP, kaliuretic peptide, and ANP eliminated 67%, 50%, 67%, and 33% of the human breast adenocarcinomas in athymic mice when infused subcutaneously for 28 days 3 nM min^{-1} kg^{-1} body weight.[399] There was no recurrence of the breast cancers in the primary site, and no metastasis except in the ANP-treated group[399] (Table 37.2).

TABLE 37.2 Cardiac Hormones Ability to Eliminate Human Cancer Growing in Athymic Mice

	Breast Cancer	Pancreatic Adenocarcinoma	Small-cell Lung Cancer
VDL	67%	33%	71%
LANP	50%	20%	86%
ANP	33%	80%	43%
KP	67%	14%	57%

The numbers in each column are the percentages of human cancers which are eliminated and never recur in the primary site in athymic mice when treated with each of the cardiac hormones for 28 days at 3 nM/kg body weight/minute. Abbreviations: VDL: vessel dilator; LANP: long acting natriuretic peptide; ANP: atrial natriuretic peptide; KP: kaliuretic peptide.

CARDIAC AND KIDNEY HORMONES ELIMINATE UP TO 86% OF HUMAN SMALL-CELL LUNG CANCERS IN MICE *IN VIVO*

Cancer of the lung and bronchus is the leading cause of cancer death in both men and women in the United States, with an estimated 88,900 deaths in men and 70,490 deaths in women in 2009.[165] The same trend is seen in many other countries.[353] In the current management of small-cell lung cancers, the majority of patients are treated first with chemotherapy plus radiotherapy, but with this combination survival is only 20% with limited disease and 0% survival with more extensive disease at three years.[182,353]

Long-acting natriuretic peptide, vessel dilator, kaliuretic peptide, ANP, and urodilatin eliminated 86%, 71%, 57%, 43% ($p < 0.001$ for each of the cardiac hormones), and 25% ($p < 0.05$; urodilatin) of the human small-cell lung carcinomas.[86] One vessel dilator-treated small-cell lung carcinoma animal developed a large tumor (8,428 mm^3 volume) on treatment, and this tumor was eliminated utilizing atrial natriuretic peptide and then long-acting natriuretic peptide each for four weeks sequentially.[86]

ANTI-CANCER MECHANISM WITHIN CANCER CELLS OF THE CARDIAC HORMONES

The Ras mitogen-activated protein kinase (MAPK)/extracellular signal-related kinase (ERK) kinase-(MEK)-ERK cascade (Figure 37.8), hereafter referred to as the Ras-MAPK pathway, is the prototypical signal transduction pathway in cancer.[224,313] This pathway is aberrantly activated in many types of neoplasms, including prostate and breast cancer, with this activation being associated with a poor prognosis.[224,313] The integral role of the Ras-MEK-ERK pathway in mediating multiple hallmarks of cancer has suggested that the different kinases in this pathway may be targets for the treatment of cancer.[225,289,319,320]

Ras

Structural alteration in the GTPase Ras occur in 25 to 30% of human cancers, which allows them to relay

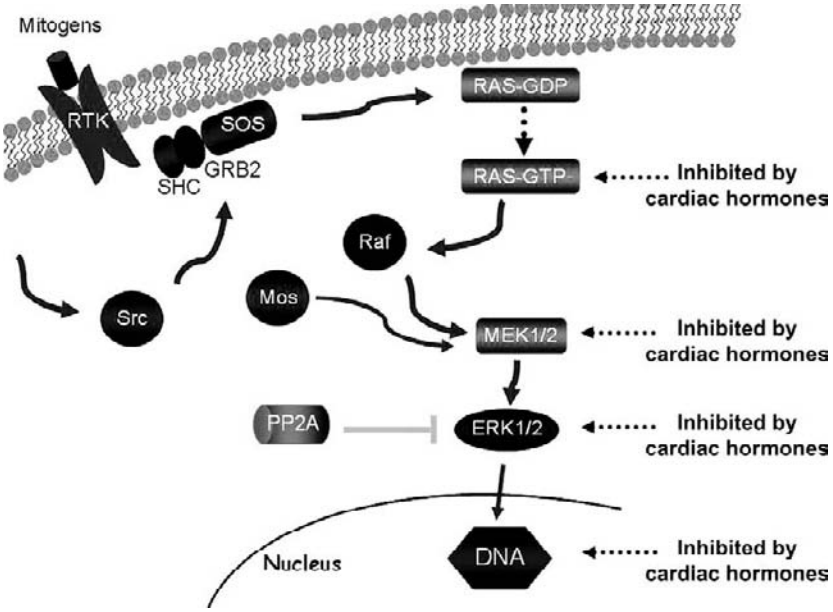

FIGURE 37.8 **Mitogens such as epidermal growth factor bind to their tyrosine kinase receptor (RTK) to convert inactive Ras-GTP mainly via SHC to active Ras-GTP.** Cardiac hormones inhibit up to 98% of 5 metabolic targets (kinases) important in cancer cell growth, i.e., Ras-GTP, MEK 1/2 kinases, and ERK 1/2 kinases of the Ras-MEK 1/2-ERK 1/2 kinase cascade in cancer cells. They are also strong inhibitors (up to 91%) of DNA synthesis within cancer cells. The cardiac hormones also block mitogens such as epidermal growth factor's ability to stimulate the conversion of Ras-GDP to Ras-GTP. [442]

mitogen signals in a ligand-independent manner, thereby obviating the need for ligand activation of growth factor receptors that occurs in normal cells.[225,319] Attempts to target Ras by perturbing its interaction with either Son of Sevenless gene (SOS) or growth factor receptor-bound 2 (GRB2) (Figure 37.8) have not yielded viable drug development candidates, largely because of the inherent difficulties of disrupting protein−protein interactions with drug-like molecules.[319] Several drug discovery programs have also been devoted to finding inhibitors of farnesyltransferase as a means to prevent the membrane localization of Ras.[319] Despite the successful identification of several chemical leads that effectively inhibited this prenylation enzyme, tumor cells, however, have proved generally to be impervious to the action of this class of inhibitors.[319]

Vessel dilator and kaliuretic peptide decrease the activation of Ras-GTP over a concentration range of 0.01 μM to 1 μM.[335] Vessel dilator and kaliuretic peptide (each 1 μM) inhibit the activation of Ras by 95% ($p < 0.001$) and 90% ($p < 0.001$), respectively. At 0.01 μM of kaliuretic peptide, the maximal inhibition was 95%. The inhibition of Ras lasted for 48 to 72 hours secondary to both peptides.[335] Their ability to inhibit Ras was inhibited by cyclic GMP antibody, and cyclic GMP itself inhibited Ras phosphorylation (89%; $p = 0.0015$).[335]

ANP and long-acting natriuretic peptide (each 0.1 μM) inhibited the phosphorylation of Ras 90% ($p < 0.0001$) and 83% ($p < 0.0001$), respectively.[336] At 0.01 μM of long-acting natriuretic peptide, the maximal inhibition was 89%, which occurred within 5 minutes. Both peptide hormones inhibited the activation of Ras for 3 to 4 hours.[336] Their ability to inhibit Ras was inhibited by cyclic GMP antibody and cyclic GMP itself inhibited Ras phosphorylation (72%; $p = 0.009$).[336] Thus, ANP, vessel dilator, kaliuretic peptide, and long-acting natriuretic peptide inhibit the activation of Ras via cyclic GMP as part of their anti-cancer mechanism(s) of action.[335,336]

MEK 1/2 Kinases

The prototype member of the MEK kinases, designated MAP kinase kinase (MKK-1)/or MEK-1, specifically phosphorylates the MAP kinase regulatory threonine and tyrosine residues present in the Thr-Glu-Tyr motif of ERK 1/2[61,425] (Figure 37.8). A second MEK family member, i.e., MEK-2, resembles MEK-1 at its substrate specificity, but is seven residues longer than MEK-1 with the amino acid sequence of MEK-2 being 81% identical to MEK-1.[425]

Vessel dilator and kaliuretic peptide decrease the activation of MEK 1/2 (Figure 37.8) over a concentration range of 0.01 μM to 10 μM.[339] Vessel dilator and kaliuretic peptide (each 10 μM) inhibited the phosphorylation of MEK 1/2 kinase 98% ((Figure 37.9, $p < 0.0001$) and 81% ($p < 0.001$), respectively.[339] The inhibition of MEK 1/2 lasted for at least two hours, where it was maximal, secondary to both peptides.[339] Their ability to inhibit MEK 1/2 was inhibited by cyclic GMP antibody, and cyclic GMP itself inhibited MEK 1/2 phosphorylation, indicating that cyclic GMP is important for mediating these cardiac hormones' effects.[339]

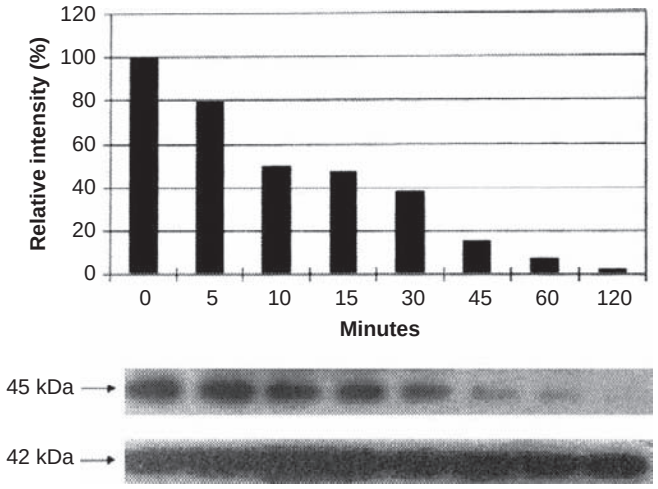

FIGURE 37.9 **Vessel dilator at 10 μM inhibits 98% of the phosphorylation of mitogen-activated protein kinase kinase (MEK 1/2), which was maximal at two hours and significant at $p < 0.00001$ when evaluated by analysis of variance (ANOVA). MEK 1/2 is at 45 kDa while B-actin (loading control) is at 42 kDa.** The relative intensity in the bar graphs is a comparison against untreated MEK 1/2 (100% intensity). *(Reprinted from Anticancer Res.* ***27****, 1387–1392, 2007.)*

ANP and long-acting natriuretic peptide decreased the activation of MEK 1/2 over a concentration range of 0.01 μM to 10 μM.[340] Long-acting natriuretic peptide and atrial natriuretic peptide (each 10 μM) inhibited the phosphorylation of MEK 1/2 kinase 97% ($p < 0.00001$) and 88% ($p < 0.00001$), respectively.[340] The inhibition of MEK 1/2 was maximal at two hours, and ceased by four hours secondary to both peptides.[340] The ability of peptides to inhibit MEK 1/2 was inhibited by cyclic GMP antibody, and cyclic GMP itself inhibited MEK 1/2 phosphorylation by 93%,[340] indicating that cyclic GMP is an important mediator of the cardiac natriuretic peptides' effects on MEK 1/2 kinase.

Cardiac Hormones Inhibit Activation of ERK 1/2 Kinases

Extracellular-signal regulated kinase (ERK) 1/2 is a mitogen-activated protein kinase (MAP kinase) important for the growth of cancer(s).[67,311] Growth factors such as epidermal growth factor (EGF), fibroblast growth factor, platelet derived growth factor, and vascular endothelial growth factor (VEGF) after binding to their specific receptor tyrosine kinases work via ERK 1/2 kinase to cause proliferation.[311]

Vessel dilator and kaliuretic peptide decrease the activation of ERK 1/2 over a concentration range of 0.01 μM to 1 μM. Vessel dilator and kaliuretic peptide (each 1 μM) inhibit the phosphorylation of ERK 1/2 kinases 96 and 70% ($p < 0.001$), respectively.[337] Both have significant effects within five minutes at their 0.01 μM concentrations.[337] The inhibition of ERK 1/2 lasted for at least two hours secondary to both. Their ability to inhibit ERK 1/2 was inhibited by cyclic GMP antibody, and cyclic GMP itself inhibited ERK 1/2 phosphorylation.[337]

ANP and LANP, likewise, decrease the activation of ERK 1/2 over a concentration range of 0.01 μM to 10 μM[(297d)]. ANP and LANP's maximal inhibition of the phosphorylation of ERK 1/2 kinase were 94 and 88% ($p < 0.0001$), respectively.[338] Their ability to inhibit ERK 1/2 was inhibited by cyclic GMP antibody, and cyclic GMP itself inhibited ERK 1/2 phosphorylation, suggesting that cyclic GMP mediates their effects of inhibition the phosphorylation of ERK 1/2.[338]

Growth promoting hormones such as insulin and epidermal growth factor (EGF) work as mitogens via ERK 1/2 (mitogen-activated) protein kinase (MAP kinase) to cause growth.[67,311] Insulin (1 μM) and EGF (10 ng/ml) each enhance the phosphorylation of ERK 1/2 by 66%.[341] This enhanced phosphorylation of ERK 1/2 by EGF and insulin was decreased down to 10%, 8%, 27%, and 13% above non-stimulated ERK 1/2 by vessel dilator, kaliuretic peptide, LANP, and ANP.[341]

CARDIAC HORMONES' MECHANISM OF ACTION: INHIBITION OF DNA SYNTHESIS

Vessel dilator, LANP, kaliuretic peptide, and ANP each at their 1 μM concentrations inhibit DNA synthesis when incubated with pancreatic adenocarcinoma cells for 24 hours by 91%, 84%, 86%, and 83%, respectively ($p < 0.001$ for each).[361] One of the known mediators[369,409] of these peptide hormones' mechanism(s) of action, i.e., cyclic GMP, inhibited DNA synthesis in these adenocarcinoma cells by 51%.[361] These four cardiac hormones inhibit DNA synthesis by 80–91% in all human cancer cell lines.[85,131,355–359,361,364] Thus, after inhibiting ERK 1/2, DNA synthesis (a further or final step in the Ras-ERK 1/2 pathway) is inhibited within the nucleus. The ability of these peptide hormones to inhibit DNA synthesis is specifically mediated by the intracellular mediator cyclic GMP, as when a cyclic GMP antibody is incubated with the cardiac hormones they are unable to inhibit DNA synthesis.[131]

LOCALIZATION OF CARDIAC HORMONES TO THE NUCLEUS OF PANCREATIC ADENOCARCINOMAS

All four of these cardiac hormones synthesized by the ANP gene localize to the nucleus of human

pancreatic adenocarcinomas by immunocytochemical evaluation, where they can inhibit DNA synthesis.[298,299] These are the first antigrowth peptide hormones that have been demonstrated to localize to the nucleus of cancers, and all four cardiac hormones localized to the nucleus.[298,299] These four cardiac hormones also localize to the capillaries growing into the human cancers, and the cytoplasm and fibroblasts within the tumors.[298,299]

SUMMARY AND FUTURE DIRECTIONS

Cardiac natriuretic peptides are synthesized both in the kidney and the heart,[130,271,347] and have some of their most potent biologic effects, such as natriuresis and diuresis, in the kidney.[24,27,78,139,141,220,405,434] Vessel dilator, via its ability to ameliorate acute renal failure and enhance tubule regeneration in acute tubular necrosis,[54] may prove useful in the future for the treatment of acute renal failure. BNP and adrenomedullin, with their effects in glomerular hypertrophy[179] and glomerular injury,[248] respectively, may be useful for the treatment of renal glomerular diseases. Since BNP, ANP, and adrenomedullin do not appear to help tubular diseases such as acute tubular necrosis, the major cause of acute renal failure,[154,423] their therapeutic potential in acute tubular necrosis appears limited. Future studies with these peptide hormones in humans with acute renal failure and/or glomerular diseases are necessary to determine whether the findings in animal models of ARF are applicable to the treatment of humans with acute renal failure.

Future research will concentrate on these cardiac hormones in humans with acute renal failure and renal cancer. With respect to side-effects, there have been no side-effects when infused for 28 days in athymic mice.[86,399] These cardiac hormones have been infused for one hour in 50 healthy humans and 50 humans with congestive heart failure, and one person had a marked decrease in blood pressure with ANP which was immediately corrected with 0.9% saline.[380,382] There have been no side-effects with the other three cardiac hormones in humans,[380,382] suggesting that they will be safe to treat persons with acute tubular necrosis and renal cancer and other cancers.

INTRODUCTION

Extracellular fluid (ECF) volume is determined by the balance between sodium intake and renal excretion of sodium. Under normal circumstances, wide variations in salt intake lead to parallel changes in renal salt excretion, such that ECF volume is maintained within narrow limits. This relative constancy of ECF volume is achieved by a series of afferent sensing systems, central integrative pathways, and renal and extrarenal effector mechanisms acting in concert to modulate sodium excretion by the kidney.

In the major edematous states, effector mechanisms responsible for sodium retention behave in a more-or-less nonsuppressible manner, resulting in either subtle or overt expansion of ECF volume. In some instances, an intrinsic abnormality of the kidney leads to primary retention of sodium, resulting in expansion of ECF volume. In other instances, the kidney retains sodium secondarily as a result of an actual or sensed reduction in effective circulatory volume.

Renal sodium wastage can be defined as the inability of the kidney to conserve sodium to such an extent that continued loss of sodium into the urine leads to contraction of intravascular volume and hypotension. Renal sodium wastage occurs in circumstances where renal sodium transport is pharmacologically interrupted (administration of diuretics), where the integrity of renal tubular function is breached (tubulointerstitial renal disease) or when mineralocorticoid activity or tubular responsiveness are diminished or absent.

SODIUM INTAKE AND SODIUM BALANCE

Under normal circumstances, renal excretion of sodium is regulated so that balance is maintained between intake and output, and ECF volume is stabilized. A subject maintained on a normal-sodium diet is in balance when body weight is constant, and sodium intake and output are equal. When the diet is abruptly decreased, a transient negative sodium balance ensues. A slight contraction of ECF volume signals activation of sodium-conserving mechanisms, which lead to decreases in urinary sodium excretion. After a few days, sodium balance is achieved and ECF volume and weight are stabilized, albeit at a lower value. If sodium intake is increased to the previous normal values, transient positive sodium balance leads to expansion of ECF volume, thereby suppressing those mechanisms that enhanced sodium reabsorption. A new steady-state is reached when ECF volume has risen sufficiently so that sodium excretion now equals intake (Figure 38.1). In both directions a steady-state is achieved, whereby sodium intake equals output, while ECF volume is expanded during salt loads and shrunk during salt restriction. The kidney behaves as though ECF volume is the major regulatory element modulating sodium excretion.

The major edematous states – congestive heart failure, cirrhosis of the liver, and nephrotic syndrome – depart strikingly from those constraints. These states are characterized by persistent renal salt retention despite progressive expansion of ECF volume.

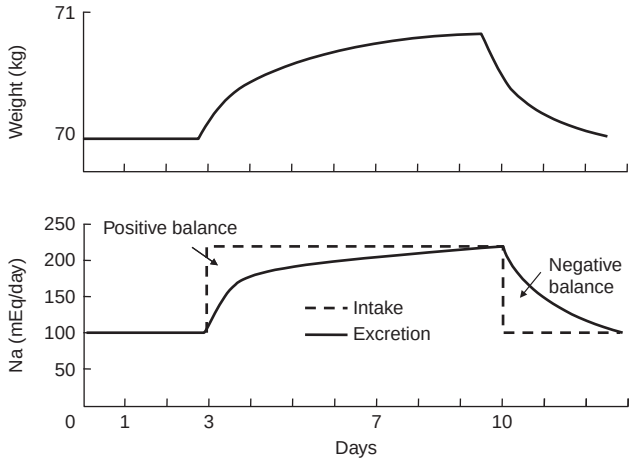

FIGURE 38.1 **Changes in body weight in response to abrupt changes in dietary salt demonstrating the ability of a normal subject to maintain salt balance with only minimal changes in extracellular fluid volume.**

Unrelenting sodium reabsorption is not the result of diminished sodium intake or even in most cases diminished plasma volume, as dietary salt is adequate and total ECF and plasma volumes are expanded. Renal sodium excretion no longer parallels changes in ECF volume; rather, the kidney behaves as if sensing a persistent low-volume stimulus. Some critical component of ECF volume remains underfilled.

PRIMARY AND SECONDARY EDEMA

A common feature of the major edematous states is persistent renal salt retention despite progressive expansion of both plasma and ECF volume. Two themes have been proposed to explain the persistent salt retention that characterizes the major edematous states: salt retention may be a primary abnormality of the kidney or a secondary response to some disturbance in circulation.

Primary edema (overflow, overfill, nephritic) refers to expansion of ECF volume and subsequent edema formation consequent to a primary defect in renal sodium excretion. Increased ECF volume and expansion of its subcompartments result in manifestations of a well-filled circulation. Hypertension and increased cardiac output are commonly present. The mechanisms normally elicited in response to an underfilled circulation are suppressed (↓renin–angiotensin–aldosterone,↓antidiuretic hormone (ADH),↓activity of sympathetic nerves,↓circulating catecholamines). Acute post-streptococcal glomerulonephritis and acute or advanced chronic kidney disease are disorders in which edema formation is primary in origin.

Secondary edema (underfill) results from the response of normal kidneys to actual or sensed underfilling of the circulation. In this form of edema, a primary disturbance within the circulation secondarily triggers renal mechanisms for sodium retention. Those systems that normally serve to defend the circulation are activated (rises in renin–angiotensin–aldosterone, ADH, activity of sympathetic nerves, and circulating catecholamines). The renal response in underfill edema is similar to that in normal subjects placed on a low-salt diet, that is, low fractional excretion of sodium, increased filtration fraction, and prerenal azotemia. Despite these similarities, a number of critical features distinguish these two states: (1) sodium balance is positive in underfill edema while salt-restricted normal subjects are in balance; and (2) administration of salt to sodium-restricted normals transiently expands ECF volume, after which sodium excretion equals intake, whereas in underfill edema, ECF volume expands progressively consequent to unyielding salt retention; and features of an underfilled circulation persist in underfill edema, while the circulation is normalized in normals.

The circulatory compartment that signals persistent activation of sodium-conserving mechanisms in secondary edema is not readily identifiable. Cardiac output may be high (arteriovenous shunts) or low (dilated cardiomyopathy). Similarly, plasma volume may be increased (arteriovenous shunts and heart failure) or decreased (some cases of nephrotic syndrome). The body fluid compartment ultimately responsible for signaling a volume-regulatory reflex leading to renal sodium retention is effective arterial blood volume (EABV). EABV identifies that critical component of arterial blood volume, actual or sensed, that regulates sodium reabsorption by the kidney.[184] In both normal circumstances and the major edematous states, the magnitude of EABV is the major determinant of renal salt and water handling.

CONCEPT OF EFFECTIVE ARTERIAL BLOOD VOLUME

In order to explain adequately persistent sodium retention in underfill edema, two cardinal features must exist. First, there must be a persistent low-volume stimulus sensed by the kidney that is then translated into persistent, indeed often unrelenting, retention of sodium despite adequate salt intake and overexpansion of ECF volume. Second, there must be a disturbance in those forces that partition retained fluid into the various subcompartments of the ECF space, resulting in an inability to terminate the low-volume stimulus. The first feature can be ascribed to a shrunken EABV, a

feature common to all major edematous states. The second feature can be attributed to a disruption in Starling forces, which normally dictate the distribution of fluid within the extracellular compartment. A disturbance in the circulation exists such that retained fluid is unable to restore EABV but rather is sequestered, resulting in edema formation.

Fluctuations in EABV are modulated by two key determinants: (1) filling of the arterial tree (normally determined by venous return and cardiac output); and (2) peripheral resistance (a factor influenced by compliance of the vasculature and degree of arteriolar runoff). A reduction in EABV can be the result of decreased arterial blood volume owing to low cardiac output, as in congestive heart failure. Conversely, EABV can be reduced in the face of increased arterial blood volume when there is excessive peripheral runoff, as seen in arteriovenous shunting and vasodilation. Increased compliance of the arterial vasculature in which arterial blood volume is reduced relative to the holding capacity of the vascular tree results in decreased EABV. For example, administration of salt to a subject with a highly compliant or "slack" circulation (as in pregnancy or cirrhosis) results in a sluggish natriuretic response, in contrast to a high resistance or "tight" circulation (as in primary aldosteronism or accelerated hypertension) in which salt administration causes prompt natriuresis.

Under normal circumstances, EABV is well-correlated with ECF volume. Figure 38.1 depicts the relationship between subcompartments of ECF volume and renal sodium excretion in both normal and edematous states. Under normal circumstances, subcompartments of ECF volume freely communicate in response to changes in dietary sodium, such that expansion or shrinkage of these compartments occurs in concert (Figure 38.2, states 1A and 1B). In steady-state conditions, sodium intake and output are in balance; the set point at which balance is attained is dictated by salt intake.

By contrast, major edematous states are characterized by a shrunken EABV, which cannot be filled despite expansion of one or more subcompartments. No longer is EABV well-correlated with total ECF volume and salt intake. Due to a disturbance in the forces that normally partition fluid into the various subcompartments of ECF space, EABV remains contracted even though total ECF volume is greatly expanded. Activation of sodium-conserving mechanisms persists, despite plentiful salt intake. Such derangements in fluid distribution can be categorized as disturbances in Starling forces within the interstitial space, between interstitial space and vascular tree, and disturbances within the circulation. These disturbances are summarized next.

1. *Trapped fluid* (Figure 38.2, state 2A). In the first type of disturbance, fluid is trapped within a pathologic compartment such that it cannot contribute to effective extracellular volume, that is, volume capable of filling interstitial and vascular spaces. Decrease in effective extracellular volume leads to decreases in total blood volume, arterial blood volume, and EABV, and renal sodium retention is stimulated. Retention of salt and water cannot re-expand effective extracellular volume, as fluid is sequestered into an abnormal fluid compartment behind the "Starling block" within the interstitial space. Such spacing of fluid into inflamed tissue, vesicles and bullae, peritonitis, necrotizing pancreatitis, rhabdomyolysis, and burns functionally behaves as if lost from the body.
2. *Reduced oncotic pressure.* A reduction in the circulating level of albumin can lead to a second type of fluid maldistribution. Decreased plasma oncotic pressure allows fluid to translocate from the vascular compartment to the interstitial space. Reductions in total blood volume, arterial blood volume, and EABV lead to sodium retention. The retained salt and water, owing to a "Starling block" across the capillary bed, leaks into the interstitial space.
3. *Vascular disturbances* (Figure 38.2, states 2B and 2C). A third type of fluid distributory disturbance results from abnormalities within the circulation, and can be of two types. The prototypical example of the first type is congestive heart failure. A failing ventricle results in decreased cardiac output and high diastolic intraventricular pressures. Venous return is impeded, with consequent reductions in arterial blood volume and EABV. Sodium retention is stimulated, but arterial blood volume and EABV remain contracted due to a circulatory block across the heart. In consequence, venous volume expands and leads to transudation of fluid into the interstitial space. The second type of circulatory abnormality that leads to fluid maldistribution is exemplified by arteriovenous shunting (e.g., Paget's disease, beriberi, thyrotoxicosis, anemia, cirrhosis). Widespread shunting through multiple small arteriovenous communications results in increased venous return, thereby augmenting cardiac output and arterial filling. However, arterial runoff and vasodilation lead to underperfusion of some critical area in the microcirculation. The circulatory block lies between the arterial blood volume and EABV.

What distinguishes secondary edematous states from the normal circumstance is an inability to expand EABV owing to Starling or circulatory blocks within the extracellular space. Normally, the system of

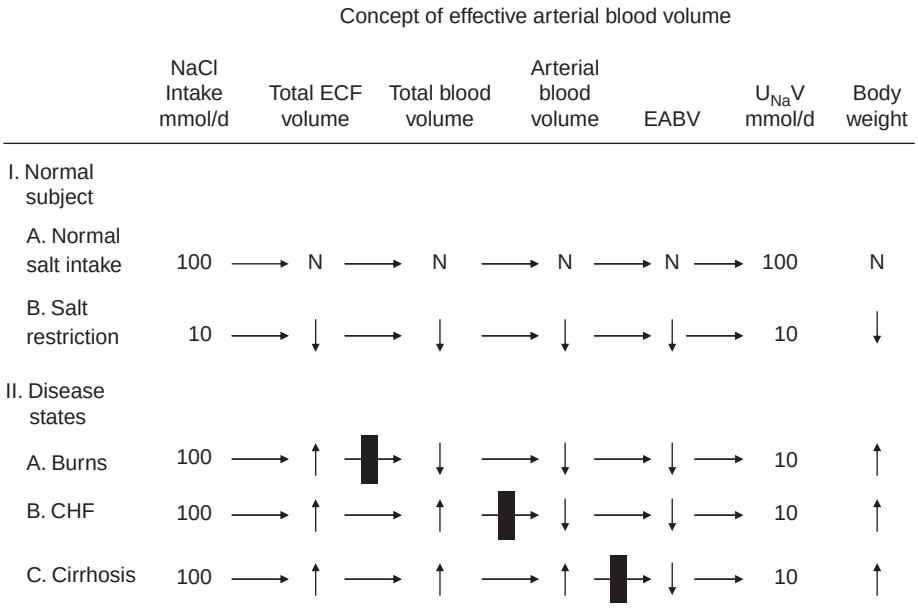

FIGURE 38.2 Concept of effective arterial blood volume and effect of fluid distributory disturbances on sodium balance and sodium excretion.

volume regulation behaves as an open system, such that fluctuations in one compartment are quickly translated into parallel changes in other compartments; total ECF volume and EABV are closely related. In contrast, volume regulation in underfill edema can be regarded as clamped; EABV remains shrunken despite expansion of the subcompartments of the extracellular space. EABV becomes dissociated from total ECF volume; salt retention becomes unrelenting and salt administration cannot re-expand the contracted EABV.

The reader is referred to the fourth edition of this book, in which a comprehensive discussion is provided on the afferent and efferent mechanisms involved in the regulation of extracellular fluid volume under normal circumstances. An overview of renal sodium handling in each segment of the nephron was also provided in that discussion. In this edition, the chapter will focus exclusively on the pathophysiology of the major edematous and salt-wasting states.

CONGESTIVE HEART FAILURE

The fundamental abnormality underlying congestive heart failure is an inability of the heart to maintain its function as a pump. As a result, a series of complex compensatory reflexes are initiated that serve to defend the circulation. The renal response to a failing myocardium is retention of salt and water resulting in expansion of ECF volume. If myocardial dysfunction is mild, expansion of ECF volume leads to increased left ventricular end-diastolic volume, which raises cardiac output according to the dictates of the Frank–Starling principle. In this state of compensated congestive heart failure, salt intake and output come into balance, but at the expense of an expanded ECF volume. Further deterioration in ventricular function leads to further renal retention of salt and water. There is progressive expansion of ECF volume and features of a congested circulation become manifest: peripheral edema, engorged neck veins, and pulmonary edema. Despite massive overexpansion of ECF volume, the kidneys behave as though they were responding to a low-volume stimulus. In subsequent sections, a detailed analysis of the afferent and efferent regulatory limbs in congestive heart failure will be provided.

Afferent Sensing Mechanisms in Congestive Heart Failure

Low and High Pressure Baroreceptors

A characteristic feature in many forms of congestive heart failure is increased stretch and transmural pressure within the cardiac atria. These alterations would normally provide afferent signals that suppress sympathetic outflow and decrease the release of renin and ADH, and ultimately result in a diuretic and natriuretic response. In congestive heart failure, this afferent signaling mechanism is markedly perturbed. Despite the presence of venous congestion and elevated cardiac filling pressures, sympathetic nervous activity and serum concentrations of renin and ADH are increased and urinary salt excretion is blunted. Both clinical and experimental studies are consistent with a decrease in sensitivity of the pressure-sensitive receptors in the cardiac atria.

Increased renal sympathetic nerve activity in cardiac failure has also been attributed to impaired arterial

baroreceptor function. High pressure baroreceptors in the carotid sinus and aortic arch normally exert a tonic inhibitory effect on central nervous system sympathetic outflow. Although the precise mechanism for the sympathoexcitation is not known, a sustained reduction in arterial pressure is unlikely to be the sole explanation, since arterial pressure is usually normal in congestive heart failure. Rather, sympathetic tone becomes insensitive to manipulations that normally suppress or enhance its activity. For example, infusion of nitroprusside increases both the heart rate and the circulating norepinephrine levels in normal subjects, whereas equivalent hypotensive doses in subjects with congestive heart failure elicit a blunted response.[149] Similarly, patients with heart failure show less bradycardia when arterial pressure is raised by infusion of phenylephrine. Such alterations in baroreflex function may result from abnormalities peripherally or alterations in central autonomic regulatory centers.

Several observations suggest angiotensin II may contribute to the depressed baroreflex sensitivity in heart failure. Angiotensin II has been shown to upwardly reset the arterial baroreflex control of heart rate in the rabbit, independent of a change in arterial pressure.[20] In the rat, increased levels of endogenous angiotensin II produced by changes in dietary salt intake tonically increase the basal level of renal sympathetic nerve activity, and upwardly reset the arterial baroreflex control of renal sympathetic nerve activity.[36] In experimental models, administration of an angiotensin II receptor blocker can reverse these changes and improve the sensitivity of the arterial baroreflex mechanism. Interestingly, captopril administered to patients with congestive heart failure restores the normal hemodynamic response to postural tilt and infusion of vasoconstrictive agents.[30]

Cardiac Output

A reduction in cardiac output has been suggested as the afferent signal that leads to Na retention in heart failure. When cardiac output is reduced by constriction of the abdominal or thoracic vena cava, urinary sodium excretion is typically decreased.[166,186] Restoring cardiac output to normal by autologous blood transfusion ameliorates renal salt retention, despite persistently elevated venous and hepatic pressures.[166] By contrast, rats with small-to-moderate myocardial infarctions have normal capacities to increase cardiac output in response to volume loads, and yet renal sodium excretion remains blunted in these animals. Even when cardiac output is increased above normal, as with the creation of an arteriovenous fistula in dogs, clinical findings of ascites and peripheral and pulmonary edema develop.[218] Despite increased cardiac output, levels of renin, aldosterone, and ANP are high.[202] Thus, the signal which initiates renal salt retention in congestive heart failure cannot originate solely from a decrease in cardiac output.

Other Sensors

Other afferent sensing mechanisms potentially active in congestive heart failure include intrahepatic baroreceptors and mechanoreceptors within the kidney. Chemosensitive receptors that respond to changing levels of metabolic breakdown products may participate in sensing of ECF volume. One such sensing mechanism may relate to the cardiac sympathetic afferent reflex. The reflex begins with sympathetic afferent fibers that respond to changes in cardiac pressure and dimension or substances that may accumulate in ischemia or heart failure. The reflex is excitatory in nature, such that activation of the afferent fibers leads to increased central sympathetic outflow. In summary, a contracted EABV serves as the afferent signal that elicits activation of effector mechanisms resulting in sodium retention. As with other edematous disorders, the exact volume compartment that comprises EABV has not been elucidated (Figure 38.3).

Effector Mechanisms in Congestive Heart Failure

Nephron Sites of Renal Sodium Retention

Renal sodium handling in the setting of congestive heart failure is similar to that which occurs in an otherwise normal individual who is volume-depleted. Activation of effector mechanisms lead to alterations in renal hemodynamics and tubular transport mechanisms that culminate in renal salt retention.

Renal hemodynamics in congestive heart failure are characterized by reduced renal plasma flow and a well-preserved glomerular filtration rate, such that filtration fraction is typically increased. In a rat model of myocardial infarction, Hostetter et al.[75] found a positive correlation between the decline in renal plasma flow and the degree to which left ventricular function was impaired. The glomerular filtration rate remained well-preserved as a result of an increased filtration fraction, except in animals with a severely compromised left ventricle. When examined at the level of the single nephron, these hemodynamic changes were found to be the result of a disproportionate increase in efferent arteriolar vasoconstriction and increased glomerular capillary hydraulic pressure.[76] Treatment with an angiotensin-converting enzyme inhibitor caused a decline in filtration fraction and efferent arteriolar resistance, suggesting an important role for angiotensin II in mediating efferent arteriolar constriction.

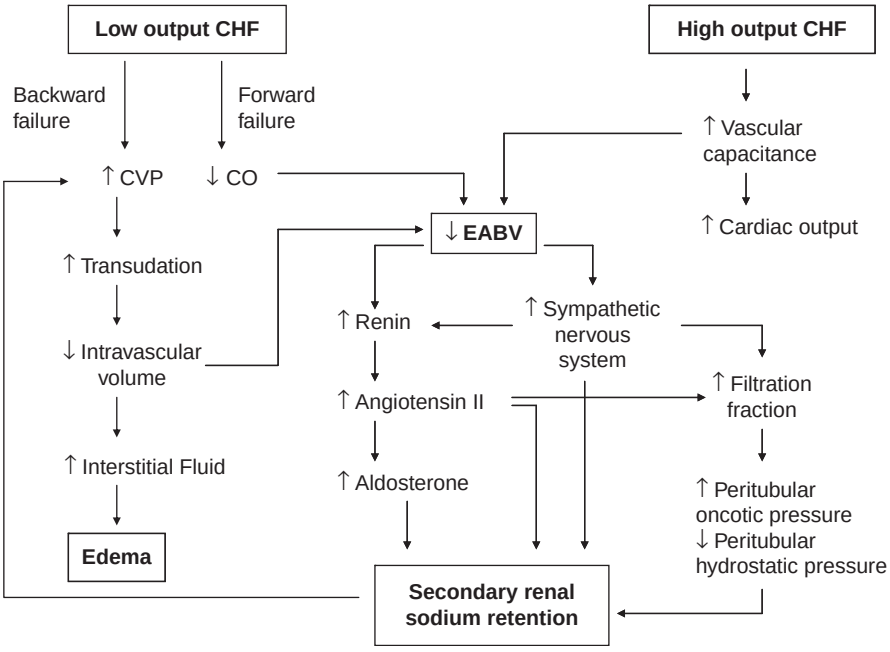

FIGURE 38.3 **Summary of pathways leading to renal sodium retention in low- and high-output congestive heart failure** (CO: cardiac output; EABV: effective arterial blood volume; CVP: central venous pressure).

Changes in glomerular and proximal tubular function in heart failure are similar to those that result from infusion of angiotensin II or norepinephrine. Angiotensin II, catecholamines, and renal nerves are all capable of increasing both the afferent and the efferent arteriolar tone, but predominantly act on the latter. These changes serve to maintain glomerular filtration rate near normal as renal plasma flow declines secondary to impaired cardiac function. As cardiac function progressively declines and the reduction in renal plasma flow becomes severe, the glomerular filtration rate will begin to fall. At this point there is an inadequate rise in filtration fraction, because efferent arteriolar vasoconstriction can no longer offset the intense afferent arteriolar constriction. Higher plasma catecholamines and further increases in sympathetic nerve activity acting to provide circulatory stability result in greater constriction of the afferent arteriole, such that glomerular plasma flow and transcapillary hydraulic pressure are reduced. In this setting, the glomerular filtration rate becomes dependent on afferent arteriolar flow.

These observations are similar to what has been observed in human subjects with varying degrees of left ventricular function.[119] As left ventricular function declines, the glomerular filtration rate is initially maintained by an increased filtration fraction. However, in patients with severely depressed left ventricular function, a progressive decline in renal blood flow becomes associated with a fall in glomerular filtration rate due to an inadequate rise in filtration fraction. In this setting, administration of an ACE inhibitor can result in a further lowering of the glomerular filtration rate, even though systemic arterial pressure remains fairly constant.[151]

Both experimental and clinical studies support the proximal nephron as a major site of increased sodium reabsorption in the setting of congestive heart failure. In human subjects, clearance techniques have primarily been employed to demonstrate the contribution of the proximal nephron. For example, infusion of mannitol was shown to increase free water excretion to a greater extent in patients with congestive heart failure as compared to normal controls. Since mannitol inhibits fluid reabsorption proximal to the diluting segment, it was inferred that enhanced free water clearance was reflective of augmented delivery of Na from the proximal tubule to the diluting segment.[10] In dogs with an arteriovenous fistula, there is a failure to escape from the Na-retaining effects of deoxycorticosterone acetate. In addition, these animals do not develop hypokalemia in contrast to normal controls.[82] The absence of hypokalemia in the setting of mineralocorticoid excess is best explained by decreased delivery of Na to the distal nephron due to enhanced proximal Na reabsorption. Alterations in peritubular hydrostatic and oncotic forces, as well as direct effects of various neurohormonal effectors, account for enhanced proximal sodium and water absorption in this setting.[76]

Clearance and micropuncture studies are also consistent with enhanced sodium reabsoption in the distal tubule in states of congestive heart failure. The loop of Henle has been identified as a site of enhanced sodium reabsoption in dogs with chronic vena cava obstruction[112] and rats with an arteriovenous fistula.[193]

Renin–Angiotensin–Aldosterone System

The renin–angiotensin–aldosterone system is activated when the heart fails as a pump.[139] Components of this system serve to compensate for decreased cardiac output by stabilizing the circulation and expanding ECF volume.

Several mechanisms are activated in the setting of a failing myocardium which serve to increased renin release. Diminished pressure in the afferent arteriole enhances renin release via a baroreceptor mechanism, the sensitivity of which is heightened consequent to augmented baseline sympathetic nerve activity.[94] Enhanced salt and water reabsorption in the proximal tubule and loop of Henle diminishes sodium chloride concentration at the macula densa, providing a stimulatory signal for renin release by way of the tubuloglomerular feedback mechanism. Finally, increased sympathetic nerve activity directly enhances renin release via stimulation of β-adrenergic receptors on the juxtaglomerular cells.

Renin acts on angiotensinogen synthesized in the liver and elsewhere to produce the decapeptide, angiotensin I. Angiotensin I is converted to angiotensin II by the angiotensin-converting enzyme present in the lungs, kidney, and blood vessels throughout the circulation.

Angiotensin II plays a pivotal role in glomerular and proximal tubule function in models of congestive heart failure (Figure 38.4). By selectively increasing efferent arteriolar tone, adjustments in the glomerular and postglomerular circulatory network favor net reabsorption in the proximal tubule. Increased filtration fraction leads to increased peritubular oncotic pressure, and in combination with decreased peritubular hydrostatic pressure net sodium reabsorption is enhanced. Angiotensin II also stimulates salt and water reabsorption through a direct effect on proximal tubular cells.[70,187] Increased efferent arteriolar resistance increases glomerular capillary hydrostatic pressure, mitigating any fall in GFR that would otherwise occur from decreased renal blood flow. In clinical, as well as experimental, models of heart failure, administration of ACE inhibitors improves renal blood flow and increases urinary sodium excretion, consistent with important angiotensin II-mediated effects on the renal microvasculature.[44]

Angiotensin II also contributes to renal salt and water retention through effects mediated by increased renal sympathetic nerve activity. As previously mentioned, angiotensin II decreases the sensitivity of the baroreflex mechanism such that a higher pressure is required to decrease central sympathetic outflow. In addition, angiotensin II directly stimulates sympathetic outflow at the level of the central nervous system. Chronic administration of an ACE inhibitor to patients with congestive heart failure reduces central sympathetic outflow and improves the sympathoinhibitory response to baroreflex stimulation.[65]

Angiotensin II also influences renal salt and water handling in the distal nephron, primarily through stimulatory effects on aldosterone release in the adrenal gland.[183] Aldosterone acts primarily on the collecting duct to promote tubular reabsorption of sodium. Aldosterone-stimulated sodium reabsorption generates a luminal-negative voltage that secondarily enhances excretion of hydrogen and potassium ions. The magnitude of potassium secretion will depend on the volume and composition of filtrate reaching the collecting duct. In this regard, patients with heart failure rarely manifest hypokalemia and alkalosis, despite oversecretion of mineralocorticoid, unless distal sodium delivery is increased by use of a diuretic. In the absence of diuretic therapy, distal delivery of sodium is low due to enhanced proximal reabsorption mediated by angiotensin II, sympathetic nerves, and peritubular physical factors. Thus, although plasma renin and aldosterone levels are frequently elevated in heart failure, there is conflicting data as to the importance of aldosterone in mediating renal salt retention.[43,71,206]

Conflicting data regarding the importance of the renin–angiotensin–aldosterone system in the generation of cardiac edema is best resolved when analyzed with respect to severity of heart failure. The initial response to constriction of the pulmonary artery or thoracic inferior vena cava in dogs is a reduction in blood pressure, and increases in renin and aldosterone levels. During this acute phase there is avid renal sodium retention,[206] and stability of blood pressure is critically dependent on circulating angiotensin II. Over several days plasma volume and body weight increase, while renin, aldosterone, and sodium balance return to control values. During the acute phase, administration of a converting enzyme inhibitor results in hypotension, while no effect on blood pressure is observed during this chronic phase. If plasma renin and aldosterone fail to decrease due to severe impairment of cardiac output, then converting enzyme inhibitor-induced hypotension persists.

A similar pattern is seen in dogs with an arteriovenous fistula.[202] In the early phase of this high-output cardiac failure model, significant elevations in renin and aldosterone levels occur, and renal sodium retention is marked. Several days later, after development of peripheral edema and ascites, renin and aldosterone levels return to baseline and daily sodium excretion begins to match dietary intake.

A similar relationship between the renin–angiotensin–aldosterone system and stage and

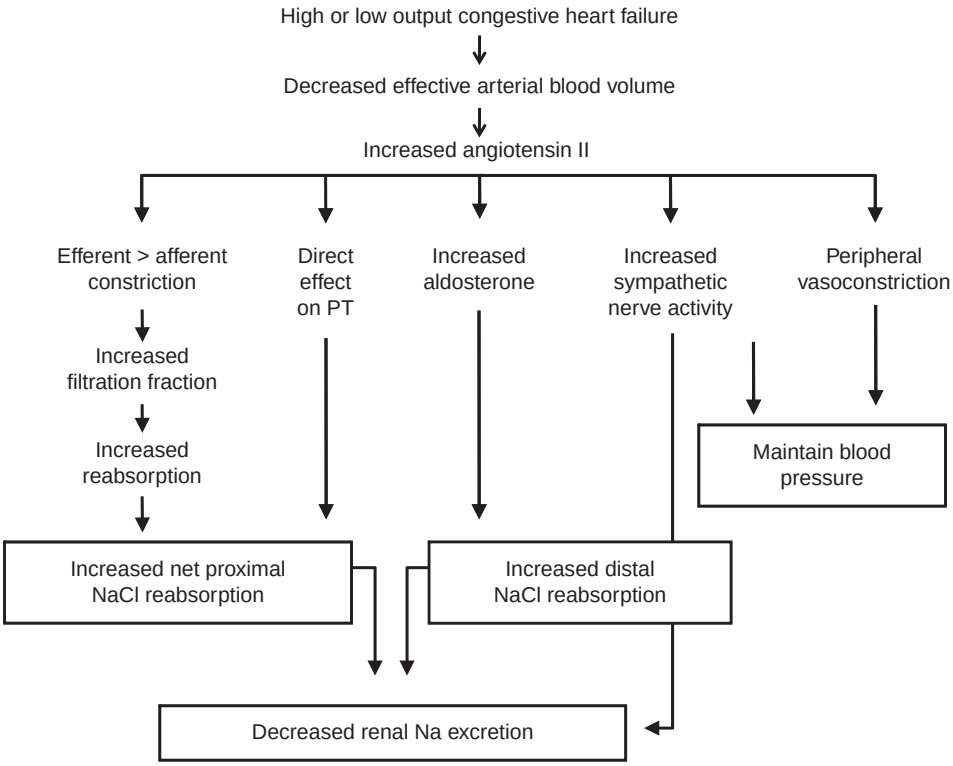

FIGURE 38.4 **Pathways by which angiotensin II regulates renal sodium excretion in response to a decrease in effective arterial blood volume.**

severity of congestive heart failure exists in humans.[43] This relationship may explain why renal function improves in some patients treated with ACE inhibitors, whereas renal function deteriorates in others.[152] In subjects whose renal function worsens after administration of the drug, there is a greater fall in mean right atrial pressure, left ventricular filling pressure, mean arterial pressure, and systemic vascular resistance as compared to subjects with stable renal function. In addition, plasma renin activity increases to a greater extent. These changes suggest a more contracted EABV and greater dependency of systemic vascular resistance on circulating angiotensin II in patients with ACE inhibitor-induced renal dysfunction.

In summary, during severe decompensated left ventricular failure, decreased EABV elicits release of renin with consequent activation of angiotensin II and aldosterone. Acutely, increased circulating levels of angiotensin II serve to maintain systemic blood pressure and augment renal sodium reabsorption. Salt retention is the result of hemodynamic and direct effects of angiotensin II at the level of the proximal tubule, and enhanced sodium reabsorption in the distal nephron primarily mediated by increased aldosterone. As ECF volume expands, renin, angiotensin II, and aldosterone become suppressed, although not necessarily to normal levels. Maintenance of systemic blood pressure is more dependent on volume rather than angiotensin II. Sodium balance is now achieved, but at the expense of increased steady-state ECF volume. ACE inhibitor therapy is not associated with deleterious effects on renal function at this stage of the disease. Should further deterioration in cardiac function ensue, persistent activation of the renin–angiotensin–aldosterone system may result, such that systemic blood pressure remains dependent on circulating angiotensin II despite expansion of ECF volume. In this setting, ACE inhibitor therapy can precipitate hypotension and significant reductions in the glomerular filtration rate. One has to consider this sequential change in renin to volume dependency of mean arterial blood pressure in attempting to predict net renal and hemodynamic effects of converting enzyme inhibition.[156,194]

Sympathetic Nervous System

The sympathetic nervous system is activated in congestive heart failure. Plasma norepinephrine levels are elevated, and concentrations correlate with the degree of left ventricular dysfunction.[111] Direct nerve recordings demonstrate a direct relationship between central sympathetic nerve outflow and left ventricular filling pressures.[109]

Increased sympathetic tone influences renal reabsorption of salt and water by indirect, as well as direct, mechanisms (Figure 38.5). Glomerular hemodynamics are affected similarly to that produced by angiotensin II. In addition, sympathetic nerves directly stimulate

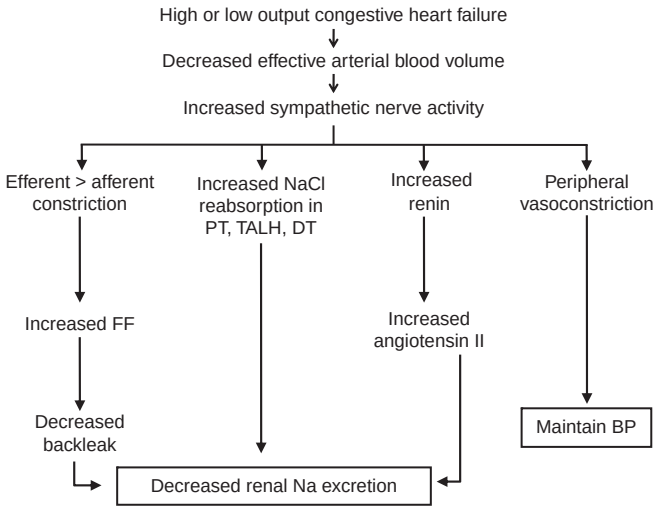

FIGURE 38.5 **Pathways by which sympathetic nerves regulate renal sodium excretion in response to a decrease in effective arterial blood volume.**

tubular reabsorption of salt and water in both the proximal and the distal nephron.

Increased sympathetic nerve activity stimulates renin release. The subsequent formation of angiotensin II provides a positive feedback loop leading to further increases in sympathetic nerve activity. Angiotensin II sensitizes tissues to the actions of catecholamines, and acts synergistically with renal nerves in modulating renal blood flow.[158]

Arginine Vasopressin

Increased circulating levels of AVP is a characteristic finding in patients with congestive heart failure.[172] The nonosmotic release of AVP plays an important role in the development of hyponatremia, which in turn is a well-defined predictor of mortality in heart failure patients. In experimental heart failure, there is upregulation of the mRNA for vasopressin in the hypothalamus.[91] In addition, there is increased expression of the mRNA and the protein for the aquaporin-2 water channel.[216] In a rat model of heart failure, selective antagonism of the V-2 receptor is associated with a significant improvement in free water clearance.[216] Administration of a V-2 receptor antagonist to patients with congestive heart failure is associated with a significant reduction in body weight and improvement in dyspnea, but has not been shown to reduce mortality.[173]

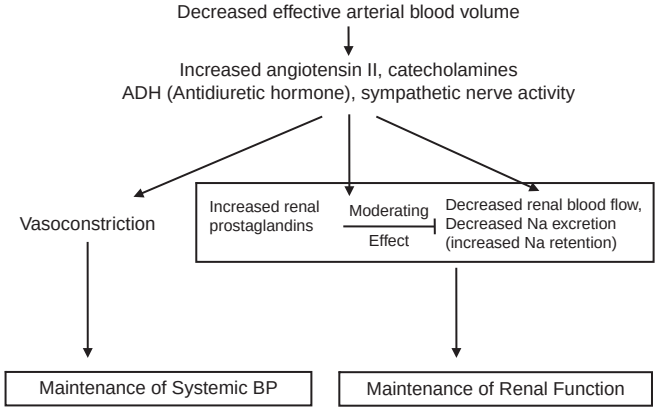

FIGURE 38.6 **Renal prostaglandins moderate the effect of various effector mechanisms, thereby allowing renal function to be well-maintained in the setting of increased systemic vasoconstrictor input.**

Prostaglandins

Increased production of prostaglandins plays an important role in maintaining circulatory homeostasis in congestive heart failure. In response to decreases in cardiac output, neurohumoral vasoconstrictor forces (i.e., the renin–angiotensin–aldosterone system, the neurosympathoadrenal axis) participate in the maintenance of systemic arterial pressure, and result in increased total peripheral vascular resistance. These same vasoconstrictors stimulate the renal production of vasodilatory prostaglandins, such that the rise in renal vascular resistance is less than that seen in the periphery. Vasodilatory prostaglandins function in a counterregulatory role, attenuating the fall in renal blood flow and glomerular filtration rate that would otherwise occur if vasoconstrictor forces were left unopposed.[154]

Renal prostaglandins also serve to moderate salt and water retention that would otherwise occur in the setting of unopposed activation of effector mechanisms such as angiotensin II, aldosterone, renal sympathetic nerves, and ADH.[154] The importance of prostaglandins in modulating renal hemodynamics, sodium excretion, and circulatory homeostasis progressively increases in proportion to the severity of the heart failure (Figure 38.6).

Natriuretic Peptides

Circulating atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) are circulating hormones which are primarily synthesized in the cardiac atria and ventricles respectively. The synthesis and release of these peptides provide a mechanism whereby cardiac atria and ventricles serve both an afferent and efferent function in the control of ECF volume. Levels of ANP are elevated and correlate with the severity of disease in humans and experimental animals with heart failure.[29,168]

The natriuretic and vasodilatory properties of ANP suggest that this peptide plays an important counterregulatory role in congestive heart failure. However, attempts to use ANP therapeutically in congestive heart failure have produced disappointing results.[29,95] ANP infused in patients with heart failure causes only

a minimal change in fractional sodium excretion and urine flow rates, as compared to the robust response in normal controls.[29] The mechanism of renal nonresponsiveness in heart failure is not entirely clear. A downregulation of receptors due to sustained exposure to high levels of ANP or altered intrarenal hemodynamics are possibilities. Decreased delivery of sodium to the distal nephron where ANP normally exerts its natriuretic effect is also a likely cause of resistance. While ANP levels are uniformly elevated in congestive heart failure, potentially beneficial natriuretic properties are overwhelmed by more powerful antinatriuretic effector mechanisms.

Similar to ANP, plasma levels of BNP are elevated in congestive heart failure, and in proportion to the severity of systolic and diastolic dysfunction.[153] Infusion of BNP is associated with a significant reduction in pulmonary capillary wedge pressure, pulmonary artery pressure, right atrial pressure, and mean arterial pressure, as well as an increase in cardiac index. These hemodynamic benefits are accompanied by significant increases in urinary volume and sodium excretion, in some but not all studies.[131,133] Infusion of BNP can be associated with hypotension, particularly when given with other vasodilators. Measurement of plasma BNP levels is often utilized as a diagnostic tool to differentiate between cardiac versus other causes of pulmonary congestion. In addition, BNP levels can be used as a prognostic indicator and a marker reflecting the degree of cardiac dysfunction.

Endothelin and Nitric Oxide

Circulating levels of endothelin are increased in congestive heart failure, and correlate positively with the degree of myocardial dysfunction. Studies in which endothelin antagonists have been administered suggest this substance may play a role in the pathophysiology of cardiac failure.[130,172] In a randomized, double-blind study of human subjects with heart failure, infusion of an ETa and ETb receptor blocker (bosentan) was associated with a reduction in right atrial pressure, pulmonary artery pressure, pulmonary capillary wedge pressure, and mean arterial pressure.[93] In a dog model of heart failure,[204] ETa blockade alone lead to a reduction in cardiac filling pressures and increased cardiac output. These hemodynamic changes were associated with an increase in GFR and renal plasma flow, as well as increased urinary sodium excretion. By contrast, administration of an ETb receptor blocker caused an increase in cardiac filling pressures and a decrease in cardiac output, suggesting endogenous endothelins adversely effect cardiac hemodynamics and cause fluid retention, primarily through ETa receptors.

Nitric oxide production is increased in congestive heart failure.[210] Increased release of nitric oxide from resistance vessels may partly antagonize neurohumoral vasoconstrictor forces. Inhibiting nitric oxide production in heart failure patients causes a significant increase in pulmonary and systemic vascular resistance, as well as a decline in cardiac output. In the renal vasculature, nitric oxide production is also increased; however, the renal vasodilatory response to nitric oxide is impaired.[2] Administration of an angiotensin receptor antagonist restores nitric oxide-mediated renal vasodilation, suggesting angiotensin II plays a contributory role in this defect.[1]

CIRRHOSIS

Renal sodium excretion is normally regulated so that extracellular fluid (ECF) volume is maintained within normal limits. Any maneuver that increases ECF volume will lead to a prompt and sustained natriuresis until the volume returns to normal. In patients with cirrhosis, this homeostatic mechanism becomes deranged such that large increases in ECF volume are accompanied by continued renal salt retention, resulting in edema and ascites formation.

Presinusoidal Versus Postsinusoidal Obstruction and Ascites Formation

In patients with cirrhosis, the kidneys are normal but are signaled to retain salt in an unrelenting manner. The critical event in the generation of this signal is development of hepatic venous outflow obstruction. In the normal state, the portal circulation is characterized by high flow, low pressure, and low resistance. The imposition of a resistance into this high-flow vasculature will uniformly raise portal pressure, but development of ascites is critically dependent on location of the resistance. Conditions associated with presinusoidal vascular obstruction, such as portal vein thrombosis and schistosomiasis, raise portal pressure but are not generally associated with ascites. By contrast, hepatic diseases such as Laennec's cirrhosis and Budd Chiari syndrome cause early postsinusoidal vascular obstruction, and are associated with marked degrees of salt retention, anasarca, and ascites. Thus, during the development of the cirrhotic process, ascites will accumulate primarily when the pathologic process is associated with hepatic venous outflow obstruction and sinusoidal hypertension.

This distinction between presinusoidal and postsinusoidal obstruction can best be explained by comparing the characteristics of fluid exchange in capillaries of the splanchnic bed versus those in the hepatic sinusoids. The intestinal capillaries are similar to those in the peripheral tissues, in that they have continuous

membranes with small pores such that a barrier exists, preventing plasma proteins from moving into the interstitial space. An increase in capillary hydrostatic pressure will cause the movement of a protein-poor fluid to enter the interstitial compartment and decrease the interstitial protein concentration. Interstitial protein concentration is further reduced by an acceleration in lymph flow that is stimulated by the fluid movement. As a result, the interstitial oncotic pressure falls, and the plasma oncotic pressure remains unchanged. The net oncotic force therefore rises and offsets the increase in hydrostatic force, providing a buffer against excessive fluid filtration. The fall in intestinal lymph protein concentration is maximal at relatively low pressures, and is much greater than that observed from the cirrhotic liver.[8,213] Thus, the increase in net oncotic force associated with dilution of the interstitial protein and accelerated lymph flow contribute to the protection against ascites in patients whose only abnormality is portal hypertension.

The situation across the liver sinusoids is quite different. Hepatic sinusoids, unlike capillaries elsewhere in the body, are extremely permeable to protein. As a result, colloid osmotic pressure exerts little influence on movement of fluid. Rather, direction of fluid movement is determined almost entirely by changes in sinusoidal hydraulic pressure. Thus, efflux of protein-rich filtrate into the space of Disse is critically dependent on hepatic venous pressures. Obstruction to hepatic venous outflow will lead to large increments in the formation of hepatic lymph and flow through the thoracic duct. Unlike the intestinal capillaries, there is little or no restriction in the movement of protein into the interstitium, such that the protein concentration of hepatic lymph will quickly approach that of plasma.[64] As a result, no significant oncotic gradient develops between plasma and the interstitium at high sinusoidal pressures and flow.

When sinusoidal pressure increases to such a degree that hepatic lymph formation exceeds the capacity of the thoracic duct to return fluid to the circulation, interstitial fluid weeps off the liver into the peritoneal space and forms ascites. Lymph formation in the setting of cirrhosis can be more than 20-fold greater than that which occurs under normal circumstances.[213] Whereas in normal humans 1−1.5 liters/day of lymph are returned to the circulation, subjects with cirrhosis, even without ascites, may have lymph flow through the thoracic duct as high as 15−20 liters/day.[212] The predominance of hepatically-produced lymph to overall lymph production is illustrated by studies in experimental animals with cirrhosis. Barrowman and Granger[8] found a 29-fold increase in hepatic lymph flow, while only a three-fold increase was noted in the splanchnic lymphatics. Eleven of 19 animals had normal flows of intestinal lymph, while all the cirrhotic animals had increased flows in liver lymph.

Conditions associated with the rapid onset of postsinusoidal obstruction, such as acute right-sided congestive heart failure and Budd−Chiari syndrome, initially give rise to ascitic fluid that has a high protein concentration that may even approach that of plasma. This high protein concentration is reflective of the liver being the predominant source of the ascitic fluid. However, over time the protein content of ascites in these conditions begins to decrease. Witte et al.[214] measured the total protein in ascitic, pleural, and peripheral edema fluid in acute and chronic heart failure patients. In the setting of acute heart failure, the mean concentration of protein in ascitic fluid was approximately 5 g/dl. By contrast, the protein concentration in ascitic fluid of chronic congestive heart failure patients was 2.7 g/dl. A lower protein concentration is also typical of conditions such as Laennec's cirrhosis, in which postsinusoidal obstruction develops slowly.

Two phenomena contribute to this change in ascitic fluid protein concentration. If the hepatic sinusoids are subject to an increased hydrostatic pressure for a long period of time, they begin to assume the anatomic and functional characteristics of capillaries found elsewhere in the body, a process referred to as capillarization.[181] This change leads to a decrease in albumin permeability, such that oncotic forces begin to play some role in hepatic lymph formation. At the same time, hypoalbuminemia develops secondary to decreased hepatic synthesis, as well as dilution secondary to ECF volume expansion. As a result, the protein content of hepatic lymph, although still high, falls to approximately 50−55% of plasma values.[213]

The second factor contributing to the lower ascitic protein concentration is the superimposition of portal hypertension. Early in the development of portal hypertension when plasma protein concentration is normal only minimal amounts of ascitic fluid are derived from the splanchnic bed, due to the buffering effect of increased net oncotic force opposing fluid filtration. Extremely high hydrostatic pressures are required to produce significant amounts of ascitic fluid in the setting of normal plasma protein concentrations. By contrast, less and less hydrostatic pressure is required for the formation of ascitic fluid, as the plasma albumin concentration decreases and the net osmotic force declines. In this setting, the splanchnic bed begins to make a greater contribution to the generation of ascites, and the fluid is characterized by a low protein concentration.[9]

The development of portal hypertension is also associated with changes in the splanchnic circulation that secondarily lead to increased lymph production in the splanchnic bed. The importance of the splanchnic

lymphatic pool in the generation of ascites is reflected by the fact that in most instances ascitic fluid is transudative and characterized by a protein concentration of approximately 2.5 g/dl. Classically, portal hypertension was considered to be the sole result of increased resistance to portal venous flow. However, studies in experimental models suggest that increased portal venous flow resulting from generalized splanchnic arteriolar vasodilation also plays a role in the genesis of increased portal pressure.[19,203] This vasodilation leads to changes in the splanchnic microcirculation that may predispose to increased filtration of fluid. For example, an acute elevation of venous pressure in the intestine normally elicits a myogenic response that leads to a reduction in blood flow. This decrease in flow is thought to serve a protective role against the development of bowel edema. However, in chronic portal hypertension this myogenic response is no longer present. In this setting, arteriolar resistance is reduced, such that capillary pressure and filtration are increased.[12,174] The loss of this autoregulatory mechanism may account for the greater increase in intestinal capillary pressure and lymph flow seen under conditions of chronic portal hypertension when compared to acute increases in portal pressure of the same magnitude.[102] The potential causes of splanchnic arteriolar vasodilation are discussed below.

The importance of portal hypertension in the pathogenesis of ascites is highlighted by several observations. First, patients with ascites have significantly higher portal pressures as compared to those without ascites.[143] Although the threshold for ascites development is not clearly defined, it is unusual for ascites to develop with a pressure below 12 mmHg. Gines found that only 4 of 99 cirrhotic patients with ascites had a portal pressure <12 mmHg, as estimated by hepatic venous wedged pressure.[63] Second, portal pressure correlates inversely with urinary sodium excretion.[143] Third, maneuvers designed to reduce portal pressure are known to have a favorable effect on the development of ascites. For example, surgical portosystemic shunts used in the treatment of variceal bleeding reduce portal pressure, and are associated with a lower probability of developing ascites during follow-up.[29] Both side-to-side and end-to-side portocaval anastomosis have been shown effective in the management of refractory ascites in cirrhosis. Recent studies also suggest that reducing portal pressure with a transjugular intrahepatic portasystemic shunt has a beneficial effect on ascites.[148]

In summary, ascites develops when the production of lymph from either or both the hepatic sinusoids and the splanchnic circulation exceeds the transport capacity of the lymphatics. In this setting, fluid will begin to weep from the surface of the liver and the splanchnic capillary bed, and accumulate as ascites. The final protein concentration measured in the peritoneal fluid is determined by the sum of the two contributing pools of fluid; one relatively high in protein originating in the liver and the other, a low protein filtered across splanchnic capillaries. Hepatic venous outflow obstruction leading to increased sinusoidal pressure and portal hypertension are the major determinants of whether lymph production will be of a magnitude sufficient for ascitic fluid to accumulate. Increased sinusoidal pressure is also related to the subsequent development of renal salt retention. The mechanism by which sinusoidal hypertension signals the kidney to retain sodium is discussed in the following section.

Afferent Limb of Sodium Retention: Overfill Versus Underfill Mechanisms

Classical Underfill Mechanism for Renal Salt Retention

The mechanism by which hepatic venous outflow obstruction leads to sufficiently high sinusoidal pressures for ascites formation is controversial. The classical (underfill) theory predicts that the degree of hepatic venous outflow obstruction is sufficient in the presence of normal splanchnic perfusion to perturb the balance between rates of hepatic lymph formation and thoracic duct flow, thereby resulting in the formation of ascites. Both increased sinusoidal and portal venous pressures, in conjunction with hypoalbuminemia, cause formation of ascites in the presence of normal splanchnic perfusion. The formation of ascites, however, occurs at the expense of decreased intravascular volume. In consequence, a low venous filling pressure and a low cardiac output activate baroreceptor mechanisms, resulting in renal salt retention. According to this formulation, development of ascites is the primary event that leads to an underfilled circulation and subsequent renal salt retention.

The failure of measured hemodynamic parameters to satisfy predictions of the classical theory has raised questions regarding its validity. As originally conceived, it was predicted that extrasplanchnic plasma volume would be decreased, and that cardiac output would be low. When measured, however, these values have rarely been low. In fact, measurements have indicated that total plasma volume is usually elevated in cirrhotic patients. Similarly, cardiac output is rarely low, but tends to vary from normal to very high. In addition, studies performed in animal models of cirrhosis have found that sodium retention precedes the formation of ascites, suggesting that salt retention is a cause and not a consequence of ascites formation.

Overfill Mechanism for Renal Salt Retention

The incompatibility of measured hemodynamic parameters and timing of renal salt retention with the classical theory of ascites has led others to propose the overflow theory.[118] Once again, hepatic disease with venous outflow obstruction is viewed as a prerequisite for development of increased sinusoidal and portal pressures. In contrast to the classical theory, however, normal splanchnic perfusion fails to raise sinusoidal pressure sufficiently to cause ascites formation. Rather, venous outflow obstruction signals renal sodium retention independent of diminished intravascular volume. Salt retention, in turn, increases plasma volume, cardiac output, and splanchnic perfusion, thus raising sinusoidal and portal pressures sufficiently to culminate in translocation of fluid into the interstitial space and eventually the peritoneum. The combination of portal hypertension and increased arterial volume would lead to overflow ascites formation. This hypothesis is supported by the positive correlation between plasma volume and hepatic venous pressure, and the persistence of increased plasma volume after portacaval anastomosis. Moreover, patients with ascites have significantly higher portal pressure than patients without ascites, and portal pressure correlates inversely with urinary sodium excretion.[63]

Additional evidence linking hepatic venous outflow obstruction directly to renal sodium retention comes from studies performed in dogs fed the potent hepatotoxin dimethylnitrosamine.[115–117] The pathophysiologic disturbances and histologic changes that develop over a 6–8-week period are similar in nature to those seen in Laennec's cirrhosis. In this model, sodium retention and increases in plasma volume precede formation of ascites by about 10 days.[115] In order to exclude the possibility that the increase in plasma volume was solely due to an increased splanchnic plasma volume, repeat measurements were obtained after ligation of the superior and inferior mesenteric arteries, the celiac axis, and portal vein. In this way, any contribution of the splanchnic circulation could be excluded. These studies clearly showed that extrasplanchnic plasma volume was elevated at a time when dogs were in positive sodium balance. To further prove that extrasplanchnic plasma volume was increased, end-to-side portacaval shunts were placed prior to inducing cirrhosis.[117] This maneuver was designed to prevent any increase in splanchnic plasma volume. In these studies, evidence of salt retention preceded the formation of ascites, and was accompanied by a parallel increase in plasma volume.

In another series of studies using this same model, hemodynamic parameters were monitored during control, precirrhotic, and postcirrhotic sodium balance periods.[116] Sodium retention was found to precede any detectable change in cardiac output or peripheral vascular resistance. Once ascites developed, plasma volume increased further, and this was associated with increased cardiac output and a fall in peripheral vascular resistance. It was concluded that initiation of sodium retention and plasma volume expansion was not dependent on alterations in systemic hemodynamics. This conclusion has been corroborated in the canine model of hepatic cirrhosis induced by bile duct ligation,[197] as well as in rats made cirrhotic with carbon tetrachloride inhalation and oral phenobarbital.[123]

The pathway by which primary renal sodium retention would be linked to venous outflow obstruction in the overfill theory is not clear. Convincing evidence does exist for the presence of an intrahepatic sensory network composed of osmoreceptors, ionic receptors, and baroreceptors. Studies in which hepatic venous pressure is raised have demonstrated increases in hepatic afferent nerve activity.[113,114,197] Furthermore, a neural reflex pathway linking hepatic venous congestion and augmented sympathetic nerve activity has been identified.[104] In addition, acute constriction of the portal vein in dogs results in renal sodium and water retention in the innervated unilateral kidney, while these effects are abolished in the contralateral denervated kidney.[2] In addition to a neural mechanism, there may also be a hormonal system by which the liver and kidney can communicate. Hepatically-produced cAMP has been proposed to be a component of such a system.[6] Circulating cAMP is known to inhibit proximal salt and water absorption, as well as to contribute to the regulation of glomerular filtration rate. According to this hypothesis, decreased circulating cAMP levels as a result of liver disease could secondarily lead to renal salt retention and impaired renal function.

In summary, the overfill hypothesis is supported by a number of observations that indicate sodium retention precedes development of ascites in the absence of hemodynamic factors known to lead to salt retention. Moreover, high cardiac output coupled with increased plasma volume argues strongly for increased arterial blood volume, a finding seemingly incompatible with the underfill theory. Against such an analysis, however, is that mechanisms that sense arterial volume physiologically may be more sensitive than methods used to measure it. It should be noted that while statistically insignificant, there was a fall in blood pressure at the time of positive sodium balance in the dimethylnitrosamine model. This decrease may have been of sufficient magnitude to signal renal salt retention.[116] Since cardiac output was unchanged, total peripheral resistance may have decreased. Similarly, patients with hepatic cirrhosis and ascites behave as if they are effectively volume-depleted. Despite an increase in cardiac

output and plasma volume, arterial pressure is typically low. This fall in systemic blood pressure is consistent with an underfilled arterial vascular compartment. Thus, the distinction between classical and overflow theories better rests on the measurement of effective arterial blood volume (EABV).

Use of EABV to Distinguish Underfill and Overfill Mechanisms of Renal Salt Retention

The classical (underfill) theory predicts that EABV is low in patients with ascites, and is the afferent mechanism signaling renal salt retention. The overflow theory predicts that EABV is expanded due to primary salt retention. While EABV cannot be measured directly, assessing the level of activation of neurohumoral effectors known to be regulated by EABV can be considered a measure of it. In this regard, levels of renin, aldosterone, ADH, and norepinephrine can serve as markers reflective of the magnitude of the EABV.

When renin and aldosterone values have been measured in patients with cirrhosis, values have varied from low to high. It is important, however, to consider these levels in the context of whether ascites is present or not. In the absence of ascites, subjects are in sodium balance, and renin and aldosterone levels are normal.[171] In the presence of ascites, mean renin and aldosterone levels are elevated, but individual values are often still normal.[4,63] This observation seems in conflict with the classical theory, as all patients with ascites who are in positive sodium balance should have decreased EABV and high aldosterone levels. However, not all patients with ascites are retaining sodium. In fact, some patients are in balance such that sodium intake equals output. Thus, in examining the mechanism of sodium retention in cirrhosis with ascites, neurohumoral effectors such as renin, aldosterone, ADH, and sympathetic nerve activity should be considered with respect to the rate of sodium excretion. When examined in this fashion, a significant inverse relationship is found between urinary sodium excretion and neurohumoral markers, suggesting the presence of a contracted EABV.

One component of the circulation that appears to be contributing to the overall decrease in EABV is the central circulation. Indirect measurements demonstrate that central blood volume is reduced, while noncentral blood volume is expanded.[140] In fact, the size of central and arterial blood volume is inversely correlated with sympathetic nervous system activity, suggesting that unloading of central arterial baroreceptors is responsible for enhanced sympathetic activity. This conclusion is supported by studies using the technique of head-out water immersion (HWI).[49,50] In this technique, subjects are seated and immersed in a water bath up to their necks. This technique results in redistribution of ECF volume from the interstitial space into the vasculature, with a sustained increase in central blood volume. The central volume expansion is comparable to that induced by infusion of 2 liters of isotonic saline.[50] Such a maneuver would be expected to raise both the EABV and the hepatic sinusoidal pressure. The classical theory would predict that HWI would lead to decreases in renin, aldosterone, ADH, and norepinephrine concentrations in response to expansion of EABV. Since renin levels correlate with wedged hepatic vein pressures, the overfill theory would predict further rises in renin and other hormonal systems consequent to initiation of a sinusoidal pressure-sensitive hepatorenal reflex. When HWI was performed in a heterogeneous group of patients with cirrhosis, the natriuretic response was variable, but suppression of renin and aldosterone levels was uniform.[52] In a more homogenous group of patients characterized by impaired ability to excrete water and sodium, HWI was shown consistently to suppress plasma AVP, renin, aldosterone, and norepinephrine, as well as to increase sodium and water excretion.[17,146]

Taken together, the multiplicity of data support the presence of decreased EABV in patients with decompensated cirrhosis, and is most consistent with an underfill mechanism of renal salt retention (Figure 38.7). Since blockade of endogenous vasoconstrictor systems in patients with cirrhosis and ascites leads to marked arterial hypotension, activation of these systems function to contribute to the maintenance of arterial pressure. At least one component of the decrease in EABV may be due to an underfilled central circulation. As discussed in the following paragraphs, increased perfusion of arteriovenous communications, systemic vasodilation, and increased perfusion of the splanchnic bed are important factors in the genesis of an underfilled circulation. In addition, these factors play a major role in the hyperdynamic circulation that is typical of patients with chronic liver disease.

Hyperdynamic Circulation in Cirrhosis

Arteriovenous Communications

The characteristic circulatory changes observed in animal, as well as clinical, studies of cirrhosis consist of increased cardiac output, low mean arterial pressures, and low peripheral vascular resistance. The most attractive explanation for a contracted EABV in the setting of such a hyperdynamic circulation assigns a pivotal role to increased vascular capacitance.[92] An increased vascular holding capacity out of proportion to plasma volume results in an underfilled circulation and decreased EABV. One factor that may account for increased vascular capacitance and a hyperdynamic

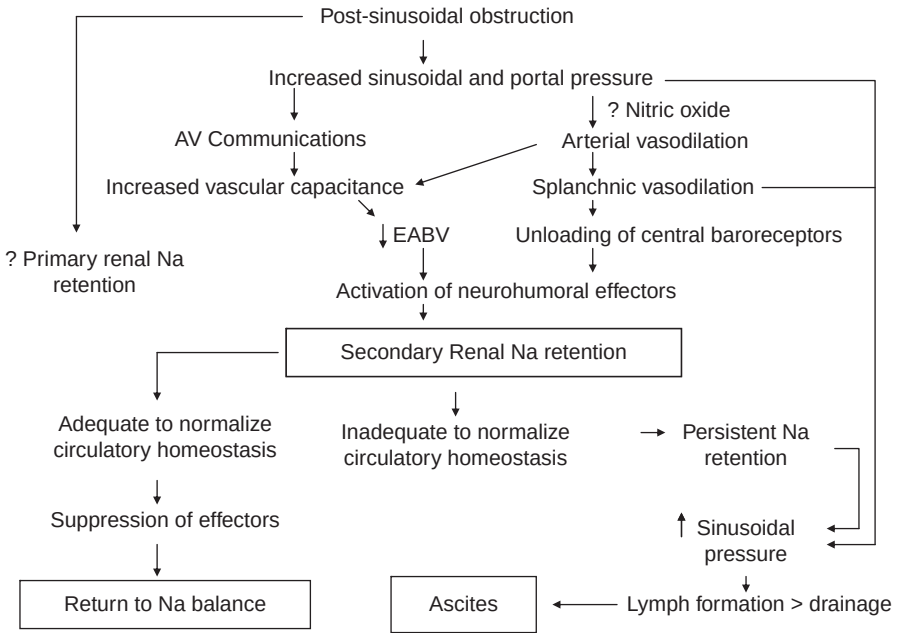

FIGURE 38.7 **Unified theory of ascites formation: a modified underfill mechanism.**

circulation is the formation of widespread arteriovenous communications.[15] In cirrhotics, arteriovenous fistula formation has been identified in the pulmonary, mesenteric, and upper and lower extremity circulations. In addition, increased blood flow has been measured in muscle and skin of the upper extremity not attributable to increased oxygen consumption, anemia or thiamine deficiency.[97] Postmortem injection demonstrated intense proliferation of small arteries in the splenic vasculature of patients with cirrhosis.[129]

The hemodynamic changes and salt retention that occur with an arteriovenous fistula are reminiscent of what occurs in cirrhotic humans.[48] With an open fistula, peripheral vascular resistance falls, cardiac output increases, and diastolic and mean blood pressures fall. The proportionately greater increase in vascular capacitance over cardiac output results in a contracted EABV. Consequent sodium retention expands ECF volume, raises venous filling pressure, and further increases cardiac output until balance is achieved between cardiac output and lowered peripheral resistance. At this point, sodium intake equals excretion, EABV is normalized, and the patient is in balance.

In cirrhosis, a similar imbalance occurs between plasma volume and vascular capacitance, such that EABV remains contracted and renal sodium retention is stimulated. In contrast to a simple arteriovenous fistula, however, several factors are present in cirrhosis that make sodium balance more difficult to achieve. First, these patients often have impaired cardiovascular function.[15] Diminished venous return consequent to tense ascites or cardiomyopathy from alcohol or malnutrition may limit increases in cardiac output. Furthermore, depression of left ventricular function in response to increased afterload suggests subclinical cardiac disease, despite elevated forward output.[120] Second, retained sodium does not remain in the vascular space and lead to increased venous return. Rather, retained sodium becomes sequestered within the abdomen as ascites. Third, increased vascular permeability may further impair the ability of retained sodium to expand EABV. Peripheral arterial vasodilation in cirrhotic rats is associated with increased vasopermeability to albumin, electrolytes, and water.[25] Examination of interstitial fluid dynamics by means of a subcutaneous plastic capsule reveals substantial increases in interstitial fluid volume early in cirrhosis before the appearance of ascites or peripheral edema.[179] Such capillary leakage impedes filling of the intravascular compartment and prevents replenishment of a contracted EABV.

Primary Arterial Vasodilation

Arteriovenous fistulas and formation or hyperdynamic perfusion of pre-existing capillary beds are changes that develop as cirrhosis progresses. Nevertheless, salt retention occurs early in the cirrhotic process before these anatomic changes are fully-established. Since sodium retention antedates the formation of overt ascites and portosystemic shunting, peripheral arterial vasodilation has been proposed to be a primary event in the initiation of sodium and water retention in cirrhosis.[185] In this manner, a decreased EABV and increased vascular capacitance could still be the signal for renal salt retention, even in the earliest stages of liver injury. The peripheral arterial vasodilation

hypothesis is supported by several studies in animal models.[209] In rats with partial ligation of the portal vein, evidence of a reduced systemic vascular resistance precedes the onset of renal salt retention. In addition, a direct correlation has been found between the onset of decreased arterial pressure and renal sodium retention in spontaneously hypertensive rats with experimental cirrhosis.[123] As opposed to the classical underfilling theory, the arterial vascular underfilling would not be the result of a reduction in plasma volume, which in fact is increased, but rather to a disproportionate enlargement of the arterial tree secondary to arterial vasodilation. In the rat with carbon tetrachloride-induced cirrhosis, the fall in peripheral vascular resistance and hyperdynamic circulatory state precede ascites formation, suggesting that generalized vasodilation is indeed an early finding with hepatic injury.[56]

Perhaps the best evidence to date in support of an underfilled circulation due to arterial vasodilation comes from human studies of HWI accompanied by infusion of a vasoconstrictor. HWI is associated with increased perfusion of the central circulation, however, urinary excretion rates of salt and water improve, but do not normalize with this procedure alone.[17] Since systemic vascular resistance falls during HWI, it was proposed that further vasodilation may prevent complete restoration of EABV in subjects already peripherally vasodilated. Infusion of a vasoconstrictor will increase peripheral vascular resistance, but will do little to improve an underfilled central circulation. Predictably, infusion of norepinephrine alone into cirrhotic subjects fails to significantly increase urinary sodium excretion.[188] By contrast, when norepinephrine is infused during HWI so as to increase central perfusion and at the same time attenuate the fall in systemic vascular resistance, sodium excretion increases significantly. In six subjects with decompensated cirrhosis, this combined maneuver was found to increase urinary sodium excretion to an amount that when extrapolated over a 24-hour period was greater than sodium intake.[188] These results are consistent with the hypothesis that arterial vasodilation causes an abnormal distribution of the total blood volume, such that effective central blood volume is reduced.

SPLANCHNIC ARTERIAL VASODILATION

As alluded to earlier, arterial vasodilation is particularly marked in the splanchnic arteriolar bed.[80,180,203] Increasing degrees of splanchnic vasodilation contribute to the fall in mean arterial pressure and unloading of baroreceptors in the central circulation.[32,135] As a result, central afferent sensors signal the activation of neurohumoral effectors, which in turn decrease perfusion of other organs, but in particular in the kidney. The importance of splanchnic vasodilation in the genesis of renal ischemia has been indirectly illustrated by the response to ornipressin, an analog of AVP that is a preferential splanchnic vasoconstrictor.[67,110] The administration of ornipressin to patients with advanced cirrhosis leads to correction of many of the systemic and renal hemodynamic abnormalities that are present. These include an elevation in mean arterial pressure, reductions in plasma renin activity and norepinephrine concentration, and increases in renal blood flow, glomerular filtration rate, and urinary sodium excretion and volume. Similar benefits have been reported with the combined use of octreotide and midodrine.[85]

ROLE OF NITRIC OXIDE IN ARTERIAL VASODILATION

The underlying cause of arterial vasodilation, particularly in the early stages of cirrhosis, has not been fully-elucidated, but a great deal of attention has been focused on humoral factors.[79] There is an increasing body of experimental and preliminary human evidence suggesting that increased nitric oxide production may be an important factor in this process. In both experimental models and in human subjects with cirrhosis, increased production of nitric oxide can be demonstrated.[176,192,207] In the cirrhotic rat, evidence of increased production is already present when the animals begin to retain sodium, and antedates the appearance of ascites.[11] Administration of nitric oxide synthase inhibitor L-NMMA to cirrhotic human subjects improves the vasoconstrictor response to noradrenaline, suggesting that overproduction of nitric oxide is an important mediator of the impaired responsiveness of the vasculature to circulating vasoconstrictors.[24] In addition, this same inhibitor administered in low doses has been shown to correct the hyperdynamic circulation in cirrhotic rats.[147] In a more recent study utilizing this same model, normalization of nitric oxide production was associated with a marked natriuretic and diuretic response, as well as a reduction in the degree of ascites in cirrhotic rats.[132]

The precise mechanism for increased nitric oxide production in cirrhosis is not known, but may be mediated at least in part via the release of tumor necrosis factor-alpha.[121] In experimental models of hepatic disease, for example, the administration of anti-TNF-alpha antibodies or an inhibitor of nitric oxide synthesis results in increases in splanchnic and total vascular resistance, an elevation in the mean arterial pressure, and a reduction in cardiac output toward or, with nitric oxide inhibition, to normal.[121,147] Similarly, blocking the signaling events induced by TNF and nitric oxide production, via inhibition of protein tyrosine kinase, ameliorates the hyperdynamic abnormalities in rats with cirrhosis and portal hypertension.[122] Studies in

cirrhotic humans with an increased cardiac output and systemic vasodilatation have shown evidence of enhanced nitric oxide production, a finding compatible with the experimental observations. Portosystemic shunts and decreased reticuloendothelial cell function may allow intestinal bacteria and endotoxin to enter the systemic circulation, providing a potential stimulus for tumor necrosis factor-alpha and/or nitric oxide production.

It is not yet known with certainty whether the endothelial (eNOS) or the inducible (iNOS) isoform is primarily responsible for increased production of nitric oxide. The hyperdynamic circulatory state of cirrhosis may impose a shear stress on the vascular endothelium, thus providing a stimulus for the upregulation of eNOS.[134,207] On the other hand, increased activity of nitric oxide synthase in polymorphonuclear cells and monocytes (cells that primarily contain iNOS) in cirrhotic human subjects suggest the inducible isoform may also play a role in increased production.[134]

In summary, an underfill mechanism appears to explain the bulk of experimental, as well as clinical, findings in established cirrhosis (Figure 38.7). Less certain are mechanisms responsible for sodium retention that precede the development of ascites. The overfill theory invokes the presence of a hepatorenal reflex sensitive to subtle rises in intrahepatic pressure mediating initiation of renal salt retention. However, the finding of decreased peripheral vascular resistance, even at this early stage, suggests diminished arterial filling.[116] Early peripheral arterial vasodilation and later formation of anatomic shunts lead to disproportionate increases in vascular capacitance with subsequent contraction of EABV, thereby signaling renal salt retention.[59,103,141] While it is conceivable that both overfill mechanisms and underfill mechanisms may be operative at different stages of disease, the multiplicity of data both clinical and experimental can be assimilated into an underfill theory.

Concept of Balance in Cirrhosis

In the earliest stages of cirrhosis when arterial vasodilation is moderate and the lymphatic system is able to return increased lymph production to the systemic circulation, renal sodium and water retention are sufficient to restore EABV and thereby suppress neurohumoral effectors. Balance is re-established such that sodium intake equals sodium excretion, but at the expense of an increased ECF volume. As liver disease progresses, this sequence of arterial underfilling followed by renal salt retention is repeated. As long as the EABV can be restored to near normal levels the activation of effector mechanisms will be moderated, and balance will be achieved albeit at ever-increasing levels of ECF volume (Figure 38.8). Eventually, lymph production will begin to exceed the drainage capacity of the lymphatic system. At this stage of the disease renal salt retention becomes less efficient at restoring EABV, as retained fluid is sequestered in the peritoneal cavity as ascites. At the same time arterial underfilling is more pronounced, particularly as splanchnic arteriolar vasodilation becomes more prominent. Activation of neurohumoral effectors is magnified, resulting in more intense renal salt retention. Even at this stage of the disease cirrhotic patients with ascites eventually re-establish salt balance. The terminal stages of the cirrhotic process are characterized by extreme arterial underfilling. At this time there is intense and sustained activation of neurohumoral effectors. As a result, renal salt retention is nearly complete as the urine becomes virtually devoid of sodium. The vasoconstrictor input focused in on the kidney is of such a degree that renal failure begins to develop.

Effector Mechanisms in Cirrhosis

Nephron Sites of Renal Sodium Retention

Salt retention and impaired free water clearance are characteristic disturbances in renal function in cirrhotic patients. Evidence is available to support an important role for proximal and distal nephron segments in mediating enhanced sodium reabsorption.

PROXIMAL NEPHRON

Indirect evidence supporting enhanced proximal salt reabsorption comes from studies in human cirrhotic subjects in which infusion of mannitol or saline improves free water clearance.[27,182] Increased proximal

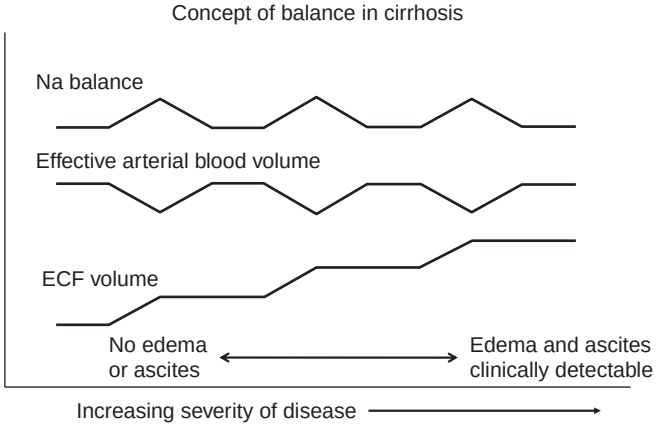

FIGURE 38.8 **As liver disease progressively worsens, salt balance is continually re-established as total extracellular fluid (ECF) volume increases.** Early in the disease process the increase in ECF volume is not clinically detectable. With more severe disease, peripheral edema and ascites are readily apparent.

tubular salt reabsorption leads to decreased delivery of filtrate to the distal diluting segments, thereby impairing free water formation. Presumably, by restoring distal delivery of filtrate, mannitol and saline infusions result in increased solute free water formation. Similar increases in free water clearance occur when central hypervolemia is induced by HWI. The increase in urine sodium is accompanied by increased K excretion, suggesting enhanced distal delivery of sodium. Increased water excretion seen in response to HWI, combined with simultaneous infusion of norepinephrine, is also consistent with baseline enhanced proximal sodium reabsorption in decompensated cirrhotics.[188]

Experimental models of cirrhosis have provided more direct assessment of nephron function. Micropuncture studies in rats made cirrhotic by ligation of the common bile duct demonstrated increases in both the proximal tubule solute reabsorption and filtration fraction.[5] Enhanced proximal reabsorption was attributed to increased peritubular oncotic pressure. In a dog model of cirrhosis,[136] intrarenal administration of the vasodilator acetylcholine was found to ameliorate the blunted natriuretic response to saline infusion. In this model, sodium reabsorption was enhanced in both the proximal and the diluting segments of the nephron.[16]

DISTAL NEPHRON

Clinical and experimental evidence also supports an important role for distal nephron sodium retention in cirrhosis. In cirrhotic patients manifesting a sluggish natriuretic response to HWI, phosphate clearance was found similar to a group who demonstrated an appropriate increase in urinary sodium excretion.[53] Since phosphate clearance was used as a marker of proximal sodium reabsorption, it was concluded that distal sodium reabsorption contributed importantly to renal sodium retention in patients with a sluggish natriuretic response. The results of a prospective, double-blind study comparing the diuretic response of furosemide to spironolactone in cirrhotic patients with ascites suggest that salt absorption in the cortical collecting tubule is enhanced.[161] When administered furosemide, only 11 of 21 patients exhibited a diuresis, while 18 of 19 patients responded to spironolactone. Furthermore, 10 patients who failed to respond to furosemide demonstrated a diuretic response to spironolactone. Furosemide inhibits sodium reabsorption in the loop of Henle, thereby increasing delivery to the collecting duct. All patients treated with furosemide had increases in the rate of potassium excretion, including the 11 patients who failed to increase urinary sodium excretion. These results, combined with the clinical effectiveness of spironolactone in treatment of cirrhotic ascites, suggest enhanced salt absorption in the aldosterone-sensitive cortical collecting tubule.[7]

In summary, clinical and experimental studies suggest an important role for proximal, as well as distal, nephron sites mediating renal salt retention in cirrhosis. The relative contribution of different nephron sites to impaired salt and water excretion may depend on the degree to which systemic hemodynamics are altered. With each stage of advancing liver disease there becomes a greater contraction of the EABV. In the earliest stages of liver disease, enhanced proximal reabsorption limits distal delivery of solute in a manner analogous to a nonedematous subject with intravascular volume depletion. If distal delivery can be normalized at this early stage, distal nephron sites may continue to reabsorb sodium avidly, and therefore appear as the primary site responsible for ECF volume expansion. With severe reductions in EABV, presumably the proximal nephron becomes the dominant site of fluid reabsorption, such that the contribution of the distal nephron becomes much less apparent.

Sympathetic Nervous System

The sympathetic nervous system has been shown to contribute importantly to abnormalities in body fluid homeostasis in cirrhosis. Studies in rats made cirrhotic by ligating the common bile duct suggest that increased renal nerve activity is a major factor in the progressive salt retention that occurs in these animals.[35,37] In this model, baseline renal nerve activity is increased, and fails to decrease appropriately in response to intravenous saline. Renal denervation significantly improves the impaired ability to excrete an oral or intravenous salt-load. In addition, renal denervation has been shown to normalize the attenuated diuretic and natriuretic response to the intravenous administration of ANP.[96] In chronic metabolic studies, renal denervation also leads to a significant improvement in the positive cumulative sodium balance. The cause of increased renal nerve activity is multifactorial. Impaired aortic and cardiopulmonary baroreceptor regulation, as well as[175] abnormalities in hepatic NaCl-sensitive receptors and their immediate intrahepatic afferent connections, have been implicated as a cause of heightened autonomic activity.

Studies in human cirrhotic subjects are more indirect, but also suggest an important role for the sympathetic nervous system. Levels of norepinephrine in patients with cirrhosis are high, and are inversely correlated with urinary sodium excretion.[18] In addition, direct measurement of peripheral nerve firing rates show evidence of increased central sympathetic activity. Patients characterized by impaired ability to excrete water loads have plasma levels of norepinephrine that

correlate positively with levels of ADH, aldosterone, and plasma renin activity.[18]

Decreased EABV leads to baroreceptor-mediated activation of sympathetic nerve activity, with subsequent enhancement of proximal salt reabsorption. The subsequent decrease in sodium delivery to the diluting segment, in addition to nonosmotic release of ADH, contributes to the inability to maximally excrete water-loads. Increased renal nerve activity also contributes to enhanced distal sodium reabsorption through activation of the renin–angiotensin–aldosterone system.

In addition to stimulating renal salt and water retention, activation of the sympathetic nervous system serves as a compensatory response to cirrhosis-induced vasodilation. Increased renal nerve activity contributes to increased renal vascular resistance, and is one of several factors responsible for the progressive decline in renal function which occurs as patients develop the hepatorenal syndrome.[38,51]

In summary, the sympathetic nervous system is activated under conditions of decompensated cirrhosis. Overactivity of this system is the result of a contracted EABV. In addition, there is impaired regulation of sympathetic outflow due to abnormalities in several afferent sensing mechanisms. Increased renal nerve activity contributes to the cumulative salt retention that accompanies advancing liver disease. In addition, activation of sympathetic outflow plays an important compensatory role in maintaining vascular tone in the setting of decreased vascular resistance.

Aldosterone

In patients with cirrhosis and ascites, plasma concentrations of aldosterone are frequently elevated. Although aldosterone metabolism is impaired in liver disease, secretion rates are greatly elevated, and are the major cause of elevated levels.[177] The relationship between hyperaldosteronism and sodium retention is not entirely clear. Several studies have provided evidence that argues against an important role of aldosterone in mediating salt retention in cirrhosis. For example, patients treated with an aldosterone synthesis inhibitor do not necessarily exhibit a natriuretic response.[177] In one study, renal salt excretion and changes in plasma renin and aldosterone levels were examined in 11 patients with ascites subjected to 5 days of high-salt intake. In patients with normal suppression of renin and aldosterone, salt retention and weight gain occurred to the same extent as patients who had persistent hypersecretion of renin and aldosterone.[28] In addition, cirrhotic patients in positive sodium balance, as compared to controls with matched sodium excretion, have increased fractional distal sodium reabsorption despite lower plasma aldosterone levels. In 16 cirrhotic patients subjected to HWI, plasma renin activity and plasma aldosterone levels were found to decrease promptly. Despite suppression of the hormones, however, half of the patients manifested a blunted or absent natriuretic response.[52] In another group of cirrhotic patients with ascites and edema, HWI induced a significant natriuresis despite acute administration of desoxycorticosterone, suggesting that enhanced sodium reabsorption can occur independently of increased mineralocorticoid activity.

By contrast, other studies suggest aldosterone is an important factor in the pathogenesis of sodium retention in patients with cirrhosis. For example, adrenalectomy or administration of a competitive inhibitor of aldosterone increases urinary sodium excretion.[45] Patients who fail to manifest a diuretic response to furosemide tend to have higher renin and aldosterone levels and lower urinary sodium concentrations prior to treatment.[16] Inability of furosemide to increase urinary sodium in these patients may result from reabsorption of delivered sodium in the collecting tubule under the influence of aldosterone. Similarly, patients with the highest renin and aldosterone levels are those who fail to diurese in response to HWI.[52,144,145]

As with the conflicting data regarding the role of the proximal and distal nephron in salt retention discussed previously, the degree to which systemic hemodynamics and EABV are impaired may explain some of the conflicting data noted above. It is possible that in patients with the greatest contraction of EABV, intense proximal sodium reabsorption limits distal delivery to such an extent that the contribution of aldosterone to increase salt absorption is difficult to detect. By contrast, with less impairment in EABV, distal delivery is better maintained, and the contribution of aldosterone to renal sodium retention is more obvious.

Alternatively, acquired inhibition of 11β-hydroxysteroid dehydrogenase type 2 may be of importance in the salt retention that occurs in some patients with cirrhosis of the liver. Bile acids which can accumulate in the setting of chronic liver disease have been shown to inhibit the activity of 11β-hydroxysteroid dehydrogenase type 2.[195] Such an effect would allow cortisol-mediated stimulation of the mineralocorticoid receptor, and potentially explain aldosterone-independent salt retention in the distal nephron in liver cirrhosis. Studies in the bile duct ligation and carbon tetrachloride models of chronic liver disease are consistent with a component of cortisol-mediated stimulation of the mineralocorticoid receptor.[195] In these models there is decreased activity of 11β-hydroxysteroid dehydrogenase type 2 that is temporally related to increased ENaC abundance in the apical membrane of the cortical collecting duct. These changes are most pronounced in the sodium-retaining stage of disease.

Prostaglandins

Prostaglandins function in a protective role in decompensated cirrhosis. Similar to other hypovolemic states, prostaglandins act to maintain renal blood flow and GFR by ameliorating pressor effects of angiotensin II and sympathetic nerves.[154] These agents counterbalance the salt retaining effects of these effectors and mitigate the impairment in free water clearance mediated by AVP. Administration of prostaglandin inhibitors can partially correct excessive hyperreninemia and hyperaldosteronism, and restore the pressor response to angiotensin II.

Kallikrein–Kinin System

Urinary kallikrein activity is increased in cirrhotic patients with ascites and preserved GFR, while urinary activity decreases in association with impaired renal function.[160] The correlation between renal plasma flow and GFR suggests that the renal kallikrein–kinin system may contribute to maintenance of renal hemodynamics in cirrhosis.

At the level of the renal tubule, bradykinin has been shown to exhibit a natriuretic effect. However, bradykinin also is a potent peripheral vasodilator, and can cause microvascular leakage. In cirrhosis, these later effects could exacerbate an already contracted EABV, and cause further salt retention. MacGilchrist et al.[127] studied the effects of kinin inhibition by systemically infusing aprotinin (a strong inhibitor of tissue kallikrein) into a group of patients with cirrhosis. This infusion was associated with a doubling of urinary sodium excretion, and an increase in renal plasma flow and GFR. This beneficial effect on renal function in the setting of kinin inhibition was attributed to an improvement in systemic hemodynamics as systemic vascular resistance increased. Similarly, administration of a bradykinin receptor antagonist to cirrhotic rats normalized renal sodium retention, and reduced the activity of the renin–angiotensin–aldosterone system.[211] Inhibiting bradykinin-induced microvascular leakage and lessening the degree of vascular underfilling was felt to be the mechanism of the beneficial effect.

Natriuretic Peptides

The role of ANP in the pathogenesis of edema in hepatic cirrhosis remains undefined. While atrial ANP content was reduced in cirrhotic rats, most data indicate ANP levels are either normal or elevated in cirrhotic humans.[81,190] Elevated levels are the result of increased cardiac release rather than just impaired clearance. The cause of the high levels is not understood, because atrial pressure is normal and central blood volume is reduced. Stimulating the endogenous release of ANP induces a natriuretic response in some patients with cirrhosis, while other patients are insensitive.[190] However, both groups of patients exhibited an increase in urinary cGMP, suggesting that the kidney is still capable of responding to ANP even in the absence of a natriuretic effect.[190]

Several potential mechanisms may account for ANP resistance in cirrhosis. This resistance could be the result of a defect intrinsic to the kidney or could be the result of altered systemic hemodynamics leading to activation of more potent sodium-retaining mechanisms.[128] With regards to the first possibility, an altered density of glomerular ANP-binding sites has been demonstrated in the bile duct-ligated rat model of cirrhosis.[62] In addition, ANP resistance was found in the isolated perfused kidney taken from sodium avid rats with cirrhosis induced by carbon tetrachloride.[157] In the chronic caval dog model of cirrhosis, intrarenal infusion of bradykinin restored ANP responsiveness to previously resistant animals, suggesting that an intrarenal deficiency of kinins could be a contributing factor.[108]

Other studies have focused on systemic hemodynamics as a cause of ANP resistance. With each stage of advancing liver disease there becomes a greater reduction in EABV. Since ANP resistance tends to occur with more severe and advanced disease, it is possible that ANP resistance is directly related to the impairment in EABV. Decreased EABV is associated with enhanced proximal reabsorption of solute. As a result, ANP resistance may be due to decreased delivery of salt to the site where ANP exerts its natriuretic effect. In support of this possibility, ANP resistance could be restored in cirrhotic rats by infusions of vasopressors so as to normalize arterial pressure, and presumably improve the decrease in EABV.[124] In human cirrhotics, ANP responsiveness can be markedly improved when distal sodium delivery is increased by administration of mannitol.[143]

Circulating brain natriuretic peptide (BNP) levels are also increased in patients with cirrhosis.[107] Infusion of BNP at a dose that elicits an increase in GFR, renal plasma flow, and urinary sodium excretion in normal controls has no effect in cirrhotic humans. The infusion is associated with an increase in urinary cGMP, as well as a fall in plasma aldosterone levels, suggesting that the peptide is capable of interacting with its receptor in these patients. As with ANP, the lack of natriuretic response to BNP may be due to overactivity of other antinatriuretic factors, as well as decreased delivery of sodium to its tubular site of action.

Adrenomedullin is a peptide with vasodilatory properties that is highly expressed in cardiovascular tissues. Increased circulating levels that correlate with severity of disease have been described in patients with cirrhosis.[57] Urodilatin is a natriuretic factor that is

exclusively synthesized within the kidney. Unlike other natriuretic factors, levels are not increased in patients with cirrhosis.[178]

Endothelin

Increased circulating levels of endothelin have been reported in cirrhosis.[142] The stimulus and pathophysiologic significance of these levels is not known with certainty. The peptide may play a role in the renal vasoconstriction seen in the hepatorenal syndrome.[63,142]

Therapeutic Implications for Treatment of Salt Retention in Cirrhosis

Renal salt retention is the most common abnormality of renal function in chronic liver disease. Whenever urinary sodium excretion falls to an amount less than dietary salt intake ECF volume will begin to expand and eventually lead to the development of ascites and peripheral edema. The approach to the treatment of the cirrhotic patient with ascites is to alter sodium balance in such a way that urinary sodium excretion exceeds dietary salt intake.

In the earliest stages of the disease, urinary sodium excretion is plentiful and negative salt balance can be achieved by simply lowering dietary sodium intake. As the disease advances, neurohumoral effectors become more activated, initially resulting in more intense renal salt retention and later in a progressive decline in renal function. Eventually, the filtered load of sodium becomes completely reabsorbed by the tubule, such that the final urine becomes virtually devoid of salt. If some component of the filtered load reaches the collecting duct or beyond spironolactone will be effective in increasing urinary sodium excretion. Once sodium reabsorption is complete proximal to the collecting duct then thiazides, and later loop diuretics, will have to be added to spironolactone in order to increase urinary sodium excretion. Eventually, the filtered load is completely reabsorbed proximal to the thick ascending loop of Henle. At this point the patient is resistant to the effects of diuretics, and requires more invasive procedures such as repetitive large-volume paracentesis in order to remain in salt balance. In the terminal stages of the disease, the glomerular filtration rate falls to such a degree that oliguria, azotemia, and eventually uremia are present, and the patient is clinically diagnosed with hepatorenal syndrome (Figure 38.9). Vasoconstrictive input focused on the kidney is severe. The renal failure is functional in nature, however, since restoration of near normal renal function can be obtained following a liver transplant.

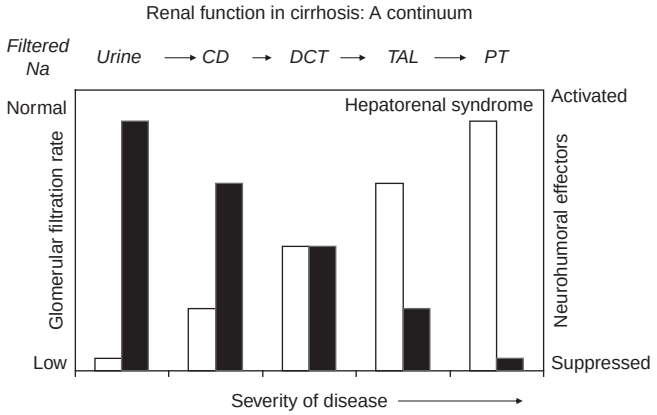

FIGURE 38.9 **The fall in glomerular filtration rate (solid bars) and activation of neurohumoral effectors (open bars) can be viewed as a continuum that varies according to severity of the underlying cirrhotic process.** As the disease advances, the urinary Na concentration falls. The filtered load of Na is completely reabsorbed at progressively more proximal sites along the nephron. A patient with hepatorenal syndrome is merely at the end of this continuum, when the glomerular filtration rate has fallen sufficiently to cause significant azotemnia.

NEPHROTIC SYNDROME

The development of edema is one of the cardinal features of nephrotic syndrome. The mechanism of its formation is not entirely understood. The classical view of edema formation in nephrotic syndrome describes the process as an underfill mechanism. According to this theory, urinary loss of protein results in hypoalbuminemia and decreased plasma oncotic pressure. As a result, plasma water translocates from the intravascular space into the interstitial space. When the magnitude of this transudation is sufficiently great, clinically detectable edema develops. Reduction in intravascular volume elicits activation of effector mechanisms that signal renal salt and water retention in an attempt to restore plasma volume. The renal response leads to further dilution of plasma protein concentration, thereby exaggerating the already reduced plasma oncotic pressure and further enhancing edema formation. In order for this formulation of edema genesis to be true, three critical predictions must be satisfied: (1) blood and plasma volume must be reduced during accumulation of edema; (2) measurement of neurohumoral effectors should reflect activation consequent to contraction of effective arterial blood volume; and (3) maneuvers that increase plasma volume into the normal range should result in a natriuretic response. As discussed below, these predictions are satisfied in some patients, especially those with minimal-change nephrotic syndrome, whereas the majority of nephrotic patients fail to conform to this conceptual model.

Blood and Plasma Volume in Nephrotic Syndrome

The classical view of edema formation assigns a pivotal role to decreased plasma volume serving as the afferent mechanism signaling renal salt and water retention. When measured directly, plasma volume has indeed been low in a variable proportion of patients with nephrotic syndrome.[106,138,198] Even in patients judged to be normovolemic, an exaggerated fall in plasma volume has been observed when nephrotic patients go from the recumbent to the standing position.[46,84] This orthostatic reduction in plasma volume can be profound and may, in part, explain the development of acute oliguric renal failure and hypovolemic shock that has been reported in patients with nephrotic syndrome.[191]

Most studies, however, have failed to find a consistent reduction in blood and plasma volume in patients with nephrotic syndrome.[39,47,61,100] In a survey of 10 studies, plasma volume measurements were analyzed in 217 nephrotic patients.[40] In only one-third of patients was plasma volume reduced, whereas it was normal in 42% and increased in 25%. It has been suggested that conflicting measurements of plasma volume in patients with nephrotic syndrome can be reconciled by separating patients according to histologic class.[137] In this regard, one study compared the volume status of four patients with minimal change disease to that in five patients with membranous or membranoproliferative lesions.[137] In patients with minimal change disease, plasma volume was decreased and plasma renin activity and aldosterone levels were increased. By contrast, plasma volume was either normal or increased and plasma renin activity was suppressed in the latter group. These authors concluded that edema formation in minimal change disease was primarily the result of decreased effective circulatory volume inciting secondary renal salt retention. By contrast, patients with more distorted glomerular architecture were felt to have a primary defect in renal salt excretion, leading secondarily to an expanded plasma volume and eventually formation of edema.

Other studies have failed to find such a correlation between histology and plasma volume measurements. Even in patients with untreated minimal change disease, plasma volume has been found to be increased.[40] In order to avoid potential methodologic problems, a recent study first established a reference frame for blood volume that was normalized to lean body mass, and measured directly from plasma volume and red cell volume in otherwise normal children.[205] Blood volume measurements in children with nephrotic syndrome due to minimal change disease, as well as other histologic lesions, were all found to be within this defined normal range. Following successful therapy with steroids, patients with minimal change disease demonstrate a fall in plasma volume and blood pressure, and an increase in plasma renin activity.[40] These changes are exactly the opposite of what one would expect if arterial underfilling were the proximate cause of renal salt retention. Finally, a large study of nephrotic patients, including 35 patients with minimal change disease, found virtually all patients have normal or increased plasma and blood volume.[60]

Neurohumoral Markers of Effective Circulatory Volume

Measurements of plasma renin activity and aldosterone concentration have been utilized as a method to indirectly differentiate primary sodium retention from an underfill mechanism of edema formation in nephrotic patients. Elevated values would be expected if blood volume was decreased, while suppressed values would occur in the setting of primary renal sodium retention and blood volume expansion. In this regard, plasma renin activity values collated from nine studies were found to be normal or low in 64 of 123 patients investigated.[39] Plasma aldosterone levels were also decreased in the majority of these patients. When measured with respect to salt intake or urinary sodium excretion, no consistent relationship was found. While some studies have found elevated plasma renin activity and aldosterone concentrations in patients with minimal change diseases, others have not.[69,137] In a study examining plasma renin activity with respect to blood volume, no relationship was found in either patients with minimal change disease or those with histologic lesions on light microscopy.[61] Although a higher proportion of patients with minimal change disease have elevated plasma renin and aldosterone levels as compared to those with histologic glomerular lesions, these values tend to overlap.[61,69] Thus, measurement of various elements of the renin–angiotensin–aldosterone axis suggests that an underfill mechanism may mediate renal sodium retention in some but not all patients with nephrotic syndrome.

Effects of Manipulations to Expand Central Blood Volume

Another approach utilized to investigate the pathogenesis of sodium retention in the nephrotic syndrome has been to examine renal sodium handling and hormonal indices of effective circulatory volume in response to expansion of the intravascular blood volume. This has been primarily achieved by infusing albumin or expanding central blood volume

by head-out body water immersion (HWI).[34,87] The classical view of nephrotic edema would predict that expansion of the intravascular volume should correct renal salt and water retention. In children with minimal change disease, infusion of albumin has been reported to decrease plasma renin activity, arginine vasopressin (AVP), aldosterone, and catecholamines.[169,196] In association with these hormonal changes, there was a significant increase in the glomerular filtration rate, urine flow, and sodium excretion. In a less homogenous group of adult patients with nephrotic syndrome, baseline blood volumes were found to be low when expressed per kilogram wet weight.[199] Plasma AVP was inversely correlated with blood volume and failed to decrease in response to a water-load. When blood volume was expanded with 20% albumin, plasma levels of AVP fell, accompanied by an augmented water diuresis. It was concluded that a contracted blood volume was responsible for the nonosmotic release of AVP. By contrast, other studies have found either no or only a minimal increase in urinary sodium excretion in response to infusion of albumin. In one study, infusion of hyperoncotic albumin in quantities sufficient to expand blood volume by 35% resulted in only a modest natriuretic response.[100] In order to exclude the possibility that the blunted natriuretic response was due to an increase in peritubular colloid osmotic pressure, similar studies have been performed utilizing a prolonged infusion of iso-oncotic albumin. This maneuver was similarly accompanied by only a modest increase in sodium excretion, such that the patients remained in positive salt balance.[167] Studies utilizing HWI to expand blood volume have likewise produced conflicting results. Expansion of central blood volume by HWI in children with minimal change disease resulted in decreased levels of AVP, aldosterone, noradrenaline and plasma renin activity.[169,170] These changes were accompanied by significant increases in urine flow and sodium excretion. Similarly, adult patients with a variety of histologic lesions subjected to HWI were found to have significant increases in urinary sodium excretion.[13,105] By contrast, a more recent study in 10 patients with a variety of underlying glomerular diseases found only a blunted natriuretic response to HWI.[165] While ANP levels rose to the same extent in control and nephrotic subjects, suggesting equivalent degrees of volume expansion, peak urinary sodium excretion and urine flow in the nephrotic patients were one-third that in the control group.

A number of other observations also question the pivotal role assigned to hypoalbuminemia and reduced plasma oncotic pressure in the initiation of edema formation.[3,83,84] For example, reducing plasma protein concentration in humans[3] or experimental animals[83,84] with plasmapheresis results in either no change or actually increases plasma volume. In addition, patients with congenital analbuminemia demonstrate no disturbance in water and electrolyte balance, and do not necessarily develop edema. Despite the reduction in plasma oncotic pressure, these patients exhibit an exaggerated natriuretic response when administered isotonic saline.

In summary, available data would argue for a contracted plasma volume as the afferent mechanism initiating sodium retention in some but not all patients with nephrotic syndrome. Rather, some component of primary renal sodium retention appears to be operative in nephrotic syndrome with histologic glomerular lesions, as well as in many patients with minimal change disease (Table 38.1). Studies in experimental animals also suggest a defect intrinsic to the nephrotic kidney as the mechanism responsible for salt retention in nephrotic syndrome. In the rat model of unilateral proteinuric renal disease induced by infusing puromycin aminonucleoside (PAN) into one kidney, diminished urinary sodium excretion was confined to the proteinuric kidney, despite the fact that each kidney shared the same systemic milieu.[77] In kidneys taken from rats previously exposed to PAN and then perfused *in vitro*, less sodium was excreted as compared to kidneys taken from control rats. Utilizing this experimental design, the defect in renal salt excretion was found to be localized to the kidney, as systemic and circulating factors were eliminated.

In some patients, primary salt retention and an underfill mechanism of edema formation may coexist. For example, in the earliest stages of a glomerular disease salt retention by the kidney may be primary in origin. As hypoalbuminemia develops and becomes progressively severe, plasma volume may fall and result in an element of superimposed secondary salt retention. The coexistence of these two mechanisms

TABLE 38.1 Evidence for Primary Renal Sodium Retention in the Nephrotic Syndrome

Blood volume is often normal or increased.
Blood pressure is often increased.
Renin activity and aldosterone levels are not uniformly increased.
Onset of natriuresis during recovery precedes rise in plasma protein concentration.
Sodium excretion is modest in response to HWI or albumin infusion.
Experimental models.
Sodium retention in a unilateral nephrosis model is confined to the diseased kidney.
Kidneys taken from nephrotic animals and perfused *in vitro* retain Na.

may account for the lack of uniformity in hemodynamic, as well as hormonal and neurocirculatory, profiles in patients with nephrotic syndrome.

Peripheral Capillary Mechanisms of Edema Formation

The presence of normal or increased plasma volume in the setting of a decreased serum albumin concentration is difficult to reconcile with the classical view of edema formation in the nephrotic syndrome. These findings can best be explained by examining the alterations that are known to occur in transcapillary exchange mechanisms in the setting of hypoproteinemia. Fluid movement within the capillary bed between intravascular and interstitial spaces is determined by the balance of Starling forces between these two compartments:

$$J_v = K_f[(P_c\text{-}P_i)\text{-}(\Pi_c\text{-}\Pi_i)]$$

where J_v is fluid flux along the length of a capillary, K_f is the ultrafiltration coefficient, P_c is capillary hydrostatic pressure, P_i is interstitial hydrostatic pressure, Π_c is capillary oncotic pressure, and Π_i is interstitial oncotic pressure. On the arterial side of the capillary, the net hydrostatic pressure gradient $P_c - P_i$ (ΔP) exceeds the net colloid osmotic pressure gradient $\Pi_c - \Pi_i$ ($\Delta\Pi$), resulting in net filtration of fluid into the interstitial space. Due to an axial fall in capillary hydrostatic pressure, the balance of Starling forces at the venous end of the capillary ($\Delta\Pi > \Delta P$) favors net reabsorption of fluid back into the capillary. In some tissues, net hydrostatic pressure exceeds opposing net colloid osmotic pressure throughout the length of the capillary, such that filtration occurs along its entire length. Net ultrafiltrate is returned to the circulation via lymphatic flow, such that in steady-state conditions total body capillary flux is equal to lymph flow; interstitial and intravascular volume remain stable and edema formation does not occur.

Absence of compensatory mechanisms would predict that small changes in ΔP, $\Delta\Pi$ or K_f would lead to increased fluid transudation and result in clinically detectable edema. However, the poor correlation between plasma albumin concentration and the presence or absence of edema suggests that counter-regulatory adjustments do occur in those forces that govern fluid exchange between the intravascular and interstitial space (Table 38.2). One such factor relates to compliance characteristics of the interstitium.[68] Under normal circumstances, interstitial pressure ranges from 6 mmHg to 10 mmHg. Due to the noncompliant nature of this compartment, small increases in interstitial volume result in large increases in interstitial pressure.

TABLE 38.2 Edema Defense Mechanisms which Limit Excessive Capillary Fluid Filtration

Increased interstitial hydrostatic pressure.
Increased lymph flow.
Decreased interstitial oncotic pressure.
Decreased permeability of the capillary to protein.

Such increases in P_i act to oppose further transudation of fluid, and provide an initial defense against the formation of edema. Increased interstitial pressure leads to the development of a second factor that also protects against edema formation, namely, increased lymphatic flow. Lymph flow can increase many-fold under conditions of augmented net capillary fluid filtration. In patients with edema resulting from heart failure or nephrosis, the disappearance rate of a subcutaneous injection of ^{131}I-albumin is markedly enhanced consistent with increased lymphatic flow.[73]

A third factor that minimizes fluid filtration is a reduction in interstitial oncotic pressure.[54] In normal human plasma, colloid oncotic pressure (COP) is about 24 mmHg, and interstitial COP is about 12 mmHg, creating a transcapillary COP gradient of about 12 mmHg.[84] Since transcapillary fluid flux consists primarily of a protein-free ultrafiltrate, interstitial protein concentration tends to become diluted. In addition, increased lymphatic flow removes fluid and protein from the interstitial space, and returns both to the vascular compartment thereby further reducing interstitial oncotic pressure. Body albumin pools are redistributed such that a greater fraction than normal is located in the vascular compartment.[84] As hypoalbuminemia develops in the nephrotic syndrome, the COP of the interstitial fluid space falls in parallel with the COP of plasma.[74,99,101] Nephrotic patients studied both in remission and in relapse demonstrate almost equivalent changes in the COP of plasma and the interstitium at all levels of serum albumin.[101] The maintenance of the net COP gradient within the normal range mitigates this potential driving force for transudation of fluid into the interstitial space. A final factor that favors decreased fluid filtration is a change in the permeability of the capillary. Under conditions of hypoalbuminemia, the intrinsic permeability of the capillary to protein tends to decrease, thereby increasing Π_c along the capillary.[215]

In summary, the reduction in serum oncotic pressure that accompanies the nephrotic syndrome would be predicted to alter Starling forces in a direction favoring net flux of fluid across the capillary bed. Despite this alteration, however, fluid tends not to accumulate within the interstitium in response to

hypoalbuminemia, because of the activation of a series of defense mechanisms that serve to oppose those forces favoring fluid movement from the intravascular space. These edema-preventing factors include increased interstitial hydrostatic pressure, accelerated lymphatic flow, a parallel decline in plasma and interstitial oncotic pressure, and decreased capillary permeability to protein. However, in the setting of ongoing primary renal salt retention, these buffering mechanisms become exhausted and clinically apparent edema may become evident. This occurs because salt retention leads to increases in capillary hydrostatic pressure at the very time defense mechanisms normally employed to prevent edema have been maximized. In the hypoproteinemic patient without salt retention, edema-preventing factors may be sufficient to protect against the development of edema. Thus, edema formation in the nephrotic syndrome results from the combined effects of primary salt retention coupled with exhausted defenses against edema (Figure 38.10).

The changes in mean arterial pressure and blood volume as a function of varying extracellular fluid volume in hypoalbuminemic nephrotic patients as compared to normoalbuminemic chronic renal-failure patients illustrate these principles.[98] In hypoalbuminemic patients with nephrotic syndrome, expansion of the extracellular fluid volume leads to immediate translocation of fluid into the extravascular space, as evidenced by little change in mean arterial pressure or blood volume. Presumably, factors that serve to prevent edema are already maximized, and are overwhelmed by increases in capillary hydrostatic pressure that occur as a result of extracellular fluid volume expansion. By contrast, normoalbuminemic patients with chronic renal failure develop an increase in mean arterial pressure and blood volume as extracellular fluid volume expands. In these patients, more of the fluid is retained in the vascular tree due to activation of edema preventing factors. At some point of extracellular fluid volume expansion, these factors would also become overwhelmed and clinically detectable edema would develop.

Mechanism of Salt Retention in Nephrotic Syndrome

The bulk of experimental and clinical data implicate a tubular mechanism as the primary cause of salt retention in the nephrotic syndrome. Both experimental and clinical studies implicate the distal nephron as the site responsible for sodium retention. Utilizing clearance techniques, proximal sodium handling was assessed during diuretic-induced distal tubular blockade using chlorothiazide and ethacrynic acid.[66] Nephrotic patients exhibited a greater natriuretic response than controls, suggesting that distal nephron sites were responsible for enhanced sodium reabsorption. Measurement of tubular glucose handling has been used as a marker of proximal sodium reabsorption.[198] In a group of nephrotic patients, glucose titration curves revealed a reduced threshold for glucose reabsorption, further suggesting diminished proximal sodium reabsorption.

In volume-expanded rats with autologous immune complex nephritis, a model that resembles membranous nephropathy, micropuncture, and clearance methodology were used to study the site of sodium retention.[14] Absolute proximal sodium reabsorption was decreased in nephrotic rats, while sodium delivery to the late distal tubule of superficial nephrons was comparable in control as well as nephrotic animals. Since fractional excretion of sodium was significantly lower in nephrotic versus control rats, the collecting duct was suggested as a possible site of altered handling of sodium. Enhanced sodium reabsorption in juxtamedullary nephrons not accessible to micropuncture could not be excluded. In the rat model of unilateral proteinuric renal disease induced by infusing PAN into one kidney, diminished urinary sodium excretion was confined to the proteinuric kidney.[77] Since sodium delivery to the initial portion of the collecting duct was similar to the control kidney, increased sodium reabsorption at the collecting duct must have been the primary site of salt retention.

Studies using immunocytochemical analysis are consistent with the distal nephron being a major site for sodium retention in nephrotic syndrome.[33,41,89,90,125] The activity of the $Na^+ - K^+$-ATPase is increased in the colleting duct in the puromycin aminonucleoside rat model of nephrosis. There is also increased expression and targeting of the epithelial sodium channel (ENaC) in the connecting tubule and collecting duct in these animals, as well as those made nephrotic through injection of $HgCl_2$.

Neurohumoral Control of Enhanced Tubular Sodium Excretion

Renin–Angiotensin–Aldosterone

Studies demonstrating increased sodium retaining activity in the urine of nephrotic patients lead early investigators to suggest that aldosterone might play an important role in mediating sodium retention in the nephrotic syndrome.[126] In rats made nephrotic with PAN, juxtaglomerular cell granularity was found to vary directly with the degree of sodium retention. In this same model, prior adrenalectomy prevented sodium retention that otherwise occurred in nephrotic

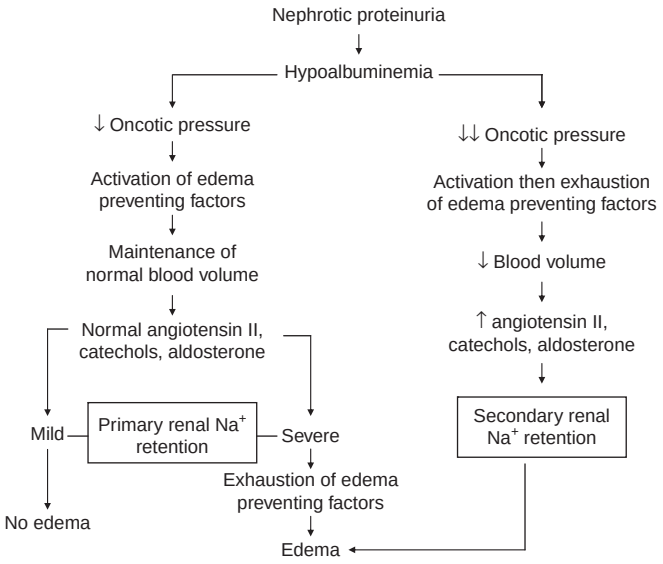

FIGURE 38.10 **The left side of the figure depicts the mechanism of edema formation in most patients with nephrotic syndrome.** An important variable that helps to explain the poor correlation between serum albumin concentration and the presence or absence of edema is the degree of primary renal Na retention. With severe Na retention by the kidney, edema-preventing factors become exhausted and edema becomes clinically apparent, even when the serum albumin concentration is only mildly depressed. In the setting of mild renal Na retention, these factors remain adequate to prevent edema formation, even in the presence of severe hypoalbuminemia. **The right side of the figure depicts the classical view of edema formation in which low blood volume serves as the signal for secondary renal Na retention.** This mechanism of edema formation is most commonly present in children with minimal change disease. In some patients, both mechanisms of edema formation may be operative. For example, early in the nephrotic syndrome, blood volume is normal and only primary renal Na retention is present. With worsening hypoalbuminemia, blood volume may begin to fall and result in a component of superimposed secondary renal Na retention.

controls with intact capacity to secrete aldosterone.[86] When plasma renin activity and aldosterone concentrations were measured in a large group of nephrotic patients placed on a low-sodium diet values varied widely, although a negative correlation was found between urinary sodium and plasma aldosterone concentration.[61] In a study of five nephrotic patients placed on a high-salt diet for 8 days, plasma renin activity and plasma aldosterone levels were similar in both nephrotic subjects and control subjects.[189] Administration of the aldosterone antagonist, spironolactone, on day 4 of the study resulted in an increase in urinary sodium excretion in the nephrotic patients, while no change was observed in the control group. Since aldosterone exerts salt-retaining effects on the distal nephron, a site implicated in formation of nephrotic edema, excess aldosterone activity is an attractive explanation for observed salt retention.

Most data, however, fail to confirm an important role for aldosterone. In patients spontaneously retaining sodium, measurements of plasma renin activity and aldosterone concentration may be either low or high.[21,23] This disassociation is also seen during steroid-induced remission of nephrotic syndrome. In four patients with minimal change disease, plasma renin and aldosterone concentrations fell during steroid-induced diuresis, but once in remission these hormones returned to the same plasma concentrations observed when edema was present.[137] Studies involving administration of either saralasin or converting enzyme inhibitors also fail to support an important role for the renin–angiotensin–aldosterone system in mediating salt retention.[22,23,42] In nephrotic patients selected for high plasma renin activity, captopril administration also failed to prevent sodium retention, despite producing marked reductions in plasma aldosterone.[22] In the unilateral model of PAN-induced nephrosis, infusion of saralasin led to substantial increases in total kidney and single-nephron GFR of the perfused kidney, but urinary sodium excretion remained unchanged.[77] This observation lends support for an intrarenal mechanism of salt retention independent of changes in GFR or activation of the renin–angiotensin–aldosterone system.

Sympathetic Nervous System

Increased plasma and urinary catecholamine concentrations have been found in patients with nephrotic syndrome.[88,150] The role of renal sympathetic nerve activity in mediating salt retention in nephrotic syndrome has been studied in rats made nephrotic by injection of adriamycin. An impaired ability to excrete an acute oral or intravenous isotonic saline-load was improved by bilateral renal denervation.[35] In response to acute infusion of saline, efferent renal sympathetic-nerve activity decreased to a lesser extent than that in control rats. Metabolic balance studies carried out over 26 days revealed an overall decrease in cumulative sodium balance only in those nephrotic rats with bilateral renal denervation.[72] Given the evidence for a distal nephron site of sodium reabsorption in nephrotic syndrome, it is noteworthy that beta-adrenergic stimulation of rabbit cortical collecting tubules enhances chloride transport.[78]

Other studies show enhanced sodium retention in nephrotic syndrome cannot be entirely explained by sympathetic nervous system activity. In kidneys taken from rats previously exposed to puromycin aminonucleoside and perfused *in vitro* so as to remove extrinsic neural factors, urinary sodium excretion is decreased as compared to kidneys taken from control animals.[58] Similarly, bilateral renal denervation does not correct

the blunted natriuretic response to volume expansion in the adriamycin model of nephrosis.[200]

Atrial Natriuretic Peptide

Levels of ANP are reported to be normal or slightly elevated in patients with nephrotic syndrome.[196] In animal models of nephrotic syndrome, renal responsiveness to ANP has generally been found to be blunted.[162] In contrast, infusion of synthetic human ANP to nephrotic patients results in increased sodium and water excretion, similar to that in normal subjects. Infusion of albumin in children with nephrotic syndrome resulted in a rise in ANP levels that closely correlated with urinary sodium excretion. However, other studies have found a blunted natriuretic response to ANP in nephrotic patients.[162] It has been proposed that enhanced distal sodium reabsorption in the nephrotic syndrome may, in part, be due to resistance of the collecting duct to the natriuretic actions of ANP.[159,163] The cellular basis of this resistance does not appear to be an abnormality in ANP binding to its receptor. Rather, the mechanism appears to be an inability to generate adequate amounts of the intracellular cGMP as a result of heightened activity of intracellular cGMP phosphodiesterase.[201]

In summary, edema formation in the majority of patients with nephrotic syndrome can best be explained by an overfill mechanism. The maintenance of a normal plasma volume in the setting of hypoalbuminemia is the result of a series of edema preventing factors that act to both oppose fluid filtration across the capillary wall, and to return fluid back into the vascular tree. The single most important variable in determining whether these factors are sufficient to prevent edema formation is the degree of renal salt retention. The variability in renal salt retention explains the poor correlation between the presence or absence of edema and the serum albumin concentration. In patients with severe hypoalbuminemia and no edema, renal salt retention is likely to be minimal, such that edema preventing factors are sufficient in preventing excessive fluid filtration across the capillary wall. By contrast, edematous patients with near normal serum albumin concentration are more likely to have avid renal salt retention, such that the factors opposing fluid filtration become exhausted. The defect in renal salt excretion has not been precisely localized, but appears to reside in the distal nephron. The exact mechanism underlying this defect is unknown.

SODIUM-WASTAGE

Renal salt-wastage may be defined as persistent inappropriate renal loss of sodium from the body sufficient in magnitude to result in shrinkage of extracellular fluid volume causing azotemia, hypotension, and when extreme, circulatory collapse. When evaluating the relationship between urine sodium excretion and dietary intake, the initial status of the extracellular fluid volume must be taken into consideration before concluding renal salt-wasting is present. For example, renal salt-wasting should not be considered present when urine sodium excretion greatly exceeds dietary intake in edematous patients placed on a low salt diet. In this instance, negative salt balance is an appropriate response to correct the volume-expanded state. As extracellular fluid volume normalizes, the natriuresis will stop and sodium balance will be re-established. By contrast, the imposition of a salt-restricted diet to a euvolemic patient with chronic kidney disease may result in negative salt balance, and contraction of extracellular fluid volume below normal limits. Even though the cumulative amount of sodium lost from the body may be far less than in the diuresing edematous patient, renal salt-wasting is considered present since the reduction of extracellular fluid volume has fallen below normal. In this setting, worsening azotemia and hypotension may be present. The critical feature of renal salt-wasting is the continued shrinkage of extracellular fluid volume below the lower limit of normal as a result of ongoing natriuresis. Disorders of renal salt-wasting can be divided into intrinsic disorders of the kidney and disorders of efferent mechanisms that regulate renal sodium handling.

Intrinsic Renal Disease

Chronic Kidney Disease

Patients with advanced chronic kidney disease may exhibit mild renal salt-wastage when subjected to rigid dietary sodium restriction. The pathogenesis of salt-wastage is related to the adaptive increase in perfusion of remaining viable nephrons, as total nephron mass progressively declines. Accompanying nephron hyperperfusion is a large increase in solute-load. This solute-load exceeds the reabsorptive capacity of remaining nephrons, resulting in increased excretion of salt and water. The nephrons of patients with chronic kidney disease are continuously undergoing an osmotic diuresis of solutes, including urea and the sodium salts of acids.

Studies by Coleman et al.[31] support an important role of osmotic diuresis in hyperfiltering nephrons in the genesis of salt-wastage in chronic kidney disease. In these experiments, patients with chronic kidney disease are placed on a low sodium diet and then subjected to a water diuresis. As urine volume increases, the urine sodium concentration falls to a minimum

value and thereafter remains fixed. At this point, urine sodium excretion increases in parallel with further increases in urine flow rates. In salt-restricted normal participants subjected to a water diuresis combined with mannitol diuresis, the urine sodium concentration at which flow dependence of urine sodium excretion commences is greater compared to the level during water diuresis alone. These data indicate that an osmotic diuresis is at least in part responsible for the mild salt-wastage observed in patients with chronic kidney disease.

Clinical evidence of salt-wastage in most patients with chronic kidney disease is typically only found when dietary salt restriction is extreme. Patients ingesting dietary sodium of 10–15 mEq/day require a much longer period of time to establish salt balance compared to normals, and in many patients salt balance is never achieved. A persistent negative sodium balance leads to volume depletion, weight loss, relative hypotension, and worsening azotemia. In most instances, these findings are seen during the course of an intercurrent illness when salt intake is abruptly stopped or markedly reduced.

There are several reports in the literature in which renal salt-wastage is more severe.[26] Most of these cases have been described in patients with what appears to be chronic tubulointerstitial disease accompanied by cystic transformation of the renal medulla. In these unusual cases, urine sodium excretion is of such a magnitude that contraction of extracellular fluid volume develops in the setting of normal salt intake. Medullary cystic disease is an autosomal recessive disorder with cystic changes in corticomedullary and medullary regions of the kidney in which renal salt-wastage can be severe.

Acute Renal Failure

Transient renal salt-wastage is often seen in patients during the recovery phase of acute tubular necrosis. The magnitude of the natriuresis is a function of the amount of salt and water retained as the renal failure developed. Massive salt-wasting leading to volume-depletion and cardiovascular collapse is not a feature of this disorder. Some degree of salt-wastage is often seen following the relief of urinary obstruction. The excretion of retained urea and other solutes contribute to an osmotic diuresis and account for the natriuresis. However, persistent salt-wastage after these solutes are cleared does not typically occur.

Renal Tubular Disorders

Proximal or type II renal tubular acidosis is associated with renal salt-wastage owing to the loss of sodium bicarbonate into the urine. Defective proximal acidification leads to a large increase in distal sodium bicarbonate delivery that is subsequently lost into the urine. The bicarbonaturic effect will continue until the serum bicarbonate concentration falls to a level that matches the reabsorptive capacity of the proximal nephron, at which point sodium-wastage will cease. As a result, salt-wastage is transient in this disorder, but nevertheless causes mild volume-depletion from inappropriate renal salt loss.

Distal or type I renal tubular acidosis is also characterized by a mild form of renal salt-wastage. The defect in distal acidification leads to the development of a hyperchloremic metabolic acidosis. Systemic acidosis impairs proximal salt reabsorption, resulting in mild sodium-wastage.[55]

Bartter's and Gitelman's syndromes are characterized by renal salt-wastage due to genetic defects in ion transporters involved in sodium reabsorption. In Bartter's syndrome, impaired salt transport is localized to the thick ascending limb, while in Gitelman's syndrome the defect is localized to the distal convoluted tubule.

A variety of drugs can cause renal salt-wastage as a result of tubular injury. This injury can be due to direct toxic effects of the drug, as with Cis-platinum, aminoglycosides, and amphotericin B or be the result of acute tubulointerstitial nephritis, as reported with methicillin and trimethoprim/sulfamethoxazole.

Disorders of Effector Mechanisms that Regulate Renal Sodium Transport

Decreased Mineralocorticoid Activity

Mineralocorticoid activity plays an important role in renal sodium conservation. Decreased activity and renal resistance to mineralocorticoids are causes of renal sodium-wastage.[217] The most clinically relevant form of mineralocorticoid deficiency results from primary diseases of the adrenal cortex. These diseases may either be acquired or congenital in origin. Subnormal aldosterone secretory rates lead to decreased reabsorption of sodium chloride in the cortical collecting tubule of the kidney. The kidney is fundamentally intact and the cortical collecting tubule cell responds normally to exogenously administered mineralocorticoids.

Renal salt-wastage is a hallmark of Addison's disease, in which patients may demonstrate severe volume-depletion and cardiovascular collapse. Addison's disease results from progressive adrenocortical destruction, leading to deficiencies in glucocorticoid and mineralocorticoid activity. These patients present with anorexia, vomiting, abdominal pain, weight loss, weakness, and salt craving. Physical examination reveals generalized hyperpigmentation, particularly in

skin folds and the axillae, as well as bluish-grey hyperpigmentation of the lingual and buccal mucosa. Orthostatic hypotension is very common, indicative of volume depletion. Laboratory examination reveals increased blood urea nitrogen-to-creatinine ratio characteristic of prerenal azotemia and elevated urinary sodium concentration. Hyponatremia, hyperkalemia, and hyperchloremic metabolic acidosis are the characteristic electrolyte abnormalities.

Isolated aldosterone deficiency accompanied by normal glucocorticoid production occurs in association with hyporeninism, as an inherited biosynthetic defect, during protracted heparin administration, and postoperatively following the removal of an aldosterone secreting adenoma. These patients have an inadequate ability to release aldosterone during salt restriction. In severe cases, salt-wastage may be present on a normal salt intake.

Mineralocorticoid Unresponsiveness

Defective transport of sodium may also result from abnormalities in tubular responsiveness to aldosterone. Disorders in which there is a resistance to aldosterone have been localized to abnormalities in the mineralocorticoid receptor, and to postreceptor defects in the epithelial sodium channel (ENaC).[217]

Pseudohypoaldosteronism type I is an inherited disorder of salt-wasting that presents in infancy. The autosomal dominant form of this disease has been linked to functional mutations in the mineralocorticoid receptor. Renal salt-wasting in these patients tends to be mild, and spontaneously improves as patient's age. A second form of the disease is inherited in an autosomal recessive fashion, and is caused by inactivating mutations in either the alpha- or beta-subunits of the epithelial sodium channel in the collecting duct. The clinical manifestations are more severe in this form of the disease. Patients present in infancy with severe unrelenting salt-wasting, hyperkalemia, and hyperchloremic metabolic acidosis, and a failure to survive syndrome. In addition to renal manifestations, patients also display frequent respiratory tract illnesses caused by an increase in the volume of airway secretions.

Cerebral Salt-Wasting

The concept of a CSW syndrome was first introduced by Peters and colleagues in 1950 in a report describing three patients with neurological disorders who presented with hyponatremia, clinical evidence of volume depletion, and renal sodium-wasting without an obvious disturbance in the pituitary–adrenal axis.[164] These findings were subsequently confirmed in additional patients with widely varying forms of cerebral disease.[208] The mechanism by which cerebral disease leads to renal salt-wasting is poorly-understood. The most probable process involves disruption of neural input into the kidney and/or central elaboration of a circulating natriuretic factor (Figure 38.11).

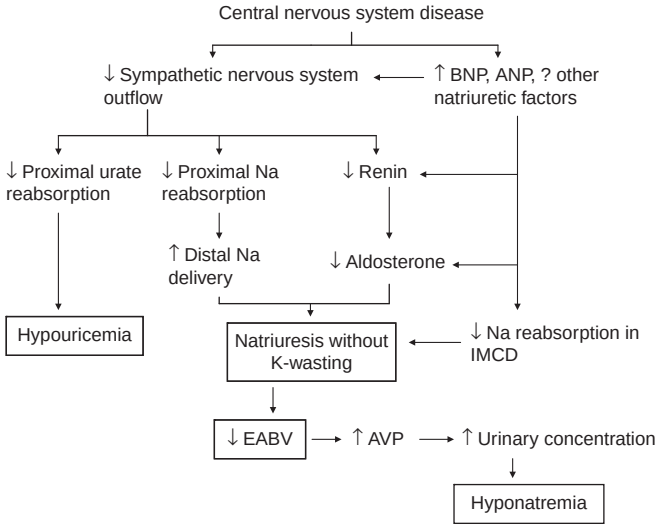

FIGURE 38.11 **The pathophysiology of cerebral salt-wasting.** Conditions associated with increased urinary sodium excretion in the setting of volume contraction would be expected to result in renal potassium-wasting, because of increased delivery of sodium to the cortical collecting duct in the setting of increased aldosterone levels. The lack of renal potassium-wasting in CSW can be accounted for by the failure of aldosterone to increase in spite of low extracellular fluid volume (ANP: atrial natriuretic peptide; AVP: arginine vasopressin; BNP: brain natriuretic peptide; CSW: cerebral salt-wasting; EABV: effective arterial blood volume; IMCD: inner medullary collecting duct).

CSW should be considered in patients with central nervous system disease who develop hyponatremia and otherwise meet the clinical criteria for a diagnosis of SIADH, but have a volume status that is inconsistent with that diagnosis. Unlike patients with SIADH who are volume-expanded, patients with CSW show evidence of negative salt balance and reductions in plasma, as well as total blood volume.[155] The onset of this disorder is typically seen within the first 10 days following a neurosurgical procedure or after a definable event, such as a subarachnoid hemorrhage or stroke. CSW has been described in other intracranial disorders, such as carcinomatous or infectious meningitis and metastatic carcinoma.

INTRODUCTION

Hypertension is the leading risk factor for cardiovascular deaths, causing approximately 7.6 million premature deaths per year worldwide.[1] Over 1 billion people including more than 50 million Americans have hypertension, making it the most common chronic disease.[1,2] Blood pressure (BP) typically rises with age and in the United States, approximately 50% of people 60–69 years old and 75% of people 70 years and older have hypertension.[1] In non-industrialized populations, however, BP does not rise with aging and only a small fraction of the population develops hypertension. This suggests that environmental factors play a major role in causing hypertension, and that a rise in BP with aging is not inevitable when these conditions are absent.

A direct positive relationship between BP and cardiovascular disease CVD risk has been observed in men and women of all ages, races, ethnic groups, and countries, regardless of other risk factors for CVD.[2] Observational studies indicate that death from CVD increases progressively as BP rises above 115 mmHg systolic and 75 mmHg diastolic pressure.[2] For every 20 mmHg systolic or 10 mmHg diastolic increase in BP there is a doubling of mortality from ischemic heart disease and stroke in all age groups from 40 to 89 years old.[3]

Despite major advances in our understanding of its pathophysiology, and the availability of many drugs that can effectively reduce BP in most hypertensive subjects, hypertension is still poorly-controlled in most countries, including the United States, and continues to be the most important modifiable risk factor for CVD.

BLOOD PRESSURE CLASSIFICATION FOR HYPERTENSION TREATMENT

BP is a variable, quantitative trait with a normal distribution slightly skewed toward higher BPs. Although there is no clear level of BP where cardiovascular or renal disease begins to occur, a definition of hypertension is useful for treatment decisions. A commonly used BP classification was proposed in 2003 by the Seventh Report of the United States Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High BP JNC 7 and is now widely used.[4]

According to these criteria, normal BP is defined as a systolic BP <120 mmHg and a diastolic BP <80 mmHg. Persons with a systolic BP between 120–139 mmHg or diastolic BP between 80–89 mmHg are designated as having *prehypertension*. Hypertension is further characterized by two stages: Stage 1, the milder (systolic 140–159 mmHg and/or diastolic 90–99 mmHg) and most common form of hypertension, accounts for approximately 80% of hypertension. Stage 2 hypertension includes those with systolic BP ≥160 mmHg and/or diastolic BP ≥100 mmHg. Isolated systolic hypertension is defined as systolic BP of ≥140 mmHg and diastolic BP <90 mmHg.

Using these definitions, and including those taking antihypertensive medications, approximately 24% of the adult population in the United States has hypertension.[4] This percentage varies with: 1) race, being higher in blacks 32% and lower in whites 23% and Mexican Americans 23%; 2) age, because systolic BP rises throughout life in the United States, as well as in most

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00039-2

industrialized countries, whereas diastolic BP rises until age 55–60 years; 3) gender, with hypertension being more prevalent in men than in premenopausal women, after menopause women have BPs that are nearly the same as in men; 4) geographic patterns, with hypertension being more prevalent in the Southeastern United States; and 5) socioeconomic status, which is inversely related to the prevalence of hypertension.

Primary hypertension accounts for about 95% of all cases of hypertension, and is usually defined as elevated BP for which an obvious secondary cause (e.g., renovascular disease, aldosteronism, pheochromocytoma or gene mutations) cannot be determined. Although primary hypertension is a heterogeneous disorder, some of the main risk factors are known. For example, overweight and obesity may account for as much as 65–75% of the risk for primary hypertension. Other factors, such as sedentary lifestyle, excess consumption of alcohol or sodium chloride, and low potassium intake are also thought to contribute to increased BP in many patients.[5] This review discusses basic concepts of BP control and pathophysiological changes that may cause primary hypertension, as well as selected forms of genetic and secondary hypertension.[5,6]

BASIC PHYSIOLOGY OF BLOOD PRESSURE REGULATION

BP regulation depends on integrated actions of multiple cardiovascular, renal, neural, endocrine, and local tissue control systems. Although hypertension is usually considered as a disorder of the average level at which BP is regulated, there is increasing interest in other measures of BP, including peak arterial pressure, BP variability, nighttime and daytime BP, and responses of BP to stress, which may affect cardiovascular risk.

The complex local control, hormonal, neural, and renal systems that regulate BP are often discussed in terms of how they influence cardiac function or vascular resistance because of the well-known formula: *mean arterial pressure = cardiac output × total peripheral resistance*. This conceptual framework, with the addition of factors that influence vascular capacity and transcapillary fluid exchange, is adequate to explain short-term BP regulation, but not chronic hypertension.[5,7] Two additional concepts are useful when considering chronic BP regulation: 1) BP control mechanisms are time-dependent; and 2) renal excretion of water and electrolytes play a key role in long-term BP regulation.

Blood Pressure Control Systems are Time-Dependent

Figure 39.1 shows the maximum feedback gains of major BP controllers following a sudden disturbance,

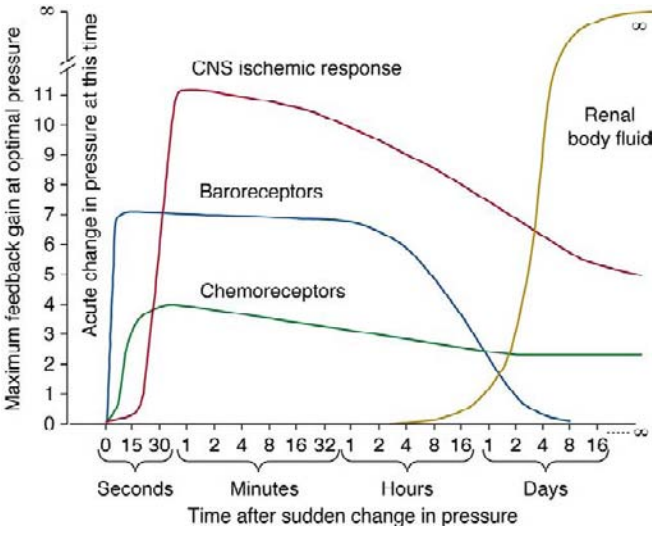

FIGURE 39.1 **Time-dependency of blood pressure control mechanisms.** Approximate maximum feedback gains of various blood pressure control mechanisms at different time intervals after the onset of a disturbance to arterial pressure.

as might occur with rapid blood loss. Three important neural control systems begin to function powerfully within a few seconds: 1) the arterial baroreceptors, which detect changes in BP and send appropriate autonomic reflex signals back to the heart and blood vessels to return the BP toward normal; 2) the chemoreceptors, which detect changes in oxygen or carbon dioxide in the blood and initiate autonomic feedback responses that influence BP; and 3) the central nervous system, which responds within a few seconds to ischemia of the vasomotor centers in the medulla, especially when BP falls below about 50 mmHg. Each of these nervous control mechanisms works rapidly and has potent effects on BP. Also note, however, that the feedback gains of these systems decrease with time, as disturbances of BP are maintained.

Within a few minutes or hours after a BP disturbance, additional control systems react, including: 1) a shift of fluid from the interstitial spaces into the blood in response to decreased BP or a shift of fluid out of the blood into the interstitial spaces in response to increased BP; 2) the renin–angiotensin–aldosterone system RAAS which is activated when BP falls too low and is suppressed when BP increases above normal; 3) multiple vasodilator systems not shown in the figure that are suppressed when BP decreases and stimulated when BP rises above normal.

Most of the BP regulators are *proportional* control systems. This means that they can correct a BP abnormality only part of the way back toward the normal level, but never all the way back. The arterial baroreceptor reflex system, for example, has a feedback gain of approximately 2.0 during acute changes in BP, and

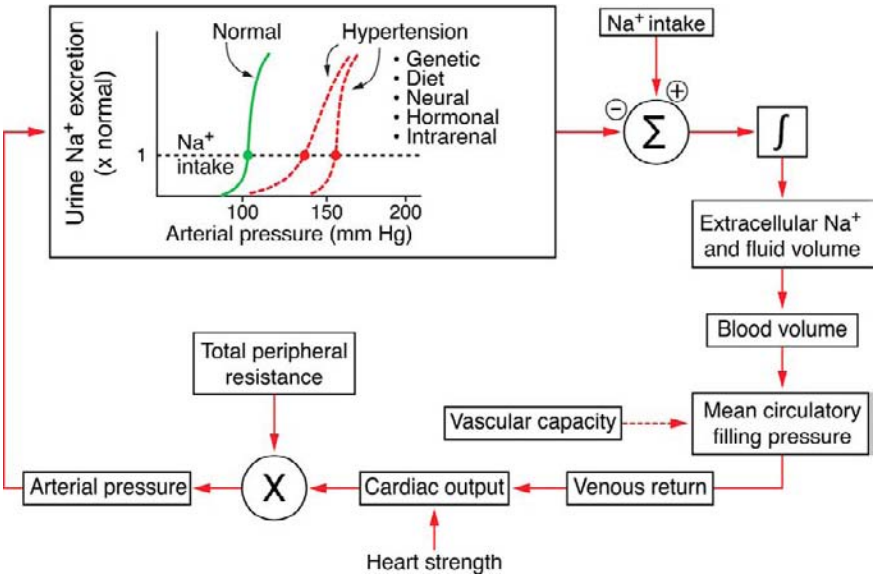

FIGURE 39.2 **Block diagram showing the basic elements of the renal–body fluid feedback mechanism for long-term regulation of arterial pressure.**

therefore buffers about two-thirds of a sudden change in the BP. The renal–body fluid feedback system, however, is the one BP control system with *near infinite feedback gain* if it is given enough time to operate.[7]

The Renal–Body Fluid Feedback Mechanism for Long-Term BP Regulation

Figure 39.2 shows the basic components of the renal–body fluid feedback mechanism. Extracellular fluid volume is determined by the balance between intake and excretion of salt and water by the kidneys. Even a temporary imbalance between intake and output can lead to a change in extracellular volume, and potentially a change in BP. Under steady-state conditions there must be a precise balance between intake and output of salt and water; otherwise, there would be continued accumulation or loss of fluid leading to circulatory collapse within a few days. A key component of this mechanism for regulating salt and water balance is *pressure natriuresis*—the effects of increased BP to raise sodium excretion.[5] Under many conditions this mechanism stabilizes BP. For example, when BP is increased above the renal set-point, because of increased TPR or increased cardiac pumping ability, this also tends to increase sodium excretion, via pressure natriuresis, if the effectiveness of pressure natriuresis is not impaired (Figure 39.3). As long as fluid excretion exceeds intake, extracellular fluid volume will continue to decrease, reducing venous return and cardiac output, until BP returns to normal and fluid balance is re-established.

An important feature of pressure natriuresis is that it continues to operate until BP returns to the original set-point. Another key aspect of pressure natriuresis is that various neurohumoral systems can amplify or blunt the pressure natriuresis mechanism.[5] For example, increases in sodium intake are associated with only small changes in BP in many people. One reason for this insensitivity of BP to changes in salt intake is decreased formation of antinatriuretic hormones such as angiotensin II and aldosterone, which enhance the effectiveness of pressure natriuresis and allow sodium balance to be maintained with minimal increases in BP. On the other hand, excessive activation of these antinatriuretic systems reduces the effectiveness of pressure natriuresis, necessitating greater increases in BP to maintain sodium balance.

In all forms of human or experimental hypertension studied thus far, there is a shift of pressure natriuresis toward higher BPs. In some cases, impaired pressure natriuresis is caused by *intrarenal* disturbances that reduce glomerular filtration rate GFR or increase tubular reabsorption. In other instances, impaired pressure natriuresis is caused by *extrarenal* factors, such as increased activity of the SNS or antinatriuretic hormones that reduce the kidney's ability to excrete sodium and eventually raise BP.

Vasoconstrictors May Decrease Extracellular Volume Despite Impairing Renal-Pressure Natriuresis

Some forms of hypertension, especially those associated with increased levels of vasoconstrictors such as norepinephrine, are associated with reduced rather than increased extracellular fluid volume. How can the hypertension in these instances be attributed to impaired renal pressure natriuresis when there is no evidence of sodium retention? Consider the physiological changes caused by infusion of a powerful

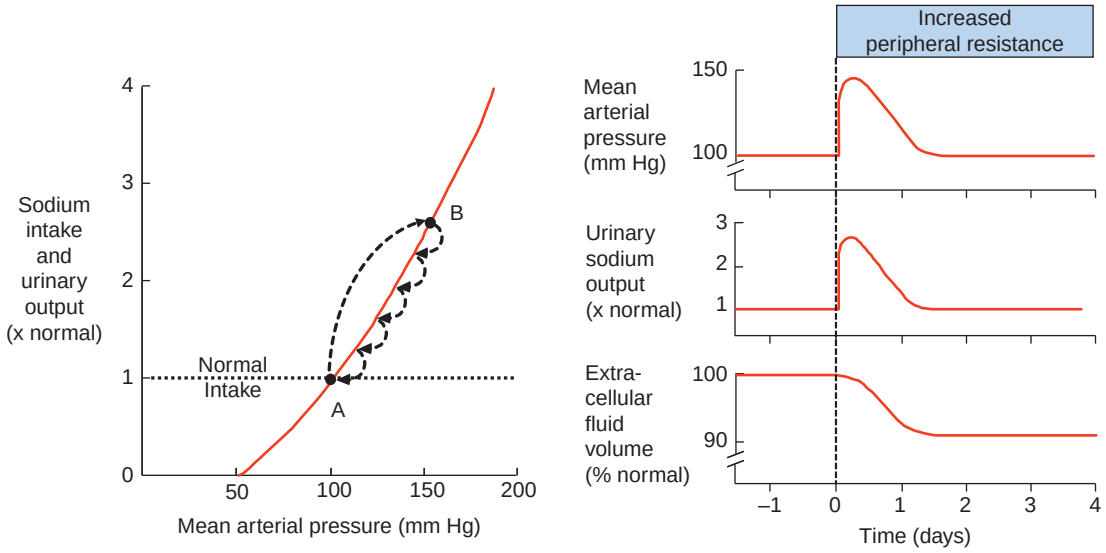

FIGURE 39.3 **Long-term effects of increased total peripheral resistance (TPR), such as that caused by closure of a large arteriovenous fistula, with no change in the renal pressure natriuresis relationship**. BP is initially increased from point A to point B, but elevated BP cannot be sustained because sodium excretion exceeds intake, reducing extracellular fluid volume until BP returns to normal and sodium balance is re-established.[10]

vasoconstrictor such as norepinephrine. Chronic iv infusion of norepinephrine causes mild hypertension associated with an initial increase in sodium excretion as BP rises.[8] After several days, sodium excretion returns to normal but extracellular fluid volume is reduced. On the other hand, if norepinephrine is infused directly into the renal artery at a low dose so that its effect on other vascular beds is minimal or if renal perfusion pressure is servo-controlled and prevented from increasing during iv norepinephrine infusion there is significant sodium retention, demonstrating a direct antinatriuretic effect on the kidneys, as well as development of hypertension.[5,8]

Figure 39.4 shows the relationship between BP and sodium excretion caused by a powerful vasoconstrictor, such as norepinephrine, which has a relatively weak antinatriuretic action. The antinatriuretic effect shifts pressure natriuresis to higher BPs, but because norepinephrine has a weak antinatriuretic effect, compared to its peripheral vasoconstrictor effect, BP initially increases above the renal set-point for sodium balance and causes transient natriuresis. After a few days, extracellular fluid volume decreases and BP stabilizes at a point where sodium intake and output are balanced. The sodium retaining actions are obscured by peripheral vasoconstriction which raises BP above the renal set-point at which sodium balance is maintained, causing increased renal excretion and decreased extracellular fluid volume. However, the maintenance of high BP chronically depends on the changes in renal function that shift pressure natriuresis to higher BPs.

RENAL MECHANISMS OF HYPERTENSION

Commonly used measurements of kidney function, such as GFR, renal blood flow, serum creatinine, and sodium excretion, are often within the normal range in hypertensive patients, at least prior to renal damage due to prolonged high BP. On the other hand, increased TPR is found in many hypertensive patients, leading to emphasis on peripheral vasoconstriction as a cause of increased BP. However, increased TPR may be an autoregulatory response to increased BP, and may not cause sustained hypertension in the absence of impaired pressure natriuresis.

Almost all forms of experimental hypertension and all monogenic forms of human hypertension discovered thus far are caused by insults to the kidneys that alter renal hemodynamics or tubular reabsorption. For example, constriction of the renal arteries e.g., Goldblatt hypertension, compression of the kidneys e.g., perinephritic hypertension or administration of sodium-retaining hormones (e.g., mineralocorticoids or angiotensin II) are all associated with either initial reductions in renal blood flow and GFR or increases in renal tubular reabsorption prior to development of hypertension. Likewise, in all known monogenic forms of human hypertension there is impaired renal excretory function caused by mutations that increase renal sodium reabsorption or activity of antinatriuretic hormones. As BP rises, the initial changes are obscured by compensations that restore kidney function toward

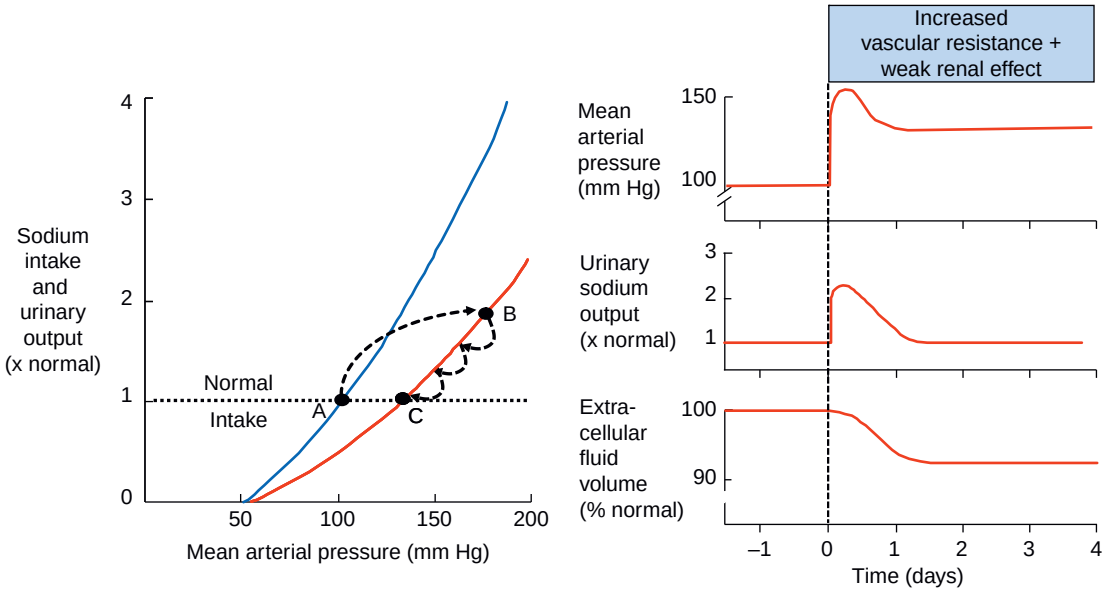

FIGURE 39.4 **Long-term effects of norepinephrine, a vasoconstrictor that has a relatively weak effect to impair pressure natriuresis**. The normal curve (blue) is compared with the vasoconstrictor curve (red line). Initially the vasoconstrictor raises BP (from point A to point B) above the renal set point for sodium balance. Increased BP, however, causes a transient natriuresis and decreases extracellular fluid volume until BP eventually stabilizes at a level (point C) at which sodium intake and output are balanced at a reduced extracellular fluid volume.[10]

normal. The rise in BP then initiates a cascade of cardiovascular changes, including increased TPR that may be more striking than the initial kidney disturbance. For this reason, the importance of renal dysfunction in causing hypertension has often been underestimated.

Although specific abnormalities of kidney function are difficult to identify in most patients with primary hypertension, one aspect of kidney function that is invariably abnormal is renal pressure natriuresis.[9,10] Maintenance of a normal sodium excretion equal to sodium intake despite elevated BP, which would normally cause natriuresis and diuresis, indicates that pressure natriuresis is reset in hypertensive subjects.

Some types of renal abnormalities that cause chronic hypertension include: 1) increased preglomerular resistance; 2) decreased glomerular capillary filtration coefficient; 3) reduced numbers of functional nephrons; and 4) increased tubular reabsorption (Figure 39.5). As discussed below, some of these abnormalities cause blood pressure to be more sensitive to changes in dietary salt intake (salt-sensitive), whereas other renal abnormalities may cause hypertension that is relatively insensitive to changes in salt intake (salt-insensitive).

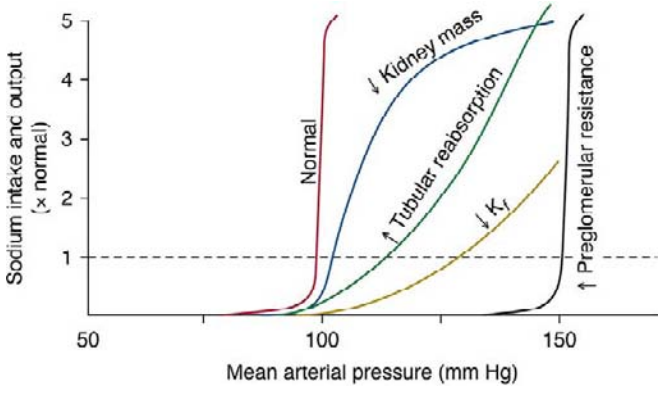

FIGURE 39.5 **Steady-state relationships between BP, sodium excretion, and sodium intake for subjects with normal kidneys and four general types of renal dysfunction that cause hypertension: decreased kidney mass; increased reabsorption in distal and collecting tubules; reductions in glomerular capillary filtration coefficient (K_f); and increased preglomerular resistance**. Note that increased preglomerular resistance causes *salt-insensitive* hypertension, whereas the other renal abnormalities cause *salt-sensitive* hypertension.

Generalized Increases in Preglomerular Resistance Cause Salt-Insensitive Hypertension

Examples of a generalized increase in preglomerular resistance are those caused by suprarenal aortic coarctation or constriction of one renal artery and removal of the contralateral kidney (e.g., 1-kidney, 1-clip Goldblatt hypertension). After renal artery constriction or aortic coarctation, renal blood flow, GFR, and sodium excretion are initially reduced, and there is a rapid rise in renin secretion. Renal blood flow and GFR may return to near normal if autoregulatory mechanisms are not impaired, and if constriction is not so severe that it reduces renal perfusion pressure

below the autoregulatory range ~65–70 mmHg. Even if GFR is not fully autoregulated, sodium excretion returns to normal and sodium balance is re-established within a few days. If sodium and fluid intakes are normal, renin secretion also returns to normal in the established phase of hypertension. At this point, most indices of renal function are nearly normal, including BP distal to the stenosis if the constriction is not too severe.[11]

Homogeneous increases in preglomerular resistance typically cause salt-insensitive rather than salt-sensitive hypertension. One of the main reasons that increased salt intake does not greatly exacerbate this form of hypertension is that after BP increases sufficiently to restore renal perfusion pressure and renin secretion to nearly normal, the RAAS is fully capable of appropriate suppression during high salt intake. As discussed later, the ability to effectively modulate RAAS activity is critical for preventing salt-sensitivity of BP.

Functional or pathologic increases in preglomerular resistance at other sites besides the main renal arteries, such as the interlobular arteries or afferent arterioles, could also increase BP through the same mechanisms activated by clipping the renal artery. For example, structural increases in afferent arteriolar resistance (e.g., nephrosclerosis or functional increases in resistance caused by excessive activation of the SNS) could also cause hypertension through the same mechanisms as constriction of the main renal artery. Some patients with primary hypertension have essentially the same characteristics seen in 1-kidney, 1-clip Goldblatt hypertension, including nearly normal GFR and plasma renin activity, a parallel shift of pressure natriuresis to higher BP, and a relatively salt-insensitive form of hypertension.[5,11] Also, drug therapies that decrease preglomerular resistance, such as calcium channel blockers, cause a parallel shift of pressure natriuresis toward lower BP.[6] Thus, primary hypertension in some patients may be caused by functional or pathologic increases in preglomerular resistance. This is almost certainly the case in patients who have severe atherosclerotic lesions in the renal blood vessels.

Non-Homeogeneous Increases in Preglomerular Resistance Cause Salt-Sensitive Hypertension

In 2-kidney, 1-clip Goldblatt hypertension or in patients with a stenosis in only one renal artery, there is a non-homogeneous increase in preglomerular resistance, with ischemia occurring in nephrons of the clipped/stenotic kidney, while nephrons in the contralateral nonstenotic kidney have normal or increased single-nephron blood flow and GFR. The underperfused clipped kidney secretes large amounts of renin, whereas the untouched kidney secretes little renin.[6,12]

In the 2-kidney, 1-clip model, the glomeruli of the untouched kidney are subject to the full effects of increased BP. With prolonged hypertension, pathologic changes in the untouched kidney may further impair renal function. At this stage, removal of the clipped kidney only partially normalizes BP. However, removal of the contralateral untouched kidney and unclipping the stenotic kidney usually normalizes BP if the underperfusion of the clipped kidney is not too severe and ischemic injury has not occurred. Thus, chronic exposure to high BP in the untouched kidney may cause pathological changes that increase the severity of hypertension.

Non-homogeneous increases in preglomerular resistance may also cause salt-sensitivity of BP. The main reason is that the underperfused nephrons secrete large amounts of renin, whereas the remaining nephrons are overperfused and have reduced renin secretion.[5,6] In both cases, the nephrons have impaired ability to adequately suppress renin secretion during high salt intake, and BP becomes more salt-sensitive.

Some patients with essential hypertension may have non-homogenous nephrosclerosis within each kidney, providing another clinical counterpart to the 2-kidney, 1-clip Goldblatt model of hypertension. In these instances, the combined effects of hypertension and hyperfiltration in non-ischemic nephrons may eventually damage the nephrons that were not initially ischemic, leading to progressive nephron loss.

Reduced Glomerular Capillary Filtration Coefficient

Decreased glomerular capillary filtration coefficient K_f initially lowers GFR and sodium excretion, while stimulating renin release and causing vasodilation of afferent arterioles via macula densa feedback.[5,6] The sodium retention and increased angiotensin II formation raise BP, which helps to normalize GFR and renin release. After these compensations, the main persistent abnormalities of kidney function are reduced filtration fraction, increased glomerular hydrostatic pressure, and increased renal blood flow. Unfortunately, compensatory increases in BP and glomerular hydrostatic pressure, which offset a fall in K_f and restore sodium excretion to normal, may also cause further glomerular injury, loss of glomeruli, further reductions in K_f, and additional increases in BP.

The clinical counterparts of this sequence may be found in hypertension caused by glomerulonephritis or by other conditions that cause thickening and damage to the glomerular capillary membranes, such as chronic diabetes mellitus.

Nephron Loss Increases Salt-Sensitivity

Surgical removal of large amounts of the kidney, to the point that uremia occurs, rarely cause much hypertension as long as sodium intake is normal.[6,9,13] In this case, GFR and tubular reabsorption capability are proportionally reduced so that balance between filtration and reabsorption are maintained without major changes in BP. Reducing the number of nephrons, however, makes the kidneys susceptible to additional challenges of sodium homeostasis. For example, hypertension associated with excess mineralocorticoids is more severe after reducing kidney mass. Likewise, high sodium intake is accompanied by larger BP increases when kidney mass is reduced.[6]

Nephron loss also initiates compensatory changes that may damage the surviving nephrons. For example, renal vasodilation and increased single nephron GFR, over long periods of time, may lead to glomerulosclerosis and reductions in K_f. These pathologic changes, in addition to loss of functional nephrons, may further impair pressure natriuresis and cause hypertension. Thus, even though hypertension may not begin with nephron loss, chronic elevations in glomerular pressure and other metabolic abnormalities often associated with hypertension may cause progressive nephron loss that amplifies the hypertension and makes BP salt-sensitive.

Partial renal infarction causes high renin hypertension. In contrast to the effects of surgical removal of kidney mass, loss of nephrons because of ischemia or infarction of renal tissue usually causes marked hypertension, even with normal salt intake. The so-called *5/6 ablation* model is produced by removing one kidney and obstructing two of the three branches of the renal artery of the remaining kidney. In this model, hypertension develops even without high salt intake because of ischemia of the surviving nephrons, activation of the RAAS, and immune-mediated renal injury.[14] This hypertension model has non-homogeneous areas of renal ischemia with characteristics similar to that described for the 2-kidney, 1-clip Goldblatt model. The clinical counterpart of this model occurs with partial renal infarction caused by septic emboli, thrombus, trauma or sometimes after corrective surgery for renal artery stenosis.

Increased Renal Tubular Sodium Reabsorption

Hypertension caused by increased *distal* or *collecting tubular reabsorption* is exacerbated by increased salt intake. Increased reabsorption at sites beyond the macula densa elicits increased sodium chloride delivery to the macula densa which, in turn, suppresses renin secretion,[5,10] sometimes to very low levels, which prevents further suppression of angiotensin II formation during high sodium intake, making BP salt-sensitive.

An increase in *proximal* or *loop of Henle* tubular reabsorption, however, may result in a salt-insensitive hypertension. Increased proximal tubular reabsorption tends to increase renin secretion, and elicits a compensatory renal vasodilation that raises GFR and renal plasma flow in response to reduced macula densa NaCl delivery. However, as hypertension develops, macula densa NaCl delivery and renin secretion return to nearly normal, and the RAAS may be fully capable of responding to increased salt intake. Therefore, high salt intake may be accompanied by appropriate suppression of angiotensin II formation, which permits sodium balance to be maintained with only small increases in BP.[10] Nevertheless, pressure natriuresis is shifted to higher BP.

A feature of hypertension caused by increased tubular reabsorption is that it may initially be associated with extracellular volume-expansion. However, volume-expansion and increased cardiac output usually subside because of pressure natriuresis, and TPR increases secondarily to increased BP. When increased tubular reabsorption is also associated with marked peripheral vasoconstriction, such as occurs with very high levels of angiotensin II, the degree of volume-expansion depends on the relative effects of the vasoconstrictor on peripheral and renal blood vessels.[5] With severe peripheral vasoconstriction and decreased vascular capacitance, relatively small amounts of volume retention can lead to substantial hypertension.

Significance of Salt-Sensitive Hypertension

Many factors are associated with salt-sensitivity of BP. Older individuals are usually more salt-sensitive than young people, and African Americans are often more salt-sensitive than whites. However, there are exceptions to these generalizations and considerable heterogeneity exists in the BP responses to increased salt intake.

Genetic factors independent of ethnicity have been linked to salt-sensitivity of BP, especially monogenic disorders that increase distal and collecting tubule sodium reabsorption or that increase secretion of sodium-retaining hormones.[15] Also, diabetes mellitus, renal diseases that cause nephron loss, and abnormalities of the RAAS are associated with increased salt-sensitivity of BP.[5] Many of these examples share two common pathways to salt-sensitivity: 1) loss of functional nephrons as discussed previously or 2) reduced responsiveness of the RAAS.

Figure 39.6 shows the importance of changes in angiotensin II formation in maintaining BP relatively constant during wide variations in salt intake. In dogs with a fully-functional RAAS, only small increases in

BP were associated with a 100-fold increase in sodium intake.[16,17] However, when angiotensin II was prevented from being suppressed as sodium intake was raised, BP became salt-sensitive. After blockade of angiotensin II formation, BP was also salt-sensitive, although maintained at lower levels.[17] Thus, a major function of the RAAS is to permit wide variations in sodium intake and excretion without large fluctuations in BP.

As discussed previously, focal nephrosclerosis or patchy preglomerular vasoconstriction, as occurs with renal infarction, leads to increased renin secretion in ischemic nephrons and very low levels of renin release by overperfused nephrons.[6] Thus, in ischemic and overperfused nephrons, the ability to suppress renin secretion during high salt intake is impaired. Another cause of reduced responsiveness of the RAAS is increased distal and collecting tubular sodium reabsorption, as occurs with mineralocorticoid excess or mutations that increase distal and collecting tubule reabsorption (e.g., Liddle syndrome). In these conditions, excess sodium retention causes almost complete suppression of renin secretion, resulting in an inability to further decrease renin release during high sodium intake. Consequently, BP becomes very salt-sensitive.

Salt-Sensitive Subjects May Have Greater Target Organ Injury

Some studies suggest that salt-sensitivity predicts hypertensive target organ injury. Salt-sensitive hypertension may be associated with glomerular hyperfiltration and increased glomerular hydrostatic pressure that is further amplified by the hypertension[5]; together the hypertension and renal hyperfiltration may promote glomerular injury and cause loss of nephron function. Clinical studies support this concept, and demonstrate that salt-sensitive individuals typically have increased glomerular pressure and albumin excretion when given a salt-load, whereas salt-resistant individuals have lower glomerular pressure and less urinary albumin excretion.[18]

There is also evidence that salt-sensitive subjects may die earlier than individuals who are salt-resistant. Weinberger et al. studied individuals for more than 20 years and found that normotensive individuals with increased salt-sensitivity died almost at the same rate as hypertensive individuals, and much faster than salt-resistant individuals who were normotensive.[19] Whether this increased mortality was related to BP effects of salt or to other effects is still unclear. It is also not known whether long-term high salt intake may cause a person who is initially salt-insensitive to become salt-sensitive as a consequence of gradual renal injury.

NEURAL AND HORMONAL MECHANISMS OF HYPERTENSION

The following sections discuss the multiple neural, hormonal, and autacoid mechanisms that alter renal pressure natriuresis, and their potential roles in hypertension.

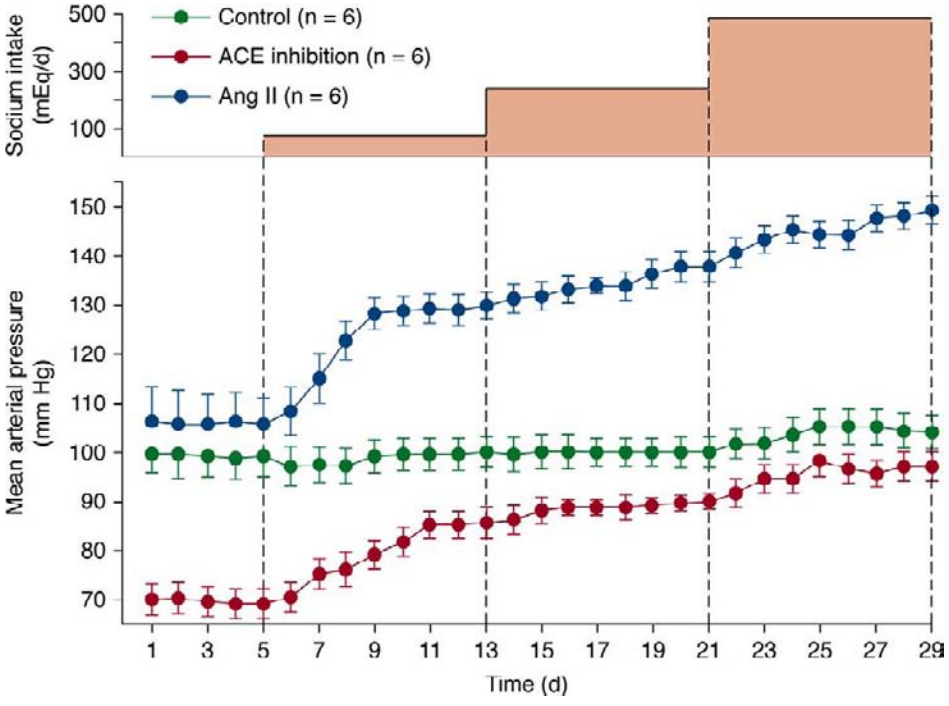

FIGURE 39.6 **Changes in mean arterial pressure during chronic changes in sodium intake in normal control dogs, after ACE inhibition, or after angiotensin II infusion (5 ng/kg/min) to prevent angiotensin II from being suppressed when sodium intake was raised ref. [17].**

The Sympathetic Nervous System SNS

Activation of the SNS can raise BP within a few seconds by causing vasoconstriction, increased cardiac pumping capability, and increased heart rate. Conversely, sudden inhibition of SNS activity can decrease BP to as low as half normal in less than a minute. Therefore, changes in SNS activity, caused by various reflex mechanisms, central nervous system ischemia or by activation of higher centers in the brain, provide powerful and rapid moment-to-moment regulation of BP.

The SNS also plays an important role in long-term regulation of BP and in the pathogenesis of hypertension by activation of the renal sympathetic nerves.[20] There is extensive innervation of the renal blood vessels, the juxtaglomerular apparatus, and the renal tubules, and overactivation of these nerves causes sodium retention, increased renin secretion, and impaired renal pressure natriuresis.[20] Even mild increases of the renal sympathetic nerve activity (RSNA) stimulate renin secretion and sodium reabsorption in multiple segments of the nephron, including the proximal tubule, the loop of Henle, and more distal segments.[20] Thus, the renal nerves provide a mechanism by which the various autonomic reflexes and central nervous system (CNS) centers contribute to long-term BP regulation.

Multiple studies have shown that renal denervation reduces BP in some experimental models of hypertension.[20] For example, renal denervation attenuates hypertension in (SHR)[20] as well as in obese hypertensive dogs.[21] Renal denervation also delays or attenuates increased BP in other forms of experimental hypertension, although some studies have not found an important role for the renal nerves in various forms of secondary hypertension.[5]

Human primary hypertension, especially when associated with obesity, is often associated with increased RSNA.[22] Bilateral renal denervation in humans, using a percutaneous, catheter-based radiofrequency method to selectively ablate the nerves that run along the renal arteries, reduced BP in patients who were resistant to the usual antihypertensive drugs.[23,24] Moreover, reductions in BP were sustained for up to two years of follow-up, suggesting the absence of substantial nerve fiber regrowth. However, longer follow-up periods will be needed to determine if the renal nerves eventually regrow and reinitiate increased BP, as observed in experimental animal models of renal denervation.

Although the mechanisms that activate renal sympathetic nerves in primary hypertension or in most experimental models are still unclear, we will briefly discuss two that have attracted the interest of many researchers.

Resetting of Baroreceptor Reflexes in Hypertension

The importance of the arterial baroreceptors in buffering moment-to-moment changes in BP is clearly evident in baroreceptor-denervated animals in which there is extreme BP variability associated with normal daily activities.[25] After baroreceptor denervation, BP increases to very high levels or falls to low levels with normal daily activities, although the average 24-hour BP is not markedly altered. However, some studies suggest that the baroreceptors are relatively unimportant in chronic regulation of BP, because they tend to reset within a few days after a change in BP.[25] To the extent that resetting of baroreceptors occurs, this would attenuate their potency in long-term control of BP.

Other experimental studies suggest that the baroreceptors do not completely reset and may contribute to chronic BP regulation. With prolonged increases in BP, the baroreflexes may contribute to *reductions* in renal sympathetic activity, and promote sodium and water excretion.[26] This, in turn, may attenuate the rise in BP. Thus, impairment of baroreflexes may cause increased lability of BP in hypertension, and fail to attenuate the rise in BP caused by other disturbances.

Currently, there is little evidence that primary disturbances of baroreceptor function play a major role in *causing* chronic hypertension. However, experimental studies in dogs indicate that chronic electrical stimulation of carotid sinus baroreceptors reduces BP in some forms of experimental hypertension.[26] In humans with hypertension resistant to drug treatment, electrical stimulation of baroreceptors also reduced BP.[26] These observations are consistent with the hypothesis that strong activation of baroreceptors can have long-term influences on BP. However, this finding does not necessarily imply that impaired baroreflexes actually *cause* chronic hypertension. The primary role of arterial baroreceptors in hypertension, as in normotension, appears to be buffering of rapid deviations in BP from the set-point determined by renal pressure natriuresis.

Obesity Causes Chronic SNS Activation

Excess weight gain appears to be a major cause of human primary hypertension, and one key mechanism that links obesity with increased BP is SNS activation.[10] Obese persons have elevated SNS activity in various tissues, including the kidneys.[10,22] Studies in experimental animals and humans indicate that combined α-and β-adrenergic blockade markedly attenuates obesity-associated hypertension.[10] Moreover, renal sympathetic efferent nerves mediate much of the chronic effects of SNS activation on BP in obesity, as bilateral renal denervation greatly attenuates sodium retention and hypertension in obese dogs.[10] Thus, obesity

increases renal sodium reabsorption, impairs pressure natriuresis, and causes hypertension in part by increasing RSNA. The mechanisms for SNS activation in obesity have not been fully-elucidated, as discussed in more detail later in this chapter.

The Renin–Angiotensin–Aldosterone System (RAAS)

The RAAS is perhaps the body's most powerful hormone system for regulating BP, as evidenced by the effectiveness of various RAAS blockers in treating hypertension. Although the RAAS has many components, its most important effects on BP are exerted by angiotensin II, a powerful vasoconstrictor that maintains BP in conditions associated with blood volume depletion, sodium depletion or circulatory depression e.g., heart failure. The long-term effects of angiotensin II on BP, however, are closely intertwined with volume homeostasis through direct and indirect effects on the kidneys.

Blockade of the RAAS, with angiotensin II receptor blockers ARBs, angiotensin converting enzyme ACE inhibitors or mineralocorticoid receptor MR antagonists, increases renal excretory capability so that sodium balance is maintained at reduced BP.[5,6] However, blockade of the RAAS also makes BP salt-sensitive.[16] Thus, effectiveness of RAAS blockers in lowering BP is greatly diminished by high salt intake; conversely, reducing sodium intake or addition of a diuretic improves effectiveness of RAAS blockers in reducing BP.

Inappropriately high levels of angiotensin II reduce renal excretory capability and impair pressure natriuresis, thereby necessitating increased BP to maintain sodium balance. The mechanisms that mediate the potent antinatriuretic effects of angiotensin II include direct and indirect effects to increase tubular reabsorption, as well as renal hemodynamic effects.[16]

Angiotensin II Stimulates Renal Sodium Reabsorption

Angiotensin II increases renal sodium reabsorption through stimulation of aldosterone secretion, by direct effects on epithelial transport, and by hemodynamic effects. Angiotensin II-mediated constriction of efferent arterioles reduces renal blood flow and peritubular capillary hydrostatic pressure, and increases peritubular colloid osmotic pressure as a result of increased filtration fraction.[16] These changes, in turn, increase the driving force for fluid reabsorption across tubular epithelial cells. Reductions in renal medullary blood flow caused by efferent arteriolar constriction or by direct effects of angiotensin II on the vasa recta may also enhance reabsorption in the loop of Henle and collecting ducts.[16]

Angiotensin II also directly stimulates tubular sodium reabsorption. This effect occurs at low angiotensin II concentrations, and is mediated by actions on the luminal and basolateral membranes.[16,27] In proximal tubules, angiotensin II stimulates the Na^+–H^+ exchanger on luminal membranes and increases sodium–potassium ATPase activity, as well as sodium bicarbonate co-transport on basolateral membranes[13,27] (Figure 39.7). These effects are partly mediated by inhibition of adenyl cyclase and increased phospholipase C activity.

Angiotensin II also stimulates sodium reabsorption in the loop of Henle, macula densa, and distal nephron segments. At physiologic concentrations, angiotensin II increases loop of Henle bicarbonate reabsorption and stimulates Na^+–K^+–2Cl transport in the medullary thick ascending loop of Henle.[5,16] In the distal parts of the nephron, angiotensin II stimulates multiple ion transporters, including H^+-ATPase activity, as well as epithelial sodium channel activity in the cortical collecting ducts.[5,16]

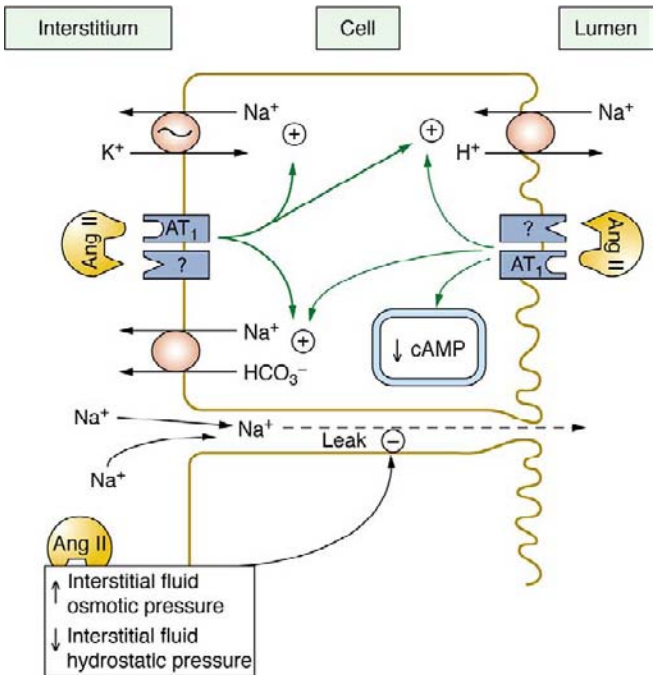

FIGURE 39.7 **Angiotensin II increases proximal tubular reabsorption by binding to receptors on the luminal and basolateral membranes and stimulating Na^+/H^+ antiporter, Na^+/HCO_3 co-transport, and Na^+/K^+ adenosine triphosphatase (ATPase) activity.** Angiotensin II also increases reabsorption by increasing interstitial fluid colloid osmotic pressure and decreasing interstitial fluid hydrostatic pressure.

Renal hemodynamic Effects of Angiotensin II

Angiotensin II is a powerful renal vasoconstrictor, but in most physiological conditions the constriction is confined mainly to postglomerular efferent arterioles. For example, efferent arteriolar constriction by angiotensin II acts in concert with other autoregulatory mechanisms, such as tubuloglomerular feedback (TGF) and myogenic activity, to prevent excessive reductions in GFR when kidney perfusion is threatened.[16] In these cases, administration of ARBs or ACE inhibitors may reduce GFR further, even though renal blood flow is preserved. Impairment of GFR after RAS blockade is caused, in part, by inhibition of the constrictor effects of angiotensin II on efferent arterioles, as well as reduced BP.[16]

The relatively weak constrictor action of angiotensin II on preglomerular vessels is due partly to protection of these vessels by autacoid mechanisms, such as prostaglandins or endothelial-derived nitric oxide NO.[16] When the ability of the kidney to produce these autacoids is impaired by treatment with nonsteroidal anti-inflammatory drugs (NSAIDS) or by chronic vascular disease (e.g., atherosclerosis) angiotensin II may reduce GFR by constricting afferent arterioles.

ANGIOTENSIN II MAY CONTRIBUTE TO GLOMERULAR INJURY IN OVERPERFUSED KIDNEYS

Although blockade of angiotensin II vasoconstrictor of efferent arterioles may cause a further decline of GFR in ischemic nephrons, RAAS blockade may be beneficial when nephrons are hyperfiltering, especially if angiotensin II is not appropriately suppressed. For example, in diabetes mellitus and in certain forms of hypertension associated with glomerulosclerosis and nephron loss, angiotensin II blockade, by decreasing efferent arteriolar resistance and BP, lowers glomerular hydrostatic pressure and attenuates glomerular hyperfiltration.[16] Thus, RAAS blockers are more effective than other antihypertensive agents in preventing glomerular injury, even with similar reductions in BP.[28,29]

DOES ANGIOTENSIN II CAUSE TARGET ORGAN INJURY INDEPENDENT OF INCREASED BP?

Angiotensin II has been suggested to cause injury to the kidneys and other organs through direct actions, in addition to its hemodynamic effects. Although RAAS blockers may provide greater renal protection than other antihypertensive drugs, decreases in glomerular hydrostatic pressure because of efferent arteriolar vasodilation may have contributed to these beneficial effects. In studies where BP was measured accurately, using 24-hour telemetry, the renal protective effects of angiotensin II blockade appeared to be largely a result of reduced BP.[30]

An observation that is difficult to reconcile with the concept that ANG II directly mediates target organ injury, independent of BP, is the finding that physiologic activation of the RAAS is not associated with vascular or renal injury as long as the BP is not elevated. For example, sodium depletion does not cause renal, cardiac or vascular injury, despite marked increases in renal angiotensin II levels. Also, the clipped kidney in 2-kidney, 1-clip Goldblatt hypertension is exposed to high angiotensin II levels, but is protected from increased BP by the clip on the renal artery and has no visible injury as long as the stenosis is not too severe. However, the nonclipped kidney, exposed to lower angiotensin II concentrations but higher BP, has marked focal segmental glomerular sclerosis, as well as tubulointerstitial changes characteristic of hypertension.[31]

Convincing evidence in this controversial area of research comes from the observations of Coffman and colleagues who studied the effects of chronic angiotensin II infusion in normal wild-type mice, in wild-type mice that received transplanted kidneys from AT1 receptor knockout mice, and in AT1 receptor knockout mice that received transplanted kidneys from normal wild-type mice.[32] Chronic angiotensin II infusion in normal wild-type mice increased BP and caused cardiac hypertrophy and fibrosis. However, in wild-type mice that received transplanted kidneys from AT1 receptor knockout mice (i.e., AT1 receptors were present in the heart and other organs, but not in the kidneys), angiotensin II infusion did not chronically raise BP or cause cardiac hypertrophy and fibrosis. In AT1 receptor knockout mice that received transplanted kidneys from normal wild-type mice (i.e., AT1 receptors were present only in the kidneys and not in the heart or other organs), angiotensin II infusion caused chronic hypertension, as well as cardiac hypertrophy and fibrosis.[32] These observations indicate that: 1) the renal effects of angiotensin II, and not the peripheral vascular or other non-renal effects, mediate chronic increases in BP; and 2) in the absence of hypertension, angiotensin II does not cause cardiac hypertrophy or fibrosis. Thus, the hemodynamic effects appear to account for most of the target organ injury that occurs in angiotensin II-dependent hypertension, and the effects of angiotensin II to raise BP are due to its renal actions, not to extrarenal effects, such as peripheral vasoconstriction or central nervous system effects.

Aldosterone

Aldosterone is also a powerful sodium-retaining hormone, and consequently has important effects on renal pressure natriuresis and BP regulation. The

primary sites of actions of aldosterone on sodium reabsorption are the principal cells of the distal tubules, cortical collecting tubules, and collecting ducts where aldosterone stimulates sodium reabsorption and potassium secretion. Aldosterone binds to intracellular mineralocorticoid receptors (MRs) and activates transcription by target genes which, in turn, stimulate synthesis or activation of the Na^+—K^+-ATPase pump on the basolateral epithelial membrane and activation of amiloride-sensitive sodium channels on the luminal epithelial membrane.[33] These effects are termed *genomic*, because they are mediated by gene transcription and require 60—90 minutes to occur after aldosterone administration.

Aldosterone also exerts rapid *nongenomic* effects on the cardiovascular and renal systems.[33] Aldosterone increases the sodium current in principal cells of the cortical collecting tubule through activation of the amiloride-sensitive channel, and stimulates the Na^+—H^+ exchanger a few minutes after application.[33] In vascular smooth muscle cells, aldosterone stimulates sodium influx by activating the Na^+—H^+ exchanger in less than 4 minutes. Acute aldosterone administration may rapidly reduce forearm blood flow in humans, although some investigators have found no change or an increase in blood flow.[33] The putative membrane receptor and the cell-signaling mechanisms responsible for these rapid actions of aldosterone have not been identified, especially with physiologic levels of aldosterone. Thus, the importance of the nongenomic effects of aldosterone on long-term regulation of BP is still unclear.

The overall effects of aldosterone on pressure natriuresis are similar to those observed for angiotensin II. With low sodium intake, increased aldosterone helps prevent sodium loss and reductions in BP. Conversely, during high sodium intake, suppression of aldosterone prevents excessive sodium retention and attenuates increased BP. Excess aldosterone secretion reduces the slope of pressure natriuresis so that BP becomes salt-sensitive. Consequently, increasing plasma aldosterone six-to ten-fold causes marked hypertension when sodium intake is normal or elevated, but there is very little effect on BP when sodium intake is low.[5]

The role of aldosterone and MR activation in human hypertension is a topic of renewed interest in recent years. Hyperaldosteronism may be more common than previously believed, especially in patients with hypertension that are resistant to treatment with the usual antihypertensive medications. For example, the prevalence of primary aldosteronism is reported to be almost 20% among patients referred to specialty clinics for resistant hypertension. Many of these patients, however, are overweight or obese.[34]

There is also emerging evidence that MR antagonism may provide an important therapeutic tool for reducing BP and preventing target organ injury in hypertension[34]; for example, antagonism of MR attenuated sodium retention, hypertension, and glomerular hyperfiltration in obese dogs fed a high-fat diet even though plasma aldosterone concentration was only slightly elevated.[35] However, even mild increases of plasma aldosterone may increase BP when accompanied by high sodium intake and volume-expansion, because aldosterone greatly enhances salt-sensitivity of BP.

In obese, insulin-resistant patients there may be enhanced sensitivity to the effects of aldosterone because of increased abundance of epithelial sodium channels ENaCs, which would amplify the effects of MR activation on sodium reabsorption and BP. It is also possible that glucocorticoids may contribute to MR activation in obese, insulin-resistant patients.

Endothelin

Endothelin-1 ET-1 is derived from a 203 amino acid peptide precursor, preproendothelin, which is cleaved after translation to form proendothelin. A converting enzyme cleaves proendothelin to produce the 21 amino acid peptide, endothelin. ET-1 receptor-binding sites have been identified throughout the body, with the greatest numbers of receptors in the kidneys and lungs.[36,37] ET-1 can either elicit a hypertensive effect by activating endothelin type A (ET_A) receptors or an antihypertensive effect via endothelin type B (ET_B) receptor activation in the kidneys.[36,37] Thus, the ability of ET-1 to influence BP regulation is highly dependent on where ET-1 is produced, and which ET receptor type is activated (Figure 39.8).

ET-1 Elicits a Hypertensive Effect by Activating ET_A Receptors in the Kidneys

Endothelin-1 produces renal and systemic vasoconstriction, impairs renal pressure natriuresis, and increases BP via ET_A receptor activation.[36,37] ET-1 exerts multiple actions via ET_A receptor activation that, if sustained chronically, could contribute to the development of hypertension and progressive renal injury. ET-1 decreases GFR and renal plasma flow through stimulation of vascular smooth muscle and mesangial cell contraction.[36,37] Long-term effects of ET-1 on the kidneys include stimulation of mesangial cell proliferation and extracellular matrix deposition, as well as vascular smooth muscle hypertrophy in renal resistance vessels.[36,37] Expression of ET-1 is greatly enhanced in several animal models of severe hypertension with renal vascular hypertrophy, and in models of

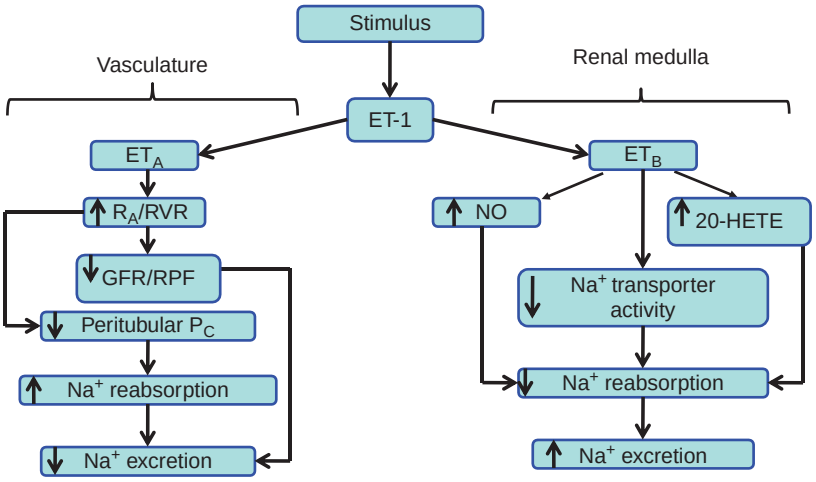

FIGURE 39.8 **Summary of the pro- and antihypertensive actions of endothelin-1 (ET-1).** The ability of ET-1 to influence blood pressure and renal pressure natriuresis is highly dependent on where ET-1 is produced, and which renal ET receptor type is activated. ET-1 can elicit a prohypertensive anti-natriuretic effect by activating ET_A receptors in the kidneys. Activation of renal ET_A receptors increases renal vascular resistance (RVR), which decreases renal plasma flow (RPF) and glomerular filtration rate (GFR), and enhances sodium reabsorption by decreasing peritubular capillary hydrostatic pressure (Pc). The net effect of renal ET_A receptor activation is decreased sodium excretion and increased BP. Conversely, ET-1 can elicit an antihypertensive natriuretic effect via ET_B receptor activation. Activation of the renal ET_B receptor leads to enhanced synthesis of nitric oxide (NO) and 20-HETE, and suppression of the renin–angiotensin system. The net effect of renal ET_B receptor activation is increased sodium excretion and decreased BP.

progressive renal injury.[36,37] Treatment with endothelin receptor antagonists attenuated the hypertension and small artery morphologic changes, and improved kidney function in these models.[36,37]

ET-1 Elicits an Antihypertensive Effect by Activating ET_B Receptors in the Kidneys

ET_B receptor activation by ET-1 causes vasodilation, enhances renal pressure natriuresis, and decreases BP. While much attention has been given to ET_A receptor activation, several studies indicate an important antihypertensive role for ET_B receptor.[37] The most compelling evidence comes from reports that transgenic mice deficient in ET_B receptors develop salt-sensitive hypertension, and that pharmacologic antagonism of ET_B receptors produces hypertension in rats.[36–38]

Because ET_B receptors are located on multiple cell types throughout the body, including endothelial cells and renal epithelial cells, both intrarenal and extrarenal mechanisms could theoretically mediate the hypertension produced by chronic disruption of ET_B receptors. Bagnall et al. reported that ablation of ET_B receptors exclusively from endothelial cells produced endothelial dysfunction, but did not cause hypertension.[39] In contrast to models of total ET_B receptor ablation, the BP response to a high-salt diet was unchanged in endothelial cell-specific $ET_A/_B$ receptor knockouts compared to control mice.[37,40,41] These findings suggest that ET_B receptors in non-endothelial cells are important for BP regulation. Supporting this concept are the findings that collecting duct ET_B knockout mice on a normal-sodium diet were hypertensive and a high-sodium diet worsened the hypertension.[40,41] Moreover, collecting duct ET_B knockout mice on a normal-sodium diet were hypertensive, and a high-sodium diet worsened the hypertension.[37,40,41] These findings provide strong evidence that the intrarenal effect of ET_B receptor activation on the collecting duct is an important physiologic regulator that increases renal sodium excretion and reduces BP.

ET-1 Plays an Important Role in Experimental Salt-Sensitive Hypertension

Dahl salt-sensitive (DS) rats placed on a high-sodium diet have impaired pressure natriuresis and develop hypertension and progressive renal injury. ET-1, acting via an ET_A receptor, may play a role in mediating renal injury in DS hypertension. Prepro-ET-1 mRNA and vascular responsiveness to ET-1 are increased in the renal cortex of DS rats compared with Dahl salt-resistant (DR) rats, and a positive correlation between ET-1 generation in the renal cortex and the extent of glomerulosclerosis has been reported in DS hypertensive rats.[42] Acute infusion of a nonselective ET_A-ET_B receptor antagonist directly into the renal interstitium improved renal hemodynamic and excretory function in DS rats, but not in DR rats.[43] Moreover, chronic blockade of ET_A receptors attenuated hypertension and proteinuria, and ameliorated glomerular and tubular damage associated with high-salt intake in DS rats. An important unanswered question is whether these beneficial effects of ET_A blockade

are mediated through lower BP or through direct renal mechanisms.

Role of Endothelin in Human Hypertension

Bosentan, a combined ET_A-ET_B receptor antagonist, lowered BP in a large, double-blind, clinical trial, indicating that the endothelin system helps maintain BP in human hypertension.[44,45] However, the magnitude of the BP reduction by bosentan was almost the same as that observed in normotensive humans. This observation suggests that endothelin probably may not play a major role in raising BP in most patients with essential hypertension, although bosentan blocks both ET_A and ET_B receptors and antagonism of the antihypertensive ET_B receptor may have masked an important role of endothelin on BP via ET_A receptor activation. In another study, six weeks of darusentan, a selective ET_A receptor antagonist, lowered systolic and diastolic BP.[44] Bakris et al.[46] and Weber et al.[47] also showed that darusentan reduced mean 24 hour systolic BP more than placebo in patients with treatment-resistant hypertension. There are currently no clinical studies that directly compare selective and mixed ET receptor antagonism in the treatment of hypertension, although both approaches clearly reduce BP. Moreover, clinical studies examining the effect of selective ET_A receptor antagonism in humans with salt-sensitive hypertension are lacking. Therefore, the importance of ET-1 in human essential hypertension deserves further investigation.[37,45]

Nitric Oxide

Release of nitric oxide NO by the vascular endothelium and renal tubular cells plays a major role in regulating renal hemodynamics and tubular function.[48–50] Long-term inhibition of NO synthase causes impaired renal pressure natriuresis and sustained hypertension.[48–50] The renal mechanisms whereby reduction in NO synthesis impairs pressure natriuresis can be divided into hemodynamic and tubular components, each of which may be modulated by processes that are intrinsic or extrinsic to the kidneys Figure 39.9. For example, reduced NO synthesis may decrease renal sodium excretory function by increasing renal vascular resistance directly or by enhancing responsiveness to vasoconstrictors such as angiotensin II or norepinephrine.[49,50] Reductions in NO synthesis also increase renal sodium reabsorption via direct effects on tubular transport, and through changes in intrarenal physical factors, such as renal interstitial hydrostatic pressure (RIHP) and medullary blood flow. Inhibition of NO synthesis reduces RIHP and urinary sodium excretion.[49,50] Stimulation of NO production normalizes the blunted pressure natriuretic response in DS rats as a result of improvement in the kidney's ability to generate increased RIHP in response to increased BP.[49,50]

Impaired NO Production Produces Salt-Sensitive Hypertension

Increased renal NO production, as evidenced by increased urinary excretion of NO metabolites or the NO second messenger, cyclic guanosine mono-phosphate, has been reported to be essential for the maintenance of normotension during a dietary salt challenge. Prevention of this increase in renal NO production resulted in salt-sensitive hypertension.[48–51]

There is also evidence that NO-induced vasodilation is impaired in many models of hypertension, and in some vascular beds in human essential hypertension.[52,53] The extent to which these effects are secondary to hypertension or reflect important mechanisms for the etiology of hypertension remains unclear. NO activity does not increase with increasing dietary salt-loading in the Dahl salt-sensitive DS hypertensive rats as it does in normotensive Dahl salt-resistant DR rats; furthermore, chronic administration of L-arginine prevents hypertension during dietary salt-loading in the DS rat, but has no effect on BP in DR rats.[54] We have shown that injections of L-arginine will prevent the development of hypertension in DS rats, even during prolonged exposure to an 8% sodium diet.[49,50] This is

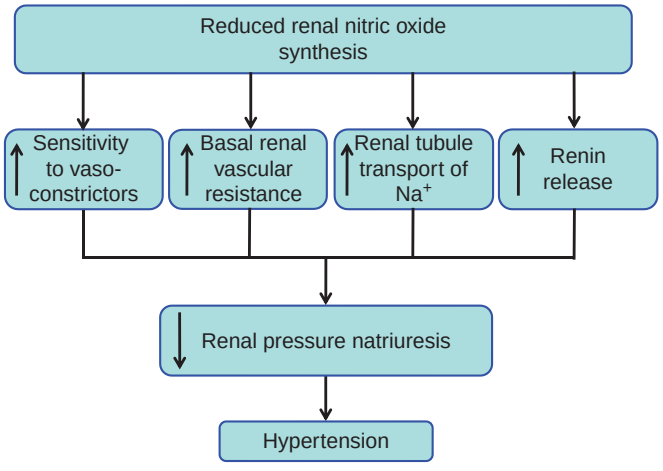

FIGURE 39.9 **Renal mechanisms whereby reduced nitric oxide (NO) synthesis decreases pressure natriuresis and increases BP.** Decreased endothelial-derived nitric oxide (EDNO) synthesis impairs renal sodium excretory function by increasing basal renal vascular resistance, enhancing the renal vascular responsiveness to vasoconstrictors such as angiotensin II or norepinephrine, or activating the renin–angiotensin system. Reductions in NO synthesis also impair sodium excretory function, either by directly increasing tubular reabsorption or by altering intrarenal physical factors, such as renal interstitial hydrostatic pressure or medullary blood flow.

not the case in all models of hypertension, even when individual tissues from these animals show impaired NO responses. Thus, in 2-kidney, 1-clip renovascular hypertension, inhibitors of NO synthesis result in an exaggerated increase in BP and vascular resistance compared to normotensive rats, but L-arginine does not prevent hypertension. Similarly, in the DOCA salt-hypertensive model, L-arginine administration improves agonist-induced NO release, but has no effect on BP.[48–50]

Because of the central role of the kidney in sustaining changes in BP, it is reasonable to postulate that the long-term increases in BP induced by inhibition of NO synthase in normal animals, as well as the reduction in blood pressure induced by NO agonists in DS rat, should be associated with changes in the relationship between renal perfusion pressure and urinary sodium excretion. This has been confirmed in several studies.[48–50] In normal animals, the acute intrarenal administration of the NO synthesis inhibitor NG nitro L-arginine methyl ester L-NAME significantly reduces the natriuresis and diuresis usually induced by increases in renal perfusion pressure. Chronic NO synthase inhibition also blunts the chronic renal function curve measured during changes in sodium intake.[48–50] Stimulation of NO production by L-arginine supplementation has also been reported to alter BP and enhance renal pressure natriuresis. Chronic L-arginine supplementation in DS rats maintained on a high-sodium diet normalizes the blunted pressure natriuresis relationship which usually characterizes these hypertensive-prone animals.[48–50,54] Thus, alterations in NO production or release can have important effects on renal pressure natriuresis.

Role of NO in Human Hypertension

There is also evidence that NO synthesis is impaired in vascular beds in human primary hypertension.[52] The extent to which these changes are secondary to increased BP or reflect important mechanisms for the pathogenesis of hypertension, however, remains unclear. NO deficiency can occur by multiple mechanisms, including altered NOS enzyme expression, NO scavenging or NOS enzyme inhibition by endogenous inhibitors. Recent studies have implicated the endogenous NO synthase inhibitor asymmetric dimethylarginine ADMA in the pathogenesis of hypertension.[55,56] While there is a strong correlation between ADMA levels and severe cardiovascular events and mortality, only a few clinical studies have shown a relationship between high BP and high plasma ADMA concentrations.[55,56] However, when hypertension and renal disease are present, increased plasma ADMA is observed. Thus, it appears that the observed increase in ADMA during hypertension may be secondary to chronic kidney disease.[52,54–56]

Oxidative Stress

Recent studies suggest that reactive oxygen species (ROS) may play a role in the initiation and progression of cardiovascular dysfunction associated with hypertension.[57–59] In many forms of hypertension, increased ROS appear to be derived mainly from nicotinamide adenine dinucleotide phosphate (NADPH) oxidases, which could serve as a trigger for uncoupling endothelial nitrous oxide synthase NOS by oxidants. Four members of the NADPH oxidase Nox enzyme family have been identified as important sources of ROS in the vasculature: Nox1, Nox2, Nox4, and Nox5.[57,59] Multiple factors control the expression and activity of these enzymes and of their regulatory subunits, such as p22phox, p47phox, Noxa1, and p67phox.[57,59] Several physical, hormonal, and local autocoid factors are known to be important stimuli for the production of ROS. For example angiotensin II, aldosterone, ET-1, and sodium intake all enhance production of ROS.[57,59] Moreover, BP-induced endothelial damage is also associated with increased production of ROS. Thus, in many forms of hypertension, the elevation in ROS production may be secondary to the increased BP.

ROS produced by migrating inflammatory cells and/or vascular cells cause endothelial dysfunction, increased renal tubule sodium transport, cell growth and migration, inflammatory gene expression, and stimulation of extracellular matrix formation.[57,59] ROS, by affecting vascular and renal tubule function, can also impair renal pressure natriuresis, alter systemic hemodynamics, and raise BP[60–62] (Figure 39.10).

There is growing evidence that supports a role for ROS in various animal models of hypertension, especially salt-sensitive models.[60–62] The DS rat, for example, has increased vascular and renal superoxide production, and increased levels of H_2O_2. Renal expression of superoxide dismutase is decreased in the kidneys of DS rats, and long-term administration of Tempol, a superoxide dismutase mimetic, significantly decreases BP and attenuates renal damage.[62] Another salt-sensitive model, the stroke-prone SHR, has elevated levels of superoxide and decreased plasma antioxidant capacity.[60–62] Superoxide production is also increased in the deoxycorticosterone acetate (DOCA)-salt hypertensive rat, and treatment with apocynin, a nicotinamide adenine dinucleotide phosphate NADPH oxidase inhibitor, decreases BP.[60–62] ROS also appears to play an important role in chronic angiotensin II hypertension. Angiotensin II is a potent stimulator of

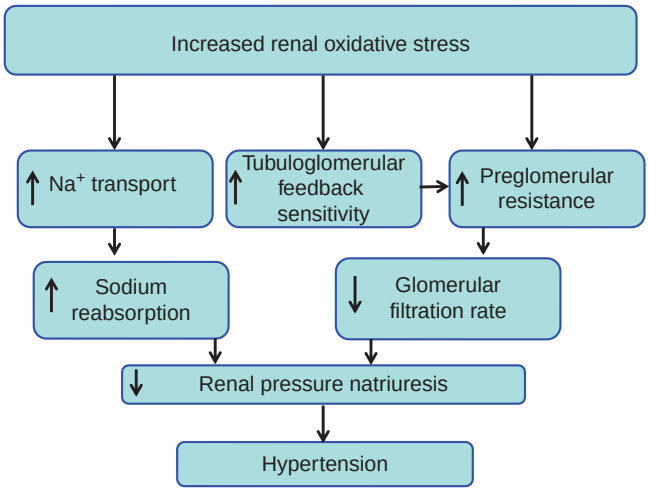

FIGURE 39.10 **Renal mechanisms whereby ROS impair pressure natriuresis and increase BP.** An increase in renal oxidative stress impairs renal pressure natriuresis by increasing renal vascular resistance or enhancing tubuloglomerular feedback, both of which decrease the glomerular filtration rate. Renal oxidative stress also reduces sodium excretion by direct effects to increase renal tubular reabsorption.

NADPH oxidase, and long-term administration of Tempol significantly decreases the chronic BP response to angiotensin II.[60–62]

Despite the fact that elevated ROS plays an important role in many experimental models of hypertension, antioxidant therapy has failed to lower BP in clinical studies.[63] An imbalance between total oxidant production and the antioxidant capacity in human primary hypertension has been reported to occur in some, but not all, studies. Equivocal findings in humans are partly due to the difficulty of assessing oxidative stress in clinical studies. Measurement of ROS in tissues represents a challenge, because of their low levels and relatively short half-lives.[64] Most human studies have found that chronic antioxidant therapy with vitamin E and C supplementation has little effect on BP. However, a major shortcoming of clinical trials using vitamin E and C is the lack of verification that antioxidant treatment actually decreased ROS.[63]

Inflammatory Cytokines and the Immune System

While inflammation and the immune system activation were first associated with hypertension over four decades ago, it has become increasingly evident over the last few years that inflammatory cytokines and the immune system play an important role in the progression of various models of experimental and genetic hypertension.[65–68]

Increased Inflammatory Cytokines in Hypertension

Plasma levels of proinflammatory cytokines correlate with increased BP in human hypertension, and in some experimental animal models of hypertension.[65,67] Moreover, several studies have demonstrated that chronic increases in plasma cytokines, comparable to concentrations observed in hypertension associated with pre-eclampsia, cause significant increases in BP.[69,70] A two-fold elevation in the plasma levels of Tumor Necrosis Factor alpha (TNF-α) significantly increased BP and renal vascular resistance in pregnant rats.[69,70] These studies are consistent with the hypothesis that increasing plasma levels of cytokines may contribute to pregnancy-induced hypertension. Etanercept, a selective TNF-α inhibitor, was not only effective in lowering BP, but also in dampening the ET-1 transcript that is typically observed in response to placental ischemia in pregnant rats.[69,70] Whether etanercept and other cytokine inhibitors would have beneficial effects in pre-eclamptic women remains unknown, because elevated levels of cytokines and exaggerated inflammatory responses have been reported in some studies.

Lee and co-workers[71] found that hypertension caused by chronic angiotensin II excess may depend, at least in part, on the presence of Interleukin-6 (IL-6). Mice with knockout of IL-6 had significantly lower BP than wild-type mice during two weeks of angiotensin II infusion. Although these findings demonstrate a significant role for IL-6 in mediating the chronic hypertensive response to angiotensin II in mice, the importance of inflammatory cytokines in the pathogenesis and progression of the various forms of human hypertension is unclear, and is currently an area of active investigation.

Several recent studies have demonstrated that T-cells play an important role in the progression of hypertension. Harrison and colleagues proposed that hypertensive stimuli lead to renal injury, neoantigen formation, and eventual T-cell activation within the kidney.[67,68,72] T-cell-derived signals promote entry of other inflammatory cells such as macrophages, which result in renal vasoconstriction and increased sodium reabsorption, thereby increasing the severity of the hypertension.[68] Supporting this concept is a recent report that RAG-$1^{-/-}$ mice, which lack T-cells and B-cells, do not develop the degree of hypertension in response to angiotensin II infusion as the wild-type mice, an observation that was attributed to lack of T-cells. Moreover, chronic angiotensin II infusion was associated with a greater number of activated T-cells, as well as increased Rantes, a chemotaxic protein, in the vasculature and perivascular fat.[67,68,72] These observations were confirmed by Crowley et al.[73] using a model very similar to the RAG-$1^{-/-}$ mice. They reported that angiotensin II hypertension, renal injury,

left ventricular hypertrophy, and cardiac fibrosis were prevented in mice lacking T-cells. While these findings in experimental models of hypertension are intriguing, the importance of the immune system in the pathogenesis of essential hypertension in humans remains to be determined.

Eicosanoids

The kidneys produce several types of prostaglandins with multiple functions, including prostacyclin, thromboxane, 20-hydroxyeicosatetraenoic acid 20-HETE, and epoxyeicosatetraenoic acids (EETs), all of which have been reported to influence renal pressure natriuresis and BP. However, the major renal prostaglandin controlling sodium excretion is probably PGE_2.[74] The largest production of PGE_2 occurs in the renal medulla, with decreasing synthesis in the cortex. PGE_2 is synthesized and released, not stored. Once released, PGE_2 inhibits sodium reabsorption by several mechanisms, including direct effects on the renal tubules.

Even though long-term administration of PG synthesis inhibitors has very little effect on volume and/or BP regulation under normal physiologic conditions, renal PGs may be important in pathophysiologic states associated with enhanced activity of the RAAS. *In vitro* and *in vivo* studies indicate that renal PGs protect the preglomerular vessels from excessive angiotensin II-induced vasoconstriction. In the absence of this protective mechanism, the renal vasculature could be exposed to the potent vasoconstrictor actions of angiotensin II in various conditions, such as sodium and volume depletion. This could, in turn, lead to significant impairment of renal hemodynamics and excretory function.

Inhibitors of the COX-2 enzyme reduce pressure natriuresis, cause vasoconstriction, and increase BP.[74–76] There are at least two distinct cyclooxygenases—COX-1 and COX-2. COX-1 is called the *constitutive enzyme*, because of its wide tissue distribution, whereas COX-2 has been termed as *inducible*, because of its more restricted basal expression and its upregulation by inflammatory and/or proliferative stimuli. Based on the concept that COX-1 performs cellular housekeeping functions for normal physiologic activity and COX-2 acts at inflammatory sites, it was initially hypothesized that the BP and renal effects of nonsteroidal anti-inflammatory drugs might be linked to COX-1 inhibition.[74] However, experimental and clinical evidence indicates that COX-2 metabolites may also play a role in the regulation of vascular and renal function under various physiologic and pathophysiologic conditions.[74–76]

Selective COX-2 inhibitors were designed to minimize gastrointestinal complications of traditional NSAIDs—adverse effects attributed to suppression of COX-1-derived PGE_2 and prostacyclin. However, randomized controlled clinical trials of inhibitors of COX-2 indicate that such compounds may elevate the risk of hypertension, myocardial infarction, and stroke, possibly by removing the protective action of prostacyclin in counteracting thrombogenesis, hypertension, and atherogenesis.[75,76]

Eicosanoids produced by cytochrome P450 monooxygenase metabolism of arachidonic acid alter vascular function and renal pressure natriuresis. In addition to the PGs generated via the COX pathway, other eicosanoids that affect vascular function and/or renal sodium transport are produced by cytochrome P450 CYP monooxygenase metabolism of arachidonic acid. CYP enzymes metabolize arachidonic acid primarily to 20-HETE and EETs. 20-HETE is a potent vasoconstrictor that may regulate vascular tone and contribute to the autoregulation of renal blood flow. 20-HETE also inhibits sodium reabsorption in the proximal tubule and thick ascending limb of the loop of Henle.[77,78] Therefore, the ability of 20-HETE to influence BP regulation and renal pressure natriuresis is highly dependent on where 20-HETE is produced. The effect of 20-HETE to inhibit sodium transport tends to lower BP, whereas its vasoconstrictor effects on the renal vasculature and glomerulus tend to lower glomerular filtration rate, promote sodium retention, and increase BP (Figure 39.11).

Compelling evidence suggests that the renal production of CYP metabolites of arachidonic acid is altered in genetic and experimental models of hypertension, and contributes to the resetting of pressure natriuresis and increased BP.[77,78] Studies in humans also suggest that CYP metabolites may play a role in sodium homeostasis. Urinary 20-HETE excretion is regulated by salt intake, and is differentially regulated in salt-sensitive versus salt-resistant individuals.[79,80] Moreover, there appears to be a strong negative relationship between 20-HETE excretion and body mass index BMI, suggesting that some factor related to obesity may be responsible for decreased synthesis or excretion of this eicosanoid.[79,80] These observations support the possibility that attenuated renal production of 20-HETE could impair pressure natriuresis in human hypertension, especially when associated with obesity. However, further mechanistic studies are needed to test the importance of 20-HETE in human hypertension.

Atrial Natriuretic Peptide (ANP)

ANP is a 28 amino acid peptide synthesized and released from atrial cardiocytes in response to stretch.

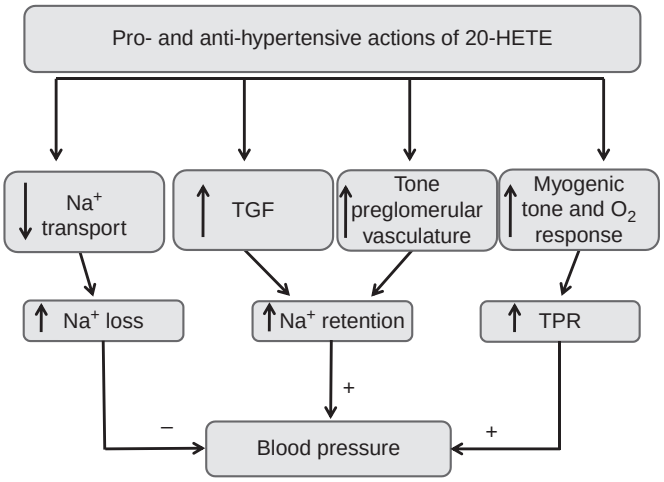

FIGURE 39.11 **Summary of the pro- and antihypertensive actions of 20-HETE. 20-HETE produced in the renal tubules which inhibits sodium transport and lowers BP.** In the renal vasculature and glomerulus, 20-HETE is a constrictor that lowers glomerular filtration rate, promotes sodium retention, and increases BP. In the peripheral circulation, 20-HETE increases vascular tone and increases BP (TGF: tubuloglomerular feedback; TPR: total peripheral resistance).

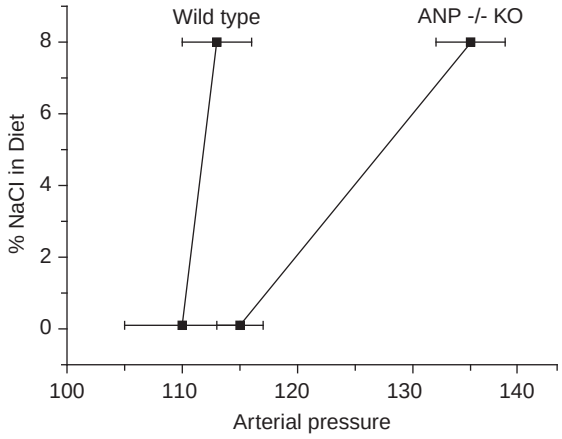

FIGURE 39.12 **Effect of atrial natriuretic peptide (ANP) receptor knockout on the chronic pressure natriuresis relationship.**[83]

ANP reduces vascular resistance, while enhancing sodium excretion through extrarenal and intrarenal mechanisms. ANP increases GFR, but has little effect on renal blood flow. However, an increase in GFR is not a prerequisite for ANP to enhance sodium excretion. ANP may also inhibit renal tubular sodium reabsorption directly by inhibiting active tubular sodium transport or indirectly via alterations in medullary blood flow, physical factors, and inhibiting formation of antinatriurectic hormones such as angiotensin II and aldosterone.

Plasma levels of ANP are elevated in numerous physiologic conditions associated with enhanced sodium excretion. Acute blood volume expansion consistently elevates circulating ANP. Some investigators report that chronic increases in dietary sodium intake also raise circulating levels of ANP.[81] Infusions of exogenous ANP at rates that result in physiologically relevant plasma concentrations, comparable to those observed during volume-expansion, elicit significant natriuresis, especially in the presence of other natriuretic stimuli, such as high renal perfusion pressure. Long-term physiologic elevations in plasma ANP also enhance pressure natriuresis and reduce BP.[82]

Transgenic mice overexpressing ANP are hypotensive relative to their wild-type littermates, whereas mice harboring functional disruptions of the ANP or NPR-A genes are hypertensive.[81,83] ANP gene knockout mice develop a salt-sensitive form of hypertension (Figure 39.12) in association with failure to adequately suppress the RAAS.[83] While these findings suggest that genetic deficiencies in ANP or its receptors could play a role in the pathogenesis of salt-sensitive hypertension, the importance of this system in the pathogenesis of human hypertension remains unclear.

PRIMARY ESSENTIAL HYPERTENSION

Human primary essential hypertension appears to be largely a modern disorder associated with industrialization and the ready availability of food. Nearly all studies of Westernized, industrialized populations have demonstrated that BP, and therefore the prevalence of hypertension, rises with age.[84] Hunter-gatherers living in non-industrialized societies, however, rarely develop hypertension or age-related increases in systolic and mean pressures.[84] Thus, environmental factors appear to play a major role in raising BP in most patients with primary hypertension. However, it is likely that genetic variation contributes to differences in baseline BP that result in the normal distribution of BP in a population. When hypertension-producing environmental factors are added to the population baseline BP, the normal distribution is shifted toward higher BP; variations in the impact of environmental factors appear to flatten the BP curve and cause greater variability in BP of the population.

What elements of industrialized societies cause BP to increase in the majority of people as they age? How do they affect the physiologic controllers of BP? One factor that is clearly important is resetting of renal pressure natriuresis to higher BPs.[10] In some cases, this resetting may be related to increased renal sodium reabsorption, because of abnormalities intrinsic to the kidneys or altered neurohumoral control of the

kidneys.[10] In other instances, resetting of pressure natriuresis may be associated with renal vasoconstriction and reductions in GFR, as a result of intrarenal mechanisms or nervous and hormonal mechanisms.[10] However, many of these initial changes in kidney function are difficult to discern after hypertension is established, because increased BP often returns renal function to normal. Experimental, clinical, and population studies suggest one of the key factors that affect BP is excess weight gain.

Overweight and Obesity are Major Risk Factors for Primary Hypertension

The prevalence of obesity has risen dramatically in the past 2–3 decades, and is now the most important public health problem in many industrialized countries, including the United States. Current estimates indicate that more than 1 *billion* people in the world are overweight or obese.[85] In the United States, more than 65% of adults are overweight, and one-third of the adult population is obese with a BMI greater than 30.[86] Population studies show that the relationship between BMI and systolic and diastolic BP is nearly linear in diverse populations throughout the world. Risk estimates from the Framingham Heart Study, for example, suggest that approximately 78% of primary hypertension in men and 65% in women can be ascribed to excess weight gain.[87] Clinical studies also indicate that weight loss is effective in reducing BP in most hypertensive subjects, and that weight loss, if it can be achieved, is effective in primary prevention of hypertension.[88]

If excess weight gain is a major cause of hypertension, why are some obese persons not hypertensive (i.e., BP greater than 140/90 mmHg)? Perhaps this is not so surprising if one considers that excess weight gain shifts the normal frequency distribution of BP toward higher levels. Although obesity increases the probability that a person's BP will register in the hypertensive range, not all obese people will have BPs greater than 140/90 mmHg. However, obese individuals who are classified as "normotensive" have higher BP than they would at a lower body weight. Thus, weight loss lowers BP in "normotensive" as well as "hypertensive" obese subjects.[5] Although the importance of obesity as a cause of hypertension is well-established, the physiologic mechanisms by which excess weight gain alters renal function and raises BP are only beginning to be elucidated.

Obesity is associated with extracellular fluid volume expansion, as well as increased tissue blood flow and cardiac output.[10] Studies in experimental animals and in humans indicate that blood flow is increased in many tissues, including the heart, kidneys, gastrointestinal tract, and skeletal muscles.[10] Some of the increased flow is caused by growth of skeletal muscle and organs in response to increased workload and the metabolic demands associated with obesity. However, obesity also causes functional vasodilation, perhaps as a consequence of an increased metabolic rate, higher oxygen consumption, and accumulation of vasodilator metabolites. This vasodilation occurs despite mild activation of the RAAS and SNS. Although resting blood flows are increased in many tissues, there appears to be reduced blood flow "reserve" during exercise or during reactive hyperemia in obese, compared to lean, individuals.[10] Cardiac reserve is also reduced in obesity, despite higher resting cardiac outputs.

Increased renal tubular sodium reabsorption and impaired pressure natriuresis play a major role in initiating the rise in BP associated with excess weight gain. At least three mechanisms are important in altering renal function in obesity hypertension (Figure 39.13): 1) increased SNS activity; 2) activation of the RAAS; and 3) physical compression of the kidneys by fat accumulation within and around the kidneys, and by increased abdominal pressure.

SNS Activation in Obesity Hypertension

Several observations indicate that increased SNS activity contributes to obesity hypertension[10]: 1) SNS activation, especially renal sympathetic activity, is increased in obese subjects; 2) pharmacologic blockade of adrenergic activity lowers BP to a greater extent in obese, compared to lean, individuals; and 3) renal denervation markedly attenuates sodium retention and hypertension associated with a high-fat diet in experimental animals.

Administration of α-and β-adrenergic blockers or clonidine, a drug that stimulates central α-2 receptors and reduces SNS activity, prevents most of the rise in BP in obese dogs fed a high-fat diet.[10,89] In obese hypertensive patients, combined α-and β-adrenergic blockade for one month reduced ambulatory BP significantly more in obese than in lean essential hypertensive patients.[10] These findings suggest that increased adrenergic activity contributes importantly to the development and maintenance of obesity hypertension in experimental animals and in humans.[10,89] The renal sympathetic nerves mediate most, if not all, of the chronic effects of SNS activation on BP in obesity. Bilateral renal denervation greatly attenuated sodium retention and hypertension in obese dogs fed a high-fat diet.[10]

Obesity does not cause mass activation of the SNS. Instead, increased SNS activity in various tissues is modest, and appears to be differentially controlled in obesity. For example, cardiac sympathetic activity does

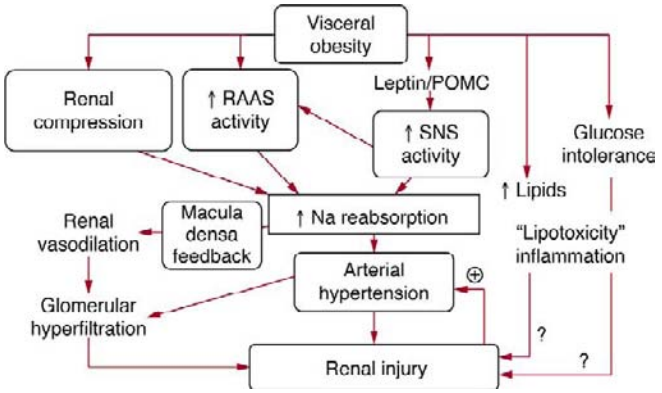

FIGURE 39.13 **Summary of mechanisms by which obesity causes hypertension and renal injury.** Visceral obesity increases BP by activation of the sympathetic nervous system (SNS), the renin–angiotensin–aldosterone system (RAAS), and by physical compression of the kidneys from the fat surrounding the kidneys. SNS activation may be caused by, in large part, the effects of leptin, which acts on proopiomelanocortin (POMC) neurons in the hypothalamus and brainstem. Obesity-induced hypertension and glomerular hyperfiltration may cause renal injury, especially when combined with dyslipidemia and hyperglycemia. Renal injury then exacerbates the hypertension and makes it more difficult to control.

not appear to be substantially elevated, whereas renal and skeletal muscle SNS activity is usually increased in obese subjects.[90–92] Obesity-induced SNS activation is usually not sufficient to cause vasoconstriction in most tissues, such as skeletal muscle or the kidneys, but does contribute to renin secretion and increased renal tubular sodium reabsorption.[60]

Several potential mediators of SNS activation in obesity have been suggested, including: 1) hyperinsulinemia; 2) angiotensin II; 3) increased levels of free fatty acids; 4) impaired baroreceptor reflexes; 5) activation of chemoreceptor-mediated reflexes associated with sleep apnea; and 6) cytokines released from adipocytes i.e., "adipokines" such as leptin, TNF-α and IL-6. Although these mechanisms have been reviewed previously,[5,6,10] there is little direct evidence to support cause-and-effect relationships for most of these factors and obesity-induced SNS activation.

Leptin–Melanocortin Activation May Mediate SNS Activation in Obesity

A promising candidate for linking obesity with hypertension is hyperleptinemia (Figure 39.14). Leptin, released from adipocytes in proportion to the degree of adiposity, acts on the hypothalamus and other regions of the brain to reduce appetite and increase SNS activity. In rodents, leptin increases sympathetic activity and BP.[10,93] Moreover, the hypertensive effects of leptin are enhanced when NO synthesis is inhibited,[10] as often occurs in obese subjects with endothelial dysfunction.

Additional support for leptin as a potential mechanism of obesity hypertension is the finding that leptin-deficient, obese mice and obese mice with mutations of the leptin receptor usually have little or no increase in BP compared to their lean controls.[89] Similar results have been found in obese children with leptin gene mutations who have early onset morbid obesity, but normal BP and impaired SNS activity.[94] Furthermore, children with leptin gene mutations did not have hypertension, despite having many other characteristics of the metabolic syndrome, including severe insulin resistance, hyperinsulinemia, and hyperlipidemia.[94] These observations suggest that the functional effects of leptin may be critical in linking obesity with SNS activation and hypertension.[89]

Leptin's stimulatory effect on SNS activity appears to be mediated by interactions with other hypothalamic factors, especially the proopiomelanocortin POMC pathway (Figure 39.14). In mice with leptin receptors deleted specifically in POMC neurons, leptin's hypertensive effects were completely abolished.[95] Also, pharmacological antagonism of melanocortin 3/4 receptors MC3/4R completely prevented leptin's chronic BP effects,[89] and the chronic hypertensive effects of leptin were absent in MC4R knockout mice.[89] These observations indicate that leptin's chronic BP effects are mediated almost entirely by activation of POMC neurons which, in turn, release α-melanocyte-stimulating hormone α-MSH, leading to activation of MC4R and increased SNS activity.[89]

A study in humans also suggests that MC4R activation may contribute to obesity-induced hypertension. The prevalence of hypertension is lower in MC4R-deficient humans compared to obese control subjects, despite severe obesity and associated metabolic disorders.[96] Moreover, subcutaneous administration of an MC4R agonist for seven days significantly increased BP. Thus, in humans and rodents, chronic activation of MC4R raises BP, and the presence of a functional MC4R system appears to be necessary for obesity and hyperleptinemia to increase SNS activity and BP.[96]

RAAS Activation in Obesity

Obese subjects, especially those with visceral obesity, often have mild-to-moderate increases in plasma renin activity PRA, angiotensinogen, ACE activity, angiotensin II, and aldosterone levels.[5] Activation of the RAAS occurs despite sodium retention, volume expansion, and hypertension, all of which normally tend to suppress renin secretion and angiotensin II formation.

An important role for angiotensin II in stimulating renal sodium reabsorption and in mediating obesity hypertension is supported by studies in experimental animals demonstrating that angiotensin II receptor blockade or ACE inhibition markedly attenuates

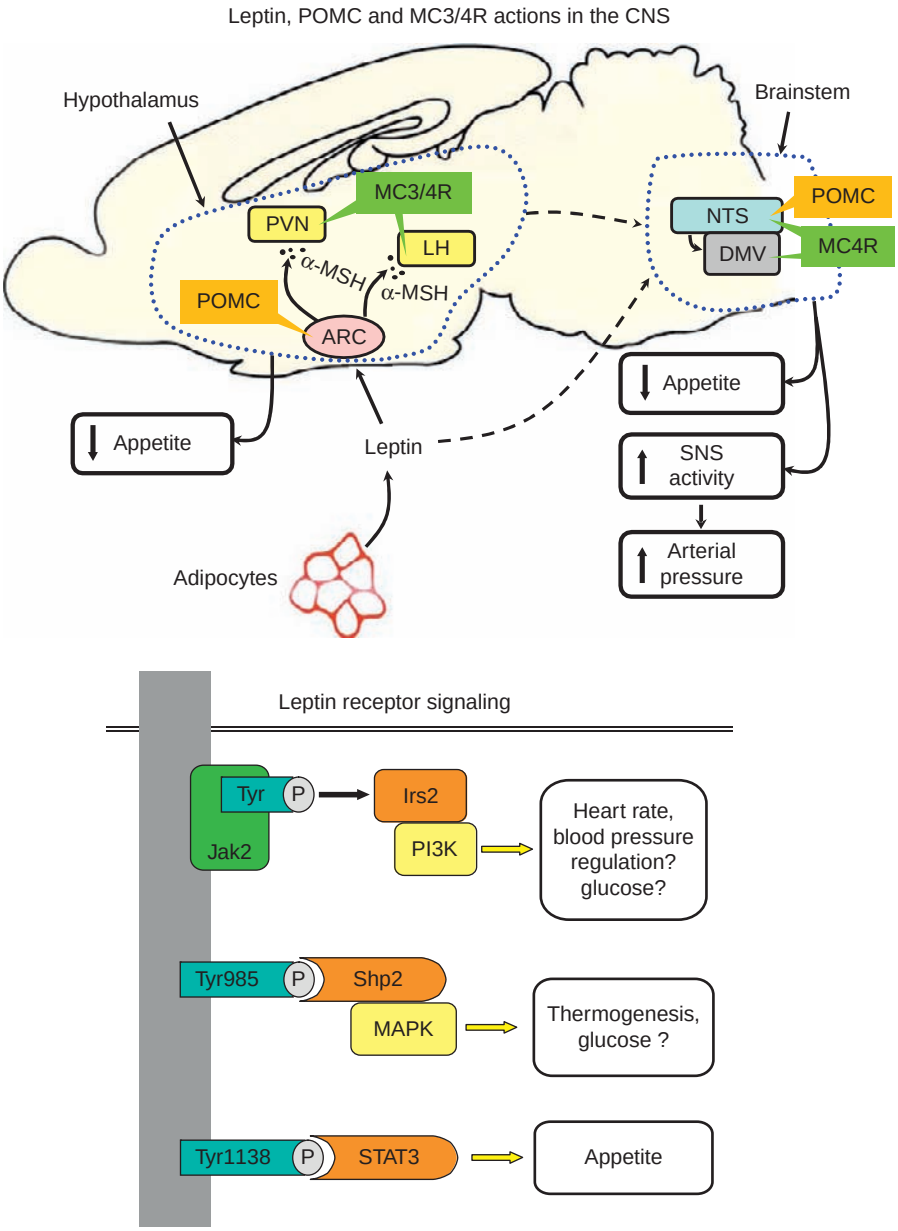

FIGURE 39.14 **Possible links among leptin and its effects on the hypothalamus, sympathetic activation, and hypertension.** Within the hypothalamus, one of the key pathways of leptin's action on appetite, SNS activity, and BP is stimulation of the proopiomelanocortin (POMC) neurons in the arcuate nucleus (ARC). These neurons send projections to the paraventricular nucleus (PVN) and lateral hypothalamus, releasing α-melanocyte-stimulating hormone (α-MSH), which then acts as an agonist for melanocortin 4 receptors (MC4R). These neurons, in turn, send projections to the nucleus of the solitary tract (NTS) to effect changes in appetite, SNS activity, and blood pressure. Leptin also suppresses the NPY/AGRP neurons, but their role in controlling SNS activity and BP are still unclear. Leptin–melanocortin activation in distinct areas of the brain and through multiple intracellular signaling pathways may differentially regulate appetite, energy expenditure, and BP (LH: lateral hypothalamus; RSNA: renal sympathetic nerve activity).

sodium retention, volume expansion, and increased BP during the development of obesity.[5,6,97] Whether the effects of angiotensin II to raise BP in obesity are due primarily to direct actions on the kidneys or stimulation of aldosterone secretion is unclear. The direct renal sodium-retaining effects of angiotensin II are well-known, as are the effects of angiotensin II to stimulate aldosterone secretion.

Although smaller clinical trials have clearly shown that both ARBs and ACE inhibitors are effective in lowering BP in obese hypertensive patients, there have been no large-scale clinical studies comparing the effectiveness of RAAS blockers in obese and lean hypertensive patients.

Activation of the RAAS may also contribute to the glomerular injury and nephron loss associated with obesity. By constricting efferent arterioles, increased angiotensin II formation exacerbates the rise in glomerular hydrostatic pressure caused by systemic arterial hypertension.[5] Studies in type II diabetic patients, who are usually overweight or obese, clearly indicate that ACE inhibitors or ARBs slow the progression of renal disease.[28,98] Thus, ARBs and ACE inhibitors may be particularly useful in obese patients, especially those with diabetes and renal disease.

Mineralocorticoid Receptor (MR) Activation in Obesity Hypertension

Studies in experimental animals and in humans suggest that antagonism of MR may provide an important therapeutic tool not only for lowering BP, but also for

attenuating target organ injury in obesity hypertension. Antagonism of MR in obese dogs markedly attenuated sodium retention, hypertension, and glomerular hyperfiltration.[35] The observation that MR antagonism attenuated glomerular hyperfiltration may also have important implications for renal protection in obesity, although there are no studies, to our knowledge, that have directly tested this in non-diabetic obese humans. Administration of MR antagonists also provides significant antihypertensive benefit in resistant obese patients.[34] Reductions in BP caused by MR antagonism in obese patients with resistant hypertension occurred despite concurrent therapy with ACE inhibitor or ARB, calcium channel blocker, and thiazide diuretic, suggesting that MR activation in obesity can occur independently of angiotensin II-mediated stimulation of aldosterone secretion.

Visceral Obesity May Cause Renal Compression

Visceral obesity initiates several changes that lead to compression of the kidneys, increased intrarenal pressures, impaired renal pressure natriuresis, and hypertension.[10] Intra-abdominal pressure rises in proportion to abdominal diameter, reaching levels as high as 35–40 mmHg in some individuals.[5] In addition, retroperitoneal adipose tissue often encapsulates the kidney and penetrates the renal hilum into the renal medullary sinuses in obese dogs as well as in obese humans, causing additional compression and increased intrarenal pressures.[99]

Obesity also causes changes in renal medullary histology and increased extracellular matrix that exacerbate intrarenal compression and hypertension.[97] Increased intrarenal hydrostatic pressure may, in turn, cause compression of the loops of Henle and vasa recta, thereby increasing tubular sodium and water reabsorption. Although these physical changes in the kidneys cannot account for the initial increase in BP that occurs with rapid weight gain, they may help to explain why abdominal obesity is much more closely associated with hypertension than subcutaneous obesity.[97]

Kidney Injury in Obesity Hypertension

Obesity has not been widely recognized as a major risk factor for ESRD, and is not included as a cause of kidney failure in renal data registries. However, the impact of obesity on renal disease is clear when one considers that diabetes and hypertension, both of which are closely associated with excess weight gain, account for more than 70% of ESRD. Moreover, the rapid rise in the prevalence of ESRD in the past two decades has paralleled increasing obesity and diabetes.[97] Although most of the increasing prevalence of ESRD has been attributed to the increase in type II diabetes, patients with diabetes are usually hypertensive, and the increased BP likely contributes to renal injury.

Population studies indicate that obesity is a major cause of renal disease, even after adjustment for hypertension, diabetes or pre-existing renal disease. In a retrospective analysis of adults who were followed for 15–35 years, the rate of ESRD increased in a stepwise manner as BMI increased.[100] This relationship was not affected by BP or diabetes, and the analysis was adjusted for age, sex, race, education level, smoking status, history of myocardial infarction, serum cholesterol level, proteinuria, hematuria, and serum creatinine level. Thus, observational studies suggest that obesity may be an important risk factor for renal disease through other mechanisms in addition to hypertension and diabetes.

Obesity may also amplify the effect of other primary renal insults, even those that are usually considered to be relatively benign, such as unilateral nephrectomy. Praga and co-workers[101] reported that of patients with a BMI greater than 30 who had undergone unilateral nephrectomy, 92% developed proteinuria or renal insufficiency, whereas only 12% of patients with a BMI less than 30 developed these disorders. Similar findings have also been reported for patients with immunoglobulin A nephropathy.[102] These observations suggest that obesity exacerbates the loss of kidney function in patients with pre-existing glomerulopathies, and that weight loss may lessen the impact of renal injury from other causes.

Animals placed on a high-fat diet for only a few weeks also have significant structural changes in the kidneys, including enlargement of the Bowman space, glomerular cell proliferation, increased mesangial matrix, and increased expression of glomerular TGF-β.[103] These early changes occur with only modest hypertension, only mild metabolic abnormalities, and may be the precursors of more severe renal injury as obesity is sustained. Obese patients often develop proteinuria, frequently in the nephrotic range, that is followed by progressive loss of kidney function.[97] The most common types of renal lesions observed in renal biopsies of obese subjects are focal and segmental glomerular sclerosis and glomerulomegaly.

The gradual loss of kidney function, as well as the hypertension and diabetes that commonly coexist with obesity, may lead to progressive impairment of pressure natriuresis, salt-sensitivity, and greater increases in BP. Thus, renal injury in obese subjects not only exacerbates the hypertension, but also makes BP more difficult to control with antihypertensive drugs. The mechanisms of obesity-induced renal injury are not fully-understood, but likely involve a combination of hemodynamic and metabolic abnormalities.

As discussed previously, obesity causes marked glomerular hyperfiltration and preglomerular vasodilation that permits greater transmission of the increased BP to the glomerular capillaries. These renal hemodynamic changes, along with the metabolic abnormalities, such as hyperglycemia and hyperlipidemia, exacerbate the effects of increases in BP to cause renal injury. A synergistic relationship may exist between the metabolic abnormalities and increased glomerular pressure in causing chronic renal vascular disease and nephron loss, similar to the synergistic effects of hypertension, diabetes, and dyslipidemia in increasing the risk for coronary artery disease and myocardial infarction. However, there are no large-scale studies that have tested this idea.

How Does "Metabolic Syndrome" Relate to Primary Hypertension?

Dyslipidemia, hyperinsulinemia, and hyperglycemia often occur concurrently with hypertension, leading to the proposal of a unique pathophysiologic condition that is often called the *metabolic syndrome*. Definitions of the metabolic syndrome have been proposed by the World Health Organization WHO,[104] the Third Report of the National Cholesterol Education Program's Adult Treatment Panel ATP III,[105] and other organizations.[104] All of these definitions include disordered glucose homeostasis or measures of insulin resistance, dyslipidemia, hypertension, and obesity.

Recent analyses of the metabolic syndrome have questioned whether insulin resistance and hyperinsulinemia are the underlying causes of this complex cluster of cardiovascular risk factors.[104,106] Chronic hyperinsulinemia, in the absence of obesity, does not raise BP in dogs or humans.[107] Multiple studies in humans have also shown that chronic insulin treatment does not raise BP in patients with type 1 or type 2 diabetes, and patients with severe hyperinsulinemia as a result of insulinoma are not hypertensive.[107] Taken together, these observations suggest that hyperinsulinemia *per se* is insufficient to cause chronic hypertension.

Insulin resistance has been proposed to cause hypertension independent of hyperinsulinemia. However, there are several disorders associated with severe insulin resistance and hyperinsulinemia in humans and experimental animal models that are not linked with hypertension. In mice, mutations of the leptin gene or the leptin receptor or mutations of the MC4-R, cause severe insulin resistance and many characteristics of the metabolic syndrome, but BP is not increased compared to wild-type controls.[5,89] Likewise, humans with leptin gene or MC4R mutations have severe insulin resistance, but no indication of SNS activation or hypertension.[94,96] These observations do not support a direct role for insulin resistance in causing hypertension.

Several reports indicate that agents that increase insulin sensitivity, such as the thiazolidinediones, also lower BP. However, these drugs influence expression of multiple genes by binding to the peroxisome proliferator-activated receptor-γ (PPARγ), a nuclear receptor. Thiazolidinediones may also inhibit L-type calcium channels, and they reduce BP in renovascular hypertension that is not associated with insulin resistance or hyperinsulinemia.[5,108] Therefore, it appears that the BP-lowering effects of these drugs are related to other actions besides improvement of insulin sensitivity.

Abnormalities of glucose and lipid metabolism associated with insulin resistance may, over many years, lead to athereosclerosis and vascular injury, and in this way contribute indirectly to increased BP, especially if the renal blood vessels and glomeruli are damaged. Progressive loss of kidney function could contribute to salt-sensitivity of BP and gradual development of hypertension. Thus, the metabolic disturbances associated with severe insulin resistance may exacerbate hypertension by causing renal injury, although the importance of these effects, in the absence of diabetes, is still unclear.

Although insulin resistance and hypertension are often closely correlated, much of the available evidence suggests that this association is largely a consequence of obesity which causes both insulin resistance and high BP through parallel mechanisms. There is little doubt that obesity, especially visceral obesity, is a major cause of the entire cluster of CVD risk factors associated with the metabolic syndrome.[104,107] Importantly, all of the disorders associated with the metabolic syndrome can usually be reversed by weight loss.

GENETIC CAUSES OF HYPERTENSION

Success in identifying genes that contribute importantly to human primary hypertension has been limited mainly to identification of monogenic forms of hypertension. When one considers the complexity of the multiple neural, hormonal, renal, and vascular mechanisms that contribute to short-term and long-term BP regulation, it is perhaps not surprising that finding a few variant genes alleles to account for a major portion of BP variation has been challenging. The complexity of the problem is compounded by the likelihood that BP variation is caused not only by single-gene variants, but also by polymorphic genetic differences, complex interactions among several genes, and interaction among genetic and environmental factors. The finding that

hypertension does not often occur in populations living in non-industrialized regions of the world suggests that environmental influences play a major role in common forms of hypertension.

What is the evidence that gene variants play a major role in human primary hypertension? Multiple studies provide evidence that the closer the genetic relatedness, the greater the similarity of BP.[109] For monozygotic twins (with genetic similarity of 100%), the correlation coefficient for systolic BP has ranged from 0.5 to 0.8 (average: 0.6), for dizygotic twins it has ranged from 0.19 to 0.46 (average: 0.35), and for non-twin siblings (genetic similarity of around 50%) the correlation coefficient has averaged around 0.23. There is also a better correlation of BP values in biologic children than in adopted children. However, the importance of shared family environment is also evident from the BP correlations observed in genetically unrelated adopted siblings.

Comprehensive familial analyses that include other relatives in addition to twins suggest that environment may contribute to as much as 30% of BP variance, and genetic factors may contribute 40 to 50% of BP variance.[109] However, despite the use of sophisticated mathematical models for these calculations, the possibility of nonlinear gene−environmental interactions makes it difficult to quantify the precise roles of genes and environment in BP variation.

Hypertension has been suggested to result from additive effects of multiple variant genes acting in concert to elevate BP. Each gene variant is presumed to have a relatively weak impact on BP, but may produce significant hypertension when they act together in the presence of the necessary environmental conditions. This *polygenic* model also applies to other complex diseases such as diabetes or cancer, where multiple genes and environmental factors may play a role in the development of the disease.

Although the hypertension research literature is replete with studies showing associations of gene polymorphisms and BP, the genetic alterations that contribute to primary hypertension remain unknown.[109] Most of these genetic studies have produced mixed results, even for widely studied polymorphisms such as the ACE insertion/deletion and angiotensinogen polymorphisms.[110] Polymorphisms and mutations in other genes such as α-adducin, atrial natriuretic factor, the insulin receptor, β_2-adrenergic receptor, calcitonin gene-related peptide, angiotensinase C, renin-binding protein, endothelin-1 precursor, G-protein β_3-subunit have also been associated with the development of hypertension in some studies[110]; however, all of these polymorphisms show weak associations, if any, with BP, and many of the early studies showing statistically significant associations have not been confirmed. Large-scale genome-wide association studies (GWAS) in which hundreds of thousands of common genetic variants are genotyped and analyzed for blood pressure association have shown limited success in identifying genes that contribute to hypertension. At best, the gene variations discovered thus far explain only a tiny part of the BP variation found in humans.[111]

Monogenic Disorders that Cause Hypertension

Table 39.1 shows some of the monogenic disorders that are associated with high BP. An interesting feature of these genetic disorders is that they all affect electrolyte transport in the renal tubule or the synthesis and/or activity of RAAS hormones. In all monogenic hypertensive disorders thus far, the final common pathway to hypertension appears to be increased sodium reabsorption and volume expansion. Monogenic hypertension, however, is rare, and all of the known forms together account for less than 1% of human hypertension.

Familial Hyperaldosteronism Type I

Also called *glucocorticoid remediable aldosteronism (GRA)*, familial hyperaldosteronism type I (FH-I) is inherited as an autosomal dominant trait caused by a chimeric gene derived from a meiotic mismatch and unequal crossing between the promoter of the 11β-hydroxylase *CYP11B1* controlled by the structural portion of the aldosterone synthase gene *CYP11B2*.[15] This causes aldosterone secretion to be abnormally regulated by adrenocorticotrophic hormone (ACTH). Because ACTH is suppressed by glucocorticoids, administration of excess glucocorticoids is effective in reducing aldosterone secretion in patients with FH-I.

Patients with FH-I exhibit many of the same characteristics as those with primary aldosteronism, including high aldosterone, hypokalemia, volume expansion, metabolic alkalosis, and low renin. Although some patients with FH-I have severe hypertension, others have only moderate hypertension or may even be normotensive. This wide range of BP could be related to variable expression of the chimeric gene or to other differences in genetic background that would place the inherited BP in the low or normal range in the absence of the FH-I mutation. The final BP could therefore be the combined result of the low or normal inherited BP, the hypertensive effect of the FH-I mutation, and other environmental factors, such as salt intake. Patients with FH-I respond well to thiazide diuretics, as well as spironolactone.

TABLE 39.1 Known Genetic Causes of Hypertension

Genetic Disorder	Age of Onset	Pattern of Inheritance	Aldosterone Level	Serum Potassium Level	Treatment[a]
FH-I (GRA)[b]	2nd or 3rd decade	Autosomal dominant	High	Decreased in 50% of cases; marked decrease with thiazides	Glucocorticoids
FH-II[c]	Middle age	Autosomal dominant	High	Low to normal	Spironolactone, eplerenone
DOC oversecretion due to CAH[c,d]	Childhood	Autosomal recessive	Low	Low to normal	Glucocorticoids
Activating MR mutation exacerbated by pregnancy[e]	2nd or 3rd decade	Unknown	Low	Low to normal	Delivery of fetus
AME2[c,f]	Childhood	Autosomal recessive	Low	Low to normal	Spironolactone, dexamethasone
Liddle's syndrome[g]	3rd decade	Autosomal dominant	Low	Low to normal	Amiloride, triamterene
Gordon's syndrome[h]	2nd or 3rd decade	Autosomal dominant	Low	High	Thiazide diuretic, low-sodium diet

ACTH: adrenocorticotropic hormone; AME: apparent mineralocorticoid excess; CAH: congenital adrenal hyperplasia; DOC: deoxycorticosterone; FH-I: familial hyperaldosteronism type I; FH-II: familial hyperaldosteronism type II; GRA: glucocorticoid-remediable aldosteronism; MR: mineralocorticoid receptor.

Familial Hyperaldosteronism Type II

Familial hyperaldosteronism type II (FH-II) is a rare disease in which hypertension is caused by excessive aldosterone secretion that is not suppressed by glucocorticoid administration, distinguishing it from FH-I.[112] Patients with FH-II have the same clinical symptoms as patients with primary hyperaldosteronism caused by bilateral adrenal hyperplasia. The genetic abnormality causing FH-II has been localized to chromosome 7p22.[112] Although hypertension in FH-II is unresponsive to glucocorticoids, spironolactone is effective in reducing BP and correcting the metabolic disturbances.

Congenital Adrenal Hyperplasia and Excess Deoxycorticosterone Secretion

This disorder describes a group of syndromes caused by defects in cortisol biosynthesis. Congenital adrenal hyperplasia is an autosomal recessive disorder. When 21-hydroxylase *CYP21A2* is deficient, the most common cause of congenital adrenal hyperplasia, patients are normotensive.[112] When 11β-hydroxylase *CYP11B1* and 17β-hydroxylase *CYP17* are deficient, production of deoxycorticosterone, which has mineralocorticoid activity, is increased, leading to hypertension. Defects in *CYP11B1* and *CYP17* cause inhibition of cortisol production with a subsequent reduction in feedback inhibition of ACTH secretion by the anterior pituitary and hypothalamus. Increased ACTH secretion then stimulates production of steroid precursors proximal to the blocked step, leading to excessive levels of deoxycorticosterone.

Both forms of congenital adrenal hyperplasia are associated with early-onset hypertension and hypokalemia. Signs of androgen excess distinguish the two disorders: 11β-hydroxylase deficiency causes virilization in girls and precocious puberty in boys, whereas 17α-hydroxylase deficiency causes sex hormone deficiency, primary amenorrhea, and delayed sexual development in girls, and ambiguous genitalia in boys. Genetic diagnosis of both conditions relies on testing for mutations that either severely depress or abolish enzyme activity. Both conditions can be effectively treated by administering glucocorticoids that normalize ACTH secretion and ACTH-mediated build-up of cortisol precursors proximal to the enzymatic deficiency, including deoxycorticosterone.

Liddle's Syndrome

This is an autosomal dominant form of monogenic hypertension that results from mutations in the amiloride-sensitive ENaC. Several mutations that result in the elimination of 45–75 amino acids from the cytoplasmic carboxyl terminus of β- or γ-subunits of the channel

have been reported. Mutations that increase ENaC activity, in turn, cause excessive distal and collecting tubule sodium reabsorption and hypertension.[15,112]

Liddle's syndrome is characterized by early-onset hypertension with hypokalemia and suppression of renin and aldosterone. Decreased aldosterone and lack of responsiveness to MR antagonists differentiates this syndrome from primary aldosteronism. Both hypertension and hypokalemia vary in severity, depending on salt intake, and can be treated with amiloride or triamterene, specific inhibitors of ENaC.

Apparent Mineralocorticoid Excess (AME)

AME is an autosomal recessive form of monogenic hypertension that results from a mutation in the renal-specific isoform of the 11β-hydroxysteroid dehydrogenase 2 gene.[15,112] This enzyme normally converts cortisol to the inactive metabolite cortisone and "protects" the MR from being activated by cortisol. This is important, because the renal epithelial MR receptor in the distal and collecting tubules has a similar affinity for aldosterone and cortisol, while cortisol concentrations are normally much higher than aldosterone. Deficiency of 11β-hydroxysteroid dehydrogenase 2 allows the tubular MR to be occupied and activated by cortisol, causing sodium retention and volume expansion, low renin, low aldosterone, and a form of hypertension that is salt-sensitive.

A non-genetic form of the AME syndrome is found in persons ingesting large amounts of licorice which contains glycyrrhetinic acid, an inhibitor of the enzyme 11β-hydroxysteroid dehydrogenase. Both forms of apparent mineralocorticoid excess are effectively treated with MR antagonists, such as spironolactone or eplerenone.

Pseudohypoaldosteronism Type II

Also called *Gordon's syndrome*, pseudohypoaldosteronism type II is a rare Mendelian form of hypertension that is salt-sensitive and associated with hyperkalemia, hyperchloremia, metabolic acidosis, and suppressed renin and aldosterone levels. The disorder is caused by mutations in two genes encoding the serine/threonine protein kinases, WNK1 and WNK4.[113]

The phenotypes of excessive salt retention and hypertension are caused by loss of normal inhibition or constitutive activation of the renal tubular NaCl co-transporter by mutant WNK1 or WNK4 genes. WNK4 normally inhibits NaCl co-transporter activity, and loss-of-function mutations therefore increase NaCl reabsorption and cause hypertension. WNK1 does not regulate NaCl co-transporter activity directly, but exerts an indirect effect through suppression of WNK4 inhibition of the NaCl transporter. Therefore, gain-of-function mutations of WNK1 result in highly active NaCl co-transporter, volume expansion, and hypertension with characteristics similar to those caused by loss-of-function mutations of WNK4.[113]

Hyperkalemia is a major feature of pseudohypoaldosteronism type II[112] and may be due, in part, to decreased NaCl delivery to the cortical collecting tubules, which limits their secretion of potassium. Mutant WNKs may also cause hyperkalemia by inhibiting activity of renal outer medullary potassium (ROMK) channels, the major potassium secretory channels in the distal nephron. The fact that hyperkalemia is invariably present in pseudohypoaldosteronism type II is often used to distinguish it from other monogenic forms of hypertension.

Thiazide diuretics, which inhibit distal nephron NaCl reabsorption, are especially effective in reducing BP and correcting hyperkalemia in patients with pseudohypoaldosteronism type II. Because NaCl co-transporter activity is regulated by luminal salt delivery, decreased NaCl intake also reduces activity of the transporter, and therefore attenuates volume-expansion and hypertension in patients with pseudohypoaldosteronism type II syndrome. Therefore, BP in Gordon's syndrome is highly salt-sensitive.

Mineralocorticoid Receptor Activating Mutation

This monogenic disorder is caused by a substitution of leucine for serine at codon 810 of the MR.[15] This mutation alters the shape and specificity of the MR, and eliminates the usual requirement for the 21-hydroxyl group of aldosterone to interact with the MR. This explains why other steroids, such as progesterone, activate the MR and why spironolactone, which is normally an antagonist of the MR, acts as an agonist for the MR in this disorder. Thus, treatment of these patients with spironolactone or increased levels of progesterone worsens the sodium retention, hypokalemia, and hypertension.

SECONDARY CAUSES OF HYPERTENSION

In a small fraction of patients, the clinical features, history, and physical examination point to a specific cause of increased BP, and the hypertension is therefore said to be *secondary*. Some types of secondary hypertension have a genetic basis, whereas others are caused by cardiovascular diseases and target organ injury associated with various disorders such as diabetes and kidney disease, and in some instances hypertension can be caused by drugs or treatments that patients receive. Table 39.2 lists some of the most frequently-diagnosed causes of secondary hypertension, although we discuss only a few of the more common types.

TABLE 39.2 Some Secondary Causes of Hypertension

- **A.** Renal parenchymal disease
  - Acute and chronic glomerulonephritis
  - Chronic nephritis e.g., pyelonephritis, radiation
  - Polycystic disease
  - Diabetic nephropathy
  - Hydronephrosis
  - Neoplasms
- **B.** Renovascular
  - Renal artery stenosis/compression
  - Intrarenal vasculitis
  - Suprarenal aortic coarctation
- **C.** Renoprival renal failure, loss of kidney tissue
- **D.** Endocrine disorders
  - Renin-producing tumors
  - Cushing syndrome
  - Primary aldosteronism
  - Pheochromocytoma adrenal or extraadrenal chromaffin tumors
  - Acromegaly
- **E.** Pregnancy-induced hypertension
- **F.** Sleep apnea
- **G.** Increased intracranial pressure brain tumors, encephalitis
- **H.** Hormones and drugs (partial list)
  - Glucocorticoids
  - Mineralocorticoids
  - Sympathomimetics
  - Tyramine-containing foods and monoamine oxidase inhibitors
  - Estrogen (e.g., oral contraceptive pills)
  - Apparent mineralocorticoid excess (e.g., licorice)
  - Nonsteroidal anti-inflammatory drugs
  - Cyclosporine
  - Excess alcohol use
  - Drug abuse (e.g., amphetamines, cocaine)

Renovascular Hypertension

Renovascular hypertension, although accounting for only 2–3% of all hypertension, is one of the most common causes of secondary hypertension. The pathophysiology of renovascular hypertension is due to an initial reduction in renal perfusion that occurs as a result of stenosis of the main renal artery, one of its branches or stenosis/injury of other smaller preglomerular blood vessels and glomeruli. The majority of renal vascular lesions reflect either fibromuscular dysplasia or atherosclerosis.[114] The predominant lesion found in the main renal artery or its branches in patients older than 50 years of age is atherosclerotic disease. More subtle functional constriction or structural changes in smaller blood vessels (e.g., afferent arterioles, glomeruli) are difficult to detect clinically, but can contribute to increased BP.

Renovascular hypertension can be unilateral or bilateral, and can result in a homogeneous or non-homogeneous ischemia of nephrons. As discussed earlier in the chapter, there are some important differences in the pathophysiology of homogeneous compared to non-homogenous impairments of renal perfusion. Experimental counterparts of these two clinical forms of renovascular hypertension can be found in the 1-kidney, 1-clip and the 2-kidney, 1-clip models of Goldblatt hypertension, respectively.

Renal Artery Stenosis in a Single Remaining Kidney or Aortic Coarctation above Both Renal Arteries

Renal artery constriction or aortic coarctation, if severe enough to reduce renal perfusion pressure below the range of autoregulation (approximately 70 mmHg), initially decreases renal blood flow, GFR, and sodium excretion, while increasing renin secretion. However, if the stenosis is not too severe, sodium excretion returns to normal, and if sodium intake is normal and adequate volume is available, renin secretion also returns to nearly normal in the established phase of hypertension.[9,115] At this point, the hypertension is stable, and most indices of renal function are relatively normal, including pressure distal to the stenosis.

Increased angiotensin II accounts for much of the rapid increase in BP after stenosis of the renal artery or suprarenal aortic coarctation. However, even after blocking the RAAS, BP still increases although more slowly until renal perfusion pressure returns to nearly normal. This increase in renal perfusion pressure, at the expense of systemic arterial hypertension, permits normal excretion of sodium and water to be maintained. As long as the sodium intake is normal, activation of the RAAS serves mainly to increase the rate at which BP is elevated. In the established phase of hypertension, blockade of the RAAS causes only small reductions in BP, similar to the decreases observed in normal subjects after angiotensin II blockade.[5]

The importance of volume-expansion in elevating BP in 1-kidney, 1-clip Goldblatt hypertension or suprarenal aortic coarctation depends on the sodium intake. With normal-or high-sodium intake, significant volume-expansion occurs, whereas a low-sodium diet converts this model of hypertension to one that is highly angiotensin II-dependent. When the stenosis is severe and adequate renal perfusion cannot be restored even with increased systemic BP, renin secretion continues to increase, as does BP, leading eventually to malignant hypertension and renal failure. Thus, the ability to return renal perfusion pressure to normal or nearly normal, by volume retention or activation of the RAAS, is critical to maintaining homeostasis when there is stenosis of a single remaining kidney. The same sequence occurs when there are widespread homogeneous increases in preglomerular resistance caused by bilateral renal artery stenosis or aortic coarctation above both renal arteries.[11]

Non-Homogeneous Increases in Renal Vascular Resistance or Unilateral Renal Artery Stenosis in Patients with two Kidneys

As discussed previously, non-homogeneous increases in preglomerular resistance can occur as a result of stenosis of one renal artery and normal perfusion of the contralateral kidney. Also, patchy increases in preglomerular resistance within the kidneys, with some nephrons being underperfused and others having normal or increased blood flow, can cause hypertension with characteristics similar to those found in the 2-kidney, 1-clip form of Goldblatt hypertension. These forms of hypertension all have underperfusion of some nephrons, and normal or increased blood flow in adjacent nephrons or in the nonstenotic kidney.

In experimental models with unilateral renal artery stenosis, the increase in BP is less predictable if the contralateral kidney does not become injured because of the hypertension. In this situation, underperfused nephrons or the entire underperfused kidney in the case of a unilateral renal artery stenosis are exposed to reduced perfusion pressure, secrete increased amounts of renin, and excrete less sodium and water than kidneys with normal blood flow. In contrast, the non-ischemic nephrons or nonstenotic kidney are exposed to increased renal perfusion pressure, causing renin secretion to fall to low levels and increasing sodium excretion above normal. However, even with increased perfusion pressure, the function of the non-ischemic nephrons or unclipped, nonstenotic kidney is impaired because of high circulating angiotensin II, which exerts an antinatriuretic effect and helps to sustain hypertension.

The higher BPs experienced by the nonstenotic kidney may eventually cause nephron damage which then maintains increased BP, even after correction of the stenosis in the other kidney. However, correction of the stenosis plus nephrectomy of the non-stenotic kidney may normalize BP if the stenosis is not so severe that it causes vascular rarefaction and permanent injury to the stenotic kidney.[5,6]

Administration of ACE inhibitors or ARBs as a treatment for renovascular hypertension may improve the structure and function of the non-stenotic kidney, but can in severe cases produce serious reductions in GFR and shrinkage of the stenotic kidney, resulting in fibrosis and further deterioration of its function. This is partly a result of the fall in BP, which may reduce renal perfusion pressure distal to the lesion to below the range of autoregulation. Blockade of angiotensin II also causes vasodilation of efferent arterioles which contributes to a decline in GFR in the stenotic kidney. In some patients with severe renal vascular lesions, administration of ACE inhibitors or ARBs may cause severe decreases in renal function, especially when there is also volume-depletion because of concomitant use of diuretics. Therefore, renal function should be monitored frequently after administration of RAS inhibitors in patients suspected of having renovascular hypertension. Fortunately, these effects appear to be reversible upon cessation of ACE inhibition or ARB, and in many patients the beneficial effects of angiotensin II blockade to reduce BP can be achieved without precipitating further loss of kidney function.

Adrenal Cortex Hypertension

Aldosterone normally exerts nearly 90% of the mineralocorticoid activity of the adrenocortical secretions. However, cortisol can also provide a significant amount of mineralocorticoid activity in some conditions. Aldosterone's mineralocorticoid activity is about 3000 times greater than that of cortisol, but the plasma concentration of cortisol is nearly 2000 times that of aldosterone. Normally, the renal MR is protected from activation by cortisol by 11β-HSD2, which converts active cortisol into inactive cortisone. However, when activity of this enzyme is reduced or when cortisol levels are very high, the MR can be activated by cortisol.

Primary Aldosteronism (Conn Syndrome)

Primary aldosteronism, also called *Conn Syndrome*, results from hypersecretion of aldosterone in the absence of a known stimulus. The excess aldosterone secretion almost always comes from the adrenal cortex, and is usually associated with a solitary adenoma or bilateral hyperplasia of the adrenal cortex. *Secondary aldosteronism* refers to increased aldosterone secretion caused by a known stimulus, such as high levels of angiotensin II. This is the most common form of aldosteronism, and occurs in various conditions associated with increased renin secretion and angiotensin II formation, such as congestive heart failure, sodium depletion or renal artery stenosis.[116]

Primary aldosteronism can occur as a result of an aldosterone-producing adenoma (APA) or because of unilateral or bilateral adrenal hyperplasia.[117] The effects of excess aldosterone were discussed earlier, but the most important actions with regard to BP regulation are increased sodium reabsorption and increased potassium secretion by the renal tubules. This leads to extracellular fluid volume-expansion, hypertension, decreased renin secretion, hypokalemia, and metabolic alkalosis. Most of these effects are highly salt-sensitive, and low sodium intake can greatly attenuate the hypertension and hypokalemia.

Adrenal adenomas and bilateral adrenal hyperplasia account for more than 95% of primary aldosteronism. However, in most studies of unselected patients, the classic form of primary aldosteronism was found in less than 1% of hypertensive patients. Some adrenal glands in patients with primary aldosteronism may have varying degrees of hyperplasticity, and the term *idiopathic hyperaldosteronism* (IHA) was coined to describe this condition. Clinically, APA and IHA are difficult to distinguish, although patients with APA often have more severe hypertension and hypokalemia compared to those with IHA.

The measurement of the aldosterone−renin ratio has been used in an attempt to define more subtle cases of primary aldosteronism.[34,117] This approach has led to the suggestion that excess aldosterone secretion may account for as much as 5 to 10% of essential hypertension. However, there is still debate about whether patients with increased aldosterone−renin ratio truly have primary aldosteronism. In many of these patients, the main reason for the increased aldosterone−renin ratio is the low level of renin, rather than excess aldosterone secretion.[116]

"ESCAPE" FROM SODIUM RETENTION DURING HYPERALDOSTERONISM

Although aldosterone is a powerful sodium-retaining hormone, sodium excretion eventually returns to match sodium intake, even in patients with very high levels of aldosterone. This "escape" from sodium retention is secondary to increased extracellular fluid volume and pressure natriuresis.[118] Thus, after the extracellular fluid volume increases 5−15% above normal, BP also increases 15−25 mmHg, and the elevated BP returns the renal output of salt and water to normal, despite the excess aldosterone. The importance of pressure natriuresis in permitting aldosterone escape has been demonstrated experimentally by servo-controlling renal perfusion pressure; when renal perfusion pressure was servo-controlled, aldosterone infusion caused continued sodium retention and progressive increases in cumulative sodium balance and extracellular fluid volume, resulting in severe circulatory congestion and edema.[118] Failure of the kidneys to escape from aldosterone-induced sodium retention also occurs in patients with heart failure who, because of a severely weakened heart, cannot increase BP sufficiently to re-establish salt and water balance.

Cushing Syndrome Glucocorticoid Excess

Cushing syndrome is characterized by excess secretion of glucocorticoids, with hypertension occuring in approximately 80% of patients.[119] The hypertension with cortisol excess is often difficult to control, morbidity is substantial, and risk for death is largely a result of cardiovascular events, including heart attack and stroke.

Cushing syndrome can be caused by administration of excess cortisol (e.g., for treatment of various inflammatory disorders) or by oversecretion of endogenous cortisol. The most common cause of endogenous cortisol excess is overproduction of ACTH from a pituitary adenoma, a condition referred to as *Cushing disease*. The increased ACTH causes adrenal hyperplasia and stimulates cortisol secretion. Cushing disease can also occur as a result of ectopic secretion of ACTH by tumors outside the pituitary, such as an abdominal carcinoma.

ACTH-independent hypercortisolism can also occur as a result of adenomas of the adrenal cortex. Primary overproduction of cortisol by the adrenal glands, independent of ACTH, accounts for approximately 20−25% of Cushing syndrome, and is usually associated with suppressed ACTH caused by cortisol-induced feedback inhibition of ACTH secretion by the anterior pituitary gland. Administration of large doses of dexamethasone, a synthetic glucocorticoid, can distinguish between ACTH-dependent and ACTH-independent Cushing syndrome. In patients with overproduction of cortisol because of an ACTH-secreting pituitary adenoma or hypothalamic−pituitary dysfunction, even large doses of dexamethasone usually do not suppress ACTH secretion. In contrast, patients with primary adrenal overproduction of cortisol ACTH-independent usually have low or undetectable levels of ACTH. However, the dexamethasone test may occasionally give an incorrect diagnosis, because some ACTH-secreting pituitary tumors respond to dexamethasone with suppression of ACTH secretion.

Glucocorticoids modulate many cell processes, and the precise mechanisms by which hypercortisolism causes hypertension are incompletely-understood. One potential mechanism is activation of the MR; the high levels of cortisol in Cushing syndrome may simply overwhelm the ability of renal 11β-HSD2 to convert active cortisol into inactive cortisone at the MR receptor, so that cortisol stimulates the MR and causes sodium retention, volume-expansion, hypertension, and hypokalemia. High levels of cortisol may also increase the responsiveness to various pressor stimuli, including angiotensin II and norepinephrine.[120]

Studies in experimental animals suggest that excess cortisol may also raise BP through mechanisms that may be at least partially independent of activation of classical glucocorticoid receptor or MR.[120] Most of the available evidence, however, suggests that sodium retention may play a key role, although the precise mechanisms that lead to sodium retention are incompletely-understood.

Pheochromocytoma

Pheochromocytoma is a rare form of secondary hypertension occurring in approximately 0.05% of hypertensive patients.[116] Although rare, pheochromocytoma can provoke fatal hypertensive crises if unrecognized and untreated. Pheochromocytoma can arise from neuroectodermal chromaffin cells, which are part of the sympathoadrenal system. The chromaffin cells have the capacity to synthesize and store catecholamines, and are normally found mainly in the adrenal medulla. Although most chromaffin cell tumors are found in the adrenal medulla, as many as 15 to 30% may be extra-adrenal, located along the sympathetic chain or, rarely, in other sites.[116]

The symptoms and severity of hypertension associated with pheochromocytoma vary depending on the secretory pattern and amount of catecholamines released.[121] With tumors that continuously release large amounts of catecholamines, there may be sustained hypertension with few paroxysms or sudden bursts of very high BP. Tumors that are less active may have cyclical release of catecholamine stores that induce paroxysms of hypertension.

The clinical presentation also depends on whether the predominant catecholamine secreted is norepinephrine or epinephrine. Norepinephrine produces α-adrenergically-mediated vasoconstriction with diastolic hypertension, whereas epinephrine produces β-adrenergically-mediated systolic hypertension and tachycardia, along with sweating, tremors, and flushing. Patients with predominantly epinephrine-secreting tumors sometimes have hypertension alternating with hypotension, and approximately 5% of patients with pheochromocytoma remain normotensive.[116]

Pheochromocytoma patients often have decreased blood volume, consistent with the potent vasoconstrictor effects of norepinephrine. This observation, and the finding that chronic excess catecholamines often increase sodium excretion, could be interpreted as evidence that the hypertensive effects of catecholamines are unrelated to any impairment of renal function. However, the natriuretic effect of catecholamines and volume contraction appear to be secondary to peripheral vasoconstriction, decreased vascular capacitance, and increased BP, which causes pressure natriuresis.[10] Chronic intrarenal infusion of norepinephrine causes sodium retention and sustained hypertension, indicating important direct effects of catecholamines on the kidney to cause hypertension.

Although a high level of circulating catecholamine is the ultimate cause of hypertension in pheochromocytoma, BP is often only modestly correlated with the level of plasma catecholamines. However, the periodic burst of catecholamine release may cause moderate-to-severe hypertension, and lead to target organ injury. Consequently, diagnosis and effective treatment of pheochromocytoma are essential.

Pre-eclampsia

Pre-eclampsia occurs in approximately 5–7% of all pregnancies, with significantly higher rates in certain subpopulations. It remains one of the leading causes of maternal and fetal morbidity and mortality.[122,123] Disease manifestations, including hypertension, proteinuria, and edema, typically occur after 20 weeks of gestation.[69,123–126]

Pre-eclampsia is postulated to occur in two distinct phases: an early maternally asymptomatic phase in which abnormalities of vascular remodeling lead to placental insufficiency and hypoxia; and a later symptomatic phase characterized by widespread maternal endothelial dysfunction. The direct result of the failure to remodel the maternal arteries is that the placenta becomes severely hypoxic. In response, the placenta produces several factors that are released into the maternal circulation, and elicit many of the symptoms characteristic of pre-eclampsia. Several pathways which have been recently elucidated include altered angiogenic balance, increased maternal inflammation/immunological dysfunction, suppression of NO production, enhanced endothelin-1 production, and the creation of harmful ROS, as shown in Figure 39.15.

Multiple Placental Factors Cause Endothelial Dysfunction

One of the most intensely studied pathways activated by placental ischemia is abnormal circulating levels of pro-and antiangiogenic factors. Experimental reductions in vascular endothelial growth factor (VEGF), a protein necessary for the maintenance of endothelial cell health, result in hypertension, proteinuria, and glomerular endotheliosis, all common symptoms of pre-eclampsia.[123] In pre-eclampsia, VEGF and placental growth factor (PLGF) are antagonized by soluble fms-like tyrosine kinase-1 (sFlt-1), an inducible splice variant of the VEGF receptor flt-1 which binds to circulating VEGF and renders it unavailable for receptor binding.[123] Thus, sFlt-1 effectively acts as a competitive inhibitor of VEGF. In pre-eclamptic patients, circulating sFlt-1 levels increase significantly, sometimes well before pre-eclampsia symptoms develop. Furthermore, several models of experimental pre-eclampsia demonstrate elevated production of sFlt-1, and concomitant decreases in the amount of bioavailable VEGF.[123] Finally, administration of VEGF in these models has been shown to attenuate the associated hypertension.[123–126]

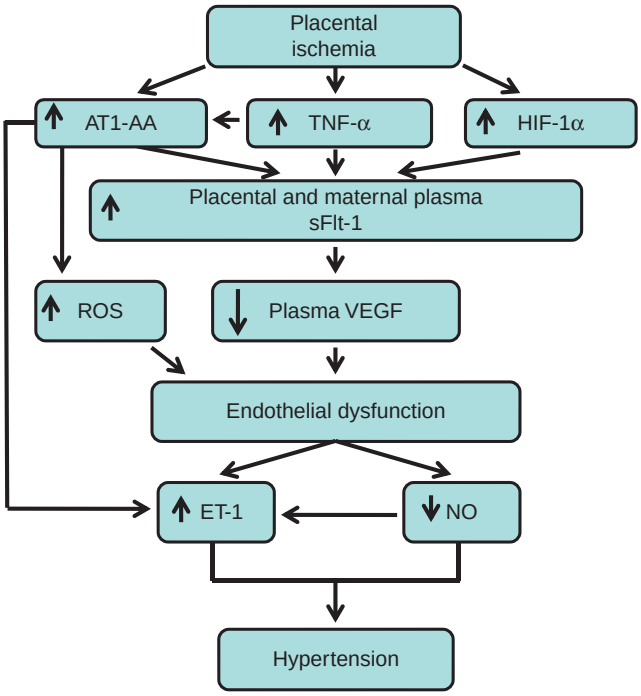

FIGURE 39.15 **Mechanisms linking placental ischemia and hypertension during pre-eclampsia.** (AT1-AA: angiotensin 1 receptor auto antibody; TNF-α: tumor necrosis factor-α; HIF-1α: hypoxia inducible factor-1α; ROS: reactive oxygen species; VEGF: vascular endothelial growth factor; sFlt-1: soluble fms-like tyrosine kinase-1; PlGF: placental growth factor; sEng: soluble endoglin; ET-1: endothelin-1; NO: nitric oxide.)

Another major pathway activated by the ischemic placenta is maternal inflammation. Even during normal pregnancy there is a heightened maternal inflammatory response. In pre-eclampsia, however, this seems to be exaggerated.[70] Inflammatory cytokines, such as IL-6 and TNF-α, are increased in pre-eclamptic women. Administration of either cytokine in pregnant rodents induces a gestational hypertension, similar to that seen in placental ischemia models. Administration of the soluble TNF-α receptor Etanercept in a rodent model of placental ischemia blunted the hypertension through ET-1 suppression, implicating TNF-α as an important link between placental ischemia and endothelial dysfunction.[70]

The maternal immune component of pre-eclampsia also includes circulating agonistic autoantibodies to the angiotensin type 1 receptor AT1-AA.[124] Besides its proposed role in the activation of the AT1 receptor, there appears to be a significant correlation between AT1-AA levels and the production of sFlt-1. Infusion of the purified antibody into pregnant rodents leads to gestational hypertension similar to that seen in placental ischemia models. This effect can be blocked by concurrent infusion of a synthetic heptapeptide which mimics the antibody's natural epitope on the AT1 receptor.[124]

Another important factor implicated in the characteristic maternal endothelial dysfunction associated with pre-eclampsia is elevated levels of the signaling peptide endothelin-1 ET-1.[126] The preponderance of published studies indicate that there is no significant increase in circulating endothelin in pre-eclamptic women compared to non-pregnant controls; however, local tissue levels of preproET-1 are elevated in women with pre-eclampsia.[126] One interesting aspect of ET-1 in pre-eclampsia is that increased vascular and renal ET-1 production have been shown to result from several independent mechanistic pathways, suggesting that it is a central connecting agent in the pathologies associated with these models.[126]

While an effective treatment for pre-eclampsia remains elusive, improved understanding of the mechanisms underlying the disease pathology offer new targets for intervention. Continued research into these molecular and physiological pathways should prove illuminating in the search for a treatment for pre-eclampsia.

CHAPTER

40

Physiology and Pathophysiology of Diuretic Action

David H. Ellison

Oregon Health & Science University & VA Medical Center, Portland, OR, USA

INTRODUCTION

The term *diuretic* derives from the Greek *diouretikos*, meaning "to promote urine." Although infusion of saline or ingestion of water would therefore qualify as being diuretic, the term *diuretic* usually connotes a drug that can reduce the extracellular fluid (ECF) volume by increasing urinary solute or water excretion. The term aquaretic has sometimes been applied to drugs that increase excretion of solute free water, distinguishing them from traditional diuretics, which increase solute and water together. The clinical picture of ECF volume expansion leading to edema or "dropsy" (from the Latin, *hydrops*) has been recognized since the earliest days of recorded history. Ancient Egyptians referred to "flooding of the heart," and the Hippocratic Corpus later suggested specific remedies for dropsical patients, although their results are not noted. In 1553, Paracelsus recorded the first truly effective form of therapy for dropsy, inorganic mercury (Calomel). Inorganic mercury remained the mainstay of diuretic treatment until the beginning of this century.

In 1919, the ability of organic mercurial antisyphilitics to effect diuresis was discovered by Vogl, then a medical student. This observation led to the development of effective organic mercurial diuretics, drugs that were used commonly until the 1960s. In 1937, the antimicrobial, sulfanilamide, was found to cause metabolic acidosis in patients. Carbonic anhydrase had been discovered in 1932; it was know that sulfanilamide inhibited this enzyme. Pitts demonstrated that sulfanilamide inhibited Na bicarbonate reabsorption in dogs, and Schwartz showed that sulfanilamide could induce diuresis in patients with congestive heart failure who were resistant to organic mercurial diuretics. Soon, more potent sulfonamide-based carbonic anhydrase inhibitors were developed, but these drugs suffered from side-effects and limited potency. Nevertheless, a group at Sharp & Dohme Inc. was stimulated by these developments to explore the possibility that modification of sulfonamide-based drugs could lead to drugs that enhanced Na *chloride* rather than Na *bicarbonate* excretion. The result of this program was the synthesis of chlorothiazide and its marketing in 1957. This drug ushered in the modern era of diuretic therapy, and revolutionized the clinical treatment of edema.

The search for more potent classes of diuretics continued, based on the structure of chlorothiazide and sulonamyl derivatives. This led to the development of ethacrynic acid and furosemide in the United States and Germany, respectively. The safety and efficacy of these drugs led them to replace the organic mercurials as drugs of first choice for severe and resistant edema. Spironolactone, marketed in 1961, was developed after the properties and structure of aldosterone had been established, and steroidal analogs of aldosterone were found to have aldosterone-blocking activity. Triamterene was initially synthesized as a folic acid antagonist, but was found to have diuretic and K-sparing activity.

The availability of safe, effective, and relatively inexpensive diuretic drugs has made it possible to treat edematous disorders and hypertension effectively. Driven by clinical need, however, the development of effective diuretic drugs generated specific ligands that interact with Na and Cl transport proteins in the kidney. In the 1990s, these ligands were used to identify and clone the Na and Cl transport proteins that mediate the bulk of renal Na and Cl reabsorption.

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00040-9

The diuretic-sensitive transport proteins that have been cloned include the sodium hydrogen exchanger (NHE) family of proteins, the bumetanide-sensitive Na-K-2Cl co-transporters, the thiazide-sensitive Na-Cl co-transporter, and the epithelial Na channel. The information derived from molecular cloning has also permitted identification of inherited human diseases that are caused by mutations in these transport proteins. The phenotypes of several of these disorders resemble the manifestations of chronic diuretic administration. The recognition, for example, that Gitelman's syndrome results from mutation of the thiazide-sensitive Na-Cl co-transporter, has spurred interest in determining how blockade or dysfunction of this transport protein leads to magnesium-wasting. Thus, the development of clinically useful diuretics permitted identification, and later cloning, of specific ion transport pathways. The molecular cloning then helped to define mechanisms of diuretic action and diuretic side-effects, permitting the development of specific antibodies and probes, and of animals in which diuretic-sensitive transport pathways have been "knocked-out." Many primarily historical references included in prior editions of this book have been omitted here. The interested reader is referred to prior editions for more complete references and details.[1]

Diuretic-Sensitive Salt Transport

In a normal human kidney, approximately 23 moles of NaCl are filtered in 150 liters of fluid each day. Approximately 6–10 grams of salt (102–170 mEq NaCl) are consumed each day by individuals on a typical Western diet. To maintain balance, renal NaCl excretion must be approximately 92–160 mmol/day (the difference owing to nonrenal losses). Such calculations imply that 99.2% of the filtered NaCl load is reabsorbed by kidney tubules each day (the fractional sodium excretion, FE_{Na}, is 0.8%). Sodium, chloride, and water reabsorption along the nephron is driven by the metabolic energy in ATP. The ouabain-sensitive Na/K-ATPase is expressed at the basolateral cell membrane of nearly all Na transporting epithelial cells along the nephron. This pump maintains large ion gradients across the plasma membrane, with the intracellular Na concentration maintained low and the intracellular K concentration maintained high. Because the pump is electrogenic, and because it is associated with a K channel, renal epithelial cells have a voltage across the plasma membrane oriented with the inside negative relative to the outside.

The combination of the low intracellular Na concentration and the plasma membrane voltage generates a large electrochemical gradient favoring Na entry from lumen or interstitium. Specific diuretic-sensitive Na transport pathways are expressed at the apical surface of cells along the nephron, permitting vectorial transport of Na from lumen to blood (see Figure 40.1). Along the proximal tubule, where approximately two-thirds of filtered Na is reabsorbed, a major component of Na reabsorption is exchanged for H^+ via an isoform of the Na/H exchanger (NHE3) at the apical membrane. Along the thick ascending limb, where approximately 20–25% of filtered Na is reabsorbed, an isoform of the Na-K-2Cl co-transporter (NKCC2) is expressed at the apical membrane. Along the distal convoluted tubule (DCT), where approximately 5% of filtered Na is reabsorbed, the thiazide-sensitive Na-Cl co-transporter (NCC) is expressed. The DCT comprises two subsegments, the DCT1 (or "early DCT") and the DCT2 (or "late DCT"). Along the DCT1, the NCC is the predominant Na transporter. Along the connecting tubule and cortical collecting duct, where approximately 3% of filtered Na is reabsorbed, isoforms of the amiloride-sensitive epithelial Na channel are expressed (ENaC). DCT2 cells express both NCC and ENaC. Together, these apical Na transport pathways along the nephron form the molecular targets for diuretic action.

This chapter will discuss the physiological and pharmacological bases for diuretic action in the kidney. Although some aspects of clinical diuretic usage will be discussed, we have emphasized physiological principles and mechanisms of action. Several recent texts provide detailed discussions of diuretic treatment of clinical conditions.[2] Extensive discussions of diuretic pharmacokinetics are also available.[3] The influence of renal disease on diuretic drug usage is discussed in the following chapter of this volume.

One classification of diuretic drugs is based on the primary nephron site of action. Such a scheme emphasizes that drugs of more than one chemical class can affect the same ion transport mechanism. Although most diuretic drugs have actions on more than one nephron segment, most owe their clinical effects primarily to their ability to inhibit Na transport by one particular nephron segment. An exception is the osmotic diuretics. Although these drugs were initially believed to inhibit solute and water flux primarily along the proximal tubule, subsequent studies have revealed effects in multiple segments. Other diuretics, however, will be classified according to their primary site of action.

OSMOTIC DIURETICS

Osmotic diuretics are substances that are freely filtered at the glomerulus, but are poorly reabsorbed (see Figure 40.2). The pharmacological activity of drugs in

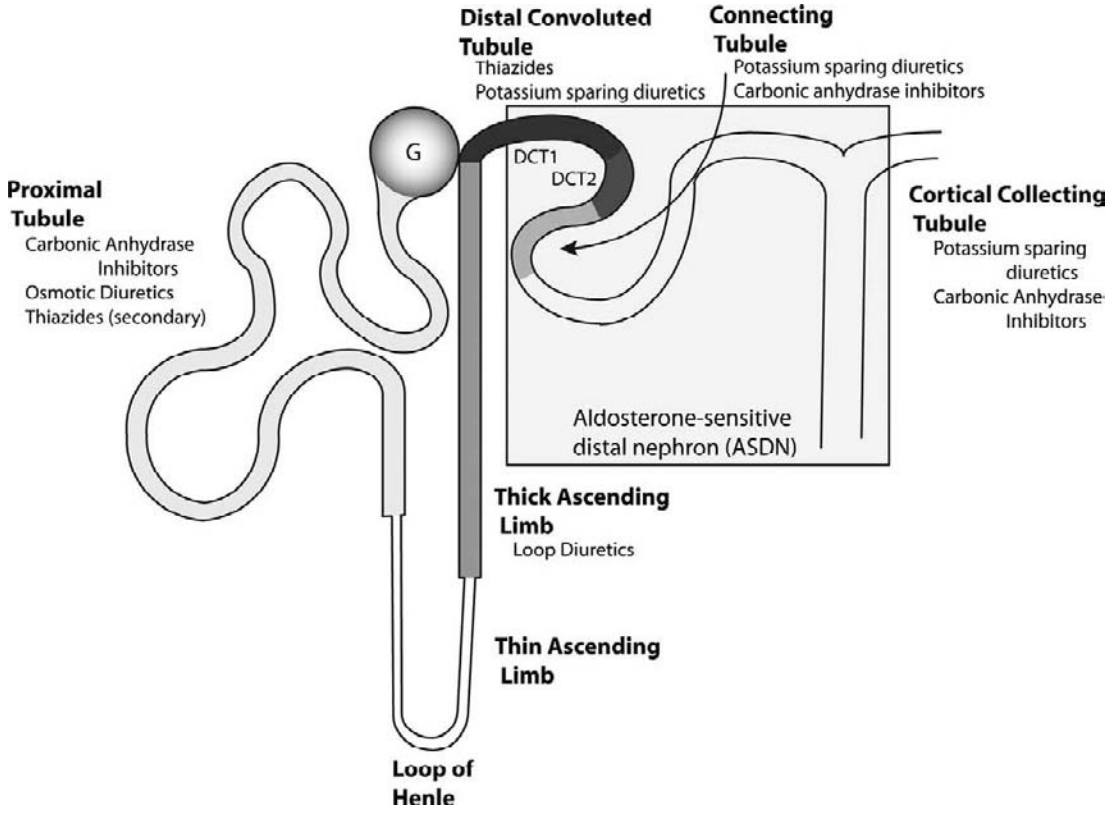

FIGURE 40.1 **Sites of diuretic action along the nephron.** Carbonic anhydrase inhibitors reduce Na reabsorption along the proximal tubule (light gray). Loop diuretics inhibit Na and Cl transport along the thick ascending limb of the Loop of Henle (medium gray). Distal convoluted tubule diuretics (thiazides and others) inhibit Na and Cl transport primarily along the distal convoluted tubule (DCT1 and the DCT2, as shown), with a secondary effect along the collecting duct, under some conditions. Potassium-sparing diuretics inhibit electrogenic Na transport along the aldosterone-sensitive distal nephron, which is indicated by the gray box.

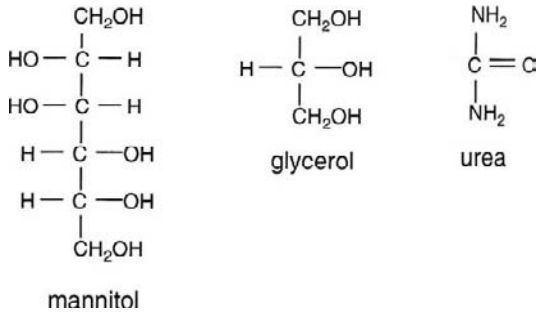

FIGURE 40.2 **Structures of osmotic diuretics.**

this group depends entirely on the osmotic pressure exerted by the drug molecules in solution, and not on interaction with specific transport proteins or enzymes. Mannitol is the prototypical osmotic diuretic. Its diuretic effect is not due to interactions with receptors or renal transporters, but rather it is due to more complex mechanisms that involve osmotic effects on tubule epithelium and reduction of the medullary interstitial osmolality. Because the relationship between the magnitude of effect and concentration of osmotic diuretic in solution is linear, all agents used clinically are small molecules. Other agents considered in this class include urea, sorbitol, and glycerol.

Urinary Electrolyte Excretion

Although osmotic agents do not act directly on transport pathways, the rate of transport of ions is affected. Following the infusion of mannitol, the excretion of sodium, potassium, calcium, magnesium, bicarbonate, and chloride is increased (see Table 40.1). The fractional reabsorption rates for sodium and water are reduced substantially following the infusion of mannitol. Reabsorption of magnesium and calcium are also reduced in the proximal tubule and loop of Henle, and phosphate reabsorption is inhibited slightly along the proximal tubule. In addition to increasing electrolyte excretion, mannitol infusion increases cortical and medullary blood flow, and has a variable effect on GFR. The most pronounced effect observed with mannitol is a brisk diuresis and natriuresis.

TABLE 40.1 Effects of Diuretics on Electrolyte Excretion

	Na	Cl	K	Pi	Ca	Mg
Osmotic diuretics	↑(10–25%)	↑(15–30%)	↑(6%)	↑(5–10%)	↑(10–20%)	↑(>20%)
Carbonic anhydrase inhibitors	↑(6%)	↑(4%)	↑(60%)	↑(>20%)	↑ or ⇔ (<5%)	↑(<5%)
Loop diuretics	↑(30%)	↑(40%)	↑(60–100%)	↑(>20%)	↑(>20%)	↑(>20%)
DCT diuretics	↑(6–11%)	↑(10%)	↑(200%)	↑(>20%)	↓	↑(5–10%)
Na channel blockers	↑(3–5%)	↑(6%)	↓(8%)	⇔	⇔	↓
Spironolactone	↑(3%)	↑(6%)	↓	⇔	⇔	↓

Figures indicate approximate maximal fractional excretions of ions following acute diuretic administration in maximally effective doses. ↑ indicates that the drug increases excretion; ↓ indicates that the drug decreases excretion; ⇔ indicates that the drug has little or no direct effect on excretion. During chronic treatment, effects often wane (Na excretion), may increase (K excretion during DCT diuretic treatment) or may reverse as with uric acid (not shown).

Mechanism of Action

The mechanisms by which mannitol produces a diuresis are thought to be secondary to: (1) an increase in osmotic pressure in the proximal tubule fluid and loop of Henle, thereby retarding the passive reabsorption of water; and (2) an increase in renal blood flow and washout of the medullary tonicity.

Mannitol is freely filtered at the glomerulus, and its presence in the tubule fluid minimizes passive water reabsorption primarily by the proximal tubule and by the thin limbs of the loop of Henle. Normally, within the proximal tubule, sodium reabsorption creates an osmotic gradient for water reabsorption. When an osmotic diuretic is administered, however, the osmotic force of the nonreabsorbable solute in the lumen opposes the osmotic force produced by sodium reabsorption. Isoosmolality of the tubule fluid is preserved, because molecules of mannitol replace sodium ions reabsorbed. Sodium reabsorption eventually stops, however, because the luminal sodium concentration is reduced to a point where a limiting gradient is reached. Surprisingly, mincropuncture experiments showed that mannitol has a greater effect on inhibiting Na and water reabsorption in the loop of Henle than in the proximal tubule. Within the loop of Henle the site of action of mannitol appears to be restricted to the thin descending limb, resulting in a decrease in reabsorption of Na and water. In the thick ascending limb, reabsorption of Na will continue in proportion to its delivery to this segment. The sum of net transport in the thin and thick limbs will determine the net effect of mannitol in the loop of Henle. Further downstream in the collecting duct, mannitol also reduces sodium and water reabsorption.

Renal Hemodynamics

During the administration of mannitol, its molecules diffuse from the bloodstream into the interstitial space. In the interstitial space, the increased osmotic pressure draws water from the cells to increase ECF volume. This effect increases total renal plasma flow. Cortical blood flow and medullary blood flow are both increased following mannitol infusion. Single nephron GFR, on the other hand, increases in the cortex and decreases in the medulla, this action on the medulla washes out the medullary osmotic gradient by reducing papillary sodium and urea content. The mechanisms that contribute to the increase in renal blood flow include a decrease in hematocrit and blood viscosity, and the release of vasoactive agents. Experimental studies indicate that the osmotic effect of mannitol to increase water movement from intracellular to extracellular space leads to a decrease in hematocrit and in blood viscosity. This fact contributes to a decrease in renal vascular resistance and increase in renal blood flow. Both prostacyclin (PGI_2) synthesis and atrial natriuretic peptide could mediate the effect of mannitol on renal blood flow. The vasodilatory effect of mannitol is reduced when the recipient is pretreated with indomethacin or meclofenamate, suggesting that PGI_2 is involved in the vasodilatory effect.

The effect of mannitol on GFR has been variable, but most studies indicate that the overall effect of mannitol is to increase GFR.[4] Whereas mannitol increased cortical and medullary blood flow, it increased cortical but decreased medullary single nephron GFR. The mechanisms by which mannitol reduces the GFR of deep nephrons are not known, but it has been postulated that mannitol reduces efferent arteriolar pressure. Micropuncture studies examining the determinants of GFR in superficial nephrons have demonstrated that the increase in single nephron GFR is owing to an increase in single nephron plasma flow, and a decrease in oncotic pressure. Alterations in renal hemodynamics contribute to the diuresis observed following administration of mannitol. An increase in medullary blood flow rate reduces medullary tonicity primarily by

decreasing papillary sodium and urea content, and increasing urine flow rate.

Pharmacokinetics

Mannitol is not readily absorbed from the intestine;[4] therefore it is routinely administered intravenously. Following infusion, mannitol distributes in ECF with a volume of distribution of approximately 16 liters; its excretion is almost entirely by glomerular filtration.[5] Of the filtered load, less than 10% is reabsorbed by the renal tubule, and a similar quantity is metabolized, probably in the liver. With normal GFR, plasma half-life is approximately 2.2 hours.

Clinical Use

Mannitol is often used prophylactically to help prevent acute kidney injury (AKI) in the setting of rhabdomyolysis,[4] although some controlled studies have not confirmed benefit.[6] It was previously used for prophylaxis from contrast-induced nephropathy, but appears of no benefit here, and is of potential harm.[7] In the past, it was also used to treat established AKI, but its use here has also fallen from favor, as convincing evidence of benefit has been lacking.

Mannitol is used for short-term reduction of intraocular pressure. By increasing the osmotic pressure, mannitol reduces the volume of aqueous humor and the intraocular pressure by extracting water. Mannitol also decreases cerebral edema and the increase in intracranial pressure associated with trauma, tumors, and neurosurgical procedures, where its benefits are most clearly established.[8] Mannitol is used perioperatively in patients undergoing cardiopulmonary bypass surgery. The beneficial effects may be related to its osmotic activity reducing intravenous fluid requirement,[9] and its ability to act as a free radical antioxidant.[10] Mannitol and other osmotic agents have been used in the treatment of dialysis disequilibrium syndrome.[11,12] This syndrome is characterized acute symptoms immediately following hemodialysis. Most significant symptoms are attributable to disorders of the central nervous system, such as headache, nausea, blurred vision, confusion, seizure, coma, and death. Rapid removal of small solutes such as urea during dialysis of patients who are markedly azotemic is associated with the development of an osmotic gradient for water movement into brain cells producing cerebral edema and neurologic dysfunction. Dialysis disequilibrium syndrome can be minimized by slow solute removal and raising plasma osmolality with saline or mannitol.

Adverse Effects

In patients with reduced cardiac output, an increase in extracellular volume induced by mannitol infusion may lead to pulmonary edema. Intravenous administration of mannitol increases cardiac output and pulmonary capillary wedge pressures. Acute and prolonged administration of mannitol leads to different electrolyte disturbances. Acute overzealous use or the accumulation of mannitol leads to dilutional metabolic acidosis and hyponatremia. Accumulation of mannitol also produces hyperkalemia, as a result of an increase in plasma osmolality. An increase in plasma osmolality increases potassium movement from intracellular to extracellular fluid from bulk solute flow, and increases the electrochemical gradient for potassium secretion. Prolonged administration of mannitol can lead to urinary losses of sodium and potassium, leading to volume-depletion, hypernatremia (as urinary loss of sodium is invariably less than water), and hypokalemia. Marked accumulation of mannitol in patients can lead to reversible AKI that appears to be due to vasoconstriction and tubular vacuolization. Mannitol-induced AKI usually occurs when large cumulative doses of $\sim$295 g are given to patients with previously compromised renal function.[6]

PROXIMAL TUBULE DIURETICS

(Carbonic Anhydrase Inhibitors)

Through the development of carbonic anhydrase inhibitors, important compounds were discovered that have utility as therapeutic agents, and as research tools. Carbonic anhydrase inhibitors (CAI) have a limited therapeutic role as diuretic agents, because of weak natriuretic properties. They are used primarily to reduce intraocular pressure in glaucoma, and to enhance bicarbonate excretion in metabolic alkalosis. CAIs have been useful in the development of other diuretic agents, such as thiazide and loop diuretics, and have been instrumental in elucidating transport function in proximal and distal nephron segments. Structures of carbonic anhydrase inhibitors are shown in Figure 40.3.

Urinary Electrolyte Excretion

Through their effects on carbonic anhydrase in the proximal tubule, CAIs increase bicarbonate excretion by 25–30% (see Table 40.1). Chronic CAI administration, however, causes only a modest natriuresis, despite the magnitude of carbonic anhydrase-dependent proximal Na reabsorption. Several factors account for this. First, carbonic anhydrase is required for reabsorption of HCO_3^-, whereas about two thirds of the proximal Na^+ reabsorption is accompanied by Cl^-. Second, some proximal HCO_3^- reabsorption persists

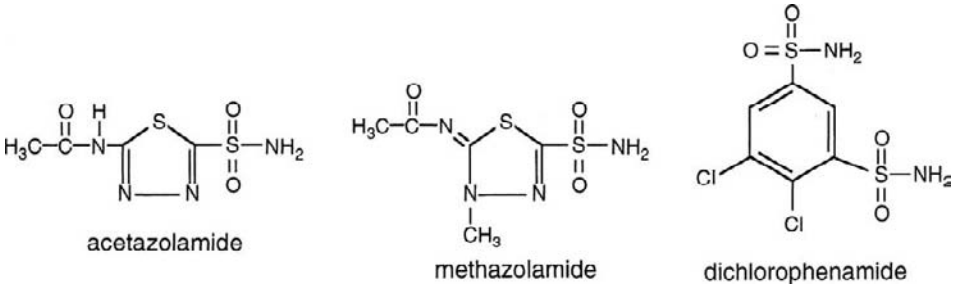

FIGURE 40.3 **Structures of carbonic anhydrase inhibitors.**

even after apparently full inhibition of carbonic anhydrase. Third, some of the HCO_3^- that is delivered from the proximal tubule can be reabsorbed at more distal sites. Fourth, the metabolic acidosis that develops limits the filtered load to HCO_3^-, and thereby curtails the natriuresis. Fifth, the increased delivery of filtered Na^+ to the macula densa elicits a tubuloglomerular feedback (TGF)-induced reduction in the GFR. Micropuncture studies of mice with deletion of the proximal Na^+/H^+ exchanger, NHE3, also show that inhibition of proximal Na reabsorption is largely balanced by reduced GFR,[13] suggesting that the reduction of GFR with CAI use contributes importantly to limiting their natriuretic potency.

The effecs of CAI on calcium excretion are complex. Proximal tubule calcium and phosphate reabsorption are inhibited by acetazolamide, partly because sodium and calcium reabsorption are closely linked within this segment.[14] Yet fractional calcium excretion is often unchanged or reduced, because distal calcium reabsorption is stimulated[15] and because luminal bicarbonate promotes calcium reabsorption. Over the longer-term, however, CAI can increase urinary calcium excretion and predispose to nephrocalcinosis and kidney stone formation.[16] In contrast, phosphate appears to escape distal reabsorption following acetazolamide administration, resulting in an increase in fractional excretion of phosphate by ~3%.[17] Although proximal tubule magnesium transport is inhibited by CAI, fractional excretion is either unchanged or is increased as a result of variable distal reabsorption.[17]

Acetazolamide increases potassium excretion.[17] Although a direct effect of acetazolamide has not been established, it is likely that several indirect effects could contribute to the observed kaliuresis. Carbonic anhydrase inhibition could block proximal tubule potassium reabsorption and increase delivery to the distal tubule, but the reported effects of carbonic anhydrase inhibition on proximal tubule transport have been conflicting. Whereas CAI decreases proximal tubule sodium, bicarbonate, and water absorption during both free flow micropuncture and microperfusion, the effects of CAI on *proximal* tubule potassium transport have been less consistent. In free flow micropuncture studies, carbonic anhydrase inhibition did not affect proximal tubule potassium reabsorption, whereas net potassium transport was reduced during proximal perfusion *in vivo*.[18] The effect of acetazolamide on the proximal tubule ion transport does, however, facilitate an increase in tubular fluid flow rate and delivery to the distal nephron of sodium bicarbonate. This effect is thought to increase the concentration of nonreabsorbable anions, creating an increase in lumen-negative voltage and an increase in flow rate,[19] factors known to increase potassium secretion by the distal tubule.

Most diuretics have some CAI action.[20] This contributes to the weak inhibition of proximal reabsorption by furosemide and chlorothiazide, and to the relaxation of vascular smooth muscle cells by high-dose furosemide Goldfarb diuretics.[20]

Mechanism of Action

In the kidney, CAI likely acts via three distinct, but related mechanisms (see Figure 40.4). First, they inhibit the hydration of CO_2 within cells, thereby reducing the generation of substrate for H^+ and HCO_3^- transporters; second, they reduce the dehydration of carbonic acid to CO_2 and H_2O in the luminal compartment, thereby inhibiting continued H^+ secretion; finally, intracellular CA appears to associate with several membrane transport proteins, and may affect their activity more directly. These actions take place along the nephron, but actions along the proximal tubule and collecting duct are especially important. The biochemical, morphological, and functional properties of carbonic anhydrase have been reviewed previously.[21] Carbonic anhydrase (CA), a metalloenzyme containing one zinc atom per molecule, is important in sodium bicarbonate reabsorption and hydrogen ion secretion by renal epithelial cells.

CA is expressed by many tissues, including erythrocytes, kidney, gut, ciliary body, choroid plexus, and glial cells. Although at least 15 isoforms of CA have been identified,[21] two play predominant roles in renal acid–base homeostasis: CAII and CAIV. CAII is widely expressed, comprising the enzyme expressed by red blood cells and a variety of secretory and absorptive

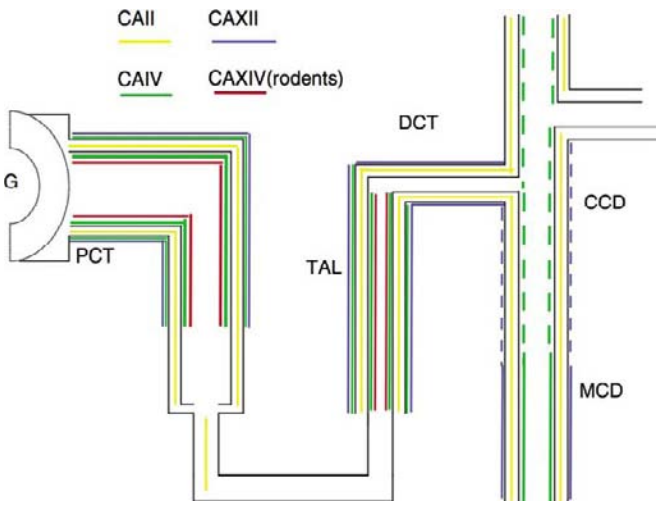

FIGURE 40.4 **Localization of CA isoforms along the nephron.** CAII (yellow stripe) is expressed within the cytoplasm of virtually all nephron segments with the exception of the loop of Henle and the thin ascending limb. CAIV (green stripe) is both apically and basolaterally expressed in the S1 and S2 segments of the proximal tubule and the thick ascending limb. In the distal nephron CAIV is expressed exclusively on the luminal (apical) surface of a-intercalated cells of the CCD and acid secreting cells of the medullary collecting duct. CAXII (blue stripe) is found on the basolateral membrane of S1and S2 segments of the proximal tubule and the thick ascending limb. In the distal nephron, CAXII is located in distal convoluted tubules, principal cells of the CCD, and the medullary collecting duct of some species. In rodent species CAXIV is expressed on the luminal surface of cells in the S1 and S2 segments of the proximal tubule and the thick ascending limb. *(Figure 40 from ref. [21], with permission.)*

epithelia. In the kidney, CAII is a cytoplasmic protein expressed, comprising 95% of renal CA.[21] It is present in proximal tubule cells and intercalated cells of the aldosterone-sensitive distal nephron (ASDN)[21](see Figure 40.4). In rodents, carbonic anhydrase XIV is expressed at the luminal border of the cells of the proximal tubule, thick ascending limb (TAL) of the loop of Henle, and α-intercalated cells of the ASDN,[22] but its role in other species is not as clear.[21]

Carbonic anhydrase (CA) catalyzes the reversible hydration of CO_2 according to the reaction:

$$H^+ + HCO_2^- \leftrightarrow H_2CO_2 \leftrightarrow CO_2 + H^+$$

CO_2 gas dissolves in water and is in equilibrium with the acid H_2CO_3. The Henderson–Hasselbalch equation relates pH, HCO_3^- concentration, and partial pressure of CO_2 gas in physiologic solutions:

$$pH = 6.1 + \log_{10}\frac{(HCO_3^-)}{0.03 \times pCO_2}$$

The uncatalyzed hydration of CO_2 is relatively slow, whereas the turnover number for CAII is in the order of $10^6\ s^{-1}$.

Type IV carbonic anhydrase is bound to renal cortical membranes, comprising up to 5% of the overall activity in kidney, and is sensitive to sulfonamides.[23,24] Type IV carbonic anhydrase, expressed on basolateral and luminal plasma membranes of proximal tubule cells and luminal membrane of intercalated cells,[25] catalyzes the dehydration of intraluminal carbonic acid generated from secreted protons.

Evidence for the physiological importance of carbonic anhydrase is apparent, as a deficiency of CAII leads to a renal acidification defect resulting in renal tubular acidosis.[26] Furthermore, metabolic acidosis leads to an adaptive increase in both CAII and CAIV mRNA expression in kidney,[27] suggesting the importance of both carbonic anhydrase isoforms in this disorder.

Carbonic anhydrase, which is associated with the brush border, prevents H^+ from accumulating in tubule fluid, and secondarily permits the continued secretion of H^+ (see Figure 40.5). Carbon dioxide rapidly diffuses from the lumen into the cell across the apical membrane. Within the cell, H is secreted into the tubule lumen via Na/H exchange, and perhaps other pathways such as H-ATPase. Following H secretion, OH^- formed combines with CO_2, forming HCO_3, which exits the basolateral membrane via $Na(HCO_3)_3$ co-transport.[28] Thus, in the early proximal tubule, the net effect of the process described results in the isosmotic reabsorption of $NaHCO_3$. The lumen chloride concentration increases, because water continues to be reabsorbed producing a lumen-positive potential. These axial changes provide an electrochemical gradient for transport of chloride via paracellular and transcellular pathways. The latter pathway for chloride likely involves a chloride–base exchanger operating in parallel with a Na/H proton exchanger.[29] The dual operation of these parallel exchangers results in net transepithelial NaCl absorption.

The participation of a membrane-bound component of carbonic anhydrase was first suggested by Rector, Carter, and Seldin.[30] The observation that carbonic anhydrase inhibitors produced an acid disequilibrium pH in the proximal tubule suggested that luminal fluid was normally in contact with carbonic anhydrase. Disequilibrium pH refers to the difference between the pH of tubule fluid *in situ* (in this case during infusion of carbonic anhydrase inhibitors), and the pH achieved after the tubule fluid is allowed to reach chemical equilibrium at known pCO_2. Thus, when carbonic anhydrase is present, the pH measured *in situ* should be the same as the pH measured at equilibrium (in other words, CA should make the HCO_3 dissociate into CO_2 and H_2O very rapidly). When carbonic anhydrase is inhibited by the administration of CAI, the dissociation of HCO_3 to OH and CO_2 is slow, allowing H to accumulate in the lumen, and reducing pH.

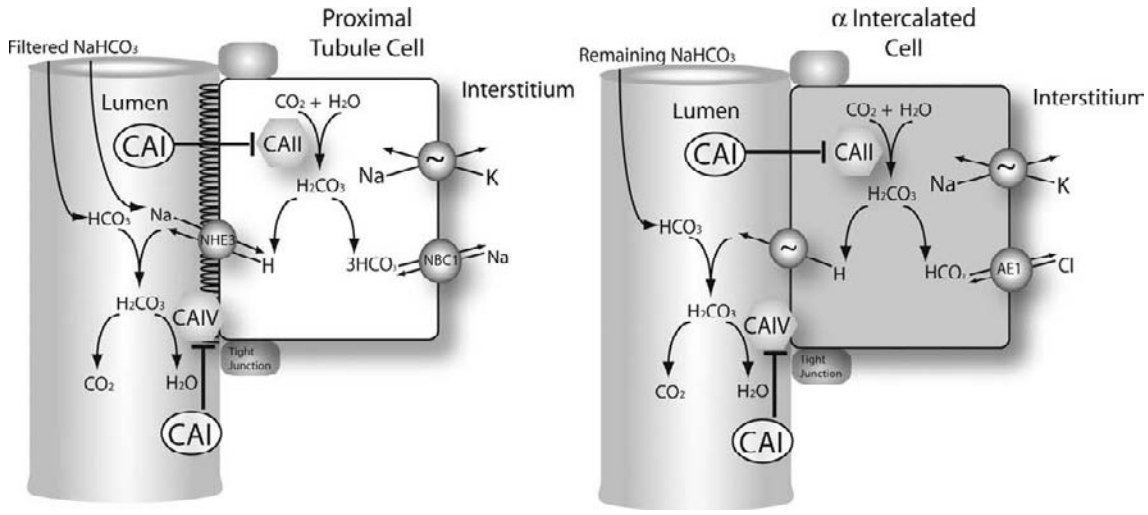

FIGURE 40.5 **Mechanisms of carbonic anhydrase inhibitors in the proximal tubule.** Water and CO_2 form carbonic acid (H_2CO_3) inside proximal cells. Carbonic anhydrase inside the cell (isoform II, CAII) catalyzes the formation of HCO_3 from OH and CO_2. Bicarbonate leaves the cell via the Na,HCO_3 co-transporter (see text). A second pool of carbonic anhydrase (isoform IV, CAIV) is located in the brush border. This participates in disposing of luminal carbonic acid, formed by the combination of filtered bicarbonate and secreted protons. Both pools of carbonic anhydrase are inhibited by acetazolamide and other carbonic anhydrase inhibitors (see text for details).

The demonstration of an acid disequilibrium pH provided physiological evidence in support of previous histochemical findings that a fraction of enzymatic activity was present in the tubule lumen. Although the cytoplasmic carbonic anhydrase constitutes the majority of enzyme activity in kidney, it is believed that the membrane bound carbonic anhydrase plays a significant role in bicarbonate reabsorption by the proximal tubule. Studies addressing this question have employed CAIs that differ in their ability to penetrate proximal tubule cell membranes. Benzolamide is charged at normal pH and is relatively impermeant, whereas acetazolamide enters the cell relatively easily. Both intravenous and intratubular administration of benzolamide resulted in an acid disequilibrium pH, indicating that luminal carbonic anhydrase inhibition contributes to bicarbonate absorption. Furthermore, proximal tubular perfusion of benzolamide resulted in 90% inhibition of bicarbonate reabsorption. Despite near equal efficacy in inhibiting proximal tubule bicarbonate reabsorption, benzolamide lowered tubular fluid pH, whereas acetazolamide increased tubular fluid pH. These results suggest that the site of action of benzolamide is at the luminal membrane, whereas the site of action of acetazolamide is within the cell. Inhibition of luminal carbonic anhydrase causes lumen pH to decrease, because of the continued secretion of hydrogen ions and its accumulation in the tubular lumen. In contrast, acetazolamide does not produce an acid disequilibrium pH.[31] The conclusion that tubular fluid was in direct contact with membrane carbonic anhydrase was substantiated by the use of dextran-bound carbonic anhydrase inhibitor. In proximal tubules perfused *in vivo*, Lucci et al.[32] determined that dextran-bound inhibitors, which inhibit only luminal carbonic anhydrase, decreased proximal tubule bicarbonate absorption by approximately 80%, and reduced lumen pH. Although these studies establish the importance of luminal carbonic anhydrase, they also support a role for intracellular carbonic anhydrase, and as acetazolamide is the only CAI used for its renal properties, suggesting that cytoplasmic CA is the predominant drug target in humans.

Following administration of carbonic anhydrase inhibitors, proximal tubule bicarbonate reabsorption is inhibited variably between 35 and >85%. As suggested from the sites of expression along the nephron (see Figure 40.4), however, additional sites of action of carbonic anhydrase inhibitors include proximal straight tubule or loop of Henle, distal tubule, collecting tubule, and papillary collecting duct.

As noted, CAII may participate more directly in facilitating net bicarbonate and, perhaps, NaCl reabsorption. CAII has been shown to associate with several proximal tranpsporters, including the basolateral bicarbonate exit transport system, kNBC1,[33] the apical Cl/base exchanger, SCL26A6,[34] and the basolateral Na/H exchanger, NHE1,[35] by binding to their respective carboxyl-terminal tails, associations that may be physiologically relevant.[36] Thus, CAIs may act both directly on transporters and via inhibition of substrate production.[37,38]

In α-intercalated cells (see Figure 40.5) within the DCT2, connecting tubule, and collecting duct, CA

facilitates acid secretion that is mediated by a vacuolar H adenosinetriphosphatase (H-ATPase)[39] H-K-ATPase, and the blood group protein RhCG at the apical membrane;[40] RhCG is now known to be an important contributor to renal ammonia secretion.[41–43] The anion exchanger (AE3) at the basolateral cell membrane participates importantly in bicarbonate reabsorption. As for the proximal tubule, both membrane-associated and cytosolic forms of CA likely contribute to distal acidification. Individuals with CAII deficiency display both proximal and distal acidification defects,[44] confirming a role for this enzyme in the distal nephron. Yet, luminal administration of acetazolamide produced an acid disequilibrium pH in the outer medullary collecting duct, suggesting contribution a of luminal carbonic anhydrase as well.[45] In subsequent studies, a membrane-impermeant carbonic anhydrase inhibitor reduced bicarbonate absorption, thus confirming the presence of membrane-bound carbonic anhydrase in the outer medullary collecting duct.[46] The K_i for inhibition of bicarbonate absorption was 5 μM, consistent with the inhibition of Type IV carbonic anhydrase.

Like the proximal tubule, where CAII association with solute transporters may contribute to their regulation and activity, CAII has been shown to associate with CAII at the basolateral membrane,[47,48] and inhibition of CA nearly completely blocked the bicarbonate transport induced by transfection of cells with AE1.

Effects of CAI on renal calcium transporters have also been examined. In mice, acetazolamide increased urinary pH and urinary calcium excretion, in association with a reduced TRPV5 abundance. Similar changes were induced by loading with NH_4Cl, but not by treatment with $NaHCO_3$, suggesting that they were the result of systemic acidosis, and not high urine pH. The importance of TRPV5 in these processes was confirmed by showing that acetazolamide did not alter urinary calcium excretion in TRPV5 knockout mice.[49] These studies suggest that the hypercalciuria and tendency to stone formation induced by CAI is the result of systemic acidosis.

Renal Hemodynamics

Inhibition of carbonic anhydrase produces an acute decrease in GFR by activating TGF.[18] Systemic infusion of acetazolamide resulted in a 30% decrease in GFR. Distally measured single nephron glomerular filtration rate (SNGFR) was reduced by 23% during acetazolamide infusion, whereas proximally measured SNGFR was not affected. These results indicated that acetazolamide blocked activated TGF, which in turn reduced GFR. Similar results were observed following infusion of benzolamide.[50] Sar-ala8-angiotensin I, an angiotensin II antagonist, prevented the decrease in SGNFR, suggesting the involvement of local angiotensin II in response to benzolamide.[50]

Pharmacokinetics

Acetazolamide is well-absorbed from the gastrointestinal (GI) tract. More than 90% of the drug is plasma protein-bound. The highest concentrations are found in tissues that contain large amounts of carbonic anhydrase (e.g., renal cortex, red blood cells). Renal effects are noticeable within 30 minutes, and are usually maximal at 2 hours. Acetazolamide is not metabolized, but is excreted rapidly by glomerular filtration and proximal tubular secretion. The half-life is approximately 5 hours, and renal excretion is essentially complete in 24 hours.[5] In comparison, methazolamide is absorbed more slowly from the GI tract, and its duration of action is long, with a half-life of approximately 14 hours.

Adverse Effects

Generally, carbonic anhydrase inhibitors are well-tolerated, with infrequent serious adverse effects. Side-effects of carbonic anhydrase inhibitors may arise from the continued excretion of electrolytes. Significant hypokalemia and metabolic acidosis may develop. In elderly patients with glaucoma treated with acetazolamide (250 mg to 1000 mg/day), metabolic acidosis was a frequent finding in comparison to a control group.[51] Acetazolamide is also associated with nephrocalcinosis and nephrolithiasis, due to its effects on urine pH facilitating stone formation.[52] Premature infants treated with furosemide and acetazolamide are particularly susceptible to nephrocalcinosis, presumably due to the combined effect of an alkaline urine and hypercalciuria.[53] Other adverse effects include drowsiness, fatigue, CNS depression, and parathesias. Bone marrow suppression has been reported.[51,54]

Clinical Use

The popularity of carbonic anhydrase inhibitors as diuretics has waned, principally because more effective agents are available, but in specific settings these drugs remain useful. In general, tolerance to the natriuretic effects of CAI develops rapidly, and renders them relatively ineffective in treatment of edema. Daily use produces systemic acidemia from an increase in urinary excretion of bicarbonate. Nevertheless, acetazolamide can be administered for short-term therapy, usually in combination with other diuretics to patients who are resistant or who do not respond adequately to other agents. The rationale for using a combination of diuretic agents is based on the summation of their effect at different sites along the nephron.[55]

The major indication for the use of acetazolamide as a diuretic agent is in the treatment of patients with metabolic alkalosis that is accompanied by edematous states or chronic obstructive lung disease.[56] In patients with cirrhosis, congestive heart failure or nephrotic syndrome, aggressive diuresis with loop diuretics promotes intravascular chloride and volume-depletion, secondary hyperaldosteronism, and renal insufficiency, conditions that promote metabolic alkalosis. Administration of sodium chloride to correct the metabolic alkalosis may exacerbate edema. Acetazolamide can improve metabolic alkalosis by decreasing proximal tubule bicarbonate reabsorption and distal proton secretion, thereby increasing the fractional excretion of bicarbonate. An increase in urinary pH (>7.0) indicates enhanced bicarbonaturia. However, it should be noted that potassium-depletion should be corrected prior to acetazolamide use, as acetazolamide will increase potassium excretion. The time-course of acetazolamide effect is rapid. In critically ill patients on ventilators, following the correction of fluid and electrolyte disturbances, intravenous acetazolamide produced an initial effect within 2 hours, and a maximum effect in 15 hours.[57]

Acetazolamide was used to treat chronic open-angle glaucoma, but its popularity has been limited by side-effects and limited efficacy. The high bicarbonate concentration in aqueous humor is carbonic anhydrase-dependent, and oral carbonic anhydrase inhibition can be used to reduce aqueous humor formation. Dorzolamide is a topical CAI that is in clinical use to treat glaucoma.

Acute mountain sickness usually occurs in sojourners who ascend to heights greater than 2500−3000 feet. Symptoms occur within the 12−72 hours, and are characterized by a symptom complex consisting of headache, nausea, dizziness, and breathlessness. Carbonic anhydrase inhibitors improve symptoms and arterial oxygenation.[58−60]

The administration of acetazolamide has been used in the treatment of familial hypokalemic periodic paralysis,[61,62] a disorder characterized by intermittent episodes of muscle weakness and flaccid paralysis. Its efficacy may be related to a decrease in influx of potassium as a result of a decrease in plasma insulin and glucose[63] or to metabolic acidosis. Carbonic anhydrase inhibitors can also be used as an adjunct treatment of epilepsy,[64] pseudotumor cerebri,[65] and central sleep apnea.[66]

By increasing urinary pH, acetazolamide has been used effectively in certain clinical conditions. Acetazolamide is used to treat cystine and uric acid stones by increasing their solubility in urine. Acetazolamide, in combination with sodium bicarbonate infusion, is also used to treat salicylate toxicity. Salicylates are weak acids (pK_a 3.0), therefore their ionic and nonionic forms exist in equilibrium. They are excreted primarily by the kidney through secretion via the organic anion transport pathway in the proximal tubule. Acetazolamide and sodium bicarbonate infusions increase urinary pH, thereby favoring formation of a nondiffusible nonionic form of salicylate, thus increasing excretion of salicylates.[67]

LOOP DIURETICS

The loop diuretics inhibit sodium and chloride transport along the loop of Henle. Although these drugs also impair ion transport by proximal and distal tubules under some conditions, these effects probably contribute little to their action clinically. Although the predominant natriuretic effects result from blockade of NKCC2, the apical transporter of the TAL, other effects may result from blockade of NKCC1, the more widely-expressed form. The affinity of loop diuretics for the two classes of transporter appears to be similar;[68] differential selectivity for the renal isoform during topical use is likely the result of the concentration of secreted drug within the tubule lumen, leading to a higher concentration adjacent to TAL cells. The role of NKCC1 inhibition in pharmacological actions of loop diuretics is discussed below. The loop diuretics available in the United States include furosemide, bumetanide, torsemide, and ethacrynic acid (see Figure 40.6). Organic mercurial diuretics also inhibit ion transport along the loop of Henle, but these drugs are of historical interest, as they are no longer available for clinical use.

Urinary Electrolyte and Water Excretion

Loop diuretics increase the excretion of water, Na, K, Cl, phosphate, magnesium, and calcium (see Table 40.1). The dose−response relationship between loop diuretic and urinary Na and Cl excretion is sigmoidal (see Figure 40.7). The steep dose−response relationship in the therapeutic range has led many to refer to these as "threshold" drugs.[3] Loop diuretics have the highest natriuretic and chloriuretic potency of any class of diuretics; they can increase Na and Cl excretion to more than 25% of the filtered load. Following oral water-loading, the administration of a loop diuretic decreases free water clearance (C_{H2O}) and increases osmolar clearance, although the urine always remains dilute. This effect contrasts with that of osmotic diuretics, in which increases in osmolar clearance are associated with increase in C_{H2O}. During water deprivation, loop diuretics impair the reabsorption of solute free water (T^C_{H2O}). Loop diuretics may induce a "negative"

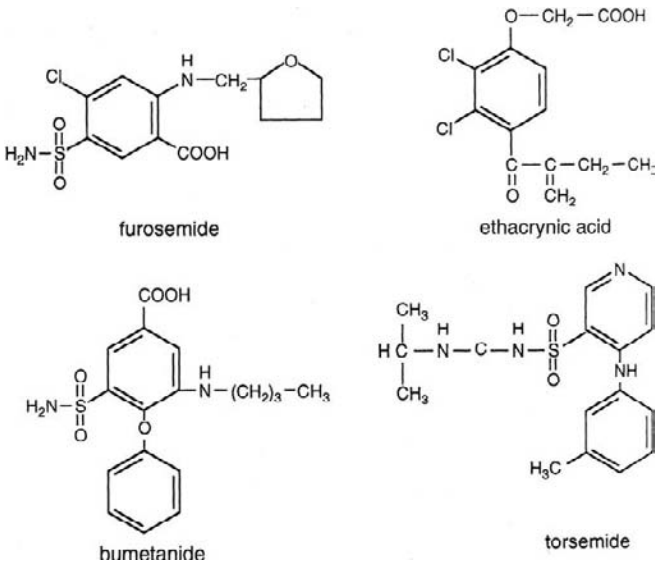

FIGURE 40.6 **Structures of loop diuretics.**

T^C_{H2O}, even during water deprivation. During maximal loop diuretic action, the urinary Na concentration is usually between 75−100 mM.[69] Because urinary K concentrations during furosemide-induced natriuresis remain low, the clearance of electrolyte free water (C_{H2O}) is increased when loop diuretics are administered during conditions of water diuresis or water deprivation.[69]

Mechanisms of Action

Na and Cl Transport

The predominant effect of loop diuretic drugs is to inhibit the electroneutral Na-K-2Cl co-transporter at the apical surface of thick ascending limb cells. The loop of Henle, defined as the region between the last surface proximal segment and the first surface distal segment, reabsorbs from 20−50% of the filtered Na- and Cl-load (see Figure 40.1); approximately 10−20% is reabsorbed by thick ascending limb cells. The model in Figure 40.8 shows key components of Na, K, and Cl transport pathways in a thick ascending limb cell. Although mechanisms of Na and Cl transport are discussed more thoroughly in other chapters in this volume, some important points deserve emphasis. First, as in other nephron segments, the Na/K-ATPase at the basolateral cell membrane maintains the intracellular Na concentration low (approximately 10-fold lower than interstitial) and the K concentration high (approximately 20-fold higher than interstitial). Potassium channel(s) in the basolateral cell membrane permit K to diffuse out of the cell, rendering the cell membrane voltage oriented with the intracellular surface negative, relative to extracellular fluid.[70] A chloride channel in the basolateral cell membrane[71] and a barium-sensitive K channel permit Cl to exit the cell.

The transporter inhibited by loop diuretics is one member of the cation-chloride co-transporter family.[72] The cation-chloride co-transporters are part of the amino acid, polyamine, organocation (APC) superfamily.[73] This Na-K-2Cl co-transporter of the thick ascending limb, NKCC2 (formerly called the bumetanide-sensitive co-transporter, BSC1), is encoded by the gene *SLC12A1*. It is a protein with 12 putative membrane-spanning domains that is expressed at the apical membrane of thick ascending limb[74] and macula densa (MD) cells.[75] It lies in parallel with a K channel (ROMK, Kir 1.1) that permits potassium to recycle from the cell to the lumen.[76] Along the thick ascending limb, the asymmetrical orientation of channels (apical versus basolateral), and the action of the Na/K-ATPase and Na-K-2Cl co-transporter, combine to create a transepithelial voltage oriented with the lumen-positive, with respect to the interstitium. This lumen-positive potential drives paracellular absorption of Na, Ca, and Mg. The paracellular component of Na reabsorption comprises as much as 50% of the total transepithelial Na transport by thick ascending limb cells[77]; it should be noted, however, that both the transcellular and the paracellular components of Na transport are inhibited by loop diuretics, the former directly and the latter indirectly; this is because loop diuretics reduce the magnitude of the transepithelial voltage, which normally drives paracellular transport. The thick ascending limb is virtually impermeable to water. The combination of solute absorption and water impermeability leads to dilution of tubule fluid.

Until recently, models of ion- and diuretic-binding to NKCC2 were largely inferential. One model of Na-K-2Cl co-transport, based on the ionic requirements for transport, postulates that ion-binding sites on the transporter must be occupied sequentially, first by Na, then by chloride, then by potassium, and finally by a second chloride.[78] Loop diuretics are organic anions that bind to the NKCC2 from the luminal surface. Early studies showed that [^{3}H] bumetanide binds to membranes that express the NKCC proteins. Optimal binding requires the presence of all three transported species, and binding and inhibition is competed by Cl^-.[79] Binding of bumetanide is also known to be a relatively slow process, and bumetanide becomes "occluded" with Na, K, and Cl.[80] Studies using chimeric NKCC molecules investigated sites of bumetanide-binding and interactions with ions by determining effects on ion transport of heterologously expressed NKCC proteins. Using this approach, it was shown that changes in amino acids that affected bumetanide-binding are not the same as those affecting the kinetics of ion translocation, and it

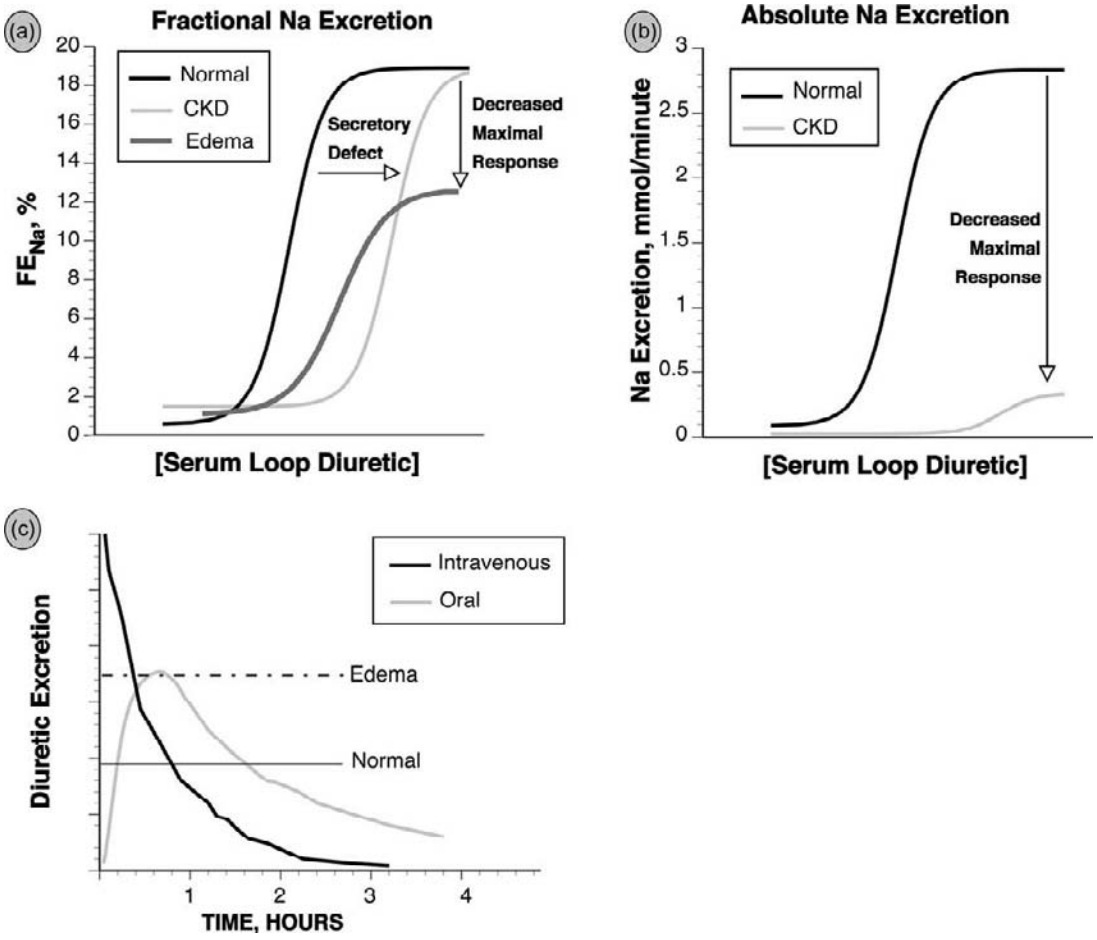

FIGURE 40.7 **Dose–response curve for loop diuretics.** Panel a shows the fractional Na excretion (FE_{Na}) as a function of loop diuretic concentration. Compared with normal patients, patients with chronic renal failure (CKD) show a rightward shift in the curve, owing to impaired diuretic secretion. The maximal response is preserved when expressed as FE_{Na}, but when expressed as absolute Na excretion, (Panel b), maximal natriuresis is reduced in patients with CKD. Patients with edema demonstrate a rightward and downward shift, even when expressed as FE_{Na} (Panel a). Panel c compares the response to intravenous and oral doses of loop diuretics. In a normal individual (Normal), an oral dose may be as effective as an intravenous dose, because the time above the natriuretic threshold (indicated by the "normal" line) is approximately equal. If the natriuretic threshold increases (as indicated by the dashed line, from an edematous patient), then the oral dose may not provide a high enough serum level to elicit natriuresis.

was suggested that bumetanide- and Cl-binding did not occur to the same site.[81,82]

More recently, however, a substantial advance in understanding mechanisms of ion transport and diuretic action has been made possible by solution of the crystal structure of two members of the APC superfamily.[83–86] The insights derived recently permitted Forbush and colleagues[73] to perform homology-based modeling of NKCC1, and to use cysteine mutagenesis of putative pore and binding regions to investigate function. While the work utilized NKCC1, the ubiquitous form, rather than NKCC2, the apical form from TAL, it is likely that the structural insights apply, at least in part. The results suggest that functionally important residues in transmembrane segment 3 (TM3) face the translocation pathway; in contrast to past results in which effects of mutations on affinity were modest, mutations of residues in TM3 led to large changes in inhibitor affinities. Three mutations led to dramatic alterations, one (M382) at the extracellular entry port, and two (F372 and I371) at the inner end of the proposed pore. The investigators suggested, therefore, that loop diuretics bind within the translocating pore, and that the binding site may be near its inner surface. The work also identified a mutation that produces a virtually bumetanide-insensitive NKCC, but which retains some furosemide sensitivity. This work appears to help resolve some discrepancies, and confirm that loop diuretics interact with vital ion transporting segments of the protein.

Although direct inhibition of ion transport is the most important natriuretic action of loop diuretics,

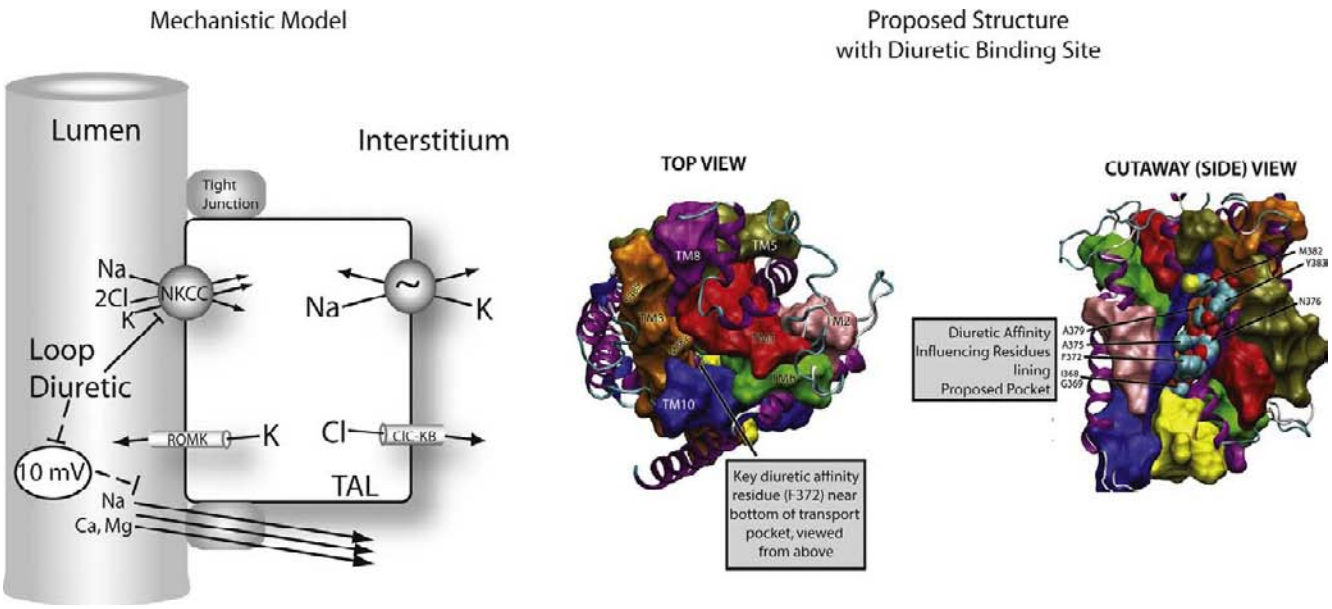

FIGURE 40.8 **Mechanisms of loop diuretic action and proposed NKCC1 structure.** Left panel: Na and Cl are reabsorbed across the apical membrane via the loop diuretic-sensitive Na-K-2Cl co-transporter, NKCC2. Note that the transepithelial voltage along the thick ascending limb is oriented with the lumen-positive relative to interstitium. This transepithelial voltage drives a component of Na (and calcium and magnesium) reabsorption via the paracellular pathway (the "tight junction," shown). Loop diuretics block the NKCC2 directly, thereby reducing the magnitude of the transepithelial voltage, and reducing Na, K, Cl, Mg, and Ca reabsorption. Right panel: Proposed structure of NKCC1. On the left, a view from above shows the translocation pocket, where residue F372, which lies nears its bottom, can be seen through the open pocket. On the right, a cutaway view into transmembrane segment 3, showing pore-lining residues colored blue and labeled. *(Structural models are adapted from J. Biol. Chem. (2012). Mar 21. (Epub ahead of print) PMID: 22437837, with permission.)*

other actions may contribute to natriuresis. Thick ascending limb cells have been shown to produce prostaglandin E_2 following stimulation with furosemide[87] or low luminal NaCl concentration.[88] Blockade of cyclooxygenase reduces the effects of furosemide to inhibit loop segment chloride transport in rats[89]; prostaglandin E_2, but not I_2, can restore this effect.[90] Animals defective in PGE_2 receptors also demonstrate blunted natriuresis, compared with wild-type animals,[91] indicating an important role for PGE_2 in loop diuretic-induced natriuresis. Increases in renal prostaglandins may contribute to the hemodynamic effects of loop diuretics, described below.

Ca and Mg Transport

Loop diuretics increase the excretion of the divalent cations, calcium and magnesium. This effect to increase calcium excretion is used to advantage when furosemide is added to saline to treat hypercalcemia,[92] although this approach is no longer recommended routinely[93] (see below). Although a component of magnesium and calcium absorption by thick ascending limbs may be active (especially when circulating PTH levels are high[94]), a large component of their absorption is passive and paracellular, driven by the transepithelial voltage. As described above, active NaCl transport by thick ascending limb cells leads to a transepithelial voltage, oriented in the lumen-positive direction. The paracellular pathway in the thick ascending limb is cation selective; expression of claudins 16 and 19 appear to play dominant roles.[95–97] The positive voltage in the lumen, relative to interstitium, drives calcium and magnesium absorption through the paracellular pathway; because these are divalent cations, the electrical driving force is double that for Na. Loop diuretics, by blocking the activity of the Na-K-2Cl co-transporter at the apical membrane of thick ascending limb cells, reduce the transepithelial voltage, impairing passive calcium and magnesium absorption.

Renin Secretion

In addition to enhancing Na and Cl excretion, effects that result directly from inhibiting Na and Cl transport, loop diuretics also stimulate renin secretion. A portion of this effect results from contraction of the ECF volume and a reduction of blood pressure (see below), but loop diuretics also stimulate renin secretion by inhibiting NaCl uptake by macula densa cells (see Figure 40.9). Macula densa cells sense the NaCl concentration in the lumen of the thick ascending limb, because NaCl enters the cell across the apical membrane.[98] High luminal NaCl concentrations in the

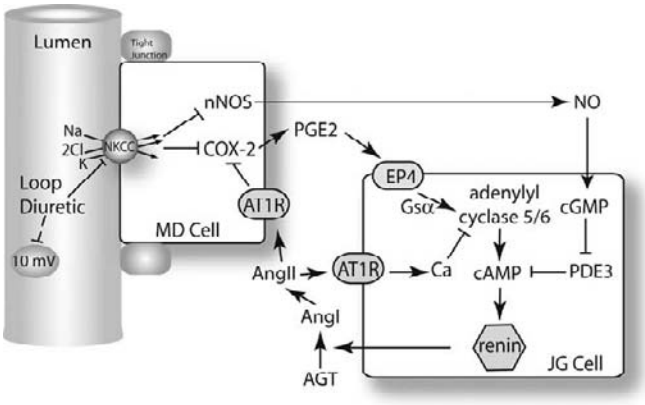

FIGURE 40.9 **Regulation of renin secretion by diuretics**. A macula densa (MD) cell is shown expressing NKCC2 at its apical surface, in parallel with a K channel. Movement of NaCl across the apical membrane inhibits production of nitric oxide (NO) via nitric oxide synthase I (nNOS). When loop diuretics inhibit NaCl uptake, nitric oxide is produced and diffuses to the extraglomerular mesangium or directly to juxtaglomerular (JG) cells, where it increases cGMP. cGMP inhibits phosphodiesterase 3 (PDE_3) which metabolizes cAMP to 5′ AMP. cAMP stimulates renin secretion. NaCl entry across the apical membrane also inhibits cyclooxygenase (COX-2). When loop diuretics block NaCl entry, COX-2 produces prostaglandin E_2 (PGE_2), which acts via Gsα to stimulate adenylyl cyclase, thereby increasing cAMP and renin.

region of the macula densa lead to two distinct but related effects. First they activate the TGF response, which suppresses the GFR. Second, they inhibit renin secretion. The relation between these two effects is complex and has been reviewed,[98] but both appear to be controlled, at least in part, by NaCl movement across the apical membrane.

The pathways mediating Na and Cl uptake into macula densa cells are similar to those expressed by adjacent TAL cells. These include the loop diuretic-sensitive Na-K-2Cl co-transporter at the apical surface. Under normal conditions, an increase in luminal NaCl concentration in the thick ascending limb raises the NaCl concentration inside macula densa cells. Because the activity of the basolateral Na/K-ATPase is lower in macula densa cells than in surrounding thick ascending limb cells,[99] the cell NaCl concentration is much more dependent on luminal NaCl concentration than in TAL cells.[100] When luminal and macula densa cell NaCl concentrations decline, COX-2 activity and expression are induced; this leads to the production of PGE_2, which diffuses to juxtaglomerular cells. There, PGE_2 activates EP4 receptors, resulting in Gsα-mediated activation of adenylyl cyclase. This process, in turn, increases the concentration of cyclic AMP, which eventually stimulates renin secretion.[98]

The constitutive (neuronal) isoform of nitric oxide synthase (NOS I) is expressed by macula densa cells, but not substantially by other cells in the kidney. Nitric oxide produced by macula densa cells has a paracrine effect to increase cAMP in adjacent juxtaglomerular cells (Figure 40.9). In these cells, nitric oxide increases cellular concentrations of cGMP, which inhibit phosphodiesterase 3.[101] Inhibition of phosphodiesterase 3 permits cAMP accumulation. Renin secretion induced by dietary NaCl depletion or furosemide is dependent on an intact nitric oxide system,[102] although it appears that basal renin secretion is not.

The second isoform of cyclooxygenase, COX-2, is also highly expressed by macula densa cells; its expression is increased by loop diuretic treatment.[88,103–105] Blockade of prostaglandin synthesis either by nonspecific cyclooxygenase inhibitors or by specific COX-2 blockers[106] reduces the renin secretory response to loop diuretics. Current views suggest that loop diuretics, like low luminal NaCl delivery, stimulate renin secretion by macula densa cells by activating COX-2, leading to PGE_2 production. PGE_2 stimulates EP4 receptors leading to renin synthesis.[107]

RENAL HEMODYNAMICS AND OXYGENATION

Most classes of diuretic reduce glomerular filtration; in contrast, loop diuretics tend to preserve GFR and renal blood flow, although GFR and RPF can decline when ECF volume contracts. NKCC1 is expressed by many cells, including vascular smooth muscle cells,[108] where it appears to contribute to vasoconstriction. The ability of loop diuretics to inhibit NKCC1, therefore, would suggest that the hemodynamic effect of loop diuretics in the kidney should consist of vasodilatation. In addition, a reduction of renal vascular resistance should result from the well-known blockade of TGF mechanism by loop diuretics, discussed below. In several species, an effect of loop diuretics to increase renal blood flow and dilate renal vessels has been observed in studies in humans[69] and dogs.[109,110] In contrast, in the majority of studies in the rat, furosemide led to a ~10–20% reduction of RBF.[111,112] In the rodent, the renal hemodynamic effects of NKCC inhibition may be unrelated to the primary actions of the diuretic on tubular and vascular functions, but to result from secondary effects on RBF activated by the diuretic. In addition, loop diuretics are known to rapidly stimulate renin secretion and prostaglandin formation, so that differences in the response of these regulatory systems to the diuretic could cause species-specific responses. Oppermann and colleagues[112] found that furosemide dilated glomerular afferent arterioles, when perfused *in vitro*, as expected from a direct effect to inhibit NKCC1, but rather led to a 50% reduction in total renal

blood flow and a 27% reduction in superficial blood flow. Notably, mice in which NKCC1 was knocked-out responded with qualitatively similar reductions in renal blood flow. These workers suggested that the effects on renal blood flow may have resulted from increased angiotensin II production, production of vasoconstrictor prostaglandins or intrarenal pressure changes consequent to diuresis.

Changes in renal hemodynamics are associated with changes in renal oxygen consumption and tissue oxygenation. Most studies in animals show that renal oxygen consumption declines and renal oxygen tension increases, especially in the medulla.[113,114] This information was used to suggest that loop diuretics might be beneficial in preventing or treating AKI; although this prediction was not borne out by clinical trials (see below), it is clear that loop diuretics do increase renal medullary oxygen tension, both in animals and in humans, as detected by BOLD MRI.[115,116]

Another factor that may contribute to the tendency of loop diuretics to maintain GFR and renal plasma flow despite volume contraction is their effect on the TGF system. The sensing mechanism that activates TGF involves NaCl transport across the apical membrane of macula densa cells by NKCC2 (see Figure 40.9). Under normal conditions when the luminal concentration of NaCl reaching the macula densa rises (as during volume expansion) GFR decreases via TGF. To a large degree, the TGF-mediated decrease in GFR results from afferent arteriolar constriction.[98] Although the mechanisms by which ion transport across the apical membrane of macula densa cells translates to afferent arteriolar vasoconstriction are unclear, they appear to involve the production of adenosine (an afferent arteriolar vasoconstrictor) and an increase in mesangial and smooth muscle cell calcium concentrations.[98] ATP release from macula densa cells[117] leads to the extracellular formation of adenosine by ecto-5′-nucleotidase. The fact that TGF is blunted in animals where ecto-5′-nucleotidase and A1 receptors are pharmacologically inhibited, and in A1 receptor and ecto-5′-nucleotidase knockout mice, supports the importance of adenosine formation and activation of adenosine A1 receptors in mediating TGF.[118–121] In a manner analogous to the effects on renin secretion, loop diuretic drugs block TGF by blocking the sensing step. In the absence of direct effects to inhibit NaCl uptake by macula densa cells, loop diuretics would be expected to suppress GFR and RPF, because they increase NaCl delivery (this action explains the effects of CAI and distal convoluted tubule diuretics on TGF[18]). Instead, blockade of NaCl uptake actually inhibits the TGF, despite increased delivery, permitting GFR and RPF to be maintained.

Systemic Hemodyanamics

Acute intravenous administration of loop diuretics tends to increase venous capacitance.[122] Most studies suggest that this effect results from stimulation of prostaglandin synthesis by the kidney.[123,124] Other studies, however, suggest that loop diuretics have effects in peripheral vascular beds as well[125] or may stimulate nitric oxide production.[126] Pickkers and co-workers examined the local effects of furosemide in the human forearm. Furosemide had no effect on arterial vessels, but did cause dilation of veins, an effect that was dependent on local prostaglandin production.[127] As noted above, there is increasing interest in the role of NKCC1 in maintaining vascular smooth muscle tone. Some,[128,129] but not other,[130] investigators have reported that NKCC1 knockout leads to basal hypotension; although NKCC1 inhibition may contribute to vasodilation under some circumstances, the plasma diuretic concentration needed for this effect is probably rare in clinical practice, for reasons noted above.

Although venodilation and improvements in cardiac hemodynamics frequently result from intravenous therapy with loop diuretics, the hemodynamic response to intravenous loop diuretics is more complex. Johnston et al. reported that low-dose furosemide increased venous capacitance, but that higher doses did not.[131] It was suggested that furosemide-induced renin secretion may generate angiotensin II-induced vasoconstriction. This vasoconstrictor might overwhelm the prostaglandin-mediated vasodilatory effects in some patients. In two series, 1–1.5 mg/kg furosemide boluses, administered to patients with chronic congestive heart failure, resulted in transient *deteriorations* in hemodyanamics (during the first hour), with a decline in stroke volume index, an increase in left ventricular filling pressure,[132,133] and exacerbation of congestive heart failure symptoms. These changes were attributed to activation of both the sympathetic nervous system and the renin–angiotensin system by the diuretic drug. Evidence for a role of the renin–angiotensin system in the furosemide-induced deterioration in systemic hemodynamics includes the temporal association between its activation and hemodynamic deterioration,[132,133] and the ability of angiotensin I-converting enzyme inhibitors to prevent much of the pressor effect.[132,133] Other studies have shown that acute loop diuretic administration frequently produces a transient decline in cardiac output; whether diuretic administration increases or decreases left atrial pressure acutely may depend primarily on the state of underlying sympathetic nervous system and renin–angiotensin axis activation. Interestingly, these complex interactions between prior physiological state and hemodynamic response to loop diuretics in humans parallel the

TABLE 40.2 Pharmacokinetics of Loop Diuretics

	Bioavailability, % Oral Dose Absorbed	Healthy	Kidney Disease	Liver Disease	HF
Furosemide	50% (range: 10–100%)	1.5–2	2.8	2.5	2.7
Bumetanide	80–100%	1	1.6	2.3	1.3

Data from ref. [72].
Elimination half-life: h; HF: heart failure.

complex interactions postulated to explain the paradoxical effects of loop diuretics in mice.[112]

Pharmacokinetics

The three loop diuretics that are used most commonly, furosemide, bumetanide, and torsemide, are absorbed quickly after oral administration, reaching peak concentrations within 0.5–2 hours (see Table 40.2). Furosemide absorption is slower than the rate of elimination in normal subjects; thus, the time to reach peak serum level is slower for furosemide than for bumetanide and torsemide. This phenomenon is called "absorption-limited kinetics".[3] The bioavailability of loop diuretics varies from 50 to 90% (Table 40.2), with furosemide having the lowest, and most variable oral bioavailability. For this reason, when changing a patient from intravenous to oral furosemide, the dose is frequently doubled to account for its limited oral bioavailability.[3] The half-lives of the loop diuretics available in the United States vary, but all are relatively short (ranging from approximately 1 hour for bumetanide to 3–4 hours for torsemide). The half-lives of muzolimine, xipamide, and ozolinone, none of which is available in the United States, are 6–15 hours.

Loop diuretics are organic anions that circulate tightly bound to albumin (>95%); thus their volumes of distribution are small, except during extreme hypoproteinemia.[134] Approximately 50% of an administered dose of furosemide is excreted unchanged into the urine. The remainder appears to be eliminated by glucuronidation, probably by the kidney. Bumetanide and torsemide are both metabolized by the liver, and also excreted unchanged by the kidney. These differences mean that furosemide kinetics are affected by renal disease, whereas bumetanide and torsemide kinetics tend not to be; this has clinical implications, discussed below.[135]

Clinical Use

Indications for loop diuretic use are given in Table 40.3. They are used commonly to treat the edematous conditions, heart failure, cirrhosis of the liver, and nephrotic syndrome. In addition, a variety of other electrolyte, fluid, and acid–base disorders can respond to loop diuretic therapy. Essentials of diuretic treatment of disease are the focus of other reviews, and will not be discussed here. The interested reader is referred to other sources for information.[2,55,136]

Loop diuretics are commonly used in the treatment of AKI. Diuretics might be thought to reduce the severity of AKI by preventing tubule obstruction and decreasing oxygen consumption,[114] as discussed above, but studies have failed to demonstrate convincingly that diuretics affect rates of renal recovery rate of patients with established AKI.[137]

Adverse Effects

There are at least three types of adverse effects of loop diuretics. The first and most common effects result directly from the effects of these drugs on renal electrolyte and water excretion. The second are toxic effects of the drugs that are dose-related and predictable. The third are idiosyncratic allergic drug reactions.

Loop diuretics are frequently administered to treat edematous expansion of the ECF volume. Edema usually results from a decrease in the "effective" arterial blood volume. Thus, zealous diuretic usage or the development of complicating illnesses can lead to excessive contraction of the ECF volume. This can be manifested by orthostatic hypotension, renal dysfunction or evidence of sympathetic overactivity. Although patients suffering from heart failure usually require diuretic therapy, the combination of diuretics and angiotensin-converting enzyme inhibitors can exacerbate prerenal azotemia. High diuretic doses or extreme dietary NaCl restriction may predispose to renal dysfunction during therapy with diuretics and angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers for heart failure.[138,139] In this case, renal failure often abates when the diuretic dose is reduced or the dietary NaCl intake is liberalized, permitting continued administration of the ACE inhibitor.

Other patients at increased risk for relative contraction of the ECF volume during loop diuretic therapy include elderly patients,[140] patients with pre-existing renal insufficiency,[141] patients with right-sided heart failure or pericardial disease, and concomitant use of non-steroidal anti-inflammatory drugs.[142,133]

Disorders of Na and K concentration are among the most frequent adverse effects of loop diuretics. Hyponatremia may be less common with loop diuretics than with distal convoluted tubule diuretics (DCT diuretics; see below), but it still may occur. Its pathogenesis is usually multifactorial, but involves the effect of loop diuretics to impair the clearance of solute-free water. Additional factors that may contribute include

TABLE 40.3 Indications for Diuretic Drugs

I. INDICATIONS FOR OSMOTIC DIURETICS
A. Prevention of rhabdomyolysis
B. To reduce intraocular or intracranial pressure
II. INDICATIONS FOR CARBONIC ANHYDRASE INHIBITORS
A. Glaucoma
B. Acute mountain sickness
C. Metabolic alkalosis
D. Cystinuria
E. Resistant Edema (used in combination with other diuretics)
F. Pseudotumor cerebri
III. INDICATIONS FOR LOOP DIURETICS
A. Edematous Conditions
1. Congestive Heart Failure
2. Cirrhotic Ascites
3. Nephrotic Syndrome
B. Hypercalcemia (now recommended only as second line treatment)
C. Hyperkalemia
D. Hyponatremia (with saline)
E. Hyperkalemic, hyperchloremic metabolic acidosis (Type 4 RTA)
F. Hypermagnesemia
G. Intoxications
H. Hypertension
I. AKI
IV. INDICATIONS FOR DISTAL CONVOLUTED TUBULE DIURETICS
A. Hypertension
B. Edematous Conditions
1. Heart Failure
2. Cirrhotic Ascites
3. Nephrotic Syndrome
C. Prevention of recurrent nephrolithiasis
D. Nephrogenic Diabetes Insipidus
E. Osteoporosis
F. Hypoparathyroidism
G. Diuretic Resistance (used in combination with other diuretics)
V. INDICATIONS FOR POTASSIUM-SPARING DIURETICS
A. Cirrhotic Ascites
B. Lithium-induced diabetes insipidus
C. Prevention of hypokalemia (owing to potassium-wasting diuretics)
D. Prevention of hypomagnesemia (owing to potassium-wasting diuretics)
E. Diuretic Resistance (used in combination with other diuretics
F. Heart Failure with systolic dysfunction
G. Resistant hypertension
H. Aldosteronism
VI. INDICATIONS FOR AQUARETICS
A. Euvolemic hyponatremia
B. Hypervolemic hyponatremia

the non-osmotic release of arginine vasopressin,[144] hypokalemia, and hypomagesemia.[145] Conversely, loop diuretics have been used to treat hyponatremia when combined with hypertonic saline, in the setting of the syndrome of inappropriate ADH secretion.[146,147] In contrast, the combination of loop diuretics and angiotensin I-converting enzyme inhibitors has been reported to correct hyponatremia in the setting of heart failure, presumably in part owing to improved cardiac function.[148]

Hypokalemia occurs commonly during therapy with loop diuretics, although the magnitude is smaller than the magnitude of hypokalemia induced by diuretics that act in the DCT (loop diuretics, 0.3 mM versus DCT diuretics, 0.5–0.9 mM[149,150]). Loop diuretics increase the delivery of potassium to the distal tubule, because they block potassium reabsorption via the Na-K-2Cl co-transporter. In rats, approximately half the excreted potassium is delivered to the "early" distal tubule. During furosemide infusion, the delivery of potassium to the "early" distal tubule rose to 28% of the filtered load.[151] Thus, it appears that a large component of the effect of loop diuretics to increase potassium excretion acutely reflects their ability to block potassium reabsorption by the thick ascending limb. By increasing flow to the aldosterone-sensitive distal nephron, loop diuretics will also stimulate potassium secretion by activating flow-dependent maxi-K (BK) channels.[152] Nevertheless, during chronic diuretic therapy, when urinary flow has returned to or close to baseline, the degree of potassium-wasting correlates best with volume contraction and serum aldosterone levels.[153] These data suggest that, under chronic conditions, the predominant effect of loop diuretics to stimulate potassium excretion results from their tendency to increase mineralocorticoid hormones, while simultaneously increasing distal Na and water delivery.

Metabolic alkalosis is very common during chronic treatment with loop diuretics. Loop diuretics cause metabolic alkalosis via several mechanisms. First, they increase urine volume; the elaborated urine is bicarbonate-free, but contains Na and Cl. This leads to contraction of the ECF around a fixed amount of bicarbonate buffer; a phenomenon known as "contraction alkalosis." This probably contributes only slightly to the metabolic alkalosis that commonly accompanies chronic loop diuretic treatment. Loop diuretics directly inhibit transport of Na and Cl into thick ascending limb cells. In some species, these cells also express an isoform of the Na/H exchanger at the apical surface. When Na entry via the Na-K-2Cl co-transporter is blocked by a loop diuretic, the decline in intracellular Na activity will stimulate H secretion via the Na/H exchanger.[154–156] Loop diuretics also stimulate the renin–angiotensin–aldosterone pathway, both directly

and indirectly, as discussed above. Aldosterone directly stimulates H secretion by the medullary collecting tubule,[157] but more importantly increases the magnitude of the transepithelial voltage in the cortical collecting duct. This effect stimulates H secretion via the electrogenic H-ATPase present at the apical membrane of α-intercalated cells. Loop diuretics frequently cause hypokalemia, which may contribute to metabolic alkalosis by increasing ammonium production,[158] stimulating bicarbonate reabsorption by proximal tubules,[159] and increasing the activity of the H/K-ATPase in the distal nephron.[160] Finally, contraction of the ECF volume stimulates Na/H exchange in the proximal tubule, and may reduce the filtered load of bicarbonate. All of these factors may contribute to the metabolic alkalosis observed during chronic loop diuretic treatment.

Ototoxicity is the most common toxic effect of loop diuretics that is unrelated to their effects on the kidney. Deafness, which is usually temporary but can be permanent, was reported shortly after the introduction of loop diuretics.[161] It appears likely that all loop diuretics cause ototoxicity, because ototoxicity can occur during use of chemically dissimilar drugs, such as furosemide and ethacrynic acid. The mechanism of ototoxicity remains unclear, although the stria vascularis, which is responsible for maintaining endolymphatic potential and ion balance, appears to be a primary target for toxicity.[162] Loop diuretics reduce the striatal potential from +80 mV to −10 to −20 mV within minutes of application.[163] A characteristic finding in loop diuretic ototoxicity is strial edema. This suggests that toxicity involves inhibition of ion fluxes.[162] Ikeda and Morizono detected functional evidence for the presence of a Na-K-2Cl co-transporter in the basolateral membrane of marginal cells.[164] According to the model proposed by these investigators, marginal cells resemble secretory cells in other organ systems, with a Na-K-2Cl co-transporter and Na/K-ATPase at the basolateral cell membrane and channels for K and Cl at the apical surface. According to this model, loop diuretic-induced shrinkage of marginal cells results from inhibition of cell Na, K, and Cl uptake across the basolateral cell membrane.

The ototoxic effects of loop diuretics appear to be related to their ability to inhibit NKCC1. This protein has been localized in the lateral wall of the cochlea, using specific antibodies[165] and RT-PCR.[166] Mice lacking the secretory isoform of the Na-K-2Cl co-transporter are profoundly deaf.[167,168] Loop diuretics cause loss of outer hair cells in the basal turn of the cochlea, rupture of endothelial layers, cystic formation in the stria vascularis, and marginal cell edema in the stria vascularis.[163]

Ototoxicity appears to be related to the peak serum concentration of loop diuretic, and therefore tends to occur during rapid drug infusion of high doses. This is likely to be related to the need to attain levels in the plasma that typically are only achieved in the renal tubule, for inhibition of NKCC1 to occur. For this reason, this complication is most common in patients with uremia,[169] where higher loop diuretic doses are frequently administered. It is recommended that furosemide infusion be no more rapid than 4 mg/minute, to avoid this complication.[169] In addition to renal failure, infants, patients with cirrhosis, and patients receiving aminoglycosides or cisplatin may be at increased risk.[169]

DISTAL CONVOLUTED TUBULE DIURETICS

The first orally active drug that inhibited Na and Cl transport along the DCT was chlorothiazide. Chlorothiazide was developed when chemical modification of sulfonamide-based CA inhibitors resulted in substances that increased NaCl, rather than $NaHCO_3$, excretion. The development of modified CA inhibitors that increased NaCl excretion preferentially was recognized immediately as significant, because ECF contains predominantly NaCl rather than $NaHCO_3$, and acidosis limited the effectiveness of CA inhibitors. Subsequent development led to a wide variety of benzothiadiazide (thiazide) diuretics (see Figure 40.10); all are analogs of 1,2,4-benzothiadiazine-1,1-dioxide. Other structurally related non-thiazide diuretics include the quinazolinones (such as metolazone) and substituted benzopehenone sulfonamide (such as chlorthalidone). Although there was some confusion initially about the site of their action along the nephron, molecular identification of their target ion transporter permitted delineation of their predominant site of action as the DCT. Recent studies, however, suggest an additional site of action along the collecting duct. Based upon the common site at which both true thiazide and "thiazide-like" diuretics inhibit ion transport, it is reasonable to refer to this class of drugs as *distal convoluted tubule diuretics*, in analogy with the *loop diuretics*.

Urinary Electrolyte and Water Excretion

Acute administration of these drugs increases the excretion of Na, K, Cl, HCO_3, phosphate, and urate, although the increases in HCO_3, phosphate, and urate excretion are probably related primarily to CA inhibition (see below). As such, the effects of DCT diuretics to increase HCO_3, phosphate, and urate excretion may vary, depending on the CA inhibiting potency of the

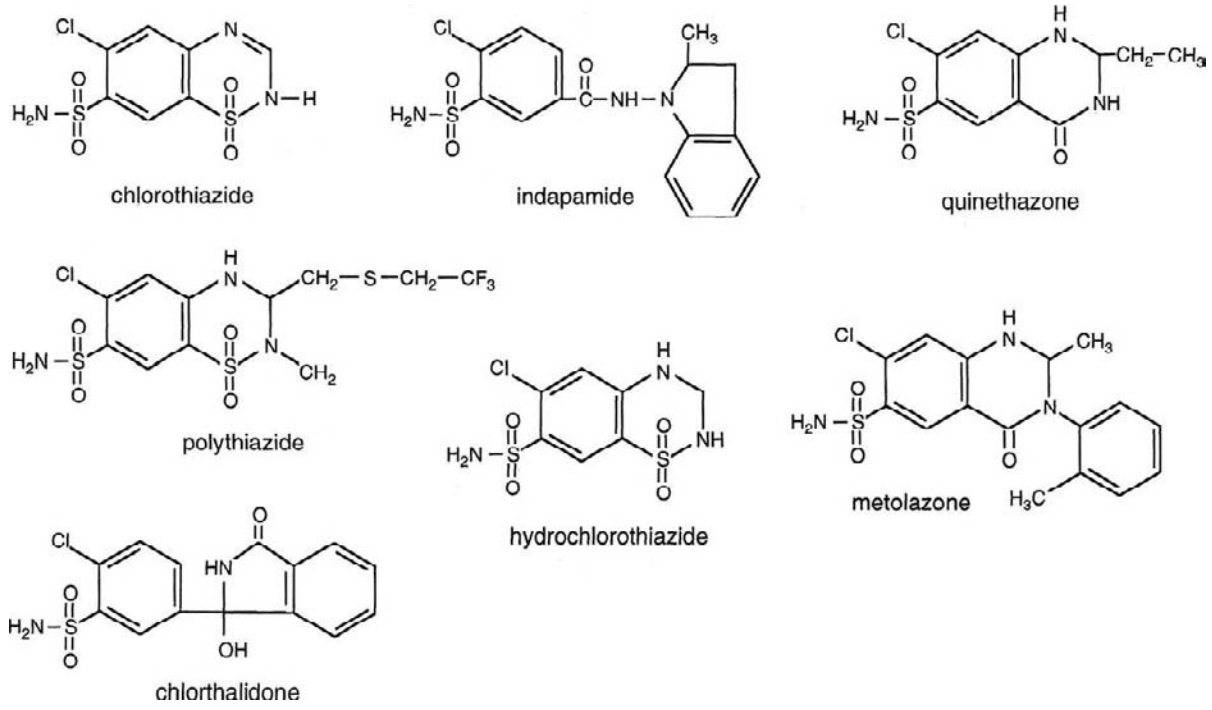

FIGURE 40.10 **Structures of DCT diuretics.**

DCT diuretic. Chronically, as contraction of the ECF volume occurs, uric acid excretion declines and hyperuricemia can occur. Further, any initial excretion of bicarbonaturia ceases, whereas continuing losses of chloride without bicarbonate and ECF volume contraction may lead to metabolic alkalosis. In contrast to loop and proximally acting diuretics, DCT diuretics tend to reduce urinary calcium excretion. Although the effects on urinary calcium excretion can be variable during acute administration,[170] these drugs uniformly lead to calcium retention when administered chronically, and also lead to positive calcium balance in humans.[171]

DCT diuretics inhibit the clearance of solute-free water (C_{H2O}) when administered during water diuresis. This effect is similar to that of loop diuretics, and originally led to the mistaken inference that they act along the thick ascending limb. In contrast to loop diuretics, however, DCT diuretics do not limit free water reabsorption during antidiuresis.

Mechanism of Action

Na AND WATER TRANSPORT IN THE PROXIMAL TUBULE

DCT diuretics are related chemically to CA inhibitors, and most retain significant CA-inhibiting potential. As discussed above, CA inhibitors interfere indirectly with the activity of NHE3 in the proximal tubule. Although this effect of DCT diuretics may be useful when these drugs are administered acutely (as during intravenous chlorothiazide administration), it probably contributes little to the overall natriuresis during chronic use. Yet this effect may play a role in the tendency for DCT diuretics to reduce the GFR and activate the TGF mechanism.[18] The relative CA inhibiting potency (shown in parentheses, compared with hydrochlorothiazide) of some commonly used DCT diuretics is chlorthalidone (67) >benthiazide (50) >polythiazide (40) >chlorothiazide (14) >hydrochlorothiazide (1) >bendroflumethiazide (0.07).[172]

NaCl ABSORPTION IN THE DISTAL NEPHRON

The predominant site at which DCT diuretics inhibit ion transport is the DCT. Although clearance studies had identified one site of thiazide action as the cortical diluting segment, and a second site as the proximal tubule, micropuncture studies pinpointed the primary site of action as the superficial "distal tubule".[173] This region of the nephron, which lies between the macula densa and the confluence with another nephron to form the cortical collecting duct, is morphologically heterogenous. It comprises a short stretch of post macula densa thick ascending limb, the DCT, the connecting tubule, and the initial portion of the cortical collecting duct. When this morphological heterogeneity became evident, experiments were designed to determine the site of thiazide action more precisely. Microperfusion experiments in rats indicated that thiazide diuretics inhibit Na and Cl transport along the

"early" portion of the distal tubule,[174,175] a segment known to contain predominantly DCT cells.[176]

Although microperfusion data from rats indicated that thiazide diuretics inhibit Na transport in the DCT, the transition along the distal nephron segments in rats is gradual. For several years, therefore, it was impossible to attribute thiazide-sensitive Na-Cl transport to a specific cell type in the rat. In contrast, rabbit distal nephron segments have abrupt transitions. *In vitro* studies suggested that thiazide-sensitive Na-Cl co-transport is present in connecting tubules instead of DCTs,[177,178] but Velázquez and Greger obtained indirect evidence for thiazide-sensitive transport in rabbit DCTs.[179] Molecular cloning[180] permitted definitive identification of DCT cells as the only sites of thiazide-sensitive Na-Cl co-transporter expression in both rat and rabbit.[181–183] Friedman and colleagues developed a clonal cell line from immunodissected mouse thick ascending limb and DCT cells that expresses thiazide-sensitive transport.[184] Molecular studies identified the DCT as the site of thiazide-sensitive Na-Cl co-transport in this species, as well.[185]

In 1984, Velázquez and colleagues reported the mutual dependence of Na and Cl transport in the superficial rat distal tubule.[186] The same year, Stokes reported evidence that a directly-coupled thiazide-sensitive Na-Cl co-transporter is expressed in the urinary bladder of the Winter Flounder.[187] Gamba et al. cloned this protein[180] and detected homologous mRNA in mammalian kidney. The same group cloned a rat form of the thiazide-sensitive Na-Cl co-transporter.[188] Mouse, human, and rabbit forms were cloned shortly thereafter;[189–191] the gene is *SLC12A3*; it is a member of the cation-chloride co-transporter family, which includes NKCC1 and NKCC2. This transport protein was previously termed the TSC (thiazide-sensitive co-transporter), and the NCCT (sodium chloride co-transporter), but most investigators prefer the term NCC (sodium chloride co-transporter), for its analogy with NKCC. At the molecular level, the NCC is expressed only by DCT cells in all mammalian species examined to date. In humans, rats, and mice, expression of NCC also extends into a transitional segment, referred to as the "late" DCT or DCT-2, which shares properties of the distal convoluted and connecting tubules.[181,185]

Evidence for thiazide action in other nephron segments has also been obtained, however. *In vivo* catheterization experiments demonstrated a component of thiazide-sensitive Na transport in medullary collecting tubules of rats.[192] Some,[193] but not other[194] investigators have detected thiazide-sensitive Na-Cl transport in rat cortical collecting ducts perfused *in vitro*. In those experiments, pretreatment of animals with mineralocorticoid hormones was necessary to elicit the thiazide-sensitive Na and Cl transport. Eladari and colleagues[195] detected an effect of DCT diuretics on NaCl excretion in NCC knockout mice; these mice lack NCC entirely, and therefore the observed effect must be related to NCC-independent pathways. They also found that collecting ducts from animals exposed to aldosterone reabsorbed Na and Cl in a thiazide-sensitive manner. They went on to show that this transport was dependent on the Na-dependent chloride bicarbonate transporter (NDCBE) and on pendrin (SLC26A4), transport proteins expressed by intercalated cells. While this work deserves verification, it strongly suggests that DCT diuretics may have important effects on net NaCl transport within segments other than the DCT. A model of NaCl transport by DCT cells and a proposed model for NaCl transport by intercalated cells in the collecting duct are shown in Figure 40.11.

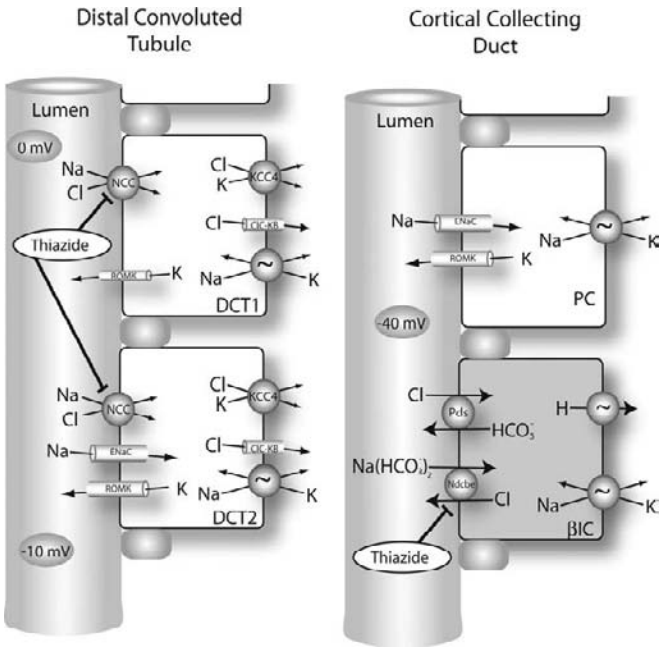

FIGURE 40.11 **Mechanisms of thiazide diuretics.** The left panel shows the mechanism of action of thiazide diuretics in the DCT. Two types of DCT cells have been identified; referred to here as DCT1 and DCT2. Na and Cl are reabsorbed across the apical membrane of DCT1 cells only via the thiazide-sensitive Na-Cl co-transporter. This transport protein is also expressed by DCT2 cells, where Na can also cross through the epithelial Na channel, ENaC (see text for details). Thus, the transepithelial voltage along the DCT-1 is near to 0 mV, whereas it is lumen-negative along the DCT-2. The right panel shows recently established mechanisms of action of thiazide diuretics along the collecting duct, in the presence of aldosterone stimulation. Here Na is reabsorbed in exchange for K by principal cells (PC), but in beta type intercalated cells (βIC) Na reabsorption occurs via a Na-dependent chloride bicarbonate exchanger (Ndcbe). This occurs in parallel with the action of pendrin (Pds) to achieve net NaCl reabsorption. The Ndcbe appears to be sensitive to thiazide diuretics.

Like loop diuretics, DCT diuretics, including the thiazides, are organic anions that bind to the transport

protein from the luminal surface. Results of studies to determine the mechanism by which DCT diuretics interact with the transport protein have varied, depending on the methods employed, and in a manner that resembles those described above concerning loop diuretics and NKCC. Before the transport protein was identified at the molecular level, Fanestil and colleagues showed that [^{3}H] metolazone binds avidly to kidney membrane proteins; its binding is inhibited competitively by Cl^-, suggesting that Cl^- and diuretic compete for the same binding site.[196,197] These results are reminiscent of those that utilized [^{3}H] bumetanide to study properties of the NKCC proteins and were used to develop a kinetic model for the NCC.[198] More recently, Gamba and colleagues have expressed chimeras of the NCC in *Xenopus* oocytes and determined thiazide affinity based on transport inhibition. The results suggest a more complicated picture. They conclude that thiazide diuretic affinity is conferred by transmembrane segments 8–12, whereas transmembrane segments 1–7 affect chloride affinity. Both segments are involved in determining Na^+ affinity.[199] These data suggest that that the affinity of thiazide diuretics for binding to the transport protein is in a region distinct from that which participates in Cl^- transport. As was the case for NKCC, however, it seems likely that the recent data concerning the crystal structure of APC transporters, coupled with molecular modeling, will provide new information concerning potential binding sites that can then be tested empirically.[73]

Calcium and Magnesium Transport

When administered chronically, DCT diuretics reduce calcium excretion. This effect has been utilized clinically to reduce the risk of recurrent calcium nephrolithiasis (see below). As noted above, acute administration of DCT diuretics has a variable effect on calcium excretion, sometimes leading to increases in calcium excretion. This probably reflects the CA-inhibiting capacity of these drugs, because CA inhibitors increase urinary calcium excretion acutely. Ca reabsorption by proximal tubules is functionally coupled to sodium reabsorption (see Figure 40.12); drugs that inhibit proximal Na reabsorption also inhibit proximal calcium reabsorption. During chronic treatment, however, the filtered calcium-load decreases, owing to the hemodynamic effects discussed below, and the proximal calcium reabsorption increases, owing to ECF volume contraction.

Mechanisms and sites responsible for the hypocalciuric effects of DCT diuretics have been quite controversial.[200] Early micropuncture and microperfusion studies showed that DCT diuretics stimulate Ca reabsorption along the DCT costanzo.[201,202] Three potential

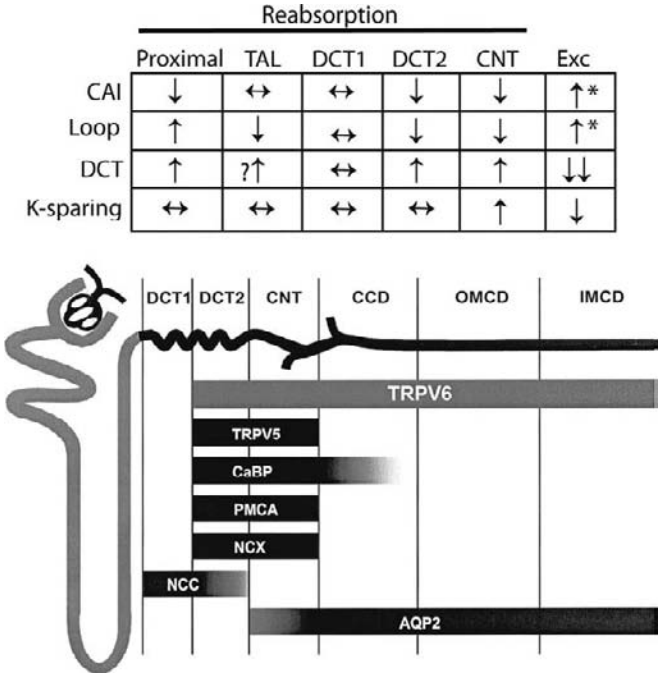

FIGURE 40.12 **Summary of diuretic effects on calcium excretion and sites of calcium transport protein expression.** Top panel: Effects of diuretics, including carbonic anhydrase inhibitors (CAI), loop diuretics (Loop), distal convoluted tubule diuretics (DCT), and K-sparing diuretics on calcium reabsorption along the proximal tubule, the thick ascending limb (TAL), the distal convoluted tubule (segments 1, DCT1, and 2, DCT2), and connecting tubule (CNT). Also shown are effects of these diuretics on urinary excretion (Exc). As noted by *, effects of CAI and loop diuretics to increase urinary calcium excretion may be inhibited when moderate depletion of the ECF volume increases reabsorption further along the proximal tubule. CAIs have been shown to reduce the abundance of TRPV5, as discussed in text. Effects of DCT diuretics on transport along TAL are speculative.[212] Bottom panel: Sites of expression of calcium-transporting proteins, including TRPV5 and -6, the calcium-binding proteins (CaBP), the plasma membrane Ca ATPase (PMCA), the Na/Ca exchanger (NCX). It also shows sites of NCC and AQP expression. Note the concurrence of expression within the DCT2 and CNT. *(Bottom panel from Nijenhuis, T., et al. (2003). J. Am. Soc. Nephrol.* ***14*** *(11); 2731–2740, with permission.)*

and non-redundant mechanisms were postulated to account for this.[203] First, blockade of luminal NaCl entry should reduce the tubule cell [Na^+] sufficiently to enhance the basolateral Na^+/Ca^{2+} exchange.[202] A low cellular Na concentration provides part of the driving force for basolateral calcium exit via the 3Na/Ca exchanger. Second, thiazides reduce cell [Cl^-] concentration, which should hyperpolarize the membrane voltage (making the interior of the cell more negative, electrically). Hyperpolarization should enhance calcium absorption, because the 3Na/Ca exchanger is electrogenic, so transport (in the reabsorptive direction) should be stimulated, and the transient receptor potential channel subfamily V, member 5 (TRPV5) channel,

which is expressed at the apical membrane of DCT and connecting tubule cells, may be stimulated.[204,205]

More recently, the role of proximal tubular processes has been re-emphasized. In one study[206] thiazides were found to reduce Ca^2 excretion, even when the major calcium reabsorptive pathway of the distal nephron, TRPV5, was deleted genetically. TRPV5 deletion produced a marked rise in urinary calcium excretion at baseline, but hydrochlorothiazide still reduced urine calcium excretion in these animals, albeit to levels which were quite high. A prominent role for ECF volume contraction and enhanced proximal reabsorption is consistent with older data suggesting that thiazides stimulate proximal reabsorption of Ca^2.[207] Yet, there are several reasons to consider that a distal effect also contributes importantly. First, HCTZ induced a profound hypocalciuria in parvalbumin knockout mice, without increasing NaCl excretion.[208] This argues that ECF volume depletion is not a prerequisite for DCT diuretic-induced hypocalciuria. Second, saline infusion does not normalize urinary calcium excretion, either in humans with Gitelman syndrome,[209] in whom NCC is dysfunctional or in mice with the kinase SPAK deleted, in whom the abundance and phosphorylation of NCC is missing.[210] One difference may be related to species and dose. Animals such as the TRPV5 knockout animals, often display evidence of marked ECF volume-depletion in response to thiazide treatment (as indicated by hemoconcentration and weight loss), whereas ECF volume, at least at steady-state, is typically normal in people treated with DCT diuretics clinically. Most recently, it was shown that individuals with Gitelman syndrome have evidence of activated NaCl transport along the TAL.[211] It has been suggested on this basis that increased solute transport along the TAL might then contribute to increased calcium reabsorption there, as transepithelial voltage should vary directly with solute transport.[212]

DCT diuretics also increase urinary magnesium excretion when administered chronically, and can cause hypomagnesemia,[213,214] although the acute effects of DCT diuretics are more variable. Magnesium transport across the apical membrane of DCT cells is mediated, largely, by the transient receptor potential channel, TRPM6.[215] Chronic treatment of rats with hydrochlorothiazide reduced the abundance of this transport protein, a finding that is mimicked by genetic disruption of the NCC.[206] Thus, thiazides may induce magnesium-wasting, at least in part, by reducing the abundance of the apical magnesium channel. These data are consistent with findings from NCC knockout animals, and from results of chronic thiazide treatment of rats. In NCC knockout animals, the DCT1 is atrophic,[216] an effect that appears to be mimicked by chronic thiazide infusion.[217] Inasmuch as this segment normally expresses TRPM6 at high levels, such atrophy may explain the reduced TRPM6 expression and magnesium-wasting. This finding, however, may also account for the relatively mild effects of DCT diuretics on magnesium homeostasis in humans. The effects of DCT diuretics to cause apoptosis and atrophy of parts of the DCT may be a species-specific phenomenon[218]; thiazide treatment of humans has not been reported to cause substantial tubule disruption.

Other effects of DCT diuretics have been suggested to contribute to magnesium-wasting. Dai et al. proposed that magnesium is transported across the apical membrane of DCT cells by a hyperpolarization-activated magnesium channel.[219] They found that DCT diuretics stimulated magnesium uptake into DCT cells by reducing the intracellular activity of chloride, hyperpolarizing the membrane voltage, and activating magnesium channels. These magnesium channels are sensitive to dihydropyridines, but appear to be distinct from calcium channels. Amiloride was found to have similar effects on magnesium uptake.[220] The importance of these channels in renal magnesium homeostasis, however, is unclear, as molecular and genetic studies have suggested the key role played by TRPM6.[221]

Quamme proposed that magnesium-wasting in Gitelman"s syndrome (and by analogy during DCT diuretic treatment) results from hypokalemia and from hyperaldosteronism.[222] Ellison suggested that distal magnesium transport is dependent on the transepithelial voltage. In this case, thiazide diuretics, by increasing aldosterone concentrations and blocking electroneutral Na reabsorption, would enhance the luminal negativity. This would inhibit magnesium reabsorption.[203] The mechanisms of drugs that cause distal depolarization, such as amiloride magnesium,[223–225] or that block mineralocorticoid receptors (MR), such as spironolactone,[226,227] remain to be defined.

Renal Hemodynamics

DCT diuretics increase renal vascular resistance and decrease the GFR when given acutely. Okusa et al.[18] showed that intravenous chlorothiazide reduced the GFR by 16% when measured as whole kidney clearance or by micropuncture of a superficial distal tubule. In contrast, however, when flow to the macula densa was blocked and the SNGFR was measured by micropuncture of a proximal tubule, intravenous chlorothiazide had no effect on GFR. These data indicate that diuretic-induced stimulation of the TGF system mediates the effect of DCT diuretics on GFR; DCT diuretics are known to increase the concentration of Na in luminal fluid entering the superficial distal tubule. It is

assumed that a change in the tubule fluid ion concentration mediates this effect.

During chronic treatment with DCT diuretics, contraction of the ECF volume develops, thereby increasing solute and water reabsorption by the proximal tubule. This effect reduces the distal Na delivery to levels that are lower than under control conditions. In view of the fact that the initial suppression of GFR resulted from TGF, initiated by distal NaCl delivery, the GFR usually returns close to control values during chronic treatment with DCT diuretics.[228,229] Thus, when used chronically, DCT diuretics lead to a state of very mild ECF volume contraction, increased fractional proximal reabsorption, and relatively preserved glomerular filtration.

When administered acutely, the effect of DCT diuretics on renin secretion is variable. If urinary NaCl losses are replaced, these drugs tend to suppress renin secretion, probably by increasing NaCl delivery to the macula densa.[18] In contrast, during chronic administration, renin secretion increases both because solute delivery to the macula densa declines, and because volume-depletion activates the vascular mechanism for renin secretion.[102]

Pharmacokinetics

DCT diuretics are organic anions that circulate in a highly protein-bound state. As with loop diuretics, the amount reaching the tubule fluid by filtration across the glomerular basement membrane is small; the predominant route of entry into tubule fluid is by secretion via the organic anion secretory pathway in the proximal tubule. DCT diuretics are rapidly absorbed, reaching peak concentrations within 1.5 to 4 hours.[3] The amount of administered drug that reaches the urine varies greatly (for a review see [3]), as does the half-life. Short-acting DCT diuretics include bendroflumethiazide, hydrochlorothiazide, tizolemide, and trichlormethiazide. Medium-acting DCT diuretics include chlorothiazide, hydroflumethiazide, indapamide, and mefruside. Long-acting DCT diuretics include chlorthalidone, metolazone, and polythiazide.[3] The clinical effects of the differences in half-life are increasingly being appreciated. The incidence of hypokalemia may be higher in patients taking the longer-acting drugs such as chlorthalidone,[149,230] but it also appears that longer-acting drugs, and especially chlorthalidone, have greater antihypertensive efficacy.[231]

Clinical Use

Indications for the use of DCT diuretics are listed in Table 40.3. Many details of DCT diuretic use are available in other reviews[2,55,232] and will not be discussed here. DCT diuretics are used most commonly to treat essential hypertension. Despite a great deal of recent debate about their potential complications in the setting of essential hypertension, DCT diuretics continue to be recommended as drugs of first choice in the treatment of hypertension.[233] DCT diuretics are also used commonly to treat edematous conditions, although they are frequently perceived as being less effective than loop diuretics. Although the maximal effect of loop diuretics to increase urinary Na, Cl, and water excretion is greater than that of DCT diuretics, Leary and colleagues have shown that the cumulative effects of DCT diuretics on urinary Na and Cl excretion are greater than those of once daily furosemide.[234] Although these studies were conducted in normal volunteers, they may extend to patients with mild cases of edema. In addition, DCT diuretics have proved useful to treat edematous patients who have become resistant to loop diuretics. In this case, the addition of a DCT diuretic to a regimen that includes a loop diuretic frequently increases urinary Na and Cl excretion dramatically (see below).

DCT diuretics have become drugs of choice to reduce the recurrence of risk for kidney stones in patients with idiopathic hypercalciuria.[235] As noted, these drugs decrease urine calcium excretion, and in randomized controlled trials they significantly reduced recurrence rates of calcium stones by more than 50% during three-year periods, as compared with placebo. Long-acting agents like chlorthalidone and indapamide are effective with once-daily doses, whereas twice-daily doses are recommended for hydrochlorothiazide.

The ability of DCT diuretics to reduce urinary calcium excretion suggests that these drugs may prevent bone loss. Some,[236,237] but not all,[238,239] epidemiological studies suggested that DCT diuretics reduce the risk of hip fracture and osteoporosis. Clinical trials have confirmed that thiazide diuretics reduce the loss of cortical bone and may prevent hip fracture, although the effect seems modest, and does not persist once the drug has been discontinued.[240–242]

DCT diuretics are also employed to treat nephrogenic diabetes insipidus, causing a paradoxical decrease in urinary volume flow rate. This action of DCT diuretics results from the combination of actions. The best-studied effects include the induction of mild ECF volume contraction, owing to diuretic-induced natriuresis, suppression of GFR, owing largely to diuretic-induced activation of the TGF, and reduced distal water delivery. Such a mechanism would require depletion of the ECF volume, a requirement that has been documented in several studies.[229,243] The human DCT, like the thick ascending limb, is nearly impermeable to water.[244] Solute reabsorption by the thiazide-sensitive Na-Cl co-transporter therefore contributes directly to urinary dilution; thus, blocking Na-Cl co-transport reduces urinary diluting capacity. More

recently, DCT diuretics have been shown to alter the abundance of water and salt transport pathways in the distal nephron. Kim and colleagues used a rat model of lithium-induced diabetes insipidus. They showed a lithium-induced decrease in aquaporin expression that could be reversed, partially, by DCT diuretics.[245] Another report showed that DCT diuretics enhance water absorption in IMCD from normal rats (in the absence of ADH) and from Brattleboro rats, and that HCTZ-stimulated water permeability was blocked partially by PGE_2.[246]

Adverse Effects

Electrolyte disorders, such as hypokalemia, hyponatremia, and hypomagnesemia, are common side-effects of DCT diuretics. A measurable fall in serum K concentration is nearly universal in patients given DCT diuretics, but most patients do not become frankly hypokalemic.[230] In the Allhat study, the largest controlled antihypertensive trial, mean plasma K concentrations were 0.3 mM lower in patients randomized to cholorthalidone, compared with amoldipine (which has little effect on K metabolism). The clinical significance of diuretic-induced hypokalemia continues to be debated.[247,248] Unlike the loop diuretics, DCT diuretics do not influence K transport directly.[249,250] Instead, they increase K excretion indirectly. DCT diuretics increase tubule fluid flow in the connecting tubule and collecting duct, the predominant sites of K secretion along the nephron. Increased flow stimulates K secretion both via flow-dependent potassium channels[152] and by diluting luminal potassium.[251] In addition, DCT diuretic-induced ECF volume contraction activates the renin−angiotensin−aldosterone system, further stimulating K secretion. Evidence for the central role of aldosterone in diuretic-induced hypokalemia includes the observation that hypokalemia is somewhat more common during treatment with long-acting DCT diuretics, such as chlorthalidone, than with short-acting DCT diuretics, such as hydrochlorothiazide or with the very-short-acting loop diuretics.[149] Another reason that DCT diuretics may produce more potassium-wasting than loop diuretics is the differences in effects on calcium transport. As discussed above, loop diuretics inhibit calcium transport by the thick ascending limb, increasing distal calcium delivery. In contrast, DCT diuretics stimulate calcium transport, reducing calcium delivery to sites of potassium secretion. Okusa and colleagues[252,253] showed that high luminal concentrations of calcium inhibit ENaC in the distal nephron, thereby inhibiting potassium secretion. DCT diuretics also increase urinary magnesium excretion and can lead to hypomagnesemia, as discussed above. Hypomagnesemia may cause or contribute to the hypokalemia observed under these conditions.[254] Some studies suggest that maintenance magnesium therapy can prevent or attenuate the development of hypokalemia,[255,256] but this has not been supported universally.

Diuretics have been reported to contribute to more than 50% of all hospitalizations for serious hyponatremia. Hyponatremia is especially common during treatment with DCT diuretics,[257] compared with other classes of diuretics, and the disorder is potentially life-threatening. Several factors contribute to DCT diuretic-induced hyponatremia. First, as discussed above, DCT diuretics inhibit solute transport in the terminal portion of the "diluting segment," the DCT. This impairs the ability to excrete free water. Second, DCT diuretics can reduce the GFR, primarily by activating the TGF system. This limits solute delivery to the diluting segment, and impairs free water clearance. Third, DCT diuretics lead to volume-contraction, which increases proximal tubule solute and water reabsorption, further restricting delivery to the "diluting segment." Fourth, hyponatremia has been correlated with the development of hypokalemia in patients receiving DCT diuretics,[258] suggesting total cation depletion. Finally, susceptible patients may be stimulated to consume water during therapy with DCT diuretics; although the mechanisms are unclear, this may contribute importantly to the sudden appearance of hyponatremia that can occur during DCT diuretic therapy. Of note, one report suggests that patients who are predisposed to develop hyponatremia during treatment with DCT diuretics will demonstrate an acute decline in serum sodium concentration in response to a single dose of the drug.[259] Recent studies suggest that female gender, advanced age, and low body mass are risk factors for thiazide-induced hyponatremia.[260,261]

DCT diuretics frequently cause metabolic alkalosis. The mechanisms are similar to those described above for loop diuretics, except that DCT diuretics do not stimulate Na/H exchange in the TAL.

DCT diuretics cause several disturbances of endocrine glands. Glucose intolerance has been a recognized complication of DCT diuretic use since the 1950s. This complication appears to be dose-related.[262,263] The pathogenesis of DCT diuretic-induced glucose intolerance remains unclear, but several factors have been suggested to contribute. First, diuretic-induced hypokalemia may alter insulin secretion by the pancreas, via effects on the membrane voltage of pancreatic β-cells. When hypokalemia was prevented by oral potassium supplementation, the insulin response to hyperglycemia normalized, suggesting an important role for hypokalemia.[264] Hypokalemia may also interfere with insulin-mediated glucose uptake by muscle, but most patients demonstrate relatively normal insulin sensitivity.[265] Yet others have suggested that hypokalemia is not likely the only factor, as individuals with familial

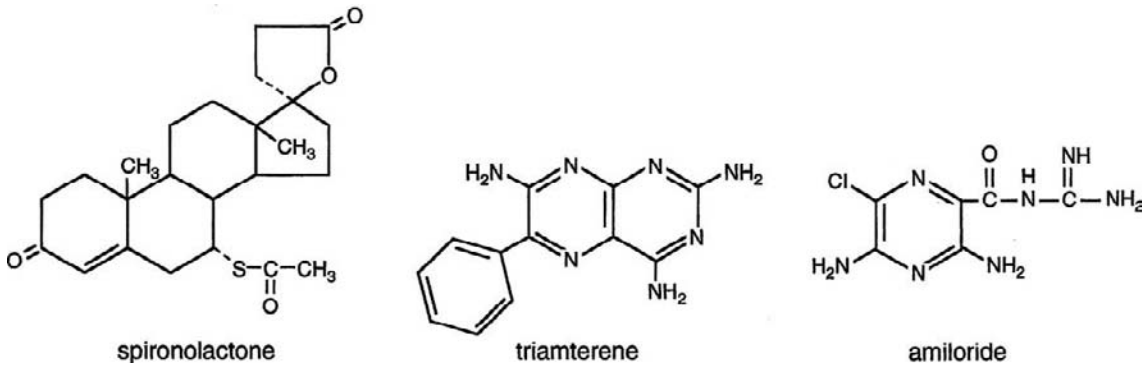

FIGURE 40.13 **Structure of collecting duct diuretics.**

hyperkalemic hypertension who are treated with DCT diuretics can manifest impaired glucose tolerance, despite normal-to-high serum potassium.[218] Other factors may contribute to glucose intolerance as well. Volume-depletion may stimulate catecholamine secretion, but volume-depletion during therapy with DCT diuretics is usually very mild. DCT diuretics directly activate calcium-activated potassium channels that are expressed by pancreatic β-cells, perhaps contributing to the hyperglycemia.[266] Activation of these channels is known to inhibit insulin secretion.

DCT diuretics increase levels of total cholesterol, total triglyceride, and LDL cholesterol. These drugs reduce the HDL.[265] Definitive information about the mechanisms by which DCT diuretics alter lipid metabolism is not available, but many of the mechanisms that affect glucose homeostasis have been suggested to contribute. Hyperlipidemia, like hyperglycemia, is a dose-related side-effect, and one that wanes with chronic diuretic use. In several recent large clinical studies, the effect of low-dose DCT diuretic treatment on serum LDL was not significantly different from placebo.[267] In the ALLHAT study, mean cholesterol concentrations were higher in the group randomized to chlorthalidone, but the absolute differences at two and four years were 2–3 mg/dl.

POTASSIUM-SPARING DIURETICS

Diuretic drugs that act primarily along the aldosterone-sensitive distal nephron (which includes the DCT2, the connecting tubule, and the collecting duct) comprise three pharmacologically distinct groups: aldosterone antagonists (spironolactone); pteridines (triamterene); and pyrazinoylguanidines (amiloride, see Figure 40.13). The site of action for all diuretics of this class is the segment of the nephron that begins within the DCT. It has been recognized increasingly that the DCT2 and the connecting tubule play especially important roles in modulating renal Na and K balance in response to aldosterone.[268] Because of the ability to minimize the normal tendency of diuretic drugs to increase potassium excretion, these drugs are considered "potassium-sparing." Acute diuretic activity is weak, because fractional sodium reabsorption in the collecting tubule usually does not exceed 3% of the filtered load. For this reason, potassium-sparing drugs are ordinarily used in combination with thiazides or loop diuretics, often in a single preparation, to restrict potassium losses and sometimes augment diuretic action. However, in certain conditions potassium-sparing diuretics are used as first line agents (see Table 40.2). For example, spironolactone is used in the treatment of edema in patients with cirrhosis,[269] and amiloride or triamterene is used as a first line treatment of Liddle's syndrome.[270]

Urinary Electrolyte Excretion

Amiloride, triamterene, and spironolactone are weak natriuretic agents (see Table 40.1). Their major effect is to diminish potassium excretion. Additionally, these three diuretic agents decrease hydrogen ion secretion by the ASDN. Evidence that spironolactone decreases hydrogen ion excretion comes from the finding of metabolic acidosis associated with mineralocorticoid deficiency, and the finding that spironolactone produces metabolic acidosis in patients with cirrhosis who have mineralocorticoid excess. In rats, the administration of amiloride and triamterene has been shown to inhibit urinary acidification. A common mechanism is likely to be involved in mediating the effects of all three diuretic agents on hydrogen ion secretion. These drugs reduce the voltage across the distal epithelium, which is oriented in the lumen-negative direction; they thus decrease the gradient for hydrogen ion secretion (see Figure 40.14).

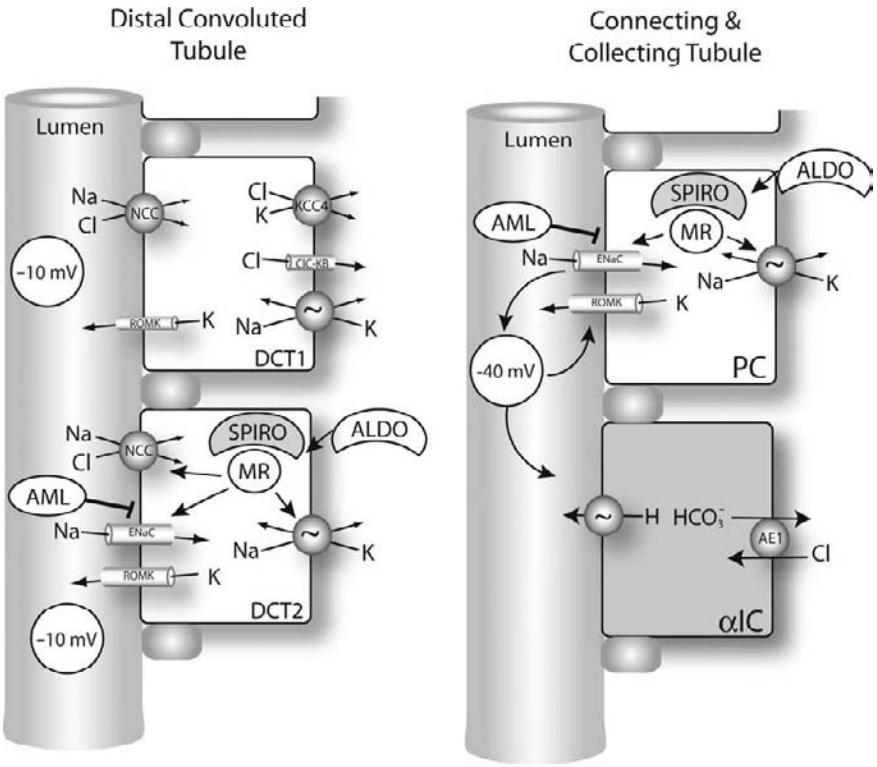

FIGURE 40.14 **Mechanisms of potassium-sparing diuretics.** Amiloride (AML, and triamterene, not shown) block ENaC directly, as discussed in the text. This occurs in the DCT2 and in the connecting and collecting tubules. Blockade reduces the magnitude of the transepithelial voltage, which secondarily inhibits K secretion and H secretion. Spironolactone (and eplerenone, not shown) act by blocking mineralocorticoid receptors (MR), impeding aldosterone's (ALDO) ability to bind. These drugs, therefore, only act when aldosterone levels are elevated. DCT1 and DCT2 cells are shown (PC: principal cell; βIC: beta intercalated cell).

Clearance studies in rats have demonstrated that amiloride produces a decrease in calcium excretion.[202] In these studies, amiloride produced both a decrease in the calcium clearance/Na clearance ratio (C_{Ca}/C_{Na}), as well as a decrease in the fractional excretion of calcium. The effect of triamterene on clearance of calcium was less clear, although it did decrease the C_{Ca}/C_{Na} ratio. *In vivo* microperfusion of rat distal tubules demonstrated that the effect of chlorothiazide on calcium absorption was enhanced when amiloride was added, suggesting that amiloride also increased calcium absorption by the distal tubule.[175] Furthermore, *in vitro* perfusion of connecting tubules has shown that amiloride stimulates calcium absorption.[271] Amiloride is believed to stimulate calcium absorption through its ability to block sodium channels, thereby hyperpolarizing the apical membrane.[94] Hyperpolarization of the apical membrane stimulates calcium entry through epithelial calcium channels TRPV5 (see DCT diuretics, above). Amiloride has also been reported to reduce magnesium excretion,[214,272] and to prevent the development of hypomagesemia during therapy with a DCT diuretic (see above).

Mechanism of Action

The site of action of potassium-sparing diuretics is ASDN (see Figure 40.1 and above). The ASDN comprises the second part of the DCT, the DCT2, where amiloride-sensitive Na channels intermingle with NCC at the apical membrane.[176] It also includes the connecting tubule, a segment that may play the dominant role in regulating urinary K excretion. Finally, it comprises the cortical and medullary collecting tubules. The connecting and collecting tubules are composed of two cell types; although they appear to have separate functions, some information has suggested that the view that principal cells are responsible for the transport of sodium, potassium, and water, whereas intercalated cells are primarily responsible for the secretion of hydrogen or bicarbonate ions, is oversimplified. The apical membrane of principal cells expresses separate channels that permit selective conductive transport of sodium and potassium (Figure 40.14). The mechanism by which sodium reabsorption occurs is through conductive sodium channels (for a review see [273]). The low intracellular sodium concentration as a result of the basolateral Na,K-ATPase generates a favorable electrochemical gradient for sodium entry through sodium channels. Because sodium channels are present only in the apical membrane of principal cells, sodium conductance depolarizes the apical membrane, resulting in an asymmetric voltage profile across the cell. This effect produces a lumen-negative transepithelial potential difference. The lumen-negative potential difference, together with a high intracellular-to-lumen potassium concentration gradient, provides the driving force for potassium secretion.

Sodium is the principal extracellular cation whose conductance across the principal cell of the collecting duct is amiloride-sensitive, and is regulated by the activity and apical membrane expression of the epithelial sodium channel (ENaC).[274,275] The functional channel comprises at least three homologous subunits, α, β, γ. The biophysical characteristics of ENaC include a low single channel conductance of ~5 pS, long open and closed times, a high Na^+ to K^+ selectivity ratio of >100:1, and it is inhibited by submicromolar concentrations of amiloride.[276] Although inferential work suggested several different stoichiometries,[277,278] the crystal structure of the structurally-related acid sensing channel, ASIC, provides strong support for a heterotrimeric model, in which one of each subunit is present.[279,280,283]

Although the crystal structure should permit clearer insights into the site of ENaC blockade by amiloride, a great deal of information has already accumulated. Amiloride and other large cations block apical Na^+ channels in a voltage-dependent manner, suggesting that amiloride block occurs within the pore of these channels.[281] Schild et al.[282] found that mutations at equivalent positions in all three subunits reduce the efficacy of amiloride block. When cysteine residues were introduced at these sites, they were susceptible to chemical modification by methanethiosulfonate compounds from the extracellular space,[283] suggesting that amiloride gains entry to and binds within the channel pore. If this is confirmed, it is strikingly similar to the new model for loop diuretic binding to NKCC1.[73]

Kleyman and colleagues[283] describe two potential models for ENaC structure. Mutation of sites within the proposed selectivity tract and an upstream site one helical turn away alters the efficacy of amiloride block. In one model, these sites face the pore lumen, but lie on the cytosolic side of the most constricted part. The selectivity tract lies one turn further toward the cytosol. In the other model, these sites lie near the extracellular entry of the most constricted part of the pore. It was suggested that the requirement for amiloride addition to the extracellular side of the membrane for inhibition is more consistent with the latter configuration, but these issues should be clarified now that relevant crystal structures are becoming available.

This group further suggested that the glycines at β525 and γ537 (the greek letters correspond to the ENaC subunits), and the tolerance of a wide variety of substitutions for serine α583, indicate that these residues probably do not interact directly with amiloride, but instead affect the shape of the amiloride-binding pocket. They proposed a model for amiloride-binding where the pyrazine ring is positioned at the αSer583/βGly525/γGly537 site, and the guanidinium group is positioned at the outer mouth of the selectivity tract.[284] As the ASIC crystal structure is not in the open-state likely to bind to the diuretic, it is not surprising that the pore models do not allow for amiloride to interact with the channel at these sites, and that neither model is fully consistent with functional data. Both models are based on structures of ASIC1 in a nonconducting state, and amiloride blocks ENaC in the open state. It is likely, however, that progress in unraveling what has been a difficult question concerning the mechanisms of amiloride association with the channel will now be more rapid, and should resolve these confusing issues.

The amount of sodium and potassium present in the final urine is tightly controlled by aldosterone action on cells of the ASDN. Extensive studies have demonstrated that, in epithelia, aldosterone produces an early increase in sodium conductance,[285,286] followed by a sustained increase in transepithelial sodium transport. As a result, transepithelial sodium transport is increased, an effect that depolarizes the apical membrane (see Figure 40.14). An increase in the lumen negative potential in turn enhances potassium secretion through conductive potassium channels located in the apical membrane. The cellular mechanisms that are responsible for these events have been extensively studied and reviewed.[287,288] The effects of aldosterone are largely mediated through a classical genomic effect through action on MR. Nongenomic actions in extrarenal tissues are likely to occur, but appear less prominent in the kidney.[287–289] Genomic actions of aldosterone are initiated by penetration of the hormone through the basolateral membrane of principal cells and attachment to a cytosolic MR, a heterotrimeric 8–9 s complex of proteins. This receptor complex includes the steroid-binding protein and heat shock proteins (HSP). Binding of aldosterone to this complex stimulates the release of HSPs, leading to the translocation of the receptor-aldosterone complex to the nucleus. The function of HSPs is not clear. It is thought that they facilitate anchoring of unbound steroid receptors to the cytoskeleton, maintaining a high-affinity conformation.[290] Evidence also indicates that released HSP90 stimulates calcineurin, a protein phosphatase that regulates sodium transport, in a transcription-independent process.[291] This binding and translocation sequence leads to production of proteins called *aldosterone-induced proteins* (AIPs)[292] that regulate sodium flux.[293] These AIPs regulate channel activity.[292,294] Although signaling pathways for aldosterone in the ASDN remain incompletely understood, a central role for serum and glucocorticoid-regulated kinase (sgk1) is generally inferred.[289] Sgk is regulated at the level of transcription by corticosteroids, including aldosterone,[295,296] and in turn is known to phosphorylate Nedd4 ubiquitin ligases.[297] Serum and glucocorticoid-regulated kinase modulates Nedd4–2-mediated

inhibition of the epithelial Na^+ channel. Nedd4−2 phosphorylation induces serum and glucocorticoid-regulated kinase (SGK) ubiquitination and degradation,[298] and prolongs the surface expression and activity of ENac. The reader is referred to other chapters in these volumes for a more thorough discussion of aldosterone signaling.

SPIRONOLACTONE AND EPLERENONE

Spirolactones are compounds that have the principal effect of blocking aldosterone action.[299,300] One of these, spironolactone (Figure 40.13), is an analog of aldosterone that is extensively metabolized. Spironolactone is converted by deacylation to 7α-thiospironolactone or by diethioacetylation to canrenone.[300] The appearance of active metabolites means that the physiological effects of spironolactone outlast the half-life of the parent drug (see below). In the kidney, spironolactone and its metabolites enter target cells from the peritubular side, and compete for binding to cytosolic MRs. In studies using radiolabeled spironolactone or aldosterone, [^{3}H]-spironolactone-receptor complexes were found to be excluded from the nucleus. In contrast, [^{3}H]-aldosterone-receptor complexes were detected in the nucleus.[301] These results are consistent with the proposal that aldosterone antagonists block the translocation of MRs to the nucleus. The mechanism by which aldosterone antagonists block nuclear localization of antagonist-receptor complexes is not known, however, it has been suggested that they destabilize MRs, facilitating proteolysis.[302] As discussed previously MRs, like other steroid receptors, contain a steroid-binding unit associated with other cellular components including HSP90, in its inactive state. Steroid-binding produces dissociation of HSP90 from the steroid-binding unit, uncapping the DNA-binding sites. Spironolactone facilitates the release of HSP90, and in combination with rapid dissociation of ligand, could lead to degradation of the receptor.[302]

A newer aldosterone receptor antagonist, eplerenone, is also a competitive antagonist of the aldosterone receptor. Replacing the 17alpha-thoacetyl group of spironolactone with a carbomethoxy group confers improved selectivity for aldosterone receptors, and negligible activity at the cytochrome P450 enzyme,[303] but 10−20-fold lower affinity for its receptor.[304] Eplerenone has a slightly longer half-life of 3.5 hours compared to spironolactone, but it does not produce important metabolites; thus, the apparent effective half-life of eplerenone is shorter than that of spironolactone, in clinical use. *In vitro* receptor-binding studies have revealed that the affinity of eplerenone is approximately 10- to 20-fold less than the affinity of spironolactone for the MR.

Spironolactone induces a mild increase in sodium excretion (1−2%), and a decrease in potassium and hydrogen ion excretion.[305,306] Its effect depends on the presence of aldosterone, as spironolactone is ineffective in adrenalectomized animals, and in patients with Addison"s disease or patients on a high-salt diet. In cortical collecting tubules perfused *in vitro*, spironolactone added to the bath solution reduced the aldosterone-induced lumen-negative transepithelial voltage. By blocking sodium absorption in the collecting tubule, a decrease in lumen-negative potential reduces the driving force for passive sodium and hydrogen ion secretion (see Figure 40.14). It is likely that the mechanism of eplerenone action on Na and K transport along the ASDN is identical.

AMILORIDE AND TRIAMTERENE

Amiloride and triamterene (see Figure 40.13) differ structurally, but both are organic cations that use the same primary site of action (see Figure 40.14). Triamterene is an aminopteridine chemically related to folic acid, and amiloride is a pyrazinoylguanidine. Systemically administered amiloride results in an increase in sodium excretion and a decrease in potassium excretion.[151] Their actions on sodium and potassium transport, unlike spironolactone, are independent of aldosterone. Systemically administered amiloride produced a small increase in sodium excretion, and a much larger decrease in potassium excretion. Sampling of tubule fluid from the distal tubule demonstrated an inhibition of the normal rise in the tubule fluid-to-plasma potassium ratio. These results indicated that amiloride decreased distal tubule potassium secretion. Experiments employing *in vivo* microperfusion of distal tubules[250,307] and *in vitro* perfusion of isolated cortical collecting tubules[308,309] demonstrated that luminally administered amiloride reduced sodium absorption and potassium secretion. Similar results were obtained following *in vivo* microperfusion with benazamil,[253] a more potent amiloride analog that is not available for use clinically. The mechanism by which amiloride decreases potassium secretion is due to its effect in blocking sodium conductance in the apical membrane of distal tubule and collecting tubule cells (see Figure 40.14), thereby decreasing the electrochemical gradient for potassium secretion.

In high concentrations (>100 μM), amiloride interacts nonspecifically with different transporters, enzymes, and receptors, however, at concentrations of 0.05 to 0.5 μM, amiloride interacts specifically with sodium channels. Furthermore, aromatic substitutions on the guanidinium moiety render the molecule even more potent (IC_{50} 10−20-fold lower than amiloride).[310,311]

Clearance and free-flow micropuncture studies using triamterene demonstrated results similar to studies with amiloride,[151] although the mechanism of action is not as clearly defined. In earlier studies of rabbit cortical collecting tubules perfused *in vitro*, triamterene produced a gradual, reversible inhibition of the potential difference after a latent period of 10 minutes, suggesting a mechanism different from amiloride. Recent studies, however, suggest that triamterene binds to the epithelial sodium channel, and thus has a mechanism of action similar to amiloride.[312]

Pharmacokinetics

Spironolactone is poorly soluble in aqueous fluids. Bioavailability of an oral dose is approximately 90% in some, but not all, commercial preparations. The drug is rapidly metabolized in the liver into a number of metabolites. Until recently, canrenone was thought to be the major metabolite of spironolactone.[299,313] This conclusion was based on fluorometric assays. Assays of spironolactone and its metabolites by the use of high performance liquid chromatography (HPLC), however, demonstrated that fluorometrically measured levels of canrenone overestimated true canrenone levels.[314] Using HPLC, the predominant metabolite, 7α-methylspironolactone,[315] is responsible for roughly 80% of the potassium-sparing effect. Spironolactone and its metabolites are extensively bound to plasma protein (98%). In normal volunteers, taking spironolactone (100 mg/day) for 15 days, the mean half-lives for spironolactone, canrenone, 7-thiomethylspironolactone, and 6β-hydroxy-7α-thiomethylspironolactone were 1.4, 16.5, 13.8, and 15 hours, respectively. Thus, although unmetabolized spironolactone is present in serum, it has a rapid elimination time. The onset of action is extremely slow, with peak response sometimes occurring 48 hours or more after the first dose; effects gradually wane over a period of 48 to 72 hours. Spironolactone is used in cirrhotic patients to induce a natriuresis. In these patients, pharmacokinetic studies indicate that the half-lives of spironolactone and its metabolites are increased. The half-lives for spironolactone, canrenone, 7α-thiomethylspironolactone, and 6β-hydroxy-7α-thiomethylspironolactone are 9, 58, 24, and 126 hours respectively.[316]

Less information concerning pharmacokinetics is available for amiloride and triamterene. Amiloride is rapidly absorbed, and reaches peak serum concentrations after approximately 4 hours. Its elimination half-life is 17−26 hours, with 40−60% appearing in the urine unchanged.[3] Both amiloride and triamterene are organic cations that are secreted into proximal tubule fluid by an organic cation transporter, in a manner analogous to secretion of loop and DCT diuretics by the organic anion transporter.

Clinical Use

The uses of potassium-sparing diuretics are broadening, as negative effects of aldosterone in human disease are discovered. Traditionally, an important indication for potassium-sparing diuretics is to prevent or attenuate K losses that are consequent to administration of DCT or loop diuretics.[317]

MR antagonists become effective natriuretics in patients with high circulating aldosterone levels, such as in primary (adrenal adenoma or bilateral adrenal hyperplasia)[318] or secondary hyperaldosteronism (congestive heart failure, cirrhosis, nephrotic syndrome). Spironolactone is especially appropriate for the treatment of cirrhosis with ascites, a condition invariably associated with secondary hyperaldosteronism. In comparison to loop or thiazide diuretics, spironolactone is equivalent or more effective.[319] The reason for this observation could be related to the differences in the mechanism of drug action, including the fact that MR antagonists do not require secretion by transporters to reach their sites of action. A combination of loop diuretic in addition to spironolactone is considered to be the best combination between safety and efficacy in cirrhotic patients with resistant edema (ratio of 40 mg furosemide to 100 mg spironolactone[320]).

Although its acute natriuretic action is weak, MR antagonists lower blood pressure and are often quite effective in the control of resistant hypertension.[321] Spironolactone or eplerenone is also indicated for the treatment of mineralocorticoid hypertension. Several controlled randomized studies have shown benefits of MR blockade on outcomes in patients with heart failure. A discussion of these indications is beyond the scope of this chapter, but it has been suggested that these beneficial effects are independent of effects of these drugs on the kidney.[322]

Triamterene or amiloride is generally used in combination with potassium-wasting diuretics (thiazide or loop diuretics), especially when maintenance of normal serum potassium concentrations is clinically important. In addition, amiloride (or triamterene) has also been used as initial therapy in potassium-wasting states, such as primary hyperaldosteronism,[323,324] Liddle's[325] or Gitelman's syndrome.[326] Amiloride has been used in the treatment of lithium-induced nephrogenic diabetes insipidus. The efficacy of amiloride in this disorder relates to the ability of amiloride to block collecting duct sodium channels, a pathway which lithium uses to gain entry into cells.[327]

Adverse Effects

The most serious adverse reaction encountered during therapy with spironolactone and eplerenone is hyperkalemia.[328] Serum potassium should be monitored

periodically, even when the drug is administered with a potassium-wasting diuretic. Patients at highest risk are those with low GFRs, and those individuals who take potassium supplements concurrently. In patients with cirrhosis and ascites treated with spironolactone, hyperchloremic metabolic acidosis can develop independent of changes in renal function. Unwanted antiandrogenic and progestational side-effects of spironolactone include gynecomastia, decreased libido, and impotence in men. Women may develop menstrual irregularities, hirsutism or swelling and tenderness of the breast. These troublesome side-effects were the impetus for developing eplerenone. In subjects receiving eplerenone for heart failure, the incidence of gynecomastia and impotence among men was similar to placebo.[329] These differences in side-effects are likely related to eplerenone's greater selectivity for the MR versus androgen and progesterone receptors. Spironolactone-induced agranulocytosis has also been reported.[330]

Triamterene and amiloride may cause hyperkalemia. The risk of hyperkalemia is highest in patients with limited renal function (e.g., renal insufficiency, diabetes, and elderly patients). Additional complications included elevated blood urea nitrogen and uric acid, glucose intolerance, and GI disturbances. Triamterene induces crystalluria or cylinduria,[331] and may contribute to or initiate formation of renal stones[332] and AKI when combined with nonsteroidal anti-inflammatory agents.[333,334] The drugs are contraindicated in patients with hyperkalemia, individuals taking potassium supplements in any form, and in patients with severe renal failure with progressive oliguria.

AQUARETICS (VASOPRESSIN RECEPTOR ANTAGONISTS)

Urinary Electrolyte Excretion

Vasopressin-receptor antagonists are nonpeptide molecules that competitively inhibit one or more of the human vasopressin receptors V1a, V1b or V2. Conivaptan is a combined V1a/V2-receptor antagonist for intravenous use, whereas tolvaptan, mozavaptan, and lixivaptan are orally active V2-selective receptor antagonists. All of these agents cause a free water diuresis without appreciable natriuresis or kaliuresis, and they are therefore sometimes referred to as "aquaretics." This effect is mainly attributed to inhibition of the V2-receptor in the collecting duct, which prevents vasopressin from recruiting AQP2 water channels to increase water reabsorption. Therefore, vasopressin-receptor antagonists can be used to treat hypervolemic or euvolemic hyponatremia, in which increased vasopressin is considered "inappropriate."

Mechanism of Action

The effects of arginine vasopressin (AVP, also called antidiuretic hormone, ADH) are mediated by two major receptor subtypes: V_1- and V_2. V_1 receptors are expressed in many cell types, including vascular smooth muscle (V_{1a}) and adenohypophysis (V_{1b}). V_2-vasopressin receptors are expressed in kidney and seminal vesicles. V_2 receptors have been localized to principal cells of the connecting tubule, cortical and medullary collecting duct. Binding of AVP to V_2-vasopressin receptors in collecting duct cells results in water reabsorption. Many clinical disorders such as cirrhosis, congestive heart failure, and syndrome of inappropriate antidiuretic hormone secretion (SIADH) are associated with high levels of AVP that prevent appropriate water excretion, resulting in hyponatremia.

Nonpeptide vasopressin receptor antagonists (conivaptan and tolvaptan) are now available for clinical use in the United States; they are indicated to treat euvolemic and hypervolemic hyponatremia. Conivaptan is a benzazepine derivative and the first combined vasopressin V1aR/V2R antagonist.[335] This agent displaces a selective vasopressin V1aR antagonist in a dose-dependent manner from rat liver membranes; the IC_{50} was 2.2 ± 0.1 nmol/L. The agent also caused a concentration-dependent displacement of a vasopressin V2R antagonist from renal medullary membranes, and the IC_{50} of the binding affinity was 0.4 ± 0.1 nmol/L.[336] Oral conivaptan given for seven days in normotensive rats caused a dose-dependent aquaresis, with no effect on specific blood pressure.[337] When administered to healthy volunteers orally, conivaptan effects were observed after two hours including a seven-fold increase in the urinary flow rate, and a decrease in urinary osmolality from 600 mOsm/kg to $<$100 mOsm/kg. Plasma osmolality increased from 283 ± 1.3 mOsm/kg to 289 ± 1.7 mOsm/kg.[336]

Clinical Use

In double-blind, randomized, placebo-controlled clinical trials conivaptan was shown to increase serum Na concentrations in a variety of settings.[336] Although conivaptan was originally discovered as an orally active V1a/V2 antagonist, it was developed for intravenous application. In one study it was given intravenously by continuous infusion over four days at doses of 40 mg/day and 80 mg/day following a loading dose of 20 mg intravenously on the first day. During the study, patients adhered to fluid restriction of 2 L/day. In the group of patients receiving high-dose conivaptan (80 mg/day), the treatment increased the serum sodium concentration significantly from a baseline of 125 mmol/L to 134 mmol/L.[336] These data suggest that conivaptan is an efficient therapy of hyponatremia and

is safe. Unfortunately, infusion side-effects, including infusion site reactions are quite common.

At present, some 20 clinical trials have tested these agents against placebo or conventional therapy in patients with liver cirrhosis, heart failure or hyponatremia secondary to SIADH.[338] In all trials, vasopressin-receptor angatonists effectively raised serum sodium and helped to correct hyponatremia. In addition, a positive effect on some secondary endpoints was observed, including improved mental condition and reductions in body weight, dyspnea, and ascites.[339–341] Unfortunately, these effects have not led to improvements in most hard endpoints. The Efficacy of Vasopressin Antagonist in Heart Failure Outcome Study with Tolvaptan (EVEREST), which included 4133 patients hospitalized for heart failure, did not show a beneficial effect on the primary outcomes of death or rehospitalization for heart failure.[339] Thus, vasopressin-receptor antagonists appear effective in the correction of hyponatremia, but have not yet shown an effect on primary outcomes.

GENERAL PRINCIPLES OF DIURETIC ACTION

When a diuretic drug (other than an aquaretic) is first administered to a normal individual, urinary sodium and chloride excretion rates increase. The magnitude of the increase is determined by the nature of the drug, the dose, the gastrointestinal absorption, the delivery to the kidney, entry into tubule fluid (for diuretics that act from the tubule lumen), and the physiological state of the individual. Except for diuretics that act predominantly in the proximal tubule, such as the CA inhibitors, the maximal natriuretic potency of a diuretic can be predicted from its site of action. Table 40.1 shows that loop diuretics can increase fractional Na excretion to 30%, DCT diuretics can increase it to 9%, and Na channel blockers can increase it to 3% of the filtered load. Because CA inhibitors enhance excretion of Na with bicarbonate rather than chloride, and because they induce adaptive processes that are described more fully below, the maximal natriuretic potency of CA inhibitors is much lower than would be predicted from their site of action. The dose–response curve for diuretic action has been best characterized for loop diuretics. In this case, the relationship is sigmoidal (see Figure 40.7), when the fractional Na excretion is plotted versus the urinary diuretic concentration.[136] Most diuretics act from the luminal surface. Therefore, the best external indicator of diuretic drug concentration at the active site is the urinary diuretic concentration.

The bioavailability of diuretic drugs varies widely, between classes of drugs, between different drugs of the same class, and even between days of the week with the same drug. The bioavailability of loop diuretics ranges from 10–100% (mean of 50% for furosemide, 80–100% for bumetanide and torsemide (see Table 40.2). Limited bioavailability can usually be overcome by appropriate dosing, but some drugs, such as furosemide, are variably absorbed, making precise titration difficult.[136] Although the bioavailability predicts that oral furosemide should be half as potent as intravenous furosemide, the relationship is not simple, and depends on the clinical state of the individual. For example, the amount of Na excreted during 24 hours is similar when furosemide is administered to a normal individual by mouth or by vein (see Figure 40.7). Yet the total amount of furosemide excreted in the urine during the same period is approximately half as great following oral compared with intravenous administration.[342,343] This paradox results from the fact that oral furosemide absorption is slower than its clearance, leading to "absorption-limited" kinetics. Thus, effective serum furosemide concentrations persist longer when the drug is given by mouth, because a reservoir in the gastrointestinal tract continues to supply furosemide to the body. This relationship holds for a normal individual (Figure 40.7), but not necessarily for a patient who suffers from an edematous disorder. In this case, a higher serum drug level may be needed to elicit natriuresis, and the lower serum drug level achieved by oral treatment may be inadequate to reach the natriuretic threshold. For this reason, it is customary to double the furosemide dose when changing from intravenous to oral therapy.[136] Variations in bioavailability may lead to increased hospitalizations for patients with congestive heart failure treated with furosemide, compared to a drug such as torsemide that is more completely absorbed, but this remains to be established in larger studies.[344]

A third factor that determines the maximal natriuresis following diuretic drug administration is drug delivery to its active site. Most diuretics, including the loop diuretics, DCT diuretics, and amiloride, act from the luminal surface. Thus, to be effective, these drugs must be delivered into tubule fluid by glomerular filtration or by tubular secretion. Although most diuretics are small molecules, most circulate tightly bound to protein and reach tubule fluid primarily by secretion. When serum albumin concentrations are very low, the volume of diuretic distribution increases,[134] but this factor may not be as important in causing diuretic resistance as believed previously.[345] Nevertheless, when serum albumin concentrations are less than 2 g/L, reduced diuretic delivery to the kidney may play a role in resistance.[346–349]

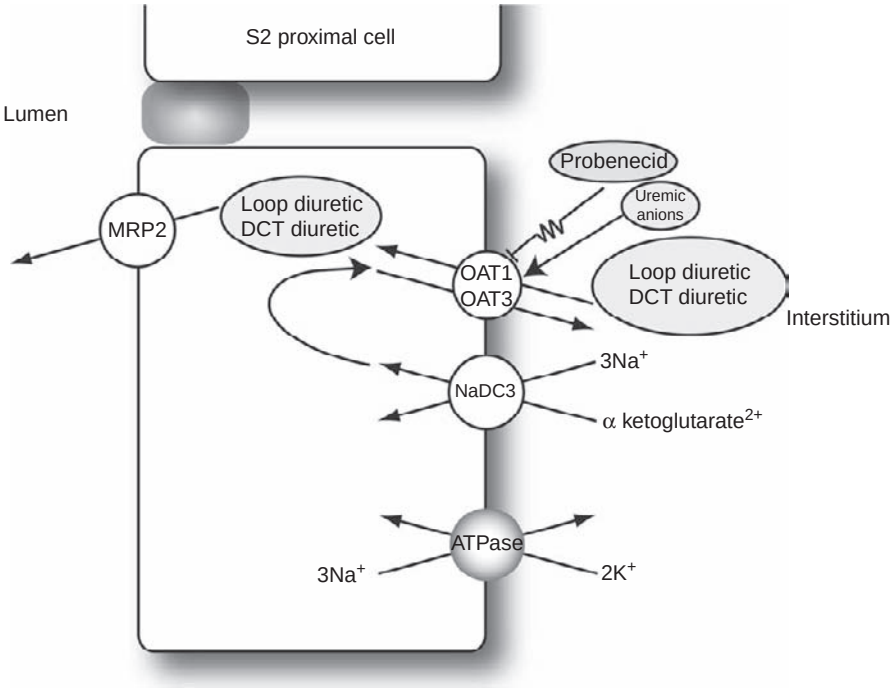

FIGURE 40.15 Mechanisms of diuretic secretion by proximal tubule cells. Cell diagram of the S2 segment of the proximal tubule, showing secretion of anionic diuretic, including loop diuretics and DCT diuretics. Peritubular uptake by an organic anion transporter (primarily OAT1, although OAT3 may play a smaller role) is in exchange for α-ketoglutarate. α-Ketoglutarate is brought into the cell by the Na-dependent cation transporter, NaDC-3. Luminal secretion can be via a voltage-dependent pathway or in exchange for luminal hydroxyl (OH^-) or urate. A portion of the luminal transport traverses the multidrug resistance protein-2 (MRP-2).[412]

Loop and DCT diuretics are organic anions that circulate bound to albumin, and reach tubule fluid primarily via organic anion secretory pathways in the proximal tubule.[350] Four isoforms of organic anion transporters (OATs) have been cloned and are expressed in the kidney.[351,352] Peritubular uptake by an OAT is a tertiary active process (see Figure 40.15). Energy derives from the basolateral Na^+,K^+-ATPase that provides a low intracellular [Na^+] that drives an uptake of Na^+ coupled to a-ketoglutarate (aKG^-) to maintain a high intracellular level of aKG^-. This, in turn, drives a basolateral OA^-/aKG^- countertransporter. OAT translocates diuretics into the proximal tubule cell where they can be sequestered in intracellular vesicles. They are secreted across the luminal membrane by a voltage-driven OAT,[353] and by a countertransporter in exchange for urate or OH^-.[352] OAT1 is expressed on the basolateral membrane of the S2 segment of the proximal tubule. Genetic OAT1 causes dramatically impaired renal organic anion secretion, and also furosemide resistance.[354] Thus, OAT1 plays a central role in mediating loop diuretic secretion by proximal cells. Albumin has been reported to stimulate renal organic anion secretion directly, in a dose-dependent manner, up to a maximum when the concentration reaches 1 g/dl.[355]

Endogenous and exogenous substances may compete with diuretics for secretion into tubule fluid and affect diuretic response. Uremic anions,[356] non-steroidal anti-inflammatory drugs,[357] probenecid,[358] and penicillins all inhibit loop and DCT diuretic secretion into tubule fluid. Under some conditions, this may predispose to diuretic resistance, because the concentration of drug achieved in tubule fluid does not exceed the diuretic threshold. For example, in chronic kidney disease, diuretic delivery into the urine is reduced. This shifts the diuretic dose–response curve to the right, requiring a higher dose to achieve maximal effect (see Figure 40.7). Surprisingly, however, probenecid *increases* the natriuretic effects of chlorothiazide and furosemide when administered to normal individuals.[358,359] This effect results from the probenecid-induced impairment in renal diuretic clearance, which prolongs the effective half-life, permitting diuresis to continue over a longer period of time. Thus, achieving sufficient levels, the effect of a secretory inhibitor will be to increase the natriuretic response, owing to a prolonged half-life. In contrast, in a patient whose dose is near to the diuretic threshold, impairments of secretion can lead to achievement of sub-threshold levels in tubule fluid, and to diuretic resistance.

Amiloride and triamterene are organic cations that reach tubule fluid via organic cation secretory pathways in the proximal tubule. Movement of cationic diuretics from cell to lumen occurs, at least in part, via an organic cation/H exchanger, which is coupled functionally to the apical Na/H exchanger.[350] Creatinine, cimetidine, trimethoprim, quinidine, quinine, atropine, ofloxacin, morphine, and paraquat are all secreted by this pathway.[350] Cimetidine has been shown to inhibit the secretion of amiloride.[360]

A fourth factor that may influence diuretic effectiveness is protein-binding in tubule fluid. Diuretic drugs are normally bound to proteins in the plasma, but not once they are secreted into tubule fluid. This reflects the normally low protein concentrations in tubule fluid. In contrast, when serum proteins such as albumin are filtered in appreciable quantities, diuretic drugs will interact with them.[361] This protein−drug interaction appears to inhibit the ability of the diuretic to interact with luminal transport proteins. Kirchner and colleagues showed that adding albumin to diuretic-containing fluid used to perfuse rat loops of Henle reduced the effects of the loop diuretic by approximately 50%. This effect was specific for albumin, since IgG did not mimic it,[362] and the effect could be prevented by adding inhibitors of protein-binding such as warfarin or sulfisoxizole.[363] The role of this process in human diuretic resistance, however, has been questioned, as protein-binding inhibitors do not increase diuretic efficacy in proteinurinc humans.[364] Although the reasons for the discrepant results between animal models and humans are unclear, it seems unlikely that urinary albumin-binding to diuretics is an important contributor to diuretic resistance.

Patients given diuretic drugs to treat edematous conditions all manifest some diuretic resistance (see Figure 40.7). This is evident in the shift to the right and downward in the dose−response curve for a loop diuretic.

DIURETIC ADAPTATIONS AND DIURETIC RESISTANCE

Although the clinically useful diuretic drugs all increase urinary solute and water excretion, the goal of diuretic therapy of edema is to reduce the ECF volume. This usually requires an increase in urinary solute and water excretion, but such an increase is not sufficient to effect ECF volume contraction by itself. Furthermore, any initial increase in daily urinary NaCl and water excretion begins to wane after several days of diuretic treatment. That is because of specific renal adaptations that occur during diuretic therapy. When diuretic adaptation becomes manifest once the desired ECF volume has been attained, it is clinically useful and prevents progressive ECF volume contraction. When these same processes develop prior to achieving the desired ECF volume, they would be viewed as contributing to diuretic resistance. Because specific therapeutic approaches can be devised to overcome these adaptations, an understanding of renal adaptations to diuretic treatment is crucial for understanding diuretic treatment of edema. For the purposes of this discussion, diuretic adaptations will be classified as *immediate*, *short-term*, and *chronic*. Immediate adaptations limit the intrinsic potency of diuretic drugs; these occur during the initial diuretic-induced natriuresis, and generally result from intrinsic renal processes. Short-term adaptations occur after the initial effect of the diuretic drug has worn off, and may result from both systemic and intrarenal processes. Chronic adaptations occur only when diuretic drugs have been administered during a long period of time (days to weeks). Because diuretic resistance is most commonly observed in patients who have received high doses of loop diuretics during long periods of time, these chronic adaptations may be especially relevant to the phenomenon of diuretic resistance in patients.

Immediate Adaptations

About 25 moles of sodium are filtered every day by the kidneys in a normal human. Because dietary salt intake on a Western diet is typically 110−260 mmol daily, approximately 3 pounds of salt (17 moles = 1 kg NaCl) must be reabsorbed every day by the renal tubules to maintain salt balance. As discussed above, all sodium chloride reabsorption along the mammalian nephron is driven by the action of Na/K-ATPase, which is present along the basolateral cell membrane of most renal epithelial cells. Transepithelial sodium transport occurs because apical transport pathways permit Na to move down its electrochemical gradient from tubule lumen to cell, often coupled to the movement of other ions across the same membrane. Most diuretics drugs act by inhibiting apical Na transport pathways. Because apical Na transport pathways are nephron segment-specific, each class of diuretic inhibits Na transport *predominantly* along a single segment of the nephron (see Figure 40.1). The axial organization of renal tubules, and the nephron segment-specific inhibition of salt transport by diuretics, means that diuretics have both direct effects and indirect effects on solute transport along the nephron.

When NaCl reabsorption along the thick ascending limb is inhibited by loop diuretics, the NaCl concentration in fluid that enters the distal tubule is greatly increased. In one study, the Na concentration in fluid entering the distal tubule of rats rose from 42 to 140 mM during acute loop diuretic infusion.[151] The higher luminal NaCl concentration increased Na absorption along the distal tubule (from 148 to 361 pmol/minute), because NaCl transport varies directly with the luminal NaCl concentration. Further, loop diuretics have little or no effect on ion transport along the distal tubule.[250] The bulk of the increased NaCl transport along the distal tubule appears to result from enhanced transcellular transport via the thiazide-

sensitive Na-Cl co-transporter. In microperfused rat distal tubules, raising the luminal NaCl concentration two-fold increased transepithelial Na transport by a factor of 3; this increase could be blocked entirely by luminal chorothiazide.[365] The dependence of transepithelial NaCl transport on luminal NaCl concentration probably results from a dependence of the thiazide-sensitive Na-Cl co-transporter on extracellular Na and Cl concentrations,[180] although effects to increase the abundance of NCC may also be involved.

This first level of adaptation to diuretic drugs occurs *during* the period of diuretic-induced natriuresis; this is the compensatory increase in NaCl reabsorption along segments that are not targets of diuretic action. The *net* effect of acute diuretic administration on urinary Na and Cl excretion, therefore, reflects the sum of effects in the diuretic-sensitive segment (inhibition of NaCl reabsorption) and in diuretic-insensitive segments (secondary stimulation of NaCl reabsorption). Although the most clinically important example of this form of adaptation involves loop diuretics, these compensatory processes occur during administration of most classes of diuretics. The importance of compensatory processes to blunt the acute effects of diuretics is exemplified by CA inhibitors, which inhibit Na transport across cells of the proximal tubule. Because a large portion of the Na that is rejected by the proximal tubule during CA inhibitor administration is reabsorbed along the loop of Henle and distal tubule, only a fraction escapes into the urine. CA inhibitors, therefore, are drugs of only modest potency. Blockade of immediate adaptive processes enhances the effects of the administered diuretic, as when loop diuretics are combined with CA inhibitors, acutely. A similar phenomenon has been observed in animals lacking NHE3, the apical Na/H exchanger of the proximal tubule.[13] These animals exhibit minimal salt-wasting, owing to compensatory processes.

Short-Term Adaptations (Post-Diuretic NaCl Retention)

The half-life of most diuretics (especially the loop diuretics) is relatively short. Thus, serum diuretic concentrations are often below the natriuretic threshold during a portion of each day, except when the drugs are infused constantly. This second type of adaptive response to diuretic administration occurs after the peak natriuresis has occurred, and is most prominent when the drug concentration in plasma and tubular fluid declines below the diuretic threshold. In this situation, diuretic is no longer present in tubule fluid to inhibit renal Na reabsorption and a period of NaCl retention, often termed "post-diuretic NaCl retention" begins (see Figure 40.16). The net effect of the diuretic drug during 24 hours, therefore, results from a period of natriuresis (when NaCl transport is inhibited by the diuretic), and a period of anti-natriuresis (when the drug concentration is low, before the next dose is given).

Mechanisms that contribute to post-diuretic NaCl retention have been investigated intensively and may be grouped into three classes: first, factors that result from changes in ECF volume; second, factors that result from diuretic-induced increases in distal sodium, chloride, and fluid delivery; and third, factors that result from direct effects of diuretic drugs on tubule transport processes. One signal initiating NaCl retention in the post-diuretic period is the change in ECF volume and the change in "effective" arterial blood volume. Evidence indicating a central role for changes in ECF volume includes the observation that post-diuretic NaCl retention can be prevented by administering Na, K, and Cl at rates sufficient to equal diuretic induced losses.[366] This observation does not, however, exclude a contributory role for mechanisms that occur independent of changes in ECF volume, as will be discussed below.

Diuretic drugs have effects on vascular and ECF volume within minutes of administration, both because of their ability to increase renal Na and Cl excretion, and because they have direct vascular effects. These changes activate a number of physiological control systems, which tend to favor NaCl retention and act to attenuate further NaCl loss. Important contributors to ECF volume-dependent NaCl retention have been discussed above, and include changes in the GFR, activation of the renin–angiotensin–aldosterone system, stimulation of efferent renal sympathetic nerves, suppression of atrial natriuretic peptide secretion, and suppression of renal prostaglandin secretion. Post-diuretic NaCl retention has been shown to occur in humans whether dietary NaCl intake is high or low, suggesting that true ECF volume *depletion* may not be essential. Some *decline* in ECF volume, however, was shown to be necessary for secondary NaCl retention during furosemide-induced natriuresis in rats. In rats given furosemide continuously, the secondary decline in NaCl excretion was associated with a 25% decline in GFR, suggesting that decreases in filtered NaCl-load contribute to short-term adaptations to diuretic treatment.[367] In normal humans, changes in GFR were reported to be statistically insignificant during post-diuretic NaCl retention, suggesting a decline in filtered Na does not contribute.[368] Although a statistically significant decline in GFR can be observed in the post-diuretic period when the data from several subgroups are pooled,[368] the magnitude of this effect is small, and increases in NaCl reabsorption rather than declines in GFR probably play the larger role.

One mechanism that may mediate a decline in GFR after loop diuretic drug concentrations decline may be

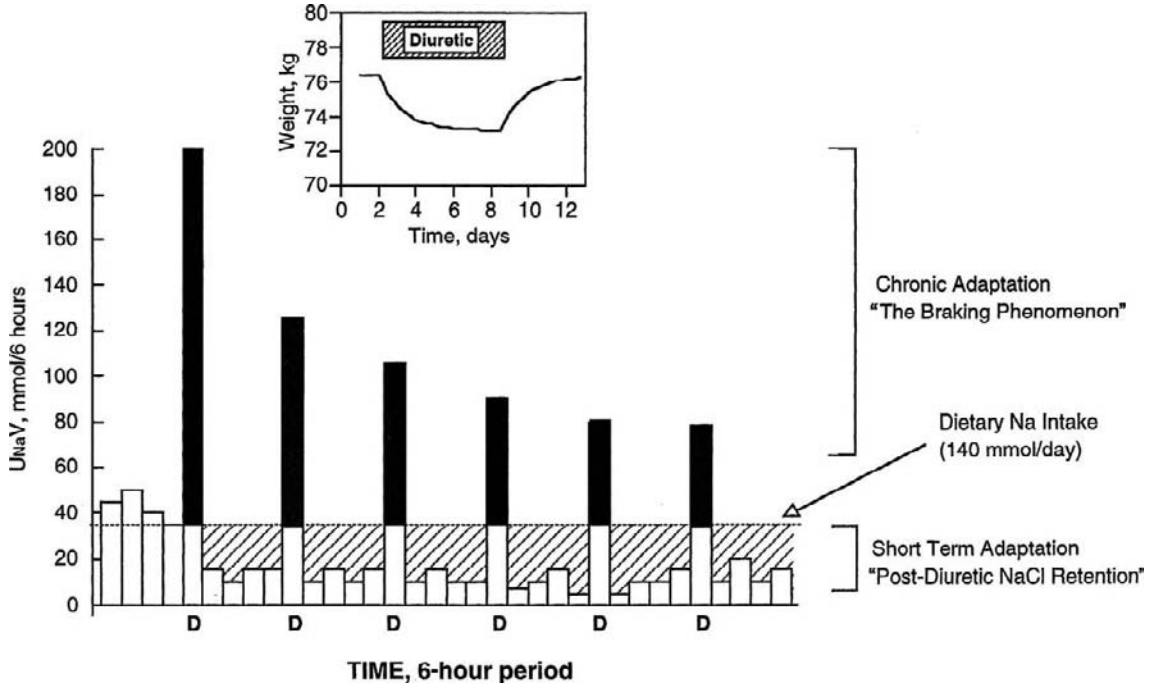

FIGURE 40.16 **Effects of diuretics on urinary Na excretion and ECF volume.** Inset: Effect of diuretic on body weight, an index of ECF volume. Note that steady-state is reached within 6–8 days, despite continued diuretic administration. Main graph: Effects of loop diuretic on urinary Na excretion. Bars represent six-hour periods before (in Na balance) and after doses of loop diuretic (D). The dotted line indicates dietary Na intake. The solid portion of bars indicates the amount by which Na excretion exceeds intake during natriuresis. The hatched areas indicate the amount of positive Na balance after the diuretic effect has dissipated. Net Na balance during 24 hours is the difference between the hatched area (post-diuretic NaCl retention) and the solid area (diuretic-induced natriureisis). Chronic adaptation is indicated by progressively smaller peak natriuretic effects (the "braking phenomenon"), and is mirrored by a return to neutral balance, as indicated in the inset, where the solid and hatched areas are equal. As discussed in the text, chronic adaptation requires ECF volume depletion.

activation of the TGF system. Loop diuretics block this system directly by interfering with Na and Cl uptake by macula densa cells, as discussed above. Thus, loop diuretics tend to maintain the GFR higher than would be expected in the absence of diuretic action. When the diuretic concentration declines, and the inhibitory effects at the macula densa wane, the TGF system is poised to respond again to NaCl delivery and to suppress the GFR, thus contributing to post-diuretic NaCl retention.

Diuretic drugs stimulate the renin–angiotensin–aldosterone axis via mechanisms described above and in Figure 40.9. The renin–angiotensin–aldosterone axis contributes importantly to renal NaCl homeostasis, but evidence for an important role of these hormones in post-diuretic NaCl retention has been mixed. In normal volunteers, post-diuretic NaCl retention was unaffected by the angiotensin-converting enzyme inhibitor captopril[369] given in doses sufficient to block furosemide-induced changes in angiotensin II and aldosterone levels. Further, in those studies, diuretic-induced changes in blood pressure were similar with or without captopril, suggesting that hypotension did not mediate the NaCl retention in the ACE inhibitor group. These data indicate that post-diuretic NaCl retention *can* occur without activation of the renin–angiotensin–aldosterone system; they do not indicate, however, that stimulation of the renin–angiotensin–aldosterone axis has no role in post-diuretic NaCl retention when it occurs. An important role for the renin–angiotensin–aldosterone axis is implied by comparing the effects of volume removal via loop diuretics and hemofiltration. In one study, diuresis of patients with heart failure led to a larger increase in renin than did removal of the same fluid using an ultrafiltration device.[370,371] Yet this effect was not supported by more recent studies.[372]

Stimulation of alpha adrenergic renal nerves enhances NaCl reabsorption. Petersen et al. showed that systemic α-1 blockade attenuated the secondary reduction in NaCl excretion that occurs during short-term furosemide-induced volume-depletion in rats.[373] They concluded that stimulation of α-1 adrenoceptors on proximal tubules contributed to the compensatory response to short-term furosemide infusion. In humans, however, administration of prazosin, in doses that block the pressor response to α-adrenergic agonists, does not prevent post-diuretic NaCl retention. Even when both prazosin and captopril are

administered concurrently, to block both the renin–angiotensin–aldosterone axis and the effects of renal nerve activity, post-diuretic NaCl retention may occur ([374]; although in this case, furosemide did reduce mean arterial pressure significantly). Thus, ECF volume-dependent stimulation of α-1 adrenergic receptors, especially along the proximal tubule, may contribute to post-diuretic NaCl retention.

Diuretic-induced decrements in ECF volume have been shown to be associated with suppression of atrial natriuretic peptide secretion. These changes occur following diuretic administration in both normal individuals, and in patients with nephrotic syndrome,[375] chronic glomerulonephritis, and essential hypertension. In some studies, atrial natriuretic peptide concentrations have declined before significant changes in extracellular or blood volume occur; in these cases it has been suggested that furosemide-induced changes in venous capacitance may underlie the effect.

The studies discussed above in which post-diuretic NaCl retention occurred despite blockade of several effector mechanisms raise the possibility that changes in ECF volume are not required for post-diuretic NaCl retention to occur. Wilcox and colleagues investigated acute effects of the loop diuretic bumetanide in the absence of ECF volume-depletion. Na, K, Cl, and water were administered to volunteers during loop diuretic administration to balance electrolyte losses completely. When changes in ECF volume were prevented, post-diuretic NaCl retention did not occur, indicating that decrements in ECF volume do play a critical role in post-diuretic NaCl retention. A volume-independent component of adaptation may also contribute to NaCl retention, however. When volunteers were challenged with a 100 mmol NaCl-load with or without prior diuretic treatment, differences were observed. The NaCl-load was excreted fully within two days under control conditions; after pretreatment with bumetanide, however, much less of the administered load was excreted during the subsequent two days.[366] This result occurred despite complete replacement of water and electrolyte losses induced by the loop diuretic. These results suggest that there are subtle but physiologically significant effects of diuretic administration, even in the short-term, that favor NaCl retention in the absence of changes in ECF volume status (see below).

In normal individuals, diuretic administration strongly activates the control systems discussed above; in edematous individuals, however, one or more of these control systems may be active at baseline, having contributed to the pathological accumulation of extracellular volume. The role of these control systems in the adaptive response to diuretic may, therefore, be different in normal and edematous individuals.

One mechanism by which diuretic drugs may increase the tendency for NaCl retention directly without changes in ECF volume involves diuretic-induced *activation* of ion transporters within the diuretic sensitive nephron segment. The cation chloride co-transporters, such as the NKCC2, are phosphorylated and activated by low intracellular chloride concentrations[376]; because loop diuretics reduce the Cl concentration in cells of the thick ascending limb, pre-existing transporters should be activated leading to increased NaCl transport capacity. This increase will be unmasked once the luminal concentration of loop diuretic declines. Ecelbarger et al.[377] reported evidence that furosemide administration activates NKCC2 via more than one mechanism. Five days of furosemide infusion led to a 50–100% increase in abundance of NKCC2, and also to an upward mobility shift of 9 kDa in apparent molecular mass. These results were interpreted as suggesting that furosemide blockade of apical NaCl uptake led to both increased expression and "modification" of NKCC2. As phosphorylation of NKCC2 regulates its activity, one possibility is that loop diuretic blockade activates the transporter via phosphorylation.

A similar mechanism has been reported to occur along the distal tubule during short-term administration of thiazide diuretics. Within 60 minutes of thiazide administration, the number of thiazide-sensitive Na-Cl co-transporters in kidney cortex (measured as the number of [^{3}H]metolazone binding sites) increases substantially.[378] The techniques used to estimate the number of transporters in these experiments do not permit one to determine whether the increased number reflects insertion of pre-existing transporters from a subapical storage pool or activation of transporters that are present but inactive in the apical membrane. It is now clear that a subapical pool of NCC shuttles to and from the apical membrane in response to physiological perturbation.[379] An increase in the number of activated ion transporters at the apical membrane would be expected to increase the transport capacity, so that when diuretic concentrations decline, increased Na and Cl transport would result.

Another mechanism by which diuretic drugs may enhance the tendency to NaCl retention directly involves stimulation of transport pathways in nephron segments that lie distal to the target of diuretic action (segments that are insensitive to the diuretic drug). For example, the number of metolazone-binding sites increases within 60 minutes after a loop diuretic has been administered.[378] Because NCC is expressed by nephron segments that do not express loop diuretic-sensitive pathways, the increased NCC is believed to result from increases in salt and water delivery to DCT cells (discussed in more detail below).

Post-diuretic NaCl retention can have major effects on the clinical efficacy of diuretic drugs. The half-life of most loop diuretics is short, so that NaCl retention can occur during 18 hours per day, if the drug is administered once daily (see Figure 40.16). If dietary NaCl intake is low, then post-diuretic NaCl retention does not compensate for the drug-induced NaCl losses, and NaCl balance becomes negative (the desired therapeutic response). If, on the other hand, dietary NaCl intake is high, then post-diuretic NaCl retention can compensate entirely for the initial NaCl losses during the period of drug action. When dietary NaCl intake is high, therefore, salt balance may be neutral, even from the first day of diuretic therapy,[368] despite impressive increases in urine volume after each dose of diuretic. This is one reason that dietary NaCl intake is a key determinant of diuretic efficacy, especially for the short-acting loop diuretics.

Chronic Adaptations (The "Braking" Phenomenon)

When diuretics reduce ECF volume effectively, NaCl balance gradually returns to neutral, despite continued diuretic administration[368,380] (see Figure 40.16). This "braking phenomenon" occurs when the magnitude of natriuresis following each diuretic dose declines. Several factors, acting in concert, may participate in chronic adaptation. A critical factor that is necessary for the braking phenomenon to occur is a decline in the ECF volume. Wilcox and co-workers showed that the magnitude of each diuretic-induced natriuresis declined during ECF volume-depletion of humans consuming a low-NaCl diet. In contrast, when dietary NaCl intake was high, ECF volume-depletion did not occur, and the magnitude of diuretic-induced natriuresis did not decline.[368,380] Relative or absolute ECF volume contraction limits NaCl excretion by reducing the amount of NaCl that is filtered, and by increasing the amount of NaCl that is reabsorbed. In experimental animals, declines in renal blood flow occur during chronic diuretic treatment. Declines in GFR are usually modest, however, unless volume depletion is extreme or unles renal perfusion is compromised by drugs or physical factors such as renal artery stenosis. The effects of diuretics on glomerular filtration and renal blood flow are not caused primarily by changes in mean arterial pressure, as the renal autoregulatory response tends to maintain GFR and renal blood flow relatively constant when arterial pressure changes. Instead, ECF volume contraction itself leads to decrements in renal blood flow and GFR; because renal blood flow declines proportionately more than GFR, ECF volume-contraction increases the filtration fraction (GFR/RPF).

The role of the proximal tubule in diuretic adaptation has been documented clearly in rats treated chronically with thiazide diuretics, and in animals and humans treated with loop diuretics. In the case of thiazide treatment, micropuncture studies showed that hydrochlorothiazide initially inhibited Na and Cl absorption along both the proximal tubule (by inhibiting CA) and the distal tubule (by inhibiting Na-Cl co-transport) of rats.[228] After 7–10 days of treatment, however, ECF volume-contraction led to increases in proximal solute reabsorption, thereby limiting delivery of Na and Cl to the distal sites of thiazide action. During the chronic phase of treatment, inhibition of NaCl transport along the distal nephron (the predominant site of thiazide action) counterbalanced the reduction in distal NaCl delivery; under these conditions, at steady-state, urinary NaCl was equal to dietary NaCl intake.[228] Loop diuretics such as furosemide have also been shown to inhibit Na and Cl absorption by the proximal tubule, although the mechanism is unclear. But, as with DCT diuretics, chronic treatment with loop diuretics leads to ECF volume-contraction and enhanced proximal NaCl reabsorption.[381] That effects on proximal absorption require decrements in ECF volume was shown by comparing NaCl delivery out of the proximal tubule during furosemide administration, with and without volume replacement. Only when the ECF volume was permitted to decline was proximal absorption stimulated.[367] Many of the same effector systems that participate in post-diuretic NaCl retention also may participate in chronic adaptations to diuretic drugs.

Physical Factors

A rise in filtration fraction increases the protein oncotic pressure in peritubular capillaries (more protein free filtrate is formed per ml of blood flow, thereby contracting the plasma volume around a constant amount of serum protein). The increased peritubular oncotic pressure increases solute and fluid reabsorption, especially in the proximal tubule. ECF volume contraction also enhances proximal solute and fluid reabsorption by decreasing the renal interstitial pressure during chronic diuretic treatment.

Sympathetic Renal Nerve Activity

Efferent sympathetic nerves innervate the renal vasculature, the macula densa, and essentially all segments of the nephron. Stimulation of sympathetic nerves reduces urinary NaCl excretion by reducing renal blood flow, by stimulating renin release at the macula densa, by stimulating tubule NaCl reabsorption along the nephron, and by interacting with hormonal modulators of NaCl transport. Renal nerves may contribute to NaCl retention in edematous disorders, and renal nerve activity is stimulated when furosemide is administered either to normal or volume-depleted

animals.[382] Yet experimental models of chronic diuretic administration have failed to substantiate a central role for renal nerve activity in adaptive processes. Chronic sympathectomy or blockade of α-1 receptors inhibits the compensatory increase in proximal NaCl reabsorption that occurs during furosemide-induced ECF volume-depletion, but these maneuvers did not enhance the natriuretic response to furosemide.[383] This indicates that the inhibition of proximal solute reabsorption which occurs secondary to adrenergic blockade is compensated by increased reabsorption distally. Use of systemic pharmacological sympathetic blockade to study the role of renal nerves in diuretic adaptation is limited because of drug-induced systemic hypotension, but Petersen and DiBona showed that even anatomical renal denervation in normal rats does not abrogate the compensatory response to chronic furosemide administration.[384] Although it seems clear that renal nerves do not play a critical role in mediating compensation to chronic diuretic use in normal humans and animals, the consistent observation that diuretics do stimulate renal nerve activity suggests that renal nervous activity may contribute to diuretic adaptation in some patients. In patients suffering from edematous disorders, distal Na reabsorption may already be stimulated; denervation in this situation might lead to significant impairment in adaptation to diuretic drugs.

Renin–Angiotensin–Aldosterone

A third factor participating in chronic adaptation to diuretic drugs is the renin–angiotensin–aldosterone system. Renin acts on angiotensinogen to generate angiotensin I, which is converted to angiotensin II by converting enzyme. Angiotensin II stimulates aldosterone secretion from the adrenal cortex; aldosterone stimulates salt reabsorption by the distal nephron. Recent studies indicate that, in addition to stimulating Na transport by ENaC of the collecting duct, as discussed above, mineralocorticoid hormones stimulate Na transport by the thiazide-sensitive Na-Cl co-transporter of the DCT.[191,385–387] In addition, however, angiotensin II directly stimulates Na reabsorption along both the proximal and distal tubule by stimulating Na/H exchange activity.[388] Thus, diuretic drugs frequently result in stimulation of the renin–angiotensin–aldosterone system, and the Na retention that occurs during diuretic treatment may result in part from this. As is the case with renal nerves, it has been difficult to show conclusively that the renin–angiotensin–aldosterone system plays a critical role in chronic adaptation to diuretic drugs. Yet as with renal nerves, the systemic effects of inhibition of the system, either with angiotensin I-converting enzyme inhibitor, angiotensin II receptor blockers or competitive aldosterone blockers make it difficult to exclude a role for this hormonal system in the compensation to diuretic therapy.

Epithelial Hypertrophy and Hyperplasia

Other factors that can enhance renal NaCl reabsorptive capacity are structural and functional changes in the nephron itself. When a diuretic is administered, solute delivery to segments that lie distal to the site of diuretic action increase, leading to load-dependent increases in solute reabsorption, as discussed above.[389] When solute delivery and solute reabsorption increase chronically, epithelial cells undergo both hypertrophy and hyperplasia (see Figure 40.17). Infusion of furosemide into rats continuously for seven days increased the percentage of renal cortical volume occupied by distal nephron cells. DCT cell volume increased by nearly 100%, with accompanying increases in luminal membrane area per length of tubule, in basolateral membrane area per length of tubule, and in mitochondrial volume per cell.[365,390,391] Chronic loop diuretic administration increases the Na/K-ATPase activity in the distal convoluted and cortical collecting tubules[392,393](see Figure 40.17), and increases the number of thiazide-sensitive Na-Cl co-transporters, measured as the maximal number of binding sites for [^{3}H] metolazone.[181,385] In one study, chronic furosemide treatment increased expression of mRNA encoding the thiazide-sensitive Na-Cl co-transporter, as detected by *in situ* hybridization[181](see Figure 40.18). In another study, however, mRNA expression of the thiazide-sensitive Na-Cl co-transporter, as well as ouabain-sensitive Na/K-ATPase, were not affected by chronic furosemide infusion, when detected by Northern analysis.[394] Distal tubule cells that express high levels of transport proteins and are hypertrophic have a higher Na and Cl transport capacity than normal tubules. Compared with tubules from normal animals, tubules of animals treated chronically with loop diuretics can absorb Na and Cl up to three times more rapidly than control animals, even when salt and water delivery are fixed by microperfusion (Figure 40.18). When distal tubules are presented with high NaCl-loads, as occurs during loop diuretic administration *in vivo*, Na and Cl absorption rates approach those commonly observed only in the proximal tubule.[365] Chronic treatment of rats with loop diuretics also results in significant hyperplasia of cells along the distal nephron. Whereas mitoses of renal tubule epithelial cells are infrequent in adult kidneys, distal tubules from animals treated with furosemide chronically demonstrate prominent mitoses; increased synthesis of DNA in these cells was confirmed by showing increases in labeling of DCT cells with bromodeoxyurindine and proliferating cell nuclear antigen.[395]

The diuretic-induced signals that initiate changes in distal nephron structure and function are poorly-

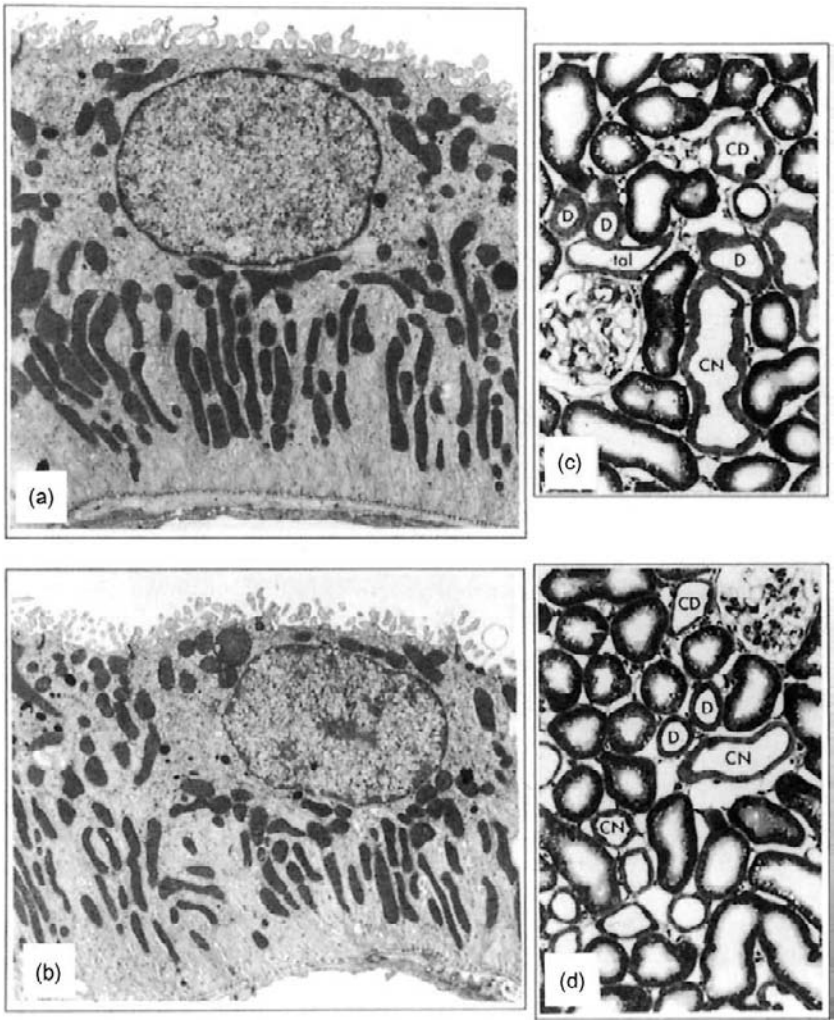

FIGURE 40.17 **Effects of chronic loop diuretic administration on distal convoluted tubule cells of rats.** Rats received furosemide continuously for seven days. Panels (a) and (b): Electron micrographs (×10,000) of distal convoluted tubule cells from control- and furosemide-infused animals respectively. Note that furosemide increases the size of the cell, the size of the nucleus, the amount of mitochondrial volume, and the amount of basolateral membrane area. Panels (c) and (d): Photomicrographs of kidney cortices from control and furosemide infused animals respectively (×480) (*D*: distal convoluted tubule; *CN*: connecting tubule; *CD*: cortical collecting duct: *tal*: thick ascending limb). Note thickening of the epithelium in all distal segments. *(Photomicrographs are used with permission from ref. [365].)*

understood.[389] Several factors, acting in concert, may contribute to these changes; these include diuretic-induced increases in Na and Cl delivery to distal segments, effects of ECF volume depletion on systemic hormone secretion and renal nerve activity, and local effects of diuretics on autocrine and paracrine secretion. Increased production of angiotensin II or increased secretion of aldosterone resulting from increases in renin activity may contribute to hypertrophy and hyperplasia. Angiotensin is a potent mitogen; angiotensin II receptors have not been localized definitively to DCT cells, but recent functional studies do suggest that DCT cells express angiotensin II receptors.[396] Beck et al.[397] showed that angiotensin I-converting enzyme inhibitors do not prevent loop diuretic-induced hypertrophy of DCT cells. Yet the hypertrophy during angiotensin I-converting enzyme inhibition is one that results from lengthening of kidney tubules; in their absence the hypertrophy results from thickening of the tubular cells.

Aldosterone also promotes growth of responsive tissues under some circumstances[398]; when salt delivery to the collecting duct is increased in the presence of high levels of circulating aldosterone, principal cell hypertrophy develops; when salt delivery is high in the absence of aldosterone secretion, hypertrophy is absent. This indicates that aldosterone plays a permissive role in the development of cellular hypertrophy in this aldosterone-responsive renal epithelium. Aldosterone does affect ion transport by cells of the DCT,[185,190,399,400] and aldosterone almost certainly contributes to adaptations along the cortical collecting tubule. Yet hypertrophy of DCT cells has been shown to occur during chronic loop diuretic infusion, even when changes in circulating mineralocorticoid, glucocorticoid, and vasopressin levels are prevented.[391]

One intriguing hypothesis is that cellular ion concentrations regulate epithelial cell growth directly.[401] Increases in Na uptake across the apical plasma

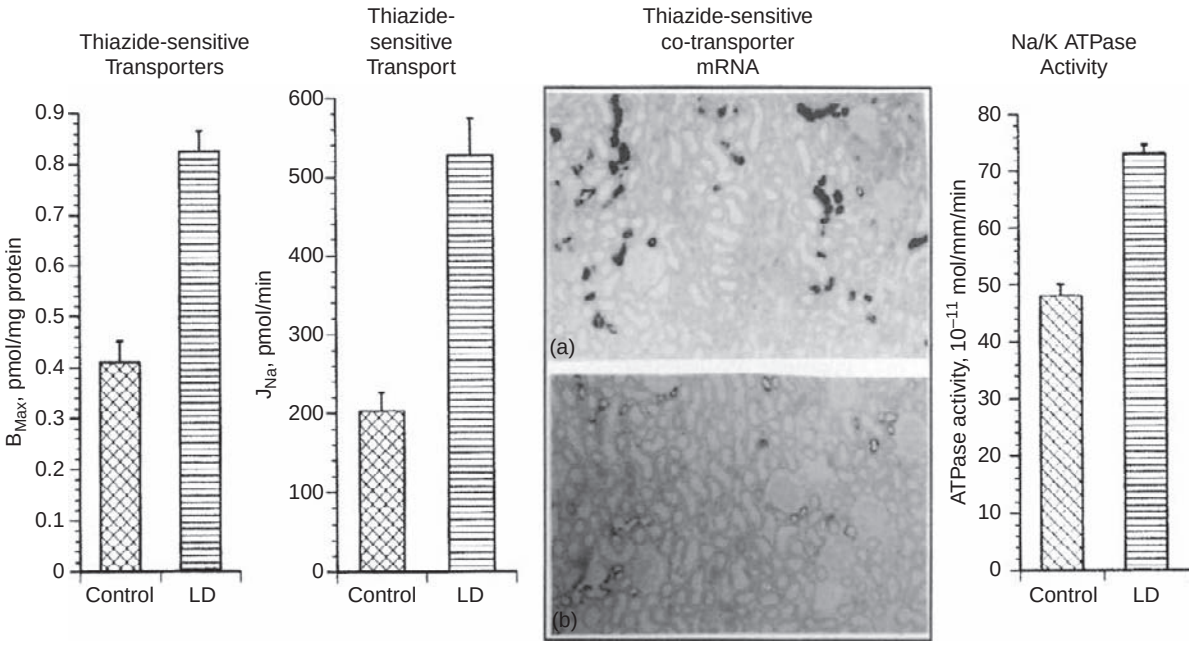

FIGURE 40.18 **Effects of continuous loop diuretic infusion on rat kidney.** Loop diuretic infusion increased the number of thiazide-sensitive Na-Cl co-transporters,[378] the rate of thiazide-sensitive Na transport along the distal tubule,[365] the abundance of thiazide-sensitive Na-Cl co-transporter mRNA (a: furosemide-treated kidney cortex; b: control kidney cortex). *(Ref. [181], used with permission),* and Na/K-ATPase activity along the distal convoluted tubule. *(Data from ref. [392].)*

membrane precede cell growth in the TAL during treatment with ADH,[402] in principal cells of the CCT during treatment with mineralocorticoid hormones,[403,404] and in the DCT during treatment with loop diuretics.[365,398] Although the cause of the increased Na uptake varies, changes in the intracellular Na concentration appear to precede growth in each example. This hypothesis predicts that blockade of apical Na entry would lead to atrophy of epithelial cells. Chronic treatment of rats with DCT diuretics reduces activity of Na/K-ATPase and Na transport capacity of DCT segments,[405,406] but these experiments are complicated by other structural effects of chronic DCT diuretic treatment, discussed below. Regardless of the proximate stimulus for DCT cell growth, recent experiments have shown that immunoreactivity for insulin-like growth factor-1 (IGF-1), and for an IGF-binding protein (IGFBP-1), increases during chronic treatment of rats with loop diuretics.[407] The changes in IGF-1 expression appeared not to result from changes in IGF-1 mRNA expression, but rather appeared to reflect post-transcriptional events. IGFBP-1 mRNA was increased by three-fold 18 hours after loop diuretic treatment was initiated. IGF-1 has been shown to participate in regeneration of injured or ischemic renal tissue, and promotes cell proliferation and differentiation *in vitro*; whether these changes in IGF expression mediate the effects of diuretics on distal nephron structure remains to be established.

Morphological changes in the distal nephron during loop diuretic administration are not restricted to Na reabsorbing cells. Chronic diuretic infusion stimulates selective hypertrophy of type-B intercalated-cells.[408] Type-B intercalated-cells secrete bicarbonate and express apical Cl/HCO_3 exchangers and basolateral H-ATPase pumps; chronic bumetanide infusion increased the number of apical microvilli in Type-B cells, increased the basolateral cell membrane area, and led to marked cytoplasmic and basolateral labeling for H-ATPase. Type-A cells, which normally mediate acid secretion, were small; H-ATPase was distributed primarily within intracellular tubulovesicles in the tubules of treated animals. The authors concluded that the structural changes in intercalated cells resulted from increased distal chloride delivery, because serum pH and electrolyte concentrations were not affected by the diuretic treatment. Increased distal chloride delivery might be expected to enhance Cl/HCO_3 exchange, increasing transepithelial solute transport, stimulating cell growth via mechanisms similar to those discussed above. These effects are likely to contribute to the profound metabolic alkalosis that can complicate aggressive treatment with loop diuretics.

Chronic diuretic administration has structural effects not only on nephron segments that lie distal to the site of diuretic action, but also on the nephron segments that are directly inhibited by the drugs themselves.

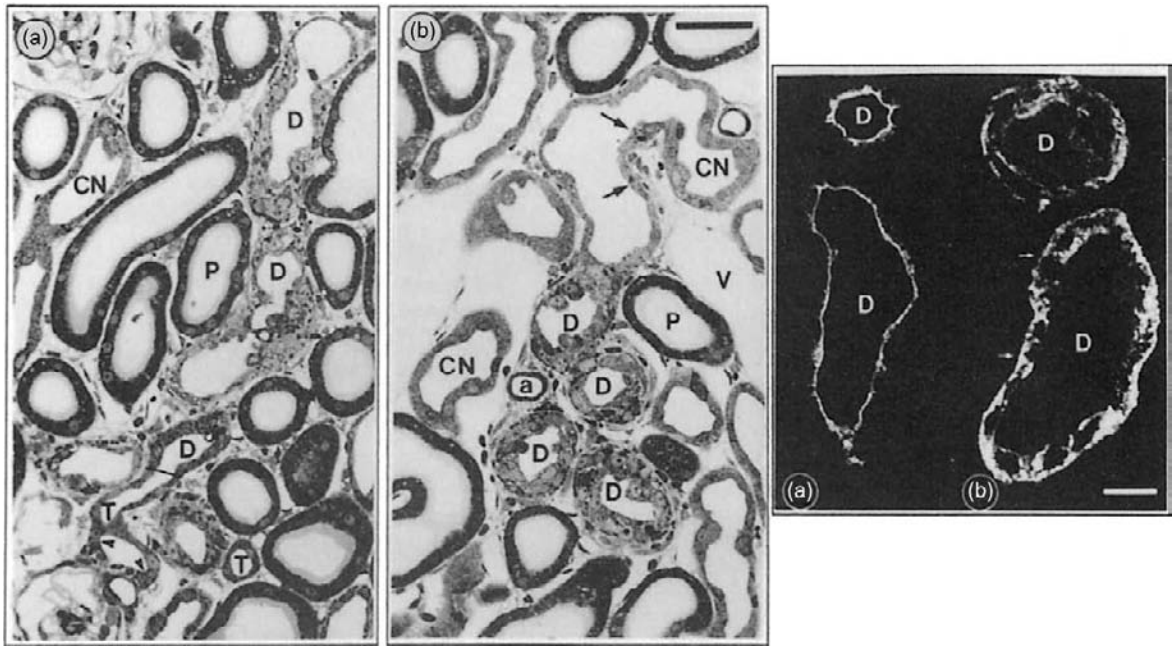

FIGURE 40.19 **Effects of continuous DCT diuretic treatment on the structure of distal convoluted tubules.** Panels a and b at the left show photomicrograph of kidney cortex from animals treated chronically with thiazide diuretics; note extreme hyperplasia and dysmorphology of distal segments (compare normal distal convoluted tubules in Figure 40.16, above) (T: thick ascending limb; D: distal convoluted tubule; CN: connecting tubule; CD: collecting duct; P: proximal tubule; a: arteriole). Double arrow indicates transition from thick ascending limb to distal convoluted tubule; note normal morphology of the thick ascending limb. Panels a and b on the right show immunostaining for the thiazide-sensitive Na-Cl co-transporter from control rats (a) and rats infused with a thiazide continuously for 10 days (b). Note that the normal apical localization of the transporter immunoreactivity (a) is distributed throughout the cytoplasm in animals exposed to diuretics chronically (b). *(From ref. [217]. Used with permission.)*

Within hours of furosemide administration to rats, autophagocytic vacuoles develop in thick ascending limb cells.[409] Following seven days of furosemide treatment of rats, the cell height of thick ascending limb cells was significantly reduced.[365] Chronic treatment of rabbits with loop diuretics decreased Na/K-ATPase activity in medullary thick ascending limb cells by approximately one-third.[410] These results are consistent with an effect of transepithelial ion transport to stimulate "work hypertrophy" and blockade of transepithelial transport to stimulate "disuse atrophy." When DCT diuretics are administered chronically, Na/K-ATPase activity in the DCT is reduced,[406] and the capacity of DCT cells to reabsorb Na and Cl declines.[405] Yet chronic administration of DCT diuretics, like genetic disruption of the thiazide-sensitive Na-Cl co-transporter,[216] to rats leads to profound changes in cellular morphology; the DCT epithelium becomes disordered, DCT cells undergo apoptosis and necrosis, and interstitial fibrosis occurs (see Figure 40.19). Chronic treatment also leads to the disappearance of normal polarization of thiazide-sensitive Na-Cl co-transporter proteins. Under normal conditions, immunoreactivity for the thiazide-sensitive Na-Cl co-transporter is restricted to the apical membrane and to a small subapical pool of vesicles (see Figure 40.19**)**. During chronic treatment with DCT diuretics, the protein is distributed uniformly throughout the cell. Surprisingly, based on the severe morphological degenerative changes in tubular morphology, chronic thiazide administration results in an *increase* in the density of [^{3}H] metolazone-binding sites (functional thiazide-sensitive transporters) in kidney cortex,[406] despite a decline in mRNA expression for the transporter.[395] These results demonstrate that chronic thiazide administration regulates the thiazide-sensitive transporter in a complex way. Further studies are necessary to determine the mechanisms involved.

Although experimental data concerning structural and functional responses of the distal nephron to chronic treatment with diuretic drugs come predominantly from studies employing experimental animals, Loon et al.[411] reported that chronic treatment with loop diuretics in humans enhanced ion transport rates in the distal tubule. They estimated the transport capacity of the DCT as the portion of Na and Cl reabsorption that could be inhibited by thiazide diuretics. When furosemide was administered to volunteers for one month, the enhancement in sodium excretion that occurred resulting from dose of a thiazide diuretic was

significantly larger. Although these data are necessarily indirect, they are entirely consistent with the data derived from experimental animals given loop diuretics chronically. The ECF volume-independent component of NaCl retention that occurs following loop diuretic administration[366] may also reflect changes in distal nephron structure and function.

INTRODUCTION

Water is the most abundant component of all cells, and the ability to absorb and release water is considered a fundamental process of life. Plasma membranes serve as selective barriers that control the solute composition of the cell and regulate the entry of ions, small uncharged solutes, and even water. Epithelial tissues have apical and basolateral plasma membranes that constitute serial barriers that regulate the transepithelial movement of solutes and water, thereby contributing to the homeostasis of multicellular organisms. Identification and characterization of the molecular entities responsible for the function of biologic membranes have been long-standing goals of physiologists; however, the molecular identity of water transporters remained unknown until less than two decades ago.

Because water can slowly diffuse through lipid bilayers, all biologic membranes exhibit some degree of water permeability. Nevertheless, observations made in multiple laboratories indicated that specialized membrane water-transport molecules must exist in tissues with distinctively high water permeability (see review [1]). For example, the water permeability of red cell membranes is higher than that of many other cell types or artificial lipid bilayers, and the activation energy of this process is equivalent to the diffusion of water in solution, E_a <5 kcal/mol.[2] In addition, reversible inhibition by $HgCl_2$ and a subset of organomercurials suggested that the water transporter is a membrane protein (see review [3]). Further evidence that a membrane protein is involved in water transport was provided by the observation that some epithelial tissues exhibit changes in water permeability on a timescale that is not compatible with changes in lipid composition.

Kidneys are the major determinant of body water and electrolyte composition. Thus, comprehending the mechanisms of water transport is essential to understanding mammalian kidney physiology and water balance. Because of its importance to human health, water permeability has been particularly well-characterized in the mammalian kidney (see review [4]). Approximately 180 L/day of glomerular filtrate is generated in an average adult human, the majority of this is reabsorbed by the highly water-permeable proximal tubules and descending thin limbs of Henle's loop. The ascending thin limbs and thick limbs are relatively impermeable to water, and empty into renal distal tubules and ultimately into the collecting ducts. The collecting ducts are extremely important clinically in water-balance disorders, because they are the chief site

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00041-0

of regulation of water reabsorption. Basal epithelial water permeability in collecting duct principal cells is low, but the water permeability can become exceedingly high when stimulated with vasopressin (also known as ADH, antidiuretic hormone). In this regard, the toad urinary bladder behaves like the collecting duct, and it has served as an important model of vasopressin-regulated water permeability. Stimulation of this epithelium with vasopressin produces an increase in water permeability in the apical membrane, which coincides with the redistribution of intracellular particles to the cell surface.[5–8] These particles were believed to contain water channels.

DISCOVERY OF AQUAPORIN-1 (AQP1)

The molecular identity of membrane water channels long proved elusive. Attempts to purify water channel proteins from native tissues or to isolate water channel cDNAs by expression cloning, were unproductive (see review [9]). This may be explained by the physical characteristics of water, a simple molecule not amenable to chemical modification such as introduction of chemical cross-linking groups or labels. In addition, $HgCl_2$ was known to inhibit membrane water channels, a property potentially useful in the identification of the water channel proteins. However, because the agent reacts with free sulfhydryls in other proteins, its inhibitory effect on water channels is not specific. This circumstance led to the mistaken identification of the band 3 anion exchanger as a molecular water channel.[10] In addition, the diffusional permeability of all biologic membranes results in high background permeability, and frustrated efforts to clone cDNAs for water channels by functional expression.

The recognized characteristics of membrane water channels led to chance identification of the first known water channel. In the process of isolating the 32 kDa bilayer-spanning polypeptide component of the red cell Rh blood group antigen,[11] a 28 kDa polypeptide was partially co-purified.[12] Initial studies demonstrated that the 28 kDa polypeptide comprised hydrophobic amino acids and exhibited an unusual detergent solubility, which facilitated purification and biochemical characterization. The 28 kDa polypeptide was found to exist as an oligomeric protein with physical dimensions of a tetramer; a unique N-terminal amino acid sequence was identified[13] which permitted cDNA cloning.[14] Also of note, radiation inactivation studies of water permeability by renal vesicles yielded a target size of 30 kDa.[15] Because the 28 kDa polypeptide was found to be abundant in red cells, renal proximal tubules, and descending thin limbs,[12] it was suggested that this protein might be the sought-after water channel. Although this protein was first known as "CHIP28" (channel-like integral protein of 28 kDa), the need for a functionally relevant name was recognized. The name "aquaporin" was coined. After recognition of related proteins with similar functions, this name was formally proposed for the emerging family of water channels now known as the aquaporins.[16] Thus, CHIP28 was designated aquaporin-1 (symbol AQP1). The Human Genome Nomenclature Committee has embraced this nomenclature for all related proteins,[17] and presently a total of 13 such related proteins have been identified in mammals.

The measurement of the movement of water across cell membranes poses a unique experimental challenge. Unlike ion conductances, which may be measured electrophysiologically, or solute transport, which may be measured with radioactive substrates, transmembrane water movement in cells relies on determination of changes in cell volume in response to an osmotic driving force. The *Xenopus laevis* oocyte expression system was used to search for water channel RNAs, because these cells are known to exhibit remarkably low membrane water permeability.[18,19] Oocytes injected with cRNA encoding AQP1 exhibit remarkably high osmotic water permeability ($P_f \sim 200 \times 10^{-17}$ cm/s), causing the cells to swell rapidly and eventually rupture in hyposmotic buffer.[20] In contrast, control oocytes not injected with AQP1 cRNA exhibited less than one tenth of this permeability.

Oocyte studies demonstrated that AQP1 behaves like the water channels in native cell membranes.[20] Osmotically-induced swelling of oocytes expressing AQP1 occurs with a low activation energy, and is reversibly inhibited by $HgCl_2$. Moreover, AQP1 oocytes fail to demonstrate any measurable increase in membrane current. Although these early studies demonstrated only swelling of oocytes, it was predicted that the direction of water flow through AQP1 is determined by the orientation of the osmotic gradient. Thus, AQP1 oocytes swell in hyposmolar buffers but shrink in hyperosmolar buffers.[21]

To confirm that the interpretation of the oocyte studies was correct, highly purified AQP1 protein from human red cells was reconstituted with pure phospholipids into proteoliposomes, which were compared with simple vesicles (liposomes) by rapid transfer to hyperosmolar buffer.[22] These studies permitted determination of the unit water permeability, which had an astonishingly high value ($P_f \sim 3 \times 10^9$ water molecules subunit^{-111} sec^{-111}). Moreover, the water permeability is reversibly inhibited by $HgCl_2$, and exhibits low activation energy. Several of these studies have been confirmed by using red cell membranes partially depleted of other proteins,[23] and attempts to demonstrate permeation by other small solutes or even

protons showed that AQP1 is water selective.[24] Together, these studies indicated that AQP1 is both necessary and sufficient to explain the well-recognized membrane water permeability of the red cell, and suggested that AQP1 or similar proteins could be the long-sought-after epithelial water channels of the nephron and collecting ducts.

STRUCTURE AND FUNCTION OF AQUAPORINS

General Structure of AQP1

The availability of pure AQP1 protein in milligram quantities and the simple functional assay in oocytes led to rapid advances in the understanding of the molecular structure of AQP1. Hydropathy analysis of the deduced amino acid sequence of AQP1 predicted that the protein resides primarily within the lipid bilayer,[14] a feature in agreement with initial studies of red cell AQP1.[12,13] As previously described for the homolog major intrinsic protein from lens (MIP, now referred to as AQP0), the polypeptide contains an internal repeat (Figure 41.1), with the N- and C-terminal halves being sequence-related, and each containing the signature motif Asn-Pro-Ala (NPA),[25,26] suggesting ancestral gene duplication.[14] When evaluated by hydropathy analysis, six bilayer-spanning domains, five connecting loops (A–E), and intracellular N-and C-termini are predicted. Attenuated total reflection-FTIR (Fourier Transform InfraRed spectroscopy) of highly-purified red cell AQP1 reconstituted into membrane crystals demonstrated a lack of beta structure in AQP1, indicating the existence of tilted alpha helices.[27]

The two homologous domains equivalent to the N-and C-termini halves of the protein each consist of three transmembrane helices that are thought to be oppositely orientated in the lipid bilayer.[28] A system was adapted for analyzing the structure of AQP1 after minimally perturbing the molecule by adding peptide epitopes at various sites. It was important that the epitope did not destroy function, and could be localized to intracellular or extracellular sites with antibodies and by selective proteolysis of intact membranes or inside-out membrane vesicles. These studies demonstrated that loop C resides at the extracellular surface of the oocytes and the intracellular location of loop D as well as the N-and C-termini. Moreover, the obverse symmetry of the N-and C-terminal halves of the molecule was confirmed[29] (Figure 41.1).

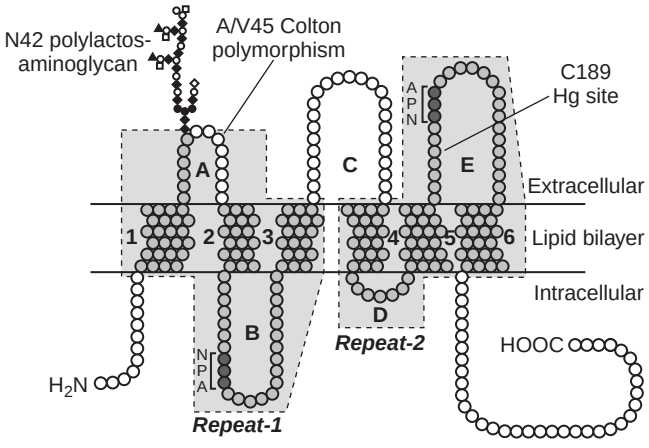

FIGURE 41.1 **Proposed membrane topology of AQP1 subunit.** Each molecule subunit spans the plasma membrane six times with the N- and C-termini in the cytoplasmic space. Extracellular and intracellular loops are labeled A–E.[32] Loop A contains an attachment site for a polylactosaminoglycan at asparagine-42 and the Co blood group polymorphism at alanine/valine-45.[100] The aquaporin signature motif asparagine-proline-alanine (NPA) is present in the loop Band E. Loop E also contains the site of mercury inhibition at cysteine-189. The amino acid sequences of C-termini of the known aquaporins are not conserved, and are sufficiently immunogenic to permit preparation of specific polyclonal antibodies to each aquaporin (see text) *(reproduced and modified from ref. [370], with permission).*

Loops B and E

Loops B and E encompass the two NPA motifs, and are the most conserved regions in the major intrinsic protein family. The loops exhibit significant hydrophobicity, suggesting association with the lipid bilayer.[14] Subsequent studies implicated loops B and E as a structural component of the aqueous pathway. Experiments expressing AQP1 in *Xenopus* oocytes led to the observation that Cys^{189} in loop E is the site of mercurial inhibition.[30,31] Site-directed mutagenesis experiments in oocytes revealed that substitution of Cys^{189} with a serine residue eliminates $HgCl_2$ sensitivity and increases osmotic water permeability, while substitution with larger amino acids residues prevents facilitated water transport.[30] These results suggest that water transport and selectivity in AQP1 is somehow dependent on the steric properties of Cys^{189}. In accordance with the internal repeat theory, Ala^{73} located in loop B, the equivalent to Cys^{189} in loop E, was investigated. By creating double mutants expressing Cys^{189} as a serine and Ala^{73} as a cysteine, the $HgCl_2$ sensitivity and osmotic water permeability were restored.[32] These results suggested that loops B and E were arranged in a symmetrical fashion, and underlined that these loops were functionally essential for water permeability. This line of inquiry lead to the "hourglass" model,[32] in which these domains overlap midway between the leaflets of the bilayer, creating a constitutively open, narrow aqueous pathway (Figure 41.2).

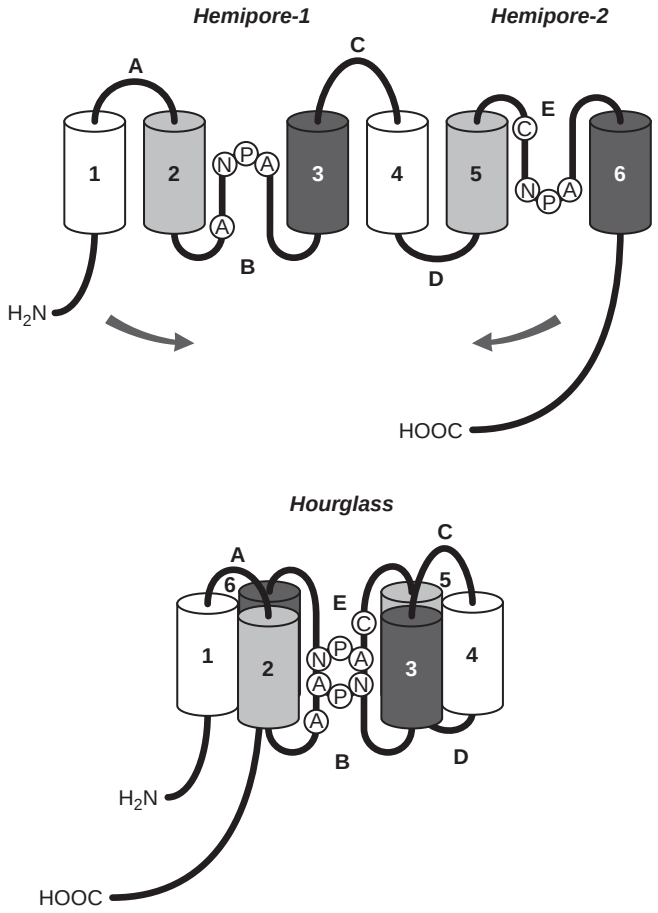

FIGURE 41.2 **Hourglass model of aquaporin-l (AQP1) structure.** Bilayer spans 1–3 (Repeat-l) and spans 4–6 (Repeat-2) are sequence-related, and are oriented in obverse symmetry. Loop B and loop E are believed to dip into the bilayer and emerge from the same side (top). When folded together, loops B and E form a single aqueous pathway (the "hourglass"), flanked by the site of mercury inhibition at cysteine189 (bottom) *(reproduced and modified from ref. [32], with permission).*

Tetrameric Organization

Early biophysical characterization of AQP1 suggested that the protein formed multisubunit oligomers.[13] Rotary and unidirectionally shadowed freeze-fracture electron microscopic analyses of AQP1 protein from human red cell membranes reconstituted in proteoliposomes provided detailed molecular insights. AQP1 had an oligomeric structure, consisting of four subunits surrounding a central depression. These tetrameric structures were also seen in highly water-permeable nephron segments expressing native AQP1.[33] Although the oligomerization of AQP1 is still not understood in detail, all studies indicate that the protein is a tetramer composed of functionally-independent aqueous pores.[15,30,32,34]

Structural Analyses and Molecular Dynamics of Aquaporins

By reconstituting the highly-purified red cell AQP1 into membranes under controlled conditions, membrane crystals were produced with AQP1 in highly uniform lattices. These membranes appeared as flat sheets or as large, resealed vesicles in which the AQP1 protein was found to fully retain water permeability.[35] Thus, the opportunity to define the structure of AQP1 in a biologically-active state became possible. Electron microscopic studies by multiple groups permitted the elucidation of the protein at increasing levels of resolution. By performing high-resolution electron microscopic evaluation of negatively-stained membranes at a series of tilts, a three-dimensional view was obtained.[36] Image projections revealed the presence of multiple bilayer-spanning domains, and atomic force microscopy further defined the orientation and extramembranous dimensions of AQP1.[37] Electron crystallographic analysis of cryopreserved specimens has been undertaken at tilts of up to 60°. These analyses revealed the three-dimensional structure of AQP1 at increasing resolutions, down to 3.8 Å.[38–46] X-ray crystallographic analysis has added further information about the structure of AQP1. Using the above method, the structure of AQP1 has been determined down to a resolution of 2.2 Å.[47] In contrast to the previous studies, the high resolution enables observation of water molecules in transit through the channel. Based on combined efforts, a detailed picture of AQP1s tertiary structure could be formed.

As earlier studies indicated, the AQP1 monomers form a tetrameric cluster. The model shows an extension of the tetramer from the extracellular plane, while the intracellular surfaces form a shallow depression. The N-termini from one monomer is closely situated near the C-termini of the neighboring monomer. The gap formed by the four monomers narrows from 8.5 Å down to 3.5 Å. The residues surrounding the gap are hydrophobic, suggesting an interaction with a hydrophobic molecule.[43] So, despite the monomeric formation of a central cavity, the tetrameric structure does not support the transport of water. This is in agreement with earlier observations, suggesting that each monomer is capable of facilitating water transport.

The dimensions of each monomer are 40 Å across and 60 Å long, as reported by Sui et al.[47] (Figure 41.3). The monomer is composed of six bilayer-spanning alpha helices surrounding a central density. The C loop located on the extracellular surface connects the N-and C-termini halves of the protein. Part of the central density represents the B and E loops, which appear as two short α-helix structures not permeating the

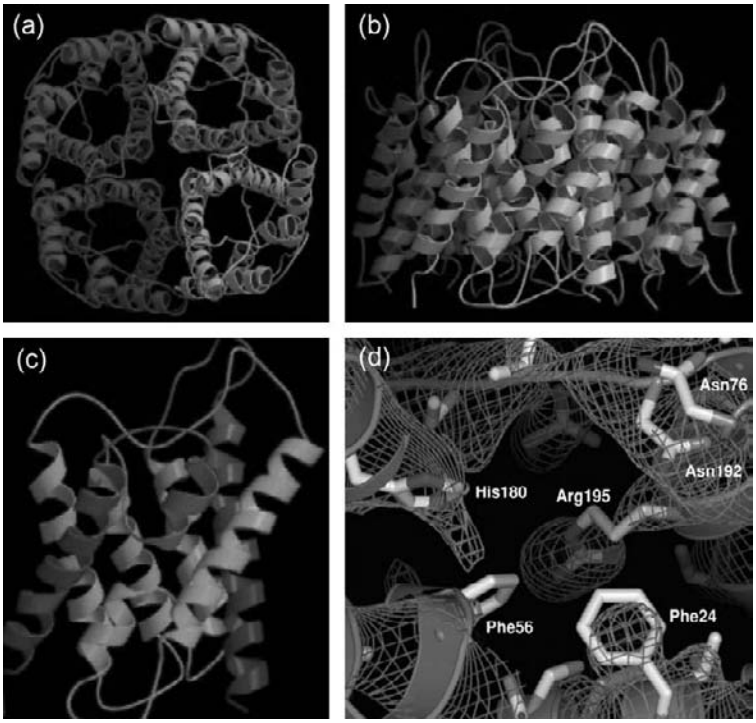

FIGURE 41.3 (a)–(b): Structure of the human AQP1 tetramer, viewed from the top (a) and side (b). (c): Structure of the human AQP1 monomer. (d): Model of the central pore region of human AQP1-EM3 structure (pdb code 1H6I [371] together with the 3.8 Å resolution EM potential map rendered at 1.0s.[43] Several residues critical for AQP1 facilitated water transport are marked *(reproduced and modified with permission from ref. [372]).*

membrane[42] (Figure 41.3). This organization is strikingly similar to the proposed hourglass arrangement of the B and E loops.[32] The NPA containing loops are located on opposite sides of the membrane, juxtapositional to each other, interacting through their NPA motifs. The central density is composed of an extracellular and intracellular vestibule, separated by a narrow pore. The extracellular vestibule is approximately 15 Å at its widest.[47] Following the extracellular vestibule towards the lipid bilayer, a decrease in diameter occurs and the pore becomes exceedingly small.[43,47] The constriction site (also referred to as the aromatic/arginine constriction) is located 20 Å from the beginning of the extracellular vestibule, and is composed of several highly-conserved residues in conventional aquaporins. The constriction site is approximately 2.8 Å wide, about the diameter of a water molecule.[47] After the constriction site the pore continues for 20 Å, a region termed the "selectivity filter".[47] The selectivity filter is slightly wider and part of the region is formed by the helical loops B and E.[43,47] This locates the asparagine residues in the NPA motifs within the selectivity filter.[43,47] Additionally, Cys^{189} in loop E protrudes into the pore, confirming earlier studies, suggesting that $HgCl_2$ sensitivity was due to steric hindrance of water movement through the pore.[32,43,47] Following the pore towards the intracellular vestibule, the diameter increases again, reaching 15 Å[47] (Figure 41.3).

Using molecular dynamic simulations, de Groot and Grubmüller obtained time-resolved, atomic resolution models of water transport through AQP1.[48] From the extracellular vestibule, water molecules enter the constriction site, composed of side chains from the aromatic Phe^{56} and His^{180}, and the charged Arg^{195}. This conformation situates the water molecule, allowing hydrogen bonding with the polar residues, thereby reducing hydrogen bonding between water molecules. In addition, electrostatic repulsion by Arg^{195} suggests that the constriction site is the main site for exclusion of protons (hydronium ions) and other ions.[48] This is further supported by mutagenic analysis of the residues in the constriction site, showing permeation of urea, glycerol, and ammonia in AQP1 when altered. Moreover, replacing Arg^{195} with a valine residue appears to facilitate proton transport.[49] Passing onward through the hydrophobic selectivity filter, exposed polar moieties mainly consisting of backbone carbonyls, lead the water molecules towards the NPA motifs. The water molecule transiently reorientates to bond with the two asparagines residues of the NPA motifs, and is led out of the selectivity filter towards the intracellular vestibule, again by hydrogen bonding with a few selected backbone carbonyls. Hence, the selectivity filter encompassing the highly-conserved NPA motifs appears to serve mainly as a filter for size,[48] while the ar/R constriction is a major checkpoint for solute amd ion permeability. The *Escherichia coli* aquaglyceroporin (GlpF) selectively facilitates glycerol transport over that of water.[50] Evaluation of differences between AQP1 and GlpF using molecular dynamic

simulations revealed a larger selectivity filter in GlpF. Moreover, the preference for glycerol could be explained by what de Groot and Grubmüller describe as a glycerol-mediated "induced fit" gating motion (i.e., glycerol transport serves as the prime mechanism for water exclusion).[48]

Structural characterizations of crystallized human AQP2 in two-dimensional protein–lipid arrays by atomic force microscopy and electron crystallography have revealed the structure of AQP2 at a resolution of 4.5 Å in the membrane plane.[51] As with AQP1, AQP2 is found in a tetrameric assembly in the lipid bilayer.[51,52] The AQP2 monomer shows structural features similar to those earlier reported for AQP1,[51] while structural variation is found around the tetramer's axis.[51,53]

The structure of AQP0 has also been determined down to a resolution of 2.2 Å.[54,55] The water conductance of AQP0 is much lower than that reported for AQP1,[56] possibly due to highly-conserved tyrosine residues in AQP0 imposing further constriction on the channel.[55] The constriction site is smaller than that in AQP1, and the selectivity filter is also narrower.[54,55] Molecular dynamics studies suggest that water movement is facilitated by AQP0 due to thermal motions of certain side chains, although this builds up a free energy barrier, possibly contributing to the lower permeability of AQP0.[57] The extensive analyses of the structure of various AQP isoforms have provided detailed insight into the molecular basis for transmembrane water transport. Future studies aimed at defining the distinct structure of other members, including aquaglyceroporins such as AQP7 and AQP9 that appear to be involved in metabolism rather than water transport may provide further insights. Several studies have also been aimed at identifying novel aquaporin blockers. Although some progress has been reported so far, only a few compounds, including related tetraammonium compounds, have shown selective effects on AQPs.[58–60] Copper[61] and nickel[62] also significantly block aquaporins. Over the past five years the overall structural concepts of aquaporins have been confirmed.[63–74]

DISTRIBUTION OF AQP1 IN KIDNEY AND OTHER TISSUES

Well before recognition of its function, the red cell AQP1 protein was known to be expressed at high levels in the proximal convoluted tubules and descending thin limbs of kidney.[12] This was confirmed with polyclonal rabbit antiserum,[75] and was defined in rat and human kidney with affinity-purified immunoglobulin specific for the N- and C-terminal domains of

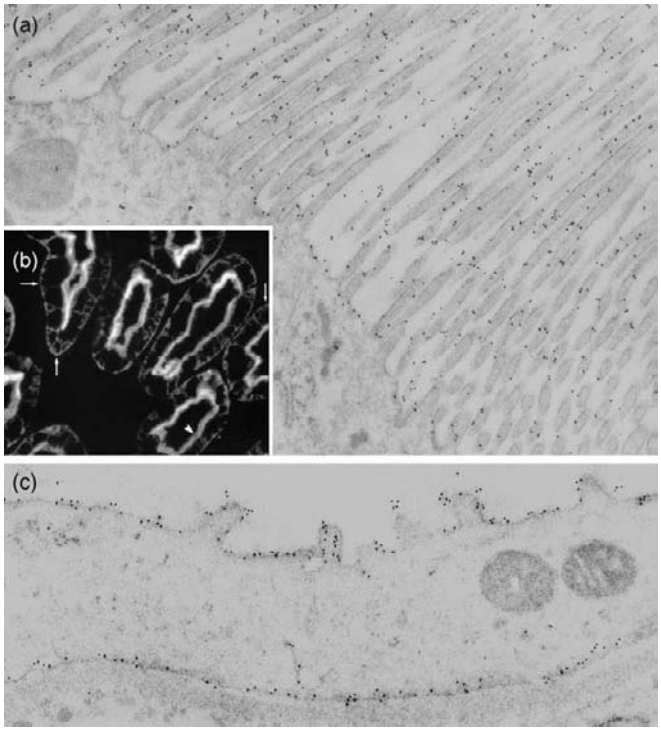

FIGURE 41.4 **Distribution of aquaporin 1 (AQP1) in kidney.** Ultrathin cryosections of rat renal cortex and inner medulla stained with anti-immunogold AQP1. (a): Strong labeling is present over the apical brush border of S3 section of proximal tubule. (b): Strong labeling is present over apical and basolateral membrane of thin descending limb of Henle's loop *(reproduced and modified from ref. [77], with permission).*

AQP1.[76,77] In all studies, AQP1 was demonstrated to be constitutively present in the apical plasma membranes (i.e., the brush borders), and in basolateral membranes of S2 and S3 segment proximal tubules (Figure 41.4). Quantitative immunoblotting indicated that AQP1 makes up 0.9% of total membrane protein from rat renal cortex and 4% of brush border proteins.[77] Enzyme-Linked Immunosorbent Assay (ELISA) measurements of microdissected tubules revealed that proximal tubules contain approximately 20 million copies of AQP1 per cell.[78] Additionally, AQP1 is found in the plasma membrane of glomerular mesangial cells in humans, although not in rat.[76,77,79] Other immunohistochemical and immunogold electron microscopic studies have demonstrated AQP1 in multiple capillary endothelia throughout the body,[80–82] including the renal vasa recta.[83] AQP1 is also abundant in peribronchiolar capillary endothelium, where expression is induced by glucocorticoids,[80,84] apparently acting through the classic glucocorticoid response elements in the *AQP1* gene.[85] In addition, AQP1 has been defined in multiple water-permeable epithelia including choroid plexus, peritoneal mesothelial cells,[86] fetal

membranes,[87] at multiple locations in eye, including ciliary epithelium, lens epithelium, and corneal endothelium,[81,88,89] and in hepatobiliary epithelium,[90] pancreatic interlobular ducts,[91] heart and skeletal muscle,[92] gall bladder,[93] salivary glands,[94] inner ear,[95] and several other organs including the nervous system (see review [96]). AQP1 has also been localized in tumor cells and their vasculature.[97] Developmental expression of AQP1 is complex: transient expression occurs in some tissues before birth; expression in other tissues is subsequent to birth; constitutive life-long expression is found in other tissues.[84,98,99]

AQP1 DEFICIENCY

Humans have been identified who totally lack the AQP1 protein. The human *AQP1* gene was localized to chromosome 7p14 and the Co blood group antigens were previously linked to 7p, suggesting a molecular relationship. It was determined that the Co blood group antigen results from an Ala/Val polymorphism at the extracellular surface of red cell AQP1[100] (Figure 41.1). Although the International Blood Group Referencing Laboratory in Bristol, England, has detailed phenotyping information on millions of donors worldwide, only six individuals had been shown to lack Co. Most of these Co-null individuals are women who developed anti-Co during pregnancy. Three of these Co-null individuals were found to have mutations in the *AQP1* gene.[101] Although the exceedingly rare blood group phenotype makes them impossible to match for blood transfusion, it was surprising that none of them exhibited any other obvious severe clinical phenotype. The extreme rarity of the Co-null state may reflect an important developmental role, resulting in reduced fetal survival; however, the frequency of the heterozygous state is unknown. Detailed studies of the urinary concentrating ability of Co-null individuals revealed a marked inability of the individuals to concentrate urine to more than 400 mOsm/l, even in the presence of dehydration or dDAVP treatment, revealing a significant urinary concentrating defect.[102] Moreover, Co-null individuals display reduced pulmonary vascular permeability.[103]

The development of *AQP1* gene knockout mice has provided further insights into the role of AQP1 in renal water homeostasis. AQP1-null ($AQP1^{-/-}$) mice appeared moderately polyuric under basal conditions. However, $AQP1^{-/-}$ animals exhibited an extreme degree of polyuria and polydipsia when undergoing water deprivation, including rapid hyperosmolar extracellular fluid volume depletion.[104] Additionally, $AQP1^{-/-}$ mice failed to respond appropriately to vasopressin, suggesting that renal water conservation and urinary concentration is highly dependent on AQP1 protein.[104] Detailed classic *in vivo* and *in vitro* physiological evaluation of proximal tubules from the $AQP1^{-/-}$ mice established that transepithelial water permeability was reduced by 80%, and led to an approximate 50% decrease in proximal tubule fluid reabsorption.[105] The apparent differences in transepithelial water permeability and proximal tubule fluid reabsorption are likely dependent on the generation of a hypotonic filtrate in proximal tubules of $AQP1^{-/-}$ mice.[106] Despite these observations, distal fluid delivery in $AQP1^{-/-}$ remained unchanged, due to a compensatory reduction in single nephron glomerular filtration.[105] When blunting the TGF response, and thereby the compensatory reduction in glomerular filtration observed in $AQP1^{-/-}$ mice, ambient urine osmolalities and urinary flow rates appeared no different from normal $AQP1^{-/-}$ mice, probably due to distal tubular compensatory mechanisms.[107] The impaired proximal fluid reabsorption observed in $AQP1^{-/-}$ mice, albeit with normal distal fluid delivery, suggests that the polyuric phenotype largely depends on a concentrating defect impairing collecting duct water reabsorption

Studies using isolated perfused thin descending limbs have revealed that the osmotic water permeability of the type II thin descending limbs (outer medullary thin descending limbs from long loop nephron) is decreased by 90% relative to wild-type values in kidneys from AQP1 knockout mice.[108] Additionally, earlier observations using freeze-fracture electron microscopic techniques showed a remarkably high density of intramembrane particles in the thin descending limb of rat, which has been attributed to the tetrameric assembled AQP1 subunits.[33] In the thin descending limb of $AQP1^{-/-}$ mice, the abundance and size of these intramembrane particles was markedly reduced.[108] Moreover, the distribution of AQP1 in the vasa recta suggests a role in microvascular exchange, hence affecting urinary concentration. In the presence of a NaCl gradient, osmotic water permeability was almost eliminated in the descending vasa recta of $AQP1^{-/-}$ mice, leading to a predicted reduction in medullary interstitial osmolality and likely an impairment of countercurrent multiplication.[109] Additional studies using adenoviral gene delivery restored AQP1 protein expression in the proximal tubule epithelia and renal microvessels of $AQP1^{-/-}$ knockout mice, albeit not in the descending thin limbs. The adenovirus-treated mice showed slight restoration of the concentrating defect during water deprivation, probably due to reinsertion of AQP1 water channels in the vasa recta, although urinary concentrating ability was still highly insufficient in comparison to wild-type mice.[110] In conclusion, the severe concentrating defect seen in the $AQP1^{-/-}$ mice primarily results from impaired water

absorption in the thin descending limb, underlining the necessity for a constitutively high water permeability in this segment for a functional countercurrent multiplication system.

ADDITIONAL FUNCTIONS OF AQP1

AQP1 is generally believed to be a constitutively active, water-selective pore. Nonetheless, some observations contradict this. A small degree of permeation by glycerol has been seen in oocytes which may represent opening of an unidentified leak pathway,[111] and the biologic significance remains unclear.[21] Forskolin was reported to induce a cation current in AQP1-expressing oocytes,[112] but multiple other scientific groups have failed to reproduce this effect.[113] Although small changes in water permeability by oocytes expressing a bovine homolog of AQP1 have also been ascribed to vasopressin and atrial natriuretic peptide, the significance is uncertain.[114] Likewise, secretin-induced membrane trafficking has been noted in isolated cholangiocytes[115,116]; however, this awaits confirmation by immunoelectron microscopy. Permeation of AQP1 by CO_2 has also been evaluated. Rates of pH change are about 40% higher in oocytes expressing AQP1[117] than in control oocytes. Although the background permeation of lipid bilayers by CO_2, as well as oxygen, ammonia, nitric oxide, and other gases, may be high,[118] the potential physiological relevance of AQP1 permeation by gases warrants more study (see review [119]). Additionally, AQP1 appears to play a role in cell migration.[120] $AQP1^{-/-}$ mice implanted with tumor cells show reduced tumor vascularity and growth, thus leading to improved survival in comparison to wild-type mice. Moreover, *in vitro* analysis of endothelial cells isolated from $AQP1^{-/-}$ mice showed marked impairment in cell migration.[120] In primary cultures of proximal tubule cells from $AQP1^{-/-}$ mice, *in vitro* cell migration was impaired compared to $AQP1^{+/+}$ mice. Furthermore, in an ischemia–reperfusion model of acute renal tubular injury, $AQP1^{-/-}$ mice showed more severe pathological changes, including more prominent tubule degeneration.[121] Thus, although the evidence that AQP1 functions as a water channel is incontrovertible, the possibility of yet undiscovered transport functions cannot be excluded.

AQUAPORINS IN KIDNEY

The first functional definition of one member of a protein family often prompts a search for related proteins. This has certainly been the case for the aquaporins, and the homology cloning approach has been undertaken by multiple laboratories whose combined efforts have expanded the aquaporin family membership list. Homology cloning has most frequently been undertaken by using polymerase chain amplification with degenerate oligonucleotide primers.[122] Thirteen mammalian aquaporins are now known, and they form at least two subgroups: water-selective channels (orthodox aquaporins) and channels permeated by water, glycerol, and other small molecules (aquaglyceroporins). Given the large potential for confusion, the Human Genome Organization has established an Aquaporin Nomenclature System,[117] accessible by internet (http://www.gene.ucl.ac.uk/nomenclature). Of the known aquaporins, eight are expressed in mammalian kidney (Table 41.1). Soon after AQP1 was discovered to be a water channel, AQP2 was identified in renal collecting duct,[123] where it is regulated by vasopressin and is involved in multiple clinical disorders (Table 41.2). AQP3 was identified in kidney and other tissues, and was found to be permeated by glycerol and water.[124–126] AQP4, a $HgCl_2$-insensitive water channel is most abundantly expressed in brain, and is present in kidney collecting duct in the basolateral plasma membrane of principal and IMCD cells and in other tissues, but it is not inhibited by mercury.[127,128] AQP6 was identified at the cDNA level and found to be localized in intracellular vesicles in the collecting duct intercalated cells in the kidney.[129–131] AQP7 is permeated by water and glycerol.[132,133] First cloned from testis,[132] AQP7 is present in segment 3 proximal tubule brush border membranes, where it facilitates glycerol and water transport.[134] AQP8 is a $HgCl_2$-sensitive water channel found in intracellular domains of proximal tubule and collecting duct cells[135,136]; however, its function remains unclear. AQP11 is found in the cytoplasm of renal proximal tubule cells.[137] The exact function is not established, although deletion of the *AQP11* gene produces a severe phenotype with renal vacuolization and cyst formation.[137]

Localization and Function of AQP2, AQP3, AQP4, AQP6, AQP7, AQP8, and AQP11 in Kidney

The amino acid sequences of the N-and C-termini of the different aquaporins are not closely related, and specific polyclonal antibodies can be raised in rabbits immunized with synthetic peptides conjugated to carrier proteins such as keyhole limpet hemocyanin. As with AQP1, these antibodies have permitted localization of the other aquaporins in kidney by immunocytochemistry, immunoelectron microscopy, and single

TABLE 41.1 Aquaporins in Kidney

AQP	Localization (renal)	Subcellular Distribution	Regulation	Localization (extrarenal)
AQP1	S2, S3 segments of proximal tubules	Apical and basolateral plasma membranes	Glucocorticoids (peribronchiolar capillary endothelium)	Multiple tissues, including capillary endothelia, choroids plexus, ciliary and lens epithelium, etc.
AQP2	Collecting duct principal cells	Intracellular vesicles, apical plasma membrane	Vasopressin stimulates short-term exocytosis long-term biosynthesis	Epididymis
AQP3	Collecting duct principal cells	Basolateral plasma membrane	Vasopressin stimulates long-term biosynthesis	Multiple tissues, including airway basal epithelia, conjunctiva, colon
AQP4	Collecting duct principal cells	Basolateral plasma membrane	Dopamine, protein kinase C	Multiple tissues, including central nervous system astroglia, ependyma, airway surface epithelia
AQP6	Collecting duct intercalated	Intracellular vesicles	Rapidly gated	Unknown
AQP7	S3 proximal tubules	Apical plasma membrane	Insulin (adipose tissue)	Multiple tissues, including adipose tissue, testis, and heart
AQP8	Proximal tubule, collecting duct cells	Intracellular domains	Unknown	Multiple tissues, including gastronintestinal tract, testis, and airways
AQP11	Proximal tubule	Intracellular domains	Unknown	Multiple tissues, including liver, testes, and brain

AQP, aquaporin.

tubule microdissection combined with ELISA (Figure 41.5).

Three aquaporins (AQP2, AQP3, and AQP4) are expressed in the collecting duct principal cells and the connecting tubule segment, sites where vasopressin regulates epithelial water permeability. AQP2 is located in the apical plasma membrane and small intracellular vesicles of collecting duct principal cells[138] (Figure 41.6). ELISA measurements of microdissected rat collecting ducts have revealed that AQP2 is an extremely abundant protein in the collecting duct, with more than six million copies per cell throughout the collecting duct system.[139] Additional studies using the single-tubule ELISA method and immunocytochemistry demonstrated co-localization of AQP2 and V2 vasopressin receptor expression on connecting tubule arcades, suggesting that regulated water transport may occur in the arcades of the cortical labyrinth in addition to the collecting duct.[139,140] Additionally, AQP2 has been identified in the basolateral membranes of connecting tubules and inner medullary collecting ducts.[141]

The apical plasma membrane is the rate-limiting barrier for transepithelial water transport across the collecting duct principal cell, and is the site where vasopressin regulates water permeability.[142] Localization of AQP2 in the apical plasma membrane suggested that it is the target for vasopressin-regulated collecting duct water permeability (Figure 41.6). This conclusion was firmly established by multiple studies. A direct correlation between AQP2 expression and collecting duct water permeability has been demonstrated in Brattleboro rats, which lack circulating vasopressin owing to a mutation in the gene encoding vasopressin precursor protein.[143] Likewise, human patients with mutations in the *AQP2* gene manifest severe vasopressin-resistant nephrogenic diabetes insipidus,[144] demonstrating the requirement for AQP2 in collecting duct water transport. Lack of functional AQP2 expression in mice, by generation of *AQP2* gene knockouts, produces a severe concentration defect, resulting in early postnatal death.[145,146] Moreover, morphological changes including renal medullary atrophy and dilation of the collecting ducts is observed in these mice.[145,146] Generation of $AQP2^{-/-}$ knockouts selectively in the collecting ducts, but not in the connecting tubule segments, rescues mice from the lethal phenotype; however, body weight, urinary production, and the response to water deprivation is still severely impaired.[145] Additionally, in a tamoxifen-inducible mouse model of AQP2 gene deletion, adult mice present with severe polyuria, a marked urinary concentration defect, and develop mild renal damage.[147] Together these studies demonstrate the pivotal role of AQP2 in urinary concentration.

AQP3 is localized in a large variety of organs and highly-expressed in the kidney. AQP3 was originally cloned from rat kidney,[124–126] and when expressed in *Xenopus* oocytes it facilitated glycerol transport (discussed below) and increased $HgCl_2$-sensitive osmotic water permeability.[148–150] Moreover, channel-gating is

regulated by protons and copper.[61,150] AQP4 was found to be expressed in several tissues with high abundance in the brain. In oocyte expression studies, the protein increased osmotic water permeability in a $HgCl_2$-insensitive manner.[127,149]

AQP3 and AQP4 are also present in the connecting tubule and collecting duct principal cells; however, the sites where they are expressed do not overlap with the expression of AQP2 in most portions of the collecting duct.[140,151–153] AQP3 and AQP4 are restricted to the basolateral plasma membranes of collecting duct principal cells, where they are presumed to permit water entry into the interstitium. Although both are basolateral water channels, they are distributed differently along the collecting duct system, with the greatest abundance of AQP3 in cortical and outer medullary collecting ducts, and the greatest abundance of AQP4 in inner medullary collecting duct.[153] AQP4 is also found in basolateral membranes of proximal tubule S3 segments, although only in mice.[154] Using freeze-fracture electron microscopy, orthogonal arrays of intramembrane particles (OAP) were demonstrated in the basolateral membranes of the proximal tubule S3 segment in $AQP4^{+/+}$, but not in $AQP4^{-/-}$, mice.[154] AQP4 is expressed in two splice isoforms, the M1 and M23 splice variants. The M23-AQP4 appears to be the OAP-forming water channel when expressed in LLC-PK1 cells. When organized in OAPs, a significantly higher single-channel water permeability coefficient is observed in comparison to the non-AOP forming M1-AQP4.[141,155] Shuttling of AQP3 or AQP4 is not expected to occur, as the predominant fraction is found in the plasma membrane (short- and long-term regulation of these aquaporins will be discussed later). Sodium restriction or aldosterone infusion in normal and Brattleboro rats greatly increases the abundance of AQP3, while AQP3 abundance is markedly reduced during aldosterone deficiency, suggesting a direct effect of aldosterone on collecting duct AQP3 expression.[156] AQP4 appears to be regulated by PKC and dopamine, where stimulation by these factors decreases water permeability in AQP4 transfected cells.[157]

Deletion of the *AQP3* gene induces polyuria and polydipsia and a marked reduction in osmotic water permeability in the basolateral plasma membrane of the cortical collecting duct.[148] Moreover, urinary osmolality is reduced in $AQP3^{-/-}$ mice and they fail to respond appropriately to dDAVP, thus presenting with a urinary concentrating defect.[148] Targeted disruption of AQP4 in mice results in a 75% reduction in the osmotic water permeability of the inner medullary collecting duct.[158] However, phenotypically the $AQP4^{-/-}$ mice appeared grossly normal, presenting with a very mild urinary concentrating defect.[159] In double $AQP3^{-/-}/AQP4^{-/-}$-knockout mice, concentrating ability was only slightly more impaired than in the $AQP3^{-/-}$ mice.[148] It should be noted that the localization of AQP2 in basolateral membranes in both the connecting tubule and inner medullary collecting duct raises the possibility that the observed effect is partly compensated by this mechanism.[141]

AQP6 vesicles reside in subapical vesicles within intercalated cells of the collecting duct, where it is co-expressed with the V-type H^+-ATPase.[131,160] AQP6 appears functionally distinct from other known aquaporins. Oocyte expression studies have revealed low water permeability of AQP6 during basal conditions, while in the presence of $HgCl_2$ a rapid increase in water permeability and ion conductance is observed.

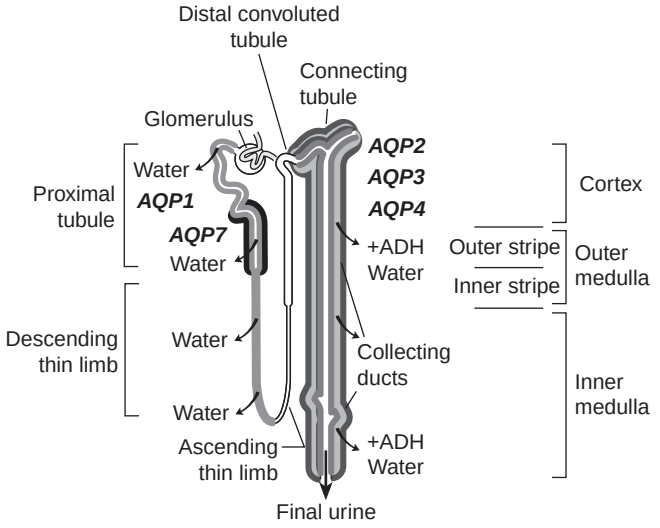

FIGURE 41.5 **Sites of aquaporin (AQP1) expression in kidney and segmental water-transport function.** Proximal nephron: AQP1 is present in apical and basolateral plasma membranes of proximal tubules and thin descending limbs. AQP6 is present in intracellular vesicles of collecting duct intercalated cells. AQP7 is present in proximal tubules. Distal nephron: aquaporins are not present in ascending limbs. Collecting duct: AQP2 is present in intracellular vesicles and apical plasma membranes of principal cells; AQP3 and AQP4 are present in basolateral membranes. AQP6 is present in intracellular vesicles in type A intercalated cells.

Additionally, reductions in pH (below 5.5) quickly and reversibly increase anion conductance and water permeability in AQP6 expressing oocytes.[160] Subsequent studies have shown that the channel is permeable to halides, with the highest permeability to NO_3^-,[160,161] while the ionic selectivity becomes less specific after the addition of $HgCl_2$.[162] Moreover, when Asn^{60}, a residue unique in mammalian AQP6, is converted to glycine, a highly-conserved residue in other mammalian aquaporins, anionic permeability is abolished and osmotic water permeability is increased during basal conditions.[163]

AQP7 is a member of the aquaglyceroporin family, and was originally cloned from rat testis.[132] Additionally, AQP7 is expressed in several organs, including adipose tissue and kidney.[132,164] In the kidney, AQP7 localizes to the brush border membrane of the proximal tubule S3 segment.[165,166] Expression of AQP7 in *Xenopus* oocytes showed that AQP7 facilitated the transport of glycerol and urea in addition to water.[132] The development of AQP7 knockout mice has aided understanding of the physiological role of AQP7. Glycerol excretion is markedly increased in $AQP7^{-/-}$ mice, suggesting a role for AQP7 in facilitating proximal tubular glycerol transport, and possibly renal gluconeogenesis (discussed below).[134] In terms of water transport, $AQP7^{-/-}$ mice experience only a slight reduction in proximal tubule membrane water permeability, and AQP7/AQP1 double knockout mice showed only a slightly more severe urinary concentrating defect than $AQP1^{-/-}$ mice during water deprivation.[134] Additionally, evaluation of the channels' permeability to urea in $AQP7^{-/-}$ mice revealed no change in urinary urea excretion or urea accumulation in the papilla, indicating a less prominent physiological role in urea transport.[134] Expression of AQP7 in *Xenopus* oocytes increases the permeability to arsenite, thereby providing a possible route for arsenite uptake in mammalian cells[167]; the physiological role of these observations awaits further investigation.

Cloning of the murine AQP8 water channel[136,168,169] revealed its presence in many organs, including the kidney.[135,136,168,169] In kidney, AQP8 localizes to intracellular domains of proximal tubule and collecting duct cells.[135] Expression of AQP8 in *Xenopus* oocytes increased $HgCl_2$-sensitive osmotic water permeability. Additionally, oocyte expression of AQP8 showed permeability to urea.[136] Targeted deletion of the *AQP8* gene produced a mild phenotype in $AQP8^{-/-}$ mice, with no obvious changes in renal parameters.[170] Subsequent studies have suggested that AQP8 facilitates NH_3 transport in *Xenopus* oocytes[171,172] and in ammonia transport-deficient yeast.[173] In $AQP8^{-/-}$ mice, ammonia-loading mildly reduced hepatic ammonia accumulation and increased renal ammonia excretion,[174] indicating that AQP8 does not play a significant physiological role in facilitated NH_3 transport.

Recently a new aquaporin was cloned from rat testis, namely AQP11.[168] This AQP has only one NPA motif, and shares low similarity with the conventional aquaporins. AQP11 is most abundantly expressed in the testis, kidney, and liver.[168] In the kidney, the AQP11 protein localizes to the cytoplasm of the renal proximal tubules.[137] While lack of plasma membrane expression of the AQP11 protein in *Xenopus* oocytes greatly impaired measurements of transport,[137] targeted deletion of the *AQP11* gene in mice resulted in a severe phenotype with vacuolization and cyst formation in the proximal tubule. The $AQP11^{-/-}$ mice died of renal failure and kidneys were polycystic. The cyst epithelia contained vacuoles, and the $AQP11^{-/-}$ mice also presented with a proximal tubular endosomal acidification defect.[137]

AQUAGLYCEROPORINS

AQP3, AQP7, and AQP9 constitute a subgroup of aquaporins with a broader permeation range that includes glycerol, hence the name "aquaglyceroporins." AQP3, which transports water and glycerol, was cloned by three groups at the same time.[124–126] The

distribution at multiple sites, including the kidney collecting duct principal cells, airway epithelia, skin, urinary bladder, and secretory glands, suggests several functions.[151,152,175] AQP3-null mice exhibit a nephrogenic diabetes insipidus phenotype; however, human mutants have not yet been reported. AQP7 is also permeated by water and glycerol, and is localized to the apical brush border of the proximal tubules, especially to the S3 segment. Recent studies have indicated that AQP7 may play a role in glycerol metabolism by showing adaptation to fasting by glycerol transport through AQP7 in adipose tissue.[176] AQP7$^{-/-}$ mice have a significantly lower plasma glycerol concentration than wild-type mice, and impaired adipocytic glycerol release in response to a β3 receptor stimulation.[176] Moreover, AQP7$^{-/-}$ mice experience severe hypoglycemia, but show normal hepatic gluconeogenesis during fasting, indicative of defective adipocytic glycerol transport in these mice.[176] Glycerol excretion is also markedly increased in AQP7$^{-/-}$ mice, suggesting a role for AQP7 in facilitating proximal tubular glycerol transport.[134] AQP9, which is expressed in the liver but not in kidney,[177–179] is permeated by a range of solutes including glycerol and urea.[180] Recently, it has been demonstrated that expression of AQP9 in liver was induced up to 20-fold in rats fasted for 24–96 hours, and that AQP9 levels gradually declined after re-feeding.[181] This indicates that the liver takes up glycerol for gluconeogenesis through AQP9 during starvation.

VASOPRESSIN REGULATION OF KIDNEY AQUAPORINS

Of all the aquaporins, AQP2 has invoked the largest interest by nephrologists, because it is expressed

in principal cells of the renal collecting duct, where it is the primary target for short-term regulation of collecting duct water permeability.[182–184] AQP2 and AQP3 are also regulated either directly or indirectly by vasopressin through long-term effects that alter the abundance of these water-channel proteins in collecting duct cells.[138,143,151,185–187]

Short- and Long-Term Regulation of Water Permeability in the Collecting Duct

Two modes of vasopressin-mediated regulation of water permeability have been identified in the renal collecting duct. Both involve regulation of the AQP2 water channel. Short-term regulation is the widely recognized process by which vasopressin rapidly increases water permeability of principal cells by binding to vasopressin V2-receptors at the basolateral membranes, a response measurable within 5 to 30 minutes after increasing peritubular vasopressin concentration.[188,189] It is believed that vasopressin, acting through a cyclic adenosine monophosphate (cAMP) cascade, causes intracellular AQP2 vesicles to fuse with the apical plasma membrane, which increases the number of water channels in the apical plasma membrane (Figures 41.6 and 41.7). Long-term regulation of collecting duct water permeability is seen when circulating vasopressin levels are increased for 24 hours or more, resulting in an increase in the maximal water permeability of the collecting duct epithelium.[185] This response is a consequence of an increase in the abundance of AQP2 water channels per cell in the collecting duct,[138,143] apparently due to increased transcription of the *AQP2* gene (Figure 41.7).

Short-Term Regulation of AQP2 by Vasopressin-Induced Trafficking

The final concentration of the urine depends on the medullary osmotic gradient built up by the loop of Henle, and the water permeability of the collecting ducts through the cortex and medulla (see review [190]). Collecting duct water permeability is regulated by vasopressin, and it has been suspected for many years on the basis of indirect biophysical evidence that the vasopressin-induced increase in water permeability depended on the appearance of specific water channels in the apical plasma membrane of the vasopressin-responsive cells. Molecular actions of vasopressin to increase epithelial water permeability were first demonstrated in the 1950s and early 1960s in the skin and urinary bladder of amphibia.[191,192] Direct demonstrations that vasopressin rapidly increases water permeability of isolated collecting ducts were made during the next few years.[193,194] These studies, undertaken with *in vitro* preparations, showed that vasopressin applied to the basolateral aspect of the collecting duct cells directly increased transepithelial osmotic water permeability within minutes. Kinetic studies in isolated perfused inner medullary collecting ducts revealed an increase in osmotic water permeability after only 40 seconds of incubation at 37°C, and half of the maximal water permeability was reached within 10 minutes.[189,195] cAMP has been implicated in the regulatory process, because direct application of cAMP analogs to the collecting duct was found to mimic the short-term effects of vasopressin.[193]

Multiple studies with affinity-purified polyclonal antibodies to AQP2 have unequivocally established that AQP2 is specifically involved in vasopressin-induced increases of renal collecting duct water permeability. Soon after isolation of the AQP2 cDNA and generation of specific antibodies,[123] immunoperoxidase microscopy and immunoelectron microscopy clearly demonstrated that principal cells within renal collecting ducts contain abundant AQP2 in the apical plasma membranes and in subapical vesicles.[138,143] These studies strongly supported the "shuttle hypothesis" originally proposed more than a decade earlier.[196] This hypothesis proposed that water channels can shuttle between an intracellular reservoir in subapical vesicles and the apical plasma membrane, and that vasopressin alters water permeability by regulating the shuttling process.[8] Shuttling of AQP2 was directly demonstrated in isolated perfused tubule studies.[182] In these studies, water permeability of isolated perfused collecting ducts was measured before or after stimulation with vasopressin, and the tubules were fixed directly for immunoelectron microscopic examination (Figure 41.6). Vasopressin stimulation resulted in a markedly decreased immunogold labeling of intracellular AQP2, accompanied by a five-fold increase in the appearance of AQP2 immunogold particles in the apical plasma membrane. This redistribution was associated with an increase in osmotic water permeability of similar magnitude. These findings were reproduced *in vivo* by injecting rats with vasopressin, which also caused redistribution of AQP2 to the apical plasma membrane of collecting duct principal cells.[183,197] In contrast to the effect of vasopressin treatment, removal of vasopressin led to a reappearance of AQP2 in intracellular vesicles, and a decline in osmotic water permeability in the isolated perfused collecting duct system[182,186] (Figure 41.6). Moreover, the off-set response to vasopressin has been examined *in vivo* by acute treatment of rats with vasopressin-V_2-receptor antagonist[198,199] or acute water-loading (to reduce endogenous vasopressin levels[200]). These treatments (both reducing

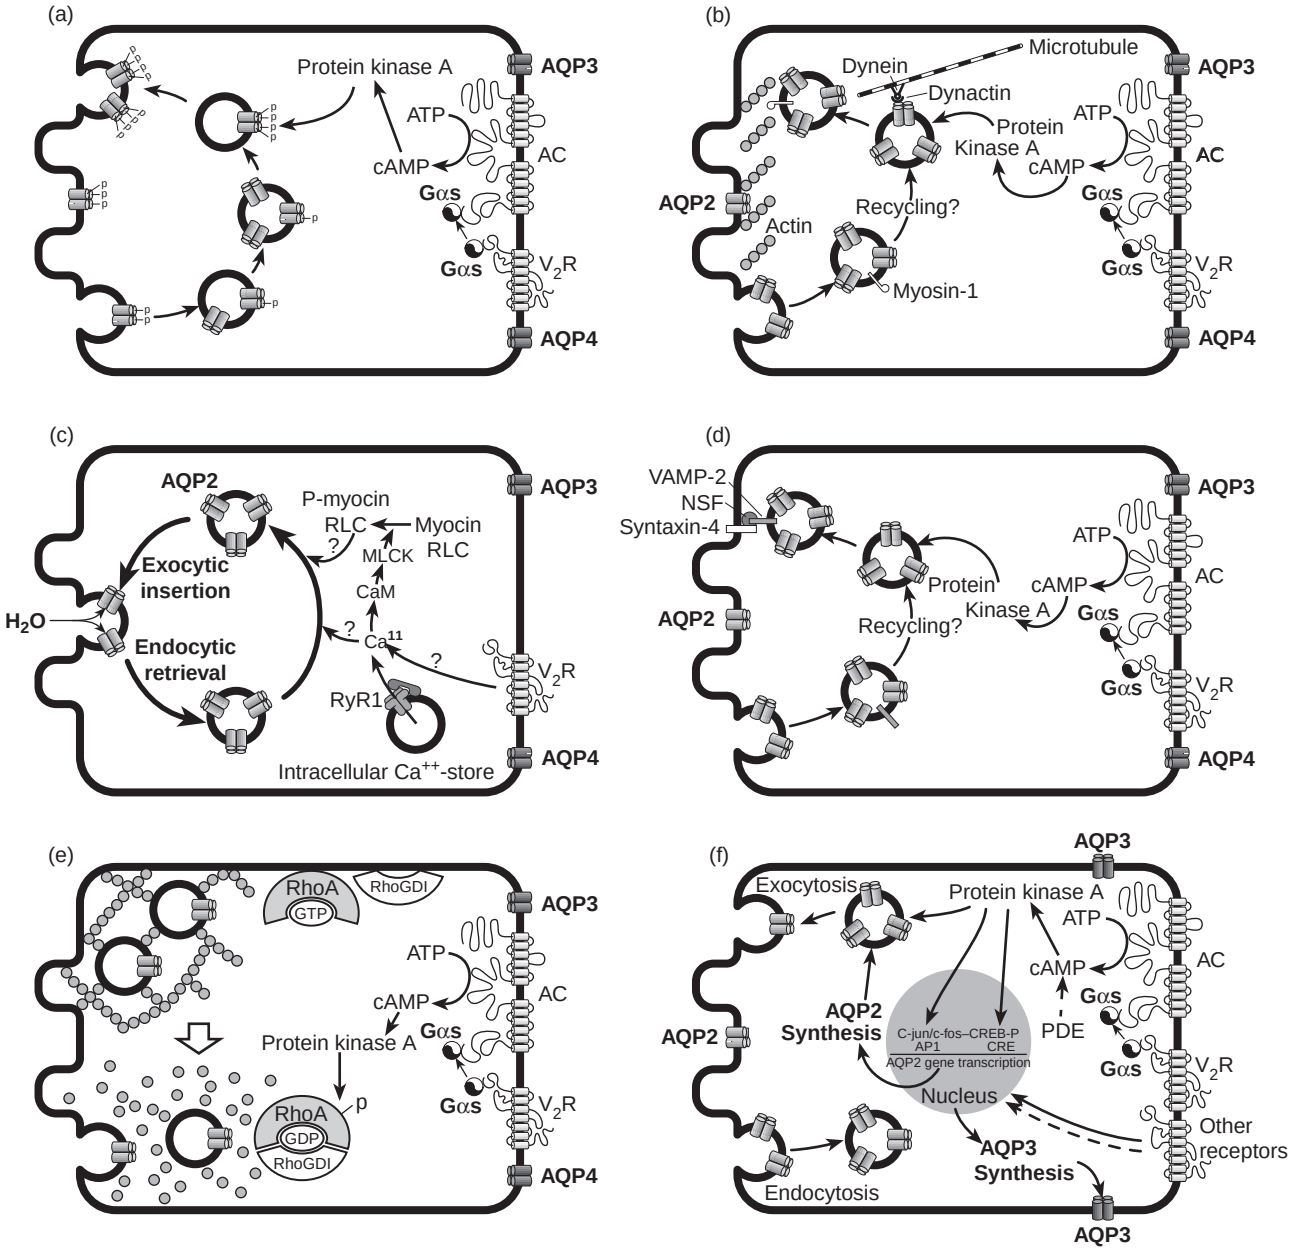

FIGURE 41.7 **Regulation of AQP2 trafficking (Panels a–e), and expression (Panel F) in collecting duct principal cells.** (a):Vasopressin binding to basolateral G-protein-linked V2-receptor stimulates adenylyl cyclase (AC); cyclic adenosine monophosphate (cAMP) activates protein kinase A to phosphorylate AQP2 in intracellular vesicles; phosphorylated AQP2 is exocytosed to the apical plasma membrane, resulting in increased apical membrane water permeability. (b): Overview of cytoskeletal elements, which may be involved in AQP2-trafficking. AQP2-containing vesicles may be transported along microtubules by dynein/dynactin. The cortical actin web may act as a barrier to fusion with the plasma-membrane. (c): Intracellular calcium signaling and AQP2-trafficking. Increases in intracellular Ca^{2+} concentration may arise from stimulation of the V2 receptor. The existence and potential role of other receptors and pathways, e.g., VACM-1, in Ca^{2+} mobilization is still uncertain. The downstream targets of the calcium signal are unknown, and conflicting data exist on the importance of a rise in intracellular Ca^{2+} for the hydrosmotic response to vasopressin. (d): Vesicle-targeting receptors and AQP2-trafficking. AQP2 vesicles dock at the apical membrane by association of VAMP-2 with syntaxin-4 targets in the presence of NSF; the exact role of these remains to be established. (e): Changes in the actin cytoskeleton associated with AQP2-trafficking to the plasma membrane. Inactivation of RhoA by phosphorylation and increased formation of RhoARhoGDI complexes seem to control the dissociation of actin fibers seen after vasopressin stimulation. (f): Specifically, cAMP participates in the long-term regulation of AQP2 by increasing the levels of the catalytic subunit of PKA in the nuclei, which is thought to phosphorylate transcription factors such as CREB-P (Cyclic AMP Responsive Element Binding Protein) and C-Jun/c-Fos. Binding of these factors are thought to increase gene transcription of AQP2, resulting in synthesis of AQP2 protein which in turn enters the regulated trafficking system. In parallel, AQP3 and AQP4 synthesis and trafficking to the basolateral plasma membrane takes place. Importantly, AQP2 regulation can be modified by a number of hormones including dopamine, ANP, PGE2, and adrenergic hormones. See text for details (Vasopressin-V2-receptors: V2R; adenylyl cyclase: AC; cAMP and protein kinase A: PKA) *(redrawn and modified from ref. [190]).*

vasopressin action) resulted in a prominent internalization of AQP2 from the apical plasma membrane to intracellular subapical vesicles, further underscoring the role of AQP2 trafficking in the regulation of collecting duct water permeability and the reversibility of AQP2 trafficking to the plasma membrane.

The quantity of AQP2 in the apical plasma membrane is determined by the relative rates of exocytosis and endocytosis. Both processes occur continuously, and their relative rates are regulated to effect changes in water permeability. Kinetic evidence indicates that vasopressin regulates both endocytosis and exocytosis of apical water channels.[195,201] These conclusions are supported by multiple earlier experiments with fluid-phase markers, which assessed rates of internalization of the apical plasma membrane.[202–204] Intravenous injection of horseradish peroxidase was followed by uptake of the material into intracellular vesicles and multivesicular bodies by collecting duct principal cells.[202] When compared with normal rats, the rate of uptake by vasopressin-deficient Brattleboro rats was much lower; however, this difference was lost after administration of vasopressin, presumably reflecting an effect of vasopressin in accelerating exocytosis, followed by a secondary increase in the rate of endocytosis to re-establish the steady-state. These observations were supported by studies with fluorescein-labeled dextrans,[203] which confirmed that vasopressin enhances the rate of endocytosis of the apical plasma membrane under steady-state conditions. In apparent contrast, removal of vasopressin from isolated perfused rabbit cortical collecting ducts also was accompanied by increased endocytosis of horseradish peroxidase from the lumen, and it was suggested that water channels would also be internalized at an increased rate.[204] Similar results were obtained in isolated rat inner medullary collecting duct, which showed that vasopressin washout was associated with increased appearance of albumin-gold or cationic ferritin in small apical vesicles and multivesicular bodies.[205] Presumably this response reflects a direct effect of vasopressin to decrease the intrinsic rate of endocytosis and is reversed on vasopressin removal. Therefore, it appears that two factors affect the rate of endocytosis of the apical plasma membrane of collecting duct principal cells: (1) vasopressin directly decelerates endocytosis by unknown mechanisms; and (2) vasopressin indirectly accelerates the rate of endocytosis by stimulating exocytosis and increasing the total amount of apical plasma membrane. The latter effect is believed to be slower than the former, resulting in a biphasic decline in water permeability on vasopressin removal.[195,201] Other studies have demonstrated that apical endocytosis is most rapid at about 3 to 5 minutes after vasopressin washout from isolated perfused inner medullary collecting ducts,[205] corresponding to the period of the most rapid decrease in transepithelial water permeability.[195,201] Thus, the results taken together strongly suggest that vasopressin directly regulates both endocytosis and exocytosis of AQP2. Presumably the net increase in water permeability seen in response to vasopressin is due both to direct stimulation of exocytosis and to direct inhibition of endocytosis.

Several groups have now successfully reconstituted the AQP2 delivery system using cultured cells transfected with either wild-type AQP2 or AQP2 tagged with a marker protein or a fluorescent protein.[206–211] Using such cultured cells stably transfected with AQP2, it has been shown that AQP2 trafficking occurs from vesicles to the apical plasma membrane, albeit in some cases to the basolateral plasma membrane, as well as retrieval and subsequent trafficking back to the surface upon repeated stimulation. This recycling of AQP2 also occurs in LLC-PK1 cells in the continued presence of cycloheximide, preventing *de novo* AQP2 synthesis. Despite remaining uncertainties, a working model for collecting duct water permeability permits molecular insight into this process (Figure 41.7). The short-term effects of vasopressin-enhanced water permeability are explained by the redistribution of AQP2 to the apical plasma membrane in collecting duct principal cells. Acting through the V2 receptor, vasopressin stimulates adenylyl cyclase; the elevated levels of intracellular cAMP activate protein kinase A (PKA), causing a redistribution of AQP2 from intracellular vesicles to the apical plasma membrane by inducing exocytosis of AQP2 vesicles, and by inhibiting endocytosis of AQP2 from the apical membrane. The net increase of AQP2 in the apical plasma membrane increases the water permeability. In the pre-antidiuretic state, the apical membrane is the rate-limiting barrier for transepithelial water transport, because AQP3 and AQP4 are abundant in the basolateral plasma membrane. Thus, increasing the water permeability of the apical plasma membrane by insertion of AQP2 water channels results in an increase in transepithelial osmotic water permeability. Whereas the general model is now well-established, the molecular details explaining how an elevation in intracellular cAMP levels regulates trafficking of AQP2 to the apical plasma membrane and back remain uncertain. Serine at position 256, in the carboxyl-terminal tail of AQP2, is apparently a substrate for protein kinase A, and regulation of exocytosis and endocytosis of AQP2 is expected to involve phosphorylation and dephosphorylation of AQP2,[208,212,213] and of ancillary proteins involved in the trafficking processes. This

question will likely be a major focus of future research.

Signal Transduction Pathways Involved in Vasopressin Regulation of AQP2 Trafficking

The signal transduction pathways have been described thoroughly in previous reviews.[190,214–217] cAMP levels in collecting duct principal cells are increased by binding of vasopressin to V_2-receptors.[218,219] The synthesis of cAMP by adenylate cyclase is stimulated by a V_2-receptor coupled heterotrimeric GTP-binding protein, G_s. G_s interconverts between an inactive GDP-bound form and an active GTP-bound form, and the vasopressin-V_2-receptor complex catalyzes the exchange of GTP for bound GDP on the ∀-subunit of G_s. This causes release of the ∀-subunit, G_s∀-GTP, which subsequently binds to adenylate cyclase, thereby increasing cAMP production. Protein kinase A is a multimeric protein which is activated by cAMP, and consists in its inactive state of two catalytic subunits and two regulatory subunits. When cAMP binds to the regulatory subunits, these dissociate from the catalytic subunits, resulting in activation of the kinase activity of the catalytic subunits.

AQP2 contains a consensus site for PKA phosphorylation (RRQS) in the cytoplasmic COOH terminus at Ser^{256}.[123] Recent studies using ^{32}P labeling or using an antibody specific for phosphorylated AQP2 showed a very rapid phosphorylation of AQP2 (within 1 minute) in response to vasopressin-treatment of slices of the kidney papilla.[220] This is compatible with the time-course of vasopressin-stimulated water permeability of kidney collecting ducts.[189] As described above, PKA-induced phosphorylation of AQP2 apparently does not change the water conductance of AQP2 significantly. Importantly, it was recently demonstrated that vasopressin or forskolin treatment failed to induce translocation of AQP2 when Ser^{256} was substituted by an alanine (S256A) in contrast to a significant regulated trafficking of wild-type AQP2 in LLC-PK1 cells.[208] A parallel study by Sasaki and colleagues also demonstrated the lack of cAMP-mediated exocytosis of mutated (S256A) AQP2 transfected into LLC-PK1 cells.[221] Thus, these studies indicate a specific role of PKA-induced phosphorylation of AQP2 for regulated trafficking. To explore this further, an antibody was designed that exclusively recognizes AQP2 which is phosphorylated in the PKA consensus site (Ser256). In normal rats phosphorylated AQP2 (Ser256) is present in intracellular vesicles and apical plasma membrane, indicating that it is constitutively phosphorylated even in low circulating vasopressin states.[222,223] In contrast, phosphorylated AQP2 is mainly located in intracellular vesicles in Brattleboro rats, as shown by immunocytochemistry and immunoblotting using membrane fractionation.[222] Importantly, dDAVP treatment of Brattleboro rats caused a marked redistribution of phosphorylated AQP2 (Ser256) to the apical plasma membrane, which is in agreement with an important role of PKA phosphorylation in this trafficking.[222] Conversely, treatment with V_2-receptor antagonist induced a marked decrease in the abundance of phosphorylated AQP2 (Ser256),[222] likely due to reduced PKA activity and/or increased dephosphorylation of AQP2, e.g., by increased phosphatase activity. Moreover, the necessity for the Ser^{256} phosphorylation in AQP2-regulated urine concentration is underlined by the recent identification of this site as being spontaneously mutated in congenital progressive hydronephrosis (cph).[224] The spontaneous conversion of the serine phosphorylated site (Ser 256) to leucine in the cytoplasmic tail of the AQP2 protein in cph-mice prevents its phosphorylation at Ser^{256}, and inhibits the subsequent accumulation of AQP2 on the apical membrane of the collecting duct principal cells. This causes polydipsia, polyuria, and a severe urinary concentration defect leading to hydronephrosis and obstructive nephropathy in these mice. Recently, three previously unknown phosphorylation sites in the C-terminus of AQP2 were identified (S261, S264, and S269) by using liquid chromatography coupled to mass spectrometry neutral loss scanning.[225] During basal conditions, AQP2 phosphorylated on Ser^{261} is approximately 24-fold more abundant than Ser^{256} phosphorylated AQP2. During administration of dDAVP a decrease in Ser261 phosphorylation was observed, while AQP2 phosphorylated on Ser256, Ser264, and Ser269 increased.[225,226] It is clear that phosphorylation of AQP2 is required for cell surface expression; however, it is still unclear how phosphorylation of AQP2 (S256, S261, S264, S269) induces apical trafficking of AQP2. One possibility is that phosphorylation of AQP2 directly influences an interaction between AQP2-containing vesicles and the cell cytoskeleton, microtubules or accessory cross-linking proteins. Indeed, S256 is important for a direct interaction of AQP2 with 70 kDa heat-shock proteins.[227] Alternatively, phosphorylation could prevent endocytosis of AQP2, leading to accumulation at the cell surface.

Prostaglandin E_2 (PGE_2) has been known to inhibit vasopressin-induced water permeability by reducing cAMP levels. Zelenina et al.[228] investigated the effect of PGE_2 on PKA phosphorylation of AQP2 in rat kidney papilla, and the results suggest that the action of prostaglandins are associated with retrieval of AQP2 from the plasma membrane, but this appears to be independent of AQP2 phosphorylation by PKA.[228] In contrast, a recent study revealed the effect of selective

E-prostanoid receptor agonists on the vasopressin-independent targeting of AQP2.[229] *In vitro*, PGE2 and selective agonists for the E-prostanoid receptors EP2 or EP4 all increased trafficking and AQP2 phosphorylation (Ser264) in MDCK cells. *In vivo*, a V2R antagonist caused a severe urinary concentrating defect in rats, which was greatly alleviated by treatment with a selective agonist for the EP2 receptor.[229] Further studies are still needed on the effects of PGE2 on urine concentration.

Phosphorylation of AQP2 by other kinases, e.g., protein kinase C or casein kinase II, may potentially participate in regulation of AQP2 trafficking. Angiotensin II-induced activation of protein kinase C could be, at least in part, involved in the AQP2 trafficking/expression.[207,230,231] S256 is also a substrate for Golgi casein kinase 2, which is required for the Golgi transition of AQP2.[232] Additionally, the phosphatase inhibitor okadaic acid induces increased AQP2 expression at the cell surface, even in the presence of the PKA inhibitor H89 and S256A AQP2 mutants (that lack S256 phosphorylation) which are able to accumulate at the cell surface after treatment with cholesterol-depleting agents.[233] Phosphorylation of other cytoplasmic or vesicular regulatory proteins may also be involved. These issues remain to be investigated directly.

Involvement of the Cytoskeleton and Ca^{2+} in AQP2 Trafficking

The cytoskeleton has been shown to be involved in AQP2 trafficking in the kidney collecting duct. In particular, the microtubular network has been implicated in this process, since chemical disruption of microtubules inhibits the increase in permeability both in the toad bladder and in the mammalian collecting duct.[234,235] Thus, AQP2 vesicles may be transported along microtubules on their way to the apical plasma membrane. The microtubule-based motor protein dynein and the associated protein Arp1, which is part of the protein complex dynactin, were found by immunoblotting to be among the proteins associated with AQP2 vesicles from rat inner medulla. Immunoelectron microscopy further supported the presence of both AQP2 and dynein on the same vesicles.[236] Moreover, both vanadate (a non-specific inhibitor of ATPases) and EHNA (a specific inhibitor of dynein) inhibit the antidiuretic response in toad bladder[237,238] and kidney collecting duct.[239] Thus, it is likely that dynein may drive the microtubule-dependent delivery of AQP2-containing vesicles to the apical plasma membrane.

Actin filaments are also involved in the hydrosmotic response.[240–245] Recently evidence was provided that the myosin light chain kinase (MLCK) pathway, through calmodulin-mediated calcium activation of MLCK, leads to phosphorylation of myosin regulatory light chain and non-muscle myosin 2 motor activity.[246] Studies in isolated perfused rat inner medullary collecting ducts showed the MLCK inhibitors ML-7 and ML-9 reduce the vasopressin-induced increase in water permeability,[246] indicating that MLCK may be a downstream target for the vasopressin-induced Ca^{2+} signal.

The intracellular Ca^{2+} concentration has been shown to increase upon stimulation of isolated perfused rat inner medullary collecting ducts with vasopressin or dDAVP.[247] These observations have been followed by a number of studies on the role of Ca^{2+} in the vasopressin-induced increase in water permeability. Vasopressin or 8−4-chlorophenylthio-cAMP induced a marked increase in intracellular [Ca^{2+}] in isolated perfused IMCD, and BABTA blocked the rise in intracellular [Ca^{2+}] and co-contaminantly led to inhibition of the vasopressin-induced increase in tubular water permeability.[248] Moreover, blocking calmodulin with W7 or trifluoperazine also inhibited the effect of vasopressin on tubular water permeability, and inhibited the vasopressin-induced AQP2 plasma membrane targeting in primary cultured IMCD cells.[248] Removing Ca^{2+} from both bath and lumen in isolated perfused tubules did not affect the vasopressin-induced Ca^{2+} signal, indicating that Ca^{2+} was released from an intracellular source. This was further supported by the observations that ryanodine inhibited the Ca^{2+} signal in perfused IMCDs and inhibited AQP2 accumulation in the plasma membrane in primary cultured IMCD cells. In addition, RyR1 ryanodine receptor was localized to rat IMCD by immunohistochemistry.[248] Ryanodine receptors are generally known to mediate a positive feedback and release Ca^{2+} from intracellular stores in response to an initial rise in intracellular [Ca^{2+}]. Thus, it is likely that another mechanism is responsible for the initialization of the rise in intracellular [Ca^{2+}]. Further studies revealed that vasopressin or dDAVP elicited oscillations in intracellular [Ca^{2+}] in isolated perfused rat IMCD.[249] The results on isolated perfused IMCDs indicate that an intracellular increase in [Ca^{2+}] is an obligate component of the vasopressin response leading to increased AQP2 expression in the apical plasma membrane. However, it should be mentioned that there is a discrepancy between the results from primary cultured IMCD cells[250] and isolated perfused IMCD tubules[248] with regard to the role of intracellular [Ca^{2+}] in vasopressin-induced AQP2 trafficking. Consistent with this, Lorenz et al.[250] demonstrated that AQP2 shuttling is evoked neither by AVP-dependent increase of [Ca^{2+}] nor by AVP-independent increase of [Ca^{2+}] in primary cultured IMCD cells from rat kidney, although clamping of intracellular [Ca^{2+}] below resting levels inhibits AQP2 exocytosis. Further studies are

required to clarify this discrepancy, which may be related to altered expression levels of vasopressin receptors and/or AQP2 or other elements in the AQP2 trafficking system.

Mechanism of AQP2 Trafficking by Targeting Receptors

The mechanism by which AQP2 vesicles are targeted to the apical plasma membrane and the mechanism by which cAMP controls docking and fusion of vesicles is a current area of active investigation. Considerable insight into this problem has been obtained from previous studies of regulated exocytosis of synaptic vesicles, which involve the actions of multiple proteins.[251,252] Vesicle-targeting receptors (often referred to as "SNAREs") are believed to induce specific interaction of vesicles with membrane sites. Vesicle-targeting receptors associated chiefly with translocating vesicles are known as "VAMPs" (vesicle associated membrane proteins, also referred to as "synaptobrevins") and "synaptotagmins." Two other families of membrane proteins are believed to serve as receptors in target membranes: the "syntaxins" and SNAP-25 homologs. Several of these SNAREs have been found in the renal collecting duct.[253–260]

Syntaxins are 30 to 40 kDa integral membrane proteins. Syntaxins have a one bilayer-spanning domain near the C-terminus, so the majority of the protein resides in the cytoplasm. Syntaxins are widely distributed among mammalian tissues. It has been established that syntaxin-4 is expressed in the mammalian collecting duct by studies using polyclonal antibodies raised to conjugated peptides specific for individual syntaxins, and this has been confirmed by reverse transcription polymerase chain reaction.[258] Immunolocalization studies have demonstrated that syntaxin-4 is predominantly located in the apical plasma membrane of collecting duct principal cells, where AQP2 is targeted in response to vasopressin.

VAMPs are believed to induce specific docking of vesicles by interacting directly with syntaxins in the target plasma membrane (Figure 41.7). Although their primary amino acid sequences are not related to syntaxins, VAMPs also have a single bilayer-spanning domain near the C-terminus, and the majority of the protein resides in the cytoplasm. Three VAMP isoforms were initially identified[261]: VAMP-1; VAMP-2; and VAMP-3 (also referred to as "cellubrevin"), and subsequently several additional homologs have been cloned.[262] VAMP-2 and VAMP-3 have been localized in principal cells of renal collecting duct.[253–260] Double-labeling immunoelectron microscopy revealed that AQP2 and VAMP-2 reside in the same intracellular vesicles in collecting duct principal cells.[260] Furthermore, AQP2 vesicles isolated by differential centrifugation were found to contain VAMP-2.[254,257]

At this time, several putative vesicle-targeting proteins are known to reside in collecting duct principal cells. VAMP-2 resides in AQP2 intracellular vesicles, and syntaxin-4 resides in the apical plasma membrane. *In vitro* binding assays have documented that VAMP-2 binds syntaxin-4 with high affinity, but VAMP-2 has not been shown to interact with syntaxin-3 or syntaxin-2.[263,264] Thus, VAMP-2 and syntaxin-4 are likely participants in the targeting of AQP2 vesicles to the apical plasma membrane; however, a functional role for these targeting proteins remains to be formally demonstrated. A third SNARE protein, SNAP-23, has also been identified in principal cells of the collecting duct.[255] Although considered a target-membrane SNARE (t-SNARE), SNAP-23 is present both in AQP2-containing vesicles and in the apical plasma membrane of principal cells. VAMP-2, syntaxin-4, and SNAP-23 may potentially form a complex with the N-ethylmaleimide-sensitive factor (NSF). Finally, synaptotagmin VIII, a calcium-insensitive homolog, was identified in collecting duct principal cells,[256] and may potentially also play a role in vesicle targeting.

Recently, LC-MS/MS-based proteomic analysis of immunoisolated AQP2-containing intracellular vesicles from rat inner medullary collecting duct revealed that AQP2-containing vesicles are heterogeneous, and that intracellular AQP2 resides chiefly in endosomes, trans-Golgi network, and rough endoplasmic reticulum.[265] Vasopressin-stimulated exocytosis of AQP2 vesicles involves several steps including: (1) translocation of vesicles from a diffuse distribution throughout the cell to the apical region of the cell; (2) translocation of AQP2 across the apical part of the cell composed of a dense filamentous actin network; (3) priming of vesicles for docking; (4) docking of vesicles; and (5) fusion of vesicles with the apical plasma membrane. Theoretically, each of these steps could be a target for regulation by vasopressin. If the SNARE proteins are involved in the vasopressin-induced trafficking of AQP2 to the apical plasma membrane, the regulatory mechanism might involve selective phosphorylation of one of the SNARE proteins or an ancillary protein that binds to them, possibly via protein kinase A or calmodulin-dependent kinase II. Although the SNARE proteins are recognized as potential targets for phosphorylation,[266–268] there is presently no evidence for phosphorylation in the collecting duct. As noted above, however, AQP2 itself appears to be a target for PKA-mediated phosphorylation at a serine in position 256.[212] The phosphorylation does not modify the single channel water permeability of AQP2,[213] and instead the phosphorylation is believed to play a critical role in

regulation of AQP2 trafficking to the plasma membrane.[208,221] The establishment of a role for these SNARE proteins in regulated trafficking of AQP2 will most likely depend on the preparation of targeted knockouts for each of these genes in the collecting duct.

Long-Term Regulation of Aquaporin Expression

It has been known for more than 40 years that urinary concentrating ability is regulated through a long-term conditioning effect of sustained increases in vasopressin levels exerted over a period of days.[269] The physiological and molecular basis for long-term conditioning of urinary concentrating ability is still being investigated. Water restriction causes a large, stable increase in water permeability of inner medullary collecting ducts dissected from rat kidneys and perfused *in vitro*.[185] Thus, water permeability of the tubules from water-restricted rats became five-fold greater than that measured in well-hydrated rats by a mechanism independent of the short-term action of vasopressin. Other studies confirmed that water restriction enhances the vasopressin-independent water permeability of collecting ducts,[270,271] and increases vasopressin-stimulated water permeability.[272] This contrasts with the lack of an observed increase in urea permeability in water-restricted rats.[185] These studies provided the firm conclusion that restriction of water intake for 24 hours or longer leads to a marked increase in the water-reabsorbing capacity of the renal collecting duct epithelium.

Further studies with anti-peptide antibodies have documented that the conditioned increase in water permeability is associated with increased expression of aquaporin proteins in collecting duct principal cells. Specifically, the increased water permeability that occurs in response to water restriction is accompanied by significant increases in the levels of AQP2 and AQP3 proteins in rat collecting ducts.[138,151,195] Water restriction for 24 to 48 hours resulted in an approximately five-fold increase in AQP2 protein in the rat renal inner medulla when measured by immunoblotting[138,195] and by immunostaining.[199] This increase paralleled the increase in water permeability in response to water restriction.[185]

A direct role for vasopressin in AQP2 expression has been established by multiple studies. Continuous infusion of arginine vasopressin into Brattleboro rats for 5 days resulted in a three-fold increase in AQP2 expression and a three-fold increase in water permeability of inner medullary collecting ducts.[143] When the time-course of AQP2 expression in inner medullary collecting duct was studied, it was found that 5 days of vasopressin infusion were required to reach maximal AQP2 levels in Brattleboro rats.[139]

Vasopressin is believed to be essential for evoking AQP2 expression, because Brattleboro rats totally lack circulating vasopressin fail to exhibit increased expression of AQP2 protein after long-term water restriction.[273] Moreover, administration of a selective V2-receptor antagonist blocked the increase in AQP2 expression usually seen with thirsting in normal rats,[199] whereas administration of the V2-selective agonist dDAVP (1-desamino-8-D-arginine vasopressin) to rats elicited a large increase in renal AQP2 mRNA[274] and AQP2 protein abundance.[275] The question of hyperosmolar induction of AQP2 during thirsting has been raised; however, five-day infusion of arginine vasopressin increased AQP2 comparably in renal cortex and medulla. This indicates that the vasopressin-induced expression of AQP2 is not critically dependent on increased osmolality or ionic strength in the tissue surrounding the collecting ducts.[187] Thus, it has been clearly established that the major increase in AQP2 water channel expression elicited by restriction of water intake is due to vasopressin binding to the V2 receptor in collecting duct principal cells. However, studies of the mechanism of escape from the antidiuretic effects of vasopressin[275,276] make it clear that AQP2 expression is regulated by other factors in addition to vasopressin (see later).

AQP3 protein expression also has been found to parallel AQP2 expression. A marked increase in AQP3 protein expression was observed in rats in response to restriction of water intake[151] and after a five-day infusion of arginine vasopressin.[187] These conditions did not lead to observed changes in AQP1 or AQP4 protein expression.[153,187] Thus, it is concluded that long-term circulation of high vasopressin levels is associated with an adaptive increase in maximal water permeability in collecting ducts, apparently due a selective increase in the expression of both AQP2 and AQP3 in the principal cells of the collecting duct. However, immunoelectron microscopy has demonstrated that AQP3 is predominantly present in the basolateral plasma membranes with little labeling of intracellular vesicles.[151] This suggests that AQP3 is not regulated by vesicular trafficking (in contrast to the findings with AQP2[182]). Moreover, there are several examples where there is a decoupling of AQP2 and AQP3 expression, suggesting that other factors in addition to vasopressin may regulate one or other of the aquaporins. This is seen in conditions such as hepatic cirrhosis,[277] vasopressin-escape,[275] low-protein diet,[278] and restriction of NaCl intake.[156]

The adaptive changes in AQP2 and AQP3 expression are believed to be due to transcriptional regulation of these genes. Increased AQP2 mRNA was found in the inner medullae of water-restricted rats,[279] and in response to infusion of dDAVP.[274,275] All of these

studies indicate that the long-term upregulation of AQP2 expression in the rat kidney is due to elevation of the levels of AQP2 mRNA. Vasopressin-induced increase in AQP2 mRNA expression could reflect either increased gene transcription or reduced transcript degradation. Examination of the 3′-untranslated region of the AQP2 mRNA has not revealed the presence of recognizable mRNA stabilization motifs, and it is presumed that vasopressin directly increases *AQP2* gene transcription; however, no direct evidence supports this presumption. Transcriptional regulation would most likely occur through the vasopressin-induced increases in intracellular cyclic AMP that activates protein kinase A in collecting duct cells. Examination of the 5′-flanking region of the *AQP2* gene revealed a putative cAMP-response element (CRE), which may play a role in the vasopressin-induced increase in AQP2 expression.[280] Attempts to demonstrate expression of AQP2 promoter-luciferase reporter constructs have been undertaken in cultured renal epithelial cells and suggest that the putative CRE can drive increased expression of the *AQP2* gene; however, the inability of the cell line to express AQP2 protein limits the interpretation.[281–283]

As with AQP2, AQP3 mRNA levels were induced by infusion with the selective V2 agonist dDAVP.[275] Examination of the 5′-flanking DNA of AQP3 failed to reveal a CRE; however, Sp1 and AP2 cis-regulatory elements are present,[284] and these are known to be associated with cyclic AMP-mediated transcriptional regulation of other genes. A previous study revealed that AQP2 is ubiquitinated with one UbLys63-linked poly-Ub chain at K270 of AQP2 and lysosomal degradation was extensive for ubiquitinated AQP2.[285] The degradation pathways, therefore, balance the abundance of proteins which play an important role in body water homeostasis.[186]

DYSREGULATION OF RENAL AQUAPORINS IN WATER BALANCE DISORDERS

In a variety of conditions renal water handling is disturbed. Over the past decade, the role of changes in the expression and/or function of aquaporins have been investigated in a range of these conditions, including genetic defects or acquired defects showing a decreased renal responsiveness to vasopressin (acquired nephrogenic diabetes insipidus). The importance of aquaporins playing an essential role for regulation of renal water balance has been established (Table 41.2), and the following text represents extracted and updated information reported in previous reviews by the authors or other investigators.[190,286–288]

URINARY CONCENTRATING DEFECTS

Inherited Diabetes Insipidus

There are two significant inherited forms of diabetes insipidus (DI): central and nephrogenic. In central (or neurogenic) DI, there is a defect of vasopressin production. Central DI is rarely hereditary in man, but usually occurs as a consequence of head trauma or diseases in the hypothalamus or pituitary gland. The Brattleboro rat provides an excellent model of this condition. These animals have a total or near-total lack of vasopressin production.[289,290] Consequently, Brattleboro rats have substantially decreased expression levels of vasopressin-regulated AQP2 compared with the parent strain (Long Evans), and the AQP2 deficit was reversed by chronic vasopressin infusion, suggesting that patients lacking vasopressin are likely to have decreased AQP2 expression.[143] The subsequent work showing that expression of AQP3 is also regulated by vasopressin implies that the expression levels of these water channels will also be decreased in patients with CDI. The most important denominator is the deficiency of AQP2 trafficking to the apical membrane. These deficits are likely to be the most important causes of the polyuria from which these patients suffer, which will be reversed by desmopressin treatment. The second form of DI is called nephrogenic diabetes insipidus (NDI), and is caused by the inability of the kidney to respond to vasopressin stimulation. The most common hereditary cause (in 95% of cases) is an X-linked disorder associated with mutations of the V2 vasopressin receptor (AVPR2) making the collecting duct cells insensitive to vasopressin.[291] Although there is no direct evidence, it is likely that this form of NDI will be associated with decreased expression of AQP2, since the cells are unable to respond to circulating vasopressin.[292] This will compound the lack of AQP2 trafficking. Consistent with this, urinary AQP2 levels are very low in patients with X-linked NDI.[196,293] However, since the amount of AQP2 in the urine appears to be determined largely by the response of the collecting duct cells to vasopressin[294] rather than their content of AQP2, the data must be interpreted with caution with respect to predicting AQP2 expression levels. More rarely (in 5% of cases), congenital diabetes insipidus (CNDI) is inherited in an autosomal recessive fashion which is not due to mutations in the gene encoding the V2 vasopressin receptor, but these patients have been found to possess mutations in both alleles of the *AQP2* gene, and the sites of point mutations were observed at functionally important sites in the water transport pathway.[144,295–298] Since these patients manifest a particularly severe form of diabetes insipidus, the critical role of AQP2 in renal water conservation was

established. It is believed that these mutations lead to abnormal intracellular routing of the expressed protein.[299] More than 155 mutations in the vasopressin receptor gene have been recognized to cause CNDI. Functional analysis has been carried out for over 79 of these mutations.[300] The analyses have revealed four different types of mutant receptors. The most common is impaired intracellular trafficking, which is seen in up to 70% of cases.[300] The remaining types include reduced ligand-binding capacity, failure to generate cAMP, and defects in the synthesis of stable mRNA.[301] Only five of the 155 known mutations cause partial CNDI (D85N, R104C, G201D, P322S, and S329R). Recently, a different kindred was identified with a dominant form of nephrogenic diabetes insipidus, and biochemical evaluations revealed that the mutation in the cytoplasmic C-terminus blocked the trafficking of AQP2 vesicles to the cell surface.[302] Thus, intracellular trafficking of vesicles containing products of the mutant allele and the product of the normal allele may be misdirected. It is not known if these individuals suffer a more or less severe clinical defect, and recently it was shown that the ligand-binding and signal transduction capability are dependent on localization of the amino acid variation, suggesting that striking divergences at the level of receptor functionality may thus underlie similar clinical phenotypes in CNDI.[303–305]

Acquired Nephrogenic Diabetes Insipidus

Acquired abnormalities of AQP2 expression have been implicated in multiple clinical disorders associated with abnormal water balance (Table 41.2). The role of vasopressin-regulated AQP2 has been established in a number of rat models with acquired NDI. In many of these conditions the kidney is unable to handle water, due to an impaired responsiveness to vasopressin; in the following text the most important of these condtions are described.

Lithium-Induced NDI

Lithium is a major therapeutic agent used to treat bipolar disorder (also referred to as "manic depressive disease") which affects approximately 1% of the US population.[306] However, lithium treatment is associated with a variety of renal side-effects, including nephrogenic diabetes insipidus (NDI, i.e., a pronounced vasopressin-resistant polyuria and inability to concentrate urine),[307,308] increased urinary sodium excretion,[309] and distal renal tubular acidosis.[310] Patients who have been treated with lithium manifest a slow recovery of urinary concentrating ability when treatment is discontinued. In rats treated with lithium for 4 weeks, AQP2 and AQP3 levels were progressively reduced to approximately 5% of levels in control rats.[307,308] AQP2 downregulation was paralleled by a progressive development of severe polyuria.[307,308] Quantitative immunoelectron microscopy of AQP2 labeling in the inner medullary collecting duct principal cells showed that there was a reduction of AQP2 in the apical plasma membrane, as well as in the basolateral plasma membrane and intracellular vesicles. Reduction in AQP2 (and AQP3) expression may be induced by a lithium-dependent impairment in the production of cAMP in collecting duct principal cells,[309,311] indicating that inhibition of cAMP production may in part be responsible for the reduction in AQP2 expression, as well as the inhibition of targeting to the plasma membrane in response to lithium treatment. This is consistent with the presence of a cAMP-responsive element in the 5′-untranslated region of the AQP2 gene,[281,282] and with the demonstration that mice with inherently low cAMP levels have low expression of AQP2 ($DI^{+/+}$ severe mouse).[312] Lithium treatment is also associated with a concomitant increase in urinary sodium excretion, which is likely to play a role in the polyuria. It has also been demonstrated that chronic lithium treatment induces a marked decrease in protein abundance of epithelial sodium channel β- and γ-ENaC in the cortex and outer medulla, whereas the other renal sodium transporters upstream from the connecting tubule are unchanged.[313] This was also revealed by immunocytochemistry showing an almost complete absence of β-ENaC and γ-ENaC labeling in cortical and outer medullary collecting duct. This suggests a reduced responsiveness to aldosterone and vasopressin in these specific renal tubule segments, and that dysregulation of ENaC subunits is likely to play a role in the development of natriuresis and partly in the decreased urinary concentrating ability in rats with lithium-induced NDI.[314] Additional studies have identified proteins with altered abundance in the inner medullary collecting ducts (IMCD) of lithium-treated rats and their possible cellular function.[315,316] Moreover, it has been shown that prostaglandins, in lithium-treated mpkCCD cells, dcreases APQ2 protein stability by increasing its lysosomal degradation, indicating that *in vivo* paracrine-produced prostaglandins might have a role in lithium-induced NDI via this mechanism.[317]

Hypokalemia and Hypercalcemia

Hypokalemia and hypercalcemia are also associated with polyuria due to a vasopressin-resistant urinary concentrating defect. Rat models of these conditions are valuable tools to study the molecular defects. Treating rats with a potassium-deficient diet for 4 days

induced a significant hypokalemia which was associated with downregulation of AQP2 expression and polyuria.[318] Likewise, hypercalcemia induced in rats by oral treatment for 7 days with dihydrotachysterol produced a urinary concentrating defect and polyuria which was also associated with downregulaion of AQP2.[319,320] Thus, both hypokalemia and hypercalcemia are associated with downregulation of AQP2 expression, and immunolocalization studies of AQP2 demonstrated similar features. In addition to the downregulation of AQP2, expression of Na-K-2Cl co-transporter in the thick ascending limb was decreased in both conditions,[321,322] suggesting that reduced sodium and chloride reabsorption in the thick ascending limb, and hence decreased medullary hyperosmolality, could also partly contribute to the polyuria and decreased urinary concentration in hypokalemia and hypercalcemia. Thus, these studies in part describe the underlying molecular defects involved in the development of the polyuria in these conditions.

Urinary Tract Obstruction

Another serious condition seen in both children and adults is urinary tract obstruction which is associated with complex changes in renal function involving marked alterations in both glomerular and tubular function and bilateral urinary tract obstruction (BUO) which may result in long-term impairment of the ability to concentrate urine.[323] BUO for 24 hours in rats is associated with markedly reduced expression of AQP2, AQP3, AQP4, and AQP1.[324–327] In addition, BUO is associated with marked downregulation of key sodium transporters and urea transporters.[328] Following release of the obstruction, there is a marked polyuria, during which period AQP2 and AQP3 levels remain downregulated up to two week after release, providing an explanation at the molecular level for the observed post-obstructive polyuria. In a number of studies BUO has been demonstrated to be associated with COX2 induction and cellular infiltration of the renal medulla.[292,329–331] Using specific COX2 inhibition to rats subjected to BUO it was demonstrated that this treatment prevents downregulation of AQP2 and several sodium transporters located to the proximal tubule and mTAL.[329,330] Also, increased expression and activity of the P2Y2, EP1, and EP3 receptors have been suggested to play important roles in post-obstructive polyuria.[332] Moreover, specific inhibition of the AT1 receptor in rats subjected to BUO prevented AVP2R downregulation of NaPi2 in the PT, BSC-1 in the mTAL, and AQP2/pS256-AQP2 in the CD three days after release of BUO,[134,333] confirming that the renin–angiotensin system plays an important role for the pathophysiological changes in urinary tract obstruction.

In contrast to BUO conditions, unilateral ureteral obstruction is not associated with changes in the absolute excretion of sodium and water since the non-obstructed kidney compensates for the reduced ability of the obstructed kidney to excrete solutes.[328,334] These studies demonstrated a profound downregulation of AQP1, AQP2, AQP3, and AQP4, and pAQP2 levels in the obstructed kidney, suggesting that 1ocal factors play a major role.

Renal Failure

Renal failure, both acute and chronic, is associated with polyuria and a urinary concentrating defect, and in both cases there is a wide range of glomerular and tubular abnormalities that contribute to the overall renal dysfunction. Ischemia and reperfusion (I/R)-induced experimental acute renal failure (ARF) in rats is a model that is widely used. In this model there are structural alterations in the renal tubule, in association with an impaired urinary concentration.

ARF is associated with defects both in collecting duct water reabsorption and proximal tubule water reabsorption, as well as defects in solute handling.[335–337] Using the isolated tubule microperfusion model, it was demonstrated that water reabsorption in the proximal tubule and cortical collecting duct was significantly reduced following ischemia,[335] and no differences in either basal or vasopressin-induced cAMP levels in outer or inner medulla in rats with ARF were demonstrated,[338] supporting the view that there are defects in collecting duct water reabsorption. Consistent with these findings, it was demonstrated that AQP2 and AQP3 expression in the collecting duct, as well as AQP1 expression in the proximal tubule, are significantly reduced in response to ARF.[339,340] The decreased levels of aquaporins were associated with impaired urinary concentration in rats with both oliguric or nonoliguric ARF. The reduced expression of AQP1–3 and the reduced urinary concentration capacity was significantly prevented by co-treatment with alpha-melanocyte-stimulating hormone (α-MSH), which is an anti-inflammatory cytokine that inhibits both neutrophil and nitric oxide pathways.[340] This finding indicates that decreased levels of aquaporins in both the proximal tubule and collecting duct in post-ischemic kidneys may play a significant role in the impaired urinary concentration. Recently it was also demonstrated that hemorrhagic shock-induced acute renal failure is associated with decreased expression of collecting duct water channel AQP2 and AQP3,[341] and that erythropoietin treatment (single or combined with

α-MSH) in rats with I/R-induced ARF, which is known to prevent caspase-3, -8, and -9 activation *in vivo* and reduces apoptotic cell death,[342] prevents or reduces the urinary concentrating defects and downregulation of AQP expression levels.[341] Consistent with this, it was demonstrated that NF-kappaB activation is of importance for the downregulation of AQP2 channel and vasopressin V2-receptor expression during sepsis in a cecal ligation and puncture (CLP) mouse model of ARF, and that NF-kappaB inhibition ameliorates sepsis-induced ARF in the CLP model.[343]

Patients with advanced chronic renal failure (CRF) have urine which remains hypotonic to plasma despite the administration of supramaximal doses of vasopressin.[344] This vasopressin-resistant hyposthenuria specifically implies abnormalities in collecting duct water reabsorption in CRF patients. Recent observations demonstrated virtual absence of V2 receptor mRNA in the inner medulla of CRF rat kidneys,[345] providing evidence for significant defects in the collecting duct water permeability. Consistent with these observations, it has shown both decreased collecting duct water channel AQP2 and AQP3 expression and a vasopressin-resistant downregulation of AQP2 in a 5/6 nephrectomy-induced CRF rat model.[346]

WATER RETENTION

Congestive Heart Failure

Retention of sodium and water is a common and clinically important complication of congestive heart failure (CHF). Two studies have examined the changes in renal AQP expression in rats with CHF induced by ligation of the left coronary artery[347,348] to test if upregulation of AQP2 expression and targeting may play a role in the water retention in CHF. Both studies demonstrated that renal water retention in severe CHF in rats is associated with dysregulation of AQP2 in the renal collecting duct principal cells, involving both an increase in the AQP2 expression and a marked redistribution of AQP2 to the apical plasma membrane.[347,348] Rats with severe CHF had significantly elevated left ventricular end-diastolic pressures (LVEDP), and had reduced plasma sodium concentrations.[347] Immunoblotting revealed a three-fold increase in AQP2 expression compared with sham operated animals. These changes were associated with elevated LVEDP or hyponatremia, since animals with normal LVEDP and plasma sodium did not have increased AQP2 levels compared with sham operated controls.[347] Furthermore, this study showed an increased plasma membrane targeting, providing an explanation for the increased permeability of the collecting duct and an increase in water reabsorption. This may provide an explanation for excess free water retention in severe CHF, and for the development of hyponatremia. In parallel, the other study showed upregulation of both AQP2 protein and AQP2 mRNA levels in kidney inner medulla and cortex in rats with CHF.[348] These rats had significantly decreased cardiac output and, importantly, increased plasma vasopressin levels. Furthermore, in this study administration of V2 antagonist OPC 31260 was associated with a significant increase in diuresis, a decrease in urine osmolality, a rise in plasma osmolality, and a significant reduction in AQP2 protein and AQP2 mRNA levels compared with untreated rats with CHF. Consistent with this, treatment of V2-receptor antagonist in human patients and rats with heart failure is associated with a dose-related increase in water excretion and a decrease in urinary AQP2 excretion.[349,350] Moreover, it has been shown in patients with CHF that treatment with furosemide increases the urinary excretion of AQP2, free water clearance, and sodium exceretion.[351]

Hepatic Cirrhosis

Hepatic cirrhosis is another chronic condition associated with water retention.[352] It has been suggested that an important pathophysiological factor in the impaired ability to excrete water could be increased levels of plasma vasopressin. However, unlike CHF, the changes in expression of AQP2 protein levels vary considerably between different experimental models of hepatic cirrhosis. Several studies have examined the changes in renal AQP expression in rats with cirrhosis induced by common bile duct ligation (CBDL).[277,353,354] The rats displayed impaired vasopressin-regulated water reabsorption despite normal plasma vasopressin levels. Consistent with this, semiquantitative immunoblotting showed a significant decrease in AQP2 expression in rats with hepatic cirrhosis.[277,353] In addition, the expression levels of AQP3 and AQP4 were downregulated in CBDL rats. This may predict a reduced water permeability of the collecting duct in this model[277]; hence, renal water reabsorption in the collecting duct is decreased in rats with compensated liver cirrhosis. In contrast, Fujita et al.[274] demonstrated that hepatic cirrhosis induced by intraperitoneal administration of carbon tetrachloride (CCl_4) was associated with a significant increase in both AQP2 protein levels and AQP2 mRNA expression. Interestingly, AQP2 mRNA expression correlated with the amount of ascites, suggesting that AQP2 may play a role in the abnormal water retention followed by the development of ascites in hepatic cirrhosis.[355] In a different model of CCl_4-induced cirrhosis, using CCl_4 inhalation, AQP2

expression was not increased.[356] There was, however, evidence for increased trafficking of AQP2 to the plasma membrane, consistent with the presence of elevated levels of vasopressin in the plasma. Interestingly, there was a marked increase in AQP3 expression that is likely to be due to increased vasopressin levels. The pattern of increased AQP3 expression without upregulation of AQP2 is consistent with previous findings observed in the vasopressin escape,[276] suggesting that the lack of increase in AQP2 expression could be a result of a normal compensatory response related to the escape phenomenon. Although the explanation for the differences between cirrhosis induced by CBDL and CCl_4 administration remains to be determined, it is well-known that the dysregulation of body water balance depends on the severity of cirrhosis.[357–360] CBDL results in a compensated cirrhosis characterized by peripheral vasodilation and increased cardiac output, whereas cirrhosis induced by 12 weeks of CCl_4 administration may be associated with the late state of decompensated liver cirrhosis characterized by sodium retention, edema, and ascites.[358,359,361] Thus, the downregulation of AQP2 observed in milder forms of cirrhosis (i.e., in a compensated stage without water retention) may represent a compensatory mechanism to prevent development of water retention. In contrast, the increased levels of vasopressin seen in severe "non-compensated" cirrhosis with ascites may induce an inappropriate upregulation of AQP2 that would in turn participate in the development of water retention. Recent studies have shown a prominent role for AQP1 in angiogenesis, fibrosis, and portal hypertension after bile duct ligation in wild-type and AQP1 knockout mice.[362]

Experimental Nephrotic Syndrome

Nephrotic syndrome is characterized by extracellular volume expansion with excessive renal salt and water reabsorption. The underlying mechanisms of salt and water retention are poorly-understood; however, they can be expected to be associated with dysregulation of solute transporters and water channels.[359] In contrast to congestive heart failure and liver cirrhosis, a marked downregulation of AQP2 and AQP3 expression was demonstrated in rats with PAN-induced and adriamycin-induced nephrotic syndrome.[363–365] The reduced expression of collecting duct water channels could represent a physiologically appropriate response to extracellular volume expansion. The signal transduction involved in this process is not clear, but circulating vasopressin levels are high in rats with PAN-induced nephrotic syndrome. Thus, the marked downregulation of AQP2 in experimental nephrotic syndrome may share similarities with the downregulation of AQP2 in water-loaded dDAVP-treated rats that escape from the action of vasopressin.[275,276]

SIADH and Vasopressin Escape

Hyponatremia, defined as a serum sodium less than 135 mmol/L, is one of the most commonly encountered electrolyte disorders of clinical medicine.[366] The predominant cause of hyponatremia is an inappropriate secretion of vasopressin relative to serum osmolality or the "syndrome of inappropriate antidiuretic hormone secretion" (SIADH).[367] SIADH occurs most frequently in association with vascular, infectious or neoplastic abnormalities in the lung or central nervous system. In an experimental rat model of SIADH it was shown that AQP2 mRNA expression and AQP2 protein expression were increased in the collecting duct.[274] Thus, increased expression of AQP2 in the collecting duct accounts for the water retention and hyponatremia in SIADH.

The degree of hyponatremia is limited by a process that counters the water-retaining action of vasopressin, namely "vasopressin escape." Vasopressin escape is characterized by a sudden increase in urine volume with a decrease in urine osmolality independent of high circulating vasopressin levels. The onset of escape coincided temporally with a marked decrease in renal AQP2 protein, as measured by immunoblotting, as well as decreased mRNA expression, as assessed by Northern blotting.[276] In contrast to AQP2, there were no decreases in renal expression of AQP1, AQP3, and AQP4.[276] These results suggest that escape from vasopressin-induced antidiuresis is attributable, at least in part, to a selective vasopressin-independent decrease in AQP2 expression in the renal collecting duct.[368,369]

Acknowledgments

Support for this chapter was partially provided by funds from the Danish National Research Foundation, The European Commission, the Danish Medical Research Council, Novo Nordic Foundation, Karen Elise Jensen Foundation and the National Institutes of Health. Portions of the text were previously published in abridged form and are reproduced and modified with permission.[122] Moreover, the authors gratefully acknowledge the major contributions from Peter Agre and Mark Knepper, who together with SN authored a previous version of this chapter.

Thirst and Vasopressin

Gary L. Robertson

The Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

INTRODUCTION

Thirst and the antidiuretic hormone, arginine vasopressin, are the principal elements of a powerful homeostatic system that regulates the "effective" osmotic pressure of body fluids. This variable, usually referred to as "tonicity," must be important for survival since mechanisms to regulate it are found throughout the animal kingdom, and abnormalities in humans can have adverse effects, especially on central nervous function. However, it is less clear why it is important. It may be that regulating the *tonicity* of body fluids is mainly an indirect way to minimize changes in the *volume* of water within cells, particularly those of the brain.[1] It may also be that tight control of intracellular water and solute concentrations is necessary for optimum function of the cell.[2]

The tonicity of body fluids is regulated primarily by raising or lowering total body water to keep it in balance with solute. In a healthy adult, about 55 to 60% of body weight is water.[3] It is slightly lower in women than men, owing to differences in body fat. About two-thirds of body water is intracellular. The rest is in the extracellular space, where it is subdivided further between the interstitial and intravascular (plasma) compartments in a ratio of about 3:1. Thus, a human weighing 70 kg contains about 39 L of water, of which 26 L is intracellular, 10 L is interstitial fluid, and 3 L is plasma.

A change in total body water results in a proportionate change in the volume of all compartments, providing the solute content of the compartments does not also change. The reason is that almost all cell membranes are penetrated by channels composed of aquaporin proteins[4] that permit the passive diffusion of water selectively in response to an osmotic gradient. In contrast, these membranes resist the passage of sodium, potassium, and most other solutes by actively pumping them in or out of the cell (see Chapter 2). Thus, a change in the amount of water in one compartment creates an osmotic gradient that results in a rapid flow of water from one compartment to the other, thereby restoring osmotic equilibrium and redistributing the change in volume in a similar proportion to each compartment. Thus, a reduction in the water content of the extracellular compartment due, for example, to increased perspiration, increases the tonicity and reduces the volume of the intracellular and extracellular compartments in equal proportion. A rise in total body water has the opposite but equivalent effect on the tonicity and volume of the two compartments.

In contrast, the volume of extracellular and intracellular water changes in opposite directions if the *amount* of osmotically effective solute in either compartment changes, but total body water does not. Osmotically effective solutes are those, such as sodium and its anions, which do not equilibrate readily across cell membranes. Thus, if the *amount* of sodium and its anions in extracellular fluid increases, the effective osmotic pressure or "tonicity" of this fluid also increases, resulting in a rapid osmotically-driven inflow of water from the intracellular compartment until osmotic equilibrium is re-established. The net effect is again an increase in the osmotic pressure of both compartments, but at a level lower than if the shift of water had not occurred. In fact, because of this shift, the effect on plasma sodium *concentration* of adding a given amount of sodium to the extracellular compartment is the same as if the sodium was distributed throughout total body water. In this circumstance, however, the volume of extracellular fluid increases, while that of intracellular fluid decreases. A reduction in the amount of sodium in extracellular fluid has opposite effects.

Because sodium and its anions normally make up 95% of all solutes, and nearly 100% of osmotically effective solute in extracellular fluid, the measurement of either plasma sodium or osmolarity probably

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00042-2

provides an accurate estimate of the "tonicity" or effective osmotic pressure of both the intracellular and extracellular fluids. Urea and glucose contribute little if anything because, normally, they are present in relatively low molar concentrations, and can enter or leave cells very rapidly. In the absence of insulin, however, glucose becomes osmotically effective because it enters cells much more slowly. In that situation, hyperglycemia induces a shift of water from the intracellular to extracellular space, and the tonicity of body fluids is determined much more reliably by measuring plasma osmolarity than plasma sodium. In intracellular fluid (ICF), the major solutes are potassium and its anions, but others including proteins, polyols, and some as yet unidentified solutes are also present.[2]

Body water is in a constant state of flux, owing to obligatory unregulated losses and gains produced by physical activity, the environment, diet, and the metabolism of fat. The rate of evaporative water loss from skin and lungs can vary markedly, depending on ambient temperature and physical activity, but it amounts to at least 10 mL/kg a day (0.7 L in a 70 kg human), even at rest in a comfortably cool environment.[5] The rate of solute-free water loss in urine is tightly regulated by vasopressin but, in humans, it cannot be reduced below a certain minimum required to excrete the load of sodium, chloride, potassium, urea, and other waste solutes derived from the diet and metabolism. This load varies with the diet, but is usually about 700 mosmols a day. Since humans cannot increase their urine osmolarity much above 1400 mosmols/L, the amount of urine required to carry this solute load is at least 7 ml/kg a day (0.5 L a day in a 70 kg human) even under conditions of maximum antidiuresis. The total daily obligatory water loss in a healthy adult is, therefore, at least 17 mL/kg (1.2 L in a 70 kg human), and may be much more at times depending on diet, activity, and temperature. Normally, this loss does not result in dehydration because it is replaced by an equivalent intake of water. Much of the intake is incidental to other physiological needs. About 7 mL/kg (0.5 L in a 70 kg human) comes from water in food, and about 4 mL/kg (0.3 L/day in a 70 kg human) is derived from metabolism of fat. The rest is consumed as beverages with meals in response to various influences,[6] including a slight increase in plasma osmolarity and thirst induced by adsorption of salt and other solutes in food. Thus, water balance is usually maintained at relatively low levels of urine output and discretionary fluid intake. Alterations in this basic state bring into play corrective changes in water excretion and/or intake under control of the antidiuretic and thirst mechanisms.

VASOPRESSIN AND RELATED PEPTIDES

Chemistry

Arginine vasopressin (AVP) is a nonapeptide containing an intrachain disulfide bridge and a tripeptide tail on which the terminal-carboxyl is amidated[7] (Figure 42.1). Substitution of lysine for arginine in position 8 yields lysine vasopressin (LVP), the antidiuretic hormone found exclusively in pigs and other members of the suborder Suina.[8] Vasopressin is structurally similar to oxytocin, another nonapeptide hormone found in the posterior pituitary of all mammals Oxytocin differs chemically from vasopressin by the substitution of isoleucine for

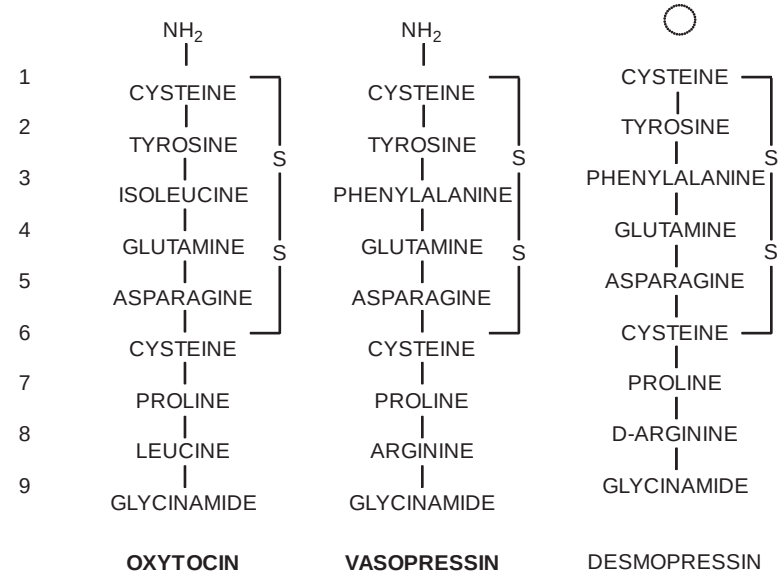

FIGURE 42.1 **The primary amino acid structures of oxytocin, vasopressin and desmopressin.**

phenylalanine at position 3, and of leucine for arginine at position 8.[7] Desmopressin is a potent synthetic analog of vasopressin used therapeutically because of its longer half-life and reduced effects on smooth muscle.

ANATOMY

Vasopressin and oxytocin are produced and stored in large amounts by magnocellular neurons in the hypothalamic neurohypophyseal tract.[9–14] These neurons arise bilaterally in the supraoptic and paraventricular nuclei of the hypothalamus, project medially to merge in the pituitary stalk, and continue through the diaphragm sella into the sella turcica, where they form the posterior lobe of the pituitary (Figure 42.2). Microscopically, the posterior pituitary appears as a densely interwoven network of capillaries, pituicytes, and large nonmyelinated neurons containing many electron-dense secretory granules. The neurons terminate as bulbous enlargements on capillary networks at many different levels throughout the stalk and body of the neurohypophysis. In healthy adults and children, the posterior pituitary usually appears as a hyperintense signal or "bright spot" on T-l weighted magnetic resonance images (MRI) of the brain.[15] The origin of this signal is still unknown, but it appears to be closely related to the content or turnover of vasopressin, and is almost invariably absent not only in patients with the pituitary form of diabetes insipidus, but also in many of those with nephrogenic diabetes insipidus (unpublished data). Vasopressin is also present in the suprachiasmatic nucleus and parvocellular neurons that originate in the paraventricular nucleus and project to the portal veins, anterior pituitary, and many other areas of the brain.[11,13] Oxytocin is also present in

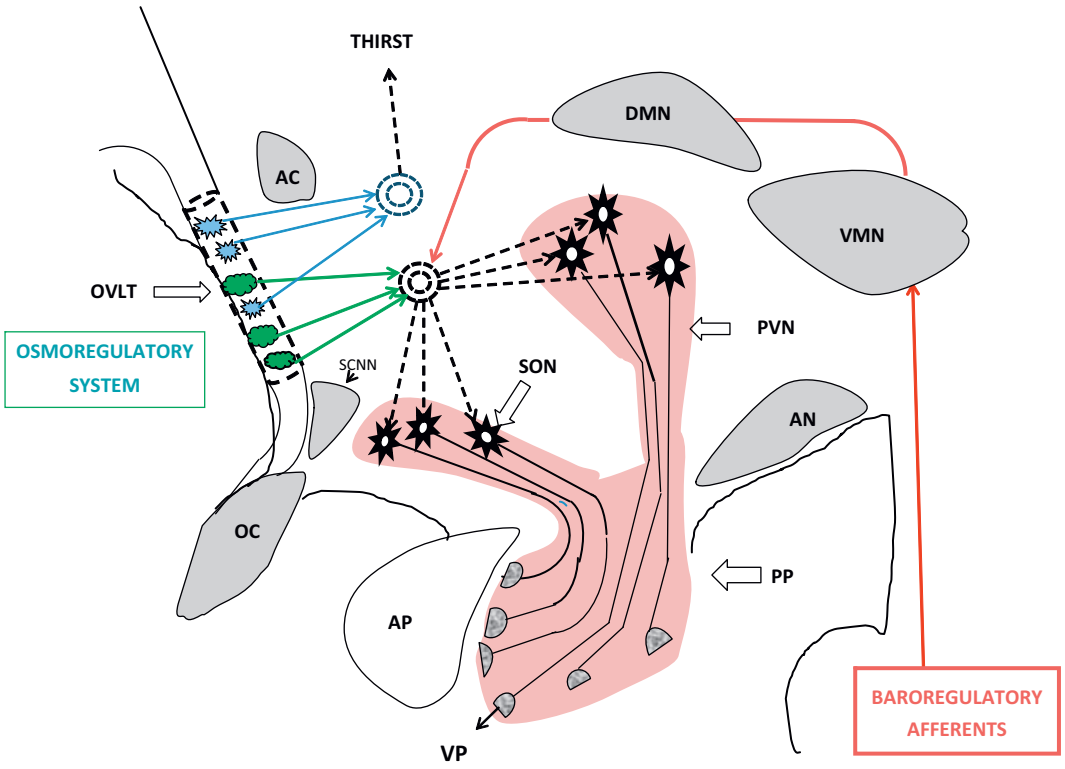

FIGURE 42.2 **Schematic diagram of the hypothalamic–neurohypophyseal tract and areas that osmoregulate thirst and vasopressin secretion.** The supraoptic nucleus (SON), paraventricular nucleus (PVN) and posterior pituitary are shaded red. The origin and course of the magnocellular neurons that form the tract and posterior pituitary are indicated in black. The green and blue icons represent the osmoreceptors that regulate vasopressin secretion and thirst, respectively. They appear to be in distinct but overlapping areas within in the organum vasculosum of the lamina terminalis (OVLT). The vasopressin osmoreceptors probably do not project directly to the SON or PVN but, as indicated by the black concentric circle with broken borders, appear to interact somewhere with ascending input from the baroregulatory system before the integrated signal is relayed to the magnocellular neurons in the SON and PVN. Signals from the thirst osmoreceptors probably follow a similar path to integration with baroregulatory input before projecting onwards to of the cerebral cortex. Other nearby landmarks shown include the anterior commissure (AC), optic chiasm (OC), suprachiasmatic nucleus (SCM), anterior pituitary (AP) and arcuate nucleus (AC). The ventral medial nucleus (VMN) and dorsal medial nucleus (DMN) probably transmit afferent input from the baroregulatory system. Not shown are the parvocellular vasopressinergic neurons which project to many other areas of brain including the SCM and portal venous system of the AP.

many parvocellular neurons of brain,[11–14] as well as in the uterus, prostate, and other peripheral tissues.[16]

The hypothalamic neurohypophyseal tract is supplied with blood by branches of the superior and inferior hypophyseal arteries that arise from the posterior communicating and intracavernous portions of the internal carotids.[9] In the body of the neurohypophysis, the arterioles break up into the aforementioned capillary networks that drain directly into the jugular vein by way of the sellar, cavernous, and lateral venous sinuses. In the stalk or infundibulum, the primary capillary networks coalesce into another system, the portal veins, which perfuse the anterior pituitary before discharging into the systemic circulation.

BIOSYNTHESIS

Vasopressin is synthesized as part of a protein precursor composed of a signal peptide at its amino terminus, vasopressin, the vasopressin-binding protein, neurophysin II, and a glycosylated peptide, copeptin, at its carboxyl-terminus[17,18] (Figure 42.3). During or after translocation to the endoplasmic reticulum, the signal peptide is removed and the N-terminus of the vasopressin moiety binds to a pocket in the neurophysin moiety. The prohormone then folds, forms a number of intrachain disulfide bridges, and dimerizes, before moving through the Golgi and into the neurosecretory granules where it is transported down the axon and further processed to yield amidated vasopressin, neurophysin, and copeptin.[19] Vasopressin and its neurophysin are stored in nerve terminals as insoluble complexes which dissociate completely after release into the systemic circulation.[20] Biosynthesis of vasopressin appears to be accelerated by stimuli, such as dehydration or hypertonic saline infusion,[21] which increase secretion. However, this compensatory response develops slowly, and may not completely offset the increased rate of release because pituitary stores of the hormone are severely depleted by a strong, sustained secretory stimulus such as prolonged water deprivation.[22]

The gene encoding the vasopressin–neurophysin precursor in humans is located distally on the short arm of chromosome 20 (20p13).[23] It contains three exons which code, respectively, for: (1) the signal peptide, vasopressin, a dipeptide link, and the N-terminal variable portion of neurophysin; (2) the middle, highly-conserved part of neurophysin; and (3) the C-terminal, variable portion of neurophysin, a peptide link and the glycopeptide, copeptin[24] (Figure 42.3). The 5′ untranslated region upstream of the transcription start site also has many conserved sequences, suggesting a role in regulation of gene expression.[25,26] Dehydration or osmotic stimulation increases expression of the vasopressin gene in the supraoptic nucleus,[27,28] whereas adrenal insufficiency or febrile stress does so in parts of the paraventricular nucleus.[28] In contrast, sustained hypoosmolarity inhibits expression.[29] The vasopressin genes in rats,[30] cows,[31] and mice[32] are similar to those in humans, but have several substitutions at either end of the highly-conserved central portion of the neurophysin moiety.

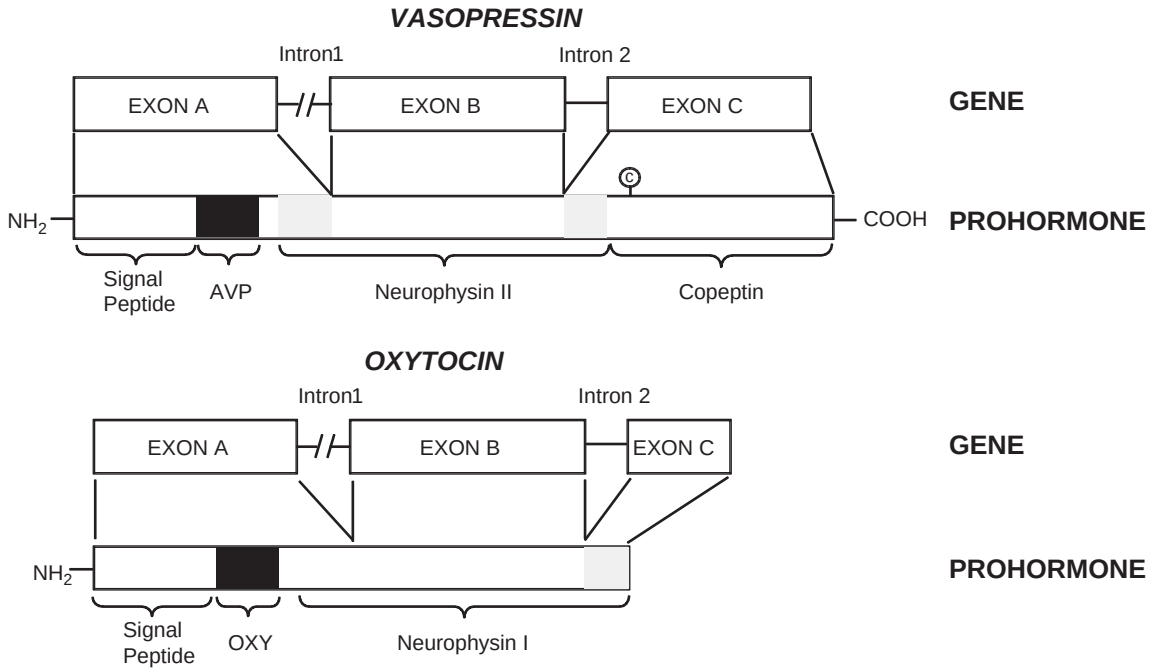

FIGURE 42.3 **Structure of the genes and the protein prohormones of vasopressin and oxytocin.**

The oxytocin gene is closely linked to the vasopressin gene on chromosome 20 with an intergenic region of only 11 kilobases.[24,33] However, the two genes are transcribed from opposite DNA strands, implying a tail-to-tail orientation, differ significantly in putative regulatory regions,[25] and are expressed in mutually-exclusive sets of neurons.[34] The oxytocin gene also differs significantly from the vasopressin gene, in that it does not contain a copeptin encoding sequence in exon 3.[25] Expression of the oxytocin gene in brain and some peripheral tissues is promoted by gonadal steroids.[16]

SECRETION

Vasopressin- and oxytocin-containing secretory granules are released from the terminals of magnocellular neurohypophysial neurons by a process of calcium-mediated exocytosis that is triggered by action potentials generated in the cell bodies of the supraoptic or paraventricular nucleus.[35] Many different neurotransmitters or neuromodulators including, possibly, vasopressin itself, can stimulate or inhibit this activity.[36,37] However, it is not yet known which, if any, of them are important in the regulation of secretion in health or disease. Secretory activity may also be influenced by the many glial cells in close proximity to the dendrites of the vasopressin cell bodies in the supraoptic nucleus.[38]

Vasopressin as well as the neurophysin and copeptin moieties with which it is associated are released into capillaries scattered throughout all levels of the posterior pituitary.[39–41] From there, they travel via the cavernous sinus to the subclavian vein, and thence to the inferior vena cava, heart, and general circulation. Neurophysin, which binds vasopressin in magnocellular neurons, dissociates from the hormone at the concentrations and pH present in plasma.[42] Binding of vasopressin to other plasma proteins has not been demonstrated. However, it does attach to platelets.[43] It is unclear whether or not the platelet-bound vasopressin represents a store of the hormone in equilibrium with free plasma vasopressin. However, the bound and unbound fractions of vasopressin do not appear to track together, at least during acute changes in secretion.[44] Oxytocin is also co-secreted with its neurophysin.[16]

ASSAY

The measurement of vasopressin at physiologic levels in plasma presents an unusual combination of concerns that must be addressed with exceptional care.[45] One problem is the large amount of hormone bound to platelets (see above). Because of it, vasopressin must be assayed not in serum, but in plasma that has been harvested very carefully to avoid contamination with platelets or fragments thereof.

A second problem is the fastidious requirements of the vasopressin assay itself. It must be unusually sensitive, because the hormone normally circulates and acts at very low concentrations. In healthy, normally hydrated, recumbent humans, the plasma concentration of "free" vasopressin is usually between 0.5 and 2.5 pg/mL ($\sim 10^{-12}$ M), an amount sufficient to concentrate the urine (Figure 42.4a). Basal levels in other mammals are similar. The assay must also be very specific, because plasma also contains oxytocin, a nonapeptide that is structurally similar to vasopressin but has different biologic effects. The only practical method now available

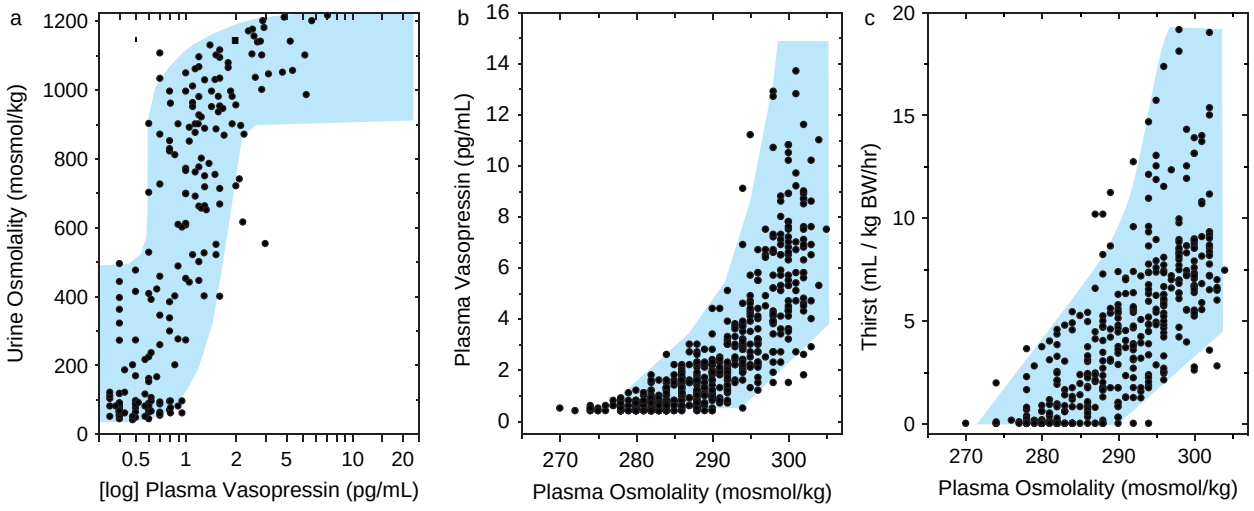

FIGURE 42.4 **Relationship of urine osmolality to plasma vasopressin (a), plasma vasopressin to plasma osmolality (b), and thirst to plasma osmolality (c) in healthy adults in various states of water balance.**

that can meet both requirements is radioimmunoassay. However, it too presents unusual problems, because vasopressin is relatively small and weakly antigenic. To complicate matters, most, if not all, the vasopressin antisera generated to date are susceptible to non-specific interference by one or more other unidentified components of plasma. Moreover, the characteristics and abundance of this interference can vary with the antiserum and type of anticoagulant used to prevent the blood from clotting. Consequently, vasopressin must be extracted from plasma, even if the antiserum employed is sensitive enough to detect the hormone at physiologic levels in unconcentrated extracts. Unfortunately, there is no one extraction method that is suitable for all assays. Therefore, the extraction method, as well as the anticoagulant, must be selected and tailored for the particular antiserum being used.

A third problem for vasopressin assays is the lack of a universal reference standard. Judging from the advertised biologic potencies, those available vary by as much as two-fold in purity, and unknown values reported in weight usually are not corrected for these differences. Therefore, unless the purity or potency of the standards is specified, it is impossible to compare absolute values reported by different laboratories unless they use the same standard, antiserum, and extraction technique.

The radioimmunoassay of vasopressin in urine would appear to be much easier than plasma, because the concentrations in urine are usually much higher, and interference by other substances is much less. However, urine samples must usually be diluted or concentrated to a constant solute concentration (preferably hypotonic), because some antisera are affected by high concentrations of salt or urea. Also, to adjust for the effect of changes in antidiuresis *per se*, the total amount of vasopressin in a urine sample must be expressed as a function of the length of time over which the sample was collected or of the amount of a solute such as creatinine that is excreted at a relatively constant rate. Finally, although changes in urinary excretion of vasopressin usually parallel the changes in plasma, this relationship can be distorted by changes in glomerular filtration or solute clearance.[45]

REGULATION

Osmotic

The most important determinant of vasopressin secretion under physiologic conditions is the "tonicity" or effective osmotic pressure of body water.[46] This influence is mediated by a group of cells known collectively as osmoreceptors,[47] that are located near but separate from the supraoptic nucleus, in or near a part of the anterior hypothalamus known as the organum vasculosum lamina terminalis[48–54] (Figure 42.2). Unlike the neurohypophysis, which receives its blood supply from a branch of the internal carotic artery, the area containing the osmoreceptors is supplied by small perforating branches of the anterior cerebral or communicating arteries.[9] Thus, the interruption of these perforators (or damage to the anterior hypothalamus by other diseases or experimental lesions) can eliminate the osmoregulation of vasopressin secretion, without affecting the neurohypophysis or its response to hemodynamic or other nonosmotic stimuli.[55,56] This dissociation indicates that the osmoregulation of vasopressin is mediated not by the magnocellular neurons that make the hormone, but by afferent inputs from osmosensitive cells located in other, anatomically discrete areas of the anterior hypothalamus. It is not yet known exactly how many such areas there are, whether they contain inhibitory as well as stimulatory elements, how they integrate with other regulatory afferents or how they communicate with vasopressin-producing neurons. Therefore, it may be more appropriate to refer to them as an osmoregulatory system.

The functional properties of the system that osmoregulates vasopressin resemble those of a discontinuous or "set-point" receptor (Figure 42.4b). Thus, in healthy adults and children, plasma vasopressin is very low or undetectable (<0.5 pg/mL) when plasma osmolarity is below a certain minimum or threshold level. Above that "set-point," plasma vasopressin increases steeply in direct proportion with the increase in plasma osmolality. The slope of the line describing this relationship indicates that, on average, a rise in plasma osmolality of 1% increases plasma vasopressin by 1 pg/mL, an amount sufficient to significantly alter urinary concentration and flow (Figure 42.4).

The functional properties of the osmoregulatory system are similar in men and non-pregnant women,[57,58] as well as in blacks and whites.[59] Within each group, however, they vary considerably from person to person.[58] Individual differences in the slope or sensitivity of the response are particularly large, varying as much as 10-fold. Differences in the apparent threshold or set-point are smaller, but still range from 274 to 293 mosmoles/L. These individual differences are constant over time, and appear to be determined largely by genetic factors.[58] However, neither the sensitivity or the set-point is totally immutable, because they can be altered by a variety of conditions, drugs, and hormones (see below).

It is uncertain whether the threshold concept accurately represents the operation of the osmoreceptor at

its most fundamental level. The relation of plasma vasopressin to plasma osmolarity in the population as a whole appears to be slightly curvilinear[60–62] (Figure 42.4). This curvilinearity could be due simply to individual variation, since there as a positive correlation between slope and threshold, i.e., the higher the threshold the steeper the slope. It is also possible, however, that the stimulation of vasopressin secretion is self-amplifying.[44] At present, however, the precision and reproducibility of the vasopressin assays at the low levels present under basal conditions are insufficient to determine if the best fit of the relationship is linear or exponential. It is also possible that vasopressin secretion reflects the balance of inhibitory as well as stimulatory inputs from a bimodal osmoregulatory system, because patients and animals with adipsic hypernatremia due to destruction of the osmoreceptors may lose the capacity to osmotically suppress, as well as to stimulate, vasopressin secretion.[54,55,57,63] As a practical matter, however, the concept of an osmotic threshold remains, for the present, a valid and useful way of describing many aspects of normal and abnormal osmoregulatory function in the intact animal.

It is also uncertain whether vasopressin is secreted continuously or episodically in response to osmotic stimulation. When nonosmotic stimuli such as posture, activity, and blood pressure are controlled, infusion of hypertonic saline in humans almost always produces a smooth progressive increase in systemic venous plasma vasopressin that correlates very closely with the increase in plasma osmolality.[45,58,64–67] However, samples obtained from experimental animals nearer the source of the hormone, for example, from the internal jugular vein, exhibit large fluctuations in plasma vasopressin during osmotic stimulation.[68] Whether these fluctuations reflect an intrinsic property of the neurohypophysis or the osmoreceptors, or are artifacts of the experimental conditions is unknown. Irregular phasic firing of the neurosecretory neurons has been observed by unit recording techniques during stimulation,[69] but this activity is unlikely to be related to episodic fluctuations in plasma vasopressin because the discharge cycles have a much shorter periodicity and are not synchronized from cell to cell.

The system that osmoregulates vasopressin secretion is not equally sensitive to all the solutes in plasma and extracellular fluid.[70–72] The most potent stimuli are sodium and its anions, the solutes that ordinarily account for more than 95% of measured plasma osmolarity. However, certain sugars, such as mannitol and sucrose, are also very effective when infused intravenously. In fact, particle-for-particle, mannitol is as potent as sodium chloride.[72] In contrast, an increase in plasma osmolarity produced by infusion of urea or glucose causes little or no increase in plasma vasopressin in healthy adults.[70–72] Thus, the concentration of sodium and its anions is the principal, if not the only, determinant of osmotically-mediated vasopressin secretion under normal conditions. The basic mechanism by which the osmoregulatory system senses changes in the plasma concentration of sodium and its anions has not been completely established. On the basis of studies in dogs, Verney proposed that the osmoreceptor is stimulated when its intracellular volume is reduced by an osmotically driven efflux of water.[47] If so, solutes that enter the osmoreceptor cells slowly or not at all would be "effective" stimuli, whereas those that penetrate rapidly would have little or no effect. This theory is consistent with the observations that vasopressin secretion is stimulated similarly by infusing hypertonic saline or mannitol, both of which are excluded from cells. In addition, vasopressin is not stimulated by a rise in plasma osmolarity produced by rapid infusion of hypertonic glucose, a solute which enters cells rapidly in the presence of insulin. If anything, the hyperglycemic hyperosmolarity produced by infusion of hypertonic glucose suppresses plasma vasopressin, probably because it also lowers the plasma concentration of sodium salts by inducing an osmotically driven efflux of water from the intracellular to the extracellular compartment. This disparity suggests that, in the presence of insulin, glucose enters osmoreceptor cells even more rapidly than many other cells of the body.

Another theory posits that the osmoreceptors are actually sodium receptors located on the brain side of the blood–brain barrier.[70,73] It is consistent with the observed effects of hypertonic mannitol infusion, because this solute does not cross the blood–brain barrier and, as a consequence, causes an osmotically driven efflux of water from brain that probably raises the extracellular concentration of sodium in that organ. However, the sodium receptor theory is not consistent with the relatively small rise in plasma vasopressin produced by an acute rise in plasma urea,[72] because this solute also crosses the blood–brain barrier slowly and, as a consequence, reduces brain water and raises brain extracellular sodium concentration much like mannitol. This singular disparity indicates that most, if not all, of the osmoreceptors are probably located outside the blood–brain barrier, and that another factor, most likely the solute permeability of the osmoreceptor cell itself, determines the solute-specificity of the system. This concept is also consistent with two other observations: (1) the osmoregulatory system appears to be located in or near the organum vasculosum lamina terminalis, a region of the anterior hypothalamus that is known to lack a blood–brain barrier; and (2) a severe deficiency of insulin sensitizes the osmoreceptors to stimulation by hyperglycemia,[74] presumably by

decreasing its permeability to glucose. It is not yet known, however, what distinguishes the cells of the osmoregulatory system from all the others whose volume and solute concentrations are similarly affected by changes in the extracellular concentration of sodium and its anions.

NON-OSMOTIC

Hemodynamic

An acute decrease of blood pressure or blood volume increases plasma vasopressin by an amount that is roughly proportional to the degree of hypotension or hypovolemia.[75–77] However, the stimulus–response relationship follows a distinctly exponential pattern (Figure 42.5). Small decreases in blood pressure or volume of 5 to 10% usually have little or no perceptible effect on plasma vasopressin, whereas decreases of 20 to 30% result in plasma hormone levels many times those required to produce maximum antidiuresis. Acute orthostasis, which decreases "effective" blood volume by 10 to 15%, usually doubles plasma vasopressin. In rats, chronic or sustained hypovolemia of 24 to 48 hours duration has even less effect on vasopressin, even though pituitary stores of the hormone

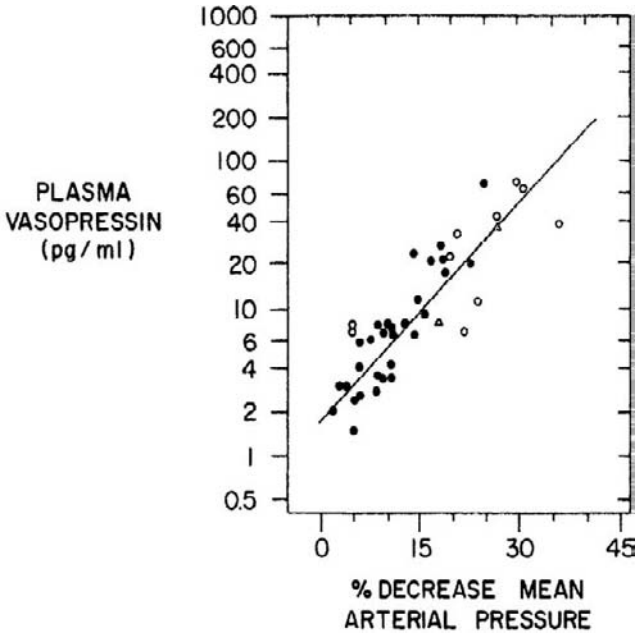

FIGURE 42.5 **Relationship between plasma vasopressin and percentage decrease in arterial pressure in healthy adults.** Hypotension was produced by infusion of a ganglionic blocker (filled symbols) or phlebotomy followed by orthostasis (open symbols). Note that plasma vasopressin is plotted on a log scale.

are undiminished.[78] This suggests that chronic stimulation selectively desensitizes the volume control mechanism.

The effects of acute hypovolemia on vasopressin secretion appear to be mediated largely by neuronal afferents that arise in pressure-sensitive receptors in the left side of the heart[79] and project by way of the vagus and glossopharyngeal nerves to primary synapses on the nuclei of the solitary tracts in the medulla. From there, signals ascend to the hypothalamus via postsynaptic pathways that appear to be mediated in part by a highly selective opioid neurotransmitter of the kappa subclass in the lateral parabrachial nucleus.[80–83] The vasopressin response to acute hypotension is mediated by neurogenic afferents that arise in high-pressure receptors in the aorta and carotid sinus, and project via the vagus and glossopharyngeal nerves, presumably, to the nuclei of the solitary tracts.[84,85] From there, pathways that are at least partly noradrenergic[86] ascend to the hypothalamus. At least for part of their length, these ascending pathways are separate from those that mediate the vasopressin response to hypovolemia, because they are not blocked by opioid antagonists that abolish the response to hypovolemia.[80,81,83]

Acute hypervolemia or hypertension can inhibit vasopressin secretion.[87–90] However, the increase in blood volume or pressure required is relatively large, and the inhibition of AVP is slight. The pathways that mediate the hemodynamic inhibition have not been fully-elucidated, and they may be the same as those that mediate stimulation. Interruption of primary vagal afferents eliminates the effect of hemodynamic stimuli, but also results in an acute rise in basal vasopressin secretion.[91,92] This suggests that the baroregulatory afferents tonically inhibit vasopressin secretion under basal, normovolemic, and normotensive conditions. If so, the slight decrease in vasopressin produced by acute hypervolemia and hypertension may be simply enhancement of this tonic inhibitory effect. Likewise, the increase in vasopressin produced by acute hypovolemia or hypotension could result from a reduction in basal inhibition of secretion. The effect of a *chronic* increase in blood volume or pressure is largely undefined. The osmoregulation of vasopressin secretion appears to be normal in patients with uncomplicated essential hypertension,[93,94] but may be inhibited slightly in primary hyperaldosteronism,[95] suggesting that chronic expansion of the blood volume has an effect opposite to that of hypovolemia.

Changes in blood volume or pressure large enough to affect vasopressin secretion do not interfere with osmoregulation of the hormone. Instead, they appear to act by shifting the set of the system in such a way as

to increase or decrease the effect on vasopressin of a given osmotic stimulus.[46,75,96–98] This means that the osmoregulatory and baroregulatory systems, although different in location and function, ultimately converge and act upon the same population of neurosecretory neurons[46,99] (Figure 42.2). Exactly how and where this integration occurs is unknown.

Emetic

Nausea is an extremely potent stimulus for vasopressin secretion in humans.[100] The pathways that mediate this effect have not been defined, but they probably involve the chemoreceptor trigger zone in the area postrema of the medulla. The effect on vasopressin is instantaneous and extremely potent. Increases of 100 to 500 times basal levels are not unusual, even when the nausea is transient and unaccompanied by vomiting or changes in blood pressure. Pretreatment with fluphenazine, haloperidol or promethazine in doses sufficient to prevent nausea completely abolish the vasopressin response.[100] The inhibitory effect of these dopamine antagonists is specific for emetic stimuli, because they do not alter the vasopressin response to osmotic or hemodynamic stimuli. Water-loading blunts, but does not abolish, the effect of nausea on vasopressin release, suggesting that osmotic and emetic influences interact in a manner similar to osmotic and hemodynamic pathways. The effect of emetic stimuli is also species-dependent. Whereas emetics such as apomorphine, cholecystokinin, lithium chloride, and copper sulfate stimulate the secretion of vasopressin but not oxytocin in humans[100,101] and monkeys,[102] they increase the secretion of oxytocin but have little effect on vasopressin in rodents.[103]

Emetic stimuli probably mediate many pharmacologic and pathologic effects on vasopressin secretion. These include not only apomorphine,[100] but also high doses of morphine,[104] nicotine,[105] alcohol,[100] cholecystokinin,[101,102] and motion sickness.[106] They may also be responsible, at least in part, for the increases in vasopressin secretion that have been observed with intravenous cyclophosphamide,[107] acute hypoxia,[108] diabetic ketoacidosis,[109] vasovagal syncope,[110] and hyperemesis gravidarum.[111] Because nausea and vomiting are frequent side-effects of many other drugs and diseases, additional examples of nausea-induced vasopressin secretion doubtlessly will be observed. The potency and ubiquity of emetic stimuli create special problems for research studies of vasopressin secretion in animals and unconscious subjects, because the occurrence of nausea is difficult to ascertain except by verbal report.

OTHER INFLUENCES

Glucopenia

Acute insulin-induced hypoglycemia also stimulates vasopressin release in proportion to the decrease in plasma glucose.[112] The rate of decrease in glucose is probably the critical determinant, however, because the increase in plasma vasopressin is not sustained even when the hypoglycemia persists.[113] The receptor and pathway that mediate this effect are unknown. They are probably separate from those that mediate the effects of other recognized stimuli, because hypoglycemia stimulates vasopressin secretion in patients who have selectively lost the capacity to respond to osmotic, hemodynamic or emetic stimuli.[112] However, the vasopressin response is accentuated by dehydration and abolished by water-loading,[113] indicating that hypoglycemic stimuli probably act in concert with osmotic influences even though the osmoreceptors *per se* are unnecessary for the response. The effect of hypoglycemia is not due to nonspecific stress, because it can occur in the absence of symptoms and is more pronounced in rats, a species in which vasopressin secretion appears to be unaffected by pain and other noxious stimuli. The variable that actually triggers the release of vasopressin may be an intracellular deficiency of glucose or one of its metabolites, because 2-deoxyglucose is also an effective stimulus.[114,115]

Angiotensin

The renin–angiotensin system has also been implicated in the control of vasopressin secretion.[116] The precise site and mechanism of action have not been defined, but one or more central receptors seem likely, because angiotensin II is most effective when injected directly into brain ventricles or cranial arteries.[117] The magnitude of the vasopressin response may depend on the concurrent osmotic stimulus.[118,119] This dependency may account for the failure of some investigators to demonstrate stimulation by peripherally administered angiotensin.[120] However, if angiotensin is directly involved in the physiologic control of vasopressin, it is more likely that produced by the renin–angiotensin system of the brain.[121]

Stress

Nonspecific stress caused by pain, emotion or physical exercise has long been thought to release vasopressin.[122] However, it has never been determined whether this effect is mediated by a specific pathway or is secondary to other stress-induced stimuli, such as the severe hypotension and/or nausea that often

accompanys the vasovagal reaction to pain or fear. In rats and humans, stresses severe enough to activate the pituitary adrenal axis and sympathetic nervous system do not stimulate an increase in plasma vasopressin unless they also lower blood pressure or alter blood volume.[123,124] If anything, stress seems to transiently suppress plasma vasopressin, possibly as a consequence of an acute rise in blood pressure or activation of other inhibitory input.[125] However, stresses of various types have been found to stimulate the release of vasopressin (as well as corticotropin releasing hormone) from parvocellular neurons which project to portal veins of the anterior pituitary and appear to play a role in the regulation of ACTH secretion.[126]

Temperature

Environmental temperature can also influence plasma vasopressin. In healthy adults, exposure to cold for a relatively short period of time depresses plasma vasopressin, and heat has the opposite effect.[127,128] These changes are independent of changes in plasma osmolality, but they cannot as yet be divorced from changes in effective blood volume or blood pressure. Experimentally-induced hypothermia or fever in animals is also associated with changes in plasma vasopressin,[129–131] but the effects seem to vary, possibly as a function of the species, the dose of endotoxin administered or the time interval. Thus, it is still uncertain how exogenous or endogenous changes in temperature effect vasopressin secretion by magnocellular neurons.

Oropharynx

Drinking can also inhibit vasopressin secretion, even before it produces a detectable decrease in plasma osmolarity or sodium.[132–134] This effect does not depend on the water reaching the stomach, and is unrelated to changes in blood pressure or blood volume. It may depend on the volume or temperature of the fluid ingested because, in humans at least, small volumes of water (100 mL) at room temperature are less inhibitory than larger volumes (700–1200 mL) or small amounts of ice. Thus, the inhibition may be mediated by neural afferents that originate in taste, temperature or other sensory receptors in the oropharynx. Inhibition of vasopressin by oropharyngeal receptors is rapid and transient. This may explain why it is not associated with a concurrent decrease in urine concentration. The rapidity of the decrease is also unexplained, since it appears to exceed the rate at which vasopressin is cleared from plasma under steady-state conditions (see below).

Age

Normal aging also appears to alter the osmoregulation of vasopressin secretion in humans, but the nature of the change is controversial.[135–138] Some find that the vasopressin response to an osmotic stimulus is enhanced, but others report no change or a decreased response. These differences are unexplained, and may represent individual variation in the impact of aging on various components of the osmoregulatory and other interacting control systems. Histologic studies of the human brain show variable changes in the suprachiasmitic nucleus and other vasopressin-containing parvocellular pathways, but no decrease in the number of large cell bodies in the supraoptic and paraventricular nucleus.[12,139] MRI studies indicate that the posterior pituitary bright spot is diminished or absent more often in the elderly than in the young,[140] but this decrease can be due either to atrophy of the gland or to more rapid turnover of vasopressin due, for example, to decreased fluid intake or decreased renal effect of the hormone. Aging does not seem to impair the ability to osmotically suppress vasopressin secretion and dilute the urine, but it does diminish the capacity to excrete a water-load, because of the large age-related reduction in glomerular filtration rate.[141] The capacity to maximally concentrate the urine also diminishes with age, but this may also be due largely to renal factors.[142]

Gender, Pregnancy, the Menstrual Cycle, and Gonadal Hormones

The effects of gender on the osmoregulation of vasopressin secretion are complex and unsettled. There appears to be little or no difference between adult human males and non-gravid females,[57,58] but pregnancy results in a relatively large reduction in the osmotic threshold for vasopressin release in rats as well as in humans.[143,144] Downward resetting of the osmostat also occurs during the luteal phase of the human menstrual cycle,[66,145] but the shift is small relative to that in pregnancy and is smaller even than the range of individual variation in men and non-gravid women.[58] The cause of the resetting is uncertain, but it may be mediated by relaxin,[144] an increase in estrogens[67] or chorionic gonadotropin,[65] since they also lower the set of the osmostat in humans. Progesterone appears to have no effect.[146] In rats, large doses of estrogen seem to have a different effect than in humans, since they enhance the slope or sensitivity of the vasopressin response to plasma osmolality, but do not significantly alter its set-point.[143]

TABLE 42.1 Drugs and Hormones that Affect Vasopressin Secretion

Stimulatory	Inhibitory
Acetycholine	Fluphenazine
Morphine (high doses)	Haloperidol
Epinephrine	Promethazine
Histamine	Oxilorphan
Bradykinin	Butorphanol
Prostaglandins	Opiods (κ and δ agonists)
β-Endorphin	Morphine (low doses)
Cyclophosphamide	Alcohol
Vincristine	Carbamazepine
Lithium	? Glucocorticoids
? Chlorpropamide	? Phenytoin
? Clofibrate	
? Corticotropin-releasing factor	

Drugs and Other Hormones

Many drugs and hormones also influence vasopressin secretion (Table 42.1). Those that stimulate, such as histamine, bradykinin, prostaglandin, β-endorphin, and high doses of morphine, have not been studied sufficiently to define their mechanisms of action, but may act by decreasing blood pressure or producing nausea. Vincristine may have a direct toxic effect on the neurohypophysis or peripheral neurons involved in the regulation of vasopressin secretion. Lithium, which antagonizes the antidiuretic effect of vasopressin, also increases secretion of the hormone. This effect is independent of changes in water balance, and appears to result from an increase in sensitivity of the osmoregulatory system.[147] The stimulatory effects of chlorpropamide and clofibrate are still controversial, and a mechanism of action has not been proposed.

Inhibitors such as the dopaminergic antagonists fluphenazine, haloperidol, and promethazine probably act by suppressing the emetic center, because they inhibit the vasopressin response to nausea but not to osmotic or hemodynamic stimuli. Antihistamines inhibit the vasopressin response to dehydration[148] which is largely an osmotic stimulus, indicating that some part of the osmoregulatory afferents may be histaminergic. Many opiates are also inhibitory. They include oxilorphan and butorphanol, the KAPPA agonists U50488[149] leu-morphin and U62066E, as well as low doses of morphine. In the case of morphine and butorphanol,[150] the inhibition is due to an increase in the osmotic threshold for vasopressin release, and is independent of changes in blood volume or pressure. The mechanism of the resetting has not been completely defined. However, it would appear to be due to the agonist properties of these opiates, because it can be blocked by naloxone.[150,151] The inhibitory effect of alcohol[136] may also be mediated in part by endogenous opiates, because it is also due to upward resetting of the osmostat and can be partly reversed by treatment with naloxone.[152] Carbamazepine inhibits vasopressin secretion by diminishing the sensitivity of the osmoregulatory system.[153] This effect is not dependent on changes in blood volume or blood pressure, and suggests that the ability of carbamazepine to produce antidiuresis in patients with neurogenic (pituitary) diabetes insipidus is due to an independent action on the kidney. The regulation of oxytocin secretion has not been studied extensively, partly because of the limited availability of reliable assays. However, it appears to be stimulated by gonadal steroids, as well as by labor and parturition.[16]

DISTRIBUTION AND CLEARANCE

After release into the systemic circulation, vasopressin distributes quickly into a space approximating extracellular fluid volume.[45,154] The mixing phase is followed by a second, slower decline that presumably reflects the metabolic or irreversible phase of clearance. It has a half-life of 10 to 30 minutes. Thus, the total clearance rate of vasopressin ranges from about 10 to 20 mL/kg body weight per minute. The metabolic clearance rate increases markedly during pregnancy, reaching a level three- to four-fold greater than normal by the third trimester.[155] Smaller animals, such as rats, also clear vasopressin much more rapidly because their cardiac output is much higher relative to body weight and surface area.[154] Although many tissues have the capacity to inactivate vasopressin *in vitro*, most metabolism *in vivo* appears to occur in liver and kidney.[154] In pregnancy, vasopressin is also degraded by a vasopressinase produced by the placenta.[155]

Some vasopressin is excreted intact in the urine. The amount can vary considerably depending on the overall rate of solute excretion,[45] but it is never more than a fraction of total irreversible clearance. In healthy, normally hydrated adults, the urinary clearance of vasopressin ranges from 0.1 to 0.6 mL/kg/min. The mechanisms involved in the excretion of vasopressin have not been defined, but the hormone is probably filtered at the glomerulus and variably reabsorbed at one or more sites along the tubule. The latter process seems to be influenced by the reabsorption of sodium and chloride in the proximal nephron, because the urinary clearance rate of vasopressin varies by as much as

20-fold in direct relationship to the clearance rate of total solute.[45] Thus, changes in urinary vasopressin excretion do not provide a reliable guide to changes in plasma vasopressin unless glomerular filtration or solute clearance rates are constant and normal.

ACTIONS

The biologic effects of vasopressin are mediated by three subtypes of a heptahelical transmembranous receptor coupled to guanine nucleotide-binding (GNB) proteins. Two of the receptors, V1a and V1b, activate phospholipase via GBN−protein coupling. The third, V2, activates adenyl cyclase and increases cyclic-AMP, also via GBN−protein coupling.[156,157] The genes encoding these receptors are located on different chromosomes: V1a on 12q14−15; V1b on 1q32; and V2 on Xq28. Among humans of different ethnic backgrounds, the gene encoding V1a receptors shows considerable polymorphism in the upstream regulatory regions and intron−exon junctions.[158] The anatomic distribution and sensitivity of the three receptors also differs. V1a receptors are found mainly in liver, platelets, the central nervous system, and vascular/gastrointestinal smooth muscle. V1b receptors are found mainly in the ACTH-producing cells of the anterior pituitary, but may also be in other areas of the brain. The V2 receptors are expressed in the distal and collecting tubules of the kidney. The V2 receptors bind vasopressin at very low plasma concentrations (10^{-12} M), and mediate the effect of the hormone on urinary concentration and flow. The V1 receptors, in contrast, are stimulated by vasopressin only at concentrations much higher than those found in plasma under physiological conditions. Thus, their role in other possible physiological functions of this hormone in the periphery is uncertain but unlikely. However, the relative insensitivity of the V1 receptors may not prevent them from acting as neurotransmitters in the brain, the anterior pituitary or other areas where locally high concentrations of the hormone may be produced in synapses with little or no dilution.

The biologic effects of oyxtocin are also mediated by a 7-transmembrane domain receptor coupled to GNB protein.[157] It is encoded by a gene on chromosome 3p25-26 and expressed in uterine smooth muscle, as well as other sites that vary according to the species and the effect of gonadal steroids. The oxytocin receptor is less specific than those for vasopressin, and can be activated by the latter at concentrations only tenfold higher than oxytocin.

Numerous peptide and non-peptide agonists and antagonists of the vasopressin and oxytocin receptors have been, and are still being, developed.[159] One peptide, a V2-selective agonist known generically as desmopressin, has been used for decades to treat the vasopressin-deficient form of diabetes insipidus, and recently also enuresis in children and nocturia in adults. Several non-peptides, antagonists with variable specificity for the V2 receptor, are now being used to treat certain types of hyponatremia resulting from osmotically inappropriate antidiuresis.[160] Non-peptide antagonists for the V1 or oxytocin receptors are now in various stages of development and testing. They may prove to be very helpful in determining if these receptors play a significant role in physiology or pathophysiology. The results of such studies should be interpreted with caution, however, because the receptor specificity and activity of many agonists and antagonists differ considerably, especially between species.[159]

RENAL ACTIONS

The principal, if not the only, clearly documented physiological role of peripherally secreted vasopressin in humans is to decrease urine output by increasing urine concentration. This antidiuretic effect is achieved by binding to G-protein-coupled V2 receptors located on the basal surface of principal cells in the distal and collecting tubules of the kidney (Figure 42.6). Binding to these receptors activates adenyl cyclase and increases intracellular cyclic AMP which, in turn, results in phosphorylation of aquaporin-2, one of a large family of proteins that self-associate to form water channels in other tissues of the body.[4] Aquaporin-2 is encoded by a gene on chromosome 12q13, and expressed almost exclusively in the collecting ducts of the cortex and inner/outer medulla of the kidney. It self-associates to form homotetramers that when phosphorylated are routed to the apical (luminal) surface of the principal cells and inserted through the membrane. There, they function as channels that selectively permit some of the water in dilute tubular fluid to back-diffuse across the membrane into the cell, and then out again into the body through channels formed on the basolateral side by aquaporin 3 and aquaporin 4.[161−164] This process of reabsorption is driven by the hyperosmolar gradient created in the renal medulla by the countercurrent mechanism of the kidney (see Chapter 43). Since water is reabsorbed without solute, the fluid that remains is decreased in volume and increased in concentration, by an amount proportional to the level of vasopressin stimulation and the number of water channels inserted through the apical surface of the cell.

The maximum antidiuresis achievable in healthy adult humans usually occurs at a plasma vasopressin concentration of about 2 to 3 pg/mL (Figure 42.4).

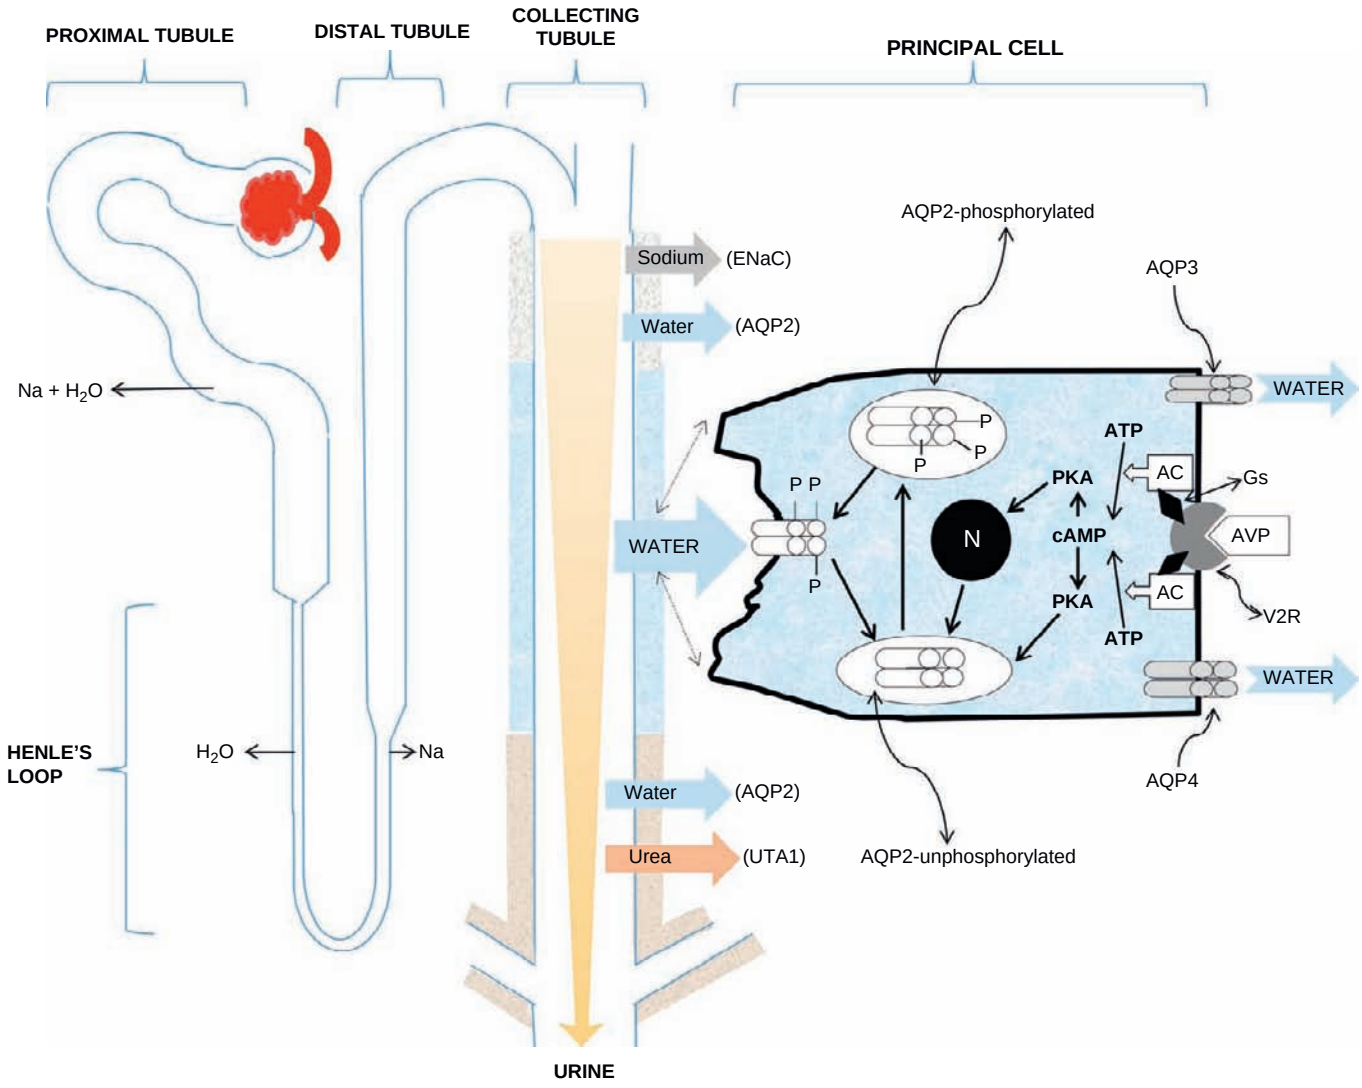

FIGURE 42.6 **Schematic diagram of renal nephron and a principal cell of the collecting tubule.** In healthy adults, the glomerulus filters about 180 L a day of ultrafiltrate with an osmolarity and sodium concentration approximating that of plasma. Water and sodium chloride are reabsorbed from the filtrate in the proximal tubule, Henle's loop, and the distal tubule, reducing the volume and the osmolarity of the fluid that enters the collecting tubules to about 15 L/day and 60 mosmols/L, respectively. In the absence of vasopressin action most, if not all, of this dilute fluid passes unmodified through the collecting tubules and is excreted as urine because the luminal (apical) surface of the principal cells that line the collecting tubules are impermeable to water and solute. This condition is known as a water diuresis. In the presence of vasopressin (AVP), the apical and basal lateral surfaces of the principal cells become permeable to water, allowing it to back-diffuse through the cell down the hyperosmotic gradient formed by the countercurrent mechanism in the renal medulla. As a consequence, the fluid that remains in the collecting tubules to be excreted as urine is more concentrated and less voluminous. Under conditions of maximal antidiuresis, the osmolarity can reach 1200–1400 mosmols/L, and the volume can be as low as 0.5 to 0.7 L/day. The increase in water permeability of the principal cell occurs by a series of intracellular reactions that begin with binding of AVP to a V2 receptor (V2R) on the basal surface, activation of adenyl cyclase (AC) via coupling of G-protein (◇) and conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), which activates protein kinase A (PKA). The PKA has two effects. First, it causes the phosphorylation of preformed tetramers of aquaporin-2 (AQP2) which are stored in vesicles just below the apical surface of the cell. This phosphorylation, indicated in the diagram by −P, directs the tetramers to the apical surface of the cell, where they are inserted and function as channels allowing the passage of water into the cells and out the basolateral side through water channels formed by aquaporin 3 and 4 (AQP3 and AQP4). This process of reabsorption of water is driven by the hyperosmotic gradient created in the renal medulla by the countercurrent system.

It usually results in a urine osmolality of 1000 to 1200 mosmols/L, and a rate of excretion as low as 0.5 to 0.7 ml/min. By reducing the amount of urine needed to excrete urea and other waste solutes, this antidiuretic mechanism serves to minimize the amount of water that must be ingested to prevent dehydration. Rats and many other mammals are capable of even greater levels of antidiuresis, largely because their renal papilla are longer and, consequently, able to generate greater levels of hypertonicity in the medulla. The level of

antidiuresis produced in humans by a given level of plasma vasopressin also varies considerably, depending on the rate of solute excretion as well as, probably, the abundance of aquaporin channels available for insertion, and the rate at which they are removed from the membrane and recycled for later use. The factors that determine the abundance of water channels remain to be fully-defined, but probably include the level of prior vasopressin stimulation because the hormone also stimulates the synthesis of aquaporin-2. This may partly explain why antidiuretic response to vasopressin or desmopressin observed after a prolonged deficiency of the hormone (e.g., in pituitary diabetes insipidus or primary polydipsia) is blunted for several hours.[165] The variables that influence the removal of water channels from the membrane have not been fully-defined, but may include prostaglandin, dopamine, and hypertonicity itself.[163]

Vasopressin also has two other effects on the kidney that enhance its antidiuretic effects. One is to stimulate the activity of a urea transporter (UTA1) in the inner medullary collecting duct.[166,167] This effect, which is also mediated by V2 receptors and cyclic AMP, replenishes the concentration of urea in the renal medulla, thereby helping to maintain the hypertonic gradient generated by the countercurrent mechanism. The other renal effect of vasopressin is to stimulate the readsorption of sodium through an epithelial sodium channel (ENaC) in the collecting duct.[168] This also helps to reinforce the medullary concentration gradient. It does not appear to result in a sustained increase in total body sodium, probably because there is a compensatory decrease in proximal readsorption of sodium.

In the absence of vasopressin stimulation, the apical surfaces of the principal cells, as well as the tight junctions between them, are impermeable to water because the aquaporin-2 water channels remain in vesicles within the cell. As a consequence, the large volume of dilute filtrate that normally issues from the ascending limb of Henle's loop passes unmodified through the collecting ducts to be excreted as urine. In this condition, known as a water diuresis, the osmolarity of urine approximates 40 to 60 mosmols/L (Figure 42.4a), and the rate of excretion may be as high 10–15 mL/min. The excretion of water at this rate normally provides an effective barrier to over-hydration, since it suffices to offset all but the most pathologically excessive rates of water intake.

EXTRARENAL ACTIONS

Apart from its actions on the kidney, vasopressin has been investigated extensively for other effects that might be mediated via V1a or V1b receptors in the periphery or brain. These studies have yet to provide convincing evidence for a significant role in human physiology. However, they suggest that the V1 receptors may mediate certain pharmacologic or *in vitro* effects of the hormone on vascular resistance[169,170] or platelet aggregation,[171] and may also mediate the effects of parvocellular vasopressinergic neurons in brain to modulate various types of complex social behavior[172–174] or the effect of stress on ACTH secretion.[126,175]

The actions attributed to oxytocin are numerous,[16] but their role in human physiology or pathophysiology is not yet fully-defined. Most relate to sexual activity or reproduction, earning oxytocin the sobriquet of "the hormone of love." In the periphery, it stimulates contraction of smooth muscle in reproductive tissues, especially the uterus and mammary glands. However, it is not yet clear whether those effects are essential or only supportive for birth and nursing. In the brain, it has also been implicated in the genesis of various sexual behaviors and social bonding, in addition to regulation of temperature and cardiovascular function.

THIRST

The regulation of fluid intake is an indispensable part of the homeostatic system that regulates the tonicity of body fluids. It ensures that obligatory losses of water through urination, perspiration, and respiration are always replaced promptly and completely. This protection is provided by the thirst mechanism. Thirst may be defined as the subjective sensation of a desire or need for water. It is sometimes associated with feelings of dry mouth, headache or irritability, but these symptoms are not specific to thirst since they also have other causes. It must also be distinguished from cultural, social, psychological, medical, and other motivations to drink. Its vital importance is shown dramatically by the episodes of severe and sometimes fatal hypertonic dehydration that occur in patients who lack the sensation of thirst due to pathology in the anterior hypothalamus.[54] The opposite risk – that of hypotonic overhydration due to too much fluid intake – is not as great, because the mechanisms for suppressing vasopressin and excreting excess water can normally offset all but the most pathologically extreme polydipsia. However, excretory capacity can be impaired by a decrease in urinary solute load or a non-osmotic stimulus to vasopressin secretion. Therefore, the mechanism for regulating fluid intake also seems to include an inhibitory component that operates by producing a sense of satiation or distaste for water.

ANATOMY

The parts of the brain that mediate the conscious awareness of thirst and satiation have not been fully-defined. Studies using functional magnetic resonance imaging or positron emission tomography of the brain in healthy adults have shown that thirst is associated with activation in several areas, including the anterior wall of the third ventricle, anterior cingulate cortex, parahippocampal gyrus, inferior and middle frontal gyrus, insula, and cerebellum.[176] The difficulty with such findings, however, is that the sensation of thirst probably activates many brain areas involved in secondary feelings, thoughts or responses such as anxiety, discomfort or physical movement induced by feelings of thirst. To differentiate these secondary areas of arousal from those that mediate the consciousness of thirst *per se*, it will be necessary to employ a variety of other unpleasant stimuli as controls[177] or study the effect of discrete strokes or other ablative lesions in different brain areas.

REGULATION

Osmotic

Like the secretion of vasopressin, thirst is regulated primarily by the tonicity or effective osmotic pressure of body fluids.[54] This effect is also mediated via hypothalamic osmoreceptors that appear to be anatomically distinct from, but intermingled with, those that regulate vasopressin[178–180] (Figure 42.2). Their functional properties also seem to be similar to the vasopressin osmoreceptors, in that the intensity of thirst increases steeply in direct proportion to plasma osmolarity (Figure 42.4). The only difference is that the threshold for initiation of thirst seems to be set slightly higher than that for the initiation of vasopressin secretion.[54,58] In healthy adults, the level of plasma osmolality at which thirst begins averages about 287 mosmols/L, but varies from person to person over a range from 277 to 294 mosmols/L. In each individual, the the osmotic threshold for thirst tends to be about 4 mosmols/kg higher than that for vasopressin release. Therefore, thirst is not experienced until plasma osmolality rises to a level at which plasma vasopressin is high enough to maximally concentrate the urine. In other respects, the thirst osmoreceptors behave much like those for vasopressin secretion. They have the same solute specificity, since increases in plasma osmolality produced by infusion of hypertonic saline or mannitol are dipsogenic, whereas those resulting from infusions of hypertonic urea or glucose are not.[71,72] Their sensitivity – that is, the intensity of the thirst produced by a given rise in plasma osmolality – also differs significantly from person to person, and these differences also appear to be genetically determined.[58] However, one or both properties also can be altered by changes in blood volume,[181] pregnancy,[144] the menstrual cycle,[66] and human chorionic gonadotrophin.[65]

OTHER INFLUENCES

Hemodynamic

Anecdotal evidence indicates that thirst can also be stimulated by severe reductions in blood volume or blood pressure. The pathways that mediate this effect have not been defined, but are probably the same as those that mediate the effects on vasopressin (see above). In rats, a hypovolemia-induced increase in angiotensin II may also play an important role (see below), but such an effect has not been convincingly documented in humans. Also like vasopressin, moderate reductions in blood volume lower the osmotic threshold for thirst, but do not otherwise interfere with continued operation of the osmoregulatory system.[181]

Angiotensin

In rats and some other animals, angiotensin II stimulates water intake, particularly when injected into the lateral ventricles or other areas of brain.[180] Presumably, the increased intake is due to thirst, although some other type of inducement cannot be excluded. In humans, the dipsogenic effect of angiotensin II has not been investigated.

Glucopenia

Although anecdotal evidence suggests that thirst can also be induced by acute, insulin-induced hypoglycemia, controlled studies are lacking. However, it is clear that an intracellular deficiency of glucose produced by administration of 2-deoxy-glucose stimulates thirst as well as vasopressin release.[115]

Oropharynx

Like vasopressin secretion, thirst is also inhibited rapidly and transiently by the act of drinking *per se*.[182] The characteristics of this effect are similar to those for vasopressin (see above). They appear to be independent of osmotic and hemodynamic influences as well as the solute content of the fluid, but may be influenced by its volume or temperature. The inhibition of thirst is extremely rapid and nearly complete, decreasing the sensation to near zero in a matter of minutes.

However, it is also transient, lasting no more than 10 to 15 minutes, well short of the time required to absorb enough water to begin reducing the osmotic stimulus. Thus, thirst begins to increase again before undergoing a second decline due to absorption of the water and lowering of plasma osmolality. This timing is consistent with the temporal dissociation between the drinking-induced decrease of PET and MRI activity in the anterior cingulated cortex and the anterior hypothalamus (organum vasculosum lamina terminalis).[176] It may also explain why drinking in response to a strong osmotic stimulus often occurs in two or more bouts separated by 15 to 30 minutes.

Eating

It is common knowledge documented by observational studies that most of the water ingested each day is drunk in association with meals.[183] The finding that the amount of liquid drunk with each meal correlates with its estimated protein and carbohydrate content, and not with its estimated sodium content, lead to a theory that eating *per se* is a major independent stimulus to thirst unrelated to osmotic stimulation.[184] However, in healthy adults allowed to eat, drink, and ambulate at will, there appear to be slight increases in plasma osmolality and decreases in plasma protein during meals. Thus, it is not yet certain if drinking with meals is due to osmotically-induced thirst or to some other stimulus, such as taste or cultural habit.

Aging

In contrast to vasopressin secretion, the sensation of thirst and the drinking response to dehydration is diminished among the elderly.[185] The reason, however, is controversial. One theory holds that the sensitivity of the response is decreased due to loss of the potentiating effect of the mild volume depletion that occurs during dehydration. Others find that the decrease in thirst is due largely to upward resetting of the thirst osmostat, with little or no decrease in sensitivity. Compared to healthy young adults, however, there does not appear to be any change in the amount of fluid consumed in response to a given level of thirst or in the rapidity and extent of thirst suppression by oropharyngeal influences.

EFFECTS

Thirst induces the ingestion of water or other fluids in amounts proportional to the strength of the osmotic stimulus.[58] The water is absorbed from the gastrointestinal tract within 30 to 45 minutes, and is carried by blood throughout the body, distributing rapidly between ECF and ICF in a ratio of about 1:2. Thus, it dilutes all body fluid equally. The total amount of fluid drunk at one time, commonly referred to as a "bout" of drinking, is usually less than the amount required to restore tonicity to normal. This pause in drinking may be due to rapid inhibition of thirst by neural pathways arising in oropharyngeal receptors (see above). However, the inhibition is of short duration (10 to 15 minutes), and soon gives way to a return of thirst and drinking until enough water is absorbed to lower plasma osmolality to basal levels. These bouts may be repeated 2 or 3 times for up to 2 to 3 hours, until the hypertonicity is completely eliminated.

Hypotonicity often induces feelings of satiation which help to prevent further overhydration by producing a conscious aversion to drinking water. In humans, it occurs less often and less strongly than the sensation of thirst, but seems to result in negative "thirst" ratings and a marked reduction of spontaneous fluid intake after induction of plasma hypotonicity either by water-loading or repeat administration of high doses of the V2 agonist, desmopressin.[186]

VASOPRESSIN AND THIRST IN OSMOREGULATION

Vasopressin and thirst act in concert to control the tonicity of body fluids by raising or lowering body water to keep the concentration of osmotically effective solutes within a very narrow range. This control must be exerted largely, if not completely, by the osmoregulatory system because fluctuations in plasma osmolarity rarely exceed 1−2%, a change in body water too small to activate the baroregulatory system. The upper and lower limits of plasma osmolarity and sodium are determined by the osmotic thresholds for thirst and vasopressin secretion, because the very large increases in water intake or excretion that normally occur at these thresholds present almost insurmountable barriers to further dehydration or overhydration. Thus, even patients with a severe polyuria due to a deficiency of vasopressin maintain plasma osmolarity and sodium within normal limits simply by drinking more, while those with severe polydipsia do the same by rapidly increasing urine output. However, because the set of the thirst and vasopressin osmostats differs appreciably from person to person, the level at which plasma osmolarity is maintained also differs among healthy adults. This difference is reflected in the normal laboratory values for plasma osmolarity and sodium concentration which, depending on the laboratory methods employed, range from about 270 to 295 mosmols/L

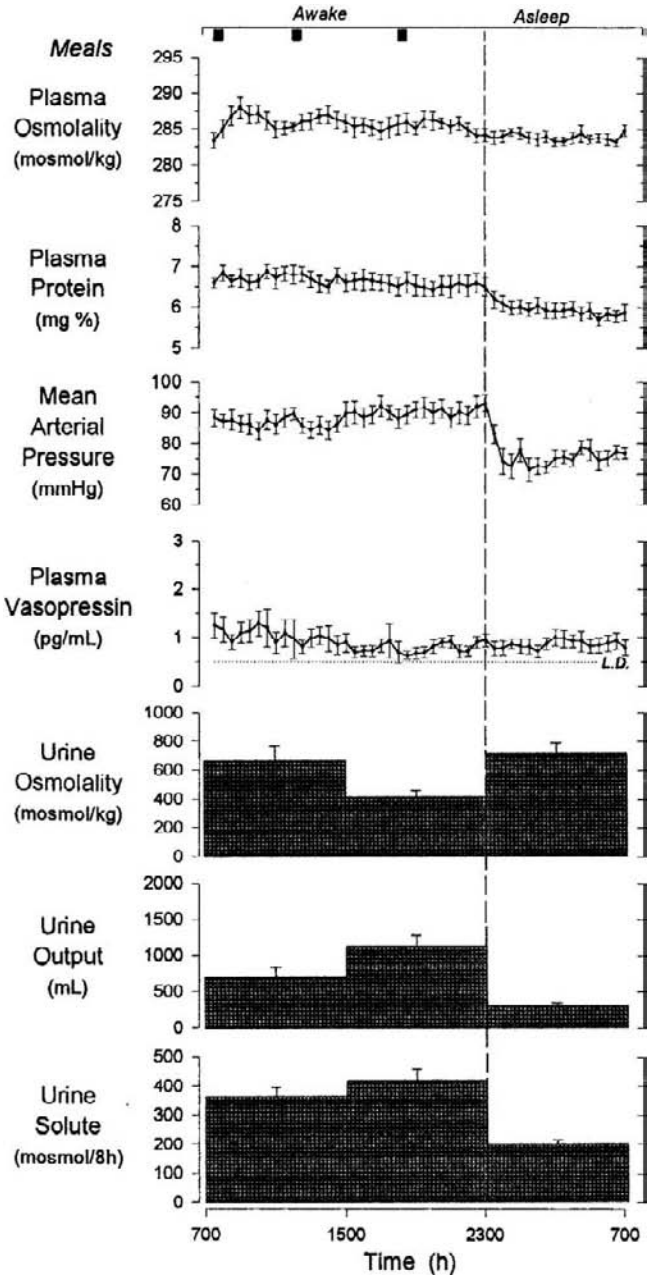

FIGURE 42.7 **Circadian variations in antidiuretic function and related variables in healthy young adults.** Each value is the mean ± SEM of 9 subjects (4 females and 5 males) on *ad libitum* intake of food and water. The three closed squares at the top indicate meals. Fluid intake, which is not shown, averaged 3.1 liters a day. It occurred in equal amounts during the two periods of the day (7 am to 3 pm, and 3 pm to 11 pm), usually with meals. *(From Robertson, G. L., Rittig, S., and Kovacs, L. (1993). Unpublished.)*

and 133 to 145 mmols/L, respectively. Within each person, however, these values are maintained even more tightly about half-way between his or her own set-point for thirst and vasopressin secretion. From that point, even a tiny increase or decrease in tonicity resulting from a change in water or sodium balance elicits a prompt change in vasopressin secretion and urine production, as well as in thirst and water intake. Consequently, the osmolality of plasma and other body fluids within each person rarely deviates by more than 3 to 5 mosmols/kg (1−1.5%), even in the face of large variations in insensible water loss and dietary solute load. In humans, the operation of this elegant osmoregulatory system is subject to changes in blood pressure or volume induced by posture and sleep. However, these influences do not seen to affect osmoregulation, probably because the system that mediates hemodynamic influences on thirst and/or vasopressin is relatively insensitive to normal fluctuations in blood pressure and volume, and even large changes produce only transient small changes in the set of the osmoregulatory system. Thus, plasma osmolarity, plasma vasopressin and urine osmolarity are relatively constant in the course of a normal day (Figure 42.7).

CHAPTER

43

The Urine Concentrating Mechanism and Urea Transporters

Jeff M. Sands[1] *and Harold E. Layton*[2]

[1]Renal Division, Department of Medicine, Emory University School of Medicine, Atlanta, GA, USA
[2]Department of Mathematics, Duke University, Durham, NC, USA

The ability to vary water excretion is essential for mammals, which generally do not have continuous access to water, but must maintain a nearly constant blood plasma osmolality. Mammals, therefore, need a mechanism that allows them to regulate water loss to closely match water intake. In addition, because sodium and its anions are the principal osmotic constituents of blood plasma, and plasma sodium concentration must be kept nearly constant, water loss must be regulated by a mechanism that decouples water and sodium. These critical regulatory capabilities are provided by the kidney's urine concentrating mechanism: when water intake is large enough to dilute blood plasma, urine more dilute than plasma is produced to concentrate the plasma; when water intake is so small that blood plasma is concentrated, urine more concentrated than plasma is produced to dilute the plasma. In both cases, the rate of sodium excretion is small and varies little; indeed, the total solute excretion rate varies little (Figure 43.1).

Urine osmolality varies widely in response to changes in water intake. Following a prolonged period without water intake, such as occurs when an individual sleeps, human urine osmolality may rise to ~1200 mOsm/kg H_2O, about four times plasma osmolality (~290 mOsm/kg H_2O). However, following the ingestion of large quantities of water, such as commonly occurs at breakfast, urine osmolality may decrease rapidly. Humans (and other mammalian species) are able to dilute their urine to ~50 mOsm/kg H_2O. Such large and rapid changes in osmolality require that the cells of the inner medulla have adaptive mechanisms (e.g., osmolytes) to protect them from osmotic damage.

Maximum urine osmolality varies widely among mammalian species. The long-nosed bat *Leptonycteris sanborni* can concentrate only to about 350 mOsm/kg H_2O, while the Australian hopping mouse *Notomys alexis* can concentrate to nearly 9400 mOsm/kg H_2O.[1] Primates can typically concentrate their urines from ~1000 to 2000 mOsm/kg H_2O.[1–3] Beluga whales and bottle-nosed dolphins, which have access only to hypertonic ocean water (~1000 mOsm/kg H_2O), can concentrate urine up to ~1800 mOsm/kg H_2O.[4] Most laboratory data relevant to the urine concentrating mechanism have been obtained from rabbits or rodents that can achieve higher maximum urine osmolalities than humans: the European rabbit can concentrate to ~1400 mOsm/kg H_2O, whereas the eastern cotton tail can concentrate to ~3300 mOsm/kg H_2O; rats to ~3000 mOsm/kg H_2O; mice and hamsters to ~4000 mOsm/kg H_2O; and chinchillas to ~7600 mOsm/kg H_2O.[1,4,5]

Regardless of maximum concentrating ability, the kidneys of all mammals maintain an osmotic gradient that increases from the cortico-medullary boundary to the tip of the medulla (papillary tip). This osmotic gradient is sustained even in diuresis, although it is diminished in magnitude relative to antidiuresis.[6,7] The major constituent of the osmotic gradient in the outer medulla is NaCl; in the inner medulla, the major constituents are NaCl and urea.[6,7] The cortex is nearly isotonic to plasma, while the papillary tip is hypertonic to plasma and, in antidiuresis, has osmolality similar to urine.[5] The major urinary solutes are sodium and potassium accompanied by univalent anions and by urea; urea is the predominant solute in urine during antidiuresis.[6,7] The sodium, potassium, and urea concentrations in rat plasma, papillary tissue, and urine,

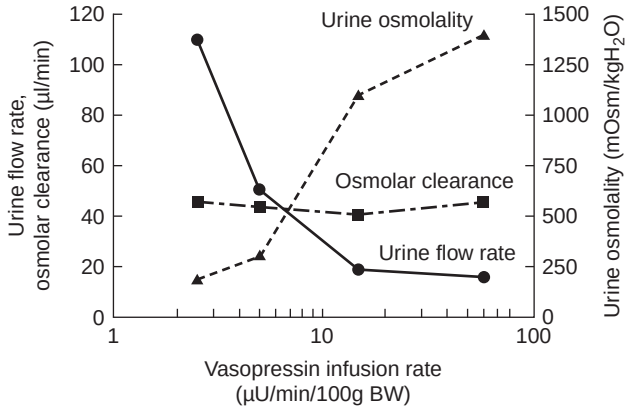

FIGURE 43.1 **Independent control of water and solute excretion.** Rats were infused with exogenous vasopressin and given a water-load (4% of body weight) to suppress endogenous vasopressin secretion. Vasopressin infusion causes a significant decrease in urine flow rate (left axis, circles) and increase in urine osmolality (right axis, triangles), but has little effect on osmolar clearance (left axis, squares). *(Figure is modified, with permission, from reference [232], using data from reference [450].)*

TABLE 43.1 Plasma, Papilla, and Urine Composition During Diuresis and Antidiuresis in Rats

A. Diuresis (urine flow/animal = 192:l/min)			
Component	Plasma	Papilla	Urine
Na^+ (mEq/l)	138	159	5.4
K^+ (mEq/l)	6.0	66.0	5.9
Urea (mM)	4.5	34.1	22.6
Osmolality (mOsm/kg H_2O)	304	572	59
B. Antidiuresis (urine flow/animal = ~5:l/min)			
Component	Plasma	Papilla	Urine
Na^+ (mEq/l)	145	417	148
K^+ (mEq/l)	6.7	102	140
Urea (mM)	4.4	605	946
Osmolality (mOsm/kg H_2O)	314	1832	1805

The data given in this table is from tables and figures in references [6,36,454].

during both diuresis and antidiuresis, are given in Table 43.1.

The mechanisms responsible for the separate control of water and sodium excretion are largely located in the renal medulla, where the nephron segments and vasa recta are arranged in complex but specific anatomic relationships, both in terms of which segments connect to which segments, and in terms of three-dimensional configuration. The production of concentrated urine involves complex interactions among the nephron segments and vasculature. In the outer medulla, thick ascending limbs of the loop of Henle actively absorb NaCl, diluting the luminal fluid and providing NaCl to increase the osmolality of the medullary interstitium, pars recta, descending limbs, collecting ducts, and vasculature. The countercurrent configuration of nephron segments and vessels allows the generation of a medullary osmolality gradient along the cortico-medullary axis. In the inner medulla, osmolality continues to increase, but the source of the concentrating effect remains controversial. However, the most widely accepted mechanism remains passive absorption of NaCl, in excess of solute secretion, from thin ascending limbs of the loops of Henle.[8,9]

KIDNEY STRUCTURE

The structural organization of the mammalian kidney is discussed in detail elsewhere in this book. This section, based in large measure on key studies (e.g., [10–12]), summarizes features that are pertinent to the urine concentrating mechanism.

In most mammals studied, the kidney contains short looped and long-looped nephrons; both have loops of Henle that are arranged in a hairpin configuration (Figure 43.2). They differ in two important aspects: the loops of short-looped nephrons turn near the inner-outer medullary border and lack a thin ascending limb, whereas the loops of long-looped nephrons extend into the inner medulla and contain a thin ascending limb. Thin ascending limbs are found only in the inner medulla, and their transition to thick ascending limbs defines the inner–outer medullary border. Thus, only thick ascending limbs are found in the outer medulla, regardless of the type of loop. Some mammalian kidneys, e.g., human kidneys, have nephrons whose loops of Henle do not reach into the medulla; these nephrons are called cortical nephrons. Tubular fluid flows from thick ascending limbs of both short and long looped nephrons to distal convoluted tubules. Several distal tubules merge to form cortical collecting ducts that descend through the cortex and then become medullary collecting ducts that pass through the outer medulla. The collecting ducts merge along the entire length of the inner medulla, ultimately forming the ducts of Bellini, which open into the renal pelvis at the papillary tip.

Small mammals, such as rodents, have unipapillate kidneys. In these mammals, the papilla is an inverted pyramid-shaped portion of the innermost inner medulla; the papilla descends into the renal pelvis. Larger mammals (including humans) have multipapillate kidneys in which each papilla descends into a renal calyx. The renal pelvis is formed from the merging of these calyces. In all mammals, urine exits through the ducts of Bellini into the renal pelvis.

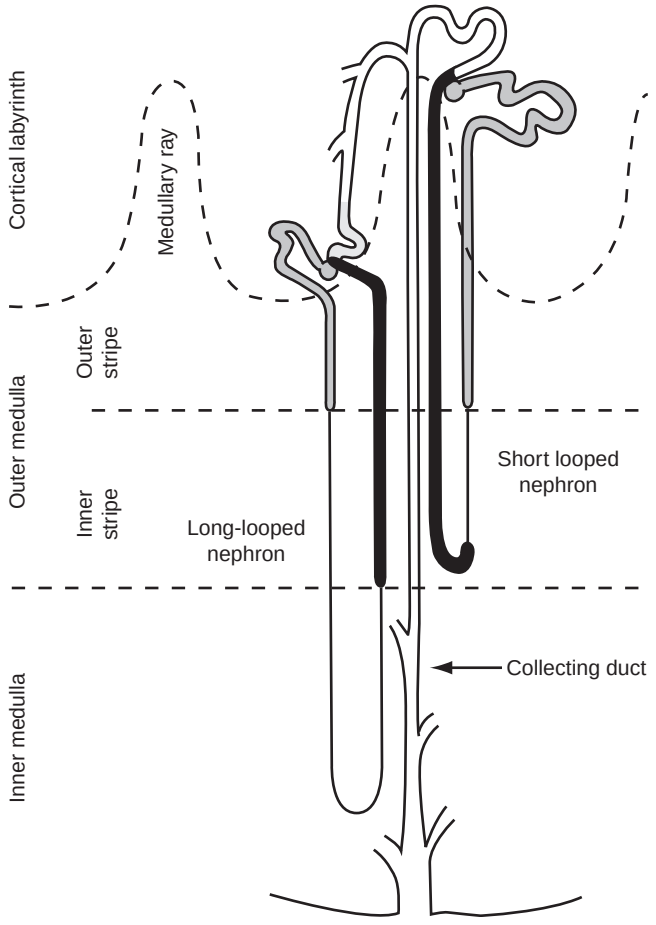

FIGURE 43.2 **Basic structure of mammalian kidney.** Diagram shows both a long-looped and a short-looped nephron. Glomeruli are shown as circles, proximal tubules are hatched, thin limbs of Henle's loop are lines, thick ascending limbs of Henle's loops are solid, distal convoluted tubules are stippled, and collecting duct system is open. *(Reproduced with permission, from reference [232].)*

The pelvis, which connects to the ureter, is bounded by two epithelia: the papillary surface epithelium lining the surface of the papilla, and a ureteral-type epithelium extending from the ureter up into the renal pelvic fornices.[13–16]

The descending and ascending vasa recta, which provide the blood supply for the medulla, are arranged roughly in parallel. Although their configuration is similar to the hair-pin configuration of the loops of Henle, there is an important anatomic difference: the tubular segments that make up the loops of Henle are contiguous, whereas the descending and ascending vasa recta are separated by capillary plexuses. Blood enters the medulla through descending vasa recta, passes through capillary plexuses located at various depths within the medulla, and then enters ascending vasa recta. Vascular bundles, which are aggregations of both descending and ascending vasa recta, form in the outer stripe, but become much more prominent in the inner stripe. Lemley and Kriz have proposed using the vascular bundle (see detail, Figure 43.3) as the histotopographical core around which the various outer medullary tubule structures are arranged.[10–12,17]

Studies of inner medullary structure by Kriz and co-workers,[10–12,17] and recent studies by Pannabecker and Dantzler,[18,19] found that the inner medullary collecting ducts (IMCDs) in the inner medullary base form clusters that coalesce along the cortico–medullary axis. Using immunohistochemical labeling and computer-assisted reconstruction, Pannabecker, Dantzler, and colleagues have elucidated new detail of the functional architecture of the rat inner medulla (see recent review [20]). A computerized reconstruction of the inner medullary portion of several long-looped nephrons from rats is shown in Figure 43.4, in which antibodies to the water channel aquaporin-1 (AQP1, shown in red) and the chloride channel ClC-K1 (shown in green)[18] are used to label the thin descending and ascending limbs of the loops of Henle, respectively (reviewed in [20]). In the base of the inner medulla, thin descending limbs are predominantly present at the periphery of these clusters, and appear to form an asymmetric ring around each collecting duct cluster. In thin descending limbs of loops of Henle that turn within the upper first millimeter of the inner medulla, no AQP1 was detected. In contrast, there are three discernible functional subsegments in thin descending limbs of loops of Henle that turn below the first millimeter: the upper 40% expresses AQP1, whereas the lower 60% do not. ClC-K1, a marker of the thin ascending limb-type epithelium, is first detected in the final ~165 micrometers of the thin descending limb, as well as in the contiguous thin ascending limb. Thus, ClC-K1 is detected before the bend of the loops of Henle. This finding is consistent with previous morphological studies demonstrating that the descending limb to ascending limb transition occurs before the loop bend. In addition, a substantial portion of the inner medullary thin descending limbs of long-looped nephrons did not express either AQP1 or ClC-K1, as indicated in gray in Figure 43.4a.

In contrast, thin ascending limbs are distributed relatively uniformly among collecting ducts and thin descending limbs. In Munich-Wistar rats, Pannabecker and Dantzler[19] identified three population groups of loops of Henle, distinguished by thin ascending limb position at the base of the inner medulla and by differing loop length. Group 1 loops, having thin ascending limbs that are interposed between collecting ducts, reach a mean length of 700 μm into the inner medulla; Group 2 loops, having thin ascending limbs that are adjacent to just one collecting duct, reach 1500 μm and Group 3 loops, having thin ascending limbs that lie more than a half-tubule diameter from a collecting

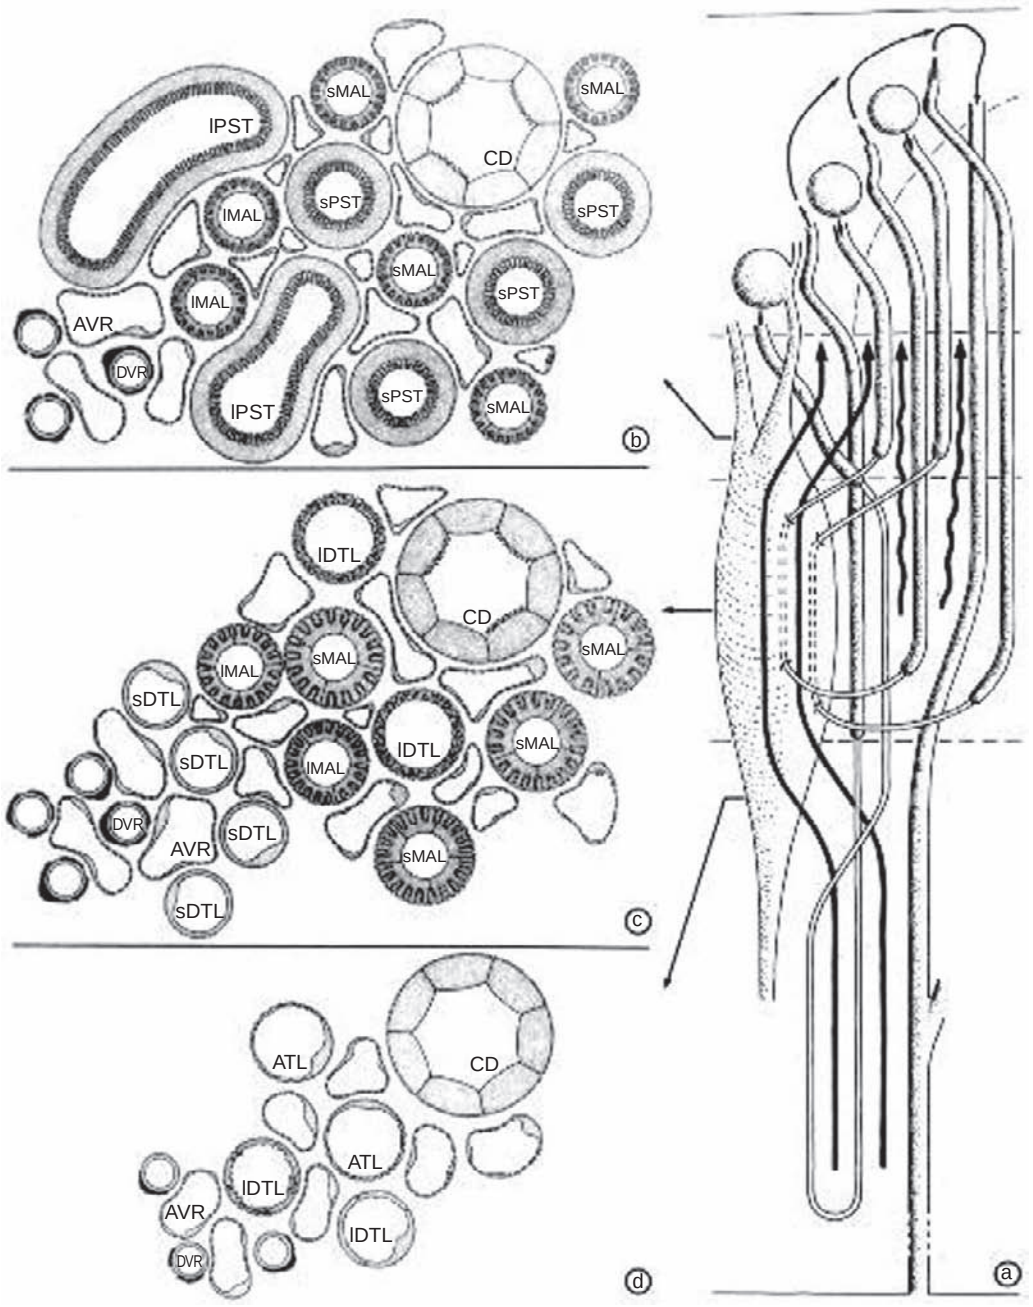

FIGURE 43.3 **Lemley and Kriz model of the architectural organization of the rat renal medulla.** Shown are a schematic longitudinal section (a); and cross-sections through the outer stripe of the outer medulla (b); inner stripe of the outer medulla (c); and the inner medulla (IM) (d). In (a) 1 long and 2 short loops of Henle, the collecting duct, and a vascular bundle (shown in three-dimensional solid form) are shown. The vascular bundle contains ascending vasa recta (AVR) originating from the inner medulla (AVRIM, long, bold-face arrows) and the descending limbs of the short-looped nephrons (sDTL). Ascending vasa recta originating from the inner stripe (AVRIS, bold, wavy arrows) ascend directly within the interbundle region. In the cross-sections (b)–(d), the relationships of 4 short and 2 long loops of Henle are shown with the collecting duct (CD) and vasa recta. (b) In the outer stripe, the proximal straight tubules (PST) and medullary thick ascending limbs of long-looped nephrons (lMAL) are located among the AVRIM near the vascular bundle. Located at a distance from the vascular bundle are the collecting ducts (CD) and the PSTs, and thick ascending limbs from short looped nephrons (sMAL). These structures are surrounded by AVRIS and the true capillaries (smaller unlabeled structures). (c) In the inner stripe, the core of a vascular bundle contains AVR and descending vasa recta (DVR), whereas sDTL are found among the AVRIM in the periphery. In the interbundle region, the thin descending limbs of long looped nephrons (lDTL) and CD run together with thick ascending limbs of short looped nephrons (sMAL); the lMAL are found bordering the vascular bundle. (d) In this section through the upper IM, a vascular bundle is still discernible, but AVR are already present throughout the cross-section. The CD is distant from the vascular bundle. Between the bundle and the CD are lDTL (with different wall structures corresponding to upper and lower part epithelia) and ascending limbs of long looped nephrons (ATL) (Abbreviations: AVR and DVR: ascending and descending vasa recta; CD: collecting duct; DTL: descending thin limb; MAL: medullary thick ascending limb; PST: proximal straight tubule (pars recta); subscripts s and l: short-looped and long-looped nephrons, respectively; OS, IS, and IM: outer and inner stripe of the outer medulla and inner medulla, respectively). *(Reproduced with permission, from reference [12].)*

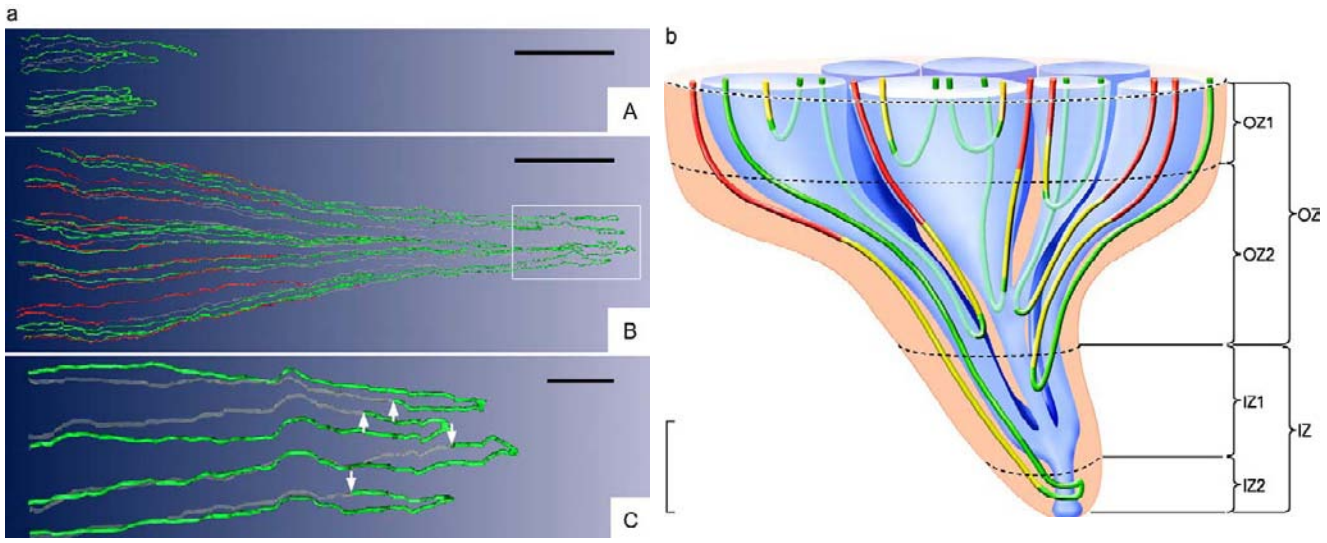

FIGURE 43.4 (a) Computer-assisted reconstruction of loops of Henle from rat inner medulla showing expression of aquaporin-1 (AQP1; red) and ClC-K1 (green); gray regions (B-crystallin) express undetectable levels of AQP1 and ClC-K1. Loops are oriented along the corticopapillary axis, with the left edge of each image nearer the base of the inner medulla. Panel A: Thin limbs that have their bends within the first millimeter beyond the outer–inner medullary boundary. Descending segments lack detectable AQP1. ClC-K1 is expressed continuously along the prebend segment and the thin ascending limb. Panel B: Loops that have their bends beyond the first millimeter of the inner medulla. AQP1 is expressed along the initial 40% of each thin descending limb, and is absent from the remainder of each loop. ClC-K1 is expressed continuously along the prebend segment and the thin ascending limb. Boxed area is enlarged in panel C. Panel C: Enlargement of near-bend regions of 4 thin limbs from box in panel B. ClC-K1 expression, corresponding to thin descending limb prebend segment, begins, on average, 165 μm before the loop bend (arrows). Scale bars, 500 μm (panels A and B); and 100 μm (panel C). *(Reproduced with permission, from reference [20].)* (b) Based on computer-assisted functional anatomy reconstructions that included immunolabeling of key transporters along the limbs of long loops of Henle, Pannabecker et al.[21] have proposed that the inner medulla of the rat can be considered to have four four zones (or subsections): (1) an outer-most zone (OZ1), about 1 mm thick, that lies just below the OM and in which loops labeling for little or no AQP1 have their bends; (2) a larger outer zone (OZ2), 2 to 2.5 mm in thickness that lies just below OZ1 that has well-organized CD clusters and tubules where loop bends turn within central portions of the clusters; (3) an outer inner zone (IZ1) where the organization of CD clusters diminishes, and all vasa recta are fenestrated; and (4) an inner-most zone (IZ2) where CD clusters can no longer be distinguished, where all vasa recta are fenestrated, and where many loops of Henle have transversely-running segments that wrap alongside CDs. The two inner zones combined are 1.5 to 2 mm thick. Representative collecting duct clusters are shown in blue; intercluster tissue is orange. AQP1-positive and AQP1-negative descending thin limbs are shown in red and yellow, respectively. Prebend segments and ascending thin limbs are shown in green. This color scheme differs from that of Figure 43.4A only by the use of yellow rather than gray for AQP-1 negative descending thin limbs. *(Reproduced with permission from [21].)*

duct, reach 2200 μm. As collecting ducts coalesce and shorter loops disappear, the originating portions of longer thin ascending limbs run alongside the collecting ducts for substantial distances (a more detailed description of inner medullary loop subgroups was given in [20]).

Moreover, Pannabecker et al.[20,21] proposed that the inner medulla has at least four distinguishable zones (axial subsections) that can be differentiated by the variable characteristics of vasa recta and loops of Henle. The four zones are illustrated in Figure 43.4b. Three countercurrent systems were hypothesized to exist within these zones: (1) an intercluster system within the CD clusters where most of the work of concentrating is conducted in and around nodal spaces that are surrounded by IMCDs, thin ascending limbs, and AVR; (2) an extracluster system in the outerzones (outer 3 to 3.5 mm) that serves to carry water absorbed from water-permeable portions of descending limbs back to the OM via AVR; and (3) a papillary system in the inner zones where the highest concentrations are attained with the aid of direct interactions between transversely-running segments of loops of Henle and collecting ducts.

Distinct types of interstitium are found in the vascular bundle in the outer medulla, in the interbundle region of the outer medulla, and in the inner medulla.[12] These interstitia may play an important role in medullary solute and water transfer, especially in the inner medulla, where interstitial cells are interspersed in a gelatinous matrix of acid mucopolysaccharides, which is largely devoid of any capillary plexuses, laterally flowing capillaries or lymphatics.[12,22,23] Thus, the inner medullary interstitium should greatly slow lateral bulk flow of solutes and water.

The number of nephrons found in mammals, and thus the number of loops of Henle, varies over many

orders of magnitude, increasing sub-linearly with increasing body mass.[24] The mouse has about 12,400 nephrons per kidney[24]; rat, 30,000–40,000[24,25]; rabbit, 230,000[24,25]; human, 0.3–1.4 million[26,27]; elephant, 7.5 million[24]; and fin whale, 192 million.[27] In contrast, medullary thickness in mammals varies from 3 to 25 mm, thus indicating that maximum loop of Henle length varies over about an order of magnitude[4]; proximal tubule diameter changes little from rat to fin whale, increasing by a factor of about 1.3.[27,28]

Although loops of Henle of variable length are found in all mammals, most mammals are thought to have both short- and long-looped nephrons. Exceptions include the dog, with all long loops,[29] and the mountain beaver *Aplodontia rufa*, which has thick ascending limbs only, and has a renal medulla that corresponds to the outer medulla of other mammals.[30] Generally, however, there are more short-looped than long looped nephrons, and the long-looped nephrons tend to exhibit substantial variation in the depth reached within the inner medulla. Measurements in the rabbit[31] and rat[25,32] indicate that the decrease in loop of Henle and collecting duct population in the inner medulla is approximately exponential, with most loops of Henle turning back in the outer portion of the inner medulla, and with collecting ducts converging to a few ducts of Bellini. A similar pattern is seen in the medullary cones of the avian kidney[33] which, like the mammalian kidney, is able to produce a concentrated urine, although only to osmolalities of about twice that of blood plasma.[34]

The pattern of decrease in the tubule populations of the rat renal medulla[25,32] is portrayed in Figure 43.5, which gives curves approximating loop and collecting duct population as a function of normalized medullary depth. About 38,000 loops and 7300 collecting ducts extend through most of the outer medulla.[25] About 28–33% of the loops of Henle in rat have thin ascending limbs and reach into the inner medulla.[10,29] The populations of loops of Henle and collecting ducts both decline rapidly, but the loop population decreases more rapidly, so that the loop and collecting duct populations are more nearly equal in the papilla. In human, about $\frac{1}{7}$ of the loops of Henle reach into the inner medulla.[27]

Figure 43.5 also portrays the concentration of urea, the sum of the concentrations of sodium and its anions, and the osmolality, as a function of medullary depth, as determined in tissue slices harvested from vasopressin-treated Wistar rats.[6,35,36] The experimental data points indicated in Figure 43.5 are connected by natural cubic splines which generate smooth curves; these curves have shapes supported by other studies in rat.[37,38] Osmolality increases by a factor of about 2 in the outer medulla, and by an additional factor of 3 in the inner medulla, where urea makes a substantive contribution. As can be inferred from the values for urine (U) in Figure 43.5, sodium is largely carried by flow in the loops of Henle and vasculature, while urea makes up a large portion of the solute in collecting duct flow. Potassium has a tissue concentration of

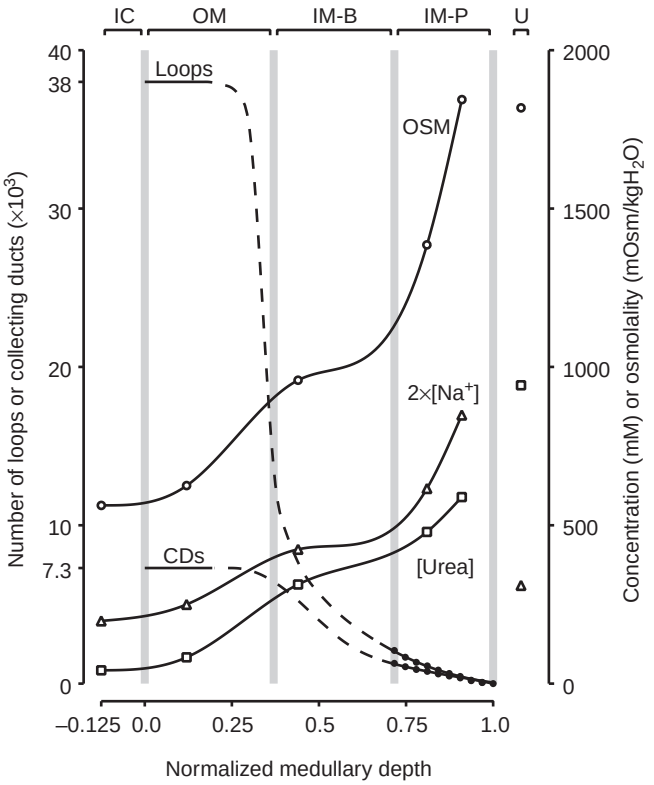

FIGURE 43.5 Loop of Henle and collecting duct population in rat (scale at left) as a function of normalized medullary depth; also, tissue osmolality, concentration of urea, and concentration of sodium plus its anion (scale at right). Loop of Henle and collecting duct populations decrease in inner medulla because loops turn back and collecting ducts merge. The osmolality gradient is larger in the outer medulla and papilla than in the outer part of the inner medulla. The gradient is largest in the papilla, where the osmolality and concentration profiles appear to increase exponentially. The shape of the sodium profile has been corroborated by electron microprobe measurements [38] (Key: IC: inner cortex; OM: outer medulla; IM: outer part (base) of inner medulla; P: papilla or inner part (tip) of inner medulla; U: urine). Figure based on published data. Curves connecting data points are natural cubic splines, computed by standard algorithms.[451] Dashed curve segments are interpolations without supporting measurements. Tubule populations in papilla are from reference [32]; tubule populations in outer medulla are based on estimates in reference.[25] Concentrations and osmolalities are from tissue slices and urine samples collected 4.5 hours after onset of vasopressin infusion at 15 μU/min/100 g body weight. Data is from Figure 5 in reference [36] and Figures 1, 3, and 9 in reference [6]; slice locations were given in reference.[35] The osmolality reported in the inner cortex seems high relative to the reported plasma concentration of 314 mOsm/kg H_2O. The osmolality and concentration profiles, as drawn in reference [6], apparently do not take into account relative distances between tissue sample sites.

about 80–100 mM along the medulla, but it makes a larger contribution (~150 mM) to urine.[6,36]

The osmolality increase along the outer medulla arises from the vigorous transepithelial transport of NaCl from thick ascending limbs into the surrounding interstitium. This effect is believed to be augmented by a process of countercurrent multiplication, described in a subsequent section (*vide infra*). However, as shown in Figure 43.5, the osmolality gradient is largest in the papilla, even though only a small fraction of the loops, tubules, and vasa recta reach into the papilla, and even though the population of tubules and vessels is rapidly decreasing there. The remarkable capacity for generating high osmolalities in so small a volume (~0.5% of total kidney volume[22]) has thus far resisted a generally satisfactory explanation.

TRANSPORT PROPERTIES OF INDIVIDUAL NEPHRON SEGMENTS

This section will review the water, urea, and sodium permeability values measured in isolated perfused tubules in nephron segments involved in producing concentrated or dilute urine. Thin limb segments are difficult to perfuse, and most measurements involving different species have been made by different laboratories. Thus, some caution must be used in comparing these values. Tables 43.2–43.5 contain values obtained from animals receiving food and water *ad libitum*; representative values were chosen since space does not permit citing every original manuscript.

In the past two decades, many of the proteins which mediate water, urea, and sodium transport in nephron segments important for urinary concentration and dilution have been cloned (Figure 43.6). The water channels (called aquaporins) and sodium transporters are discussed in detail elsewhere in this book. The urea transport proteins and their role in the long-term regulation of the urine concentrating mechanism are discussed later in this chapter.

In general, the water, urea, and sodium transport proteins are highly specific. Reflection coefficients are not included in Tables 43.2–43.5, since the specificity of these transport proteins appears to eliminate a molecular basis for solvent drag and suggests that the reflection coefficients should be 1.

THIN DESCENDING LIMB

Thin descending limbs are conventionally divided into types I, II, and III: types I and II are located in the outer medulla in short and long looped nephrons, respectively, while type III limbs are located in the inner medulla.[39,40] The osmotic water permeability of thin descending limb subtypes that express aquaporin 1 (AQP1) water channels[41] is extremely high in all species studied[42–45] (Table 43.2). AQP1, a constitutively active water channel, is present in both the apical and basolateral plasma membranes in sufficient abundance to account for the measured rates of transepithelial water transport.[46] Transgenic mice lacking the AQP1 channel (which is also found in proximal tubule and descending vasa recta), were found to have greatly impaired urine concentrating capability, which was attributed in large measure to defective water absorption from the proximal tubules and descending limbs, which may lead to an overloading of available concentrating capacity.[47,48]

The chinchilla has an additional inner medullary subsegment (type II distal) in the deepest 20% of the

longest loops of Henle.[42] This subsegment has low osmotic water permeability[42,49] and lacks AQP1.[50] The Munich-Wistar rat has a similar subsegment in the deepest 60% of the longest loops[51,52] and also a prebend segment of ~164 μm in length that labels for the ClC-K1 chloride transporter, but not for AQP1.[18] Avian loops of Henle appear to have similar pre-bend segments.[53] The pre-bend segments may be functionally important as a site of NaCl absorption.[52,54–56]

Urea permeability varies in different portions of the thin descending limb (Table 43.2). Urea permeability is relatively low in types I and II thin descending limbs.[57–62] Urea permeability is higher in type III thin descending limbs,[52,57,59,63] and is quite high in the chinchilla type III distal thin descending limb.[57] The reflection coefficient for urea is close to 1 in thin descending limbs.[58,64]

Sodium permeability is relatively low in rabbit types I and II[64–66] and hamster types I and III thin descending limbs,[58,59] but is relatively high in hamster type II and chinchilla types III and III distal thin descending limbs.[57–59] Na^+/K^+-ATPase activity is very low in all thin descending limb segments in which it has been measured.[67,68] Rabbit types I and II thin descending limbs have a NaCl reflection coefficient that is close to 1.[64] However, the measured NaCl reflection coefficient is heterogeneous in hamster: 0.83 in type II and 0.99 in type III thin descending limbs.[58,69]

The perfused tubule studies reviewed above provide important information about the transport properties of

the individual nephron segments comprising the descending limb of the loop of Henle. In contrast, micropuncture studies provide *in vivo* information about the concentrations of solute within the portions of the descending limb that are accessible to micropuncture: comparisons can be made between the composition of tubular fluid near the ends of those proximal convoluted tubules that are accessible on the cortical surface and the composition of fluid in the bends of the longest loops of Henle near the papillary tip. Since proximal tubules on the surface of the kidney originate from superficial glomeruli, and the loops of Henle which reach the papillary tip generally originate from juxtamedullary nephrons, it is not possible, currently, to compare fluid samples taken from cortical and medullary sites in a single nephron. Thus, the validity of this comparison depends upon the assumption that the composition and delivery of solute and water to the beginning of the superficial and juxtamedullary descending limbs are similar. In addition, papillary micropuncture requires the removal of the ureter, which also reduces maximum urinary concentrating ability by a mechanism that is not completely understood.[70–72] Thus, micropuncture studies are limited to studies performed during moderate, not maximal, antidiuretic conditions.

In the rat, osmolality increases along the length of the descending limb. Water removal accounts for 90% of this increase in osmolality in Brattleboro rats that are not treated with vasopressin.[73] When Brattleboro rats are treated with vasopressin, there is an increase in the osmotic pressure of the descending limb fluid and in the volume of water absorbed from the descending limb.[73] This rise in descending limb fluid osmolality results from water extraction (60%), and from urea addition (40%).[72,73] The delivery of urea to the end of the thin descending limb averages 550% of the filtered load of urea.[72] Thus, urea is either secreted into the descending limb fluid[74] or there is a major difference between the filtered load of urea in superficial versus juxtamedullary glomeruli. When urea is infused into rats fed a low-protein diet, both water extraction from the descending limb and urinary concentrating ability are significantly increased.[75]

In hamster, ~65% of the osmotically active solute in fluid obtained near the bend of the loop of Henle is due to sodium (plus a univalent anion), while ~20% is due to urea.[70] Since only ~10% of the filtered load of water reaches the bend of the loop of Henle, the high luminal fluid sodium concentration results primarily from water extraction from the descending limb.[70] Both sodium and inulin concentrations increase along the length of the hamster descending limb, showing that water is extracted from the descending limb fluid.[76,77] As in the rat, significant amounts of urea are added to the descending limb fluid.

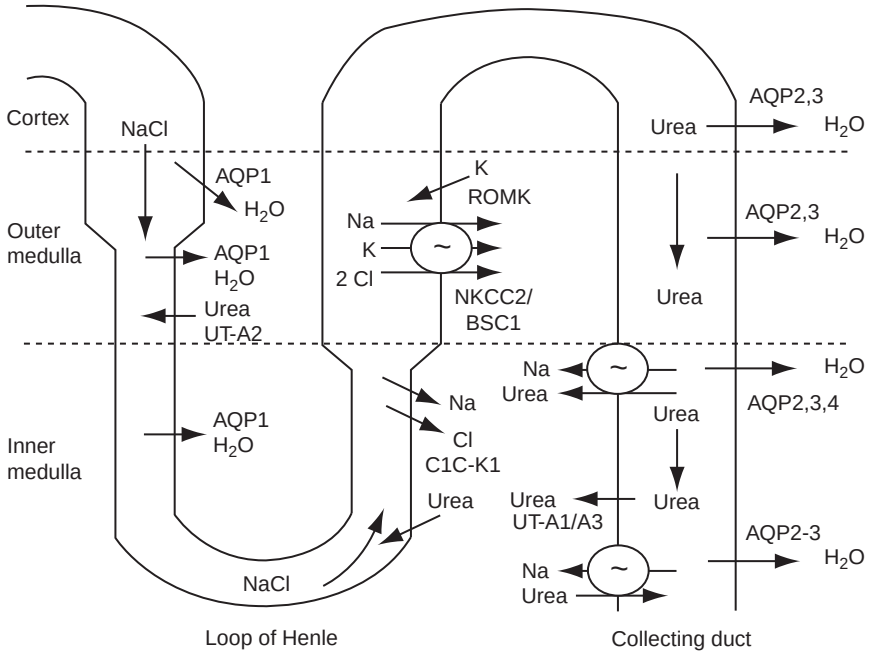

FIGURE 43.6 **Location and identities of the water, urea, and sodium transport proteins involved in the passive mechanism hypothesis for countercurrent multiplication in the inner medulla.**[8,9] The major kidney regions are shown on the left. NaCl is actively absorbed across the thick ascending limb by the apical membrane Na^+-K^+-$2Cl^-$ co-transporter (NKCC2, BSC1), and the basolateral membrane Na^+/K^+-ATPase (not shown). K^+ is recycled through an apical membrane ROMK channel. Water is absorbed across the descending limb by AQP1 water channels in both apical and basolateral plasma membranes. In the presence of vasopressin, water is absorbed across the apical plasma membrane of the collecting duct by AQP2 water channels. Water is absorbed across the basolateral plasma membrane by AQP3 water channels in the cortical and outer medullary collecting duct, and by both AQP3 and AQP4 water channels in the inner medullary collecting duct (IMCD). Urea is concentrated within the collecting duct lumen (by water absorption) until it reaches the terminal IMCD where it is absorbed by the UT-A1 and UT-A3 urea transporters. According to the passive mechanism hypothesis (see text), the fluid which enters the thin ascending limb from the contiguous thin descending limb has a higher NaCl and a lower urea concentration than the inner medullary interstitium, resulting in passive NaCl absorption and dilution of the fluid within the thin ascending limb. Also shown are 2 active urea transport pathways: a Na^+-urea counter-transporter is expressed in the terminal IMCD of normal rats and is upregulated by water diuresis[115]; a Na^+-urea co-transporter is expressed in the initial IMCD of hypercalcemic rats or rats fed a low-protein diet but not from rats fed a normal protein diet[423,118,358] (Abbreviations: AQP: aquaporin; UT: urea transporter).

Psammomys obesus, a desert rodent, feeds on halophilic plants which provide water along with large quantities of NaCl. In these animals, tubular fluid flow rate decreases by 1.7-fold along the descending limb, while osmotic pressure increases four-fold.[37,78] Water removal accounts for 40% of the increase and solute addition accounts for 60% under moderate NaCl-loading conditions.[37] Unlike the rat, NaCl is the principal solute added to descending limb fluid[37]; urea is added but is much less important than in the rat. In *Psammomys* which are producing more highly concentrated urine (although still less concentrated than can be achieved by the intact animal), NaCl addition accounts for nearly 80% of the rise in osmolality.[37]

Thin Ascending Limb

The thin ascending limb (Table 43.3) has an extremely low osmotic water permeability in all species studied,[42,49,79,80] and no aquaporin proteins have been detected (reviewed in [81]). Although the thin ascending limb has a urea permeability that is lower than its NaCl permeability,[57,63,79,82] it is significantly higher than the value that mathematical models indicate is required for the effective operation of the hypothesized passive mechanism (*vide infra*). While this is true in all species, it is especially true in chinchilla.[52,57]

The thin ascending limb has a very low level of Na^+/K^+-ATPase activity[67,68] that would not support a significant rate of active sodium transport.[83] However, some *in vivo* studies have found evidence for active sodium transport in thin ascending limbs.[72,77] The thin ascending limb has a high passive NaCl permeability.[57,63,79,80,82] Chloride transport occurs transcellularly via the ClC-K1 chloride channel, which is present in both the apical and basolateral plasma membranes.[84] Vasopressin increases chloride transport in thin ascending limbs,[85] and water deprivation increases the mRNA abundance of ClC-K1.[86] Transgenic mice lacking the ClC-K1 transporter were found to have greatly

reduced urine concentrating capability, which was attributed to defective chloride transport in the thin ascending limb.[87] Sodium transport is thought to occur paracellularly, since no apical plasma membrane sodium transport pathway has been demonstrated.[88,89]

When rabbit thin ascending limbs are perfused *in vitro* with concentration gradients of NaCl and urea that simulate *in vivo* conditions (NaCl gradient from lumen-to-bath and a urea gradient from bath-to-lumen), they are able to dilute their luminal fluid by purely passive means. Perfusing rabbit thin ascending limbs *in vitro* with solutions whose osmolality is increased from 290 to 600 mOsm/kg H_2O by adding NaCl to the perfusate and urea to the bath (to mimic the higher concentration of NaCl in the tubule lumen and the higher urea concentration in the medullary interstitium) reduces collected fluid osmolality to 70% of perfusate osmolality, suggesting that it may be possible to dilute the luminal fluid within thin ascending limbs without active transport *in vivo*.[80]

Heterogeneity in Thin Limbs of Long Loops

Pannabecker et al.[18] investigated inner medullary functional structure in Munich-Wistar rats by means of computer-assisted three-dimensional reconstructions of cross-sections in which tubules were identified and labeled by direct immunofluorescence of antibodies raised against specific transport proteins. The reconstructions indicate that thin descending limbs of Henle's loops that have bends within the first millimeter below the outer–inner medullary boundary lack the water transporter AQP1. Thin descending limbs of loops that have bends beyond the first millimeter express AQP1 for about the first 40% of their length below the outer–inner medullary boundary, but beyond that point lack AQP1 expression. Expression of ClC-K1 chloride channels begins abruptly with a prebend segment of length ~165 μm, and ClC-K1 expression continues uniformly along the entire length of thin ascending limbs. Co-localization of AQP1 and ClC-K1 was not found in any loop of Henle segment. Preliminary sections show no evidence of expression of the urea transporters UT-A1, UT-A2 or UT-A4 in thin limbs below the first millimeter of the inner medulla.[54] These observations are generally consistent with expression patterns indicated in other immunocytochemical studies in rat.[43,90] However, Mejia and Wade[91] found in Sprague-Dawley rats that ~30% of thin descending limbs that reached deep into the papilla labeled for AQP1 (in Brattleboro rats, ~11%); and Wade et al.[90] found co-labeling of a UT-A urea transport protein and AQP1 in thin descending limbs in the base of the inner medulla of Brattleboro rats (these limbs may correspond to the longer population identified by Pannabecker et al.[18]).

Thick Ascending Limb

Both the medullary and cortical portions of the thick ascending limb (Table 43.3) have osmotic water permeabilities that are essentially zero, and neither subsegment expresses aquaporin proteins (reviewed in [81]). Thus, the primary mechanism for diluting the luminal fluid in thick ascending limbs is net absorption of solute, particularly NaCl. NaCl is actively absorbed by the Na^+-K^+-$2Cl^-$ co-transporter (NKCC2, BSC1) in the apical plasma membrane, and the sodium pump (Na^+/K^+-ATPase) in the basolateral plasma membrane. The thick ascending limb from short looped nephrons can lower the concentration of NaCl in the luminal fluid at loop bend from ~300 to ~117–40 mM at the cortico–medullary border,[92,93] while the cortical thick ascending limb can lower the concentration of NaCl to ~32 mM.[94] However, the medullary portion has the capacity to absorb more NaCl than the cortical portion, as evidenced by the higher Na^+/K^+-ATPase activity in the medullary thick ascending limb.[67,95] The regulation of NaCl absorption in the thick ascending limb is discussed in detail in Chapter 34.

Vasopressin increases NaCl absorption in medullary and cortical thick ascending limbs in mouse.[96,97] This response is consistent with vasopressin's role in urinary concentration, and suggests that vasopressin can increase or maintain concentrating ability by increasing NaCl absorption across thick ascending limbs. However, vasopressin does not increase NaCl absorption in human and canine, and only weakly stimulates absorption in rabbit medullary thick ascending limbs.[96]

Urea permeability in the medullary thick ascending limb is lower than in the cortical thick ascending limb.[98,99] In rat, the transition to a higher urea permeability occurs between the inner and outer stripe portions of the medullary thick ascending limb, while in rabbit it occurs between outer medulla and cortex.[98] Urea permeability in the thick ascending limb could permit dilution of tubular fluid by passive urea absorption or increase urea concentration in the thick ascending limb by secretion.

Cortical Collecting Duct

The cortical collecting duct has an extremely low osmotic water permeability (Table 4) in the absence of vasopressin.[100–102] Vasopressin significantly increases the osmotic water permeability by a factor of 10 to 100 in both rat[101,102] and rabbit.[100] Arachidonic acid metabolites, produced by cytochrome P450, inhibit vasopressin-stimulated osmotic water permeability by a post-cyclic AMP (cAMP) mechanism[103]; the mechanism by which vasopressin increases osmotic water permeability is discussed in detail in Chapter 41 on Water Channels.

The cortical collecting duct has a low urea permeability that is unaffected by vasopressin.[98,104] Thus, vasopressin-induced water absorption will increase the urea concentration within the lumen of the cortical collecting duct, and also the osmolality, provided that there is no significant net absorption of solutes.

The cortical collecting duct is the major site for aldosterone-mediated sodium absorption and potassium secretion.[105] Vasopressin also stimulates sodium absorption in the cortical collecting duct.[106] Sodium is actively absorbed via the epithelial sodium channel (ENaC) in the apical plasma membrane of principal cells,[107] and sodium absorption is responsible for the generation of a lumen-negative voltage.[105] Sodium exits the principal cell via Na^+/K^+-ATPase in the basolateral plasma membrane.[67,95] Chloride is transported by both paracellular and transcellular pathways. Chloride absorption is primarily passive in rabbit, although some evidence for chloride absorption against an electrochemical gradient exists.[108] Active chloride absorption occurs in rat, and is stimulated by vasopressin and inhibited by bradykinin.[109]

Outer Medullary Collecting Duct

Few permeability measurements exist for the rat outer medullary collecting duct (Table 43.4). In rabbit, the outer medullary collecting duct has a low osmotic water permeability which is increased 20- or 30-fold by vasopressin.[99,110] The urea permeability is low in the outer medullary collecting duct in both rat and rabbit.[98,99]

Inner Medullary Collecting Duct

The inner medullary collecting duct (IMCD) was originally divided into three subsegments: $IMCD_1$; $IMCD_2$; and $IMCD_3$.[111] Subsequent studies showed that the inner medullary collecting duct could generally be viewed as consisting of two morphologically and functionally distinct subsegments: the initial IMCD (corresponding to the $IMCD_1$) and the terminal IMCD (corresponding to the $IMCD_2$ and $IMCD_3$).[102,104,112,113] However, some recent studies have found functional differences between the $IMCD_2$ and $IMCD_3$.[114,115] Histologically, the rat initial IMCD (or $IMCD_1$) contains 90% principal cells and 10% intercalated cells[112]; the rat terminal IMCD (or $IMCD_2$ and $IMCD_3$) contains a unique cell type, the IMCD cell.[113] Most of the permeability values available for IMCD subsegments are from the rat (Table 43.5).

In the absence of vasopressin, the initial IMCD has a low osmotic water permeability which is increased 10- to 30-fold by vasopressin.[102,116,117] Urea permeability is low in the initial IMCD, and is unaffected by vasopressin.[102,104,114,116,118] The initial IMCD from normal rats does not show any active urea transport.[115,118,119]

The terminal IMCD has a higher basal (no vasopressin) osmotic water permeability than other portions of the collecting duct.[102,116,117] Vasopressin can rapidly increase osmotic water permeability by a factor of 10.[102,117] The terminal IMCD also has a higher basal urea permeability than other portions of the collecting duct.[102,104,114,116,120] Vasopressin and hypertonicity can each increase urea permeability by a factor of 4–6, and together they can increase urea permeability by a factor of 10.[102,116,119–121] Although early studies suggested a urea reflection coefficient of less than 1, more recent studies which re-measured the urea reflection coefficient and explicitly measured the dissipation of the imposed urea gradient, showed that the urea reflection coefficient equals 1.[50,122] The $IMCD_2$ subsegment from normal rats does not show any active urea transport.[115,118] However, active urea secretion, which is completely dependent upon luminal sodium, is present in the $IMCD_3$ from normal rats, suggesting that sodium absorption may be coupled to urea secretion.[115]

Sodium and chloride permeabilities are low in the terminal IMCD.[116,123,124] Micropuncture studies indicate substantial rates of NaCl absorption from the IMCD, but perfused tubule studies have been unable to detect it.[124–126]

Papillary Surface Epithelium

Only a few permeability coefficients have been measured across the papillary surface epithelium, and these have been measured only in rabbit (Table 43.5). The urea and osmotic water permeabilities are low and unaffected by vasopressin.[104,127] The basal chloride permeability is higher than that of the terminal IMCD, and is inhibited by vasopressin.[127] The apical membrane of the papillary surface epithelial cell, which faces the urinary space, expresses a $Na^+–K^+–Cl^-$ co-transporter that is stimulated by vasopressin and inhibited by bumetanide.[15] The basolateral membrane contains a potassium conductive pathway in rat and rabbit.[128,129]

GENERAL FEATURES OF URINARY CONCENTRATION AND DILUTION

Countercurrent Multiplication Hypothesis

Since the late 1950s, the countercurrent multiplication hypothesis has been the generally accepted explanation for the generation of the osmolality gradient along the cortico–medulary axis in both the outer and inner medullas.[130] This hypothesis holds that, at each

level of the medulla, a small osmolality difference between tubular fluid flows in ascending and descending limbs is multiplied by the countercurrent flow configuration to establish a large axial osmolality difference. The principle of countercurrent multiplication is illustrated in Figure 43.7. The loop shown in the figure panels may be identified with a short loop of Henle: the left channel is analogous to the descending limb, whereas the right channel is analogous to the thick ascending limb. The channels are separated by a water-impermeable barrier. Vertical arrows indicate flow down the left channel and flow up the right channel. Left-directed horizontal arrows indicate active transport of solute from the right channel to the left channel. The numbers within channels indicate local fluid osmolality. Successive panels represent the time course of the multiplication process.

Panel (a) of Figure 43.7 illustrates a loop with isosmolar fluid throughout. In panel (b), an active transport mechanism has pumped enough solute to establish a 20 mOsm/kg H_2O osmolality difference between the ascending and descending flows at each level. This small difference, transverse to the flow, is called the "single effect." Panel (c) illustrates the osmolality values after the fluid has advected (or carried) the solute half-way down the left channel and half-way up the right channel. In panel (d), the active transport mechanism has re-established a 20 mOsm/kg H_2O osmolality difference, and the luminal fluid near the bend of the loop has attained a higher osmolality than in panel (a). By successive iterations of this process, a progressively higher osmolality is attained at the loop bend, and a large osmolality difference is generated along the flow direction. This is illustrated in panel (e), where the osmolality at the loop bend is nearly 300 mOsm/kg H_2O above the osmolality of the fluid entering the loop. Thus, the "single effect" of a 20 mOsm/kg H_2O difference has been multiplied axially down the length of the loop by the process of countercurrent multiplication.

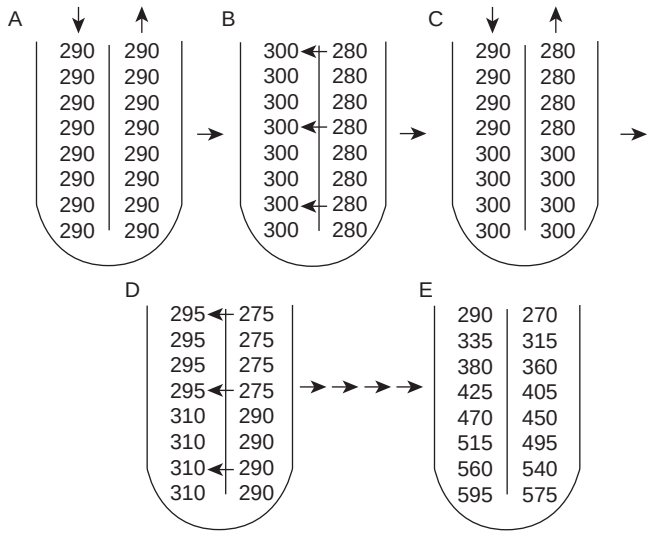

FIGURE 43.7 **Countercurrent multiplication of a single effect.** Panel (a): Process begins with isosmolar fluid throughout both channels. Panel (b): Active solute transport establishes a 20 mOsm/kg H_2O transverse gradient (single effect) across the boundary separating the channels. Panel (c): Fluid flows half-way down the descending limb and up the ascending limb. Panel (d): Active transport reestablishes a 20 mOsm/kg H_2O transverse gradient. Note that the luminal fluid near the bend of the loop achieves a higher osmolality than loop-bend fluid in panel (b). Panel (e): As the processes in (c) and (d) are repeated, the bend of the loop achieves a progressively higher osmolality so that the final axial osmotic gradient far exceeds the transverse 20 mOsm/kg H_2O gradient generated at any level.

In the outer medulla, countercurrent multiplication is believed to occur in the short loops of Henle by a process that is similar to that shown in Figure 43.7. The tubular fluid of the proximal tubule that enters the outer medulla is isotonic to plasma (about 290 mOsm/kg H_2O). That fluid is concentrated, as it passes through the pars recta and the thin desending limb, by osmotically driven water absorption; the absorption is driven by vigorous active transport of NaCl from the thick ascending limbs. At the bend of the loop of Henle, the tubular fluid osmolality attains an osmolality about twice that of blood plasma. Because the thick ascending limbs are nearly impermeable to water, its tubular fluid is diluted by NaCl absorption as it flows toward the cortex, so that the fluid emerging from this segment is hypoosmotic to blood plasma.

Countercurrent multiplication in the outer medulla, however, differs in important ways from the process illustrated in Figure 43.7. In some of the most completely studied mammals, the descending and ascending limbs do not abut one another[131]; therefore, solute is not directly transported from ascending limbs to descending limbs. Rather, NaCl is pumped from thick ascending limbs to the interstitium, raising the osmolality of the interstitial fluid and the blood flowing through the vasa recta and capillaries. The increased interstitial osmolality withdraws water from thin descending limbs, and some NaCl may diffuse into thin descending limbs, thus raising the osmolality of descending limb fluid. The NaCl absorbed from ascending limbs and the water absorbed from descending limbs is carried to the cortex by the vasa recta, which, somewhat like the loops of Henle, are arranged in a countercurrent configuration. Thus, a large axial osmolality difference, from the cortico–medullary boundary to the boundary of the inner and outer medulla, is established in the loops of Henle, the vasculature, and the interstitium.

In addition, Figure 43.7 does not represent the flow in the collecting ducts. Some of the water and solute in thick ascending limb tubular fluid delivered to the

cortex re-enters the outer medulla in the collecting ducts, and in the presence of vasopressin, sufficient water is absorbed from the collecting ducts, as a consequence of the hyperosmotic medullary interstitium, to bring collecting duct flow to near osmotic equilibrium with the surrounding interstitium. Thus, a large axial osmolality difference, similar to that in the thin descending limb, is established in collecting duct fluid.

Finally, the discrete, sequential process represented in Figure 43.7 does not arise under normal physiological conditions. Rather, the axial osmolality difference, or gradient, is sustained in near steady-state, much as indicated in panel (e), with a bend osmolality that is limited primarily by the rate of active transport, the diffusive back-leak of NaCl into the thick ascending limb, the length of the loop, the rate of water absorption from collecting duct flow, and the dissipative effects of the vasculature.

In recent years, some reasons have emerged for skepticism of the countercurrent multiplication hypothesis as the explanation for the axial osmolality gradient in the outer medulla. Several laboratories have reported evidence for the absence of AQP1 in significant portions of the terminal thin desending limbs of short loops of Henle.[43,90,132] Moreover, two modeling studies[55,133] have suggested that the osmotic load that is put on the concentrating mechanism in the outer medulla may be increased by water-permeable descending limbs, relative to water-impermeable limbs, and thus may reduce or eliminate the hypothesized concentration advantage of water absorption from descending limbs of short loops.

The axial osmolality gradient in the inner medulla has also been generally believed to be generated by the countercurrent multiplication of a small transverse osmolality difference, presumably between thin ascending and thin descending limbs. However, evidence for significant active transport from thin ascending limbs is lacking, and experiments indicate that the thin ascending limbs are highly permeable to both NaCl and urea. Thus, the inner medullary single effect must arise from a mechanism different from that found in the outer medulla. The roles of the vasculature and collecting duct are considered below; a more detailed treatment of countercurrent multiplication, and in particular, the concentrating mechanism of the inner medulla, is given in a subsequent section (*vide infra*).

Countercurrent Exchange

The descending and ascending vasa recta are arranged in a counter-flow configuration connected by a capillary plexus. Vasa recta are freely permeable to water, sodium, and urea, and achieve osmotic equilibration through a combination of water absorption and solute secretion.[134] Descending vasa recta gain solute and lose water, while ascending vasa recta lose solute and gain water. The exchange of solute and water between the descending and ascending vasa recta and the surrounding interstitium is called "countercurrent exchange."

Efficient countercurrent exchange is essential for producing concentrated urine, because hypotonic fluid carried into the medulla and hypertonic fluid carried away from the medulla both tend to dissipate the cortico−medullary gradient of countercurrent multiplication. Thus, to minimize wasted work, fluid flowing through the vasa recta must achieve near osmotic equilibrium with the surrounding interstitium at each medullary level, and fluid entering the cortex from the ascending vasa recta must have an osmolality close to that of blood plasma. Conditions which decrease medullary blood flow, such as volume depletion, improve the efficiency of countercurrent exchange and urine concentrating ability by allowing more time for blood in the ascending vasa recta to lose solute and achieve osmotic equilibration.[134] Conversely, conditions which increase medullary blood flow, such as osmotic diuresis, impair the efficiency of countercurrent exchange and decrease urine concentrating ability.[134] For a detailed treatment of countercurrent exchange, see Chapter 24.

Role of the Collecting Duct

The collecting duct, under the control of vasopressin and other factors, is the nephron segment responsible for final control of water excretion. Whereas the osmolality gradient along the cortico−medullary axis, in both the outer and inner medulla, presumably arises from mechanisms that principally involve participation of the loops of Henle, and countercurrent exchange in the vasa recta minimizes the dissipative effect of vascular flow, the excretion of water requires another structural component, the collecting duct system, which starts in the cortex and ends at the papillary tip. In the absence of vasopressin, the cortical, outer medullary, and initial inner medullary portions of the collecting duct are nearly water-impermeable. (The terminal IMCD has a moderate water-permeability even in the absence of vasopressin (*vide supra*).) Since the fluid that leaves the thick ascending limb and enters the cortical collecting duct is dilute relative to plasma, excretion of dilute urine only requires that not much water be absorbed nor much solute be secreted along the collecting duct.

In the presence of vasopressin, the entire collecting duct becomes highly water-permeable. This process

takes place in the following way. Plasma osmolality increases when a person or an animal becomes water depleted. Osmoreceptors in the hypothalamus, which can sense an increase of only 2 mOsm/kg H_2O, stimulate vasopressin secretion from the posterior pituitary. Vasopressin binds to V_2-receptors in the basolateral plasma membrane of principal and IMCD cells in the collecting duct, stimulates adenylyl cyclase to produce cAMP, activates protein kinase A (PKA), phosphorylates aquaporin-2 (AQP2) at serines 256, 261, 264, and 269, inserts AQP2 water channels into the apical plasma membrane, and increases water absorption across the collecting duct ([135–138] and reviewed in [81]). This regulated trafficking of AQP2 between subapical vesicles and the apical plasma membrane is the major mechanism for acute regulation of water absorption by vasopressin (reviewed in [81]). Wade and colleagues originally proposed the "membrane shuttle hypothesis," which proposes that water channels are stored in vesicles and inserted exocytically into the apical plasma membrane in response to vasopressin.[139] Since the cloning of AQP2, the shuttle hypothesis has been proven experimentally in rat inner medulla (reviewed in [81]). Subsequent studies have elucidated several signal transduction pathways that are involved in regulating AQP2 trafficking (insertion and retrieval of AQP2), the role of vesicle targeting proteins (SNAP/SNARE system), and the cytoskeleton (reviewed in [81]); these processes are discussed in more detail in Chapter 41.

Vasopressin-induced water permeability allows water to be absorbed across the collecting ducts at a sufficiently high rate for collecting duct tubular fluid to attain near osmotic equilibration with the hyperosmotic medullary interstitium; the absorbed water is returned to the systemic circulation via the ascending vasa recta. The majority of water is absorbed from collecting ducts in the cortex and outer medulla. Although the inner medulla has a higher osmolality than the outer medulla, its role in absorbing water from the collecting duct is important only when maximal water conservation is required. More water is actually absorbed across the IMCD during diuresis than antidiuresis, owing to the large transepithelial osmolality difference.[140]

URINE CONCENTRATING MECHANISM: HISTORY AND THEORY

Overview

The conceptual history of the urine concentrating mechanism may be divided into three periods. The first period, extending from 1942 through 1971, was inaugurated by the publication of a study by Kuhn and Ryffel,[141] who proposed that concentrated urine is produced by the countercurrent multiplication of a "single effect," and who constructed a working apparatus that exemplified the principles of countercurrent multiplication. During this first period, the theory of the countercurrent multiplication hypothesis was developed further, and experimental evidence accumulated that supported the hypothesis as the explanation for the concentrating mechanism of the outer medulla. In particular, active transport of NaCl from thick ascending limbs was identified as the source of the outer medullary single effect.[94,142]

The second period of conceptual history, extending from 1972 through 1992, was inaugurated by the simultaneous publication, by Kokko and Rector and by Stephenson, of papers proposing that a "passive mechanism" provides the single effect for countercurrent multiplication in the inner medulla.[8,9] According to the passive mechanism hypothesis, a net solute efflux from thin ascending limbs results from favorable transepithelial NaCl and urea gradients; these gradients arise from the separation of NaCl and urea, which is largely driven by the outer medullary concentrating mechanism. Although initially much experimental evidence appeared to support the passive mechanism, findings from many subsequent studies are difficult to reconcile with this hypothesis.[22,143,144] Moreover, mathematical models incorporating measured transepithelial permeabilities failed to predict a significant inner medullary concentrating effect.[52,145,146] The discrepancy between the consistently negative results from mathematical modeling studies and the very effective inner medullary concentrating effect has persisted through more than three decades. The discrepancy has helped to stimulate research on the transport properties of the renal tubules of the inner medulla and the formulation of several highly sophisticated mathematical models (notably,[147]), but no model study has resolved the discrepancy to the general satisfaction of experimentalists and modelers.

In the early 1990s, new hypotheses for the inner medullary concentrating mechanism began to receive serious consideration, and a third period of conceptual thought may be considered to have begun in 1993: in that year, Knepper and colleagues proposed a key role for the peristalsis of the papilla,[143,148] and in 1994 Jen and Stephenson[149] examined the principle of "externally driven" countercurrent multiplication, arising, e.g., by the net production of osmotically active particles in the interstitium. At about the same time, perfused tubule studies in chinchilla, which can produce very highly concentrated urine, provided evidence that the passive mechanism, as originally proposed, cannot explain the inner medullary concentrating mechanism.[57] Recent studies have sought

to further develop hypotheses involving peristalsis,[150] the potential generation of osmotically active particles, especially lactate,[151,152] and the role of complex inner medullary anatomy and detailed transporter localization.[21,54,153] In 2004, evidence suggesting an absence of significant urea transport proteins in loops of Henle reaching deep into the medulla led to a reconsideration of hypotheses related to the passive mechanism.[54]

Countercurrent Multiplication Hypothesis

In 1942, Kuhn and Ryffel proposed that urine is concentrated by means of multiplication (or augmentation) of a single effect ("Vervielfältigung des Einzeleffektes").[141] More precisely, they suggested that a small osmotic pressure difference between flows in parallel renal tubules (the single effect) was multiplied by means of the countercurrent principle ("Gegenstromprinzip"), resulting in a large increase in osmotic pressure along the cortico−medullary axis (*vide supra*: Figure 43.7 and accompanying discussion). Kuhn and Ryffel, however, made no specific conjectures regarding which tubules or what transport properties were involved. To test their hypothesis, Kuhn and Ryffel constructed an apparatus that, by embodying the countercurrent principle and by employing phenol and sucrose solutions separated by selectively permeable membranes, was able to increase the concentration of the sucrose solution by a factor of 3.5. This apparatus suggested that three fundamental components are needed for a physiologically plausible mechanism for generating concentrated urine: (1) countercurrent flow; (2) a source of energy to sustain a single effect (in this case, potential energy in the form of the differing solutions); and (3) specific membrane permeability characteristics.

In a 1951 study, Hargitay and Kuhn[154] proposed the basic framework for the modern conception of the urine concentrating mechanism. They hypothesized that the loop of Henle is a biological realization of a hairpin counterflow system, that the loops of Henle would generate a cortico−medullary osmolality gradient, and that final urine concentration would be achieved by the osmotic withdrawal of water from collecting ducts. Their study, which included both a working apparatus and a mathematical model, confirmed that countercurrent multiplication could generate a significant axial concentration gradient. However, their apparatus relied on the transport of water across the separating membrane, and they employed a mechanical pressure as a driving force to sustain the single effect. The pressure required for a significant axial gradient (estimated at 550 mmHg) was judged by the authors to far exceed a pressure likely to be found *in vivo* (~120 mmHg). They proposed, as an alternative, a single effect arising from water transport driven by a process of electro-osmosis ("Electroosmose"), which was hypothesized to arise from metabolic processes in epithelial cells. In 1959, a mathematical analysis by Kuhn and Ramel showed that active NaCl transport from ascending limbs could serve to provide the required single effect.[155]

The countercurrent multiplier hypothesis was bolstered by a 1951 study in which Wirz, Hargitay, and Kuhn used slices of renal tissue from hydropenic rats to demonstrate an osmotic pressure gradient, starting at approximately the cortico−medullary boundary, and increasing along the cortico−medullary axis to the papillary tip. In subsequent experimental studies, active transport of NaCl from thick ascending limbs was established as the driving force required to sustain the transepithelial osmolality difference needed for countercurrent multiplication in the outer medulla,[94,142] and the osmotic absorption of water from collecting ducts into the hypertonic interstitium was established as the ultimate process by which collecting duct fluid is concentrated in antidiuresis.[156] However, investigation of the inner medullary renal tubules revealed no active transport process that could generate a significant transepithelial osmolality difference.[63,130]

Concentrating Mechanism of the Outer Medulla

In the presence of vasopressin, the outer medullary concentrating mechanism is believed to operate as follows. Transepithelial active transport of NaCl, from the tubular fluid of thick ascending limbs and into the surrounding interstitium, raises the osmolality of interstitial fluid and promotes the osmotic absorption of water from the tubular fluid of nearby descending limbs and collecting ducts. Because of the absorption of fluid from descending limbs, the fluid delivered to the ascending limbs has a high NaCl concentration that favors the transepithelial transport of NaCl from ascending limb fluid. (There may also be some diffusion of NaCl into descending limb fluid.) NaCl transport dilutes the tubular fluid of thick ascending limbs, so that at each medullary level the fluid osmolality is less than that in the other tubules and in the vessels, and so that the fluid delivered to the cortex is dilute relative to blood plasma. The ascending limb fluid that enters the cortex is further diluted by active NaCl transport from cortical thick ascending limbs, so that its osmolality is less than the osmolality of blood plasma. In cortical collecting ducts, which are water-permeable in the presence of vasopressin, sufficient water is absorbed to return the collecting duct tubular fluid to isotonicity with blood plasma. This water absorption greatly reduces the load that is placed on

the concentrating mechanism by the fluid that re-enters the medulla. In the absence of vasopressin, the collecting duct system, both in the cortex and outer medulla, is much less water-permeable, and even though some water is absorbed due to the very large osmotic pressure gradient, fluid that is dilute relative to plasma is delivered by the collecting ducts to the border of the outer and inner medulla.

This modern conceptual formulation of the outer medullary concentrating mechanism (which is very similar to the proposal of Hargitay and Kuhn as modified by Kuhn and Ramel[154,155]) is supported by recent mathematical modeling studies using parameters compatible with micropuncture and perfused tubule experiments.[52,133,157–160] In particular, the osmotic gradients in the outer medulla predicted by simulations are consistent with the gradients reported in tissue slice experiments, where osmolality is increased by a factor of 2–3.[37,161]

Mass Balance in the Renal Medulla

For the outer medullary gradient to be sustained in a steady-state, the water and solute flows in the tubules and vessels of the outer medulla and, therefore, the spatial distribution of water and solute, must remain nearly fixed (provided there are no significant metabolic solute sources or sinks). Thus, for any transverse slice of the medulla, say of a thickness extending from location X_1 to X_2, the directed sum of water flow rates in all tubules and vessels at X_1 must equal that at level X_2, and the directed sum of solute flow rates in all tubules and vessels at level X_1 must equal that at level X_2. This is the principle of steady-state mass balance (for an explicit mathematical formulation see reference [7]).

Global mass balance for the outer medulla is thought to be preserved as follows (the relatively small effects of long looped nephrons, of vasa recta reaching into the inner medulla, and of solutes other than NaCl are ignored here for simplicity). At the cortico–medullary boundary, the water flowing in ascending vasa recta exceeds that flowing in descending vasa recta, owing to water absorption from thin descending limbs and collecting ducts. In contrast, the water flow emerging from thick ascending limbs is significantly reduced relative to the flow entering descending limbs at the cortico–medullary boundary. The directed sum of these flows, plus flow entering collecting ducts at the cortico–medullary boundary results in a small net flow from the cortex into the outer medulla that nearly equals net water flow at the outer–inner medullary boundary.

Similarly, solute flows must be balanced. At the cortico–medullary boundary, the solute emerging from ascending vasa recta exceeds that flowing in descending vasa recta, owing to NaCl absorption from thick ascending limbs. In contrast, the solute flow emerging from thick ascending limbs is reduced (relative to flow entering descending limbs) by a larger fraction than the thick ascending limb fluid flow. The directed sum of these solute flows at the cortico–medullary boundary, plus solute flow entering collecting ducts at that boundary, results in a small net solute flow nearly equal to net solute flow at the inner–outer medullary boundary.

The ratio of NaCl to water in net flow across the cortico–medullary boundary, and the ratio of NaCl to water in collecting duct flow at the inner–outer medullary boundary, both depend on whether the animal is in a diuretic or antidiuretic state. In either case, a greater fraction of loop of Henle solute flow is absorbed, relative to water flow, in the outer medulla and, consequently, a greater fraction of water is delivered to the cortex, relative to solute. Consequently, dilute fluid is delivered by the thick ascending limbs to the cortex, and this fluid is further diluted by NaCl transport from the cortical thick ascending limb.

In diuresis, little water is absorbed from the cortical collecting ducts. Consequently, the net fluid absorbed into the cortical circulation (taking into account NaCl absorption from cortical thick ascending limbs) is concentrated relative to blood plasma, and the fluid re-entering the outer medulla in collecting ducts remains dilute relative to blood plasma. The low water permeability of the outer medullary collecting duct in diuresis will prevent any significant dilution of vasa recta flow, and thus prevent any significant reduction in the concentrating capacity of the countercurrent mechanism. Thus, combined with slightly concentrated flow from ascending vasa recta, the ultimate effect of fluid absorbed in the cortex will be to raise the osmolality of the systemic circulation. Moreover, owing to the dominating effect of hypotonic fluid flowing from the cortical collecting ducts into the outer medullary collecting ducts, the net fluid flow from the cortex to the outer medulla will be dilute relative to systemic plasma, and as a consequence of mass balance, the net fluid flow across the inner–outer medullary boundary will be dilute relative to blood plasma.

In antidiuresis, much water is absorbed from the water-permeable cortical collecting ducts. Consequently, the net fluid absorbed in the cortex, from fluid entering the cortex via the thick ascending limbs, is dilute relative to plasma, and its diluting effect on the cortex outweighs the concentrating effect of slightly hypertonic ascending vasa recta flow. Collecting duct fluid entering the outer medulla is isotonic to blood plasma, and relative to the case of diuresis, reduced in flow rate, so that the fluid absorbed from the now-permeable outer medullary collecting duct

does not significantly reduce the concentrating capacity of the countercurrent mechanism. Thus, the ultimate effect of dilute fluid absorbed from the cortical collecting duct is to lower the osmolality of the systemic circulation. Moreover, owing to the dominating effect of dilute fluid emerging from the outer medullary thick ascending limbs into the cortex, the net flow from the cortex to the outer medulla will be concentrated relative to systemic blood plasma, and as a consequence of mass balance, the net flow of collecting duct fluid across the inner–outer medullary boundary will be concentrated relative to blood plasma.

Because the inner medullary concentrating effect remains elusive, and because the net generation of osmotically active molecules has been suggested as a possible source of the single effect for the inner medulla,[149,151,162] the role of the inner medullary concentrating mechanism has been ignored in our description of mass balance. However, a mass balance analysis similar to that given above for the outer medulla would apply to the inner medulla separately, and thus also to the whole medulla, according to most hypotheses for the inner medullary concentrating mechanism. (In the presence of oscillations in tubular flow mediated by the tubuloglomerular feedback mechanism[163] or in the presence of peristalsis of the papilla,[164] mass balance would have to be reformulated for time-averaged flows.) In any case, the overall effect of mass balance in the renal medulla, in diuresis, is that systemic blood plasma is concentrated by the production of urine that is dilute relative to plasma; in antidiuresis, blood plasma is diluted by the production of urine that is concentrated relative to plasma.

The Passive Mechanism Hypothesis for the Inner Medulla

Although active NaCl transport from thick ascending limbs was identified as the fundamental source of the outer medullary concentrating mechanism, isolated perfused tubule experiments in rabbits demonstrated that the thin ascending limb had no significant active NaCl transport,[63,94] but instead had relatively high permeabilities to sodium and urea, while being impermeable to water.[80] The inner medullary thin descending limb in rabbit, in contrast, was found to be highly water-permeable, but to have low sodium and urea permeabilities.[60,64] Moreover, evidence from some species showed that urea tended to accumulate in the inner medulla, with concentrations similar to those of NaCl,[6] and it had long been known that urea administration enhances maximum urine concentration in protein-deprived rats and humans.[165,166] Several models were published that sought to explain the inner medullary concentrating mechanism,[167–171] but they failed to gain general acceptance.

In 1972, independent papers by Kokko and Rector and by Stephenson (appearing in the same volume of *Kidney International*) proposed that the concentrating effect in the inner medulla arises from a "passive mechanism".[8,9] The key components of the passive mechanism are represented in Figure 43.6. Active absorption of NaCl from the thick ascending limb, and the subsequent absorption of water from the cortical and outer medullary collecting ducts work together to increase the urea concentration of collecting duct fluid. Urea diffuses down its transepithelial concentration gradient from the highly urea-permeable terminal IMCD into the inner medullary interstitium; urea is trapped in the inner medulla by countercurrent exchange in the vasa recta (*vide supra*). The fluid entering the thin ascending limb has a high NaCl concentration relative to urea, and the thin ascending limb is hypothesized to have a high NaCl permeability relative to urea. In addition, due to accumulation of urea in the interstitium, the NaCl concentration in the thin ascending limb exceeds the NaCl concentration in the interstitium, and consequently NaCl diffuses down its concentration gradient into the interstitium. If the thin ascending limb has sufficiently low urea permeability, the rate of NaCl efflux from the ascending limb will exceed the rate of urea influx, resulting in the dilution of thin ascending limb fluid, and the flow of relatively dilute fluid up the thin ascending limb at each medullary level and into the thick ascending limb. Thus, dilute fluid is removed from the inner medulla, and mass balance requires that the osmolality of the inner medulla be progressively elevated along the tubules of the inner medulla. The elevated osmolality will draw water from the thin descending limbs, thus raising the NaCl concentration of the descending limb flow that enters thin ascending limbs. In addition, the elevated osmolality of the inner medulla will draw water from the water-permeable IMCD, raising the concentration of urea in collecting duct flow; accumulation of NaCl in the interstitium will tend to sustain a transepithelial urea concentration gradient favorable to urea absorption from the terminal IMCD.

Several matters are worthy of note. First, this process, described above in step-wise fashion, should be thought of as a continuous, steady-state process. Second, although the mechanism is characterized as "passive," it depends on the separation of NaCl and urea that is sustained by the active absorption of NaCl by thick ascending limbs. The separated high concentration flows of NaCl (in the loop of Henle) and of urea (in the collecting duct) constitute a source of potential energy that is used to effect a net transport of solute from the thin ascending limb. Thus, the laws of

thermodynamics are not violated. Third, the description above speaks rather loosely of NaCl and urea as solutes having equal standing, but the atoms of NaCl are nearly completely dissociated, so that each NaCl molecule has nearly twice the osmotic effect of each urea molecule. This distinction must be represented in formal mathematical descriptions. Fourth, the passive mechanism hypothesis is very similar to the concentrating mechanism of the outer medulla, inasmuch as it depends on net solute absorption from the thin ascending limb to dilute thin ascending limb fluid and raise the osmolality of adjacent flows and structures. Finally, the concentrating effect is balanced, as in the outer medulla, by the dissipative effects of vascular flows, and by the production of a small amount of highly concentrated urine. These dissipative effects limit the achievable urine osmolality.

The passive mechanism hypothesis, as described above, closely follows the Kokko and Rector formulation,[8] which made use of key ideas set forth by Kokko in a largely experimental study.[60] Kokko and Rector acknowledged Niesel and Rosenbleck[169] for the proposal that urea absorbed from the IMCD contributes to the inner medullary osmolality gradient. Kokko and Rector presented the passive mechanism hypothesis conceptually, and although it was accompanied by a plausible set of solute fluxes, concentrations, and fluid flow rates that are consistent with the requirements of mass balance, their presentation did not include a mathematical treatment, and it did not demonstrate that measured loop of Henle permeabilities were consistent with the hypothesis. Stephenson's presentation of the passive hypothesis[9] included a more mathematical treatment, and it introduced the highly influential central core assumption (*vide infra*), but it also did not contain a mathematical reconciliation of tubular transport properties with the hypothesis.

The crucial test needed to confirm the passive mechanism hypothesis was an adequate mathematical representation of all the major components of the hypothesized mechanism, including tubular and vascular flows, transepithelial transport, tubular and vascular interactions, and medullary anatomy. The mathematical representation was needed to show that the magnitudes and distributions of the flow rates, transport rates, interactions, and structures, could produce a medullary gradient consistent with tissue slice experiments and measured urine osmolalities.

The Central Core Assumption

In the same paper that set forth the passive mechanism hypothesis,[9] Stephenson introduced the central core assumption, in which the interstitium and the vasculature are merged into a single compartment through which the renal tubules interact. Stephenson argued that if the vasa recta were sufficiently permeable to solutes and water, the vasa recta would serve as a nearly perfect countercurrent exchanger, in nearly complete osmotic equilibrium with each other, and with the interstitium, at each medullary level. In such a case, a very substantial simplification in conceptual and mathematical analysis could be obtained: the central core could be treated very much as an additional species of tubule, but serving a special role as the medium through which other tubules interact. Using the central core assumption, Stephenson was able to derive simplified mathematical expressions that not only aided the model analysis of the passive mechanism, but which were also general enough to permit extensive analysis in terms of fundamental quantities.[9,172–175]

The central core assumption, as illustrated by Stephenson, is represented in Figure 43.8. The upper panel depicts the interaction of the renal tubules with the central core. The lower panels show that the central core may be conceptualized as a single tubule through which the other tubules interact. The central core may be considered to carry, from the medulla to the cortex, the net water and solutes absorbed from the tubules.

The central core assumption has been examined in several theoretical studies,[176–178] all of which concluded that the assumption is a good approximation provided that vasa recta permeabilities are sufficiently high; experiments on vasa recta have tended to confirm the high permeabilities that are required for nearly ideal countercurrent exchange (see Chapter 24). The central core assumption has been used in a number of mathematical models and computer simulations.[10–12,17,23,52,54,55,159,178–181] However, models based on the central core assumption cannot incorporate the effects of the radial organization of medullary structures with respect to the vascular bundles in the outer medulla or with respect to the collecting duct clusters in the inner medulla, because that organization is likely to result in differing solute concentrations in the various interstitial spaces, tubules, and vessels as a function of their positions.[12,147]

Computer Simulations

Computer simulations of the urine concentrating mechanism are based on detailed mathematical models; the models consist of differential equations and algebraic relations that embody transepithelial transport processes and the requirements of water and solute mass balance. The degree of sophistication of these models has varied substantially in the number of molecular species represented, the degree of detail in

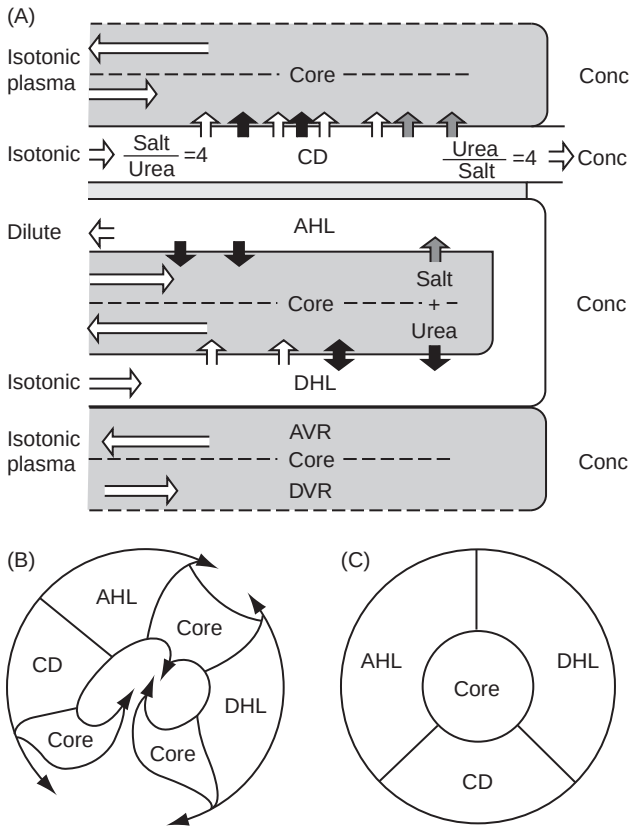

FIGURE 43.8 **Schematic representation of central core assumption, in which the interstitium and vasa recta (AVR, DVR) are merged into a single compartment (Core).** Upper panel (a) shows interaction of tubules with Core. Vertical arrows indicate transepithelial fluxes of NaCl (black), urea (hatched), and water (white); horizontal arrows indicate relative fluid flow. Water is absorbed from descending limb (DHL) into Core, urea enters DHL from Core, and NaCl may move in either direction. NaCl is absorbed from ascending limb (AHL) into Core, while urea enters AHL. Water, NaCl, and urea are absorbed from collecting duct (CD) into Core; as a result of differential absorption, salt/urea concentration reverses. Panel (b) shows Core from (a) being consolidated into a final cross-section (c), in which a single Core compartment interacts with AHL, DHL, and CD. *(Reproduced with permission, from reference [9].)*

the formulation of epithelial transport, the numbers of loops of Henle and collecting ducts, the representation of the vasculature, and the representation of three-dimensional connectivity. Because the mathematical models involve a large number of nonlinear equations, explicit solutions in terms of elementary functions cannot be obtained, and approximate solutions must be found by the methods of numerical analysis. Owing to the very large permeabilities measured in some renal tubules, and to orders-of-magnitude changes in the water and solute flow rates along the nephron, model solutions are difficult to approximate, and consequently a large amount of effort has been expended in the development of suitable numerical methods (see, e.g.,[20,133,153,157,182–186]). For comprehensive reviews of models and simulations of the concentrating mechanism, including substantial mathematical detail, see[187,188].

The passive mechanism hypothesis was developed at about the same time that it was becoming practical for large-scale simulations to be conducted on digital computers. Indeed, a computer simulation by Stewart and collaborators[189,190] appeared in the same issue of *Kidney International* that contained the papers that set forth the passive mechanism hypothesis.[8,9] In the absence of active NaCl transport from thin ascending limbs, a significant inner medullary osmolality gradient was generated when loop urea permeabilities were set to 0.1×10^{-5} cm/s. But the gradient was greatly diminished when thin descending limb urea permeability was increased to 0.3×10^{-5} cm/s, a small value compared to measurements in all species examined (see Table 43.2). Thus, the addition of a small amount of urea to thin descending limb fluid resulted in a marked decrease in the inner medullary gradient. Moreover, the authors reported that: "Computer simulation confirmed that low sodium or high urea permeability in ascending limb or high sodium or urea permeability in descending limb, singly or in combination, virtually abolished the osmotic gradient in the inner medulla." These results were difficult to reconcile with experiments that had shown significant net urea addition to both thin descending and ascending limbs in the hamster.[76]

This early simulation immediately cast doubt on the passive mechanism hypothesis, and it reported a result that was confirmed in many subsequent simulations: the addition of urea to the loops of Henle reaching into the inner medulla tends to dissipate the transepithelial NaCl and urea gradients that are required for the successful operation of the passive mechanism (see, e.g.,[145,146,179,180,191,192]). Thus, for example, if the thin ascending limb is significantly urea-permeable, diffusion of urea from the interstitium into thin ascending limb fluid counterbalances the diluting effect of the diffusion of NaCl from ascending limb fluid into the interstitium. Consequently, fluid in the ascending limb tends to osmotic equilibrium with respect to surrounding interstitial fluid. Because thin ascending limb fluid is not dilute relative to fluid in tubules and vessels at the same level, there is no inner medullary single effect to be multiplied by means of the countercurrent flow configuration.

Figure 43.9, based on data from a simulation published in 1996,[52] shows results that are representative of most simulation studies. Medullary osmolality and concentrations of electrolytes and urea are given as flow-weighted averages, taken across all tubules at each medullary level. Figure 43.9 has been drawn so that it may be easily compared with Figure 43.5.

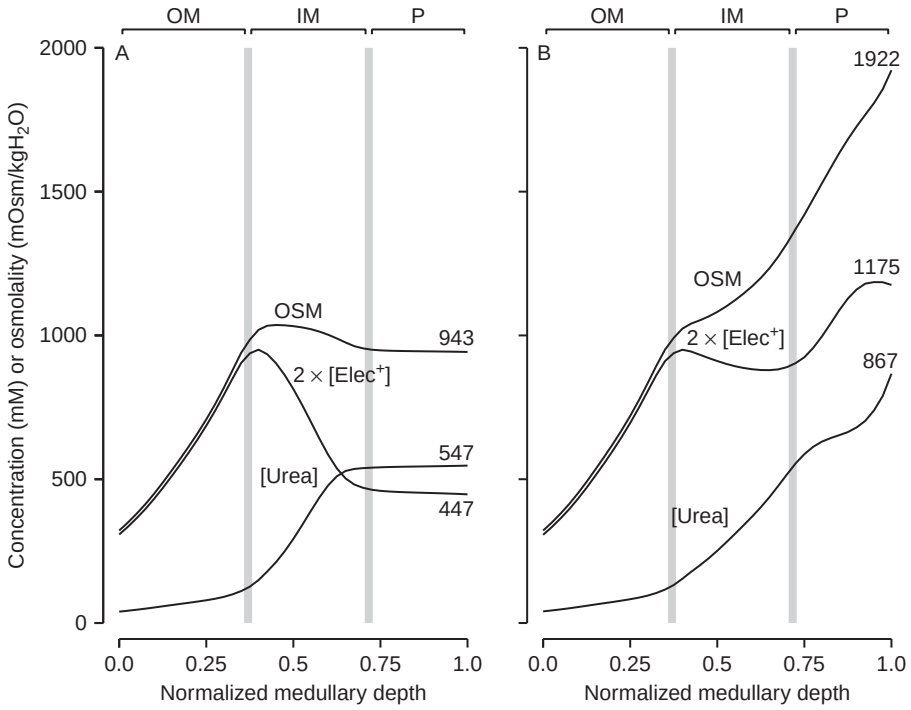

FIGURE 43.9 **Concentration and osmolality profiles as a function of medullary depth from computer simulation by Layton et al.**[52] Profiles represent flow-weighted averages across all tubules. Cation concentration [$Elec^+$] arose from Na^+, except in collecting ducts, where both Na^+ and K^+ were represented. Urine values are given at right of each panel. Profiles in panel (a) were computed from loop of Henle permeabilities based on measurements in chinchilla ([57]; see Tables 43.2 and 43.3). The non-increasing osmolality profile in the inner medulla is similar to that computed with lower permeability values from rabbit, rat, and hamster in a number of model studies (e.g., references[191,179,180,145,146]). Profiles in panel (b) were obtained when urea permeability ($\times 10^{-5}$ cm/s) was reduced from 16.8 to 1 in inner medullary descending limbs and from 170 to 1 in thin ascending limbs. Resulting profiles compare favorably with data from rat (cf. Figure 43.4), but despite greatly reduced urea permeabilities, model urine osmolality falls far short of 7600 mOsm/kg H_2O, the maximum concentrating capability of chinchilla.[1] Note that while tubular electrolytes (principally Na^+ and accompanying anions) account for most of the simulated osmolality in the outer medulla (in both panels (a) and (b)), the experimental results in Figure 43.4 show a large osmotic gap; this gap is mostly accounted for by large intracellular concentrations of K^+. *(The profiles in panels (a) and (b) were computed from data generated for cases designated V and I, respectively, in reference [52].)*

The simulation used loop and collecting duct distributions that are similar to those displayed in Figure 43.5, and the flow-weighted profiles in Figure 43.9 are roughly comparable to the tissue-slice profiles in Figure 43.5, although it must be kept in mind that Figure 43.5 includes the effects of intracellular fluid.

Panel (a) in Figure 43.9 shows results obtained using NaCl and urea permeabilities based on values measured in inner medullary thin descending and ascending limbs of chinchilla (see Tables 43.2 and 43.3). Owing to the significant entry of urea into descending and ascending limbs, no inner medullary gradient is generated. Moreover, the profile labeled as $2 \times [Elec^+]$, arising mostly from sodium and its anions, fails to show an exponential rise as it does in Figure 43.5 and in electron microprobe experiments.[106] Parameter studies showed that loop urea permeabilities and descending limb NaCl permeability must all be reduced to the range of $1-5 \times 10^{-5}$ cm/s to elicit a significant concentrating effect.[52]

Panel (b) in Figure 43.9 shows profiles obtained when loop urea permeability and descending limb NaCl permeability were reduced to 1×10^{-287} cm/s. Ascending limb NaCl permeability remains high, 294×10^{-5} cm/s. With these parameters, simulation profiles are remarkably similar to those reported for the rat in Figure 43.5. However, the greatly reduced permeabilities used for urea and NaCl in descending limbs, and for urea in ascending limbs, are much smaller than those measured in rat (see Tables 43.2 and 43.3), and the urine osmolality obtained, 1922 mOsm/kg H_2O, is far smaller than the maximum urine osmolality obtained in chinchilla, 7600 mOsm/kg H_2O.[1,4,5]

In recent years, mathematical simulations of the urine concentrating mechanism have become increasingly comprehensive and sophisticated in the representation of tubular transport (e.g.,[158,159,162]) and medullary architecture.[52,55,133,147,153,157,193,194] This evolution is a consequence of the increasing body of experimental knowledge, faster computers with

increased computational capacity, and the sustained failure of simulations to exhibit a significant inner medullary concentration gradient.

Stephenson and collaborators re-examined the passive mechanism hypothesis in a two-nephron central core model, in which the electrolyte concentrations for sodium, potassium, and chloride were represented, along with urea.[159] In a simulation using transport parameters from rabbit inner medulla, a significant inner medullary gradient could only be obtained when the urea permeabilities in both descending and ascending limbs had been reduced to less than 10^{-6} cm/s. For permeability values obtained from the hamster, both urea and electrolyte permeabilities needed to be greatly reduced, especially in thin descending limbs. Although it has been frequently suggested that a reduction in the urea reflection coefficient for the collecting duct epithelium could augment collecting duct osmolality by retaining urea in excess of fluid, this study showed that such a reduction was ineffective without a mechanism for generating a salt gradient in the core.

Layton and collaborators, in a series of papers, have sought to elucidate the role of the distributed loops of Henle.[52,55,180,195–197] These studies employ a model representation of the loops of Henle that allows the simulation of loops turning back at all levels of the inner medulla, while also representing the fluid flow and concentrations in individual loops.[195] Previously, models had typically used a small number of discrete loops (see, e.g.,[184]) or had employed shunts between a merged descending and ascending flow to represent the decreasing number of loops of Henle as a function of inner medullary depth (e.g.,[145]).

The distributed loop representation has been used to obtain several theoretical results. If solute is mostly absorbed near loop bends, then the loop distribution may allow a cascade effect that tends to increase the achievable concentration, provided, of course, that a net solute absorption can be obtained.[55,195] The concentrating effect can be further enhanced if solute is absorbed from a short, prebend segment of the descending limb with low water permeability[55] as has been detected in chinchilla,[42] and which may be present in other species (*vide supra*). Layton hypothesized that a cascade effect could allow the generation of an inner medullary osmolality gradient, despite large loop urea permeabilities, provided that the passive mechanism could operate near loop bends.[196,180] Average flow, taken over all thin ascending limbs at each medullary level, would be hypoosmotic relative to the flows in the surrounding tubules and vessels, due to the effect of more and more loops turning, as one proceeds from the papillary tip to the outer medulla. However, simulations using reported permeabilities in rat or chinchilla failed to support this hypothesis.[52,180]

Studies by Wexler and collaborators have sought to assess the role of preferential interactions among tubules and vessels.[147,160,162,194,198,199] Wexler, Kalaba, and Marsh introduced what has become known as the WKM model,[147,199] which was based on the organization of tubules around vascular bundles (Figure 43.3), and which therefore allowed both axial and radial concentration gradients. The preferential interaction of collecting ducts with both thick and thin ascending limbs was proposed as the key principle that allowed the generation of an inner medullary osmolality gradient. The preferential interaction with thick ascending limbs allowed highly concentrated collecting duct fluid to pass from the outer medulla to the inner medulla. The preferential interaction with thin ascending limbs allowed the passive mechanism to operate, since a urea-rich environment could be sustained around thin ascending limbs, and dissipative interaction of collecting ducts with thin descending limbs was diminished.

The WKM model drew criticism for some of its structural and transport assumptions.[32,176,200,201] Subsequent studies responded to these criticisms (with modified model assumptions), and acknowledged that preferential interactions are not sufficient to explain the inner medullary concentrating effect in the papilla.[160,162,198] Nonetheless, results from the WKM model and its successors have provided persuasive evidence that preferential interactions can be a significant factor in the degree of the outer and inner medullary concentrating effects. Moreover, the model structure permitted sensitivity testing as a function of interaction strength, and compared to other model studies, it allowed for a more accurate assessment of solute and water recycling pathways.

Two hypotheses closely related to the passive mechanism have been recently proposed by Layton et al.[54]; these hypotheses were motivated by the implications of recent studies in rat by Pannabecker et al..[18,19] One hypothesis is based directly on the principles of the passive mechanism: low urea permeabilities in thin limbs of Henle were assumed because no significant labeling for urea transport proteins was found in loops reaching deep into the inner medulla.[54] A second, more innovative hypothesis assumed very high urea loop of Henle permeabilities, but limited NaCl-permeability and zero water-permeability in thin descending limbs reaching deep into the inner medulla. Thus, in the innermost inner medulla, tubular fluid urea concentration in loops of Henle would nearly equilibrate with the local interstitial urea concentration; thin descending limb fluid osmolality would be raised by urea secretion; and substantial NaCl absorption would occur in the prebend segment and early thin ascending limb. Both hypotheses emphasize the role of the decreasing loop of Henle population, which facilitates

a spatially distributed NaCl absorption along the inner medulla, from prebend segments and early thin ascending limbs. A distinctive aspect of both hypotheses is an emphasis on NaCl transport from the IMCDs as an important active transport process that separates NaCl from tubular fluid urea, and that indirectly drives water and urea absorption from the collecting ducts. Computer simulations for both hypotheses predicted urine osmolalities, flow, and concentrations consistent with urine from moderately antidiuretic rats. The critical dependence of the first hypothesis on low loop urea permeabilities is subject to the criticism that urea transport may be paracellular rather than transepithelial: that hypothesis depends on more conclusive experiments to determine urea transport properties in rat. The second hypothesis may contribute to understanding the concentrating mechanism in chinchilla, in which high loop urea permeabilities have been measured.[57]

Subsequently, a modeling study by Marcano et al.,[181] which was based on the principles of the passive mechanism, produced somewhat higher osmolalities than reported by Layton et al.,[54] but did not reach osmolalities as large as those found in highly-concentrating rats. A modeling study by Layton et al.[153] that sought to represent the interactions among tubules and vessels hypothesized by Pannabecker et al.[20] exhibited concentrating capability similar to that found by Marcano et al.[181] A second modeling study by Layton et al.[202] that represented the interactions hypothesized by Pannabecker et al.[20] set forth the hypothesis that plentiful urine flow rates in rats accompanied by high urine concentrations may arise, in some cases, from altered boundary conditions at the boundary of the inner and outer medulla. Such altered conditions may arise from hyperfiltration and from inner stripe hypertrophy that result from feeding urea (thus providing, in part, an explanation for for findings by Gamble et al.[166]) or from a high-protein diet, water restriction or the administration of antidiuretic hormone.[203]

Steady-State Alternatives to the Passive Mechanism

The passive mechanism hypothesis is a comprehensive explanation for a large body of experimental findings, including the dilution of thin ascending limb fluid without active transport,[80,204,205] a role for urea in the concentrating mechanism,[166] and the NaCl and urea permeabilities measured in loops of Henle from rabbit inner medulla (see Tables 43.2 and 43.3). However, the larger permeabilities measured in rat, hamster, and chinchilla, in conjunction with the results of numerous simulation studies, have provided little support for the hypothesis. Significant concentrations of urea measured in long loops of Henle from rat and hamster[72,73,76] are generally consistent with studies reporting high loop urea permeabilities. In addition, some animals with high urine-concentrating ability, e.g., *Psammomys*, generate a medullary gradient that depends mostly on NaCl, with little medullary urea accumulation,[206] a result which suggests that, at least in some species, a mechanism differing from the passive mechanism is involved. Thus, while the passive mechanism hypothesis remains highly influential in both experimental and theoretical research, the accumulated evidence, from both experimental and mathematical studies, indicates that crucial elements are missing in our understanding of the inner medullary concentrating effect.

Alternatives to the original passive mechanism hypothesis have taken three forms. First, many simulation studies have attempted to show that a better representation of transepithelial transport or of medullary anatomy is required for the effective operation of the passive mechanism; some of these studies were summarized in the preceding section. Second, a number of steady-state mechanisms involving a single effect generated in either thin descending limbs or collecting ducts have been proposed. Third, several hypotheses which depend on the peristaltic contractions of the pelvic wall and their impact on the papilla have been proposed. The steady-state alternatives involving descending limbs or collecting ducts are considered directly below, within a general context of possible steady-state mechanisms; mechanisms involving peristalsis are considered in the subsequent subsection.

Based on the principle of mass balance, Knepper and colleagues have provided a systematic classification of possible steady-state concentrating models for the inner medulla.[7,148] The classification shows that a single effect for countercurrent multiplication can exist in any structure having axial flow. Thus, a single effect could be present in thin descending limbs, thin ascending limbs, collecting ducts, descending vasa recta or ascending vasa recta. The classification also shows that a concentrating single effect in an upward flowing stream (toward the cortex) would require a luminal osmolality less than that of the surrounding interstitium, whereas a single effect in a downward flowing stream would require a luminal osmolality exceeding that of the interstitium. Thus, for example, the active transport of NaCl from the thick ascending limbs of the outer medulla lowers the osmolality of the upward flowing luminal fluid relative to the surrounding interstitium; similarly the passive mechanism hypothesis proposes that diffusion of NaCl from thin ascending limbs renders luminal fluid hypoosmotic relative to the interstitium.

Several investigators have proposed a single effect in descending limbs arising from flow that is

hyperosmotic relative to the interstitium. Bonventre and Lechene proposed that the equilibration of descending limb flow with a compartment rendered hyperosmotic by active NaCl transport from ascending limbs or active secretion of solute into descending limb produces a relatively hyperosmotic descending flow from the outer medulla into the inner medulla.[207] In a mathematical simulation, Lory showed that an inwardly-directed NaCl transport combined with a loop of Henle cascade could produce a significant concentrating effect.[208] Jen and Stephenson performed a general mathematical analysis of mechanisms involving a hyperosmotic descending limb flow, and concluded that such mechanisms, in theory, could generate a potent single effect.[149] Their claim was supported by a subsequent simulation study by Thomas and Wexler,[162] which represented an external osmotic driving force to extract water from descending limbs and collecting ducts; the driving force was hypothesized to arise from the accumulation of osmotically active particles in local vessels or capillaries as a consequence of osmolyte production. Layton and colleagues[52] suggested that a descending limb single effect is consistent with the high NaCl and urea permeabilities of chinchilla ascending limb: the ascending limb could function as an equilibrating segment in which high permeabilities reduce dissipative osmotic lag. However, despite the attractive features of a descending limb single effect, experimental support for a relatively hypertonic descending limb is lacking. Moreover, in most species examined, the NaCl and urea permeabilities in thin descending limbs are too high to sustain a significant transepithelial osmolality gradient in the papilla, where the concentrating effect is most pronounced.

A single effect in the IMCD would require that the osmolality of luminal flow exceed the osmolality of the surrounding interstitium. Rabinowitz proposed such a single effect, based on the assumption that the urea reflection coefficient for the collecting duct is significantly less than unity.[209] He showed that the resulting reduction in the osmotic effect of urea in the collecting duct could, in theory, result in a water flux from collecting duct to interstitium that would significantly raise the osmolality of collecting duct fluid. A number of investigators have proposed or analyzed this hypothesis, including Sanjana et al.,[210] Bonventre and Lechene,[207] Chandhoke et al.,[211] and Imai et al.[39] However, experimental studies indicate that the urea reflection coefficient in rat does not differ significantly from unity.[50,122]

Thomas[152] and Hervy and Thomas[151] have investigated the hypothesis that the concentrating mechanism of the inner medulla may be driven or aided by lactate accumulation in the rat papilla. Anaerobic glycolysis in the hypoxic inner medulla is a net source of osmoles, because two lactates are produced for each glucose molecule. The rate of production, however may not be sufficient to produce a general concentrating effect. Modeling studies[151] indicate that lactate produced from glucose by anaerobic glycolysis could concentrate tubular fluid in thin descending limbs and collecting ducts (thus producing descending flows in these tubules that are relatively hyperosmotic to flows in other structures at each medullary level), provided that the descending limbs and collecting ducts are impermeable to lactate, as appears to be the case from low lactate levels in urine. However, several conditions require experimental verification: sufficient lactate production, impermeability of thin descending limbs to lactate, and sufficient intramedullary lactate cycling by vascular countercurrent exchange. The lactate-based mechanism is attractive because it appears to be insensitive to thin descending limb urea permeability, and independent of a necessary role for urea. However, modeling results for this mechanism appear to produce subphysiological urine flow, and do not explain the experimentally observed urea gradient in rat.

Hypotheses Based on the Peristalsis of the Papilla

Regular, sustained peristaltic contractions of the smooth muscles of the renal pelvic wall have been observed in a number of mammalian species. In the unipapillate kidneys of hamsters and rats, peristaltic contractions are propagated from the fornices to the lower pelvis, and continue in synchrony down the ureter. In the multipapillate kidneys of both humans and pigs, peristaltic contractions pass from the fornices down the calyces surrounding each papilla, but contractions in calyces are not synchronized with each other or with the peristalsis of the ureter. For a comprehensive review of the anatomy, physiology, and peristalsis of the renal pelvic region, see [212].

In hamsters and rats, the rates of pelvic contractions are about 13/min and 25/min, respectively.[164,213] The contractions interrupt fluid flow by forcing the collecting ducts, loops of Henle, and capillaries of the papilla to collapse. In hamster, the contractions induce bolus flow down the papillary collecting duct, with a bolus speed of about 1.6 mm/second. At the low urine flow rates characteristic of antidiuresis, boluses are so short that, 1 mm from the papillary tip, collecting ducts may be collapsed up to 94% of the time.[164] Even so, large quantities of urea, electrolytes, and, especially, water are absorbed in the final millimeters of the collecting duct system. Indeed, about 50% of the water in a bolus passing through the final millimeter of the collecting duct is absorbed.[214]

The blood in the capillaries of the papilla undergoes complicated motion during a pelvic contraction.[213] As a peristaltic wave approaches, blood is trapped in the capillaries closest to the papillary tip, which are full and expanded. As the wave passes over, the capillaries empty, with blood moving up both the descending and ascending *vasa recta*; after the wave has passed, the capillaries refill. The fluid motion in the loops of Henle is much like that of blood in the capillaries: fluid is trapped at the turns of the loops, and may move retrograde up the descending and ascending limbs as the peristaltic wave passes.[215] A net orthograde flow through the capillaries and loops of Henle is ensured by glomerular filtration pressure.

During the rising urine flow rates that accompany the onset of diuresis, the peristalsis in hamsters and rats induces refluxes of urine over the papilla and up into the fornices.[213] These refluxes, called full refluxes, may bathe the papillary surface epithelium with urine that is hypoosmotic and that has a low urea concentration, relative to the medullary structures; thus, water may diffuse into the medulla, and urea may diffuse out. Experiments in hamsters suggest that full refluxes accelerate the transition to the diuretic state.[216] When urine flow is constant or decreasing, refluxes are sporadic and limited to the lower 50–100 μm of the papilla.[213]

Experiments have shown that the excision of the pelvic wall results in a substantial reduction in urine osmolality[217–219]; the reduction has been attributed to the disruption of pelvic urea recycling[219–221] or to the dissipative effect of medullary blood flow, increased by continuous flow[164] or by prostaglandin release.[217] However, no significant change in osmolality was found in urine samples from rats 5–40 minutes after the smooth muscles of the pelvic wall were paralyzed with a topical application of verapamil and dimethylsulfoxide.[218] In the same study, the excision of the pelvic wall dramatically reduced the osmolality gradient in the papilla, and the gradient was substantially reduced when the ureter was severed just beyond the papillary tip, a procedure that preserved pelvic peristalsis (and intermittent urine flow), but eliminated urine reflux.[218] These results were interpreted to mean that while an intact pelvic wall, continuous with the ureter, is required for the production of maximally concentrated urine, the pelvic contractions are not. However, some experiments suggest that the peristaltic contractions do play a direct role in the concentrating mechanism. When the pelvic wall in rats was removed, causing a 10% decrease/hour in urine osmolality, and peristalsis was then simulated by a mechanical system, the decrease was reduced to 5%/hour.[222] When the muscles of the pelvic wall in hamster were paralyzed by cauterization or by xylocaine, urine osmolality was reduced by about 20% after one hour,[223] through a reduction in papillary sodium content.

Several studies have provided evidence of solute and water transport across the papillary surface epithelium. When the papillae of rats and gerbils were bathed in a solution containing ^{14}C-urea and ^{3}H-water, there was a marked tissue label for urea, increasing from cortex to inner medulla, and a smaller effect for water.[226] When the papilla was bathed *in vivo* with artificial solutions containing varying concentrations of urea, higher concentration of urea in the superfusate led to a higher osmolality in the urine that was collected as it emerged from the terminal IMCD.[220] Fluid collected from small catheters inserted far up into the fornices of the rat pelvis extracted fluid with concentrations of inulin and total solutes that were significantly lower than the concentrations in urine collected at the papillary tip.[227]

Recycling of urea from urine across the papillary surface epithelium has been proposed as a component of the inner medullary concentrating mechanism.[207,228] However, a comparison of ureteral urine and urine collected from the ducts of Bellini of hydropenic hamsters showed no significant differences in filtered water and urea,[229] and an analysis based on measured urea permeability and papillary surface area in rabbits suggests that urea transport across the papillary surface epithelium is negligible.[104]

The lack of a satisfactory explanation for the inner medullary concentrating effect has led to the formulation of hypotheses based on the peristaltic contractions of the smooth muscles of the pelvic wall. Layton proposed that the NaCl and urea concentrations in the tubular cells and interstitium undergo oscillations in tandem with the contractions.[196] Urea absorbed from boluses advancing down the collecting duct system would transiently, and substantially, increase urea concentration in collecting duct cells and in the interstitium. Immediately following passage of the peristaltic wave, NaCl absorbed from restored orthograde loop of Henle flow would significantly raise the interstitial NaCl concentration. The very large urea concentration encountered by loop flow would, perhaps, be sufficient to result in the transient operation of the passive mechanism near loop bends, raising interstitial osmolality. Consequently, water, in excess of solute, would be absorbed from the next bolus passing down the collecting duct, and a large urea gradient, resulting from increased interstitial NaCl, would favor urea absorption. However, as in the case of the steady-state formulation of the passive mechanism, the large permeabilities measured in chinchilla[57] suggest that rapid equilibration of NaCl and urea concentrations across thin ascending limbs would compromise this hypothesis.

Knepper and collaborators proposed that water may be driven out of thin descending limbs by the advancing peristaltic wave, thus concentrating tubular fluid and generating a single effect in descending limbs.[143,148] A sufficient net water flux might be achieved if the compliance of the papillary surface epithelium exceeds that of the thin descending limb, and if large enough pressures are attained by the compression wave. After the passage of the wave, solute would be absorbed in the relatively water-impermeable prebend segment, and in the early portion of the thin ascending limb, where NaCl and urea permeabilities are high. This hypothesis provides no explanation for the special role of urea in the production of high urine concentrations.[166]

Schmidt-Nielsen proposed that the contraction–relaxation cycle creates negative pressures in the interstitium that act to transport water, in excess of solute, from the collecting duct system.[230] According to this hypothesis, the compression wave would raise hydrostatic pressure in the collecting duct lumen, promoting a water flux into collecting duct cells. Because pressure would induce water flow through aquaporin water channels, without a commensurate solute flux, the remaining luminal fluid would be concentrated, relative to the contents of collecting duct cells and the surrounding interstitium. After the peristaltic wave had passed, the collecting ducts would be collapsed. The papilla, transiently lengthened and narrowed by the wave, would rebound, and a negative hydrostatic pressure would develop in the elastic interstitium, which is rich in glycosamine glycans and hyaluronic acid. The negative pressure would withdraw water from the collecting duct cells (through aquaporins) and into the vasa recta, which re-open during the relaxation phase of the contraction and carry reabsorbate toward the cortex. This hypothesis appears to provide no role for long loops of Henle, and it does not explain the large NaCl gradient generated in the papilla[6,106] or the special role of urea in producing concentrated urine.[166]

Knepper and colleagues[150] have recently hypothesized that hyaluronic acid, which is plentiful in the interstitium of the rat papilla, could serve as a mechano-osmotic transducer, i.e., that the intrinsic viscoelastic properties of hyaluronic acid could be utilized to transform the mechanical work of papillary peristalsis into osmotic work that could be used to concentrate urine. Three distinct concentrating mechanisms arising from peristalsis are proposed: (1) in the contraction phase, interstitial sodium activity would be reduced through the immobilization of cations by their pairing with fixed negative charges on hyaluronic acid. This would result in a lowered NaCl concentration in fluid that can be expressed from the interstitium, and that relatively dilute fluid would enter the ascending vasa recta. In the relaxation phase, water would be absorbed from descending thin limbs: (2) as a result of decreased interstitial pressure (previously proposed by Knepper and co-workers[143,148]); and (3) as a result of elastic forces exerted by the expansion of the elastic interstitial matrix arising from hyaluronic acid. If water is so absorbed, without proportionate solute, then the descending limb tubular fluid would be relatively concentrated relative to other flows.

All of the hypotheses summarized above involve complex, highly coordinated cycles, with critical combinations of permeabilities, flow rates, compliances, pressures, and frequencies of peristalsis. Moreover, a determination of the adequacy of these hypotheses would appear to require a comprehensive knowledge of the physical properties of the renal papilla, and a demonstration that the energy input of the contractions, plus any other sources of harnessed energy, is sufficient to account for the osmotic work performed. Thus, the evaluation of these hypotheses, whether by means of experiments or mathematical models, presents a daunting technical challenge.

OSMOPROTECTIVE OSMOLYTES

Since the osmolality in the renal medulla is able to vary rapidly over a wide range, medullary cells must be able to adapt to this unusual osmotic environment in order to survive.[207,231] One way for medullary cells to achieve osmotic balance would be for these cells to accumulate intracellularly the major osmotically active compounds (osmolytes) that are found extracellularly in the medullary interstitium and urine, i.e., NaCl and urea.[232] The problem with this approach is that NaCl and urea can perturb protein function.[231] If medullary cells accumulated such perturbing osmolytes to achieve osmotic balance, then it is likely that these cells would need to develop special mechanisms that would allow their proteins to function over a wide range of intracellular ionic compositions and/or in high concentrations of urea.

An alternative mechanism would be for medullary cells to accumulate osmotically active substances that do not alter protein function, i.e., non-perturbing osmolytes.[231,233,234] This second approach is actually employed by medullary cells (Figure 43.10). Medullary cells accumulate non-perturbing or "organic" osmolytes such as sorbitol, glycerophosphocholine, betaine, inositol, and taurine.[232,235–238] These organic osmolytes are divided into two general categories: compatible and counteracting osmolytes. Sorbitol, inositol, and taurine are the major compatible osmolytes, and have no effect on protein function. They are accumulated intracellularly to osmotically balance extracellular

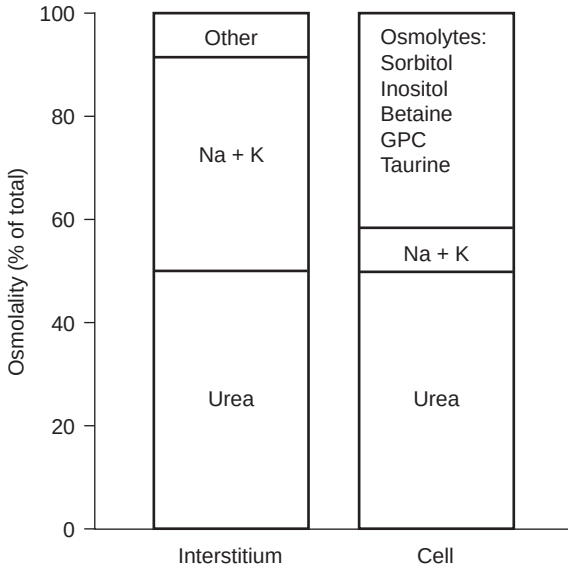

FIGURE 43.10 **Comparison of osmotic composition of the inner medullary interstitium and of cells in the inner medulla.** Sodium and potassium salts in the interstitium are balanced by compatible osmolytes (sorbitol, inositol, taurine). The denaturing effect of urea is balanced by counteracting osmolytes (betaine, glycerophosphocholine (GPC)). Data from references [452,453]. *(Figure is modified, with permission, from reference [232].)*

NaCl.[236,237,239] Glycerophosphocholine and betaine are the major counteracting osmolytes: in addition to being osmotically active, they have stabilizing effects on protein function and counteract the destabilizing effects of urea when they are accumulated intracellularly at a ratio of 1 mole of counteracting osmolyte to 2 moles of urea.[231,233,234,239,240,241]

In the medulla, organic osmolytes are regulated to respond to prolonged periods without water ingestion followed by short periods in which water is ingested.[236] During periods of antidiuresis, medullary cells maintain high intracellular concentrations of organic osmolytes to match extracellular osmolality. When water is ingested, these cells respond by rapidly losing osmolytes into the urine by increasing their cell membrane permeability to these osmolytes, thus decreasing intracellular osmolality.[236,237] However, the medullary cells continue osmolyte production during these short periods of diuresis. Although this continued osmolyte production may appear inefficient, it enables the cell to respond rapidly to the cessation of water ingestion. When water ingestion ceases, the cell's permeability to osmolyte efflux decreases, and intracellular osmolyte concentration is rapidly restored, since osmolyte production is maintained.[236,237] However, if the diuresis is prolonged (days), then osmolyte production is decreased in addition to the increase in cell permeability.[236,237] In this case, osmolyte concentration cannot be restored rapidly, since the upregulation of osmolyte production requires an increase in the transcription of osmolyte genes and new protein synthesis.[236]

ROLE OF UREA

Urea plays a unique role in the urine concentrating mechanism. Its importance to the generation of a concentrated urine has been appreciated since 1934, when Gamble and colleagues described "an economy of water in renal function referable to urea".[166] Several studies show that maximal urine concentrating ability is decreased in protein-deprived animals and humans, and is restored by urea infusion.[75,165,166,242–246] This is the mechanism that has been proposed to explain why protein-restricted and malnourished humans are unable to concentrate their urine maximally. Recently, a UT-A1/UT-A3 knockout mouse,[144] a UT-A2 knockout mouse,[247] and a UT-B knockout mouse[248–250] were each shown to have urine concentrating defects. Thus, any solution to the question of how the inner medulla concentrates urine needs to take into account some effect derived from urea.

Facilitated Urea Transporters

Several early studies in dog and rat suggested that vasopressin could increase urea permeability across the IMCD.[63,251–253] Direct evidence was obtained in the 1980s, when three groups showed that vasopressin could increase passive urea permeability in isolated perfused rat IMCDs.[102,120,123] A specific facilitated or carrier-mediated urea transport process in rat and rabbit terminal IMCDs was first proposed in 1987.[102] The physiologic studies provided a functional characterization for a vasopressin-regulated urea transporter (reviewed in [254–258]). Two urea transporter genes have been cloned: the UT-A (*Scl14A2*) gene encodes 6 protein and 9 cDNA isoforms; the UT-B (*Scl14A1*) gene encodes two protein isoforms[259] (and reviewed in[260]) (Table 43.6). The UT-A gene was initially cloned from rat,[261] then from human and mouse.[262,263] It has two promoter elements: promoter I is upstream of exon 1 and drives the transcription of UT-A1, UT-A1b, UT-A3, UT-A3b, and UT-A4; promoter II is located within intron 12 and drives the transcription of UT-A2 and UT-A2b.[224,261]

The mouse UT-A promoter α, equivalent to the rat UT-A promoter I, has been further studied by the creation of transgenic mice in which 4.2 kb of the 5′-flanking region of the UT-A gene is linked to a β-galactosidase reporter gene.[264] This transgene is sufficient to drive IMCD-specific expression of β-galactosidase in terminal IMCDs.[264] The β-galactosidase transgene is regulated by both water restriction and

TABLE 43.6 Cloned Mammalian Urea Transporters

Gene	Isoform	Tissue Localization
Slc14A1	UT-B1	red blood cells, endothelial cells, descending vasa recta
	UT-B2	bovine rumen
Slc14A2	UT-A1/UT-A1b	inner medullary collecting duct, apical membrane
	UT-A2/UT-A2b	thin descending limb (also heart and liver)
	UT-A3/UT-A3b	inner medullary collecting duct, apical and basolateral membranes
	UT-A4	rat medulla (not detected in mouse)
	UT-A5	mouse testis (not expressed in kidney)
	UT-A6	human colon (not expressed in kidney)

glucocorticoids, similar to the regulation of the endogenous UT-A promoter α.[263–266]

UT-A1 is the largest UT-A protein and is expressed in the apical plasma membrane of cells in the IMCD.[262,267,268] Urea transport by UT-A1 is stimulated by cAMP when expressed in *Xenopus* oocytes,[269–271] and by vasopressin in cells that are stably transfected with UT-A1, UT-A1-MDCK cells,[272–274] and UT-A1-mIMCD3 cells.[275] Western blots of inner medullary tip proteins show bands at both 117 and 97 kDa; both bands represent glycosylated versions of a non-glycosylated 84 kDa UT-A1 protein.[276] UT-A1 protein is most abundant in the inner medullary tip; only the 97 kDa protein is detected in the inner medullary base, and it is not detected in outer medulla or cortex.[268,277,278]

UT-A3 is also expressed in the IMCD,[279] although reports of its location have varied in different studies. Initial studies performed in rat detected UT-A3 staining in the apical plasma membrane and intracellular cytoplasmic vesicles of terminal IMCDs, but none in the basolateral plasma membrane.[268,280] Subsequent studies detected UT-A3 staining only in the IMCD basolateral plasma membrane in mouse IMCD, and in mUT-A3-MDCK cells.[281,282] The most recent study detected UT-A3 staining in the basolateral plasma membrane in rats, but in both the apical and basolateral plasma membranes in rats following vasopressin administration.[283] UT-A3 expression in the basolateral plasma membrane provides a mechanism for transepithelial urea transport in the IMCD, with UT-A1 in the apical plasma membrane and UT-A3 in the basolateral plasma membrane.

Urea transport by UT-A3 is stimulated by cAMP analogs when expressed in human embryonic kidney (HEK) 293 cells or *Xenopus* oocytes in three studies,[269,279,284] but not in a fourth.[285] Vasopressin also stimulates urea transport via a PKA-dependent pathway in cells that are stably transfected with mouse UT-A3, mUT-A3-MDCK cells.[282]

UT-A2, the first urea transporter cloned,[286] is expressed in thin descending limbs.[90,267,268] Urea transport by UT-A2 is not stimulated by cAMP analogs when expressed in either *Xenopus* oocytes or human embryonic kidney HEK-293 cells.[270,271,279,286–289] UT-A4 is expressed in rat kidney medulla, although its exact location is unknown, and it has not been detected in mouse kidney.[248,263,269] Urea transport by UT-A4 is stimulated by cAMP analogs when expressed in HEK-293 cells.[279] UT-A5 and UT-A6 are expressed in testis and colon, respectively, but not in kidney.[284,290] In addition, there are three UT-A cDNA variants with alternative 3′-untranslated regions, but no difference in coding region, named UT-A1b, UT-A2b, and UT-A3b, respectively.[224]

The UT-B1 cDNA was initially cloned from a human erythroid cell line,[291] then from rodents.[249,292–294] UT-B1 protein is the Kidd antigen (in humans), and several mutations of the UT-B1/Kidd antigen gene exist[295–299]; red blood cells from these individuals also lack phloretin-sensitive facilitated urea transport.[300] The human UT-B gene encodes a single cDNA and a single protein[295]; both the N- and C-termini are located intracellularly.[296] However, in rat, two cDNA sequences that differ by only a few nucleotides at their 3′ end have been reported.[292,294] Whether the two cDNAs truly represent different rat UT-B1 isoforms, a polymorphism or a sequencing artifact is uncertain, since humans have only a single isoform. UT-B1 protein is detected as a broad band between 45–65 kDa in human red blood cells and 35–55 kDa in rodent red blood cells and kidney medulla.[249,301,302] UT-B1 protein and phloretin-inhibitable urea transport are present in descending vasa recta.[61,249,301–306]

Several studies have addressed the question of whether UT-B1 transports urea only, or water and urea.[249,307,308] Although red blood cells from a UT-B1/AQP1 double-knockout mouse show that UT-B1 can function as a water channel, the amount of water transported through UT-B1 under physiologic conditions is small (in comparison to AQP1), and is probably not physiologically significant to the urine concentrating mechanism.[250]

Rapid Regulation of Facilitated Urea Transport

The primary method for investigating the rapid regulation of urea transport has been perfusion of rat IMCDs. This method provides physiologically relevant

functional data, although it cannot determine which urea transporter isoform is responsible for a specific functional effect in rat terminal IMCDs, since both UT-A1 and UT-A3 are expressed in this nephron segment. Vasopressin addition to the basolateral membrane of a rat terminal IMCD results in binding to V_2-vasopressin receptors, stimulating adenylyl cyclase, generating cAMP, and ultimately increasing facilitated urea permeability.[63,102,120,121,253,309,310] This effect occurs within minutes of adding vasopressin to the bath.[311] Oxytocin also increases urea permeability by binding to V_2-receptors and increasing cAMP production in rat terminal IMCDs.[312] Functional studies show that phloretin-inhibitable urea transport is present in both the apical and basolateral plasma membranes, with the apical membrane being the rate-limiting barrier for vasopressin-stimulated urea transport.[313] As discussed above, it is unclear whether UT-A3 is the basolateral membrane urea transporter.[280,281]

The acute stimulation of urea permeability by vasopressin occurs by an increase in the number of functional urea transporters (V_{max}), without a change in the transporter's affinity (K_m) for urea.[314] Adding vasopressin to the lumen of a perfused rat terminal IMCD also increases urea permeability by binding to luminal V_2-receptors.[315] However, when vasopressin is first added to the bath, adding vasopressin to the lumen inhibits urea permeability, suggesting that luminal vasopressin is a negative modulator of basolateral vasopressin on urea permeability in rat terminal IMCDs.[315]

One mechanism for rapid regulation is a vasopressin-stimulated increase in UT-A1 phosphorylation.[316] The deduced amino acid sequence for UT-A1 contains several consensus sites for phosphorylation by PKA, as well as by protein kinase C (PKC) and tyrosine kinase.[279] UT-A1 and UT-A3 have been identified in proteomic and cDNA array approaches as proteins that are phosphorylated by vasopressin in the inner medulla.[137,317–322] Vasopressin increases the phosphorylation of both the 117 and 97 kDa UT-A1 proteins in freshly isolated suspensions of rat IMCDs within 2 minutes,[316] and of the 67 and 44 kDa UT-A3 proteins.[283] Vasopressin also increases UT-A1 phosphorylation in UT-A1-MDCK cells[273,274] and UT-A1-mIMCD3 cells.[275] The time-course and dose–response for vasopressin-stimulated increases in UT-A1 phosphorylation is similar to the time-course and dose–response for vasopressin-stimulated increases in urea permeability in perfused rat terminal IMCDs.[309–311,316] Cyclic AMP, dDAVP (a V_2-selective agonist), and forskolin also increase UT-A1 phosphorylation, and PKA inhibitors block vasopressin or forskolin-stimulated UT-A1 phosphorylation in rat IMCD suspensions[316] and UT-A1-MDCK cells.[274] Vasopressin/cAMP can stimulate Epac, exchange protein activated by cAMP,[323–328] in addition to stimulating PKA. Epac activation increases urea permeability in perfused rat terminal IMCDs, and increases UT-A1 phosphorylation in IMCD suspensions.[329]

Serine 486 was identified in a phosphoproteomic analysis as a potential vasopressin-stimulated phosphorylation site in UT-A1.[137] Serine 486 was identified in a second study, which also identified serine 499 as a second potential PKA phosphorylation site.[330] Using site-directed mutagenesis and transient transfection in heterologous expression systems, PKA was shown to phosphorylate UT-A1 at both serine 486 and serine 499.[330] Phospho-specific antibodies to serine 486 show that vasopressin increases UT-A1 phosphorylation at serine 486.[275,331] Phospho-serine 486-UT-A1 is detected primarily in the apical plasma membrane in rat IMCDs.[275] Recent work with chimera proteins of UT-A that attached the loop region of UT-A1 (aa 460–532) containing serines 486 and 499 to the UT-A2 protein, which normally lacks these amino acids, showed that this section conferred vasopressin sensitivity to UT-A2.[332]

A subsequent phosphoproteomic analysis showed that purified PKA could phosphorylate UT-A1 at serines 486 and 499; that analysis also showed that serine 84, which is present in both UT-A1 and UT-A3, could be phosphorylated by PKA.[317] In rat, vasopressin phosphorylates both UT-A1 and UT-A3 at serine 84, based upon studies utilizing a phospho-specific antibody to serine 84.[331] However, the equivalent site in mouse UT-A3, serine 85, was shown not to be a PKA phosphorylation site, based on site-directed mutagenesis.[284] The latter study also showed that serine 92 was not a PKA phosphorylation site.[284]

Another mechanism by which vasopressin rapidly increases urea transport is regulated trafficking or redistribution of UT-A1 between an intracellular compartment and the apical plasma membrane. In freshly isolated suspensions of rat IMCDs from normal rats, vasopressin increases the plasma membrane accumulation of UT-A1 and UT-A3.[283,333] However, in IMCDs from Brattleboro rats or two week water diuretic rats, vasopressin does not increase the plasma membrane accumulation of UT-A1.[333,334] (Brattleboro rats have central diabetes insipidus due to a congenital absence of vasopressin production in the hypothalamus.) When forskolin is used as the agonist, rather than vasopressin, it does increase the plasma membrane accumulation of UT-A1 in IMCDs from two week water diuretic rats.[333] Since chronically diuretic animals have a blunted cAMP response to vasopressin,[335–337] directly stimulating adenylyl cyclase with forskolin[337] may result in higher levels of cAMP production, which may result in an increase in UT-A1 accumulation in the

plasma membrane.[333] Epac activation also increases UT-A1 plasma membrane accumulation in rat IMCD suspensions.[329]

Either vasopressin or forskolin increases UT-A1 apical plasma membrane accumulation in UT-A1-MDCK cells[272,333] and UT-A1-mIMCD3 cells.[275] Mutation of both serines 486 and 499, but not either one alone, eliminates the stimulation of UT-A1 apical plasma membrane accumulation and urea transport by vasopressin, indicating that at least one of these serines must be phosphorylated in order to increase apical plasma membrane accumulation and urea flux.[330] A phospho-specific antibody to S486-UT-A1 also showed that vasopressin increases UT-A1 accumulation in the apical plasma membrane, and that the S486-phospho-UT-A1 form is primarily detected in the apical plasma membrane.[275]

Vasopressin also increases UT-A3 accumulation in both the basolateral and apical plasma membranes in rat IMCDs.[283] In mUT-A3-MDCK cells, vasopressin stimulation for 10 minutes increases urea flux through transporters already in the basolateral plasma membrane.[338] Vasopressin stimulation for one hour increases UT-A3 localization in the basolateral plasma membrane and further increases urea flux in mUT-A3-MDCK cells.[338] The basal expression of UT-A3 in the basolateral plasma membrane involves PKC and calmodulin, while UT-A3 regulation by vasopressin involves a casein-kinase II-dependent pathway.[338]

UT-A1 is linked to the SNARE machinery via snapin in rat IMCDs, suggesting that the SNARE-SNAP vesicle trafficking mechanism may be functionally important for regulating urea transport.[339] UT-A1 also interacts with caveolin-1 in lipid rafts, providing another mechanism for UT-A1 regulation of UT-A1 activity within the plasma membrane.[340] Both UT-A1 and UT-A3 proteins can be ubiquitinated.[341,342] However, only UT-A1 has been rigorously shown to express ubiquitinated higher molecular weight forms by immunoprecipitation and Western analysis.[341] The ubiquitin ligase MDM2 mediates UT-A1 ubiquitination and degradation, providing another regulatory mechanism for UT-A1.[341] Finally, mutation of the two N-linked glycosylation sites in UT-A1 that are predicted to reside in extracellular domains, Asn 279 and Asn 742, reduces urea flux by reducing UT-A1 half-life and apical plasma membrane accumulation in MDCK cells.[272]

Increasing osmolality to high physiological values, either by adding NaCl or mannitol, in the absence of vasopressin, acutely increases urea permeability in rat terminal IMCDs,[119,121,343] suggesting that hyperosmolality is an independent stimulator of urea transport. When osmolality is increased and vasopressin is present, they have additive stimulatory effects on urea permeability.[119,121,343,344] Hyperosmolality-stimulated urea permeability is inhibited by phloretin and the urea analog thiourea.[119] Kinetic studies show that hyperosmolality, like vasopressin, stimulates urea permeability by increasing V_{max} rather than reducing K_m.[119] However, hyperosmolality stimulates urea permeability via increases in intracellular calcium and activation of PKC,[345,346] whereas vasopressin stimulates urea permeability via increases in adenylyl cyclase.[310] Hypersomolality increases the phosphorylation and the plasma membrane accumulation of both UT-A1 and UT-A3, similar to vasopressin.[283,316,333,347] Thus, both hyperosmolality and vasopressin increase urea permeability by increasing V_{max}, but they do so via different second messenger pathways.

Active Urea Transporters

Functional evidence exists for two types of active urea transport in the rat collecting duct: sodium-urea co-transport and sodium-urea countertransport (reviewed in [255,256]). Although no sodium-dependent active urea transporter has been cloned to date, several sodium-coupled co-transporters (rabbit sodium-glucose co-transporters 1 and 3, human sodium-chloride-GABA co-transporter 1) behave as urea channels when expressed in *Xenopus* oocytes.[348,349]

LONG-TERM REGULATION OF UREA TRANSPORTERS

Vasopressin

Administering vasopressin to Brattleboro rats (which lack vasopressin) for 5 days decreases UT-A1 protein abundance in the inner medulla.[350,351] However, administering vasopressin for 12 days increases UT-A1 protein abundance.[350] This delayed increase in UT-A1 protein is consistent with the time-course for the increase in inner medullary urea content in Brattleboro rats following vasopressin administration.[352] In normal rats, suppressing endogenous vasopressin levels by two weeks of water diuresis also decreases UT-A1 protein abundance.[350] This time-course may be explained by analysis of UT-A promoter I, since the 1.3 kb that has been cloned does not contain a cAMP response element (CRE), and cAMP does not increase promoter activity.[261,265] However, promoter I does contain a tonicity enhancer (TonE) element, and hyperosmolality increases promoter activity.[261,265] Thus, vasopressin may increase UT-A1 indirectly after directly increasing the transcription of other genes, such as the Na-K-2Cl co-transporter NKCC2/BSC1 and the AQP2 water channel, which begin to increase inner

medullary osmolality.[353,354] Consistent with this hypothesis, water restricting rats with primary polydipsia results in an increase in plasma vasopressin, but no increase in medullary osmolality or UT-A1 protein abundance.[355]

In Brattleboro rats, UT-A2 mRNA increases at both 4 and 72 hours after administering dDAVP, while UT-A1 mRNA is unchanged.[318] The dDAVP-stimulated increase in UT-A2 mRNA is consistent with the presence of a CRE in UT-A promoter II, and the stimulation of promoter II activity by cAMP.[261]

Administering either vasopressin or dDAVP for 6 hours reduces UT-B mRNA abundance in both the outer and inner medulla of Brattleboro rats.[356] In contrast, administering vasopressin or dDAVP for 5 days increases UT-B mRNA abundance in the inner stripe of the outer medulla and the inner medullary base, while it is still decreased in the inner medullary tip.[356] Administering dDAVP for 7 days to normal rats decreases UT-B protein abundance in the inner medulla.[302]

Low-Protein Diet

Feeding rats a low-protein diet for at least 2 weeks results in a decrease in the fractional excretion of urea,[246] induces the functional expression of vasopressin-stimulated urea permeability in the initial IMCD,[118,287,357] increases basal urea permeability in the $IMCD_3$,[358] and increases the abundance of the 117 kDa glycoprotein form of UT-A1 in the inner medulla.[351] The vasopressin-stimulated urea permeability in the initial IMCD from low-protein fed rats is stimulated by hyperosmolality and inhibited by phloretin and thiourea.[118,287] Thus, it has the same functional characteristics as the vasopressin-stimulated urea permeability which is normally expressed in the terminal IMCD.[287] Whether the mRNA abundance of UT-A1 or UT-A2 changes in the inner medulla of low-protein fed rats is controversial.[287,289,359] Varying dietary protein between 10 and 40% has no effect on UT-B mRNA abundance in any portion of the medulla in either normal or Brattleboro rats.[359]

Glucocorticoids

Glucocorticoids (dexamethasone) increase the fractional excretion of urea[360] and decrease UT-A promoter I activity, UT-A1 and UT-A3 mRNA abundances, UT-A1 protein abundance, and facilitated urea transport.[266,361,362] Mineralocorticoids (aldosterone) also decrease UT-A1 protein abundance in the inner medulla of adrenalectomized rats, and this decrease can be blocked by spironolactone, a mineralocorticoid-receptor antagonist.[361] In contrast, spironolactone does not block the decrease due to dexamethasone,[361] indicating that each steroid hormone works through its own receptor. Aldosterone-induced volume-expansion (with a high-NaCl diet) decreases both UT-A1 and UT-A3 protein abundance.[363]

Dahl salt-sensitive rats have increased abundances of UT-A1 and UT-A3 proteins in the inner medulla, and of facilitated urea transport in the terminal IMCD.[364] They also have an increased level of the corticosterone-inactivating enzyme 11-hydroxysteroid dehydrogenase type II.[364] Inactivating glucocorticoids by increasing 11-hydroxysteroid dehydrogenase type II would lessen the repression of UT-A promoter I activity, thereby increasing UT-A1 and UT-A3 transcription and abundance.

Diabetes Mellitus

Uncontrolled diabetes mellitus (induced by streptozotocin) causes an osmotic diuresis and increases urea excretion, corticosterone production, and plasma vasopressin levels.[365–367] UT-A1 protein abundance decreases at 3–5 days after inducing diabetes mellitus in the rat inner medulla, but not in adrenalectomized diabetic rats.[336,368] The decrease in UT-A1 protein abundance is restored by giving dexamethasone to adrenalectomized diabetic rats, indicating that glucocorticoids mediate the decrease in UT-A1 protein.[368]

In contrast, UT-A1 mRNA and protein are increased 10–21 days after diabetes mellitus is induced in normal rats.[336,369] UT-A1 protein did not increase in diabetic Brattleboro rats, indicating that vasopressin is necessary for this increase in UT-A1.[350] In addition, vasopressin did not increase UT-A1 phosphorylation in either Brattleboro rats or diabetic Brattleboro rats, indicating that vasopressin is necessary for the increase in UT-A1 protein abundance and phosphorylation that occurs at 10–21 days after diabetes is induced.[350] UT-A2 is also decreased in the streptozotocin-induced diabetic rat. The reason for the decrease is not known, but it appears to result from a post-translational alteration in protein abundance, since the message for UT-A2 in control and diabetic rats is not different.[369]

The increase in UT-A1 protein abundance in the inner medulla from diabetic rats is accompanied by a shift in the glycoprotein forms expressed in inner medullary tip versus base.[336,370,371] The base of the inner medulla, which normally expresses only the 97 kDa glycoprotein form of UT-A1, shows both 97 kDa and 117 kDa forms in the diabetic rat.[336,370,371] Vasopressin sensitivity is also changed in the diabetic rat inner medulla. In the normal rat, only urea transport in the inner medullary tip is subject to stimulation by

vasopressin, whereas in the diabetic kidney, urea permeability in both the tip and the base are increased by vasopressin.[372] In addition, both UT-A1 and UT-A3 protein abundance increases in response to treatment of the diabetic rat with the angiotensin receptor-blocker candesartan, apparently to reduce the loss of solute during uncontrolled diabetes.[370]

A model of type 2 diabetes is the obese Zucker rat, which has a genetic mutation of the leptin-receptor gene that leads to obesity, insulin resistance, hypertension, and diabetes.[373] UT-A1 protein abundance is decreased in the obese Zucker rat when compared to the lean Zucker (non-diabetic) rat.[374] The decrease in UT-A1 protein abundance may be a response to the hypertension present in the obese Zucker rat, similar to the decrease in UT-A1 observed in normal Sprague-Dawley rats made hypertensive with angiotensin II.[375]

Angiotensin II

Angiotensin II does not affect basal (no vasopressin) facilitated urea permeability in rat terminal IMCDs.[346] However, it increases both vasopressin-stimulated urea permeability and UT-A1 phosphorylation via a PKC-mediated effect.[346] Thus, angiotensin II may play a physiologic role in the urine concentrating mechanism by augmenting the maximal urea permeability response to vasopressin. In the inner medulla of mice that lack tissue angiotensin-converting enzyme, and hence lack angiotensin II, UT-A1 protein abundance is decreased to 25% of the level in wild-type mice.[376,377] Administering angiotensin II to these mice for 2 weeks did not correct the reduction in UT-A1 protein, nor in urine concentrating ability.[377]

Osmolality

Renal medullary osmolality varies between diuresis and antidiuresis. The major solutes contributing to inner medullary osmolality are urea and NaCl. Urea-specific signaling pathways are present in mIMCD3 cells (reviewed in [378,379]). When the percentage of urea in total urinary solute is low, UT-A1 protein abundance increases.[380–383] The increase in UT-A1 may occur in order to restore inner medullary interstitial urea and urine concentrating ability.[380] In the outer medulla, UT-A2 and UT-B1 protein abundance increases when medullary interstitial urea concentration is high, such as during a urea-induced osmotic diuresis, but not during a NaCl- or glucose-induced osmotic diuresis.[380–383] During osmotic diuresis, the urinary urea and NaCl concentrations regulate UT-A1 and UT-A3 protein abundances, but in opposite directions.[384] This regulation involves the tonicity enhancer-binding protein, Ton EBP, and appears to be an attempt to minimize changes in plasma osmolality and maintain water homeostasis.[384]

TonEBP, which is also named OREBP (osmotic response element binding protein) or NFAT5, is an essential regulator of urine concentrating ability.[385,386] Transgenic mice that overexpress a dominant-negative form of TonEBP have reduced urine osmolality, and UT-A1 and UT-A2 mRNA abundance.[386] In these mice, water deprivation or vasopressin administration increases urine osmolality and UT-A1 mRNA abundance, but not UT-A2 mRNA abundance.[386] TonEBP also stimulates the transcription of genes whose products drive cellular accumulation of organic osmolytes, such as aldose reductase.[385] Mice with genetic deletion of aldose reductase have a urine osmolality below 1000 mOsm/kg H_2O.[387] The urine concentrating defect was largely corrected in bitransgenic mice in which an aldose reductase transgene was knocked-in. These mice displayed a tendency toward increased UT-A1 expression that might contribute to the restoration of urine concentration.[387]

Electrolye Abnormalities

Hypercalcemia or hypokalemia reduce urine concentrating ability.[278,388–390] Basal urea permeability is increased in terminal IMCDs from hypercalcemic rats compared to normocalcemic control rats.[278] Consistent with this functional increase, the abundance of UT-A1 protein is also increased.[278] These changes may be regulated by a calcium-sensing receptor in the apical plasma membrane of cells in the terminal IMCD.[391] In a mouse model of autosomal dominant polycystic kidney disease (ADPKD) or a rat model of autosomal recessive PKD (ARPKD), treatment with a type 2 calcimimetic, R-568, results in hypocalcemia, polyuria, and minimal changes in UT-A1 protein abundance, with significant increases in UT-A1 seen only in the female ARPKD rats.[392]

A low-potassium diet reduces the abundance of UT-A1, UT-A3, and UT-B proteins in the inner medulla, but increases UT-A2 protein abundance in the outer medulla.[389] TonEBP protein abundance and nuclear distribution in the medulla are reduced by hypokalemia.[393] TonEBP downregulation contributes to the reduced expression of UT-A1 and UT-A2, although UT-A2 expression is transcriptionally reduced whereas UT-A1 is reduced post-transcriptionally.[393] In addition, UT-B1 expression is reduced, along with a decrease in mRNA abundance in response to hypokalemia.[393] Another study also found that feeding rats a low-potassium diet reduces the abundance of UT-A1, UT-A3, and UT-B1 proteins in the inner medulla.[389] However,

this latter study found that hypokalemia increases UT-A2 protein abundance in the outer medulla.[389] The reason for the differing findings regarding UT-A2 in these studies is unclear.

Hypothyroidism

Hypothyroidism reduces urine concentrating ability, but does not alter UT-A1 or UT-A2 protein abundance in rats.[394] Water-restricting hypothyroid rats alters neither UT-A1 nor UT-A2 abundance.[394] Urine concentrating ability is reduced in normal aging (reviewed in [395]). UT-A1, UT-A3, and UT-B1 proteins are reduced in kidneys of aged rats.[396–398] A supra-physiologic dose of dDAVP increases UT-A1 and UT-B1 protein abundance and urine osmolality in aged rats, but not to the levels observed in younger rats.[399]

Purinergic P2Y2 Receptor

P2Y2 receptor activation in the IMCD tends to oppose the actions of vasopressin.[400] Urine concentrating ability, and UT-A1 and UT-A2 protein abundances, are higher in P2Y2-receptor knockout mice than in wild-type mice.[400] Vasopressin administration for 45 minutes or 5 days increases UT-A1 protein abundance in P2Y2-receptor knockout mice.[400] Vasopressin administration for 5 days increases UT-A2 protein abundance in both control and P2Y2 purinergic receptor-null mice,[400] suggesting a role for cAMP in the regulation of UT-A2. While acute treatment with PKA agonists did not increase UT-A2,[269] longer treatment times did upregulate UT-A2 protein abundance,[90,401] suggesting that cAMP may be involved in the long-term regulation, rather than in the acute response, for UT-A2.

Ureteral Obstruction

UT-A1, UT-A3, and UT-B1 protein abundances are reduced by bilateral or unilateral ureteral obstruction in rat inner medulla.[402] The abundance of all three urea transporters remained reduced at 2 weeks after release of bilateral ureteral obstruction.[402]

Lithium

Lithium causes nephrogenic diabetes insipidus and an inability to concentrate urine (reviewed in [403]). Lithium causes a marked reduction in inner medullary interstitial osmolality due to reductions in interstitial urea and NaCl concentrations.[404] Lithium-treated rats have marked reductions in AQP2, UT-A1, UT-A3, and UT-B1 proteins, and vasopressin-stimulated UT-A1 phosphorylation.[405–408] UT-A1 and UT-A3 protein abundances return to control levels 14 days after stopping lithium therapy.[405] A proteomic analysis shows that several proteins involved in various signaling cascades that have been implicated in urea transporter function and/or trafficking are altered after 14 days of lithium treatment.[409] However, immunohistochemistry shows that UT-A1 localization appears normal after recovery from lithium treatment,[405] indicating that the trafficking machinery remains intact. Surprisingly, lithium stimulates urea flux in UT-A1-MDCK cells, despite suppressing cAMP formation.[410] Lithium does not increase UT-A1 biotinylation, which suggests that the increased urea flux in UT-A1-MDCK cells is due to an alteration in cellular signaling, rather than the trafficking of UT-A1.[410]

Genetic Knockout of UT-B

Humans with genetic loss of Kidd antigen (UT-B1) are unable to concentrate their urine above 800 mOsm/kg H_2O, even following overnight water deprivation and exogenous vasopressin administration.[411] Mice with a genetic knockout of UT-B1 also have mildly reduced urine concentrating ability, which is not improved by urea loading.[249,412] UT-A1 and UT-A3 abundance unchanged in UT-B1 knockout mice, but UT-A2 protein abundance is increased.[248] Since UT-A2 mediates urea recycling through the thin descending limb, it may be upregulated to partially compensate for the loss of urea recycling through UT-B1, thereby contributing to the mild phenotype observed in humans lacking UT-B1/Kidd antigen, and in UT-B1 knockout mice.

Mathematical models of microcirculatory exchange between the descending and ascending vasa recta predict that the absence of UT-B1 will decrease the efficiency of small solute trapping within the renal medulla, thereby decreasing the efficiency of countercurrent exchange and urine concentrating ability.[413,414] Thus, UT-B1 protein expression in red blood cells and/or descending vasa recta is necessary for the production of maximally concentrated urine.[411–416]

UT-B1 knockout mice have an impaired ability to concentrate their urine, achieving a maximal urine osmolality of 2400 mOsm/kg H_2O, compared to 3400 in a wild-type mouse.[249] This is similar to the phenotype in humans lacking UT-B1, the Kidd antigen, who are unable to concentrate their urine above 800 mOsm/kg H_2O, even following overnight water deprivation and exogenous vasopressin administration.[411] These findings support the concept that urea transport in red blood cells is necessary to preserve the efficiency of countercurrent exchange.[415] Both red blood cells and perfused rat descending vasa recta exhibit phloretin-inhibitable urea transport and express

UT-B1 protein,[61,301,303–306] suggesting that UT-B1 mediates urea transport in red blood cells and descending vasa recta.

UT-A2 protein abundance is increased, while UT-A1 and UT-A3 abundance is unchanged in UT-B1 knockout mice.[248] UT-A2 may be upregulated to compensate for the loss of UT-B1, since both UT-A2 and UT-B1 are involved in urea recycling.[248] This may account for the mild phenotype observed in UT-B1 knockout mice, and in humans lacking UT-B1/Kidd antigen.

Genetic Knockout of UT-A1 and UT-A3

Genetic knockout of both UT-A1 and UT-A3 in mice results in reduced urine concentrating ability, reduced inner medullary interstitial urea content, and a lack vasopressin-stimulated or phloretin-inhibitable urea transport in the IMCD.[144,417] When these mice are fed a low-protein diet, they are able to concentrate their urine almost as well as wild-type mice fed a low-protein diet,[144,417] supporting the concept that IMCD urea transport contributes to urine concentrating ability by preventing urea-induced osmotic diuresis.[418] Inner medullary tissue urea content was markedly reduced following water restriction, but there was no measurable difference in NaCl content between UT-A1/UT-A3 knockout mice and wild-type mice.[144,417] This finding was initially interpreted as being inconsistent with the predictions of the passive mechanism hypothesis.[8,9,144,417,419,420] However, a mathematical modeling analysis of these same data concludes that the results found in the UT-A1/UT-A3 knockout mice are exactly what one would predict for the passive mechanism hypothesis.[20]

The UT-A1/UT-A3 knockout mice were used to revisit Gamble's classic study from 1934.[166] Urea and NaCl each induce an osmotic diuresis when given in large amounts, supporting the concept that the decrease in water excretion with mixtures of urea and NaCl added to the diet results from the separate abilities of these two solutes to induce osmotic diuresis, rather than to any specific interaction of urea and NaCl transport at the epithelial level.[421]

Genetic Knockout of UT-A2

UT-A2 knockout mice also have an impaired ability to concentrate urine.[247,419,422] The reduction in urine concentrating ability results from an impairment of urea recycling.[247,419,422]

Active Urea Transport

When urine concentrating ability is reduced, there are changes in active urea transport that follow one of two patterns.[115,118,357,358,423,424] The first pattern, which occurs in response to water diuresis, is upregulation of active urea secretion in the $IMCD_3$ and its induction in the $IMCD_2$. This increase in urea secretion will directly decrease urea content in the deep inner medulla. The second pattern, which occurs in response to a low-protein diet, hypercalcemia, and furosemide, is induction of active urea absorption in the $IMCD_1$ and inhibition of active urea secretion in the $IMCD_3$. This second pattern will increase urea delivery to the inner medullary base, thereby decreasing urea delivery to the inner medullary tip; the accompanying inhibition of active urea secretion in the $IMCD_3$ may prevent an even greater reduction in urea content in the deep inner medulla.

UREA RECYCLING

Several urea recycling pathways are believed to contribute to high urea concentrations within the inner medulla.[418,425,426] The major recycling pathway involves urea absorption from the terminal IMCD, mediated by UT-A1 and UT-A3, secretion into the thin descending limb, and, especially, the thin ascending limb (Figure 43.11). Collecting ducts and thin ascending limbs are nearly adjoining within much of the inner medulla.[12] The urea that enters the thin ascending limb is carried distally as the luminal fluid moves through several nephron segments having very low urea permeability until it reaches the urea-permeable terminal

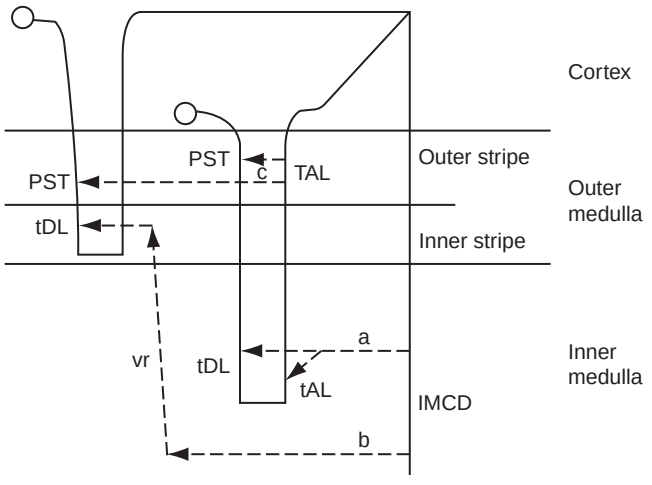

FIGURE 43.11 **Urea recycling pathways in mammalian kidney.** Diagram shows a short looped nephron (left) and a long looped nephron (right). Dashed lines labeled a, b, and c show urea recycling pathways (Abbreviations: PST: proximal straight tubule; tDL: thin descending limb of Henle's loop; tAL: thin ascending limb of Henle's loop; TAL: thick ascending limb of Henle's loop; IMCD: inner medullary collecting duct; vr: vasa recta). *(Figure is modified, with permission, from reference [425].)*

IMCD. Thus, urea is recycled from the terminal IMCD through the interstitium into the thin ascending limb, and back to the terminal IMCD.

Two other pathways for urea recycling may exist in the kidney.[425] One pathway is urea absorption from terminal IMCDs through ascending vasa recta and secretion into thin descending limbs of short looped nephrons[427] mediated by UT-A2[90] or into descending vasa recta mediated by UT-B1. The other pathway is urea absorption from cortical thick ascending limbs and secretion into proximal straight tubules.[425] All three urea recycling pathways would limit urea dissipation from the inner medulla where it is needed to increase interstitial osmolality.[425]

It must be emphasized that the terminal IMCD is the only portion of the collecting duct in which vasopressin increases urea permeability, even though the entire collecting duct is permeable to water when vasopressin is present. Water absorption from the cortical, outer medullary, and initial inner medullary collecting ducts concentrates urea within the collecting duct lumen. When the luminal fluid finally reaches the urea-permeable terminal IMCD, the luminal urea concentration is very high and exceeds that in vasa recta,[72,75,428,429] allowing urea to be rapidly absorbed into the deepest portion of the inner medullary interstitium where, in many studied mammals, it is needed to concentrate urine maximally.[102,192] This pattern of urea and water permeabilities separates the primary sites of urea and water absorption (Figure 43.6); water is primarily absorbed in the cortex and outer medulla where there is extensive vascularization with high blood flow, and the absorbed water can be returned to the circulation without diluting the deep inner medulla. Urea is principally absorbed in the deep inner medulla.[102,192]

Urea serves a second function in the medulla: it is the major source for excretion of nitrogenous waste; large quantities of urea need to be excreted daily. The kidney's ability to concentrate urea reduces the need to excrete water simply to remove nitrogenous waste. In addition, a high interstitial urea concentration is able to osmotically balance urea within the collecting duct lumen. If interstitial urea were unavailable to offset the osmotic effect of luminal urea destined for excretion, then the interstitial NaCl concentration would have to be much higher.[144,430]

DEVELOPMENT OF URINE CONCENTRATING ABILITY

Newborn mammals and birds are unable to concentrate their urine.[431–435] Rats and rabbits do not develop the ability to concentrate their urine maximally until 14–21 days after birth.[434,436–439] In rats, the increase in urine osmolality is paralleled by an increase in both medullary sodium and urea content.[440] In 10-day-old rats, neither urea- nor NaCl-loading enhances urine concentrating ability.[441] However, in 20-day-old rats, urea-loading significantly increases urine osmolality following water deprivation; NaCl loading has no effect.[441] The development of urine concentrating ability can be hastened by giving glucocorticoids to 10–17-day-old rats, but not to older rats.[440,442] Conversely, adrenalectomizing 16-day-old rats slows the development of urine concentrating ability and abolishes the increase in inner medullary sodium and urea concentrations that normally occurs at this age.[440]

In 1-day-old rats, the thin descending limb, thin ascending limb, and IMCD are all nearly water-impermeable.[433] At day 4, AQP1 mRNA is detected in the thin descending limb and water-permeability increases, however, it does not reach adult levels until day 14.[433] Even though AQP2 protein is detected starting at day 1, water-permeability remains low in the IMCD at day 7, but reaches adult levels at day 14.[368,433,443] However, AQP2 trafficking in the immature kidney responds normally to vasopressin[443] and AQP2 mRNA, and protein levels increase 24 hours after a single dose of betamethasone.[442]

In fetal rat kidney, UT-A protein is not detected and UT-B1 protein is weakly detected at embryonic age 20 days.[267] In 1-day-old rats, UT-A1, UT-A2, and UT-B1 proteins appear,[267] but the IMCD has a low urea permeability that is not stimulated by vasopressin.[433] At day 14, urea permeability becomes vasopressin-stimulatable and UT-A1 mRNA is detected, although the values are only one-third of adult levels.[433] UT-A1, UT-A2, and UT-B1 proteins increase progressively until adult levels are achieved at 21 days of age.[267] Thus, the time-course for the increases in UT-A1, UT-A2, and UT-B1 proteins coincides with the development of urine concentrating ability. On the basis of the functional implications of these findings, Lui et al.[433] proposed that the concentrating mechanism in newborn rats is similar to that in the avian kidney, which has very low descending limb water permeability, does not utilize urea, and can concentrate urine to only moderate levels; however, within about 14 days, the neonatal rat kidney more closely resembles the adult rat kidney.

In rabbits, the sodium concentration in cortex and medulla is similar regardless of age.[437] However, the medullary/cortical urea concentration ratio increases markedly between 14 and 21 days of age, coincident with the development of concentrated urine.[437] This increase in medullary/cortical urea concentration is primarily due to a reduction in cortical urea concentration, rather than an increase in medullary urea content.[437] However, in dogs, the developmental increase

in urinary concentrating ability is due predominantly to an increase in the medullary sequestration of urea.[444]

Newborn humans also have an inability to concentrate their urine.[445] Infants fed a high-protein diet are able to increase their urine osmolality following water deprivation; infants given a diet in which the extra protein is replaced by NaCl achieve a lower urine osmolality.[445] Thus, even in infants, urea has a special role in the production of concentrated urine.[166,445]

Aldose reductase enzyme activity is absent in IMCDs from newborn rat pups (<12 hours old), but is present in 3-day-old pups and increases progressively up to 20 days of age; enzyme activity then decreases to adult levels.[434] Consistent with these functional measurements, aldose reductase mRNA cannot be detected, even by RT-PCR, in inner medullas from newborn rats (<12 hours old), but can be detected in 3-day-old pups.[434] Aldose reductase mRNA abundance peaks between 8–20 days after birth, then decreases to levels found in adult rats.[434,446] Thus, aldose reductase mRNA and enzyme activity are induced prior to urine concentrating ability during development.

TonEBP is detected in the kidney at fetal day 16, and its expression increases at fetal day 20 and at postnatal day 1.[447] At day 21, the adult pattern of TonEBP expression is achieved, along with the development of urine concentrating ability.[434,447] Thus, TonEBP expression precedes the expression of its target genes, UT-A1 and UT-A3, and UT-A promoter I is under the transcriptional control of TonEBP.[265,447] In mouse kidney, NKCC2/BSC1 is first detected at fetal day 14, TonEBP at day 15, UT-A at day 16–18, and UT-A immunoreactivity increases markedly after birth.[448] Neonatal mice treated with furosemide have reduced expression of both TonEBP and UT-A.[448] These findings support the hypothesis that hypertonicity produced by NKCC2/BSC1 activates TonEBP, which in turn increases the transcription of UT-A during development and early postnatal life in mice,[448] consistent with UT-A promoter I containing a TonE.[224,261]

KLF12 is a transcription factor that is expressed in the fetal kidney starting at day 15.[449] KLF12 is able to increase UT-A promoter I activity by binding to a CACCC motif.[449] Thus, UT-A1 is a target gene of KLF12, which may be involved in collecting duct maturation after birth.[449]

SUMMARY

Concentrated urine is produced in the renal medulla through the generation of an osmotic gradient extending from the cortico–medullary boundary to the papillary tip. In the outer medulla, the gradient is generated by active NaCl transport from the thick limbs, and the resulting increase in osmolality in the interstitium and in water-permeable tubules and vessels; the effectiveness of this transport is widely believed to be augmented by a countercurrent multiplication mechanism involving interactions between descending and ascending limbs of Henle. Although the passive mechanism, proposed by Kokko and Rector[8] and by Stephenson,[9] remains the most widely-accepted hypothesis for the generation of the inner medullary osmolality gradient, much of the evidence from perfused tubule and micropuncture studies, and from the UT-A1/UT-A3 knockout mouse[144] is either inconclusive or at variance with the passive mechanism. Moreover, the passive mechanism has not been supported by mathematical simulations using measured transepithelial transport parameters.

Nonetheless, there have been important recent advances in the understanding of key components of the urine concentrating mechanism, notably the identification and localization of key transport proteins for water, urea, and sodium, and the elucidation of the role and regulation of osmoprotective osmolytes. Continued experimental investigation of transepithelial transport and its regulation, both in normal animals and in genetically-engineered mice, a more complete understanding of the interaction of anatomy and transmural transport among tubules and vessels, and incorporation of the resulting information into mathematical simulations, may help to more fully elucidate the inner medullary concentrating mechanism.

THE PLASMA SODIUM CONCENTRATION AND BODY FLUID TONICITY

Sodium and its accompanying anions are the principle osmotically active solutes in extracellular fluid.[1,2] When extracellular osmolality is low, intracellular osmolality is equally low. Therefore, although there are exceptions (Table 44.1), hyponatremia is usually associated with hypoosmolality and dilution of all body fluids.[1,2,3]

When (as is usually the case) the concentration of non-permeant extracellular solutes other than sodium is very low, the plasma sodium concentration is a function of three variables, as indicated by the following equation:

$$\text{Plasma}[Na^+] \cong \frac{\text{Exchangeable } Na^+ + \text{Exchangeable } K^+}{\text{Total body water}} \quad (44.1)$$

Only the exchangeable fractions of sodium and potassium are included in the equation, because one-third of body sodium is bound to bone and osmotically inactive.[1] This relationship, which has been validated empirically,[3,4] indicates that the plasma (or serum) sodium concentration can be reduced by depletion of body cations, by an increase in body water or by a combination of these processes.[5] Recently, it has been emphasized that the original equation describing the relationship between the plasma sodium concentration, exchangeable sodium, exchangeable potassium, and total body water has an intercept that can be explained theoretically.[6] The simplified form of the relationship Eq. (44.1), which omits the intercept, is useful conceptually, but should not be considered a completely accurate basis for predicting the effect of therapy on the plasma sodium concentration.

It is intuitively obvious that the extracellular sodium concentration should be proportional to the body's content of water and soluble sodium. The sodium concentration falls when the body retains water (without solute) or when there are net external losses of sodium (without water). The importance of intracellular potassium stores to the plasma sodium concentration is less obvious.[7,8] In potassium depletion, sodium ions move intracellularly as intracellular potassium is lost, balancing negative charges on intracellular macromolecules. Thus, external loss of exchangeable potassium causes an internal loss of extracellular sodium. Similarly, when intracellular potassium is replaced by hydrogen ions, rather than sodium or when it is lost with phosphate (an intracellular anion), the loss of osmotically active intracellular solute causes a redistribution of water from the intracellular to the extracellular fluid compartments, diluting extracellular sodium ions.

PHYSIOLOGIC CONTROL OF WATER EXCRETION

Osmotic Regulation

Controlled by changes in water intake, vasopressin secretion, and water excretion, the plasma sodium

Seldin and Giebisch's The Kidney, Fifth Edition.

TABLE 44.1 Causes of Non-Hypotonic Hyponatremia

Plasma Osmolality	Disorder	Pathogenesis
Normal	Pseudohyponatremia	Excess non-aqueous material decreases plasma water content; no change in ECF or ICF volume
	Hyperlipidemia	
	Multiple myeloma	
	Exogenous solutes	Expansion of ECF volume with non-sodium solutes and water; no change in ICF volume
	Isotonic IV mannitol	
	Irrigant absorption	
Increased	Hyperglycemia, hypertonic IV mannitol, and maltose containing IgG solutions	Initial expansion of ECF volume and shift of water out of cells; decrease in ICF volume

concentration is normally prevented from rising above 142 mEq/L or falling below 135 mEq/L. When the plasma sodium concentration changes by as little as 1% (with a corresponding change in plasma osmolality), cell volume receptors ("osmoreceptors") in the hypothalamus respond, relaying signals to vasopressin-secreting neurons located in the supraoptic and paraventricular nuclei whose axons terminate in secretory bulbs in the neurohypophysis.[9–11] The antidiuretic hormone, arginine vasopressin, which is released into the systemic circulation by the neurohypophysis, controls water excretion by the kidneys. The hormone activates V_2 receptors on the basolateral membrane of principal cells in the renal collecting duct, initiating a cyclic AMP-dependent process that culminates in increased production of water channels (aquaporin 2), and their insertion into the cells' luminal membranes.[12] The effect of vasopressin on water flow is inhibited by locally produced prostaglandin E_2, which is stimulated by vasopressin action on V_1 receptors.[13] Vasopressin's short half-life in the circulation and continuous shuttling of aquaporins between the collecting duct's cell membrane and cytosol allow rapid changes in urinary water excretion in response to changes in body fluid tonicity.

Vasopressin levels are normally unmeasurable when the plasma sodium concentration falls to approximately 135 mEq/L. Low levels of the hormone allow the excretion of large volumes of a maximally dilute urine ($\approx$50 mOsm/kg) which reduces body water content and restores the plasma sodium concentration to normal. At higher plasma sodium levels, plasma vasopressin is directly related to the plasma sodium concentration, reaching levels that are high enough to promote the excretion of maximally concentrated urine ($\approx$1200 mOsm/kg) at a plasma sodium concentration of approximately 142 mEq/L. A rising plasma sodium concentration also stimulates thirst. Ingested water is retained, returning the plasma sodium concentration back towards normal.

Hemodynamic Regulation

Under day-to-day conditions, vasopressin secretion, urinary free water excretion, and thirst respond primarily to changes in body fluid tonicity. Under pathologic conditions, osmotic control of vasopressin secretion and thirst can be overridden by hemodynamic stimuli.[14] In addition to input from osmoreceptors, the hypothalamic neurons that secrete vasopressin also receive neural input from baroreceptors in the great vessels, and volume receptors in the atria. When these receptors are stimulated by hypotension or by a major reduction in plasma volume, impulses are carried via cranial nerves IX and X to the hypothalamus. The thirst center in the hypothalamus responds to similar non-osmotic stimuli. Vasopressin and thirst responses to hypovolemia and hypotension lead to water retention, despite hypotonicity of body fluids. These hemodynamic responses can be regarded as back-up systems that serve to maintain arterial blood volume under emergency conditions, sacrificing tonicity to tissue perfusion. Although high levels of vasopressin occur in response to hypovolemia, under experimental conditions, a rather large stimulus is required; while plasma vasopressin is measurably increased by a 1% change in plasma osmolality, a 10% change in extracellular fluid volume is required to elicit the same response. However, these experimental findings are difficult to reconcile with clinical observations, suggesting that non-osmotic vasopressin secretion occurs with more subtle volume depletion.

HYPOTONIC HYPONATREMIA: CLASSIFICATION AND PATHOGENESIS

Traditionally, patients with hyponatremia are divided into categories according to their body sodium content and/or intravascular volume: low body sodium content (volume depletion); high body sodium content (edematous conditions) or normal body sodium content (euvolemic hyponatremia or SIADH).[15] Although this time-honored approach is often helpful to clinicians, intravascular volume and body sodium content do not always change in parallel (e.g.,

self-induced water intoxication), and some causes of hyponatremia (e.g., diuretic-induced and cerebral salt-wasting) may be difficult to classify by intravascular volume. Moreover, physiologic responses to extracellular volume expansion and contraction often create ambiguities in volume status. Thus, secondary water retention in response to volume depletion and secondary natriuresis in response to water overload may ultimately yield similar values for total body sodium and water (Figure 44.1).

Table 44.2 classifies hyponatremia by the physiologic mechanism underlying the electrolyte disturbance. As the plasma sodium concentration is proportional to the ratio of exchangeable cations and total body water, it follows that changes in sodium concentration are related to external balances of sodium, potassium, and water. However, because the plasma sodium concentration is normally maintained within a narrow physiologic range by control systems which regulate water balance, hypotonic hyponatremia can only occur if water excretion is impaired or overwhelmed. The various causes of hyponatremia are therefore divided according to the status of urinary water excretion. Disordered water balance is often accompanied by changes in cation balance, which also play a pivotal role in the pathogenesis of hyponatremia.

TABLE 44.2 Pathophysiologic Classification of Hypotonic Hyponatremia

Urine Diluting Ability	Cause of Hyponatremia
Unimpaired	Psychotic polydipsia
	Beer potomania
	Infantile water intoxication
Impaired: vasopressin-independent	Oliguric renal failure
	Tubular interstitial renal disease
	Diuretics
	Nephrogenic syndrome of antidiuresis[a]
Impaired: vasopressin-dependent	Hemodynamically-mediated
	Volume-depletion
	Spinal cord disease
	Congestive heart failure
	Cirrhosis
	Addison's disease[b]
	Cerebral salt-wasting[b]
	SIADH (see Table 44.3)

[a]*Hereditary disorder of the V2 receptor with clinical features of SIADH, but with undetectable plasma vasopressin levels.*
[b]*Disorders with both hemodynamic and non-hemodynamic bases for vasopressin release.*

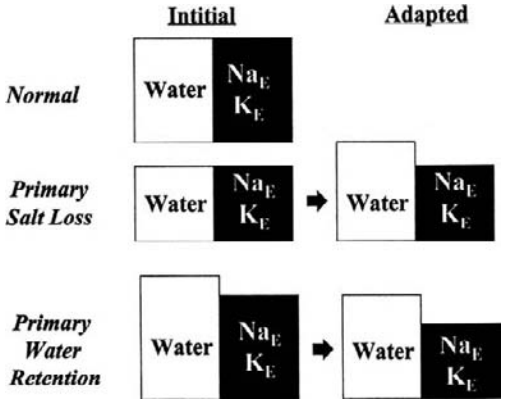

FIGURE 44.1 **Body water and cation content in hyponatremia.** When the primary disturbance is loss of salt water (middle figures), compensatory mechanisms are triggered—hemodynamically mediated thirst and vasopressin secretion—which result in secondary water retention. When the primary disturbance is pathologic secretion of vasopressin and water retention (bottom figures), compensatory mechanisms are triggered—increased secretion of atrial natriuretic peptide, decreased secretion of aldosterone, and pressure natriuresis—which result in secondary salt loss. Because of these adaptations, primary salt loss and primary water retention both result in near normal values for total body water and decreased body cation stores.

WATER INTOXICATION WITH MAXIMALLY DILUTE URINE

Pathophysiology

Rarely, fluid intake can overwhelm normal mechanisms for water excretion. In the absence of vasopressin, urine osmolality falls to approximately 50 mOsm/kg. A typical American diet provides a daily load of 600 to 900 milliosmoles of solute (electrolytes and urea) that must be excreted. At this rate of solute excretion, the volume of maximally dilute urine equals 12 to 18 liters per day or 500 to 750 ml/hour. Water intake can occasionally exceed this large excretory capacity. Patients with severe acute water intoxication are truly "waterlogged," and susceptible to pulmonary edema due to retained water.

Self-Induced Water Intoxication in Psychotic Polydipsia

Polydipsia and polyuria are extremely common among institutionalized patients with mental illness.[16–20] Many patients with polydipsia have frequent

episodes of hyponatremia, which may present with seizures. About half the reported cases have had maximally dilute urine (urine osmolalities below 100 mOsm/kg) at presentation. In others, inappropriately concentrated urine was present immediately following seizures or in association with nausea,[19] but the rate of correction of hyponatremia indicates that the urine became dilute soon afterwards.

In most psychotic water drinkers, hyponatremia can be ascribed to a generalized dilution of body solutes by retained water; thus, body weight increases in proportion to the severity of hyponatremia. Patients gain weight and become hyponatremic during the course of the day, and then spontaneously diurese, normalizing their plasma sodium concentration and body weight during the night. Caregivers in psychiatric hospitals routinely monitor weight changes in patients who are habitual water drinkers to determine when access to water must be rigidly restricted to avoid severe symptomatic hyponatremia.

Agents that interfere with the ability to maximally dilute the urine (e.g., diuretics or carbamazepine) should be avoided in polydipsic patients, as they can precipitate a rapid onset of life-threatening hyponatremia.[21,22]

Water Intoxication in Infants

Acute water intoxication is common among infants who are given excessively dilute formula.[23,24] The hungry infant ingests large volumes of fluid leading to water retention, despite the excretion of maximally dilute urine. Once water is restricted, the plasma sodium concentration self-corrects as large volumes of urine are excreted.

Beer Drinkers Potomania

Alcoholics who eat little and subsist on large volumes of beer may also become hyponatremic while excreting maximally dilute urine.[25–27] Beer's low protein content and the protein-sparing effect of its carbohydrate result in profoundly reduced blood urea nitrogen concentrations and urinary urea excretion. The total daily excretion of urinary solute may be only 200 to 300 milliosmoles. Thus, even at a urine osmolality of 50 mOsm/kg, urine output is limited to 4 to 6 liters per day, an amount that fails to match the enthusiastic beer drinker's intake of electrolyte free water. A similar phenomenon has been reported in non-beer drinkers with a high fluid and low protein intake.[27,28] Volume-depletion from gastrointestinal losses, and transient vasopressin release caused by nausea or alcohol withdrawal, may further limit the beer drinker's ability to excrete free water, contributing to the development and persistence of hyponatremia.[29]

VASOPRESSIN-INDEPENDENT DEFECTS IN WATER EXCRETION

Pathophysiology

Maximal free water excretion depends on adequate delivery of glomerular filtrate to the renal diluting segments (the ascending limb of the loop of Henle and the distal tubule), reabsorption of salt without water by the diluting segments to create hypotonic fluid within the tubular lumen, and a collecting duct that is relatively impermeable to water, so that the dilute tubular fluid formed "upstream" can be eliminated in the final urine. Hyponatremia occurs when water is taken in at a time when these mechanisms are not functioning normally.

Renal Failure

The most obvious cause of impaired water excretion is oliguric renal failure. Even when nonoliguric, patients with advanced renal failure have fixed isosthenuria, and are unable to excrete dilute urine despite normally suppressed vasopressin secretion. In the absence of renal failure, urinary dilution can still be impaired, despite low levels of vasopressin, by two mechanisms: (1) enhanced proximal reabsorption of the glomerular filtrate, limiting fluid delivery to the renal diluting segments (as in volume depletion, congestive heart failure, and cirrhosis)[30]; and (2) impaired sodium reabsorption in the renal diluting segments (by diuretics or tubular interstitial disease).[31]

Diuretic-Induced Hyponatremia

Both thiazides and loop diuretics interfere with the ability to maximally dilute the urine.[32] Thus, both classes of diuretic can lead to water intoxication in patients who habitually ingest extremely large volumes of water. Diuretics are one of the most important causes of hyponatremia.[33–37] Most cases are caused by thiazide or thiazide-like agents; loop diuretics are implicated much less commonly. Thiazides may be the sole factor responsible for causing hyponatremia, and they may also exacerbate hyponatremia in patients with disorders associated with SIADH.[36,38] The mechanism of thiazide-induced hyponatremia remains somewhat unclear; however, as for all causes of hyponatremia, water retention and/or cation depletion must be responsible. There is evidence that thiazides have a

direct antidiuretic effect mediated by upregulation of aquporin 2 (AQP2).[39]

Most cases of thiazide-induced hyponatremia have occurred in elderly small women who have been prescribed diuretics for the treatment of hypertension.[35,40–42] The impairment of renal diluting ability caused by thiazides is more pronounced in elderly people, especially those who have previously experienced thiazide-induced hyponatremia.[43] The predisposition of elderly women to severe hyponatremia may be explained by body size, in that small changes in body water and electrolyte content can lead to marked changes in serum sodium.

In susceptible individuals, the serum sodium may fall within hours of diuretic ingestion, and severe hyponatremia can develop in less than two days.[41,44–46] While in many cases the diuretic had been recently prescribed, in others thiazides had been used chronically without incident until, for some reason, water intake increased, dietary salt and protein intake decreased or an intercurrent illness led to "inappropriate" antidiuretic hormone secretion.[33,47] Mild hyponatremia often persists for a few weeks when diuretic therapy is withdrawn from patients with diuretic-induced hyponatremia,[48] apparently reflecting temporary "resetting" of the osmostat[49] or alternatively, slow restoration of depleted cation stores.

Although thiazide diuretics do not inhibit the ability to concentrate the urine, they do impair diluting ability in several ways[31,39,50–52]: inhibition of electrolyte transport at the cortical diluting sites; direct stimulation of vasopressin release; direct upregulation of AQP2; reduction of glomerular filtration; and enhancement of fractional proximal water reabsorption, reducing delivery to diluting sites.

Positive water balance during the onset of thiazide-induced hyponatremia and negative balance during its correction have been documented.[22,44,46] Some patients with thiazide-induced hyponatremia have low serum uric acid levels and high uric acid clearances (markers of volume expansion) which return to normal as the serum sodium normalizes.[36,53] Most affected patients drink large amounts of water, and the superimposed diuretic prevents urine output from keeping pace with water intake.[44]

Although increased total body water often contributes to the pathogenesis of thiazide-induced hyponatremia, there are many cases in which body weight decreased or remained the same during the fall in serum sodium.[41,54,55] In others, direct measurements of total body water in affected patients have been normal.[41] In these cases, other explanations for hyponatremia must be sought.

Negative cation balance plays a major role in the pathogenesis of diuretic-induced hyponatremia. Rejected cations may be excreted at a total concentration which exceeds that of plasma, directly "desalinating" the plasma even in the absence of water intake.[44] Potassium depletion is an important factor in many cases; treatment of hypokalemia has been shown to increase the plasma sodium concentration with no change in body weight.[41] Magnesium repletion may act similarly, presumably through an effect on skeletal muscle Na-K-ATPase.[56] Surprisingly, despite negative cation balance, many patients appear to be euvolemic. Apparently, enough water is retained to offset the initial tendency toward hypovolemia. Once diuretics are withdrawn, urinary sodium excretion falls to very low levels.[41,46]

VASOPRESSIN-DEPENDENT DEFECTS IN WATER EXCRETION

Pathophysiology

Normally, in response to hypotonicity, vasopressin secretion is suppressed, the collecting duct is impermeable to water, and a maximally dilute urine is formed. In two large surveys of hospitalized patients with hyponatremia, over 90% of cases were associated with elevated vasopressin levels.[57,58] Vasopressin levels are rarely elevated into pathologic ranges, even in cases associated with ectopic secretion by tumors. Rather, vasopressin levels are inappropriately high relative to the plasma osmolality. Non-osmotic vasopressin secretion may be an adaptive response driven by hemodynamic stimuli or it may be "inappropriate" and independent of any of the usual physiologic mechanisms which regulate water excretion. Persistent vasopressin secretion despite hypoosmolality allows ingested or infused free water to be retained, causing hypotonic hyponatremia. Vasopressin-mediated hyponatremia is characterized by urine which is more concentrated (usually much more) than 100 mOsm/kg and which becomes more dilute after administration of a V2 receptor antagonist (see section "V_2-Receptor Antagonists").

Patients with inappropriate vasopressin secretion must take in water to become hyponatremic. In some cases, hyponatremia develops when electrolyte-free water is administered parenterally. More commonly, patients become hyponatremic while ingesting water. Theoretically, osmotic inhibition of thirst should prevent water ingestion when the ability to excrete water is impaired. However, patients with SIADH continue to drink despite plasma osmolalities below the normal osmotic threshold for thirst. Formal testing has shown that there is downward resetting of the osmotic threshold for thirst in SIADH, but that thirst responds to

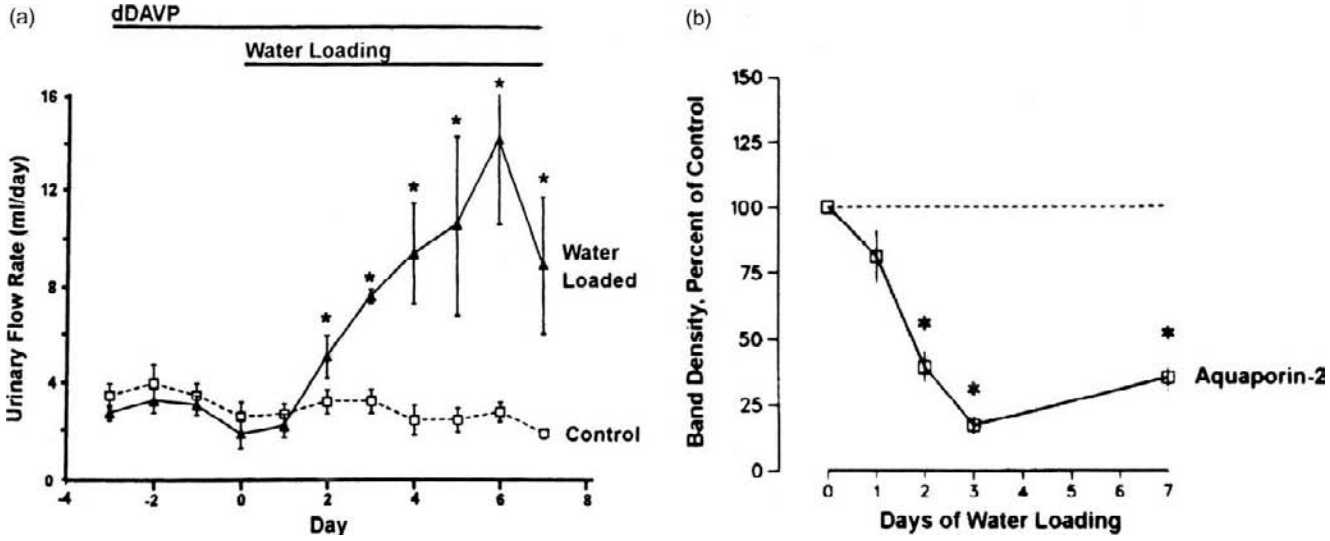

FIGURE 44.2 **Vasopressin escape.**[64] Panel (a) illustrates the gradual increase in urine flow rate (accompanied by a decrease in urine osmolality) that occurs when rats treated continuously with dDAVP are made hyponatremic with water-loading. The escape from the antidiuretic effect of vasopressin begins on the second day of water-loading. Panel (b) illustrates the levels of acquaporin 2 protein levels from kidney homogenates taken on each day of water-loading. Levels of acquaporin 2 protein decrease despite continued administration of vasopressin, and correlate with changes in urine volume.

osmotic stimulation and is suppressed by drinking around the lowered set-point.[59]

Escape from Vasopressin-Induced Water Retention

Experimentally, after several days of constant vasopressin infusion and constant water intake, there is an escape from the antidiuretic effect of vasopressin. With the onset of vasopressin escape, the urine becomes less concentrated, allowing water balance to be re-established at a new steady-state in which the plasma sodium concentration stabilizes at a level lower than normal. In experimental models, escape is temporally associated with a marked decrease in renal aquaporin-2 protein, accompanied by suppression of aquaporin-2 mRNA levels (Figure 44.2).[60] V2-receptor mRNA expression and binding are decreased, as is c-AMP production in response to vasopressin,[61] Plasma and urine aldosterone and mean arterial pressure are increased as are thiazide-sensitive Na-Cl co-transporter and ENaC proteins in the distal nephron that are known to be upregulated by aldosterone.[62] Inhibition of nitric oxide synthase or prostaglandin synthesis synergistically inhibit the escape phenomenon, supporting a role for nitric oxide and prostaglandins in mediating vasopressin escape.[63]

In conditions characterized by vasopressin-mediated water retention, (e.g., SIADH, congestive heart failure), renal escape from vasopressin-induced antidiuresis (along with decreased water intake in some cases) permits patients with vasopressin-mediated hyponatremic states to manifest a relatively stable level of hyponatremia, despite continued water intake and continued presence of vasopressin.

HEMODYNAMIC CAUSES OF VASOPRESSIN-MEDIATED HYPONATREMIA

Pathophysiology

Hypovolemia, heart failure, and cirrhosis are the most common non-osmotic stimuli for antidiuretic hormone secretion.[64] In a series of 100 consecutive hospitalized patients with hypotonic hyponatremia, volume contraction (29%), advanced heart failure (25%), and liver cirrhosis (16%) were identified as the cause of hyponatremia in a high percentage of cases.[58] The hemodynamic abnormalities that stimulate vasopressin release in these conditions also promote sodium reabsorption by the renal tubules (mediated by aldosterone, increased sympathetic nervous system activity, peritubular Starling forces, etc.), causing both sodium and water retention. In volume-depletion, sodium retention serves to replace a sodium deficit; in heart failure and cirrhosis, sodium retention serves to compensate for the circulatory abnormality, but it also causes edema.

Volume-Depletion

Sodium and potassium losses associated with gastrointestinal fluids (or with urinary losses caused by osmotic or loop diuretics) do not directly lower the plasma sodium concentration, because these fluids are either hypotonic or isotonic. However, the intravascular volume-depletion caused by such losses is a hemodynamic stimulus for thirst and vasopressin secretion; as a result, ingested water is retained, lowering the plasma sodium concentration. Thus, hyponatremia in these conditions is associated with a reduced content of both total body cations and water. However, in many patients, compensatory water retention makes it difficult to detect the underlying volume depletion. Laboratory clues, including a low urine sodium concentration and elevated serum uric acid levels, can be helpful diagnostically.[65]

Spinal Cord Disease

Hyponatremia is very common after spinal cord injury, particularly among patients with complete quadriplegia.[66,67] Contributing factors include a large water intake (reflecting physician recommendations, angiotensin II-mediated thirst, and loss of pharyngeal and gastric satiety signals), and baroreceptor-mediated vasopressin release. One study showed normal osmoregulation of vasopressin secretion and excretion of a water-load when subjects were supine, but with the subjects in a sitting position, there was a reduced osmotic threshold and increased sensitivity for vasopressin release, and urine diluting ability and free water clearance were markedly impaired.[68]

Edematous Conditions

Severe hyponatremia can occur despite increased body sodium content if retained sodium is offset by a disproportionate increase in body water.

Congestive Heart Failure

Hyponatremia in heart failure stems from reduced cardiac output and blood pressure which stimulate vasopressin, catecholamines, and the renin–angiotensin–aldosterone axis.[64,69–71] Increased vasopressin levels have even been documented in patients with impaired left ventricular function before the onset of symptomatic heart failure.[72] Hyponatremic patients with congestive heart failure have higher levels of plasma renin activity, norepinephrine, epinephrine, and lower renal and hepatic plasma flows than normonatremic patients with an apparently similar degree of heart disease. Hyponatremia in heart failure is associated with a poor prognosis.[73]

Hepatic Cirrhosis

Cirrhosis is characterized by a hyperdynamic circulation with low blood pressure, low systemic vascular resistance, and high cardiac output.[74] Systemic vasodilatation causes relative underfilling of the arterial vascular compartment and neurohumoral responses similar to those that occur in response to a low cardiac output.[75] Activation of the renin–angiotensin–aldosterone axis and the sympathetic system, combined with non-osmotic release of vasopressin, results in renal water and sodium retention.[76,77] Escape from the sodium-retaining effect of aldosterone does not occur, and there is renal resistance to atrial natriuretic peptide. Although the pathogenesis of the peripheral arterial vasodilation is incompletely understood, increased vascular nitric oxide by the endothelium may play a role. In a rat model of cirrhosis, normalization of vascular nitric oxide production with a nitric oxide synthetase inhibitor corrects the hyperdynamic circulation, improves sodium and water excretion, and decreases neurohumoral activation.[74]

Peritoneovenous shunting of hyponatremic cirrhotic patients with refractory ascites improves cardiac output, renal plasma flow, and creatinine clearance, and results in an immediate diuresis and natriuresis with a decrease in urine osmolality and an increase in plasma sodium concentration associated with a small but significant decrease in plasma vasopressin levels.[74]

INAPPROPRIATE VASOPRESSIN SECRETION (SIADH)

Pathophysiology

Definitions

Non-osmotic release of vasopressin without a hemodynamic stimulus to account for it is considered "inappropriate".[78] When Bartter and Schwarz first described the syndrome of inappropriate antidiuretic hormone secretion (SIADH), they defined clinical criteria for the disorder which are still generally accepted: hypoosmolality and clinical euvolemia with a sodium-containing urine (>30 mmol/L) that is less than maximally dilute (>100 mOsm/kg) without recent diuretic use or impaired renal function. Schwarz and Bartter also excluded endocrine disorders—primary and secondary adrenal insufficiency and hypothyroidism—from this designation. We have not made this exclusion, because patients with undiagnosed endocrine disturbances may present with all the clinical features of SIADH. Indeed, the discovery of SIADH is often the presenting feature of a clinically important systemic disease. Abnormal vasopressin secretion may be caused by ectopic

production of the hormone by tumors, from disordered secretion by the neurohypophysis or from increased sensitivity to the hormone (Table 44.3).

Patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) retain ingested water, but they have no evidence of volume depletion and no tendency to form edema. Because of water retention, SIADH causes mild, subclinical volume-expansion, which is reflected by high uric acid clearance, a low plasma uric acid concentration, and urine sodium excretion which matches or exceeds sodium intake.[79,80] Clinicians make use of these characteristics to distinguish SIADH from hyponatremia caused by volume-depletion. The recently described syndrome of nephrogenic inappropriate antidiuresis (see section "Common Causes of SIADH") is discussed in this section because it exhibits clinical features of SIADH; in physiological terms, however, it is a cause of hyponatremia that is independent of vasopressin, as plasma vasopressin levels are undetectable (Table 44.2).[81]

TABLE 44.3 Causes of SIADH

Major Classification	Common Examples
Tumors	Small-cell lung cancer
	Head and neck tumors
Lung diseases	Pulmonary infection
	Hypoxia and hypercarbia
	Severe asthma
Neurologic disorders	Subarachnoid hemorrhage[a]
	Guillain-Barre syndrome[a]
	CNS infections
	Cerebral hemorrhage and infarction
	Brain tumors
Endocrine diseases	Hypothyroidism[a]
	Hypopituitarism
	Isolated ACTH deficiency
Medications	Arginine vasopressin and desmopressin acetate
	Amiodarone
	Chlorpropamide
	Carbamazepine and oxcarbazepine
	Cyclophosphamide
	Nonsteroidal anti-inflammatory agents; serotonin reuptake inhibitors
	Tricyclic antidepressants
	Vincristine
	3,4-methylenedioxymethamphetamine (ecstasy)
Hereditary	Nephrogenic syndrome of antidiuresis[b]
Miscellaneous, transitory causes	Surgery
	Pain and stress
	Nausea
	Alcohol withdrawal

[a]*Disorders with both hemodynamic and non-hemodynamic bases for vasopressin release.*
[b]*Hereditary disorder of the V2 receptor with clinical features of SIADH, but with undetectable plasma vasopressin levels.*

Patterns of Vasopressin Secretion

In most patients with SIADH, vasopressin secretion has followed one of two basic patterns: "reset osmostat" or "vasopressin leak".[11,82] In the reset osmostat variant of SIADH, seen in patients with chronic, debilitating illness and in normal pregnancy, the urine can be diluted maximally, but at a lower set-point than normal.[49] Such patients are thus mildly hyponatremic, but unlike other patients with SIADH, their plasma sodium concentration is very stable and they do not require dietary water restriction or other measures used to treat chronic hyponatremia. In the vasopressin leak variant, the basal level of vasopressin is elevated and unresponsive to osmotic stimuli when the plasma osmolality is low, but the levels increase appropriately when the plasma osmolality increases above a threshold level. Less commonly, patients exhibit erratic vasopressin secretion which is unrelated to osmotic stimuli. In about 10% of patients who present with typical clinical manifestations of SIADH, plasma vasopressin levels are at a low basal level that fails to increase as plasma osmolality increases. Such a pattern would be expected if an antidiuretic factor other than vasopressin were produced or if the collecting tubules were hypersensitive to normal hormone levels.

Interplay of Water Retention and Cation Depletion in SIADH

In SIADH, increased intravascular volume decreases renin secretion and increases release of atrial natriuretic peptide. These volume and hormonal changes promote sodium excretion, despite a low serum sodium concentration. Natriuresis in SIADH blunts the increase in extracellular volume caused by water retention (Figure 44.1),[80,83] but it also exacerbates hyponatremia (Eq. (44.1)). Balance studies in a group of patients with SIADH showed that during a period of high water and low sodium intake, the plasma sodium concentration decreased by 8 mEq/L with no gain in weight and no increase in chloride space (a measure of extracellular fluid volume).[84] Negative sodium and potassium balances accounted for the stability of

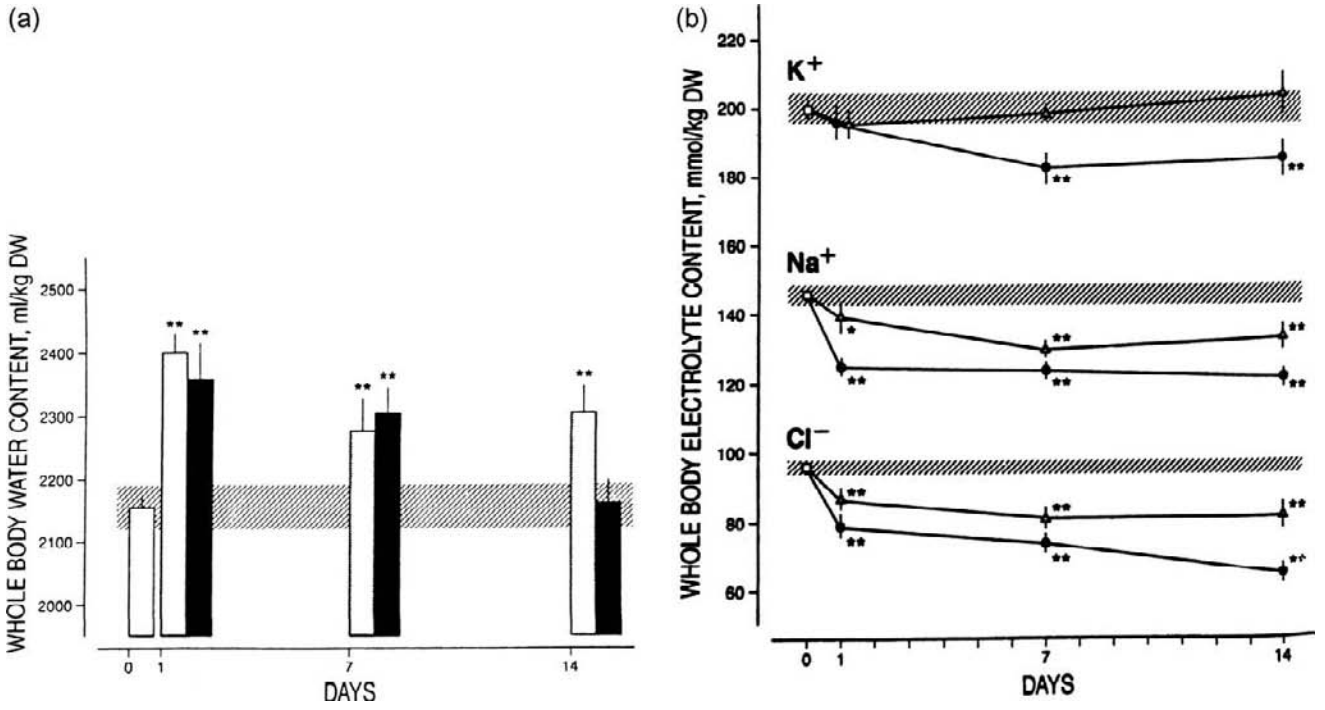

FIGURE 44.3 **Body water content in experimental SIADH.**[88] Panel (a) depicts measurements of body water content in rats made hyponatremic with dDAVP and a liquid diet. The open bar at the far left of the figure represents measurements obtained in normonatremic controls given no dDAVP. The black bars represent measurements obtained in animals made severely hyponatremic (plasma sodium 106 to 112 mmol/l) by giving dDAVP at 5 ng/hr; the gray bars represent measurements obtained in animals made less hyponatremic (plasma sodium 119 to 124 mmol/l) by giving dDAVP at 1 ng/hr. Body water content initially increases after the first day of hyponatremia at both doses of dDAVP, but falls to control levels after 14 days of severe hyponatremia. Panel (b) depicts whole body Na, K, and Cl measurements in the same experiment. Cation and chloride losses occur, beginning on the first day of hyponatremia, and are more severe in animals given the higher dose of dDAVP (with lower plasma sodium levels). Depletion of Na and Cl most likely represent adaptive responses to extracellular fluid volume expansion caused by retained water. Depletion of body K most likely represents a cell volume adaptive response.

extracellular volume, and for over 80% of the calculated solute loss. During a period of high sodium intake, over 600 mEq of sodium was retained (with only a small increase in weight and chloride space), fully accounting for the 11 mEq/L increase in serum sodium concentration.[84] In this study, there was a strong negative correlation between water intake and sodium balance, and between water intake and aldosterone secretory rate. Similar findings have been reported in studies in which pituitary extract was administered chronically to normal subjects.[83,85,86]

In an experimental model of SIADH produced by DDAVP and half-isotonic saline in the rat, hyponatremia was caused exclusively by negative balances of sodium and potassium; water balance, which was slightly negative, did not contribute to the decrease in sodium concentration.[87] Despite negative balances for sodium, chloride, and water, the extracellular volume (measured by inulin space) was not contracted, suggesting that water shifted from the intracellular to the extracellular space in response to the loss of intracellular solute (potassium and phosphate).

Similarly, direct measurements of body composition in a rat model of chronic SIADH showed that after 14 days of severe hyponatremia, body water content had returned to control levels[88] (Figure 44.3). Body sodium and chloride levels were reduced after one day of hyponatremia and were sustained for 14 days, and body potassium was significantly decreased after 7 days. Acutely, water retention was the major cause of hyponatremia, but solute depletion was primarily responsible when the electrolyte disturbance was sustained.

Urinary losses can directly lower the plasma sodium concentration when the concentration of sodium plus potassium in the urine is higher than the plasma sodium concentration. This can occur when high vasopressin levels (which concentrate the urine) and high rates of sodium and potassium excretion occur together. The excretion of hypertonic urine generates free water, in essence "desalinating" the plasma.[89]

Serum Bicarbonate Concentration in SIADH

In SIADH, the serum sodium and chloride concentrations are lowered by dilution, but the serum

bicarbonate concentration is typically normal.[90,91] This finding has been explained by a direct effect of hyponatremia on the adrenal gland to increase aldosterone secretion, which then augments renal net acid excretion.[92] Patients with hyponatremia due to hypopituitarism have many features in common with patients with non-endocrine SIADH, but their serum bicarbonate concentrations are about 5 mmol/l lower. Consistent with the hypothesis that hyponatremia-induced hyperaldosteronism is responsible for the normal serum bicarbonate in classic SIADH, aldosterone levels are much lower in patients with ACTH deficiency than in patients with non-endocrine SIADH.[90]

Common Causes of SIADH

Tumors

The first cases of SIADH were described in patients with lung cancer.[78] Small-cell carcinoma of the lung remains a common cause of the syndrome; approximately 10 to 15% of these patients present with SIADH, whereas fewer than 1% of patients with non-small-cell lung cancer become hyponatremic.[93,94] Ectopic production of vasopressin appears to be responsible for most cases hyponatremia associated with small-cell carcinoma.[95,96] Arginine vasopressin, oxytocin, and neurophysins have been found by radioimmunoassay in tumors, and are produced by the vast majority of small-cell lung cancers; the quantity of vasopressin peptide is closely correlated with the presence of hyponatremia.[97–99] Atrial natriuretic peptide mRNA has also been detected in a high percentage of cell lines from patients with small-cell cancer.[100] Hyponatremia develops in approximately 3 to 7% of patients with head and neck cancer[94,101]; the mechanism for SIADH associated with these tumors is unknown. Although a number of other tumors can produce vasopressin, there are very few reports of hyponatremia associated with them.[94] SIADH may also emerge in patients with acute tumor lysis syndrome.[102,103]

Pulmonary Disease

Mild hyponatremia has long been recognized in patients with tuberculosis.[104,105] The mechanism for vasopressin release has not been determined, but hormone levels fall in response to water-loading, reflecting the reset osmostat variant of SIADH. Ectopic secretion of antidiuretic hormone was the presumptive cause of SIADH in a patient with central diabetes insipidus who developed pulmonary tuberculosis.[106] Tuberculosis-associated hyponatremia resolves within days to weeks of antituberculous therapy. Plasma vasopressin levels are typically elevated on admission in patients with bacterial pneumonia, and fall rapidly during treatment.[107] Hyponatremia is common,[108,109] and usually self-corrects relatively rapidly after a few days.[110] Abnormal vasopressin secretion in simple pneumonia is not attributable to hypovolemia, hypotension or abnormal PO_2 or PCO_2. An antidiuretic decapeptide ("pneumadin"), which rapidly increases arginine vasopressin (AVP) levels, has been isolated from rat and human lung.[111,112] Further study is needed to determine if the decapeptide mediates SIADH associated with pneumonia and other lung disorders. Acute respiratory failure (hypoxia and hypercarbia) and severe asthma are also associated with SIADH.[113,114]

Endocrine Disease

Hyponatremia is present in up to 88% of patients with Addison's disease, and in 28% of patients with isolated ACTH deficiency.[115] In Addison's disease, vasopressin is released in response to volume-depletion caused by mineralocorticoid deficiency, and altered hemodynamics caused by glucocorticoid deficiency. Glucocorticoids may also directly inhibit vasopressin release. Unlike Addison's disease, impaired water excretion in hypopituitarism is not associated with hyperkalemia, and it does not respond to volume replacement with isotonic saline so that hyponatremia in this condition has all the features of SIADH.[116–119] However, hyponatremia in patients with hypopituitarism is associated with a lower serum bicarbonate concentration than in patients with hyponatremia from other causes of SIADH (see section "Serum Bicarbonate Concentration in SIADH").[90] Impaired water excretion in hypopituitarism and in adrenalectomized mineralocorticoid replaced subjects is associated with elevated vasopressin levels; administration of a vasopressin V2 receptor-antagonist normalizes urinary water excretion in adrenalectomized mineralocorticoid replaced rats.[120] Inhibitory glucocorticoid receptors have been identified in the magnocellular neurons which secrete vasopressin, and these receptors are markedly increased under hypoosmolar conditions.[121–123] Hyponatremia with clinical features of SIADH has been described frequently in hypothyroidism; impaired water excretion can be corrected rapidly by the administration of thyroid hormone. However, it is unclear whether hemodynamic or intrarenal factors, rather than vasopressin, is responsible for impaired water excretion in this condition.[124,125]

Non-Diuretic Drugs

Arginine vasopressin used therapeutically in the treatment of gastrointestinal bleeding or in the management of septic shock, and the vasopressin analog desmopressin acetate (DDAVP), a pure V2

receptor-agonist used to treat diabetes insipidus, enuresis, and von Willebrand disease, may cause hyponatremia.[126,127] In addition, a growing number of drugs that are unrelated to vasopressin have been reported to cause hyponatremia. Most published reports involve thiazide and thiazide-like diuretics, chlorpropamide, carbamazepine, oxcarbantipsychotics, antidepressants, and nonsteroidal anti-inflammatory drugs.[128–130] Vincristine and vinblastine increase vasopressin release by unknown mechanisms, and hyponatremia associated with these agents is dose related.[128]

Several drugs associated with hyponatremia appear to increase the response of the collecting duct to circulating vasopressin.[128,131] Chlorpropamide has been the most thoroughly studied.[132] In addition to augmenting release of vasopressin from the neurohypophysis, chlorpropamide increases the number of vasopressin receptors on collecting tubule cells[133] and inhibits renal medullary synthesis of prostaglandin E_2, an agent which blunts the hydroosmotic effect of vasopressin by diminishing adenylate cyclase activity.[134–136] Inhibition of PGE_2 permits increased cAMP formation, enhancing the effect of the hormone. Nonsteroidal anti-inflammatory agents increase the hydroosmotic effect of vasopressin by a similar mechanism. Hyponatremia attributable solely to nonsteroidals has been rarely reported, but these commonly used drugs may exacerbate other causes of hyponatremia.[137,138]

Carbamazepine most commonly causes hyponatremia when it is given to subjects who habitually drink large volumes of water.[130,139] Carbamazepine increases water permeability of the distal inner medulary collecting duct in the absence of vasopressin, an effect that is cAMP-dependent and negated by a vasopressin V2 receptor-antagonist, implying an action on the V2 receptor–protein G complex.[140] Oxcarbazepine, which is enjoying increased use because of fewer drug interactions than carbamazepine, causes hyponatremia in 9% of patients with epiliepsy who are treated with the drug.[141]

Hyponatremia caused by cyclophosphamide may also be due to enhanced vasopressin action, but the mechanism for this effect has not yet been elucidated.[130] Cyclophosphamide's antidiuretic effect is delayed, with a time-course which parallels excretion of active metabolites of the drug.[142] Cyclophosphamide's antidiuretic effect may be enhanced by indomethacin.[143] There are many reports of SIADH associated with psychotropic drugs, including phenothiazines, monoamine oxidase inhibitors, and tricyclic antidepressants; causality has been most convincingly demonstrated with tricyclics.[144] More recently, a large number of cases of SIADH have been reported in patients taking serotonin reuptake inhibitors (SSRIs).[145–147] Prospective series in elderly patients have shown that 12 to 40% became hyponatremic within two weeks of starting therapy with paroxetine.[147–149] All of these agents act centrally, and could conceivably affect vasopressin release directly. There is evidence that SSRIs may have a direct effect on water permeability of the inner medullary collecting duct, increasing AQP2 without changing vasopressin levels.[150] The recreational drug, 3,4-methylenedioxymethamphetamine ("Ecstasy") has been associated with severe, and sometimes fatal, acute hyponatremia.[151] Ecstasy induces vasopressin secretion, and users of the drug who become hyponatremic typically manifest marked polydipsia.[152,153] Many cases of SIADH associated with amiodarone have been reported.[154–157]

Post-Operative SIADH

Vasopressin levels are elevated after operative procedures, and remain elevated for several days.[158] Administration of hypotonic fluid during this period of antidiuresis causes acute hyponatremia, with potentially disastrous consequences.

Urinary cation loss has been shown to play an important role in the pathogenesis of hyponatremia in patients with post-operative SIADH. In the post-operative period, it is common for physicians to infuse several liters of isotonic or hypotonic saline solutions, exceeding the intended replacement of third-space and external losses, and actually causing extracellular fluid volume-expansion. A balance study in women undergoing uncomplicated gynecological surgery showed that sodium plus potassium concentrations in the urine peaked at 295 ± 9 mEq/L, and remained hypertonic to plasma for the first 16 hours after induction of anesthesia[89](Figure 44.4). Because of the action of vasopressin and the natriuretic response to saline-induced volume-expansion, electrolyte-free water was generated, lowering the plasma sodium concentration despite infusion of isotonic saline. The infused saline was, in effect, "desalinated." A similar phenomenon occurs when patients with subarachnoid hemorrhage and "cerebral salt-wasting" are given large volumes of isotonic saline to protect cerebral perfusion.[159]

Neurologic Disorders and Cerebral Salt-Wasting

An association between hyponatremia and intracranial disease has been recognized since the 1950s, and hyponatremia has been reported in a wide variety of systemic diseases involving the CNS, including systemic lupus erythematosus, Guillain-Barre syndrome, meningitis, encephalitis, brain tumors, and brain abscesses.[160] Noting increased urinary sodium excretion in hyponatremic patients with neurologic disorders, Peters referred to the condition as "cerebral salt-wasting".[161] Once it was recognized that high rates

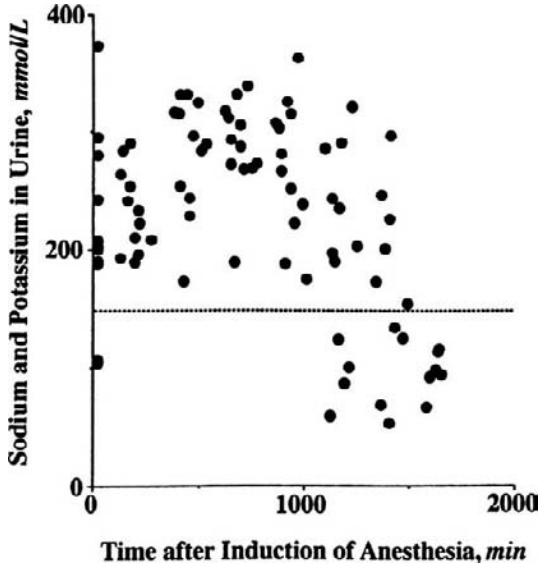

FIGURE 44.4 **Urine electrolytes in post-operative SIADH.**[89] The figure depicts the sum of urine sodium and potassium concentrations obtained post-operatively in 22 women undergoing uncomplicated gynecologic surgery and receiving infusions of 0.9% saline (sodium concentration 154 mmol/l) or lactated Ringer's solution (sodium concentration 130 mmol/l). The dotted line represents a urine cation concentration of 150 mmol/l, isotonic to normal plasma water. During the first 1000 minutes after the induction of anesthesia, urine cation concentrations were uniformly hypertonic to plasma, contributing to the genesis of hyponatremia. In samples obtained after 1000 minutes (from 16 to 24 hours), the urine remained hypertonic in some patients and became hypotonic in others. Hypotonic urine (below the dotted line) contributes to the correction of hyponatremia.

of urinary sodium excretion could be caused by unregulated secretion of antidiuretic hormone, most investigators ascribed hyponatremia in brain disease to SIADH, a syndrome which has been associated a wide array of central nervous system disorders, consistent with the multiple anatomic pathways leading to vasopressin secretion by hypothalamic neurons (Table 44.3).[162]

Cerebral salt-wasting was generally a forgotten term until the early 1980s, when a more concerted effort was made to understand the pathogenesis of hyponatremia in patients with intracranial disease (especially subarachnoid hemorrhage).[163,164] Reduced blood and plasma volume were found in most patients with intracranial disease who were presumed to have hyponatremia secondary to SIADH.[165–167] Prospective studies of patients with subarachnoid hemorrhage given maintenance fluids documented negative sodium balance, decreasing plasma volume, and increasing BUN among patients who became hyponatremic within a week of presentation.[164,168,169] A course consistent with cerebral salt-wasting was also observed in patients with head injury, brain metastases, and hydrocephalus.[170–172]

Maintaining an adequate circulatory volume has important clinical implications, especially in subarachnoid hemorrhage, where volume depletion and fluid restriction have been reported to predispose to cerebral ischemia and infarction.[173,174] This finding, and evidence that volume-expansion protects against cerebral ischemic events in subarachnoid hemorrhage, has led to a general acceptance of "hypertensive, hypervolemic, hemodilutional" therapy for the disorder.[175–177] When such treatment is given, a high urine sodium concentration and hyponatremia are not reliable indicators of salt-wasting, because hyponatremia may be due to SIADH and the natriuresis may be a response to iatrogenic volume-expansion. In one study, a positive balance for sodium could be documented in most patients believed to have cerebral salt-wasting when calculations included all infusions from the time of first contact with medical or paramedical personnel.[178] High levels of catecholamines which are often associated with brain injury decrease venous capacitance and raise blood pressure, potentially increasing "effective arterial blood volume," and promoting a physiological natriuresis.[179]

A valid diagnosis of cerebral salt-wasting requires proof of urinary sodium losses, despite reduced effective arterial blood volume. Attempts to establish a diagnosis of hypovolemia have included clinical impressions, central venous pressure, and measurements of plasma and blood volume; none of these can define hypovolemia definitively.[180]

As in patients with SIADH, plasma vasopressin levels are increased and urine sodium concentrations are elevated, but the increased vasopressin secretion in cerebral salt-wasting has been attributed to volume-depletion caused by the primary salt-wasting. Investigation into the pathogenesis of cerebral salt-wasting has focused primarily on the relative roles of natriuretic hormones and vasopressin after subarachnoid hemorrhage.[181–183] Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) are both derived from cardiac tissue, and have natriuretic and aldosterone-inhibiting properties. Although BNP has been localized to the hypothalamus, it is primarily of cardiac origin. Cardiac release of ANP and BNP is regulated in part by the CNS, and brain injury may induce their release from cardiac tissue. Plasma ANP levels generally correlate with the presence and severity of blood in the ventricles and increased intracranial pressure.[182] In one study, however, plasma levels of BNP, but not ANP or vasopressin, were correlated with urinary sodium excretion,[184] and in a rat model of cerebral salt-wasting, ANP levels decreased and BNP levels did not change.[185] Jugular venous sampling in

suspected cerebral salt-wasting did not support cerebral release of BNP.[186] It is thus unclear whether elevated natriuretic peptide levels are responsible for natriuresis in subarachnoid hemorrhage, and other factors, such altered sympathetic tone, depressed aldosterone levels, ouabain-like compound, and endothelin may contribute.[160,167,181,187] In fact, several studies have indicated that fludrocortisone may be effective in the treatment of cerebral salt-wasting.[188–191]

Regardless of the pathogenesis of renal salt-wasting in patients with subarachnoid hemorrhage, hyponatremia appears to be caused by vasopressin release that is independent of volume-depletion, and is thus "inappropriate." In a large prospective study of acute aneurysmal subarachnoid hemorrhage treated aggressively with isotonic saline (between 3 and 8 liters daily), hyponatremia developed in one-third of the patients within 4 to 6 days, despite positive fluid balance, increased blood volume, and suppressed plasma renin and aldosterone levels.[159] Plasma vasopressin was measured at concentrations of 1 to 4 pg/ml, despite plasma osmolalities at which the hormone should have been undetectable. Although plasma ANP levels were also increased in most patients, they did not correlate with serum sodium concentration. Thus, it is likely that both salt loss and SIADH contribute in varying degrees to the pathogenesis of hyponatremia after subarachnoid hemorrhage.

The true incidence of cerebral salt-wasting among patients with subarachnoid hemorrhage is probably low, and a clear distinction between this entity and SIADH in neurosurgical patients may not be important, because in either case the most effective treatment is intravenous hypertonic saline.[180]

Nephrogenic Syndrome of Inappropriate Antidiuresis

A gain-of-function mutation of the V2 receptor gene, named nephrogenic syndrome of antidiuresis (NSIAD), was first described in 2005.[81] Patients with this X-linked disease present with clinical and laboratory evaluations typical of SIADH, with undetectable plasma vasopressin levels. Missense mutations substituting cysteine or leucine for arginine on codon 137 cause constitutive activation of the vasopressin receptor, analogous to loss-of-function mutations found in patients with X-linked nephrogenic diabetes insipidus. Infants with NSIAD are at high risk for hyponatremia, because their diet consists primarily of liquid with little solute. However, the disease can escape detection until adulthood, and it should be suspected in young patients with a clinical diagnosis of idiopathic SIADH, especially if there is unresponsiveness to vasopressin antagonists. Female heterozygotes with skewed X-inactivation may develop spontaneous hyponatremia or an abnormal water-loading test.[192,193]

ADAPTATIONS TO HYPOTONIC HYPONATREMIA

Organic Osmolytes and Cell Volume Regulation

The osmotic challenges faced by hyponatremic patients are analogous to those faced by invertebrate organisms when they are exposed to a hypotonic environment. Throughout nature, cells respond to water stress in a similar manner. Water crosses cell membranes in response to osmotic forces, equalizing the activities of intracellular and extracellular solute. Cell volume is determined by the amount and concentration of intracellular solute. Since at equilibrium intracellular and extracellular osmolalities are equal, the relationship between cell volume and extracellular osmolality can be described by the following equation:

$$\text{Cell water} \approx \frac{\text{Cell solute content}}{\text{Extracellular osmolality}} \qquad (44.2)$$

Hypotonicity causes cells to swell initially as water diffuses into them, equalizing the osmolality of intracellular and extracellular fluids. Almost immediately, however, most cells begin to adjust their volume back towards normal.[194–196] This "volume regulatory decrease," is explained by reductions in cell solute content. The first response to osmotic stress is a loss of potassium. With time, loss of organic solutes dominate the response.

Most cells maintain relatively high concentrations of small, osmotically-active organic molecules known as "organic osmolytes." The major organic osmolytes found in nature are limited to a few classes of compounds—polyols, methylamines, and free amino acids—that are shared by diverse species. Organic osmolytes are non-perturbing solutes; unlike sodium and potassium, their intracellular concentrations may vary widely without affecting tertiary protein structure. Cells accumulate organic osmolytes under hypertonic conditions and lose them when confronted with hypotonicity. Several organic osmolytes are exported from swollen cells through a common channel, the volume-sensitive organic osmolyte/anion channel (VSOAC).[196,197] Osmolytes are transported into the cell by specific transporters, such as the sodium-myoinositol transporter (SMIT)[198] and the taurine transporter (TAUT).[199]

Cell volume control mechanisms could modify the relationship between the plasma sodium concentration and body water, sodium, and potassium content

shown in Eq. (44.1). For example, if the intracellular fluid compartment were to lose 15% of its solute (exclusive of potassium) in response to cell swelling, the amount of water needed to lower the plasma sodium concentration would be reduced by one-third. Some balance studies in patients with very low plasma sodium concentrations have failed to fully account for the severity of hyponatremia, a finding that would be expected if there were substantial losses of organic osmolytes from body cells.

Brain Adaptations to Hyponatremia

The need for cell volume regulation is greatest in the brain, where the rigid calvarium limits the degree of tissue swelling that can be tolerated.[200,201] An increase in brain water content of more than about 5 to 10% is incompatible with life. Although the capillary endothelium that forms the blood–brain barrier has a limited permeability to ions and other solutes, it allows relatively rapid water movement into the brain. Therefore, an osmotic gradient between the brain and plasma can exist only transiently, and it is dissipated by water movement in less than one hour. Hydraulic conductivity of the capillaries which form the blood–brain barrier decreases in response to hypotonicity.[202] However, because the brain and plasma must eventually come into osmotic equilibrium, this adaptation can only postpone brain swelling. The brain's interstitial fluid compartment communicates with the spinal fluid through a series of extracellular channels. Bulk flow of fluid between the brain's interstitial space and the cerebrospinal fluid provides a rapid defense against osmotic brain swelling. Ultimately, protection against lethal cerebral edema depends on the ability of brain cells to reduce their solute content.

In experimental hyponatremia in the rat, depletion of brain sodium, potassium, and chloride accounts for about two-thirds of the adaptive decrease in brain osmolality, while approximately one-third is contributed by organic osmolyte losses. Within 24 hours of the onset of hyponatremia, diminished brain concentrations of myoinositol, glutamate, creatine/phosphocreatine, and taurine can be detected.[203] During sustained hyponatremia, these compounds, plus glycerophosphorylcholine and glutamine, continue to be lost from the brain for approximately three days.[204,205] Reduced concentrations of these solutes persist when animals are kept severely hyponatremic for as long as two weeks. The loss of organic osmolytes contributes substantially to both the early and late adaptations to hyponatremia. In rats whose serum sodium concentrations were reduced to 96 mmol/L in one day, brain water content increased by less than 5%; it was estimated that the increase would have been 11% had there been no losses of organic osmolytes.[203] After three days of hyponatremia, additional losses of brain solute further decrease the severity of brain edema; animals exhibit minimal neurologic findings despite serum sodium concentrations of 95 to 100 mmol/L.[206]

Magnetic resonance spectroscopy has provided evidence of reduced concentrations of organic osmolytes in the brains of patients with hyponatremia.[207] One study showed that the peak associated with inositol remained depressed for at least two weeks after correction of hyponatremia (Figure 44.5).[208] An adaptive response of the brain is evident among patients with chronic hyponatremia. Computed axial tomography and magnetic resonance images do not show evidence of brain edema, and neurologic symptoms may be subtle even in patients with serum sodium concentrations less than 110 mEq/L. Most patients with hyponatremia of this severity survive, and the few neurologic sequelae that occur appear to be caused by overzealous correction of hyponatremia, rather than the electrolyte disturbance itself.[36,209]

In contrast to chronic hyponatremia, patients who become severely hyponatremic in less than 48 hours develop headaches, vomiting, agitated delirium, and eventually stupor, seizures, and coma. The clinical syndrome in both humans and experimental animals is associated with cerebral edema which can be reversed by the administration of hypertonic saline. On occasion, acute hyponatremia can lead to respiratory arrest, transtentorial herniation, and death.[210–214] When large volumes of water are retained in a short period of time, the arterial sodium concentration (to which the brain is exposed) may be up to 4 mmol/l lower than the venous concentration (which is most commonly sampled for clinical sodium measurements).[215]

Age, Sex, and the Adaptation to Hyponatremia

Recently, a single group of investigators have reported on over 100 previously healthy patients who became hyponatremic 1–2 days after routine elective surgery, and who subsequently died or suffered permanent brain damage. Individual patients had serum sodium concentrations as high as 129 mEq/L when they developed respiratory arrest and brain herniation.[212–214] The most recent reports emphasize the frequent association of hyponatremic encephalopathy with neurogenic pulmonary edema[213] and terminal diabetes insipidus.[216] Remarkably, virtually all of the reported patients were women, usually of child-bearing age[214] or prepubescent children.[212] These findings led these authors to suggest that sex hormones alter

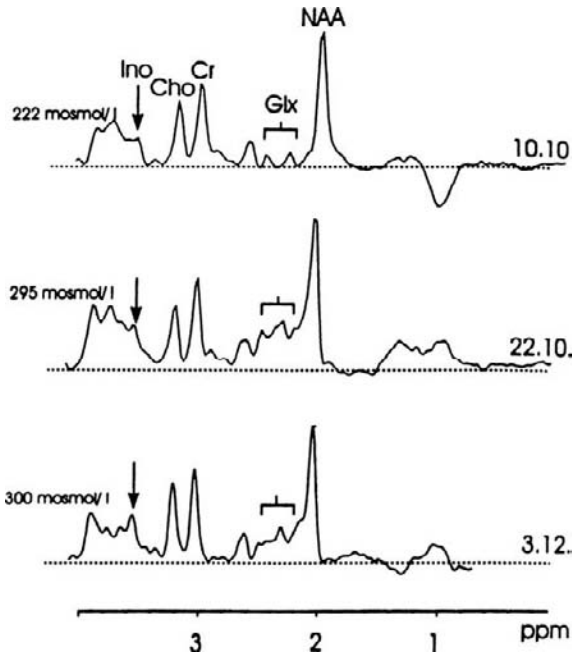

FIGURE 44.5 **Brain organic osmolytes in human hyponatremia.**[208] The figure depicts the results of magnetic resonance spectroscopy of the brain of a single patient before and after treatment of severe hyponatremia (plasma sodium 101 mmol/l, plasma osmolality 222 mosm/kg). The spectroscopy tracings were obtained on three different dates. The top tracing, taken on October 10, when the plasma osmolality was 222 mosm/l, shows an extremely low inositol peak (arrow). The middle tracing, taken on October 22, ten days after treatment of hyponatremia when the plasma osmolality was 295 mosm/l, shows an inositol peak that is still depressed. The bottom tracing, taken on December 3, 7 weeks after correction of hyponatremia shows a much higher inositol peak.

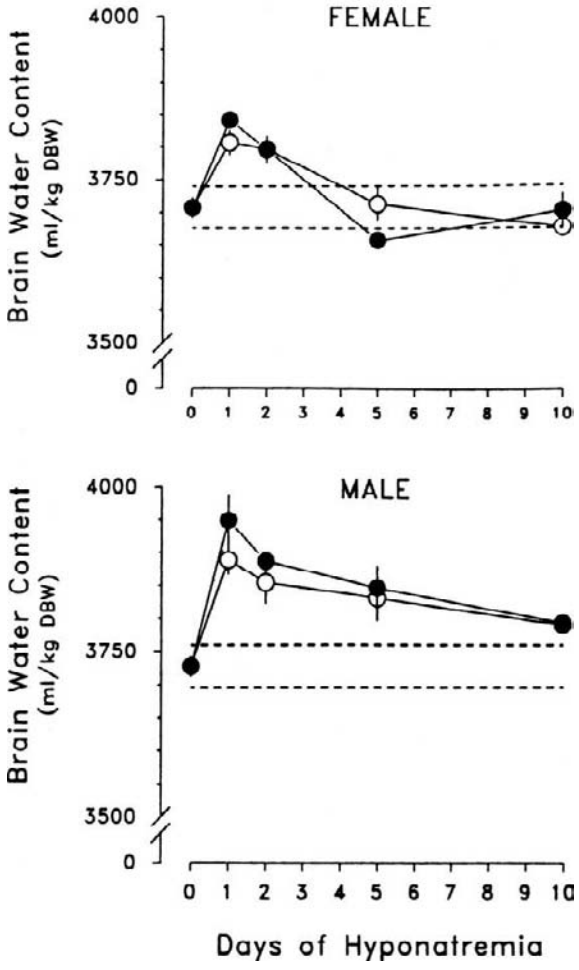

FIGURE 44.6 **Brain water content in hyponatremic male and female rats.**[219] The figure depicts measurements of brain water content obtained in male and female rats made hyponatremic with a liquid diet and either arginine vasopressin (solid circles) or dDAVP (open circles). Brain water contents are comparable in the two sexes, returning to or toward control values after ten days of hyponatremia.

the adaptive mechanisms that protect against brain edema in hyponatremia.[217]

The same investigators have used experimental models to test their hypothesis that hyponatremia causes more severe brain swelling in females than in males. The results of these studies are inconclusive. The investigators initially found that mortality from hyponatremia was markedly increased in adult female rats[218] (a finding that has not been reproduced by other laboratories[219]). They attributed excess mortality in females to lower levels of brain Na-K-ATPase (and thus a decreased ability to extrude brain sodium), and to increased susceptibility to vasopressin-induced vasoconstriction of the cerebral vasculature. *In vitro* studies showed that estrogens inhibit volume regulation in rat brain astrocyte culture.[220] However, measurements of brain water and solutes in whole brain by these and other investigators show comparable responses to hyponatremia in male and female animals[219] (Figure 44.6).

More recently, Arieff and co-workers reported that although brain water and electrolyte contents in hyponatremic adult male and female rats do not differ, the brains of newborn rats paradoxically accumulate excess sodium in response to hyponatremia, unless the animals are pretreated with testosterone.[221] Silver and co-workers were unable to reproduce this provocative finding.[222]

Hypoxia and the Adaptation to Hyponatremia

Some investigators have emphasized the adverse effects of hypoxia in hyponatremic patients. According to this view, when brain damage complicates symptomatic hyponatremia, an hypoxic episode can usually be implicated.[223] Although it is likely that hypoxia is an important factor among patients with acute hyponatremia who die of cerebral edema, the role of hypoxia in the demyelinating brain lesions which

complicate the treatment of chronic hyponatremia has not been proven (see section "Rapid Correction of Hyponatremia and Osmotic Demyelination").[224,225] Despite recurrent episodes of acute hyponatremia, hyponatremic seizures, respiratory arrests requiring endotracheal intubation, and rapid correction of hyponatremia (due to spontaneous diuresis), infants and psychotic patients with acute water intoxication rarely develop neurologic sequelae.[209]

Hyponatremic animals are more likely to die when exposed to hypoxia than normonatremic animals, and ischemic brain injury impairs the adaptive loss of brain sodium which protects against brain swelling in hyponatremia.[226] In addition, hyponatremia has been shown to lower levels of the antioxidants taurine, glutathione, and ascorbate in brain tissue, which could predispose to oxidant injury when a period of hypoxia is followed by reoxygenation.[227,228]

RAPID CORRECTION OF HYPONATREMIA AND OSMOTIC DEMYELINATION

Biochemical Effects of Rapid Correction of Hyponatremia

Adaptations that protect against brain swelling also predispose to injury when sustained hypotonicity is suddenly corrected. When the plasma sodium is returned to normal, cellular solutes lost in the adaptive phase must be recovered to prevent cellular dehydration. Electrolytes and glutamate quickly return to the brain after correction, but reaccumulation of other organic osmolytes requires several days, because it requires upregulation of sodium-dependent transport proteins.[229,230] The taurine transporter, SNAT2, may be particularly important because of its preferential localization on oligodendrocytes, the cells that are selectively damaged and lost when chronic hyponatremia is rapidly corrected.[231] After rapid correction of hyponatremia, solute-depleted brain cells are initially dehydrated. Brain electrolyte content then "overshoots," increasing to supernormal levels, possibly in compensation for the deficit in organic osmolyte content[225,232] (Figure 44.7).

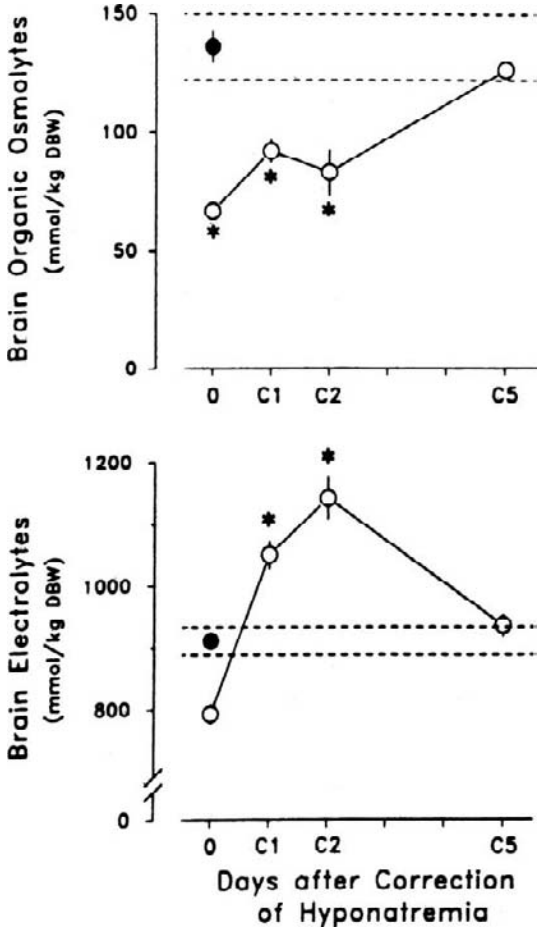

FIGURE 44.7 **Brain organic osmolytes and brain electrolytes after rapid correction of experimental hyponatremia.**[232] The figure depicts measurements of brain organic osmolytes (top panel) and brain electrolytes (bottom panel) made in rats made hyponatremic with dDAVP and a liquid diet and then corrected by withdrawal of dDAVP. Brain organic osmolytes remain significantly below normonatremic control levels (solid circle and dotted lines) on the first two days after correction (C1 and C2), and have not reached normal levels until five days after correction (C5). During the first two days after correction, brain electrolyte content "overshoots" exceeding control levels.

Clinical Effect of Rapid Correction of Hyponatremia

In humans, correction of severe chronic hyponatremia by more than 10 mEq/L in 24 hours or 18 mEq/L in less than 48 hours is associated with a distinctive clinical disorder known as the "osmotic demyelination syndrome".[210,233–236] In typical cases of the syndrome, improvement of hyponatremic symptoms during correction of hyponatremia is followed within one to several days by gradual neurologic deterioration. Behavioral disturbances, seizures, movement disorders or akinetic mutism may emerge, and severe cases develop clinical features of a pontine disorder (pseudobulbar palsy, quadriparesis, and pseudocoma).

The clinical symptoms are associated with demyelinating brain lesions which can be demonstrated by magnetic resonance images.[237,238] The most characteristic lesions are located in the center of the pons ("central pontine myelinolysis"),[239,240] but histologically similar lesions are often found in a symmetrical distribution in extrapontine areas of the brain where there is a close

admixture of gray and white matter.[234] The lesions are distinctly different from those caused by hypoxia, and they may develop without a preceding hypoxic insult.[209,235,236,241]

Patients with acute hyponatremia (e.g., infants and psychotic patients) usually tolerate rapid correction of hyponatremia without developing complications, and patients with liver disease (a disorder characterized by low levels of brain myoinositol,[242]) alcoholism, malnutrition, and potassium depletion[243] seem to be particularly susceptible to osmotic demyelination.

Experimental Models of Osmotic Demyelination

The osmotic demyelination syndrome has been reproduced in animal models in three different species by multiple laboratories.[206,244–248] These studies have confirmed the strong clinical impression that the disorder is caused by treatment of hyponatremia, rather than hyponatremia itself. Osmotic demyelination does not develop in animals with uncorrected or slowly-corrected hyponatremia. Rapid correction of chronic (three days), but not acute, hyponatremia produces a delayed onset of neurologic symptoms and brain lesions that are histologically similar to those seen in the human disease. Neurologic deterioration and histologic brain damage are preceded by pathologic evidence of blood–brain barrier disruption which can be demonstrated ultrastructurally as early as three hours, and by magnetic resonance imaging one day after rapid correction of hyponatremia.[249–251] After excessive correction of chronic hyponatremia, re-induction of hyponatremia when neurologic findings begin to appear improves survival and prevents the subsequent appearance of myelinolysis in rats, and this strategy has been successfully employed in isolated clinical case reports.[252–254]

Depletion of brain organic osmolytes is felt to play a key role in the blood–brain barrier disruption and demyelination that occurs after rapid correction of hyponatremia. In rats, measurements of organic osmolyte content in different areas of the brain after rapid correction of hyponatremia has shown that areas with the most severe demyelinating lesions are those with the least recovery of organic osmolytes.[255] It has been suggested that blood–brain barrier disruption can be explained by loss of organic osmolytes from brain capillary endothelial cells during the adaptation to hyponatremia with subsequent endothelial cell shrinkage after rapid correction. Blood–brain barrier disruption permits complement, and possibly other toxic plasma constituents, to enter the brain, which may explain the occurrence of progressive myelinolysis even after blood–brain integrity is restored.[249] Re-induction of hyponatremia following rapid correction prevents blood–brain barrier opening and microglial activation, and this can also be achieved by administering glucocorticoids; however, while therapeutic re-lowering of the serum sodium concentration reduced mortality after rapid correction, glucocorticoids did not, suggesting that the increased permeability seen in osmotic demyelination syndrome may not be a primary pathophysiological insult in this syndrome.[252]

Hyponatremic animals with uremia are relatively tolerant of rapid correction, with a lower incidence and severity of myelinolysis than non-uremic animals.[225,256] Resistance to myelinolysis in uremia is associated with more rapid reuptake of organic osmolytes, in particular myoinositol, following rapid correction of hyponatremia. In addition, rapidly corrected uremic animals do not exhibit the "overshoot" in brain sodium content seen in non-uremic animals. Normalization of brain myoinositol can be accelerated in non-uremic hyponatremic rats by administering myoinositol exogenously during rapid correction of the electrolyte disturbance.[257] Exogenous myoinositol improves survival and reduces mortality from rapid correction of chronic hyponatremia in rats.[258]

BONE DISEASE IN HYPONATREMIA

Even mild hyponatremia is associated with gait instability and an increased incidence of falls and fractures.[259,260] Hyponatremia-induced bone loss amplifies the risk of fracture. Three months of severe hyponatremia reduces bone mineral density by 30% in the rat, and is associated with decreased bone formation and increased bone resorption; cross-sectional human data showing that mild hyponatremia is associated with significantly increased odds of osteoporosis are consistent with the experimental data in rodents.[261]

TREATMENT OF HYPOTONIC HYPONATREMIA

Treatment Modalities

Water Restriction

Even with maximally-concentrated urine, evaporative water losses from the skin and lungs will lead to negative water balance and gradual correction of hyponatremia, regardless of the cause of the electrolyte disturbance. In patients whose ability to dilute the urine is intact (e.g., self-induced water intoxication) or can be restored to normal (e.g., by saline infusion in volume-depleted subjects), restriction of free water leads to a steady and sometimes rapid increase in the plasma sodium concentration. In patients with persistent

defects in water excretion (e.g., SIADH caused by tumors), water restriction alone increases the plasma sodium concentration extremely slowly, and it will be totally ineffective if the concentrations of sodium plus potassium in the urine exceed that of plasma.[262]

Sodium Chloride

Assuming that free water intake is restricted, sodium chloride solutions increase the plasma sodium concentration as long as the electrolyte concentration of the solution exceeds that of the urine. As urine cation concentrations rarely exceed 400 mEq/L, 3% sodium chloride (513 mEq/L) is always an effective treatment for hyponatremia. Isotonic saline itself does little to increase the plasma sodium concentration, unless it provokes a water diuresis by eliminating a hemodynamic stimulus for vasopressin secretion caused by volume-depletion. In fact, large volumes of isotonic saline can exacerbate hyponatremia in patients with SIADH who excrete highly concentrated urine.[89] The rate of hypertonic saline infusion must be adjusted frequently in response to the observed increase in serum sodium concentration; predictive formulas are unreliable, because urinary water losses often increase during therapy, even in patients who appear to have euvolemic hyponatremia.[263,264]

Potassium Chloride

Given the relationship between the plasma sodium concentration and exchangeable sodium and potassium,[3,8] it follows that potassium repletion of hypokalemic hyponatremic subjects should increase the plasma sodium concentration. There is limited published experience validating this expectation in patients with diuretic-induced hyponatremia,[41] and in the authors' experience (unpublished observations) potassium effectively corrects hyponatremia, regardless of the cause of potassium depletion.

Loop Diuretics

By blocking sodium reabsorption in the ascending limb of the loop of Henle, loop diuretics impair the ability to maximally concentrate the urine, even in the presence of high levels of plasma vasopressin. Used alone or in combination with angiotensin-converting enzyme inhibitors, loop diuretics are effective in treating hyponatremia associated with edematous conditions.[265–267] In patients with SIADH, loop diuretics can be combined with 3% saline for the treatment of hyponatremic emergencies.[268] Traditionally, in this maneuver, urinary sodium losses are matched with infused saline. However, given the adaptive loss of sodium that occurs in SIADH, it may be more appropriate to allow sodium intake to exceed urinary losses. In patients with SIADH who require chronic outpatient therapy, loop diuretics combined with oral salt tablets and potassium replacement (or concurrent therapy with a potassium sparing diuretic) are effective.

Demeclocycline

Demeclocycline is a tetracycline antibiotic which blocks the effect of vasopressin in the collecting duct. After a few days of therapy, demeclocycline induces a state of nephrogenic diabetes insipidus, which resolves within several days when the drug is stopped.[269] This side-effect of the antibiotic has been exploited in the long-term treatment of SIADH.[270,271] Demeclocycline is nephrotoxic in patients with heart failure and liver disease.[272,273]

Urea

Urea, administered orally in a daily dose of 0.5 g/kg body weight per day, increases urinary electrolyte free water losses, allowing liberalized fluid intake in patients with chronic hyponatremia due to SIADH, and other disorders such as congestive heart failure.[274,275] However, it tastes poorly and is contraindicated in liver and renal failure. Intravenous urea has also been effective in treating acute hyponatremia.[276] In experimental models, Soupart and Decaux have demonstrated that acute correction of chronic hyponatremia with urea decreases the risk of myelinolysis.[277] Although the mechanism of this protection is unknown, it has been speculated that urea enters the brain and then is cleared from the plasma more slowly than it is cleared from brain tissue,[278,279] thereby protecting against brain cell shrinkage after rapid correction. Experience with urea is much more extensive in Europe than in the United States.

V_2-Receptor Antagonists

Vasopressin antagonists, called "vaptans" because of the suffix applied to their generic names, block the binding of vasopressin to its renal receptor, preventing water reabsorption, decreasing urine osmololality, and increasing urine output. These agents induce a dose-related water diuresis lasting approximately six hours without a significant increase in urinary sodium or potassium excretion; therefore, vasopressin receptor-antagonists are sometimes called "aquaretics"[280–282] (Figure 44.8).

Tolvaptan (OPC-41061), and conivaptan (YM-087) have been approved by the United States Food and Drug Administration for the treatment of hyponatremia. Tolvaptan is selective for the vasopressin-2 (V2) receptor responsible for the antidiuretic actions of arginine vasopressin, conivaptan is active at both the V2 receptor and the V1a receptor responsible for the vasoconstricting properties of arginine vasopressin. Selective V2-antagonists have been shown to be

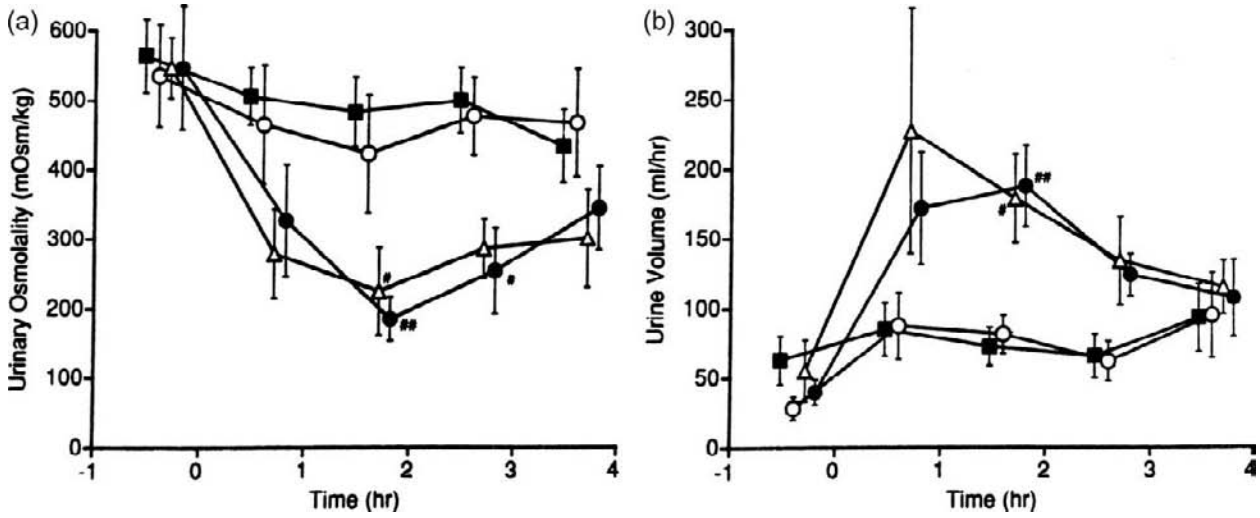

FIGURE 44.8 **Response to V2 receptor blocker in patients with SIADH.**[321] The figure depicts urine osmolality (panel a) and volume (panel b) in control subjects (closed squares) and in patients with SIADH given OPC-31260 intravenously in three doses: 0.1 mg/kg (open circles); 0.25 mg/kg (open triangles); 0.5 mg/kg (closed circles). The urine osmolality falls significantly below control values and urine volume increases significantly above control values after one hour at the two higher doses of the drug.

effective in correcting hyponatremia due to SIADH, cirrhosis, and heart failure in humans.[283–285] Conivaptan corrects hyponatremia in animal models of cirrhosis,[286] but it may be contraindicated in the human disease, because blockade of the V1a receptor may potentially provoke the hepatorenal syndrome. However, the dual receptor activity may be particularly useful in patients with CHF, because of load reduction from V1a receptor-blockade combined with reduced cardiac preload and increased sodium concentrations induced by V2 receptor antagonism.[287,288]

Because these agents cause a brisk and relatively prolonged water diuresis, V_2-receptor antagonists may risk overly rapid correction and osmotic demyelinization if they are used to treat severe chronic hyponatremia. Indeed, in an experimental model of chronic hyponatremia, increasing the plasma sodium concentration with a V_2-receptor antagonist was comparable to hypertonic saline in causing osmotic demyelination.[289]

Therapeutic Guidelines

The proper treatment of hyponatremia has been a controversial topic that has been extensively reviewed.[210,290,291] There is a general consensus that the dangers of cerebral edema and seizures mandate prompt and definitive treatment with one of the above modalities to ensure that the plasma sodium concentration begins to return to normal. Initial therapy in patients with acute hyponatremia or severe symptoms should probably begin with a bolus infusion of 1 to 2 ml/kg body weight of 3% saline, aiming for an increase of 1 to 2 mEq/L.[291–293] Therapy in all patients should be limited to avoid iatrogenic injury. Most investigators now agree that correction should not exceed 10 mEq/L in a single day or 18 mEq/L in two days, because these rates are sometimes harmful in susceptible patients, and have no proven advantage over more limited correction.[291,294] It should be emphasized that these are limits and not therapeutic goals; given the risks of severe neurological injury, and the danger of inadvertently "overshooting the mark" owing to an unexpected water diuresis, therapeutic regimens should be targeted at an increase of 6 to 8 mEq/L/day, with adjustments based on frequent measurements of the serum sodium concentration.[210,264,295]

Managing Unintentional Overcorrection

If a water diuresis occurs during therapy, sodium administration should be discontinued and, to avoid overcorrection, water losses should either be replaced or halted with the administration of desmopressin.[296,297] Alternatively, particularly in patients likely to have reversibly impaired ability to excrete dilute urine, desmopressin can be administered prophylactically, thereby maintain relatively constant urinary water losses while raising the serum sodium concentration with a concurrent infusion of 3% saline.[298]

Even with careful management, many patients experience a greater than intended increase in sodium concentration.[264,299] If this occurs, therapeutic re-lowering

of the serum sodium concentration with a brief infusion of 5% dextrose in water, using desmopressin to prevent further water losses, has been shown to be well-tolerated in a small series and a few case reports.[296,297] As discussed previously, this strategy prevents osmotic demyelination and mortality in experimental models.[252]

NON-HYPOTONIC HYPONATREMIA

Pseudohyponatremia

Plasma is normally 93% water. Thus, a sodium concentration of 143 mEq/L in a sample of whole plasma reflects a sodium concentration of 154 mEq/L in plasma water (143/0.93 = 154). Physiologic saline solutions (e.g., 0.9% NaCl) were designed to reproduce the sodium concentration in plasma water.

Pseudohyponatremia is an exaggeration of the physiologic dilution of plasma sodium by non-aqueous material.[300] High concentrations of intravascular protein (as in multiple myeloma) or lipid "dilute" the plasma sodium concentration, but do not alter the solute concentrations of the intracellular or interstitial fluid compartments. Because the "diluent" in these conditions is non-aqueous, the sodium concentration of the aqueous portion of a plasma sample, as determined by an ion-specific electrode in undiluted serum or plasma, is normal.[301,302] Plasma osmolality, as measured by an osmometer, is also normal. Thus, hyponatremia associated with hyperlipidemia or hyperproteinemia can be considered artifactual, and is called "pseudo-hyponatremia." Laboratory determinations which depend on a diluting step yield artifactually low sodium concentrations in samples taken from patients with severe hyperlipidemia or plasma cell dyscrasias, even if the instrument employs an ion-specific electrode.[301,303] In these disorders, the plasma aliquot obtained for dilution contains less plasma water (and therefore less sodium) than normal; the sodium concentration in the diluted sample is thus artifactually reduced.

Hypertonic and Isotonic Hyponatremia

Pathophysiology

If non-permeant solutes other than sodium salts accumulate in the extracellular space, the extracellular fluid volume expands, reducing the concentration of the sodium normally present in this fluid compartment. Plasma osmolality varies, depending on the cause of the syndrome.

Retention of a sodium-free isotonic solution (e.g., infusion of isotonic mannitol in a patient with renal insufficiency who excretes the solute slowly) causes isotonic hyponatremia. Mannitol, a solute that is unable to permeate cell membranes, is confined to the extracellular space; the fluid infused with the solute is similarly confined.[304] Thus, the extracellular fluid expands, and the intracellular compartment is unaffected. Sodium-free hypotonic solutions containing impermeant solutes can be considered isotonic solutions to which water has been added; hyponatremia caused by these solutions is primarily extracellular, but plasma osmolality is slightly reduced and the intracellular compartment is slightly diluted.

Retention of a sodium-free hypertonic solution (e.g., infusion of hypertonic mannitol) causes hypertonic hyponatremia.[305] In this case, intracellular water is osmotically drawn to the extracellular fluid compartment, compounding the dilution of extracellular sodium caused by the infused diluent. Thus, the sodium concentration of the extracellular space is reduced, while the osmolality of both extracellular and intracellular fluid compartments is increased.[306] A similar phenomenon has been described after administration of IgG solutions containing maltose or sucrose.[307]

Hyperglycemia

Glucose normally contributes only 5 milliosmoles per liter to plasma osmolality. The osmotic importance of glucose increases dramatically in patients with diabetic hyperglycemia. As glucose cannot permeate most cell membranes without insulin, hyperglycemia attracts intracellular water to the extracellular space, causing hyponatremia despite hyperosmolality of both extracellular and intracellular fluid compartments. Several correction factors have been offered to quantify this relationship.[308] However, a precise correction factor is probably unobtainable, because in practice hyperglycemia develops, in part, from the ingestion of glucose with water and resolves, in part, from the urinary excretion of glucose with water.[309] In patients with oliguric kidney failure, whose hyperglycemia is corrected solely by metabolism, the change in serum sodium during correction of hyperglycemia averages 1.6 mEq/L per 100 mg/dl change in blood glucose, but with considerable variability.[310]

Irrigant Absorption Syndrome

Until recently, fluid used to irrigate the operative field during transurethral resection of the prostate (TURP) and hysteroscopy had to be electrolyte free.[311] To avoid hemolysis, isosmotic to slightly hypoosmotic solutions of mannitol, sorbitol or glycine have been utilized. Several liters of irrigant may be absorbed systemically during these procedures, causing profound hyponatremia.[312–314] There are fundamental

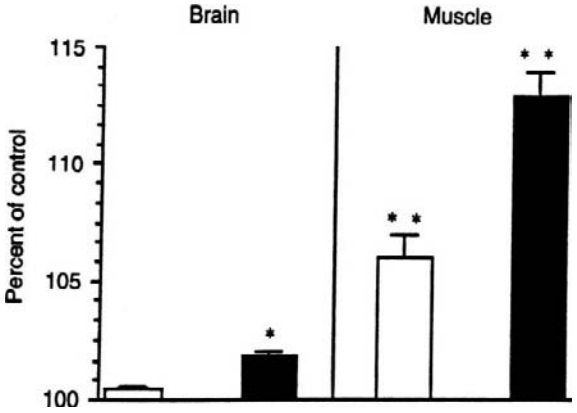

FIGURE 44.9 **Muscle and brain water contents in experimental irrigant absorption syndrome.**[318] The figure depicts measurements of brain and skeletal muscle tissue water contents, expressed as a percentage of normonatremic controls, made in ureter-ligated rats, two hours after infusion of intravenous infusion of isotonic mannitol (open bars) or glycine (black bars). Brain water content is only slightly higher after infusion of glycine than after infusion of mannitol (reflecting minimal but statistically significant penetration of the blood-brain barrier by glycine), and muscle water content is markedly higher in glycine infused animals, reflected the diffusion of glycine into muscle cells.

differences between irrigant absorption hyponatremia and post-operative hypotonic hyponatremia.

The most commonly used irrigant is 1.5% (200 mOsm/kg) glycine. Unlike patients dying of water intoxication, cerebral edema is not a prominent finding after systemic absorption of glycine irrigant and, in contrast to water intoxication, plasma osmolality is only mildly decreased despite severe hyponatremia.[315,316] Glycine and its metabolites, primarily serine and glucose, remain in the plasma for hours after absorption, contributing to plasma osmolality.[315,317]

Studies in experimental animals indicate that isosmotic (2.2%) glycine is initially confined to the extracellular space, markedly diluting the plasma sodium concentration without changing plasma osmolality.[318] As the amino acid enters skeletal muscle cells, carrying water with it, the plasma sodium concentration increases, but plasma osmolality remains constant, owing to increased plasma levels of glycine, serine, and other amino acids, urea, and glucose; in the absence of hypoosmolality brain water content increased only slightly because glycine did not enter the brain[318] (Figure 44.9). Toxicity from glycine or its metabolites, rather than hyponatremia, may contribute to the neurologic symptoms that develop after irrigant absorption. Glycine is a major inhibitory transmitter in retina, and visual hallucinations and transient blindness may occur even in the absence of hyponatremia after prostatectomy using glycine irrigant.[319] Plasma ammonia levels increase in glycine-infused animals and in humans who have absorbed glycine irrigant.[315,320] In brain, ammonia is metabolized by glutamine synthase to form glutamine, which may serve to protect the brain from the effects of hyperammonemia in liver failure.[242] In animals infused with isosmotic glycine, increased brain glutamine may contribute to the small increase in brain water content which occurs.[318] Levels of ammonia, a major metabolite of glycine, have correlated with neurologic symptoms in some, but not all, studies.

Recently, new resectoscopes have become available which permit endoscopic surgery using isotonic saline. As their use becomes more widespread, it is likely that irrigant absorption syndromes, although fascinating, will be relegated to historical interest.[311]

Hyperosmolality without Hyponatremia

Increased concentrations of permeant solutes like urea or ethanol do not affect the distribution of water in body fluid compartments, and do not cause hyponatremia. However, these solutes increase the plasma osmolality and may cause diagnostic confusion if they are present in patients with hypotonic hyponatremia from other causes.

CHAPTER

45

Hypernatremic States

Christopher J. Rivard, Wei Wang and Laurence Chan

University of Colorado Denver, Aurora, Colorado, USA

Hypernatremia can occur with normal, increased or decreased total body sodium content. In healthy individuals and in normal conditions, the plasma concentration of sodium ranges between 136 and 143 mEq/l of plasma, despite large individual variations in the intake of salt and water. The concentration is maintained at constant levels because of the homeostatic mechanism in the body. Claude Bernard was the first to appreciate that higher animals: "have really two environments: a *milieu exterieur* in which the organism is situated, and a *milieu interieur* in which the tissue elements live." The latter is the extracellular fluid (ECF) that bathes the cells of the body.[1,2,3] Maintenance of this consistency of plasma sodium and solute activity is the function of the thirst–neurohypophyseal–renal axis.[4,5] Thirst and urinary concentration are the main defenses against hyperosmolality, and hence hypernatremia. Hypernatremia is a relatively common problem, with prevalence in hospitalized patients of 0.5 to 2%. It is defined as plasma Na^+ concentration ($[Na^+]$) greater than 145 mEq/l. It can be produced by the administration of hypertonic sodium solutions or in almost all cases, by the loss of free water. Since $[Na^+]$ is an effective osmole, the increase in the plasma osmolality (P_{osm}) induced by hypernatremia creates an osmotic gradient that results in water movement out of the cells into the ECF. It is this cellular dehydration, particularly in the brain, that is primarily responsible for the neurologic symptoms associated with hypernatremia. A similar syndrome can be produced when the plasma osmolality is elevated by hyperglycemia. However, when hyperosmolality is due to the accumulation of cell-permeable solute, such as urea or ethanol, there is no water shift in the steady-state because osmotic equilibrium is reached by solute entering the cell.

REGULATION OF WATER HOMEOSTASIS

Significance of the Plasma Sodium Concentration

The total body water (about 60% of body weight in males and 50% in females) is distributed between the intracellular fluid (ICF, 60% of body water) and extracellular fluid (ECF, 40% of body water) spaces.[6–9] Flame photometry and, more recently, ion selective electrode technology have made the plasma sodium concentration one of the simplest and most frequently measured constituents of the body fluids. It is not always appreciated that a given concentration of the plasma sodium may be consistent with different functional states.[10,11] The plasma sodium is simply a concentration term, and as such reflects only the relative amounts of sodium and water present in the sample. The concentration is not a measure of total body sodium content.[12] It is determined empirically by the following relationship:

$$\text{Plasma } [Na^+] = \frac{\text{Total-body } Na^+ + \text{Total-body } K^+}{\text{Total-body water}} \qquad \text{(Eq.45.1)}$$

The relationship indicates the fact that hypernatremia can occur as a consequence of a decrease in total body water, an increase in total body sodium or a combination of these events. It gives no information regarding replacement or removal of sodium. When flame spectrophotometry is used to measure the amount of sodium in a plasma sample, substances such as plasma proteins, abnormally high glucose, and lipid can occupy a large fraction of the plasma volume and underestimate the actual sodium concentration. The

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00045-8

ionic composition of the plasma is measured as milliequivalents per liter of plasma. Only about 930 ml of each liter of plasma is water. The remaining 70 ml is occupied by the plasma proteins and, to a lesser degree, lipids. In the presence of hyperlipidemia or hyperproteinemia, the plasma water content may be less than 93%.

Generation of Hypernatremia

Since Na^+ and its accompanying anions are the major effective ECF osmoles, hypernatremia is a state of hyperosmolality. As a result of the fixed number of ICF particles, maintenance of osmotic equilibrium in hypernatremia results in ICF volume-contraction. The increase in the plasma osmolality induced by hypernatremia creates an osmotic gradient that results in water movement out of the cells into the ECF. A similar syndrome can be produced when plasma osmolality is elevated by hyperglycemia. When hyperosmolality is due to the accumulation of a cell-permeable solute, such as urea or ethanol, there is no water shift because osmotic equilibrium is reached by solute entry into cells. Therefore, both urea and ethanol are ineffective osmoles. Plasma osmolality can be measured directly by determining freezing point depression or vapor pressure.[13,14] Variable changes in the plasma sodium concentration occur with hyperglycemia. Since glucose enters cells slowly, an increase in the plasma glucose concentration raises effective plasma osmolality and causes water to move from the cells into the ECF. By dilution, this lowers the plasma Na^+ concentration. In theory, every 62 mg/dl increment in the plasma glucose concentration should draw enough water out of the cells to reduce the plasma Na^+ concentration by 1 mEq/l.[15,16]

The number of particles per gram of water determines the osmolality of a solution. Since sodium salts (particularly NaCl and $NaHCO_3$), glucose, and urea are primary extracellular osmoles, the plasma osmolality can be approximated from:

$$\text{Plasma osmolality } (P_{osm}) = 2 \times \text{Plasma } [Na^+] + \frac{[\text{Glucose}]}{18} + \frac{\text{BUN}}{2.8} \quad \text{(Eq.45.2)}$$

where 2 reflects the osmotic contribution of the anion accompanying Na^+, and 18 and 2.8 represent the conversion of the plasma glucose concentration and blood urea nitrogen (BUN) from units of milligrams per deciliter (mg/dl) into millimoles per liter (mmol/l).

Although urea contributes to the absolute value of the P_{osm}, it does not act to hold water within the extracellular space because of its membrane permeability. Therefore, urea is an ineffective osmole and does not contribute to the effective P_{osm}.

In general, the effective plasma osmolality can be calculated from or estimated from:

$$\text{Effective plasma osmolality} = \text{Measured plasma osmolality} - \frac{\text{BUN}}{2.8}$$

or estimated from

$$\text{Effective plasma osmolality} = 2 \times \text{Plasma } [Na^+] + \frac{[\text{Glucose}]}{18} \quad \text{(Eq.45.3)}$$

Under normal circumstances, glucose and urea contribute less than 10 mOsm/kg H_2O, and the plasma Na^+ concentration is the main determinant of the plasma osmolality, the osmolality of body fluids can be estimated to be twice the plasma sodium concentration.[14]

The major ECF particles are Na^+ and its accompanying anions Cl^- and HCO_3^-; a high plasma sodium concentration is always associated with a high osmolality. This indicates that water is needed to restore isotonicity. The water deficit can be estimated from the plasma sodium level. The percentage increase in sodium concentration approximates the percentage decrease in total body water. The water deficit can be estimated by the equation:

$$\text{Water deficit} = \text{Total-body Water} \times \left(\frac{\text{Plasma } [Na^+]}{140} - 1 \right) \quad \text{(Eq.45.4)}$$

Total body water varies with body size and fat content. It is approximately 60% of body weight in young men, 50% of body weight in old men and young women, and only 40% in elderly women.

DEFENSE MECHANISMS AGAINST WATER DEPLETION

Two primary mechanisms defend the body against water depletion and hyperosmolality of extracellular fluid space. These two defense mechanisms are the capacity of the kidney to excrete a concentrated urine, and stimulation of thirst to increase water intake. Each pathway is very effective and disturbance of the urinary concentrating mechanism alone generally does not cause hyperosmolality if the thirst mechanism is intact.

Control of ADH Secretion

Hypernatremia results in the stimulation of both the antidiuretic hormone (ADH) release and thirst by the

hypothalamic osmoreceptors (Figure 45.1). Argenine vasopressin is the ADH in humans.[17] Argenine vasopressin binds to specific receptors on collecting ducts (V_2 receptors), which are coupled to cyclic AMP (cAMP) formation. The regulation of ADH release from the posterior pituitary is dependent primarily on two mechanisms: osmotic and nonosmotic pathways (Figure 45.2). The osmotic regulation of ADH is dependent on osmoreceptor cells in the anterior hypothalamus.[18] These cells, most likely by altering their volume, recognize changes in ECF osmolality. Cell volume is decreased readily by substances that are restricted to the ECF, such as hypertonic saline or hypertonic mannitol. These substances are effective in stimulating ADH release. In contrast, urea moves readily into cells, and therefore does not alter cell volume and does not effectively stimulate ADH release. A similar response pattern is evident when vasopressin release is studied in the hypothalamo–neurohypophyseal complex in organ culture. Specifically, sodium chloride, sucrose, and mannitol at 310 mOsm/kg H_2O cause a three-fold increase in argenine vasopressin release, while urea and glucose fail to stimulate vasopressin. These studies also support the view that the receptor responds to changes in osmolality rather than sodium. The effects of increased osmolality on vasopressin release are associated with a measurable increase in vasopressin precursor messenger RNA (mRNA) in the hypothalamus[19,20] and salt-loading increases vasopressin RNA in the pituitary.[21,22] Vasopressin release can also occur in the absence of changes in plasma osmolality.[23] Physical pain, emotional stress, hypoglycemia, and a decrease in blood pressure or blood volume are important nonosmotic stimuli for vasopressin release. A 7 to 10% decrement in blood pressure or blood volume causes the prompt release of vasopressin (Figure 45.2). Although there are considerable genetically-determined individual variations in both the threshold and sensitivity, a close correlation between argenine vasopressin and plasma osmolality has been demonstrated in subjects with various states of hydration (Figure 45.3).

The secretion of ADH generally begins when the plasma osmolality exceeds 275 to 285 mOsm/kg H_2O.

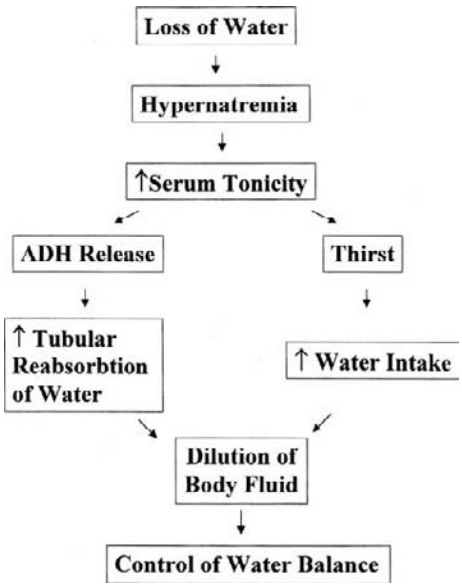

FIGURE 45.1 **Regulation of water homeostasis: feedback loop for the stimulation of antidiuretic hormone (ADH) release and thirst. Hypernatremia results in an increase in the plasma osmolality, which enhances ADH secretion and thirst, resulting in water retention and a reduction in the plasma osmolality toward normal.**

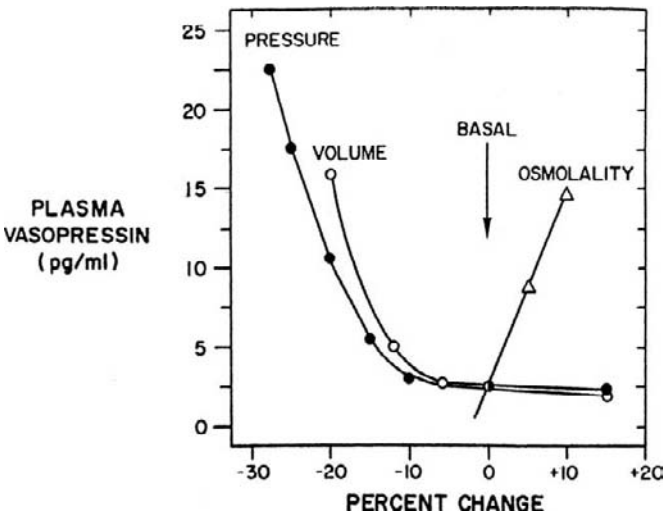

FIGURE 45.2 **Osmotic and nonosmotic stimulation of arginine vasopressin release.** *(from ref. [90]).*

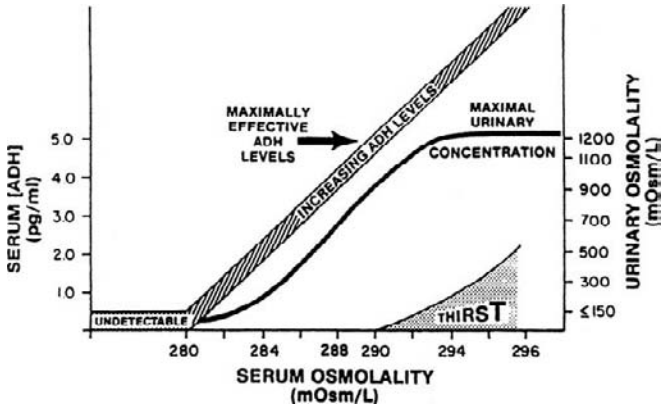

FIGURE 45.3 **Antidiuretic hormone (ADH) levels, urinary osmolality, and thirst as functions of serum osmolality.** *(from ref. [188]).*

The threshold for thirst appears to be approximately 10 mOsm/kg H_2O above that of vasopressin release. Prevention of a total body water deficit is thus largely dependent on water intake as modulated by thirst. The thirst center appears to be closely associated anatomically with the osmoreceptors in the region of the hypothalamus. Defects in thirst response may involve either organic or generalized central nervous system lesions, and can lead to severe water deficit even in the presence of a normal concentrating mechanism. The water deficit will occur more promptly if renal concentrating ability is also impaired.[24]

Thirst and the Maintenance of Hypernatremia

Thirst is, in fact, so effective that even patients with complete diabetes insipidus avoid hypernatremia by fluid intake in excess of 10 l/day.[25–27] Hypernatremia supervenes, therefore, only when hypotonic fluid losses occur in combination with a disturbance in water intake. This is most commonly seen in the aged with an alteration in level of consciousness, in the very young with inadequate access to water or in a rare subject with a primary disturbance in thirst.[28,29] Prevention of a total body water deficit is thus largely dependent on water intake as modulated by thirst. The thirst center appears to be closely associated anatomically with the osmoreceptors in the region of the hypothalamus. Defects in thirst response may involve either organic or generalized central nervous system lesions, and can lead to severe water deficit even in the presence of a normal concentrating mechanism.

In summary, persistent hypernatremia does not occur in normal subjects, because the ensuing rise in plasma osmolality stimulates both the releases of ADH, thereby minimizing further water loss and, more importantly, thirst. The associated increase in water intake then lowers the plasma sodium concentration back to normal. This regulatory system is so efficient that the plasma osmolality is maintained within a range of 1% to 2%, despite wide variations in sodium and water intake. Even patients with diabetes insipidus, who often have marked polyuria due to diminished ADH effect, maintain a near-normal plasma sodium concentration by appropriately increasing water intake. The net effect is that hypernatremia primarily occurs in those patients who cannot express thirst normally: infants and adults with impaired mental status.[30] The latter most often occurs in the elderly, who also appear to have diminished osmotic stimulation of thirst. A patient with a plasma sodium concentration of 150 mEq/l or more who is alert but not thirsty has, by definition, a hypothalamic lesion affecting the thirst center.

CELLULAR RESPONSE TO HYPERNATREMIA

Volume Regulation

When exposed to a change in extracellular osmolality, a cell shrinks or swells and subsequently exhibits either a regulatory volume increase or a regulatory volume decrease.[31–33] When exposed to hypertonicity, a cell loses water until the intracellular and extracellular osmolality are equal. Recovery of water is mediated by accumulation of inorganic and organic solutes known as osmolytes.[31,34] The principle inorganic osmolytes are Na^+, K^+, and Cl^-. The principle organic osmolytes may be classified into three general groups: polyols; methylamines; and amino acids.[35] A comparison of major and minor organic osmolytes for the kidney and brain are depicted in Table 45.1.

While hypernatremia in mammals affects all tissues, the greatest potential for harm is to the brain and kidney. Of these two organs, even modest changes in serum osmolality can have severe consequences to the brain, resulting in volume changes.[36] In the brain, acute hypernatremia is associated with a rapid decrease in water content and a corresponding increase in solute concentration.[32] In a study of rats by Cserr and co-workers,[37,38] acute hypernatremia (plasma $Na^+ = 180$ mEq/l) was accompanied by a prompt

TABLE 45.1 Organic Osmolytes in Kidney and Brain

Organic Osmolyte	Kidney [252–254]	Brain [32,33]
Major	Glutamate	Glutamate
	Glutamine	Glutamine
	Taurine	Taurine
	Myoinositol	Myoinositol
	Urea	Urea
	Alanine	Alanine
	Sorbitol	Aspartate
	GPC	Glycine
	Betaine	GABA
Minor	Val/Leu/Isoleu	Theonine
	Phosphocreatine	GPC
	Creatine	Betaine
		Choline
		Phosphocreatine
		Lysine
		Serine

GABA: γ-aminobutyric acid; GPC: glycerophosphorylcholine.

TABLE 45.2 Proposed Hypothesis for Cellular Osmoregulation in the Kidney

Name	Details	Reference
Compatible osmolyte principle	Cells accumulate high levels of polyols or certain amino acids that do not affect protein function in contrast to NaCl or KCl	255
Counteracting osmolyte principle	Cells accumulate methylamines (i.e., GPC or betaine) to attenuate the destabilizing effect of urea on protein structure	256,257
Constant transmembrane gradient	Cells maintain constant transmembrane gradients for sodium and potassium, thus the driving force for sodium gradient-coupled transport systems for organic and inorganic solutes	258,259

TABLE 45.3 Effect of Early Hypertonic Stress on Kidney Cell Function

General Function	Reference
DNA: Damage, inhibition of repair, dissociation of protein from chromatin, induction of p53	44,58,260,261,262
Metabolism, cell growth: Disruption of mitochondria function, cell cycle arrest, growth factor-dependent signaling inhibition, alteration in cytoskeletal structure, inhibition of protein translation	261,263–272
Secondary stress, apoptosis: Induction of secondary oxidative stress, apoptosis	261,265,273

decrease (7%) in total brain water content. The fall in water content was less than expected for simple osmotic behavior, indicating significant volume regulation had occurred. Moreover, the decrease in total brain water was the result of a fall in extracellular volume. Intracellular volume was not significantly changed at 30 and 90 minutes. The rapid regulatory volume increase was mediated by increases in Na^+, K^+, and Cl^-.[38] Most of these ions were derived from bulk flow of NaCl from cerebral spinal fluid (CSF). There was also a lesser contribution of electrolytes from the blood. During experimental hypernatremia in rabbits, intracellular brain water content also decreased by 12% at 1 hour and by 17% at 4 hours, accompanied by a corresponding increase in intracellular osmolality.[39] Most of the acute increase in brain osmolality was due to an increase in intracellular sodium and potassium concentration.[40] Although a substantial component of the increase in electrolyte concentration resulted from transcellular water loss, whole brain electrolyte content also increased, with the sodium content increasing from 268 ± 9 mm/kg dry weight in control animals to 321 ± 19 mmol/kg dry weight after 4 hours of hypernatremia. After sustained hypernatremia of 7 days duration, brain water and volume values were restored to normal. More prolonged hypernatremia results in accumulation of organic osmolytes to restore total brain water content to normal levels.[41–43]

In the kidney, the general mechanism for cellular osmoregulation in the face of hypertonic conditions involves the accumulation of organic rather than inorganic osmolytes. This strategy for the transport of organic rather than inorganic osmolytes across the cellular membrane has been explained in at least three hypothesized mechanisms, as detailed in Table 45.2. However, before mounting a coordinated osmoresponse, cells experience a "molecular mayhem"[44] due to the initial decrease in cellular volume, resulting in crowding of macromolecules and an increase in ionic osmolytes. These early changes in the cellular status, as well as the loss of water which can affect a variety of biochemical processes, can result in a variety of deleterious effects on normal cellular functions and viability, as depicted in Table 45.3.

Osmolytes

Organic molecules serve an important biologic function in the process of cellular osmoregulation.[4] When extracellular osmolality increases, organic molecules accumulate in the cells, thus maintaining cell volume and counteracting the perturbation of enzyme function and protein structure by high concentrations of inorganic ions and other molecules such as urea.[45] Lien and his co-workers[32] studied the effect of varying degrees and duration of hypernatremia on the concentrations of substances believed to be important idiogenic brain osmoles in rats using conventional biochemical assays, nuclear magnetic resonance spectroscopy, and high performance liquid chromatography. Idiogenic osmoles have been postulated to develop in the brain cells of patients suffering from chronic elevations in the osmolality of ECF. Moreover, the rapid correction of the osmolality in such patients is associated with the development of cerebral edema.

It has been known for more than 35 years that changes in intracellular brain sodium and potassium concentrations cannot account for all of the observed changes in brain osmolality that occur during chronic exposure to extracellular hypernatremia. The solutes that develop to maintain equality between extracellular and intracellular brain osmolality during this adaptation to hyperosmotic stress have been investigated by several groups. Arieff and his associates[46,47] have demonstrated that osmoles accumulated in the brain of chronic hypernatremic, but not in acute hypernatremic,

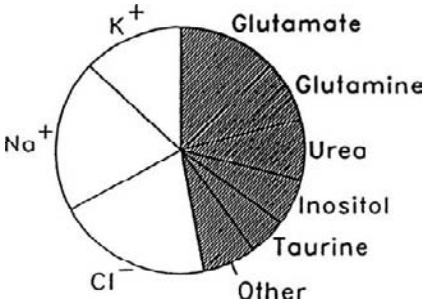

FIGURE 45.4 **Relative changes in brain osmolytes in chronic hypernatremia.** *(from ref. [32]).*

rabbits. Other investigators have shown that the level of amino acids and their derivatives, such as glutamine, taurine, and urea, rise in the brain of chronic hypernatremic animals, and account for about half of the increment of brain osmoles.[48] However, many of the idiogenic osmoles have not yet been characterized in brain tissue. Polyols and trimethylamines accumulate intracellularly in marine animals, plants, and bacteria when extracellular or environmental osmolality is significantly increased. In this study, it was found that the inorganic osmolytes account for 50% to 60% of the increase in solute content, whereas organic osmolytes account for the remainder during adaptation to chronic hypernatremia (Figure 45.4).

Recovery from chronic hypernatremia involves a small transient rise in brain water, which is restored to normal within 48 hours. With the exception of myoinositol, all the electrolytes and organic osmoles fall to normal levels within 24 to 48 hours. The cellular mechanisms responsible for the loss of intracellular organic osmolytes are poorly understood. *In vitro* studies of brain tissue found that cell swelling causes rapid loss of electrolytes and organic osmolytes. The losses of cellular K^+ and Cl^- are likely mediated by swelling-activated ion channels. Characterization of the organic osmolyte efflux pathways suggests that they represent pores or channels in the membrane that are permeable to Cl^-, as well as small organic salts. Roy and Banderali described a chloride channel that can transport small organic solutes, such as taurine and amino acids.[5] No specific inhibitors of the pathways are known. However, inhibitors of arachidonic acid metabolism are able to prevent activation of the efflux pathway, implicating eicosanoids in the signal transduction mechanism.

Lien et al. [32,33] reviewed previous studies to estimate the percentage of the osmolality that is still idiogenic. The contributions of electrolytes and other solutes to the changes in brain osmolality for various durations and degrees of hypernatremia were reported in different studies (Table 45.4).

As a group, amino acids represent the major pool of brain organic osmolytes (20−30%); polyols and methylamines represent 7 to 10%. Taurine, a sulfonated amino acid, appears to be very important in neonatal brain volume regulation. Urea (8%−9%), unlike other osmolytes, is not preferentially accumulated intracellularly. Therefore, the vast majority of the total change in brain osmolality can be accounted for by changes in the concentrations of measured solutes. In other words, there are no significant idiogenic brain osmoles.[49,50]

Response to hypertonic conditions in the kidney depends on the cell type, as determined by presence along the nephron. Microdissection of kidney nephron segments for study is difficult; however, data may be obtained from *in vitro* studies of stable cell lines derived from specific nephron segments. An example of the heterogeneous nature of osmolyte accumulation in response to hypertonic stress in cells along the nephron is depicted in Figure 45.5.

While these data only summarize the changes in selected organic osmolytes, the data indicate that different cells accumulate different osmolytes when challenged to increasing extracellular tonicity. Proximal and distal tubule cells accumulate more myoinositol compared with inner medullary collecting duct cells, and the reverse is true for glycerophosphorylcholine (GPC) in collecting duct cells. The cells located in the inner medullary collecting duct (IMCD) cells are exposed to the greatest range in tonicity, and are therefore valuable in studying the effects of chronic hypertonicity on cellular accumulation of organic osmolytes. Figure 45.6 demonstrates that $IMCD_3$ cells accumulate varying amounts of different organic osmolytes in response to increasing levels of tonicity.

Of interest in these cells is the substantial accumulation of sorbitol at substantially high hypertonic conditions. Sorbitol plays an important role in the osmotic response, especially at high tonicity, because it is not required to be transported across the membrane in the face of a substantial concentration gradient, but rather is metabolized from glucose by the cellular protein aldose reductase (AR). Thus, within the same cell line of the kidney, substantial changes in the accumulation of specific osmolytes occur with increasing tonicity. In the kidney, further metabolism of sorbitol by sorbitol dehydrogenase (SDH) produces fructose (polyol pathway). Studies show that $IMCD_3$ cells chronically adapted to increasing levels of tonicity increase AR message, while at the same time decreasing message for SDH (Figure 45.7). This allows cells to accumulate the organic osmolyte sorbitol. During a reduction in tonicity, cells can export sorbitol from the cell via

sorbitol permease or by upregulation of SDH, thereby converting sorbitol to fructose with eventual recycling to glucose in the cell.

Accumulations of minor organic osmolytes in the kidney are similar to major organic osmolytes in demonstrating differential accumulation with increasing levels of hypertonicity. Figure 45.8 shows that, similar to major organic osmolytes, IMCD cells accumulate various amino acids as minor organic osmolytes to different levels in response to increasing extracellular tonicity. Glutamate and glutamine constitute the greatest level of accumulation.

Adaptation to Hypertonicity: *in Vivo* versus *in Vitro*

Interestingly, osmotic tollerance and adaptation is quite different in kidney tissues compared to cells grown *in vitro*. In the medulla of the kidney, cells routinely are bathed in hypertonic interstitum which

reaches 1000 mOsm/kgH_2O or more during antidiuresis[51] without signs of cell injury.[52,53] However, cultured kidney cells including mouse IMCD3[54] and inner medullary epithelial cells[53,55] demonstrate substantial cell death with acute changes in media tonicity. For cultured cells, the rate at which cells are exposed to increases in tonicity plays an important role in adaptation and survival. Capasso and co-workers demonstrated that small increases of 50–100 mOsm/KgH_2O allow IMCD3 cells to be adapted to levels of 900 mOsm/KgH_2O or greater.[56,57] Extensive studies by Cai and co-workers determined a similar finding for mIM cells, in that a linear increase in culture tonicity allowed for better adaptation and survival.[53,55] Furthermore, they demonstrated that hormone additions, including insulin-like growth factor I, epidermal growth factor or vasopressin, and use of growth supports including porous media, collagen I, collagen IV, fibronectin, laminin or fibrillar collagen I, have no significant effect on cellular adaptation to acute increases in tonicity.[55] Rather, these researchers suggested that cells which demonstrate greater proliferative rates, and thus increased DNA replication, are more sensitive to acute changes in tonicity.[53,58] This level of sensitivity to acute changes in tonicity can be blunted if cells in culture are preadapted to moderate levels of tonicity.[53]

Regulation of Transcription in Response to Hypertonicity

Hypertonicity-induced stimulation of transcription plays an important role in the adaptation of renal cells to hypertonicity.[59,60] The regulatory sequence element named tonicity-responsive enhancer (TonE) has been found in the promoter region of a large number of osmotic response genes identified in Table 45.5. The TonE-binding protein (TonEBP) mediates the transcriptional stimulation in response to hypertonicity. These sequences have been found in the 52 flanking region of the aldose reductase gene in several species, suggesting a common mechanism by which tonicity response genes are regulated.[59,60] The TonEBP protein has been cloned by a number of researchers naming this protein nuclear factor of activated T-cell 5 (NFAT5),[61] NFAT-like protein 1 (NFATL1),[62] and osmotic response

TABLE 45.5 Tonicity Enhancer Binding Protein (TonEBP) Target Genes

Target Gene			
Gene Name	**Abbreviation**	**Function**	**Reference**
Aldose reductase	AR	Conversion of glucose to sorbitol	78,276

element-binding protein (OREBP).[63] TonEBP/NFAT5 belongs to the Rel family of transcription factors which includes NF-kB and the calcineurin binding NFATs.[64] This family is defined by the conserved Rel DNA-binding domain.[65] The DNA-binding domain of TonEBP/NFAT5 has the ability to encircle the DNA, which may allow for greater kinetic stability.[66] The TonEBP/NFAT5 DNA-binding domain requires dimerization similar to NF-kB proteins to bind to DNA. In addition, TonEBP/NFAT5 forms dimers only with itself and not with other members of the Rel family. It also has a stricter recognition sequence (TGGAAAC/A/T) as compared to other Rel proteins.

Regulation of TonEBP/NFAT5 transcriptional activity in response to hypertonicity involves: (1) nuclear translocation; (2) upregulation of transcriptional activity; and (3) enhanced synthesis. Under unstimulated conditions, TonEBP/NFAT5 proteins shuttle in and out of the nucleus. However, following exposure of cells to hypertonic conditions, essentially all of the TonEBP/NFAT5 protein is translocated to the nucleus. This trafficking of TonEBP/NFAT5 to the nucleus is regulated by both specific nuclear localization sequences (NLS) and specific nucleoporin complexes.[67] Under hypertonic conditions, Nucleoporin 88 is upregulated in IMCD3 cells, and acts in concert with other nucleoporins to form a complex which retains TonEBP/NFAT5 to the nucleus. Transcriptional activation of TonEBP/NFAT5 is via the hypertonicity-responsive C-terminal domain.[68,69] While TonEBP/NFAT5 is phosphorylated in response to hypertoncity, and phosphorylation correlates with increased transactivation activity, activation can also occur in the presence of increased tonicity without phosphorylation.[68] Various studies have identified a number of kinases to be involved in phosphorylation of TonEBP/NFAT5 including p38, Fyn, PKA, ATM, and PI3K.[70−73] Finally, TonEBP/NFAT5 is also regulated by increased synthesis, resulting in substantial increases in protein under hypertonic conditions.[69,74] Increased levels of TonEBP/NFAT5 mRNA under hypertonic conditions are in part due to enhanced stabilization of pre-existing mRNA mediated by the 5′UTR of the message.[75]

An alternative role for TonEBP/NFAT5 has slowly emerged as additional transcriptional targets are identified. Lee and co-workers have used microarray analysis to identify greater than 100 genes in which transcription was upregulated two-fold or greater under a moderate increase in tonicity.[76] While the conventional osmotic response targets were identified (see Table 45.5), non-osmolyte accumulating genes were identified including asporin, insulin-like growth factor-binding protein 5 and 7, and extracellular lysophospholipase D. While mice lacking TonEBP/NFAT5 demonstrate reduced embryo survival and substantial perinatal death, implicating renal defects,[77,78] embryonic lethality may not be renal in nature as the maintenance of the extracellular milieu of the developing embryo is dependent on the placenta, and not the developing kidney.[64] In fact, TonEBP/NFAT5 has been shown to be expressed in most developing organs of the mouse embryo.[79] Furthermore, Dressler and co-workers have shown that Pax-2 knockout mice, which fail to develop kidneys, do not suffer from embryonic lethality.[80] While the exact nature of TonEBP/NFAT5 involvement in embryonic organ development is still unknown, it is likely extremely important to embryo development.

Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) is a physical phenomenon of atomic nuclei that has many biochemical and biophysical applications.[81−83] The methodologies derived from NMR imaging enable the chemical identification of different molecules, kinetic analysis of suitable chemical reactions, studies of secondary and tertiary protein structure, and analysis of receptor−ligand interactions. It is this latter application that has become an important clinical tool. The application

of spectroscopy, in concert with different imaging methods, ultimately may prove even more valuable than imaging alone in our understanding of the pathogenesis of different diseases. Bloch and Purcell first demonstrated NMR as a physical phenomenon, independently, in 1946. The fundamental basis of the NMR phenomenon is that nuclei have a quantum characteristic called spin, which because of the charged nature of the nucleus results in these nuclei having magnetic moments, and the net biological samples having magnetic moment in the direction of an applied external magnetic field (Bo). Transitions between the spin state aligned with and against the Bo field can be induced by a radiofrequency pulse, and sampled by radiofrequency antenna as free induction decay (FID). The FID can be transformed from a plot of magnetization-versus-time to a plot of magnetization-versus-frequency, also called an NMR spectrum, by a mathematical manipulation called a Fourier transformation. The frequency of the FID (υ) can be predicted by the knowledge of the nucleus under study and its gyromagnetic ratio (τ), and the magnitude of the Bo field by the following relationship:

$$\upsilon = \tau \mathrm{Bo}/2\pi \tag{45.5}$$

The area under the resultant spectral peak is directly proportional to the quantity of nuclei existing free in solution in the sample being studied. This, in fact, is the basis of NMR imaging experiments. Spectroscopic methodologies make use of the fact that the chemical environment of a given nucleus placed in a Bo field will affect the effective magnetic field of a given nucleus (B_{eff}). This can be described by the chemical environment of a nucleus defining the density of the electron cloud about that nucleus, which tends to appose the Bo field. We can, therefore, describe a shielding constant σ that results from this electron cloud apposing the Bo field in the following equation:

$$\mathrm{B_{eff}} = \mathrm{Bo}\ \ (1 - \sigma) \tag{45.6}$$

The magnitude of σ is usually small, and it is expressed in the dimensionless term of parts per million (ppm). This means that the spectrum acquired from a sample, containing the same nucleus in different chemical environments, will have multiple spectral peaks corresponding to these different chemical environments, allowing for chemical identification on the basis of the shielding constants of these nuclei, also known as chemical shift. Chemical shift, expressed in parts per million, is independent of the strength of the Bo field. Although other physical phenomena may be used in chemical identification (e.g., spin coupling, nuclear Overhauser effect), chemical shift is the primary method of chemical identification that has been used in NMR of living tissues.[81,82]

Figure 45.9 shows the H-1 NMR spectra of brain extract from normal and hypernatremic rats. The most prominent peaks represent N-acetylaspartate (2.02 ppm) and phosphocreatine (3.03 and 3.93 ppm). The peaks in the range of 2.0 to 2.5 ppm represent primarily amino acids, which have not been completely characterized yet. But it was evident that the peak area was larger in severe chronic hypernatremia than normal rat. The major peaks of polyols and trimethylamines were located between 3.1 and 3.9 ppm; GPC, 3.23; betaine, 3.26; myoinositol, 3.27, 3.57, 3.59, 3.61, and 4.06; and sorbitol, 3.85 ppm. We observed the increase of GPC, betaine, and myoinositol in severe chronic hypernatremia compared with normal rats. Sorbitol peak was not visualized in normal rats with severe chronic hypernatremia. The spectra of brain extracts from acute hypernatremia were similar to those of normal rats, and thus are not shown.[32]

Using clinical magnetic resonance imaging (MRI) and spectroscopy, Lee and his co-workers[84] examined an 18-month-old girl with severe dehydration and hypernatremia (plasma sodium concentration 195 mEq/l). A conventional 1.5 Tesla (1.5 T) Sigma General Electric magnetic resonance scanner was used. After MRI, quantitative proton NMR spectroscopy was performed in the parietal and occipital regions of the patient's cerebral cortex, revealing primarily white matter and gray matter, respectively. Spectra from the same regions in 50 healthy infants were also acquired. MRI revealed partial haloprosencephaly. Proton NMR spectroscopy of occipital gray matter and parietal white matter revealed several striking abnormalities (Figure 45.10). The principle abnormality was a reversal of the normal ratio of peak intensities between the neuronal metabolite N-acetylaspartate and the putative osmolyte myoinositol. The principle change was in the concentration of myoinositol, which was three times normal, whereas that of N-acetylaspartate was normal. Concentrations of choline and glutamine (plus glutamate) were also increased. The sequential spectra obtained during correction of the dehydration are shown (Figure 45.10).

The calculated concentrations of the five principle metabolites shown in the spectra of the infant's brain on days 4 to 36 are shown in Table 45.6. The direct determination of patterns of disordered cerebral organic osmolytes by proton NMR spectroscopy may be valuable in guiding therapy.[84,85]

NMR analyses of metabolic changes in the kidney in response to hypertonic stress have focused on specific cell lines and, in particular, the inner medullary collecting duct. Analysis of changes in organic osmolytes with respect to chronic adaptation of $IMCD_3$ cells to increasing tonicity from 300 to 900 mOsm/kg H_2O were studied by proton NMR, as shown in

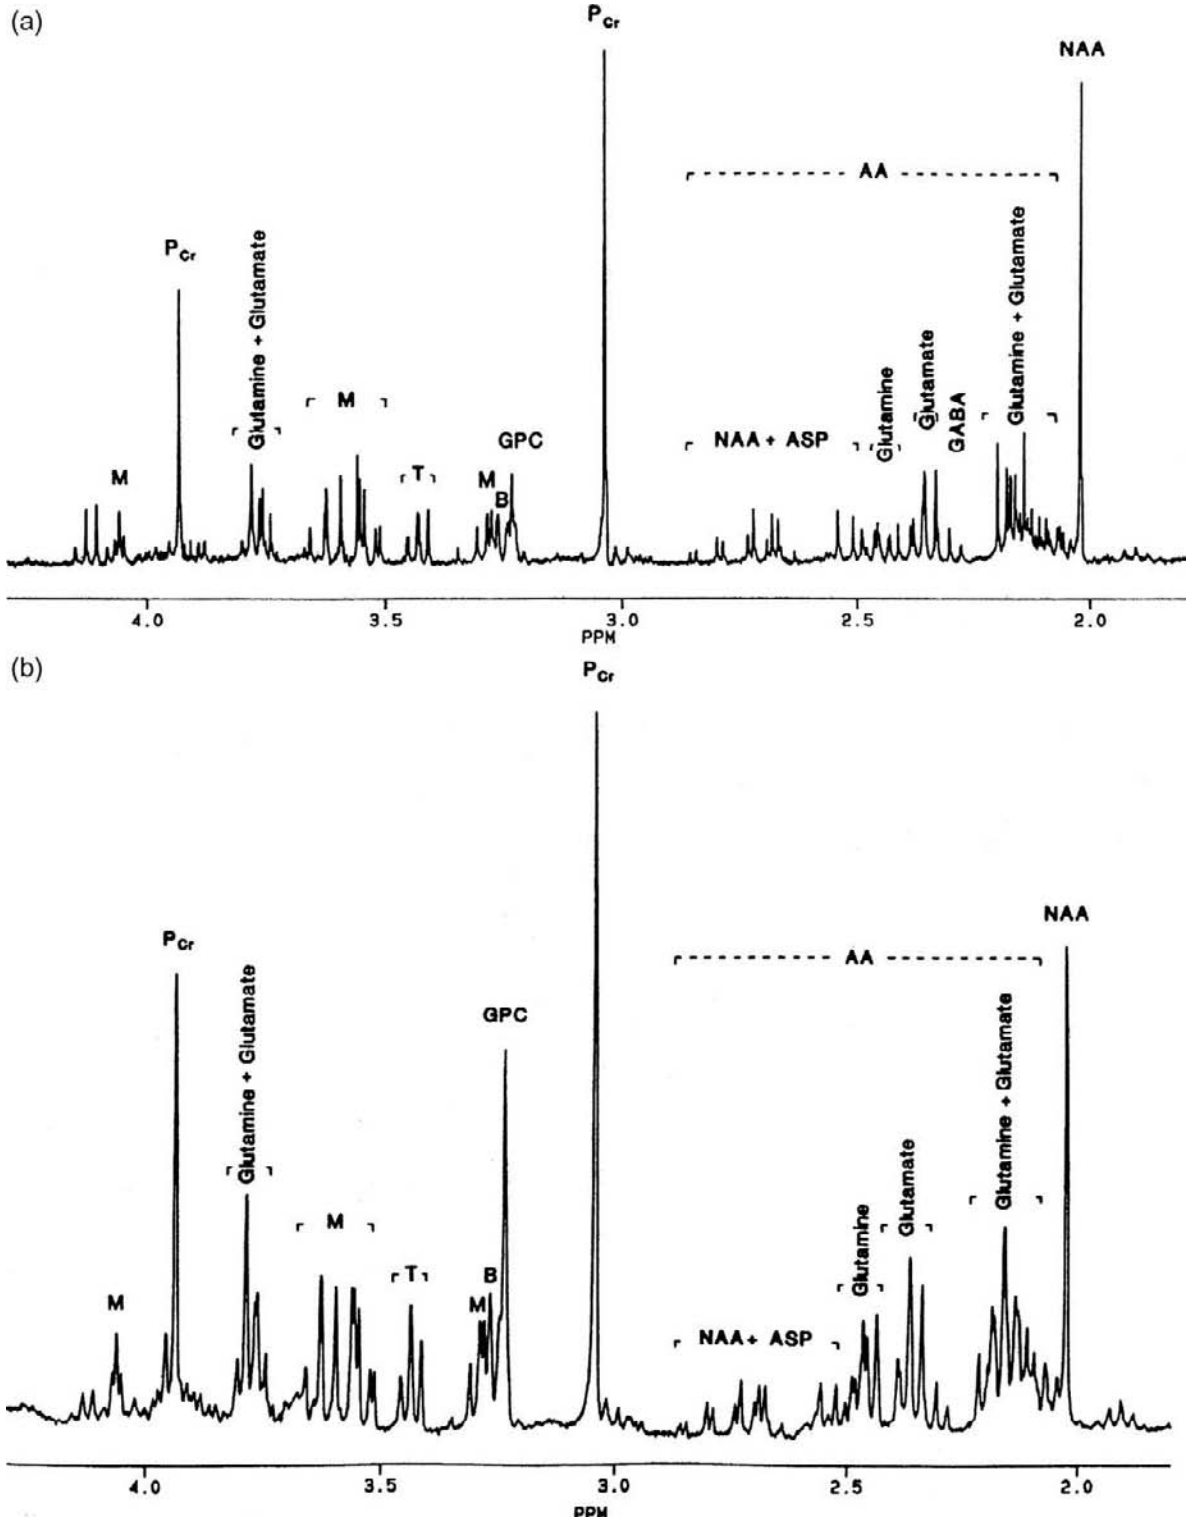

FIGURE 45.9 **Proton nuclear magnetic resonance (NMR) spectra of brain extracts from normal rat (a) and severe chronic hypernatremic rat (b).** These spectra are the sum of 128 transients and are referenced to trimethylsilylproprionate (TSP). Only peaks derived from glycerophosphoryl choline (GPC), betaine 67, myoinositol (M), amino acids (AA), phosphocreatine (PCr), and N-acetylaspartate (NAA) have been labeled. *(from ref. [32]).*

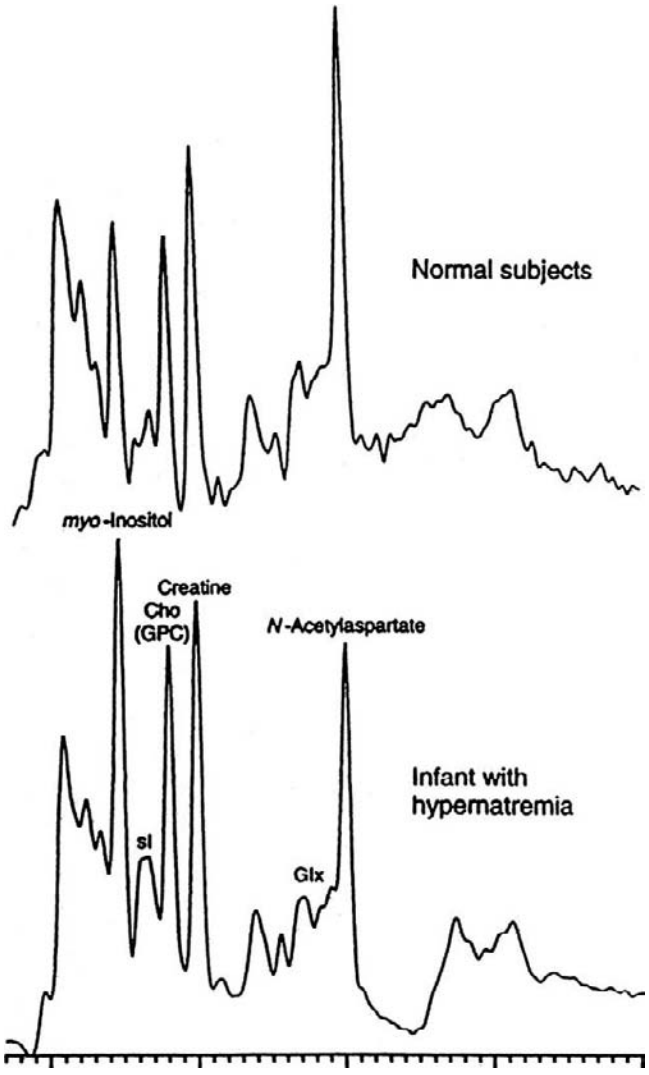

FIGURE 45.10 **Short-echo-time proton nuclear magnetic resonance (NMR) spectrum of cortical gray matter in an infant with severe dehydration.** The striking differences from normal in this patient were the apparent increase in myoinositol and the decrease in N-acetylaspartate. The increase in myoinositol was accompanied by increases in the concentrations of its stereoisomer, scyllo-inositol (sl), and choline-containing compounds (ho), especially glycerophosphoryl choline (GPC), glutamine plus glutamate (Glx), and creatine. *(from ref. [84]).*

Figure 45.11. Gross examination of NMR spectra demonstrates profound changes in nearly all organic osmolytes. Analysis of phosphorylated compounds can be determined by ^{86}P NMR, as shown in Figure 45.12. In a similar fashion, initial reflection indicates a substantial increase in GPC with more minor changes in GPE and PCr. While ^{86}P NMR has been used for analysis of nucleotide triphosphates (NTPs), possibly improved techniques involving HPLC-MS appear to provide for higher sensitivity, greater reproducibility, and throughput for analytical measurements.

ETIOLOGY OF HYPERNATREMIC STATES

Hypernatremia may be due to primary Na^+ gain or water deficit (Table 45.7). The two components of an appropriate response to hypernatremia are increased water intake stimulated by thirst, and the excretion of the minimum volume of maximally-concentrated urine reflecting ADH secretion in response to an osmotic stimulus.[87,88] Most cases of hypernatremia result from the loss of water. Since water is distributed between the ICF and the ECF in a 2:1 ratio, a given amount of solute-free water loss will result in a two-fold greater reduction in the ICF compartment than the ECF compartment. Sodium overload will result in hypernatremia with an increase in total body sodium, and the patient will have an increase in ECF. Water deficit, however, may occur with low or normal total body sodium.

Water deficit in excess of sodium deficit is associated with hypovolemic hypernatremia, and the patient will have low total body sodium. When hypernatremia is caused by pure water loss, the patient is euvolemic and the total body sodium remains normal. The causes of water losses in both of these settings may be renal or extrarenal. Renal losses of water may be a consequence of diabetes insipidus or osmotic diuresis. Diabetes insipidus will be discussed in more detail later in this chapter, in hypernatremia associated with normal total body sodium.

In the absence of increased water losses, hypernatremia can still develop (with normal total body sodium) if there is primary hypothalamic disease impairing thirst (called *hypodipsia*). Two different syndromes have been described, which are most often due to tumors, granulomatous diseases (such as sarcoidosis) or vascular disease. In the first, there is a defect in thirst, with or without concomitant diabetes insipidus. In this disorder, forced water intake is usually sufficient to maintain a normal plasma sodium concentration.[89,90] Other hypodipsic patients will not respond to water-loading, as the excess water will be excreted in the urine with little change in the plasma sodium concentration.[91,92]

Transient hypernatremia (in which the plasma sodium concentration can rise by 10 to 15 mEq/l within a few minutes) can be induced by severe exercise or seizures, which are also associated with the development of lactic acidosis. In this setting, the breakdown of glycogen into smaller, more osmotically active molecules (such as lactate) can increase the cell osmolality, thereby causing the osmotic movement of water into the cells. The plasma sodium concentration returns to normal within 5 to 15 minutes after the cessation of exertion.

From Lee, J.H., Arcinue, E., and Ross, B. D. (1994). Brief report: Organic osmolytes in the brain of an infant with hypernatremia (see comments). N. Engl. J. Med. ***331****, 439–442, with permission.*

Peak areas were converted to concentrations as previously described .[266] The T1 and T2 relaxation times of water and each metabolite were within the normal range given in that report, except for myoinositol, for which the value obtained in this study was 209 msec. As compared with a mean (± SD) of 301 ± 33 in the study by Ernst et al.[266]

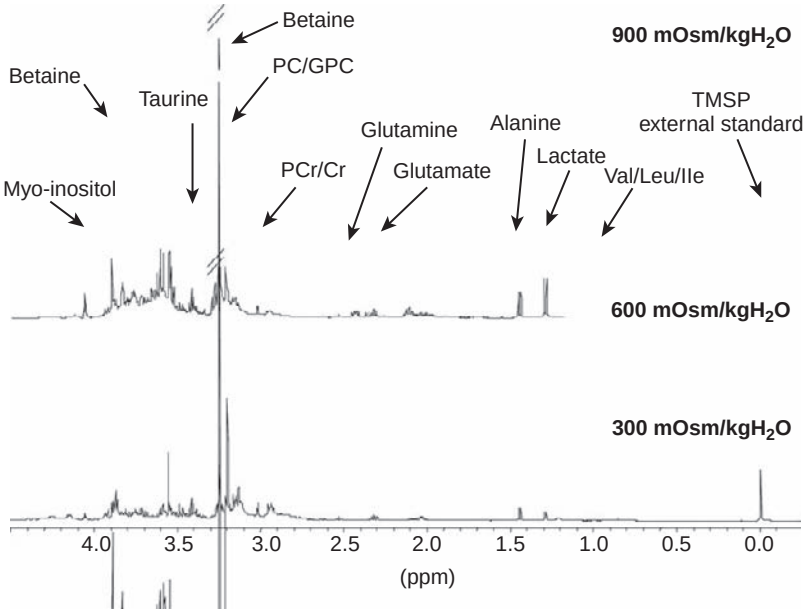

FIGURE 45.11 ^{1}H-nuclear magnetic resonance (NMR) spectra of PCA cell extracts. These spectra show the differences between cells cultivated in media containing 300 (bottom), 600 (middle), and 900 mOsm/kg H_2O (upper spectrum) (GPC: glycerophosphocholine; PC: phosphocholine; Cr: creatine; PCr: phosphocreatine; TMSP: trimethylsilyl propionic-2,2,3,3,-d4 acid).

CLASSIFICATION OF HYPERNATREMIA BASED ON TOTAL BODY SODIUM

Another clinical approach to the hypernatremic patient is based on the assessment of the ECF volume status and the total body sodium.

Hypernatremia in Patients with Low Total Body Sodium

Patients who sustain losses of both sodium and water, but with a relatively greater loss of water, are classified as having hypernatremia with low total body sodium. Signs of hypovolemia include orthostatic hypotension, tachycardia, flat neck veins, poor skin turgor, and dry mucous membranes. Isotonic sodium chloride should be given until systemic hemodynamics are stabilized.

The sources of free water loss that can lead to hypernatremia if intake is not increased include insensible water loss from the skin by evaporation and sweat, the loss of which is increased by fever, exercise, and exposure to high temperatures. Burns and infections will also increase the water loss. Some gastrointestinal losses, particularly osmotic diarrheas, will promote the

development of hypernatremia, because the sodium plus potassium concentration is less than that in the plasma.[93] Although primarily recognized in children, lactulose-induced diarrhea leading to hypernatremia appears to be common. Since the renal water- and sodium-conserving mechanisms operate normally in these patients, urinary osmolality is high (usually >800 mOsm/kg H_2O), and urinary sodium concentration is low (<10 mEq/l). An elevation in the plasma sodium concentration with diarrhea illness is particularly common in infants in whom fluid replacement with a relatively dilute solution can minimize the risk of hypernatremia. Decreased release of ADH or renal resistance to its effect causes the excretion of relatively dilute urine.[94,95] Most of these patients have a normal thirst mechanism. As a result, they typically present with polyuria and polydipsia, and at most a high-normal plasma sodium concentration. However, marked and symptomatic hypernatremia can occur if a central lesion impairs both ADH release and thirst, thereby preventing replacement of the urinary water losses.

An osmotic diuresis due to glucose, mannitol or urea causes an increase in urine output in which the sodium plus potassium concentration is well below that in the plasma, because of the presence of the nonreabsorbed organic solute. Patients with diabetic ketoacidosis or nonketotic hyperglycemia typically present with marked hyperosmolality, although the plasma sodium concentration may not be elevated due to hyperglycemia-induced water movement out of the cells. Hypotonic losses can also occur by the renal route during a loop diuretic-induced hypotonic diuresis or an osmotic diuresis with mannitol, glucose, glycerol or, more rarely, urea. Elderly patients with partial urinary tract obstruction can excrete large volumes of hypotonic urine.[96] The urine in these cases is hypotonic or isotonic, and the urinary sodium concentration is greater than 20 mEq/l. Since glucose and mannitol enhance osmotic water movement from the intracellular fluid to the ECF compartment, some of these patients may have a normal or even low serum sodium concentration, in spite of serum hypertonicity.

Hypernatremia in Patients with Normal Total Body Sodium

When hypernatremia is caused by pure water loss, total body sodium remains normal. Patients are usually euvolemic. The extrarenal sources of such water losses are the skin and the respiratory tract. A high environmental temperature, as well as a febrile or hypermetabolic states, can cause considerable water losses. If such hypotonic losses are not accompanied by appropriate water intake, hypernatremia supervenes. Urine osmolality is very high, reflecting an intact osmoreceptor–vasopressin–renal response. Urinary sodium concentration will vary according to the patient's sodium intake. This kind of hypernatremia has been reported in hepatic failure.[97] It was believed to occur due to total body water loss. The possible mechanisms include

increased insensible losses, decreased access to water secondary to hepatic encephalopathy, and increased hypotonic losses in stool secondary to osmotic cathartics used for treatment of encephalopathy. Chronic alcoholic subjects with end-stage liver disease who present with fulminant liver failure and hepatic encephalopathy have a high mortality rate.[97,98] Patients with liver disease who develop hypernatremia are particularly susceptible to the development of cerebral demyelinating lesions.

Diabetes insipidus is a polyuric disorder characterized by high rates of electrolyte-free water excretion.[99] When these are not appropriately replaced, hypernatremia supervenes. The causes of central neurogenic diabetes insipidus are listed in Table 45.8. If the thirst mechanism is intact and water is available, patients with central diabetes insipidus do not develop hypernatremia, and thus have no symptoms except for the inconvenience associated with the marked polyuria and polydipsia. With concomitant hypodipsia, no access to water or an illness that precludes adequate water intake, however, severe and even life-threatening hypernatremia can supervene.

Hypernatremia secondary to nonosmotic urinary water loss is usually due to central or neurogenic diabetes insipidus characterized by impaired argenine vasopressin secretion or nephrogenic diabetes insipidus resulting from end-organ (renal) resistance to the actions of AVP. The most common cause of central diabetes insipidus is destruction of the neurohypophysis. This may occur as a result of trauma, neurosurgery, granulomatous disease, neoplasms, vascular accidents or infection. In many cases, central diabetes insipidus is idiopathic and may occasionally be hereditary. The familial form of the disease is inherited in an autosomal dominant fashion, and has been attributed to mutations in the propressophysin (argenine vasopressin precursor) gene.[100–104] Nephrogenic diabetes insipidus may be either inherited or acquired. Congenital nephrogenic diabetes insipidus I is an X-linked recessive trait due to mutations in the V2 receptor gene.[105–112] Mutations in the autosomal aquaporin-2 gene may also result in NDI.[113–118] The aquaporin-2 gene encodes the water channel protein whose membrane insertion is stimulated by AVP. The causes of sporadic nephrogenic diabetes insipidus are numerous, and include drugs (especially lithium),[119–126] hypercalcemia, hypokalemia, and conditions that impair medullary hypertonicity (e.g., papillary necrosis or osmotic diuresis).[127–131] Pregnant women, in the second or third trimester, may develop nephrogenic diabetes insipidus as a result of excessive elaboration of vasopressinase by the placenta.[132,133]

Congenital nephrogenic diabetes insipidus is a rare hereditary disorder in which the renal tubule is insensitive to vasopressin.[134] The disease manifests itself in the complete clinical form only in males and in a subclinical form in females, suggesting a sex-linked dominant inheritance with variable penetrance in the female. The gene responsible for the defect has, in fact, been mapped to region 28 on the long arm of the X-chromosome (Xq28). Although the disease is most probably inborn, the diagnosis is usually not made until the infant has hyposmolar urine with severe dehydration, hypernatremia, vomiting, and fever. Unlike some of the females, who have partial responsiveness to vasopressin, the male with the full-blown complete form of this disorder will not have hypertonic urine even in the face of severe dehydration. The impaired growth and occasional mental retardation that supervene in these cases are most likely due to repeated episodes of dehydration and hypernatremia, rather than being integral components of the disease. Hydronephrosis is also common in these patients, perhaps because of voluntary retention of large volumes of urine, with subsequent vesicoureteral reflux.[135]

Neither vasopressin nor other pharmacologic agents that potentiate its action or stimulate its release, such as chlorpropamide, are effective in concentrating the urine of patients with nephrogenic diabetes insipidus. An intact thirst mechanism is, therefore, indispensable for the maintenance of good hydration in children with this disorder, as is careful monitoring of fluid balance.

TABLE 45.8 Causes of Central Diabetes Insipidus (CDI)

Hereditary
Autosomal dominant
Autosomal recessive (Wolfram syndrome)
Acquired
Head trauma, skull fracture, and orbital trauma
Posthypophysectomy

Infections
Encephalitis
Meningitis
Guillain-Barre syndrome
Vascular
Cerebral aneurysm
Cerebral thrombosis or hemorrhage
Sickle cell disease
Postpartum necrosis (Sheehan syndrome)
Pregnancy (transient)

Since the excretion of solute requires further water losses, children with this disorder who need rehydration should receive hypotonic (2.5%) rather than isotonic (5%) glucose solutions. Glucosuria may occur with the latter solution, and thus aggravate fluid losses.

Limitation of oral solute intake (low-sodium diet) may also lead to a decrease in urine flow in patients with nephrogenic diabetes insipidus. Thiazide diuretics, which inhibit sodium reabsorption in the cortical diluting segment of the nephron, have met with some success in the management of these patients. The ability of thiazides to diminish sodium reabsorption in this water-impermeable portion of the nephron would itself decrease C_{H2O}, but not urine flow. It seems most likely that the decrease in urine flow is secondary to the sodium loss and ECF volume-contraction. ECF volume-depletion in turn decreases glomerular filtration rate (GFR), and increases proximal tubular sodium and water reabsorption. These secondary effects of the diuretic agent then decrease urine flow. The ECF volume-contraction can be maintained with a low sodium intake after discontinuance of the diuretic, so that the therapy still remains effective. The addition of amiloride to hydrochlorothiazide may provide added benefit.[136–139] Nonsteroidal anti-inflammatory agents have been found to be effective.

The acquired form of nephrogenic diabetes insipidus is much more common than the congenital form of the disease, but it is rarely severe.[140] While maximal concentrating ability is impaired in this disorder, the ability to elaborate a hypertonic urine is usually preserved. Nocturia, polyuria, and polydipsia may occur in this acquired form of nephrogenic diabetes insipidus, but the urine volumes are generally less ($<3–4$ l/day) than those observed with complete central diabetes insipidus, psychogenic water-drinking or congenital nephrogenic central diabetes insipidus. The more common causes of acquired nephrogenic diabetes insipidus are listed in Table 45.9.

A defect in renal concentrating capacity is a consistent accompaniment of most forms of advanced renal failure.[141,142] Thus, chronic renal failure constitutes a form of acquired nephrogenic diabetes insipidus. Advanced renal insufficiency of any cause can cause a vasopressin resistance associated with hypotonic urine. In some forms of kidney disease vasopressin unresponsiveness can occur at a stage when GFR is not markedly diminished. The occurrence of a profound diuresis in association with a concentrating defect in glomerular diseases of the kidney is rare and, in general, a close correlation exists between GFR and maximal urinary osmolality. The causes of the defect in renal concentrating capacity associated with chronic renal failure are probably multiple.[143–145] These include: (1) a disruption of inner medullary structures or local alterations in medullary blood flow, as is seen in tubulointerstitial diseases, sickle cell disease,[146,147] and analgesic nephropathy; (2) impairment in sodium chloride transport out of the thick ascending limb of Henle's loop, a process that limits maximal interstitial tonicity; and (3) increase in solute excretion in the remaining few functioning nephrons, an adaptive response to the need to excrete the same solute load as the normal kidney.

Miscellaneous
Gestational diabetes insipidus

Hypokalemia has long been known to cause polyuria as a consequence of a vasopressin-resistant renal concentrating defect.[40] A direct effect of hypokalemia on the collecting tubule is supported by studies in the toad bladder which show a decrease in cyclic AMP and vasopressin-stimulated water flow when potassium is removed from the bathing solution.[148] These findings suggest both a precyclic AMP and postcyclic AMP defect. The hypokalemia-induced resistance to vasopressin is associated with decreased cyclic AMP accumulation, apparently due to decreased adenylyl cyclase activity. Hypokalemia from any cause, such as diarrhea, chronic diuretic use or primary aldosteronism, may be associated with a urinary concentrating defect. The defect is generally reversible, but requires a longer time (1–3 months) than would be expected from a purely functional defect.

Hypercalcemia is another well-recognized cause of impaired urinary concentrating ability.[149–151] A decrement in medullary interstitial tonicity is clearly present

with hypercalcemia, which may be related to diminished solute reabsorption in the thick ascending limb. This defect is associated with a decrement in AVP-stimulated adenylate cyclase in this nephron segment. The concentrating defect is, however, multifactorial, as the elaboration of hypotonic urine implies an intrinsic defect in the collecting tubule. In this regard, studies in isolated toad bladders, as well as papillary collecting ducts, reveal a decreased response to vasopressin in hypercalcemia.

Various pharmacologic agents have been found to impair the renal capacity to concentrate urine (Table 45.9). Ethanol and phenytoin (Dilantin) seem to exert their action by a central effect on vasopressin release.[152] Some hypoglycemic agents cause a diuresis by a mechanism probably unrelated to suppression of vasopressin release. The renal toxicity of amphotericin can manifest in the form of a concentrating defect.[153] Foscarnet, an agent increasingly employed in the treatment of cytomegalovirus (CMV) infection in patients with acquired immune deficiency syndrome (AIDS), has been described to cause a nephrogenic diabetes insipidus.[91,154]

The drugs most commonly associated with nephrogenic diabetes insipidus are demeclocycline and lithium.[119,120,122,123,125,155] Since it was first recognized as a cause of nephrogenic diabetes insipidus, demeclocycline has become the drug of choice for the treatment of the syndrome of inappropriate ADH secretion (SIADH). It has yet to be determined if demeclocycline reduces argenine vasopressin secretion. It is clear, however, that demeclocycline induces dose-dependent decreases in human renal medullary adenylate cyclase activity. Since the drug decreases not only vasopressin but also cyclic AMP-stimulated water flow, a postcyclic AMP defect may be operant.[156]

Lithium is the most common cause of nephrogenic diabetes insipidus. There is no evidence that lithium impairs vasopressin release. In terms of the mechanism of its renal action, lithium does not interfere with accumulation of medullary solutes. Thus, an intrinsic tubular defect is postulated. In this regard, lithium decreases vasopressin-stimulated water transport in the perfused cortical collecting duct. An inhibition in adenylate cyclase or in cyclic AMP generation is observed in human tissue and cultured cells exposed to the cation, as well as in animals chronically treated with lithium. More recently, a downregulation of the vasopressin-regulated water channel (aquaporin) has been described in lithium-treated rats.[157] It is of interest that the urinary aquaporin levels remained low after removal of lithium, in line with the slow recovery of concentrating ability seen in man.

A renal concentrating defect is a common accompaniment of sickle cell anemia and sickle cell trait.[146,158,159] Sickling of red blood cells in the hypertonic medullary interstitium with occlusion of the vasa recta appears to cause inner medullary and papillary damage. Microradioangiographic studies have failed to demonstrate vasa recta blood flow in patients with sickle cell disease. The resultant medullary ischemia may impair sodium chloride transport in the ascending limb, and thus diminish medullary tonicity. Transfusions of normal blood have been shown to restore renal concentrating capacity in children, thus indicating that the sickled red blood cells have a role in the defect. With more prolonged disease, medullary infarcts occur and the concentrating defect is no longer reversible with transfusions.

The syndrome of essential hypernatremia and hypodipsia has been described in patients with normal total body sodium. A partial list of causes of this hypodipsia-hypernatremia syndrome is shown in Table 45.10. These patients exhibit persistent hypernatremia not explained by any volume loss. There is absence or attenuation of thirst. The patient may also have partial diabetes insipidus and a normal renal response to ADH. This is due to a primary hypothalamic disease impairing thirst (called *hypodipsia*). Two different syndromes have been described, which are most often due to tumors, granulomatous diseases (such as sarcoidosis) or vascular disease. In the first, there is a defect in thirst, with or without concomitant diabetes insipidus. In this disorder, forced water intake is usually sufficient to maintain a normal plasma sodium concentration.[89,160] Other hypodipsic patients will not respond to water-loading, as the excess water will be excreted in the urine with little change in the plasma sodium concentration.[91,92] It had been postulated that these

patients had a reset osmostat upward (called *essential hypernatremia*), so that the new high plasma sodium concentration was recognized as normal.[161,162] Thus, giving water will decrease ADH release, and the excess water will be excreted in dilute urine. It is now clear, however, that these patients have selective injury to the osmoreceptors, with ADH secretion being primarily governed by changes in volume.[163] Thus, the suppression of ADH release by water-loading in this setting is due to the associated mild volume expansion, rather than a fall in plasma osmolality. True resetting of the osmostat upwards has been described only in patients with primary mineralocorticoid excess (such as primary hyperaldosteronism). The plasma sodium concentration in these patients is usually between 143 and 147 mEq/l. It is presumed that the suppressive effect of chronic mild volume expansion on ADH release is responsible for the resetting. This appears to be due to a specific osmoreceptor defect resulting in nonosmotic regulation of argenine vasopressin release. These patients are characterized by persistent hypernatremia not explained by any apparent extracellular volume loss with a normal response to AVP. It has been proposed that these patients have a "resetting" of the osmoreceptor, since these patients tend to concentrate and dilute urine at inappropriately high levels of plasma osmolality.[164–169] However, using the regression analysis of plasma argenine vasopressin level versus plasma osmolality, it has been shown that in some of these patients the tendency to concentrate and dilute urine at inappropriately high levels of plasma osmolality is due solely to a marked reduction in sensitivity or gain of the osmoregulatory mechanism. In other patients, however, plasma argenine vasopressin levels fluctuate in a random manner, bearing no apparent relationship to changes in plasma osmolality. Such patients frequently display large swings in serum sodium concentration. It appears that most patients with essential hypernatremia fit one of these two patterns.[88,170] Hypodipsia can also occur in elderly patients without overt hypothalamic lesions, and can culminate in severe hypernatremia.[168,171] It has been suggested that a decrement in angiotensin II-mediated thirst existed in the elderly.[29,172]

Hypernatremia in Patients with Increased Total Body Sodium

Hypernatremia with increased total body sodium is the least common type of hypernatremia, and is usually due to exogenous administration of hypertonic sodium containing solutes (Table 45.11).[13] Acute and often marked hypernatremia (in which the plasma sodium concentration can exceed 175–200 mEq/l) can be induced by the administration of hypertonic sodium-containing solutions. Hypernatremia supervenes during resuscitative efforts with hypertonic sodium bicarbonate,[46,173] inadvertent intravascular infusion of hypertonic saline in therapeutic abortions, inadvertent dialysis against a high sodium concentration dialysate, sea water drowning, and even after ingestion of large quantities of sodium chloride tablets.[174–178] Accidental or nonaccidental salt poisoning has been reported in infants and young children, and in patients taking highly concentrated saline emetic or gargle.[174,179,180] The hypernatremia in this setting will correct spontaneously if renal function is normal, since the excess sodium will be rapidly excreted in the urine. This process can be facilitated by inducing a sodium and water diuresis with a loop diuretic, and then replacing the urine output with water. Too rapid correction should be avoided if the patient is asymptotic. Since the hypernatremia is generally very acute with little time for cerebral adaptation, these patients are less likely to develop cerebral edema during correction.[181,182] The degree of hyperosmolality is typically mild, unless the thirst mechanism is abnormal or access

TABLE 45.11 Therapeutic Hypertonic Solutions

Solute	Molecular Weight	Concentration (mg/dL%)	Osmolality (mosm/kg water)	Typical Container Size (ML)	Use

to water is limited. This occurs in infants, the physically handicapped, patients with impaired mental status, in the postoperative state, and in patients on ventilators. Patients with primary hyperaldosteronism and Cushing syndrome have slight, clinically unimportant elevations in serum sodium concentration. As expected, patients with hypernatremia and high total body sodium excrete generous quantities of the cation in the urine.

CLINICAL FEATURES IN HYPERNATREMIA

A complete history and physical examination will often provide clues as to the underlying cause of hypernatremia.[183,184] Relevant symptoms and signs include the absence or presence of thirst, diaphoresis, diarrhea, polyuria, and the features of ECF volume contraction.[185–188] The major symptoms of hypernatremia are neurologic and include altered mental status, weakness, neuromuscular irritability, focal neurologic deficits, and occasionally coma or seizures (Table 45.12). As a consequence of hypertonicity, water shifts out of cells, leading to a contracted ICF volume. A decreased brain cell volume is associated with an increased risk of subarachnoid or intracerebral hemorrhage.[189–192] Patients may also complain of polyuria or thirst. For unknown reasons, patients with polydipsia from CDI tend to prefer ice-cold water. The signs and symptoms of volume depletion are often present in patients with a history of excessive sweating, diarrhea or an osmotic diuresis.[132,183,193–197]

The severity of the clinical manifestations is related to the acuity and magnitude of the rise in plasma Na^+ concentration. Chronic hypernatremia is generally less symptomatic as a result of adaptive mechanisms designed to defend cell volume. Brain cells initially take up Na^+ and K^+ salts, later followed by accumulation of organic osmolytes, such as inositol. This serves to restore the brain ICF volume towards normal.

The signs and symptoms of hypernatremia are most likely related to a variety of anatomic derangements.

The most prominent manifestations of hyperosmolar disorders are of a neurologic nature.[198–204] The loss of volume and the shrinkage of brain cells associated with the hyperosmolar states causes tearing of cerebral vessels. In addition to these gross anatomic changes, the brain sustains alterations in the composition of water and solutes that may be of great importance in the pathophysiology of the symptoms of hypernatremia. These are responses designed to regulate volume and restore cell size. Thus, the water losses are not as severe as would be predicted. In the early phase, the entry of sodium and chloride into brain cells greatly mitigates the loss of water that would otherwise occur from ideal osmotic behavior. After 7 days of hypernatremia, brain water has returned to control levels as brain osmolality remains elevated. At this time idiogenic osmoles account for as much as 60% of the increase in intracellular osmolality. It now seems possible that some of these idiogenic osmoles are due to an increase in intracellular amino acids, particularly taurine. In addition, accumulation of osmolytes such as urea, glutamine, glycerolphosphorylcholine, and myoinositol has been documented in hypernatremic rats, as well as in human using NMR spectroscopy.

Measurement of urine volume and osmolality are essential in the evaluation of hypernatremia. The appropriate renal response to hypernatremia is the excretion of the minimum volume (500 ml/d) of maximally-concentrated urine (urine osmolality greater than 800 mOsm/kg H_2O). These findings suggest extrarenal or remote renal water loss or administration of hypertonic Na^+ salt solutions. The presence of a primary Na^+ excess can be confirmed by the presence of ECF volume expansion and natriuresis (urine Na^+ concentration usually greater than 100 mmol/l). Many causes of hypernatremia are associated with polyuria and a submaximal urine osmolality. The product of the urine volume and osmolality, i.e., the solute excretion rate, is helpful in determining the basis of the polyuria. To maintain a steady-state, total solute excretion must equal solute production. Individuals eating a normal diet generate approximately 600 mOsm/d. Therefore, daily solute excretion in excess of 750 mOsm/d defines an osmotic diuresis. This can be confirmed by measuring the urine glucose and urea. In general, both CDI and NDI present with polyuria and hypotonic urine (urine osmolality less than 250 mOsm/kg H_2O). The degree of hypernatremia is usually mild unless there is an associated thirst abnormality.

THERAPY FOR HYPERNATREMIA

The therapeutic goals are to stop ongoing water loss by treating the underlying cause, and to correct the

water deficit. The specific approach depends on the patient's ECF volume (Table 45.13). Reversal of hypernatremic state must be undertaken slowly to prevent neurological complications. Rapid correction may result in cerebral edema, seizure, and death.[183,205–211]

When the patient has low total body sodium, as evidenced by circulatory manifestations (e.g., orthostatic hypotension), isotonic sodium chloride should be given until systemic hemodynamics are stabilized. Thereafter, the hypernatremia can be treated with 0.45% sodium chloride or 5% dextrose. When the patient is hypervolemic and hypernatremic, the removal of excess sodium is the goal, which can be achieved either by administration of diuretics along with 5% dextrose or, if renal function is impaired, by dialysis. The euvolemic hypernatremic patient who has sustained pure water losses requires water replacement as a 5% dextrose infusion. The water deficit in this setting can be calculated based on the current sodium concentration and body weight, using the assumption that total body water is approximately 50 or 60% of body weight:

$$\text{Water deficit} = \text{Total-body water} \times \left(\frac{\text{Plasma } [Na^+]}{140}\right) \quad (45.7)$$

In addition to replacing the calculated water deficit, ongoing fluid losses should be replaced. In acute hypernatremia, repletion of the water deficit may be faster. The electrolytes accumulated in the brain during hypernatremia are rapidly extruded into the extracellular space during treatment, minimizing the risk of cerebral edema.[206] In contrast, rapid correction in chronic hypernatremia is potentially dangerous. In this case, a sudden decrease in osmolality could potentially cause a rapid shift of water into cells that have undergone osmotic adaptation. This would result in swollen brain cells, and increase the risk of seizures or permanent neurologic damage.[212] A slower rate of correction probably can prevent this sequence of events by allowing idiogenic osmoles time to be dissipated.

The plasma Na^+ concentration should be lowered by 0.5 mmol/L per hour, and by no more than 12 mmol/L over the first 24 hours. The safest route of administration of water is by mouth or via a nasogastric tube (or other feeding tube). Alternatively, 5% dextrose in water or half-isotonic saline can be given intravenously. The patient's neurological status should be monitored carefully throughout treatment. Deterioration of neurological status after an initial improvement suggests the development of cerebral

edema, and mandates temporary discontinuation or slowing the rate of water replacement.

In patients with essential hypernatremia and the elderly with hypodipsia, 1 to 2 liters of water per day may need to be administered as a prescription. Chlorpropamide itself augments thirst, and its use with desmopressin in patients with adipsia has been proposed.

Patients with central diabetes insipidus do not develop hypernatremia if the thirst mechanism is intact and water is available. Hormonal replacement and pharmacologic agents are available for the treatment of central diabetes insipidus. In acute settings, such as after hypophysectomy, the aqueous vasopressin (Pitressin) preparation is preferable. Its short duration of action allows for more careful monitoring, and decreases the likelihood of complications such as water intoxication. In chronic settings, vasopressin tannate in oil (Pitressin Tannate) is potent and effective for 24 to 72 hours. It requires a deep subcutaneous or intramuscular injection by a fairly large-gauge needle, because of the viscosity of the oil vehicle. This material can cause sterile abscesses in some subjects, and on occasion be associated with resistance due to development of antibodies.[213–215] A modification of the natural vasopressin molecule to form desmopressin acetate (dDAVP) has resulted in a compound with prolonged antidiuretic activity (6–24 hours) and virtual elimination of vasopressor activity (antidiuretic to pressor ratio of approximately 2000:1) compared with the natural hormone argenine vasopressin (duration of action of 2–4 hours and antidiuretic to pressor ratio of 1:1[216–220]). Substitution of D-argenine for L-argenine at position 8 resulted in a peptide DAVP with diminished vasopressor activity, and deamination of the hemicysteine at position 1 gave rise to a second peptide, with enhanced antidiuretic to pressor activity and prolonged duration of action. dDAVP is administered intranasally in the dosage ranging from 10 to 20 μg every 8 to 12 hours.[221,222] Intranasal dDAVP is now the treatment of choice for central diabetes insipidus.

In some patients with partial central diabetes insipidus, drugs that stimulate argenine vasopressin secretion or enhance its action on the kidney have been useful. These include chlorpropamide, clofibrate, carbamazepine, and nonsteroidal anti-inflammatory drugs (NSAIDs).[223–226] Since, with very dilute urine of fixed osmolality, the urine volume is determined by the solute-load requiring excretion, a reduction of salt and protein in the diet will reduce the major urinary solutes, and thus the volume of urine necessary to accommodate their excretion.[14] A number of pharmacologic agents with antidiuretic properties are also used. Chlorpropamide (Diabinese) is the most commonly used. Its antidiuretic effects are manifested only if some vasopressin is present, and it is therefore useful only in partial diabetes insipidus. In Brattleboro rats with diabetes insipidus, chlorpropamide augmented the antidiuretic responses to dDAVP. A trial of 250 mg every day or twice a day may be offered to patients with partial central diabetes insipidus and at least 7 days allowed for an effect to occur. The anticonvulsant carbamazepine (Tegretol) has also caused antidiuresis in subjects with diabetes insipidus. A combination of chlorpropamide and carbamazepine has been found to provide an effect that could be synergistic.[227,228] Clofibrate also has been used to treat partial central diabetes insipidus.

In patients with nephrogenic diabetes insipidus, the concentrating defect may be reversible by treating the underlying disorder or eliminating the offending drug. Symptomatic polyuria can be treated with a low-sodium diet and thiazide diuretics.[136] This induces mild volume-depletion, which leads to enhanced proximal reabsorption of salt and water, and decreased delivery to the site of action of AVP, the collecting duct. By impairing renal prostaglandin synthesis, NSAIDs potentiate argenine vasopressin action, and thereby increase urine osmolality and decrease urine volume.[229] Amiloride may be useful in patients with nephrogenic diabetes insipidus who need to be on lithium.[126,230] The nephrotoxicity of lithium requires the drug to be taken up into collecting duct cells via the amiloride-sensitive Na^+ channel.

CLINICAL STUDIES AND OUTCOME

The clinical outcome of patients with hypernatremia depends on the age of the patient and the rapidity with which the hypernatremic state was attained.[231–233] Acute hypernatremia is associated with a 40% mortality, whereas the mortality for chronic hypernatremia is about 10%. In children, the mortality of acute hypernatremia ranges between 10 and 70%, with a mean of approximately 45%. Unfortunately, even in survivors, neurologic sequelae are common, affecting as many as two-thirds of the children.[30,234–237] In adults, acute elevation of serum sodium above 160 mEq/l is associated with a 75% mortality, while the mortality in chronic cases is approximately 60%. Note, however, that in the adult, hypernatremia frequently occurs in the setting of serious underlying diseases, which may be the primary cause of the high mortality.[153,238–240]

Table 45.14 summarizes clinical studies of hypernatremia in adults that have been published over the past two decades. From these varied studies,[232,233,241–246] it is apparent that hypernatremia is a common disturbance, with an incidence ranging from less than 1% to more than 3%. The variation in incidence is, in part, a

TABLE 45.14 Published Clinical Series of Patients with Hypernatremia

Series reference	Definition [Na], mmol/L	*N*	Incidence	Age years, mean ± SD	Etiologic Factors	Mortality
Daggett et al. [242]	>154	20	0.12%	N/A	Diabetes mellitus (57%)	40%

					Mental status changes (255%)	

CNS: central nervous system; GI: gastrointestinal.

function of the populations at risk and the definition of hypernatremia used in various studies. The patient groups at increased risk for development of severe hypernatremia are listed in Table 45.15. Hypernatremia developing in nonhospitalized adults is predominantly a disease of the elderly,[86,245,247–249] is commonly a manifestation of underlying infection, and may reflect inadequate nursing care of patients in chronic care facilities. However, hospital-acquired hypernatremia occurs in a wider range of patients with an age distribution more similar to the general hospitalized population. The main factor contributing to the development of hypernatremia is the inability to control water intake in the setting of increased water losses. Pure water loss from diabetes insipidus rarely contributes to its development; more common etiologies of water loss include diuretic administration, solute diuresis, enteral fluid loss, and fever. The results from these clinical series

TABLE 45.15 Patient Groups at Increased Risk for Development of Severe Hypernatremia

Elderly patients
Hospitalized patients
Hypertonic infusions
Tube feedings
Osmotic diuretics
Lactulose
Mechanical ventilation
Patients with decreased baseline levels of consciousness
Patients with uncontrolled diabetes
Patients with underlying polyuric disorders

support the recommendation that the serum sodium concentration be corrected promptly, but gradually, over 48 to 72 hours.

ARGININE VASOPRESSIN

Synthesis

Nonapeptides of the vasopressin family are the key regulators of water homeostasis in amphibia, reptiles, birds, and mammals. Since these peptides reduce urinary output, they are also referred to as antidiuretic hormones. Oxytocin and AVP (Figure 46.1) are synthesized in separate populations of magnocellular neurons of the supraoptic and paraventricular nuclei.[1] Oxytocin is most recognized for its key role in parturition and milk letdown in mammals.[2] The axonal projections of AVP- and oxytocin-producing neurons from supraoptic and paraventricular nuclei reflect the dual function of AVP and oxytocin as hormones and as neuropeptides, in that they project their axons to several brain areas, and to the neurohypophysis. The regulation of the release of AVP from the posterior pituitary is primarily dependent, under normal circumstances, on tonicity information relayed by central osmoreceptor neurons expressing TRPV1[3] (Figure 46.2) and peripheral osmoreceptor neurons expressing TRPV4.[4] AVP and its corresponding carrier, neurophysin II, are synthesized as a composite precursor by the magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus (for review see [5]). The precursor is packaged into neurosecretory granules and transported axonally in the stalk of the posterior pituitary. En route to the neurohypophysis, the precursor is processed into the active hormone. Pre-provasopressin has 164 amino acids, and is encoded by the 2.5 kb *AVP* gene located in chromosome region 20p13.[6,7] The *AVP* gene (coding for AVP and neurophysin II) and the *OXT* gene (coding for oxytocin and neurophysin I) are located in the same chromosome region, at a very short distance from each other (12 kb in humans) in head-to-head orientation. Data from transgenic mouse studies indicate that the intergenic region between the *OXT* and the *AVP* genes contains the critical enhancer sites for cell-specific expression in the magnocellular neurons.[5] It is phylogenetically interesting to note that *cis* and *trans* components of this specific cellular expression have been conserved between the *Fugu* isotocin (the homolog of mammalian oxytocin) and rat oxytocin genes.[8] Exon 1 of the *AVP* gene encodes the signal peptide, AVP, and the NH_2-terminal region of neurophysin II. Exon 2 encodes the central region of neurophysin II, and exon 3 encodes the COOH-terminal region of neurophysin II and the glycopeptide. Provasopressin is generated by the removal of the signal peptide from pre-provasopressin, and from the addition of a carbohydrate chain to the glycopeptide (Figure 46.3). Additional post-translational processing occurs within neurosecretory vesicles during transport of the precursor protein to axon terminals in the posterior pituitary, yielding AVP, neurophysin II, and the glycopeptide. The AVP–neurophysin II complex forms tetramers that can self-associate to form higher oligomers.[9] Neurophysins should be seen as chaperone-like molecules facilitating intracellular transport in magnocellular cells. In the posterior pituitary, AVP is stored in vesicles. Exocytotic release is stimulated by minute increases in serum osmolality (hypernatremia, osmotic regulation), and by more pronounced decreases in extracellular fluid (hypovolemia, non-osmotic regulation). Oxytocin and neurophysin I are released from the posterior pituitary by the suckling response in lactating females.

Immunocytochemical and radioimmunologic studies have demonstrated that oxytocin and vasopressin are synthesized in separate populations of the supraoptic nuclei and the paraventricular nuclei neurons,[10,11] the central and vascular projections of which have

[241]; and the conformation of OT was obtained from the Protein Data Bank (PDB Id 1XY1).)*

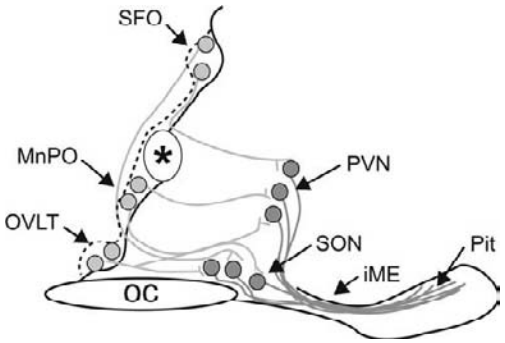

FIGURE 46.2 **Schematic representation of the osmoregulatory pathway of the hypothalamus (sagittal section of midline of ventral brain around the 3rd ventricle in mice).** Neurons (lightly filled circles) in the lamina terminalis (OVLT), median preoptic nucleus (MnPO) and subfornical organ (SFO) that are responsive to plasma hyptertonicity send efferent axonal projections (gray lines) to magnocellular neurons of the paraventricular (PVN) and supraoptic nuclei (SON). The OVLT is one of the brain circumventricular organs and is a key osmosensing site in the mammalian brain (*vide infra*). The processes (dark lines) of these magnocellular neurons form the hypothalamo–neurohypophysial pathway that courses in the median eminence to reach the posterior pituitary, where neurosecretion of vasopressin and oxytocin occurs. *(Modified from ref. [242].)*

been described in great detail.[12] Some cells express the *AVP* gene and other cells express the *OXT* gene. Immunohistochemical studies have revealed a second vasopressin neurosecretory pathway that transports high concentrations of the hormone to the anterior pituitary gland from parvocellular neurons to the hypophyseal portal system. In the portal system, the high concentration of AVP acts synergistically with corticotropin-releasing hormone (CRH) to stimulate adrenocorticotropic hormone (ACTH) release from the anterior pituitary. More than half of parvocellular neurons co-express both *CRH* and *AVP*. In addition, while passing through the median eminence and the hypophyseal stalk, magnocellular axons can also release AVP into the long portal system. Furthermore, a number of neuroanatomic studies have shown the existence of short portal vessels that allow communication between the posterior and anterior pituitary. Therefore, in addition to parvocellular vasopressin, magnocellular vasopressin is able to influence ACTH secretion.[13,14]

Mammals are Osmoregulators: the Cellular Perception of Tonicity to Stimulate Thirst and Vasopressin Release

Mammals are osmoregulators: they have evolved mechanisms that maintain extracellular fluid (ECF) osmolality near a stable value. Yet, although mammals strive to maintain a constant ECF osmolality, values measured in an individual can fluctuate around the set-point owing to intermittent changes in the rates of water intake and water loss (through evaporation or diuresis), and to variations in the rates of Na intake and excretion (natriuresis). In humans, for example, 40 minutes of strenuous exercise in the heat[15,16] or 24 hours of water deprivation[17] causes plasma osmolality to rise by more than 10 mosmol kg^{-1}. In a dehydrated individual, drinking the equivalent of two large glasses of water (~850 ml) lowers osmolality by approximately 6 mosmol kg^{-1} within 30minutes.[18] Similarly, ingestion of 13 g of salt increases plasma osmolality by approximately 5 mosmol kg^{-1} within 30 minutes.[19] Although osmotic perturbations larger than

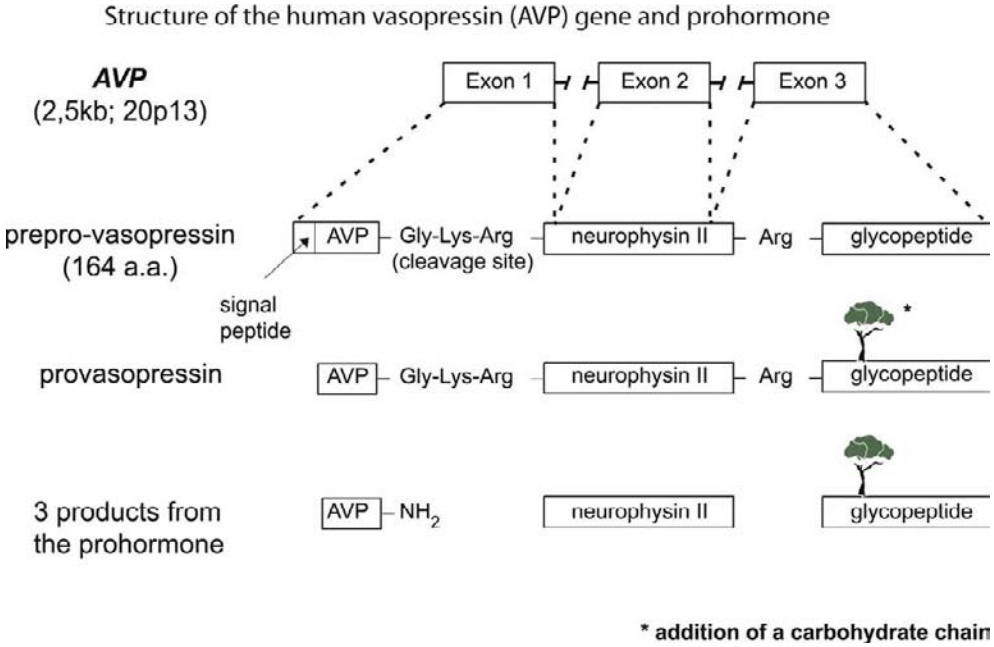

FIGURE 46.3 **Structure of the human vasopressin (AVP) gene and prohormone.** Cascade of vasopressin biosynthesis signal peptide; AVP, arginine-vasopressin; neurophysin; glycoprotein.

these can be deleterious to health, changes in the 1–3% range play an integral part in the control of body fluid homeostasis. Differences between the ECF osmolality and the desired set-point induce proportional homeostatic responses according to the principle of negative feedback.[3] ECF hyperosmolality stimulates the sensation of thirst to promote water intake, and the release of vasopressin to enhance water reabsorption in the kidney. By contrast, ECF hypoosmolality suppresses basal VP secretion in rats and humans.[20]

As summarized elegantly by Bourque,[3] early studies provided clear evidence that "cellular dehydration" (that is, cell shrinking) was required for thirst and vasopressin release to be stimulated during ECF hyperosmolality: these responses could be induced by infusions of concentrated solutions containing membrane-impermeable solutes, which extract water from cells, but not by infusions of solutes that readily equilibrate across the cell membrane (such as urea). Verney coined the term "osmoreceptor" to designate the specialized sensory elements. He further showed that these were present in the brain, and postulated that they might comprise "tiny osmometers" and "stretch receptors" that would allow osmotic stimuli to be "transmuted into electrical" signals.[21] Osmoreceptors are therefore defined functionally as neurons that are endowed with an intrinsic ability to detect changes in ECF osmolality, and it is now known that both cerebral and peripheral osmoreceptors contribute to the body fluid balance.

Although magnocellular neurons are themselves osmosensitive, they require input by glutamatergic afferents from the lamina terminalis to respond fully to osmotic challenges (Figure 46.2).

Hypertonicity is sensed by Organum Vasculosum Lamina Terminalis (OVLT) neurons expressing TRPV1 (Transient Receptor Potential Vanilloid-1, *vide infra*): OVLT serves as the brain's primary osmoreceptor area,[22] and neurons in this nucleus transduce hyperosmotic conditions into proportional increases in action-potential firing rate.[23] The information encoded by the electrical activity of these neurons is then relayed synaptically to diverse subsets of homeostatic effector neurons that induce appropriate osmoregulatory responses such as thirst, natriuresis, and antidiuretic hormone release.[3,24–27] The mechanical modulation of TRPV1 is well-demonstrated.[28]

Because the subfornical organ (SFO) and the organum vasculosum of the lamina terminalis (OVLT) lie outside the blood–brain barrier, they can integrate this information with endocrine signals borne by circulating hormones, such as angiotensin II (Ang-II), relaxin, and atrial natriuretic peptide (ANP). While circulating angiotensin II and relaxin excite both OT and vasopressin magnocellular neurons, ANP inhibits vasopressin neurons. The non-osmotic pathways are more physiologically described now as "osmoregulatory gain," since angiotensin II amplifies osmosensory transduction by enhancing the proportional relationship between osmolality, receptor potential, and action potential firing in rat supraoptic nucleus neurons[29] (Figure 46.4). Modifications in osmoregulatory gain induced by angiotensin explain why the changes in the

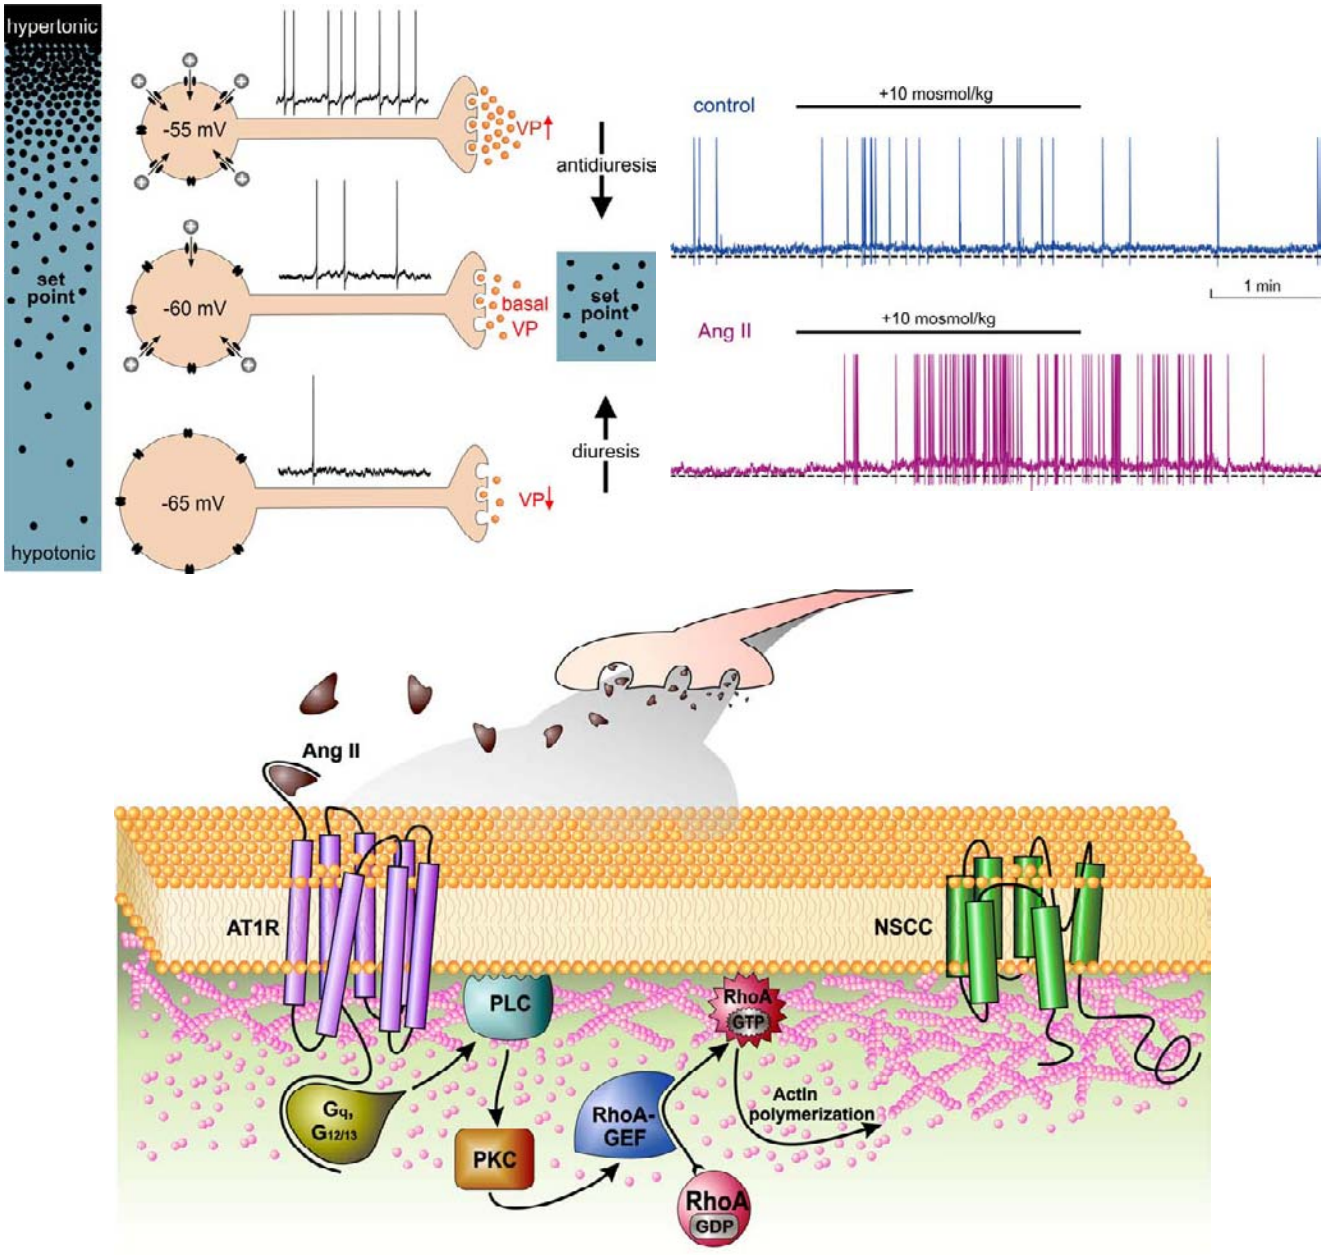

FIGURE 46.4 Upper left: Cell autonomous osmoreception in vasopressin neurons. Changes in osmolality cause inversely proportional changes in soma volume. Shrinkage activates nonselective cation channels (NSCCs) and the ensuing depolarization increases action potential firing rate and vasopressin (VP) release from axon terminals in the neurohypophysis. Increased VP levels in blood enhance water reabsorption by the kidney (antidiuresis) to restore extracellular fluid osmolality toward the set point. Hypotonic stimuli inhibit NSCCs. The resulting hyperpolarization and inhibition of firing reduces VP release and promotes diuresis. Upper right: Whole cell current clamp recordings from isolated MNCs (left) and averaged data from multiple cells show that the depolarizing and action potential firing responses induced by a hypertonic stimulus are significantly enhanced in the presence of 100 nM angiotensin II. Lower right: Hypothetical events mediating central angiotensin II enhancement of osmosensory gain. Angiotensin II released by afferent nerve terminals (e.g., during hypovolemia) binds to AT1 receptor (AT1R) coupled to G-proteins such as Gq or/and G12/13. Activated G-proteins signal through phospholipase C (PLC) and protein kinase C (PKC) to activate a RhoA-specific guanine nucleotide exchange factor (RhoA−GEF), such as p115RhoGEF or LARG (leukemia-associated Rho guanine−nucleotide exchange factor). Activation of RhoA−GEF converts inactive cytosolic RhoA (RhoA−GDP) into active, membrane-associated RhoA−GTP by promoting the exchange of GDP to GTP. ActivatedRhoA induces actin polymerization and increases submembrane F-actin density to enhance the mechanical gating of non-specific cation channels. *(With permission from ref. [243].)*

slope and threshold of the relationship between plasma osmolality and vasopressin secretion are potentiated by hypovolemia or hypotension, and are attenuated by hypervolemia or hypertension[30] (Figure 46.5).

The osmotic stimulation of AVP release by dehydration or hypertonic saline infusion, or both, is regularly used to test the AVP secretory capacity of the posterior pituitary. This secretory capacity can be assessed directly by comparing the plasma AVP concentration measured sequentially during a dehydration procedure with the normal values, and then correlating the plasma AVP with the urinary osmolality measurements obtained simultaneously[31] (Figure 46.6).

The AVP release can also be assessed indirectly by measuring plasma and urine osmolalities at regular intervals during the dehydration test.[32] The maximum urinary osmolality obtained during dehydration is compared with the maximum urinary osmolality obtained after the administration of vasopressin or 1-desamino-8-D-arginine vasopressin (dDAVP; Pitressin: 5 units subcutaneously (SQ) in adults; 1 unit SQ in children or dDAVP 1–4 mg intravenously over 5 to 10 minutes).

The nonosmotic stimulation of AVP release can be used to assess the vasopressin secretory capacity of the posterior pituitary in a rare group of patients with the essential hyponatremia and hypodipsia syndrome. Although some of these patients may have partial central diabetes insipidus, they respond normally to nonosmolar AVP release signals such as hypotension, emesis, and hypoglycemia.[33] In all other cases of suspected central diabetes insipidus, these nonosmotic stimulation tests will not give additional clinical information.[34]

Minus numbers to the left indicate percentage fall, and positive numbers to the right, percentage rise in blood volume or pressure. *(Data from Vokes, T. P., and Robertson, G. L. (1985) Physiology of secretion of vasopressin,* In *"Frontiers in Hormone Research: Diabetes Insipidus in Man," Vol. 13, 127–155, Czernichow, A. G. R. P., (ed.). S. Karger, Basel.*[244]*)*

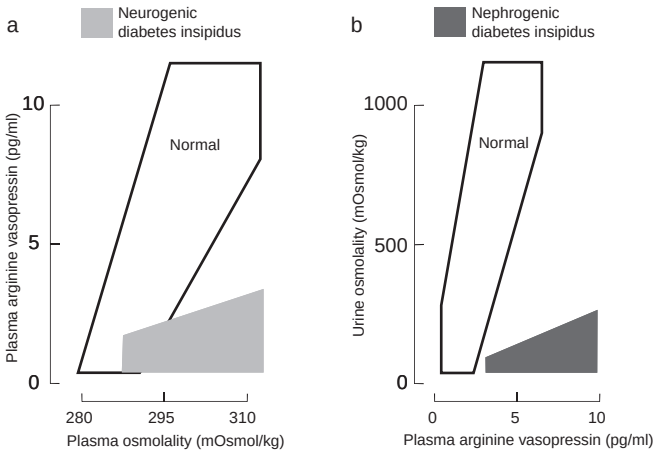

FIGURE 46.6 (a) Schematic diagram of the relationship between plasma arginine-vasopressin (AVP) and plasma osmolality during hypertonic saline infusion. In patients with neurogenic diabetes insipidus, plasma AVP is almost always subnormal relative to plasma osmolality. In contrast, patients with primary polydipsia or nephrogenic diabetes insipidus (NDI) have values within the normal range (light gray area). (b) Relationship between urine osmolality and plasma AVP during a dehydration test. Patients with NDI have hypotonic urine despite high plasma AVP. In contrast, patients with neurogenic diabetes insipidus or primary polydipsia have values within the normal range (dark gray area). *(from ref. [31].)*

Tonicity Information is Relayed by Central Osmoreceptor Neurons Expressing TRPV1 and Peripheral Osmoreceptor Neurons Expressing TRPV4

The osmotic regulation of the release of AVP from the posterior pituitary is primarily dependent, under normal circumstances, on tonicity information relayed by central osmoreceptor neurons expressing TRPV1,[3] and peripheral osmoreceptor neurons expressing TRPV4.[4]

The cellular basis for osmoreceptor potentials has been characterized using patch-clamp recordings and morphometric analysis in magnocellular cells isolated from the supraoptic nucleus of the adult rat. In these cells, stretch-inactivating cationic channels transduce osmotically evoked changes in cell volume into functionally relevant changes in membrane potential. In addition, magnocellular neurons also operate as intrinsic Na^+ detectors. The N-terminal variant of the transient receptor potential channel (TRPV1) is an osmoticaly activated channel expressed in the magnocellular cells producing vasopressin,[35] and in the circumventricular organs, the OVLT, and the SFO.[23] Since osmoregulation still operates in *Trpv1*$^{-/-}$ mice, other osmosensitive neurons or pathways must be able to compensate for loss of central osmoreceptor function.[23,35,36] Afferent neurons expressing the osmotically-activated ion channel, TRPV4, in the thoracic

dorsal root ganglia that innervate hepatic blood vessels and detect physiological hypoosmotic shifts in blood osmolality have recently been identified.[4] In mice lacking the osmotically-activated ion channel, TRPV4, hepatic sensory neurons no longer exhibit osmosensitive inward currents, and activation of peripheral osmoreceptors *in vivo* is abolished. In a large cohort of human liver transplantees, who presumably have denervated livers, plasma osmolality is significantly elevated compared to healthy controls, suggesting the presence of an inhibitory vasopressin effect of hyponatremia, perceived in the portal vein from hepatic afferents.[4] TRPV1 (expressed in central neurons) and TRPV4 (expressed in peripheral neurons) thus appear to play entirely complementary roles in osmoreception. Lechner et al. have thus identified the primary afferent neurons that constitute the afferent arc of a well-characterized reflex in man and more recently also in rodents.[37] This reflex engages the sympathetic nervous system to raise blood pressure and stimulate metabolism.[38,39] Of clinical interest, it has already been demonstrated that orthostatic hypotension and postprandial hypotension respond to water drinking.[40–42] Moreover, water drinking in man can prevent neutrally-mediated syncope during blood donation or after prolonged standing.[43] Finally, water drinking is also associated with weight loss in overweight individuals.[44] Other peripheral sensory neurons expressing other mechanosensitive proteins may also be involved in osmosensitivity.[45]

Cellular Actions of Vasopressin

The neurohypophyseal hormone AVP has multiple actions, including the inhibition of diuresis, contraction of smooth muscle, platelet aggregation, stimulation of liver glycogenolysis, modulation of adrenocorticotropic hormone release from the pituitary, and central regulation of somatic and higher functions (thermoregulation, blood pressure, autonomic expression of fear, neurobiology of attachment).[46–48] These multiple actions of AVP could be explained by the interaction of AVP with at least three types of G-protein-coupled receptors: the V1a (vascular hepatic) and V1b (anterior pituitary) receptors act through phosphatidylinositol hydrolysis to mobilize calcium[49]; and the V2 (kidney) receptor is coupled to adenylate cyclase.[48]
