Renal Cortical and Medullary Microcirculations: Structure and Function

Thomas L. Pallone and Chunhua Cao

Division of Nephrology, Department of Medicine, University of Maryland at Baltimore, Baltimore, MD, USA

ANATOMY OF THE RENAL CIRCULATION

Cortical Microcirculation

The basic vascular pattern of the kidney is preserved across mammalian species[1,3–9] (Figure 24.1). The renal artery branches into interlobar arteries that ascend within the renal pelvis to enter the parenchyma. In multipapillate organisms, the interlobar arteries travel toward the cortex along the columns of Bertin. These vessels change direction and follow an arc-like course near the corticomedullary border to become arcuate arteries. The arcuate artery gives rise to the interlobular arteries that ascend, in radial fashion, toward the cortical surface. Afferent arterioles arise from interlobular arteries at angles that vary with their cortical depth. Afferents that supply deep glomeruli near the corticomedullary junction (juxtamedullary glomeruli) leave the interlobular artery at a recurrent angle. In contrast, superficial afferent arterioles that supply glomeruli near the surface of the kidney line up with the interlobular artery at its termination.

In some species (rat, cat, dog, and *Meriones*) a pair of intra-arterial "cushions" exist as parallel ridges that project from the origin of the juxtamedullary afferent arteriole into the lumen of the parent intralobular artery (Figure 24.2a).[10,11] The cushions are 18–30 μm in length, composed of a ground substance in which smooth muscle cells are embedded and covered by a layer of continuous endothelium (Figure 24.2b).[12] The cushions are ideally placed to regulate blood flow distribution within the cortex. Given that blood flow to the renal medulla arises largely from the efferent flow of juxtamedullary glomeruli, it is also plausible that the cushions play a role in the regulation of blood flow to the medulla. The cushions have been hypothesized to separate plasma and red blood cells, and alter medullary hematocrit by "skimming" plasma from a red cell-free layer near the vessel wall.[10,13]

The structure of afferent and efferent arterioles varies with cortical location. Afferent arterioles are composed of one to three layers of smooth muscle cells. Muscle and elastic tissue diminish near the glomerulus and the media is replaced by granular cells of the juxtaglomerular apparatus. The diameters of efferent arterioles vary from as small as 12 μm in the superficial cortex to 28 μm for juxtamedullary glomeruli. Efferent arterioles in the superficial cortex branch to form a dense peritubular capillary plexus. Ten different branching patterns have been described.[14] In contrast to the efferent arterioles of superficial glomeruli, those of juxtamedullary glomeruli most frequently cross the corticomedullary junction to enter the outer stripe of the outer medulla, where they give rise to descending vasa recta (DVR). DVR are transitional vessels along which smooth muscle is replaced by contractile pericytes.[8,15] A small fraction of blood flow to the renal medulla may bypass juxtamedullary glomeruli in "shunt" vessels (dashed line, Figure 24.1). Casellas and Mimran have described variations of those shunts as: (1) branches of afferent arterioles; (2) continuous vessels from which afferent arterioles arise as side branches; (3) short vascular connections between

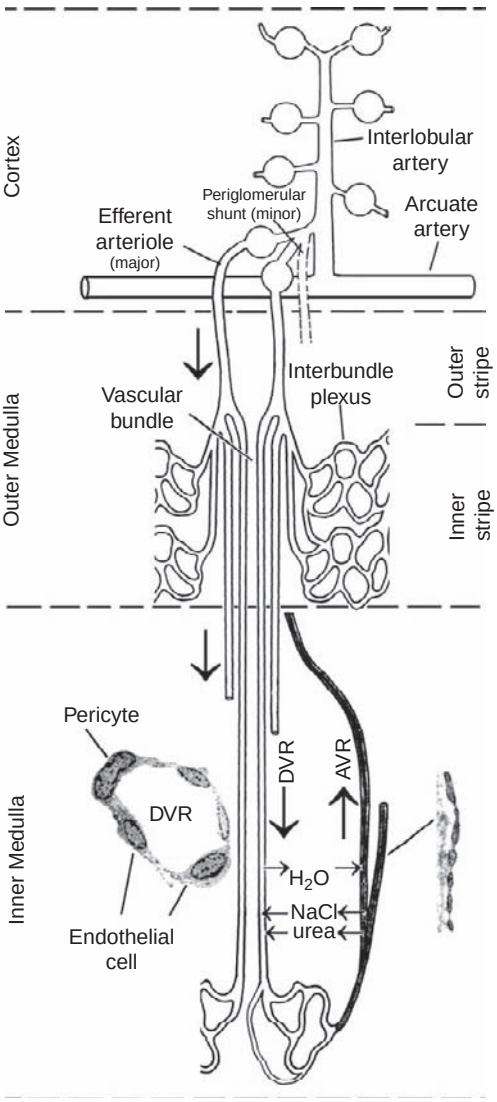

FIGURE 24.1 Microcirculation of the renal cortex and medulla. Within the renal cortex, interlobular arteries, derived from the arcuate artery, ascend toward the cortical surface. Superficial and midcortical glomeruli arise at obtuse and right angles, while juxtamedullary glomeruli arise at an acute, recurrent angle from the interlobular artery. The majority of blood flow to the medulla arises from juxtamedullary efferent arterioles. A minor fraction might also be derived from periglomerular shunt pathways (dashed lines). In the outer stripe of the outer medulla, juxtamedullary efferent arterioles give rise to DVR that combine with AVR, and sometimes thin descending limbs of Henle, to form vascular bundles. Vascular bundles are the prominent feature of the inner stripe of the outer medulla. DVR on the periphery of vascular bundles perfuse the interbundle capillary plexus that supplies nephrons (thick ascending limb, collecting duct, long looped thin descending limbs, not shown). DVR in the center of the bundles continue across the inner–outer medullary junction to perfuse the inner medulla. In some species, thin descending limbs of short looped nephrons migrate toward or become associated with vascular bundles. In the inner medulla, vascular bundles disappear and vasa recta become dispersed with thin loops of Henle and collecting ducts. Blood from the interbundle capillary plexus is returned without rejoining vascular bundles. DVR have a continuous endothelium (inset) and are surrounded by contractile pericytes. Like cortical peritubular capillaries, the AVR endothelium is highly fenestrated. As blood flows toward the papillary tip, NaCl and urea diffuse into DVR and out of AVR. Transmural gradients of NaCl and urea drive water efflux across the DVR wall via aquaporin-1 water channels. The increasing size of the circled "P" is to represent the rise in DVR plasma protein concentration with medullary depth. *(Reproduced with permission from ref. [31].)*

afferent and efferent arterioles; and (4) pelvic arterioles derived from afferent arterioles near the renal hilus (Figure 24.3).[16] Several reviews of arteriolar patterns in the renal cortex have been written.[4,11,17]

The bulk of glomerular filtrate is reabsorbed by the proximal convoluted tubule. That reabsorbate is conducted through the cortical interstitium and taken up by peritubular capillaries. The peritubular interstitium of the cortex has been divided into "narrow" and "wide" portions comprising 0.6 and 3.4% of tissue volume.[18,19] The narrow interstitium is flanked by a highly fenestrated capillary wall on one side and the basolateral membrane of the PCT on the other (Figure 24.4).[9,20] Since only 26% of the tubular surface faces the narrow interstitium it follows that substantial quantities of fluid must flow from the wide to the narrow portion, implying that hydrostatic pressure gradients exist within the cortical interstitium.[18,21]

Medullary Microcirculation

Blood flow to the renal medulla is supplied by DVR. Descending vasa recta (DVR) arise largely from efferent arterioles of juxtamedullary glomeruli and supply all blood flow to the renal medulla (Figure 24.1). The afferent arterioles that supply juxtamedullary glomeruli arise from interlobular arterioles (cortical penetrating arterioles) at recurrent angles. Muscular intra-arterial cushions exist at the origins of afferent arterioles (Figure 24.2), particularly near the corticomedullary junction, and have been proposed to participate in reduction of medullary hematocrit by "plasma skimming" (see below).[10,11] Juxtamedullary efferent arterioles are larger, longer, and have a more robust smooth muscle layer than those derived from superficial or midcortical glomeruli (Figure 24.5).[15,17] They often divide into branches that either remain in the cortex to supply cortical peritubular

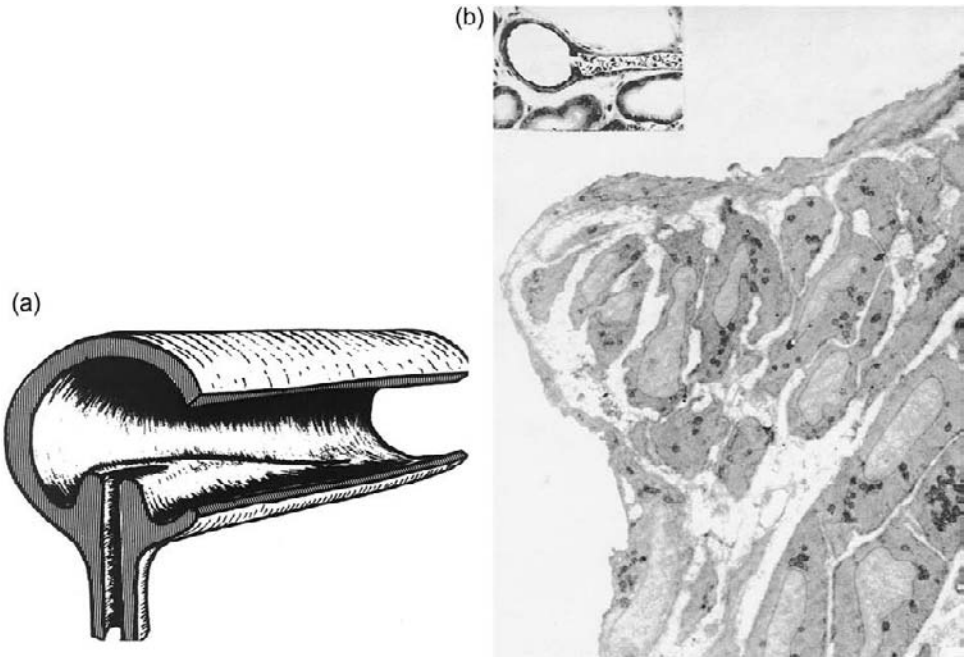

FIGURE 24.2 **The intra-arterial cushion.** (a) In some species intra-arterial cushions are present where juxtamedullary afferent arterioles arise from interlobular arterioles. (b) A longitudinal section through an afferent arteriole shows an intra-arterial cushion at its origin from the interlobular artery (inset: ×160). The cushion protrudes into the lumen of the parent vessel. Smooth muscle cells of the cushion are embedded in a copious matrix (×4000). Intra-arterial cushions might affect the relative volume fraction of RBCs versus plasma (hematocrit) that is directed from intralobular arterioles to juxtamedullary glomeruli and renal medulla. It is also conceivable that they regulate the relative distribution of blood flow between the superficial and juxtamedullary cortex (see text). *(Reproduced with permission from ref. [11,12]).*

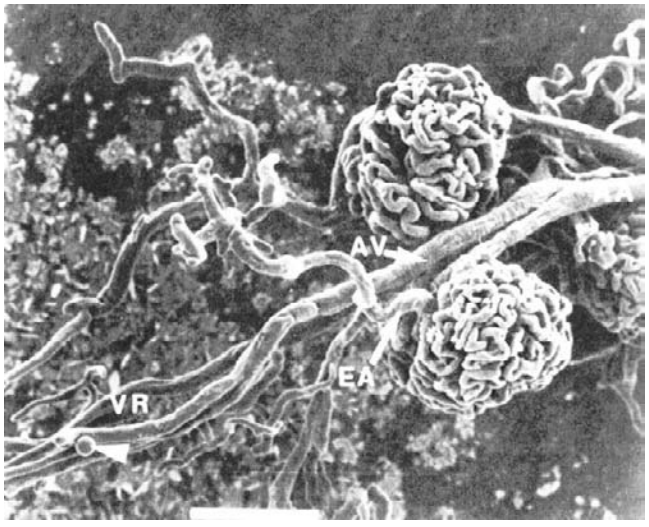

FIGURE 24.3 **Corrosion cast showing a periglomerular shunt vessel at the corticomedullary junction.** The afferent arteriole (AA) of a juxtamedullary glomerulus gives rise to a side branch (AV) which forms descending vasa recta (VR). The efferent arteriole (EA) of the juxtamedullary glomerulus is visible (Arrowhead: 16 μm sphere; Bar: 100 μm). It is probable that some blood flow that reaches the renal medulla bypasses juxtamedullary glomeruli by shunts such as the one illustrated, but the overall fraction of medullary blood flow derived from shunts is probably small (i.e., <10%). *(Reproduced with permission from ref. [16]).*

capillaries or, alternatively, descend into the medulla to form DVR.[14,22,23] DVR are about one half of the diameter of parent juxtamedullary efferent arterioles, in the range of 12 to 18 μm; some may be as large as 20 μm. DVR branch from their parent efferent arteriole in the outer stripe of the outer medulla and then coalesce within vascular bundles in the inner stripe of the outer medulla[4,5,8,24,25] (Figure 24.1). Larger diameter DVR lie in the center of vascular bundles and penetrate to the deepest regions of the inner medulla.[15,17,26] DVR are transitional vessels, wherein smooth muscle is replaced by contractile pericytes.[27] Pericytes become increasingly scarce with medullary depth, but are retained well into the inner medulla[28] (Figure 24.6). DVR have a continuous endothelium with tight junctions. In contrast, ascending vasa recta (AVR) that arise from DVR are highly fenestrated[25,29,30](Figure 24.7). DVR peel off from the periphery of the vascular bundles as they pass through the inner stripe to supply the interbundle capillary plexus (Figure 24.8a,b,c). AVR within vascular bundles are only those that originate from the inner medulla.[24] Blood flow from the outer medullary interbundle capillary plexus returns to the cortex without rejoining vascular bundles. Thus, countercurrent exchange in the vascular bundles of the inner stripe of the outer medulla involves all DVR, but only those AVR that return from the inner medulla.

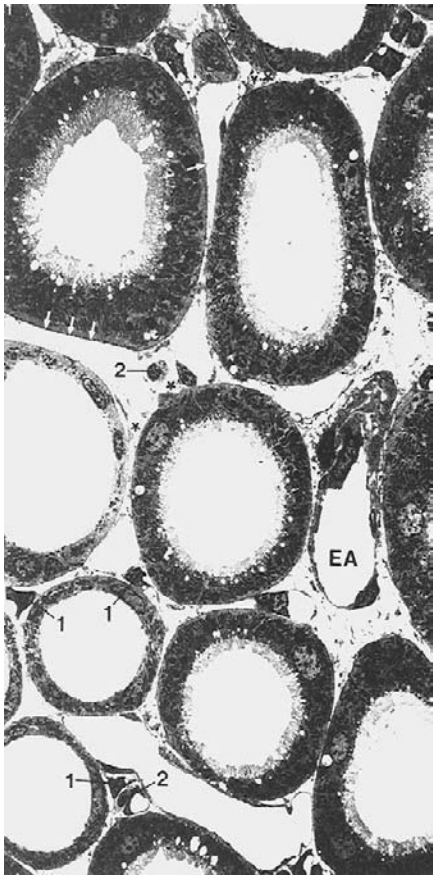

FIGURE 24.4 **Peritubular interstitium of the renal cortex.** The narrow portion of the cortical interstitium (arrows) lies immediately adjacent to the basement membrane of the proximal tubule. The wide portion (stars) lies between peritubular capillaries and cortical nephrons. Interstitial cells are fibroblast-like[780] or rounded[746] (EA: efferent arteriole (× 1000). *(Reproduced with permission from ref. [20]).*

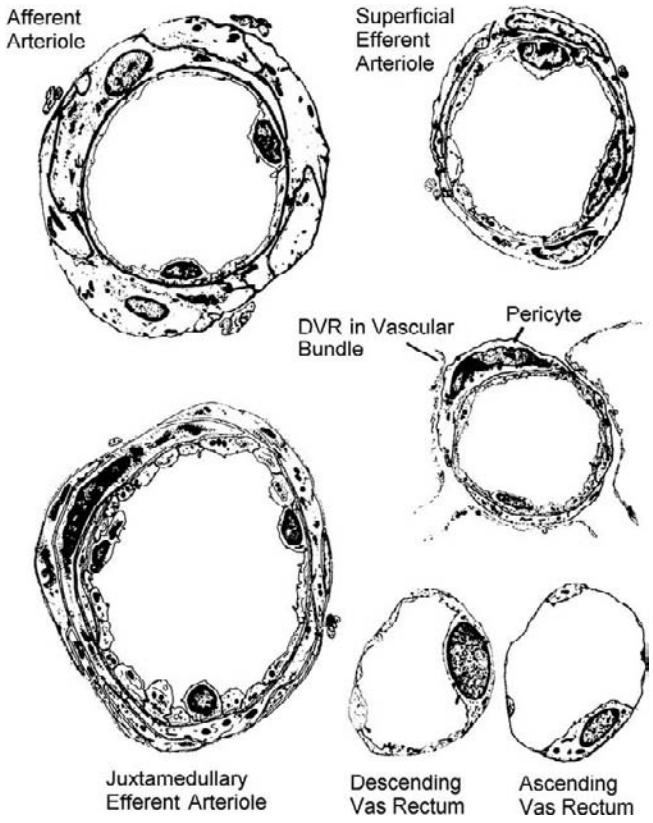

FIGURE 24.5 **Structure and transition of cortical and medullary vessels.** The proximal afferent arteriole is composed of at least two layers of smooth muscle cells. The muscularity and size of cortical efferent arterioles differ with location. Note the difference between the superficial and juxtamedullary efferent arterioles. The juxtamedullary efferent arteriole is larger, has a thicker, multilayered media, and its endothelium is composed of more numerous endothelial cells. In the illustration, a descending vas rectum (DVR) in a vascular bundle is adjacent to three fenestrated ascending vasa recta (AVR). The DVR wall is surrounded by a contractile pericyte. At the bottom right, DVR and AVR from the inner medulla are shown. Inner medullary DVR have a continuous endothelium through most of their length as pericytes become scarcer with medullary depth. Terminal DVR and the entire AVR wall is fenestrated. *(Reproduced with permission from ref. [15]).*

The most striking characteristic of the outer medullary circulation is its separation into vascular bundles and the dense capillary plexus that supplies the interbundle region of the inner stripe[4,5,15,17,24–26,31] (Figures 24.1, and 24.8). Species variation exists with respect to the association of nephrons with vascular bundles. The "simple" vascular bundle of the rabbit, guinea pig, dog, cat, monkey, and man is comprised only of DVR and AVR, excluding nephrons.[4,17,26] The "complex" vascular bundle of some rodents incorporates the descending thin limbs of short looped nephrons (nephrons that return from the inner–outer medullary junction). The degree to which thin descending limbs of Henle are incorporated into vascular bundles varies with species, and is highly developed in the mouse[4,17,26,32] (Figure 24.9). *Psammomys obesus* is a desert-dwelling rodent in which vascular bundles combine in the outer stripe of the outer medulla to form "giant" vascular bundles (Figure 24.8a).[5] By anatomical inference, the parallel arrangement of DVR within vascular bundles of all species contributes to the regulation of regional blood flow distribution in the kidney. Constriction of DVR on the vascular bundle periphery should favor perfusion of the inner medulla. Conversely, constriction of DVR in the bundle center should preferentially favor flow to the capillary plexus of the interbundle region. Experimental evidence that supports such differential regulation of perfusion of the outer and inner medulla is sparse, because few studies have simultaneously measured outer and inner medullary blood flow.[33]

The vascular bundles that are characteristic of the inner stripe of the outer medulla disappear below the inner–outer medullary junction. Throughout the medulla, AVR are larger and more numerous than DVR. As a consequence, during passage of blood from the

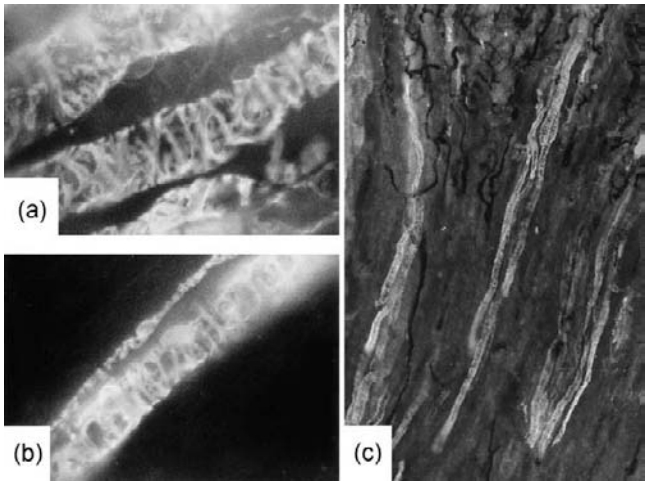

FIGURE 24.6 **Distribution of descending vasa recta pericytes.** (a) (b) Immunofluorescent staining of DVR pericytes using anti α-smooth muscle actin as primary antibody. The pericytes are present on DVR from outer medullary vascular bundles (Panel a), and those from the inner medulla (Panel b) (×1000). (c) Low power image of immunofluorescent staining of DVR pericytes using anti α-smooth muscle actin antibody. Some vessels show pericytes throughout their length to the papillary tip. Black vessels are filled with Indian ink (×100). *(Reproduced with permission from ref. [28]).*

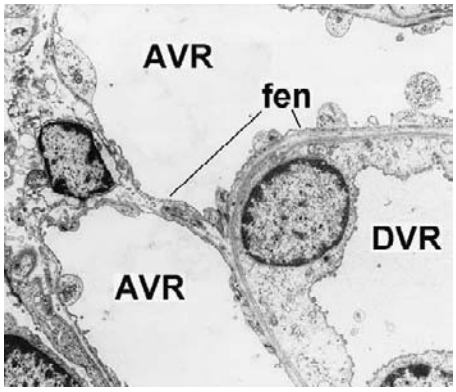

FIGURE 24.7 **Electron micrograph of DVR and AVR.** Electron micrograph of DVR and AVR in rat vascular bundles. DVR have a continuous endothelium and AVR are fenestrated. Note the minimal interstitium that exists between vessels in this region (×12,400). *(Reproduced with permission from ref. [111]).*

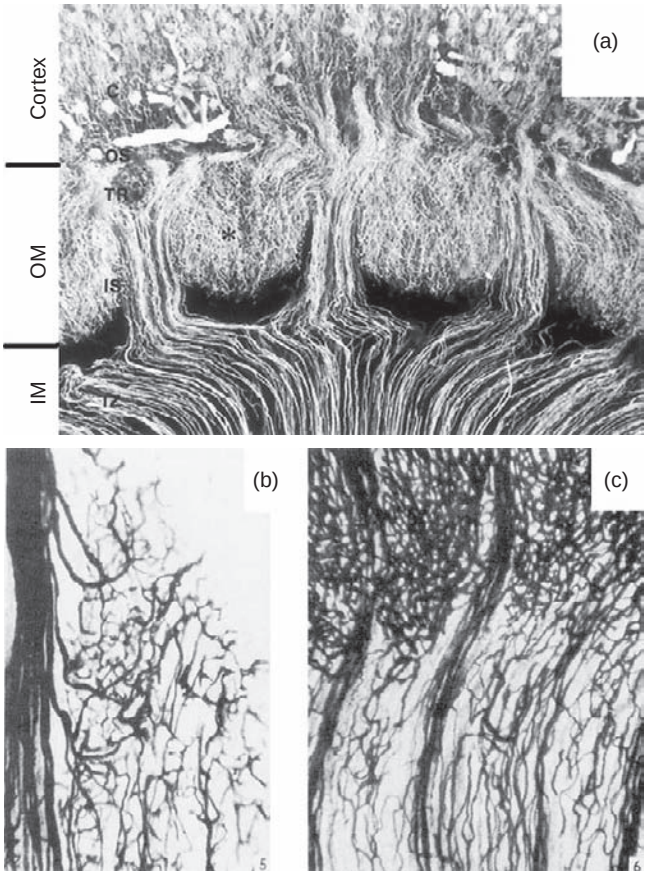

FIGURE 24.8 **Arterial injection of *Psammomys obesus*.** (a) Photograph of the microvasculature of the desert rodent *Psammomys obesus* obtained by injecting the arteries of the kidney with Microfil and digesting the tissue. The distinct arteriolar patterns of the cortex, outer, and inner medulla are apparent. In *Psammomys*, the separation of the outer medulla into vascular bundles and the dense capillary plexus of the interbundle region (*) is striking, because vasa recta coalesce into giant vascular bundles (OM: outer medulla; IM: inner medulla). Designations on the original figure are: c: cortex; TR: transitional region (outer stripe of the outer medulla); IS: inner stripe of the outer medulla; IZ: inner zone (inner medulla).*(Reproduced with permission from ref. [5]).* (b),(c) Indian ink injection study of vascular bundles in the outer medulla of the rat. In contrast to *Psammomys*, individual vascular bundles do not coalesce into giant bundles. The bundles are more evenly dispersed throughout the inner stripe of the outer medulla. This pattern is typical of many mammalian species including the rat, mouse and human. *(Reproduced with permission from ref. [790]).*

juxtamedullary efferent arteriole to DVR and then AVR, single vessel flow rate falls as overall microvessel cross-sectional area increases.[17,31,34–36] The latter increases transit time, presumably to favor greater equilibration of solute concentrations between AVR blood and interstitium. Outer medullary vascular bundles have little interstitial space. In contrast, the fraction of medullary cross-section attributable to interstitium rises substantially toward the deepest regions of the inner medulla, particularly near the papillary tip.[17,20,37] In some species, renal medullary interstitial cells (RMIC) of the inner medulla appear to be tethered between thin limbs of Henle and vasa recta[20,25,36] (Figure 24.10). It is likely that the horizontal arrangement of RMIC helps to preserve corticomedullary solute gradients by limiting axial diffusion along the medulla.[20,38] RMIC have receptors for vasoactive peptides such as angiotensin II, bradykinin, and endothelin. In addition, they release vasoactive agents such as PGE_2 and medullipin. RMIC are contractile and respond to various paracrine factors.[39–42]

Three-dimensional computer reconstructions of images derived from immunostained serial sections have yielded insight into relationships between tubules,

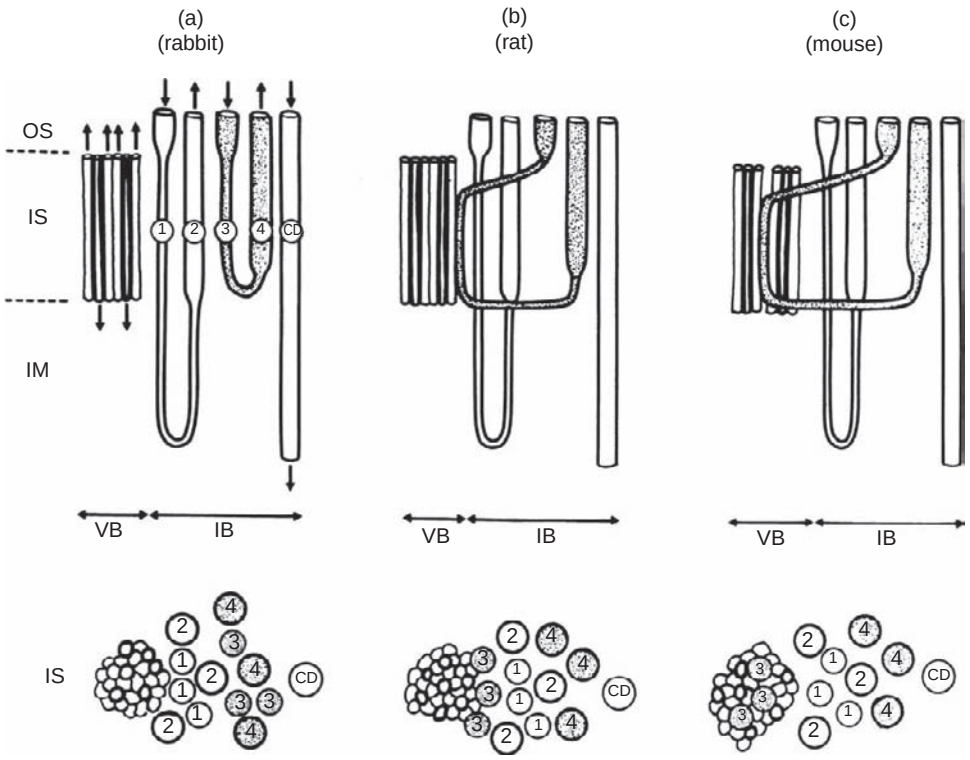

FIGURE 24.9 **Tubular-vascular relationships in the outer medulla.** Organization of the inner stripe of the outer medulla. Top and bottom panels show longitudinal and cross-sectional views, respectively. The extent to which the thin descending limbs (tDLH) of short looped nephrons associate with vascular bundles varies between species. In the rabbit (a) no association exists, whereas in the rat (b) and mouse (c), the tDLH migrates to the periphery or becomes incorporated within vascular bundles, respectively (Abbreviations: VB: vascular bundle; IB: interbundle region; 1 and 2: thin descending and thick ascending limbs of long looped nephrons; 3 and 4: thin descending and thick ascending limbs of short looped nephrons.) *(Reproduced with permission from ref. [4]).*

collecting ducts, and the vasculature in rats and mice.[25,32,43–46] Specifically, collecting ducts (CD), descending thin limbs of Henle (DLH), ascending thin limbs of Henle (ALH), descending vasa recta (DVR), and ascending vasa recta (AVR) are identified by their respective expression of aquaporin 2 (AQP2), aquaporin 1 (AQP1), chloride channel (ClCK1), urea transporter type B (UTB), and the fenestral protein, PV-1. Thin DLH frequently lack AQP1 expression, and are identified as thin limbs lacking ClCK1 but expressing α,β-crystallin, an antigen that is present along the entire loop of Henle.[47,48] Thin DLH include an entirely AQP1-null group that turns early in the inner medulla, and longer limbs that are AQP1-positive for the first ~40% of their length; the latter turn to form thin ALH within deeper regions of the inner medulla. More than 50% of the AQP1-positive DLH also express ClC-K1. AQP1-positive segments have semilunar cell bodies that regularly jut into the lumen.[49] Murine tubulovascular relationships in the outer medulla may exhibit an important characteristic, in that some thick ascending limbs of long looped nephrons may lie within vascular bundles. In that species, short looped thin DLH are known to be incorporated into the more peripheral parts of vascular bundles.[4,20,26,32]

Pannabecker and colleagues have described clustering of collecting ducts that eventually coalesce to form single large collecting ducts in the deep medulla (Figure 24.11). The tubules and vessels that surround the collecting duct clusters occupy structured patterns.[43,46–48] DVR and DLH occupy regions outside the clusters, while AVR and ALH are diffusely distributed both within the central regions of the CD clusters and throughout the surrounding inner medulla. Within clusters, four AVR abut individual CDs.[25] AVR closely approach the CD wall and appear to be tethered to it. That arrangement may be critical to vascular reabsorption in the medulla, allowing interstitial pressure to exceed AVR luminal pressure without inducing collapse.[38,50,51] The implications of those tubulovascular relationships have been examined in mathematical simulations.[52–55] The organization of the outer medulla into vascular bundles and the peribundle region enhances the delivery of high osmolality fluid to the inner medulla by long looped DLH and CD. Reduction of the number of DVR that reach the inner–outer medullary junction is predicted to favor enhancement of urinary concentration, as is a high AVR solute permeability. The striking observation of thick ascending limbs of Henle within vascular bundles

FIGURE 24.10 **Renal medullary interstitial cells (RMIC).** RMIC from the rat kidney appear to be tethered between thin limbs and vasa recta in the inner medulla. Interstitial spaces lie between the cells, and the cells are stacked like rungs of a ladder. RMIC are contractile and secrete vasoactive paracrine agents (see text). The stacked arrangement or RMICs in some species has been suggested to help retard axial diffusion that would otherwise tend to dissipate corticomedullary gradients of NaCl and urea (V: venous or ascending vasa recta; Arrows point to lipid droplets within RMIC). *(Reproduced with permission from ref. [20]).*

of the mouse[32] may have important implications for urinary concentration, because sodium chloride reabsorption from those structures might raise vicinal osmolality to favor water uptake from AQP1-expressing DVR, thereby concentrating their contents en route to the inner medulla.

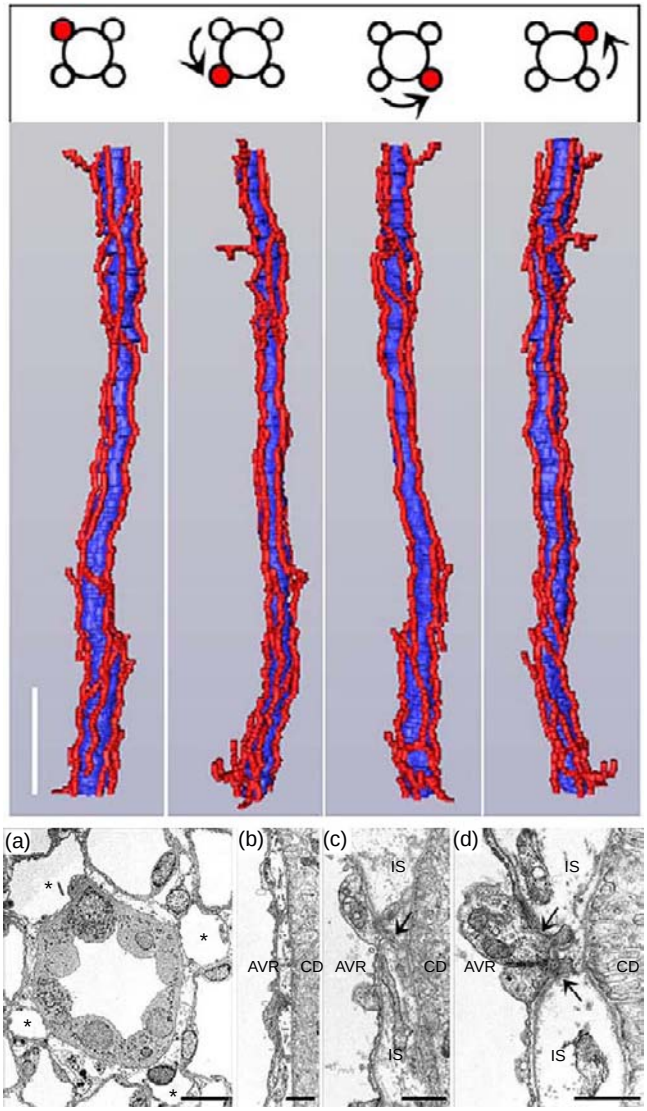

FIGURE 24.11 **Relationship between vasa recta and collecting duct clusters.** Upper panel: A single collecting duct (blue) with adjacent AVR (red) is shown in four 90° rotated views (Bar = 100 microns). Lower panel: (a–c) Electron micrographs of sections through a collecting duct (CD) and adjacent AVR, demonstrating the close apposition and interstitial space (IS). (d) Close approximation of AVR and CD where the two appear to be tethered with microvilli (arrows). *(Reproduced with permission from ref. [25]).*

TRANSPORT FUNCTIONS AND PROPERTIES

The Renal Cortex and Capillary Uptake of Tubular Reabsorbate

Cortical peritubular capillaries are fenestrated, have a large surface area and high hydraulic conductivity. It is generally accepted that fluid is driven into the cortical interstitium from the PCT due to the generation of a locally hypertonic fluid within the lateral intercellular space between PCT epithelial cells. The local hypertonicity results from the secretion of small hydrophilic solutes by proximal tubular cells. Dilution of the interstitium in the vicinity of the capillary wall with protein-free fluid both lowers interstitial oncotic pressure and raises interstitial hydraulic pressure. These effects generate Starling forces that favor capillary reabsorption.

A substantial body of evidence has demonstrated that modulation of cortical peritubular capillary oncotic pressure alters PCT reabsorption. Intra-aortic injection or peritubular perfusion of colloid free or hyperoncotic fluid leads to decreases or increases proximal reabsorption, respectively.[56–58] While it seems inviting to surmise that protein oncotic pressure acts directly to enhance fluid movement out of the PCT, several lines of evidence

suggest otherwise. Oncotic pressure changes fail to modulate reabsorption when active transport by PCT epithelia is inhibited,[59] PCT reabsorption rates correlate with GFR (glomerulotubular balance) but not with interstitial Starling forces,[60] hydropenia blunts the capacity of hyperoncotic albumin to enhance PCT reabsorption,[61] and elevation of luminal pressure in the PCT fails to enhance reabsorption.[62] The osmotic water permeability of the proximal convoluted tubule ($P_f = 0.1 - 0.4$ cm/s) is probably too low for small oncotic pressure changes to substantially affect transmembrane water flux.[63,64] It has been suggested that peritubular oncotic pressure might modulate PCT volume reabsorption by affecting solute reabsorption rate[65,66] or by enhancing paracellular backleak into the PCT lumen.[67] More recently, attention has turned to mechanosensation of luminal shear forces as a transducer of glomerulotubular balance.[68–70]

Whatever mechanisms converge to influence PCT reabsorption it is immense, and its removal from the interstitium is the task of the cortical microcirculation. Since lymphatics remove less than 1% of the reabsorbate,[71] the route for return to the systemic circulation must be via peritubular capillaries. As reviewed by Aukland et al., the high oncotic pressure of postglomerular plasma cannot be invoked as the primary driving force for capillary uptake in all cases. Older rats in which renal lymphatic (and therefore presumably interstitial) protein concentration is equal to that of plasma continue to reabsorb tubular fluid.[18,71] Furthermore, PCT reabsorption occurs even in kidneys perfused with colloid free solutions.[72] Particularly in the latter case, it is apparent that interstitial pressure must exceed intracapillary luminal pressure to provide the driving force for transcapillary volume flux. It also follows that the peritubular capillaries must be tethered to the interstitium in a way that prevents an inwardly directed transmural pressure from collapsing the lumen.

The Renal Medulla and Countercurrent Exchange

Like the capillary bed of other organs, the renal medullary microcirculation supplies oxygen and nutrients to the surrounding tissue. Additionally, however, corticomedullary gradients of NaCl and urea must be preserved to enable urinary concentration. This task is accommodated by countercurrent exchange between DVR and AVR.[17,31,73,74] Countercurrent exchange is an adaptation found throughout nature. The maintenance of high gas tensions in swim bladders of deep sea fish, and the minimization of heat loss from the extremities of aquatic and arctic animals relies upon this strategy.[31,75]

The microcirculation of the renal medulla traps NaCl and urea deposited to the interstitium by the loops of Henle and collecting ducts. Countercurrent exchange provides the means by which blood flow through the medulla is concentrated and then diluted to preserve corticomedullary solute gradients established by countercurrent multiplication. The hypothesis that vasa recta are a purely "U-tube" diffusive countercurrent exchanger implies the following function. NaCl and urea diffuse from interstitium into DVR plasma en route from the corticomedullary junction toward the papillary tip. The solutes diffuse out from AVR plasma to be returned to the interstitium as blood returns to the cortex. That theory predicts that countercurrent exchanger efficiency will be enhanced if permeability to solute is high.

In fact, vasa recta probably do not function as a purely diffusive countercurrent exchanger. Several features point to greater complexity. Tubulovascular relationships in the outer and inner medulla differ markedly (Figures 24.1, 24.9, 24.11), and the endothelium of DVR and AVR are continuous and fenestrated, respectively (Figure 24.7). The discoveries of aquaporin-1 (AQP1) water channels and the facilitated urea carrier, UTB, in DVR endothelia (see below) shows that transcellular as well as paracellular pathways involving water and urea are involved in equilibration of DVR plasma with the interstitium. Efflux of water across the DVR wall to the medullary interstitium occurs across AQP1 water channels, and AQP1 excludes NaCl and urea implying that both water removal and diffusive influx of solute contribute to transmural equilibration.[31,76–78] Expression of AQP1 within the vasculature has been found to vary with axial location, greater in those DVR that turn in the outer portion of the inner medulla.[45,46]

Transport of Small Solutes and Water by Vasa Recta and Red Blood Cells

Transport of Water across the DVR Wall: Small Solutes, Osmotic Pressure, and Starling Forces

Mass balance dictates that water, NaCl, and urea must be removed from the medullary interstitium at a rate that equals deposition by the loops of Henle and collecting tubules.[17,79] Papillary micropuncture studies in the hydropenic rat[80] and hamster[81,82] have shown that DVR and AVR plasma osmolality rises in parallel with tubular fluid from the loops of Henle and collecting ducts. DVR plasma protein also becomes concentrated along the direction of flow, implying that water is lost from DVR lumen to the interstitium (Table 24.1, Figure 24.1).[83,84] Uptake of fluid into AVR exceeds that lost from DVR, accounting for mass balance in the medulla.[15,85–88] Volume efflux from the DVR occurs despite an intracapillary oncotic pressure that exceeds hydraulic pressure, so that "Starling forces" cannot fully explain transmural volume efflux. According to Starling, volume flux (J_v) across a

capillary wall is a function of capillary (P_c) and interstitial hydraulic pressure (P_i), and luminal (π_c) and interstitial (π_i) oncotic pressure.[89]

$$J_V = L_P[(P_c - P_i) - (\pi_c - \pi_i)] \quad (24.1)$$

where L_p is the hydraulic conductivity. In order to explain volume efflux from the DVR in a manner compatible with Eq. (24.1), a negative interstitial hydraulic pressure or very high interstitial oncotic pressure has to be postulated. In either of those cases, however, interstitial driving forces would prevent volume uptake by AVR violating mass balance. Neither possibility can be the explanation.[17,84,90]

Due to the lag in equilibration of DVR plasma with the interstitium, NaCl and urea concentrations in the interstitium exceed those in DVR so that a transendothelial osmotic gradient favors water efflux across the DVR wall. That driving force could account for water efflux only if there is a transendothelial pathway across which small solutes are effective to drive water movement.[84] Volume flux across a membrane can be simulated by Eq. (24.2) that accounts for osmotic reflection coefficients (σ) to individual solutes. In the current context, small solutes (σ_{ss}) and proteins (σ_{pr}) are of importance, leading to[91]:

$$J_V = L_P[\Delta P - \sigma_{pr}\Delta\pi_{pr} - \sigma_{ss}\Delta\pi_{ss}] \quad (24.2)$$

where ΔP is transmembrane hydraulic pressure, and $\Delta\pi_{pr}$ and $\Delta\pi_{SS}$ are the transmembrane osmotic pressure due to protein and small solutes, respectively.[84] The hypothesis that small solutes act to promote volume movement across the DVR is equivalent to postulating that $\sigma_{ss} > 0$. Support for this was readily obtained. Volume efflux from DVR was prevented by elimination of corticomedullary (and therefore transendothelial) NaCl and urea gradients by furosemide,[86] and *in vivo* microperfusion of DVR with buffers made hypertonic or hypotonic to the papillary interstitium generated volume uptake or efflux, respectively ($\sigma_{NaCl} > 0$).[92]

DVR Hydraulic Conductivity and Osmotic Water Permeability

The predominant pathway that conducts water efflux across the DVR is the AQP1 water channel. AQP1 but not other aquaporins are expressed by DVR endothelia.[36,45,93,94] *Diffusional* water permeability (P_D) of isolated, microperfused DVR, measured by efflux of ^3H_2O, was reduced by the AQP1 blocking mercurial agent p-chloromercuribenzene sulfonate (pCMBS). Dramatic confirmation was provided by the demonstration that *osmotic* water permeability (P_f) of microperfused DVR, measured by driving water flux with transmural gradients of NaCl, was driven from ~1100 μm/s to nearly zero by pCMBS (Figure 24.12a). In contrast, when albumin rather than NaCl was used to drive water flux, P_f was much higher, ~16,700 μm/s and insensitive to pCMBS, implying that a different pathway conducts transmural volume flux driven by oncotic pressure.[77,78] The results support the notion that NaCl and urea drive water flux across the DVR wall exclusively through AQP1 (contribution to total transmural water conductivity is P_f ~1100 μm/s), while hydraulic pressure and oncotic pressure drive most water flux through a high conductivity parallel pathway (paracellular or other). Mathematically, the AQP1 and parallel pathways are best stimulated as[85,95]:

$$J_{V,P} = L_{P,P}[\Delta P - \sigma_{pr}\Delta\pi_{pr}] \text{ and, } J_{V,C} = L_{P,C}[\Delta P - \textstyle\sum_i \Delta\pi_i] \quad (24.3a, b)$$

where the additional subscript "P" (probably pericellular) refers to the high conductivity pathway for which $\sigma_{NaCl} = \sigma_{urea} = 0$,[96] and the subscript "C" refers to the transcellular AQP1 pathway for which $\sigma_{NaCl} = \sigma_{urea} = 1$. Hydraulic conductivity (Lp) and osmotic water permeability (P_f) are related according to $Lp = (P_f \times V_w)/(RT)$, where V_W is the partial molar volume of water. Existing measurements of DVR osmotic water permeability are summarized in Table 24.2. A rigorous discussion of the measurement of, and relationships between, these transport parameters has been provided.[78,96]

The AQP1 knockout mouse provided additional confirmation of the role of AQP1 in DVR water transport. P_f of DVR in AQP1 knockout mice, driven by NaCl, was indeed very low (Figure 24.12b). An intriguing finding was that urea and larger solutes (raffinose, MW 594, glucose, MW[97]) drive significant water flux despite AQP1 deletion, a finding that implies the existence of a non-AQP1 route across which those solutes are osmotically active. A potential candidate for the non-AQP1, pCMBS insensitive pathway is the UTB urea transporter (see below) which is expressed by the DVR endothelium and can function as a water channel.[98–102]

Insights from Modeling: AQP1 and the Enhancement of Exchanger Efficiency

Mathematical models of urinary concentration have played an important role in the evolution of our understanding. Simulation of both nephrons and the microcirculation is difficult, so that investigators prefer to account for one while neglecting the other. Vasa recta models typically assume specified corticomedullary solute concentrations, and simulate transport properties of the vessel wall. Wang and Michel revised this approach by specifying the rate of deposition of NaCl, urea, and water to the medullary interstitium as though they are generated within the interstitium. In agreement with electron probe measurements, they predicted an exponential increase in corticomedullary solute

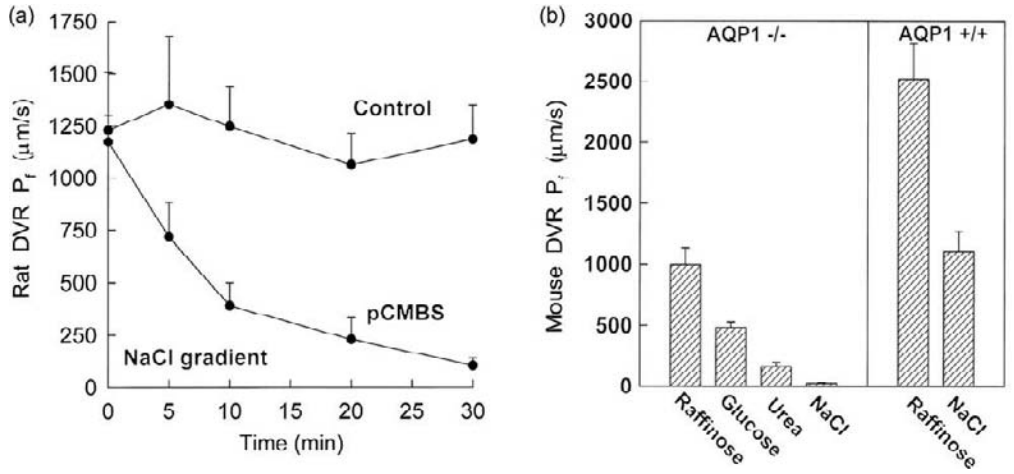

FIGURE 24.12 **Osmotic water permeability (P_f) of outer medullary DVR.** (a) Pf was measured in glutaraldehyde-fixed rat DVR by measuring the rate of transmural water flux generated by a bath > lumen NaCl gradient. Sequential measurements in controls were stable. In contrast, exposure to p-chloromercuribenzene sulfonate (pCMBS, 2 mM), an agent that covalently binds to cysteine residues on aquaporin-1, reduced Pf to nearly zero. In these experiments, glutaraldehyde fixation was necessary to prevent deterioration of the vessel caused by pCMBS and other harsh conditions of the experiment. (b) Pf was measured in AQP1-null($^{-/-}$) or replete($^{+/+}$) murine DVR by transmural gradients of NaCl, urea, glucose or raffinose. When NaCl was the solute used to drive water flux, deletion of AQP1 reduced Pf from ~1100 μm/s to nearly zero. Water flux driven by raffinose (MW 564) was markedly reduced by AQP1deletion (compare AQP1$^{-/-}$ to $^{+/+}$), but remained unexpectedly high. Similarly, glucose (MW 180) and urea (MW 60) gradients drove measurable water flux across AQP1($^{-/-}$) DVR. *(Reproduced with permission from ref. [76,77]).*

concentration in the medulla.[103–105] A weakness of models that neglect simulation of loops of Henle and collecting ducts is that solute generation rates in the interstitium are assigned as inputs and interstitial solute concentrations calculated as predictions. Variations of blood flow and transport properties cannot affect the interstitial appearance of NaCl, urea, and water from nephrons as would occur *in vivo*. Convincing evidence has been provided that structure and properties of nephrons can abruptly vary with medullary depth.[28,40,49,106,107]

Many key parameters needed to simulate microvascular exchange in the renal medulla (solute permeabilities, reflection coefficients, hydraulic conductivities) have been measured. That data has been combined with more complete simulations of transcellular pathways for urea and water transport to perform additional simulations. The models predict that AQP1 might play an important role to raise medullary interstitial osmolality by driving water efflux from DVR to the medullary interstitium across AQP1 water channels (see above); that water movement effectively shunts DVR plasma volume to the AVR reducing blood flow to the deep medulla; and that favors high diffusive exchanger efficiency in the deep inner medulla where urea is added to the interstitium from the collecting duct. Stated another way, it reduces the lag in equilibration that leads to solute "washout" from the deep medulla.[76,108,109] The net effect is to enhance interstitial osmolality (Figure 24.13). Interest in this intriguing prediction is heightened by the observation that transmural water flux can be driven across the wall of AQP1-null mice by solutes other than NaCl (Figure 24.12b). If the non-AQP1 pathway is important *in vivo*, it might also enhance shunting of water from DVR to AVR.[31,76,108]

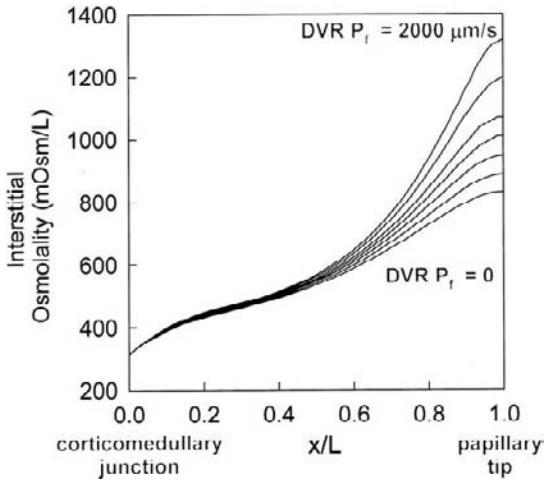

FIGURE 24.13 **Effect of AQP1 deletion on predictions of renal medullary interstitial osmolality.** A mathematical simulation of the renal medulla was solved to predict interstitial osmolality. Interstitial osmolality is shown as a function of corticomedullary axis (x/L = 0 is the corticomedullary junction; x/L = 1 is the papillary tip). Various curves denote predictions for different values of Pf (DVR osmotic water permeability). Pf was varied between 0 (equivalent to AQP1 deletion) and 2000 μm/s. AQP1 expression in DVR is predicted to enhance concentrating ability by conducting water flux from DVR to interstitium where after it is taken up by AVR. The net result is a secondary reduction of blood flow in the deepest regions of the inner medulla (papillary tip). *(Reproduced with permission from ref. [76]).*

Transport of Small Hydrophilic Solutes across the DVR Wall

It is likely that the majority of NaCl and urea equilibration across the DVR wall occurs by diffusive influx. AQP1 contributes to the process of equilibration through molecular sieving. Evidence supports the notion that small hydrophilic solutes (NaCl, urea) diffuse through the same "shared" pathway that conducts the component of water flux driven by Starling forces, because DVR permeability to tracers (^{22}Na, ^{36}Cl, ^{3}Hraffinose, ^{14}Cinulin) correlate with each other and hydraulic conductivity.[31,96,110,111] Urea transport across the DVR wall is more complicated, because it diffuses both via paracellular and transcellular routes. A summary of available solute diffusive permeability measurements is provided in Table 24.3.

Facilitated Transport of Urea across DVR and RBCs

Transmural flux of urea across the DVR wall is complicated, because DVR endothelia express a facilitated urea carrier.[112,113] Sodium and urea have similar free water diffusivity, and are therefore expected to have the same transvessel permeability if they diffuse, sterically unrestricted, through a large pore. In contrast to this, some outer medullary DVR have low or moderate P_{Na} but high P_U (Figure 24.14). DVR permeability to ^{14}C urea can be partially inhibited by phloretin, pCMBS, and structural analogs of urea, verifying the presence of an endothelial carrier.[111,112] Histochemical evidence and *in situ* hybridization studies have shown that the DVR urea carrier is the same as that in the RBC (urea transporter type B, UTB), and is distinct from the urea carrier in the thin limbs of Henle (UTA2) and collecting duct (UTA1, UTA3, UTA4).[100,114–118]

Rat UTB carries the Kidd blood group antigen, has 62% identity to UTA2, and is expressed in RBCs, DVR endothelium, papillary surface, and pelvic epithelium of the kidney.[100,119] The presence of UTB in the DVR endothelium and RBCs facilitates medullary urea recycling. Urea tends to exit the renal medulla in AVR plasma and RBCs. To prevent associated dissipation of corticomedullary urea gradients, urea recycles from AVR into DVR plasma and RBCs via UTB, and into thin limbs of Henle via UTA2 (Figure 24.15). Those processes are highly evolved in the outer medullary inner stripe where DVR and AVR are closely

positioned in vascular bundles. Many water-conserving species also incorporate UTA2 expressing thin limbs of Henle within or on the periphery of vascular bundles[5,6,15,24,26] (Figure 24.9). Interesting insights into function have been obtained from the study of UTB-null mice. UTB deficiency results in reduced urinary concentrating ability, reduced urea clearance, and an increased plasma urea concentration.[100,114,118] In contrast to wild-type mice, infusion of urea into UTB-null animals fails to enhance urinary concentrating ability.[114] Acute regulation of UTB by vasopressin or other factors has not been demonstrated. In contrast to upregulation of UTA transporters,[119] chronic vasopressin treatment may reduce UTB expression.[99,120] UTB expression in the renal medulla increases during osmotic diuresis induced by urea, but not NaCl or glucose infusion.[121] In contrast, UTB expression is depressed by ureteral obstruction, lithium treatment, potassium deficiency, and cyclosporine toxicity.[122–125]

UTB expression in RBCs should limit AQP1-mediated water transport and the associated osmotic shrinking and swelling that would otherwise accompany RBC transit through the medulla. Macey and Yousef proposed that this might prevent osmotic lysis.[126] Against this hypothesis is the finding that humans devoid of Kidd antigen have mildly depressed urinary concentrating ability, but no hemolytic anemia. It seems most likely that RBC expression of UTB serves to increase the overall mass of urea that is efficiently recycled from the AVR and DVR lumens in the renal inner medulla.[98,100,102]

Transport of Solutes and Water across the AVR Wall

Transport of solutes and water in AVR has not been as thoroughly evaluated as that in DVR, because AVR cannot be isolated for *in vitro* microperfusion. Measurements of AVR transport properties have been performed by *in vivo* micropuncture and microperfusion of vessels on the surface of the exposed papilla (inner

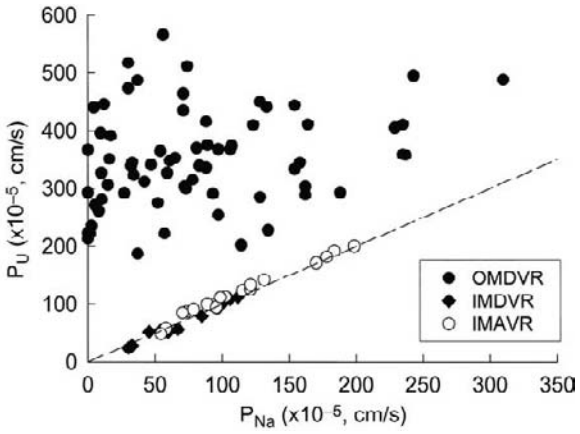

FIGURE 24.14 **Vasa recta solute permeabilities.** [^{14}C]urea permeability (P_U, ordinate) versus ^{22}Na permeability (P_{Na}: abscissa) is shown for outer medullary DVR (OMDVR) isolated from Sprague-Dawley rats and perfused *in vitro*. Results are also shown for inner medullary DVR and AVR (IMDVR, IMAVR) perfused on the surface of the exposed papilla of Munich-Wistar rats *in vivo*. The dashed line is identity. P_U and P_{Na} are highly correlated and nearly equal in inner medullary vasa recta. In contrast, P_U of outer medullary DVR is always very high and is not correlated with P_{Na}. The dissociation of P_{Na} and P_U in OMDVR results (at least in part) from the expression of the UTB facilitated urea carrier. In separate experiments (not shown), P_U of OMDVR was inhibited by exposure to urea analogs or phloretin. *(Data reproduced with permission from ref. [111]).*

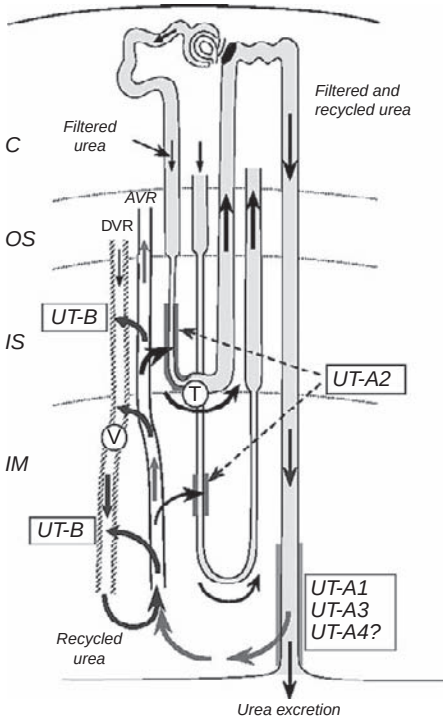

FIGURE 24.15 **UTB and urea recycling in the medulla.** Schematic of vascular and tubular urea recycling in the kidney. Short and long loops of Henle and vasa recta are shown. The UTA2 urea transporter is expressed in the thin descending limbs of Henle. The UTB urea transporter is expressed in DVR endothelium and red blood cells (not shown). Thin descending limbs of short looped nephrons become associated with vascular bundles (see Figure 24.9) so that urea recycling from thin limbs to DVR via UTA2 and UTB is accommodated. UTB is not expressed by the AVR endothelium, but AVR are fenestrated and urea permeability is high. Thus, urea in AVR plasma and RBCs can readily recycle back to DVR in vascular bundles using UTB in the RBC membrane and DVR endothelium. The UTA1, A3, and A4 collecting duct conduct urea transporters conduct urea from the lumen to the inner medullary interstitium (C: cortex; OS: outer stripe of outer medulla; IS: inner stripe of outer medulla; IM: inner medulla). *(Reproduced with permission from ref. [100]).*

third of the inner medulla) of rats. Some reliable measurements of AVR hydraulic conductivity (Lp) have been obtained. Consistent with the highly fenestrated endothelium, Lp is high, about 12.5×10^{-613} cm/(s•mmHg) (P_f = 13.4 cm/s).[50,127] The reflection coefficient of the AVR wall to albumin has been measured by molecular sieving[128] and by osmosis.[50] Mean values of 0.78 and 0.70 were obtained, respectively. A summary of AVR hydraulic conductivity and reflection coefficient measurements is provided in Table 24.2.

When blood ascends toward the cortex in AVR it encounters decreasing NaCl and urea concentrations, so that luminal osmolality exceeds that of the adjacent interstitium. Perfusing AVR *in vivo* with buffers made hypertonic or hypotonic to the papillary interstitium with NaCl generated no measurable water flux, suggesting that, for the AVR wall, $\sigma_{SS} = 0$ (Eq. (24.2)).[129] Transmural AVR NaCl and urea gradients *in vivo* are likely to be smaller than those in DVR, because AVR blood flow rates are lower. AVR are larger in diameter and more numerous than DVR.[34,35,88] Consequently, high permeability, high surface area, and an increased transit time of blood all favor a high degree of equilibration between AVR plasma and interstitium.[90,95]

Vasa recta diffusional solute permeabilities, measured in the rat[129,130] and hamster,[35] are higher than those in DVR (Table 24.3). Even so, AVR permeabilities have probably been underestimated, because all measurements relied upon ^{22}Na and ^{14}Curea efflux during microperfusion *in vivo*. That method probably underestimates permeability, because accumulation of tracers near the abluminal surface during microperfusion violates the assumption that abluminal tracer concentrations are zero.[92,129]

Transport of Macromolecules in the Cortex and Medulla

It is generally accepted that lymphatics are sparse in the outer medulla, and absent from the inner medulla.[79,131] It has long been recognized that proteins permeate the walls of capillaries[89,132,133] to be drained

by lymphatics and returned to the systemic circulation. Given the absence of lymphatics in the inner medulla, the mechanisms that regulate interstitial oncotic pressure and protein trafficking through the interstitium have been enigmatic. Early studies led to the conclusion that a large extravascular pool of albumin is present within the medulla.[134–136] Leakage of fluorescent albumin[137,138] and Evans blue dye-labeled albumin[139,140] into the medullary interstitium were observed. Ultrastructural studies with horseradish peroxidase (molecular radius 50 Å), catalase (elliptical molecule, 240,000 Da, major axis 240 Å), and ferritin (spherical molecule, 500,000 D, 110 Å) demonstrated that these markers can cross the fenestrations of cortical peritubular cortical capillaries[141] and medullary AVR.[142]

Measurements of albumin transport rates across the DVR and AVR walls have been technically limited. Using molecular sieving of Texas red-labeled albumin, Turner estimated the reflection coefficient of the DVR wall to albumin to be 0.89 (not significantly different from unity).[96] In separate studies with different methods, the reflection coefficient of the AVR wall to albumin was estimated to be 0.7 and 0.78.[50,128] No reliable measurements of the diffusional permeability of either the DVR or AVR wall to albumin exist. Attempts have been made to determine Starling forces within the medullary interstitium through direct measurement of interstitial protein concentration. Using a differential centrifugation technique, MacPhee and Michel obtained a mean value of 0.9 g/dl.[50] By an alternative approach, interstitial protein concentrations of 4 to 6 g/dl were predicted and interstitial hydraulic pressures in the range of 5 to 10 mmHg were found.[143]

Whatever the concentration of albumin in the medullary interstitium, the fundamental question remains, in the absence of lymphatics, how is medullary interstitial protein deposited and cleared by the microcirculation? Protein transport into the AVR lumen by convective influx is the most likely answer.[50,74,143] Michel pointed out that molecular sieving at the AVR wall would indicate convective movement of protein into the AVR lumen, were it not for continuous deposition of protein-free fluid by medullary nephrons.[74] The plausibility of convective protein uptake is also supported by the finding that papillary AVR withstand an inwardly-directed hydraulic pressure without collapsing.[51] Pinter and colleagues have suggested that the combined effects of negative charge exclusion resulting from compartmentation of hyaluron and albumin, Donnan equilibrium, and hydrostatic pressure variation from ureteral contractions provide key driving forces for fluid movements and urinary concentration.[144,145]

INTRARENAL HEMATOCRIT

When the volumes of distribution of plasma and red blood cells within the kidney were examined by injecting labeled albumin and red blood cells (RBCs), intrarenal hematocrit was found to be less than systemic hematocrit. Given the observation of Fahraeus that red cells migrate to the center of small vessels, Pappenheimer and Kinter proposed that cell free blood is "skimmed" from the periphery of the interlobular arteries to enter the afferent arterioles of deep glomeruli,[13,146] an effect which might be facilitated by intraarterial cushions[10–12] (Figure 24.2). This possibility was tested by Lilienfield et al. who found that RBC transit time was shorter than plasma transit time, and that tissue hematocrit varies with medullary axis.[147] Rasmussen performed a technically superior examination using ^{131}I-IgM, a larger and therefore more reliable plasma marker. Simultaneous injection with ^{51}Cr-RBCs, led to the estimates of tissue hematocrit shown in Figure 24.16.[148] Using videomicroscopic techniques, Zimmerhackl estimated the "dynamic" or "tube" hematocrit of the papillary DVR and AVR to be 26 and 25%, respectively.[149] Direct measurements with micropuncture gave similar results. A low microvessel hematocrit in the renal medulla has been consistently found.

In addition to plasma skimming,[10,13] other mechanisms could reduce medullary hematocrit. Fahraeus demonstrated that the hematocrit of a microvessel is reduced by migration of RBCs to the centerline where the velocity of flow is highest.[146] Based on this alone,

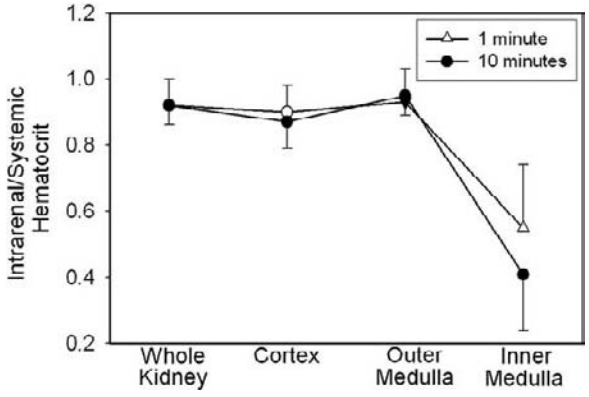

FIGURE 24.16 **Distribution of hematocrit in the kidney.** ^{51}Cr-RBC's and ^{131}I-IgM (plasma volume marker) were simultaneously infused into the kidney. An equilibration period of either 1 or 10 minutes followed before ligation of the renal artery and vein. The distribution of RBCs and plasma were inferred by measuring activity of the isotopes in tissue and dividing their ratio by the systemic ratio. Results show that the hematocrit of inner medullary blood is lower than that whole kidney, cortex or outer medulla. *(Data redrawn with permission from ref. [148]).*

vasa recta (10–20 μm diameter) are expected to have hematocrits reduced by 40 to 50% of that in a large vessel.[150] Pries et al. have shown that a "network" Fahraeus effect can further reduce microvessel hematocrit by as much as 20%. When a vessel bifurcates, the higher flow branch receives blood of higher hematocrit. Conservation of RBC and plasma dictates that the increase of hematocrit in one branch must be less than the reduction in the other branch, tending to reduce average capillary hematocrit.[151] Shrinkage of RBCs in the hypertonic medulla must also tend to lower medullary microvessel hematocrit.[17]

METHODS FOR MEASUREMENT OF REGIONAL BLOOD FLOW TO THE CORTEX AND MEDULLA

The relative contribution of various renal microvessels to renal vascular resistance can be inferred from the luminal hydrostatic pressure profile. As shown in Figure 24.17, the largest pressure drop, and therefore the dominant resistance, is the afferent arteriole. Glomerular capillaries, due to their large combined cross-sectional area, are thought to offer little resistance to flow. Efferent arterioles and DVR contribute significantly to renal vascular resistance, but less than that attributed to afferent arterioles. Vasoactivity of the afferent arteriole is governed by myogenic autoregulation and tubuloglomerular feedback via the macula densa, important topics that are covered by other chapters of this text. The afferent and efferent arterioles may also be influenced by other nephron to vascular crosstalk mechanisms.[152,153] Measurement of regional blood flows in the kidney that result from the actions and distributions of resistance arterioles has been the frequently pursued. Early approaches to the measurement of regional blood flow within the kidney relied upon tracers, gave widely varying estimates of tissue blood flow, and have fallen into disfavor. Results from those methods are summarized in Table 24.4 from which one can conclude that inner medullary tissue blood flow rate is much lower than that of the cortex.[34,148,154–173] The associated details have been reviewed in prior versions of this text and other sources.[1,17,174] Videomicroscopic measurement of RBC velocity is a more reliable means for calculating single vessel blood flow rates, but it is limited to surface microvessels in the cortex or exposed papilla.[149,175] Use of a pencil lens camera for measurement of glomerular and cortical peritubular RBC velocities has been described by Goligorsky and colleagues.[176] It has been used to examine effects of pharmaceutical calcium channel blockers on glomerular arteriolar tone *in situ*.[177] Laser-Doppler flowmetry is the dominant method for examining regional blood flow, due to the ease of applying optical fibers to the kidney surface or inserting them into otherwise inaccessible regions within the parenchyma[167]; laser speckle[178,179] and ultrasound imaging of microbubbles[180,181] may offer future improvements.

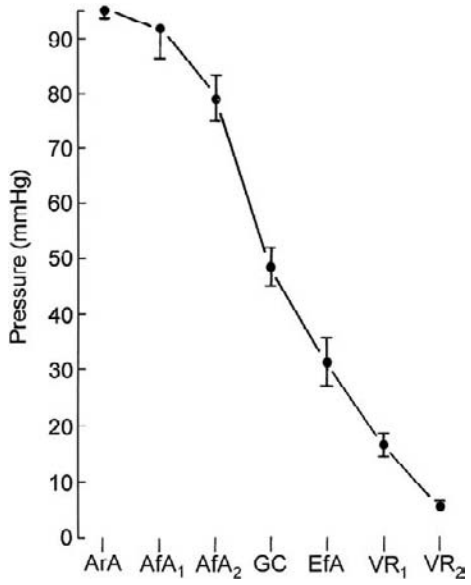

FIGURE 24.17 **Microvessel pressure distribution within the kidney.** The values on the ordinate were obtained by micropuncture and servo-nulling pressure measurements using the juxtamedullary nephron preparation. Pressure falls successively from the arcuate artery to vasa recta (ArA: arcuate artery; AfA_1 and AfA_2: early and late afferent arteriole; GC: glomerular capillaries; EfA: efferent arterioles; VR_1: descending vasa recta; VR_2: ascending vasa recta). *(Reproduced with permission from ref. [202]).*

Videomicroscopy

Measurement of microvessel diameter and RBC velocity (V_{RBC}) can be combined to calculate single vessel blood flow rates.[35] Gussis and colleagues measured V_{RBC} in vasa recta on the surface of the exposed renal papilla, following which Holliger and co-workers coupled V_{RBC} with diameter measurement to calculate single vessel blood flow rates.[34,182] In later refinements, contrast between red cells, plasma, and the capillary wall was enhanced by injection of fluorescein isothiocyanate-labeled gamma globulin, and V_{RBC} was determined from the video images captured with a silicon intensified target camera. Additionally, the Fahraeus effect[146] was accounted for by calibrating RBC streaming effects in quartz capillaries.[175] Application of videomicroscopy to measurement of renal blood flow is limited by regional accessibility. Observation of the medulla for videomicroscopy is limited to the papilla (distal third of the inner medulla) because only that

part of the medulla can be exposed for visualization by excising the ureter of young rodents.

Laser-Doppler

The laser-Doppler method for measuring tissue blood flow rates relies upon the frequency shift of light emitted from a laser due to scattering by flowing RBCs.[183] Among other advantages, sequential measurements in the same region are possible, and signals can be obtained on the renal surface or from optical fibers implanted into the parenchyma. The counterflow arrangement of vasa recta within the medulla would appear to violate the requirement that the laser-Doppler receive random backscattered light. Despite this concern, agreement between laser-Doppler and videomicroscopy[184] or ^{51}Cr-RBC accumulation[167] has been demonstrated. The laser-Doppler device provides a voltage proportional to tissue perfusion in the immediate vicinity of the fiber-optic probe. Calibration to convert the signal to absolute units that quantitatively describe local perfusion is generally not possible. This limits absolute comparisons of measurements between regions of the kidney of the same or different animals.

METHODS FOR DIRECT MEASUREMENTS OF MICROVESSEL REACTIVITY

Other important methods for investigation of the regulation of regional blood flow examine the effects of vasoactive agents on pressurized microvessels. Important information on the sites of action, the concentrations at which specific hormones modulate reactivity, and receptor subtypes responsible for mediating vasoactivity can be obtained. Extrapolation of results to arrive at conclusions concerning the effects of hormones and autocoids on regional blood flow within the kidney is fraught with uncertainty. This topic has been frequently reviewed.[1,2,15,185–188]

In Vitro Microperfusion

The *in vitro* microperfusion method commonly used for study of transport processes in renal tubules has also been applied to microvessels[189,190](Figure 24.18). The first applications of this method were in canine glomeruli.[191] Subsequent adaptations in rabbits permitted examination of vasomotor tone in afferent and efferent arterioles.[192–196] Using this approach, it has been possible to measure effects of vasoactive agents on afferent arterioles (Figure 24.19a) and vasa recta[111,197,198] (Figure 24.19b,c). As with all methods, limitations exist. Hormones that cause vasoconstriction often activate compensatory mechanisms that inhibit their actions. Endothelium-dependent vasodilators such as nitric oxide, prostacyclin, and hyperpolarizing factors[199] might be blunted, substrate-limited[200] or simply diluted into the bathing buffer. The actions of nitric oxide (NO) might be enhanced *in vitro* due to the absence of hemoglobin, a NO scavenger[201] or reduced by endothelial damage during vessel isolation.

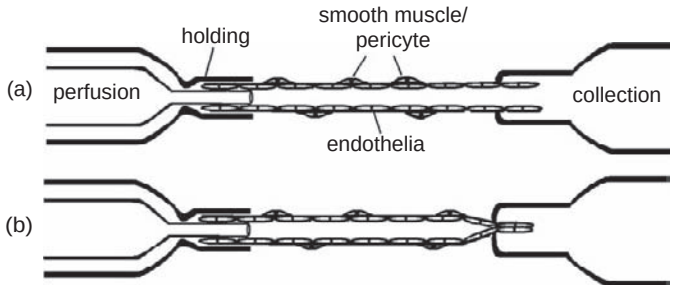

FIGURE 24.18 ***In vitro* microperfusion.** (a) An isolated microvessel is cannulated on concentric pipettes by drawing the vessel into an outer holding pipette and cannulating its orifice with a perfusion pipette. By pressurizing the perfusion pipette, fluid is forced to flow through the vessel lumen into a collection pipette. (b) The collection end can be crimped to create a "stop-flow" condition in which the lumen is pressurized to that of the holding pipette in the absence of flow. *(Reproduced with permission from ref. [393]).*

[197]).* (b), (c) Perfusion of an isolated DVR. Images obtained before (b) and after (c) exposure to angiotensin II. Compare the thick smooth muscle layer of the afferent arteriole to the sporadically distributed pericyte cell bodies of DVR.

Juxtamedullary Nephron Preparation

The ingenious blood-perfused juxtamedullary nephron preparation was devised by Casellas and Navar (Figure 24.20, top panel). The surgically isolated kidney, perfused with artificial buffers or blood, is hemisected. Dissection of perihilar fat and reflection of the papilla exposes the juxtamedullary circulation to enable observation of RBC flow and microvessel diameters. Advantages of the method are many, including relative preservation of tubulovascular relationships, continuous oxygenation of the tissue under study, the ability to measure pressures by servo-nulling, and the ability to control hormone concentrations in the perfusate and superfusate.[202]

The Split Hydronephrotic Kidney

Steinhausen et al. developed a method for reducing the kidney to a transparent layer of tissue within which transilluminated microvessels are readily visualized. After transient ischemia to the kidney, ureteral ligation is performed, inducing hydronephrosis. Weeks later,

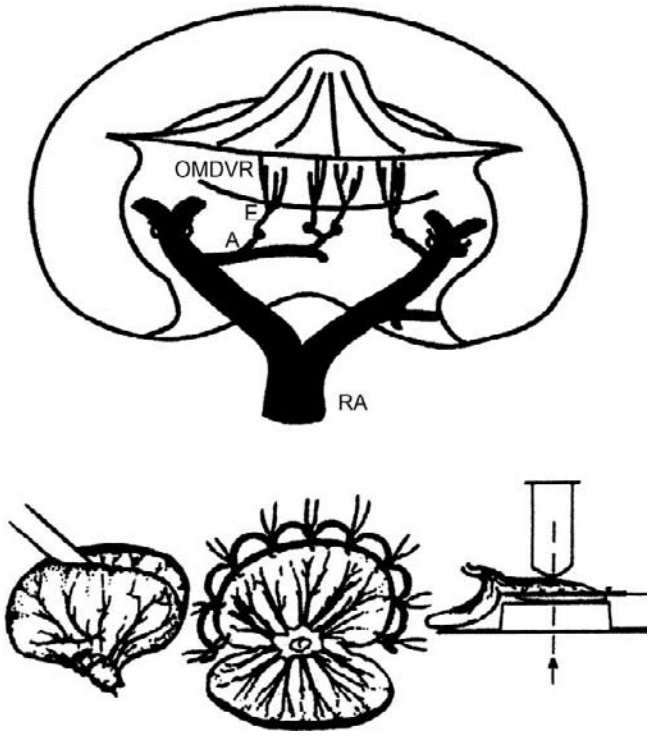

FIGURE 24.20 **Juxtamedullary nephron and split hydronephrotic kidney preparations.** Top panel: The juxtamedullary nephron preparation is created by perfusing the kidney, sectioning it longitudinally and reflecting the papilla to expose the underlying microvasculature (RA: renal artery; A and E: afferent and efferent arterioles; OMDVR: outer medullary descending vasa recta). Bottom panel: The split hydronephrotic kidney preparation is created by ligating the ureter for 3 to 10 weeks prior to isolation of the kidney. Ureteral ligation eventually reduces the kidney to a thin sheet of tissue in which tubules have atrophied but the vasculature remains. The kidney is exposed, split along the greater curvature, and sutured onto a chamber for observation and experimentation. *(Reproduced with permission from ref. [2]).*

the hydronephrotic kidney, reduced to a thin layer, can be split along its curvature and suspended on a microscope stage for study[203,204] (Figure 24.20, bottom panel). The actions of vasoactive agents can be studied by infusing them into the rat or by applying them directly onto the preparation. Changes in blood flow rate can be measured by videomicroscopy, and the reactivity of microvessels quantitated as changes in luminal diameter. The possibility of phenotypic drift in the altered tissue has to be considered.

VASOACTIVITY OF THE RENAL MICROCIRCULATION: ION CHANNEL ARCHITECTURE

Voltage-Gated Ca^{2+} Channels

Contraction of microvessels is generally tied to elevation of cytoplasmic calcium ($[Ca^{2+}]_{CYT}$) of smooth muscle cells (SMC). The increase of $[Ca^{2+}]_{CYT}$ is often mediated by influx through voltage-gated channels that are activated by membrane depolarization. This is observed experimentally, exposing SMC to high extracellular KCl induces depolarization by raising the K^+ equilibrium potential (Keq), activating voltage-gated Ca^{2+} entry and inducing vasoconstriction. Studies have shown that KCl depolarization constricts afferent arterioles more than efferent arterioles.[205–207] A role for high voltage-gated, L-type channels to mediate afferent SMC contraction is supported by the observation that both $[Ca^{2+}]_{CYT}$ elevation and vasoconstriction are blocked by diltiazem.[208,209] In the split hydronephrotic kidney preparation, angiotensi II constricts both afferent and efferent arterioles, but depolarizes only the former.[210] Application of agonists such as angiotensin II, endothelin, and ATP to preglomerular smooth muscle preparations consistently elicits $[Ca^{2+}]_{CYT}$ and current responses that are sensitive to L-type antagonists.[211–215] Taken together, sensitivity of the preglomerular microcirculation to L-type calcium channel blockade has been a very consistent finding.[216–221] Reduction of afferent vasoconstriction due to impairment of L-channel function could conceivably lead to transmission of elevated pressures to the glomerulus, resulting in injury. Such a mechanism has been invoked in rodent models of diabetes and hypertension.[222–224]

Voltage-gated Ca^{2+} channels (CaV) exist as a variety of subtypes and splice variants thereof. The nomenclature has evolved. Modern CaV classification follows the identity of the pore forming α-subunit (Table 24.5). Isoforms of classic high voltage-activated (HVA), L-channels are CaV 1.1– 1.3, and those of low voltage-activated (LVA) T-type channels are CaV 3.1–3.3. Other HVA types, originally identified in neurons, are the P/Q, R, and N which are CaV 2.1–2.3. Recently, RT-PCR and immunochemistry have been used to examine the distribution of voltage-gated Ca^{2+} channel α-subunits in the kidney. In addition to the anticipated expression of L-type (CaV 1.x) in the afferent circulation, T-type as well as unexpected P/Q-type Ca^{2+} channels were found.[206,225–229] Consistent with the earlier literature (see above), superficial efferent arterioles were not found to express L-type channels.[206]

Functional confirmation of CaV expression in the afferent and efferent circulation has been obtained in various studies. The CaV 1.x, L-type blocker diltiazem, partially reversed angiotensin II vasoconstriction and $[Ca^{2+}]_{CYT}$ elevation in DVR pericytes.[230,231] Similarly, the L-type blocker calciseptine and nonselective T-type blockers nilvadipine, mibefradil, pimozide, and Ni^{2+} reversed KCl and angiotensin II-induced constriction of afferent and efferent arterioles.[206,227,228,232,233] Elegant patch-clamp recordings by Gordienko et al. demonstrated signature currents consistent with both

high (L-type) and low (T-type) voltage-gated Ca^{2+} entry into isolated preglomerular smooth muscle.[234] Glomerular mesangial cells have a smooth muscle phenotype and express L-type dihydropyridine-sensitive voltage-gated Ca^{2+} channels.[235]

It is now clear that CaV are not just confined to the preglomerular circulation; juxtamedullary efferent arterioles and DVR express them. Despite positive immunostaining for T-type and P/Q-type channels in DVR pericytes,[206,225] a rigorous search for signature currents found only L-type activity.[236] Feng and colleagues examined the roles of arteriolar CaV with the juxtamedullary nephron preparation. Pimozide and mibefradil (T-type blockers) reduced basal tone of both afferent and efferent arterioles. In contrast, successful blockade with diltiazem (L-type blocker) occurred only in afferent arteriole, except when generation of NO was prevented by NO synthase inhibition. In their hands, T-type channel blockade with pimozide reversed both afferent and efferent contraction by angiotensin II.[232,237,238] Elegant studies in the renal cortex, performed *in vivo* using a pencil lens camera, have also documented that efferent arterioles are dilated by nonselective CCB, such as efonidipine and mibefradil.[239] Taken together, a role for CaV, particularly T-type channels, to participate in myogenic tone and agonist-induced contraction of juxtamedullary efferent arterioles is well-supported, and the ability of combined T- and L-type blockade to provide renoprotection through efferent dilation has thus become the subject of clinical investigation.[240–242]

Nonselective Cation Channels, Store Operated Channels, TRP Channels

Early study of store operated Ca^{2+} entry (SOC) in mast cells pointed to a highly Ca^{2+} selective pathway of immeasurably low single channel conductance that was referred to as a "calcium release activated current" (CRAC or I_{CRAC}).[243] That pathway is been attributed to the ER anchored stromal interacting molecule (STIM1) as the putative sensor and Orai, possibly interacting with TRPC1 as the selective pore.[244–247] Other pathways may participate in cellular Ca^{2+} entry in response to receptor activation and intracellular Ca^{2+} store depletion.[248] The routes involved are not always highly selective for Ca^{2+}, but instead also conduct other cations including Na^+. Their promiscuous transport of cations led to the designation "nonselective cation channels" (NSCC). Both receptor operated and store operated Ca^{2+} entry into cells can occur via NSCC, and channels of the transient receptor potential (TRP) families are now recognized as the major participants.[249] Fellner and Arendshorst showed that store operated Ca^{2+} entry into renal SMCs occurs and may be increased in the spontaneously hypertensive rat,[223,250] and that using SKF-96365 as an NSCC blocker, it has been shown that angiotensin II induced Ca^{2+} responses[215] and vasoconstriction[251] of the efferent arteriole involves NSCC. Assigning subtype-specific functional roles to the ubiquitously expressed TRP channel family members has proven generally difficult.[249] Takenaka and colleagues demonstrated that TRPC1 is expressed in glomerular arterioles and might conduct store or receptor operated Ca^{2+} entry.[249,251] The presence and activation of SOC has been most thoroughly examined in glomerular mesangial cells. Sansom and colleagues identified a small, 2.1 pS cation channel that is activated by thapsigargin-induced store depletion.[249,252] In whole cell patch-clamp experiments, identical currents were elicited by either thapsigargin or epidermal growth factor activation.[253,254] Activation of the pathway requires signaling through PKCα.[255,256] TRPC1 and TRPC4 are expressed in the murine mesangium, where antisense-induced suppression of TRPC4 was accompanied by inhibition of store operated currents.[257] TRPC4 has also been identified in DVR pericytes and endothelium, where it is in physical association with isoform 2 of the Na^+/H^+ exchange regulatory factor (NHERF-2), a scaffolding protein that facilitates protein−protein interactions.[258] The function of the NHERF-TRPC4 association is unknown.

Chloride Channels

For CaV to mediate Ca^{2+} entry into smooth muscle, they must depolarize the cell membrane to potentials greater than the CaV activation threshold. The equilibrium potential for K^+ ion is about -90 mV and SMC

membrane potential is held at negative values because overall conductance of the cell membrane is dominated by permeability to K^+. In many SMCs, depolarization that presages CaV-mediated Ca^{2+} entry is achieved by increasing the conductance to Cl^- ion, the equilibrium potential of which is generally −35 to −20 mV. This is accomplished through activation of Ca^{2+}-dependent Cl^- channels (CaCC).[259,260] The identity of CaCC had been confusing and enigmatic, but has recently been traced to TMEM16A and the family of proteins dubbed "anoctamins".[261,262] It seems likely that anoctamins are SMC CaCC, but confirmatory evidence in the renal vasculature is currently lacking. In the kidney, activation of CaCC channels has been described to participate in angiotnsin II-, endothelin-, and adenosine-induced constriction of afferent but not efferent arterioles.[263–267] Presumably, based on the juxtamedullary efferent expression of CaV,[206] CaCC plays a similar role in that location, but this has not been demonstrated. DVR pericyte depolarization and constriction is dependent upon CaCC activation.[268–270] In pericytes, cyclic CaCC stimulation participates in angiotensin II-induced oscillations of membrane potential,[271,272] and CaCC activity can be regulated by kinase blockade.[273] It has also been shown that high concentrations of angiotensin II also depolarize DVR pericytes by inhibiting K^+ channels.[274] The extent to which Cl^- channel activity regulates overall renal vascular resistance is uncertain.[229,248,275]

Potassium Channels

Most smooth muscle cells (SMC) express an array of K^+ channels. These include inward rectifier (K_{IR}), calcium-dependent (K_{Ca}), voltage-dependent (K_V), and ATP-dependent (K_{ATP}) varieties.[276] SMC of renal vessels are no exception, and many studies have been dedicated to the determination of their distribution and function (Table 24.6).

K_{Ca} channels are activated by depolarization and elevation of $[Ca^{2+}]_{CYT}$. They can be further subdivided into larger conductance (maxiK_{Ca} or BK_{Ca}) channels sensitive to charybdotoxin and iberotoxin, and medium and low conductance channels blocked by apamin. K_{Ca} channels are ubiquitous in smooth muscle. When stimulated by Ca^{2+} entry, they may provide a "breaking" function that opposes depolarization and deactivates CaV.

K_V channels, also refered to as delayed rectifiers, activate with depolarization, are insensitive to $[Ca^{2+}]_{CYT}$, and are specifically blocked by 4-aminopyridine. K_V can contribute to resting potential, and their voltage-dependent activation probably limits membrane depolarization.

K_{IR} are named for their avid permeation of K^+ at membrane potentials that lie below Keq. Above Keq, where the physiological function of K_{IR} occurs, K_{IR} conduct K^+ efflux from cells in a complex manner. Conductance, at membrane potentials greater than Keq, declines as the difference between membrane potential and Keq increases. The latter property imparts a very important characteristic. Small elevations of extracellular K^+ (e.g., 5–20 mM) raise Keq to a level that enhances K_{IR} conductance, but still lies below the resting membrane potential. The result is hyperpolarization of the membrane that favors inhibition of Ca^{2+} entry and vasodilation.[277] That mechanism may enable extracellular K^+ ion to function as an endothelium-dependent hyperpolarizing factor (EDHF). The increase in extracellular K^+ needed for the EDHF process to occur is thought to arise from endothelial K^+ secretion. Vasodilators, such as bradykinin and acetylcholine, increase $[Ca^{2+}]_{CYT}$ and stimulate endothelial K_{Ca} channels so that they secrete K^+ ion into the extracellular space of adjacent SMCs.[97,278–280] Stated another way, K^+ may be an EDHF, the function of which depends upon endothelial K^+ secretion and SMC K_{IR} expression. Extracellular K^+ can also activate electrogenic Na^+K^+-ATPase activity in SMC which, by exchanging $3Na^+$ for $2K^+$, favors hyperpolarization. Participation of Na^+ pumps versus K_{IR} in SMC hyperpolarization must be experimentally distinguished, generally by examining the component that is sensitive to ouabain.

SMC K_{ATP} channels are generally comprised of four K_{IR} 6.1 α-subunits combined with four type 2B sulfonurea

TABLE 24.6 Potassium Channel Expression in the Renal Microcirculation

receptors (SUR2B). Despite the participation of K_{IR} 6.1, K_{ATP} channels lack the strongly inward rectifying characteristics of other K_{IR} isoforms. K_{ATP} channels are widely expressed in SMC and, with high specificity, are inhibited by antagonists such as glybenclamide that bind to the SUR-subunits. K_{ATP} channels are named for their inhibition by intracellular ATP. In addition to ATP, nucleotide diphosphates (NDPs) regulate most K_{ATP} channels. It was historically thought that reduction of cellular ATP related to metabolic stress activates K_{ATP} channels favoring hyperpolarization, microvessel dilation, and enhancement of perfusion. It is now recognized that this is an oversimplification, because K_{ATP} channels can contribute to resting potential and are sensitive to a variety of regulatory influences.[277]

SMC of the main renal artery, interlobular, and arcuate arteries have been shown to express both BK_{Ca} and K_V channels that exhibit slow inactivation after depolarization.[234,281–286] Preglomerular renal microvessels of varying caliber obtained by hand dissection or by filling them with iron oxide particles and isolating them from collagenase-digested tissue with a magnet have provided preparations for study. SK_{Ca}, BK_{Ca}, and K_V channels have been observed in afferent SMCs.[287–289] The P450 cyclooxygenase constrictor, 20-hydroxyeicosatetraenoic acid (20-HETE), inhibits preglomerular K_{Ca} channel activity,[290–292] probably through activation of MAP kinase.[293] Preglomerular K_{Ca} channels can be activated by NO,[294] 11,12-epoxyeicosatrienoic acid (11, 12-EET),[295] and CO generated by hemoxygenase.[296] The cytochrome P450 synthesis of epoxyeicosatrienoic acids (EETs) has been shown to activate BK_{Ca}, and may participate in the function of EETs as an EDHF.[297–299] NO-mediated inhibition of 20-HETE synthesis may be the primary mechanism (versus cyclic GMP generation) that favors BK_{Ca} activation in preglomerular SMC.[291,300] Preglomerular expression of K_{ATP} component subunits has been variably observed.[301,302]

Afferent arterioles are the dominant resistance of the renal microcirculation, and play vital roles in autoregulation through myogenic constriction and tubuloglomerular feedback. The K^+ channel architecture of afferent arterioles has been intensely studied, and evidence for expression of K_{Ca}, K_{IR}, K_V, and K_{ATP} channels has been obtained. Afferent dilation by acetylcholine during inhibition of NO and prostaglandin synthesis has been traced to the participation of K_{IR} and K_{Ca} channels, because it is blocked by the combined K_{Ca} inhibitors, charybdotoxin and apamin.[298,303] As described above, the EDHF response may be related to local elevations of K^+ outside the SMC membrane. Direct participation of K_{IR} has been demonstrated by Chilton and Loutzenhiser, who found that small elevations of K^+ dilate afferent arterioles. The dilation is sensitive to low concentrations of Ba^{2+} ($<100\ \mu M$) that selectively blocks K_{IR} channels.[304–306] Juxtaglomerular cells express the strong inward rectifier, K_{IR} 2.1, where it plays a role in setting membrane potential.[307] Vasodilation of afferent arterioles by the K^+ channel activator, NS-1619, supports a role for K_{Ca} channels in that structure.[307,308] Myogenic constriction appears to be modulated through PKC that acts, at least in part, by inhibiting 4-aminopyridine sensitive K_V channels.[309] A role for K_{ATP} channel activity to affect afferent arterioles has been repeatedly verified. K_{ATP} channels activated by hypoxia, pinacidil, calcitonin gene related peptide (CGRP) or adenosine modulate constriction[310–313] and levakromlin hyperpolarizes renin-secreting cells of the afferent arteriole.[314] K_{ATP} expression in afferent arterioles is supported by the observation of [^{3}H]P-1075 binding to membranes.[315] Multiple classes of K^+ channels contribute to resting tone of afferent arterioles, and enhancement of K_{IR} and K_{ATP} activity may contribute to vasodilation and glomerular hypertension in diabetes.[316]

The role of K^+ channels in the activity of the efferent circulation has not been as thoroughly explored as that of afferent smooth muscle. The K_{ATP} opener, pinacidil, dilates the efferent arteriole.[311] Pinacidil both dilates DVR and hyperpolarizes DVR smooth muscle/pericytes.[231] High concentrations of angiotensin II inhibit DVR K^+ channel activity.[274] A modulatory role for K_{IR} and K_{Ca} channels to affect $[Ca^{2+}]_{CYT}$ signaling by angiotensin II in efferent arteriolar smooth muscle has been described.[317] Roles for strong K_{IR} isoforms to modulate contraction and membrane potential of glomerular arterioles and vasa recta pericytes have been verified.[304,318,319]

Mesangial cells are smooth muscle pericytes that contract to modulate filtration by glomerular capillaries.[320] The ability to study mesangial cells in culture has permitted study of their channel architecture. Molecular evidence exists for expression of K_V, K_{ATP}, and K_{Ca} channels in rat primary and immortalized murine mesangial cells.[321,322] Both medium and large conductance K_{Ca} channels are present.[289,323–328] The BK_{Ca} channel in mesangial cells is activated by arachidonic acid[329] and Ca^{2+}-calmodulin-dependent protein kinase.[330] Atrial natriuretic peptide[331] or nitric oxide, acting through cGMP-dependent protein kinase, also activatesK_{Ca} channels through phosphorylation of the β1-subunit.[332] Mesangial BK_{Ca} activation is favored by protein phosphatase 2A inhibition,[333] and enhancement of activity and expression by insulin-induced MAPK activation.[334]

Connexins

In addition to permitting exchange of ions with the extracellular space, specialized channel proteins, the

connexins, electrically couple smooth muscle and endothelia in the vascular wall. Of more than 20 connexins, Cx37, Cx40, Cx43, and Cx45 have been found in the vasculature where they form endothelial and myoendothelial gap junctions. Connexins are four transmembrane spanning proteins with two extracellular loops that combine as homomeric or heteromeric hexamers. Docking of the extracellular loops combines two hexameric hemichannels from adjacent cells into the transcellular "connexon" conduit that mediates cell−cell communication. Mimetic peptides have been designed that interfere with binding of the extracellular loops.[335] Connexons are true channels that generally have high conductivity (15−300 pS), high open probability, and can occupy multiple subconductance states. They are regulated by pH, Ca^{2+}, signaling molecules, and phosphorylation events. Their pores are sufficiently large to pass signaling molecules, anions, and cations. Communication between cells is often documented by cell-to-cell spreading of fluorescent molecules (e.g., Lucifer yellow 457 Da).[336−338] The physiological roles of vascular gap junctions are under study. A role for endothelial to smooth muscle transfer of vasodilators has been postulated.[97,278] This has received support from the observation that Cx40 deficient mice are hypertensive, have abnormal vasomotion, and deficient spreading of vasodilation.[336,339,340] Endothelial deficiency of Cx43 also leads to abnormal spreading of vasodilation,[341,342] and targeting of Cx43 and Cx37 with the extracellular peptide mimetic, Gap27, inhibits myogenic responses.[343]

The renal microcirculation expresses gap junctions Cx37, Cx40, Cx43, and Cx45.[29,344−352] NO- and COX-independent (EDHF-mediated) dilation of the main renal artery with carbachol was shown to be sensitive to Gap27.[353] Similarly, arachidonic acid- and bradykinin-mediated, NO- and COX-independent dilation of arcuate and interlobar arterioles was inhibited by the gap junction blocker, 18-α glycyrrhetinic acid.[354] Salmonsson and colleagues have documented Ca^{2+} spreading along interlobular arterioles that is likely to be mediated by gap junctions.[355] Cx40 is highly expressed in endothelial cells of renal vessels and glomeruli,[347,356] and may play an important role in tubuloglomerular feedback and autoregulation.[348] Endothelial cells of preglomerular arteries and arterioles also express Cx37 and Cx43. Cx37 is found in arcuate and interlobular arteries, and afferent arterioles.[352] Cx40 bridging endothelial cells are most abundantly localized in large intrarenal arteries, including interlobular artery and the proximal portion of the afferent arteriole, but then markedly decreases as the arteriole approaches a glomerulus.[347] Deficiency of Cx40 leads to ectopic renin production.[357−359] Afferent arterioles have considerably more connexin expression than efferent arterioles where Cx43 is largely present in the endothelium. Cx37 and Cx40 are expressed in juxtaglomerular cells and extraglomerular mesangial cells.[352] Cx43 is localized to extraglomerular mesangium and is found in isolated glomeruli.[360,361,362] Intraglomerular mesangial cells have primarily Cx40.[352,363] In the renal medullary microcirculation, DVR pericytes express Cx37 while the endothelia express Cx40 and Cx43 (Figure 24.21). DVR endothelia, but not pericytes, are highly connected as an electrical syncytium. DVR conduct Ca^{2+} responses to mechanical stimulation that can be inhibited by gap junction blockade.[364]

REGULATION OF BLOOD FLOW AND MICROVESSEL CONTRACTION

The most effective locations at which regional perfusion of cortex and medulla can be controlled are readily inferred from renal microanatomy (Figure 24.1). For example, constriction of intralobular arterioles should favor redistribution of blood flow toward the medulla via the juxtamedullary glomeruli. Similarly, closure of juxtamedullary intra-arterial cushions (Figure 24.2) or constriction of juxtamedullary afferent or efferent arterioles should favor perfusion of the superficial cortex. DVR are the final resistance vessels involved in the

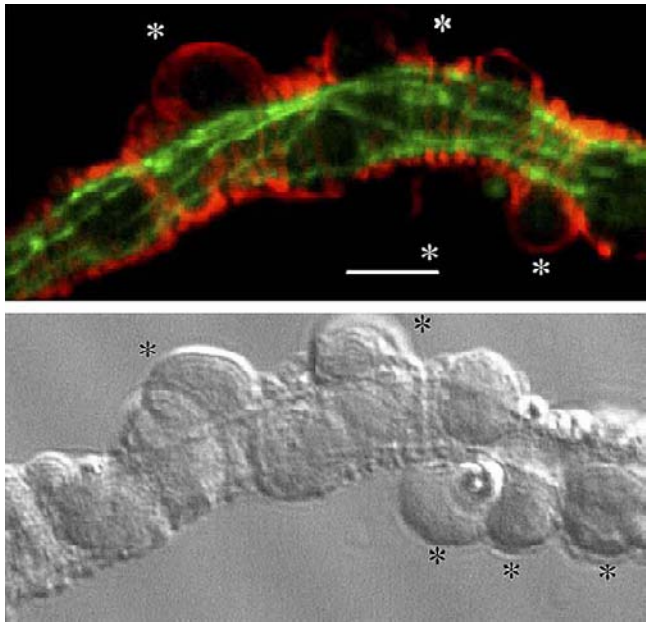

FIGURE 24.21 **Connexin staining in DVR.** Immunostaining with antibody directed against α-smooth muscle actin (SMA red, pericyte marker) or Cx40 (green) along with corresponding white light micrograph. Cx40 is linear and confined to the endothelium with very little SMA colocalization. control of medullary perfusion. The fraction of the total resistance to blood flow into the renal medulla accounted for by DVR, versus juxtamedullary afferent and efferent arterioles, is uncertain. The parallel arrangement of DVR within vascular bundles does, however, imply a probable role for them to modulate regional perfusion to the outer versus inner medulla. For example, contraction of DVR that are destined to perfuse the inner medulla should favor redirection of blood flow toward the outer medullary interbundle capillary plexus. Factors that control regional perfusion within the kidney are the subject of intense investigation.

Autoregulation and Pressure Natriuresis

Blood flow to the kidney remains relatively constant despite physiological variation of renal perfusion pressure (RPP), a phenomenon called autoregulation. Two major mechanisms account for renal autoregulation. The first is "myogenic," whereby stretch of the afferent arteriole leads to reflex vasoconstriction.[365] The second component, that reacts more slowly than the myogenic reflex, is tubuloglomerular feedback (TGF). TGF occurs when an increase in renal perfusion pressure, transiently transmitted to glomerular capillaries, results in a rise in glomerular filtration rate. After a delay traversing the nephron, the increased tubular fluid delivery is sensed at the macula densa, where a signaling cascade leads to release of ATP and adenosine formation via 5′-ecto-nucleotidase. The adenosine so formed constricts the afferent arteriole, thereby reducing filtration pressure and returning glomerular filtration rate to its set point.[366–371]

The phenomenon of "pressure natriuresis" may be tied to variation of medullary autoregulation. Pressure natriuresis refers to the observation that elevation of renal perfusion pressure (RPP) causes natriuresis even in isolated, denervated kidneys.[372,373] Increased RPP leads to increased sodium delivery to papillary thin descending limbs of Henle, implying that a mechanism exists to inhibit reabsorption by the proximal tubule of deep nephrons.[374,375] Internalization of proximal Na^+/H^+ exchanger from the apical membrane might participate. Pressure natriuresis has been traced to alteration of renal interstitial hydrostatic pressure (RIHP). An increase in RIHP occurs when RPP is elevated,[376] and both the increase in RIHP and natriuresis can be blunted through renal decapsulation.[377] Garcia-Estan and Roman have suggested that residual effects after decapsulation might be traced to the inability of decapsulation to modulate interstitial pressure in the renal medulla.[378] A role for RIHP in the phenomenon of pressure natriuresis is supported by experiments in which it has been altered without changing RPP. Infusion of 2.5% albumin into the renal interstitium increases RIHP and causes natriuresis through inhibition of sodium reabsorption by superficial and deep nephrons.[379,380]

It is accepted that renal cortical blood flow is autoregulated over a physiological range of renal perfusion pressure. In contrast, the extent to which medullary blood flow is autoregulated is controversial. It has been proposed that lack of medullary autoregulation is essential to pressure natriuresis, and the control of salt and water excretion.[76,184,381–385] The renal medulla is largely perfused by postglomerular blood. Flow through a small population of shunt vessels that bypass glomeruli has been invoked to explain the escape of the medulla from tubuloglomerular feedback-mediated autoregulation (Figures 24.1 and 24.3).[16,381] Nearly 50 years of investigation have failed to completely support or refute the hypothesis that blood flow to the renal medulla lacks autoregulation. Work with microvascular transit time indicators favored lack of autoregulation,[171] but several early studies favored its presence.[183,386,387] Studies performed in the rat suggest that the efficiency of medullary autoregulation is a function of volume status. Measurement of blood flow to the cortex and medulla using videomicroscopy or laser-Doppler probes placed on the renal surface[388] or within the parenchyma[389] showed that medullary blood flow of volume-expanded rats does not autoregulate, but instead increases with perfusion pressure (Figure 24.22). Both an increase in single vessel blood flow rate and recruitment of flow through

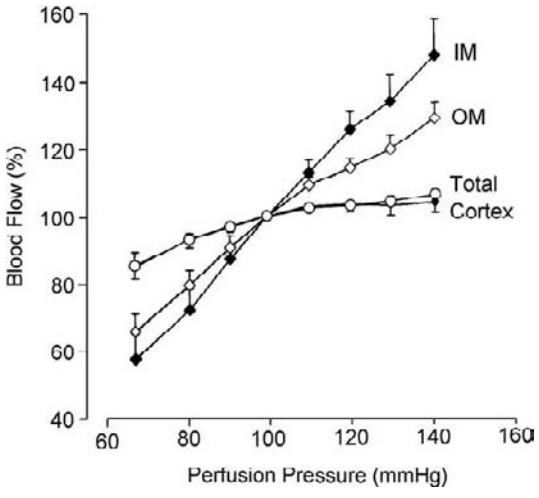

FIGURE 24.22 **Autoregulation in different regions of the kidney.** An electromagnetic flow device on the renal artery was used to measure total renal blood flow. Laser-Doppler flow probes were inserted into the renal parenchyma at various depths to measure regional blood flow in the outer and inner medulla. Total renal blood flow and cortical tissue blood flow shows intact autoregulation (stability of blood flow over a range of perfusion pressure). In contrast, in these volume-expanded rats (see text) the small fraction of blood flow that reaches the outer or inner medulla is not autoregulated. *(Reproduced with permission from ref. [389]).*

previously unperfused vasa recta may contribute to the process.[388] In contrast to volume-expanded animals, hydropenic rats autoregulate medullary blood flow and minimal pressure natriuresis[381,382,384,390](Figure 24.23). Studies of regional blood flow in sodium-replete dogs by Majid, and in rabbits by Eppel et al. support intact medullary autoregulation.[391,392] Zhang and colleagues recently demonstrated that pressurizing the DVR lumen leads to endothelial $[Ca^{2+}]_{CYT}$ elevation and generation of NO.[393] If transmission of pressure to the medulla is a key event in pressure natriuresis, release of NO could conceivably inhibit salt reabsorption by adjacent nephrons generating pressure natriuresis. Such a paracrine role for NO to signal between the vasculature and nephrons is frequently postulated.[382,394–397]

Blood flow to the renal medulla is dependent on generation of NO.[382,384] This is particularly true in the spontaneously hypertensive rat (SHR).[398] Roald and colleagues observed poor autoregulation of juxtamedullary blood flow in the SHR. They proposed that the tendency toward early tissue damage in the juxtaglomerular cortex is due to poor autoregulation.[399] The superoxide dismutase mimetic, tempol, enhances tissue NO levels by eliminating its reaction with superoxide.[400] Feng and colleagues found that tempol reduced blood pressure and enhanced medullary blood flow in the SHR.[401]

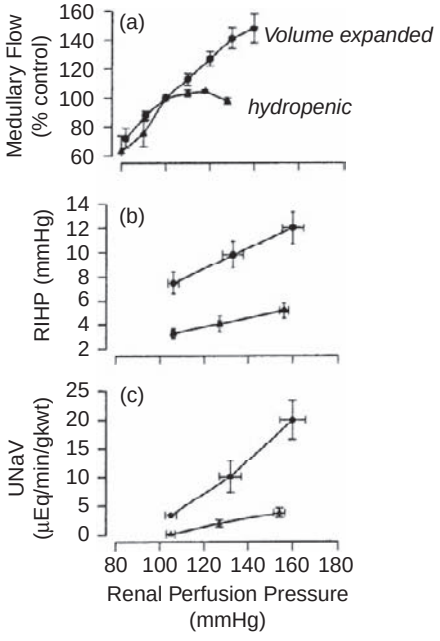

FIGURE 24.23 **Pressure natriuresis.** Panel a: Medullary blood flow is autoregulated in hydropenic but not volume-expanded rats. Panel b: Renal interstitial hydrostatic pressure (RIHP) is higher and increases to a greater degree with renal perfusion pressure in volume-expanded animals. Panel c: When renal perfusion pressure is increased, urinary sodium excretion (UNaV) increases much more markedly in volume-expanded than in hydropenic animals. *(Reproduced with permission from ref. [381]).*

Vasopressin and Excretion of Water

Changes in medullary blood flow might have a diuretic effect by reducing the efficiency of countercurrent exchange, leading to "solute washout" and loss of corticomedullary axial gradients of NaCl and urea.[17] The role of vasopressin to modulate medullary blood flow during antidiuresis has been the focus of much investigation.[2,381,390,402] Early studies, based on indicator transit times, showed that vasopressin reduces medullary blood flow.[171] Homozygous Brattleboro rats that lack vasopressin secretion have elevated papillary plasma flow.[156] The effect of vasopressin and specific V_1 (vasoconstrictor) and V_2 (antidiuretic) receptor subtype inhibitors on vasa recta blood flow was studied with videomicroscopy. Vasopressin reduces vasa recta blood flow in a manner that was partially blocked with either vasopressin V1 or V2 receptor subtype inhibitors.[403–405]

Studies with laser-Doppler and implantable probes confirmed that intrarenal infusion of a selective V_1 receptor agonist reduces inner medullary blood flow more than outer medullary blood flow.[406] Similarly, elevation of circulating vasopressin, stimulated by depriving conscious rats of water, led to selective reduction of only inner medullary blood flow, sparing perfusion of the cortex and outer medulla. Infusion of a V_1-antagonist into the medullary parenchyma blocked the decline in inner medullary perfusion and interfered with urinary concentration.[33] When vasopressin was infused into decerebrate rats to maintain plasma levels within a physiological range of 2.9 to 11.2 pg/ml (about 1 to 10 pM), inner medullary blood flow fell to an extent that correlated with urinary osmolality[33] (Figure 24.24). Those studies support the V_1-mediated vascular effect of vasopressin as a modulator of inner medullary blood flow favoring antidiuresis. The renal cortex might be spared from V_1

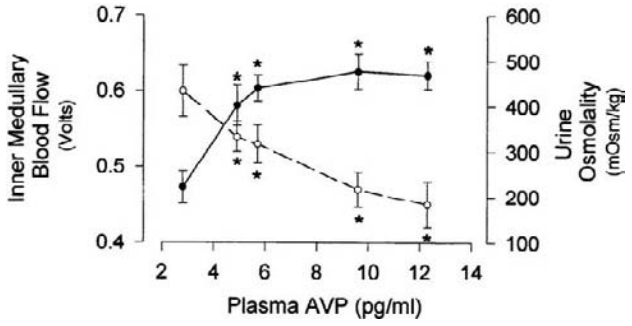

FIGURE 24.24 **Effect of arginine vasopressin (AVP) on inner medullary blood flow and urine osmolality.** To control plasma vasopressin concentrations, decerebrate rats were infused with AVP. Increasing AVP concentration within the physiological range caused a reduction of inner medullary blood flow and an improvement in urinary concentration. *(Reproduced with permission from ref. [33]).*

receptor-mediated vasoconstriction by reflex generation of vasodilator epoxyeicosatrienoic acids.[407]

Vasopressin reduces inner medullary perfusion by acting at various sites. It constricts juxtamedullary afferent (1 pM−1 nM) and efferent (1 nM) arterioles in isolated, perfused rat kidneys.[408] Afferent AVP constriction is dependent upon voltage-gated Ca^{2+} entry, whereas efferent constriction may be related to Ca^{2+} mobilization from stores.[409] Vasopressin also constricts rabbit afferent arterioles,[410] efferent arterioles (0.1 pM−100 nM), and rat outer medullary DVR (100 pM−1 microM) *in vitro*.[411,412] Correia and colleagues showed that vasopressin V_1-agonist reduced medullary blood flow in rabbits, but did not constrict either juxtamedullary afferent or efferent arterioles. They concluded that DVR might be the primary site at which vasopressin acts to regulate inner medullary blood flow.[413]

In addition to the constrictor effects of vasopressin, mediated by the V1 receptor, it has been demonstrated that vasodilation of some vessels can be mediated through vascular V2 receptors, leading to elevation of nitric oxide.[414−417] Selective V2 agonists have been shown to dilate preconstricted afferent arterioles[418] and outer medullary DVR[412] *in vitro*. In contrast, however, efforts to date have failed to show V2 receptor mRNA in dissected renal microvessels by RT-PCR.[419] Chronic infusion of the V2 agonist dDAVP was shown to elevate renal medullary nitric oxide and increase medullary blood flow,[420] an effect that may be related to release of NO by collecting duct.[421,422] Blockade of NO production during vasopressin elevation leads to hypertension. That finding suggests that V2-mediated NO production in the medulla serves as a buffer to protect the outer medulla from ischemia, as well as to prevent salt retention and hypertension.[423,424] The probable source of V2-mediated NO production is the inner medullary collecting duct.[421]

Angiotensins

Studies that employ isolated microvessel perfusion,[193,194,198,396,410,421,425,426] the juxtamedullary nephron preparation[205,263,427] or the split hydronephrotic kidney,[204,210] have all shown that angiotensin II constricts afferent arterioles, efferent arterioles, and DVR. Cultured mesangial cells also contract in response to angiotensin II.[320] Angiotensin II tonically constricts the juxtamedullary microcirculation *in vivo*[160,428−430] in a manner that is modulated by vasodilators and renal nerves.[431−435] Several vasodilators modulate angiotensin II-induced vasoconstriction. Blockade of NOS induces basal constriction of afferent arterioles and DVR, and intensifies constriction by angiotensin II stimulation.[193,194,436−438] Paracrine agents such as prostaglandin E_2 (PGE_2) and adenosine counteract angiotensin II constriction of glomerular arterioles and DVR.[198,439−441] Blockade of prostaglandin production may have a greater effect in augmenting constriction of juxtamedullary than superficial glomerular arterioles.[439]

Angiotensin II exerts its effects through type 1 ($AT1_A$ and $AT1_B$) and type 2 (AT2) receptors. AT1 stimulation activates phospholipase C (PLC) to generate inositol trisphosphate (IP_3) and elevate $[Ca^{2+}]_{CYT}$.[211,215] $AT1_A$ receptor-null mice have blunted afferent and absent efferent arteriolar responses to angiotensin II .[442] Study of the distribution of receptors on juxtamedullary efferent arterioles revealed expression of $AT1_A$, $AT1_B$, and AT2 on muscular efferents destined to perfuse the medulla. In contrast, the $AT1_B$ subtype was absent in efferent arterioles that give rise to juxtamedullary capillary plexus in the cortex.[443] AT2 receptor activation has been reported to favor vasodilation via generation of nitric oxide.[444,445] In the afferent arteriole, however, AT2 stimulation favors synthesis of vasodilatory CYP450 epoxygenase products (EETs)[436,437,446] rather than NO. The evidence favors compensatory NO generation due to AT1 stimulation.[447,448] AT2 activation also vasodilates efferent arterioles[449] and DVR, where it both inhibits reactive oxygen species formation and facilitates endothelium-dependent $[Ca^{2+}]_{CYT}$ signaling in response to vasodilators.[395,450,451] The vasodilatory response to AT2 receptors may be impaired in forms of hypertension.[452,453] Both AT1 and AT2 receptors are widely expressed in vascular and tubular elements of the kidney.[454]

The role of angiotensin II AT1 and AT2 receptors to modulate regional perfusion in the kidney has been investigated. Angiotensin II constricts DVR that supply the medulla,[198,395] but angiotensin II infusion largely reduces blood flow to the renal cortex, sparing the medulla.[432,434,435] Moreover, there are reports that angiotensin II enhances medullary perfusion in rats and rabbits.[431,455,456] The resistance of the renal medulla to angiotensin II-induced vasoconstriction has been traced to reflex generation of compensatory vasodilators, particularly NO.[394,395,455,457−459] Recent studies favor the role of endothelial nitric oxide synthase (eNOS, NOS3) to maintain basal perfusion and stimulation of neuronal nitric oxide synthase (nNOS, NOS1) to blunt vasoconstriction by angiotensin II .[460] Pressure natriuresis has been tied to renal medullary perfusion (see above). Possibly related to this, AT2 receptor-null mice are hypertensive and lack the pressure natriuretic response.[461]

Angiotensin II constricts renal microvessels over a broad range of concentrations, with efferent arterioles and DVR showing the greatest sensitivity (EC_{50} ~0.5 nM). Although circulating plasma angiotensin II concentrations are in the range of 100 pM, renal interstitial and intratubular concentrations approach 1 to 10 nM, implying that there is an intrarenal mechanism

for generation and sequestration (Figure 24.25). Interstitial concentrations are greatest in the renal medulla, where angiotensin II receptor density is high.[462–466] At very high concentrations of 1 to 10 nM, angiotensin II acting via the AT1 receptor blunts DVR endothelial $[Ca^{2+}]_{CYT}$ responses to bradykinin and acetylcholine, an effect that is partially counteracted by concomitant AT2 receptor activation.[395,450] At high concentrations, angiotensin II inhibits K^+ channel activity of DVR pericytes[274,467,468] while stimulating Ca^{2+}-dependent Cl^- channel-mediated depolarization[268,270,273] to favor voltage-gated Ca^{2+} entry.[231,236] In DVR pericytes, angiotensin II often induces oscillations of $[Ca^{2+}]_{CYT}$ and Cl^- ion conductance.[271,272] Taken together, the results favor the interpretation that high levels of angiotensin II prevent vasodilatory compensation within vasa recta by blocking NO generation and K^+ channel activation, while stimulating NO generation by adjacent nephrons. Hypothetically, DVR on the vascular bundle periphery dilate in response to NO from adjacent epithelia to preferentially maintain outer medullary perfusion.[394,459,469–471]

Angiotensin II is derived from angiotensin I through the actions of angiotensin-converting enzyme (ACE).

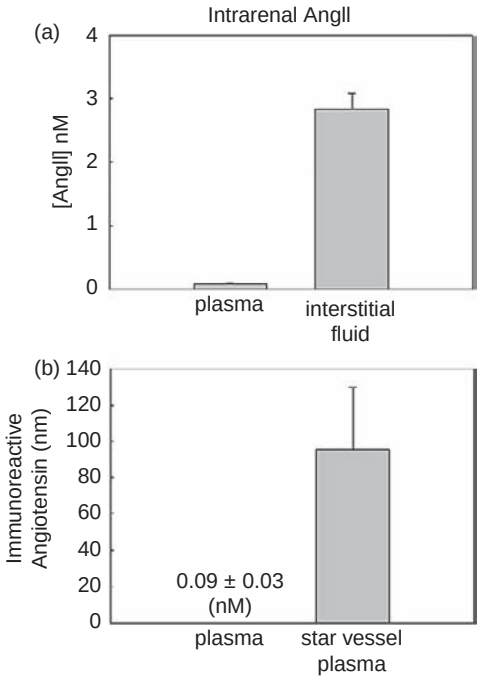

FIGURE 24.25 **Intrarenal angiotensin II concentrations.** (a) Graph shows a comparison of angiotensin II concentration in plasma and renal interstitial fluid obtained by microdialysis. Cortical interstitial angiotensin II concentrations are markedly higher than plasma values. (b) Comparison of immunoreactive angiotensins in systemic plasma and star vessel plasma (efferent arteriolar, precapillary blood) by micropuncture of the rat kidney. Angiotensin II concentration is estimated to be ~10–25% of the immunoreactive angiotensins in various compartments. *(Results redrawn from published data [465,466]).*

Angiotensin II has a short half-life, and is itself degraded by angiotensinases to form several fragments, including angiotensin [1–7] and angiotensin [3–8]. Angiotensin-converting enzyme type 2 (ACE2) is a metalloprotease that hydrolyzes angiotensin I and angiotensin II to form the heptapeptide, angiotensin [1–7]. ACE2 is not blocked by conventional converting enzyme inhibitors. ACE2 reduces formation of angiotensin II by degrading angiotensin I to other fragments.[444,464,472] Angiotensin [1–7] is a dilator of the renal and other capillary beds,[473] and accumulates during ACE inhibition, potentially contributing to antihypertensive actions of those pharmaceuticals.[474] In the kidney, angiotensin [1–7] specifically binds to the Mas receptor. Mas-null mice lack binding, aortic relaxation, and antidiuretic response to angiotensin [1–7].[475] Renoprotective roles for angiotensin [1–7] are emerging.[476–478]

Aldosterone

Aldosterone increases transcription of molecular machinery dedicated to salt reabsorption in the distal nephron. It has been shown to increase mRNA for renin in juxtaglomerular cells in a manner that is blocked by the mineralocorticoid receptor antagonist, spironoloactone.[479] Recently, it has also been shown that aldosterone acts as a paracrine agent in the vasculature to have acute "nongenomic" effects on vasoactivity.[480] This was uncovered by Schmidt and colleagues, who showed that aldosterone increased human forearm blood flow. With NOS inhibition, aldosterone enhanced blood flow reduction mediated by phenyephrine. The data were interpreted to show that aldosterone causes vasoconstriction via smooth muscle activation and compensatory vasodilation via release of NO.[481] Similarly, Arima et al. showed that aldosterone caused concentration-dependent constriction of both afferent and efferent arterioles, an effect that was insensitive to spironoloactone. The constriction was prevented by PLC inhibition, involved voltage-gated Ca^{2+} entry mediated principally by L-type and T-type channels in the afferent and efferent arterioles, respectively, and is partially offset by NO generation.[482–485]

Adrenomedullin

Adrenomedullin and adrenomedullin-2/intermedin are peptide hormones with homology to calcitonin gene related peptide (CGRP). It circulates in picomolar concentrations and is widely synthesized by tissues including vascular smooth muscle and endothelium. It has potent vasodilatory and hypotensive effects, at least partially mediated by NO.[486–488] Deletion of the gene for adrenomedullin is lethal *in utero*.

Heterozygotes live to adulthood but are hypertensive, have defective synthesis of NO, and are vulnerable to renal ischemia.[489,490] Renal synthesis of adrenomedullin is enhanced by hypoxia.[491] Intrarenal infusion induces vasodilation that is attenuated by NO synthase inhibition[492–494] and was found to increase canine cortical and medullary blood flow.[493] Adrenomedullin has been shown to dilate both afferent and efferent arterioles of the hydronephrotic kidney preparation.[495] Chronic infusion of adrenomedullin was found to limit hypertensive injury in deoxycorticosterone (DOCA) salt hypertensive rats[496,497] and limits injury during ureteral obstruction.[498] It may partially act by limiting generation of reactive oxygen species.[499]

Intermedin, also known as adrenomedullin-2, shares many of the properties of adrenomedullin. Its receptor profile overlaps that of CGRP and adrenomedullin, and its adult expression is largely in the hypothalamus, pituitary, and kidney.[500,501] Intra-arterial infusion enhances renal blood flow and induces diuresis.[502] Like adrenomedullin, intermedin has been found to ameliorate renal tissue damage in pathological models,[503] and its expression is reduced in forms of renal injury.[504]

Nitric Oxide

Endothelia and transporting epthelia secrete paracrine modulators of vascular tone, including nitric oxide (NO), prostacyclin (prostaglandin I_2, PGI_2), and endothelium-derived hyperpolarizing factors (EDHF). Nitric oxide regulates vessel tone, regional distribution of blood flow, autoregulation, pressure natriuresis, tubuloglomerular feedback, and salt reabsorption. Its effects on the microcirulation of the kidney are protean and have been frequently reviewed.[382–385,457,505–517] Nitric oxide synthase (NOS) isoforms are expressed by nephrons and vessels throughout the kidney,[384,385,510,513] but expression is greatest in the inner medullary collecting duct and vasa recta.[518] It has also been shown that NO generation by collecting duct is regulated by uptake of L-arginine via the CAT1 cationic amino acid transporter.[519–522] Infusion of competing cationic amino acids reduced medullary NO, reduced medullary blood flow, and induced hypertension.[519] Asymmetric dimethyl arginine (ADMA) is an endogenous NOS inhibitor that is metabolized by dimethylaminohydrolase (DDAH).[523–525] ADMA equilibrates with the cytoplasm via cationic amino acid transporters (CATs), competes with their ability to transport L-arginine, and inhibits NOS.[524] The DDAH2 isoform predominates to remove ADMA in the vasculature. The role of ADMA and DDAH in endothelial function and dysfunction is the subject of much current investigation.[526,527]

Infusion of the NO synthase inhibitor Nw-nitro-L-arginine methyl ester (L-NAME) into the renal artery of rats and dogs increases renal vascular resistance and blunts pressure natriuresis.[528,529] NOS inhibition constricts the preglomerular microcirculation of the juxtamedullary nephron preparation, an effect that is enhanced when RBCs, that consume NO, are included in the perfusate.[530,531] The ability of NO to modulate afferent arteriolar tone results both from its synthesis by the endothelium[193–195,532] and signaling in the macula densa.[196] Similar to cortical microvessels, NOS inhibition constricts isolated DVR, largely by preventing the consumption of superoxide by NO.[425,438]

NOS inhibition interferes with pressure natriuresis.[531,533] Infusion of an NO synthase inhibitor into rats was found to restore medullary autoregulation and blunt the pressure natriuretic response.[383] Similarly, infusion of L-arginine both altered medullary autoregulation and normalized pressure natriuresis in the spontaneously hypertensive rat (SHR).[534] Exogenous L-arginine increases NO production in cultured cells and the isolated perfused kidney.[535] Moreover, it can abrogate hypertension and renal damage in hypertension induced by chronic angiotensin II infusion.[536,537]

Chronic, global NOS inhibition causes a selective reduction of renal medullary blood flow.[538,539] Nitric oxide (NO) production in the renal medulla exceeds that in the cortex.[385,540–543] L-arginine supplementation enhances NO levels in the renal medullary interstitium,[543] and abrogates hypertension in the Dahl rat and SHR.[534,544,545] In contrast to global NOS inhibition, reduction of nNOS activity induces hypertension without affecting medullary perfusion, suggesting that the saliuretic effects of NO generated by those isoforms is of predominant importance.[546–549] Thus, NO generated by eNOS may primarily affect basal vascular resistance, while NO derived from other NOS isoforms, particularly nNOS, affects renal epithelial Na^+ reabsorption and adaptation to a high-salt diet.[550–552]

NO is released in response to administration of the vasoconstrictor agents norepinephrine, angiotensin II, and vasopressin.[420,424,458,459,553,554] Evidence also favors an important role for NO to abrogate tissue hypoxia that would otherwise arise from the action of vasoconstrictors. Low dose, subpressor infusion of L-NAME into the renal interstitium does not affect MBF or pO_2, but enables otherwise ineffective doses of angiotensin II,[459] norepinephrine[553,554] or vasopressin[424,555] to reduce those parameters. Reduced expression of NOS isoforms and NO generation in the Dahl rat may contribute to its sensitivity to angiotensin II and hypertension.[458] In the absence of NOS blockade, constrictors enhance medullary NO levels, implying that a reflex increase in medullary NO probably serves to protect the hypoxic medulla from ischemia. NO generation has

also been found to protect the medulla from the blood flow redistribution induced by endotoxemic hypotension[556,557] and radiocontrast agents.[558]

Given that NO has both vasodilatory and saliuretic effects and is widely synthesized by nephrons and endothelium, attention has been drawn to possible tubulovascular interactions. NO generated by the medullary thick ascending limb has been proposed to influence DVR tone to mitigate medullary hypoperfusion and hypoxia.[269,382,394,395,450,559,560] NO generation by DVR is highly perfusion-dependent,[393] and NOS inhibition constricts *in vitro* perfused DVR, implying a substantial tonic role for intrinsic endothelial NO generation to modify DVR function.[425] The bioavailability and actions of NO are predicted to be under the influence of opposing generation of reactive oxygen species.[471,561] Mathematical simulations of NO and superoxide trafficking in the medulla favor a role for DVR endothelial NO generation to influence tissue NO levels,[469,470] leading to the consideration that DVR might influence salt reabsorption by adjacent nephrons. The latter might mechanistically link medullary perfusion and pressure natriuresis.[393] Stated another way, hemoglobin in outer medullary vascular bundles degrades NO so that NO from transporting epithelia and DVR endothelium must generate gradients directed toward the vascular bundle centers. Accordingly, elevation of NO outside vascular bundles in the vicinity of nephrons is likely to arise from both epithelial and endothelial NO generation.

Reactive Oxygen Species

Oxygen free radicals are generated by one and two electron reductions of O_2 that generate superoxide (O_2^-) and hydrogen peroxide (H_2O_2). In turn, reactions of those species yield hypochlorous acid and hydroxyl radical (OH). Reaction of NO with O_2^- forms peroxynitrite ($ONOO^-$), reducing the availability of NO to act as a vasodilator. Oxygen-derived radicals are collectively referred to as "reactive oxygen species" (ROS). ROS can be generated through many pathways. Autooxidation of cysteine can generate O_2^- and H_2O_2. Oxygen utilizing enzymes such as cyclooxygenase, lipoxygenase, epoxygenase, and xanthine oxidase can generate ROS. When oxidative stress reduces the ratio of the NOS co-factor tetrahydrobiopterin (BH_4) relative to dihydrobiopterin (BH_2), NOS produces O_2^- rather than NO. It is generally accepted that the dominant source of ROS for bacterocidal activity in leukocytes and signaling in other cells is NADPH oxidase. NADPH oxidase consists of cytosolic components ($p47^{phox}$, $p67^{phox}$), a G-protein (Rac1 or Rac2), and membrane-associated cytochrome b_{558} comprised of $p22^{phox}$ and $gp91^{phox}$. In nonphagocytic cells, the $gp91^{phox}$-subunit may be substituted by another isoform, such as RENOX/NOX4.[400] Antioxidant systems exist within all cells. Superoxide dismutase (SOD) catalyzes the conversion of O_2^- to H_2O_2 which is then converted to water by catalase. Extracellular, cytoplasmic (Cu/ZnSOD), and mitochondrial (MnSOD) forms of SOD participate in the control of oxidative stress. Endogenous free radical scavengers also serve to limit the potential for oxidative damage to cellular macromolecules.[562]

Tissue NO levels are modulated through reaction with ROS. Generation of oxygen free radicals is known to affect agonist-induced constriction of renal microvessels in cortex and medulla,[563–565] and play a prominent role in hypertension.[516,566] The cell permeant superoxide dismutase (SOD) mimetic, tempol, prevents afferent arteriolar constriction by the TxA_2/prostaglandin H_2 (TP) receptor agonist U-46,619.[567] Similarly, tempol increased detection of NO in bradykinin stimulated DVR and vasodilated DVR preconstricted with angiotensin II.[560] Zhang et al. found that ROS are generated upon stimulation of DVR with angiotensin II and protein kinase C agonists, and angiotensin II-stimulated ROS generation was enhanced when AT2 receptors were blocked with PD123,319.[451] The role of ROS in the mediation of vasoconstriction probably varies with the vasoactive stimulus.[568] Studies of ROS generation by the medullary thick ascending limb show that reactions with superoxide from the mTAL might limit NO delivery and vasodilation of vascular bundle DVR.[394,569,570]

Intrarenal generation of ROS plays a role in vasoactivity and generation of hypertension.[506,515,566,571,572] Blood pressure elevation in the SHR is associated with enhanced urinary excretion of the ROS marker, 8-iso prostaglandin F2α. Both hypertension and 8-Iso PGF2α excretion are blunted by the superoxide dismutase (SOD) mimetic, tempol. Infusion of L-NAME eliminates the antihypertensive effect of tempol, implying that reduction of NO availability through reaction with O_2^- partially underlies the genesis of SHR hypertension.[573,574] Slow pressor hypertension due to chronic infusion of angiotensin II is also associated with an increase in cortical ROS generation,[575] but the medulla may be spared in that model.[576] Intrarenal oxygen tension and the efficiency of renal oxygen utilization are low in rodent models of hypertension, suggesting a shunt of oxygen toward formation of ROS.[577–579]

Enhancement of renal medullary ROS generation occurs in hypertensive models and intramedullary infusion of the SOD inhibitor, diethylthiocarbamate, reduces medullary blood flow and raises arterial blood pressure.[580–582] Conversely, infusion of the SOD mimetic, tempol, increases medullary blood flow and

sodium excretion, an effect that is enhanced when H_2O_2 is eliminated with catalase.[580,581,583] A role for renal medullary generation of ROS was reinforced by Meng et al. who showed that hypertension of Dahl salt-sensitive rats is accompanied by reduced expression of Cu/Zn SOD and Mn SOD in the medulla.[584] In contrast to those findings, slow pressor hypertension generated by chronic angiotensin II infusion failed to increase ROS generation by isolated DVR.[576] Instead, angiotensin II hypertension was accompanied by increased DVR generation of NO, a finding that agrees with earlier reports by Zou and Cowley.[382,459] It is possible that ROS production by medullary nephrons contributes to angiotensin II, slow pressor hypertension. NO is an endogenous diuretic, and its consumption by ROS could favor hypertension.[550,551] Enhanced generation of ROS may also play a role in enhancing arteriolar constriction in diabetes.[316,585–589]

Carbon Monoxide and Hemoxygenase

Hemoxygenases-1 and -2 (HO-1, HO-2) are microsomal enzymes that degrade heme to form carbon monoxide (CO) and biliverdin. CO, like NO, induces vasodilation via cGMP generation, while biliverdin is converted to bilirubin by biliverdin reductase. Bilirubin is a highly effective free radical scavenger and inhibits ROS generation via NADPH oxidase and protein kinase C.[590] Constitutive expression of HO isoforms in the kidney predominate in the medulla[591] under transcriptional control of oxygen and superoxide anion. Hypoxia inducible factor α1,[592,593] urea concentration, and medullary hypertonicity[594] all influence HO expression. HO inhibition with zinc deuteroporphyrin 2,4-bis glycol via the renal interstitium reduces medullary blood flow and cGMP content.[591] Treatment with cobalt protoporphyrin upregulates HO-1, reduces intrarenal levels of 20-HETE, and ameliorates SHR hypertension.[595] Exacerbation and protection of the kidney from ischemic injury can be accomplished by inhibiting or upregulating HO-1.[596] Acute HO inhibition blunts pressure natriuresis, and chronic inhibition raises blood pressure.[597–599] HO pre-induction blocks slow-pressor angiotensin II-induced hypertension.[600,601] Inducing HO also minimizes radiocontrast injury.[602,603] The protean and beneficial effects of HO upregulation have attracted considerable attention, pointing to a potential target for therapeutic intervention.[590,604]

Adenosine and P1 Purinoceptors

Adenosine acts via A1, $A2_A$, $A2_B$, and A3 receptors (P_1 purinoceptors). In the kidney, A1 and A2 receptors predominate, $A2_A$ are primarily vascular, and A3 may be absent.[605,606] Through its action, adenosine modulates vasoactivity and epithelial transport.[605,607–610] Acting via the P2X1 receptor, adenosine may be a primary mediator of renal autoregulation.[611] The microvascular effects of adenosine vary with intrarenal location.[612] Adenosine A1 receptor activation transiently reduces cortical and medullary blood flow, and constricts afferent arterioles.[613–615] When afferent A1 receptors are blocked, however, A2 mediated vasodilation can be elicited.[616] The effects of adenosine in the efferent arteriole may be primarily vasodilatory.[153,617,618] Afferent constriction by adenosine is of particular importance, because evidence supports it as a key mediator of tubuloglomerular feedback (TGF).[619–624] ATP release from macula densa cells via maxi-anion channels followed by ecto-5′-nucleotidase-mediated hydrolysis are the likely steps in its formation.[366–368,370,625] A role for adenosine to act on both afferent and efferent arterioles has been proposed as integral to the TGF response.[153,626] Adenosine constriction of the afferent arteriole is complex, because proximal portions away from the glomerulus may be regulated by both A2-mediated dilatory and A1-mediated contractile interactions. In contrast, the afferent arteriole near the glomerlar hilus may lack A2 receptors, so that it constricts as adenosine concentration is increased.[264,607]

Adenosine A2 receptor stimulation leads to preferential vasodilation, saliuresis, and enhanced perfusion of the medulla[612,613,627](Figure 24.26). Both A1 and A2 receptors are expressed by DVR,[628] and their respective stimulation induces constriction or dilation.[396] Interstitial adenosine concentrations are near the affinity for the A2 receptor, so that changes should modulate vasodilatory and saliuretic effects.[629] In preglomerular vessels, A1-induced constriction is mediated by pertussis toxin sensitive G_i-protein and phospholipase C activation.[630] A2-mediated dilation has been traced to activation of K_{ATP} channels,[313] probably activated through 11,12-epoxyeicosatrienoic acid.[631]

Evidence for and against synergism between angiotensin II and adenosine exists.[197,625] Several studies have favored the interdependence of adenosine A1 receptor- and angiotensin II AT1 receptor-mediated constriction,[632–636] while others have not.[614,637,638] The availability of adenosine A1 and angiotensin II $AT1_A$ receptor-deficient mice have permitted re-examination of the issue. Infusion of angiotensin II led to less reduction of renal blood flow and less constriction of afferent arterioles in A1 knockout mice.[197] Similarly, favoring synergism, intranephron infusion of an adenosine A1 agonist induced greater reduction of stop-flow pressure (reflecting afferent constriction) in wild-type than in angiotensin II $AT1_A$ receptor-deficient mice.[639]

A consequence of countercurrent exchange is that renal medullary oxygen tensions (pO_2) are low[640]

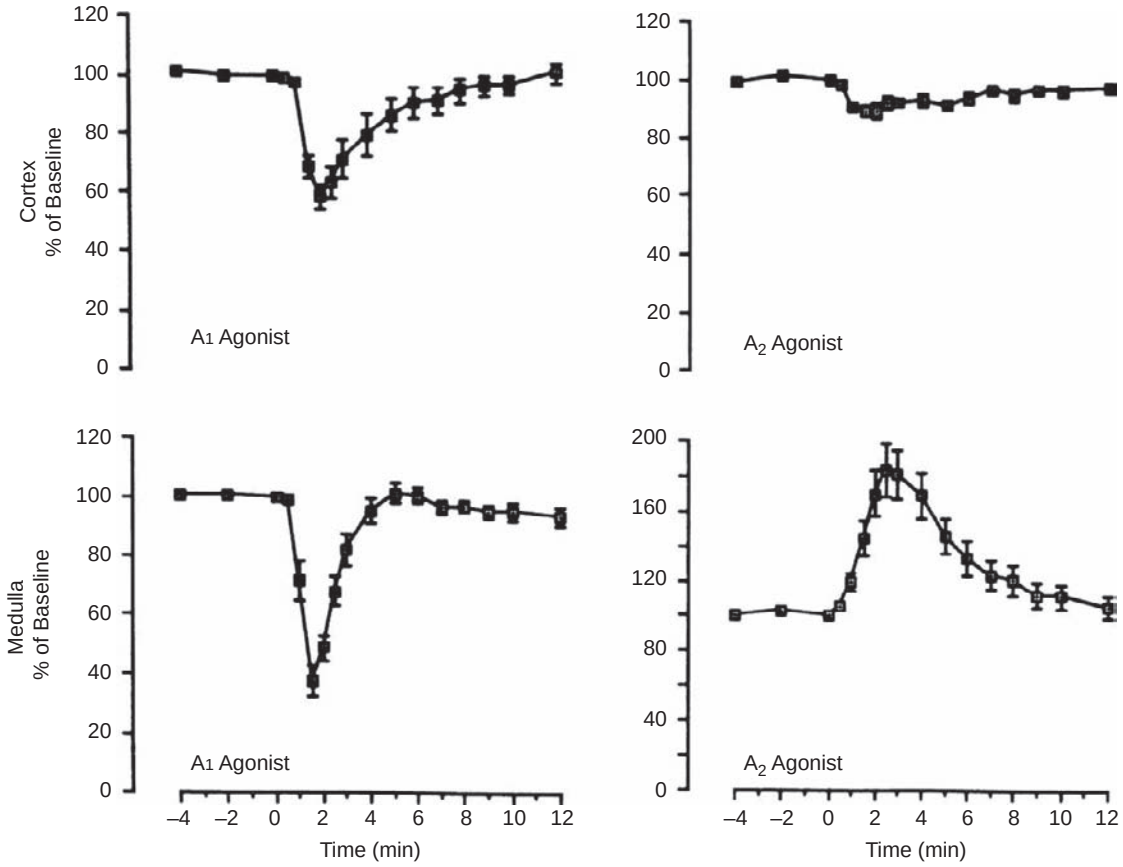

FIGURE 24.26 **Effect of intrarenal infusion of adenosine receptor A1 or A2 subtype agonists.** Top and bottom panels show the effect of adenosine agonist infusions on intrarenal blood flow. Cortical and medullary measurements were obtained using laser-Doppler flowmetry with optical fibers placed on the kidney surface or inserted into the renal parenchyma, respectively. Left and right panels show the respective effects of either A1 or A2 receptor stimulation with subtype specific agonists. At time = 0, the A1 agonist N^6-cyclopentyladenosine (left panels) or the A2 agonist CGS-21680C (right panels) were transiently infused (1 minute) into the renal parenchyma. The A1 agonist transiently reduced both cortical and medullary blood flow, while the A2 agonist caused a preferential increase in blood flow to the medulla. *(Reproduced with permission from ref. [613,465]).*

(Figure 24.27). During hypoxia, the medullary thick ascending limb of Henle (mTAL) synthesizes adenosine.[641] That finding, coupled with the close proximity of the mTAL to outer medullary vascular bundles, led to the hypothesis that adenosine, like NO and prostaglandins (see above), acts as a paracrine vasodilator to preserve medullary perfusion, raising medullary pO_2.[642] Inhibition of mTAL transport by adenosine A2 receptor activation, like the effects of furosemide, probably raises medullary pO_2 by reducing O_2 consumption.[642,643] Rats fed a high-salt diet increase tissue adenosine levels and downregulate A1 receptor expression, the activation of which encourages sodium reabsorption.[644]

Extracellular ATP and Renal P_2 Purinoceptors

In addition to the actions of adenosine mediated by P1 purinoceptors (A1, A2 adenosine receptors), micromolar concentrations of ATP modulate vasoactivity through P2 purinoceptors.[611,625,638,645–647] P2 receptors are subdivided into P2X and P2Y families, encoded by separate genes, that yield either ligand-gated nonselective cation channels or seven transmembrane spanning G-protein coupled receptors, respectively. Unlike adenosine receptors, P2 receptors seem confined to the preglomerular microcirculation.[648–650] P2 antagonists such as suramin are somewhat nonselective, however α,β-methylene-ATP and β,γ-methylene-ATP are relatively selective agonists for P2X receptors. UTP largely stimulates P2Y.[638,648,651,652] The experimental effects of ATP on the vasculature are variable, depending upon luminal versus abluminal application, the preparation, and species.[651] Both constrictor and dilator effects can be observed. Intrarenal infusion of α,β-methylene-ATP leads to constriction, but ATP (mixed P2X, P2Y agonist) and UTP (selective P2Y agonist) yield NO dependent dilation at low concentrations or constriction at high

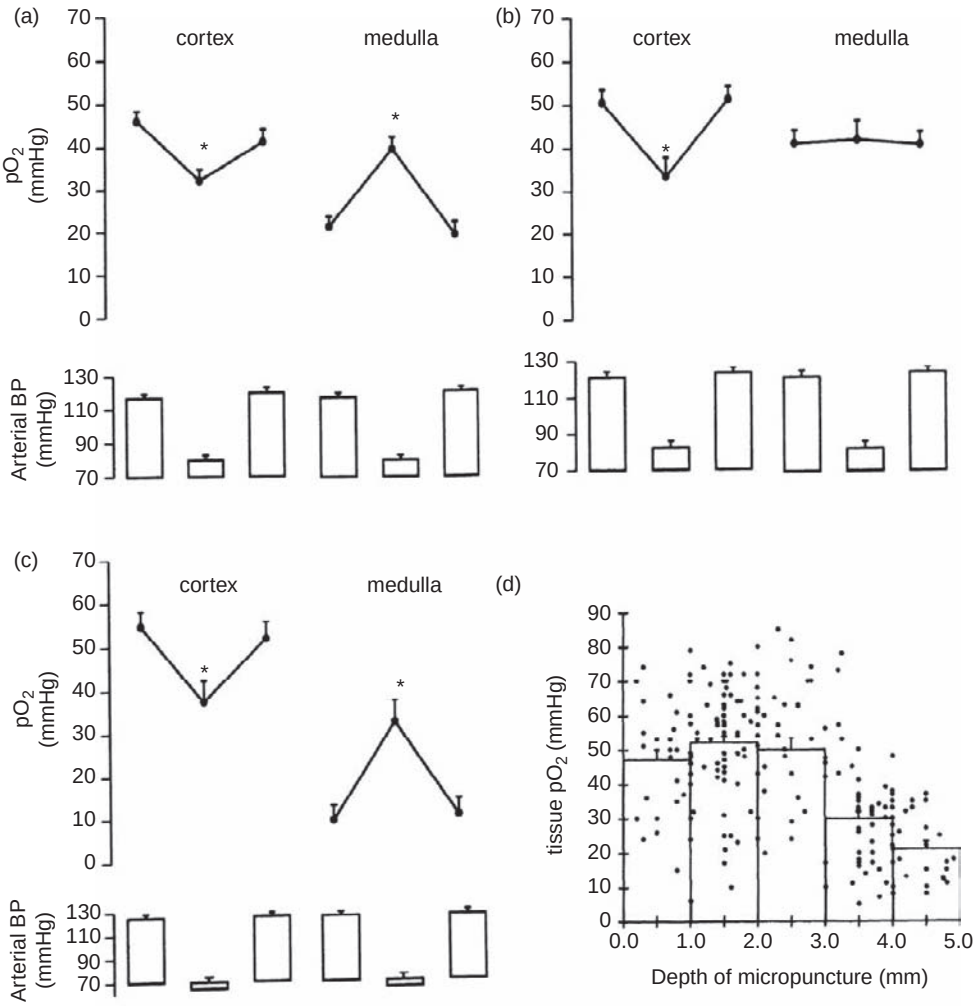

FIGURE 24.27 **Hemodynamic effects on intrarenal oxygenation.** Intrarenal oxygen tension (pO_2) was measured in the cortex and medulla with a microelectrode. Cortical pO_2 falls and medullary pO_2 increases during an episode of hypotension induced by hemorrhage, aortic ligation or nitroprusside infusion (Panel a). Inhibition of transport in the thick ascending limb of Henle with a loop diuretic (Panel b) increases basal pO_2 in the medulla (compare to Panel a), and eliminates the effect of hypotension to raise medullary pO_2. Inhibition of vasodilatory prostaglandins and nitric oxide or blockade of adenosine receptors reduces basal pO_2 in the medulla and accentuates the increase in pO_2 caused by hypotension (Panel c). Intrarenal tissue pO_2 decreases with medullary depth (Panel d). *(Reproduced with permission from ref. [643,791]).*

concentrations.[653] Exposure of preconstricted afferent arterioles of rabbit and human kidneys to ATP leads to dilation via NO generation.[647,651,654] In the juxtamedullary nephron preparation of the rat, activation of P2X leads to afferent but not efferent constriction that is dependent upon generation of 20-HETE and Ca^{2+} influx involving L-type Ca^{2+} channel blockade.[655–658] Stimulation of P2Y receptors yields sustained constriction that is independent of 20-HETE, and dependent upon Ca^{2+} release from cellular stores.[213,659,660]

Of great importance, myogenic autoregulatory constriction of afferent arterioles has been traced to activation of P2 receptors (Figure 24.28). In the juxtamedullary nephron preparation, prior desensitization or nonspecific blockade of P2 receptors attenuated pressure-induced afferent constriction.[661] Similarly, infusion of excess ATP into the dog kidney during NO sythase blockade eliminated autoregulatory constriction.[662,663] Finally, P2X1 receptor-deficient mice were shown to retain tubuloglomerular feedback responses, but to lack autoregulatory adjustments to changes in perfusion pressure.[611,645,664] Pharmacological blockade of P2X1 receptors eliminates renal whole-organ autoregulation in the rat.[611]

Arachidonic Acid Metabolites

Once liberated from the membrane by phospholipases, arachidonic acid undergoes metabolism to a very large array of metabolites that function as paracrine, autocrine, and intracellular signaling molecules (Figure 24.29). These metabolites have profound effects

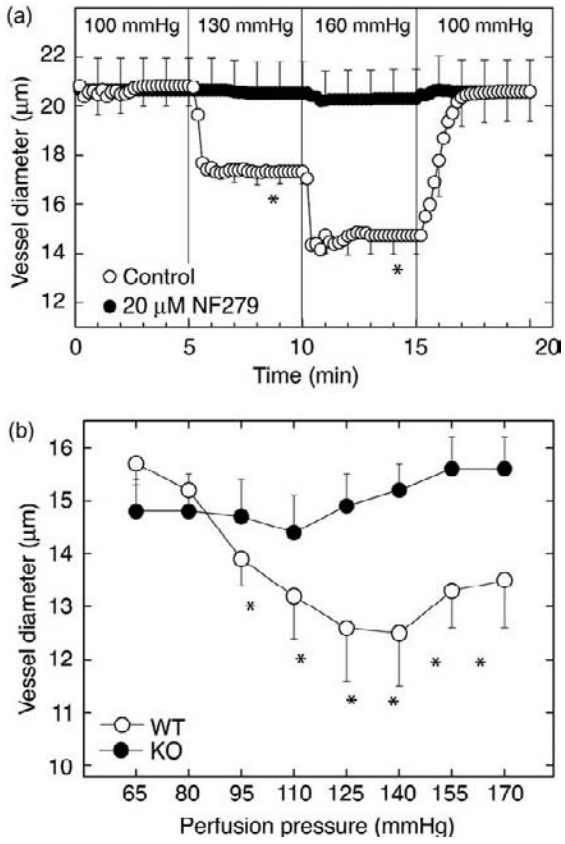

FIGURE 24.28 **Autoregulation and purinoceptors.** (a) Panel shows the effect of a P2X receptor blocker (NF279) on autoregulatory afferent arteriolar constriction resulting from step-changes in perfusion pressure from 100 to 120 and 160 mmHg. P2X blockade eliminates the afferent myogenic response associated with autoregulation. (b) Summary of the changes in murine afferent arteriolar diameter elicited by graded change of perfusion pressure. Autoregulatory vasoconstriction occurs in wild-type (WT) but not $P2X_1$ receptor-null mice. Data obtained using the juxtamedullary nephron preparation. *(Reproduced with permission from ref. [664]).*

on vascular tone, as well as on solute and water excretion. Three generalized pathways are recognized, cyclo-oxygenases (COX) that generate prostaglandins (PG) and thromboxanes (TBX), lipoxygenases that generate leukotrienes (LT) and hydroxyeicosatetraenoic acids (HETE), and cytochrome P450 pathways that synthesize HETEs and epoxyeicosatrienoic acids (EET).

Prostaglandins

Prostaglandins (PGs) are generated from arachidonic acid by cyclooxygenase (COX) (Figure 24.29a) and exert wide effects on solute reabsorption, tubuloglomerular feedback, and intrarenal hemodynamics. When injected into the renal artery, PGE_2 and PGI_2 enhance renal blood flow.[665] Early efforts showed that stimulation of PG synthesis redistributes blood flow toward the juxtamedullary cortex.[666,667] A consistent finding has been that renal medullary perfusion is protected from vasoconstrictors by NO (see above) and PGs.[668,669] Nonselective COX blockade decreased vasa recta blood flow,[670] and augmented the ability of angiotensin II infusion to decrease single vessel blood flow in the exposed papilla.[428] Laser-Doppler studies indicate that COX blockade reduces medullary blood flow with relative sparing of cortical perfusion.[671–674] Radiocontrast agents can lower cortical and medullary oxygen content, predisposing to hypoxic insult. Indomethacin potentiates medullary hypoxia and the parenchymal damage induced by either radiocontrast agents or ureteral excision.[675–677]

COX-1 and COX-2 isoforms contribute to renal PG synthesis. Of the two, COX-1 is expressed to a greater extent, while COX-2 is more highly regulated.[678–682] In a manner that predicts the effects of its inhibition, COX-2 expression is pronounced in macula densa.[678] Release of renin by juxtaglomerular cells and release of PGE_2 by the macula densa is COX-2-dependent.[683–685] In the macula densa, COX-2 is co-expressed with NOS1. Simultaneous inhibition of COX-2 and NOS in the dog markedly enhances sensitivity to vasoconstriction. Norepinephrine infusion, which otherwise has minor effects, induces a remarkable rise in renal vascular resistance and sharp reduction of GFR.[686] COX-2 blockade blunts adaptation of tubuloglomerular feedback[687] and augments afferent constriction associated with benzolamide inhibition of proximal transport.[688] Renomedullary interstitial cells express receptors for vasoconstrictors, release paracrine substances such as PGE_2 and medullipin, and express both COX-1 and COX-2.[41,678] Zhang et al. showed that COX-2 expression is stimulated by medullary tonicity.[689] Genetic deficiency of COX-2 or its inhibition leads to reduction of medullary perfusion, salt-sensitive hypertension, and enhanced response to infusion of angiotensin II.[690–694]

In isolated vessels, Edwards first showed that prostaglandins dilate *in vitro* perfused rabbit afferent (PGE_2 and PGI_2) and efferent (PGI_2) arterioles.[695] In contrast, Inscho et al. found that PGE_2 enhanced angiotensin II and norepinephrine constriction of the afferent arteriole, while PGI_2 counteracted their effects.[696] In rabbit afferent arterioles, indomethacin enhanced vasoconstriction when perfusate passed through the glomerulus, but not during retrograde perfusion, implying that glomerular PGs influence efferent vasoactivity.[697] Abluminal PGE_2 blunts angiotensin II-induced constriction of DVR.[198,397] Few studies of the effects of selective COX-2 inhibition in isolated vessel preparations are available. Wang et al. determined that augmented constriction of afferent arterioles during slow pressor angiotensin II hypertension is partially mediated by a COX-2 product from the endothelium.[698] PGE_2 is very abundant in the kidney, and its local actions are governed by the receptor subtype activated.

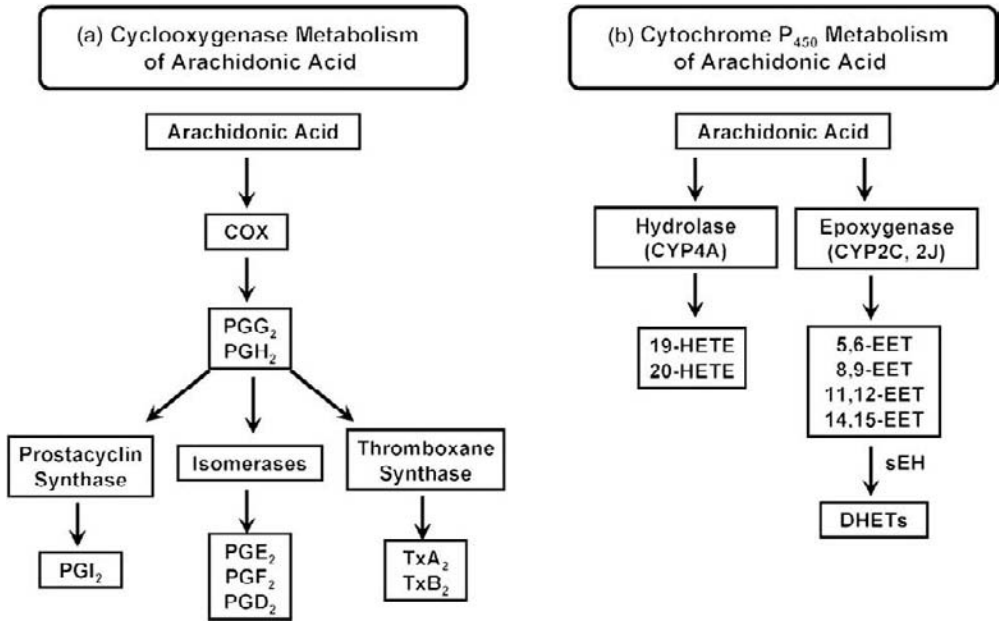

FIGURE 24.29 **Arachidonic acid metabolites.** (a) Abbreviated schematic showing signaling molecules generated from arachadonic acid by cyclo-oxygenase (COX). Prostaglandins (PG) and thromboxanes (Tx) are vasoactive end products. (b) Abbreviated schematic showing signaling molecules generated cytochrome P450 metabolism of arachidonic acid (COX). Hydrolases generate the potent constrictor 20-hydroxyeicosatetraenoic acid (20-HETE), and epoxygenases generate the epoxyeicosatrienoic acids (EETs) that most often function as vasodilators. The lipoxygenase pathway of arachidonic acid metabolism is not shown.

For example, stimulation of the EP3 receptor inhibits cAMP formation, favoring vasoconstriction, while stimulation of EP2 and EP4 receptors increases cAMP, favoring vasodilation.[297] The ability of PGE_2 to act as a vasoconstrictor has also been observed,[696] and EP3 receptor deficiency leads to reduction of renal vascular resistance.[297,699]

COX products can be metabolized by thromboxane synthase to stimulate the thromboxane/PGH_2 receptor and induce vasoconstriction. In the afferent arteriole and DVR, angiotensin II-induced constriction is reduced by TP receptor blockade, inhibition of COX with indomethacin or inhibition of thromboxane synthesis.[440,700–702] Thromboxane-mediated constriction may be exaggerated during angiotensin II slow pressor hypertension, due to enhanced sythesis of reactive oxygen species.[698,703]

Cytochrome P450 Metabolites of Arachadonic Acid

Vasoactive products of arachidonic acid are generated by cytochrome P450 (CYP) isoforms (Figure 24.29B) in the form of epoxyeicosatrienoic acids (EETs), the hydroxyeicosatetraenoic acids (HETEs) and their products, dihydroxyeicosatetraneoic acids (DHETs).[704] More than 400 CYP isoforms are recognized in various species. Those that have >40% homology are classified by an Arabic numeral and those with >55% homology by a capital letter. CYP monooxygenases metabolize arachadonic acid to 19- and 20-HETE (ω/ω-1 hyroxylase) and to 5,6-, 8,9-, 11,12-, and 14,15-EETs (epoxygenases). For the purposes of focusing on the microvasculature of the kidney, it is important to recognize that CYP2C and CYC2J isoforms are largely responsible for synthesis of EETs, and CYP4A isoforms for synthesis of the HETEs. This topic has been frequently reviewed.[280,291,704–714]

The 20 ω-hydroxylation product, 20-HETE, is a potent vasoconstrictor the synthesis of which is rate-limited by O_2.[715,716] 20-HETE depolarizes and increases $[Ca^{2+}]_{CYT}$ in smooth muscle[290] and mediates constriction by angiotensin II,[436,717] endothelin-1,[708,718] and ATP via P2X stimulation.[658] 20-HETE plays an important role in blood flow autoregulation of the cerebral and renal microcirculations.[704,719] 20-HETE inhibits K_{Ca} channel activity[292–294,299,713,716] through the actions of tyrosine and MAP kinases.[293] It is generally recognized that NO inhibits vascular smooth muscle contraction through cGMP formation. Roman and colleagues have shown that the majority of NO effects in the kidney involve inhibition of CYP4A and reduction of 20-HETE synthesis.[300,720] 20 ω-Hydroxylation products play a role in blood pressure regulation, and blockade of 20-HETE synthesis interferes with pressure natriuresis.[721] Chronic inhibition of 20-HETE synthesis induces salt-sensitive hypertension in the rat,[722,723] and exacerbates ischemia reperfusion injury.[711] Similarly, disruption of murine CYP4A14 leads to hypertension, and a variant of the CYP4A11 homolog in humans has been associated with essential hypertension.[724–726]

The EET epoxygenase metabolite arachidonic acid has several important roles in the renal microcirculation. In addition, EETs have been broadly identified as endothelium-dependent hyperpolarizing factors (EDHF).[97,278] The EETs are largely vasodilatory, but some of their metabolites can induce COX-dependent vasoconstriction.[297,727,728] Stimulation of preglomerular arteriolar $A2_A$ adenosine receptors leads to enhanced synthesis of EETs and vasodilation.[631] Similarly, angiotensin II dilation via AT2 receptor stimulation has been traced to these epoxygenase products.[436,446] Afferent vasodilation by 11,12-EET is partially mediated by PKA.[729] In contrast to inhibition by 20-HETE, 11,12-EET and 5,6-EET are associated with K_{Ca} channel activation.[292,295,713,730–732]

The ability to activate large conductance K_{Ca} channels may be tied to the role of 11,12-EET as an EDHF. Putative EDHFs are agents that elevate endothelial $[Ca^{2+}]_{CYT}$, hyperpolarize endothelium and smooth muscle and vasodilate, independent of NO and COX. Work in this area has failed to identify a single EDHF, but much evidence points to a role for EET formation and K_{Ca} channel activation in the endothelium. Adjacent smooth muscle hyperpolarization may be tied to diffusion of secondary signaling molecules or electrogenic spread of current from the endothelium via myoendothelial gap junctions.[279,280] It might also be tied to release of K^+ ion into the myoendothelial intercellular space via EET-stimulated endothelial K_{Ca} channels, resulting in hyperpolarization via activation of smooth muscle K_{IR} or Na^+,K^+-ATPase.[97,278] In the kidney, evidence points to a role for afferent arteriolar EET formation in the EDHF related actions of bradykinin[733] and acetylcholine.[298] Evidence for K_{IR} expression in afferent smooth muscle has been provided.[304,305] Reduction of vasodilatory EET formation may accompany hypertension. Imig et al. showed that enhanced afferent constriction during slow pressor angiotensin II hypertension is reversed by an 11,12-EET analog, and that reduction of EET degradation through soluble epoxide hydrolase inhibition reverses angiotensin II hypertension.[734,735] Lack of ability to upregulate CYP2C and CYP2J isoforms of P450 might underlie the abnormality.[736] Similarly, it has been found that enhancement of EET through inhibition of soluble epoxide hydrolase reverses hypertension, and protects the kidney from damage.[694,706,707,737,738]

Endothelins

Endothelins are 21 amino acid vasoactive peptides synthesized by a variety of cell types in the kidney. Three ETs have been identified (ET1, ET2, ET3). These agents are autocrine/paracrine hormones derived from ~200 amino acid preproendothelins that undergo successive proteolytic cleavage to form large (Big ET) intermediates that are processed by endothelin-converting enzymes. ETs stimulate ETA and ETB receptors on smooth muscle to induce potent vasoconstriction. Endothelia express ETB receptors, stimulation of which leads to synthesis of NO. In addition to their vascular actions, ETs have an important role to inhibit sodium reabsorption through inhibition of transport by NO and downregulation of the epithelial Na^+ of the collecting duct.[739–742] Renal ET receptors have been identified on collecting ducts, vascular bundles, and RMIC.[743–745]

The highest concentrations of ET1 occur in the renal medulla where it is synthesized by collecting duct and other cells.[746,747] ET1 is a potent vasoconstrictor and reduces overall renal blood flow via combined ETA and ETB stimulation. Isolated ETB receptor stimulation, however, can have net vasodilatory effects.[748] In the renal cortex, ET1 constricts afferent and efferent arterioles, arcuate and interlobular arteries.[2,749–754] Afferent constriction by ET1 partially depends upon voltage-gated Ca^{2+} entry, is modulated by endothelial generation of NO,[195,755] and is mediated by 20-HETE and COX products.[708,718] Preglomerular smooth muscle cells show biphasic $[Ca^{2+}]_{CYT}$ responses to ETA agonists, but small or absent responses to ETB agonists.[756–758] Isolated DVR from the outer medulla are intensely constricted by low concentrations of endothelins.[27,269,397]

The actions of ETB stimulation in the medulla favor natriuresis and vasodilation, at least partially by activating NO generation through NOS1.[743,759,760] Bolus injection of ET1 (a mixed ETA and ETB receptor agonist) selectively reduced cortical blood flow while transiently increasing medullary blood flow. Medullary vasodilation and saliuresis is abrogated by blocking ETB receptors or synthesis of NO.[423,752,753,761,762] The effects on medullary blood flow may vary with dietary salt intake.[763] ETB receptor deficient "spotted lethal" rats have been identified that have been rescued from lethal abnormalities by selective ETB gene replacement into ganglionic cells of the intestine. Those rats have salt-sensitive hypertension.[764,765] Injection of Big ET1 into ETB receptor-deficient rats or wild-type rats in which ETB receptor has been blocked fails to elicit saliuresis.[753,766] Chronic angiotensin II infusion, combined with salt-loading, increases cortical and medullary immunoreactive ET.[767,768] Reduction of endothelin-induced saliuresis may play a role in human and rodent models of hypertension.[740,767,769–771] ETs might play a significant roles in other pathological states.[743,747,772]

Natriuretic Peptides

The diuretic effect of injection of extracts of atrial tissue extracts into rats led to the discovery of atrial

(ANP), brain (BNP), and C natriuretic peptides (CNP). Each is derived by proteolytic cleavage of different gene products. They act through stimulation of guanylyl cyclase A (GC-A) (ANP, BNP ligands), GC-B type (CNP ligand), and GC-C receptors. GC-C may play a role in peptide clearance and inhibition. Deletion of ANP or its receptor leads to hypertension, while overexpression results in hypotension.[773] In the kidney, expression and alternate processing of ANP prohormone yields urodilatin.[774,775] Studies showed that that ANP infusions increased renal blood flow, glomerular filtration rate, papillary plasma flow, and sodium excretion. Diuresis and natriuresis, however, begin before the increase in medullary blood flow, so that medullary dilation is not required for the natriuretic effect.[776–779] Examination of the vasoactive effects of natriuretic peptides generally uncovered dilation of preglomerular vasculature.[780–783] Edwards and Weidley found no effect of ANP on *in vitro* perfused rabbit afferent or efferent arterioles.[784] In the efferent arteriole, either a lack of effect[783,784] or constriction[785] was reported, while urodilatin mediated vasodilation.[786] Vasodilatory effects of ANP may be mediated through cGMP formation, activation of smooth muscle K_{Ca} channels, hyperpolarization and inhibition of Ca^{2+} signaling.[320,332] Natriuresis from an oral salt load is more brisk than that from an intravenous route, a finding that may be related to intestinal release of guanylin and uroguanylin, peptide hormones that activate ANP receptors. Like ANP, these agents inhibit tubuloglomerular feedback, but their specific effects on renal arterioles have not been reported.[787,788] Trials of ANP as a renoprotective agent have yielded inconclusive results.[789]

OVERVIEW

In the course of its development, the mammalian kidney goes through three distinct forms: the pronephros; the mesonephros; and the metanephros, ultimately leading to the formation of the mature kidney (Figure 25.1). At day 22 of gestation in humans or at day 8 in mice, an epithelial streak called the pronephric duct arises in the cervical region of the developing embryo from intermediate mesodermal cells induced to undergo the transition to epithelial cells in response to signals arising from the somite and surface ectoderm.[1–3] The pronephric duct then extends caudally to form the nephric duct or Wolffian duct. The most primitive kidney, the pronephros, is formed as the pronephric duct induces surrounding mesenchyme to form the pronephric tubules. Glomerulus-like structures (glomera) are also seen, but are not physically connected to the tubules forming a non-integrated nephron.[4] The pronephros is functional only in fish and amphibians; it is thought to be rudimentary and non-functional in higher vertebrates.

Next, a more complex "protokidney," the mesonephros, arises just caudal to the pronephros at day 24 in humans or day 9.5 in mice. As with the pronephros, mesonephric development starts with induction of the surrounding mesenchyme by the Wolffian duct. Unlike the pronephros, however, the mesonephros glomeruli are linked to the Wolffian duct via mesonephric tubules. In humans, about 30 nephrons are observed in the mesonephros; their function is unclear. The mesonephric duct and some tubules persist, and are ultimately integrated into the male genital system forming, in part, the vas deferens and tubules of the epididymis.[5] In females, the mesonephros degenerates and disappears.

The permanent kidney of amniotes, the metanephros, starts to form at day 28 in humans or day 11 in mice. Unlike the pronephros and mesonephros, which are induced by the Wolffian duct, metanephric tubules are induced by an epithelial structure derived from the Wolffian duct: the ureteric bud. The ureteric bud is induced to evaginate from the Wolffian duct in response to signals arising from the metanephric mesenchyme, a loose aggregation of intermediate mesodermal cells.[6,7] The emergence of this epithelial progenitor tissue of the metanephric kidney is a key initiating event, and depends upon differentiation of the metanephric mesenchyme from the intermediate mesodermal cells.[8,9] As the ureteric bud invades the surrounding mesenchyme, it induces the mesenchymal cells to form epithelial metanephric tubules that eventually differentiate into the proximal through distal portions of the nephron. The ureteric bud, reciprocally induced by the metanephric mesenchyme, undergoes branching morphogenesis, eventually giving rise to the collecting system. Morphologically, nephron formation is completed by birth in humans, although only after birth does the nephron become fully functional.[7]

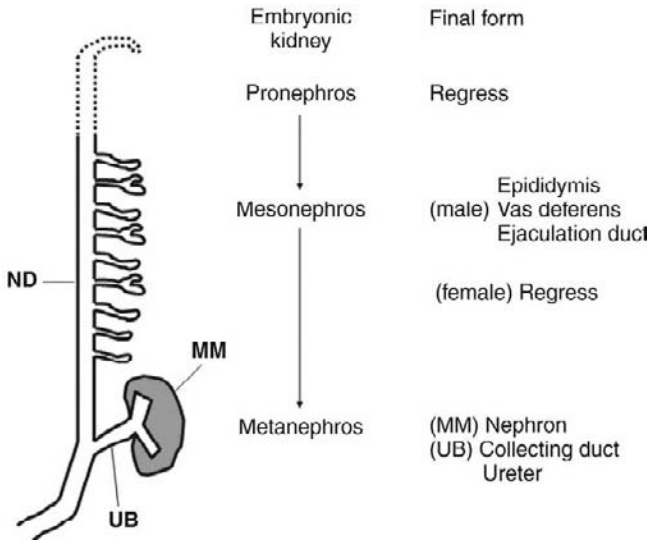

FIGURE 25.1 **Schematic illustration of mammalian kidney development.** The pronephros appears at a relatively higher position in the embryo. Then the mesonephros forms caudally around the nephric duct (ND) or Wolffian duct. In the male, the mesonephric tubules become a part of the genital system. The permanent kidney, the metanephros, forms caudally to the mesonephros. The ureteric bud (UB) derives from the Wolffian duct, ultimately becoming the collecting system. The metanephric mesenchyme, induced by the ureteric bud, forms nephron tubules and glomeruli.

DEVELOPMENT OF THE METANEPHROS

Here, the development of the metanephros is described in more detail (Figure 25.2), since it becomes the final kidney in mammals. As discussed in the previous section, the ureteric bud, the inducer of metanephric development, is formed from the Wolffian duct. This structure invades the metanephric mesenchyme, whereupon mesenchymal cells condense at the tip of the ureteric bud. The condensed mesenchymal cells then differentiate into epithelial cells: the so-called mesenchymal-to-epithelial transformation (MET). The newly formed epithelial cells gradually develop into distinct structures called "comma-shaped bodies," which subsequently become "S-shaped bodies." The S-shaped bodies, which begin to exhibit tubular morphology, continue to elongate; the end closest to the ureteric bud connects to it, while the opposite end forms podocytes and Bowman's capsule. The middle part ultimately differentiates into the proximal through distal tubules of the nephron. At the same time, the tips of the ureteric bud, induced by the metanephric mesenchyme, continue to branch to ultimately form the collecting ducts, renal pelvis, calyces, and papillae.

The process of collecting system development has been studied in detail by microdissection of the human kidney.[10,11] Initial ureteric bud branching is dichotomous and symmetric; the ureteric bud takes on a T-shape in this early stage of metanephrogenesis. Subsequently, the ureteric bud elongates and bifurcates at the tips, and eventually branches again dichotomously. At later branching events, the angle between branches lessens and branching may not be completely symmetrical, so that somehow the ureteric tree structure "fits" into the final shape of the kidney.[8] The initial branches become dilated to form the renal pelvis, while terminal branches become collecting

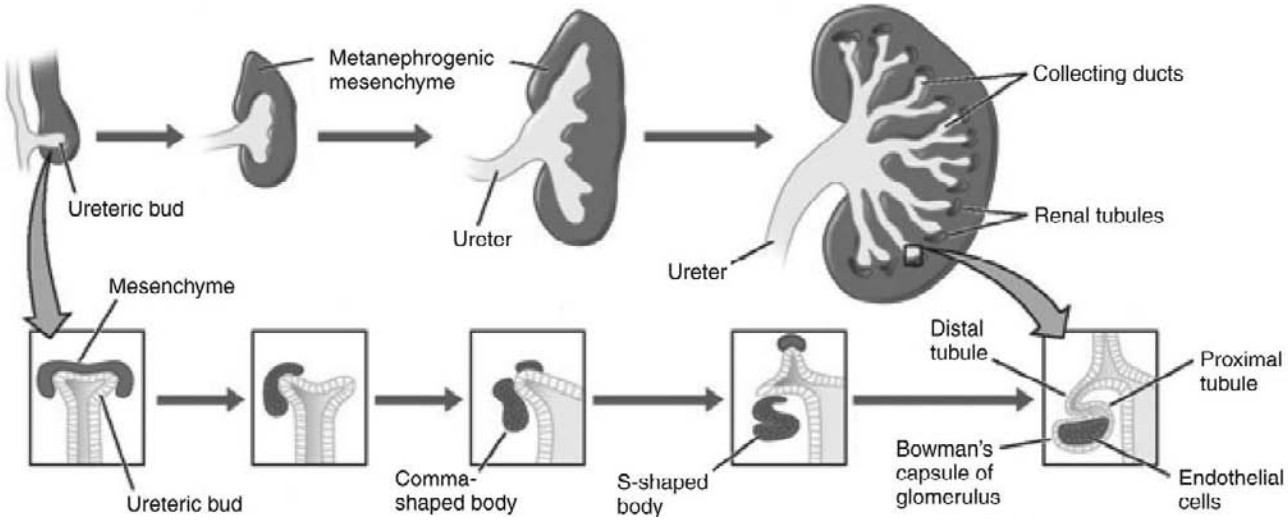

FIGURE 25.2 **Schematic illustration of metanephros development.** Top panels show a macroscopic view of kidney collecting system development through ureteric bud branching morphogenesis. Bottom panels show nephron development from metanephric mesenchyme. *adapted from ref. [82]).*

ducts. As the ureteric bud undergoes branching morphogenesis, its tips continue to induce more nephrons from the metanephric mesenchyme.

Vascular development occurs along with nephron development. Dissection of the developing kidney reveals that large vessels branch off from the dorsal aorta invading into the kidneys.[12] As will be discussed later, the extent to which the microvasculature of the kidney is derived from cells of the metanephric mesenchyme versus cells from outside the kidney is still unclear (reviewed in [13]). The origin of the mesangial cells, which closely associate with the endothelial cells in the glomerulus, also remains uncertain.

Thus, the reciprocal mutual induction and feedback between the ureteric bud and the metanephric mesenchyme represent key events in metanephric epithelial tissue development leading to a functional kidney. These reciprocal interactions induce branching morphogenesis of the ureteric bud, together with epithelialization and tubulogenesis of the metanephric mesenchyme (Figure 25.3). To better understand the mechanisms underlying induction, it is necessary to identify and analyze the key molecules that mediate signals between the metanephric mesenchyme and the ureteric bud.

EXPERIMENTAL APPROACHES TO KIDNEY DEVELOPMENT

Over the years, a variety of experimental approaches have been used for evaluation of the mechanistic details of the induction process between the ureteric bud and metanephric mesenchyme. For example, the developing kidney has been found to be amenable to extensive *in vitro* analysis. In addition to this "whole embryonic kidney organ culture," it has been demonstrated that progenitor tissues (i.e., Wolffian duct, ureteric bud, and metanephric mesenchyme) can be isolated and cultured individually. Advances in genetic manipulation have allowed the analysis of kidney development *in vivo* in genetically-engineered mice. As *in vitro* culture techniques and *in vivo* genetic manipulation become increasingly sophisticated, it is becoming clear that these approaches should be viewed as complementary.

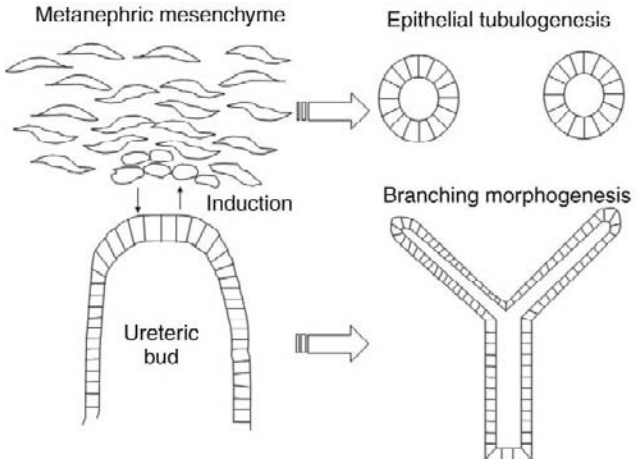

FIGURE 25.3 **Schematic illustrations of mutual induction.** The metanephric mesenchyme cells become epithelial nephron tubules (induced by the ureteric bud), while the ureteric bud undergoes branching morphogenesis to form the collecting system (induced by the metanephric mesenchyme).

Organ Culture

Whole Embryonic Kidney Organ Culture

The transfilter culture system, used by Grobstein and co-workers in the 1950s,[14–16] has been the mainstay of *in vitro* organ culture work in the developing kidney. In this system, microdissected kidneys, from as early as the beginning of metanephrogenesis (gestational day 11.5 in mice or day 13.5 in rats), are cultured on top of filters for several days. In the presence of appropriately defined serum-free medium, kidney rudiments grow and differentiate.[17] It is possible to observe branching morphogenesis of the ureteric bud, induction of the metanephric mesenchyme, and formation of nephrons by microscopy as the cultured embryonic kidneys develop (Figure 25.4a). Only vascular development does not occur to an appreciable extent. Thus, not only does the whole embryonic kidney culture resemble *in vivo* developmental processes, but it also appears to retain the inherent spatiotemporal complexity.

In this whole embryonic kidney culture, it is possible to manipulate humoral factors that play a role in nephrogenesis. The effects of growth factors or their inhibitors on kidney development can be evaluated *in vitro* by analysis of total kidney size, ureteric bud branching events, and metanephric mesenchyme tubulogenesis. For example, ureteric bud branching can be assayed by staining with a fluorescently-labeled lectin from *Dolichos biflorus*, which has been shown to bind specifically to the cells derived from the ureteric bud[18] (Figure 25.4b). However, the organ culture method is not without its limitations. For example, when antibodies and antisense oligonucleotides are used to perturb *in vitro* nephrogenesis, care must be taken to ensure that the agent is delivered to the sites of interest, since antisense oligonucleotides do not seem to penetrate the ureteric bud as well as the metanephric mesenchyme.[19] In addition, oligonucleotide toxicity may, in some instances, nonspecifically inhibit kidney growth.[19] However, recent development of RNAi technology to perturb specific gene function may prove useful in this setting.[20,21]

(b) Cultured kidney stained with fluorescent-labeled lectin from Dolichos biflorus to visualize ureteric bud-derived structures** (Bars: 100 μm). See color plate section at the end of the book.

Isolated Wolffian Duct Culture

It is possible to culture the entire mesonephros −metanephros area on top of transfilters. Addition of humoral factors can induce outgrowth of ureteric bud-like structures from the Wolffian duct.[22−26] For example, the addition of glial cell-derived neurotrophic factor (GDNF) induces numerous budding events at multiple foci along the length of the cultured Wolffian duct (Figure 25.5). The epithelial Wolffian ducts can also be dissected away from most of the non-epithelial mesoderm and cultured in the presence of soluble growth factors to induce the outgrowth of ureteric bud-like structures.[23−25,27−30] However, in this culture system GDNF alone is insufficient to induce the outgrowth of ureteric bud-like structures, and supplementation with other growth factors is required[23,24] (Figure 25.6). The Wolffian duct can also be cultured as a "naked" epithelial tube cleared of all surrounding mesodermal cells, although these isolated ducts must be cultured within a three-dimensional extracellular matrix.[25] The ureteric bud-like structures can be excised from the Wolffian duct and induced to branch in culture (Figure 25.7), indicating that the *in vitro* ureteric bud possesses the ability to branch and grow in a manner similar to that seen with the *in vivo* ureteric bud (see below). These *ex vivo* culture systems have proven useful in the elucidation of the mechanism of ureteric bud budding, and have allowed for the identification of multiple modulators/regulators (e.g., growth factors, signal transduction pathways, etc.) of this process.[23−25,27−30]

Isolated Ureteric Bud Culture

Since the 1950s, *in vitro* culture of the two individual components of metanephros, the ureteric bud and the metanephric mesenchyme, has been attempted. Of the two progenitor tissues, *in vitro* growth of the isolated ureteric bud proved to be more difficult, and it was argued that cell−cell contact between the ureteric bud

and metanephric mesenchyme was an important component in the process of ureteric bud branching. However, the isolated ureteric bud has since been shown to grow and branch extensively in the presence of appropriate extracellular matrix and soluble factors in the absence of direct contact with the metanephric mesenchyme[31] (Figure 25.8). The epithelial cells of the ureteric bud in this culture system appear to retain similar morphological characteristics to those of the ureteric bud in the whole embryonic kidney culture.[32] This system has allowed for the isolation and identification of numerous molecules, including soluble factors that modulate ureteric bud branching morphogenesis.[31–47]

Isolated Metanephric Mesenchyme Culture: Recombination with Heterologous Inductive Tissues

Another setting in which organ culture has been used focuses on metanephric mesenchyme induction and transformation to an epithelial phenotype. In this system, the isolated mesenchyme is cultured on one side of a filter while, on the other side of the filter, heterologous inducing tissues are placed. Various stages of metanephric mesenchyme induction (i.e., condensation, epithelialization, and tubulogenesis) can be observed, depending on the inductive capacity of the tissue. Using this method, it has been shown that embryonic spinal cord, salivary gland, and other tissues can induce the metanephric mesenchyme.[48,49] As is the case for isolated ureteric bud branching described previously, a key question here is the relative contribution of humoral factor(s) or cell–cell contact in this process. Electron microscopic examination revealed that the inducing tissue can contact the metanephric mesenchyme via cellular processes extending through the filter.[50] In fact, filters with pore sizes greater than 0.1 μm are unable to block cell-to-cell contact completely,[7] indicating the importance of cell–cell contact. However, complete mesenchymal induction has been demonstrated in the presence of soluble factors without cell–cell contact with inductive tissue.[51,52]

Isolated Metanephric Mesenchyme Culture: Recombination with Isolated Ureteric Bud

It has been shown that when co-cultured with freshly isolated metanephric mesenchyme, the isolated ureteric bud in culture (as described previously) is capable of inducing nephron tubules from the metanephric mesenchyme.[31] At the same time, the pattern of ureteric bud growth is altered by the presence of the metanephric mesenchyme; it is only through contact with metanephric mesenchyme that the ureteric bud undergoes vectorial branching with elongation and tapering of newly induced branches, similar to those seen in cultured whole embryonic kidneys[44] (Figure 25.9). Although this

patterning effect on the ureteric bud appears to be modulated, in part, by soluble factors, cell contact with the metanephric mesenchyme and/or short-acting factors produced by the interaction of these two progenitor tissues plays a key role in determining the arborization pattern.[44] Another potential application of this "recombination" system is to pinpoint the defective tissue in knockout mice with a kidney phenotype. Through recombination of wild-type and gene knockout tissues (e.g., wild-type ureteric bud with knockout metanephric mesenchyme), it may be possible to determine the source of the kidney defect. For example, kidneys lacking heparan sulfate 2-O sulfotransferase ($Hs2st^{-/-}$) display renal agenesis, presumably due to defects in the inductive responsiveness of the ureteric bud to undergo branching morphogenesis.[53] However, examination of cultures of recombined wild-type and $Hs2st^{-/-}$ ureteric buds and metanephric mesenchyme (Figure 25.10) provided evidence that the key defect in the knockout kidney is the inability of the metanephric mesenchyme to undergo induction.[46]

The aforementioned tissue culture systems allow one to observe certain key phenomenon in metanephric kidney development *in vitro/ex vivo*. The analysis of genetically-engineered kidneys (and/or their component tissues) in these *in vitro* systems, in combination with an advanced method of gene perturbation (e.g., RNAi), will undoubtedly provide a more mechanistic picture of kidney development.

Genetically-Engineered Mice

Genetically-engineered mice allow one to manipulate the process of kidney development *in vivo*. Introducing null mutations of the gene of interest into mouse embryonic stem cells can be used to generate gene knockout mice.[54–56] Generally speaking, knockout mice grow from conception without normal expression of the gene product. If the mice develop beyond the stage of kidney development, the effect of the gene disruption on nephrogenesis can be observed *in vivo* by direct examination of the tissue histology. In such cases, the abnormal kidney phenotype can be directly or indirectly ascribed to disruption of the gene. In fact, many important molecules involved in kidney development have been identified by gene knockout technology.[57,58] In particular, the contribution of many transcription factors, molecules acting in the nucleus to regulate gene expression in the cell, have been demonstrated by this technique. However, knockout technology has its limitations. For example, although gene knockout mice can demonstrate the indispensability of a particular gene, how the gene product acts in the complex process of kidney development often remains unclear, owing to the spatiotemporal complexity of the

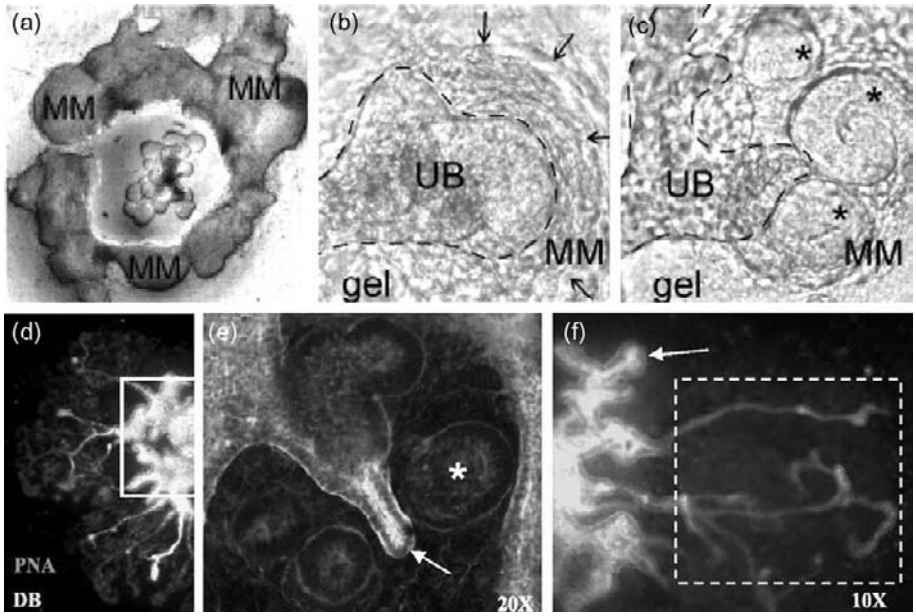

FIGURE 25.9 (a–c) Photomicrogrpahs of uninduced metanephric mesenchyme (MM) placed around the cultured UB (a); and co-cultured for 7 days (b–c). (d–f) UB and MM recombinations after 8 days of co-culture visualized with UB-specific lectin (*Dolichos biflorus*) and antibody against E-cadherin. Structures derived from mesenchymal-to-epithelial transformation, including cap-condensate (b: arrows) and coronas (indicated by asterisks) are observed. (f) Boxed area indicates elongation of UB branches and vectorial growth toward the MM; arrow indicates an area of the UB that has not undergone recombination with the MM and maintains its original architecture. *(adapted from ref. [44]).*

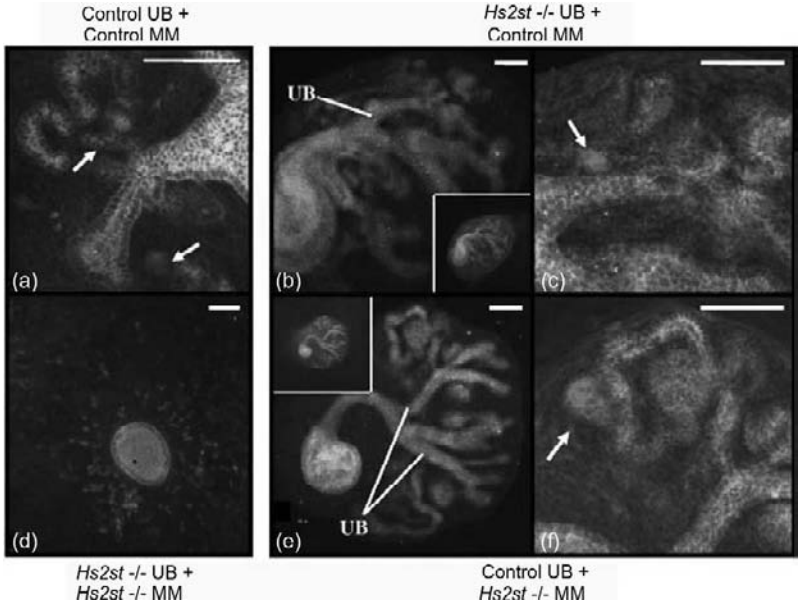

FIGURE 25.10 (a–f) Confocal photomicrographs of mix-and-match recombination cultures between heparan sulfate 2-O-sulfotransferase (Hs2st) knockout and control tissues. E-cadherin staining reveals epithelial structures derived from either ureteric bud (UB) or metanpehric mesenchyme (arrows). Mutual induction can be seen in co-cultures of control tissues recombined with control (a) or Hs2st$^{-/-}$ tissues (b), (c), (e), (f). Recombination of UB and MM from Hs2st$^{-/-}$ kidneys results in no mutual induction (d) (Scale bars: 100 μm). *(from ref. [46]).*

developing organ. Thus, if one observes defective ureteric bud branching in knockout mice, the deleted/disrupted gene product could be affecting the ureteric bud directly or it could be affecting the metanephric mesenchyme, resulting in incompetent induction of the ureteric bud. To resolve this problem, some have used organ culture type approaches ("recombination").[46,59] Another limitation of gene knockouts is that the mice may not have an apparent phenotype due to redundancy. In other words, the expression of other molecules with features or functions that overlap with the targeted gene could compensate for the defect from the gene knockout.

Perhaps the major drawback of conventional knockouts for studying genes involved in development of the kidney is the possibility that the targeted gene is critical for early embryonic survival, rendering the analysis of kidney development impossible as the embryo dies before organogenesis. In recent years, this issue (as well as some of the others listed above) has been overcome by the use of tissue-specific knockout technologies which provides the means for gene disruption in a time- and organ-specific manner.[60] This gene targeting system utilizes site-specific recombinases to excise out genes or portions of genes from the genomic DNA, resulting in the inactivation of the gene of interest.[61] Cre-loxP is the most commonly employed site-specific recombinase for these "conditional" deletions, although other site-specifc recombinases are available, including Flp-FRT and Dre-Rox. In the case of the Cre-loxP system (although the general principles are shared), conditional deletion of a gene of interest is performed by crossing two transgenic mouse lines: (1) "floxed" mice that carry the gene of interest with flanking loxP sites which can be cleaved by the enzyme; and (2) Cre-recombinase transgenic mice under the control of a tissue-specific promoter.[62] For example, deletion of β1 integrin from the epithelial cells destined to become the ureteric bud using Cre recombinase under the control of the HoxB7 promoter disrupts ureteric bud branching morphogenesis, and variably retards kidney growth, leading in a few instances to renal agenesis.[45,63] While such approaches have proven useful, the main drawback of these conditional deletions in the study of the kidney is the availability of cell-specific promoters.[61] The use of tet-operon and tamoxifen to induce recombinase activity and the modulation of gene activity have also proven to be useful.[61] In these systems, animals are exposed to tetracycline or tamoxifen which activates the site-specific recombinase under its control, resulting in the modulation of gene activity. These systems have the advantage of being under the control of the investigator; however, they are not without problems, including the toxicity of the inducing agent.[61] Nevertheless, these spatiotemporal conditional deletions have rapidly established themselves as an invaluable tool for investigating the development of the kidney.

Cell Culture

Cell culture models have the advantage of simplicity. Since they use homogenous cell populations grown under controlled conditions, it is possible to perform biochemical analysis in great detail. Moreover, gene introduction by plasmid transfection and gene knockdown by RNAi is simpler in comparison to the organ culture system. Here, the most relevant system for branching morphogenesis of the ureteric bud, the three-dimensional cell culture system, is discussed.

When certain kidney-derived epithelial cells are suspended in an extracellular matrix gel (type I collagen or a collagen–Matrigel mixture) in the presence of morphogenetic humoral factors, they form tubules and undergo branching morphogenesis *in vitro*. The tubules in the three-dimensional culture have lumens and retain apical–basolateral polarity.[64] The effect of humoral factors in epithelial tube and/or branch formation can be studied here. In addition to the humoral factors, the effect of extracellular matrix composition on morphogenesis and the cellular details of morphogenesis can be examined in this system. MDCK cells and murine inner medullary collecting duct (mIMCD3) cells have been used in the past,[65–68] but these have the limitation of being derived from mature renal epithelial cells. To address this issue, an *in vitro* cell culture system using ureteric bud (UB) cells directly derived from embryonic day (E) 11.5 mouse ureteric bud has also been established.[69] Although there is some difference in the responsiveness of the different cell lines to growth factors, all three cell lines respond to soluble factors produced by the metanephric mesenchyme by forming branching tubules.

A detailed mechanism of hepatocyte growth factor (HGF)-induced MDCK cell tubulogenesis model has been described.[70] There appear to be two steps involved in this process of invasion: epithelial–mesenchymal transition; and the re-establishment of epithelial intercellular junctions. However, it has also been shown that ureteric buds in *in vitro* culture undergo branching morphogenesis through budding, a process in which epithelial cells never lose their junctions.[32] It remains to be seen where and when these two morphogenetic processes, branching through invasion ("invadopodia") and branching through budding, are utilized *in vivo*.[71]

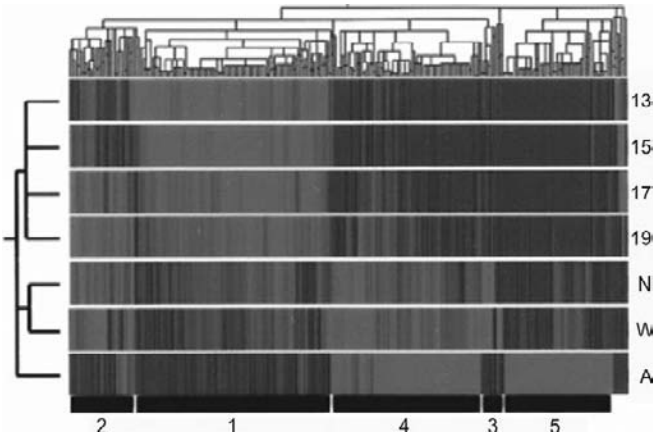

FIGURE 25.11 **Hierarchical clustering of 873 genes identified as changing significantly at some point in kidney development (out of 8740 genes examined).** Numbers at the bottom indicate group numbers derived from k-means clustering. Group 1 genes are upregulated (red) in the early embryonic period and decrease thereafter. Group 2 genes rise to a mid-late embryonic peak. Group 3 genes peak in the neonatal period. Group 4 genes rise somewhat linearly throughout development. Group 5 genes display a distinct peak in the adult versus all earlier times (13, 15, 17, 19: embryonic days; N: newborn; W: 1 week old; A: adult). *(from ref. [72]).*

MOLECULAR APPROACHES TO KIDNEY DEVELOPMENT

The development of high-density DNA microarray technology and global gene profiling has made it possible to analyze patterns of gene expression throughout embryonic and postnatal development and into adulthood in the whole developing rodent kidney.[72,73] It has also been possible to analyze gene expression changes in *in vitro* culture systems such as the isolated UB and MM.[39,42,74] For example, initial microarray analysis of a global time series of gene expression in the developing rat kidney revealed five discrete patterns or groups of gene expression[72] (Figure 25.11). mRNA encoding transcription factors and growth factors were found to be upregulated early in organogenesis (group 1). Among the genes whose expression level peaked in the middle of kidney organogenesis (group 2), many extracellular matrix related genes were found.[72] Further representing the global time series gene expression data as self-organizing maps (SOMs) made it possible to define roughly six stages of gene expression during pre- and postnatal kidney development in the rat.[73] Computational analysis suggested points of stability and transition based solely on gene expression and correlations where classically described anatomical changes were not intuitively obvious[73] (Figure 25.12). The most profound changes appear to occur at birth, when there is a sudden burst in the expression of many genes involved in redox metabolism and transport, including multispecific drug transporters such as Oat1 and Oct1.[75]

There has also been a massive effort to create an atlas of gene expression in the developing kidney, the genitourinary developmental molecular anatomy project or GUDMAP.[76–80] This multi-group international project is still continuing and has not only provided an atlas of localization information (e.g., ureteric bud, comma-shaped bodies, S-shaped bodies, renal vesicle), but has also yielded specific gene signatures for developing structures like branching ureteric bud tips. Although the function of many of these genes remains unknown, at a minimum they represent useful markers.

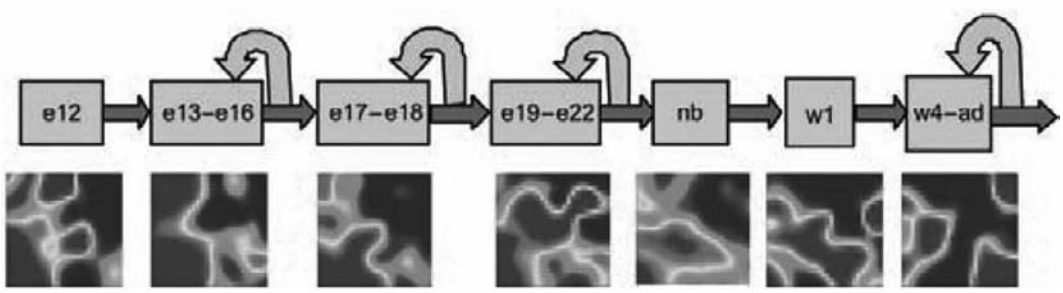

FIGURE 25.12 **Representative SOMs from each stage (Stage 1: e12; stage 2: e13 to e16; stage 3: e17 to e18; stage 4: e19 to e22; stage 5: nb (P0 to P1); stage 6: w1; stage 7: w4 to ad).** Curved arrows represent putative negative feedback loops that potentially stabilize the previous stage. *(from ref. [73]).*

One of the key tasks in the future will be to place this localization information in the context of global gene expression time series data, to obtain a more accurate picture of the dynamics of kidney organogenesis and suggest new points of regulation. Growth factor-selective heparan sulfation interactions have been proposed as important regulators of the switching between stages.[46,47] Moreover, based on current knockout and *in vitro* data, it has been suggested that key "hubs" in the network of genes regulating kidney development include the process of GDNF-dependent budding early on, and late tubulogenesis involving cilia-associated genes such as those implicated in various types of cystic kidney disease.[81,82] It is becoming increasingly clear that an abundance of knockouts reported to have "renal phenotypes" cluster around these processes. *In vivo* branching morphogenesis, especially in the middle phases, appears largely protected from disruption in many knockouts of gene products known to be involved in *in vitro* branching. When branching phenotypes are reported, it is usually in the form of a small reduction in nephron number. One interpretation, supported by a wealth of *in vitro* data, is that there are many growth factor−heparan sulfate-dependent pathways regulating branching, and deletion of any single one is likely to be compensated by another. Double knockouts, for example of the EGF receptor and the HGF receptor (c-met), are beginning to provide support for this view.[83]

In addition to these high-throughput gene profiling approaches, epigenetic transcriptional controls are becoming rapidly appreciated. These dynamic cell-inheritable processes alter transcriptional activity without affecting DNA sequence, and include covalent modifications of DNA and histones, DNA packaging, chromatin folding, and regulatory noncoding microRNAs (miRNAs).[84,85] For example, conditional deletion of Dicer, the RNase involved in the production of miRNAs (which control gene expression at the post-transcriptional level), from cells of the nephron lineage lead to elevated apoptosis and premature termination of nephrogenesis.[86] In addition, deletion of Dicer from ureteric bud epithelium disrupts branching morphogenesis, and leads to the development of renal cysts.[86] Together with other studies on Dicer and miRNAs, the data clearly indicate a role for Dicer and Dicer-dependent miRNA activity in the development of the kidney, as well as in the development and progression of kidney disease.[84,86–93]

Ultimately, high-throughput gene profiling, together with a thorough epigenetic analysis, may provide mechanistic insight into the very complex system of gene expression regulating kidney development. This may enable the development of a systems perspective on nephrogenesis. Attempts at creation of "coarse grained" models of kidney development have clearly begun.[40,82,94,95] In the following section, a number of molecules which have been shown to be involved in kidney development are discussed. Over the past two decades, a large number of developing kidney phenotypes has been reported in gene knockout studies. Together with *in vitro* studies, they provide a great deal of functional information. We will highlight some of the results below. Several recent reviews describe them in much more detail.[96–98] Moreover, we do not discuss in great detail the impressive amount of work that has been done in relation to the formation of the glomerular filtration barrier (reviewed in [99]), polycystic kidney disease (reviewed in [100]) or late nephron differentiation and acquisition of mature transport function (reviewed in [96–98,101]). We focus largely on the WD, UB, and early MM-derived structures.

TRANSCRIPTION FACTORS IN METANEPHROGENESIS

Transcription factors bind to DNA and regulate the expression of other genes that are involved in, among other things, morphogenesis and differentiation. As a result of many gene disruption studies,

several important transcription factors in kidney development have been demonstrated. With careful molecular marker analysis, it will soon be possible to draw a whole network of these molecules in this process.

Transcription Factors Regulating Glial Cell Line-Derived Neurotrophic Growth Factor

As will be described later, a key molecule in the process of the initial stage of metanephros development (i.e., ureteric bud formation and outgrowth from the Wolffian duct) is glial cell line-derived neurotrophic growth factor (GDNF). Many transcription factors regulating expression of this growth factor affect ureteric bud development, and thus kidney development.

Hox Genes

Hox genes, mammalian homologs of *Drosophilia* homeotic genes, have been shown to be critically important for early nephrogenesis. While null mutants for *Hoxa11* or *Hoxd11* mice do not have a kidney phenotype, double knockouts of *Hoxa11* and *Hoxd11* show kidney agenesis or hypogenesis.[102] Moreover, complete elimination of *Hox11* paralogs (*Hoxa11*, *Hoxc11*, and *Hoxd11*) result in a lack of ureteric bud outgrowth from the Wolffian duct.[103] In this mutant, expression of another transcription factor, *Six2* as well as *Gdnf* is lacking, suggesting that *Hox11* paralogs regulate *Gdnf* expression.

Pax Genes

Additional members of the homeotic gene family, the *Pax* genes, have been implicated in nephrogenesis. Compared with *Hox* genes, *Pax* genes appear to be restricted to certain tissues or organs. *Pax2* and *Pax8* have been shown to be expressed in the kidney. These *Pax* genes can be considered as early nephric lineage specification genes, as they are first expressed in the pronephric duct, and their simultaneous disruption causes failure in the formation of the epithelial pronephric duct from the intermediate mesoderm.[1] After the pronephric duct, *Pax2* expression is sequentially found in its extension, the Wolffian duct, the ureteric bud, as well as the condensed metanephric mesenchyme and the newly formed nephron tubules. As the kidney tubules mature, *Pax2* expression decreases.[104,105] The expression pattern suggests a role for *Pax2* in mesenchymal–epithelial transformation. Homozygous null mutant mice lacking *Pax2* show only a partially developed Wolffian duct, leading to kidney agenesis.[106] It has also been shown that the mutant Wolffian duct does not respond to GDNF to form the ureteric bud. Furthermore, the mutant metanephric mesenchyme not only lacks *Gdnf* expression, it is not competent to form nephron tubules in response to wild-type spinal cord.[22] Heterozygous *Pax2* mutant mice have hypoplastic kidneys.[106] In fact, there are Pax2-binding sites in the promoter region of *Gdnf*, and Pax2 can promote *Gdnf* expression *in vitro*.[22] Pax2 has also been shown to promote the assembly of an H3K4 methyltransferase complex, which is involved in epigenetic transcriptional regulation.[85]

Pax8 has a similar tissue expression pattern to *Pax2*; however, *Pax8* expression peaks later than *Pax2*.[107] Although kidney development is apparently normal in *Pax8* knockout mice,[108] double knockouts of *Pax2* and *Pax8* show a complete absence of a urogenital system, due to failure in the formation of the pronephric duct from the intermediate mesoderm,[1] suggesting some overlap in the roles of these two *Pax* genes in pronephric duct induction. Analysis of kidney development in mice heterozygous for *Pax2* and for *Pax8*, which form kidneys (albeit hypodysplastic with fewer ureteric bud tips and a reduced nephron number), indicates a dramatic reduction in the expression levels of *Lim1*.[109] Although normal levels of *Ret* and *Gdnf* were seen, *Wnt11* (an important downstream target of Gdnf signaling, see below) was reduced. Thus, it has been postulated that *Pax2* and *Pax8* play a key cooperative role in nephron differentiation and branching of the ureteric bud.[109]

Eya1, Six1, and Six2 Genes

These genes have been implicated in *Drosophila* eye development together with *Pax6*,[110] and are expressed in the metanephric mesenchyme in the kidney. Homozygous null mutants for *Eya1* show kidney agenesis with loss of *Gdnf* and *Six* expression,[111] suggesting that EYA1 acts upstream of SIX, and together they regulate *Gdnf* expression. In fact, EYA1 is shown to act as a co-activator[111] of the genes regulated by SIX.[112] In *Six1* knockouts, which show various kidney phenotypes ranging from hypogenesis to agenesis, *Gdnf* expression is reduced, but *Eya1* expression is preserved.[112,113] Interestingly, metanephric mesenchyme derived from *Six1* knockout mice is not competent in nephron tubule formation when it is cultured with spinal cord, a potent inducer of nephron tubulogenesis, suggesting that these factors not only control *Gdnf* expression, but also have a role in maintaining certain characteristics of metanephric mesenchyme.[113] As described previously, another member of the *Six* family, *Six2* appears to regulate *Gdnf* expression downstream of *Hox11* paralogs.[103] Although *Six1* and *Six2* show overlapping areas of expression, the fact that *Six2* expression is reduced in *Six1* knockouts[112,113] suggests a close relationship between these two molecules. *Six2* expression *in vivo* has been found to be directly

activated by a novel protein complex composed of the Hox11 paralogous proteins, Pax2 and Eya1, which clearly demonstrates that *Six2* and *Gdnf* are downstream targets of the Hox11 paralogs.[114] Moreover, *Six2* defines nephron progenitor populations in the metanephric mesenchyme and it cell-autonomously maintains progenitor populations.[6]

Sall1

Sall1 is a transcription-related protein expressed in the metanephric mesenchyme of the developing kidney.[115] It is also expressed in extrarenal tissues such as the limb buds and central nervous systems. Knockout of this gene results in failure of the ureteric bud to undergo branching after invading the metanephric mesenchyme.[116] Although *Gdnf* expression just before ureteric bud formation is reported to be normal, its expression in the metanephric mesenchyme subsequently decreases.[115] It is unclear whether this reduction of *Gdnf* expression is due to a direct effect of the *Sall1* mutation or if it is secondary to a loss of a ureteric bud-derived signal. Interestingly, exogenous Gdnf was unable to rescue branching in cultures of *Sall1* knockout kidneys despite expression of *Ret*, suggesting that the ureteric buds are unable to respond to Gdnf.[116] *In situ* hybridization demonstrates the expression of the stalk-specific marker, *Wnt9b*, as well as the β-catenin target gene *Axin2*, in the ureteric bud tips of *Sall1* knockout kidneys.[116] Since reduction of β-catenin levels in *Sall1* mutants rescued ureteric bud branching and overexpression of *Wnt9b*-inhibited branching in normal ureteric buds, the data indicate that *Sall1*-dependent signals regulate the initiation of ureteric bud branching by modulating the expression of ureteric bud tip-specific genes.[116] In addition, among metanephric mesenchyme cells, only those cells which express high levels of *Sall1* are capable of nephron formation, suggesting the possibility that activation of this gene is key for nephron-forming capacity in the metanephric mesenchyme.[117] Given the fact that *Six2* maintains nephron progenitor cells, *Sall1* may act together with *Six2* to ensure multipotency of nephron progenitors.

Foxc1

Although some of the aforementioned genes affect a number of other genes, they all normally stimulate *Gdnf* expression. However, it is also important to restrict the area of *Gdnf* expression, to avoid multiple kidneys arising from a single Wolffian duct. In this regard, a member of the forkhead transcription factor superfamily, *Foxc1*, appears to restrict *Gdnf* expression to the intermediate mesoderm around the Wolffian duct (i.e., metanephric mesenchyme). *Foxc1* homozygous null mutants display ectopic ureteric bud outgrowth resulting in duplex kidneys.[118] In this mutant, the restrictive expression pattern of *Gdnf* as well as *Eya1* is perturbed, and is abnormally extended along the Wolffian duct.

Transcription Factors Regulating Ureteric Bud Formation (or Early Kidney Development)

Lim1

Lim1 is a homeotic gene expressed in both the central nervous system and kidneys. By whole-mount *in situ* hybridization, its transcript is detected from the pronephric stage to the metanephros.[119] In the metanephros, its expression is detected in the renal vesicles, S-shaped bodies, and ureteric bud branches.[119] Knockout of *Lim1* leads to kidney agenesis, suggesting its distinct role in early nephrogenesis.[120] Since *Pax2* expression in the mesonephros is detected in *Lim1* knockouts,[121] and the ectopic expression of *Pax2* was found to induce *Lim1* in the intermediate mesoderm,[1] it is likely that *Lim1* acts downstream of *Pax2* in pronephros development. However, the exact role of *Lim1* in metanephrogenesis remains to be determined.

Wt1

One of the Wilms tumor suppressor genes, *Wt1*, a zinc-finger transcription factor, is required for kidney development. *Wt1* generally acts as a transcriptional repressor, and has been shown to repress *Igf2*,[122] *Igf1* receptor,[123] *Pax2*,[124] *Myc*,[125] and *Bcl2*[125] expression. Most of these genes are related to cell proliferation, supporting the notion that loss of *Wt1*-mediated repression could lead to disregulated proliferation (i.e., cancer). It seems paradoxical that the *Wt1* knockout suffers from kidney agenesis, not tumors.[126] In the homozygous deletion mutant of *Wt1*, the ureteric bud fails to form, despite relatively normal development of the mesonephros and in the presence of *Gdnf* expression,[127] suggesting that factor(s) other than GDNF might be required for ureteric bud initiation. In normal embryonic kidneys, *Wt1* is expressed in uninduced mesenchyme, renal vesicles, and glomerular podocytes.[128] *Wt1* mutant mesenchyme is not responsive to the inductive signal from wild-type spinal cord, while the mutant Wolffian duct can induce wild-type metanephric mesenchyme, suggesting that the primary defect is in the mesenchyme.[127] Interestingly, the mechanism(s) of WT1 remain to be fully elucidated. Genome-wide expression profiling analysis in cells expressing inducible WT1 identified some direct WT1-target genes, including EGF receptor ligands, chemokines, and transcription factors.[129]

Limb Deformity Gene/*Fmn1*

Kidney agenesis is observed in mice homozygous for the *limb deformity* (*ld*) gene, *Fmn1*, mutation. The initial outgrowth of the ureteric bud is not observed in mutant mice. The metanephric mesenchyme from *Fmn1* mutant mice is induced by embryonic spinal cord, suggesting that the defect is in the ureteric bud.[130] The *Fmn* gene encodes formin, a gene product, which is present in both the ureteric bud and the metanephric mesenchyme.[131,132] Although knockouts of certain formin isoforms display limb deformity and kidney defects, specific elimination of isoform 4 results in a pure kidney phenotype.[133]

Myc Genes

The *Myc* family members were first recognized as proto-oncogenes that function as transcription factors. While *Myc* is expressed in the uninduced metanephric mesenchyme and newly formed epithelium, *Nmyc1* is transiently expressed in the area of mesenchymal–epithelial transformation.[134] Another *Myc* family member, *Lmyc1*, is expressed in ureteric bud-derived structures, and its expression increases as these structures mature.[134] Both *Myc* and *Nmyc1* gene knockouts are lethal at E9.5–10.5 and E10.5–12.5, respectively.[135–137] *Myc* mutants apparently have no specific kidney phenotype. In *Nmyc1* mutants, mesonephric development is affected. In both cases, mice die before metanephric development, which therefore cannot be assessed. The distinct pattern of expression of the various *Myc* genes makes them useful as markers: mesenchymal stromal cells are negative for *Myc*; *Nmyc1* is a marker for induced mesenchyme or early mesenchymal epithelialization; *Lmyc1* is a marker for the collecting duct.

Transcription Factors Regulating Ureteric Bud Survival/Branching

Emx2

Disruption of a homeotic gene, *Emx2* results in urogenital defects in mice.[59] In mutant mice, the initial formation of the Wolffian duct and ureteric bud is normal, as is the initial induction of the metanephric mesenchyme. Normal *Pax2* expression is observed in these structures. However, the ureteric bud starts to degenerate around E12.5. At the same time, the expression of *Pax2* and *Ret*, a receptor tyrosine kinase normally expressed at the tip of growing ureteric bud, is greatly reduced. Recombinant organ culture between wild-type and mutant ureteric bud and metanephric mesenchyme indicates a defect in the ureteric bud. *Emx2* expression is observed at a later stage of epithelialization than *Pax2* in normal mice. The expression pattern suggests that *Emx2* regulates maturation and/or survival of epithelial cells, rather than formation of epithelial cells.

Timeless

By differential gene expression screening in the epithelial cell three-dimensional culture system for branching tubulogenesis, the mammalian ortholog of *Timeless* gene was identified as a candidate for regulation of epithelial branching morphogenesis. Its expression is detected in the active region of ureteric bud branching in the developing kidney. Selective inhibition of this gene in various *in vitro* culture models resulted in inhibition of ureteric bud branching.[33] Deletion of this gene is embryonic lethal prior to the onset of kidney development.[138] The kidney (or ureteric bud)-specific knockout data are needed to provide a definitive role of this molecule in kidney development.

ETS Transcription Factor Genes

Etv4 and *Etv5*, two members of the Pea3 family of E-twenty six (ETS) domain transcription factors, which are believed to function as transcriptional activator proteins,[139] were identified in an analysis of gene expression in ureteric buds cultured in the absence or presence of Gdnf.[140,141] *Etv4* and *Etv5* were found to have overlapping expression in ureteric bud tips which was positively enhanced by Gdnf.[140,141] Gene dosage reductions and/or deletions of these transcription factors indicated a role in the formation of the ureteric bud tip domain.[140,141]

Sox Genes

Sox genes are developmental regulators containing a DNA-binding domain with high homology with the HMG box of the sex-determining gene *Sry*. Mice with double deletions of *Sox9* and *Sox8* have kidney defects, including renal agenesis.[142] *In situ* hybridization demonstrates reduced expression of a number of downstream targets of Gdnf-Ret signaling, including *Etv4*, *Etv5*, *Met*, and *Spry1* in the ureteric bud tips. Together, the data indicate that *Sox8* and *Sox9* have key roles in Gdnf-Ret signaling regulating/modulating ureteric bud branching morphogenesis.[142]

Transcription Factors Regulating Stroma Development

Foxd1

Study of one of the forkhead box transcription factor superfamily members, *Foxd1* (*Bf2*), shed light on the

role of the third cellular component of the developing kidney, the stroma. In developing kidneys, *Foxd1* is expressed by the cortical stromal mesenchyme. Homozygous null mutants for *Foxd1* die soon after birth due to renal failure. Mutant kidneys are small, fused, and located in the pelvis.[143] Both ureteric bud branching morphogenesis and kidney tubulogenesis in the metanephric mesenchyme-derived segments are perturbed. Further analysis of this knockout mouse reveals that the mutant kidney capsule abnormally contains cells expressing bone morphogenetic protein (BMP) 4 or PECAM (endothelial marker). Abnormal signals from these cells are likely to cause disruption of normal ureteric bud branching and nephrogenesis.[144] One of the target genes for this transcription factor is placental growth factor, a family member of vascular endothelial growth factor.[145]

Pod1

The *Pod1* gene, a transcription factor expressed in mesenchymal cells surrounding the ureteric bud and visceral glomerular podocytes in the developing kidney,[146] also plays a role in regulating ureteric bud branching and nephron formation. Null mutants for this gene exhibit a phenotype similar to that seen in *Foxd1* knockouts; initial ureteric budding and mesenchymal condensation occurs, but the process appears to slow down beyond this point.[147] By chimeric mouse analysis, *Pod1* expression was shown to be critical for the medullary stroma.[148]

Pbx1

Pbx1 gene encodes a homeodomain containing transcription factor expressed in metanephric mesenchyme, and both cortical and medullary stroma in the developing kidney. The kidney phenotype of *Pbx1* knockouts is similar to that of *Pod1*/*Foxd1* knockouts.[149] It appears that expression of these genes is not dependent upon the others, and all three genes are required for the functioning stroma to be capable of supporting ureteric bud branching and nephron differentiation. Identifying the molecular nature of this "stromal effect" will provide considerable insight into kidney development.

Retinoic Acid Receptor Genes

One possible mechanism for control of ureteric bud branching morphogenesis by the stromal cells is through the vitamin A/retinoic acid pathway. Vitamin A deficiency has been known to result in small kidneys.[150] Dietary vitamin A is converted to its active form, retinoic acid, and its signal is mediated through the retinoic acid receptor, which acts as a transcription factor. Retinoic acid synthesizing enzyme localizes to the cortical stromal cells,[151] and double knockout of retinoic acid receptor *Rara* and *Rarb2* results in *Ret* downregulation and impaired ureteric branching.[152]

Transcription Factors Regulating Functional Maturation of Nephron Tubules

Hnf1

Hepatocyte nuclear factor (*Hnf*)*-1* is a homeotic gene mainly expressed in liver and kidney. *Hnf1* knockout mice have an enlarged liver and Fanconi syndrome, resulting in urinary wasting of sugars, amino acids, and electrolytes that normally are reabsorbed in the renal proximal tubules,[153] suggesting an important role for *Hnf1* in regulating the expression of proximal tubule transporters.

Brn1

Maturation of Henle's loop and distal tubule is controlled by *Brn1*, a POU transcription factor. *Brn1* is expressed only in part of the mesenchymal condensate, then the prospective Henle's loop and distal tubule in the maturing kidney. There is no expression in the glomerulus, proximal tubule or collecting duct. Knockout of this transcription factor results in an elongation and maturation defect of the Henle's loop, macula densa, and distal tubule.[154]

URETERIC BUD OUTGROWTH FROM THE WOLFFIAN DUCT

Outgrowth of the ureteric bud from the Wolffian duct in response to signals arising from the metanephric mesenchyme is the initiating event in the development of the mammalian kidney.[7] The major growth factor involved in this process is Glial-derived neurotrophic factor (Gdnf) (see below).There are several levels of regulation surrounding the GDNF pathway.

Restriction of GDNF Expressed Region by *Slit-Robo*

The secreted protein *Slit2* and its receptor *Robo2*, previously reported as a chemo-repellant factor for axon guidance,[155] also functions to restrict *Gdnf* expression. Null mutations of either *Slit2* or *Robo2* result in supernumerary ureteric buds, caused by an abnormally extended *Gdnf* expression area.[156]

Regulators for GDNF Signaling Pathway

Sprouty

Sprouty (Spry) is an intercellular protein that acts as a negative feedback regulator for FGF and other receptor tyrosine kinase-mediated signaling.[157] Knockouts of *Spry1* display multiple ureters and multiplex kidneys.[158] It appears that mutant Wolffian ducts are abnormally more sensitive to GDNF, as reduction of *Gdnf* expression rescues the phenotype.[158] Double knockouts of *Spry* and *Gdnf* ($Spry^{-/-}$; $Gdnf^{-/-}$) rescue normal ureteric bud outgrowth and kidney development.[159] When *Fgf10* was also deleted from these mice ureteric bud outgrowth failed to occur, suggesting that *Fgf10* is likely to function as the receptor tyrosine kinase responsible for ureteric bud outgrowth in the absence of *Spry* and *Gdnf*.[159]

Activin and FGF

One of the puzzles in early nephrogenesis has been that a substantial fraction of Ret knockouts develop very rudimentary kidneys, suggesting the existence of a "bypass" pathway for ureteric bud formation. A GDNF-independent pathway for *in vitro* budding has been described that appears to involve a FGF,[22] but it is possible that inhibition of activin signaling also enables a "bypass" of the GDNF-ret pathway.[23,24] The FGF-dependent bypass pathway has been recently supported by *in vivo* evidence.[159]

NPY and *BMP* through PKA

Utilizing *ex vivo* cultured Wolffian ducts, microarray analysis of ducts maintained in the absence or presence of Gdnf identified neuropeptide Y (*Npy*) as a novel modulator of ureteric bud outgrowth.[28] Npy also rescues budding in Bmp4-treated Wolffian ducts, suggesting that this neuropeptide is reciprocally regulated by Gdnf and Bmps.[28] Comparison of budded and non-budded portions of Gdnf-induced cultured Wolffian ducts also reveals an almost 15-fold increase in protein kinase A (PKA) activity in non-budded Wolffian ducts.[30] Microarray analysis reveals a marked decrease in the expression of *Ret* following activation of the PKA pathway in cultured Wolffian duct. *Bmp2* expression is also increased in unbudded Wolffian ducts, and exogenous Bmp2 inhibits *ex vivo* budding from the Wolffian duct with a three-fold increase in PKA activity.[30] Taken together, the data suggest a role for PKA in regulating the site of ureteric bud outgrowth, potentially via a Bmp-dependent downregulation of *Ret*/*Gfrα1* co-receptor expression.[30]

GDF11

Another member of this family, growth/differentiation factor (*Gdf*)11 is expressed in the Wolffian duct and the metanephric mesenchyme. Knockouts of this gene result in kidney hypoplasia to agenesis, thought to be caused by downregulation of *Gdnf* in the mesenchyme.[160,161] In these mice, molecules known to regulate *Gdnf* expression such as *Eya1*, *Six2*, *Pax2*, and *Wt1* are expressed in the metanephric mesenchyme region, and the metanephric mesenchyme from this mutant undergoes nephron tubule formation when it is cultured with embryonic spinal cord. Molecular markers for the Wolffian duct such as *Ret*, *Pax2*, *Emx2*, and *Lim1* were expressed in the right place, and mutant Wolffian duct responds to exogenous GDNF.[160] Thus, GDF11 is likely to be indispensable for *Gdnf* expression.

Outside the kidney, this mutant mouse shows deranged anterior/posterior patterning, with alteration of *Hox* gene expression pattern.[161] Given the fact that *Hox11* paralogs control *Gdnf* expression,[103] downregulation of *Gdnf* in *Gdf11* mutants may be mediated through *Hox11* expression. GDF11 acts through the activin receptor (ACVR) IIA and IIB,[162] and knockouts of *Acvr2b* result in a similar though milder phenotype than that of *Gdf11* knockouts.[163]

Unidentified Signal(s) from Metanephric Mesenchyme

Another pathway involved in the regulation of ureteric bud outgrowth is revealed by single deletions of *Fgfr2* (but not *Fgfr1*, which appeared to be normal) from the metanephric mesenchyme, which leads to the outgrowth of duplicated ureteric buds from the Wolffian duct.[164] Although it is not clear which factors are secreted from metanephric mesenchyme, this result suggests that certain FGF signaling plays a role in the metanephric mesenchyme to suppress ectopic ureteric bud formation.

URETERIC BUD BRANCHING MORPHOGENESIS

As discussed previously, ureteric bud branching morphogenesis is induced by signals from the metanephric mesenchyme. Soluble growth factors, direct cell-to-cell contact, and cell−matrix contact play key roles in the process. The molecules likely to be involved in ureteric bud branching morphogenesis are summarized in Table 25.1.

TABLE 25.1 Molecules Likely to be Involved in Ureteric Bud Outgrowth and Branching Morphogenesis

Process	Soluble Factors	Transcription Factors	ECM/ Protease/ Integrin
Initiation	GDNF	*Pax2*	
	WNT2b	*Lim1*	
	Slit/Robo	*Six1, 2*	
	Activin (inhibitory)	*Eya1*	
	BMP2/4 (inhibitory)	*Wt1*	
	Sprouty (intracellular molecule)	*Hox11 paralogs*	
		Formin	
		Foxc1	
		Sox9	
		Sall1	
Branching morphogenesis	GDNF	*Sall1*	Proteoglycans
	Pleiotrophin	*Timeless*	MMP9
	Wnt11	*Sox9*	Integrin $\alpha_3\beta_1$
	Gremlin	*Etv4*	Integrin $\beta1$
	TGFβ superfamily	*Etv5*	
	HGF		
	IGF		
	FGFs		
	FGFR2		
Maintenance/ maturation of collecting system	EGFR ligands	*Emx2*	
	Wnt9b, Wnt7b	*Foxd1*	
		Pbx1	
		Pod1	

ECM: extracellular matrix; EGFR: epidermal growth factor receptor; GDNF: glial cell line-derived neurotrophic growth factor; HGF: hepatocyte growth factor; IGF: insulin-like growth factor; TGF: transforming growth factor.

Growth Factors

The embryonic kidney or isolated metanephric mesenchyme can induce branching morphogenesis of MDCK, mIMCD3 or UB cells grown in type I collagen gels in the absence of apparent cell contact.[65,69,165] Moreover, isolated ureteric buds from E13 rats have been shown to undergo branching morphogenesis in the presence of soluble factors.[31] This suggests that the metanephric mesenchyme elaborates soluble growth factors capable of inducing branching morphogenesis in the ureteric bud. A number of key growth factors have been identified.

Glial Cell Line-Derived Neurotrophic Factor

The importance of GDNF and its receptors GFRa1 and RET in kidney development is strongly supported by gene knockout data. Kidney agenesis or severe kidney hypogenesis is found in *Gdnf*,[166–168] *Gfra1*[169] or *Ret* knockout mice.[170,171] GDNF is expressed in the prospective metanephric mesenchyme area, while GFRa1 and RET are expressed in the Wolffian duct at the time of ureteric bud induction. As discussed previously, a wide variety of genetic manipulations affecting the transcription of the GDNF/GFRα1/Ret axis lead to disruption of kidney development. Moreover, *in vitro* application of GDNF-soaked beads to the whole genitourinary tract culture induces ectopic budding of the Wolffian duct.[172] GDNF is also important in subsequent branching morphogenesis of the ureteric bud, as inhibition of this factor perturbs further branching of the isolated ureteric bud *in vitro*.[31] Gene dosage of *Gdnf* is important, as heterozygous null mutants of this gene have smaller kidneys.[173] However, unlike ureteric budding from the Wolffian duct, where GDNF appears necessary and sufficient, GDNF is necessary but not sufficient to support ureteric bud branching morphogenesis, at least in the isolated ureteric bud culture system.[31]

Fibroblast Growth Factors and Receptors

Many fibroblast growth factors (FGFs) and their receptors are expressed in the developing kidney.[174] Initial demonstration of the importance of this signaling pathway came from an analysis of transgenic mice that overexpress a soluble chimera of FGFR 2IIIb and human IgG Fc. In these animals, where FGF signaling is broadly inhibited, kidney agenesis or severe hypogenesis ensues.[175] In addition, minor kidney defects are reported in *Fgf7*,[176] *Fgf10*,[177] and *Fgfr2IIIb*[178] knockout mice. In the isolated ureteric bud culture system, FGF2 and FGF7 induce a less branched globular ureteric bud growth, while FGF1 and FGF10 support branching growth,[36] suggesting that FGFs may play a role in ureteric bud morphogenesis. Consistent with this, a ureteric bud-specific knockout of *Fgfr2*, (but not *Fgfr1*) was found to result in abnormal ureteric bud growth, as well as abnormally thickened cortical stroma.[164] Three-dimensional reconstructive imaging reveals decreases in ureteric bud tip number and increases in the length of the ureteric bud segments.[179,180]

Pleiotrophin

This heparin-binding growth factor has been implicated in neurite outgrowth[181] and mesenchymal–epithelial interaction during organogenesis.[182] In the context of kidney development, pleiotrophin (isolated from the conditioned medium made by metanephric mesenchyme-derived cells) was found to induce ureteric bud branching morphogenesis in the presence of GDNF in the *in vitro* culture system.[37] It is present in the developing kidney at the basement membrane of the ureteric bud. Although pleiotrophin may act as a mitogen for the ureteric bud after its budding through GDNF action, knockout of this gene does not appear to have a major affect in kidney development.[183]

Wnts and Related Molecules (Frizzled-Related Proteins)

A member of the WNT family of secreted glycoprotein, WNT2b is expressed in the stroma, and its presence promotes ureteric bud branching *in vitro*.[184] Null mutants of the gene encoding another member of WNT family, *Wnt11*, result in decreased ureteric bud branching with reduced *Gdnf* expression in the mesenchyme.[185] *Ret* knockout mice also show reduced expression of *Wnt11*.[185] In the trunk or stalk region of the ureteric bud, *Wnt9b* is expressed, and genetic deletion of this molecule results in cystic kidneys, presumably due to the disruption of the planar cell polarity (non-canonical beta catenin-independent) pathway of Wnt signaling.[186] Later in collecting duct development, collecting duct-specific inactivation of *Wnt7b* displays a similar phenotype.[187]

Secreted frizzled-related proteins (sFRPs) are secreted proteins that function as WNT modulators. sFRP1 is expressed in the stroma and periureter area; sFRP2 is expressed in early mesenchymal condensates and also in the periureter area in the developing kidney.[188,189] Exogenous administration of sFRP1 to embryonic kidney organ culture leads to decreased ureteric bud branching and nephron induction. While exogenous sFRP2 alone does not have a major effect, its administration to the organ culture treated with sFRP1 partially reverses the inhibitory effect of sFRP1.[189]

Transforming Growth Factor β Superfamily

Most of the soluble factors discussed thus far facilitate ureteric bud branching and growth. However, unopposed proliferation and branching is not desirable for normal kidney development. Potential candidates for these "negative regulators" include members of the transforming growth factor (TGF) β superfamily. Generally, TGFβ inhibits epithelial cell growth. In organ culture, exogenous TGFβ1 or another member of the TGFβ superfamily, activin, inhibits ureteric bud development and/or disrupts the branching pattern,[190] suggesting their role not only in regulating proliferation, but also in correct patterning. In this regard, it is interesting that TGFβ selectively inhibits HGF-induced mIMCD3 branching events with little effect on tubule formation[67]; HGF plus TGFβ induces long, straight tubules, whereas HGF alone induces branching tubules. Furthermore, detailed image analysis reveals alteration in the ureteric bud branching pattern in embryonic kidneys treated with TGFβ superfamily members.[40] In isolated ureteric bud culture, administration of TGFβ superfamily members causes growth inhibition, as well as morphological changes similar (although not so striking) to that observed in mIMCD cell culture.[40]

Heterozygous mutation of another family member, bone morphogenetic protein (*Bmp*) 4 reveals loss of ureteric bud elongation, together with ectopic budding from the Wolffian duct.[191] Its expression is detected at the intermediate mesoderm surrounding the Wolffian duct and metanephric mesenchyme surrounding the stalk of the ureteric bud.[191,192] Taken together, these data suggest that TGFβ superfamily members inhibit branching events, but have somewhat less effect on ureteric bud elongation (and may even facilitate it in the presence of stimulatory growth factors), and play a role in regulating the pattern of ureteric bud branching.

Gremlin

Gremlin is a secreted BMP antagonist[193] expressed initially in the Wolffian duct, followed by induced mesenchyme in metanephros development.[194] Knockout of this gene results in kidney agenesis. The ureteric bud forms but fails to invade the metanephric mesenchyme.[194] Subsequently, the metanephric mesenchyme undergoes apoptosis. Although the kidney phenotype of *Gremlin1* knockouts resembles that of *Sall1* knockouts, *Sall1* expression is unchanged in *Gremlin1* knockouts.[194] However, inactivation of one copy of the *Bmp4* gene or the complete absence of *Bmp7* in gremlin knockout animals rescues ureteric bud invasion and branching.[191,192] Thus, it possible that gremlin antagonization of BMP activity at ureteric bud tips acts to restrict and guide ureteric bud outgrowth and branching, although the mechanism remains unclear.[195,196] Furthermore, treatment of embryonic kidneys from *Six1* knockout animals with gremlin restores ureteric bud branching morphogenesis, while heterozygous inactivation of *Bmp4* ($Bmp4^{+/-}$) also rescues ureteric bud branching morphogenesis and kidney development in Six1 knockout animals.[197] Taken together, the

data indicate that interplay between Bmps, gremlin, and Six1 likely plays a key role in the regulation/modulation of ureteric bud growth and branching.[197]

Hepatocyte Growth Factor

Embryonic kidneys express HGF and its receptor Met.[165] Neutralizing anti-HGF antibodies inhibit the growth of the embryonic kidney and disrupt ureteric bud branching morphogenesis in serum-free organ culture.[165] These results support the notion that HGF is an important morphogen for the ureteric bud that is secreted from metanephric mesenchyme. However, kidney development appears to be unaffected up to embryonic day 14 in *Hgf* or *Met* knockout mice, which die around this time from liver failure.[198,199] Although HGF may act at later stages of ureteric bud branching morphogenesis, it is probably not critically important in the initial stages.

Epidermal Growth Factor Receptor Ligands

Epidermal growth factor (EGF), transforming growth factor α (TGFα), heparin-binding epidermal growth factor-like growth factor (HBEGF), amphiregulin, and betacellulin all bind and activate the EGF receptor.[200] TGFα is present in the embryonic kidney, and disruption of TGFα signaling by neutralizing antibodies results in a small, less well-developed kidney in organ culture.[201] As mentioned above, when mIMCD3 cells grown in collagen gels are co-cultured with embryonic kidney, the cells undergo branching morphogenesis. Unlike MDCK cells, which only undergo branching morphogenesis in the presence of HGF,[165,202] mIMCD3 cells respond to EGF receptor ligands as well.[65,68] Similar results are obtained with the UB cell three-dimensional culture system.[69] Moreover, *Met* (HGF receptor) knockout kidney epithelial cells grown in three-dimensional extracellular matrix (ECM) gels undergo *in vitro* tubulogenesis in response to EGF or TGFα.[203] A conditional deletion of *Met* from the ueteric bud results in kidneys with a reduced number of nephrons and increased epidermal growth factor (EGF) receptor expression.[83] Mice which lack both normal *Egfr* and *Met* signaling have decreased ureteric bud branching and small kidneys with a reduced number of glomeruli, suggesting that *Met* and *Egfr* can act cooperatively to regulate ureteric bud branching.[83] Although *Tgfα* knockout mice do not have a kidney phenotype,[204,205] knockout of the *EGF* receptor in mice with a certain genetic background leads to dilated collecting ducts and renal dysfunction.[206] These results suggest an important role for EGF receptor ligands in later collecting duct development.

Insulin-Like Growth Factors

In serum-free organ culture, the embryonic kidney produces insulin-like growth factors (IGFs) 1 and 2.[207] When neutralizing antibodies against IGFs are added to the culture, kidney growth is suppressed.[207] The ureteric bud expresses IGF1 receptor.[208] Addition of antisense oligonucleotides against IGF1 receptor to the embryonic kidney in organ culture leads to a small kidney with disrupted ureteric bud branching morphogenesis.[208] However, knockout mice for either *Igf1* or *Igf2* do not display a kidney phenotype.[209,210] Molecular redundancy may be part of the explanation; however, as with HGF, the apparent discrepancies between the *in vitro* and *in vivo* data need to be addressed experimentally.

Extracellular Matrix

Soluble growth factors are not the only molecules involved in ureteric bud branching morphogenesis. Cells of the ureteric bud are surrounded by ECM proteins, and to form branching tubules the cells must digest the ECM. Cells have receptors for ECM proteins, such as integrins, as well as other specific receptors. Integrins can transmit signals to cytosolic and intranuclear proteins in a fashion similar to growth factor receptors. The cell modifies its behavior in response to the combined signals from growth factors and ECM proteins.[211]

The importance of the specific composition of the ECM in kidney epithelial cell branching morphogenesis has been shown using the three-dimensional cell culture model. When MDCK cells are cultured in type I collagen gels in the presence of HGF, the cells undergo branching morphogenesis. When MDCK cells are suspended in growth factor-reduced Matrigel, a basement membrane protein mixture secreted by EHS sarcoma cells, HGF-induced tubulogenesis is inhibited.[212] By mixing individual Matrigel component proteins into type I collagen gels, it was found that collagen I, laminin, fibronectin, and entactin facilitate MDCK cell tubulogenesis, whereas collagen IV, vitronectin, and heparan sulfate proteoglycan inhibit it.[212] However, a mixture of type I collagen and Matrigel, not pure type I collagen, is the optimum ECM for UB cell (a cell line derived from embryonic kidney tissue) tubulogenesis. Interestingly, when these cells are cultured in growth factor-reduced Matrigel alone, UB cells develop into cystic structures (Figure 25.13).[69] Together with the fact that isolated ureteric buds can be cultured in an ECM containing Matrigel but not in pure type 1 collagen gels,[31] this indicates that ECM composition modulates tubulogenesis and branching morphogenesis.

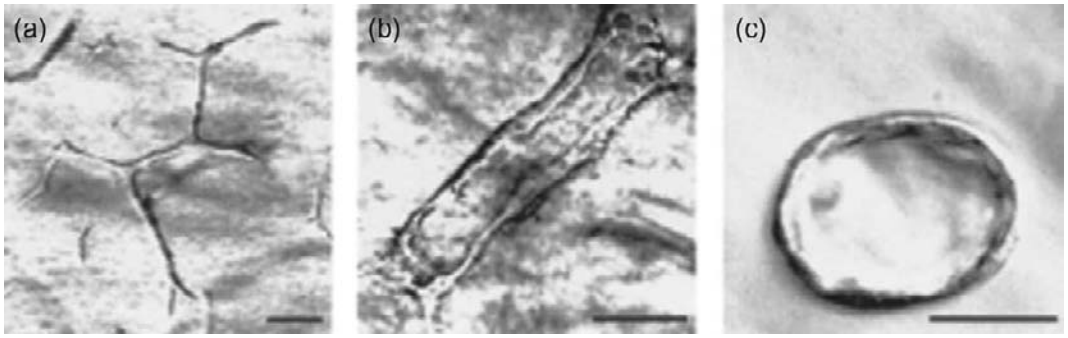

FIGURE 25.13 **Photomicrograph of ureteric bud (UB) cells cultured in three-dimensional extracellular matrix (ECM) gels.** In the presence of conditioned medium from metanephric mesenchyme cells, UB cells form branching cordlike structures in 3 to 5 days (a). In 10 to 15 days tubules with clear lumens can be observed (b). UB cells form multicellular cysts when cultured in pure Matrigel (c) instead of collagen I/Matrigel mixture (A and B) (Bars: 50 μm). *(from ref. [69]).*

Laminin

Laminins are the major component of the mature basement membrane. The role of laminin in epithelial branching morphogenesis has been shown in lung organ culture *in vitro.* Antilaminin antibodies perturb branching morphogenesis of embryonic lung in culture.[213] In the kidney, studies have shown a role for laminin in epithelial cell formation from the induced metanephric mesenchyme. It is known that antibodies against nidogen, a basement membrane protein secreted by mesenchymal cells, perturb epithelial morphogenesis in lung and kidney.[214] Nidogen binds to the γ1 chain of laminin. Thus, it is conceivable that the mesenchyme regulates epithelial branching morphogenesis through nidogen−laminin interaction. Moreover, knockouts of one of the laminin receptors, α3β1 integrin, result in decreased ureteric bud branching morphogenesis.[215] In *in vitro* whole organ culture and isolated ureteric bud culture, branching is inhibited in the presence of blocking antibodies against integrins α3, α6, β1 or β4. Interestingly, a common ligand for α3β1 and α6β4, laminin-5, is present in the developing ureteric bud, and its inhibition results in decreased branching in both whole embryonic kidney culture and isolated ureteric bud culture.[38]

Proteoglycans

Proteoglycans are protein molecules containing many bound glycosaminoglycan (GAG) chains.[216] The common GAG chains include chondroitin sulfate, dermatan sulfate, heparan sulfate, heparin, and keratan sulfate. Proteoglycans are mostly found at the cell surface or in the extracellular matrix. In embryonic kidneys, sulfated proteoglycans are concentrated around the tip of the ureteric bud, and perturbation of their synthesis by β-D-xyloside results in the inhibition of ureteric bud branching morphogenesis.[217,218] This perturbation also abolishes the expression of *Wnt11* at the tip of the ureteric bud.[219] As described previously, loss of *Wnt11* expression at the tip of the ureteric bud can lead to loss of *Gdnf* expression in the metanephric mesenchyme. However, the linking mechanism between inhibition of sulfated proteoglycan and the loss of *Wnt11* expression is unclear. Along the same lines, genetic inactivation of an enzyme, heparan sulfate 2-O-sulfotransferase, involved in heparan sulfate proteoglycan synthesis results in kidney agenesis.[53] In this case, the ureteric bud forms from the Wolffian duct, but subsequent invasion of the metanephric mesenchyme is perturbed. As for the mesenchyme, initial specification of the metanephric mesenchyme appears intact, but subsequent mesenchymal condensation is affected. Consistent with the *in vitro* result described above, heparan sulfate biosynthesis perturbation results in loss of *Wnt11* expression and reduced *Gdnf* expression. Given the fact that many growth factors that regulate branching morphogenesis of the ureteric bud are heparin (a heavily sulfated form of GAG chain)-binding, it is likely that global inhibition of GAG chain synthesis or its sulfation could compromise actions of these heparin-binding growth factors.

In contrast, inhibition of specific heparan sulfate proteoglycans results in less clear effects. One exception is *glypican* (*Gpc*) 3, a gene encoding a heparan sulfate proteoglycan linked to the cell surface via a glycosyl-phosphatidylinositol anchor. *Gpc3* knockout mice display enhanced ureteric branching and dysplastic kidneys.[220] *Gpc3* is expressed in the ureteric bud cells and modulates BMP and FGF action on the ureteric bud.[220] A potent angiogenesis inhibitor, endostatin, a breakdown product of extracellular proteoglycan, collagen XVIII, inhibits ureteric bud branching

morphogenesis.[35] Interestingly, this action is likely to be mediated through its binding to glypicans.[35]

Although it is not a proteoglycan in the strict sense, because it lacks a protein core, hyaluronic acid (HA) also plays a role in branching morphogenesis. Synthetic enzymes for this GAG are expressed in the developing kidney, and the addition of HA to three-dimensional culture of UB cells promotes tubulogenesis and survival of cells. Blocking antibodies against its receptor CD44 abolishes this effect.[221] In addition, supplementation of cultures of isolated ureteric bud or whole kidneys with hyaluronidase inhibited branching morphogenesis.[222] Specific sizes and concentrations of HA were also found to act independently in regulating UB branching, and in tubular maturation.[222]

While the protein core of proteoglycans, particularly the heparan sufate proteoglycans, play important roles in many developmental and physiologic processes, most of the function of these proteoglycans are mediated by the variably sulfated heparan sulfate GAG chain. For example, mice deficient in heparan sufate 2-O sulfotransferase, a heparan sulfate biosynthetic enzyme, display renal agenesis.[53] As described above, this is likely due to a defect in the induction of the metanephric mesenchyme.[46] On the other hand, ureteric bud branching morphogenesis appears to be more dependent upon 6-O sulfated heparan sulfate.[47]

Fibrillin1

Fibrillin1 is made in the metanephric mesenchyme and binds to integrin $\alpha 3\beta 1$, which is expressed in the ureteric bud. Antisense oligonucleotides directed against this extracellular matrix molecule induce dysmorphogenesis of cultured metanephros,[223] suggesting a role for this protein in kidney development.

Extracellular Proteinases and their Inhibitors

The idea that ECM-degrading proteases are involved in branching morphogenesis is supported by work from *in vitro* three-dimensional culture and organ culture. Two classes of proteases appear to be involved: metalloproteases (MMPs) and serine proteases. In HGF-induced MDCK cell tubulogenesis, inhibitors of collagenase (MMP1) perturb the morphogenetic events when the cells are suspended in type I collagen gels.[224] The broadly active MMP inhibitor, 1,10-phenanthroline, inhibits TGFα- or HGF-induced mIMCD3 cell tubulogenesis in collagen gels.[68] Furthermore, tubulogenic growth factors, such as HGF or EGF receptor ligands, upregulate the expression of MMPs and urokinase in the epithelial cells as they undergo tubulogenesis.[68,71] Interestingly, in the case of long, non-branching mIMCD3 cell tubules induced by HGF plus TGFβ, the balance between proteases (MMP1 and urokinase) and their inhibitors (TIMP1 and PAI1) expressed by mIMCD3 cells changes in parallel with tubular morphology.[67] In embryonic ureteric bud-derived UB cells, expression of MMPs and TIMPs changes in response to surrounding ECM and soluble factors.[34] These results suggest that tubulogenic growth factors act, at least in part, through changing the expression patterns of extracellular proteases and their inhibitors in *in vitro* tubulogenesis. It has also been shown that "tubulogenic ECM" and highly tubulogenic conditioned medium secreted by metanephric mesenchyme-derived cells contain MMP activity, and that the expression level of regulators for these MMPs in UB cells alters as branching morphogenesis progresses,[34] suggesting local control of proteolytic activity is important in the morphogenetic process. In the embryonic kidney in organ culture, antibodies against MMP9, but not MMP2, inhibit the branching morphogenesis of the ureteric bud.[225] Although *Mmp9* knockout mice do not show a kidney phenotype in some genetic backgrounds,[226] in the C57BL/6 background deletion of Mmp9 results in a $\sim$30% reduction in nephron number.[227] This is most likely through its anti-apoptotic effect in the mesenchyme, and its ability to stimulate ureteric bud branching morphogenesis.[227] Both of these enzymes act as a gelatinase, which is required to digest ECMs in basement membranes. In another study, however, antisense oligonucleotides against mesenchymal MMP2 or epithelial cell surface-expressed membrane type (MT)1-MMP inhibit metanephrogenesis in organ culture.[228]

In summary, ureteric bud branching outgrowth and morphogenesis is modulated in large part by a combination of positive and negative soluble growth factors secreted by the metanephric mesenchyme that act synergistically. In many cases, these pathways are more parallel than interdependent. These growth factors subsequently regulate downstream effector molecules such as ECM or ECM-degrading proteinases (Figure 25.14).

TUBULOGENESIS AFTER INDUCTION OF THE METANEPHRIC MESENCHYME

Early mesenchymally-derived nephrons, which will go on to form Bowman's capsule, as well as the proximal and distal tubules, are induced in the metanephric mesenchyme by the ureteric bud. In the process, mesenchymal cells transform into epithelial cells. The induced epithelial cells differentiate into kidney tubules. This transformation can be induced by a number of inducer tissues other than the ureteric bud, including embryonic spinal cord, embryonic salivary

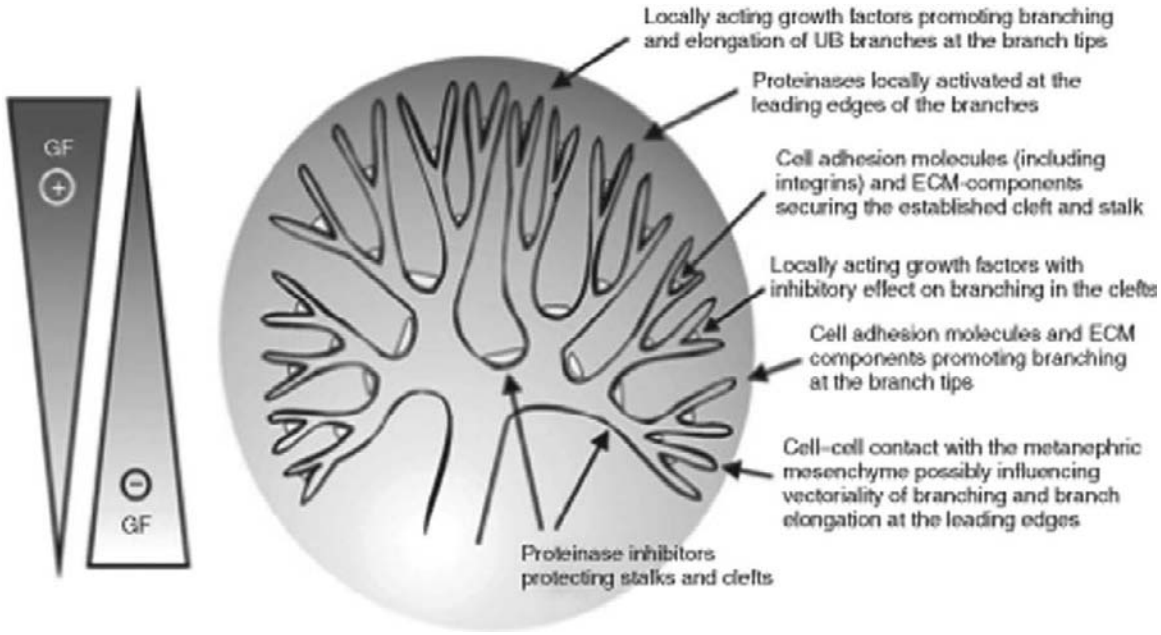

FIGURE 25.14 **Model for ureteric bud branching morphogenesis.** After induction of the ureteric bud (UB), in which GDNF appears to play a critical role, branching may be guided by gradients of promoting (GF +) and inhibiting growth factors (GF −). Distal effector molecules probably include facilitating and inhibiting extracellular matrix (ECM) components, together with signal transducing–cell adhesion molecules such as integrins, CD44, membrane-bound proteinase activators such as MT1-MMP, and active proteinases (e.g., MMP9), as well as proteinase inhibitors such as TIMP3, which binds to the ECM and could protect the matrix around the stalks from degradation. *(Reprinted with permission from the* Annual Review of Physiology, *Volume 62 © 2000 by Annual Reviews www.annualreviews.org.)*

mesenchyme, and embryonic bone.[48,49,229] Many embryonic epithelial, neural or mesenchymal tissues can thus induce the metanephric mesenchyme, although various tissues have different potency. For example, brain can only induce metanephric mesenchyme to the condensation stage, while spinal cord can induce tubule formation.[230] Thus, it is conceivable that there are several steps in the induction process: (1) rescue of metanephric mesenchyme and/or later tubular structures from apoptosis; (2) mesenchymal cell condensation; (3) epithelial polarization and junction formation; and (4) tubule formation. The molecules likely involved in the process are summarized in Table 25.2.

Prevention of Apoptosis

During kidney tubule development, apoptosis is observed among cells surrounding newly formed epithelial tubules.[231] In fact, significant levels of apoptosis appear to be occurring in many parts of the kidney during development.[232] When the metanephric mesenchyme is cultured with inducer tissues or EGF, apoptosis becomes less prominent.[231,232] These results suggest that an important early signal from the inducer tissue prevents metanephric mesenchyme cell apoptosis. In *in vitro* culture of metanephric mesenchyme, conditioned medium from UB cells also exhibits an anti-apoptotic effect.[233] One of the anti-apoptotic molecules in UB-conditioned medium is FGF2.[234] Consistent with these findings, RUB cell (derived from rat ureteric bud)-conditioned medium requires supplementation of FGF2 and TGFα to induce kidney tubule formation in the absence of inductive tissues.[235]

In addition, analysis of bone morphogenetic protein (*Bmp*)*7*-deficient mice suggests that BMP7 may act as an anti-apoptotic factor.[236,237] BMP7 belongs to the TGFβ superfamily and is expressed in the Wolffian duct, ureteric bud, and nephron structures after induction.[236] *Bmp7* knockout mice exhibit defects in eye and kidney development. Although there is a difference in the early kidney phenotype between knockout mice created by different groups, ureteric bud formation and initial induction appears unaffected; at least a few comma- and S-shaped bodies are observed at E12.5.[236,237] However, soon after this, both the ureteric bud and the metanephric mesenchyme start to degenerate, ultimately resulting in nonfunctioning disorganized kidneys. This raises the possibility that BMP7 maintains induced tubules, inhibiting them from apoptosis rather than directly inducing the metanephric mesenchyme.[236] On the other hand, *in vitro* application of BMP7 has been reported to induce E11.5 mouse metanephric mesenchyme to form epithelial glomeruli

TABLE 25.2 Molecules Likely to be Involved in Metanephric Mesenchyme Induction

Process	Transcription Factors	Soluble Factors	ECM/Other Molecules
Define	*Wt1*		
nephrogenic	*Pax2*		
mesenchyme	*Six1 Six2 Sall1 high*		
	Myc (uninduced MM)		
Rescue from apoptosis		FGF2, FGF8	
		EGFR ligands	
		BMP7	
Condensation/ epithelialization	*Pax2*	Wnt9b	Laminin
	Pax8	LIF	(γ1chain)/laminin receptor
	Nmyc	TGFβ2	(α6β1 integrin, nonmuscle dystroglycan)
	Foxd1	Lipocalin	
	Pod1	Wnt4	
	Pbx1		α8β1 integrin
Tubule formation	*Hnf1* (proximal tubule)		Laminin (γ1chain)/laminin
	Brn1 (Henle, distal)		receptor

ECM: extracellular matrix; LIF: leukemia-inhibiting factor; TGF: transforming growth factor.

without inductive tissues.[238] Whether BMP7 directly induces the metanephric mesenchyme remains to be determined.

Molecules Involved in Metanephric Mesenchyme Induction and Nephron Tubule Formation

As discussed in the transcription factor section, certain transcription factors such as *Pax2*, *Wt1*, *Six1*, *Six2* or *Sall1* are necessary to retain competency of the metanephric mesenchyme to respond to the signals from the ureteric bud. Early experiments using transfilter coculture of the metanephric mesenchyme with various inductive tissues defined several expected characteristics of "inductive molecules".[7] Experiments using different pore-size filters and multiple filters to separate the metanephric mesenchyme and inducer suggest that inductive molecules do not simply diffuse, rather, they seem to require close association of cells. In other words, direct cell-to-cell contact and/or soluble molecules associated with the cell surface are likely to be required for induction. In fact, direct interaction between the inductive tissue and the metanephric mesenchyme cells have been observed through the filter pores by electron microscopy.[239]

However, *in vitro* work indicates that combinations of soluble factors are sufficient to induce tubulogenesis of the metanephric mesenchyme. Leukemia inhibitory factor (LIF), FGF2, and TGFβ[51] or this combination plus TGFβ2[52] can induce nephron tubules in metanephric mesenchyme cultured in the absence of inductive tissues. A member of the lipocalin superfamily, 24p3, has also been shown to induce epithelialization of metanephric mesenchyme in the presence of FGFs,[240] and to deliver iron to the cell (iron is required for mesenchymal induction by this molecule[240]).

Cell surface glycoproteins of the Wnt family are candidate molecules for coordinating morphogenesis at the interface of metanephric mesenchyme and inductive tissues, as WNT1-expressing fibroblasts induce the metanephric mesenchyme to form glomeruli.[241] Although the *Wnt1* gene is not expressed in embryonic kidneys,[242] this result raises the possibility of an important role for other Wnt family members in nephrogenesis. Another Wnt family member, *Wnt4*, is expressed in the embryonic kidneys; it first appears in condensed metanephric mesenchyme, and its expression continues in comma- and S-shaped bodies, finally becoming restricted to the area where newly formed epithelial tubules are connected to collecting ducts.[243] WNT9b, secreted from the ureteric bud, triggers mesenchymal epithelial transformation, as metanephric mesenchyme induction is not observed in *Wnt9b*$^{-/-}$ mice.[244] Six2, a transcription factor important for nephron progenitor maintenance, counteracts WNT9b signaling.[6] Downstream of WNT9b, WNT4 plays an important role in metanephric mesenchyme induction as an autocrine factor for metanephric mesenchymal cells.[244] The metanephric mesenchyme of mutant mice lacking the *Wnt4* gene is able to condense around the branching ureteric bud, but fails to form peritubular aggregates.[243] There is no apparent kidney tubule development in these knockout animals. The expression of markers for early mesenchymal induction, *Pax2* and *Nmyc*, does not seem to be affected in *Wnt4* mutant mice, suggesting that *Wnt4* acts at a later stage than *Pax2* or *Nmyc*. However, *Pax8* expression by metanephric mesenchyme-derived structures cannot be detected in the mutant mice.

Another autocrine factor for metanephric mesenchyme induction is FGF8. Site specific, conditional deletion of Fgf8, either in the metanephric mesenchyme[245] or in all mesodermal tissues,[179,246] results in hypoplastic,

dysmorphic kidneys displaying disruptions in nephron formation. Conditional deletion of both *Fgfr1* and *Fgfr2* from the metanephric mesenchyme results in renal dysgenesis, due to defects in the formation of the metanephric mesenchyme and early ureteric bud.[247]

The cell-surface-signaling molecule Notch has also been implicated in tubulogenesis. Binding of Notch by its ligands (Jagged1 (Jag1), Jag2, Delta-like (Dll) 1, Dll3 or Dll4)) results in the shedding of its extracellular domain, cleavage of its transmembrane domain by γ-secretase, and translocation of its intracellular domain to the nucleus where it promotes transcription of target genes (reviewed in [248–250]). *Notch 1*, *2*, and *3* have been shown to be expressed in the developing kidney.[58,251–255] *Notch2* mutation leads to hypoplastic kidneys with glomerular defects,[256] while conditional deletion of *Notch2*, but not *Notch1*, causes the loss of glomeruli and proximal tubules.[248] However, proteolytic cleavage of Notch1 by γ-secretase is required for Notch activation, and this inhibition in kidney organ culture results in decreased S-shaped bodies despite having normal condensation.[257] Knockout and partial rescue of *Presenilin1* and *2* that are required for γ-secretase activity lead to a similar phenotype.[258] In addition, augmenting Notch1 signaling by inactivating Mint (an inhibitor of Notch-mediated transcription[250,259–262]) has the ability to partially rescue nephron development in Notch2 knockout kidneys.[250] Taken together, the data suggest that Notch1 and Notch2 likely act in concert to regulate proximal tubule and glomerular development.[250]

Extracellular matrix proteins are important for maintaining epithelial tubular structures. Much work has been done on the basement membrane glycoprotein laminin and the integrins that bind laminin. Laminin1 is composed of three chains: α1; β1; and γ1. Of these, β1- and γ1-expression increases early (day 1) when the metanephric mesenchyme is induced, while the α1 chain is expressed after epithelial cell polarization begins.[263,264] The laminin α1 chain is exclusively expressed by the epithelial cells,[263] and perturbation of this chain by antibodies inhibits kidney tubulogenesis *in vitro*.[265] The kidney epithelial cell has at least two laminin receptors: $\alpha_6\beta_1$ integrin and nonmuscle dystroglycan. Perturbation of these receptors inhibits kidney tubulogenesis *in vitro*.[38,266] Moreover, in *in vitro* culture of embryonic lung, it has been demonstrated that heterotypic cell-to-cell contact between epithelial cells and mesenchymal cells is required to synthesize the laminin α_1 chain.[267] If this result is applicable to embryonic kidney, further differentiation after cell-to-cell contact may be a function of expression of the laminin α_1 chain.

In addition to laminin-binding integrins, knockouts of integrin α8 have been shown to produce severe defects in kidney development.[268] The ureteric bud initiation and initial mesenchymal induction appear unaffected; the metanephric mesenchyme cells condense around the ureteric bud and start to express *Pax2* and p75 NGFR. However, further steps toward epithelialization and tubule formation are not observed. In normal mice, α8β1 integrin is transiently expressed in the condensing mesenchymal cells. Both spatiotemporal localization and knockout phenotype suggest that $\alpha_8\beta_1$ integrin plays an important role after the initial induction step of mesenchymal–epithelial transformation.

Evidence is beginning to accumulate on the functional maturation of the kidney tubules. Kidney tubules further differentiate into several segments. In each segment the tubular cells express different sets of transporters. For example, Northern blot analysis shows that the organic anion transporter Oat1 begins to be expressed at around E16 kidney.[269] It is likely that expression of many transporters, characteristic of mature tubules, is tightly regulated. In this regard, elucidation of the roles of transcription factors *Hnf1* (proximal tubules) and *Brn1* (Henle's loop and distal tubule) is important, and other unknown factors may be involved in this process.

VASCULAR AND GLOMERULAR DEVELOPMENT

The origin of glomerular endothelial cells and mesangial cells, and how the vascular system is integrated in the developing kidney, has been an area of controversy for years (reviewed in[13]). Vascular development occurs by: (1) angiogenesis, in which new vessels arise from existing vasculature; and/or (2) vasculogenesis, in which *de novo* endothelial cells are formed. As mentioned previously, *in vitro* kidney organ culture gives rise to epithelial glomerular structures, not mesangial cells nor endothelial cells, suggesting that either the culture conditions are not suitable for endothelial cell growth or there are no angioblasts in the metanephric mesenchyme. To study kidney vascular development, interspecies grafting techniques have been used in which E11 murine embryonic kidneys are transplanted into chick chorioallantoic-membranes (CAM).[270] When E11 mouse kidneys, which have no apparent vascular development, are grown in chick CAM, the kidneys form glomeruli containing blood vessels from the chick, as determined by staining with species-specific antibodies against basement membranes.[271,272] However, when E11 mouse kidneys are grafted into the rat anterior eye chamber, newly formed glomerular endothelial cells appear to be derived from the graft.[273] Moreover, the same group has demonstrated that vascular endothelial cell growth factor (Vegf) receptor FLK1-positive cells are

found in the E12 mouse kidney, and these cells are likely to be angioblasts, which differentiate into blood vessels in the glomeruli.[274] Thus, depending on the culture and grafting conditions, glomerular capillaries can be derived by an angiogenic process (i.e., outside of the metanephric mesenchyme or a vasculogenic process; inside of the metanephric mesenchyme). Which of these processes is more important *in vivo* remains uncertain, and it is of course possible that both are important.

The origin of mesangial cells also remains uncertain, although it has been recently proposed that they are derived from cap mesenchymal cells.[6,275] In the aforementioned different kidney graft systems, mesangial cells appear to behave similarly to glomerular endothelial cells: in CAM grafts, the mesangial cells are derived from the hosts[276,277]; while in the anterior eye chamber grafts, they are derived from the grafts.[273] Platelet-derived growth factor (*Pdgf*)-B receptor knockout mice do not have mesangial cells, and exhibited dilated capillary loops resulting in defective glomeruli.[278,279]

Recently, genetic fate tracing of *Six2*-positive nephron progenitor cells revealed that neither vasucular endothelial cells nor mesangial cells are derived from nephron progenitors.[280] This does not mean that blood vessel and mesangial cells are extrarenal in origin, because metanephric mesenchyme contains non-nephron progenitor cells. Nevertheless, it should be noted that endothelial and mesangial cells and nephron epithelial cells are derived from distinct sources.

In addition, deletion of *Crim1*, a transmembrane protein expressed in mesangial cells and podocytes, was found to induce abnormal glomerular development, characterized by simplified glomerular capillary networks with dilated capillaries.[281–283] Together with the observed mislocalization of Vegf-A, as well as increased activation of Flk1, *Crim1* appears to regulate the spatial distribution of Vegf-A during glomerular development.[282] Knockout of Semaphorin3a (*Sema3a*) also disrupts kidney vascular patterning.[101,284,285] Decreased apoptosis of endothelial cells is observed in kidneys from *Sema3a* knockout animals, while whole organ culture also indicates that Sema3a is a chemorepellant and inhibits endothelial cell migration.[101,284,285] Together with the fact that Vegf-A promotes endothelial cell survival and acts as a chemoattractant for endothelial cells,[286,287] the data suggest that endothelial cell number and vascular patterning is regulated by a balance of Vegf-A and Sema3a signaling.[284,285]

TERMINATION OF KIDNEY DEVELOPMENT

Despite the wealth of literature describing the molecules and mechanisms regulating the various morphogenetic processes involved in the development of the metanephric kidney, how the overall process is brought to an end has received little attention. In humans, kidney organogenesis is complete before birth; however, in other mammals, including rats and mice, kidney development continues into the postnatal period. Examination of this postnatal period in mice reveals the loss of nephrogenic mesenchyme by day three after birth.[288] This was not due to an increase in apoptosis, but rather appeared to result from the synchronous conversion of the remaining nephrogenic mesenchyme into new nephrons.[288] Since, during this time, the ureteric bud tips retain the capacity to induce nephrogenesis *in vitro*, this indicates that this loss of nephrogeneic mesenchyme demarcates the beginning of the end of kidney development.[288] This time period also correlates with the observed sudden burst in the expression of many genes involved in redox metabolism and transport, including multispecific drug transporters such as Oat1 and Oct1.[75] Together, the data suggest that parturition and the end of kidney development is characterized by rapid changes in: (1) the remaining metanephric mesenchyme, leading to the formation of new nephrons (which completes metanephrogenesis and sets the final nephron number); and (2) the differentiation state of existing nephrons.[75,288]

CHAPTER

26

Molecular and Cellular Mechanisms of Glomerular Capillary Development

Jeffrey H. Miner[1] *and Dale R. Abrahamson*[2]

[1]Department of Medicine, Renal Division, Washington University School of Medicine, St. Louis, MO, USA

Among all of the capillaries in the body, the glomerulus is arguably the most unusual and important, if not the most aesthetically interesting. In this chapter, we review the morphogenesis of this unique capillary, discuss the origins of its cells and extracellular matrices, and describe some of the primary regulatory events that occur during glomerular development.

GLOMERULAR MORPHOGENESIS

Formation of the permanent, metanephric kidney begins at embryonic day 11 in mice, day 12 in rats, and during the 4th-5th week of gestation in humans. As the ureteric bud projects from the mesonephric duct and enters the metanephric anlage, mesenchymal cells condense around the bud's advancing tip. Soon thereafter, the condensed mesenchyme converts to an epithelial phenotype and proceeds through a developmental sequence of nephric structures, which are termed vesicle, comma-, and S-shaped, developing capillary loop, and maturing glomerulus stages.[1,2] Bud tip stimulation of mesenchymal cell induction and aggregation, conversion to epithelium, and glomerular and tubule differentiation occur repeatedly until the full complement of nephrons has developed. Nephrogenesis concludes ~1 week after birth in rodents,[2] and during the 34th gestational week in humans.[3]

Vesicle Stage

At the inception of the vesicle stage of nephron development, the aggregated mesenchymal cells near the ureteric bud tips convert to a cluster of epithelial cells (vesicle), and begin assembling a basement membrane matrix containing collagen type IV, laminin, and basement membrane proteoglycans around the basal surface of the vesicle.[4–6] As development progresses through the comma- and then S-shaped stages, a groove (vascular cleft) forms in the lower aspect of the vesicle, into which endothelial precursor cells (angioblasts) migrate (Figure 26.1). Two epithelial layers can be distinguished beneath the vascular cleft: visceral epithelial cells (which ultimately differentiate into podocytes); and parietal epithelial cells (which will become the thin epithelium lining Bowman's capsule of the mature nephron). Epithelial cells above the vascular cleft ultimately develop into proximal, Henle's loop, and distal tubule epithelium. During the S-shaped phase of nephron development, the distal segment fuses with the same ureteric bud branch tip that initially induced the nephric structure, so that the lumen of the forming nephron is now continuous with that of the developing collecting system. Continued growth and branching of the ureteric bud leads to the induction of new mesenchymal aggregates, and glomerulo- and tubulogenesis continues until the full complement of nephrons is achieved.[2]

Vascular Clefts of Comma- and S-Shaped Stage

With the progressive invasion and differentiation of endothelial cells, the developing capillary endothelium assembles a subendothelial basement membrane matrix.

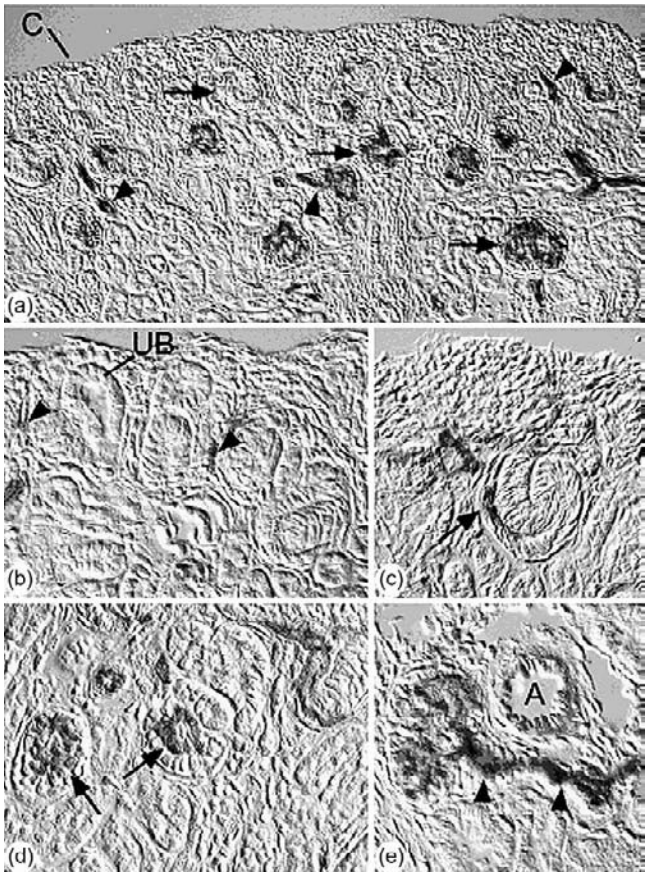

FIGURE 26.1 **Sections of developing kidney from a heterozygous Flk1/LacZ transgenic mouse.** Blue reaction product reflects cellular sites of Flk1 (VEGFR2) gene transcription. (a) Kidney cortex contains a range of glomeruli at different stages of development (arrows) that are lined by endothelial cells expressing Flk1. Vascular endothelium throughout the cortex also express Flk1 (arrowheads) (C: capsule). (b) Higher magnification view of outer cortex. Note blue cells scattered in mesenchyme (arrowheads) (UB: branch of ureteric bud). (c) Nephric figure at S-shaped stage. Endothelial cells expressing Flk1 can be seen migrating into the vascular cleft (arrow), which is the initial site of glomerular formation. (d) Two capillary loop stage glomeruli can be seen (arrows). (e) Maturing stage glomerulus with attached arteriole (arrowheads) (A: small artery). *(Reprinted from ref. [26], with permission).*

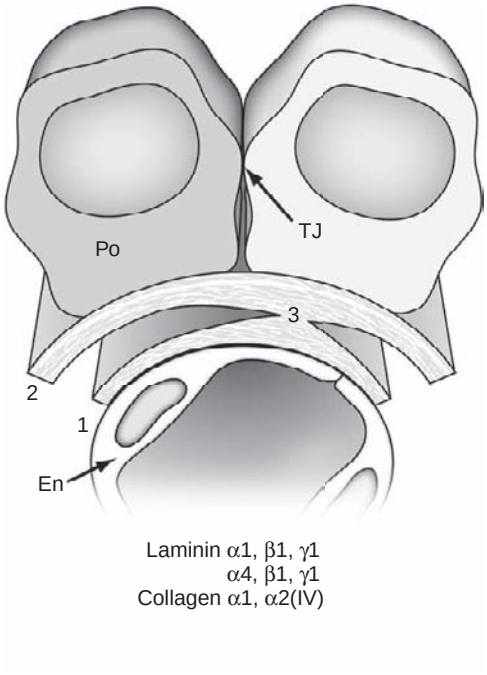

FIGURE 26.2 **Diagram showing spatial relationships during development of glomerular capillary wall.** During initial glomerular development, endothelial cells (En) migrate into vascular clefts of comma- and S-shaped nephrons. Dual sheets of subendothelial (1) and subepithelial (2) basement membranes separate the endothelium from the developing podocyte (Po) cell layers. Areas of basement membrane fusion can be seen (3). The immature GBM contains laminin α1,β1,γ1, laminin α4,β1,γ1 and collagen α1,α2(IV) at this time point. Apical tight junctional complexes (TJ) exist between immature podocytes.

Similarly, the developing podocyte cell layer assembles a subepithelial basement membrane, so that two distinct basal laminae can be seen between the endothelial and epithelial cells (Figure 26.2). As nephrons develop further, these two basement membranes layers merge to form the glomerular basement membrane (GBM), with endothelial cells lining its inner surface, and podocytes adherent to its outer surface.[7]

Capillary Loop

As glomerular capillary loops begin to form, the endothelial cells gradually flatten and become extensively fenestrated (Figures 26.3 and 26.4). Initially, the fenestrations are spanned by diaphragms, but these structures soon disappear. The epithelial podocytes, which originally were columnar with apical junctional complexes, also begin to flatten and begin sending out basolateral cytoplasmic projections that interdigitate with similar projections from neighboring cells (Figure 26.3). As glomeruli mature, these projections go on to develop into the podocyte pedicels or foot processes (Figures 26.3 and 26.4). The apical junctional complexes migrate basolaterally between these cellular projections and, although the mechanism is not fully-understood (see below), convert into the slit diaphragm complex between foot processes[8] (Figure 26.4). Metabolic labeling studies, histochemical and immunohistochemical techniques, and inter-species transplantation experiments[6,9–12] have all shown that both the endothelium and epithelium are actively synthesizing glomerular basement membrane (GBM) proteins at this time.[4]

Maturing Glomeruli

Here, capillary loop diameters expand, and endothelial and podocyte cell layers differentiate further until the

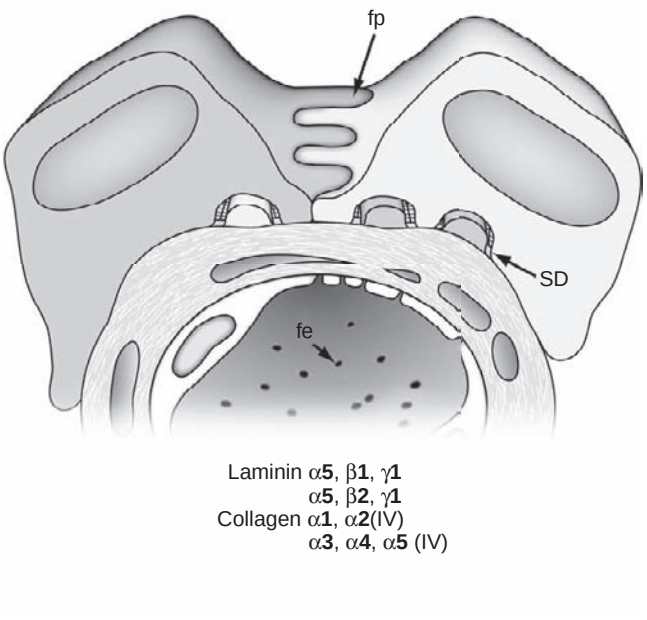

FIGURE 26.3 **During intermediate, capillary loop and maturing stages of glomerular development, fenestrae form in the endothelial cells.** Foot process (fp) extension occurs between podocytes and epithelial slit diaphragms (SD) first appear. Remodeling and splicing of newly synthesized GBM into existing, fused, GBM takes place, and new isoforms of GBM laminin and type IV collagen are seen.

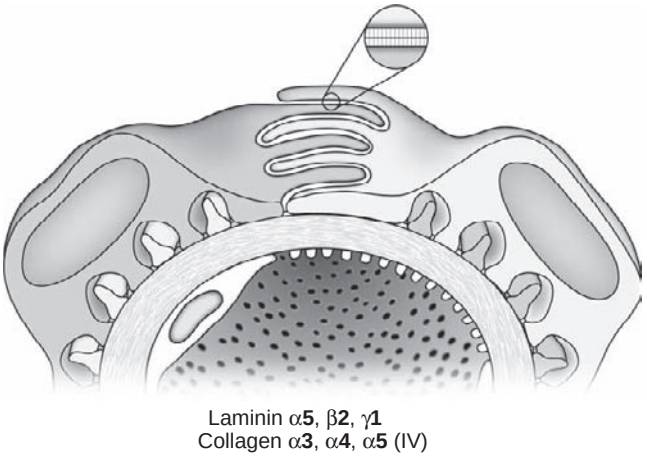

FIGURE 26.4 **As glomeruli approach full maturation, the endothelium becomes extensively fenestrated, and the mature GBM laminin and collagen type IV isoforms are now in place.** In the podocyte layer, foot process extension and interdigitation finalizes, and epithelial slit diaphragms completely span the filtration slits. Inset shows structure of SD viewed *en face*.

fully mature glomerular morphology is achieved. Unfused basement membranes are rarely seen in maturing glomeruli. On the other hand, complex, irregular projections of basement membrane are commonly found beneath podocytes at this stage, particularly in areas where foot processes are broad and their formation into relatively narrow pedicels is still incomplete. *In vivo* labeling studies have shown that these subepithelial basement membrane segments are somehow spliced or inserted into the existing fused GBM, possibly to provide the additional GBM material necessary for the inflating capillaries.[13,14] Shortly after the initial, vascular cleft stage, and continuing into maturing glomeruli, modification and remodeling of the GBM occurs, with the appearance of new basement membrane protein isoforms and the disappearance of earlier species. As discussed later, however, we do not understand how these events are regulated at either the gene or protein level. Additionally, once the glomerulus is fully mature (Figure 26.4), matrix synthesis and cell morphogenesis virtually halt (except for some poorly-understood activities responsible for GBM "maintenance" or "turnover"), and how these processes are downregulated is also not known.

ORIGIN OF THE GLOMERULAR ENDOTHELIUM

Extrarenal Origins

Although compelling evidence has accumulated showing that nephron epithelial cells, including the visceral and parietal epithelium of Bowman's capsule, all derive originally from the metanephric mesenchyme, the origin of vascular endothelial cells during kidney organogenesis has been more difficult to understand.[15] Studies conducted nearly 30 years ago convincingly showed that cells of extrarenal origin grew into the metanephros and established the microvasculature, including the glomerular capillary tufts. These studies involved the grafting of embryonic, avascular mouse or quail kidney rudiments onto avian chorioallantoic membranes. After culturing *in ovo*, the kidney grafts contained glomerular endothelial and mesangial cells stemming from host chorioallantoic tissues, therefore signifying the ingress of vessel progenitors from sites outside the kidney.[12,16]

Intrarenal Origins

Contrary to the results discussed above, several lines of evidence from a number of more recent experiments have shown that the metanephros contains its own pool of endothelial progenitors (angioblasts) capable of vascularizing nephrons *in vivo*.[17] The first clues about the existence of these intrinsic metanephric angioblasts came from transplantation studies between mice and rats. For example, when E12 mouse kidneys are grafted into anterior eye chambers of rats, the vascular and glomerular basement membranes that develop within the grafts after transplantation are almost entirely of mouse (graft) origin.[18] Similarly, when E12 kidneys are transplanted under kidney capsules of adult ROSA26 mice (which bear a

ubiquitously expressed LacZ reporter gene useful as a cell lineage marker), all of the microvascular and glomerular endothelial *cells* within grafts are derived from the engrafted kidney, not from the host.[19] Furthermore, when kidneys from E12 ROSA26 mice are grafted into the nephrogenic renal cortices of newborn wild-type hosts, endothelial cells stemming from the grafts can be seen integrating into host vasculature.[19] In additional experiments, when embryonic kidneys from Flk1 (VEGF receptor-2)−LacZ heterozygous mice are grown under routine organ culture conditions, Flk1-LacZ-positive microvessels do not develop *in vitro*, despite the extensive formation of metanephric tubules and avascular glomerular epithelial tufts.[20] When these same cultured kidneys are then transplanted into anterior eye chambers of wild-type host mice, the grafts develop microvessels and vascularized glomeruli lined by Flk1-LacZ-expressing cells, indicating again that the endothelium originates from the engrafted kidney itself, and not from the host.[20] Several other research groups have reached similar conclusions independently. For example, when avascular metanephroi from E11 Tie1/LacZ transgenic mice are transplanted into newborn wild−type hosts, widespread expression of Tie1/LacZ is found within glomeruli developing within grafts.[21] Others have immunolocalized putative angioblasts in the metanephric mesenchyme of prevascular embryonic rat kidney.[22]

Although current evidence shows that the embryonic kidney contains a pool of angioblasts capable of establishing the glomerular endothelium, whether these progenitors originate initially from outside the metanephric blastema or instead stem directly from metanephric mesenchyme is not yet clear. Nevertheless, immunolabeling experiments in developing rat kidney shows that endothelial, as well as mesangial, cell precursors share common markers during glomerulogenesis (RECA-1 and Thy1.1, respectively), suggesting that they may indeed derive from metanephric mesenchyme.[23] Other immunolocalization and transplantation experiments have shown that juxtaglomerular cells in developing kidney also originate from metanephric mesenchyme, although they appear to stem from a different lineage than endothelial and mesangial cells.[24]

ENDOTHELIAL CELL RECRUITMENT AND DIFFERENTIATION

Mechanisms controlling vascular development are highly complex and involve several different transcription factors, cell-cell and cell-matrix interactions, and many membrane receptor−ligand signaling cascades. Although our knowledge of these systems in a variety of vascular beds has improved dramatically during the past several years, many key questions regarding temporal and spatial controls still persist. With respect to the formation of glomerular capillaries, the process can be considered to progress through four interrelated events: (1) angioblast survival, proliferation and differentiation into endothelium; (2) glomerular endothelial cell recruitment; (3) initial assembly of the glomerular capillary tuft and associated mesangium; and (4) glomerular capillary stabilization and maturation.[25,26]

VEGF Signaling

Among all of the mechanisms involved with development of the systemic vasculature, signals evoked by binding of VEGF to its cellular receptors, VEGFR-1 and VEGFR-2, are singularly critical. Mice with homozygous *Vegfa* gene deletions die by E9.5 with severe vascular deficits. Remarkably, *Vegfa* heterozygote mutants also succumb by E12 with vascular phenotypes, indicating that a single *Vegfa* allele is insufficient to direct normal vascular development.[27,28] Homozygous (but not heterozygous) *Vegfr1* and *Vegfr2* mutants die at midgestation, due to failure of endothelial differentiation[29] and vessel integrity,[30] respectively.

Developing podocytes are key sources of VEGF,[31] and its secretion and binding to angioblasts bearing VEGF receptors may initiate their recruitment into the vascular cleft of comma- and S-shaped nephrons,[32] which is the initial site of glomerulogenesis. Because *Vegfa* and *Vegfr2* knockout mice die with vascular phenotypes before glomerulogenesis commences, the precise role of this ligand-receptor pair in mediating glomerular endothelial development has been difficult to analyze fully. Nevertheless, and underscoring the importance of the VEGF signaling system, injection of VEGF-blocking antibodies into developing mouse kidney cortex inhibits glomerular capillary formation *in vivo*.[33] With the advent of cell selective and/or inducible gene deletion technologies, additional evidence for the importance of podocyte-derived VEGF has been obtained. For example, homozygous deletion of *Vegfa* selectively in podocytes (obtained in bi-transgenic mice carrying nephrin-cre recombinase and floxed *Vegfa* alleles) results in animals which die perinatally with non-vascularized glomeruli.[34] Heterozygous deletion of *Vegfa* causes no evident phenotype initially. By 2.5 weeks of age, however, mice become proteinuric, and glomeruli contain swollen endothelial cells and hyaline deposits similar to those seen in patients with preeclampsia. By contrast, overexpression of the $VEGF_{164}$ isoform specifically in podocytes leads to collapsing glomerulopathy and death at ~5 days of age.[35] When *Vegfa* is selectively deleted in podocytes of adult mice (using a Tet-On conditional expression model), mice become severely proteinuric and hypertensive, and glomeruli resemble those of humans with thrombotic

microangiopathy (mesangiolysis, endothelial swelling, red cell fragmentation, and fibrin deposition).[196] Clearly, the cellular controls for maintaining VEGF protein expression within an optimal range are critically important for the appropriate establishment and maintenance of the glomerular capillary.

Regulation of Endothelial Development

Hypoxia-Inducible Transcription Factors (HIFs)

Transcription of VEGF and VEGFR genes is activated by hypoxia-inducible transcription factors (HIFs), which consist of heterodimers of HIF α- and β-subunits.[36] Under normal oxygen concentrations, the HIF α-subunit undergoes prolyl hydroxylation, binding to von Hippel Lindau protein (VHL), polyubiquitination, and proteasomal degradation. In hypoxia, the prolyl hydroxylase enzyme is inhibited, and HIF α chain degradation is avoided. Hypoxia-stabilized HIF α/β heterodimers bind to hypoxia-responsive elements (HREs) located in promoter/enhancer regions of inducible genes,[37] many of which are proteins expressed in response to hypoxic stress. For example, erythropoietin, transferrin, VEGF, VEGFR1, and VEGFR2 are among the more than 70 distinct genes known to be transcriptionally activated by HIFs.[36]

There are at least three distinct HIF α- and two β-subunits known at present, making a variety of different HIF isoforms possible. Because HIF stabilization is enhanced in cells experiencing subnormal oxygen tensions, such as those in rapidly growing tissues, robust VEGF and VEGFR synthesis commonly occurs during organogenesis. Increased VEGF/VEGFR signaling stimulates mitosis in endothelial progenitor cells, phosphorylation of the antiapoptotic kinases Akt/PKB[38] and focal adhesion kinase (FAK),[39] and upregulation of the survival factors Bcl2 and A1.[38] In time, these events can lead to the creation of new blood vessels, which can then provide appropriate levels of oxygen specifically to the formerly hypoxic tissue sites.

Renal HIF Expression

The expression patterns for several of the different HIF α- and β-subunits have been documented in developing human, rat, and mouse kidney using *in situ* hybridization and immunohistochemistry. In general, both HIF-1 and HIF-2α are found in glomeruli, with specific immunolocalization of HIF-2α protein to immature podocytes (which are rich sources of VEGF).[40,41] HIF-2α is also expressed by developing vascular endothelial cells in the kidney (most of which express VEGFR-2), whereas HIF-1α is found in cortical and medullary collecting duct epithelium. HIF-1α and HIF-2α protein are undetectable in fully mature glomeruli. Mice with a global deletion of *Hif2α* show no defects in glomerular development or function, and no deficits in VEGF or Flk1 expression.[197] Interestingly, HIF-1β is apparently ubiquitously expressed by all cells in the kidney, but HIF-2β distribution is greatly restricted during development and, in mice, becomes confined to nuclei in cells of the thick ascending limb of Henle's loop.[42]

The selective expression of certain HIF isoforms in different tissue compartments of developing kidney may reflect the coordinated regulation of different sets of HIF target genes.[43] Importantly, individuals with mutations in VHL, a key protein in mediating HIF α chain degradation, and thereby reducing expression of HIF target genes, are prone to developing hemangioblastomas and clear cell-renal cell carcinomas.[44–46] Some studies have shown that HIF-1α and HIF-2α had differential and sometimes antagonistic effects on the growth of clear cell-renal cell carcinomas, with HIF-1α retarding and HIF-2α promoting tumor growth.[47] These findings provide further evidence for differential effects of different HIF isoforms, and call for more studies examining the expression of HIF and HIF gene targets in the developing kidney. Surprisingly, when *Vhl* is selectively deleted in podocytes, glomerular vascularization patterns are not affected, and kidneys develop normally.[198] On the other hand, mice become proteinuric by 4 weeks of age, and there is ectopic deposition of collagen $(\alpha1)_2\alpha2$(IV) in peripheral loop GBMs, and upregulation of an ancient oxygen-binding protein, neuroglobin, specifically in podocytes.[198]

Once glomeruli are vascularized and fully mature, podocytes still continue VEGF synthesis. Likewise, expression of Flk1 is also maintained by glomerular endothelial cells of mature kidneys. VEGF-Flk1 signaling in glomeruli therefore probably exerts functions extending well beyond those needed for mobilization of angioblasts and initial formation of the capillary tuft. For example, in co-cultures of epithelial cells with endothelium, epithelial-derived VEGF has been shown to induce fenestrae formation in the endothelium.[48] When *Vegfr2* is inducibly deleted in adult mice, podocytes appear normal, but there is loss of viable glomerular endothelial cells.[199] Perhaps the continued expression of VEGF by podocytes and Flk1 by glomerular endothelial cells *in vivo* is necessary for maintenance of the highly-differentiated state seen in the endothelium.

Other Growth Factor/Receptors

Beyond VEGF and VEGFR, several other growth factor-receptor signaling systems important for vessel

development systemically are also crucial for glomerular capillary formation, including the Tie/angiopoietin and PDGFR/PDGF families.[25,26] Developing glomerular endothelial cells express Tie-2, and and one of its ligands, angiopoietin-1, is important for vascular organization and remodeling. Another Tie-2 ligand, angiopoietin-2, may mediate vascular integrity and permeability. The coordinated expression of these two angiopoietins may therefore regulate the maturation and stabilization phases of glomerular development (reviewed in [49]). Additionally, Tie-2 and at least some members of the angiopoietins contain defined HREs in their promoters, making their transcriptional regulation by hypoxia/HIFs seem likely.[36] Similarly, an HRE is found in the PDGFB gene promoter, although this may not necessarily be responsive to hypoxia.[50] During early glomerular development, PDGFB protein is expressed by podocytes. This may be important for the glomerular recruitment of immature mesangial cells, which express the PDGFB receptor, PDGFRβ.[51] In later developmental stages, both PDGF and PDGFRβ expression becomes confined to the mesangium, which may provide autocrine signals required for mesangial cell proliferation and/or maturation[51] (see below).

Like other developing vessels, at least some neuronal axon guidance receptors and ligands are also found in developing glomeruli.[52–54] For example, neuropilin-1 (Np1), which is a co-receptor with VEGFR2 for $VEGF_{164}$ (but lacks a cytoplasmic signaling domain), immunolocalizes to glomerular endothelial cells. Semaphorins-3A and -3F, which are ligands for Np1, have been found on podocytes, suggesting that semaphorin-Np1 signaling between podocytes and endothelium may help pattern glomerular morphogenesis.[55] One study, however, has also reported that Np1 is expressed by podocytes *in vivo*.[56] Recent experiments also showed that podocyte-derived VEGF may act as an autocrine survival factor for cultured podocytes *in vitro*.[57] Additionally, these same studies found an upregulation of VEGFR2 in cultured podocytes, suggesting that VEGF/VEGFR2 signaling is important not only for glomerular capillary formation and maintenance, but also for podocyte differentiation.[57]

Other receptor-ligand signaling systems probably crucial for glomerular capillary formation include members of the Eph/ephrin receptor/counter-receptor families.[20,25] Specifically, the receptor tyrosine kinase EphB1 and its ligand, ephrin-B1, which itself is also a transmembrane protein receptor, are both expressed in similar distribution patterns in developing kidney microvasculature.[58] Although the precise roles for Eph/ephrin signaling in the glomerulus are still uncertain, knockout mice display lethal vascular phenotypes, including defects in vessel patterning, sprouting, and remodeling (reviewed in [25]). Reciprocal gradients of Eph and ephrin protein concentrations have been identified in the developing brain, where they appear to direct accurate neuronal patterning in the visual system. Perhaps analogous events take place in the developing glomerulus, where spatial signals conveyed between endothelial cells help target them to correct microanatomical domains.[25]

DEVELOPMENT OF THE MESANGIUM

Fundamentals regarding the development of the intercapillary mesangium, as well as the origin and recruitment of mesangial cell progenitors, are still largely unresolved issues in glomerular biology. Nevertheless, we have known for some time that PDGFB and its receptor, PDGFRβ, are both expressed by mesangial cells of mature glomeruli.[51] Additionally, studies in developing kidney have shown that immature podocytes produce PDGFB which may help recruit mesangial cell progenitors expressing PDGFRβ into glomeruli. Later, podocyte expression of PDGF declines, and the synthesis of both PDGF and PDGFRβ becomes confined to the mesangial cells, perhaps to promote their proliferation or maturation.[51] Gene deletion studies in mice have conclusively shown an absolute requirement for PDGFB/PDGFRβ signaling. Null mutants for either genes die perinatally, with massive hemorrhaging systemically.[59,60] Importantly, glomeruli in these mutants entirely lack mesangial cells and consist of one or only a few large, swollen capillary loops.[59,60]

Interestingly, once the glomerulus has fully matured, there appears to be a small population of extraglomerular mesangial cells capable of completely repopulating the glomerulus if the intraglomerular mesangium becomes severely injured. These mesangial reserve cells reside in the juxtaglomerular apparatus, and are distinct from renin-secreting cells, macrophages, vascular smooth muscle cells, and endothelial cells.[61] In an anti-Thy-1 model of proliferative glomerulonephritis in rats, these extraglomerular mesangial reserve cells migrate into the glomerulus and entirely restore the depleted intraglomerular mesangium.[61] Alternatively, some studies suggest that bone marrow hematopoitic stem cells can be a source of mesangial cells.[62] Perhaps additional studies based on these fascinating observations can shed more light on the origin and development of mesangial cells during glomerulogenesis. Similarly, much more work needs to be done on the assembly and maintenance of the mesangial matrix. Although this matrix undergoes morphologic and compositional changes throughout glomerulogenesis, it has not yet been the topic of thorough study. Whether the mesangial matrix is produced exclusively by mesangial cells

or whether glomerular endothelial cells and podocytes also contribute components, are also not understood. On the other hand, and as discussed later, considerable progress has been made in understanding the assembly of the GBM (see below).

FACTORS REGULATING PODOCYTE DIFFERENTIATION

Determination of podocyte identity and regulation of podocyte differentiation are fundamental aspects of glomerulogenesis about which much remains to be learned. Although the podocyte transcription factors described below have been shown to be crucial for proper differentiation, exactly how these regulators interact to orchestrate the complex acquisition of the podocyte phenotype remains a mystery. Studies aimed at defining the entire glomerular transcriptome[63,64] have been very useful for defining what genes may play important roles in podocyte determination, differentiation, and function; however, we have only just begun to gain an understanding of how the podocyte achieves its unique and important properties through interacting pathways.[65]

WT1

The protein that likely has one of the earliest roles in podocyte differentiation is Wilms tumor 1 (WT1), a zinc-finger protein that is involved in both transcription and RNA processing.[66] WT1 is expressed at the initial stages of nephrogenesis, when it has been shown to regulate such developmentally important genes as *Bmp7*, *Six2*, and *Sall1*.[67] But once glomerulogenesis begins, there is a dramatic increase in the level of WT1 in podocyte precursors, and podocytes continue to express WT1 throughout life (reviewed in [68]). One potentially important function of WT1 is to downregulate expression of Pax2 in the immature podocytes of S-shape stage nephrons,[69] as artificial overexpression of Pax2 widely, including in podocytes, causes severe nephrotic syndrome.[70] In addition, WT1 has been shown to regulate a number of genes, including NPHS1,[71,72] the gene encoding nephrin (discussed below). This provides a clear mechanism whereby alteration in WT1 function directly affects glomerular function.

Several lines of investigation reveal important roles for WT1 in promoting proper podocyte differentiation (reviewed in [66,68,73]). Most notable is that heterozygous mutations that affect the zinc-finger structure of WT1 cause Denys–Drash syndrome in humans. This rare disease is characterized by proteinuria, nephrotic syndrome, diffuse mesangial sclerosis, and ESRD. Expression of mutant WT1 forms associated with Denys–Drash syndrome in transgenic mice, either globally or specifically in podocytes, causes various glomerular and podocyte defects that are consistent with the human pathology.[66,74] Moreover, heterozygous mutations in WT1 that affect the normal pattern of WT1 RNA alternative splicing to generate the so-called +KTS and −KTS isoforms of WT1, cause Frasier syndrome.[75] The renal component of this disease includes proteinuria that begins in early childhood and progresses to FSGS, but the course to ESRD is slower than observed in Denys–Drash syndrome. Mice engineered to express only the +KTS or the −KTS isoforms develop severe podocyte and glomerular defects, further emphasizing the important role that WT1 and these specific splice variants play in glomerular development and function.[76]

Lmx1b

Lmx1b, a LIM-homeodomain protein, is another transcription factor expressed in podocytes that is affected in human disease. Heterozygous mutations in LMX1B cause Nail–Patella syndrome,[77] an autosomal dominant disease with skeletal abnormalities, nail hypoplasia, and variably penetrant nephropathy associated with accumulation of fibrillar material in the GBM that appears to be collagen type III.[78] Although $Lmx1b^{+/-}$ mice do not exhibit a phenotype, $Lmx1b^{-/-}$ mice die shortly after birth with abnormalities in dorsal limb structures, including absence of nails and patellae, abnormal glomeruli, attenuated podocyte maturation with lack of normal slit diaphragms, and tubular protein casts.[79] Analysis of gene expression in $Lmx1b^{-/-}$ podocytes has revealed decreases in collagen α3 and α4(IV), podocin, and CD2AP,[80–82] which are all known to be important for proper glomerular filtration. The reduced expression in $Lmx1b^{-/-}$ mice suggests a basis for the partially penetrant nephropathy in $LMX1B^{+/-}$ humans, but gene expression studies in affected individuals do not support this hypothesis.[78] Thus, exactly how LMX1B haploinsufficiency causes nephropathy in humans remains a mystery. If there really is no reduction in the expression of relevant podocyte genes, then perhaps there is a lack of repression, either direct or indirect, of genes injurious to glomerular function, as previously proposed.[83]

Pod1/Tcf21

Pod1, a basic helix-loop-helix transcription factor also known as epicardin, capsulin, and Tcf21, is highly expressed early during kidney development in

condensing metanephric mesenchyme and in stromal cells. In the developing nephron, Pod1 is expressed in podocyte precursors at the S-shaped stage, and persists in adult podocytes.[73,84] The kidney phenotype in Pod1$^{-/-}$ mice, which die at birth due to heart and lung defects, is complex, but it is clear that there are fewer glomeruli associated with defects in ureteric bud branching. In addition, there is a striking arrest of glomerular development at the capillary loop stage, and podocytes fail to mature properly, elaborating only rudimentary foot processes.[85] Gene expression profiling studies of Pod1$^{-/-}$ glomeruli revealed 3986 genes expressed differently than in wild-type glomeruli, demonstrating that Pod1 has profound effects on gene expression.[86]

Kreisler/Mafb

Kreisler/Mafb is a basic domain leucine zipper transcription factor expressed in podocytes from the capillary loop stage onwards.[87] Mice that are homozygous for a point mutation affecting the kreisler DNA-binding domain die within 24 hours of birth. The podocytes of these mice fail to extend foot processes or establish slit diaphragms, and there is a significant reduction in expression of nephrin, podocin, and CD2AP.[88] Interestingly, whereas Pod1 is expressed in kreisler$^{-/-}$ podocytes, kreisler is not expressed in Pod1$^{-/-}$ podocytes. This suggests the existence of a transcriptional hierarchy in which Pod1 may activate expression of kreisler.[87]

Foxc2

Foxc2 is a member of the forkhead/winged-helix family of transcription factors. During nephrogenesis, Foxc2 is first expressed in a subset of cells in the comma-shaped body and then is expressed in developing podocytes at the S-shaped and capillary loop stages, and more weakly at maturity.[89] Foxc2$^{-/-}$ mice exhibit small kidneys and reduced numbers of glomeruli with ballooned capillaries, suggesting a defect in adhesion of mesangial cells (which are present) to the glomerular basement membrane (GBM). Ultrastructural analyses revealed that podocytes fail to extend processes or assemble slit diaphragms, and endothelial cells fail to become fenestrated, suggesting an arrest of differentiation of these two cell types. Gene expression profiling studies of Foxc2$^{-/-}$ glomeruli showed reductions in a number of known podocyte genes, such as kreisler/Mafb, Nphs2 (podocin), and Podxl1 (podocalyxin), although others, such as Nphs1, Wt1, and Cd2ap, were not affected.[89] Interestingly, in the *Xenopus* pronephros, the combined knockdown of WT1 and Foxc2 resulted in the loss of all podocyte marker gene expression.[65]

Notch2

Notch2 is expressed in developing podocytes from as early as the comma-shaped stage.[90] Although the total absence of Notch2 in mice results in embryonic lethality at E11.5 before glomerulogenesis begins, homozygosity for a hypomorphic Notch2 allele allows survival until 24 hours after birth. These latter Notch2$^{-/-}$ mice exhibit small kidneys with cortical vascular lesions. Some glomeruli arrested before the capillary loop stage and were not vascularized, whereas others became vascularized but had ballooned capillaries due to an absence of mesangial cells. In addition, genetic interaction studies demonstrated that Jagged1, a Notch ligand, is required for proper Notch2 signaling during glomerulogenesis.[90] Additional studies using a conditional Notch2 allele showed that Notch2 (but not Notch1) is required for acquisition of podocyte and proximal tubule cell fates.[91,92]

FORMATION OF THE SLIT DIAPHRAGM COMPLEX

In mature glomeruli, the slit diaphragm (SD) represents the only known connection between adjacent podocytes and podocyte foot processes. The SD spans the space between the interdigitated foot processes (Figure 26.4), and has been proposed to play a crucial role in glomerular filtration by serving as the major barrier to albumin,[93] although some data do not support this view.[94,95] The SD has also been shown to mediate important signaling events that are responsible for maintaining podocyte survival and differentiation,[96,97] suggesting that it plays dual roles in ensuring proper glomerular function. But interestingly, mutant mice without slit diaphragms due to lack of nephrin have dramatic leakage of albumin into the urine, but they do not have major alterations in podocyte survival or gene expression.[98]

Slit Diaphragm Components

Nephrin and the Neph Family

The explosion of research into SD composition and function began with the identification of the nephrin gene (*NPHS1*), as mutated in congenital nephrotic syndrome of the Finnish type,[99] and the nephrin protein as an integral component of the SD[100,101] (Figure 26.5). Nephrin is an immunoglobulin superfamily member containing eight extracellular Ig-like domains, a

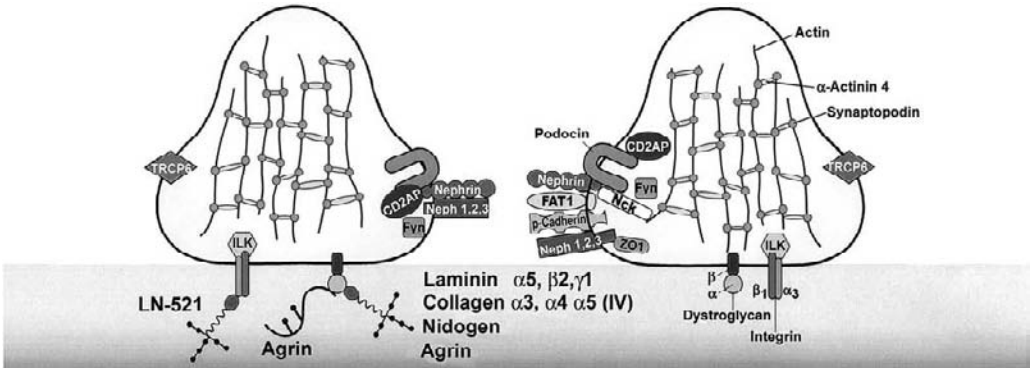

FIGURE 26.5 **Diagram showing clustering of the slit diaphragm complex proteins at the basolateral surfaces of podocyte foot processes, which are attached to the underlying GBM (shown in blue).** Molecules are not drawn to scale, but many known extracellular and intracellular protein:protein interactions are represented. Exactly how the several protein ectodomains interact to form the characteristic SD ultrastructure is not yet fully defined. See text for details. See color section at the end of the book.

fibronectin type III domain, a single-pass transmembrane domain, and a cytoplasmic tail of ~155 amino acids, including several tyrosines that have been predicted to be important for its function, perhaps by interacting with actin-binding Nck adapter proteins.[102–106] Humans and mice lacking nephrin never establish SDs, demonstrating the importance of nephrin for SD formation. A group of three related Ig superfamily molecules that interact with nephrin, Neph1-3, are also found at the SD, as well as in other tissues, and it is clear that at least Neph1 is required for maintenance of the filtration barrier.[107] Interestingly, nephrin interacts directly with the Neph proteins[108–110] (Figure 26.5), and disturbing their association *in vivo* causes proteinuria.[111]

Further evidence for the importance of nephrin-Neph interactions come from the model organisms *Drosophila* (fruitflies) and *C. elegans* (nematodes), which have conserved homologs of nephrin and Neph proteins. In both these invertebrates, a nephrin homolog on one cell interacts with a Neph homolog on another cell to promote a developmental event.[112–114] Amazingly, all three mouse Neph proteins can partially compensate for the nematode Neph-like protein SYG-1.[115] Together with data from mouse, these results suggest that nephrin-Neph interactions are conserved across phyla.

ZO-1 and Podocin

Before the identification of nephrin, zonula occludens-1 (ZO-1), an epithelial tight junction protein, was shown to be localized to the cytoplasmic face of the SD.[116] ZO-1 has recently been shown to interact with Neph1–3, which may serve to anchor it to the SD. In turn, podocin, whose encoding gene (*NPHS2*) is mutated in familial steroid resistant nephrotic syndrome, appears important for anchoring nephrin and the Neph family to the SD (Figure 26.5). Podocin is a hairpin-shaped integral membrane protein that interacts with the cytoplasmic tails of nephrin and Neph family members,[117] and is required to target nephrin to lipid raft microdomains, which have been proposed to be crucial for SD organization and function.[118]

Cadherins

Consistent with the notion that the SD is a modified adherens junction,[119] two cadherins, P-cadherin and the FAT1 protocadherin, have been localized to the SD. P-cadherin was found to associate with ZO-1 and the catenins at the SD, but the functional importance of P-cadherin at the SD has yet to be demonstrated, and humans with mutations in the P-cadherin gene (*CDH3*) are not reported to have kidney disease. FAT1, an extremely large member of the cadherin family, is involved in regulating actin cytoskeleton dynamics and cell polarization.[120] Mice lacking FAT1 die within two days of birth, and their podocytes lack SDs and significant foot process formation. This underscores the importance of FAT1 in the establishment or maintenance of SDs. A model of the SD that can accommodate the very large extracellular domain of FAT1 has not yet been presented, but FAT1 may somehow contribute to the central density of the SD that is apparent in ultrastructural analyses.[93,121]

CD2AP

CD2-associated protein (CD2AP) is a modular cytoplasmic docking protein that interacts with multiple slit diaphragm components, including nephrin and podocin, as well as with the actin cytoskeleton[122,123] (Figure 26.5). Mice lacking CD2AP exhibit congenital nephrotic syndrome with progressive loss of SDs and foot processes, and they die at 6–7 weeks of age.[124] In addition, CD2AP haploinsufficiency has been associated with renal disease in both mice and humans,[125,126] and a

patient homozygous for a premature stop codon mutation (R612X) lacking the final 28 amino acids of 639 total exhibited proteinuria, FSGS, and kidney failure by 3 years of age.[127] CD2AP is thought to be an adaptor that forms a bridge between the SD and the cytoskeleton,[128] but it also appears to play a role in the trafficking of endocytic vesicles.[122,126] Although CD2AP is very widely expressed, it seems to be required only in the podocyte[129]; this could be due to compensation by a paralog of CD2AP, CIN85, although CIN85 activity in podocytes appears to be detrimental.[130]

Nck

That mice lacking CD2AP are able to form normal foot processes and SDs initially suggests the existence of other adaptor proteins in podocytes that might play an earlier role in organizing SDs and linking them to the cytoskeleton. Indeed, the Nck adaptor proteins (Nck1 and Nck2), which contain three Src homology 3 (SH3) domains and one SH2 domain, bind to phosphotyrosine-containing motifs in the cytoplasmic tail of nephrin via their SH2 domains. In addition, clustering of nephrin-Nck complexes reorganized the actin cytoskeleton in transfected cells.[102,105] Importantly, genetically-engineered mice lacking Nck1 and Nck2 in podocytes failed to elaborate foot processes or assemble SDs,[102] and inducible deletion of Nck1 and Nck2 in adult podocytes rapidly leads to proteinuria and glomerulosclerosis.[131] These exciting findings establish a potentially pivotal role for the Nck adaptor proteins in organizing and maintaining SDs, and suggest one mechanism whereby the Fin minor mutation in NPHS1, which results in a nephrin protein lacking most of its cytoplasmic tail and all of the intracellular tyrosines,[99] causes congenital nephrotic syndrome.

TRPC6

TRPC6 is a member of the transient receptor potential family of cation channel proteins, and is associated with the SD. Mutations in TRPC6 have been shown to cause autosomal dominant FSGS in several different families, and this was associated with increased calcium current amplitude in some cases.[132,133] Calcium flux mediated by TRPC6 could have an important role in regulating podocyte and SD homeostasis, perhaps by regulating actin dynamics and motility[134] and calcium-sensitive transcription factors such as those in the NFAT family.[135]

Slit Diaphragm Assembly Mechanisms

As mentioned earlier, the slit diaphragm bears some relationship to adherens junctions, and ZO-1 immunolocalizes to the cytoplasmic domains on the lateral surfaces of podocytes adjacent to the extracellular diaphragm spanning the slit pore. The synthetic patterns of all of the SD components during glomerular development have not yet been studied in detail. However, nephrin and podocin first appear during the late S-shaped and early capillary loop stages of nephron development, which is when foot process interdigitation first occurs, simultaneous with the first ultrastructural appearance of SDs.[100,136] Also occurring at this stage of development is the apical-to-basal translocation of protein complexes involved in cell polarity, an event crucial for proper slit diaphragm and foot process formation.[137,138] The precise sequence of SD assembly, including how the linkages between the ectodomains of SD proteins are made, as well as connections with the internal cytoskeleton and associated elements, are not known. Similarly, the extent to which the SD may be dynamic and undergo modification with age is poorly-understood. Nevertheless, an increasing number of studies have shown that the SD does not merely represent a static component of the glomerular filtration barrier, but it also functions to influence podocyte behavior.[97]

Signaling at the Slit Diaphragm

The first evidence that the SD complex may have a signaling role came from studies of nephrin activity in cultured cells. Transfection of cells with nephrin increased activator protein-1 (AP1)-mediated transcriptional activation, and this effect on intracellular signaling was augmented by cotransfection with podocin, to which nephrin binds.[139] These authors later showed that podocin recruits nephrin to lipid rafts,[118] which are cholesterol-enriched plasma membrane microdomains associated with high concentrations of signaling proteins and high levels of signaling activity. Furthermore, as alluded to above, nephrin contains multiple tyrosines in its cytoplasmic tail. Some of these can be phosphorylated by the Src-family tyrosine kinase, Fyn,[106] and clustering of nephrin by Fyn increases phosphorylation.[103] Phosphorylation of nephrin both augments its interaction with podocin[104] and allows Nck adaptor proteins to bind its tail and influence the organization of the adjacent actin cytoskeleton.[102,105] Consistent with this, $Fyn^{-/-}$ mice have variably coarsened or effaced foot processes.[106] In addition, trans-heterozgyous $Fyn^{+/-}$; $Cd2ap^{+/-}$ mice exhibit marked proteinuria and FSGS, and CD2AP can be immunoprecipitated with Fyn from glomerular lysates. These findings demonstrate that Fyn-mediated signaling likely depends upon interactions with CD2AP.[125]

Nephrin-mediated signaling has also been shown to involve stimulation of phosphoinositide 3-OH kinase (PI3K). Nephrin and CD2AP interact with the p85

regulatory subunit of PI3K, recruit PI3K to the plasma membrane and, in conjunction with podocin, stimulate PI3K activation of AKT signaling in podocytes.[140] This is proposed to regulate the behavior of podocytes and protect them from detachment–induced apoptosis (anoikis), which suggests that proper signaling at the SD is important for maintaining podocyte health.

Neph family proteins, like nephrin, have cytoplasmic tails containing tyrosines that can be phosphorylated. Also like nephrin, Neph1 can induce AP-1-mediated transcriptional activation.[117] ZO-1, which binds to the cytoplasmic tail of Neph proteins, enhances tyrosine phosphorylation of Neph1 and augments AP-1 activation.[141] As ZO-1 can also interact with the actin cytoskeleton, one can envisage how the podocin-CD2AP-nephrin-Neph-ZO-1 complex can activate signaling in podocytes and provide stability to the SD via linkage to actin (Figure 26.5). Interfering with any of these interactions likely leads to abnormal podocyte behavior and proteinuria; in this regard, the actin cytoskeleton in podocyte foot processes also has specialized components. These include α-actinin-4, which is mutated in autosomal dominant FSGS,[142] and synaptopodin, which regulates α-actinin's actin bundling activity[143] and binds to CD2AP.[125] That trans-heterozygous Synpo$^{+/-}$; Cd2ap$^{+/-}$ mice develop proteinuria and FSGS-like lesions[125] underscores the importance of the SD-actin cytoskeleton linkage in maintaining podocyte health, structure, and function. Further support comes from a study showing that the action of cyclosporine A in reducing proteinuria has to do with a protective effect on synaptopodin and on the podocyte's actin cytoskeleton.[144]

DEVELOPMENTAL-ORGANIZATIONAL ROLE OF THE GLOMERULAR BASEMENT MEMBRANE

An important extracellular matrix component of developing and mature glomeruli is the glomerular basement membrane (GBM). Basement membranes are the thin sheets of specialized extracellular matrix that underlie all epithelial cells, including the vascular endothelium. The GBM is somewhat unique in that it is an unusually thick basement membrane that forms by fusion of two independent basement membranes, one secreted by podocytes and one by endothelial cells. Thus, both cell types contribute components to the GBM. Like all basement membranes, the GBM contains laminin, type IV collagen, nidogen/entactin, and sulfated proteoglycans.[145] These are all relatively large glycoproteins of which there are multiple isoforms, but only specific ones are found in the GBM.[146] These isoforms are thought to impart properties to the GBM that are important for maintaining glomerular structure and function.

Laminin

Most laminins are cruciform heterotrimers consisting of evolutionarily related α, β, and γ chains.[147] There are five α, four β, and three γ chains that associate nonrandomly and become disulfide bonded to each other to form at least 15 different heterotrimers, most of which are ~800 kDa.[148] Assembly of trimers occurs intracellularly within the endoplasmic reticulum, and then trimers are secreted into the extracellular space where they interact with cellular receptors, such as integrins and dystroglycan, and polymerize with each other to form laminin networks.[149] This network provides the foundation of the basement membrane; as shown in knockout mice, basement membranes do not form without laminin.[148]

Only a subset of the known laminin heterotrimers are expressed in glomeruli, and only a single heterotrimer, laminin α5β2γ1 (designated LM-521),[147] is found in the mature GBM[146] (Figure 26.4). The mesangial matrix, on the other hand, which is structurally and compositionally similar but distinct from basement membranes, contains an assortment of laminins, including LM-111, LM-211, LM-411, and LM-511.[146] Whether these mesangial laminins have any specific functions in glomerular biology is not yet clear, but they could certainly influence the behavior of mesangial cells and interact with laminins or other components of the GBM to strengthen the adhesion of the mesangium to GBM segments at the bases of the glomerular capillary loops. In contrast, as discussed below, the laminin content of the GBM is well-known to be extremely important for both glomerular development and function.

Developmental Transitions in GBM Laminin Composition

During glomerulogenesis there are well-characterized developmental transitions in the deposition of laminin isoforms in the GBM and its precursor.[150] From the comma-shape through the S-shape stage, LM-111 and LM-411 are present, but they are eliminated from the GBM during the transition to the capillary loop stage (Figures 26.2 and 26.3). At the S-shape stage, LM-511 is first deposited in the nascent GBM by the presumptive podocytes and the invading endothelial cells. At the capillary loop stage, both LM-511 and LM-521 are present in the maturing GBM, but LM-511 is gradually eliminated as the glomerulus begins functioning as a filter. LM-521 is from then on the major GBM laminin.[150] While little is known about

the transcriptional control of these isoform transitions during glomerular development, it is clear that the *in vivo* setting is important, as metanephroi grown *ex vivo* do not deposit LM-521. This deficiency is rescued upon reimplantation and subsequent glomerular vascularization *in vivo*, suggesting that glomerular endothelial cells are required for proper laminin isoform substitution.[151]

LAMININ A CHAIN TRANSITIONS

Experiments primarily in knockout mice have revealed the importance of some of these developmental transitions for successful glomerulogenesis and proper glomerular function. A targeted mutation in Lama5, the gene encoding laminin α5, results in breakdown of the GBM at the stage when LM-511 should begin to replace LM-111 (late S-shape stage).[152] In the absence of LM-511, LM-111 is still eliminated from the nascent GBM, and without a full-size laminin trimer, GBM architecture cannot be maintained. The loss of the GBM at this critical stage of glomerulogenesis has severe consequences, as podocytes lose their cup-shaped arrangement and instead contract into a ball of cells, leaving no place for the endothelial and mesangial cells to form capillaries. Thus, glomerular vascularization completely fails.[152] Additional studies aimed at defining the function of the laminin α5 COOH-terminal globular (α5LG) domain in glomerulogenesis showed that this domain is not important for maintenance of GBM integrity, but rather serves as a ligand for mesangial cells to adhere to the GBM at the bases of the glomerular capillary loops so that they can maintain and perhaps modulate capillary loop structure and diameter, as previously proposed.[153] When this ligand is missing, the capillaries balloon in a fashion similar to that observed in the absence of mesangial cells (discussed above), yet here mesangial cells are clearly present but apparently unable to adhere to the GBM under the stress of capillary blood flow.[154] These studies show that the GBM and the laminin that it contains serve important organizational roles, both during and after glomerulogenesis.

LAMININ β CHAIN TRANSITIONS

In contrast to the requirement for laminin α5 for successful glomerulogenesis, laminin β2 is dispensable. This is best demonstrated by the structurally normal glomeruli that form in Lamb2$^{-/-}$ mice, which correlates with maintenance of GBM integrity during glomerulogenesis.[155] The GBM is able to remain intact without LM-521, the only isoform normally found in mature GBM, because of the persistence or continued expression of laminin β1, resulting in a GBM containing LM-511 instead of LM-521. However, despite normal glomerulogenesis, Lamb2$^{-/-}$ mice exhibit congenital nephrotic syndrome and are proteinuric.[155] Similarly, humans with mutations in LAMB2 exhibit congenital nephrotic syndrome and diffuse mesangial sclerosis that is sometimes associated with distinct ocular and other abnormalities, a disease entity called Pierson syndrome.[156–158] Together these results show that laminin β2 in the GBM (as part of LM-521) is uniquely qualified to ensure that the glomerular barrier to protein is intact. This could be due to either direct effects on GBM porosity or indirect effects on behavior of the attached endothelium and overlying podocytes, as well as assembly and function of the slit diaphragm complex.

Post-fixation immunoelectron microscopy of wild-type mouse kidney has shown that the laminin α1, α5, β1, and β2 chains all originate in both glomerular endothelial cells and podocytes during glomerular development.[151] Similarly, in transgenic mice that overexpress human *LAMA5*, endothelial cells and podocytes were both positive for human laminin α5 protein.[200]

Collagen Type IV

There are six genetically distinct collagen IV chains, called α chains, that assemble in a defined fashion to form three different triple helical protomers.[159,160] These are designated $(\alpha1)_2\alpha2$, $\alpha3\alpha4\alpha5$, and $(\alpha5)_2\alpha6$. Like all collagen chains, collagen IV chains contain long stretches of Gly-X-Y amino acid triplet repeats that favor formation of a triple helix. However, unlike most other collagens, type IV contains interspersed interruptions of the triplet repeats that provide flexibility both to the protomers and to the collagen IV network. This is in turn thought to impart needed flexibility to basement membranes.[161]

Collagen IV protomers interact with each other via both covalent and non-covalent interactions to form a chicken wire-like network, and a substantial amount of cross-linking stabilizes the network. Surprisingly, knockout mice demonstrate that collagen IV is not absolutely required for basement membrane formation, but it is crucial for basement membrane maintenance and stability.[162]

Most basement membranes in the body contain the $\alpha(1)_2\alpha2$ protomer, and this is also true of the early nephrogenic epithelial structures (Figure 26.2). As is the case for the laminins, $\alpha1\alpha2\alpha1$ collagen(IV) originates in both endothelial cells and podocytes.[163] However, at the capillary loop stage, the α3, α4, and α5 chains become detectable in the GBM[150] (Figure 26.3), and have been shown to be made exclusively by podocytes.[163] At maturity, the $\alpha3\alpha4\alpha5$ protomer represents the major collagen IV component of the

GBM (Figure 26.4), although apparently small amounts of presumably residual $(\alpha1)_2\alpha2$ can also be detected, more so in human than in mouse GBM. On the other hand, the α1 and α2(IV) chains are abundant in the mesangial matrix, whereas the α3, α4, and α5 chains are absent.[146] Interestingly, the basement membrane of Bowman's capsule contains $(\alpha1)_2\alpha2$ and $(\alpha5)_2\alpha6$ protomers.[164]

As implied by the existence of only three different collagen IV protomers *in vivo*, the α3 and α4(IV) chains exist exclusively in combination with α5(IV) to make the α3α4α5 protomer.[159,160] Thus, if any one of the three genes encoding these chains is altered by genetic mutation, this protomer is affected. Mutations that prevent proper assembly of this protomer cause Alport syndrome or hereditary glomerulonephritis, in humans, dogs, and mice,[159,160] as discussed in detail in Chapter 90. In the absence of the α3α4α5 protomer, there are no defects in glomerulogenesis, primarily due to compensation by the collagen IV network containing the $(\alpha1)_2\alpha2$ protomer. However, as affected individuals age, the abnormal GBM develops characteristic lesions, including thickening and splitting, that eventually lead to renal failure in most cases.[165] Heterozygous mutations in human and mouse Col4a1 have also been shown to cause disease that includes defects in kidney function.[166–169]

Nidogen–Entactin

Nidogens are dumbbell-shaped molecules.[145] There are two isoforms of nidogen, nidogen-1 and -2, and both have been reported to be present in the GBM.[170] Nidogen-1 was previously considered to be an obligatory link between the laminin and collagen IV networks, because it binds well to each of them.[145] However, mutant mice lacking both nidogens-1 and -2 survive to birth with most basement membranes intact, demonstrating that nidogen is not required for the integrity of all basement membranes.[171] Although the double knockouts died on the day of birth, urine removed from their bladders showed only a marginal increase in low molecular weight proteins,[171] suggesting that the glomerular barrier to albumin was intact and therefore not dependent on the presence of nidogen in the GBM.

Nidogen-1 binds to laminin trimers via a high-affinity interaction with a specific domain of the laminin γ1 chain.[172] To determine the biological importance of this interaction, 56 amino acids encompassing this domain of γ1 were deleted in mice such that nidogen-1 could no longer bind laminin.[173] Interestingly, the result was a phenotype that is in many ways more severe than the total absence of both nidogen-1 and -2. For example, homozygotes died immediately after birth rather than surviving for many hours. Renal agenesis was very common, and glomerular capillary aneurisms and hydronephrosis occurred in those few kidneys that did form.[173] Together, the results of these two studies[171,173] suggest that the alteration to laminin γ1 affects more than just its ability to bind nidogens, but the phenotype of this Lamc1 mutant also underscores the importance of laminin for proper glomerulogenesis.

Sulfated Proteoglycans

Proteoglycans consist of a core protein with covalently attached glycosaminoglycan side chains (GAGs). Those proteoglycans present in basement membranes are usually modified further on their GAGs by addition of heparan sulfate and/or chondroitin sulfate. The anionic character of these sulfate-containing adducts provides much of the basement membrane's net negative charge. A large number of experiments performed in animals suggest that the glomerular filtration barrier possesses charge selectivity, and the sulfated proteoglycans that are present in the GBM are attractive candidates to provide the basis for at least part of this selectivity against the passage of negatively charged molecules into the urine. However, recent studies suggest that anionic charges within the GBM may not be involved in establishment of the glomerular filtration barrier under normal circumstances.[174,175]

Perlecan

There are four major sulfated proteoglycans with relevance to the glomerulus, and the best-studied biochemically is perlecan. Perlecan consists of a 400 kDa core protein with three heparan sulfate chains linked to residues near the NH2-terminus. It is widely found in basement membranes, and is abundant in the mesangial matrix, but perlecan is only weakly detected in the GBM.[176] Cleavage of the COOH-terminus of perlecan produces a fragment with antiangiogenic activity called endorepellin.[177]

Knockout mice lacking perlecan die during embryogenesis or in the neonatal period with multiple developmental defects. Most basement membranes form normally, but mechanical stress causes disruptions in meningeal and cardiomyocyte basement membranes. Perlecan is also normally found in cartilage extracellular matrix, and this matrix is severely disrupted in perlecan mutants.[178,179] No defects in kidneys were noted in these mice.

To investigate further the function of perlecan as a heparan sulfate proteoglycan, a deletion was made that affects only the small part of the protein to which the GAGs are normally attached. Mice carrying this

mutation are viable, but they have defects in the lens capsule.[180] Neither functional nor structural defects were noted in kidney glomeruli under normal circumstances, but these mice exhibit elevated levels of urinary protein after bovine serum albumin overload.[181] Because little perlecan is detectable in the GBM, it is somewhat surprising that removal of its GAGs can have an effect on the filtration barrier.

Agrin

Agrin is a widely expressed modular proteoglycan that consists of a core protein of ~220 kDa with two glycosaminoglycan side chains that carry heparan sulfate and/or chondroitin sulfate. These increase the molecular weight of agrin to greater than 400 kDa. Agrin exhibits robust binding to the coiled-coil domain of the laminin γ1 chain *in vitro*,[182] and this might indicate that agrin is involved in organization of basement membrane architecture.

Agrin has been intensively studied by the neuroscience community because a specific splice form of agrin is deposited by motor neurons on developing skeletal muscle fibers, where it serves as a signal that is in part responsible for maintaining the aggregation of acetylcholine receptors to ensure the proper assembly of the neuromuscular junction.[183,184] In kidney, agrin is highly concentrated in the GBM,[185] significantly more so than perlecan, but there is as yet no evidence that it serves any signaling functions. Agrin has, however, been proposed to be responsible for the anionic charge that is present in the GBM, and that is presumed to be involved in establishing the charge-selective aspect of the glomerular barrier to protein.

Several different mutations have been made in the mouse agrin gene. Whereas all but the most subtle of these have dramatic effects on the differentiation of the neuromuscular junction, no defects in the kidney have been found. Because agrin mutant mice die at birth due to an inability to breathe, agrin-null kidneys beyond the neonatal period have not been studied. Nevertheless, no defects in glomerulogenesis were noted in agrin-deficient kidneys at perinatal stages.[175] In addition, a conditional knockout of agrin in podocytes using the Cre/loxP system was successful at removing both agrin and fixed anionic sites from the GBM, yet there were no detectable defects in glomerular filtration.[175] These results show that agrin likely plays no role either in glomerulogenesis or in establishment of the glomerular barrier to protein. Further, these findings suggest that glomerular charge selectivity may be contributed by podocyte and endothelial cell surface molecules, rather than by GBM proteoglycans.

Other Proteoglycans

Although perlecan and agrin are the best-studied GBM proteoglycans, two others have been shown to be present. Collagen XVIII, the COOH-terminus of which is cleaved to form the antiangiogenic molecule endostatin,[177] is unique in that it is a basement membrane collagen with heparan sulfate glycosaminoglycan side chains.[186] It is present in the GBM, but its function there, if any, is unknown. Mutant mice lacking collagen XVIII have no reported glomerular defects, but do exhibit abnormal blood vessel formation in the eye and retinal defects.[187] Consistent with this, Knobloch syndrome in humans is caused by mutations in COL18A1.[188]

A basement membrane chondroitin sulfate proteoglycan that exhibits transient deposition in postnatal rat GBM has been described.[189] Although nothing is known about the function of this protein, of potential interest is the fact that increased levels of this proteoglycan were detected in the GBM of diabetic rats, compared to the normal situation where it is not detected in mature GBM.[190]

RECEPTORS AND RECEPTOR-ASSOCIATED PROTEINS MEDIATING GLOMERULAR CELL INTERACTIONS WITH THE GBM

In order for glomerular cells to interact appropriately with the GBM, they must express the required matrix receptors and the associated cytoplasmic proteins that mediate responses to the engagement of ligand. While there is a plethora of these molecules, only a limited set have been studied in the context of glomerulogenesis and glomerular function.

The best characterized matrix receptors are the integrins. Integrins are a large family of transmembrane αβ heterodimers that bind to extracellular matrix proteins, mediate adhesion, and transduce signals that govern cell proliferation, survival, and migration. The most studied integrin in the glomerulus is α3β1. This is primarily a laminin-binding integrin, although it has also been shown to bind collagen IV. Biochemical studies suggest that α3β1 preferentially binds laminins containing the α3 and α5 chains. This would include the LM-511 and LM-521 heterotrimers that, as discussed above, are so important for glomerular development and function.

The first indication that integrin α3β1 is important for glomerulogenesis came from studies of Itga3 mutant mice, which lack integrin α3.[191] These mice die in the neonatal period due to defects in both kidney and lung. Glomerulogenesis occurs in a mostly normal

fashion, but ultrastructural analysis reveals that formation of podocyte foot processes is defective, and the GBM appears highly disorganized.[191] These data are consistent with the fact that podocytes express integrin α3β1 at a high level, and suggest that α3β1 is involved in organizing GBM architecture, perhaps by modulating polymerization of secreted laminins, and in regulating foot process extension. Integrin α3β1 also serves as a mesangial cell receptor for the COOH-terminal LG domain of laminin α5 in the GBM. Their interaction at the base of the glomerular capillary loops allows mesangial cells to maintain loop structure. If this interaction is impaired, either by alteration of the composition of the LG domain or by deletion of integrin α3, then capillary ballooning occurs.[154,191] Ballooning is more severe in the former case, indicating that there is likely a receptor on mesangial cells besides integrin α3β1 that mediates binding to the GBM. One possibility is integrin α8β1, as older Itga8$^{-/-}$ mice exhibit widening of the glomerular capillaries, although the effect is mild.[192]

Integrin α3β1 is one of many integrins that use the integrin-linked kinase (ILK) as an intermediate in signal transduction. ILK binds to integrins and to various actin-binding proteins, and therefore serves to bridge the actin cytoskeleton with the cell's major linkage to the extracellular matrix. Whereas mice lacking ILK die as very early peri-implantation embryos, mice with a podocyte-specific deletion of ILK survive for a few months, but they eventually succumb to an end-stage renal disease that begins with thickening and broadening of the GBM, followed by focal segmental glomerulosclerosis.[193] Mutation of CD151, a tetraspanin family protein expressed by podocytes that interacts with and modulates integrin function, can also cause GBM defects and glomerular disease.[194,195] These data further underscore the importance of the podocyte in organizing GBM architecture.

CONCLUDING REMARKS

Although much progress has been made in understanding certain aspects of glomerular development, many important questions remain. First and foremost, the fundamental morphogenic events that initiate, propel, and conclude glomerulogenesis are still poorly-defined. In this chapter, we discussed a series of different transcription factors, intracellular and transmembrane proteins, growth factors, and various signaling mechanisms associated with glomerular endothelial cell and podocyte biology. With only a few exceptions, however, most of these individual proteins and processes are expressed by many other cells and tissues throughout the body, and therefore are not likely to be solely or directly responsible for development of the glomerulus. On the other hand, there are a few features of the glomerulus that are both compositionally and structurally distinct, and these include the GBM and epithelial slit diaphragm. Similarly, the intercapillary mesangial cell and its matrix are also unusual structures not found in other vascular beds. We believe that more research aimed at investigating the regulation of the synthesis, assembly, and maintenance of the GBM, SD, and mesangium specifically may yield detailed new insights into how the glomerulus develops and is maintained normally. Perhaps new therapies that retrace parts of the normal developmental pathway could then be designed and used successfully to repair injured glomeruli.

RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Renal Blood Flow

The renal blood flow in the adult human is 660 ml/min which is 20–25% of the cardiac output. In contrast, the fetal kidney receives only 2% of the cardiac output from mid-gestation to term.[178] The developmental increase in renal blood flow is due in part to an increase in cardiac output, but predominantly to a decrease in renal vascular resistance.[92,117,220] When corrected for a body surface area of 1.73 m^2, the human neonate has a renal blood flow of only 15–20% of that measured in adults.[51,177] Renal blood flow doubles in the first month of life, and is comparable to adults by one to two years of age when corrected for body surface area.[177] The maturational changes in renal vascular resistance are due to anatomical changes in the renal vasculature, as well as changes in the balance between vasoconstrictors, such as catecholamines and angiotensin II, and vasodilators, such as nitric oxide.[169] The kidney develops in a centrifugal fashion. Juxtamedullary nephrons are formed before those in the superficial cortex. The renal blood flow distribution, measured by both xenon washout and injection of microspheres, shows a paucity of blood flow to the outer cortex compared to the deep cortex in neonates.[18,117,155] During postnatal maturation there is a redistribution of blood flow, with enhanced perfusion of the outer cortex due to a decrease in renal vascular resistance.[18,117,155]

Autoregulation

Renal blood flow (RBF) and glomerular filtration rate (GFR) remain stable over a wide range of perfusion pressures.[251] As perfusion pressure falls there is vasodilatation of the afferent arteriole and vasoconstriction of the efferent arteriole which maintains RBF and GFR. As blood pressure increases during development, the range in pressure where autoregulation of renal blood flow and GFR occurs shifts accordingly.[118] While neonates can autoregulate GFR in response to changes in blood pressure, this protective mechanism is far less developed than the autoregulatory capability of adults due, at least in part, to an attenuated release and efferent arteriolar response to angiotensin II.[251]

Glomerular Filtration Rate

Initiation of glomerular filtration, as evidenced by the flow of urine, begins between nine and twelve weeks gestation in the human.[85] The glomerular filtration rate (GFR) is lower in neonates than adults, even when corrected for body surface area.[15,177] In premature human infants creatinine clearance increases as a function of postconceptual age (the sum of gestational age and postnatal age).[15] GFR is constant at ~0.5 ml/min in infants with a postconceptional age of 28–34 weeks, despite the increase in renal size.[14] GFR increases to 1.0 ml/min at 34–37 weeks and to 2 ml/min at a postconceptional age of 40 weeks.[14] In absolute terms, the GFR increases 25-fold from birth to adulthood. Corrected for a surface area of 1.73 m^2, the GFR in the human term neonate is 30 ml/min/1.73 m^2 in the first week of life.[15,67] GFR continues to increase during the first ~1–2 years of life to reach adult levels when factored for body surface area[177](Figure 27.1).

At birth, juxtamedullary glomeruli have a larger volume and greater single nephron GFR than superficial

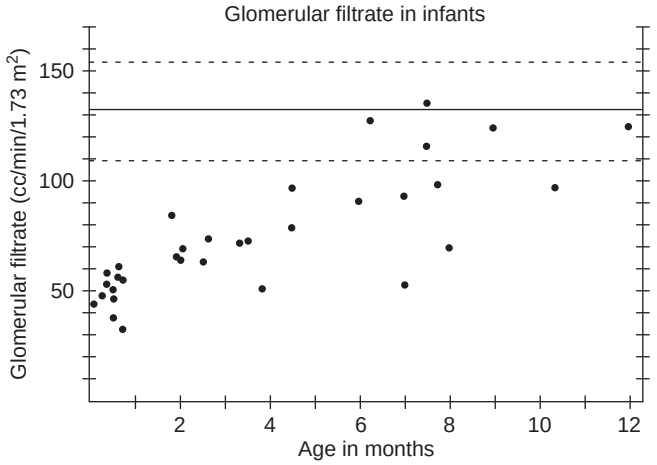

FIGURE 27.1 **Glomerular filtration rate (GFR) in infants in the first year of life (values are corrected for a surface area of 1.73 m^2).** The horizontal line is the mean adult value, and the broken line represents one standard deviation. *(from ref. [177] with permission.)*

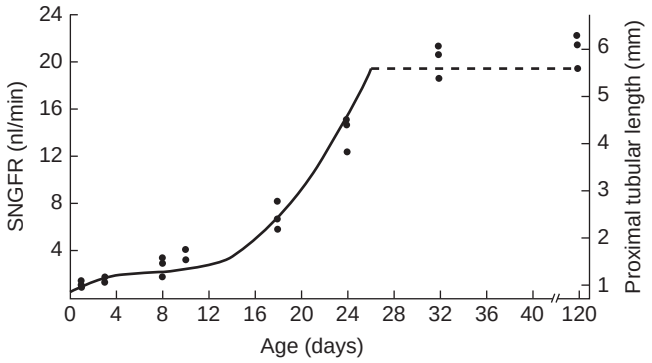

FIGURE 27.2 **Single nephron GFR (SNGFR) in guinea pigs with age.** Each point represents two to six determinations of SNGFR in an animal *(from ref. [219])*.

nephrons.[219] In the guinea pig there is a 7-fold increase in GFR in the first month of life.[219] The increase in total kidney GFR during the first week of life, a time when superficial nephron GFR is relatively constant, is predominantly due to an increase in juxtamedullary nephron GFR.[219] After two weeks of age, however, the rise in total kidney GFR is predominantly due to an increase in GFR in superficial nephrons[219](Figure 27.2).

The increase in single nephron GFR with postnatal maturation is due to a number of factors. Single nephron GFR is the product of the net ultrafiltration pressure and the glomerular ultrafiltration coefficient, K_f. The effective ultrafiltration pressure is the difference between the hydrostatic and oncotic pressures across the glomerular capillary bed. Studies comparing newborn rats and guinea pigs to adults have shown a maturational increase in effective ultrafiltration pressure.[3,220] However, these changes contribute at most 10% to the 20-fold increase in single nephron GFR.[113,220,232] The maturational increase in GFR is predominantly the result of the increase in K_f, which is the product of the hydraulic permeability of the glomerular capillary and the glomerular capillary surface area.[88,115,129,232] Studies using neutral dextrans have found that the permeability characteristics change only slightly with maturation.[88] The increase in K_f, and thus single nephron GFR, is predominately due to the 7.5-fold increase in glomerular capillary surface area during renal maturation.[115,129]

SODIUM CHLORIDE TRANSPORT

The transition from fetal to neonatal life is characterized by a dramatic decrease in urinary sodium excretion, despite an increase in GFR. The early fetus excretes ~20% of the filtered sodium, while the late gestation fetus excretes only ~0.2%.[173,211] Term neonates are able to maintain a positive sodium balance over a wide range of sodium intake which is essential for growth.[9,218] Compared to adults, neonates have a limited capacity to excrete an acute sodium load, and will develop volume expansion and hypernatremia with a sodium load.[9,65] This phenomenon is exemplified in a study where adult and neonatal dogs were given an isotonic saline infusion equal in volume to 10% of the animal's weight.[87] The results of the cumulative excretion of sodium with time are shown in Figure 27.3. Adult dogs had a brisk natriuresis and diuresis, excreting 50% of the sodium within two hours of the infusion. Dogs less than one week of age excreted less than 10% of the sodium infused by two hours. The limited ability to excrete a sodium load in neonates was not explained by a low GFR, since there was a comparable change with volume expansion in neonates and adults. Premature neonates have high urinary sodium losses and fractional excretion of sodium compared to term neonates.[2,7,9,75] The following section discusses the maturation of tubular transport, which maintains the positive sodium balance in growing neonates.

Glomerulotubular Balance

Glomerulotubular balance remains fairly constant under a number of conditions which alter the GFR in the adult. During postnatal development, the maturational increase in the GFR is paralleled by a concomitant increase in the rate of tubule solute absorption.[109,219] If this did not occur, there would be loss of essential solutes which would jeopardize the life of the neonate as GFR increases during development.[109,219]

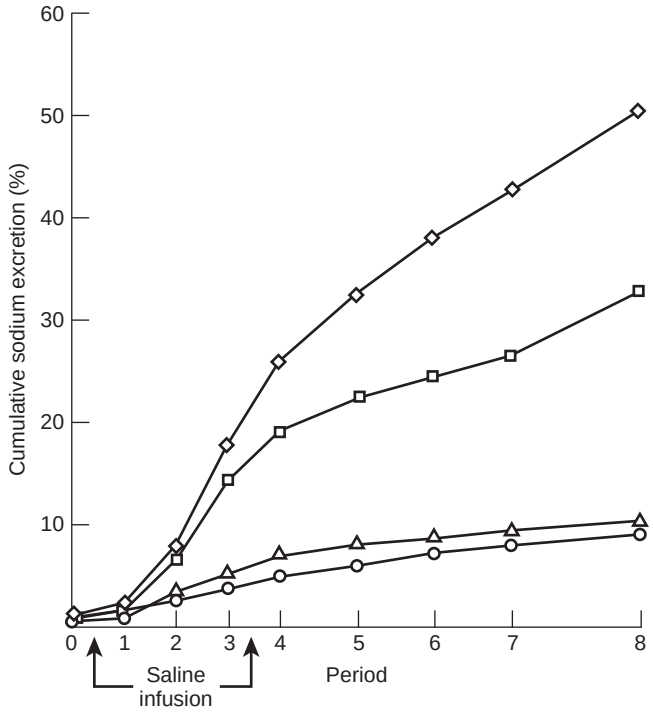

FIGURE 27.3 **Cumulative sodium excretion in dogs of various ages after infusion of isotonic saline equal to 10% of body weight over 30 minutes.** Period 8 is approximately 120 minutes after initiation of saline infusion. *(from ref. [87]).*

In the fetus, however, the GFR and delivery of solutes and water to the tubules can surpass the reabsorptive capacity of the tubules. In a clearance study examining the fractional reabsorption of volume and sodium after salt-loading in fetal, young, and adult guinea pigs, the fractional reabsorption of volume and sodium were lower in the fetus and in one-day-old animals. By 2–5 days of age, the fractional reabsorption of sodium and water were at the adult level.[149] The glomerular–tubular imbalance is not only present in the fetus, but can also be manifest in the premature neonate. This is exemplified by the fact that glucosuria is frequently present in premature human neonates born before 30 weeks of gestation.[14,235] In human neonates born before 34 weeks gestation, 93% of the filtered glucose is reabsorbed,[14] which is comparable to the fractional reabsorption in the guinea pig fetus.[149] By 34 weeks of gestation, the human neonate can reabsorb over 99% of the filtered glucose load.[14]

Maturation of Proximal Tubule Volume Reabsorption

The developing kidney exhibits a centrifugal pattern of nephron maturation, with juxtamedullary nephrons being formed before superficial nephrons.[76] The glomerular and tubular morphology of juxtamedullary nephrons are more mature than those in the superficial cortex.[76] In many species, including the mouse, rat, and rabbit, nephrogenesis continues after birth in the superficial cortex. Nephrogenesis also continues postnatally in humans born prior to 34 weeks gestation.

The reabsorptive capacity of the neonatal superficial and juxtamedullary proximal tubule is less than that of adults. The rate of volume absorption in superficial proximal convoluted tubules increases two-fold between a 22–24-day-old weanling and a 40–45-day-old adult rat.[11] In rabbit superficial proximal tubules the rate of volume absorption increased four-fold between one week and one month of age,[130] while the rate of volume absorption in rabbit juxtamedullary proximal convoluted tubules did not change appreciably during that time.[190] However, there is a two-fold increase in volume absorption in juxtamedullary nephrons between 4 and 6 weeks of age in the rabbit.[190] Proximal tubule transport for each solute is the sum of transport mediated by passive diffusion, solvent drag, and active transport, which are discussed below.

Na^+/K^+-ATPase Activity

The basolateral Na^+/K^+-ATPase provides the driving force for all sodium-dependent transport along the nephron by generating and maintaining a low intracellular sodium concentration. Inhibition of Na^+/K^+-ATPase with ouabain reduces the rate of volume absorption to zero in neonatal and adult isolated rabbit proximal convoluted tubules.[190] Thus, maturation of Na^+/K^+-ATPase activity plays a key role in the maturation of solute transport along the nephron.

The Na^+/K^+-ATPase is made up of an α-subunit and a regulatory ß-subunit. There are four α isoforms and three ß isoforms.[41] The α-subunit is the catalytic subunit, and has an ATP-binding site as well as the binding site for cardiac glycosides. The adult kidney predominantly expresses the α1 and ß1 isoforms. There is a postnatal increase in renal Na^+/K^+-ATPase activity.[12,13,188,191] In dissected rabbit tubules, the neonatal Na^+/K^+-ATPase activity is lower than the adult in each nephron segment examined[188] (Figure 27.4). The V_{max} Na^+/K^+-ATPase activity increases five-fold during renal maturation, with no change in the K_m for sodium, potassium or ATP.

The increase in Na^+/K^+-ATPase activity in the rabbit juxtamedullary proximal convoluted tubule lags behind the maturational increase in bicarbonate and volume absorption by one week,[188] consistent with the maturational increase in apical membrane transport being the driving force for the increase in basolateral

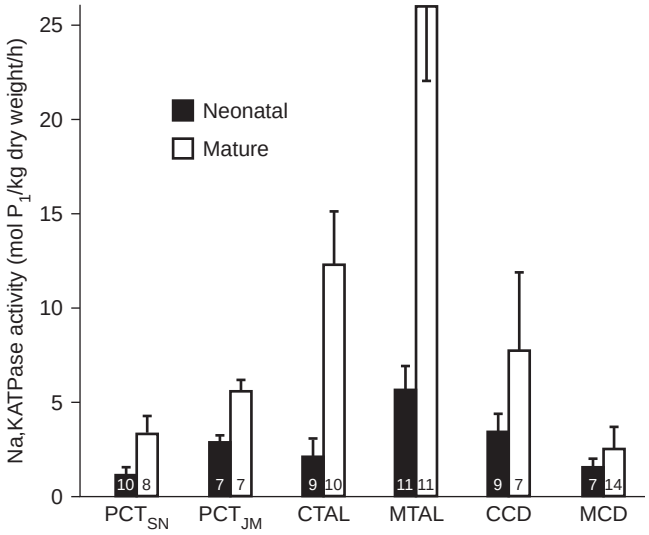

FIGURE 27.4 **Na^+/K^+-ATPase activity in neonatal and adult rabbit nephron segments** (PCT_{SN}: superficial proximal convoluted tubule; PCT_{JM}: juxtamedullaryproximal convoluted tubule; CTAL and MTAL: cortical and medullary thick ascending limbs; CCD and MCD: cortical and medullary collecting ducts) *(from ref. [188]).*

Na^+/K^+-ATPase. Several studies have supported this hypothesis. In rat proximal tubule cells in culture, stimulation of the Na^+/H^+ exchanger increases intracellular sodium and leads to an increase in Na^+/K^+-ATPase activity.[101] An increase in intracellular sodium not only increases pump activity, but also increases α and ß Na^+/K^+-ATPase subunit mRNA and protein abundance.[61] Chronic increases in Na^+/H^+ exchanger activity in rats induced by metabolic acidosis result in an increase in Na^+/K^+-ATPase activity in growing but not adult rats, an effect not seen when the rats were administered amiloride, an inhibitor of the Na^+/H^+ exchanger.[81] Thus, the maturational increase in Na^+/H^+ exchanger activity may be responsible for the increase in Na^+/K^+-ATPase activity.

Maturation of Proximal Tubule NaCl Transport

In the early proximal tubule there is preferential reabsorption of bicarbonate over chloride ions. This leaves the proximal tubule luminal fluid with a higher chloride concentration and a lower bicarbonate concentration than the peritubular fluid. Chloride transport is the sum of active transcellular reabsorption and chloride diffusion across the paracellular pathway down its concentration gradient. In the adult rabbit proximal convoluted tubule, two-thirds of NaCl transport is active and transcellular and one-third is passive and paracellular.[23] In the adult rat proximal convoluted tubule one-third of NaCl transport is active, and two-thirds is mediated by passive diffusion.[4]

Active chloride transport by the proximal convoluted tubule is mediated by the parallel operation of the Na^+/H^+ and Cl^-/base exchangers.[17,204,208] Cl^-/OH^-, Cl^-/oxalate, and Cl^-/formate exchange have all been found to mediate chloride uptake into the proximal tubule[17]; however, the relative importance of these transporters remains controversial. In the rabbit superficial convoluted tubule there is evidence for both Cl^-/OH^- and Cl^-/formate exchangers.[208] However, in juxtamedullary proximal convoluted tubules only Cl^-/OH^- exchange is present.[208] In the guinea pig there is a large increase in Na^+/H^+ exchanger activity and Cl^-/formate exchange in brush border membrane vesicles during the transition from fetus to newborn.[93] In isolated perfused rabbit proximal straight tubules the rate of active NaCl transport was two-fold greater in adult proximal straight tubules compared to neonatal tubules.[203] Both Cl^-/OH^- and Na^+/H^+ exchange activities were five-fold less in neonatal tubules compared to that in adult tubules.[203]

The relative contribution of passive chloride transport to total NaCl transport may be species-specific. In the adult rat the late proximal tubular chloride concentration is significantly higher than that in the glomerular ultrafiltrate.[133] However, in the neonatal rat, the proximal tubule luminal chloride concentration remains the same as that in the glomerular ultrafiltrate. The constant luminal chloride concentration could be due to equal rates of chloride and bicarbonate reabsorption by the immature segment or to a higher chloride permeability in the neonate mediating higher rates of passive chloride transport than in adults.[133] Direct measurements of chloride permeability and the relative contributions of passive chloride transport have not been examined *in vivo*. Thus, the reason for the lack of the chloride gradient in neonatal rat proximal tubules is unknown.

Developmental Changes in the Paracellular Transport

Direct measurements of rabbit proximal convoluted tubule chloride and bicarbonate permeabilities demonstrate that neonatal segments have a lower permeability to both solutes than in the adult.[162,165,206] In addition, the resistance of the proximal tubule is higher in the neonatal rabbit proximal tubule than the adult, providing further evidence that there are developmental changes in the paracellular pathway.[165] Finally, studies have demonstrated that solvent drag does not contribute significantly to volume absorption in the neonatal tubule, as the reflection coefficients for both

NaCl and $NaHCO_3$ were not different from one.[164] Passive chloride transport has been characterized in the rabbit using *in vitro* microperfusion.[165,203,206] In both neonates and adults chloride permeability is extremely low, indicating that passive chloride transport does not contribute significantly to chloride absorption in this nephron segment.[206] The permeability of chloride in neonatal juxtamedullary proximal convoluted tubules is more than 10-fold lower than that of the adult segment.[206] In adult rabbit proximal straight tubules there is a substantive rate of passive chloride transport[165,203]; however, the neonatal rabbit proximal straight tubule is impermeable to chloride. Thus, there is no passive NaCl transport in the neonatal proximal straight tubule.[165,203]

The maturational changes in passive paracellular transport indicate there must be a developmental change in the composition of tight junction proteins. The tight junction creates a barrier and mediates the paracellular properties of the paracellular pathway.[236] Occludin, a protein with a ubiquitous distribution, and claudins, a family of tight junction proteins that number over 20, have four membrane spanning domains forming two extracellular loops that adjoin with their partner on the neighboring cell.[236] The permeability properties, including the ion permeability and resistance of epithelia, are determined predominantly by the isoforms of the claudins in the tight junction. Using semiquantitative real-time PCR of individually dissected tubules, there was no difference in the mRNA expression of claudins 1, 2, 10a, 12, and occludin in neonates compared to adult proximal tubules. However, claudins 6 and 9 were present in neonatal proximal tubules, but were absent in the adult segment.[1] Expression of claudins 6 and 9 in Madin–Darby canine kidney II (MDCK II) cells, which have a low resistance and do not express these claudin isoforms, resulted in an increase in the paracellular resistance and increased sodium-to-chloride and bicarbonate-to-chloride permeability ratios.[179] In addition, expression of claudin 6 and claudin 9 in MDCK II cells resulted in a decrease in the transepithelial chloride permeability.[179] Thus, the expression of claudin 6 and 9 in neonatal proximal tubule is likely the cause for the higher resistance and the lower chloride permeability than in the adult tubule.

Distal Tubule NaCl Transport

The thick ascending limb and distal convoluted tubule reabsorb NaCl, and are impermeable to water. The osmolality of the luminal fluid collected by micropuncture of rat early distal tubules is 40% lower in adults compared to neonates,[253] and the fraction of filtered sodium remaining in the early distal tubule is higher in neonatal than adult rats,[10] consistent with a maturational increase in the rate of sodium transport in the thick ascending limb. *In vivo* micropuncture of 13- to 39-day-old rats showed an increase in loop NaCl reabsorption during postnatal maturation,[133] and *in vitro* microperfusion of the rabbit cortical thick ascending limb demonstrated that the rate of sodium transport in the adult segment is five-fold greater than that of the neonate.[107] Both rat and rabbit cortical and medullary thick ascending limb Na^+/K^+-ATPase activity increase approximately four-fold during postnatal maturation, consistent with a large developmental increase in sodium reabsorption by both segments.[167,188] A direct comparison of NaCl transport in neonatal and adult medullary thick ascending limb has not been performed; however, there is a maturational increase in Na^+/K^+-ATPase activity in this segment.[69,167,188]

Compared to adults, neonates have a limited capacity to excrete a sodium load which is not due solely to a lower GFR.[9,65,87] None of the nephron segments discussed thus far is responsible for this phenomenon, as this requires a segment where the relative transport rates are higher in neonates than in adults. The adult distal convoluted tubule reabsorbs only 5% of the filtered sodium, but sodium transport rates are higher in neonates.[10] In an *in vivo* micropuncture study, distal tubule transport was assayed during hydropenia and during volume expansion in 24- and 40-day-old rats. While 24-day-old hydropenic rats had a higher fraction of filtered sodium remaining in the early distal tubule than 40-day-old animals, this difference had disappeared by the late distal tubule puncture site. With volume expansion there was a comparable fraction of filtered sodium remaining in the early distal tubule in the two age groups, but there was enhanced late distal tubule sodium reabsorption in the younger rats.[10] Thus this segment is, at least in part, responsible for the blunted natriuresis with salt-loading in neonates.

The cortical collecting duct is the nephron segment responsible for the final modulation of sodium transport under the control of aldosterone. In the isolated perfused cortical collecting tubule, there is a three- to five-fold increase in sodium transport between one-week-old and adult rabbits.[180,237] Most of the maturational increase occurs between the first and second weeks of life. Sodium entry in the neonatal and adult cortical collecting tubule is via an apical sodium channel termed ENaC. ENaC is the rate-limiting step in collecting tubule sodium transport, and neonatal cortical collecting ducts have fewer apical conducting sodium channels than adult segments[112,184](Figure 27.5). ENaC is composed of α-, ß-, and γ- subunits, and the mRNA and protein abundance of each increases during postnatal life.[112,238,241,254] The driving force for conductive sodium entry across the apical conductance is the

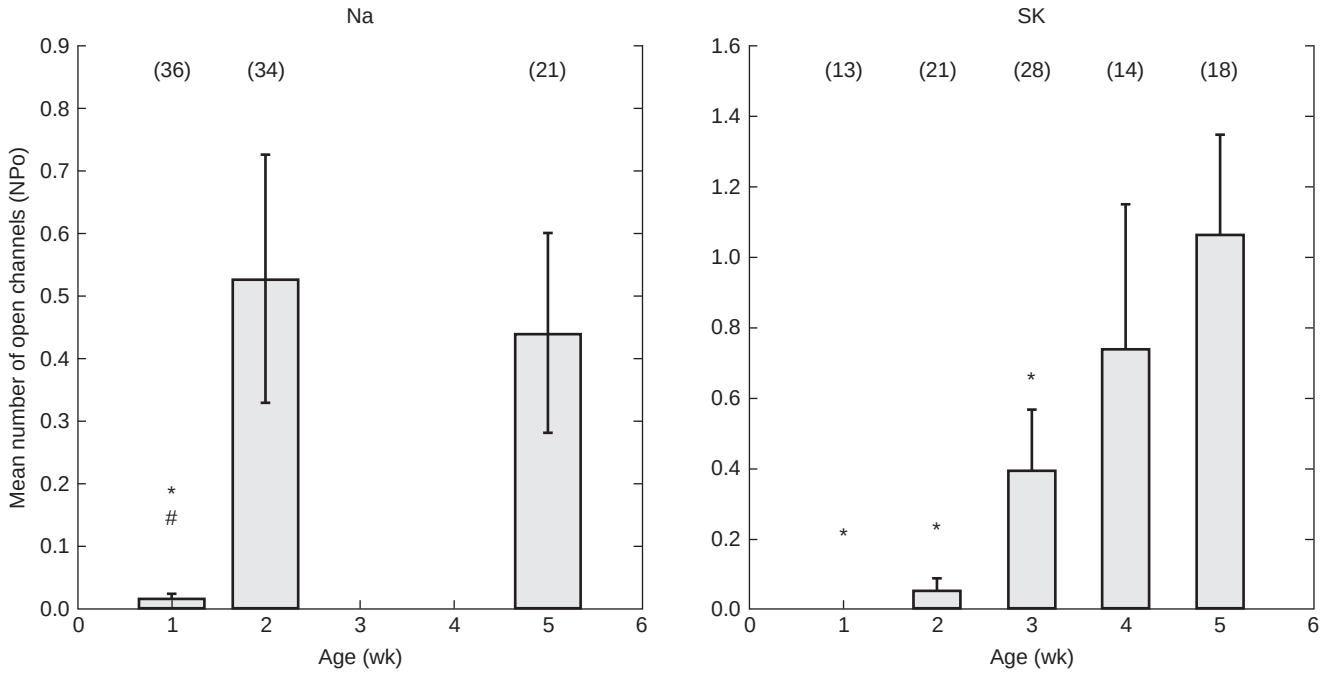

FIGURE 27.5 **Postnatal changes in number of conducting Na (ENaC) and secretory potassium (SK) channels per cell-attached patch of apical membrane of rabbit principal cells.** The number of functional Na channels increased ~30-fold between the first and second weeks of life, whereas the number of SK channels increased gradually after the second postnatal week *(from ref. [184] with permission).*

basolateral Na^+/K^+-ATPase, which increases in activity two-fold during maturation in this segment.[188] Interestingly, the fetal collecting duct expresses the Na^+/K^+-ATPase on the apical membrane; the significance of this is unknown.[50,108]

REGULATION OF SODIUM TRANSPORT

Renin–Angiotensin–Aldosterone

Plasma renin activity is higher in the neonate than the adult, and increases appropriately to a reduction in extracellular fluid volume in the fetus, premature infant, and neonate.[71,86,141,225] Plasma aldosterone levels are also significantly higher in preterm and term neonates than in adults.[8,34,141,210,225] Cord blood from term infants born to mothers who ingested a normal salt diet had significantly lower plasma aldosterone levels than those whose mothers ingested a low-salt diet or who were taking diuretics.[34] These data imply that the human fetus can also respond to volume contraction with an increase in serum aldosterone. The plasma aldosterone level has also been shown to vary inversely with sodium intake in preterm infants with respiratory distress syndrome.[210] Although the newborn can increase aldosterone secretion, the effect of aldosterone to increase distal tubule sodium reabsorption and potassium secretion is blunted compared to adults.[8,141,225] For example, in adult rats, adrenalectomy produces a 40-fold increase in urinary Na/K ratio, but in neonatal rats adrenalectomy has no effect on urinary electrolyte excretion.[222] Administration of exogenous aldosterone to adult adrenalectomized rats decreases the urinary Na/K ratio profoundly, but administration of aldosterone has no effect on urinary electrolytes in adrenalectomized neonatal rats.[222] Isolated perfused cortical collecting tubules from adult rabbits treated with mineralocorticoid had a significant increase in sodium absorption compared to control rabbits, but neonatal cortical collecting tubules were unaffected by prior mineralocorticoid treatment.[237] This resistance to aldosterone in neonatal rats is not due to a paucity of mineralocorticoid receptors, but is a postreceptor phenomenon.[222] However, in the mouse the blunted effect of aldosterone may also be due to fewer mineralocorticoid receptors compared to adults.[141]

Angiotensin II augments proximal and distal tubule sodium reabsorption by binding to both basolateral and luminal receptors. While neonatal rats have a blunted diuresis and natriuresis in response to volume expansion,

this was not the case in neonates which received Losartan, an AT_I receptor blocker, consistent with angiotensin II playing an important role in the regulation of sodium absorption in the neonate.[56]

Renal Nerves and Catecholamines

Renal nerve stimulation produces an increase in renal vascular resistance and reduction in renal blood flow in the fetus and newborn, although the effect is less in immature animals compared to adults.[174] Renal denervation of the fetal and neonatal lamb does not significantly alter renal blood flow, GFR or renal sodium handling, indicating that basal renal function is not significantly affected by renal nerves.[172,214,215] However, in the transition from fetal to neonatal life, renal nerves play a role in the decrease in sodium excretion that occurs during this period.[216] Sheep with denervated kidneys had a greater urine volume and sodium excretion in the first 24 hours after birth, as well as lower plasma atrial natriuretic peptide and renin levels.[216] There is no difference in urinary sodium or volume excretion after the first day of life, indicating that other unknown variables play an important role in mediating the profound decrease in urinary sodium and volume excretion after birth.[216]

Dopamine is a natriuretic hormone whose plasma levels are increased with volume expansion. Dopamine increases renal blood flow and GFR, and inhibits sodium transport in the proximal tubule, thick ascending limb, and collecting duct.[6] The concentration of dopamine is higher in fetal rat plasma and amniotic fluid than in the maternal blood.[39] Administration of exogenous dopamine to human premature neonates with respiratory distress syndrome increases GFR, and produces a natriuresis and diuresis.[234] However, comparative studies demonstrate that the effect of dopamine on the Na^+/H^+ exchanger and Na^+/K^+-ATPase is less in neonatal than adult tubules.[6,82,119,136]

RENAL ACIDIFICATION

The serum bicarbonate concentration in human infants in the first year of life averages 22 mEq/l, a value significantly less than that of adults.[74] Premature human neonates can have serum bicarbonate levels as low as 14.5 mEq/l.[193] The lower serum bicarbonate concentration in neonates and infants is due to a lower threshold for bicarbonate by the immature kidney.[74] This section will discuss the salient differences between the neonatal and adult kidney with regard to renal acidification.

Proximal Tubules

The adult proximal tubule reabsorbs 80% of the filtered bicarbonate. The lower bicarbonate threshold in neonates is, in large part, due to a lower bicarbonate reabsorptive capacity of the neonatal proximal tubule. In rabbit juxtamedullary proximal convoluted tubules perfused *in vitro*, the rate of bicarbonate reabsorption in proximal tubules from one-week-old rabbits is one-third that of the adult proximal tubule.[190] The rate of bicarbonate absorption does not change significantly until the time of weaning at four weeks of age. At six weeks of age, the rate of bicarbonate absorption is comparable to the adult. The maturational pattern of glucose and total volume reabsorption is quite similar to that for bicarbonate absorption.[190] The rate of bicarbonate absorption has not been directly measured in superficial nephrons. However, micropuncture studies in rats and *in vitro* microperfusion studies in rabbits have demonstrated a similar maturational increase in the rate of volume absorption in these segments.[11,130,133] Since a substantial fraction of volume absorption reflects bicarbonate absorption, a similar maturational pattern for bicarbonate is likely.

There are several potential explanations for the lower rate of bicarbonate transport in neonatal proximal tubules. In the adult proximal tubule there is a preferential reabsorption of bicarbonate over chloride ions. This leaves the luminal fluid with a higher chloride concentration and a lower bicarbonate concentration than that in the peritubular capillaries. This bicarbonate concentration difference could potentially allow bicarbonate to diffuse from the peritubular capillaries back to the luminal fluid. The amount of bicarbonate passive backflux is dependent upon the permeability of the paracellular pathway of the neonatal proximal tubule to bicarbonate.[123,162,165,203,205,206] However, bicarbonate permeability in juxtamedullary rabbit proximal convoluted tubules is less in neonatal juxtamedullary proximal tubules perfused *in vitro* than that of the adult segment.[162] Thus, the lower rate of bicarbonate transport in neonatal juxtamedullary proximal tubules is not explained by enhanced back diffusion, but is entirely due to a lower rate of active transcellular bicarbonate transport.

In the adult proximal tubule, two-thirds of apical proton secretion is mediated by the Na^+/H^+ exchanger and one-third is via an H^+-ATPase.[21,160] The driving force for the Na^+/H^+ exchanger is the low intracellular sodium concentration generated by the Na^+/K^+-ATPase. In the adult proximal tubule bicarbonate, exit is via the $Na(HCO_3)_3$ co-transporter. A lower rate of bicarbonate reabsorption by the neonatal proximal tubule could be due to a lower activity of any of these transport processes.

Studies using a variety of different techniques have demonstrated a maturational increase in proximal tubule apical membrane Na^+/H^+ exchanger activity.[20,21,31,202] In isolated perfused rabbit juxtamedullary proximal convoluted tubules the rate of Na^+/H^+ exchanger activity is approximately one-third that of the adult rate, and adult values are reached at six weeks of age.[20] These results compare well to the maturational changes in bicarbonate absorption measured in isolated perfused rabbit convoluted tubules.[190] While this study solely examined juxtamedullary proximal tubules, similar findings have been demonstrated in brush border membrane vesicles from the renal cortex.[31] Na^+/H^+ exchanger activity in late rabbit fetal kidney cortex is 25% that of the adult cortex. This difference is entirely due to a lower V_{max}, and not to a difference in the K_M for sodium.[31]

The H^+-ATPase, present on the apical membrane of the adult proximal tubules, does not contribute significantly to bicarbonate absorption in the neonatal proximal tubule. To study the relative contribution of the Na^+/H^+ exchanger and the H^+-ATPase to proximal tubule acidification, the rates of these two transporters were assayed by measuring proton secretory rates in adult and neonatal proximal convoluted tubules in response to an intracellular acid load.[21] As has previously been demonstrated, the rate of neonatal Na^+/H^+ exchanger activity is less than that in the adult. In the adult rabbit proximal tubule two-thirds of the pH recovery from an acid load is due to the Na^+/H^+ exchanger, and one-third is due to the the H^+-ATPase. In the neonate, 95% of pH recovery is due to the Na^+/H^+ exchanger, and only 5% is due to a sodium-independent mechanism. Thus, both the Na^+/H^+ exchanger and the H^+-ATPase undergo a significant increase in activity during maturation, and presumably limit bicarbonate absorption by the neonatal proximal tubule.

Three isoforms of the Na^+/H^+ exchanger, NHE1, NHE3, and NHE8 have been localized to the proximal tubule.[39,40,91,255] NHE1 has a ubiquitous distribution in tissues, and is found on the basolateral membrane of the proximal tubule.[40] NHE1 protein abundance does not vary significantly with postnatal maturation.[24] NHE3 is the apical membrane Na^+/H^+ exchanger mediating most luminal proton secretion by the adult proximal tubule.[39,249] There is a substantive postnatal maturational increase in NHE3 mRNA and protein abundance.[24] Interestingly, neonates have Na^+/H^+ exchanger activity at a time when NHE3 protein abundance is barely detectable.[202] The disparity between the presence of Na^+/H^+ exchanger activity and the paucity of NHE3 in the proximal tubule of neonates is due to the presence of NHE8.[33] NHE8 is predominantly an intracellular sodium–hydrogen exchanger that is also abundantly expressed on the apical membrane in neonates. Brush border membrane NHE8 decreases in abundance during postnatal maturation[33] (Figure 27.6). The factors responsible for this isoform switch will be discussed below.

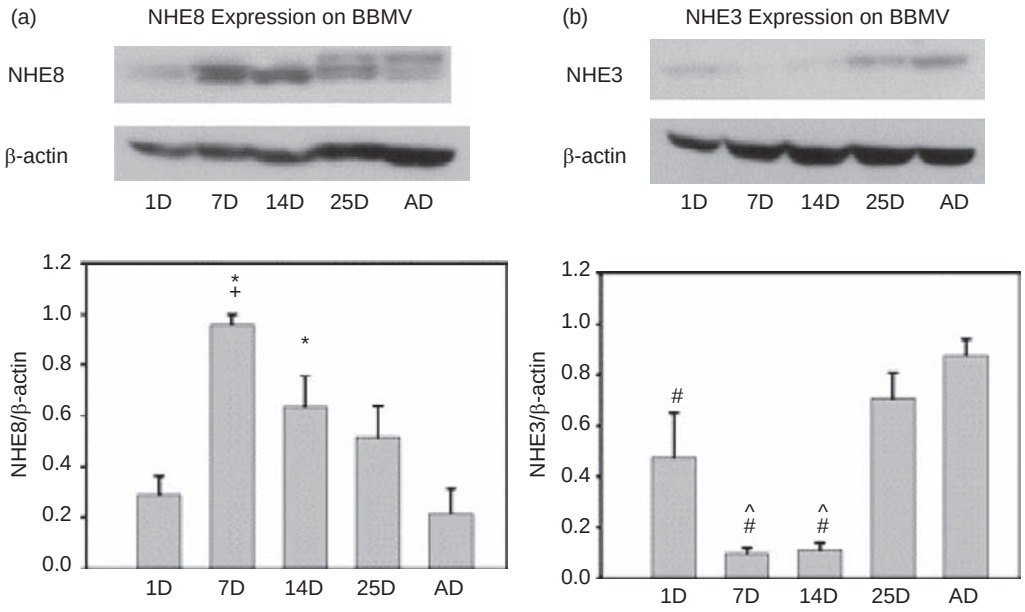

FIGURE 27.6 **Developmental change in brush border membra 33 ne NHE8 (a) and NHE3 (b) compared to β-actin.** NHE8 increased during postnatal development with a reciprocal increase in NHE3. *$P < 0.05$ vs. 1D and AD; +$P < 0.05$ vs. 26D; #$P < 0.05$ vs. 26D and AD; ^$P < 0.05$ vs. 1D. *(from ref. [33] with permission).*

The basolateral membrane $Na(HCO_3)_3$ co-transporter facilitates bicarbonate exit from the proximal tubule. $Na(HCO_3)_3$ symporter activity in neonates is only slightly less than that of adults.[20] This transporter not only plays a role in bicarbonate exit, but is also the predominate mechanism for the defense against changes in intracellular pH by the proximal tubule.[20]

Distal Tubule Acidification

The adult cortical collecting duct can absorb or secrete bicarbonate depending on the acid–base status of the animal.[146] Proton and bicarbonate secretion are mediated by α- and β-intercalated cells, respectively, which are far fewer in number than principal cells, the predominant cell in the cortical collecting duct. The number of α- and β-intercalated cells per millimeter of tubular length increases several-fold during maturation of the rabbit cortical collecting duct.[77,183] β-intercalated cells start to appear in the mouse cortical collecting tubule in the first week of life.[217] While β-intercalated cells are present in the outer medullary collecting duct of the neonate, they disappear by apoptosis and are no longer present in this segment by 2–3 weeks of age.[48,217]

Net bicarbonate transport in the cortical collecting tubule is dependent on the relative rates of bicarbonate absorption and secretion. In isolated perfused cortical collecting tubules from neonatal rabbits there is no net bicarbonate transport, whereas adult cortical collecting ducts secrete bicarbonate.[147] Bicarbonate secretion by the β-intercalated cell is via an apical chloride-bicarbonate exchanger that functions at a reduced rate in the neonatal segment.[183] Removal of bath chloride inhibits basolateral membrane chloride-base exchange on α-intercalated cells and inhibits luminal proton secretion. Removal of bath chloride had no effect on the rate of bicarbonate transport in cortical collecting tubules from neonatal rabbits, but increased net bicarbonate secretion in adult segments, indicating that there is a maturational increase in the cortical collecting tubule to secrete bicarbonate.[147] The bicarbonate absorptive capacity of the α-intercalated cell in the cortical collecting duct also increases during postnatal maturation.[183,186] The outer medullary collecting duct is an important segment for urinary acidification. Unlike the cortical collecting tubule, the number of intercalated cells per millimeter of tubular length does not change significantly with postnatal development.[77,186] The rate of bicarbonate absorption is only slightly less in the neonatal outer medullary collecting ducts compared to the adult rabbit segment.[147] Thus, there is a significant difference in the relative maturity of the cortical and medullary segments in neonates.

Titratable Acid and Ammonia Excretion

In addition to reclaiming the filtered load of bicarbonate, the kidney must excrete an amount of acid equivalent to the acid generated from metabolism. The growing animal must also excrete protons liberated during the formation of bone.[125,126] This is in part compensated for by the gastrointestinal absorption of alkali in the neonate,[125,126,240] but as in the adult, the neonatal kidney plays a major role in acid excretion. Thus, the kidney of the growing neonate must excrete 50–100% more acid per kg than the adult.

To excrete the quantity of acid generated from metabolism of proteins and growing bones, there must be urinary buffers to accept the secreted protons. If there were no titratable acids and ammonia in our urine, the secretion of a few protons would decrease the urine pH to levels that would inhibit further proton secretion. Net acid excretion, the sum of ammonium and titratable acid excretion per kg body weight, is significantly less in neonates than adults.[144] However, by seven days of age cows milk formula-fed infants have comparable rates of ammonium and titratable acid excretion as that of adults when normalized per kg of body weight.[142,144] Breast milk-fed infants, however, have significantly less phosphate intake and lower rates of titratable acid excretion than infants fed cows milk formula.[66,80,102,144] Thus, the rate of renal maturation of net acid excretion is quite brisk. However, unlike adults, human neonates function at near maximal capacity of net acid excretion to eliminate metabolically generated acid,[142] and have a limited ability to respond to an exogenous acid-load by increasing titratable acid and ammonia excretion.[142] In comparison to adults, neonates given an acid-load have a smaller increase in both titratable acid and ammonium excretion, making them more prone to develop acidosis when so challenged.[60,102] By one month of age the rate of net acid excretion in response to an acid-load is comparable to that of adults.[74,90,152,158,228] However, young infants respond to an acid-load with higher rates of titratable acid excretion to compensate for the lower rates of ammonium excretion.[74,152] *In vitro* studies have shown that the rate of renal ammonia production in kidney slices is lower in neonates compared to adults.[105] The low rate of ammonia production is in part due to lower glutamine synthetase activity limiting glutamine availability, but predominantly due to lower glutaminase activity.[89,239] As in adults, glutaminase activity increases substantively in response to an acid-load.[36] Premature neonates have significantly lower rates of titratable acid and ammonia excretion than term infants.[124,226,229] Preterm infants are thus less tolerant of a high protein formula than term infants, because sulfur containing amino acids generate an

acid-load which cannot be eliminated due to the low rates of net acid excretion.[63,228] Administration of NH_4Cl to premature infants resulted in an increase in net acid excretion, but premature infants had lower rates of ammonium and titratable acid excretion, and a higher urine pH, than term neonates.[90,124,226,227,229] As with term infants, there is a rapid maturation of the ability of premature infants to excrete an exogenous acid-load.[124,226,229]

Carbonic Anhydrase Activity

Carbonic anhydrase facilitates the reversible hydration of CO_2 to H_2CO_3.[161,192] Carbonic anhydrase is localized to all acidifying nephron segments, where it plays an important role in acidification. For example, carbonic anhydrase inhibition results in a 90% decrease in the rate of proximal tubule bicarbonate reabsorption.[139] There are 15 carbonic acid isoforms, with both species- and nephron segment-specificity.[161]

Carbonic anhydrase II is located in the cytosol of all acidifying renal tubules, and comprises 95% of carbonic anhydrase activity in the kidney.[120] Carbonic anhydrase IV comprises approximately 5% of total renal carbonic anhydrase activity, and is located on the apical and basolateral membrane of the proximal tubule and on the apical membrane of acid-secreting cells in the distal nephron.[192,194,195,245] Carbonic anhydrase XII is present on the basolateral membrane of acidifying segments.[156] In rodents, carbonic anhydrase XIV is also expressed on the apical membrane of the proximal tubule and thick ascending limb.[161] Carbonic anhydrase II protein abundance, normalized per millimeter of tubular length, increases approximately 10-fold in rat proximal convoluted tubules, cortical collecting tubules, and outer medullary collecting tubules between one and twelve weeks of age.[120] In the rabbit, carbonic anhydrase II increases only two-fold during postnatal maturation compared to carbonic anhydrase IV, which undergoes a ten-fold increase in mRNA and protein abundance with cortical maturation.[195,245] Thus, the developmental increase in carbonic anhydrase may be a factor in the postnatal increase in renal acidification.

INDUCTION OF NEPHRON MATURATION

As noted above, there are a number of quantitative and qualitative changes that occur in all nephron segments during postnatal development. Most of the studies examining the factors responsible for the postnatal changes during development come from studies of the proximal tubule, which will be the focus here. There are a number of potential factors which may be responsible for the postnatal maturational changes in proximal tubule transport. The maturational increase in GFR may induce the maturation of transporters on the apical membrane by increasing solute delivery. As previously discussed, an increase in apical membrane sodium transport could increase intracellular sodium and play a potential role in the maturational increase in Na^+/K^+-ATPase activity.[61,101,131] There are also significant postnatal maturational changes in several hormones which affect proximal tubular transport, including thyroid hormone and glucocorticoids, which increase 3-fold and 20-fold, respectively, in the postnatal period.[104]

Glucocorticoids increase renal cortical Na^+/H^+ exchanger activity. This effect can, in part, be mediated by an increase in GFR which will increase sodium delivery to the proximal tubule. However, glucocorticoids and thyroid hormone have a direct epithelial action on the proximal tubule to increase the rate of bicarbonate absorption and Na^+/H^+ exchanger activity.[22,25] This effect of glucocorticoids and thyroid hormone on NHE3 is due to an increase in NHE3 transcription.[22,52] However, glucocorticoids also increase apical membrane NHE3 by increasing the rate of exocytosis.[42] Administration of glucocorticoids to pregnant rabbits two days prior to the delivery increases the V_{max} of the Na^+/H^+ exchanger in neonates to levels the same as those seen in adults.[31] The K_m for sodium is comparable in neonates and adults. Similarly, proximal convoluted tubules from neonatal rabbits whose mothers received dexamethasone before delivery had infants with an almost two-fold increase in the rate of bicarbonate absorption to levels comparable to that measured in adult animals.[27] In addition, the rate of Na^+/H^+ exchanger and $Na(HCO_3)_3$ activity in proximal tubules increased two-fold in dexamethasone treated neonates.[27] The effect of dexamethasone is specific for the NHE3 isoform, the isoform present on the apical membrane of the proximal tubule and responsible for the majority of Na^+/H^+ exchanger activity in adults.[24] Prevention of the maturational increase of either glucocorticoids or thyroid hormone prevents the maturational increase in Na^+/H^+ exchanger activity and NHE3 protein abundance.[26,95] While glucocorticoids are the most important factor causing the maturational increase in NHE3, adrenalectomy in the neonatal period does not totally prevent an increase in both Na^+/H^+ exchanger activity and NHE3 protein and mRNA abundance, suggesting that thyroid hormone can compensate, to some extent, in the absence of glucocorticoids.[95] This was definitively demonstrated in studies using hypothyroid-glucocorticoid-deficient rats, where the maturational

increase in both hormones was prevented, and where Na^+/H^+ exchanger activity, NHE3 protein, and mRNA abundance remained at neonatal levels into adulthood.[94] As noted, there is an isoform switch from NHE8 to NHE3 during postnatal development.[33] The maturational decrease in NHE8 on the apical membrane of the proximal tubule is due the postnatal increase in thyroid hormone.[84] Administration of thyroid hormone to neonates resulted in a premature decrease in NHE8 and increase in NHE3 on brush border membranes, while prevention of developmental increase in thyroid hormone prevented the decrease in brush border membrane NHE8 abundance.[84] The regulation of NHE8 by thyroid hormone is due to a direct epithelial effect to decrease NHE8 surface expression, likely by post-transcriptional regulation.[84]

As will be discussed, there is a maturational decrease in the rate of phosphate transport during postnatal maturation.[57,66,106] This is observed at a time when there is an increase in serum glucocorticoid levels.[104] Administration of glucocorticoids to neonatal rats produced a significant inhibition in the rate of sodium-dependent phosphate uptake. This is due to a reduction in the V_{max} with no change in the K_M for phosphate.[16] This glucocorticoid-induced decrease in phosphate uptake was not accompanied by a change in NaPi-2a mRNA abundance; however, there was a three-fold decrease in NaP_i transporter protein abundance.[16] Thus, glucocorticoids play a role in the maturational decrease in phosphate transport.

Thyroid hormone appears to play an important role in postnatal development of mitochondrial enzymes in the rat proximal convoluted tubule. The normal maturational increase in the proximal tubule mitochondrial enzymes 3-keto acid-CoA transferase, an enzyme involved in ketone body oxidation, and citrate synthase and carnitine acetyltransferase were impaired in hypothyroid rats.[243] The enzyme activities were restored with thyroid replacement. Acetoacetyl-CoA thiolase, however, is not decreased in 21-day-old hypothyroid rats.[243] Finally, thyroid hormone plays a role in the maturational changes that occur in the permeability properties of the paracellular pathway.[28,205] As noted above, the adult rabbit proximal straight tubule has a high chloride permeability which results in high rates of passive chloride transport.[205] The neonatal rabbit proximal straight tubule is impermeable to chloride.[165] Neonatal proximal straight tubules have higher P_{Na}/P_{Cl} (sodium to chloride permeability ratio) and P_{HCO3}/P_{Cl} ratios than adult segments. Many, but not all, of the maturational changes in paracellular permeability properties of the proximal tubule can be accelerated by administration of thyroid hormone to neonates[205] or prevented if the neonates are made hypothyroid.[205]

PHOSPHATE TRANSPORT

Phosphate is essential for growth, and unlike adults growing animals are in positive phosphate balance. Human neonates and infants have a higher serum phosphate concentration than that of adults. While the high serum phosphate in neonates could be due to the lower GFR compared to adults, this is not the case. Studies have demonstrated that increasing the GFR by arginine infusion in young rats does not increase phosphate excretion, and lowering the GFR in adult rats by constricting the abdominal aorta does not increase the rate of phosphate absorption to that seen in the neonate.[99] The tubular reabsorptive capacity for phosphate is higher in neonates and infants than in adults.[57,66,106,171] Approximately 90–95% of the filtered phosphate is reabsorbed in human neonates during the first week of life, and growing children continue to maintain a higher maximal tubular reabsorption of phosphate than adults.[57,106]

A number of variables, such as intrinsic properties of phosphate transport in the proximal tubule, dietary phosphate content, parathyroid hormone, and growth factors can modulate phosphate transport, and could potentially explain the higher rate of phosphate transport by the neonatal kidney. The role of these factors has been extensively studied and will be reviewed in this section. A higher intrinsic rate of renal phosphate transport has been demonstrated in the isolated perfused guinea pig kidney where other *in vivo* factors were eliminated.[116] The maximal tubular reabsorption of phosphate per volume of glomerular filtrate in 3–7-day-old neonatal guinea pig kidneys is 40% greater than that measured in adult animals.[107] A higher intrinsic rate of proximal tubular phosphate reabsorption was also directly demonstrated in micropuncture studies, where 5–14 day neonatal guinea pigs reabsorbed a higher fraction of filtered phosphate than adults.[122] The maximal rate of phosphate uptake in brush border membrane vesicles (V_{max}) is five-fold higher in neonates than in adults, in the absence of a maturational change in the K_M for phosphate in growing animals.[154]

In addition to the difference in the rate of sodium-dependent phosphate co-transport with maturation, other intrinsic proximal tubular factors may play a role in the higher rates of phosphate transport in growing animals. The intracellular phosphate concentration (P_i) measured in isolated perfused kidneys using NMR was 40% lower in growing animals than in adults.[19] This provides a greater driving force for phosphate transport in growing animals. The lower intracellular phosphate concentration in the presence of a higher rate of apical phosphate transport implies that the rate

of basolateral phosphate exit is also higher in growing animals, although this has not been directly examined.

Membrane fluidity also has been shown to affect phosphate transport.[134,135,151] The brush border membrane content of cholesterol, sphingomyelin, and phosphatidylinositol increases with age.[135] This change in lipid composition decreases membrane fluidity,[135,151] which directly decreases the rate of phosphate transport.[134,151] Thus, the lipid composition and high membrane fluidity of the neonate and growing animal provides an environment which increases the V_{max} of the NaPi co-transporter. Glucocorticoids, which increase during the time of weaning, decrease membrane fluidity, and likely play a role in the postnatal decrease in phosphate transport.[16]

There are two sodium-dependent phosphate co-transporters, designated as NaPi-2a and NaPi-2c, present on the apical membrane of the proximal tubule that are primarily responsible for phosphate reabsorption.[140,197] In mice, NaPi-2a has been identified as the most important phosphate transporter in the kidney, responsible for ~70% of phosphate reabsorption.[32] NaPi-2a mRNA is first detected in early proximal convolutions in the post S-shaped body segment of the developing nephron.[189] However, NaPi-2a protein is not detected until the proximal tubules have a distinct brush border membrane.[231] Brush border membrane NaPi-2a expression is two-fold higher in 4-week-old juvenile rats than in adult rats, consistent with the higher rate of phosphate transport in growing animals.[246] A growth-specific NaPi co-transporter was postulated to be responsible for the increased phosphate transport in the weaning animals,[213] which was later identified as NaPi-2c.[197] NaPi-2c mRNA and protein expression is highest in the brush border of the convoluted proximal tubules of weanling rodents,[197] whereas it plays a negligible role in renal phosphate absorption in adults.[150,199,200] In contrast to rodents, NaPi-2c plays an important role in phosphate transport in humans. Mutations in NaPi-2c result in an autosomal recessive disorder termed hereditary hypophosphatemic rickets with hypercalciuria that is characterized by hypophosphatemia, due to renal phosphate-wasting, rickets, hypervitaminosis D, hypercalcemia, and hypercalciuria.[37,114]

Dietary phosphate content regulates renal phosphate transport in adult and in growing animals.[54,121,153,246] Thyroparathyroidectomized growing rats had a greater increase in their maximal tubular capacity for phosphate reabsorption in response to a low-phosphate diet and a blunted decrease in phosphate reabsorption on a high-phosphate diet compared to adult thyroparathyroidectomized rats.[54,153] In addition, the adaptive increase in maximal tubular capacity of phosphate reabsorption in response to phosphate deprivation took longer to occur in adult animals than in growing animals.[54] A low phosphate diet increases the rate of sodium-dependent phosphate uptake by brush border membrane vesicles in growing rats.[55] In addition, ingestion of a low-phosphate diet increases the abundance of Na-Pi transporters on the apical membrane of the proximal tubule, whereas a high-phosphate diet produces the opposite effect.[246] The dietary changes in phosphorus affect both brush border membrane NaPi-2a and NaPi-2c expression.[197,198]

The plasma concentration of PTH is lower in human neonates than in adults.[64] Fetal and neonatal rats can respond to changes in serum calcium with appropriate changes in PTH levels,[230] although there is a blunted response to PTH secretion.[242] Infusion of PTH in one-day-old human neonates produces no increase in urinary phosphate excretion.[57,137] By three days of age, infusion of parathyroid hormone results in an increase in phosphate excretion and increase in urinary cAMP.[57,137,145] However, the phosphaturic response to PTH is markedly lower in neonates than adults.[137] Furthermore, in micropuncture studies, the proximal tubule response to infusion of pharmacologic doses of PTH is attenuated in young rats compared to adults.[246] Despite the fact that PTH did not significantly increase phosphate excretion in young animals, the urinary cAMP corrected for GFR in response to PTH infusion was similar in all ages.[242] Thus, there is clearly a disassociation between the PTH-induced increase in cAMP production in neonates and the effect on phosphate excretion. The blunted response to PTH in the neonate compared to the adult is due to lower levels of phospholipase A2 activity in response to PTH and cAMP.[207]

Growth hormone administration can result in an increase in serum phosphate.[103] Brush border membrane vesicle phosphate transport is increased in dogs that received growth hormone compared to controls.[97] The effect of growth hormone on phosphate transport is mediated by IGF-1.[163] While growth hormone is not a significant regulator of phosphate transport in the adult, this may not be the case in the growing animal. Administration of growth hormone-releasing factor antagonist, which suppresses growth hormone secretion, has no effect on the maximal rate of phosphate absorption in adult rats, but significantly reduces phosphate absorption in growing rats.[100]

In addition to PTH, there are a number of hormones, known as phosphatonins, that regulate phosphate transport, including fibroblast growth factor-23 (FGF23),[29,209] secreted frizzled-related protein 4 (sFRP-4),[38] matrix extracellular phosphoglycoprotein,[49] fibroblast growth factor 7 (FGF7),[53] and dentin matrix protein-1(DMP1).[78] These hormones are dysregulated in a number of diseases with aberrant phosphate regulation, incuding X-linked hypophosphatemia and

tumor-induced osteomalacia.[83] The role of these phosphatonins in the developmental changes in phosphate transport remains to be elucidated.

POTASSIUM TRANSPORT

Potassium is transported actively across the placenta from mother to fetus,[201] ensuring that the fetal plasma potassium concentration is maintained at levels exceeding 5 mEq/L, even in the face of maternal potassium deficiency.[62,201] Both premature and term neonates have very low rates of renal potassium excretion, which maintains a positive potassium balance necessary for growth.[68,225] The low rate of renal potassium excretion is also responsible, at least in part, for the higher serum potassium concentration in neonates than in adults.[225] Renal potassium clearance in infants less than one year of age is less than that of older children, even if corrected for GFR.[181,225] Neonates can respond to potassium-loading with net tubular secretion, but this response is less than that of adults.[138,233]

The proximal tubule of neonatal and adult rats reabsorbs approximately 50% of the filtered potassium.[133] There is a maturational increase in potassium reabsorption by the loop of Henle.[70,133] The loop of Henle of adult rats has been shown to reabsorb 79% of the delivered load, while only 56% was reabsorbed by 13–15-day-old neonates.[133] The limited capability of the thick ascending limb of the neonate to reabsorb potassium will increase distal delivery of potassium. Thus, neither the proximal tubule nor the loop of Henle is responsible for the limited capability of the neonate to excrete potassium.

The distal convoluted and connecting tubules and cortical collecting duct ultimately regulate potassium excretion in adults and neonates. Clearance studies in dogs have demonstrated that the amiloride-sensitive (i.e., EnaC-dependent) component of potassium secretion is substantially less in neonates than adults, providing indirect evidence for a limited distal nephron potassium secretory capacity.[138] The developmental maturation of potassium transport in the distal nephron has been directly examined in the rabbit cortical collecting duct by *in vitro* microperfusion.[180] Baseline potassium secretory rates are not different than zero during the first three weeks of life, and did not reach mature rates until six weeks of age.[180]

The limited capacity of the distal nephron for net potassium secretion could be due to either an unfavorable electrochemical gradient across the apical membrane and/or a limited apical potassium permeability. The rate of net sodium absorption in the cortical collecting duct of the two-week-old animal is approximately 60% of that measured in the adult,[81] reflecting the rapid appearance of conducting ENaC channels in the apical membrane of this segment between the first and second weeks of life.[184] Thus, the electrochemical gradient is not considered to be limiting for potassium secretion at this age. While low rates of luminal flow and distal sodium delivery can limit potassium secretion in adults, these are unlikely to be significant variables in neonates, which have high rates of distal nephron flow and sodium delivery.[10,133]

In support of the notion that a paucity of plasma membrane potassium channels limits potassium secretion early in life is the observation that the intracellular potassium concentration in the distal nephron at birth is comparable to that measured in the adult,[182] despite Na^+/K^+-ATPase activity that is only 50% of that measured in adult.[59,188] Direct analysis of the apical potassium conductance of CCDs isolated from maturing rabbits showed that the mean number of open channels per patch (NPo) increased progressively after birth[185] (Figure 27.5).

Two populations of apical potassium channels have been identified by patch-clamp analysis in the collecting duct. The secretory K (SK) channel, encoded by ROMK and restricted to principal cells, is a small conductance channel with a high open probability. The SK/ROMK channel is considered to mediate baseline potassium secretion.[185] High conductance BK channels, present in both principal and intercalated cells, are activated by increases in intracellular calcium concentration and stretch, but are rarely open at physiological membrane potentials. BK channels mediate flow-induced potassium secretion, which does not appear until the fifth week of postnatal life.[247,248] The temporal delay between the postnatal increases in SK/ROMK and BK channel activity accounts for the sequential appearance of basal- and then flow-induced net potassium secretion at 3 and 5 weeks, respectively, of postnatal life in the rabbit. Specifically, SK/ROMK channel activity increases progressively after the second week of postnatal life,[185] whereas functional BK channel activity does not appear until 5 weeks of age in the cortical collecting duct.[248] Both developmental processes closely parallel increases in channel-specific mRNA levels and immunodetectable protein at the apical membrane of the CCD.[35,248,254]

The H^+/K^+-ATPase is a third potassium transporter, present in the apical membrane of intercalated cells in the distal nephron. The H^+/K^+-ATPase has little functional role except under conditions of potassium deficiency and metabolic acidosis, when it mediates potassium absorption and proton secretion. The activity of this transporter is comparable in neonates and adult collecting tubules.[58]

URINARY CONCENTRATING AND DILUTING ABILITY

Deprived of water for sufficient time, an adult human can concentrate urine to 1200 mOsm/Kg water, while the term and premature neonatal kidney can achieve urine osmolalities of only 400−600 mOsm/Kg water.[79,98,157,159] By six months of age, the human infant can increase the urine osmolality to 600 mOsm/Kg water[159] and by 1 to 1.5 years the human infant can concentrate the urine to levels comparable to that of an adult.[159,244] The neonate also has a limited capacity to excrete free water compared to that of adults.[132,143] However, both term and premature infants can excrete dilute urine with an osmolality approaching 50 mOsm/Kg water.[176] Thus, the primary limiting factor in the ability of the neonate to excrete free water is the low GFR that limits the distal delivery of fluid.

The ability to maximally concentrate urine requires vasopressin secretion from the neurohypophysis, a hypertonic renal medulla and a renal collecting duct that responds to vasopressin by increasing water permeability. In the developing human, there are a number of factors in the concentrating mechanism that limit the ability to maximally concentrate urine. The neonate and late gestation fetus respond to changes in plasma osmolality and volume with appropriate changes in plasma vasopressin.[96,168] These changes in plasma vasopressin are of comparable magnitude to that measured under similar conditions in the adult.[168] Perinatal stress also results in the secretion of vasopressin.[96,170] However, infusion of vasopressin in the late gestation fetal sheep resulted in a smaller increase in urinary osmolality than that measured in adult animals.[175] Thus, while the fetus and neonate can secrete vasopressin at concentrations comparable to the adult, there is a hyporesponsiveness to the renal effect of vasopressin to increase urinary osmolality.

The osmotic gradient in the renal medulla is composed of urea and sodium chloride. The urea concentration in the neonatal renal medulla is limited in part by the low dietary protein intake and the high volume of fluid ingested.[72,73] Augmentation of protein or addition of urea to the diet of neonates increases their maximal concentrating ability, albeit not to the levels measured in adults.[72,73] Urea must get into the interstitium, which is facilitated by the urea transporter (UTA) located in the inner medulla. The abundance of UTA-1, which is also regulated by vasopressin, increases during postnatal maturation.[128] The capacity of the thick ascending limb to reabsorb sodium chloride, necessary to generate a hypertonic medulla, is less in the neonate compared to that of an adult.[10,107,110,167,188,253] The developmental changes that occur in transport with age in the thick ascending limb are paralleled by an increase in the concentration of sodium and urea in the medulla and papilla.[168,221] In addition, the sorbitol concentration in the inner medulla, a major intracellular osmolyte formed by aldose reductase, is significantly less than that in the adult.[196] Fluid restriction increases aldose reductase activity in the adult medulla, but not in the neonate.[196]

The urinary concentrating ability of neonatal rats can be induced prematurely by the administration of glucocorticoids,[168,224] likely due to the premature induction of the NKCC2 in the medullary thick limb.[224,252] Adrenalectomy in rats on day 16 of life prevents the maturational increase in papillary sodium and urea concentration, but not the growth of the papilla, consistent with a role of glucocorticoids in the maturation of the tubular transport processes responsible for development of maximally concentrated urine.[168] However, adrenalectomy at 10 days of life in rats results in a poorly-developed papilla and an increase in medullary cyclooxygenase-2 protein abundance and PGE_2 levels. Administration of glucocorticoids alone to adrenalectomized neonatal rats increased, but did not normalize, urine osmolality,[223] which required both glucocorticoid and mineralocorticoid replacement.[223] The requirement for mineralocorticoids may be due to their effect of decreasing medullary cyclooxygenase-2 levels, since prostaglandins cause a natriuresis and diuresis.[223]

The osmotic water permeability of the adult and neonatal inner medullary collecting duct are very low in the absence of vasopressin.[212] Vasopressin causes an increase in cAMP that increases protein kinase A activity. Protein kinase A phosphorylates aquaporin 2, resulting in trafficking of the protein to the apical membrane and an increase in apical membrane water permeability.[43] In both the outer and inner medullary collecting collecting duct, vasopressin results in an increase in osmotic permeability, yet the response is far less than that measured in the adult segment.[111,212]

The limited response to vasopressin by the neonatal collecting tubule is due to several factors. There are fewer vasopressin-binding sites in the medullary and cortical collecting duct in the neonatal rat compared to the adult,[5,43] but is not likely to be a significant factor limiting renal concentrating ability.[30,166] Aquaporin-2 is less abundant in the renal medulla of neonatal rats than in adult animals.[45,250,252] Both aquaporin-2 mRNA and protein abundance increase with neonatal betamethasone administration,[252] providing further evidence that glucocorticoids are important in the maturation of the urinary concentrating mechanism. In the neonatal rat kidney aquaporin-2 expression and trafficking increase appropriately in response to both water deprivation and vasopressin administration.[45] The

basolateral water channels, aquaporin-3 and -4 do not change significantly with postnatal development.[30,127,250]

The basal cAMP level is comparable in immature and adult cortical collecting ducts. However, there is a diminished stimulation of cAMP production in response to vasopressin in neonates compared to that of adults.[46] Forskolin, which directly activates adenylate cyclase, does not stimulate cAMP levels in the cortical collecting duct to the same extent as the adult tubule,[46] due to elevated phosphodiesterase activity which degrades cAMP in neonatal tubules compared to adult tubules.[166] In the presence of inhibitor of phosphodiesterase IV, the neonatal collecting duct water permeability was comparable to the adult in response to vasopressin.[166] Thus, developmental change in phosphodiesterase plays an important role in the development of the concentrating ability by degrading the generated cAMP. The limited vasopressin-mediated increase in cAMP levels in the neonatal collecting tubule due to increased degradation is the predominant factor impairing the action of vasopressin to increase water permeability.[46]

Prostaglandins could also play a role in the limited response of the neonatal collecting duct to vasopressin, since prostaglandins impair cAMP production.[46] While one study showed decreased PGE_2 production in neonatal cortical collecting tubules,[187] others have demonstrated both higher rates of production and greater abundance of G_i-coupled EP_3 (prostaglandin) receptors.[44,148] cAMP production in response to forskolin and vasopressin in neonatal and adult tubules are comparable when incubated with indomethacin to inhibit prostaglandin production.[44] However, when neonatal collecting ducts were perfused *in vitro*, there was no difference in water permeability in the response to vasopressin in presence or absence of indomethacin.[47] Thus, the role of prostaglandins in the limited response to vasopressin in the neonatal collecting duct remains unclear.

INTRODUCTION

The tight regulation of cell growth and division within an organ is essential for the development and maintenance of correct structure and function. Perturbations of renal growth occurring either developmentally or following injury to mature renal cells contribute to the abnormalities observed in a wide range of diseases. The changes in growth are increasingly recognized as an influence on the progression of the initial disease process, and the ultimate clinical outcome. Abnormal cell growth is classified according to the presence of an increase in cell number or cell size. Hyperplasia refers to abnormal growth resulting in an increased absolute number of cells, whereas hypertrophy refers to an increase in individual cell size. Both processes may be present in a given cell population and contribute to the increase in overall kidney size.

Of particular interest to clinical nephrologists and renal pathologists is the fact that the kidney has several different resident cell types. Within the glomerulus, the growth responses of the mesangial cell, podocyte, parietal epithelial cell, and endothelial cell differ. The tubulointerstitial cells and vascular smooth muscle cells also vary in their growth responses following injury. Thus, characterizing the mechanisms that regulate each cell's growth response enables the potential development of specific therapies that will modify the response to injury. We recognize that renal cell hyperplasia and hypertrophy are regulated by numerous pathways, involving growth factors, signaling pathways, and transcription factors. However, the focus of this review is to update the reader on recent advances in the regulation of these growth processes at the level of the cell cycle. We will first describe cell cycle regulation by specific cell cycle proteins, and then discuss hyperplasia and hypertrophy for individual glomerular and tubular cell types.

Although highly metabolically active, under normal conditions the cells of the mature kidney are relatively quiescent with respect to cell cycle entry. Following injury to either the glomerulus or the tubules, cell cycle progression with proliferation is often an essential part of the reparative process. However, if unchecked, proliferation can lead to compromise of renal function. Similarly, renal hypertrophy may occur as a compensatory physiological response, but unregulated hypertrophy is maladaptive, and is one of the hallmarks of diabetic nephropathy.

Cell proliferation is ultimately regulated at the level of the cell cycle, which occurs within the nucleus. Within the kidney, the control of the cell cycle is particularly intriguing, given the contrasting responses of the various resident cell types to injury. For example, the mesangial cell is capable of marked proliferation, often accompanied by the deposition of extracellular matrix. In contrast, the podocyte has been considered a relatively inert cell, although this view has recently been challenged, and the reparative proliferation of glomerular endothelial cells following injury has also been described. Renal tubular cells readily undergo both proliferative and hypertrophic responses following injury. The last decade has seen a rapid expansion in our understanding of the molecular mechanisms underlying the cell cycle, and therapeutic options for its manipulation are becoming available. There is currently increasing awareness of the need to reduce the progression of renal diseases. Knowledge of the cell cycle and an understanding of how this can be

DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00028-8

influenced may be crucial to the prevention, control, and amelioration of a wide range of renal diseases.

MEASUREMENT OF CELL GROWTH

Hyperplasia

During a hyperplastic response, the number of proliferating cells is increased. A number of methods are available for measuring this increase, both *in vivo* and in cell culture. The majority of these have as their basis the detection of increased DNA synthesis. This may be done by determining the presence of proteins known to be associated with DNA synthesis, such as proliferating cell nuclear antigen (PCNA) or Ki-67, or by exogenously labeling cells with a compound known to be incorporated into newly synthesized DNA, such as ^{3}H thymidine or bromodeoxyuridine (BrdU). In cell culture, a convenient and high-throughput method for determining cell number is the MTT assay, in which the yellow tetrazolium salt is reduced in metabolically active cells to form insoluble formazan crystals, which are solubilized by the addition of detergent. The color intensity may then be quantified spectrophotometrically, allowing quantification of changes in proliferation. A caveat for this method is that a decrease in cell viability will mimic a decrease in proliferation, and concomitant apoptosis should be excluded. Analysis by fluorescent activated cell sorting (FACS) is a valuable tool for the assessment of hyperplasia, because it also allows quantification of the number of cells in each phase of the cell cycle.

Hypertrophy

Cellular hypertrophy may be defined as an increase in cell size due to an increase in protein and RNA content without DNA replication,[1,2] and this forms the basis for the majority of methods for detection of hypertrophy. Upon entry into G1, cells undergo a physiologic increase in protein synthesis prior to the DNA synthesis of S-phase. Thus, one mechanism underlying hypertrophy is cell cycle arrest at the G1/S checkpoint, so that while protein synthesis and hence content, increase, there is no subsequent increase in DNA. Hypertrophy may also occur independently of the cell cycle, due to an inhibition of protein synthesis, and this mechanism is considered to contribute to tubular cell hypertrophy.[3,4] Measurement of leucine or proline incorporation and comparison to ^{3}H thymidine incorporation allow determination of cell protein/DNA content, and hence assessment of hypertrophy. FACS analysis is also useful and enables direct measurement of cell size. Defining the growth response to a given stimulus as either hyperplastic or hypertrophic is important, as each will result from different alterations in cell signaling pathways, with implications for possible interventions.

CELL CYCLE AND CELL CYCLE REGULATORY PROTEINS

Cell Cycle

The cell cycle is divided into distinct phases, each representing a different function, and each being regulated by specific proteins[5] (Figure 28.1). Quiescent cells are termed as in G0, and upon mitogenic stimuli enter the cell cycle at early G1. Cells pass through the restriction point in late G1, beyond which they are typically unresponsive to extracellular cues, and are committed to complete the cell cycle despite the withdrawal of mitogenic stimuli. DNA synthesis occurs in S-phase. Cells then progress through G2, in preparation for mitosis (M-phase). Ultimately, cell division follows during cytokinesis. Our current understanding suggests there are at least two checkpoints to ensure fidelity of DNA duplication, at G1/S and G2/M, where cell cycle progression may be arrested. The length of the cell cycle is cell-type-specific, but this variability is largely due to differences in the duration of G1. For mammalian cells, the typical duration of G1 is approximately 12 hours, S- and G2-phases 6 hours, and mitosis 30 minutes.

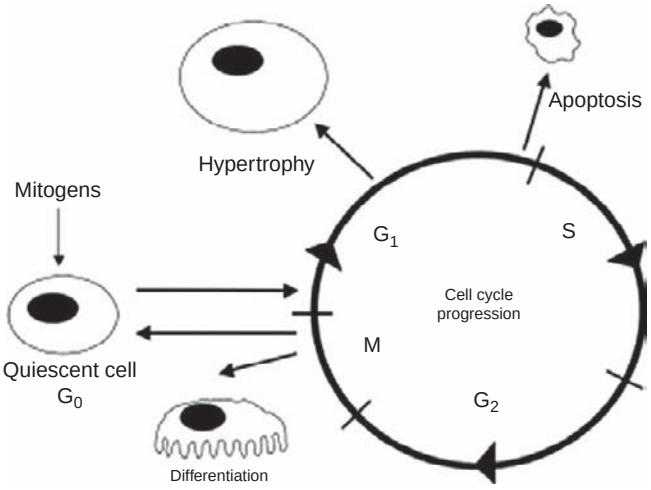

FIGURE 28.1 **The cell cycle and possible consequences of cell cycle exit.** Mitogens stimulate quiescent cells to engage the cell cycle at G1-phase. Hyperplasia then requires a coordinated and sequential series of events, including DNA synthesis at S-phase, followed by a resting G2-phase and mitosis in M-phase. This is followed by cell division. Cells that then exit the cell cycle and are quiescent again are in many cases differentiated. Of note is that if cells arrest at the G1/S-phase, they can develop a hypertrophic phenotype. Cell cycle exit with apoptosis may also occur.

Cyclins and Cyclin-Dependent Kinases: Positive Regulators of the Cell Cycle

Overview

The progress of a somatic cell through the cell cycle is dependent on the sequential and coordinated activation of the cyclin-dependent kinases (Cdks) by their specific partners, called cyclins (Figure 28.2). Cdks belong to the family of proline-directed serine/threonine kinases with a specific (K/R) (S*/T*) PX (K/H/R)-phosphorylation motif. Once active, Cdks phosphorylate downstream targets, ultimately to induce DNA synthesis.[6] While the levels of the Cdk catalytic subunits remain constant throughout the cell cycle, they are only functional following the binding of their specific cyclin partners. In contrast, cyclins are unstable proteins that are sequentially expressed and subsequently degraded by ubiquitination throughout the cell cycle,[7] which activate their partner Cdks by inducing conformational changes. Originally described for their fluctuation during the cell cycle,[8] members of the cyclin family are now defined by the presence of a conserved 100 amino acid cyclin box, which binds their complementary Cdk. In addition, the binding of inhibitors and accessory proteins, subcellular localization, and both inhibitory and activating phosphorylations influence the functional activity of the Cdk–cyclin complex.[9]

Jumpstarting the Cycle

The cell cycle is initiated by the mitogen-driven induction of cyclin D.[10–12] Depending on the cell type, three forms of cyclin D have been described (D1, D2, and D3), which interact allosterically with Cdk4 and Cdk6. Receptor-activated Ras signaling pathways lead to accumulation of cyclin D by three mechanisms: gene transcription; assembly; and stabilization of the cyclin D–Cdk complex.[13] The Ras-Raf-1-mitogen-activated, protein kinase kinase (MEK), extracellular signal-related protein kinase (ERK) pathway both induces cyclin D transcription and promotes assembly of cyclin D–Cdk.[14,15] The rate of degradation of cyclin D is controlled by a separate Ras signaling pathway involving phosphatidylinositol 3-kinase (PI3K) and protein kinase B (PKB/Akt), which inhibits the phosphorylation of cyclin D on threonine-286 (Thr-286) by glycogen synthase kinase 3β (GSKβ).[16] Thr-286 phosphorylated cyclin D would otherwise be exported to the cytoplasm for ubiquitination and degradation.[17] This requirement for mitogen signaling prevents the cell from autonomous cycling. Although ectopic expression of cyclin D is insufficient to drive cell cycle progression, constitutive activation of the cyclin D pathway can reduce the reliance of the cell on mitogenic stimulation, and lower the threshold for oncogenic transformation.[18] The cyclin D–Cdk4/6 complex enters the cell nucleus and is phosphorylated by Cdk-activating kinase (CAK).[19]

Once DNA replication begins, active cyclin D-dependent kinase activity is not required until mitosis is complete, and the cell re-enters the next G1 phase.[20] In continuously dividing cells, cyclin D1 is exported to the cytoplasm during S-phase, and its turnover is accelerated.[16,21] However, cyclin D1 synthesis stimulated by Ras is stabilized in G2 as described above, allowing reaccumulation before cells divide.[22] Hence, in the presence of continuous mitogen stimulation, the second and subsequent cell cycles are shorter than the first. Withdrawal of mitogens results in a rapid decline in cyclin D kinase activity, and cell cycle exit.

Active cyclin D-dependent kinases phosphorylate the retinoblastoma protein (pRb), which in quiescent cells has a growth-inhibitory effect.[23,24] In its hypophosphorylated state, pRb suppresses the transcription of several genes whose proteins are required for DNA synthesis, including the E2F transcription factors. Upon phosphorylation of pRb, the E2Fs are released from inhibition, leading to the transcription of cyclins E and A, and many genes whose products are required for DNA replication.[25] Furthermore, cyclin D–Cdk4 complexes also phosphorylate Smad3, negatively regulating the functions of transcriptional proteins responsible for mediating the growth inhibitory effects of transforming growth factor β (TGFβ).[26] Cyclin D-dependent kinases therefore affect the activity of at least two pathways that

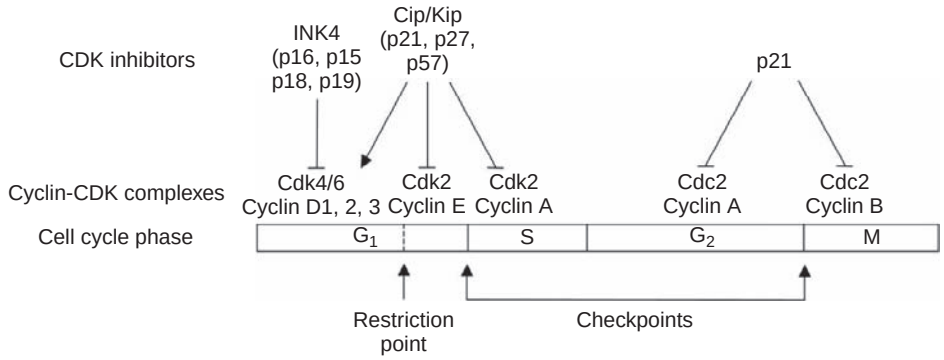

FIGURE 28.2 **Cell cycle progression: timing of activation of cyclins and Cdks, and site of action of Cdk inhibitors.** Each Cdk is activated by a partner cyclin in each phase of the cell cycle, and the resulting cyclin–Cdk complex can be inhibited by specific Cdk inhibitors.

independently inhibit the expression of cell cycle promoting genes.

The activity of cyclin E–Cdk2 is maximal at the G1- to S-phase transition,[27,28] when its function to further phosphorylate pRb releases the cell from mitogen dependency.[29,30] In addition to preferentially phosphorylating pRb on different sites to the cyclin D-dependent kinases, which may modify the interaction with E2Fs,[31] cyclin E–Cdk2 phosphorylates a second set of substrates involved in cell replication, thus affecting histone gene expression, and centrosome duplication.[32] The timing of expression and wider range of substrates suggest a role for cyclin E–Cdk2 in coordinating G1 regulation and the core cell cycle machinery.

The abrupt decline in cyclin E–Cdk2 activity in early S-phase results from cyclin E degradation. Phosphorylation by GSK-3β and Cdk2 itself target cyclin E for ubiquitination by the SCF^{Fbw7} E3 ligase, leading to proteasomal destruction.[33–35]

Low levels of cyclin A–Cdk2 activity are first detected in late G1-phase, increase as cells begin to replicate their DNA, and decline as cyclin A is degraded in early mitosis. The substrate specificity of cyclin A–Cdk2 is different from that of cyclin E–Cdk2. In S-phase, cyclin A–Cdk2 is thought to phosphorylate substrates that control the start of DNA replication from preassembled replication initiation complexes,[36–38] and control the integration of the end of S-phase with the activation of the mitotic Cdks.[39] The apparently central role of Cdk2 in coordinating cell cycle progression through S-phase and entry into mitosis has been challenged by the surprising observation that Cdk2 null mice are viable.[40,41] The possibility that other Cdks compensate for the loss of Cdk2 is currently a focus of intense research.

The entry to mitosis is controlled by cyclin B–Cdc2.[42,43] Cell cycle-regulated transcription of cyclin B begins at the end of S-phase. Phosphorylation on Thr161 by CAK parallels cyclin B binding to Cdc2.[44] During G2, cyclin B–Cdc2 complexes are maintained in an inactive state by phosphorylation on two inhibitory sites, Thr14 and tyrosine 15 (Tyr15) (Figure 28.3). Phosphorylation on Tyr15 is mediated by the nuclear Wee1 kinases,[166] and that on Thr14 by the membrane-bound Myt1.[45] In late G2 phase, both Thr14 and Tyr15 are dephosphorylated by Cdc25, thus activating cyclin B–Cdc2, and initiating mitosis.[46] Inappropriate triggering of mitosis is also prevented by the translocation of cyclin B to the cytoplasm by the nuclear export factor CRM1 (exportin 1) during S- and G2-phases.[47] Phosphorylation of cyclin B is thought to promote nuclear import at the G2/M transition.[48] Cyclin B–Cdc2 phosphorylates numerous downstream targets responsible for the structural reorganization of the cell to enable mitosis.

Although what is described above represents the basic paradigm of the control of cell cycle progression in mammalian cells, recent studies of knockout mice have demonstrated that much fetal development can occur normally despite the absence of cyclins and Cdks formerly considered to be vital.[49] Clearly, individual cyclins and Cdks are able to act more promiscuously than previously appreciated to enable compensation for the lack of a specific cell cycle protein.

Stopping the Cell Cycle: Cdk Inhibitors Act as Negative Regulators

In essence, Cdk inhibitors bind and inhibit target cyclin–Cdk complexes. Two classes of Cdk inhibitors have been described, the *INK4 proteins* and the *Cip/Kip family*.[50,51] Within each family, individual proteins are named according to their molecular weight. INK4 proteins were originally named for their ability to *in*hibit Cd*k4*. This family comprises four proteins, namely $p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$. Structurally these proteins are made up of multiple ankyrin repeats, and bind only to the catalytic subunits Cdk4 and Cdk6, thus inhibiting G1 progression. An alternate reading frame of the genetic locus encoding $p16^{INK4a}$ also encodes a second structurally and functionally unrelated protein named $p19^{ARF}$ in the mouse ($p14^{ARF}$ in the human).[52] Whereas $p16^{INK4a}$ acts to stabilize Rb by inhibition of Cdk4/6, $p19^{ARF}$ stabilizes p53 by binding its negative regulator, Mdm2.[53] Data from knockout mice suggest that $p19^{ARF}$, rather than $p16^{INK4a}$, is responsible for the tumor suppressor function of this locus.[54]

The second class of Cdk inhibitors is the Cip/Kip family, which includes $p21^{Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$,

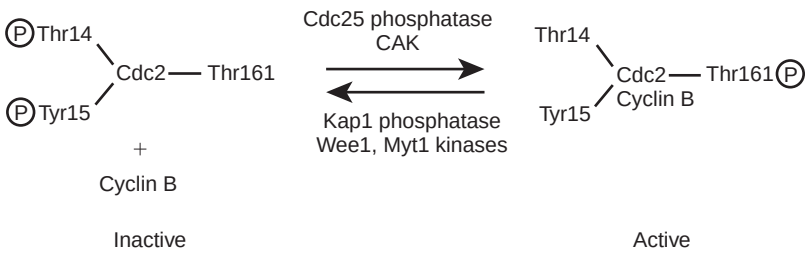

FIGURE 28.3 **Regulation of the phosphorylation status of Cdc2.** Wee1 and Myt1 kinases phosphorylate Cdc2 on Thr14 and Tyr15, inhibiting activity. Phosphorylation by CAK on Thr161 results in a 200-fold increase in kinase activity. Cdk2 is similarly phosphorylated on Thr160.

which share a conserved N-terminal Cdk-binding domain.[50] They are capable of binding a wider range of targets, and can variably affect the activities of cyclin D-, E-, A-, and B-dependent kinases.[43,51,55,56] Although potent inhibitors of cyclin E- and A-dependent CDK2, and to a lesser extent Cdc2, the Cip/Kip proteins have recently also been characterized, paradoxically, as positive regulators of the cyclin D-dependent kinases.[57]

The first member of the family to be identified was $p21^{Cip1}$,[58–60] and it is usually present at a low level in quiescent cells. As the cell enters the replicative cycle, $p21^{Cip1}$ levels rise, displace INK4 proteins from binding to Cdk 4/6, and promote the assembly of cyclin D-Cdk complexes.[61,62] This stabilizes the active complex and additionally provides a nuclear localization signal (NLS). The transcription of $p21^{Cip1}$ is increased by both p53-dependent[27] and -independent[63] pathways, such as those mediated by TGFβ.[64] The inhibitory role of $p21^{Cip1}$ becomes dominant later in the cell cycle, and levels are also increased in senescent cells.[65]

In contrast to $p21^{Cip1}$, the level of $p27^{Kip1}$ is usually high in quiescent cells, where its primary role is as an inhibitor of cell division.[66,67] Whereas $p21^{Cip1}$ is a principal mediator of the p53-dependent G1 arrest that occurs following DNA damage,[37] $p27^{Kip1}$ appears to be primarily responsible for mediating extracellular antiproliferative signals.[66,67] The levels and activity of $p27^{Kip1}$ are post-transcriptionally regulated by changes in the rates of translation, ubiquitination, and phosphorylation.[68,69] As cyclin D levels rise in response to mitogens, both $p21^{Cip1}$ and $p27^{Kip1}$ are sequestered by cyclin D–Cdk complexes, and therefore are unable to inhibit Cdk2.[51] Cyclin E–Cdk2 phosphorylates $p27^{Kip1}$ on Thr 187,[70,71] proving a recognition motif for an E3 ligase that targets $p27^{Kip1}$ for ubiquitination and proteasomal degradation.[72,73]

The most recently identified member of the family, $p57^{Kip2}$, was cloned in 1995.[74,75] While tissue expression of $p21^{Cip1}$ and $p27^{Kip1}$ is widespread, that of $p57^{Kip2}$ is restricted to placenta, muscle, heart, brain, lung, and kidney. In addition to the Cdk inhibitory domain and putative C terminal NLS, $p57^{Kip2}$ also has a proline-rich domain containing a consensus ERK phosphorylation site, and an acidic domain, the functions of which are not known.[74,75] A role for $p57^{Kip2}$ in the cell cycle exit that accompanies terminal differentiation has been suggested.

Despite their structural similarities, knockout studies have demonstrated divergent roles for the three Cip/Kip Cdk inhibitors. While $p21^{Cip1}$ and $p27^{Kip1}$ are not essential for normal embryogenesis,[50,76,77] lack of $p57^{Kip2}$ results in profound developmental abnormalities.[78–80] Most $p57^{Kip2}$ null mice die shortly after birth and have severe cleft palates, abdominal wall and gastrointestinal tract defects, and abnormal skeletal ossification. Unlike adult $p21^{Cip1-/-}$ mice,[81,82] $p27^{Kip1-/-}$ mice are larger than wild-type animals, and have hyperplasia of organs that usually express high levels of $p27^{Kip1}$, such as the thymus, spleen, adrenal and pituitary glands, testes, and ovaries.[50,76] In contrast, only 10% of $p57^{Kip2-/-}$ mice survive the weaning period and are much smaller than wild-type.[78] The kidneys of $p57^{Kip2-/-}$ mice have medullary dysplasia, although glomerular development appears normal.

HYPERPLASIA: AN INCREASE IN CELL NUMBER DUE TO PROLIFERATION

Glomerular Hyperplasia

Mesangial Cell Proliferation

Mesangial cell proliferation characterizes many forms of both experimental and human glomerular disease, including IgA nephropathy, lupus nephritis, diabetic nephropathy, and other forms of membranoproliferative glomerulonephritis (Figure 28.4). It is frequently associated with, and likely underlies, matrix expansion and subsequent glomerulosclerosis, the significance of which has been shown in a range of experimental models.[83–89] This simple observation provides the impetus for understanding what switches mesangial proliferation on and what switches it off. Several growth factors and cytokines are mitogens for mesangial cells, including platelet-derived growth factor (PDGF),[90,91] basic fibroblast growth factor (bFGF),[92] interleukin 6,[93,94] and the product of growth arrest-specific gene 6 (Gas6).[95] Intervention to reduce mesangial proliferation also reduces matrix

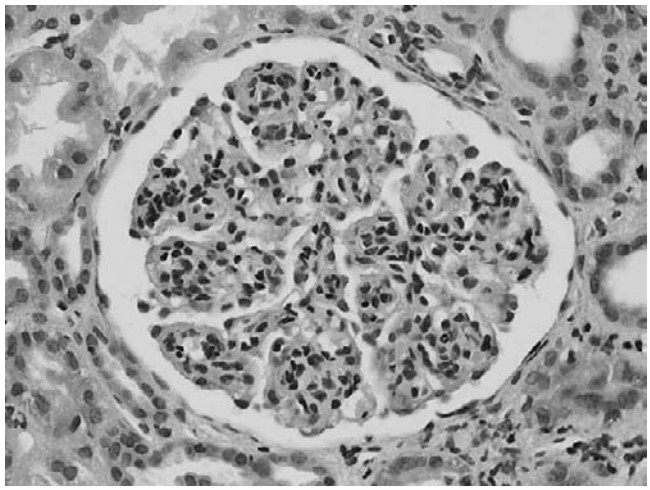

FIGURE 28.4 **Global mesangial cell proliferation occurring in the context of membranoproliferative glomerulonephritis (haematoxylin and eosin ×400).** *(Histology courtesy of Dr Meryl Griffiths, Addenbrooke's Hospital, Cambridge.)*

expansion, confirming the tight link between these two processes. This has been achieved in experimental models using complement depletion,[96,97] heparin infusion,[91] blocking the action PDGF[92,98] and bFGF,[83] and inhibiting their specific intracellular signaling pathways with phosphodiesterase inhibitors.[86] Warfarin has been used with mixed results in the treatment of glomerular diseases since the 1970s, and was originally hypothesized to reduce fibrin deposition. However, low-dose warfarin may also be effective, suggesting a mechanism of action not directly related to anticoagulation. Gas6 is a vitamin K-dependent growth factor for mesangial cells, and its inhibition by warfarin is likely to underlie the reported benefits of this treatment in human disease.[95] Careful research since the mid-1990s has delineated the role of individual cell cycle proteins in mesangial cell proliferation, and also its resolution by apoptosis (Figure 28.5).

ROLE OF CDK2 IN MESANGIAL CELL PROLIFERATION

Cdk2 protein and kinase activity increase in cultured mesangial cells in response to mitogenic growth factors.[99,100] The Thy1 model of experimental mesangial proliferative glomerulonephritis, induced in rats by an antibody directed against the mesangial Thy1 antigen, has provided an opportunity to study the regulation and consequences of mesangial cell proliferation *in vivo*.[101,102] The initial complement-dependent mesangiolysis is followed by a phase of marked mesangial proliferation, paralleled by an increase in extracellular matrix accumulation and a decline in renal function. This model is useful as not only may the fluctuations of cell cycle proteins during proliferation be defined, but also the effect of their manipulation. Mesangial cell proliferation is associated with an increase in cyclin D1 and A, and their partners Cdk4 and Cdk2.[103] Cdk2 expression is absent in the normal rat glomerulus. Proliferation is associated with increased Cdk2 activity, measured by the histone H1 kinase assay on protein extracted from isolated glomeruli. Bokemeyer et al. identified activation of the map kinase ERK as an upstream regulator of Cdk2 activity in the Thy1 model.[104] Inhibition of ERK was associated with decreased cell proliferation by 67%.[105] Cdk2 protein levels are also increased in the remnant kidney model, a nonimmune glomerular disease associated with mesangial proliferation.[106] Taken together, these studies show that in contrast to most nonrenal cells,[103] Cdk2 protein is at low levels in quiescent mesangial cells, and its levels and activity increase following injury.

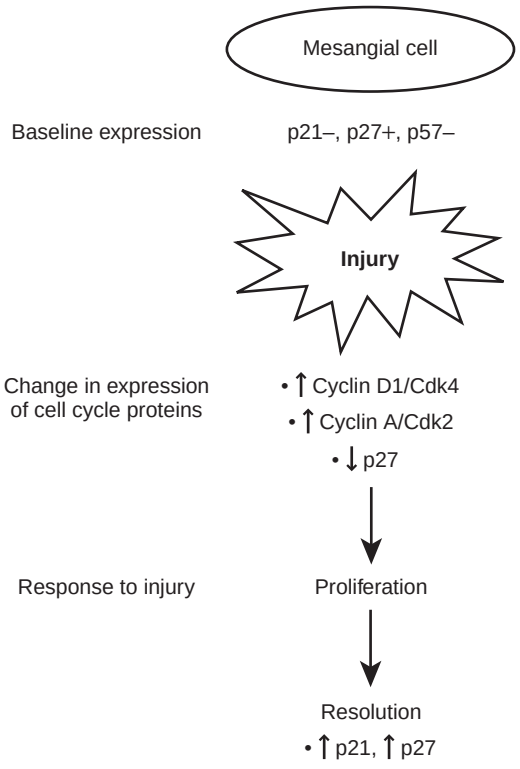

FIGURE 28.5 **Changes in cell cycle protein activity following injury to glomerular mesangial cells.** At baseline, quiescent mesangial cells express $p27^{Kip1}$, but not $p21^{Cip1}$ or $p57^{Kip2}$. Following injury, there is an increase in the positive cell cycle regulators cyclin D1/Cdk4 and cyclin A/Cdk2, with a decline in $p27^{Kip1}$, resulting in promotion of cell cycle progression and proliferation. During the resolution phase, there is an increase in the Cdk-inhibitors $p21^{Cip1}$ and $p27^{Kip1}$, with cessation of proliferation.

Cdk Inhibitors and Mesangial Cell Proliferation

The Cdk inhibitor $p27^{Kip1}$ is constitutively expressed in quiescent mesangial cells both *in vitro*[107] and *in vivo*,[103] whereas $p21^{Cip1}$ and $p57^{Kip2}$ are essentially absent.[103,108] In cultured mesangial cells, proliferation induced by mitogenic growth factors reduces $p27^{Kip1}$ levels.[107] Mesangial cells derived from $p27^{Kip1-/-}$ mice have augmented proliferation in response to mitogens,[109] and lowering $p27^{Kip1}$ levels with antisense oligonucleotides has a similar effect in rat mesangial cells.[107]

Complement-induced injury in the Thy1 model is associated with a marked decrease in $p27^{Kip1}$ levels.[103] However, there is *de novo* synthesis of $p21^{Cip1}$ in the resolution phase of the disease, coincident with a decrease in proliferation. To further explore the role of $p27^{Kip1}$ in inflammatory disease, we induced experimental glomerulonephritis in $p27^{Kip1-/-}$ mice.[110] Our results showed a marked increase in the onset and magnitude of glomerular cell proliferation and cellularity in nephritic $p27^{Kip1-/-}$ mice compared to control nephritic $p27^{Kip1+/+}$ mice. Moreover, this was associated with increased extracellular matrix proteins and a decline in renal function. To demonstrate that this

result was not specific to glomerular cells or immune-mediated injury, we also obstructed a ureter by ligation to induce nonimmune injury to tubuloepithelial cells.[110] Our results showed that tubuloepithelial proliferation was increased in obstructed $p27^{Kip1-/-}$ mice compared to obstructed $p27^{Kip1+/+}$ mice. Taken together, these studies were the first to show that in inflammatory diseases, renal cell proliferation is regulated by the CKI $p27^{Kip1}$, supporting a role for $p27^{Kip1}$ in controlling the threshold at which proliferation occurs.

Little is known about the role of the Cdk inhibtiors $p21^{Cip1}$ and $p57^{Kip2}$. In an immune-mediated model of MC disease, the absence $p21^{Cip1}$ was associated with increased focal segmental tuft necrosis, mesangiolysis, and mesangial hypercellularity.[111]

Role of Cell Cycle Proteins in Resolution of Mesangial Hyperplasia: Apoptosis

Although a characteristic response to mesangial cell injury is proliferation, apoptosis is often simultaneously increased.[85] Studies have shown that apoptosis is a vital mechanism required to normalize cell number in the reparative phase of injury.[112] However, the cellular pathways linking these opposing responses remain unclear. Many cells undergoing apoptosis have entered the cell cycle, but rather than completing their replication, they are destined to leave by programmed cell death. This suggests a role for the cell cycle proteins in directing these alternative outcomes.

Evidence to support this hypothesis was the observation that the resolution phase of Thy1 mesangial proliferation in the rat is characterized by mesangial cell apoptosis, a process that peaks when the levels of $p27^{Kip1}$ are at their lowest.[103] Considering glomerulonephritis or unilateral ureteric obstruction in $p27^{Kip1-/-}$ mice as described above, in addition to the increase in either glomerular or tubuloepithelial cell proliferation following injury, there was a marked increase in apoptosis in the $p27^{Kip1-/-}$ mice compared to wild-type disease controls.[110] Moreover, apoptosis was also increased in $p27^{Kip1-/-}$ mesangial cells in culture following growth factor deprivation or cycloheximide, and reconstituting $p27^{Kip1}$ levels by transfection-rescued cells from apoptosis.[109] In wild-type rat mesangial cells, apoptosis was increased following treatment with anti-$p27^{Kip1}$ antisense oligonucleotides.[109] These results showed for the first time that $p27^{Kip1}$ has a role beyond the regulation of proliferation, in that it also protects cells from apoptosis. This dual role of regulating the proliferative threshold and governing apoptosis makes $p27^{Kip1}$ a potent regulator of overall mesangial cell numbers. In contrast, $p21^{Cip1}$ showed no effect on MC apoptosis.[111]

HOW DOES $P27^{KIP1}$ PROTECT CELLS FROM APOPTOSIS?

A clue to a possible mechanism was the increase in Cdk2 activity in $p27^{Kip1-/-}$ mesangial cells when deprived of growth factors.[109] The increase was due specifically to cyclin A–Cdk2, and not cyclin E–Cdk2. Moreover, inhibition of cyclin A–Cdk2 activity by roscovitine or a dominant negative mutant reduced apoptosis in mesangial cells and fibroblasts. In apoptotic $p27^{Kip1-/-}$ mesangial cells, Cdk2 was bound to cyclin A, without a preceding increase in cyclin E–Cdk2 activity. We suggest that, in the absence of $p27^{Kip1}$, uncoupling of Cdk2 activity from the scheduled sequence of cell cycle protein expression may lead to an inappropriate and premature initiation of G_1/S-phase transition, causing the cell to respond by undergoing apoptosis, rather than inappropriately progressing through an unscheduled cell cycle.

HOW MIGHT Cdk2 CONTROL GROWTH AND APOPTOTIC FATE OF CELLS?

Apoptosis typically begins in the cytoplasm, whereas DNA synthesis and mitosis are nuclear events. Accordingly, we tested the hypothesis that the subcellular localization of Cdk2 determines if cells undergo apoptosis or proliferation.[113] As expected, Cdk2 protein was cytoplasmic in quiescent, and nuclear in proliferating, mesangial cells. However, in proliferating cells injured by an apoptotic stimulus, Cdk2 localized to the cytoplasm, was no longer nuclear, and importantly, remained active. Our results also showed that cyclin A, and not cyclin E, co-localized to the cytoplasm with Cdk2 in apoptotic cells, to form an active cytoplasmic cyclin A–Cdk2 complex. The translocation of Cdk2 is not p53-dependent, and inhibiting the nuclear localization signal has no effect. That inhibiting Cdk2 decreased apoptosis provides further support for a critical role for cytoplasmic Cdk2 in triggering programmed cell death. Thus, the subcellular localization of active Cdk2 determines the fate of a cell: when nuclear, cells proliferate; when cytoplasmic, cells die by apoptosis. The mechanism by which nuclear Cdk2 is translocated to the cytoplasm remains to be elucidated. These studies provide the novel paradigm that specific cell cycle regulatory proteins have a role in glomerular disease beyond the regulation of proliferation.

Therapeutic Inhibition of Mesangial Proliferation at Cell Cycle Level

In vitro and animal studies have recently revealed the potential of several novel therapies to modulate glomerular cell proliferation: the purine analog roscovitine, which inhibits Cdk2 activity; retinoids, derived from vitamin A; and lipoxins, endogenously produced

eicosanoids. Roscovitine and retinoids have also been used to beneficial effect in the treatment of podocyte diseases, discussed in the next sections.

ROSCOVITINE

The significance of increased Cdk2 activity in mesangial proliferation was demonstrated by Pippin et al.,[114] using roscovitine to inhibit Cdk2 in rats with Thy1 mesangioproliferative gomerulonephritis. Given immediately after disease induction, roscovitine significantly reduced mesangial cell proliferation. Moreover, administering roscovitine to rats once mesangial proliferation was already established also reduced proliferation. This inhibition of Cdk2 activity was accompanied by a marked reduction in the accumulation of glomerular extracellular matrix proteins (collagen IV, laminin, and fibronectin), and an improvement in renal function compared to controls. These results suggest that inhibiting Cdk2 may be a potential therapeutic target in glomerular diseases characterized by proliferation.

RETINOIDS

Retinoic acid (RA) has an established role in kidney development.[115,116] RA binds to specific nuclear receptors, and the RA receptor complex then binds to DNA–RA response elements to cause the transcription of target genes.[117] RA is used therapeutically in acute promyelocytic leukemia to slow proliferation and promote differentiation. RA-induced cell cycle arrest in nonrenal cells has been reported to involve reduction in c-Myc, cyclin D1, and cyclin E levels, with upregulation of $p21^{Cip1}$ and $p27^{Kip1}$.[118–120] The treatment of rats with experimental Thy1 glomerulonephritis with RA reduced mesangial cell proliferation, glomerular lesions, and albuminuria.[121] In addition to a direct antiproliferative action, RA has also been reported to modulate both the renin–angiotensin system[122] and TGFβ signaling,[123] in addition to anti-inflammatory and immune modulatory effects.[116] The efficacy of RA in the treatment of glomerulonephritis is likely due to its pleiotropic effects on these numerous pathways.

LIPOXINS

Lipoxins are endogenously produced eicosanoids with potent anti-inflammatory actions,[124] and are generated during the resolution phase of an acute inflammatory insult.[125] Lipoxin A_4 biosynthesis has been demonstrated in glomerulonephritis,[126] and its effects include modulation of leukocyte trafficking and phagocytic clearance of apoptotic cells.[124,125] *In vitro*, lipoxin A4 inhibits PDGF-induced activation of Akt/PKB in human mesangial cells, and modulates PDGF-induced decrements of $p21^{Cip1}$ and $p27^{Kip1}$.[127] PDGF-induced increases in Cdk2–cyclin E complex formation are also inhibited by lipoxin A_4. Prolonged exposure of mesangial cells to PDGF is associated with autocrine TGFβ production, and this is ameliorated by lipoxin A_4.

In vivo, lipoxins are rapidly metabolized. To enable study of these compounds in disease models, stable synthetic analogs have been developed that are modified at C-15, C-16, and/or C20.[128] These compounds retain the biological activity and receptor-binding affinity of the native lipoxin. The effect of a lipoxin A_4 analog, 15-epi-16-(FPho)-LXA-Me, has been studied in the immediate phase of experimental anti-GBM nephritis in mice, and found to inhibit neutrophil infiltration and glomerular nitrotyrosine staining.[129] Although animal studies with lipoxins are at an earlier stage than those with roscovitine or retinoids, their potential to augment the resolution phase of glomerulonephritis suggests that they may in the future have an important therapeutic role.

The Podocyte and Cell Cycle: Why Is Lack of Podocyte Proliferation Important?

The podocyte, or visceral glomerular epithelial cell, is a highly specialized, terminally differentiated cell overlying the outer aspect of the glomerular basement membrane. In contrast to the mesangial cell, numerous studies of both animal models and human disease have shown that aside from a few specific conditions, podocytes do not typically proliferate *in vivo* (Figure 28.6). Indeed, following injury, podocyte numbers may become depleted, because following cell loss by detachment or apoptosis, the lack of proliferation prevents normalization of podocyte number. Although initially the remaining podocytes may undergo a degree of compensatory hypertrophy, the decrease in podocyte number will eventually result in areas of "denuded" basement membrane, which is thought to predispose to the formation of synechiae between the GBM and Bowman's capsule, leading to the development of secondary focal glomerulosclerosis and subsequent decline in renal function.[130–134] Podocytes provide a size- and charge-dependent barrier to protein leakage into the urine, and are therefore a critical component of the glomerular filtration apparatus. Several studies in diverse renal diseases have shown a close correlation between the onset and progression of proteinuria and reduced podocyte number.[135–141] These events provide a compelling rationale to define the mechanisms underlying the lack of podocyte proliferation.

MATURE PODOCYTE HAS EXITED CELL CYCLE AND IS POSTMITOTIC

During glomerulogenesis, immature podocytes are capable of proliferation.[108,142] However, during the critical S-shaped body stage of glomerular development,

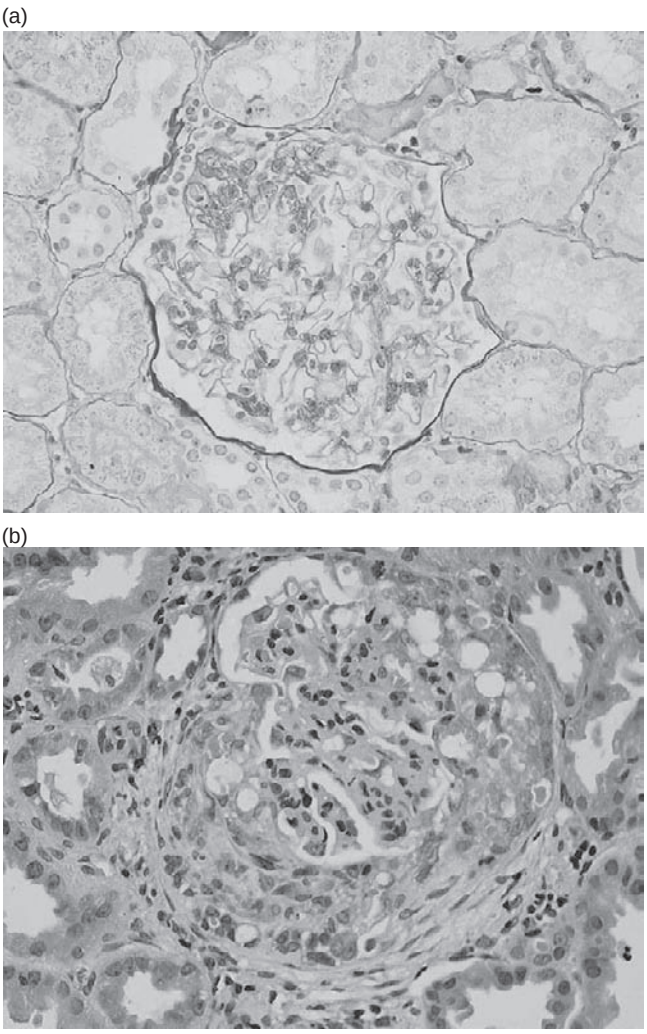

FIGURE 28.6 **The podocyte response to injury in human glomerulonephritis – to proliferate or not to proliferate?** (a) No proliferation, with development of segmental sclerosis, as occurs in idiopathic focal and segmental. (b) Proliferation, with the glomerulosclerosis (Periodic Acid Schiff, development of a cellular crescent in a patient with vasculitis (haematoxylin and eosin ×400). *(Histology courtesy of Dr Meryl Griffiths, Addenbrooke's Hospital, Cambridge.)*

podocytes exit the cell cycle in order to become terminally differentiated and quiescent, which are necessary requirements for normal function. Thus, in podocytes, proliferation and differentiation are closely linked, akin to neurons and cardiac myocytes. In both mouse and human glomerulogenesis, immunostaining for $p27^{Kip1}$ and $p57^{Kip2}$ is absent in proliferating podocytes during the S-shaped body stage.[108,142] On cessation of proliferation, there is strong expression of both Cdk inhibitors, so that $p27^{Kip1}$ and $p57^{Kip2}$ are constitutively expressed in mature podocytes. The Cdk inhibitors $p21^{Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$ alone are not required for normal glomerular development because, as described previously, the glomeruli from null mice are histologically normal. However, functional redundancy of $p27^{Kip1}$ and $p57^{Kip2}$, at least within the podocyte, has been suggested by studies of E13.5 embryonic metanephroi from double $p27^{Kip1}/p57^{Kip2-/-}$ mice. Glomeruli from these mice have been reported to be significantly larger than those from wild-type or single mutants, due to an increase in podocyte number. Differentiation of podocytes was judged to be normal by electron microscopy and immunostaining for WT-1, suggesting a synergistic role for $p27^{Kip1}$ and $p57^{Kip2}$ in determining the final complement of podocytes.

RESISTANCE OF PODOCYTES TO PROLIFERATION: ROLE OF CELL CYCLE REGULATORY PROTEINS

Studies have shown that the frequently observed lack of podocyte proliferation may be due to abnormalities in DNA synthesis or mitosis and cytokinesis (Figure 28.7).

The passive Heymann nephritis (PHN) model, induced by the administration of an antibody reactive against the Fx1A antigen on the rat podocyte, has many similarities to human membranous nephropathy.[143,144] In common with the Thy1 model of mesangial proliferative glomerulonephritis, PHN is complement (C5b-9)-dependent. However, in contrast to the observed mesangial cell proliferation in response

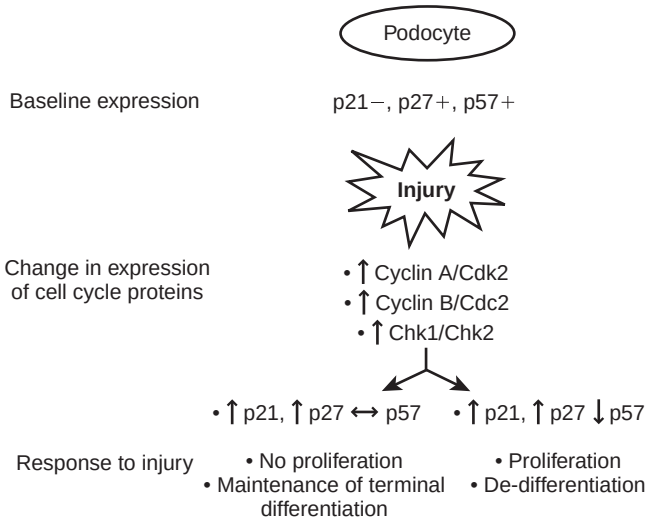

FIGURE 28.7 **Changes in cell cycle protein activity following injury to glomerular podocytes: the critical role of Cdk inhibitors in determining podocyte fate.** In contrast to mesangial cells, at baseline quiescent podocytes express both $p27^{Kip1}$ and $p57^{Kip2}$. Following injury, there is an increase in the positive cell cycle regulators cyclin A/Cdk2 and cyclin B/Cdc2; however, this is accompanied by an increase in checkpoint kinases 1 and 2. The subsequent podocyte response depends on changes in the Cdk inhibitors. If $p21^{Cip1}$ and $p27^{Kip1}$ increase, cell cycle entry remains inhibited, there is no proliferation, and terminal differentiation is maintained. However, if there is a decline in the levels of $p21^{Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$, then the cell cycle is engaged and proliferation and de-differentiation occur.

to complement-mediated injury, there is no increase in podocyte number. Mitotic figures and an increase in ploidy are seen in the acute phase of disease, but over time the number of podocytes decreases. The comparison of patterns of expression of cell cycle proteins between the PHN and Thy-1 disease models has provided an opportunity to elucidate the role of cell cycle proteins in experimental podocyte disease.

Following C5b-9-induced injury in PHN rats, protein levels for cyclin A and Cdk2 rise,[145] indicating engagement of the cell cycle. However, only a limited increase in DNA synthesis occurs, suggesting the presence of an inhibitor to cell cycle progression. Indeed, the levels of the Cdk inhibitors $p21^{Cip1}$ and $p27^{Kip1}$ increase specifically in podocytes following the induction of PHN.[145] The increase in $p21^{Cip1}$ is attenuated by administering the mitogen bFGF to PHN rats, and this augments the increase in podocyte DNA synthesis and ploidy. Furthermore, upregulation of M-phase cell cycle proteins Cdc2 and cyclin B is also observed in PHN podocytes, suggesting that a disturbance in cytokinesis is ultimately responsible for the development of polynucleated cells and lack of podocyte proliferation in this experimental glomerular disease.[146]

Cell culture studies have further explored the inability of podocytes to proliferate following C5b-9-induced injury, and support the hypothesis of a defect in completing mitosis. When cultured podocytes are exposed to sublytic C5b-9 attack, the cells engage the cell cycle. However, there is a delay or inhibition in entering mitosis, suggesting a block in the G_2/M transition, and involvement of mechanisms that regulate this checkpoint. This response is typical of that following DNA damage, to which podocytes appear to be particularly susceptible. The occurrence of DNA damage following exposure to sublytic C5b-9 has subsequently been confirmed,[147] together with increased checkpoint kinase-1 and -2 protein levels, thus arresting cells at G_2/M. The mechanism by which DNA damage occurs in podocytes is not currently well-understood, but is thought to involve the generation of reactive oxygen radicals.

A key role for $p21^{Cip1}$ in limiting the proliferative response of podocytes has been demonstrated in studies using $p21^{Cip1}$ knockout mice.[148,149] The administration of an antiglomerular antibody to induce experimental podocyte injury caused podocyte dedifferentiation and proliferation in $p21^{Cip1-/-}$ mice compared to control mice receiving the same antibody. Glomerular extracellular matrix accumulation was also increased in $p21^{Cip1-/-}$ mice, and was associated with a significant decrease in renal function. Additional *in vitro* data could link the pro-apoptotic effect of TGF-beta1 in podocytes to $p21^{Cip1}$.[150] Podocyte apoptosis induced by TGF-beta1 required sufficient $p21^{Cip1}$ levels.

Intravenous application of the podocyte toxin Adriamycin resembles the histological findings of focal segemental glomerulosclerosis (FSGS) in mice. Diseased $p21^{Cip1-/-}$ mice presented with increased podocyte apotosis and decreased podocyte number, leading to aggravated glomerular disease including worse albuminuria, glomerulosclerosis, and increased BUN compared to control animals.[151]

The resistance of podocytes to proliferation in the majority of animal models has been confirmed in human diseases, and similar underlying mechanisms have been observed. Normal quiescent podocytes express $p27^{Kip1}$ and $p57^{Kip2}$, and immunostaining for these proteins is maintained in conditions without proliferation, namely minimal change diseases and membranous glomerulopathy.[152] In contrast, expression of both these proteins is uniformly decreased in diseases characterized by podocyte proliferation, that is, cellular FSGS, collapsing glomerulopathy, and HIV-associated nephropathy. This is accompanied by the *de novo* expression of $p21^{Cip1}$. The mechanisms by which the podocyte eludes the usual constraints on proliferation are discussed below.

RESISTANCE OF PODOCYTES TO PROLIFERATION: ROLE OF MECHANICAL STRETCH

An additional factor reported to influence the proliferative capacity of the podocyte is the presence of mechanical stress.[153] Independent of the site of initial injury, a common pathway to progressive glomerulosclerosis is an increase in intraglomerular pressure, also known as glomerular hypertension.[130,132,154] Lowering intraglomerular pressure reduces progression in a number of glomerular diseases, including diabetic nephropathy.[155] Glomerular hypertension is associated with glomerular hypertrophy (see below), and the resultant mechanical stretch causes injury to all three glomerular cell types. Whereas applying mechanical stretch to cultured mesangial cells increases proliferation,[156] the opposite response is seen in cultured podocytes.[157,171] Stretching mouse podocytes in culture decreased the levels of cyclins D1, A, B1, and Cdc2, in association with an increase in the Cdk inhibitors. Stretch caused an early increase in $p21^{Cip1}$, followed by an increase in $p27^{Kip1}$ at 24 hours and $p57^{Kip2}$ at 72 hours. In contrast to the growth arrest seen in wild-type cells exposed to stretch, $p21^{Cip1-/-}$ podocytes exposed to stretch continued to proliferate, suggesting a role for $p21^{Cip1}$ in the inability of the podocyte to progress through the cell cycle in response to stretch. These studies show that in addition to being injurious to mesangial cells, mechanical stretch affects podocytes and reduces their proliferative potential by altering specific cell cycle proteins.

PODOCYTE PROLIFERATION

Although the majority of both experimental animal models of podocyte injury and human podocyte diseases are not associated with proliferation, this has been reported to occur in a limited number of settings. The true ability of the mature podocyte to proliferate remains controversial, principally because glomerular cells believed to be proliferating podocytes frequently lack defining cell-type-specific markers.[158] However, the use of transgenic animals has been invaluable in resolving the debate. A well-studied animal model of podocyte proliferation is crescentic glomerulonephritis in the mouse, which has been examined in detail by several groups. In this model, predictable proliferation of glomerular cells occurs, and early in the course of the disease this is not associated with rupture of Bowman's capsule, nor with the presence of infiltrating cells.[159] It is therefore a useful model for studying the contribution of intrinsic glomerular cells to crescent formation. Moeller et al. generated a mouse with constitutive expression of β galactosidase specifically in podocytes *in vivo*.[160] Experimental crescentic nephritis was induced by injecting rabbit IgG ip, followed six days later by an intravenous injection of rabbit anti-mouse GBM antibody. The crescents contained numerous β-galactosidase-expressing cells, confirming their podocyte origin. Furthermore, expression of the nuclear proliferation marker Ki-67 by these cells demonstrated the capability of these podocyte-derived cells to undergo proliferation. Matsusaka et al. generated a transgenic mouse with podocyte-specific expression of human CD25.[161] Injury was then induced using an immunotoxin, resulting in a proliferative glomerular lesion. However, immunohistochemistry indicated that the proliferating cells were of parietal epithelial origin, not podocytes. The disparity between these two results likely results from the different initiating injuries used, but illustrates the ongoing debate which was further fueled by recent data.[162] Smeets et al. could show, by lineage tracing of either podocytes or parietal epithelial cells (PECs), that the majority of cells within extracapillary proliferative leasions were PECs, and only a minority were of podocyte origin. This held true in the nephrotoxic nephritis model of inflammatory crescentic glomerulonephritis, and in the Thy-1.1 transgenic mouse model of collapsing glomerulopathy. As described above, once podocytes proliferate they lose several of their defining characteristic proteins, such as WT-1, making identification difficult. However, there is broad agreement that the proliferating resident glomerular cells making up crescents are of epithelial origin, although the relative contributions of parietal cells and podocytes remains disputed.

In human disease, podocyte proliferation is considered to occur in collapsing glomerulopathy, cellular focal segmental glomerulosclerosis, and HIV-associated nephropathy.[163,164] In these diseases, there is increased expression of cyclin A and the proliferation marker Ki-67, with a marked reduction in $p27^{Kip1}$ and $p57^{Kip2}$.[152,164] In contrast, all other diseases of podocytes in humans, including membranous nephropathy, minimal change disease, and focal segmental glomerulosclerosis, are not associated with a decrease in Cdk inhibitor levels, and typical markers of proliferation are absent. Interestingly, the rate of progression to end-stage renal failure is increased in glomerular diseases characterized by podocyte proliferation.[165,166] The pathogenesis of HIV-associated nephropathy has been further detailed using transgenic mice expressing HIV-1 genes.[167–169] The Tg26 mouse model develops murine HIVAN secondary o renal expression of HIV-1 mRNAs from the HIV-1 NL4-3 gag-pol proviral transgene.[169] This model has enabled characterization of the cellular effects of HIV-1 using both the intact animal and conditionally immortalized podocytes in culture. HIV-1 induces loss of contact inhibition in podocytes,[170] and expression of cyclin D1 and phosphorylation of pRb.[171] The cells become dedifferentiated, with loss of specific podocyte-expressed proteins.[167,172] Interestingly, there have been reports of reversibility of HIV nephropathy in both mice (discussed below) and human disease[173] following treatment with highly active antiretroviral therapy, suggesting that once the virus is cleared the podocyte is capable of exiting the cell cycle and redifferentiating to its mature phenotype.

ATYPICAL EFFECTS OF CELL CYCLE PROTEINS ON PODOCYTES

The traditional view of cell cycle proteins focuses on the regulation of cellular proliferation. The view on cell cycle proteins has since been broadened by the discovery of atypical cyclin proteins and dependent kinases. These include cyclin C-Cdk8, cyclin H-cdk7, cyclin K-Cdk9, cyclin T-Cdk9 or cyclin I-Cdk5.[174] We could show that cyclin I null mice are normal consistent with the notion that cyclin I is not required for cell differentation. Cyclin I is predominantly expressed in terminally differentiated cells, including neurons and podocytes. Lack of cyclin I rendered podocytes more susceptible to apoptosis.[175] A potential mechanism included a decreased expression and protein stability of p21.

The Cdk partner of cyclin I remained elusive since its discovery. We could identify Cdk5 as the Cdk partner of cyclin I.[176] Cdk5 itself is essential for normal development, as Cdk5 null mice die from developmental deficits, but little is known about its

function in the kidney. Cdk5 is mainly activated by the non-cyclin proteins p35 and p39. The latter is not expressed in podocytes, but p35−Cdk5 has been shown to be present in podocytes.[177] In 2004, Griffin et al. demonstrated an essential role for p35−Cdk5 in podocyte differentation, proliferation, and maintenance. Cdk5 levels decline in experimental disease associated with podocyte dedifferentation and proliferation, including anti-glomerular antibody disease and HIV-associated nephropathy. More recent *in vivo* and *in vitro* data support the model that Cdk5 is central to podocyte survival, and is dually regulated by cyclin I and p35. Downstream targets of Cdk5 were the pro-survival proteins Bcl-2 and Bcl-XL.[174,176,178]

Therapeutic Inhibition of Podocyte Proliferation at Cell Cycle Level

As with glomerular diseases principally affecting the mesangial cell, both roscovitine and retinoids have shown promise as therapeutic agents in modulating the podocyte response to injury. In addition, recent data suggest a direct effect of glucocorticoids on podocytes at the cell cycle level.

ROSCOVITINE

We hypothesized that inhibition of podocyte proliferation with the Cdk2 inhibitor roscovitine in a mouse model of crescentic glomerulonephritis would improve renal outcome,[179] similar to that observed following inhibition of mesangial cell proliferation in Thy 1 nephritis described previously.[114] Inhibition of Cdk2 activity was confirmed by a histone kinase assay, and podocyte DNA synthesis measured by incorporation of BrdU. Compared to control nephritic animals receiving the vehicle, in mice treated with roscovitine there was a significant decrease in BrdU at day 5 of nephritis. This was accompanied by less accumulation of laminin at day 14, and significantly improved renal function, suggesting a similar intervention may be beneficial in human diseases. Roscovitine has also been demonstrated to be beneficial in the treatment of Tg26 mice at doses that did not decrease HIV-1 transgene expression, suggesting an effect mediated by inhibition of cell cycle progression.[180]

RETINOIDS

Retinoids are particularly attractive agents for the treatment of podocyte disease, as it has been demonstrated that following podocyte injury, both decrease podocyte proliferation and maintain the expression of markers of differentiation.[181,182] The promoter region of the human nephrin gene (NPHS1) contains three putative retinoic acid-response elements, and shows enhancer activity in response to all-trans-retinoic acid (ATRA) in a dose-dependent manner. We have recently demonstrated that ATRA *in vitro* significantly retards podocyte proliferation, as measured by the MTT assay, while inducing process formation and increasing the expression of both nephrin and podocin.[182] Similarly, in mice with antiglomerular antibody nephritis, treatment with ATRA both reduces podocyte proliferation and prevents the decreases in nephrin, podocin, and synaptopodin in experimental animals. This was accompanied by a reduction in proteinuria. The dual roles of retinoids to both inhibit proliferation while promoting differentiation underscore their potential value as therapeutic agents for human podocyte diseases.

GLUCOCORTICOIDS

Glucocorticods are the clinical backbone to treat patients with glomerular diseases. Their mode of action is poorly-understood, particularly in patients with steroid-sensitive nephritic syndrome which lacks any signs of inflammation in the glomerulus. *In vitro* data in human podocytes revealed direct effects of dexamethasone on human podocytes.[183] Incubation with steroids led to decreased expression of p21 and suppression of inflammatory chemokines (IL-6/IL-8), but did not induce apoptosis.

Parietal Epithelial Cell Proliferation

As outlined above, there is an ongoing debate on the cellular origin of extracapillary proliferative lesions in glomerular disease. The parietal epithelial cell (PEC) has long been neglected, but recently moved into the center of glomerular research.[184] PECs share a common lineage with podocytes until the S-shaped stage of glomerulogenesis. Between the S-shaped body and capillary loop stages, each cell begins to express distinct genes, used as "cell-specific markers." For example, Wilm's tumor suppressor protein 1 (WT-1) expression is no longer detected in PECs, whereas podocytes maintain WT-1 and gain vimentin expression. In mice, PECs express CD10 in the capillary loop stage of development.[158] Potential mechanisms underlying PEC proliferation result from studies of cell cycle proteins. In contrast to podocytes, expression of the Cdk inhibitors $p21^{Cip1}$ and $p57^{Kip2}$ were not detected in healthy PECs, whereas $p27^{Kip1}$ was expressed at low levels. In experimental and human forms of FSGS, PECs showed increased DNA-synthesis. The increased expression of Ki-67 and cyclin A were accompanied by decreased $p27^{Kip1}$ expression in the absence of $p21^{Cip1}$ and $p57^{Kip2}$.[185] Suzuki et al. recently showed in a mouse model of FSGS, that PEC proliferation was in part regulated by $p21^{Cip1}$.[186]

Glomerular Endothelial Cell Proliferation

The endothelial cells of mature glomeruli are quiescent, but retain the capacity to proliferate and form new capillaries following injury.[187] The degree of proliferation appears to be dependent on the local balance of proangiogenic factors, such as vascular endothelial growth factor (VEGF), and antiangiogenic factors, such as thrombospondin-1. An inadequate proliferative response may lead to loss of the glomerular microvasculature, and contribute to glomerulosclerosis and progressive renal impairment. The beneficial effects of VEGF administration have been demonstrated in animal models of acute glomerulonephritis,[188–190] suggesting that amelioration of human diseases may be achieved by augmenting the reparative potential of the glomerular endothelial cells. However, the underlying role of individual cyclins, Cdk, and Cdk inhibitors in these cells remains unknown.

Tubular Cell Hyperplasia

Renal tubular hyperplasia is most frequently encountered during the reparative phase following an acute injury, such as ischemia or toxin exposure.[191] Tubular injury results in cell loss by either necrosis or apoptosis, and therefore there is a requirement for the remaining cells to spread and migrate to cover the exposed basement membrane. These cells then dedifferentiate and proliferate to restore cell number, and finally differentiate again to restore the functional integrity of the nephron. Interestingly, the tubular repair recapitulates organogenesis in patterns of gene expression, including vimentin, neural cell adhesion molecule, growth factors such as IGF-1, fibroblast growth factor, and hepatocyte growth factor; and matrix molecules such as osteopontin.[191] This dedifferentiated phenotype is likely to be important for the spreading and proliferative properties of the viable tubular epithelial cells as they cover the denuded basement membrane to replace lost cells. However, the factors controlling the reversion to a less-differentiated phenotype, and the subsequent re-establishment of the mature phenotype, remain poorly-understood.

As might be expected, the proliferation observed following a transient ischemic injury is associated with an increase in the mRNA and protein expression of cyclins D1, D3, and B, mRNA expression of cyclin A, and protein expression of Cdks 2 and 4.[192] Both cyclin-D and -E kinase activities are increased.[192] Thus, the proliferative response is due to increased expression of both the regulatory and catalytic subunits of the G1 kinases, and an increase in their activity.

The Cdk inhibitors appear to have a critical role in limiting the proliferative response. Following acute renal injury induced by ischemia, ureteral obstruction or cisplatin, $p21^{Cip1}$ protein expression is increased in the thick ascending limb of the loop of Henle, and in the distal convoluted tubule.[193] Induction of the same injury in $p21^{Cip1-/-}$ mice was associated with increased proliferation, as assessed by BrdU incorporation and PCNA staining.[194] The $p21^{Cip-/-}$ mice had a more rapid onset of acute renal failure, developed more severe morphological damage, and had a higher mortality, emphasizing the requirement for proliferation following injury to be at a controlled and appropriate level.

HYPERTROPHY

Hypertrophy has been described in most segments of the nephron, but proximal tubular hypertrophy is observed most frequently. Hypertrophy of the proximal tubule has been described in compensatory renal growth, chronic metabolic acidosis and chronic hypokalemia, diabetes mellitus, and during protein-loading.[195] In compensatory renal growth, there is also hypertrophy of the glomerulus and collecting tubules; in diabetes, hypertrophy of glomerular cells is well-described, and with prolonged protein-loading hypertrophy of the initial segments of the thick ascending limb occurs.

As mentioned previously, cellular hypertrophy may result from either cell cycle-dependent or -independent mechanisms. Within the glomerulus, an increase in cell size is predominantly due to cell cycle re-entry without progression, whereas in the tubules there appears to be a more significant contribution from the inhibition of protein synthesis.

Glomerular Hypertrophy

Glomerular cell hypertrophy occurs during many forms of chronic renal disease, and may herald the development of glomerulosclerosis.[130,196,197] Glomerular diseases associated with glomerular hypertrophy include diabetic nephropathy,[198] minimal change nephropathy,[199] focal segmental glomerulosclerosis,[200,201] and a reduction in renal mass.[202] However, there are clear differences in the prognosis of glomerular hypertrophy, depending on the underlying disease. Following uninephrectomy, the hypertrophy is compensatory, and is not typically associated with the development of glomerulosclerosis. In contrast, the hypertrophy of diabetic nephropathy antecedes and probably underlies the development of glomerulosclerosis.[169] Diabetic nephropathy is the leading cause of end-stage renal disease in Western countries, and is

discussed further below. Pathological glomerular hypertrophy leads to progressive glomerulosclerosis and scarring by a number of different mechanisms.[196] The increased metabolic rate of cells undergoing hypertrophy results in enhanced mitochondrial oxygen consumption, which may lead to tissue injury due to the generation of reactive oxygen radicals and the subsequent peroxidation of proteins and lipids. The hypertrophy is often initiated by growth factors that also stimulate the cells to increase production of extracellular matrix components, such as type IV collagen.

Diabetic Nephropathy

Diabetes mellitus is now the most frequent cause of end-stage renal failure in Western countries, and the pathogenesis of diabetic nephropathy is discussed in detail elsewhere in this book. The focus of this chapter is on the disordered cell growth seen in association with diabetic renal involvement. The hallmarks of human diabetic nephropathy are similar in both type I and type II diabetes, and consist of mesangial cell hypertrophy and podocyte loss, with accumulation of extracellular matrix in the mesangium and tubulointerstitium, resulting in glomerulosclerosis and tubulointerstitial fibrosis.[203–205] Research has concentrated principally on the ability of hyperglycemia and TGF-β to induce mesangial cell hypertrophy, and more recently the roles of RAGE[206] and hyperinsulinemia[207] have also been studied.

DIABETES AND MESANGIAL CELLS

HYPERGLYCEMIA *In vitro* culture of mesangial cells in high glucose media causes cell cycle entry and a biphasic growth response.[208] Following initial proliferation, the cells arrest in G1-phase, and there is progressive hypertrophy. Both kidney and glomerular hypertrophy induced by hyperglycemia are associated with an early and sustained increase in expression of cyclin D1 and activation of Cdk4.[209] An arrested cell cycle suggests a role for the Cdk inhibitors in mediating hypertrophy, and indeed high glucose increases the levels of both $p21^{Cip1}$ [210] and $p27^{Kip1}$ [211] in cultured mesangial cells. This is mediated by a number of factors, including glucose itself, TGF-β, which then acts in an autocrine fashion,[212,213] and CTGF.[214] High glucose directly stimulates the transcription of $p21^{Cip1}$,[215] and activates MAP kinases, which prolong the half-life of $p27^{Kip1}$ by phosphorylation on serine residues.[216] Lowering $p21^{Cip1}$ [217] or $p27^{Kip1}$ [211] levels with antisense oligonucleotides reduces the hypertrophic effects of high glucose. Moreover, hypertrophy is not induced by high glucose in $p21^{Cip1-/-}$ (unpublished observations) and $p27^{Kip1-/-}$[218] mesangial cells *in vitro*. Indeed, high glucose increases proliferation in $p27^{Kip1-/-}$ mesangial cells, whereas it arrests cell cycle progression in $p27^{Kip1+/+}$ mesangial cells.[218] Reconstituting $p27^{Kip1}$ levels in $p27^{Kip1-/-}$ mesangial cells by transfection restores the hypertrophic phenotype.[218] These studies show a compelling role for the Cdk inhibitors $p21^{Cip1}$ and $p27^{Kip1}$ in mediating the hypertrophy induced by high glucose.

These *in vitro* findings have been confirmed in experimental models of both type I and type II diabetic nephropathy. Considering type I diabetes, the glomerular protein levels of $p21^{Cip1}$ are increased in the streptozotocin (STZ)-induced model in the mouse,[210] and both $p21^{Cip1}$ and $p27^{Kip1}$ levels are increased in the glomeruli of diabetic BBdp rats.[64] A similar increase was noted in glomeruli of *db/db* mice[215] and the Zucker diabetic fatty rat,[219] models of type II diabetic nephropathy. Diabetic $p21^{Cip1-/-}$ mice are protected from glomerular hypertrophy.[220] Diabetic $p27^{Kip1-/-}$ mice have only mild mesangial expansion and no glomerular or renal hypertrophy compared to control diabetic $p27^{Kip1+/+}$ mice, despite upregulation of glomerular TGF-β.[221] These results support a critical role for the Cdk inhibitors $p21^{Cip1}$ and $p27^{Kip1}$ in mediating the glomerular hypertrophy seen not only in association with diabetes, but also as described in the following, a reduction in nephron number.

TRANSFORMING GROWTH FACTOR β The cytokine TGF-β has been shown in numerous settings to be a key mediator of progressive fibrosis in renal disease.[222–224] TGF-β also decreases proliferation in mesangial cells, an effect that appears to be independent of $p21^{Cip1}$ and $p27^{Kip1}$, and induces cell hypertrophy.[225–227] To determine the role of Cdk inhibitors in mediating the hypertrophic effects of TGF-β, mesangial cells derived from single and double null mice were studied.[226] Compared to wild-type mice, hypertrophy was significantly reduced in double $p21^{Cip1}/p27^{Kip1-/-}$ mesangial cells. A less marked reduction in hypertrophy was seen in the single $p21^{Cip1-/-}$ and $p27^{Kip1-/-}$ cells. These results show that although $p21^{Cip1}$ and $p27^{Kip1}$ each contribute to the hypertrophic action of TGF-β, the presence of both is required for maximal effect.

The expression of Cdk inhibitors has also been explored in response to CTGF, considered to be a principle mediator of the downstream effects of TGF-β. Abdel Wahab et al.[214] demonstrated that CTGF is a hypertrophic factor for human mesangial cells, and that this hypertrophy is associated with the induction of $p15^{INK4b}$, $p21^{Cip1}$, and $p27^{Kip1}$, with the maintenance of pRb in a hypophosphorylated state.

Diabetes and Podocytes

Morphometric analyses have demonstrated that the podocyte undergoes hypertrophy early in the course of

both animal models of diabetic nephropathy[219,228–230] and in human disease.[140,231] This hypertrophy may be in direct response to the metabolic changes associated with diabetes or compensatory, consequent to the loss of podocytes that is known to occur.[232,233]

At the level of the cell cycle, mRNA and protein expression of $p27^{Kip1}$ is increased in both cultured podocytes exposed to high glucose, and in glomeruli isolated from streptozotocin-induced diabetic rats.[230] The $p27^{Kip1}$ gene appears to be haplo-insufficient, as diabetic $p27^{Kip1+/-}$ mice exhibited an intermediate degree of functional and structural renal injury.[234] High glucose also significantly increased angiotensin II levels both in cell lysates and media compared with normal glucose, and exogenous angiotensin II increased $p27^{Kip1}$ mRNA and protein expression. Exposure of cultured cells and treatment of diabetic rats with an angiotensin II receptor antagonist (ARB) inhibited the increase in $p27^{Kip1}$. Glomerular hypertrophy was also significantly prevented by ARB treatment. It appears likely that similar cell cycle mechanisms drive both mesangial cell and podocyte hypertrophy in diabetic nephropathy, suggesting that podocytes in this setting are also capable of engaging the cell cycle.

Compensatory Glomerular Hypertrophy

A reduction in nephron number results in compensatory hypertrophy in the remaining viable nephron.[235] Uninephrectomy does not alter the protein expression of cyclins D1 or D2, nor of Cdk2 or Cdk4, when total renal lysates are studied at day 7.[236] However, there may be a differential effect in specific renal compartments,[187] and an increase in tubular cyclin E–Cdk2 activity was demonstrated during compensatory hypertrophy following uninephrectomy. Prior to hypertrophy, severe renal ablation produced by 5/6 nephrectomy resulted in an early proliferative glomerular response, associated with an increase in cyclin E expression and phosphorylation of pRb.[106]

A role for the Cdk inhibitors is now emerging in the pathogenesis of glomerular hypertrophy. Following partial renal ablation, $p21^{Cip1-/-}$ mice develop glomerular hyperplasia rather than hypertrophy and increased intraglomerular pressure, with protection from the development of progressive renal failure.[237] Increased intraglomerular pressure is a final pathway toward glomerulosclerosis in systemic hypertension, diabetes, and focal segmental glomerulosclerosis (FSGS). This glomerular hypertension causes stress-tension, or stretch, on resident glomerular cells, with differing consequences for the different cell types. Exposure of mesangial cells to cyclical mechanical stretch results in cell cycle entry and proliferation.[238] In contrast, mechanical stretch reduces cell cycle progression and induces podocyte hypertrophy *in vitro*.[157] This is unchanged in $p27^{Kip1-/-}$ cells, but hypertrophy was not induced in $p21^{Cip1}$ and double $p21^{Cip1}/p27^{Kip1-/-}$ podocytes, indicating a requirement for $p21^{Cip1}$. Stretch-induced hypertrophy required cell cycle entry, and was prevented by specifically blocking Erk1/2 or Akt. However, it is not clear whether podocyte hypertrophy represents a beneficial adaptive response to raised intraglomerular pressure or whether this change in podocyte phenotype is accompanied by a disturbance in function that is detrimental to the glomerulus.

TUBULAR HYPERTROPHY

The compensatory growth capacity of the kidney was known to the ancient Greeks: Aristotle (384–322 BC) described that animals born with a single kidney have a larger organ compared to those born with two. More contemporary studies have documented that the increase in renal size following nephron reduction by disease or surgical resection is due primarily to proximal tubular epithelial hypertrophy.[183,239] The initial hypertrophic response is considered adaptive;[77,235,240] however, with time persistent hypertrophy is associated with the infiltration of macrophages, T-cells, and fibroblasts into the tubulointerstitial space.[87,196] This hypertrophy is no longer beneficial to organ function, and the cellular infiltrate results in tubular atrophy and tubulointerstitial fibrosis, the final convergent pathway of many renal diseases of diverse etiologies.

Cell Cycle-Dependent Tubular Cell Hypertrophy

TRANSFORMING GROWTH FACTOR β

As in the glomerulus, TGF-β is an important mediator of tubular cell hypertrophy. The hypertrophy induced by both angiotensin II and high glucose[241] is also dependent on TGF-β. TGF-β converts a mitogen-induced proliferative response to cellular hypertrophy, and this has been studied in detail in cultures of proximal tubule cells by examining the effects of epidermal growth factor (EGF) plus TGF-β. TGF-β alone has an antiproliferative effect on tubular cell growth, but does not induce hypertrophy.[242] EGF-induced hyperplasia is associated with cell cycle entry, hyperphosphorylation of pRb, and an increase in thymidine incorporation, but no change in cell size or protein/DNA ratio.[242] In the presence of additional TGF-β, cell cycle entry is not impaired and cyclin-E protein levels increase, but there is no increase in DNA synthesis and pRb remains hypophosphorylated, with arrest of the cells in mid- to late-G1. Inactivation of pRb by expression of either SV40 large-T antigen (inactivates both pRb and p53) or

HPV E7 (inactivates pRb alone) prevents TGF-β from converting EGF-induced hyperplasia to hypertrophy. In contrast, inactivation of p53 alone with HPV E6 has no effect on the induction of hypertrophy, confirming the importance of pRb in the cell cycle arrest of tubular cells resulting from TGF-β.

The maintenance of pRb in its hypophosphorylated state suggests TGF-β modifies the activity of G1 kinases. Consistent with the observation that cell cycle entry is not impaired in the presence of TGF-β, TGF-β has no effect on EGF-induced increase in Cdk4/6−cyclin D kinase activity.[243,244] However, there is no increase in cyclin E kinase activity, with a decreased number of Cdk2−cyclin E complexes and retention of p57, but not p27 or p21, in those complexes that do form.

In summary, the proposed paradigm for the development of hypertrophy in response to TGF-β in renal tubular cells is as follows. After a proliferative stimulus, there is cell cycle entry and activation of cyclin D kinase. This is associated with an increase in protein synthesis, and hence cell size. As the cell reaches mid- to late-G1, if cyclin E kinase is sufficiently activated, pRb is further phosphorylated and becomes inactivated, allowing the cell to progress to S-phase and hyperplasia to occur. However, in the presence of TGF-β, cyclin E kinase is not sufficiently activated, pRb remains hypophosphorylated, the cell is arrested, and hypertrophy results.

ANGIOTENSIN II

Angiotensin II has an established role in stimulating hypertrophy of proximal tubular cells, mediated by the high-affinity AT_1 receptor.[245] Both angiotensin II and EGF induce the expression of early immediate genes in tubule cells, suggesting that angiotensin II-mediated hypertrophy is also dependent on cell cycle entry.[246] Indeed, angiotensin II-treated cells are arrested in G1, and do not progress to S-phase,[245,247] reminiscent of cells exposed to TGF-β. It has subsequently been shown that angiotensin II stimulates the transcription and protein synthesis of TGF-β in proximal tubule cells.[248] Exposure of cells to a neutralizing antibody to TGF-β abrogated the ability of angiotensin II to induce hypertrophy, demonstrating its dependency on the induction and autocrine activity of TGF-β.[248] In contrast to proximal tubules cells exposed to EGF and TGF-β, angiotensin II increases protein (but not mRNA) levels for $p27^{Kip1}$.[249] To characterize the functional role of $p27^{Kip1}$ in angiotensin II-mediated hypertrophy, proximal tubule cells were cultured from $p27^{Kip1}$ null mice,[250] which responded to angiotensin II with cell cycle progression but no hypertrophy. Cdk4/6−cyclin D kinase activity was stimulated in both wild-type and null cells, but Cdk2−cyclin E kinase activity only increased in the null cells, indicating that $p27^{Kip1}$ inhibits this complex, and is required for angiotensin II-mediated hypertrophy of proximal tubular cells.

The mechanism by which angiotensin II increases $p27^{Kip1}$ expression has been studied in detail.[251] Angiotensin II upregulates p22phox, a subunit of membrane-bound NADPH oxidase, and hence increases the concentration of intracellular reactive oxygen species. This results in phosphorylation and activation of the mitogen-activated protein kinases Erk 1,2, that in turn leads to serine phosphorylation of $p27^{Kip1}$.[216,252] Serine phosphorylated $p27^{Kip1}$ has increased stability and decreased degradation by the ubiquitin pathway.[216] Atrial natriuretic peptide attenuates angiotensin II-mediated $p27^{Kip1}$ expression and proximal tubule cell hypertrophy, by a mechanism that appears to involve activation of the phosphatase MKP-1, which dephosphorylates Erk1,2.[253] The importance of this pathway has also been shown *in vivo*.[254] Infusion of angiotensin II into normal rats for 7 days increased the formation of reactive oxygen species in tubular cells and augmented $p27^{Kip1}$ expression. Immunostaining for PCNA decreased, indicating G1 cell cycle arrest, although hypertrophy was not observed.

As occurs with mesangial cells, a role for CTGF has been described in mediating tubular cell hypertrophy in response to angiotensin II. Systemic infusion of angiotensin II into normal rats induced overexpression of CTGF in glomeruli, tubules, and renal arteries, with associated tubular injury and increase in fibronectin expression.[255] A similar effect was demonstrated in cultured tubular cells, with angiotensin II acting through the AT_1 receptor. The importance of CTGF in angiotensin II-mediated hypertrophy was explored in detail by another group using HK2 cells.[256] Angiotensin II induced CTGF expression, G1 cell cycle arrest, and cell hypertrophy, which were reversed by treatment with an anti-CTGF antibody. In addition to the well-described roles in apoptosis and fibrosis, further detrimental renal effects of angiotensin II are likely to be secondary to its recently described effects of cell cycle arrest and hypertrophy.

A summary of the changes in cell cycle proteins occurring in glomerular and tubular hyperplasia, and in cell cycle-dependent hypertrophy, is shown in Table 28.1. Data from knockout mice are shown in Table 28.2.

Cell Cycle-Independent Tubular Cell Hypertrophy

In addition to increased new protein synthesis, a decrease in the rate of protein breakdown may contribute to cell hypertrophy.[3] Within the kidney, this is best characterized for tubular cells. Although diabetes and acidosis are catabolic states, both are associated with decreases in renal proteolysis, which makes a significant contribution to the associated growth of the kidney.[257−259]

TABLE 28.1 Summary of Cell Cycle Proteins in Hyperplasia and Hypertrophy of Renal Cells

		Cyclin CDK			CDK Inhibitor

TABLE 28.2 Data from Knockout Mice

	Experiment	Outcome	Reference
$p21^{-/-}$	Mesangial cells exposed to high glucose *in vitro*	Resistant to hypertrophy	—[a]
	Animal models STZ diabetes Antiglomerular antibody Remnant kidney Acute tubular injury (ischemia, UUO, cisplatin)	Reduced glomerular hypertrophy	3
		Increased podocyte proliferation	100
		Glomerular hyperplasia, not hypertrophy	135
		Increased proliferation, worse renal function, increased mortality	136
$p27^{-/-}$	Mesangial cells exposed to high glucose *in vitro*	Resistant to hypertrophy	244
	Mesangial cells deprived of growth factors	Increased apoptosis	84
	Animal models STZ diabetes Antiglomerular antibody	Reduced glomerular hypertrophy	5
		Increased mesangial cell proliferation and apoptosis	158
	UUO	Increased tubular apoptosis	158
$p57^{-/-}$	Unmanipulated animal	Normal glomerulogenesis in embryonic mice	217,257,263

[a]*Unpublished.*
UUO: Unilateral ureteral obstruction.

An estimated 60% of total intracellular proteolysis in renal tubular cells occurs by the ubiquitin–proteasome pathway;[260] however, this does not appear to be a major factor in the regulation of proteolysis during the hypertrophic response of renal tubular cells. Two lines of evidence support an alteration in lysosomal function as underlying the reduced proteolysis observed in certain cases of tubular hypertrophy, and a possible mechanism by which this occurs has recently begun to be clarified.[261] First, in addition to stimulating cell cycle entry, EGF increases protein half-life by approximately 30% in cultured primary proximal tubular cells, primarily by affecting lysosomal proteolysis.[260] Second, exposure of tubular cells to ammonia leads to alkalinization of acidic intracellular compartments, including lysosomes, thus modifying their function, and stimulates hypertrophy that is independent of cell cycle entry.[262]

Several studies have demonstrated proximal tubule cell hypertrophy in response to ammonia *in vitro*,[262–264] and renal ammonia synthesis is increased in several apparently diverse clinical conditions associated with hypertrophy.[195,265] In chronic metabolic acidosis and chronic hypokalemia, mitochondrial ammoniagenesis is directly stimulated. In contrast, the increase in ammonia in diabetes mellitus, following uninephrectomy and during protein-loading, is thought to be stimulated by an increase in single-nephron glomerular filtration rate (SNGFR). Cell culture studies involving either reducing the media pH[182] or lowering potassium concentration[266] do not induce hypertrophy, indicating that it is not changes in the extracellular milieu *per se* that initiate the hypertrophic growth response. The results from direct application of ammonium chloride suggest that the accumulation of this molecule, in response to acidosis or hypokalemia, drives the development of hypertrophy. This hypothesis is supported by studies of hypertrophy in the setting of chronic hypokalemia in the rat.[267] In this model, renal ammonia production is significantly increased. Administration of bicarbonate both decreases the rate of ammonia synthesis and the hypertrophy. Renal generation of ammonia has recently been studied in patients with metabolic acidosis and normal renal function.[263] Compared to individuals with normal acid– base balance, kidney protein degradation was significantly lower and urinary ammonia excretion significantly higher. As with cell and animal studies, it was suggested that in human metabolic acidosis the increased ammonia synthesis drives the decrease in protein degradation, and is potentially responsible for kidney hypertrophy.

What is the mechanism by which altered lysosomal function affects protein degradation? Chaperone-mediated autophagy allows lysosomal import of proteins containing a specific consensus sequence, KFERQ, by the binding of heat-shock cognate protein 73 (Hsc73) to lysosomal membrane protein 2a (LAMP2a). In cultured

NRK-52E cells (a rat kidney epithelial cell line) exposed to EGF or ammonia (but not TGF-β alone), there was an increase in the half-life of KFERQ-containing proteins[261] associated with a decrease in total cellular and lysosomal LAMP2a. Furthermore, declines in LAMP2a and Hsc73 have also been demonstrated in lysosomes isolated from the hypertrophied cortex of acutely diabetic rats, and was accompanied by an increase in KFERQ-containing proteins.[268] Other lysosomal pathways may also be affected during renal hypertrophy.[3] EGF-induced suppression of proteolysis in NRK-52E cells was prevented by inhibitors of Ras and PI-3 kinase, but not by inhibitors of MAP kinase or Src.[269] PI-3 kinase and Akt activities are increased in the renal cortex of diabetic *db/db* mice and correlate with hypertrophy.[270] Products of the PI-3 kinase pathway control membrane and protein trafficking, and the suppression of chaperone-mediated autophagy may be part of a generalized abnormality in trafficking to and from lysosomes.

CONCLUSIONS

The last two decades have seen an explosion in our understanding of the underlying mechanisms governing renal hyperplasia and hypertrophy which has literally burgeoned since 1991. The goal for the next 15 years will be to identify specific modifiable targets to alter or even reverse these pathological processes. Numerous agents have been demonstrated to be beneficial in ameliorating the course of animal models of disease, and the hope is that certain of these will transfer to be of use in human disease. Indeed, Cdk2 inhibitors are now in human trials for treatment of proliferative glomerulonephritis. With the discovery of drugs that target either the network of mitogens responsible for stimulating abnormal cell growth or specific cell cycle-regulatory proteins, potential therapies may be on the horizon for patients with renal diseases in which hyperplasia or hypertrophy is a dominant feature. Much has been learned, but in addition to characterizing the role of conventional cyclins, Cdks, and Cdk inhibitors, the challenge remains to identify novel cell cycle proteins, determine their role in renal disease, and the consequences of their manipulation.

[2]Departments of Medicine and Physiology, Columbia University, New York, NY, USA

EMBRYONIC ORIGIN OF RENAL CELLS

The idea that the kidney is an organ needs to be tempered by the realization that it is the nephron that is the organ. Each nephron, as far as we know, is independent from other nephrons, and the kidney is to a first approximation a collection of these mini-organs put together in a complex three-dimensional assembly. The nephrons of all mammals are remarkably similar in size, function, and origin (as far as we know), and the differences among species are largely if not entirely due to the number of these units in the assembly, with mice having 10,000 and whales having 250 million in each kidney. But while the epithelial character of the nephron garners most of the attention, one needs to be reminded that the kidney has a very extensive vascular network with multiple distinct morphological and functional domains, as well as an abundant interstitial cell population that unfortunately is still poorly understood (see Kaissiling and Le Hir[1] for a review). While the taxonomy of the renal epithelial cells is nearly complete, that of the cells of the vascular and interstitial compartments awaits detailed characterization. Hence, analysis of renal regeneration after injury, as well as search for putative renal stem cells in the adult kidney, has essentially been restricted to the epithelial compartment. However, as epithelial cells are likely instructed by mesenchymal signals and epithelia-mesenchymal cross-talk is critical for renal epithelial differentiation and function,[2] there is a need for deeper understanding of the cell types that comprise the renal vascular and interstitial compartments, and their roles in kidney homeostasis and repair from injury. For example, in many organs including the kidney, mesenchymal cells with characteristics of precursor/stem cells have been found to reside near or in the vascular wall,[3–5] but the exact origin and normal function of these cells is unknown.

The different cellular compartments of the adult kidney have been traditionally recognized by their morphological characteristics or by their embryonic origin, since it was long ago recognized that the adult (metanephric) kidney derives from two distinct elements of the intermediate mesoderm: the metanephric mesenchyme and the ureteric bud. Within the kidney, the ureteric bud gives rise to the collecting duct cells, while some metanephric mesenchyme cells give rise to the rest of the nephron.[6] However, over the last few decades, the discovery of several genes that are expressed in the restricted group of cells of the renal anlage has allowed a different taxonomic approach that has greatly illuminated our understanding of the distinct cell populations in the adult kidney. Moreover, it has allowed development of research tools with which it is possible to probe in the adult kidney the function of specific cells, of specific genes in specific cells, and importantly for the present discussion, to identify the daughter cells of different cell types by *in vivo* genetic cell lineage methods. Thus, we briefly review the embryonic origin of the distinct cells in the adult kidney, emphasizing those aspects that might clarify the origin of new cells in the adult organ.

Epithelial Cells

All epithelial cells of the adult kidney are believed to derive from the intermediate mesoderm, from which both the ureteric bud (a branch of the Wolffian duct) and the metanephric mesenchyme originate. Renal

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00029-X

morphogenesis starts when the ureteric bud invades the metanephric mesenchyme and starts branching. The cells in the tip of each ureteric bud branch give rise to the collecting duct cells and the metanephric mesenchyme cells in contact with each ureteric bud tip give rise, after a series of morphogenic steps, to the cells of the remaining nephron segments spanning from the connecting tubule to the glomerulus. The ureteric bud, like the Wolffian duct, expresses the homeobox gene *HoxB7*,[7] and transgenic mice expressing *HoxB7*-GFP or *HoxB7*-Cre recombinase have been used to label most, if not all, of the cells in the ureteric bud branches of the embryonic collecting duct,[8] and their progeny in the adult kidney.

The metanephric mesenchymal cells undergo simultaneous differentiation (to generate a nephron for each ureteric bud tip) and growth, so that the appropriate number of nephrons will be generated for the branches of the ureteric bud. It was recently found that the metanephric mesenchymal cells that are in contact with the tips of the ureteric bud, referred to as the cap mesenchyme, are the progenitor cells of all nephron epithelia (except the collecting duct). These cells were found to express the transcription factors *Cited1*[9] and *Six2*,[10] thereby allowing generation of transgenic mice that label all nephron epithelial cells except those of the collecting ducts. More relevant to the present discussion is that these mice can be used to permanently identify the progeny of adult nephron epithelial cells,[9,10] thus providing an invaluable tool for analysis of epithelial cell regeneration after kidney injury and/or disease,[11] as discussed below.

Mesenchymal/Stromal Cells

Like renal epithelial cells, the vast majority of the stroma cells in the adult kidney derive from the intermediate mesoderm[12] that in the kidney gives rise to a cell population that expresses the forkhead transcription factor *Foxd1*.[2,13,14] These cells generate many renal interstitial cells, as well as mesangial cells, vascular smooth muscle, pericytes, and renal capsule, and likely mesenchymal stem cells.[5] *Foxd1*-expressing cells are absolutely required for normal kidney development,[2,13,14] and their adult progeny is of extreme interest because it likely contains pluripotent MSC[5] and pericytes,[4] although a clear-cut distinction between these two cell types is not yet possible. In addition, identification of *Foxd1* as marker of these cells has made it possible to develop transgenic mice that can be used to label the stroma cell progeny in the adult kidney.[15]

Another population of renal stromal cells derives from the paraxial mesoderm,[16] but the precise contribution of these cells to the interstitial and mesenchymal cell populations of the adult kidney remains to be defined. Finally, an area of the intermediate mesoderm located ventro–lateral to the dorsal aorta generates renal interstitial cells that express the stem cell factor receptor (*c-kit*).[17] During embryogenesis, these cells appear to be involved in the maintenance of the metanephric mesenchyme-derived cells, but identification of their progeny in the adult kidney remains to be established.

Endothelial Cells

The renal circulation is both anatomically and functionally complex, and likely contains many types of endothelial cells. Their exact origin is still poorly-understood. It is clear that once kidney development starts, the renal anlage contains angioblats[18,19] that give rise to endothelial cells. It is currently unknown whether these endothelial precursors migrate into the developing kidney or differentiated from cells that reside in the metanephric mesenchyme. The latter appears more likely, as we found that many cells in the renal anlage express tyrosine kinases that are characteristic of adult endothelial cells.[20] Interestingly, in addition to being endothelial precursors, angioblasts in the renal anlage appear to provide signals important for development and differentiation of the metanephric mesenchyme.[21] It is currently unknown if there exists interaction in the adult kidney between endothelial cells and either interstitial or epithelial cells that might be involved in maintaining kidney homeostasis or repair from injury. Recent work by Lin et al.[22] suggests that endothelial-to-pericyte cross-talk is involved in the generation of kidney myofibroblats, as detailed below.

NEW CELLS IN THE ADULT KIDNEY

Normal Conditions

As assayed by a variety of methods, the normal adult kidney has a low rate of cellular proliferation.[23–26] Using antibodies to Ki67, a nuclear protein expressed in cycling cells during G0 and G1, between 0.4–1% of all cells were cycling in the adult rat kidney.[24,25] Interestingly, age has a profound effect in the abundance of proliferating cells found in the kidney. Vogesterder et al.[25] found that while only ~0.4% of all renal cells were positive for Ki67 in the kidneys of 16- to 20-week-old rats, in animals that were only 4 weeks old the number of cycling cells was ~5%. This suggests that in the kidney there is an age-dependent progressive decline in the number of cycling cells, and that workers examining renal cell proliferation should take into account the age of the animal as an important variable.

Proliferating cells in the renal cortex of 4-week-old rats were found preferentially located to the S3 segment of the proximal tubule, when compared to the S1 and S2 segments.[25] This interesting result might have important implications in designing strategies to identify renal stem cells, a subject to which we will return below. In contrast, in 1-year-old rats, we found that most of the kidney parenchyma had a homogeneous fraction of ~1% of Ki67 positive cells Figure 29.1. There were two exceptions to this, however, the body of the papilla where there were extremely low numbers of cycling cells (<0.1% of the cells were positive for Ki67), and the upper part of the papilla (at the papilla–medullary junction), where we found the highest frequency of cycling cells (~2.5%),[24] indicating that it is an area of privileged cellular proliferation in the adult rat. Detailed morphological observations indicate that terminally differentiated tubular epithelia cells can generate new cells,[27,28] but these observations don't exclude the possibility that there are epithelial stem cells.

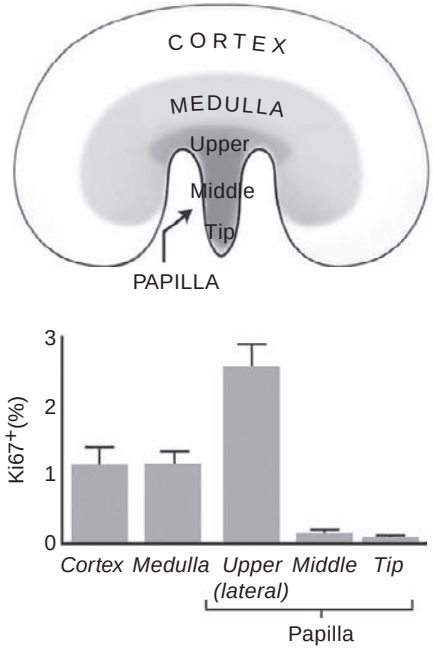

FIGURE 29.1 **Cellular proliferation in adult kidney.** Top: Kidney regions were examined for cellular proliferation. Bottom: Fraction of Ki67-positive cells in different kidney regions. Cortex and medulla had a similar number of Ki67-positive cells, but the lateral side of the papilla had significantly more Ki67-positive cells than the cortex and medulla, as well as the other regions of the papilla. The middle and tip of the papilla had significantly fewer Ki67 positive cells than other regions of the kidney. *(From ref. [27].)*

Organ Repair from Injury

In contrast to normal conditions, the kidney displays a remarkable proliferation capacity shortly after transient injury. For example, injury induced by 30–45 minutes of complete renal artery occlusion in rodents causes functional failure, and widespread cellular apoptosis and necrosis that are followed by diffuse cellular proliferation and functional recovery. What is the origin of these new cells? While the kidney has multiple cell types, studies on the generation of new cells after injury have fundamentally focused on the epithelial cells, likely because of their better-understood functional importance and easier identification. It is now established that the new epithelial cells after kidney injury develop from within the parenchyma, rather than being derived from extrarenal sources such as the bone marrow,[29,30] and thus three possibilities appear likely: (1) any surviving terminally differentiated epithelial cell can generate identical cells; (2) there exist kidney epithelial stem cells capable of generating any epithelial cell type, similar to what was found in the interfollicular epidermis;[31,32] and (3) pluripotent renal stem cells generate epithelial as well as other cell types, as in the case of the stem cells in the bulge of the skin.[33–36]

Morphological observations[35,37] and functional studies with nucleotide analogs[27,38] have provided strong evidence that terminally-differentiated epithelial cells generate new epithelial cells after injury. More recent elegant genetic cell fate-mapping studies have confirmed this suspicion; Humpreys et al.[11] used reporter mice in which the renal epithelial cell compartment was labeled by a Cre recombinase driven by the promoter of *Six2*, a gene that is specifically expressed in embryonic epithelial precursors (see above), and examined their response to acute kidney injury. They found that injury induced massive cellular proliferation, and that all new epithelial cells expressed the reporter gene (Figure 29.2). Since RT-PCR of adult kidney tissue could neither detect *Six2* nor *Cre*, it is apparent that the labeled cells originated from epithelial cells labeled previously during kidney development, thus excluding the interstitial/stroma cell compartment as the origin of new epithelial cells. Needless to say, this experiment does not address whether there exists a group of restricted epithelial cells that are responsible for all the new epithelia generated after injury; these cells could function as adult renal epithelial stem cells. In a recent study, Humphreys et al.[39] examined this possibility by labeling cycling cells after transient kidney injury with two different thymidine analogs administered sequentially. Since the number of epithelial cells that were positive for both nucleotides was very low, these workers concluded that surviving epithelial cells repopulate the nephron epithelium in a stochastic manner,

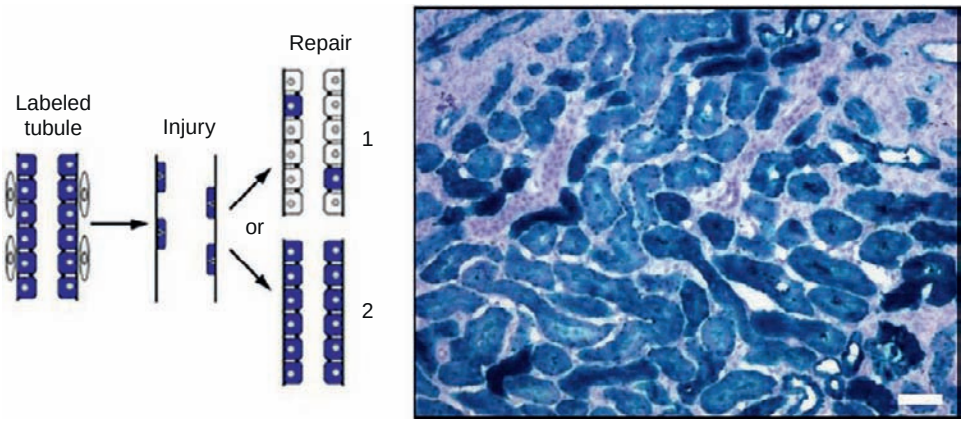

FIGURE 29.2 **Surviving epithelial cells after injury generate new epithelial cells.** (Left) New cells after acute kidney injury in mice with genetically labeled epithelial tubules will not carry the label if they derive from cells outside the epithelial cell compartment (#1), but will carry the label if they derive from terminally differentiated epithelial cells (#2). (Right) Fifteen days after transient ischemic injury and repair, there was no dilution on the number of labeled cells (dark) despite marked cellular proliferation, indicating that they derived from epithelial cells. *(From ref. [14].)*

suggesting that the nephron epithelia has no stem cells.[39] However, while control experiments clearly showed appropriate specificity of both antibodies, detection of closely related thymidine analogs during conditions that, unlike in the control experiments, probably result in incorporation of very different amounts of the two analogs in a given cell are fraught with potential problems. More importantly, their conclusion is based on the implicit assumption that a putative population of epithelial stem cells would be a small fraction of the total number of cells. Under these conditions, to repopulate the damaged epithelia the stem cell progeny would need to divide rapidly, and would thus incorporate both nucleotide analogs. However, as detailed below, stem cells in *Drosophila* Malpighian tubules are a very large fraction of the total cells, and there is no reason why this may not also be the case in mammalian kidneys. Similarly, in organs other than the kidney such as the adult airway epithelia, stem cells account for about one-third of the total number of cells.[40,41]

Identification of the site where cellular proliferation first starts after transient injury could potentially facilitate identification of precursor/stem cells. Unfortunately, for most insults that cause acute kidney injury with functional failure, cellular proliferation has most often been examined one or a few days afterwards, at which time cell proliferation, while very prominent in the S3 segment of the proximal tubule, is also widespread in other parts of the kidney parenchyma, particularly the medulla.[38,42–44]

Following acute kidney injury by renal artery occlusion we could not detect proliferating cells until ~24 hours later when we examined kidney sections of ~5 μm thickness, as is done routinely. However, with 100 μm vibrotome sections, one hour after injury we found that the upper part of the papilla had more proliferative cells than other parts of the kidney[24] (see Figure 29.3), suggesting that this is the site of initial cellular proliferation after kidney injury, which we previously found to be the site of enhanced cell cycling under normal conditions (see above). Interestingly, Vinsonneau et al.[45] reported that the first cells that they found cycling after ischemia reperfusion injury to the kidney were uro-epithelial cells in the upper part of the urinary (intrarenal) space and neighboring interstitial cells; detailed analysis with Ki67 and BrdU incorporation showed that these cells were proliferating ~16 hours after ischemic injury and ~4 hours before proliferation could be detected elsewhere in the kidney. The site identified by Vinsonneau et al.[45] is where the base of the papilla attaches to the medulla, it is in close proximity to the cortex, and appears to be the same proliferating site we identified in the upper papilla. Needless to say, identification of these "early" proliferating cells and of their progeny would be of extreme interest.

An additional observation merits mention. In the few studies that identified the cells that first started proliferating after injury, either after transient ischemic injury[44] or aminoglycoside toxicity,[46,47] it is remarkable that in all instances they were interstitial cells, perhaps suggesting that some interstitial cell plays a critical role in initiating epithelial regeneration. Indeed, the likelihood of renal functional recovery after injury was found to correlate with increases in the number of interstitial cells, many of which were likely myofibroblasts.[43,48,49] Although these results raise the possibility that myofibroblasts might be involved in epithelial regeneration, other interstitial cells such as macrophages are known

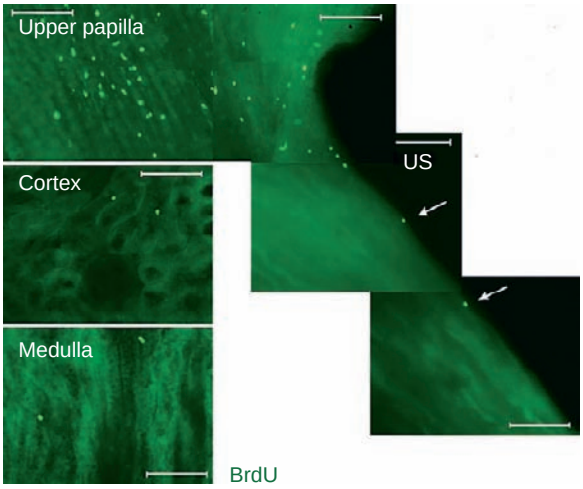

FIGURE 29.3 **Cellular proliferation was first detected in the upper papilla following kidney injury.** There was a selective increase of cells in S-phase in the upper papilla during the first hour after transient ischemic injury. Note abundant BrdU-labeled cells in the upper papilla, whereas the cortex and medulla revealed very rare BrdU-labeled cells (US: urinary space). Photomicrographs were done in 100 μm tissue sections obtained with a vibratome.*(From ref. [27].)*

to be involved in kidney repair,[50] and a detailed characterization of the interstitial cell compartment following transient kidney injury is lacking.

Effect of Age

For many organs, including the kidney,[51] the capacity to recover from injury decreases with age, an observation familiar to most practicing nephrologists. In most organs, it remains to be determined whether this is due to a decrease in the number of organ-specific stem cells or to the inability of the stem cells to be activated, but recent work suggest that the latter is more likely (reviewed by Liu and Rando[52]). For example, it was recently found that aging muscle had a normal number of satellite cells, but the cells failed to activate in response to exercise.[53] Interestingly, progenitor/stem cells in advanced age can display a "young" response by exposure to a young systemic environment,[54] indicating that the changes responsible for the functional decrease of precursor/stem cells are potentially reversible.

While the effect of age on the renal proliferative capacity after injury has not been studied in detail, it appears that cell proliferation after acute kidney injury decreases with age,[55] in agreement with the poor prognosis of recovery from acute kidney injury in elderly patients.[51] Mechanisms that could account for these observations include telomere shortening[56] and increased expression by renal epithelial cells of zinc-α^2-glycoprotein (Zag), an adipokine associated with cachexia.[58] To examine whether the poor regenerative capacity of the aging kidney is due to a decrease in the numbers or in the functionality of putative renal stem/progenitor cells awaits definitive identification of these cells.

In sum, both during normal conditions and particularly after transient kidney injury, the S3 segment of the proximal tubule is a site of intense cell proliferation, suggesting the presence of progenitor cells in this part of the nephron. In addition, the upper part of the papilla and close to the urinary space is also a site of robust cell cycling, both under normal conditions[24] and after transient kidney injury.[24,45]

IDENTIFICATION OF POTENTIAL PRECURSOR/STEM CELLS IN THE ADULT KIDNEY

Studies from several laboratories have presented evidence characterizing renal precursor cells in the adult kidney, but none of these cells meet strict criteria for traditional adult, organ-specific stem cells; i.e., asymmetric cell division and multipotency. Nonetheless, since our ultimate aim is to understand the origin of new cells in the adult kidney so that the responsible mechanisms might be manipulated, these studies are worth reviewing. In addition, the results of these studies are likely to be useful for future work to identify adult renal stem cells. Several strategies have been used to identify and characterize adult kidney precursor/stem cells, and the robustness of the obtained results varies widely. In our view, the methodological approach used for cell identification and/or isolation of the cells best separates these studies.

Cellular Markers

Several workers have isolated cells from the adult kidney using a candidate gene approach. For example, Busolatti et al.[59] used the transmembrane glycoprotein Cd133, which is expressed in hematopoietic stem cells, endothelial progenitor cells, neuronal, glial, and glioblastoma stem cells, as well as some other cell types (see Mizrak et al.[60] for a review), to select cells from the adult human kidney. The isolated cells showed strong clonogenic capacity, and when subcutaneously transplanted to SCID mice formed tubules which expressed some renal epithelial markers. Finally, when the cells were injected intravenously into mice with glycerol-mediated acute kidney injury, they integrated into tubules. However, the functional significance of the integration was not explored.

Using a somewhat similar approach, Dekel et al.[61] used Sca-1, a protein identified in several progenitor cells, to isolate a cell population from mouse kidneys. However, because Sca-1 is also expressed in renal epithelia, these workers used a collagenase digestion approach that appeared to yield interstitial cells. The *in vitro* differentiation of these cells suggested that they were mesenchymal-like stem cells, since they differentiated into myogenic, osteogenic, adipogenic, and neural lineages. When injected into kidneys with acute kidney injury, they also incorporated into tubules.

In Vitro Growth Behavior

Several laboratories have isolated cells from adult kidneys based on their characteristics when cultured *in vitro*. For example, cells were selected because of their high clonogenic potential, ability to outlast all other cultured cells or their ability to change their phenotype. For example, Gupta et al.,[62] cultured cells from collagenase digested rat kidneys, and after ~5 weeks in culture they obtained a cell population with substantial proliferative potential (which in fact was the characteristic that lead to isolation of the cells) and expressing transcription factors such as *Pax-2* and *Oct4* that are either involved in renal development or in determining cell fate. When the cells were injected into the subcapsular space of normal kidneys, some of them incorporated into tubules.

Kitamura et al.[63] used a slightly different strategy by isolating single nephrons from adult rat kidneys and culturing them *in vitro*. Cells growing out from these nephrons were harvested and individually cultured; and the clone with the fastest proliferation capacity was characterized. These clonal cells expressed several proteins important in kidney development and proteins characteristic of mature nephrons. When the cells were injected in the subcapsular region of a kidney with acute kidney injury, the cells engrafted into renal tubules.

More recently, Lee et al.[64] used a mouse with a targeted mutation in which GFP is expressed under the control of *Myh9*, a gene expressed in interstitial cells (among others). After isolation of the GFP^+ cells from the kidney and subsequent culture for eight weeks, they isolated a cell line that expressed renal embryonic or stem cell markers such as *Oct-4*, *Pax-2*, *Wnt-4*, and *WT-1*. Immunolocation of the endogenous $Oct\text{-}4^+$ and GFP^+ cells in the kidney found them in the interstitial space of the medulla and papilla. Finally, when the cells were injected directly into kidneys after acute kidney injury, they incorporated into tubules and partially decreased the functional consequences of the injury.

In Vivo Growth Behavior

The hypothesis that adult, organ-specific stem cells divide infrequently has been a powerful tool in locating and identifying several stem/precursor cells. According to this hypothesis, due to their low cycling behavior, stem cells retain S-phase labels (traditionally ^{3}H-Thymidine or a thymidine analog such as BrdU) when given as a short pulse followed by a long time of chase. Recent work has, however, demonstrated that there is more complexity than originally thought[65–67] (see Fuchs[68] for an informed discussion), as not all stem cells are low cycling and "label retention" experiments identify a heterogeneous group of cells. Nonetheless, populations of "label-retaining cells" from several organs are enriched for stem cells,[66,69–72] and identification of a "label-retaining" group of cells is of great interest. To detect low cycling cells, an S-phase label is only administered during a short period of intense growth (e.g., embryonic life or shortly after birth), so that all cells are cycling and incorporate the label; during the subsequent period of chase the label is diluted and lost by the progeny of dividing cells and selectively retained by low- or non-cycling cells. Cells cycling infrequently were thus named "label-retaining cells" (LRC). Several investigators have used this approach in the kidney.

Maeshima et al.[38] administered BrdU for one week to adult rats that were then "chased" for two weeks, and found that there were many BrdU-retaining cells the kidney parenchyma, particularly in the proximal tubules. Following transient ischemic injury, most of the tubular cells that were proliferating (expressing proliferating nuclear antigen; PCNA) were also BrdU-labeled cells. These results led Maeshima et al.[38] to conclude that a "label-retaining" cell population was the precursor of new cells during kidney repair from injury. However, the long pulse and short period of chase complicate the interpretation of these results. In addition, the increased number of BrdU-labeled cells after injury was likely due to detection of the cells loaded with BrdU during the "pulse" plus their immediate progeny after injury. Nonetheless, because a relatively small population of cells were labeled during the one-week "pulse" and many of these cells were also PCNA positive after injury, this experiment suggests that both during normal conditions and during repair from injury a group of renal epithelial cells cycles at a much higher frequency that most other epithelial cells. This raises the possibility that these cells could be adult, renal epithelial precursors.

We exploited the low cycling frequency of adult stem cells by giving BrdU to newborn rats or mice during a short pulse, and "chased" the animals to

adulthood.[73] In addition, to circumvent the use of BrdU, we[24] also followed the suggestion of Tumbar et al.[74] and used transgenic mice that expressed a fusion protein of histone 2B and GFP (referred as H2B-GFP mice) under the control of a tetracycline-responsive element. Pregnant females given doxycycline give birth to pups where all cells are GFP^+ cells, but when these pups are chased to adulthood, only low-cycling cells remain GFP^+. As shown in the Figure 29.4, after 2–3 months of chase, label-retaining cells were only found in the kidney papilla. When isolated, the cells showed pluripotency and, like other stem cells, formed spheres.[24,73]

Under normal conditions, most of these papillary label-retaining cells (LRC) in the adult kidney are, unsurprisingly, in growth arrest, but we found in the upper papilla a small population of them that were cycling[24] (see Figure 29.5), indicating that they generate new cells and explaining that the number of papillary LRC slowly decreased with age. In marked contrast to the normally low-cycling frequency of the papillary LRC, many of these cells proliferated shortly after acute kidney injury, likely generating many daughter cells, since after a few weeks the S-phase label disappeared from the papilla (see Figure 29.6). Hence, the cells we identified in the kidney papilla showed two cycling characteristics: first, during normal homeostasis, the cells are low-cycling (and thus they are LRC) except for a small population of them that are cycling in the upper papilla; second, and in marked contrast to normal conditions, may of the papillary LRC start cycling shortly after injury. These results strongly suggest that the population of LRC of the kidney papilla is involved in kidney repair, and that within the LRC cells are renal stem/precursor cells.

Because the renal capsule contains a population of nestin-expressing cells,[75] and this intermediate filament protein has been found in a variety of precursor cells,[76] Park and co-workers[77] searched for low-cycling cells in this part of the kidney. They administered a short pulse of BrdU to 4-week-old mice, and followed the pulse by a chase period of two months. They found that the kidney capsule had a sparse population of BrdU-retaining cells which further characterization showed them to be $CD29^{+,}$ $Sca\text{-}1^+$, $vimentin^+$, and $nestin^+$, but that did not express hematopoietic or endothelial markers. These cells showed marked proliferative and clonogenic capacities, and could differentiate towards adipogenic, chondrogenic, and osteogenic lineages, suggesting that they were MSC or MSC-like. The function of these cells *in vivo* remains unknown, and it would be of great interests to determine whether kidney injury induces their proliferation.

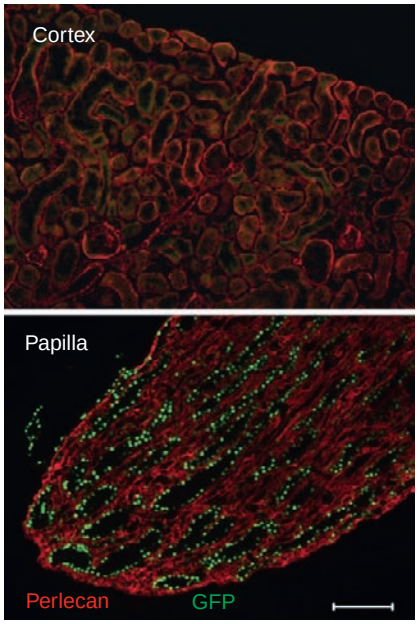

FIGURE 29.4 Papillary LRCs in mice expressing histone 2B-GFP. The kidney of an 11-week-old mouse pulsed with doxycycline during embryonic life showed low cycling cells (i.e., GFP- retaining) in the papilla but not the cortex or medulla. *(From ref. [27].)*

Cellular Function

Since first used to enrich for hematopoietic stem cells,[78–80] the *Side Population* discrimination assay has been used to identify stem cells and progenitor cells in a variety of organs and tumors.[81] The assay can be useful when stem cell-specific markers are not available, and it is based on the differential ability of cells to efflux a lipophilic fluorescent dye via the ATP-binding cassette transporter protein ABCG2. Many stem/precursor cells rapidly efflux the Hoechst 33342 dye, a process that can be blocked with ABC transporter inhibitors. By flow cytometry, such cells are recognized as being "Hoechst low" (versus "Hoechst high") and as they are a very small fraction of the total cells, they were termed side population (SP) cells. Because the assay is dependent on normal cellular metabolic function in freshly isolated cells, it is extremely challenging (for a detailed discussion see Golebiewska et al.[81]), and uncertainty exists about the significance of some of the results. Nonetheless several workers have isolated SP cells from the adult kidney.[82–85] The frequency of these cells has been reported to vary from ~5%[84] to ~0.1%.[83,85] In one study, exogenous administration of the isolated cells to mice with cisplatin-induced acute kidney injury improved the kidney's functional response.[84] These provocative results need further analysis, particularly because the SP of the kidney

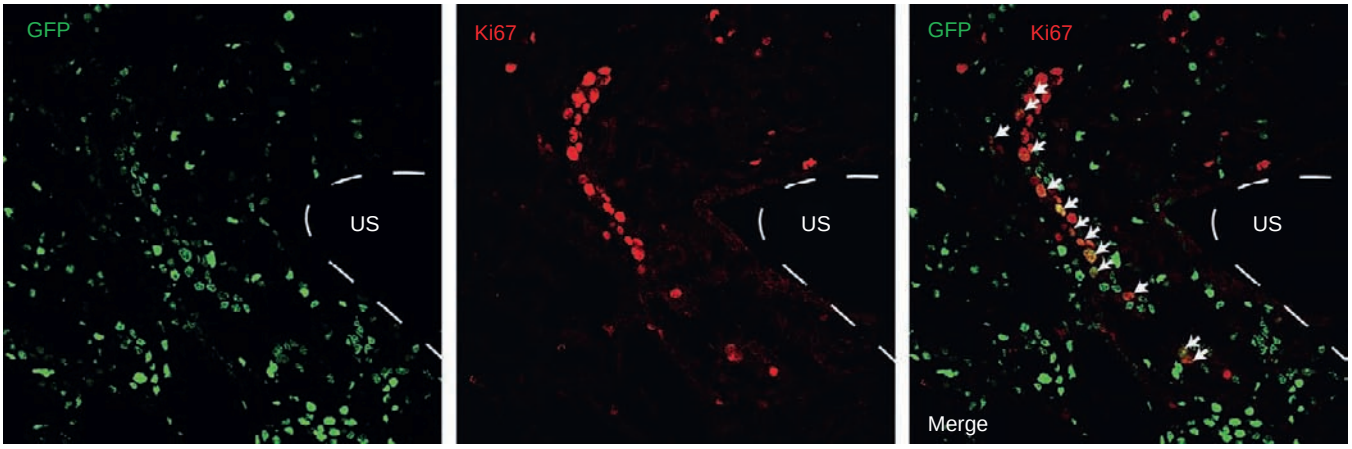

FIGURE 29.5 **LRC in the upper papilla from chains of proliferating cells.** LRCs (GFP^+: top) and proliferating cells (Ki67-positive: middle) in the upper papilla. The merged image shows that several cells are positive for both Ki67 and GFP (arrows). Broken white line depicts papillary edge (US: urinary space). *(From ref. [27].)*

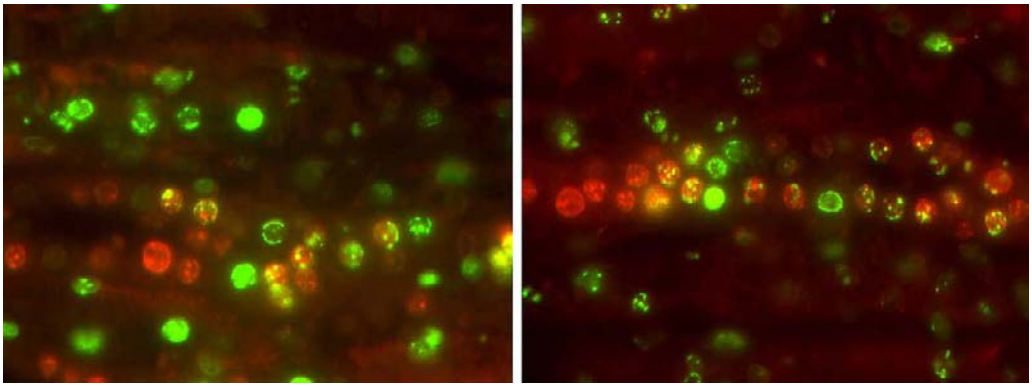

FIGURE 29.6 **Proliferation of papillary LRC after transient ischemic injury.** Cellular proliferation of papillary LRC after transient renal ischemia. Thirty-six hours after ischemic injury, many LRC of the papilla (FITC fluorescin) were cycling and labeled by a Ki67 antibody (rhodamine) (Scale bars: 50 μm). *(From ref. [76].)*

appears to show considerable heterogeneity.[83] However, the kidney is a transporting organ with a large number of ABC-type transporters expressed in several of its segments including ABCG2, the putative transporter of the Hoechst33342 dye. Hence, the presence of cells that pump the dye out may not be the best marker for progenitor cells.

Another cellular function that has been exploited to isolate putative renal stem/precursor cells is the *aldehyde dehydrogenase activity* (ALDH). This enzyme oxidizes intracellular aldehydes (for a review see Sophos and Vasiliou[86]), and it is believed to have a role in cellular differentiation by its ability to oxidize retinol to retinoic acid.[87] Hematopoietic, neural, and some cancer stem/precuror cells were found to have high ALDH enzymatic activity.[88] Similarly, Lindgren et al.[89] recently isolated from the human kidneys cells with progenitor characteristics. Using an ALDH enzymatic assay in suspensions of renal cortical cells deprived of glomeruli, they separated the cells into $ALDH^{low}$ and $ALDH^{high}$ populations. Interestingly, transcription analysis of the populations showed that one of the most upregulated genes in the $ALDH^{high}$ cells was Cd133, a membrane protein found in some progenitor/stem cells and used to isolate other renal progenitors (see above and the section on podocyte precursors next). *In vitro*, the cells showed some stem/precursor cell characteristics, but of particular interest is their finding by immunohistochemistry that there is a population of Cd133-positive cells scattered through the proximal tubule, clearly showing that there is some heterogeneity in the proximal tubular cells. Analyses of kidney biopsies of patients with acute tubular necrosis showed that in areas of regeneration tubular cells positive for Cd133 in their luminal membrane were frequently found to be also positive for vimentin in their

basolateral membrane. Since tubular epithelial cells expressing vimentin have been observed during the recovery phase of acute kidney injury,[90,91] it is possible that these Cd133- and vimentin-expressing cells might be specialized epithelial precursors.

Podocyte Precursors

It had long been assumed that in adult kidneys podocytes, the specialized epithelial cells that surround the glomerular capillary loops, have extremely low or no cycling activity. Yet, these cells are clearly renewed because they can be captured in the urine of normal subjects.[92] Interest in the origin of podocytes and their life cycle has been spurred by observations that their numbers can decrease during diseases caused by several mutations that disrupt their proteins, leading to glomerular sclerosis (reviewed by D'Agati[93]). In addition, it was recently found that a variable fraction of the cells in the glomerular "crescents" (layers of abnormal cells attached to the Bowman's capsule) often present in glomerulonephritis were found to express nestin.[94] Since normal podocytes express nestin, these results raised the possibility that cells in crescents might derive from podocytes or that podocytes and cells in crescents share a common lineage. Regardless, these interesting observations suggested that both podocyte loss and/or their uncontrolled proliferation might be involved in renal diseases.

Analyzing human kidney sections, Sagrinati et al.[95] found that a subpopulation of the parietal epithelial cells of Bowman's capsule expressed Cd24 and Cd133, two cell surface proteins found in a variety of adult stem cells. Isolation of these cells from glomerular cultures showed them to possess high cloning efficiency and some differentiation potential. In addition, when the cells were intravenously administered to mice with acute kidney injury, there was improvement in the morphological and functional renal response.[95,96] The observation that some epithelial cells in the parietal side of the Bowman's capsule had progenitor characteristics led to the hypothesis that these cells could be podocyte precursors.[97,98] With this in mind, Ronconi et al.[98] analyzed human kidneys sections, and confirmed that a group of cells in the parietal epithelia of the Bowman's capsule expressed Cd133 and Cd24 and that, in contrast, fully differentiated podocytes only expressed proteins used to identify them such as nestin, complement receptor-1, and podocalyxin. Interestingly, they also identified a third cell population that expressed Cd133, Cd24, and podocyte markers, suggesting that it could be a podocyte precursor. Isolation of these three different cell populations by FACS using Cd133, Cd24, and podocalyxin and their culture *in vitro* showed that a cell clone derived from a cell only positive for Cd133 and Cd24 contained cells that expressed both tubular epithelial markers and podocyte markers. In contrast, clones of cells derived from cells positive for Cd133, Cd24 plus podocalyxin only expressed podocyte markers. When these two different types of cells were intravenously administered to mice that had received the podocyte toxin adriamycin, they found that cells only positive for Cd133 and Cd24, but not cells positive for Cd133, Cd24, and podocalyxin, were capable of reducing urinary protein excretion and morphologic damage. Finally, labeling the cells with vital dyes showed that the former, but not the latter, localized to glomeruli. These results were interpreted as indicating that in adult kidney, podocytes derive from a precursor cell population that resides in the parietal epithelium of Bowman's capsule. One might conclude that the study shows heterogeneity in the parietal epithelial cells of Bowman's capsule, and that *in vitro* these cell types express different genes. The mechanism responsible for the functional recovery after cell injection and its significance is harder to define, since the large majority of epithelial cells administered intravenously are likely to lodge into the lung vascular bed.

The hypothesis that parietal epithelial cells might migrate into the glomerular capillaries and differentiate into podocytes was also examined by Appel et al.[97] in a detailed and elegant study. These authors reported that in adult rats, cells that had morphological characteristics of both glomerular parietal epithelial cells and podocytes could be detected by electron microscopy in the glomerular vascular stacks. That these cells could be transitional cells between parietal epithelial cells and podocytes was examined in 10-day-old mice with a variety of approaches. By immune-detection they found that some cells had markers of both parietal epithelial cells and podocytes. Administration of BrdU to young rats for two weeks showed that, while a substantial number of parietal epithelial cells were labeled with BrdU, only $\sim$0.5% of podocytes were labeled. However, as the animals aged, the number of $BrdU^+$ parietal epithelial cells decreased, while that of $BrdU^+$ podocytes increased, suggesting that the latter derived from the former. In a final genetic fate-mapping experiment, these workers generated triple-transgenic mice in which labeling of the parietal epithelial cells and their progeny could be temporarily controlled by doxycycline administration. In 5-day-old and 10-day-old mice they found that the number of podocytes that derived from parietal epithelial cells increased as the animals aged. This elegant study provides strong evidence that podocytes derive from parietal epithelial cells, at least in the young. This is a very exciting result, because even if this process only occurs at very young

ages, understanding of its controlling mechanisms might allow its modulation. An additional conclusion appears also important; it is clear that as our understanding of the homeostasis of the renal cell populations advances, the distinction between embryonic and adult lives is becoming less clear-cut than previously believed (i.e., "development" appears to be a life-long process), a subject to which we return below.

Because a variety of glomerulonephritis types are associated with hyperplasia of Bowman's capsule (a histological finding long ago termed "crescents"), the possibility that unregulated proliferation of a precursor cell could be responsible for their generation was examined. In a study of human kidney biopsies, the hypercellular lesions of crescentic glomerulonephritis were analyzed with antibodies and RT-PCR after laser capture of the lesions.[99] The authors found that these lesions contained three kinds of cells: $Cd133^+$, $Cd24^+$, $podocalyxin^-$ and $nestin^-$ (presumed podocyte precursors), $Cd133^+$, $Cd24^+$, $podocalyxin^+$ and $nestin^+$ (named intermediate cells), and finally, $Cd133^-$, $Cd24^-$ but $podocalyxin^+$ and $nestin^+$ (same profile as that of differentiated podocytes). When the lesions were examined for the presence of proliferating cells with a Ki67 antibody, most of the cells that were cycling were only positive for $Cd133^+$, $Cd24^+$. Further, *in vitro*, $Cd133^+$, $Cd24^+$, $podocalyxin^-$ and $nestin^-$ cells responded robustly to TGFβ induction of extracellular proteins. These results were taken as evidence that generation of glomerular crescents is likely due to proliferation of "podocyte progenitors." In a related experimental study, Smeets et al.[100] induced crescentic glomerulonephritis in triple-transgenic mice in which parietal epithelial cells and their progeny could be labeled by the administration of doxycycline. In these mice, "crescents" could be detected to be positive by enzymatic X-gal staining, strongly suggesting that these cells derived from epithelial cells of the Bowman's capsule. In contrast, podocyte genetic labeling experiments did not show that the cells in the crescents derived from podocytes. These interesting results strongly suggest that some cells in the parietal epithelium of the Bowman's capsule, and not the podocytes, proliferate in response to injury.

However, in a fascinating study, Ding et al.[101] found that deletion of the product of the von Hippel-Lindau gene (*Vhlh*, encoding VHL) specifically in podocytes caused glomerulonephritis with crescent formation. Loss of VHL stabilizes the hypoxia-inducible factor (HIF) α-subunit and activates hypoxia-response genes. Of great interest is their finding that the cells in the crescents were derived from podocytes; this was elegantly shown by laser-capture of the crescents and PCR demonstrating the rearrangement of the genomic DNA induced in the podocytes (a tour de force control experiment which unfortunately is rarely done). In addition, because the gene expression profile revealed induction of *Cxcr4* expression in glomeruli, Ding and co-workers overexpressed this receptor in podocytes; this resulted in podocyte proliferation and glomerulonephritis. This extremely interesting study therefore indicates that under some conditions, podocytes can proliferate, likely by the effect of Cxcl12 (SDF-1) the ligand of Cxcr4, and that their proliferation can lead to "crescent" formation.

Renal Mesenchymal Stem Cells and/or Pericytes

Mesenchymal stem cells (MSC) from the bone marrow were originally characterized by their ability to adhere to culture surfaces and when cultured with appropriate differentiation media, by their differentiation potential into adipocytes, osteoblasts, chondrocytes, and, sometimes, myoblasts. In other organs including the kidneys, MSC identification and characterization remains to be formalized, since they might be a heterogeneous population that expresses a variety of cell surface markers.[5] Nonetheless, there is widespread interest in MSC because, in addition to their differentiation potential, they appear to be present in most if not all organs[4,5] including the kidney,[5,102] and their precise function remains to be defined. They preferentially locate in the perivascular space[4,5] of even large blood vessels such as the aorta and vena cava,[5] and have pericycte-like characteristics.[3] In the kidney, mesangial cells also have MSC-like characteristics,[5] and might be the glomerular cells that express $Cd146^+$ and $Cd133^-$ found by Bruno et al.[103] in glomeruli. Because of their perivascular location and mesenchymal origin, pericytes are difficult to distinguish from MSCs, and how these two cells differ and relate is still poorly-understood. Although true renal pericytes can only be unambiguously identified by their anatomical location surrounding capillary endothelial cells, these cells have been implicated in myofibrobalst generation during renal fibrogenesis,[15] and are discussed in detail below. In organs other than the kidney, pericytes have been found to have MSC-like characteristics,[104] and in the most detailed study to date, perivascular cells from skeletal muscle, bone marrow, and adipose tissue were found to express several pericyte markers, as well as MSC markers and MSC differentiation potential,[4] suggesting that MSC and pericytes might be the same cells in different locations. It has been shown that during tooth growth and in response to injury, pericytes can give rise to MSC, although in the same organ MSC have an additional, pericyte-independent origin,[105] so that lineage analysis between MSC and pericytes is likely to be complex. In the kidney, mesangial cells,

vascular smooth muscle, pericytes, and likely, MSC derive from the *Foxd1* embryonic cellular compartment described above but as stated, the exact relationship among these different cells remains to be defined.

It is currently unknown whether renal pericytes/MSCs generate daughter cells important for normal kidney homeostasis or for repair from injury. However, recent studies showing that pericytes characterized as $Cd73^+$, platelet-derived growth factor $receptor^+$ and smooth muscle actin negative, give rise to myofibroblasts during renal fibrosis[15] have generated a great deal of interest, a finding that we discuss below. However, morphological observations indicating the transient presence of myofibroblasts after transient kidney injury[43,106] suggest that these cells, long studied from a pathogenic perspective, might also be involved in organ repair, a possibility that we believe deserves attention. Regardless, since like other organs, the kidney contains perivascular cells that are pericytes, MSC or their immediate progenitors,[15] their full characterization and role in normal renal homeostasis and if any, in organ repair from injury, would be of great interest.

POTENTIAL SITES HARBORING RENAL STEM CELLS

Given the kidney's anatomical complexity, identification of stem cells within it might be facilitated by focusing on sites that might harbor them. Several strategies are possible to locate candidate sites, but we believe that current evidence already suggests the presence of sites likely to contain stem cells.

Highly Proliferative Regions

Because many adult stem cells are low-cycling (see [37] and [107] for recent reviews), to generate needed new cells they frequently give rise to an immediate progeny that experience several "transit amplifying" (TA) divisions prior to their differentiation. In this way, many new cells can be regenerated from infrequent stem cell cycling. Hence, adult stem cells can be located close to sites of increased cell cycling. Indeed a seminal discovery in this field showed that there was postnatal neurogenesis in the granular zone of the dentate gyrus in the hippocampus,[57] and led to the discovery that the subgranular zone harbored neural stem cells (reviewed in Zhao et al.[108]). Hence, proliferative regions during normal homeostasis or after kidney injury are good candidates to harbor renal stem cells.

After nephrogenesis is completed in young rats and during normal homeostasis, it was found that the S3 segment of the proximal tubule displayed high cycling activity[25,28]: over a two-week period in 4-week-old rats, 90% of the cells of the S3 segment had cycled, a remarkable rate of proliferation. While this may reflect morphogenetic requirements of a growing kidney, the high proliferative capacity of these cells raises the possibility that they could be "transit amplifying" daughter cells of a proximal tubule stem cell. Other findings support that the S3 segment of the proximal tubule might contain stem cells. Shortly after several types of kidney injury, high proliferation activity was particularly prominent in cells from the S3 segment.[25,42,43] Moreover, Gupta et al.[62] found cells in the cortico–medullary junction which expressed Oct-4 and had progenitor characteristics, and Kitamura et al.[63] isolated a highly proliferative cell type from the S3 segment of rat kidneys that, at least *in vitro*, also expressed precursor cell markers. Whether these putative stem cells relate to the recently described podocyte precursor (see above) or renal proximal tubule progenitors[95] remains to be determined.

The S3 segment of the proximal tubule is of additional interest as a potential site to harbor renal stem cells, because indirect determinations of oxygen tension have shown that this part of the nephron surprisingly exists in a hypoxic environment quite different from other parts of the kidney cortex.[109] A low oxygen tension is characteristic of sites where stem cells in other organs reside, a subject that we discuss below.

To determine whether the adult kidney contained regions of increased cell proliferation, we used kidneys of one-year-old rats, because we reasoned that fully grown older animals would not have proliferating cells needed for organ growth. We found cycling cells by staining for Ki67, a marker of cellular proliferation.[24] As shown in Figure 29.1, Ki67-positive cells were rare in the cortex and medulla, and were solitary and of a similar frequency (~1 % of the total cells). In contrast, the papilla showed marked heterogeneity in its abundance of Ki67-positive cells; they were extremely rare in its tip and middle part (~0.1 %), but were readily apparent in the upper part of the peripheral papilla, adjacent to the urinary space (US) where the kidney parenchyma forms a narrow angle which provides an easily identifiable landmark and the papilla meets the medulla; it is also very close to the kidney cortex. In this region, and unlike other areas of the kidney, Ki67-positive cells frequently formed chain-like structures and accounted for ~2.5 % of the total cells, a significant difference from other parts of the kidney. When cellular proliferation was assayed 24 hours after labeling cells in S-phase by administration of a single dose of BrdU, proliferating cells were very rarely detected in the cortex and medulla but again, the lateral part of the upper papilla consistently contained cycling cells; i.e.,

BrdU-labeled (not shown). We also obtained similar results in kidney of six-month-old rats.

Interestingly, after acute kidney injury, the lateral part of the upper papilla is also the site in which we first detected the increased cell cycling that follows injury; rats were subjected to 45 minutes of unilateral kidney ischemia, following which were given a single dose of BrdU and sacrificed one hour later. Thus, only cells that were in S-phase during this hour could be labeled, and using 5 μm kidney sections, we saw only equally rare labeled cells in normal kidneys or in the kidneys subjected to ischemia. However, examination of 100 μm vibratome sections showed abundant cells in S-phase in the upper papilla (Figure 29.3), next to the urinary space (US) only in the kidneys subjected to ischemia. In the aggregate, these results indicate that the lateral upper part of the kidney papilla contains more proliferating cells than other parts of the kidney under normal conditions, and that it contains the first cells that start cycling in response to transient injury. As reviewed above, Vinsonneau et al.[45] found that the first intrarenal area that contains Ki67 positive cells after ischemia reperfusion injury was the uro-epithelium and adjacent interstitial space in the upper part of the urinary space at the papilla–medullary junction.

In sum, because of their proliferative behavior, both under homeostatic conditions and during repair from several types of kidney injury, the S3 segment of the proximal tubule and the lateral part of the upper papilla are domains of the kidney where stem cells appear likely to reside.

Stem Cell "Niches"

Adult stem cells receive critical signaling from their immediate microenvironment, a domain that is distinct from the rest of the organ (see Morrison and Spradling[110] for a review). In these locations (referred to as "niches"), stem cells interact with other cells and the extracellular matrix, a process that is best understood in the *Drosophila* germline stem cells (see Fuller and Spradling for a review[111]). The stem cell "niche" provides positional information that regulates both proliferation activity and cell fate identity, and in fact it can even redirect cell fate similar to what often happens during embryogenesis.[112] While characterization of mammalian stem cell niches is still very limited, some common motifs are emerging that might be useful to identify the location of renal stem cells. Among those, a hypoxic environment is a prominent characteristic. Several organ-specific stem cells such as hematopoietic stem cells[113–115] and neural stem cells[116] reside in hypoxic regions, and a large body of *in vitro* work has shown the critical role of oxygen on stem cell regulation (see Mohyeldin et al.[117] for a review). Moreover, in both hematopoietic stem cells and neural stem cells, it was recently found that regulation of the oxygen-sensitive gene *HIF-1α* is critical for the cells' maintenance and fate decisions.[114–116,118]

The kidney parenchyma possesses steep oxygen gradients,[119] and variations in renal oxygenation are undoubtedly sensed as they regulate erythropoietin synthesis. While direct determinations of oxygen tension in the kidney papilla have not been reported, it is likely that papillary pO_2 ranges are ~4–10 mmHg.[119] The presence of low-cycling cells in this very hypoxic environment[24,39,73,120] and that many of these cells express nestin,[24] an intermediate filament protein identified in a variety of progenitor/stem cells,[76] suggests that the papilla harbors renal stem cells. Interestingly, using a nestin-GFP-expressing mouse,[75] nestin$^+$ cells were detected in large clusters within the papilla, along the *vasa rectae* and, at least *in vitro*, these papillary nesting-expressing cells were found to migrate upwards in the papilla towards the cortex, an observation compatible with our *in vivo* experiments with vital dyes in which we found upward migration of papillary cells, some of which were "label-retaining cells".[24]

Several other findings also suggest that the kidney papilla is a niche for renal stem/precursor cells. Dekel and co-workers[61] isolated a population of purportedly renal stem cells from the renal interstitium that expressed the stem cell antigen-1 (Sca-1) and were enriched for β1-integrin; when the cells were located *in vivo*, they were found to be particularly abundant in the renal papilla. Using a different approach, Lee et al.[64] identified a renal interstitial cell that expressed several potential renal progenitor cell markers, such as *Oct-4*, *Pax-2*, *Wnt-4*, and *WT-1*. *In vivo*, Oct-4$^+$ cells were located in the medulla as well as in the papilla, leading these authors to suggest that the interstitium in these regions of the kidney is a "niche" for renal stem cells. Finally, and with a very different approach, Curtis et al.[121] examined whether cells from different regions of the kidneys were equally capable of contributing to cell regeneration after acute kidney injury. These workers isolated from mice constitutively expressing β-galactosidase in certain cells from the kidney cortex, medulla or papilla, and implanted them under the capsule of kidneys subjected to ischemia-reperfusion injury. Seven days later, implanted cells deriving from the three different regions of the kidney could be detected in the tubules of the renal medulla, but cells obtained from the papilla exhibited the most robust engraftment. These results suggest that cells deriving from all regions of the kidney might contribute to the reparative response of the organ after injury, and that some cells in the papilla are particularly capable of contributing to repair and might be stem cells.

RENAL STEM CELLS IN NON-MAMMALS

Renal Progenitors in Fish

Unlike mammals, fish appear to be capable of generating new nephrons during adult life, and their kidneys possess a clearly identifiable "nephrogenic zone".[122] This zone decreases in volume as the animal ages, likely because the nephron number increases with age.[123] In addition and of great interest, the nephrogenic zone can be stimulated in adult fish. For example, in the little skate the cellular proliferation and morphological complexity of the zone increased after partial nephrectomy,[122] a process that resembled embryonic nephrogenesis in mammals. While this morphological response strongly suggests *de novo* generation of nephrons, confirmation that new and functional nephrons developed remains to be established. Following acute kidney injury due to gentamicin, zebrafish can regenerate their nephrons, a process that starts shortly after injury with expression of *wt1b* (the zebrafish homolog of *Wilm's Tumor 1*) in individually dispersed cells of the mesonephric interstitium.[123]

These studies suggest that the fish could be a useful model to explore mechanisms of kidney repair where one can derive information that might facilitate identification of mammalian adult renal stem cells. Indeed, in a recent elegant study, Diep et al.[124] used zebrafish to search for potential nephron precursor cells. They reasoned that if adult kidney contains nephron progenitors these cells could be transplanted. They induced acute kidney injury by gentamicin administration, and performed a series of transplant experiments using cells from transgenic fish expressing reporters such as EGFP or Cherry with *cdh17*, thereby locating the fluorescent reporters in the distal nephron. When they injected unpurified whole kidney marrow cells (5×10^2 cells), mostly comprised of non-tubular interstitial cells, they found that the donor cells generated new nephrons in the host in 100% of the cases (Figure 29.7). Nephron number increased with time after injection and at later times, donor-derived nephrons were found at sites distal from the injection site, indicating that the cells migrated. Importantly, they found that these donor-generated nephrons connected to the host renal tubules and to the host's circulation, as shown by the fact that they could filter fluorescent dextran. Because in cell transplantation experiments it is frequently impossible to be certain that fusion of donor and recipient cells did not occur, to exclude this possibility Diep et al.[124] injected Cherry labeled cells into EGFP recipients and found that all engrafted nephrons were Cherry$^+$ and EGFP negative, indicating that cell-to-cell fusion did not take place. To identify the cells responsible for the genesis of new nephrons, the authors examined the zebrafish homologs of transcription factors know to be expressed in the mammalian renal vesicles (the precursors of the nephron). They found that kidneys from adult zebrafish transgenics expressing *lhx1:EFGP* (the homolog of Lh1/Lim 1[125,126]) contained ~100 aggregates of ~30 EGFP$^+$ cells per kidney. Examination of the evolution of these aggregates showed that they emerged from the assembly of ~3-4*lhx1:EFGP*$^+$ cells that expanded to form a renal vesicle (expressing *wt1b*, the homolog of mammalian *WT1*), which in turn elongated into a nephron. Interestingly, laser ablation of a single aggregate of *lhx1:EFGP*$^+$ cells prevented nephron formation without affecting neighboring nephrons, indicating that *lhx1:EFGP*$^+$ cells are required for nephrogenesis. However, transplantation of single *lhx1:EGFP*$^+$ cells to conditioned hosts failed to engraft, but transplantation of aggregates of *lhx1:EFGP*$^+$ cells generated nephrons. Thus, *lhx1:EFGP*$^+$ aggregates contain nephron progenitors and several cells are needed to generate a nephron. Whether the cell aggregates are clonal or contain several nephron progenitors with more restrictive differentiation potential is unclear. Nonetheless, demonstration in adult zebrafish of nephron progenitors capable of kidney regeneration and identification of their "genetic signature" is likely to facilitate design of new studies searching for renal stem cells in adult mammalian kidney.

Renal Progenitors in Invertebrates

The nephron is the basic structure of the vertebrate kidney, but many insects have tubular excretory systems with "nephron-like" features, suggesting that at least some components of the vertebrate kidneys derive from invertebrate ancestors. In addition, to regulate the composition of hemolymph, *Drosophila* has filtration cells that possess fly orthologs of the major components of the slit diaphragm, indicating that these cells are podocyte-like.[127] The similarity of the fly's excretory system to that of the nephron in vertebrates suggests that analysis of renal stem cells in *Drosophila* might be of considerable interest. Indeed, Singh et al.[128] used lineage tracing, molecular marking analysis, and BrdU incorporation to follow the fate of the different cells in the Malpigian tubules of adult flies. These tubules contain four types of cells, and Singh et al.[128] found that one type of cell was multipotent and could generate all the cell types of the Malpigian tubules of adult flies, indicating that they are renal stem cells. Singh et al. additionally found that autocrine JAK-STAT signaling in the renal stem cells regulated their renewal, and absence of signaling promoted their differentiation with loss of the stem cell

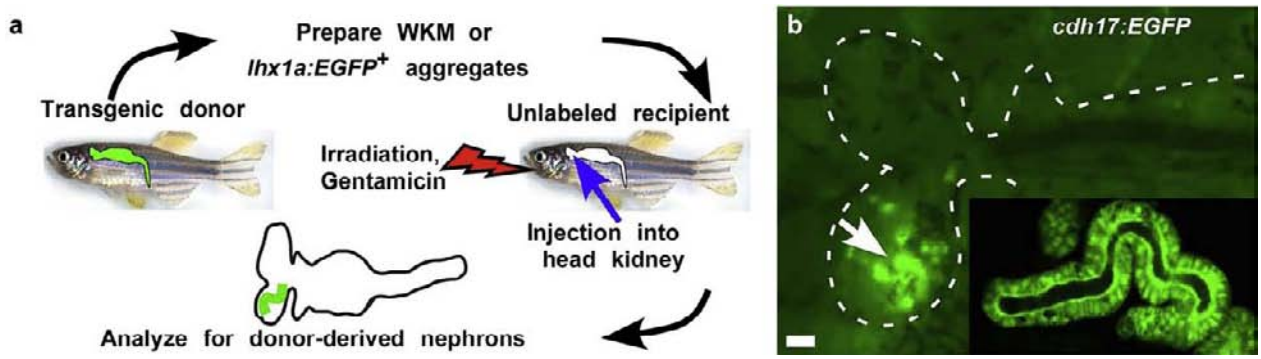

FIGURE 29.7 **The kidney of the adult zebrafish contains progenitor cells that generate new nephrons.** (a) Transplantation assay. Whole kidney marrow cells mostly comprising interstitial cells were isolated from genetically labeled donors. (b) Injection of the cells into recipients with damaged nephrons due to genatmicin injection resulted in donor-derived nephrons. *(From ref. [127].)*

population. Of great interest was their additional finding that these stem cells are present in the lower tubules and ureters, very much resembling the initial location of the nephron precursors recently identified in zebrafish,[124] and raising the possibility that the sharp distinction currently being made in mammalian adult kidneys between collecting ducts and the rest of the nephron might require re-evaluation. Also remarkable is that these stem cells are a large fraction of the total number of cells of the Malpighian tubules, rather than the anticipated small minority, another characteristic worth noting for workers on the renal stem field.

NEW CELLS IN DISEASED KIDNEYS

Renal Fibroblast and Myofibroblasts

In addition to dendritic cells, the normal adult kidney contains a network of interstitial fibroblasts and other cells that remain poorly-characterized, as they are technically difficult to detect and there is no general agreement on markers that identify them.[1] However, during many kidney diseases the renal interstitial compartment changes dramatically, with a marked increase in the number of renal fibroblasts and the invasion of the interstitium by a new type of cell called a myofibroblast. Myofibroblasts have fibroblast-like characteristics, but also express α smooth muscle actin (αSMA), and are believed to have great migratory capacity. It is currently thought that the marked proliferation of fibroblasts and myofibroblasts plus the expansion of their secreted extracellular matrix, i.e., renal fibrogenesis, is itself pathogenic as it disrupts the normal renal architecture and is the final common pathway of many kidney diseases. Indeed, expansion of the fibroblast and myofibroblast populations and the extracellular matrix are tightly correlated with the slow and inexorable progressive loss-of-function that characterizes many kidney diseases. There is thus great interest in the mechanisms responsible for appearance of these cells during diseases.

Several possibilities have attracted attention. First, the cells might derive from resident renal interstitial "fibroblasts." In this view, the disease process induces fibroblast proliferation and in some of them, a change in their phenotype that results in expression of αSMA. Detailed morphological studies suggest that at least in some forms of renal fibrosis, such as that due to unilateral ureteral obstruction (UUO), this is likely the case.[129] More recent genetic cell fate tracing studies by Humphreys et al.[15] have suggested that myofibroblasts after unilateral ureteral obstruction (UUO) or after acute ischemic kidney injury derive from interstitial cells that are likely pericytes, since they were positive for Cd73 and platelet-derived growth factor receptor β (PGDFR β). Interestingly, pericyte differentiation and proliferation appears to be dependent on endothelial cell action, since blockade of their VEGF receptor 2 attenuates the fibrogenic process.[22] However, while Cd73 and PGDFR β appear to be present in most pericytes, there is no definitive marker profile for these cells, as they can only be unambiguously identified by their location around capillary endothelium. Moreover, new studies have shown that most, if not all, organs possess a population of perivascular mesenchymal stem cells,[4,5] and the distinction between these cells and pericytes is poorly-understood (see Corselli et al.[130] for a review). Hence, whether myofibroblasts solely derive from resident interstitial fibroblasts, pericytes, mesenchymal stem cells or from a combination of these cells remains to be clarified, and must await a detailed characterization of these three interstitial cell types.

Another possibility is that myofibroblasts could derive from bone marrow mesenchymal stem cells

(MSC); i.e., cells characterized by their ability to differentiate into adipocytes, osteoblasts, chondrocytes, and, sometimes, myoblasts. While Iwano et al.[131] found a small number of bone marrow-derived fibroblasts in the renal interstitium, little additional evidence has been obtained to support that bone marrow precursor cells could be the origin of the myofibroblasts.

Another possible origin of the renal fibroblasts and myofibroblasts found in kidney diseases is that they derive from renal epithelial cells by epithelial-mesenchymal transition (EMT), a process in which epithelial cells lose the ability to maintain close contacts with their neighbors as well as apico–basal polarity, and instead develop a mesenchymal phenotype that includes migratory capacity. The process of EMT is of course widely used during embryogenesis and in some disease processes, particularly cancer (for a recent review see Thiery et al.[132]). It is of great interest that in nonrenal cells, it has been found that EMT might generate cells with the properties of stem cells,[133] but this possibility appears not to have been examined in the kidney.

There is little doubt, at least *in vitro*, that epithelial cells from both embryonic[134] and adult kidneys[15,135] can undergo EMT. However, there is currently a debate whether this process might generate fibroblasts and myofibroblasts *in vivo* (see Kapus and Quaggin[136] and Kriz et al.[137] for informed discussions). Morphological and cell marker studies during renal fibrosis have provided some evidence supporting EMT *in vivo*, both in experimental models[90,138–142] and in human diseases,[90,91,143,144] but other studies have failed to support this.[129,145] The most robust method currently to determine whether myofibroblasts might derive from renal epithelial cells is based on studies using genetic cell fate analysis. In these studies epithelial cells are genetically labeled so that their progeny (e.g., fibroblasts or myofibroblasts) can be easily identified. Using the UUO model of renal fibrogenesis, Iwano et al.[131] found that a substantial number of renal fibroblasts derived from renal epithelial cells. However, three subsequent studies with UUO plus other models of renal fibrogenesis and using different epithelial genes to drive Cre recombinase and label epithelial cells in reporter mice found no evidence that renal fibroblasts and myofibroblasts derived from epithelial cells.[15,146,147] There is currently no clear explanation for these conflicting results, and it is apparent that additional studies are needed.

Finally, another potential origin of renal fibroblasts and myofibroblasts are endothelial cells. Genetic cell fate experiments have shown that Cre recombinase driven by Tie2 (a tyrosine kinase receptor believed to be endothelial-specific in the adult) identified a reporter gene in renal fibroblasts in UUO and streptozotocin-induced renal fibrogenesis.[148,149] This unexpected result is of particular interest, because adult endothelial cells have been shown to have the capacity to transform into mesenchymal stem-like cells by activation of activin-like kinase-2,[153] and two ligands well-known to be involved in renal fibrogenesis, TGFβ and BMP4, phosphorylated activin-like kinase-2 and induced a mesenchymal phenotype in cultured endothelial cells.[150]

This brief survey shows that the precise origin of the renal fibroblasts and myofibroblasts during renal diseases remains undefined, and given the medical importance of this issue additional studies are needed. Needless to say, it is also likely that these cells might have more than one origin. While studies based on morphology and/or cell identification by cell-specific markers offer at best indirect evidence, genetic-based cell lineage tracing experiments have their own potential pitfalls (see the review by Matthaei[151]). In particular, two potential problems might complicate their interpretation. The first is that it is assumed that the reporter gene is expressed in all cells and for the duration of the animal's life, as well as during the disease process. Definitive proof of this is lacking and, for example, in the adult kidney, the robustness of the reporter expression in the *Rosa26* locus (frequently used to introduce the reporter gene) was found to be less than anticipated ([152] and our unpublished results). In addition, cell fate-mapping studies can give markedly different results depending on the genetic construct of the reporter.[153] The second, and potentially more confounding, problem in the interpretation of genetic cell-fate analyses is that the gene used to activate the reporter gene is chosen because of its restricted expression to a specific cell type during embryogenesis, and lack of expression during adult life and after injury, when the analysis is done. However, the possibility that the gene is activated later in life or by the disease process in a small number of cells might be very difficult to detect.

KIDNEY REPAIR BY EXOGENOUS STEM/PRECURSOR CELLS

While analysis of the kidney's ability to repair from injury has naturally focused on the intrinsic renal cell population, reports that cells derived from the bone marrow could generate new renal cells and perhaps contribute to organ repair generated a great deal of interest.[154–157] However, subsequent studies have firmly established that most if not all the new cells generated after kidney injury derived from other renal cells.[29,30] Nonetheless, and stimulated from work in other organs, the possibility that exogenous cells might

either facilitate kidney repair or diminish the consequences of injury has been examined in multiple studies. Indeed, clinical trials with bone marrow-derived MSC are already underway or in planned stages in a variety of diseases, particularly for myocardial infarction, but also including the kidney (http://www3.niddk.nih.gov/fund/other/akiworkshop/). In experimental animals, the potential therapeutic effect of several cell types in acute kidney injury has been examined under a variety of protocols.

Mesenchymal Stem Cells (MSC)

When HSC and bone marrow-derived MSC were administered to mice it was found that the latter, but not the former, protected the animals from the functional consequences of acute kidney injury due to cisplatin.[156] Multiple studies have confirmed that extrarenal MSC can either diminish the functional consequences of acute kidney injury or accelerate recovery of kidney function after injury. In addition to MSC derived from the bone marrow,[23,158–161] MSC from human cord blood[162] or even the kidney[163] have been shown to be effective. In these studies, acute kidney injury was induced by several methods and the cells were administered through a variety of routes: intravenously, intra-arterially and by direct intrarenal injection.

What are the potential mechanisms by which exogenous MSC might protect the kidney from injury or facilitate its repair? Although initial observations suggested incorporation of the cells into the renal parenchyma,[156] more recent studies have shown that their mechanism of action is likely to be that the cells provide endocrine/paracrine factors, perhaps growth factors[23,161,164] or chemokines such as IL10.[161] In this view, the mechanism of action of the MSC would be similar to that of directly delivering growth factors in transient kidney injury (reviewed by Hammerman and Miller[165]). Unfortunately, very little information is available on the identity of these beneficial factors, and whether MSC are more or less effective than isolated growth factors alone.

Another possible mechanism is that the transplanted MSC might modulate the host immune response by effects on macrophages,[166,167] dendritic cells,[168,169] T-cells[168] or B-cells.[170] Given the complexity of the kidney's response to the insults used to induce functional acute renal failure, it is apparent that there might be multiple mechanisms whereby exogenous cells could protect this organ from injury or facilitate its repair. An additional problem complicating analysis of these studies is that because MSC are identified *a posteriori* (based on a variety of characteristics such as high proliferation capacity and ability to differentiate into several mesenchymal lineages) there are no strict identification criteria for the administered cells, making comparison across studies extremely difficult.

Regardless, given the clinical severity and epidemiological importance of acute kidney failure, the finding that MSC can improve its evolution is of extreme interest, and studies that illuminate their mechanisms of action are urgently needed. Work in other organs has begun to provide answers. In an elegant study in myocardial repair from ischemic myocardial infarction, Lee et al.[171] found that human MSC (hMSC) administered intravenously acutely embolized into the lungs where they upregulated multiple genes, including the anti-inflamatory protein TSG-6 (the product of tumor necrosis factor-stimulated gene 6). Similar to the observations in kidney injury, the injected hMSC reduced the myocardial inflammatory response to ischemia, decreased infarct size, and improved myocardial function. Administration of recombinant TSG-6 had similar effects as hMSC, but hMSC that were transduced with TSG-6 siRNA did not. This interesting study provides a detailed mechanistic explanation of why hMSC facilitate myocardial repair without engraftment into the organ, and opens new therapeutic avenues for research.

Other Bone Marrow-Derived Cells

Earlier experiments with bone marrow-derived stem cells (other than MSC) suggested that they could ameliorate the functional consequences of transient acute kidney injury.[154] While the possibility that these cells exerted this effect by generating significant numbers of renal epithelia cells has been ruled out,[29,30] their mechanism of action remains unexplained and little explored. Lie et al.[172] used human $Cd34^+$ hematopoietic stem/progenitor cells isolated from peripheral blood after granulocyte colony stimulating factor mobilization, and injected them into mice. They found that, whereas the cells did not localize to normal kidneys, they did so in injured kidneys. Moreover, administration of the cells increased cellular proliferation in the injured kidneys, accelerated kidney functional recovery, and increased animal survival. The exact mechanism(s) whereby these cells exerted these effects remain to be determined, and many possibilities exist. For example, in the heart where bone marrow-derived cells also had significant regenerative effects, their action appears to be mediated by resident cardiac stem cells. In a model of myocardial infarction by coronary ligation, Loffredo et al.[173] administered a population of purified $c\text{-}kit^+$ bone marrow-derived cells and found that they stimulated endogenous cardiomyocite progenitors. These progenitors are capable of differentiating into several cell types, including cardiac muscle cells, and their stimulation resulted in improved

cardiac repair and enhanced function. In contrast, MSC were unable to stimulate endogenous myocardial progenitors.

Kidney Cells

A variety of studies have examined whether administration of cells derived from the kidney might facilitate this organ's repair from injury. All the cells used in these studies possess some "precursor/stem" characteristics, but were poorly-characterized and even their exact *in vivo* location is somewhat uncertain. Administration of cells derived from the S3 segment of the proximal tubule had no effect on the functional response to acute kidney injury due to ischemia-reperfusion.[62,63] However, when the kidney was injured by cisplatin, subcapsular transplantation of the cells facilitated kidney functional recovery.[174]

Several studies have used cells from the kidney that were captured by their expression of Cd24 and Cd133, either from embryonic kidney[175] or adult kidneys.[95,96] In these studies, intravenous administration of the cells facilitated kidney functional recovery from rhabdomyolysis induced by glycerol administration. Lee et al.[64] used a renal interstitial cell population expressing *Oct4*, *Pax2*, *Wnt 4*, and *WT1* (discussed above), and found that intrarenal injection of the cells markedly blunted the functional consequences of kidney injury from transient ischemia.

What is to be concluded form these experiments with exogenous cells? That the administration of MSC might improve the kidney's functional response to injury appears well-established; however, that of other bone marrow cells or renal-derived cells appears to be less robust. Significant problems in many of these studies include: (1) poor characterization of the cell population used; (2) less than ideal monitoring of the kidney functional response, notoriously difficult to do in mice; and (3) lack of analysis of where the majority of the injected cells locate. Most cells injected into the renal artery are retained by glomeruli[176] and the vast majority of intravenously injected cells remain in the lungs.[171] The recent discovery that under specific culture conditions, MSC reduce their size such that when they are injected intravenously they can cross the pulmonary circulation[166] is a finding that may allow the systemic delivery of MSC to the kidney. It is of course possible that injected cells that locate at sites other than the kidney might be responsible for the observed beneficial effects on renal function. Regardless of the location and potential mechanism of action of the injected cells, these initial results suggesting that exogenous cell therapy might be beneficial in acute kidney injury need confirmation and further analysis.

CONCLUDING REMARKS

Whether the adult mammalian kidney contains stem cells that self-renew and are pluripotent is currently unknown. However, given its multiple cell types and by analogy with other organs, it is very likely that renal stem cells might indeed be present. In contrast to the mammalian kidney, it is established that the Malpighian tubule of *Drosophila* contains true stem cells, and that the zebrafish kidney can be regenerated from a small number of specialized epithelial precursor cells, strongly suggesting that it also contains stem cells. Most work searching for a renal stem cell has focused on the epithelial cellular compartment, likely because of its understood important functional role and the relative ease with which it can be identified. However, the adult kidney also contains an abundant population of interstitial cells that are just now beginning to be understood; the discovery that the transcription factor *Foxd1* (*Bcl2*) is expressed during embryonic development in many of these cells has provided an important new research tool that should illuminate their role.

While *bona fide* adult stem cells in the mammalian kidney remain to be identified, several observations suggest that some stem/precursor cells exist in several locations. Perhaps the best evidence that a specialized precursor exists is in the glomerular podocytes, although it also appears likely that, at least under pathological conditions, podocytes themselves can generate other cell types. Perhaps podocytes are not solely terminally-differentiated cells, but can give rise to other cell progeny. A surprisingly variable cell identity was recently discovered in some of the progeny of hair follicle stem cells; these daughter cells were found to return to the stem cell niche and serve as future stem cells.[177]

Confirming classical morphological observations, new genetic cell lineage tracing experiments have provided strong evidence that after acute kidney injury epithelial cells give rise to new epithelia cells, but it remains unclear whether there exist distinct epithelial stem/precursor cells. In fact, multiple observations are compatible with the presence of specialized epithelial progenitors/stem cells in the S3 segment of the proximal tubule. Is it possible that some of the conflicting results could be explained by the presence of two types of stem/precursor cells: one that normally divides to provide new cells during homeostatic conditions and a low-cycling stem cell that is activated during organ repair, as appears to be the case in other organs (see Fuchs[68] and Li and Clevers[107] for reviews)?

Finally, several lines of evidence strongly suggest that the kidney papilla is a "niche" for renal stem cells. This very hypoxic part of the kidney contains many

low-cycling cells (identified as "label-retaining cells") that slowly disappear as the animal ages, and that after acute kidney injury quickly start cycling and markedly decrease in number after repair. While *in vitro* characterization of these cells has shown them to have many properties of stem/precursor cells, no array of specific cell markers can yet identify them, so that their identity and the identity of their progeny remains to be defined. It is our hope that genetic cell lineage analysis will allow us to answer these questions.

INTRODUCTION

From the late distal convoluted tubule, connecting tubule, and throughout the collecting duct, Na^+ exits the urinary space by passive diffusion through an apical membrane epithelial Na^+ channel, referred to as ENaC. Na^+ exits cells across basolateral membranes via the Na^+,K^+-ATPase. Koefoed-Johnson and Ussing initially proposed this model of electrogenic transepithelial Na^+ transport, with diffusion of Na^+ across an apical membrane conductance pathway, in 1958.[1] Studies using both noise analysis and single channel recordings demonstrated the presence of apical membrane Na^+ selective ion channels.[2–4] Subsequent to the cloning of ENaC, knockout studies have confirmed the role of ENaC in the reabsorption of filtered Na^+ in the distal nephron, as well as its role in facilitating renal K^+ secretion.[5–7]

Electrophysiologic Characteristics

The basic electrophysiologic characteristics of epithelial Na^+ channels have been defined using both macroscopic and single channel studies, and are presented in Figure 30.1. ENaCs are Na^+- and Li^+-permeable channels that exhibit negligible K^+ conductance, with a single channel conductance of 4 to 5 pS at room temperature with Na^+ as the charge carrier.[3,8,9] These channels exhibit a slight increase in open probability under hyperpolarizing membrane potentials.[10,11] ENaCs characteristically exhibit long open and closed times, in the order of seconds to tens of seconds, although a population of ENaCs has been described that has brief open times and long closed times that likely represent channels that have not been processed by proteases.[11–13] Channels are blocked by submicromolar concentrations of amiloride, a pyrazinoylguanidine derivative.[14,15] Amiloride is a weak base and has a pK_a of 8.8 in water. It is the charged, or protonated, form of amiloride that blocks ENaC.[15] Other organic weak bases, including triamterene, trimethoprim, and pentamidine also inhibit ENaC.[16–19]

Biochemical and Molecular Characteristics of ENaC

Amiloride was first demonstrated to inhibit electrogenic transepithelial Na^+ transport in 1968.[14] With an IC_{50} of ~100 nM, amiloride and several related compounds proved to be highly selective Na^+ channel inhibitors.[15] Prior to the cloning of ENaC subunits, several different approaches were used to isolate a Na^+ channel complex.[20–22] The relationship of this channel complex to ENaC is still unclear, although antibodies raised against a subunit of the cloned Na^+ channel have been observed to recognize a polypeptide within the purified channel complex.[23]

The molecular characteristics of this channel were elucidated in studies from Canessa and co-workers and Lingueglia and co-workers in 1993 and 1994.[9,24–26] An expression cloning technique led to the identification of a cDNA, termed α ENaC, whose cRNA induced expression of amiloride-sensitive Na^+ currents when injected into *Xenopus* oocytes.[24,25] However, Na^+ currents were lower than expected. Two subsequent cDNA clones were isolated based on their ability to complement α ENaC cRNA in the expression of amiloride-sensitive Na^+ currents in *Xenopus* oocytes, and were termed β and γ ENaC.[9] *Xenopus* oocytes coinjected with the three cRNA species expressed amiloride-sensitive Na^+ channels with characteristics nearly identical to that of Na^+ channels expressed in renal

cortical collecting tubules and in cultured cell lines derived from the distal nephron. Na^+ currents were not observed when either the β- or γ-subunits were expressed alone.

The three ENaC subunits are likely derived from a common ancestral gene, given their limited (~30 to 40%) sequence identity. ENaC subunits have been cloned from a variety of species, including rat, human, mouse, rabbit, guinea pig, chicken, cattle, sheep, salamander, clawed African frog (*Xenopus laevis*), and bullfrog.[9,24–34] The human α-subunit gene *Scnn1a* spans 17 kb on human chromosome 12p13. The β- and γ-subunit genes *Scnn1b* and *Scnn1g* are closely linked on human chromosome 16p12-p13.[35,36] The genes encoding the three ENaC subunits have a conserved exon–intron architecture, with 13 exons.[37,38] Splice variants have been described that alter the cytoplasmic N-termini or alter the extracellular domains.[39–41] Variants that result in a termination codon in the region coding the extracellular domain of the α-subunit have also been reported.[41–43] Some of these variants are associated with a reduction or loss of channel activity when expressed in heterologous systems, and with an autosomal recessive loss of function phenotype (pseudohypoaldosteronism) in humans.[42]

ENaC/Degenerin Gene Family

Canessa and co-workers noted that ENaC subunits were related to genes identified in *Caenorhabditis elegans* that participate in mechanosensation specific mutations of which result in degeneration of selected neurons.[44–46] ENaCs belong to the ENaC/Degenerin gene family (Figure 30.2). There are two additional ENaC subunits, referred to as δ and ε, that appear to be functionally related to the α-subunit. δ ENaC is a proton-activated channel expressed in primates, although its physiologic role is still unclear.[47,48] The ε-subunit was identified in *Xenopus*, and has an altered Na^+ self-inhibition response suggesting altered gating properties.[49] Members of this family also include genes identified in *C. elegans* that are involved in mechanosensation (*mecs* and *degs*) or control of defecation rhythm (*flrs*);

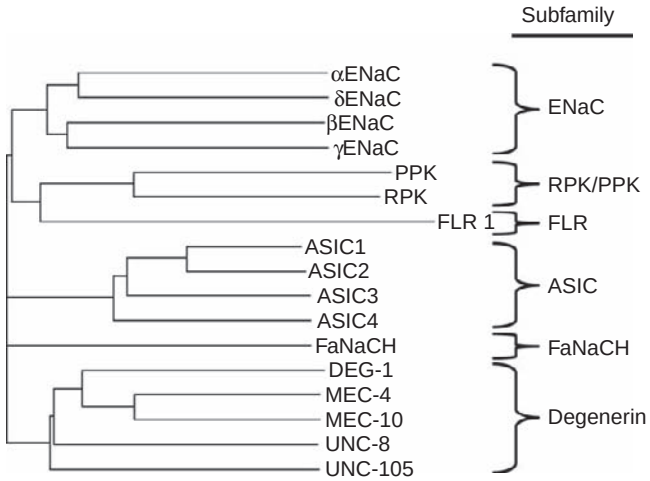

FIGURE 30.2 **Phylogenetic tree of the ENaC/DEG superfamily.** Family members are grouped into six subfamilies: ENaCs: RPK (ripped pocket)/PPK (pickpocket), expressed in *Drosophila*; FLR: expressed in *C. elegans*; ASICs or acid-sensing ion channels; FaNaCh: a peptide-gated channel expressed in marine snails; and degenerins: expressed in *C. elegans*.

H^+-gated channels (referred to as acid-sensing ion channels (or ASICs)) that are expressed in mammalian central and peripheral nervous systems and have a role in nociception, mechanosensation, fear-related behavior, and seizure termination;[50–55] a family of 16 genes expressed in *Drosophila*, referred to as pickpocket, that may have roles in airway fluid clearance, mechanosensation, salt sensation, and detection of pheromones;[56–61] and peptide-gated channels expressed in marine snails.[62–64]

Structure and Function of ENaC

Each ENaC subunit has only two predicted membrane spanning domains, similar to the topology of members of the Kir family of K^+ channels, and members of the P2X family of purinergic receptors that are ligand-gated ion channels[65,66] (Figure 30.3). Three independent groups published topologic analyses of ENaC subunits.[67,68] Each subunit has intracellular amino and carboxyl termini and two α helical membrane spanning domains connected by a large extracellular domain. The cytoplasmic domains have kinase phosphorylation sites, as well as protein–protein and protein–lipid interaction motifs that affect channel gating or trafficking.

Jasti and colleagues resolved the crystal structure of ASIC1, a member of the ENaC/Degenerin family.[69,70] Although initially lacking the N- and C-terminal cytoplasmic regions, this structure provided important insights into the structural organization of ASIC and related family members, including ENaC. ASIC1 is a trimer, suggesting that ENaC has a subunit stoichiometry of α1β1γ1, in contrast to the higher ordered stoichiometry that had been proposed based on biophysical and biochemical studies.[71–74] The extracellular region is a highly ordered structure that resembles an outstretched hand containing a ball, and has clearly defined domains termed wrist, finger, thumb, palm, knuckle, and β-ball[69] (see Figure 30.3). Jasti et al. suggested that ASIC1 proton-dependent gating occurs in conjunction with conformational changes within the thumb and finger domains, which are transmitted to the transmembrane domains.[69] The three ENaC subunits contribute residues that line the channel's pore. The resolved ASIC1 structure suggests that the channel's gate resides in the outer part of the pore,[70,75] in the vicinity of the "degenerin" site where the introduction of bulky residues in: (1) ENaC subunits; (2) mec4 or mec10 (a component of the mechanosensitive channel in *C. elegans*); and (3) ASIC subunits result in a dramatic increase in channel open probability.[46,76–79]

ASIC1 is the only member of the ENaC/Degenerin gene family whose structure has been resolved.[69] This structure provides a starting point to generate models of ENaC subunits. Kashlan and co-workers have built models of the extracellular region of the α-subunit of ENaC based, in part, on homology to ASIC1.[80–82] The extracellular regions of ENaC subunits and ASIC1 are reasonably homologous, except in the finger domain. For example, the α-subunit of ENaC has 73 additional residues when compared to ASIC (see [81,82]). The α-subunit is proteolytically processed at specific sites within its finger domain, releasing an inhibitory tract.[83–85] To determine the molecular architecture of the α-subunit finger domain, sites within α ENaC that interact with an 8 residue inhibitory peptide derived from the portion of the

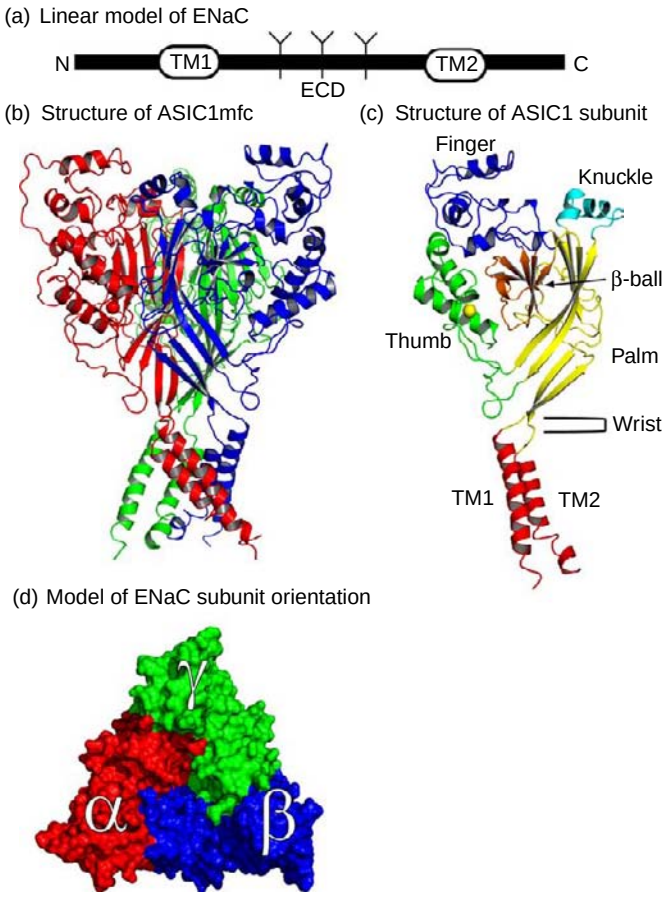

FIGURE 30.3 **Structural features of ENaC subunits.** (a) Linear model of an ENaC subunit (TM1, TM2: the first and second transmembrane domains; ECD: extracellular domain connecting TM1 and TM2; N: amino terminus; C: carboxyl terminus). Several glycosylation sites are shown as branched lines. (b) Structure of the minimally functional chicken ASIC1.[70] Three identical ASIC1 subunits are shown as ribbons with colors of red, green, and blue for the three subunits. (c) Defined subdomains within the large extracellular domain. (d) Proposed subunit orientation of ENaC, viewed from above.[187,191] Surface rendering of the relative locations of the α- (red), β- (blue), and γ- (green) subunits are shown. The structural models in this figure were generated from coordinates of ASIC1.[70]

α-subunit that is removed by furin cleavage were determined.[86] The working hypothesis was that the inhibitory tract within a non-cleaved α-subunit and the 8 residue inhibitory peptide share common binding sites. Distance constraints were introduced to construct a model of the α-subunit.[81,82] The model places the inhibitory tract at an interface of the finger and thumb domains. Kashlan and co-workers suggested that the inhibitory tract blocks channel activity by stabilizing the movement of the finger domain relative to the thumb domain.[81,82]

Stockand and co-workers have also generated a model of an ENaC trimer, based on the structure of ASIC1.[87] To generate the model areas that lacked sequence similarity within the finger regions of ENaC subunits were removed. Although this limits the utility of the model, the model provides important insights regarding sites of intersubunit interactions.

ENaC Biogenesis

Na^+ channel subunits likely undergo assembly in the endoplasmic reticulum (ER), where core, high mannose Asn- (or N)-linked glycans are added at specific sites.[88–97] Each subunit is modified by N-linked glycosylation at multiple sites. For example, rat α-, β-, and γ-subunits have six, twelve, and five consensus sites (Asn-X-Ser/Thr) for N-linked oligosaccharide addition, respectively. Exit of assembled channels from the ER appears to be inefficient.[96,98] A motif that facilitates the exit of ENaC from the ER was found in the proximal cytoplasmic carboxyl terminus of the α-subunit.[98]

Channel subunits that do not exit the ER are likely degraded via proteasome-mediated ER associated degradation (ERAD).[99–102] Integral membrane proteins such as ENaC are co-translationally inserted into the ER. The proper folding and assembly of polypeptides synthesized in the ER involves interactions with a variety of chaperone proteins.[103–105] Specific chaperones that participate in ENaC folding and assembly or targeting misfolded subunits for degradation are starting to be defined. These include members of the luminal Hsp40s, the small heat shock protein alpha A-crystallin, and calreticulin.[100–102,106,107] Cytoplasmic Hsp70s also have roles in channel trafficking, although at present it is unclear whether their roles are related to facilitating ER exit or post-ER trafficking events.[106]

The half-life of newly synthesized subunits, determined by metabolic labeling/pulse-chase experiments, is approximately an hour,[89,91–93,96,99,108] consistent with the notion that the majority of ENaC subunits synthesized within the ER are targeted for degradation via ERAD. A longer-lived pool of channels is apparent in pulse-chase studies, which likely reflects properly assembled channels that have exited the ER.[99] Several groups have determined the half-life of channels that have reached the surface. The rate of degradation of channels that have reached the surface may be in the order of many hours to days,[92,109–111] although some investigators have reported a shorter half-life for channels that have reached the cell surface of A6 cells and MDCK cells expressing exogenous ENaCs.[91,93] These differences in the half-life of channels that have reached the cell surface could result from differences in cell type, and whether ENaCs are expressed endogenously or exogenously.

ENaC Processing in the Biosynthetic Pathway

As assembled ENaCs exit the ER, it has been thought that channels follow the route used by other proteins in the secretory pathway. This involves trafficking through the Golgi where most N-glycans are processed, and the trans-Golgi network where channels are sorted into endosomes that are delivered to the apical membrane. N-glycan processing is often monitored by the enzyme endoglycosidase H, an enzyme that removes high mannose N-linked glycans prior to processing events that occur in the medial Golgi complex.

N-glycans on all three subunits of assembled channels are modified to complex-type Endo H-resistant forms.[93,97] Surprisingly, subunits with endoglycosidase H sensitive N-glycans have also been described.[97] Hughey and co-workers reported that two distinct pools of ENaC subunits were expressed at the plasma membrane: subunits with processed N-glycans and cleaved α- and γ-subunits; and full-length subunits that have non-processed N-glycans.[97] Processing of subunits within a channel complex appears to be an all-or-nothing event.[112] These findings suggest that a population of channel complexes exiting the ER transits through Golgi and post-Golgi compartments where subunits are processed (Figure 30.4). These processed channels likely represent the pool of active, functional channels. A distinct population of channels exiting the ER appears to bypass Golgi and post-Golgi processing events. This distinct pool of non-processed channels is likely a functionally inactive pool, as proteolysis of ENaC subunits appears to have a dramatic effect on increasing channel open probability.[13,83,113–115] Proteolytic cleavage of these inactive channels provides a potential mechanism to increase rates of Na^+ transport in the distal nephron. The role of proteolysis of ENaC subunits in regulating channel gating is discussed in detail later in this chapter.

Intracellular Trafficking of ENaC

Functional channels are delivered to the apical plasma membrane via the traditional secretory

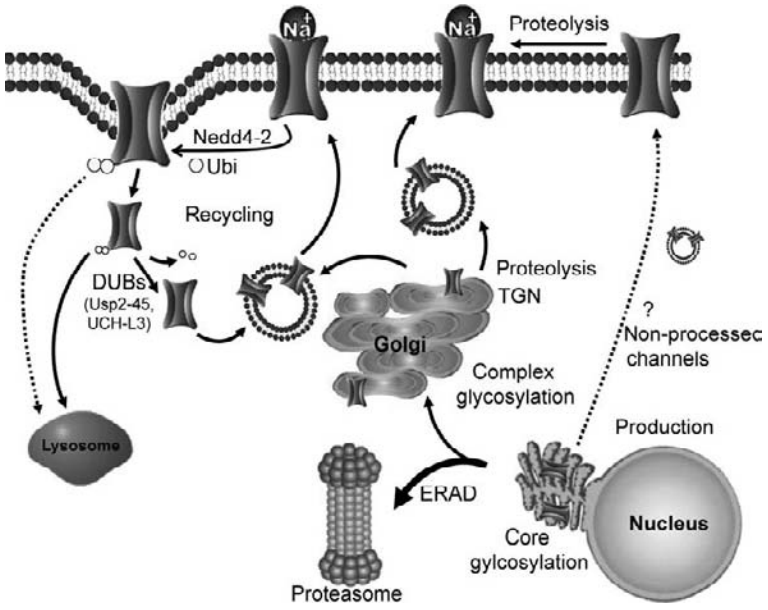

FIGURE 30.4 **Model of ENaC biogenesis and intracellular trafficking.** ENaC subunits are assembled and undergo addition of high mannose asparagine (N)-linked glycans within the endoplasmic reticulum (ER). The majority of newly synthesized subunits are targeted for ER associated degradation (ERAD) that occurs within proteasomes. Assembled ENaCs that exit the ER transit to the apical plasma membrane via distinct routes. ENaCs traffic through the Golgi, where most N-glycans are processed, and through the trans-Golgi network (TGN), where channels are processed by the protease furin prior to delivery to the apical membrane. Alternatively, ENaCs exiting the ER may be delivered directly to the apical plasma membrane, bypassing processing steps that occur in the Golgi and TGN. These non-processed channels are functionally inactive, but are potentially activated by proteases present at the plasma membrane or within the urinary space. ENaCs at the plasma membrane are targeted for internalization following Nedd4-2-dependent ubiquitination (Ubi). Internalized channels are degraded within lysosomes or proteasomes. Alternatively, internalized channels are likely deubiquitinated by specific deubiquitinating enzymes (DUBs), and recycled to the plasma membrane in a regulated manner.

pathway[112] (Figure 30.4). The exocytic insertion of channels into the apical plasma membrane occurs as a regulated process that is increased in response to a variety of hormones, including vasopressin, aldosterone, and insulin. Vesicle and target SNAREs (soluble N-ethylmaleimide sensitive factor attachment protein receptors) participate in this process, and overexpression of specific SNARE proteins disrupts the intracellular trafficking of ENaC subunits.[116–119] Channels at the plasma membrane appear to reside within specific compartments. Several groups have reported that a population of channels resides within lipid-rich microdomains, referred to as lipid rafts,[120,121] although other groups have not confirmed this finding.[91] While lipid rafts have been reported to facilitate the co-localization of membrane proteins and signaling molecules, the functional consequences of ENaCs within lipid rafts are still unclear. ENaCs interact with cytoskeletal elements, including actin and α-spectrin, which may have a role in localizing the channel to the plasma membrane and in modulating ENaC activity.[122–125]

The residency time of channels at the plasma membrane has been examined by several groups, with reported half-lives in the order of minutes to hours.[91,93,110,111,126,127] Mutations within a carboxyl-terminal PY motif within the β- and γ-subunits are associated with increases in the half-life of the channel at the plasma membrane via mechanisms that are discussed later in this chapter.[126,128] Internalization of channels from the plasma membrane has been proposed to occur via a dynamin-dependent process.[126] Dynamin is required for clathrin-dependent endocytosis, as well as for caveolae-dependent endocytosis.[129–131] Ubiquitin conjugation of defined lysine residues within ENaC subunits at the plasma membrane targets the channels for endocytosis,[132] presumably via a clathrin-dependent mechanism (Figure 30.4).[133] Once internalized, some channels are targeted for degradation via proteasomes or possibly lysosomes.[93,108,132] A significant fraction of the pool of endocytosed channels may undergo recycling to the plasma membrane in a regulated manner[111] (Figure 30.4). Specific deubiquitination enzymes have a role in removing ubiquitin from internalized channels, facilitating the recycling of channels to the plasma membrane.[134–136]

Localization within the Kidney and Other Organs

The aldosterone-sensitive distal nephron is the final site of Na^+ reabsorption within the nephron. ENaCs

are expressed in principal cells in the late distal convoluted tubule, connecting tubule, and through the collecting duct, and are the major pathway for Na^+ entry across the apical plasma membrane. In the more proximal segments of the aldosterone-sensitive distal nephron, Na^+ reabsorption via ENaC is coupled to K^+ secretion mediated by apical membrane K^+ channels, including Kir1.1 (or ROMK) and the large conductance Ca^{2+}-activated K^+ channel (maxi-K).[137–139] ENaC-dependent reabsorption of Na^+ in the distal nephron has a major role in the control of extracellular fluid volume, blood pressure, and renal K^+ secretion.

The cellular localization of individual ENaC subunits may differ within the nephron. When maintained on normal laboratory diet, β- and γ-subunits were localized within an intracellular compartment in principal cells within the cortical and outer medullary segments of the rat aldosterone-sensitive distal nephron.[140] One group reported that the α-subunit was localized primarily to apical part of principal cells,[140] whereas other groups have observed either modest cytoplasmic localization or have failed to detect the α-subunit.[141,142] Within the inner medullary collecting duct, all three ENaC subunits were localized primarily within an intracellular compartment.[140] When placed on a low-Na^+ diet or following administration of aldosterone, all three subunits were expressed at the apical membrane of principal cells.[141,143]

Mice lacking expression of the β- or γ-subunits or that have reduced expression of the α-subunit exhibit renal Na^+-wasting.[5–7,144] Mice that lack expression of the α-subunit are unable to clear airway fluids at birth, leading to death in the early postnatal period.[145] Recent work suggests that the density of ENaC expression may be greatest in the connecting tubule, an early segment within the aldosterone-sensitive distal nephron that connects the distal convoluted tubule to the collecting tubule.[146] Mice that lack expression of α ENaC beyond the connecting tubule are able to maintain Na^+ and K^+ balance, even in the setting of dietary Na^+ restriction or K^+-loading.[147]

In addition to its expression in the nephron, ENaCs are expressed within numerous other organs. They are expressed throughout the airways, as well as in both type I and type II alveolar cells.[148–152] ENaC has a key role in the reabsorption of airway fluids.[145,153] Maintaining an appropriate volume of airway surface liquids has an important role in facilitating mucociliary clearance.[153,154] ENaCs are also expressed in the distal colon, sweat ducts, salivary ducts, inner ear, lingular epithelium, keratinocytes, lymphocytes, and vascular smooth muscle. ENaC expression has also been reported in endothelia and in various sites within the eye, including epithelia within the retina, lens, and pigmented ciliary body and iris.[9,155–162] The functional roles of ENaCs within many of these tissues are unclear.

ENaC STRUCTURE AND FUNCTION

Specific structural features within channel subunits have key roles in defining the biophysical properties of ENaC. All three ENaC subunits contribute to the formation of the conduction pore, as pore properties are altered by mutations within each of the three subunits.[163] The published structures of ASIC1 reveal a homomeric trimer[69,70] (Figure 30.3). The structures of the extracellular domain (ECD) and transmembrane domain (TM) are well-defined, while the cytoplasmic amino- and carboxyl-terminal domains are not resolved in the crystal structures. The cASIC1 structures confirm a longstanding notion that the channel pore is formed largely by the second transmembrane domain (TM2s) that determines the basic biophysical properties of ENaC. Both the extracellular and cytoplasmic domains have roles in modulating channel-gating and trafficking. The functional roles of individual domains within ENaC subunits, and potential mechanisms of ion permeation, ion selectivity, channel-gating, and amiloride block are reviewed below with insights from the ASIC1 structures.

Functional Domains within ENaC Subunits

Amino-Terminus

The cytoplasmic amino-termini have regions that affect channel-gating, trafficking, and regulation by intracellular factors. Chalfant and co-workers identified a Lys-Gly-Asp-Lys tract within the rat α-subunit corresponding to residues 47–50, that may function as an endocytic signal that regulates the number of channels in the plasma membrane.[164] A domain that affects channel-gating has been characterized within the distal portion of the amino-terminus of the α-subunit, which includes a highly-conserved His-Gly tract.[165,166] A mutation in the corresponding Gly in the β-subunit was described in a patient with pseudohypoaldosteronism. Reduced channel activity attributed to a decreased open probability was observed with a mutation of the conserved Gly in each subunit, suggesting that the His-Gly tract within the amino termini of all three subunits influences channel-gating.[42,165,166] A recent study showed that mutations of this Gly in the α and γ ENaC subunits induced a strong inward rectification in the whole cell currents, reflecting voltage-dependent gating.[167] Mutations at other sites have also

been found to reduce channel activity and induce voltage-dependent gating.[168–171]

Phosphatidylinositol 4,5-bisphosphate (PIP2) activates ENaCs,[172,173] an effect that reflects an increase in channel open probability as a result of direct interactions between PIP2 and ENaC. Several groups have proposed that the amino-termini of the β- and γ-subunits of ENaC harbor putative PIP2-binding domains containing basic amino acid residues.[172,174,175] In addition, Helms and co-workers suggest that PIP3 mediates aldosterone-induced ENaC activity and trafficking, and interacts with γ ENaC.[176] The ENaC amino-termini also contain Cys residues that may interact with intracellular metals (Cd^{2+} and Zn^{2+}) and thiol-reactive chemicals, leading to a reduction in channel open probability.[177] Palmitoylation of amino-terminal Cys-43 and carboxyl-terminal Cys-557 of mouse β ENaC enhances channel open probability (see below).[98]

First Transmembrane Domain (TM1)

The ASIC1 structures were apparently resolved in a desensitized state. In these structures, the channel pore is primarily lined by TM2 helices from three identical subunits, with the three TM1 helices packed tangentially behind the TM2 helices and contacting the lipid bilayer. The TM1 helix from an individual subunit also makes extensive interactions with the TM2 helix of the same subunit, as well as specific contacts with helices from an adjacent subunit.[70] The closed-pore conformation of ENaC may be similar to that of ASIC1. A Trp scanning of the TM1 of α ENaC showed that mutations within the amino-terminal portion of αTM1 alter channel activity, selectivity, and gating,[178] consistent with the extensive intrasubunit interaction between TM1 and TM2 helices revealed in the ASIC1 structures.[69,70] A recent Cys scanning of ASIC1 TM domains is also consistent with the relative locations of TM1 and TM2 helices in the resolved structures.[75]

Extracellular Domain (ECD)

Each ENaC subunit has a large, ~450 residue extracellular region with 16 conserved Cys residues clustered within two Cys-rich domains.[179] Other members of the ENaC/DEG family also possess extracellular Cys-rich domains.[180] The size and the apparently conserved structural organization of the extracellular domain suggest that this region has important functional roles. Recent studies have examined the role of the ECD in modulating channel-gating in response to proteases, sheer stress, external Na^+, metals, H^+, and Cl^-.[49,80,97,179,181–193] These functional studies and insights from the ASIC1 structure suggest that the ECD of ENaC functions as a sensor or receptor for a variety of extracellular signals. The extracellular domains also facilitate the assembly of the heteroligomeric channel complex within the endoplasmic reticulum, and influence intracellular trafficking.[179,193,194]

Several proteases, including prostasin and related channel-activating proteases, furin, trypsin, chymotrypsin, and elastase have been shown to activate ENaC.[83,113,114,195–199] Activation of ENaC by proteases is a result of proteolytic cleavage of ENaC subunits within their extracellular domains at defined sites, releasing intrinsic inhibitory tracts.[81,84,85,200] Mechanisms by which proteases activate ENaCs are discussed below.

ENaCs are inhibited by extracellular Na^+, which presumably binds to sites within the ECD. This response, referred to as self-inhibition, reflects a reduction in channel open probability.[2,115,182,185,201,202] The structural basis of Na^+ self-inhibition has begun to emerge from mutagenesis studies.[80,182,185,186,188,190–193] At present, the sites of Na^+-binding, as well as the subsequent allosteric changes that lead to a reduction in channel open probability, have not been defined. In addition to Na^+, other external cations such as Ni^{2+}, Zn^{2+}, Cu^{2+}, Cd^{2+}, and Hg^{2+} affect ENaC activity, presumably by binding to sites within the ECDs and altering channel open probability.[181,184,187,203–206] The effects of these metals on ENaC are both metal- and species-specific.

Extracellular anions also interact at sites within the extracellular domains of ENaC subunits and alter ENaC gating. Collier and Snyder found that external Cl^- regulates ENaC activity in part through enhancing Na^+ self-inhibition. Their findings provide a mechanism by which changes in extracellular Cl^- modulates epithelial Na^+ absorption.[190] They identified two Cl^- inhibitory sites in ENaC, one formed by residues in the thumb domain of the α-subunit and the palm domain of the β-subunit, and the other formed by residues at the interface of the thumb domain of the β-subunit and the palm domain of the γ-subunit. Based on the effects of mutagenesis on Cl^- inhibition, the additive nature of mutations, and on differences in the mechanisms of Cl^- inhibition, the authors propose a model in which ENaC subunits assemble in an αγβ-orientation when viewed from above[191] (Figure 30.3). This subunit arrangement is also suggested by Chen et al., based on the identification of a putative Cu^{2+}-binding site at the α- and β-subunit interface within the ECD of human ENaC.[187] However, the model is based on the assumption that the functional ENaC complex is a heterotrimer. The possibility that multiple arrangements co-exist needs to be tested.

Within the ENaC extracellular domains are 16 Cys residues, which are largely conserved among other members of the ENaC/degenerin family. Firsov and colleagues proposed that specific Cys residues (the first and sixth Cys in all three subunits, as well as the

eleventh and twelfth Cys in the α- and β-subunits) have an essential role in the efficient transport of assembled channels to the plasma membrane.[179] A mutation of the first cysteine residue in the human α-subunit (aC133Y) is associated with PHA-1.[207] Sheng et al. proposed that there are several intrasubunit disulfide bonds, based on analyses of additivity of double Cys mutations and responses to sulfhydryl reagent of single and double mutants.[183] These predicted disulfide bonds (Cys1-Cys6, Cys4-Cys5, Cys7-Cys16, Cys11-Cys12, Cys10-Cys13, and Cys8-Cys15 (conserved Cys numbered sequentially)) were present in the resolved ASIC1 structure.[69] ASIC subunits have 14 conserved Cys residues within the ECD that form seven intrasubunit disulfide bonds, one in β-ball, one in palm, and five in thumb domain.[69] The locations of the disulfide bonds are consistent with their roles in stabilizing the conformations of these domains.

Second Transmembrane Domain (TM2)

The TM2 region is thought to be the segment that lines the conduction pore and contains important functional sites, including the degenerin (DEG) site, amiloride-binding site, and selectivity filter site[169,208,209] (Figure 30.5). The structure of the ENaC pore is expected to be similar to that of ASIC1, given the high degree of sequence homology and similar biophysical properties. For example, three ENaC TM2s likely line the channel pore, while TM1s contact the lipid bilayer. As the resolved ASIC1 structures likely represent non-conducting states, they provide limited information regarding the roles of TM2 residues in ion permeation and selectivity. Two distinct TM domain structures of ASIC1 have been described,[69,70] adding an additional layer of complexity in interpreting structure and function relationships of the TM2 domains from the resolved ASIC1 structures. Here we discuss mutagenesis results, mainly in reference to the most recent ASIC1 structure.[70]

AMILORIDE BINDING

Schild and co-workers identified a ring of residues at homologous positions within each of the three subunits (αS583, βG525, and γG537 in rat ENaC) as a putative amiloride-binding site[163] (Figure 30.5). The substitution of βG525 or γG537 weakened amiloride IC_{50} by about three orders of magnitude. In contrast, the substitution of αS583 with amino acids bearing side chains with different functional groups (e.g., Gly, Leu, Asn, Gln) had only a slight effect on amiloride block, suggesting that the side chain of αS583 does not participate in amiloride binding.[171] However, amino acids with aromatic side chains introduced at αS583 led to a large reduction in amiloride affinity, suggesting that large side chains at position α583

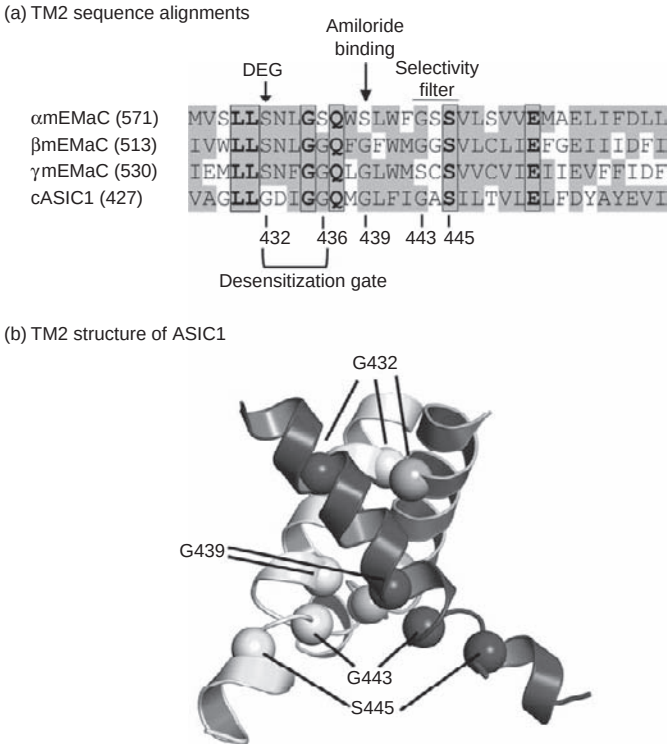

FIGURE 30.5 ENaC/ASIC pore structures. (a) Sequence alignments of the second transmembrane domains (TM2) of mouse α-, β- and γ-subunits and chicken ASIC1. Identical residues are shown as boxed and bold letters and the similar residues are shaded. Key functional sites are labeled. Selected ASIC1 residues are identified below by residue numbers. Location of the proposed desensitization gate of ASIC1[70] is indicated by a square bracket. (b) Model of the TM2 bundles of ASIC1.[70] The three TM2 helices are shown. Spheres represent α-carbons of ASIC1 residues identified in panel (a).

protrude into the pore, and limit access of amiloride to this site.[171] The effects of Cys substitutions at the amiloride-binding ring on the inhibitory constant largely reflected an increase in the microscopic k_{off} rate, consistent with an effect on the bound complex.[210] An adjacent three residue Gly/Ser-X-Ser tract that forms the primary selectivity filter may also have an important role in amiloride binding. Mutations introduced in the first position of this tract in the α- or β-subunit were associated with a large reduction in amiloride affinity,[211–213] suggesting that amiloride also interacts with this site.

The introduction of Cys residues at the amiloride-binding ring rendered channels sensitive to block by external Zn^{2+}-, Cd^{2+}-, and sulfhydryl-reactive methanthiosulfonate (MTS) derivatives.[72,76,163,209,212] Moreover, mutations of these residues reduced single channel conductance.[163,171] This site was also shown to be located within the membrane electrical field.[76,163,171] These observations suggest that this ring of residues

line the conducting pore, as was observed in the homologous residue in the resolved ASIC1 structure.[70]

SELECTIVITY FILTER

A three residue tract (Gly/Ser-X-Ser) starting four residues distal to the amiloride-binding site has a key role in conferring cation selectivity (Figure 30.5). Systematic examination of the ENaC TM2 domains by several groups found that mutations of either the first and/or third residue within the Gly/Ser-X-Ser tract of the α-, β-, and γ-subunits resulted in significant K^+ permeation.[169,208,209,211,212,214] Certain substitutions of the third residue within this tract in the α-subunit allow for permeation of divalent cations.[208]

It is unclear whether backbone carbonyl oxygens or side chains within this three residue Gly/Ser-X-Ser tract face the lumen.[213–215] Kellenberger et al. initially proposed that carbonyl oxygen atoms from third position Ser residues provide a Na^+-binding site, based on a positive correlation between increases in K^+ permeability and the volumes of several substituted residues at αSer589.[214] Alternatively, Sheng et al. proposed that the side chains of the selectivity filter residues faced the pore lumen, based on the sensitivity of channels with an introduced Cys at the first or third residue in the selectivity filter to externally applied Cd^{2+}.[213] This proposed side chain orientation is also consistent with the need for a hydroxyl group at position α589 to prevent K^+ permeation.[169] The dispute regarding the orientation of residue side chains within the selectivity filter will likely remain until a high-resolution structure of ENaC or ASIC in an open state is available.

The distal (C-terminal) portions of the TM2 domains have three well-conserved negatively charged residues that likely line one face of an α helix. The introduction of mutations at specific sites containing acidic residues has been reported to reduce channel activity without altering surface expression[216] and result in K^+ permeation, suggesting that some of these residues may also have a direct or indirect role in conferring cation selectivity.[170]

CHANNEL GATE

A five residue motif (G^{432}DIGG^{436}) in the outer part of the ASIC1 TM2 domain has been proposed to function as the desensitization gate[70] (Figure 30.5). Gly432 is conserved among ASICs and is homologous to Ala442 in MEC4, the degenerin site where substitutions with a bulky residue result in degeneration of specific neurons in *Caenorhabditis elegans*.[217,218] The three ENaC subunits bear a Ser at this site. Mutations at the degeneration site in MECs, ASICs, and ENaCs have the common phenotype of an increase in channel open probability,[76,78,79,219] suggesting similar gating machinery. ENaCs with a Cys substitution at the degenerin site are activated by externally applied sulfhydryl reagents.[76,79,219] Modification of Cys residues at the degenerin site is dependent on channels being in an open state, suggesting that either: (1) there is an extracellular gate controlling access to the degenerin site or (2) that this site undergoes a conformational change in association with channel-gating that alters the accessibility of the cysteine side chain to chemical reagents.[79] The desensitization gate of ASIC1 is formed by a helical bundle crossing, which favors the second possibility.[70]

In addition to the degenerin site, external sulfhydryl reagents activate channels with Cys substitutions at nearby sites with a periodicity suggestive of an α-helical structure,[76] suggesting that an extended helical region functions as a gating domain.[76] Consistent with the hypothesis, the sulfhydryl reactive agent MTSET transitions channels with an introduced Cys distal to the α-subunit degenerin site to a high open probability state. Furthermore, these modified channels lose their response to external Na^+ and to laminar shear stress.[182,220] Carattino and co-workers reported that mutations at multiple sites within the TM2 of the α-subunit altered the magnitude and time course of ENaC activation by laminar shear stress, suggesting that this region has a role in the channel's response to external mechanical forces.[221] While ENaCs do not undergo desensitization, these results suggest that the primary gate within ENaCs is located in the same region as the ASIC1 desensitization gate.

Previous studies also suggest that there are additional sites within the TM1 and TM2 domains that affect rates of ion permeation or channel-gating. Several amiloride-binding site mutants (see above) exhibited an altered single channel conductance, although cation selectivity was preserved.[72,163,171] Moreover, channels with a cysteine residue at the γ-subunit amiloride-binding site (γG537) had a high open probability, failed to respond to shear stress stimulus, and lacked a Na^+ self-inhibition response.[222] These results suggest that the αS583-βG525-γG537 ring participates, either directly or indirectly, in ion permeation and channel-gating, in addition to its role in amiloride-binding. The carboxyl-terminal portion of TM2 may also have a role in the regulation of gating.[223,224]

STRUCTURE OF THE PORE

Analogous to the ASIC1 pore structure, the ENaC pore is likely lined primarily by the TM2 helices. The TM1 helices may insulate the TM2 helices from the lipid bilayer. However, uncertainties regarding the ENaC pore structure remain, due in part to the distinct pore structures of the two ASIC1 structures that

apparently were resolved from channels in the desensitized state.[69,70] It is not clear which structure represents the native pore conformation and the extent to which structural distortion was generated by crystal lattice contacts. It remains possible that these two structures represent two native conformations that are captured at different stages of desensitization. The TM domains in the original structure[69] are asymmetric with the TM2 helices of two of the subunits showing a $\sim 30-33^\circ$ kink at Gly 435, with the third subunit being nearly straight. The kinks bring the TM2 helices close together, allowing Leu 440 side chains to occlude the pore and separate the outer and inner vestibules. In contrast, the second structure has a symmetric pore design with all TM helices tilted at $\sim 50^\circ$ relative to the membrane normal, with the TM2 helices crossing at the proposed desensitization gate ($G^{432}DIGG^{436}$) that separates the extracellular and intracellular vestibules.[70] The defined degenerin site is located at the top of the gate. Assuming that the ENaC pore has a similar structure, the amiloride-binding and selectivity filter sites would be located within the intracellular vestibule. Mutagenesis studies of the ENaC pore are consistent with an asymmetric open state pore structure.[76,163,169,171,208,210–213,219]

Cytoplasmic Carboxyl-Terminus

The region immediately following TM2 contains clusters of basic residues that effect channel-gating through interactions with acidic phospholipids, such as PIP3, as well as cation selectivity.[175,225–228] A major function of the carboxyl-termini appears to be related to the internalization of the channel complex, through a well-characterized Pro-Tyr (PY) motif (PPPXYXXL) that interacts with the ubiquitin ligase Nedd4-2.[128,132,229,230] ENaC subunit ubiquitination serves as a signal for channel internalization from the plasma membrane.[132] It is unclear whether the YXXL sequence within this motif serves as an independent signal for channel internalization. Other sites within the carboxyl termini may influence rates of channel endocytosis. For example, an A663T polymorphism in the α-subunit of the human ENaC affects rates of channel internalization from the plasma membrane.[231,232] ER exit of ENaC is regulated by a signal within the α-subunit carboxyl cytoplasmic tail.[99]

The carboxyl-termini have sites that are targeted by specific protein kinases that modulate ENaC activity via phosphorylation. These kinases include an extracellular regulated kinase (ERK), casein kinase 2 (CK2), a serum and glucocorticoid regulated kinase (SGK1), and a G-protein-coupled receptor kinase (Grk2).[233–237] ERK1/2-dependent phosphorylation of the carboxyl-termini of the β- and γ-subunits enhances ENaC's interactions with Nedd4.[233] Both forskolin and phorbol 12-myristate 13-acetate (PMA) have been reported to enhance phosphorylation of the β- and γ-subunits, although the target residues that are phosphorylated have not been identified.[238] A region in the proximal part of the carboxyl-terminus of the α-subunit has a role in conferring sensitivity to a staurosporine-sensitive kinase that has not been identified.[239] The carboxyl termini also bind α spectrin and possibly actin, linking the channel to the cytoskeleton.[122,124] Grk2 activates ENaC by phosphorylating the carboxyl terminus of the β-subunit, and prevents Nedd4-2-dependent inhibition of ENaC.[236] Cysteine residues in the amino and carboxyl termini of ENaC subunits may participate in the inhibition of ENaC that is observed with intracellular thiol reactive reagents.[177] Selected cytoplasmic cysteine residues in the β- and γ-subunits are targets of modified palmitoylation.[98] β-Subunit palmitoylation modulates channel-gating, possibly by facilitating interactions between cytoplasmic domains and the plasma membrane.[98]

Cation Permeation and Selectivity

While a detailed understanding of the molecular mechanisms underlying permeation and selectivity awaits a high-resolution structure of ENaC in the open state, there is a growing body of information regarding ion permeation and selectivity.[81,240,241] Organic or inorganic cations larger than Na^+ are unable to pass through the channel, in contrast to voltage-gated Na^+ channels, suggesting that permeant cations must dehydrate to cross the narrowest part of the channel pore (i.e., the selectivity filter).[242,243] Within the Gly/Ser-X-Ser tract that comprises ENaCs selectivity filter,[169,211,214] backbone carbonyl oxygens or hydroxyl oxygens present on the side chains of Ser residues may coordinate permeating Na^+ or Li^+ ions.[213,214]

The selectivity sequence of ENaC ($Li^+ > Na^+ >>> K^+$, organic cations) suggests that the relative permeability of an ion is inversely related to its ionic size, a relationship consistent with a mechanism in which ENaC discriminates cations through molecular sieving.[208,214] Alternatively, cation selectivity could be achieved by placing a negatively (or partially negatively) charged site with strong field strength that preferentially binds small cations within the channel pore.[242,243] In this regard, the selectivity sequence for ENaC corresponds to sequence XI of Eisenman. This sequence was determined based on the presence of strong electrostatic interactions between ions and the selectivity site that override differences in dehydration energies for ions.[244] Interestingly, the selectivity filter of a voltage-gated Na^+ channel has a high-field-strength anionic coordination site.[245]

Selectivity filters appear to be flexible, not static, structures.[246–250] A dynamic selectivity filter of ENaC

has been suggested,[76] and appears to be likely in the light of the resolved ASIC1 structures. Both ASIC1 structures likely represent a desensitized state, and the selectivity filter residues are not in close proximity.[81] We speculate that these residues are brought sufficiently close in the open state to interact with permeating cations. A recent study of ASIC1 is consistent with this notion.[75]

Mechanisms of ENaC-Gating

ENaC-gating is characterized by unusually long open and closed times (up to seconds or even tens of seconds) compared to other channels such as voltage-gated channels (Figure 30.1). This gating pattern seems appropriate for this channel, given its major physiological role of mediating bulk Na^+ transport across the apical membrane of epithelial cells, for which slow transitions between open and closed states may be beneficial for transport efficiency. Transitions between open and closed states appear to occur spontaneously. Another feature of ENaC-gating is the high variability in open probability observed in patch-clamp recordings.[11,251,252] Subunit composition and regulatory factors that affect gating may account for this variability.[252,253] As discussed in detail below, proteolytic cleavage of ENaC subunits converts channels that have a low open probability to channels that exhibit either an intermediate or high open probability.[13,83,97,113] Mechanical forces, external metals, and temperature have also been shown to affect channel-gating.[181,182,184,202,220,221] Studies on Na^+ self-inhibition and effects of metals on ENaC-gating have raised the question of whether ENaCs should be considered a ligand-gated channel, similar to FaNaCh and ASIC.[81,184,254]

A detailed understanding of ENaC-gating mechanisms is lacking, despite the identification of several sites within ENaC where the introduction of mutations affects ENaC-gating kinetics. These sites are present within the amino-terminal domain,[165,166] the extracellular domain,[13,83,113,181,182,184,255] TM2,[76,79,219,221,224] and the intracellular carboxyl-terminal domain.[226,227,256] However, it is unclear whether these different regions control channel-gating in an independent or coordinated manner, nor is it known whether there is a single gate or multiple gates. The location of the ENaC gate is another open question, although the region corresponding to the desensitization gate of ASIC1 is an attractive candidate.

Several recent studies have suggested that the pore helix of cation channels may be a central gating structure.[221,257–260] Yeh and co-workers suggested that the regulation of TRPV5 (a member of the transient receptor potential channel subfamily)-gating by extracellular and intracellular protons is mediated by a rotational movement of the pore helix, and the subsequent closing of a gate within the selectivity filter gate.[260] As the amino-terminal helical portion of the TM2 helices of ENaC participates in channel-gating,[76,79,219] it is possible that rotation of the TM2 helix that is initiated by conformational changes at other sites of the channels alters ENaC-gating kinetics, as suggested for ASIC1.[261] Li and co-workers proposed a gating motion for ASIC1 involving a straightening of the tilt of TM2 without significant rotation.[75]

Permeation and gating of ion channels were proposed to be two independent processes 60 years ago.[262] While previous studies have supported this concept, recent studies suggest that connections exist between permeation and gating.[263,264] For example, channel gating is often modulated by permeant or blocking ions.[265,266] Mutations within selectivity filters are associated with changes in gating kinetics in K^+ channels, voltage-gated Na^+ channels, and ENaC.[168,211,221] Lu and co-workers provided evidence suggesting conformational changes of the selectivity filter contribute directly to the spontaneous gating of an inward rectifier K^+ channel (Kir2.1).[267] Significant differences in the selectivity filter structure of KcsA K^+ channel were observed when the crystals were soaked in low-K^+ and high-K^+ solutions,[268] suggesting that the selectivity filter of this channel is flexible. Molecular simulations using the high resolution structures of bacterial K^+ channels support this idea of a flexible selectivity filter.[269,270] Conformational changes in the selectivity filter have been proposed to occur in the ligand-initiated gating of cyclic nucleotide-gated ion channels.[271] A similar notion has been proposed for inward rectifier K^+ channels.[272,273] We anticipate that future studies will examine whether ENaC's selectivity filter also serves as a gate.

ENaC REGULATION

ENaC is subject to a wide variety of regulatory influences that alter channel activity over long or short time periods in order to respond to the physiologic needs of the organism. In the kidney, these regulatory influences determine the final Na^+ concentration of urine, which may vary from virtually Na^+ free to >100 mM. Abnormalities in these regulatory mechanisms in the cortical collecting duct have been convincingly linked to excess Na^+ reabsorption and hypertension, when disordered regulation leads to gain-of-function; and salt-wasting, hypotension and hyperkalemia when abnormal regulation leads to loss-of-function.[207] Altered or abnormal regulation of ENaC in the lung

has been linked to abnormal alveolar fluid clearance in disease states such as cystic fibrosis, high altitude pulmonary edema, and acute lung injury.[153,154,274–276] In many cases, studies of abnormal ENaC function in disease states have complemented basic observations concerning channel function made in experimental settings, and led to remarkable insights concerning molecular mechanisms of regulation of channel activity.

Channel activity is subject to regulation through alteration of one of its intrinsic kinetic properties, either its number, open probability or single channel conductance. Since significant changes in single channel conductance are not found under physiologic conditions, channel regulation may be considered primarily as a matter of alterations in channel number and/or open probability. Thinking about channel regulation from this perspective would seem to simplify the subject, and certainly provides a framework within which regulation may be considered. However, the subject remains enormously complex given the number of regulatory influences that may modify either channel number or open probability.

There has been a significant paradigm shift, in that we now recognize that "near silent" channels are present in the membrane, in addition to constitutively active channels.[11–13] These "near silent" channels are capable of activation and may be viewed as the extreme case of open probability regulation, where channels move from very low to a measurable open probability, giving the appearance of increased numbers of channels.[13] The levels of "near silent" channel expression in the distal nephron under various physiological and pathological conditions are currently unclear. Channel regulation serves to either enhance or diminish Na^+ reabsorption from luminal fluids of the distal nephron, lung or colon, in accord with the needs of the organism. Given the wide variations in rates of Na^+ reabsorption and luminal Na^+ gradients that this involves, other intrinsic regulatory influences are required to maintain constant cell volume and ion gradients. To respond to these needs under normal physiologic conditions, channel activity is regulated by a number of hormones, including steroids, vasopressin, and insulin; by a variety of accessory proteins; by kinases, proteases, methyltransferases, and other signaling mediators; by other channels such as CFTR; and by ion concentrations and pH.

Cellular Regulation

Ubiquitination and Deubiquitination

Liddle syndrome is a hereditary form of salt-sensitive hypertension associated with increased ENaC activity.[207,277,278] The most common defects in ENaC primary structure leading to this disorder involve the proline-rich regions in carboxyl-termini of the β- or γ-subunit.[277,279–281] Rotin and colleagues used this region of the β-subunit as bait in a yeast two-hybrid screen to identify proteins that interact with ENaC and might regulate ENaC expression. They isolated the protein Nedd4 (Neuronal precursor cells Expressed Developmentally Downregulated) using this technique. In a series of elegant studies they examined the role of this protein in the regulation of ENaC expression.[132,282,283] Nedd4 is an E3 ubiquitin ligase composed of a C2 domain, three or four WW domains that are protein interaction modules, and a ubiquitin ligase Hect domain. The WW domains of Nedd4 bind ENaC, with the strongest interaction being between the carboxyl-terminus of the β-subunit and the third WW domain.[284] The Hect domain is an E3 ligase that receives ubiquitin from an E2 protein and transfers ubiquitin to lysines on target proteins. The C2 region is a Ca^{2+}- and phospholipid-binding domain. It is not present on all Nedd4 isoforms and, based on oocyte studies, does not appear to be essential for inhibition of ENaC expression.[230,285,286] This domain does, however, serve to localize Nedd4 to plasma membrane in response to an increase in cytosolic $[Ca^{2+}]$,[287] and mediates association with annexin XIIIb, which may be involved in apical membrane targeting in epithelia.[288]

Nedd4-2, the isoform most active in binding ENaC, is detected in tissues that express ENaC. The Nedd4-2 WW domains interact *in vitro* with the proline-rich region of carboxyl terminus of the β- and γ- (and possibly α-) subunits of ENaC.[289–291] Considerable evidence indicates that the interaction between Nedd4-2 and ENaC results in ubiquitination of the channel (Figure 30.6). ENaC has been shown to be ubiquitinated in endogenously expressing A6 cells, and when overexpressed along with Nedd4-2 in HEK-293 cells.[108,132] Co-expression studies with Nedd4-2 and ENaC in oocytes demonstrated that Nedd4-2 decreases ENaC surface expression, and that this is dependent both on the E3 ligase domain of Nedd4-2 and on the presence of Lys residues on the amino-termini of the target subunits.[132] Taken together, these studies strongly support the model that surface expression of ENaC is regulated by ubiquitination, which serves as a signal for retrieval from the plasma membrane. It is likely that ENaC is ubiquitinated at other cellular sites, including the endoplasmic reticulum. Unassembled subunits are likely degraded by the proteasome by a process involving polyubiquitination, while fully assembled trimeric channels are degraded by either the proteasome or lysosomal–endosomal pathway following ubiquitination at the cell surface.[93,95,108,132] At present, it is unclear whether monoubiquitination of

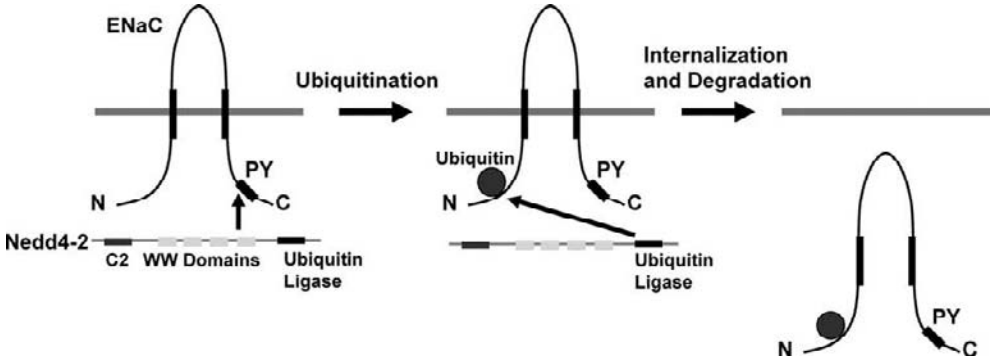

FIGURE 30.6 **Nedd4-2-dependent regulation of ENaC surface expression.** Nedd4-2 binding to ENaC subunits is facilitated through interactions between WW domains on Nedd4-2 and the PY motifs on the β- and γ-subunits. Nedd4-2-dependent ubiquitination of ENaC subunits targets the channel for internalization and degradation. *(adapted from ref. [295]).*

ENaC occurs at the cell surface. However, there is considerable evidence suggesting that ubiquitination is a signal for channel internalization from the plasma membrane,[292] and that channel internalization is a dynamin-dependent,[126] clathrin-dependent,[133] as well as caveolin-dependent process.[293]

The interaction between Nedd4-2 and ENaC is itself subject to regulation by specific hormones and kinases.[233,236,294–300] The regulation of ENaC by Nedd4-2 represents a final common pathway of several regulatory influences affecting ENaC surface expression, providing further evidence for the importance of this interaction in ENaC regulation (see below).

Recent work has elucidated an important role for deubiquitinating enzymes (DUBs) in the regulation of ENaC expression and trafficking in cells.[134,135] Specifically, the DUB Usp2-45 was found to be upregulated by aldosterone in mouse polarized collecting duct ($mpkCCD_{c14}$) cells, which causes deubiquitination of ENaC, and an increase in ENaC surface expression and activity.[134] The subcellular site(s) of action of Usp2-45 on ENaC and its precise physiological role are currently unclear. Butterworth and colleagues identified another DUB, UCH-L3, in the early endosomal compartment of these cells, which also deubiquitinates ENaC, and enhances the recycling of ENaC to the apical membrane.[135] UCH-L3 may play an important role in reversing Nedd4-2-mediated ubiquitination of ENaC upon retrieval from the plasma membrane, thereby rescuing ENaC from degradation and promoting apical recycling of the channel (Figure 30.4). Finally, Usp10 was recently identified as a vasopressin-stimulated DUB, leading to enhanced ENaC abundance and activity at the plasma membrane.[301] In summary, DUBs may respond to hormonal inputs and appear to antagonize Nedd4-2-dependent ubiquitination and inhibition of ENaC, promoting ENaC stabilization and function at the plasma membrane.[302]

Kinases

Protein phosphatase inhibitors, such as okadaic acid, activate ENaC,[303] while nonspecific kinase inhibitors, such as staurosporine, inhibit basal channel activity,[239,304] suggesting that kinases play an important role in regulating the channel. In many cases, the regulation of ENaC by a protein kinase is indirect, with kinase activation occurring within a pathway of hormonal regulation or cellular stress. Examples of this are: (1) SGK1 activation by steroid hormones induces SGK1-dependent phosphorylation of Nedd4-2 (the subsequent binding of 14-3-3 proteins to phosphorylated Nedd4-2 prevents the interaction of Nedd4-2 with ENaC subunits, and reduces ubiquitin-based retrieval of channels from the plasma membrane[305–309]) (Figure 30.7); (2) insulin-dependent activation of phosphatidyl-inositol 3 kinase and 3-phosphoinositide-dependent kinase 1 results in the phosphorylation and activation of SGK1 and ENaC;[307,310] (3) activation of protein kinase A by adenylate cyclase and cAMP in response to vasopressin or beta-adrenergic agonists leads to phosphorylation of Nedd4-2 at sites that overlap the SGK1 phosphorylation sites, and a reduction in ENaC endocytosis,[297] as well as exocytotic insertion of Na^+ channels into the plasma membrane;[111,311,312] (4) activated IKKβ, the kinase-regulating NF-κB, interacts with the cytoplasmic carboxyl terminus of β ENaC[313] and phosphorylates Nedd4-2 at a residue that is also targeted by SGK1 and PKA, reducing channel endocytosis[300] (IKKβ provides a mechanism of integrating inflammatory cascades and ENaC activation); (5) endothelin-dependent activation of Src kinase results in a decrease in channel open probability without directly phosphorylating channel subunits[314]; (6) selected protein kinase C isoforms also reduce channel open probability in a Ca^{2+}-dependent manner, protein kinase C also decreases expression of the β- and γ-subunits, which is dependent on activated

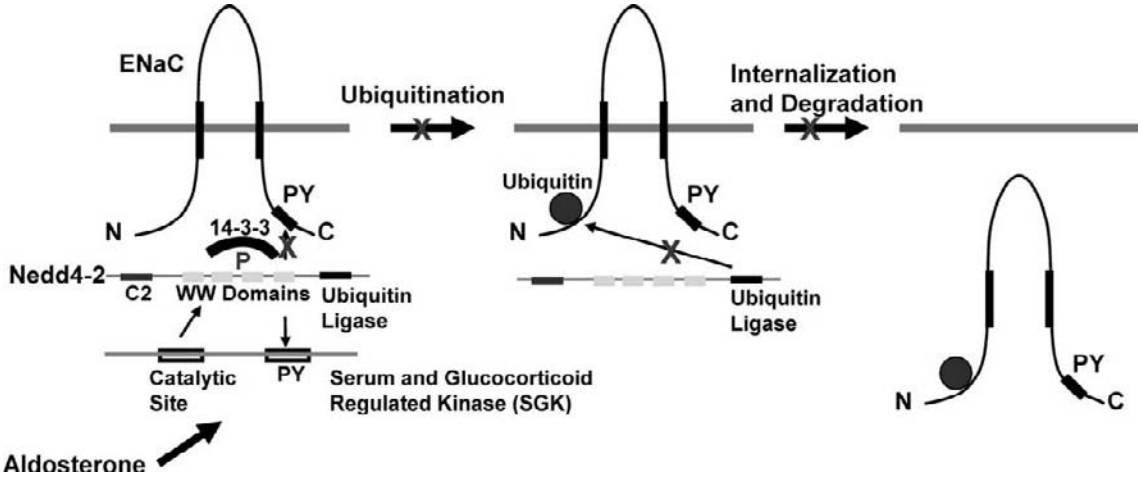

FIGURE 30.7 **Aldosterone modulates the interaction between Nedd4-2 and ENaC.** Sgk1 is targeted to Nedd4-2 through interactions between a PY motif on Sgk1 and WW domains on Nedd4-2. Sgk1-dependent phosphorylation of Nedd4-2 results in the recruitment of a 14-3-3 protein that prevents Nedd4-2 binding to ENaC. *(adapted from ref. [295]).*

ERK kinase[315–317]; (7) AMP-activated protein kinase (AMPK) is a ubiquitous metabolic sensor that phosphorylates Nedd4-2, enhances Nedd4-2 binding to β ENaC, and inhibits ENaC activity and surface expression.[77,299,318]

ENaC is also a substrate for kinases that are involved in its regulation. Studies of ENaC expressed in MDCK cells have demonstrated increased phosphorylation of the β- and γ-subunits in response to stimulation by aldosterone and insulin.[238] Phosphopeptide mapping indicated that the phosphorylated sites were carboxyl terminal Ser and Thr residues.[238] Shi and colleagues described phosphorylation of Ser631 in the β-subunit and Thr599 in the γ-subunit by the pleiotropic but essential kinase CK2.[234] Kunzelmann and colleagues found that a specific CK2 inhibitor blocked ENaC activity, and expression of a trimeric channel lacking both CK2 sites inhibited ENaC conductance and rendered ENaC insensitive to CK2.[237] They concluded that phosphorylation by CK2 is essential for ENaC activation and partly regulates ENaC surface expression. Garty and colleagues also described phosphorylation of βThr613 and γThr623 by the extracellular regulated kinase (ERK).[233] ERK-dependent phosphorylation of ENaC facilitates interactions between the channel and Nedd4-2, thereby inhibiting ENaC activity. SGK1 increases channel open probability by directly phosphorylating the carboxyl-terminus of the α-subunit at Ser-621.[235] Finally, insulin has been described to increase phosphorylation of a fully mature 65 kDa form of α ENaC in cultured epithelial cells, which correlated with an increase in channel activity.[319] The kinase-mediating of this effect was not directly identified, but the protein kinase C inhibitor chelerythrine blocked the insulin stimulation of transport and subunit phosphorylation.

It has also been reported that the G-protein-coupled receptor kinase, Grk2, phosphorylates Ser-633 in the carboxyl-terminus of the β-subunit.[236] Phosphorylation at this site renders the channel insensitive to regulation by Nedd4-2, resulting in increased surface expression and channel activity. This finding is intriguing, as: (1) it is the first report of a G-protein receptor kinase directly regulating an ion channel; and (2) increased Grk2 activity has been associated with hypertension.[320] Grk2 may also phosphorylate Nedd4-2, although the relevant site(s) and functional significance of this phosphorylation are unclear.[321] A recent study suggests that Grk2 may also stimulate ENaC via a kinase-independent mechanism that requires its interaction with α-subunits of the Gq/11 family.[322]

Another family of kinases linked to human hypertension is the WNK (with no lysine) family of serine-threonine kinases.[323] These kinases are prominently expressed in the distal convoluted tubule, connecting segment, and cortical collecting duct of the kidney (i.e., the aldosterone-sensitive distal nephron), where they coordinate with angiotensin II and aldosterone signaling pathways.[324] WNK mutations lead to hypertension and hyperkalemia typical of pseudohypoaldosteronism type II (PHA II).[325] WNK4 inhibits the renal Na,Cl cotransporter (NCC) and ROMK, and mutations associated with hypertension relieve the inhibition of NCC, but enhance inhibition of ROMK.[323] These observations suggested that under normal physiologic conditions, WNK4 regulates the balance between renal Na^+ reabsorption and K^+ excretion, but mutations would lead to exaggerated Na^+ reabsorption and hypertension

with hyperkalemia, due to impaired K^+ excretion. In addition to NCC and ROMK, one group found that WNK4 also inhibits ENaC *in vitro*, and this inhibition by WNK4 is relieved by SGK1 phosphorylation near the WNK4 C-terminus.[326] In contrast, another group suggested that WNK4 activates ENaC.[327] Another member of this family, WNK1, has also been implicated in activating ENaC.[327] Interestingly, intronic deletions that could lead to hypertension and hyperkalemia result in overexpression of WNK1.[328] Aldosterone has also been shown to stimulate expression of a kidney-specific isoform of WNK1, and overexpression of this kinase stimulates Na^+ reabsorption in cultured collecting duct cells, and in overexpression systems.[329] WNK1 expression activates SGK1 in a PI-3 kinase-dependent manner, indicating that the kinase activates ENaC by increasing its expression at the apical membrane of collecting duct cells, contributing to the human hypertension seen in association with PHA II.[327,330]

As suggested above, the E3 ubiquitin ligase Nedd4-2 has emerged as a central convergence point for the regulation of ENaC and other transport proteins in cells. A growing number of kinases have been shown to phosphorylate Nedd4-2, modulate Nedd4-2 function, and thereby regulate ENaC.[331] These include the aldosterone-induced kinase SGK1,[306] vasopressin-stimulated PKA,[297] the metabolic sensor AMPK,[299] the NF-κB inflammatory mediator IKKβ,[300] Grk2,[321] and the insulin-stimulated kinase Akt1.[332] In general, these kinases modulate the apparent binding affinity of Nedd4-2 for ENaC and/or 14-3-3 scaffolding proteins. Of note, additional putative Nedd4-2 phosphorylation sites have been recently identified by mass spectrometry that may be targets of the c-Jun N-terminal kinase (JNK1), and possibly other kinases.[333] Unlike the above paradigm, where kinases regulate protein−protein interactions involving Nedd4-2, these novel target phosphorylation sites appear to play an important role in regulating Nedd4-2 catalytic function.[333]

Proteases

Proteolysis of ENaC subunits has an important role in regulating ENaC activity. The first hint that proteases modulated ENaC activity was that serine protease inhibitors reduced transepithelial Na^+ transport across toad urinary bladder.[334] Subsequent studies identified a channel-activating protease, or CAP,[195] and demonstrated that extracellular trypsin activated ENaC by increasing channel open probability.[114] Following these initial observations, other proteases have been identified that activate ENaC when either co-expressed with the channel in heterologous expression systems or when added to a solution bathing cells expressing ENaCs. These channel activating proteases include prostasin (also referred to as CAP1), TMPRSS4 (transmembrane protease serine 4 or CAP2), and matriptase (or CAP3), elastase, chymotrypsin, kallikrein, and plasmin.[113,114,195,199,335–339]

Proteolytic processing of ENaC subunits occurs within the biosynthetic pathway. This is likely mediated by furin, a member of the proprotein convertase family of serine proteases that is expressed primarily in the trans-Golgi network.[83,340] There are two furin cleavage sites within the extracellular domain of the α-subunit, and a single site within the extracellular domain of the γ-subunit.[83,85] Furin-dependent cleavage of the α-subunit excises a 26 residue inhibitory fragment. Simply deleting this 26 residue tract from the α-subunit in the absence of subunit cleavage was sufficient to activate the channel.[84] Furthermore, a synthetic peptide corresponding to the released fragment is a reversible channel inhibitor.[84] An 8 residue tract, embedded within the 26 residue fragment, is responsible for the inhibitory properties of this fragment.[86]

While the α-subunit is cleaved by furin twice, releasing an inhibitory fragment, the γ-subunit is cleaved only once by furin. As was observed with α-subunit processing by furin, cleavage at two sites spanning an inhibitory tract within the γ-subunit increases channel activity. While furin cleaves the γ-subunit at a site preceding an embedded inhibitory tract,[200] multiple proteases have been shown to cleave the γ-subunit at sites distal to the inhibitory tract. Among the proteases that cleave the γ-subunit distal to the inhibitory tract are prostasin, TMPRSS4 (CAP2), elastase, and plasmin.[199,200,338,339,341] Deleting the γ-subunit inhibitory tract dramatically increases channel activity, even in the absence of γ-subunit cleavage.[200,342] An 11 residue tract is responsible for the inhibitory properties of the released fragment.[342] With regard to channel activation, release of the γ-subunit inhibitory tract has a more profound effect than release of the α-subunit inhibitory tract.[343]

At the single channel level, ENaCs exhibit a highly variable open probability. While ENaCs often exhibit open and closed times in the order of seconds to tens of seconds, a distinct population of ENaCs have very brief open times and long closed times.[11–13] Caldwell and co-workers have shown that this latter population of channels responds to external trypsin, with a dramatic increase in channel open probability.[13] These inactive channels likely represent a population of channels whose subunits have not been processed by proteases. Channels with α-subunit furin site mutations that have retained α- and γ-subunit inhibitory tracts have a very low open probability that reflects a dramatically enhanced reduction in ENaC activity in response to external Na^+ (referred to as Na^+ self-inhibition). When these channels are examined in the

presence of a low external [Na^+], their activity dramatically increases.[115]

Both processed (i.e., cleaved) and unprocessed subunits are expressed at the cell surface.[93,112] These nonprocessed channels provide a pool of ENaCs that could be activated by proteases in a regulated manner. In this regard, rats placed on a low-Na^+ diet or receiving exogenous aldosterone have increased levels of whole kidney expression of the processed form of the γ-subunit.[142,344–347]

The sites of protease cleavage in the α- and γ-subunits are located with the finger domain. A model of the α-subunit generated by Kashlan and co-workers suggests that the α-subunit inhibitory tract binds to sites at an interface of the finger and thumb domains. They proposed that the inhibitory tract reduces channel activity by stabilizing the movement of the finger domain relative to the thumb domain.[81,82]

Syntaxins

The factors regulating ENaC delivery to the apical membrane in epithelial cells have not been fully-defined. The SNARE proteins (soluble N-ethylmaleimide sensitive factor attachment protein receptors) have been linked to directed exocytosis and intracellular trafficking in a number of tissues.[348] A typical interaction involves binding of vesicle-associated v-SNARES to target membrane-associated t-SNARES. These interactions may be regulated by accessory proteins such as Munc 18.[349] The t-SNARE syntaxin 1A has been demonstrated to interact directly with ENaC in co-immunoprecipitation experiments, and overexpression of this protein inhibited ENaC expression in oocytes.[116,350] This effect was blocked by co-expression of Munc 18. These findings implicate the SNARE proteins in the process of exocytosis of ENaC, but are somewhat counterintuitive in that overexpression of the trafficking partners results in downregulation of the channel. The results suggest that the balance of t- and v-SNAREs may regulate this process, and that overexpression alters this interaction in a negative fashion.

The direct interaction of syntaxin 1A and ENaC suggests that there are cargo-specific interactions between SNARE proteins and apical membrane resident proteins such as ENaC. In a series of studies, Condliffe and colleagues identified domain-specific interactions between the carboxyl-termini of ENaC subunits and the H3 domain of syntaxin 1A. Interestingly, there was an effect of the H3 domain to decrease ENaC open probability, suggesting that SNARE proteins may regulate both channel exocytosis and gating.[118,119] A more recent study suggests that syntaxin 1A regulates ENaC function by multiple mechanisms that include PKA, phospholipase C, PI-3 kinase, and MAP kinase signaling systems.[351] Distinct inhibitory and stimulatory domains of syntaxin 1A interact with ENaC subunits, and the overall effect of syntaxin 1A on ENaC function depends on distinct physiological conditions.

Cystic Fibrosis Transmembrane Conductance Regulator (CFTR)

Patients with cystic fibrosis (CF) have increased amiloride-sensitive transport in airway epithelia.[352] Indeed, increased ENaC activity in airway epithelia has been proposed as one mechanism for the drying of airway fluids, which promotes progression of airway disease. Lung specific overexpression of β ENaC or knockout of Nedd4-2 in mice results in a phenotype similar to CF airway disease in humans.[153,353] CF is caused by function impairing mutations in the cystic fibrosis transmembrane conductance regulator (CFTR), an ATP-gated Cl^- channel.[354] On the basis of studies comparing ENaC activity in the presence and absence of CFTR expressed in MDCK cells, Stutts and colleagues proposed that CFTR functions as a cAMP-dependent regulator of ENaC, and the absence of this function in CF airways explained the increased ENaC activity in CF patients.[355,356] Ling and co-workers demonstrated that inhibiting CFTR expression in a renal distal nephron cell line (A6) led to an increase in ENaC open probability.[357] Studies in *Xenopus* oocytes or other overexpression systems have demonstrated that CFTR inhibits ENaC activity,[355,358,359] although this has been disputed.[360,361] However, several recent studies have questioned the role of CFTR in modulating ENaC activity.[362,363] There is also evidence that ENaC enhances the activity of CFTR, due to an increase in the number of channels expressed at the plasma membrane, as well as an increase in CFTR open probability.[364]

It is unclear if the interaction between CFTR and ENaC is indirect or results from a direct physical interaction. Changes in the intracellular [Cl^-], as well as electrochemical coupling, have been proposed as potential mechanisms by which CFTR regulates ENaC.[360,365] One group has proposed that there are interactions between the regulatory domain of CFTR and ENaC,[366] although the manner in which this interaction results in ENaC regulation is not clear. Moreover, ENaC–CFTR interactions appear to vary depending on the tissue of expression. For example, in sweat ducts, CFTR enhances ENaC activity.[367] Although both CFTR and ENaC are expressed in collecting duct principal cells, no significant abnormalities of renal Na^+ handling have been described in CF patients. In airway epithelial cells, CFTR and ENaC co-immunoprecipitate, and interestingly expression of the most common CF-causing ΔF508 CFTR mutation was recently found to increase the proportion of cleaved to uncleaved α ENaC that was bound to CFTR.[368] These

findings suggest that wild-type CFTR may normally impede the proteolytic stimulation of ENaC in airway cells, although mechanistic details of how this may occur are unclear. Elastase is one of perhaps several proteases that are present in inflamed CF airways and could contribute to an increase in the extent of γ ENaC subunit proteolysis.[113,199,337] Another recent study suggested that CFTR regulates the whole cell and surface expression of ENaC in airway epithelial cells, and that absence of this regulation may foster ENaC hyperactivity in CF airway epithelia.[369] In summary, with current data it is difficult to explain the regulatory interactions between CFTR and ENaC solely on the basis of physical interactions or alterations in electrochemical driving forces or the intracellular Cl^- concentration. The regulatory interactions may reflect changes in ENaC open probability (cleavage status) and surface expression, and vary among differing tissues, suggesting that other proteins or factors not yet recognized may be critical for functional CFTR−ENaC interactions.[370]

Methyltransferases

Methylation reactions have long been implicated in the activation of ENaC by aldosterone.[371,372] Aldosterone stimulates carboxylmethylation of proteins and phospholipids, and inhibition of these reactions blunts the ENaC response to steroid stimulation.[373] A few potential targets of methyltransferases have been identified: k-ras, β ENaC, and more recently, histones involved in the aldosterone-dependent control of transcription. Aldosterone induces k-ras in a *Xenopus* distal nephron cell line (A6) cells, and this small G-protein is methylated by isoprenylcysteine carboxylmethyltransferase (PCMTase). PCMTase is not induced by aldosterone, but is regulated by the enzyme S-adenosyl-homocysteine hydrolase that is stimulated by aldosterone and results in increased activity of PCMTase.[374] The enzyme (PCMTase) itself does not appear to stimulate ENaC, so it is unlikely to directly methylate the channel. Induction and processing of k-ras appears to be important for regulation of ENaC in A6 cells, but it is not clear that this occurs in mammalian tissues.[375] Direct methylation of β ENaC has been demonstrated using a partially purified membrane preparation as a source of enzyme, but the enzyme itself has not been identified. Methylation of ENaC in planar lipid bilayers has been shown to lead to an increase in open probability of the channel.[376] Edinger and co-workers identified a methyltransferase that activates ENaC when co-expressed with the channel in oocytes.[377] Methylation does not appear to play a role in basal channel activity.

Several recent studies have explored the role of Dot1a, which has histone H3K79 methyltransferase activity and is widely expressed in the kidney,[378] in the transcriptional control of α ENaC in response to aldosterone.[379] Aldosterone releases repression of α ENaC by reducing expression of Dot1a and its partner AF9,[380] and by impairing Dot1a−AF9 interaction via SGK1-mediated AF9 phosphorylation.[381] This network also appears to regulate transcription of several other aldosterone target genes, including SGK1.[382]

Calcium

Increases in intracellular calcium have been shown to inhibit ENaC activity by several groups.[252,383–385] This appears to happen as a biphasic process with a very quick early response and a slower downregulation after 5 minutes.[385] This is likely an indirect effect on the channel, as the activity of channels from cortical collecting ducts in excised patches exposed to increased cytosolic [Ca^{2+}] was not altered.[383] Activation of protein kinase C has been suggested to mediate the Ca^{2+}-dependent inhibition of ENaC, since this is known to decrease channel activity.[315] A second intriguing possibility, related to the delayed effect of Ca^{2+} on ENaC activity, is Ca^{2+}-dependent recruitment of Nedd4-2 isoforms that possess the Ca^{2+}-binding C2 domain to the plasma membrane,[285,286] with a subsequent increase in channel retrieval from the apical membrane.

pH and Oxidative Stress

Acidic intracellular pH, below 7.2, has been shown to decrease amiloride-sensitive Na^+ transport in isolated epithelial tissues, suggesting that intracellular pH may act as an intrinsic regulator of ENaC activity.[383,386,387] In conditions of ischemia or hypoxia where intracellular pH might fall, activation of AMPK might act to decrease channel activity, as noted above.[77] Hypoxia is known to decrease activity of ENaC through a decrease in channel expression in cultured type II alveolar cells, but the mechanism of this response is unknown. The effect of pH on channel activity appears to be direct. In excised, inside-out patches from apical membranes of rat cortical collecting tubule, a fall in pH from 7.4 to 6.4 resulted in a progressive and dramatic fall in open probability of the channel. The mechanism of this regulation is unknown. However, ENaC activity is clearly downregulated under cellular conditions where ATP is limiting.[388] It has been proposed that ENaC may be sensitive to changes in intracellular redox potential through oxidation of intracellular cysteine residues.[177] It has also been shown that transcription and expression of α ENaC subunit variants are suppressed by oxidative stress in lung epithelial cells.[389] Conversely, oxidative stress induced by hydrogen peroxide exposure appears to stimulate ENaC activity through a PI 3-kinase-dependent pathway in cultured kidney collecting duct cells.[390] Such oxidative stress-induced stimulation of

ENaC has been proposed to contribute to the pathogenesis of salt-sensitive hypertension. Similarly, superoxide formation and release by NADPH oxidase (NOX2) downstream of epidermal growth factor and Rac1 has been reported to stimulate ENaC open probability in the lung.[391]

Nitric Oxide

Several studies have shown that nitric oxide (NO) inhibits ENaC activity in both alveolar type II (AT II) cells and in cultured renal epithelial cells.[392–394] This effect may be important in inflammatory conditions such as acute respiratory distress syndrome, where NO levels may be elevated due to increased expression of inducible nitric oxide synthase (iNOS).[393] NO appears to inhibit the open probability of the channel in a cGMP-dependent manner.[392] Interestingly, aldosterone has also been shown to inhibit NO production from ATII cells, and this appears to be related to an effect of SGK1.[395] These results suggest a second, novel mechanism by which SGK1 could enhance ENaC activity through downregulation of iNOS activity, and a decrease in NO inhibition of ENaC open probability. In addition, the superoxide generation that occurs with oxidative stress appears to antagonize the NO-mediated inhibition of ENaC in lung slice patch-clamp experiments.[396]

Lipids

A number of membrane lipids and lipid intermediates have been shown to modify ENaC activity, often in complex ways. Inhibition of phospholipase A2 (PLA2) by aristolochic acid reduced arachidonic acid (AA) levels and increased ENaC activity in both *Xenopus* oocytes and A6 cells in culture.[127,397] Direct application of AA to rat cortical collecting ducts markedly reduced ENaC activity in a dose-dependent manner. While this effect was not reproduced by application of a non-metabolized analog of AA, 5,8,11,14-eicosatetraynoic acid (ETYA), it was reproduced by the CYP-epoxygenase metabolite 11,12-epoxyeicosatrienoic acid (EET).[398] A recent study found that, along with 11,12-EET, 8,9-EET, and 14,15-EET are additional eicosanoids that inhibit ENaC activity downstream of CYP2C8.[399] These results suggest that arachidonic acid effects are mediated by CYP epoxygenase metabolites. In contrast, in A6 cells current stimulation by PLA2 inhibition was blocked by ETYA, suggesting a direct effect of arachidonic acid on the channel, rather than the effect of a metabolite. The effect of ETYA on ENaC was to reduce open probability.[397] In oocytes, however, both arachidonic acid and ETYA inhibited ENaC, and this was due to an alteration in the number of surface channels. Analysis of ENaC surface expression showed a downregulation of channels consistent with a trafficking effect mediated by both increased endocytosis and decreased exocytosis.[127] Taken together, these experimental observations indicate that PLA2 activity leads to increased arachidonic acid levels that inhibit ENaC activity, but the precise molecular mechanisms remain in dispute.

Cellular phosphoinositides also affect ENaC function. Phosphatidylinositol-4,5-bisphosphate (PIP2) is a signaling molecule related to a number of intracellular processes, including endocytosis[400] and exocytosis.[401] It has also been implicated in the activation of several ion channels.[401] Patch-clamp studies have shown that anionic phospholipids, including PIP2 and PI-3,4,5-P3, can directly alter channel activity presumably by binding to cationic sequences within β and γ ENaC.[172,173] A distinct PIP3-binding site has been identified in the initial part of the carboxyl-terminus of the γ-subunit.[227] PIP2 also directly interacts with ENaC at a site distinct from the PIP3 binding site, and may be permissive for channel gating.[228] Interestingly, increases in cellular PIP2 levels have also been shown to increase surface expression of ENaC, presumably by stimulating exocytosis.[402] Kunzelmann and colleagues demonstrated that purinergic inhibition of ENaC by extracellular ATP in tracheal epithelia resulted in depletion of PIP2 from cells, and appeared to require a PIP2-binding region of the amino-terminus of the β-subunit.[174]

There are three isoforms of phosphoinositide-5-kinase, which produces PI-4,5-P2 from PI4P. These kinases have differing effects on cellular processes such as endocytosis.[400,403] PIP2 may thus induce varying effects on ENaC function, depending on the isoform of PI5K that is activated or the spatial localization of kinases and phosphatases that regulate PIP2 activity within the cellular microenvironment.[404] In summary, phosphoinositides functioning either as signaling agents or directly binding to ENaC affect channel activity.

Intracellular cytoplasmic Cys residues in β- and γ-subunits are modified by palmitoylation. Two Cys residues (Cys43 and Cys557) in the mouse β-subunit were shown to be modified by palmitoylation. Mutation of these Cys to Ala to prevent palmitoylation at these sites was associated with a reduction in channel open probability.[98] Secondary structural predictions suggest that Cys557 is within an amphipathic α helix near the second transmembrane domain, while Cys43 is in proximity to the first transmembrane α helix. Mueller and co-workers suggested that β-subunit palmitoylation modulates channel-gating by enhancing interactions between cytoplasmic domains and the plasma membrane.[98]

Intracellular Na^+

Since ENaC is present in epithelia that generate a steep lumen-to-bath Na^+ gradient, it is potentially

exposed to significant variations in both internal and external [Na^+]. ENaC is modulated by both intracellular and extracellular [Na^+]. Low levels of extracellular [Na^+] increase ENaC activity while elevated levels decrease activity, a process known as Na^+ self-inhibition.[405] Cytoplasmic [Na^+] is usually maintained quite low through the action of the Na^+,K^+-ATPase on the basolateral surface of epithelial cells. Since the pump is normally functioning well below its maximum capacity, Na^+ entry into cells is the rate-limiting step for Na^+ reabsorption. Under conditions of rapid increases in ENaC activity, regulation may also be achieved through increases in the intracellular [Na^+], a process referred to as feedback inhibition. This phenomenon has been observed in epithelial cells and *Xenopus* oocytes.[385,406] Feedback inhibition in response to an increase in the intracellular [Na^+] is a slow process that occurs over a period of minutes, in contrast to Na^+ self-inhibition, which occurs over seconds.[252] Studies in rat cortical collecting ducts suggested that PKC activation plays an important role in ENaC feedback inhibition.[407] Studies in oocytes indicated that this feedback inhibition was not readily seen in cells expressing ENaC with Liddle mutations that inhibit Nedd4-2-binding and ubiquitin-dependent internalization.[408] This finding focused attention on Nedd4-2 as the potential mediator of Na^+ feedback inhibition. In a series of studies in mouse mandibular duct cells, it was demonstrated that Na^+ feedback inhibition was dependent on Nedd4-2, and required binding of the second and third WW domains to carboxyl termini of β and γ ENaC.[409,410] More recent studies have suggested that the A-kinase anchoring protein 15 (AKAP-15) may bind to PKC and act in concert with PKC to regulate Na^+ feedback inhibition[411] or that intracellular [Na^+] may directly modulate the proteolytic activation of ENaC.[412] In summary, a few potential signaling pathways/mechanisms have been implicated in ENaC feedback inhibition by intracellular [Na^+], although the relative contributions for each and how they may integrate with one another in different cell types are still unclear.

Extracellular Na^+

Increases in extracellular [Na^+] inhibit ENaC activity, a process referred to as Na^+ self-inhibition. This phenomenon was originally observed in studies of native epithelial tissues in the setting of a rapid increase in extracellular Na^+ concentration.[413] This process reflects a decrease in channel open probability, and is not dependent on Na^+ influx.[2,182,201,202] Chraibi and Horisberger demonstrated that Na^+ self-inhibition is an intrinsic property of EnaC, and can be abolished by treatment with extracellular proteases.[202] Na^+ self-inhibition is a temperature-dependent phenomenon and has a large activation energy, suggesting that a conformational change occurs in association with the inhibition of channel activity by extracellular Na^+ that is presumably initiated by Na^+-binding to an extracellular site.[202,414] Numerous sites within the extracellular domains of the α- and γ-subunits have been identified where mutations alter Na^+ self-inhibition.[80,182,185,186,188,191,192] A number of important questions remain to be addressed regarding the Na^+ self-inhibition response, including: (1) where are the external Na^+-binding site(s); (2) what are the conformational changes that occur in response to Na^+-binding that result in a reduction in channel open probability; and (3) how do external proteases, presumably by cleaving ENaC subunits, diminish the Na^+ self-inhibition response?

Peroxisome Proliferators-Activated Receptors (PPARs)

The peroxisome proliferators-activated receptors (PPAR) have been implicated in the regulation of a wide variety of cellular processes. PPARγ is the pharmacological target of thiazolidinediones (TZDs) that have been used in the management of hyperglycemia associated with type II diabetes mellitus.[415] PPARγ is localized along the collecting duct in kidney,[416] and it is known that a side-effect of PPAR stimulation by TZDs is fluid retention.[417] It has been shown that TZD-induced weight gain was prevented in mice by amiloride or by deletion of the gene encoding PPARγ from collecting duct.[417] These studies suggested that TZDs increase ENaC activity in collecting duct cells, and increased mRNA for γ ENaC. These interesting results implicate PPARs in the regulation of transcription of at least one ENaC subunit that apparently leads to increased ENaC activity. More recent studies have suggested that the PPARγ-induced Na^+ reabsorption via ENaC in the kidney may be mediated through increased SGK1 expression.[418,419] In contrast, work from other groups suggest that PPARγ agonists do not activate ENaC[420] in cultured principal cells or decrease ENaC expression in the kidney.[421]

ATP

Luminal ATP signals through P2Y2 receptors and inhibits ENaC activity through activation of phospholipase C, activation of protein kinase C, and reducing cellular levels of PIP2 and channel open probability.[228,422,423] Recent studies suggest that this signaling pathway may have an important role in aldosterone escape, and the enhanced rates of Na^+ excretion in animals on a high-Na^+ diet.[424–426] Cellular release of ATP may be occurring through connexin 30 hemi-channels.[426]

Hormonal Regulation

Aldosterone

The major hormones regulating ENaC activity in a broad variety of tissues are corticosteroids. ENaC regulation by steroids is the subject of a separate chapter in this volume, and will not be discussed in detail here. Although non-genomic actions of aldosterone have been described in vascular and non-absorptive tissues,[427] the bulk of the available evidence supports the notion that steroid regulation of ENaC in Na^+-absorptive epithelia is mediated by processes dependent on transcription and translation. This transcriptional activity is driven by translocation of the steroid receptor to the nucleus following binding to its cognate ligand, and binding to specific domains within the genome. Interestingly, ENaC regulation varies somewhat by tissue. Steroid regulation of ENaC activity is largely due to an increase in the number of active channels in the apical membrane, although there is evidence for effects on open probability as well.[12,428,429] The increase in the number of active channels is not apparently a simple one-step procedure. An early increase in channels appears to be a trafficking event, with altered insertion or retrieval of already synthesized subunits.[142,143] A large part, but not all, of this effect is regulated by the aldosterone-induced proteins SGK1 and GILZ1 altering Nedd4-2-ENaC interactions and leading to increased membrane expression of the channel[305–307,430–433] (Figure 30.7). Synthesis and delivery of new channel subunits can be detected somewhat later in the course of steroid action in responsive tissues and, interestingly, also varies somewhat by tissue. In kidney, the predominant induced subunit is α, while in colon, the β- and γ-subunits are primarily induced.[434] This is true both at the mRNA and protein level. This phenomenon has been referred to as non-coordinate regulation, and suggests a degree of complexity of ENaC trafficking that is still not fully-understood.[92,435]

Vasopressin

Vasopressin has been shown to stimulate ENaC activity in the kidney and a number of epithelial cell lines derived from kidney.[252,312,436] The response is relatively rapid, with a time course of minutes, and does not appear to depend on transcription or translation of new proteins, at least in its initial phase.[252] Vasopressin binds to V_2 receptors on the basolateral surface of responsive epithelia, and activates adenylate cyclase. In almost all tissues studied, the action of vasopressin on Na^+ transport is fully reproduced by exogenous cAMP, and is felt to be secondary to activation of protein kinase A (PKA).[252,437,438] PKA has not been shown to phosphorylate any subunit of the channel, so its actions are felt to be indirect.[437] There has been no consistent demonstration of an effect of PKA on ENaC open probability, so it is likely that the primary effect of PKA on ENaC is to increase the number of channels at the plasma membrane. Indeed, there are now numerous demonstrations that PKA stimulation leads to an increase in surface expression of ENaC by biochemical, immunohistochemical, and electrophysiologic techniques.[111,312,439–441] By analogy to its well-described effects on insertion of aquaporins in kidney cortex and medulla, it seems reasonable to expect that the primary event in PKA stimulation of ENaC is the exocytosis of channels into the apical membrane from some pre-existing cytoplasmic pool. Strong evidence supports this likelihood. Studies by patch-clamp indicate a rapid increase in the number of surface channels in response to cAMP stimulation.[442] Stimulation of adenylate cyclase by forskolin or by addition of cAMP analogs leads to an increase in biochemical and immunohistochemically measured apical channel number,[312,439] and this increase is temporally associated with an increase in apical membrane capacitance typical of exocytic events.[111,441] Butterworth and colleagues have recently proposed that cAMP stimulation leads to exocytic insertion of channels from a subapical recycling pool of channels that is distinct from constitutive turnover of the channel, analogous to vasopressin regulation of water channels[111] (Figure 30.4).

It is also likely that vasopressin, acting through cAMP and Nedd4-2, alters channel retrieval. Snyder and colleagues reported that Nedd4-2 is a substrate for PKA phosphorylation, and they related cAMP regulation of ENaC to inhibition of Nedd4-ENaC interactions.[297] Indeed, PKA appears to phosphorylate Nedd4-2 at sites that overlap the SGK1 target phosphorylation sites, suggesting a similar mechanism of action in promoting the sequestration of Nedd4-2 through binding to 14-3-3 proteins.[308,309] There is an obvious interplay between the hormonal regulation of ENaC by aldosterone and vasopressin, and it is possible that it occurs at the point of kinase regulation. However, the fact that aldosterone and vasopressin are synergistic, and that ENaCs with Liddle's mutations which should be unresponsive to Nedd4-2 inhibition are still responsive to vasopressin stimulation,[436] suggests that, at a minimum, some distinct pathways are involved in the regulation of ENaC by these two hormones. It is also interesting to note that a long-term (days) effect of vasopressin to stimulate transcription of ENaC subunits would clearly complement and be synergistic with aldosterone effects in situations of significant Na^+ avidity.[443]

Insulin

Insulin stimulates ENaC activity in renal epithelia.[252,444] The exact mechanism(s) of this effect are a

subject of considerable controversy. This would seem odd, as it is clear that insulin stimulates phosphoinositide 3-kinase (PI3K), which in turn regulates the activity of 3-phosphoinositide-dependent kinase 1. The latter kinase phosphorylates SGK1 and converts it to an active form.[445] This represents an obvious convergence point for the effects of aldosterone and insulin, which have been shown to be synergistic, on the stimulation of ENaC activity.[445–447] Indeed, noise analysis indicates that the primary effect of insulin is to increase the number of active apical membrane channels, with little effect on open probability.[446] All of these observations are consistent with insulin increasing ENaC activity via decreasing Nedd4-2-dependent retrieval.

It is possible, however, that the action of insulin is more complex. Stimulation of ENaC activity by insulin is quite rapid (minutes), and has been associated with exocytosis and delivery of preformed channels to the apical membrane in a PI3K-dependent manner.[310] Additionally it has been proposed that insulin may directly activate channels by phosphorylation that is dependent on protein kinase C[319] or by interaction with active metabolites of PI3K, phosphoinositol 3,4 phosphate, and phosphoinositol 3,4,5 phosphate, both of which activate ENaC in excised patches.[448] As with aldosterone and vasopressin, although a great deal has been learned about the regulation and trafficking of ENaC, the final control mechanisms by which hormones regulate the channel are complex and only partially-understood.

Angiotensin II

Angiotensin II activates ENaC by signaling through angiotensin II type 1 receptors.[449–451] The signaling mechanism appears to involve activation of a Ca^{2+}-independent protein kinase C isoform and activation of NADPH oxidase, leading to an increase in channels at the plasma membrane, as well as an increase in channel open probability.[450,451]

Endothelin

Endothelin-1 signaling through ETB receptors results in a decrease in ENaC open probability. The intracellular signaling pathways subsequent to ETB receptor activation involve Src kinase and MAP kinase 1/2 signaling pathways.[314,452,453]

Regulation by Mechanical Forces

Members of the ENaC/DEG family expressed in *C. elegans* are mechanosensitive ion channels. Early studies directed at examining the mechanosensitivity of ENaC produced conflicting results that have led to lively debates.[454] Different responses of ENaC expressed in *Xenopus* oocytes to cell swelling or shrinking have been reported.[455,456] Application of a negative hydrostatic pressure to rat CCD cells by patch pipettes led to a variable increase in the open probability of Na^+ channels.[11]

The distal nephron is subject to varying flow rates and volumes, dependent in part on extracellular volume status and the use of pharmacologic agents, such as loop and thiazide diuretics. Changes in flow rates within the distal nephron affect ENaC activity. Micropuncture and microperfusion studies of distal nephron segments have demonstrated that increases in flow rates within the physiologic range led to increases in the rates of net transepithelial Na^+ flux.[457–459] Increases in tubular flow rates expose channels to a variety of mechanical forces, including hydrostatic pressure and shear stress. Carattino and co-workers demonstrated that ENaCs expressed in oocytes are activated when exposed to laminar shear stress at levels that are likely to be present at the surface of principal cells within collecting ducts exposed to flow rates within a physiologic range.[220,221] The increase in ENaC activity is due to an increase in channel open probability.[204,220,221,460] While mutations introduced at sites within the channel pore alter the channel's response to shear stress, evidence suggest that the large extracellular regions function as flow sensors.[188,221,461,462] ENaC subunits are also expressed in vascular smooth muscle, where they are also exposed to mechanical forces. ENaC subunits, possibly in conjunction with ASIC subunits, form mechanosensitive channels that function as arterial baroreceptors and participate in the myogenic response in vascular beds.[160,463–470]

ENaC AND HUMAN DISORDERS

Liddle syndrome is a rare, autosomal dominant disorder characterized by extracellular fluid volume expansion, hypertension, and hypokalemia. Mutations have been described in patients with this disorder in genes encoding the β- or γ-subunits of ENaC that result in either a truncation or frameshift within the intracellular carboxyl termini or amino acid substitutions within the PY motifs.[277,279–281] These mutations disrupt the binding of Nedd4-2 to ENaC, prevent Nedd4-2-dependent ubiquitination of ENaC subunits, and significantly retard rates of channel internalization from the plasma membrane and degradation.[126,128,282,471,472] Liddle's mutations are also associated with an increase in channel open probability that may reflect an increase in the proteolytic processing of subunits, in association with an increased residency time at the plasma membrane.[473]

It is likely that rare mutations that result in a Liddle syndrome phenotype that are not associated with the

PY motif will be identified. These mutations would result in either an increase in channel open probability or an increase in surface expression. For example, a γ-subunit N530K mutation has been described in a patient with diabetic nephropathy.[474] This mutation is within a region where mutations or chemical modification of substituted cysteine residues lead to an increase in channel open probability.[76,79,219] Common human epithelial Na^+ channel polymorphisms segregate with blood pressure, including βT594M and αA663T,[475,476] and are associated with altered channel activity.[231,477,478] A homozygous missense mutation in the gene encoding SCNN1A (α-subunit) resulting in a Ser243Pro mutation was noted in an infant with severe renal Na^+-wasting.[479] This mutation was associated with enhanced Na^+ self-inhibition, as well as enhanced Na^+ feedback inhibition (an inhibition of channel activity due to an increase in intracellular [Na^+]). Another report described an individual with atypical cystic fibrosis who was heterozygous for the ΔF508 CFTR mutation.[192] This individual also had a mutation in the α-subunit (αW493R) that resulted in a profound loss in Na^+ self-inhibition. While it is unclear whether the αW493R mutation contributed to the pulmonary symptoms, individuals who are heterozygous for the ΔF508 mutation in the cystic fibrosis transmembrane conductance regulator (CFTR) generally lack overt pulmonary symptoms. Specific disorders of mineralocorticoid and glucocorticoid metabolism are also associated with increases in ENaC activity and hypertension.

A decrease in airway fluid volume has been observed in patients with cystic fibrosis. As discussed above, it has been suggested the CFTR, a cAMP-regulated Cl^- channel, inhibits ENaC activity in airway epithelia. In the absence of functional CFTR, the activity of ENaC in airways appears to be increased,[352,355,357] although conflicting observations have been reported.[362,363]

Renal Na^+ retention occurs in nephrotic syndrome, even in the absence of activation of known volume regulatory hormones. Recent studies suggest that plasminogen is filtered by damaged glomeruli, and is converted to plasmin by urokinase that lines kidney tubules.[338,339,480] Plasmin cleaves the γ-subunit and activates ENaC, raising the possibility that aberrant activation of ENaC by plasmin may have an important role in the activation of renal Na^+ retaining mechanisms in nephrotic syndrome.[338,339,480]

ENaC loss-of-function mutations have been described in the autosomal recessive variant of type I pseudohypoaldosteronism. This disorder is characterized by volume depletion, hypotension, and hyperkalemia. Many of the mutations described to date are due to a frameshift or premature stop codon.[42] A missense mutation within the β-subunit G37S led to the identification of an N-terminal domain that affects channel-gating.[165,166]

Anion Channels

Owen M. Woodward and William B. Guggino

Department of Physiology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

INTRODUCTION

The mammalian kidney evolved to allow for the efficient secretion of metabolic waste without excess loss of water in terrestrial environments, for the maintenance of the ionic balance in the extracellular milieu, for the regulation of blood pressure, and for the recapture of essential solutes like proteins and sugars. These functions all deferentially depended on the conductance/transport of Cl^- and other anions across individual cell membranes. A classic example is NaCl reabsorption in the distal nephron, where Na^+, Cl^-, and K^+ enter the cell across the apical membrane via the NKCC2 co-transporter, driven by the Na^+ gradient established by the Na^+/K^+-ATPase, and the Cl^- gradient maintained by basolateral ClC-Kb Cl^- channels. Mutations in these basolateral Cl^- channels result in the severe salt-wasting characteristic of Type III Bartter's syndrome. As more of the major Cl^- channel family molecular identities are resolved, our understanding of the role of Cl^- channels in kidney disease will increase proportionally, and hopefully shed light on some of the long-standing mysteries of kidney function.

Although anions and negatively charged organic solutes were appreciated as necessary to balance the charges accumulated by the cations, Na^+, K^+, and Ca^{2+}, they were believed to be passive players. Cl^-, by far the most abundant physiological anion, was believed to be balanced across the membrane, a belief supported by early studies of skeletal muscle, where the resting Cl^- permeability was found to be very high,[27] and thus Cl^- was mostly known for its contribution to the "leak" current.[131] Even as later studies demonstrated that Cl^- was being actively transported in squid axons or secreted as HCl in the stomach,[27] less interest was given to anion conductances. Initial patch-clamp studies of Cl^- channels discovered that Cl^- channels are not really even Cl^- channels; their general promiscuity toward all anions makes them more accurately described as anion channels. The tide first began to change as neuroscientists found, and later cloned, the GABA- and glycine-gated Cl^- channels that worked to inhibit synaptic transmission, proving that Cl^- was not in equilibrium at rest and could be harnessed by cells to do work. But it was the cloning of two major classes of Cl^- channels, the CLCs and CFTR, which lead to an explosion of interest in Cl^- channels, and exponentially increased our understanding of their ubiquity, importance in human disease, and function in the mammalian kidney.

Anion channels are usually grouped into five major classes, based on how they are activated or regulated. There are the voltage-dependent Cl^- channels (the CLCs); ligand-gated Cl^- channels (the GABA and glycine receptor channels); cAMP-activated channels (CFTR); Ca^{2+}-activated Cl^- channels (the TMEM16 channels); and the volume-regulated anion channels (the VRAC channels). This chapter will examine the expression and function of these major classes of Cl^- channels in the kidney, but will also discuss at length Cl^- channels that are expressed ubiquitously or for which expression and functional information does not yet exist. The chapter dives right in to survey the major anion channel families and their relevance in the kidney, focusing on the CLC, CFTR, TMEM16, VRAC, and SLC26A7/9 Cl^- channels. However, the chapter will also look at a number of less well-understood anion channel genes that have currently unclear physiological relevance. Lastly, we will delve deeply into Cl^- channelopathies that affect the kidney both directly and indirectly, seeking insight into how Cl^- channels contribute to normal kidney physiology.

What's "New"?

Recent work on Cl^- channels has paid disproportionate dividends for Cl^- channel researchers, including advances in our understanding of Cl^- channel structure, molecular identity, and discovery of new Cl^- channels in familiar but surprising places. The most important advance in Cl^- channel knowledge came in 2008, when three independent groups using three novel approaches all identified the TMEM16A gene as the molecular identity of the classic Ca^{2+}-activated Cl^- channel (CaCC). The TMEM16 family of genes has 10 human homologs that are expressed widely, including in the kidney. As more and more work is done describing their function, biophysical characteristics, and expression patterns, the more certain it becomes that TMEM16a is the classic CaCC. Second, crystal structures solved for bacterial orthologs of the voltage-dependent CLC Cl^- channel family revealed via homology that a number of the human CLCs (ClC-3, 4, 5, 6, and 7) are not in fact channels, but H^+/Cl^- exchangers, a finding with ramifications in the kidney. And third, two members of a well-known anion transporter family, SLC26A7 and A9, appear to behave almost exclusively as anion channels, with no appreciable transport of bicarbonate. Which, taken in conjunction with the recent reclassification of a number of the CLC channels as exchangers, suggests a fine line between anion transporter and anion channel. Each of the recent advances mentioned above will be discussed in depth in the following chapter.

MAJOR CLASSES OF IDENTIFIED ANION CHANNELS

Similar to the study of other ion channels, extensive research into the biophysical and physiological characteristics and functions of Cl^- channels preceded the identification of their molecular identity or their corresponding human genes. One reason that the molecular identification of Cl^- channels lagged far behind that of cation channels is that there were no highly specific inhibitors that could be used for cloning Cl^- channels in a manner similar to that done for many cation channels. However, with a considerable amount of effort, more and more of the Cl^- channels recognized for their biophysical characteristics now have mammalian gene candidates, identifications of which have quickly expanded our knowledge of the roles of Cl^- channels in cellular functions and in human disease. The molecular identification has also shown just how difficult identification of all the Cl^- channels is. There is no homology between any of the identified gene families containing Cl^- channels, and very little commonality in structure.[27] Their demonstrated convergence of function, so different from the common homology of many of the families of cation channels, presents no easy bioinformatic road map to the discovery of Cl^- channel identities. Instead, a narrowly focused approach has been used on each of the functional classes of Cl^- channels to identify the known Cl^- channel families (Figure 31.1), a growing list that now includes the CLC voltage-dependent channels, CFTR, TMEM16/Anoctamins Ca^{2+}-activated Cl^- channels,

Anion Channel	Regulation	Channel Properties	Kidney Localization	Physiological Role	Human Disease
CFTR	Activated by cAMP-dependent phosphorylation	Linear I/V; $Cl^->I^-$	Proximal and distal tubule, collecting duct	Cl^-secretion from epithelium	Cystic fibrosis; Polycystic kidney disease
ClC-2	Activated by hyperpolarization and cell swelling	Inward rectifying I/V; $Cl^->I^-$	Proximal tubule	Unknown	Unknown
ClC-Ka and Kb	Weak voltage activation and requires barttin subunit	Moderate outward rectifying I/V;$Cl^->I^-$	ClC-Ka: tAL;ClC-Ka: TAL, distal tubule, collecting duct	Basolateral Cl^- secretion	Bartter's syndrome type III and IV
TMEM16 (A)	Activated by cytosolic Ca^{2+}	Outward rectifying I/V; $I^->Cl^-$	Unknown	Ca^+ dependent Cl^- secretion from epithelium	Unknown
SLC26A7	Constitutively active and pH sensitive	Linear I/V; $Cl^->I^-$	Collecting duct	pH sensor or Cl^- shunt in acid secreting cells	Unknown
VRAC/Maxi-anion	Activated by cell swelling	Outward rectifying, depolarization induced inactivation; $I^->Cl^-$	Ubiquitous; maxi-anion; macula densa cells	Regulatory volume decrease; salt-sensing and ATP secretion	Unknown

FIGURE 31.1 **Anion Channels of the human kidney.**

SLC26A7/9, GABA and glycine receptor channels, VDAC, and a myriad of less well-studied groups including the bestrophins, intracellular CLICs, CLCA, and tweety (hTTYH3). The long search for molecular identities of the Cl^- channels has lead to many ambiguous discoveries, dead ends, and great success stories. Below we review the Cl^- channels with known molecular identities, and known physiological and kidney specific functions, but we will also discuss those genes that code for proteins that can conduct Cl^-, but do not yet have known physiological functions.

CLC Cl^- Channels

Our discussion about the specific families of Cl^- channels begins with CLC Cl^- channels (Figure 31.2). Unlike CFTR, which was not immediately recognized as a Cl^- channel and appeared to be a very divergent type of ABC transporter,[27] the canonical ClC-0 shared close homology with proteins from a large gene family with members expressed across all phyla, including nine members expressed in humans. Two decades of subsequent work have revealed much about the CLC family, their biophysical properties, and their importance in human disease, yet many of the mammalian orthologs still only have vaguely defined physiological functions. However, the relevance of the CLCs in the human kidney is clear. Eight of nine human CLC orthologs are expressed in the kidney, and their dysfunction leads directly to Dent's disease and Type III Bartter's syndrome.[25]

For years the mammalian CLCs were divided into two classes, based on cellular localization with ClC-1, 2, and ClC-Ka, b channels being expressed in the plasma membranes, and the remaining ClC-3, 4, 5, 6, and 7 all being expressed on intracellular membranes. Recent evidence has substantially shifted this paradigm of understanding, with the plasma membrane CLCs now simply classified as the voltage-dependent Cl^- channel CLCs with the rest now classified as Cl^-/H^+ exchangers. It turns out that the vast majority of all CLC family members across all phyla are Cl^-/H^+ exchangers and not Cl^- channels. For the mammalian CLC proteins this has meant a revision of functions and physiological roles for the previously designated intracellular CLCs. Intrinsically, the difference between a CLC Cl^- channel and a CLC Cl^-/H^+ exchanger is little more than a few strategically placed glutamate residues; extrinsically, their thermodynamic properties are completely different.[79] These newly classified exchangers will be covered briefly below, but this section will mostly focus on the remaining CLC Cl^- channels and their functions in the kidney.

The early work investigating CLC Cl^- channels found they have very distinct biophysical properties, which immediately set them apart from the known cation channels and would later set them apart from all other known Cl^- channels. ClC-0 can be described as voltage-dependent, pH-dependent, and dependent on the Cl^- gradient across the pore, as can most of the CLC Cl^- channels.[19] The "kidney" Cl^- channels, ClC-Ka and ClC-Kb, are additionally dependent on a smaller beta-subunit, barttin (BSND); a dependence with ramifications for NaCl reuptake in the thick ascending loop and Bartter's syndrome. The halide selectivity sequence for ClC-0 is $Cl^- > Br^- > I^-$, and in most physiological circumstances it forms functional homodimers, although heterodimers from ClC-0, 1, and 2 can be formed heterologously.[19,54] ClC-0 single channel currents appeared at first glance to be two separate channels, albeit with identical conductances; however, even though the two conductances or protopores appeared to open and close independently, sporadically they both closed simultaneously and remained closed for prolonged periods before opening again.[19,70a,78] The coexpression of ClC-0 and ClC-2 heterodimers resulted in the same strange phenomenon, but this time the two protopore conductances were different. The difference in protopore conductances correlated with the varying protopore size between ClC-0, 1, and 2, being 10 pS, 1.5 pS, and 3 pS respectively.[27] This prompted the conclusion that ClC Cl^- channels function as dimers, with two separate protopores, each independently gated by a separate "fast" gate, but both gated simultaneously by a "slow" gate.[55]

This hypothesis was proven correct after the crystallization of the prokaryotic CLC proteins from *E. coli* and *Salmonella typhimurium*.[28] These prokaryotic CLCs formed dimers, with each subunit forming its own protopore. Each subunit consists of 18 membrane "embedded" domains, where many of the helices do not project completely through the bilayer.[28] Interestingly, each subunit has structurally similar halves that "twist" in an antiparallel structure that forms an hourglass shaped protopore toward the center.[28] Further work on the *E. coli* CLC, EcClC-1, crystal revealed that there are three Cl^--binding sites within the hourglass shaped pore, and in the outermost site the Cl^- appears to compete with the carboxyl group of a negatively-charged glutamate.[29] When this glutamate is replaced with a non-charged amino acid in the ClC-0 channel, the voltage-dependent gating properties are altered.[29] This suggests that the central "gating" glutamate is key in the voltage- and Cl^--dependence of CLC gating,[55] and represents the fast gate regulating each protopore. The possible protonation of the gating glutamate, thereby allowing Cl^- to enter the pore, may also help explain the pH-dependence observed for many CLCs.[27]

The reconstitution of EcClC-1 in lipid bilayers revealed that it is not a Cl^- channel, but a Cl^-/H^+

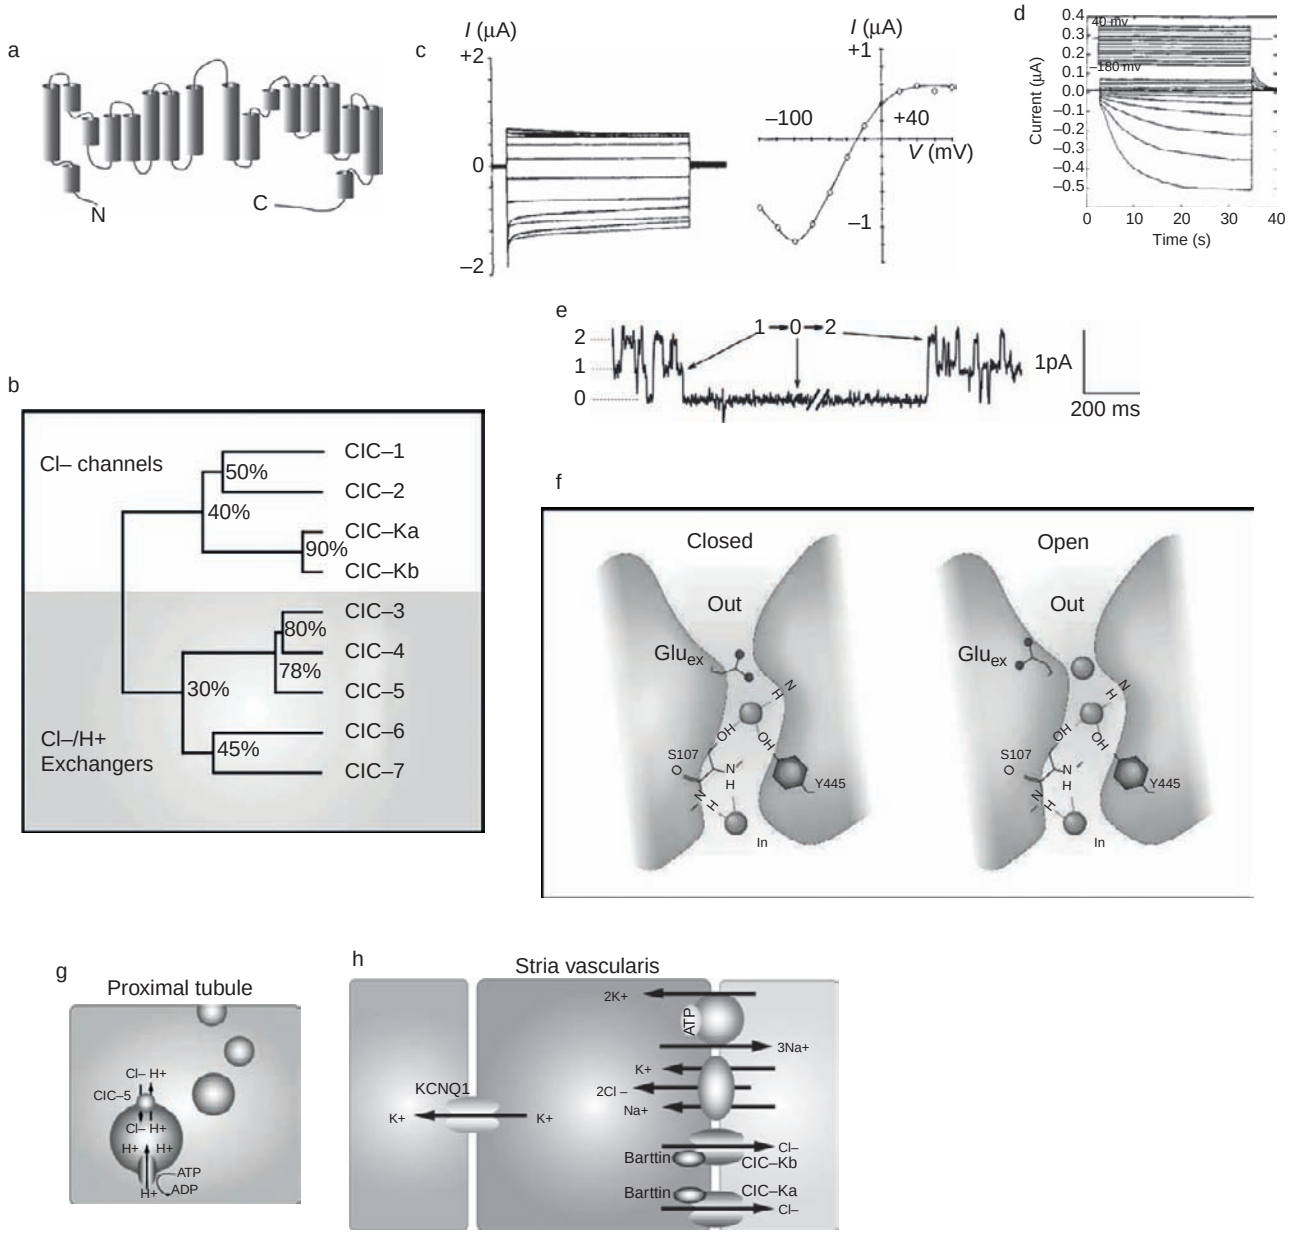

FIGURE 31.2 **CLC Gene family.** (a) Topography of representative CLC protein. (b) Dendrogram of mammalian CLC proteins. exchanger, where two Cl^- ions are substituted for one H^+.[55] Further mutational studies discovered the H^+ exchange depended on both the gating glutamate, and a second glutamate near the cytosolic surface, but not in the protopore.[79] These characteristics suggest that both protons and Cl^- are gated by the "gating" glutamate, after which they travel separate permeation paths to the cytoplasm. This theory is supported by

experiments where this second glutamate was mutated in the EcClC-1, making the protein exclusively a Cl^- channel, not an exchanger.[1] The human CLCs ClC-3, 4, 5, 6, and 7 all have this second glutamate marking them as exchangers, and mutating both glutamates in ClC-4 and 5 converted them into Cl^- channels,[96,109] demonstrating just how fine the line is between Cl^- channel and exchanger.

The pharmacology of CLC Cl^- channels, like many of the other anion channels, has been plagued by the lack of specific high affinity inhibitors. Although the mammalian CLCs are highly conserved, they do differ somewhat in their susceptibility to the classic Cl^- channel inhibitors. ClC-0, ClC-1, and ClC-2 all differ in their affinity for 9-anthracene carboxylic acid (9-AC), with ClC-1 effectively blocked by 100 μM, whereas ClC-0 and ClC-2 require mM levels.[118,125] The CLCs are also affectively inhibited by the clofibric acid derivatives 2-(-p-chlorophenoxy) propionic acid (CPP) and 2-(-p-chlorophenoxy) acetic acid (CPA).[19,131] Stilibenes can also be weakly inhibitory and can block ClC-2, as can DPC and NPPB at 0.5 to >1 mM concentrations.[131] ClC-2 is also inhibited by divalent cations like zinc and cadmium with IC_{50} in the μM range[131] as the other CLC Cl^- channels can be. Because of their human disease relevance the kidney CLCs, Ka and Kb have been scrutinized more than the others. Specifically, inhibitors could regulate dieresis and possibly blood pressure, and therapeutic activators could aid patients with Bartter's Syndrome.[70] The close shared homology of the ClC-Ks obviously suggested similar sensitivities to inhibitors, but both CPP and DIDS are more affective at blocking CLC-Ka than Kb.[28,131] Niflumic acid (NFA), another classic Cl^- channel inhibitor, was actually shown to activate the CLC-Ks at low concentrations (50−100 μM),[70] but inhibit them at higher concentrations,[131] a finding that prompted Liantonio et al.[70] to manipulate the CPP structure to recapitulate characteristics of the NFA molecule, in order to create a better inhibitor. They found that their rationally designed benzofuran carboxyl acid derivatives could inhibit both ClC-Ka and Kb with low μM IC_{50}s.[70] Their work, and the insight provided by the EcClC-1 crystal structure, make finding potential therapeutic activators and inhibitors of the CLC-Ks a real likelihood, therapies that could impact millions of patients.

Physiological Function of Mammalian CLC Cl^- Channels

With the recent identification of the intracellular CLCs as exchangers, only four human CLCs remain for further in-depth discussion: ClC-1, ClC-2, and the CLC-Ks. ClC-1 (the human gene is *CLCN1*), is the only CLC that is not expressed in the kidney.[25] It is a plasma membrane localized Cl^- channel found almost exclusively in skeletal muscle. There it represents about 80% of the resting conductance of the muscle.[55] When the muscle depolarizes along the T-tubule, and Ca^{2+} is released from the sarcoplasmic reticulum, ClC-1 is further activated. The ClC-1 activation repolarizes the muscle cell and brings it back to its negative resting potential. Cl^- and not K^+, as in most other excitable cells, is used for repolarization because it is thought that in the microdomains of T-tubules extracellular K^+ would quickly build up, causing unsolicited depolarizations.[55] The physiological importance of ClC-1 became clear after causal ClC-1 mutations were found first in myotonic mice and later in humans.[55] The human form of the disease, myotonia or "muscle stiffness" is characterized by muscles that suffer prolonged contractions, exactly the phenotype expected if repolarization cannot occur after the initial depolarizing stimulus. Humans can have either the recessive form of the disease (Becker type) with complete ClC-1 functionality loss or the dominant form (Thomsen's) with the retention of some ClC-1 function and less severe debilitation.[55,131]

ClC-2

ClC-2 is broadly expressed in many different tissues, but is prominent in epithelium (including kidney), neurons, glia, and heart muscle.[125] Unlike ClC-1, ClC-2 is inwardly rectifying and hyperpolarization activated.[108,131] It can also be activated by cell swelling, but is clearly not the ubiquitous VRAC current, which differs in selectivity, voltage-dependence, rectification, and single channel conductance.[55] Unfortunately, little is yet known about its function. Even the development of $Clnc2^{-/-}$ knockout mice has provided only minimal hints at its broad functions. $Clcn2^{-/-}$ mice did display some disease phenotypes; however, knockout mice displayed degeneration of photo receptors and seminiferous tubules in testicles.[131] There is also some evidence that ClC-2 is involved in Cl^- secretion in lung epithelium, and that it could provide an alternative source of Cl^- secretion in patients with aberrant CFTR function.[112] To that end, the FDA approved lubiprostone, the only CLC-targeted drug yet approved, for treatment in cystic fibrosis (CF).[23,131] More recent work suggests that ClC-2 may be localized more on the basolateral membrane and not apical, at least in gut epithelium,[55] and that lubiprostome may also activate CFTR or other apical Cl^- channels, not necessarily just ClC-2.[6,131] Unfortunately, $Clcn2^{-/-}$ mice have no kidney phenotype, even though ClC-2 is believed to be expressed in the proximal tubule.[128] It is possible that, like in the gut, they may be expressed on the basolateral membrane and involved in the reabsorption of Cl^- along the nephron, but to what extent is unclear.

CLC Exchangers

Before progressing to the in-depth analysis of the remaining kidney CLC Cl^- channels, it is necessary to briefly touch on the CLC intracellular exchangers, in particular ClC-5 because of its relevance in kidney function. Like most other CLCs, ClC-5 is a Cl^-/H^+ exchanger that exchanges two Cl^- for every H^+. ClC-5 is localized to the proximal tubule and to the α-intercalated cells of the cortical collecting duct.[25] ClC-5 is specifically localized to the endosomes in these cell types, alongside the v-type H^+-ATPase.[25,43,98] The human ClC-5 gene *CLCN5* was identified independently, first through positional cloning in families with Dent's disease,[25] and confirmed through homology cloning.[55] Dent's disease is an X-linked renal tubular disorder characterized by low molecular weight proteinuria (LMWP), hypercalciuria, nephrocalcinosis, kidney stones, and renal failure.[25] More than 40 mutations have been identified in human *CLCN5* that cause Dent's disease, with a wide range of severity.[55] Recapitulating some of the disease-causing mutations in ClC-5 expressed in heterologous systems showed they almost universally resulted in reduction or loss of Cl^- conductance (ClC-5 when overexpressed reaches the plasma membrane).[25] This, along with its known localization to subapical endosomes alongside H^+-ATPases, prompted the hypothesis that ClC-5 was functioning to provide Cl^- influx to offset the positive charge build-up from the acidification of the endosomes.[25,98] A Cl^- shunt would prevent a slowdown of H^+ pumping into the endosomes from positive charge build-up. Importantly, the then presumed channel characteristics of ClC-5 didn't match this function well, ClC-5 is outwardly rectifying, and most importantly is inhibited by acidic pH.[25] The creation of a $Clcn5^{-/-}$ knockout mouse allowed the testing of the role ClC-5 plays in endosomal acidification. The two models[97,135] both reproduced the LWMP and defective apical endocytosis, seemingly supporting the hypothesis that ClC-5 aids in acidification.[25,55,128] In addition, *in vitro* disruption of ClC-5 function caused reduced acidification of the endosomes.[87] But with the discovery that ClC-5 is not in fact a Cl^- channel, but a Cl^-/H^+ exchanger it became far less clear how it could provide the shunt current for acidification, and how it could be influencing the endocytosis of low molecular weight proteins. Recent work by Noarino et al.[87] addressed this question directly by comparing mouse models with either $Clcn5^{-/-}$ knockout or the knockin of a mutated Clcn5 (Clcn5unc) that removed the "gating" glutamate, uncoupling the Cl^-/H^+ exchange and thereby creating a ClC-5 Cl^- channel, not exchanger. They found, as reported previously, endosomes from the Clcn5 knockout showed reduced acidification and defective endocytosis; however, the Clcn5unc knockin mice showed normal acidification, but still had defective endocytosis.[87] These data strongly suggest that ClC-5 plays a role in acidification by acting as a charge shunt; however, as a Cl^-/H^+ exchanger it plays a further yet to be explained role in endocytosis unrelated to its role as a shunt. Novarino et al.[87] suggest the intra-endosome absolute Cl^- concentration may be key in regulating endocytosis, not just the negative charge.

CLC-Ks

There are two mammalian CLC-K channels, named because of their localization to kidney tissues, although they are now also known to be expressed in the inner ear. Mammals possess two CLC-Ks, ClC-K1 and K2, and the human orthologs are termed ClC-Ka and -Kb, respectively. The CLC-Ks are highly conserved with the rodent homologs, ClC-K1 and K2, sharing 80% homology and the human pair being over 90% homologous.[61] After the homology cloning of rodent ClC-K1 and -K2, they were heterologously expressed in *Xenopus* oocytes, but only ClC-K1 expression resulted in Cl^- currents.[127] These ClC-K1 currents displayed a linear I/V relationship, with little voltage-dependence.[133] Like the rodent ClC-K2 that failed to produce currents, the heterologous expression of the human ClC-Ka and -Kb failed to yield any Cl^- currents,[61] prompting the supposition that a β-subunit may be necessary for function. The discovery of the subunit came tangentially from the successful positional cloning of a gene mutated in human type IV Bartter's syndrome, BSND, which codes for the protein barttin.[14] Barttin has two transmembrane domains, and both N- and C-termini located in the cytoplasm.[32] The expression of barttin along with either of the human CLC-Ks resulted in robust Cl^- currents with ion selectivity similar to that of other CLC Cl^- channels, inhibited by low extracellular pH, and stimulated by extracellular Ca^{2+}[62]. The main function of barttin appears to be to increase dramatically the amount of CLC-Ks that make it to the plasma membrane, although it also appears to subtly alter gating.[134] Interestingly, the voltage-dependence described for other CLCs is absent in the CLC-Ks,[128] a phenomenon that appears connected to the "gating" glutamate described in the EcClC-1 exchanger; the two ClC-K channels in humans lack the gating glutamate and instead have a valine at the same position. However, if the valine is mutated to a glutamate, strong voltage dependence is recapitulated.[133]

Although human CLC-Ks share close homology and do have overlapping kidney expression patterns, there does appear to be some divergence in localization that is supported by a divergence in function as well. ClC-

K1 (and presumably ClC-Ka) is expressed in the cortex, inner, and outer medulla, specifically localized in the thin ascending limb (tAL) of the loop of Henle; ClC-K2 is expressed in the cortex, inner, and outer medulla, specifically localizing to the thick ascending limb (TAL), distal convoluted tubule, and the α-intercalated cells of the collecting duct. Barttin expression is co-localized with the two CLC-Ks.[25,55,61,130] All three proteins, ClC-Ka, b, and barttin, are also expressed together in the stria vascularis of the inner ear.[61]

Function of the CLC-Ks

The discussion on function will concentrate on three areas, the tAL, the TAL, and the inner ear. These are not the only areas of the nephron where the CLC-Ks have significant function, but they are the areas most directly attributed to their roles in human disease. An additional discussion of Bartter's syndrome and CLC-Kb will come at the end of the chapter.

Currently there are no described human diseases with an isolated defect in the ClC-Ka gene, *CLCNKA*.[61] Although there has been one report of an association between salt-sensitive hypertension and single nucleotide polymorphisms in humans *CLCNKA*,[7] it is not clear how the SNPs or resulting haplotypes would alter ClC-Ka function. This lack of recognized human diseases from mutant ClC-Ka may be due to functional redundancies or poor sampling, because evidence has accumulated suggesting that ClC-Ka plays an important role in the urine concentrating mechanism of the loop of Henle. As mentioned above, ClC-K1 (Ka) is localized to the tAL, the area of the nephron with the highest Cl^- permeability,[25] and early studies comparing the characteristics of heterologously expressed ClC-K1/barttin currents versus those described from *in vitro* perfusion studies found striking similarities.[128] Subsequent work demonstrated that ClC-K1 was expressed in both the basolateral and apical membranes of tAL epithelium,[25] and interestingly, dehydration appears to increase the tAL expression of ClC-K1 in rats.[61] This loose connection between volume sensing and ClC-K1 expression in the tAL may be through the skg1 protein kinase. The SKG1 gene and protein expression increases when the cell volume diminishes and, in turn, can upregulate ClC-K1/barttin currents.[31] Barttin has a PY site on its C-terminus which facilitates the binding of WW domain-containing ubiquitin ligases like Nedd4-2; sgk1 can phosphorylate Nedd4-2, preventing the ubquitination of barttin and increasing the half-life of ClC-K1/barttin at the plasma membrane.[31] Upregulation of Cl^- vectorial transport in the tAL in times of dehydration would work to increase the concentrating mechanism of the inner medulla, and allow for increased water reabsorption via Aquaporin-2 in the collecting duct principle cells. However, it wasn't until the creation of the $Clcnk1^{-/-}$ knockout mouse that the physiological significance of ClC-K1 was clearly demonstrated.

$Clcnk1^{-/-}$ mice display no physical phenotypes, no renal organ phenotype or changes in plasma creatinine, Na^+, K^+ or HCO_3^-. However, they do display a four- to five-fold increase in the volume of excreted urine and other symptoms similar to the human condition nephrogenic diabetes insipidus (NDI).[77,128] The concentrating of urine depends on the reuptake of water in the collecting duct, a process which in turn depends on the osmolarity gradient across the inner medulla.[25] The high interstitial osmolarity of the inner medulla depends on the reabsorption of $NaCl^-$ and the recycling of urea in the tAL. The dysfunction of any part of the complicated concentrating mechanism will lead to diabetes insipidus, qualified as "nephrogenic" if the application of vasopressin (AVP) has no effect on the water lost in urine.[25] The $Clcnk1^{-/-}$ mice demonstrated an increase in urinary AVP secretion, no tAL Cl^- transport, and reduction in papillary osmolarity due to decreased accumulation of NaCl and urea in the inner medulla.[77] These results clearly and unambiguously demonstrated that ClC-K1 (Ka) is solely responsible for the vectorial Cl^- transport of the tAL, and that it constitutes an important part of the urine concentrating mechanism.

The function of ClC-K2 (Kb) became clear after the mapping of human mutations in the *CLCNKB* in patients with Bartter's syndrome, a condition that includes renal salt-wasting.[61] This discovery, coupled with the localization of ClC-Kb to the TAL, prompted a model of NaCl reapportion in the TAL, where the ClC-K2 (Kb) is responsible for the basolateral Cl^- conductance out of the cell. More specifically, in TAL cells, the apical membrane contains the NKCC2 co-transporter (SLC12A1) and ROMK K^+ channels; Na^+, Cl^-, and K^+ all enter the cell via the NKCC2, K^+ exits again apically via the ROMK channel, Na^+ is pumped into the interstitium via the Na^+/K^+-ATPase, and the Cl^- moves down its gradient through basolateral ClC-Kb channels into the interstitium.[61] This model is well-supported by the human genetics underlying Bartter's syndrome, and will be discussed further at the end of the chapter. In contrast, gain-of-function mutations have also been identified in the human *CLCNKB*, most notably the T481S polymorphism prevalent in both African and Caucasian populations, with minor allele frequencies of 0.22 and 0.12 respectively.[53] The T481S mutation in ClC-Kb increases currents 20-fold, possibly by alterations to the channels open probability,[53] and was thought therefore to lead to increased salt reabsorption and thus hypertension; however, studies have mostly shown that there is no association between the T481S mutation and hypertension.[55]

More recently, ClC-Ka, ClC-Kb, and barttin have all been shown to be expressed outside the kidney, in the stria vascularis of the inner ear. This was discovered only after a connection between deafness in some patients suffering from Bartter's syndrome was made to a mutation in the barttin protein. Barttin and the CLC-Ks are expressed on the basolateral membrane of the stria vascularis epithelium, where they function to reduce the Cl^- concentration in the stria vascularis. The fluid of the stria media has a very high concentration of K^+, and an unusually low concentration of Na^+. The excess K^+ is necessary to depolarize the hair cells via mechanosensory apical K^+ channels. The high K^+ is established by the movement of K^+ out of the stria vascularis epithelium via apical KCNQ1/KCNE1 K^+ channels. The K^+ enters the stria vascularis cells via basolateral Na^+/K^+-ATPases and the NKCC1 transporter, which imports two Cl^- for every K^+. Excess Na^+ is pumped out via the Na^+/K^+-ATPase and the Cl^- is extruded through basolateral CLC-K channels.[55,61] Human mutations in either one or the other CLC-K does not result in deafness, only in the dysfunction of their common barttin subunit or in very rare cases an individual has a mutation in both CLC-K genes.[55] This suggests redundancy in function that may also occur in the kidney and help explain why human disease does not result from *CLCNKA* mutations. Intriguingly, individuals carrying at least one copy of the T481S ClC-Kb gain-of-function mutation mentioned above display a lower hearing threshold than wild-type individuals.[35]

CFTR

Cystic fibrosis (CF) is the most common autosomal recessive genetic disease in Caucasians, and is debilitating and fatal; thus, long before the cloning of the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene, CF had been the focus of extensive physiological study. It was apparent that lung epithelium from patients with CF was lacking cAMP-activated Cl^- conductance, as well as dramatically increased apical Na^+ conductance.[25] These seemingly irreconcilable phenotypes resulted in the naming of the "CF" gene as a regulator of conductances, not as a Cl^- channel.[103] In fact, even after the successful cloning of the CFTR gene in 1989,[57,103,104] it wasn't until the creation of a $CFTR^{-/-}$ knockout mouse in 1993 that CFTR was definitively described as a Cl^- channel.[38] The $CFTR^{-/-}$ knockout demonstrated that there are actually two Cl^- conductances that are dysfunctional in CF patients and in the $CFTR^{-/-}$ mouse, and that the CFTR biophysical characteristics did not match the large outwardly rectifying currents (ORCC) that were for years believed to be the dominant Cl^- conductance.[38] Instead, CFTR regulated these ORCC currents.[25] Later work demonstrated that CFTR could regulate other channels like the epithelial sodium channel ENaC and the ATP sensitive K^+ channel ROMK2.[113]

CFTR (Figure 31.3) is now known to be a member of the ABC (ATP-binding cassette) superfamily of transporters; a vast gene family found in all phyla, responsible for transporting everything from metabolic products, lipids, and sterols, to drugs[3] and uric acid.[140] CFTR is a member of the C branch of the ABC family (ABCC7), characterized by having two large multihelix transmembrane domains (TMD) and two intracellular nucleotide-binding domains (NBD).[3] CFTR, uniquely among the ABC proteins, also possesses an extra, highly-charged cytoplasmic domain, termed the regulatory or "R" domain.[103] Perhaps not coincidentally, CFTR is also the only ABC transporter, among 48 expressed in humans,[3] shown to conduct Cl^-. Both the N- and C-terminus of the protein are cytosolic, and the C-terminus contains the amino acid sequence DTRL, a sequence that is known to interact with the "PDZ" domains often found on scaffolding and linker proteins upon which regulatory protein complexes can be built.[41,82] CFTR is therefore a single channel among a large family of anion transporters, much like the CLC and SLC26A gene families, further demonstrating the relative uniqueness of proteins that are Cl^- channels and how many appear to be derivatives of exchangers or transporters.

CFTR can most aptly be characterized as activated by cAMP-dependent phosphorylation, although the activation of the channel is actually a complicated and slow process. First, the R domain needs to be phosphorylated by the catalytic subunit of protein kinase A (PKA) (activated directly by cAMP-binding)[38]; second, ATP needs to be bound (and hydrolyzed) within the conserved walker A- and B-binding sites of the NBD domains.[39] Once activated, the Cl^- currents show little or no voltage-dependence, display a linear I/V relation, show no Ca^{2+}-dependence, and have an anion selectivity sequence of $Br^- > Cl^- > I^- > F^-$.[3,131] Single channel properties are reflective of the whole cell current characteristics: linear I/V relationship under symmetrical Cl^- concentrations; 10–11 pS single channel conductance; activation by catalytic subunit of PKA; and channel-gating coupled to ATP hydrolysis.[145]

In a reccurring theme that may be the single common characteristic among the various identified Cl^- channels, for many years there was no identified high affinity or specific CFTR inhibitors. Common Cl^- channel inhibitors like glibenclamide, DPC, NPPB, and niflumic acid provided low affinity pore blocking, but DIDS and other stilbene derivatives have little effect. In the CF lung there would be little use for CFTR

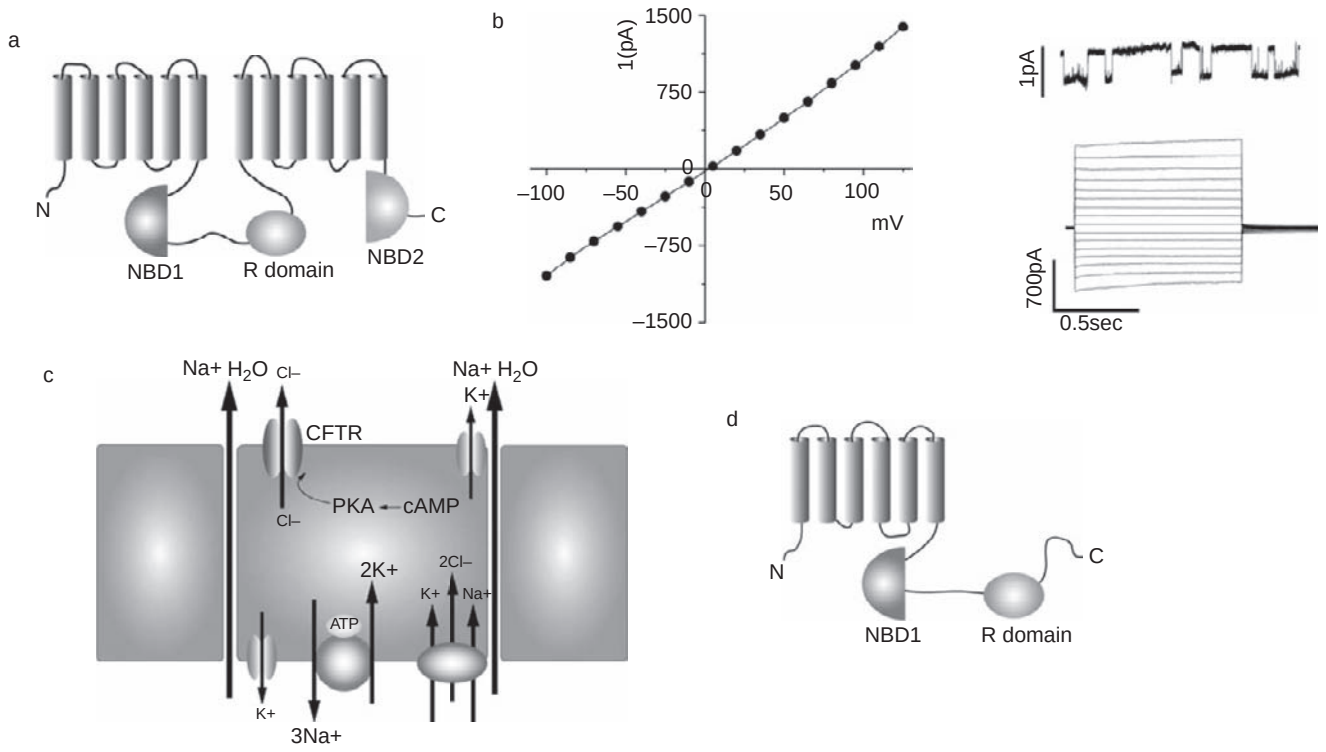

FIGURE 31.3 **Cystic fibrosis transmembrane conductance regulator (CFTR).** (a) Topography of CFTR. (b) I/V relationship, single channel recordings, and whole cell current records of CFTR heterologously expressed in CHO cells (Woodward and Guggino, unpublished data). (c) CFTR mediated Cl^- conductance drives fluid secretion in secretory airway epithelium cells. (d) Topography of kidney localized CFTR splice variant TNR-CFTR.

inhibitors therapeutically; however, CFTR expression has also been linked to fluid secretion in the kidney (see discussion of polycystic kidney disease below) and in the human gut. Specifically, toxin from *Cholera* increases cAMP levels and induces secretory diarrhea, a loss of fluids and salts that can be lethal.[74,131] The severity and pervasiveness of cholera has led to a substantial commitment of time and money to finding specific inhibitors of the cAMP-dependent Cl^- secretion of the gut epithelium. High-throughput screens of small drug-like molecules, using a fluorescent halide-based assay has yielded two classes of specific CFTR inhibitors.[74,131] The first class includes members of the 2-thioxo-4-thiazolidinone chemical class, in particular a compound named CFTRinh-172 with an IC_{50} of 300 nM.[74] CFTRinh-172 inhibits by blocking the intracellular pore in a voltage-independent fashion and prolongs the channels closed time, is non-toxic at high concentrations, is excreted with little metabolism,[131] and has been shown to effectively reduce *Cholera*-induced fluid loss by 90% in mouse models.[74] The second class of inhibitors includes the glycine hydrazides, and specifically GlyH-101.[83] It appears to block the CFTR pore from the extracellular side, is voltage- and Cl^- concentration-dependent, and in a closed loop model of cholera, GlyH-101 reduced fluid secretion by 80%.[83,131] Both classes and their lead compounds, CFTRinh-172 and GlyH-101, appear to represent therapeutic avenues for cholera and polycystic kidney disease; however, the assays used to find them also present the possibility of finding CFTR activators. The past decade has seen the discovery of a number of correctors and potentiators, small molecules targeted to bind directly to the CFTR molecule and aid in folding or in changing the gating characteristics. A number of these compounds have begun clinical trials for treating CF patients, and represent a valid avenue for chronic CF therapy.

Before progressing to a discussion of CFTRs specific role in the kidney, it is appropriate to introduce CFTR function first in the context of the human lung. CFTR was originally cloned as the gene responsible for cystic fibrosis, a disease characterized by chronic lung infection, deteriorating lung function, pancreatic exocrine insufficiency, male infertility, meconium ileus, and gastrointestinal complications.[131] In each phenotype the dysfunction stems from the reduction in fluid secretion at each relevant epithelium. CFTR is normally apically localized, and when activated Cl^- leaves the cells and enters the lumen or airway this drives paracellular Na^+, leading to water movement into the lumen.[68] In the lung, the loss of the CFTR Cl^- conductance lowers

the airway surface liquid volume (ASL), reduces the activity of the epithelial cilia, and reduces or abolishes the mucus clearance, leading to chronic infection.[124]

Currently, over 1500 CFTR mutations have been found in CF patients, representing a spectrum of disease severity directly proportional to the level of residual CFTR function. Null mutations result in no protein being produced, whereas other mutations can result in minor changes to channel-gating or cell surface expression. By far the most common CFTR mutation is the deletion of phenylalanine residue at position 508 (Δ508), carried by 90% of CF patients,[131] a mutation that causes misprocessing and trafficking, and results in no CFTR being expressed at the cell surface. Human CFTR mutations have been classified based on their severity into five classes. Class I mutants produce no CFTR, Class II includes the folding and processing mutants like Δ508, and Class III mutants produce CFTR that is trafficked to the membrane but have dysfunctional Cl^- conductance; all three classes result in severe lung disease and pancreatic insufficiency. Class IV mutants display less pronounced conductance abnormalities and often have no lung phenotypes, and Class V mutants are often asymptomatic and diagnosed only after they are found to be infertile or present with idiopathic pancreatitis.[20,21]

CFTR in the Kidney

CFTR expression is abundant in the human kidney. Early studies looking at CFTR mRNA or using RT-PCR found evidence for CFTR expression generally in the cortex and outer medulla. More specifically, CFTR was found all along the nephron, including proximal and distal tubules, thin and thick ascending limbs, and the collecting duct.[80,81] Immunostaining of CFTR protein showed CFTR expression again in the proximal and distal tubules, the tAL, and the cortical and inner medullary collecting ducts.[81] Functional studies using patch-clamp have identified CFTR-like currents in the proximal and distal tubules and the collecting ducts.[81] CFTR is also known to be expressed in the embryonic kidney, with upregulation in the ureteric bud during the later stages of branching morphogenesis.[25] Intriguingly, a large proportion of the overall CFTR expression in the kidney consists of a CFTR splice variant termed TNR-CFTR.[80] The TNR-CFTR mRNA is missing the final 145 bp including exons 13 and 14, creating an early stop codon. The splicing may be regulated by snRNAs U11 and U12, which co-localize to the same areas of the kidney as the TNR-CFTR isoform.[117] This truncation corresponds to a loss of the second TMD and NBD, as well as 7% of the R domain in the final protein. The TNR-CFTR is therefore a "half" transporter, similar to many other members of the ABC family, and like those other ABC transporters, the remaining half molecule is enough to give the protein function. When expressed in *Xenopus* oocytes the TNR-CFTR is a functional Cl^- channel, is still activated my cAMP and PKA, and possesses many of the same biophysical traits as the wild-type CFTR.[80] Its processing, however, seems less efficient,[80] and little makes it to the plasma membrane, but instead it localizes to intracellular vesicles.[81] More generally, TNR-CFTR is found mostly in the renal medulla, and has an interesting developmental expression pattern. In mice, the expression of TNR-CFTR increases throughout embryonic kidney development, reaching its highest level at birth.[81] The functional significance of TNR-CFTR remains a complete mystery.

CFTR as a Kidney Cl^- Channel

Although the expression levels of CFTR in kidney are comparable to those of the lung, there is no clear CF kidney phenotype, with the exception of increased risk of hyperoxaluria or insufficient citrate-induced kidney stones; a fact that many have taken as evidence that CFTR is not very important in salt handling in the kidney, and yet CFTR is known to play important roles in renal diseases like ADPKD. Many have attributed the lack of phenotypes to a redundancy in Cl^- channels present in the kidney. Mouse $CFTR^{-/-}$ knockout models often show little or no lung CF phenotype, a discrepancy explained by the upregulation of Ca^{2+}-activated Cl^- channels (TMEM16s; [62]) to compensate for the loss of CFTR Cl^- conductances. Likewise in the kidney, other types of Cl^- channels could be compensating for the missing functional CFTR in CF patients. However, CFTRs functional role in the kidney could be more regulatory, thus CF renal phenotypes more subtle. Recent work looking at CFTR in the apical membrane of mouse cortical collecting duct principal cells demonstrates the difficulty in establishing CFTRs function as a Cl^- channel and not as a regulator of other channels. Lu et al.[72] definitively demonstrated CFTR Cl^- channel activity on the apical membrane of mouse principal cells, and plausibly suggest that it could represent a short-circuit current meant to regulate Na^+ absorption and K^+ secretion. However, they concede that it is just as likely that phosphorylation of CFTR could act as a modulatory switch on ROMK activity, and thus exert an influence on K^+ secretion.[72] To complicate matters further, the prevailing model of ion movement in principal cells has Cl^- being reabsorbed mainly through a paracellular pathway, suggesting that for CFTR to have an effect it would need to represent a very large conductance, much larger than that measured by Lu et al. in mouse principal cells.[72] In fact, there is ample evidence that in the kidney and elsewhere CFTRs main function may be to regulate other ion channels.

CFTR as a Regulator of ENaC

From before its initial molecular identification, CFTR has been shown to regulate an ORCC Cl^- conductance and a Na^+ conductance.[113] In the airway of CF patients (but not in the sweat ducts), increased Na^+ absorption via the epithelial sodium channel, ENaC, is observed due to loss of the normal CFTR-mediated inhibition; however, the mechanism of regulation remains unclear. Currently, there are multiple hypotheses to explain how CFTR regulates ENaC. One possibility is that intracellular Cl^- regulates ENaC activity. This is supported by data showing that CFTR Cl^- conductance is necessary for ENaC regulation, and in some but not all cell types replacing CFTR Cl^- current with CLC-mediated Cl^- currents can also inhibit ENaC currents.[12] These data are conflicted by the lack of identified Cl^--binding sites on ENaCs intracellular domains, and by studies showing that alternative Cl^- channels like CaCCs cannot inhibit ENaC.[12]

A second theory proposes CFTR exerts its regulatory effects through intermediary proteins as part of a large protein complex. CFTR contains a PDZ-binding domain that enables it to interact with linking proteins like ezrin-binding phosphoprotein 50 (EB50) and NHERF1. NHERF1, through its PZD2 region, can bind YAP65 which recognizes the PY motif on the C-terminus of ENaC, creating a complex with both CFTR and ENaC. C-Yes, a c-Src kinase, is a known inhibitor of ENaC and can bind to YAP65. Thus, CFTR, in aiding the assembly of the protein complex, inhibits the activity of ENaC and the dissolution of the complex, e.g., from CFTR dysfunction or mutation, liberates ENaC from C-Yes inhibition.[42] However, this possibility has not been demonstrated in heterologous expression systems.[12]

A third possibility involves CFTR interacting directly with ENaC to cause inhibition. Patch-clamp studies of ENaC subunits and CFTR in proteoliposomes, presumably free of contaminating complex proteins, showed that CFTR directly affects the gating of ENaC single channels. FRET studies have demonstrated an association of less than 10 nM of the two proteins *in vitro*, and co-immunoprecipitation experiments show the two physically interact.[12] However, with the exception of the single channel results, the evidence does not strictly rule out the possibility of CFTR and ENaC interacting indirectly as part of a protein complex.

The relationship between CFTR and ENaC in the kidney appears as conflicting as that found for the airways and seat ducts. Some work has shown that CFTR inhibits ENaC in the kidney, similar to the relationship found in airways. Experiments in M-1 cortical collecting duct cells showed that activation of PKA reduced the amiloride-sensitive apical Na^+ current.[66] However, other studies have found CCD cells from mice carrying a mutation in ENaC, known to cause Liddles's syndrome (deletion of the PY motif in the c-terminus as the β-subunit ENaC), display increased Na^+ absorption as compared to wild-type when treated with dD-arginine vasopressin. A similar increase is seen in the CFTR-mediated apical current, implying vasopressin causes increases in both conductances,[130] an idea consistent with the cAMP-induced increases in both CFTR and ENaC seen in sweat ducts.[101] Simply put, the evidence for CFTR regulating ENaC in the kidney is sparse, and it remains unknown whether or not it acts as an inhibitor, activator or neither. It may require a final determination of how CFTR regulates ENaC in airway tissue before a renewed focus can be brought on CFTR and ENaC in the kidney.

CFTR as a Regulator of ROMK

The inward rectifier potassium channel ROMK (Kir1.1) and its isoforms are expressed highly in the distal nephron, where it plays a major role in ATP sensitive K^+ secretion.[72] Some of their defining traits are lack of sensitivity to the common K^+ channel blocker tetraethylammonium (TEA), and inhibition by ATP and sulfonylureas like glibenclamide.[113] But when the ROMK2 isoform was expressed in the *Xenopus* oocytes, it was no longer sensitive to glibenclamide. Other ATP-sensitive K^+ channels require ABC transporter subunits, SUR1 and SUR2 (ABCC8 and ABCC9), for glibenclamide sensitivity, but neither SUR1 nor SUR2 is known to be expressed in the kidney. However, CFTR is expressed in the same distal nephron cells as ROMK channels, and when CFTR and ROMK2 are co-expressed in *Xenopus* oocytes, the glibenclamide sensitivity is restored.[113] Subsequent work has demonstrated that CFTR is also necessary for ROMK's sensitivity to Mg-ATP in CCD mouse cells. Lu et al.[72] hypothesize that water diuresis and the resulting low cAMP-PKA would promote the CFTR−ROMK interaction, and so cytoplasmic ATP would inhibit excessive K^+ secretion. However, during antidiuresis when PKA levels are high, the phosphorylation of CFTR will free ROMK from ATP sensitivity and promote K^+ secretion.[72] The specifics of the ROMK−CFTR interaction are unknown, but it is probably similar to the better-understood Kir6.x/SUR complex of pancreatic β-cells. Kir6.x-subunits form tetramers, with each subunit associated with a SURx subunit to create an eight unit complex.[2] Although the CFTR regulation of ROMK appears functionally very important, there is no reported K^+ secretion phenotype in the distal nephron in CF patients.

CFTR as a Regulator of SLC26As

CFTR is also a demonstrated regulator of transporters from the SLC family of anion transporters. Earlier research showed that CFTR could interact with and activate SLC26A3 and A6, conferring cAMP sensitivity on these two transporters.[116] In the pancreatic ducts, HCO_3 secretion is a critical component of the function of the secretory epithelium, a function disrupted in patients with severe CF. Wang et al.[136] showed specifically that the SLC26A6 HCO_3^-/Cl^- exchanger was critical for HCO_3^- secretion, and that its function was regulated by co-localized CFTR expression in the luminal membrane. Further work demonstrated that a conserved region of the SLC26A transporters, the STAS domain, interacted directly with the R domain of CFTR.[59] The binding of the STAS and R domains activates SLC26A6, but also dramatically increase the Cl^- conductance of CFTR by increasing the channels open probability six-fold.[59] Interestingly, SLC26A6 is expressed throughout the kidney, but appears most prominently in the apical–luminal membrane of the proximal tubule where it is responsible for Cl^-, HCO_3^-, oxalate, and formate exchange.[59] CFTR expression is also reported in the proximal tubule, and although there is no current evidence of their interaction in the kidney it seems plausible.

CFTR more recently has also been demonstrated to be a regulator of one of the two true Cl^- channel members of the SLC26A family, SLC26A9. Both SLC26A9 and CFTR co-localize to the apical membrane of human bronchial epithelial (HBE) cells, where cAMP leads to the co-activation of SLC26A9 and CFTR Cl^- channels.[13] The nature of the CFTR–SLC26A9 interaction is similar to the other CFTR–SLC interactions, the conserved STAS domain of SLC26A9 binds directly to the R domain of CFTR.[17] However, there are conflicting reports as to the exact regulatory nature of the CFTR–SLC26A9 relationship. Bertrand et al.[13] report that endogenous SLC26 currents in HBE cells are activated by functional CFTR; whereas Chang et al.[17] report heterologous co-expression of an NBD + R domain CFTR construct with SLC26A9 in *Xenopus* oocytes results in the inhibition of SLC26A9 currents. What is clear is that the conserved STAS domain of the SLC26A channels and transporters strongly interacts with CFTR, an interaction that may extend to many of the SLC26A members. SLC26A9 is expressed mainly in the lung, but the other described SLC26A pure Cl^- channel, SLC26A7, is expressed throughout the kidney, and in particular cells of the cortical collecting ducts, an area also high in CFTR expression. The role of a possible interaction between SLC26A7 and CFTR in the cortical collecting duct is an important area for future investigation.

CFTR and Endocytosis

A new area of CFTR research has begun investigating CFTRs role in acidification of endosomes of the proximal tubule. Generally, CF patients have shown increased renal clearance of some drugs including aminoglycosides, and more specifically a cohort of patients with at least one copy of the Δ508 CFTR mutation showed significantly higher levels of albuminuria and LMW proteinuria.[56] $CFTR^{-/-}$ knockout mice have significantly increased excretion of LMW Clara Cell protein (CC16), and decreased uptake of radio-labeled ^{124}I-β2microglobulin and aminoglycosides, similar to human CF patients. Significantly, the $CFTR^{-/-}$ mice also demonstrated decreased cubilin expression in the S3 segment of the proximal tubule, a finding correlating with the observed increase of cubilin excretion.[56] Cubilin is a lipoprotein receptor and, along with megalin, is critical for the uptake of LMW proteins. In the $CFTR^{-/-}$ mouse, however, megalin is not affected, thus it appears CFTR is specifically reducing cubilin expression. Cubilin recycling to the apical membrane via endosomes is critical to maintain apical cubilin expression and for LWM protein uptake. The sorting and recycling of endosomes is pH-dependent.[56] CFTR has been localized to the apical region in proximal tubule cells and specifically it co-distributes with ClC-5 and Rab5a in endosomes,[56] where it is proposed to aid in providing a negative current shunt for the interior of the endosomes. CFTR would offset the build-up of positively-charged H^+ during acidification, a role similar to that proposed for the Cl^-/H^+ exchanger ClC-5.[56] The evidence of CFTRs involvement in receptor-mediated endocytosis from CF patient studies and $CFTR^{-/-}$ mice is compelling, but the mechanism remains unconfirmed, although it seems likely CFTR, along with ClC-5 and possibly other Cl^- channels, all contribute to the pH regulation of the proximal tubule endosomes.

Ca^{2+}-Activated Cl^- Channels (CaCC): TMEM16/Anoctamin

For 30 years Ca^{2+}-activated Cl^- channels (CaCC) with similar biophysical characteristics have been studied in a wide range of tissue and cell types, including secretory epithelia, egg cells, cardiac, smooth, and skeletal muscles, neurons, olfactory and photoreceptors, hepatocytes, and beta cells.[45,47] The classic CaCC characteristics are best described by the endogenous CaCCs of *Xenopus* oocytes or the CaCCs of acinar cells in the salivary gland (Figure 31.4). These classic CaCC channels are activated by small amounts of cytosolic Ca^{2+} (0.2–5 μM)[45] either from extracellular influx or store release. Activation appears to occur through direct binding of Ca^{2+} to the channel. When cytosolic Ca^{2+} is

limiting, CaCC shows an outward rectifying I/V relationship, but as cytosolic Ca^{2+} increases the rectification diminishes.[45,85,138,139] The open probability appears to be voltage-dependent and the single channel conductance is small 1–3 pS, although a variety of conductance sizes has been reported.[45] Classic CaCCs, like other anion channels, are relatively non-selective, with Na^+ permeability being roughly 10% that of Cl^-. Among anions the selectivity sequence is $SCN^- > NO_3^- > I^- > Br^- > Cl^- > F^-$.[45]

The ubiquitous nature of CaCC channels makes describing their physiological function difficult; it plays different roles in each cell type. In *Xenopus* oocytes CaCC plays a major role in blocking polyspermy fertilization of the egg. Fertilization generates a Ca^{2+} wave across the membrane, activating the CaCC channels and depolarizing the egg.[45] In secretory epithelia Cl^- secretion is critical to draw Na^+ and water across the apical membrane, and CaCCs appear to contribute to the Cl^- conductance across the apical membrane, often in an ATP-dependent manner.[45]

Similar to many other epithelial cell types, kidney epithelia have demonstrated CaCC currents and channels, including rabbit distal convoluted tubules, proximal convoluted tubules, and cortical collecting duct. However, most of the work has been done on a mouse medullary collecting duct cell line, IMCD-K2.[15,99] Using the IMCD-K2 line, Qu et al.[99] described CaCC currents that they suggested were the same as those found endogenously in *Xenopus* oocytes. These currents can be activated by ATP and rely on intracellular Ca^{2+} store release for activation.[15] They are co-expressed in IMCD-K2 cells with CFTR, and while their specific function in the collecting duct is not known, it may be similar to the Cl^- secretory role they play in airway epithelium. Because CaCC currents may be controlled by hormones, the CaCC-mediated Cl^- secretion in the distal kidney may help fine-tune urine composition.[45]

The molecular identity of the CaCC channels was for decades an elusive dream, with a stream of potential candidates including the CLCAs and the bestrophins, whose biophysical characteristics matched some of the classic CaCC characteristics, but not all. Recently, a new family of genes has been proposed to represent the CaCCs, the TMEM16 or Anoctamin gene family which, unlike previous candidates, shares all of the biophysical characteristics of the classic CaCC channels. The confidence in this new family of proteins as CaCC comes from a number of factors, not the least of which was the methods used to discover their

identities. Three different research groups, using three totally different methodologies, each independently arrived at the conclusion that TMEM16A/Aco 1 was the classic CaCC. Schroeder et al.[111] took advantage of the unique property of Axolotl (*Ambystoma mexicanum*) salamander oocytes of not having any CaCC currents. They used these oocytes to screen a cDNA library from size fractionated RNA isolated from *Xenopus* oocytes resulting in the identification and cloning of a gene that coded for a 979 amino acid protein, the *Xenopus* ortholog to the human TMEM16A gene. Expression of TMEM16A in the Axolotl oocytes produced Cl^- currents identical in most of the biophysical properties that define the classic CaCCs. Schroeder et al.[111] also showed that TMEM16s are expressed in salivary glands, as expected if they are the CaCCs. A second group, Yang et al.[146] used a bioinformatic search targeting putative channel or transporter-like genes with more than two transmembrane domains. Their search turned up TMEM16A, which met their criteria but became their focus because it had no described function, and the TMEM16 family has 10 human homologs. They renamed the TMEM16s anoctamins because the channels appeared to be anion selective with eight (OCT) transmembrane domains.[47] Yang et al.[146] tested the biophysical properties of TMEM16A when expressed in HEK cells, and like Schroeder et al.[111] found their properties to be very similar to those described above for the classic CaCCs, although the pharmacological sensitivities of the overexpressed TMEM16A channels in HEK cells were far more sensitive to the classic anion channel blockers DIDS, NPPB, and NFA than their endogenous counterparts.[47] Yang et al.[146] went further, and showed that mutating the putative poor region, between TM5 and TM6, disrupted anion permeability markedly. Importantly, like Schroeder et al. they showed that TMEM16s were expressed in tissues where classic CaCCs have been described, and demonstrated that knocking-down TMEM16A in acinar cells of the salivary gland reduced the endogenous CaCC currents, and reduced saliva production upon pilocarpine application. And finally, a third group, Caputo et al.,[16] identified TMEM16s through a microarray screen of airway epithelial cells treated with IL-4, a treatment known to increase CaCC currents in these cells. They isolated a group of membrane proteins with no known function, including TMEM16A, then generated RNAi against each of the most likely candidates and attempted to knock-down the endogenous CaCC activity inCFPAC-1 and CFBE410 cells. Activity was assayed using a halide sensitive YFP protein and short-circuit currents, and siRNA TMEM16A was found to very effectively reduce the endogenous CaCC currents. Caputo et al.[16] went on to express TMEM16A in FRT cells, and again described their biophysical properties as being almost identical as those known for the classic CaCC currents.

The TMEM16 family of genes is well-conserved, with members found throughout eukaryotic phyla; however, there appears to be an increased representation in mammals.[47] Humans have 10 members of the TMEM16 family (A−H, J−K) or Ano 1−10, and their predicted topology has both N- and C-termini intracellular, eight transmembrane domains, and the pore region located between TM5 and TM6.[146] Interestingly, no clear Ca^{2+}-binding domain has yet been discovered in the TMEM16s. In TMEM16A there is no EF hand region or CaM-binding sites.[47] However, there does appear to be a Ca^{2+} bowl structure, similar to that found in BK Ca^{2+}-activated K^+ channels. This same structure was predicted by Hartzell et al.[45] for classical CaCCs before the identification of the TMEM16 genes based on the demonstrated μmolar range Ca^{2+} affinity.[45] The molecular diversity of the TMEM16 family could help explain the differences in described biophysical properties of endogenous CaCCs in different cell and tissue types. Members of the TMEM16 family may have different channel properties or they may heterodimerize to create chimera channels. The TMEM16s also exhibit multiple splice variants, TMEM16A has at least four,[16] and these variants were found to have different channel properties.[16] The likelihood that members of the TMEM16 family other than TMEM16A are anion channels is high, because of the close sequence homology among the members. And although most of the descriptive work has focused on TMEM16A, Cl^- currents have also been described for TMEM16B (Ano2) which is found in olfactory receptors,[27] and for TMEM16F and TMEM16K (Ano 6 and 10).[110] In each case, like TMEM16A they share many similarities with the classic CaCC, but each has some differences as well, supporting the idea that the diversity of the TMEM16 family corresponds to the diversity of CaCCs.

The TMEM16s are only now getting the in-depth attention necessary to discern how TMEM16s function as CaCCs, which ones are expressed in which cell and tissue type, and what role if any they may play in human disease. Even before TMEM16A was known to be a Cl^- channel it had been observed to be upregulated in tumors, but why is unknown.[27,47] Initial reports on the Cl^- channel functions of TMEM16A have focused on tissues and cells historically known to have large CaCC currents, including airway epithelial cells. In these cells CaCC currents have long been seen as a potential target in treating cystic fibrosis; by upregulating CaCC currents the lost anion conductance from dysfunctional CFTR could be replaced, and disease severity lessened. Mouse models of CF, strangely devoid of the debilitating lung systems found in

humans, have been shown to express TMEM16A at much higher levels than in wild-type airway epithelia, strongly supporting the targeting of TMEM16A in humans as a CF treatment.[62] It is not clear what functional role the TMEM16s play in the kidney. Presumably they underlie the known CaCC currents identified in the kidney, but which ones and how remains unknown. Yang et al.[146] showed specifically that TMEM16A is expressed in the epithelia of proximal tubules and the distal renal tubules. In mice TMEM16F mRNA was found in the kidney at high levels, as were slightly lower levels of TMEM16K and H. Going forward it will be exciting to learn more about the TMEM16 family, and specifically their role in anion regulation in the kidney and the role they play in diseases such as ADPKD.

Solute Carrier 26 Transporters

As discussed earlier, the distinction between Cl^- transporter and Cl^- channel can be the position of one or two amino acids, and just as recently resolved crystal structures revealed members of the CLC Cl^- channel family to be transporters, recent studies of the large SLC26 transporter family revealed at least two of its members bear the hallmarks of Cl^- channels, not transporters. Specifically, SLC26A9 and SLC26A7 appear to operate solely as Cl^- channels, and have little or no bicarbonate permeability.[89] The SLC26 family is large and very diverse, much like the CLC gene family, and many of its members still lack identified physiological function, including SLC26A7 and SLC26A9 (Figure 31.5). However, present work does suggest both may play important roles in secretory epithelia in areas of the lung and kidney. As discussed earlier, SLC26A9 is expressed highly in lung epithelia, and may be regulated by CFTR[13] via the highly-conserved SLC26 STAS domain.[17] When expressed in HEK cells or *Xenopus* oocytes, the SLC26A9 channel is constitutively active, with a linear to slight inward rectification I/V relation,[13,17,26,26a,89] is only slightly permeable to bicarbonate, and is not pH sensitive.[26,26a,89] And while SLC26A9 is most highly expressed in ciliated bronchial airway epithelial and alveolar cells, its expression is widespread.[26]

SLC26A7, on the other hand, is very highly expressed in the human kidney, including in the renal

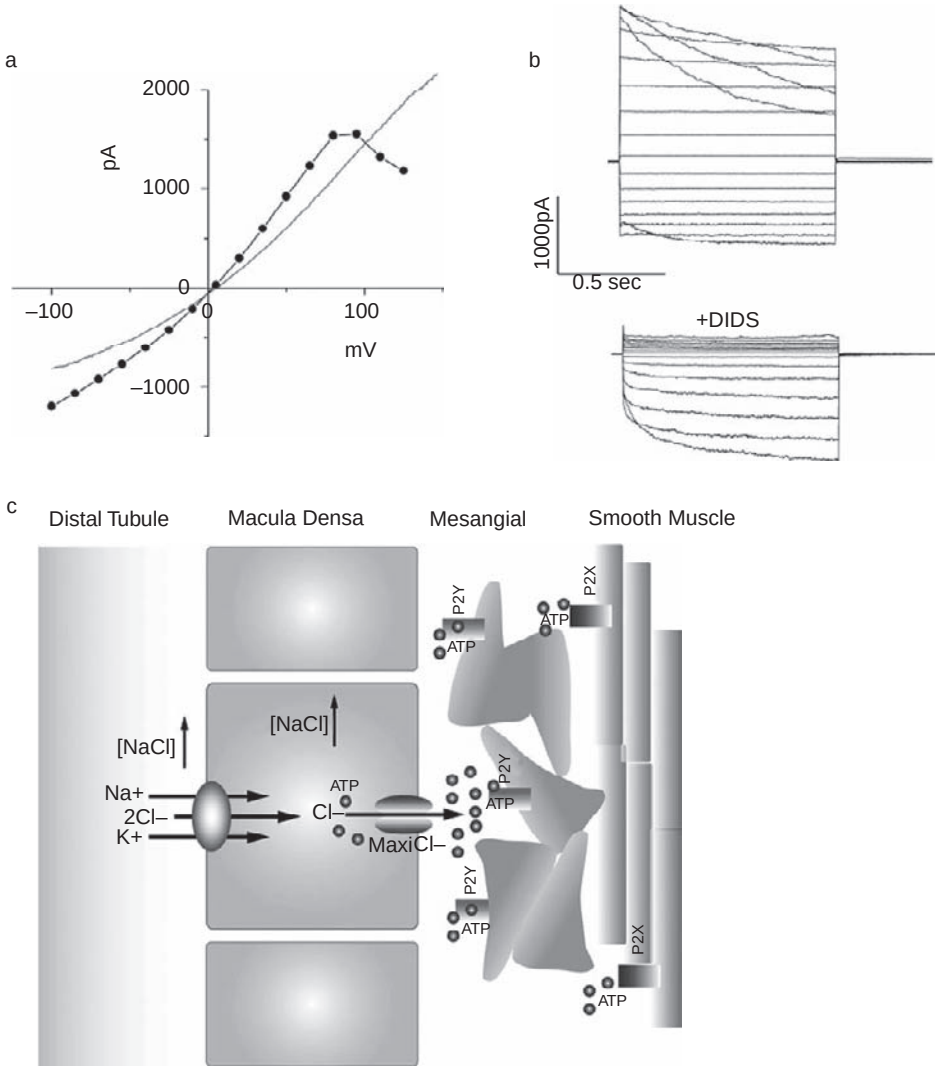

FIGURE 31.6 **Volume regulated anion channels (VRAC).** (a) Instantaneous and steady-state I/V relationships of VRAC currents in human bronchial epithelial cells (IB3-1 cells) (Woodward and Guggino, unpublished data). outer medullary collecting duct, the thick ascending limb, and the apical membrane of proximal tubule.[26] Like SLC26A9, SLC26A7 is constitutively active, has a linear I/V relation, is not permeable to bicarbonate,[58] but unlike SLC26A9, SLC26A7 is very sensitive to pH.[26,89] Acidic pHi increases the selectivity of SLC26A7 to Cl^-,[58] apparently through intracellular H^+ regulation of the channel. SLC26A7s pHi sensitivity has prompted the hypothesis that it may function as a pHi sensor[89] or function in Cl^--loading in parietal cells. The physiological function of SLC26A7 in the kidney remains unknown, although it is expressed on the basolateral membrane of the alpha-intercalated cells of the outer medullary collecting duct, cells that secrete acid[116,120] as part of the kidney's role in regulating the blood's acid–base balance (Figure 31.5). It would seem that the pHi sensitivity of SLC26A7 would make it an affective pHi sensor in alpha-intercalating cells just as in parietal cells, and it could again function as a Cl^--loading mechanism and therefore would be important in the apical secretion of H^+ from the cells. Currently no human diseases are associated with SLC26A7 or SLC27A9 dysfunction; however, it seems likely that further work will reveal their importance in human and kidney physiology.

Volume-Regulated Anion Channels

The recent success in discovering the molecular identity of the CaCC only highlights the need to identify the last remaining functional group of Cl^- channels, the volume-regulated anion channels (VRAC) (Figure 31.6). VRACs are found in every cell type as part of the normal housekeeping functions possessed by all cells. In mammalian cells when an osmotic imbalance occurs and water moves into the cell, threatening the integrity of the membrane, the cell initiates the regulatory volume decrease (RVD) response consisting of the efflux of K^+ and Cl^- ions, as well as bicarbonate and amino acids; through the loss of these

osmolites the osmotic balance can be regained and the cell shrinks. In the dynamic osmotic conditions along the mammalian nephron the VRAC channels may play a dominant role in the RVD response, protecting the cells from osmotic harm. In addition to cell volume regulation, VRAC channels are known to play roles in maintaining resting potentials, aiding in vectorial Cl^- transport, salt and fluid secretion, cell proliferation and differentiation,[85] cell migration,[92] apoptosis,[91] and ATP secretion.[85,92] In addition to VRACs role in RVD in kidney cells, another role has been described for the large conductance maxi-anion type of VRAC channels which appear concentrated in the macula densa cells of the thick ascending limb (TAL). Macular densa cells function to sense changes in the luminal NaCl concentration, and signal the regulator mechanism necessary to bring salt levels back to normal via tubuloglomerular feedback (TGF).[10] Bell et al.[10] found that maxi-anion channels in the macula densa cells could conduct ATP, and did so under conditions of experimentally high luminal NaCl. It is not yet clear how the maxi-anion channels are activated by the high luminal NaCl concentrations, nor is it clear exactly what role ATP plays in signaling as compared to NO and PGE2.[11] But it is clear that ATP is important, and that the maxi-anion channels are the only described mechanism for its secretion from the macula densa cells, implying a very important role for the VRAC channels in the TAL. Ultimately only the molecular identity of the VRAC channels will further our understanding of their function in the kidney.

The general biophysical characteristics of the VRAC channels are similar to other known anion channels, including its relative non-selectivity, and its outward rectification. The most unique characteristics of VRAC channels are their voltage-dependence: depolarization above $+60$ mV causes time and voltage inactivation, with negative potentials removing inactivation.[84,85] Intracellular Mg^{2+} and extracellular protons appear to accelerate this inactivation. The anion selectivity sequence is $SNC^- > I^- > NO_3^- > Br^- > Cl^- > F^-$, but VRAC channels are also permeable to amino acids like glutamate and aspartate, polyols, and ATP.[84,85] This promiscuity is in part due to the large calculated pore size of ~ 11 Å.[85] Pharmacologically, the usual nonspecific anion channel blockers also work on VRAC channels, NPPB > DIDS > NFA,[84] some, like DIDS, show a strong voltage-dependence to its block, demonstrating it can only block from one direction. The single channel properties suggest VRAC channels are a heterogeneous group consisting of mini-anion channels (0.1–8 pS), volume-sensitive outwardly rectifying channels (VSOR: 20–80 pS), and maxi-anion channels (100–400 pS), although most fall into either the VSOR or maxi-anion groups.

Because of their extremely important physiological role in TGF, a further look at the maxi-anion channel subclass of VRAC channels is deserved. As mentioned above, maxi-anion channels have very large single channel conductances that increase with saturating concentrations of Cl^- in excess of 640 pS.[107] In contrast to the characteristics described above for the classic VSOR type of VRAC channels, the maxi-anion channels have a much larger pore size of 1.16–1.42 nm, which again helps to explain its ability to conduct ATP. Like other VRAC channels, maxi-anion channels are voltage-dependent with inactivation at depolarizing potentials, but unlike other VRAC channels it also inactivates at hyperpolarizing potentials, resulting in a bell shaped voltage-dependence of open channel probability.[107] At potentials with little or no inactivation, the I/V relationship is linear. Further questions about maxi-anion channel structure and function in both the kidney and beyond will, as for the entire VRAC group, depend on resolving its molecular identity. This is perhaps the most pressing issue in all of anion channel research currently, and remains a gaping hole in our fundamental understanding of how anion conductances shape cellular function and life.

Other Cl^- Channels

GABA and Glycine Receptor Channels

The GABA (GABAA, GABAC) and glycine receptor (GlyR) Cl^- channels represent the only examples of anion channels within the cation channel gene families. Both GABA- and glycine-gated channels are members of the ligand-gated ion channel (LGIC) superfamily,[18] and share a large amount of structure homology with cation members of the same LGIC family, including the nicotinic acetylcholine (nACh) receptor channels and the 5HT3 receptors.[18] Like nACh channels, both the GABA and glycine receptor channels have a 5 subunit structure, with two alpha-, two beta-, and one gamma-subunit.[88] There are two GABA receptor channel groups that conduct anions, GABAA and GABAC, both are important for inhibitory synaptic transmission in the nervous system, and both have a $I^- > Cl^-$ permeability.[131] GABA receptors may play key roles in human disorders including epilepsy, multiple sleep disorders, and Alzheimer's.[18] GlyR channels are also important in synaptic inhibition in the nervous system, and have been linked to hyperekplexia[73,131] or human startle disease. GlyR channels have an ion selectivity sequence, $I^- > Br^- > Cl^- > F^-$, similar to the GABA channels, with a pore size around 5–6 Å,[88] slightly smaller than the other cation members of the LGIC family. The GlyR single channel conductance is variable depending on the arrangement and type of

subunits, but most frequently is around 90 ps.[88] Though the GABA and GlyR channels play significant roles in human disease and are very important in the function of the human nervous system, they have not been shown to express in the human kidney and therefore their discussion will remain superficial.

Voltage-Dependent Anion-Selective Channel (VDAC)

Often in a discussion of anion channels the voltage-dependent anion selective channels (VDAC) are omitted, because of their believed confinement to the outer membranes of the mitochondria (hence their alternative name of mitochondria porins),[24] loose anion selectivity, and giant poor size. Thus, the logic goes, the VDAC channels are not comparable to the Cl^- channels that inhabit the other cellular membranes. However, their recent localization to the plasma membrane has elevated them to Cl^- channel status, if just barely. VDACs were first discovered on the membrane in human B-lymphocytes, and the subsequent development of an antibody lead to the description of VDAC surface localization in numerous cell types including epithelium. Subsequent work confirmed VDAC1 to be located within caveolins, or plasma membrane subcompartments, and found VDAC in proteomic surveys of the plasma membrane of human cells.[24] Perhaps most convincingly, VDAC proteins have been purified from both the plasma membrane (using a NH-SS-biotin label) and from the mitochondria, and compared via electrophoretic mobility, antibodies, and electrophysiological recordings in reconstructed lipid bilayers.[8,9,52] The question remained, however, what were they doing there? In the mitochondria, the VDAC family of proteins resident in the outer mitochondrial membrane is responsible for a number of functions, but probably not the regulation of Cl^- conductance. The VDAC proteins are 30–35 kDa proteins that contain a single alpha helix and 13, 16 or 19 transmembrane beta sheets.[24,114] When reconstituted in a lipid bilayer VDAC forms a very large 2–3 nm pore,[114] and is loosely voltage-dependent (40% of the initial conductance persists in the "closed" state).[107] Its Cl^-/K^+ permeability ratio is an astoundingly low 1.7–1.9,[107] but its single channel conductance of Cl^- is linear up to 10 nS with no saturation.[107] However, its primary function in mitochondria is probably more related to metabolite flux (including ATP, cytochrome c, and superoxide anions),[105] membrane composition, and an important role in apoptosis.[40]

There are a number of hypotheses as to the nature of the VDAC function on the plasma membrane. The voltage-dependence of VDAC means that at most resting potentials the channel should be closed,[24] alleviating the obvious lethal potential of a large, relatively nonselective pore in the plasma membrane. There is some evidence that VDAC may be an ATP release channel,[90,114] although there is also evidence that VDAC may inhibit ATP release.[24] Other proposed functions include plasma membrane VDAC1 as a redox enzyme which reduces extracellular ferricyanide in the presence of NADH.[5] Its role as a redox enzyme is supported by evidence that transfection of COS-7 cells with a VDAC1 construct increased the plasma membrane NADH:ferricyanide reductase activity 40-fold.[5] This VDAC1 function may play a role in the reductive activation of the anticancer drug 2-methyl-furanonaphthoquinone.[115] Finally, plasma membrane VDAC has been long hypothesized to be the maxi-anion channel found in many tissue types including the kidney. There exist many superficial similarities in the biophysical properties of each, which has lead for years to the acceptance that VDAC was the molecular identity of maxi-anion channels, even though there appear to be some vast differences in characteristics and localization. For instance, surface VDAC has been shown in epithelium,[24] but not specifically in kidney. Recently this hypothesis was tested directly by Sabirov et al.,[106] where they either knocked-out or knocked-down expression of the three VDAC isoforms, and found the endogenous maxi-anion channel of mouse embryonic fibroblasts (MEFs) unaltered, strongly arguing against VDACs being the molecular identity of maxi-anion channels. However, it is worth noting that expression of surface VDAC channels is not universal and could be very cell type-specific, thus in cell types other than MEFs VDAC could still be the previously identified maxi-anion channels that are critical for renal salt balance in the human kidney (see discussion above).

Tweety (Human Homolog hTTYH3)

The VDAC proteins are not the only recent entrant in the race to win the title "identity of maxi-anion channel." Using a rather novel bioinformatic methodology Susuki[122] screened for *Drosophila* genes that coded for proteins with four or more predicted transmembrane domains and a described behavioral abnormality. Suzuki found a gene, *tweety*, within the *flightless* locus, which matched his criteria, and its knockout resulted in loss of normal flight. Suzuki further found that *tweety* has a human homology, hTTYH3, a gene encoding a 523 amino acid protein. mRNA expression of mouse TTYH3 is found in most excitable tissues as well as kidney, fat cells, thymus, and uterus, and also a number of cell lines including kidney epithelial cells (OK, HEK, and MDCK lines).[122] Using a c-terminal antibody, TTYH3 was positively localized in the glomerulus of the kidney.[122] Other *tweety* genes may also be important in the human kidney, hTTYH2 mRNA

has been shown to be upregulated in renal cell carcinoma.[48]

The electrophysiological characteristics of hTTYH3 do certainly show similarities to maxi-anion channels, but also to large conductance Ca^{2+}-activated Cl^- channels. Expression of hTTYH3 in CHO cells in the presence of ionomycin results in large linear Cl^- currents.[122] The ion selectivity for the hTTYH channel is $I^- > Br^- > Cl^-$, and the mutations of positively-charged amino acids in the pore region result in an appropriate reduction in the gluconate/Cl^- permeability ratio.[122] The large linear Cl^- currents of hTTYH3-expressing cells were not blocked by niflumic acid, DTT, ZnCl or SITS; however, the hTTYH3 currents were blocked by DIDS (10 μm).[122] Suzuki[122] also reports the single channels characteristic of the human *tweety* channel: large single channel conductance (250 pS) in the presence of high cytosolic Ca^{2+}; and a linear I–V relationship.

Although, like the VDAC channels, *tweety* channels share characteristics with the well-defined maxi-anion channels, but like the VDAC channels, recent experiments suggest they probably do not represent the molecular indentity of the maxi-anion channels.[107] They could, however, represent a novel class of large conductance CaCC channels or a prototype Cl^- channel based on its 6TMD topology and homology to other *Drosophila* cation channels.[122] Their localization to kidney epithelium and upregulation in renal cell carcinoma demands further exploration for this very interesting, newly discovered group of Cl^- channels.

CLCAs

Despite early promise, the possibility that the family of proteins called the Ca^{2+}-activated Cl^- channels (CLCAs) function as anion channels has become very remote. The CLCAs were the first cloned proteins to demonstrate CaCC characteristics under experimental conditions.[37] Specifically, expression of the bovine homolog, bCLCA1, in *Xenopus* oocytes resulted in an increase in CaCC current.[37] Single channel characteristics also seemed to fit with those previously described for CaCC channels: a single channel conductance of 25–30 pS; a mostly linear I–V relationship; and a selectivity profile of $I^- > Br^- > Cl^-$.[22,123] CLACs possible CaCC activity, its expression in airway epithelia, and its connection to airway inflammation in cystic fibrosis attracted a lot of research attention to the new family of proteins.[36] Unfortunately, the increased scrutiny brought with it increased evidence that the structure of the CLCA proteins made them unlikely candidates as integral channel proteins.[93] Newly performed structure and sequence analysis now predicts that CLCA are soluble proteins that may be secreted from the cell as signaling molecules.[93] More recent work has focused on the very real connection between the CLCAs and chronic obstructive disease (COPD), and CLCAs revised localization to the airway mucal cells, not epithelium. Specifically, mouse Clca3 expression was sufficient to drive mucin production *in vitro*, and in multiple animal models CLCAs were found to play an important role in mucal cell metaplasia and airway hyperactivity.[93] Thus, now yoked with an unfortunate name, it seems a consensus exists concluding that CLCAs do not function physiologically as anion channels.

Bestrophin

Until the discovery of the TMEM16/Anoctamin gene, the four mammalian bestrophin genes, Best 1–4, were the most obvious candidate for the CaCC channel. There is overwhelming evidence that bestrophins are Cl^- channels, and recent clear evidence that they are critical in a number of channelopathies. However, slight discrepancies in their characteristics and localization always created questions as to their identity[27] as the classic CaCC. The identification of this new family of Cl^- channels came from a study of the disease Best Vitelliform Macular Dystrophy (BVMD) within a large Swedish family.[86] Linkage analysis identified a region of chromosome 11 (11q13) as the locus for BVMD, which lead to the cloning of the VMD2 gene.[34,76,95,119] Subsequent syntax revision has renamed VMD2 as Best 1, and the other mammalian members of the gene family as Best 2, 3, and 4.

All the members of the Best gene family code for Cl^- channels. Early recordings done in HEK cells demonstrated novel Cl^- conductances in cells expressing the Best genes; however, the biophysical characteristics varied for each, strongly supporting the idea that each is a Cl^- channel and not a regulatory or support protein.[46] In HEK cells, Best 1 proved to be Ca^{2+}-dependent; removal and chelation of Ca^{2+} in the pipette substantially reduced current amplitudes. The currents showed some outward rectification, but were not time-dependent.[46] However, other Best channels display linear I–V (Best 2), strong inward rectification and time-dependence (Best 3), and linear I–V but with time-dependent inactivation.[46] The Best channels are weakly inhibited by niflumic acid and stilbenes[131] including DIDS (at 500 μM). The selectivity sequence is $I^- > Br^- > Cl^-$. Mutagenesis of the Best proteins provides further evidence that the Best proteins are Cl^- channels. A mutation W93H in mbest2 changes the channel gating, the I–V relation from linear to inwardly rectifying, and activates slowly upon hyperpolarization[100,126]; whereas an S79C mutation in mbest2 increases the IC_{50} of DIDS blockage by a factor of 5.[100] Regulation of the Best channels by calcium has also received recent attention. Extensive work has

demonstrated that Ca^{2+} can activate bestrophins with a KD of 200 nM without the need for any diffusible intermediate,[27] suggesting that Ca^{2+} can bind bestrophins directly. Structural analysis revealed an EF-hand region in the C-terminus of the bestrophin proteins, and mutation of the region reduces the channels Ca^{2+} affinity 20-fold.[27]

Clearly, bestrophins are Cl^- channels, but where they function and their role in human disease has become increasingly controversial. Best gene mutations were known from the beginning to cause the human disease BVMD, and were known to be expressed highly in the retinal pigment epithelium (RPE). BVMD results in increased fluid in the subretinal and sub-RPE spaces, and an abnormal electro-oculogram[46]; phenotypes that appeared to be related to the function of basolateral CaCC channels in the RPE cells. hBest1 seemed a logical candidate channel to mediate these important Cl^- currents. However, recent studies using mouse knockout models of mBest1 do not phenocopy the human disease, and the mice have no retinal dysfunction.[75] Further, it appears that the newly discovered TMEM16/Anoctamin CaCC channels are also expressed in the basolateral membrane of RPE cells, and are now thought more likely to mediate the CaCC currents of these cells.[27] So although hBest1 is a Cl^- channel, in this case it does not appear to be essential for the conductance of Cl^-. Subsequent work suggests that hBest1 may regulate other channels (voltage-gated Ca^{2+} channels) or be a HCO_3^- channel, and therefore be important in cellular pH regulation.[27]

The characteristics of the four hBest channels are similar to a number of Cl^- currents identified in the kidney, and mRNA expression of all four hBest genes has been demonstrated in large mRNA expression surveys. However, there is currently no specific evidence that hBest proteins are expressed in the kidney or have any involvement in kidney function.

Chloride Intracellular Channel (CLIC)

Chloride intracellular channels (CLICs) were initially discovered in an attempt to identify the elusive Cl^- channel responsible for cystic fibrosis. Landry et al.[64] affinity purified a 64 kDa protein from bovine kidney cortex membrane vesicles using a weak Cl^- channel inhibitor, IAA-94 (indanyloxyacetic acid), and found when reconstituted into a lipid bilayer it produced a novel Cl^- conductance. Using an antibody against the 64 kDa protein, they localized it to the apical membrane and to intracellular vesicles in CFPAC-1 cells.[102] Using the same antibody, the 64 kDa protein was cloned[63] from a kidney cDNA library, and subsequent work showed it to be a member of a large family of proteins that became known as the CLICs, with the original 64 kDa protein becoming CLIC5B. In humans, six homologs exist, each representative of a highly-conserved paralog; however, the most extensive research has been done on CLIC1 and CLIC4.

The early work on CLICB showed that it could insert into the membrane and can act as a Cl^- channel, but only in a reconstituted bilayer system, presumably because the protein was exclusively in intracellular membranes. Experiments overexpressing human CLIC1 in CHO-K1 cells managed to record a novel Cl^- current, and were able to measure some single channel characteristics.[4] The overexpressed CLIC1 localized to both the nuclear and plasma membrane, and patch recordings were done from both. CLIC1 demonstrated a slight inward rectification and voltage-dependent inactivation,[71] a selectivity sequence of $F^- > Cl^- > I^-$ (unfortunately from a single experiment), a single channel conductance of approximately 30 pS,[4,71] and was reversibly inhibited by 10 μM IAA-94.[4] Further work demonstrated that CLIC1 actually forms tetramers, each with a pore conductance of approximately 8 pS.[71] Importantly, a single point mutation in CLIC1 (C24A) changes the channel characteristics, demonstrating that CLIC1 is unambiguously a Cl^- channel when inserted into a membrane.[71] In contrast, overexpression of CLIC4 in HEK cells produces channels with a significantly smaller single channel conductance, 1 pS, but a similar selectivity sequence, $I^- > Cl^-$,[4] although CLIC4 appears to be poorly selective generally with K^+ and Cl^- having similar permeability.[71]

The most interesting recent CLIC protein discovery concerns their switch hitting life-style. It is clear that CLIC1 can be both a stable globular soluble protein, and an integral membrane protein. The solved crystal structure of CLIC1 demonstrated its nature as a soluble protein, and more importantly marked it as a member of the superfamily of glutathione s-transferase (GST) genes.[71] This revelation dramatically altered the hypothesized function of the CLICs; they may not act as Cl^- channels, but instead as soluble enzymes like the rest of the GST family. It appears their putative function depends on whether the CLIC proteins insert into the membrane or not, and recent work has concentrated on environmental factors that can manipulate CLIC tertiary structure. It turns out that, like other GST proteins, oxidation can drastically alter the structure of CLIC1, creating a second stable tertiary structure, marking it as a metamorphic protein.[71] This second oxidized stable state appears likely to insert into membranes, thus oxidation may control the function of CLIC1, channel or enzyme. Separate unfolding experiments on soluble CLIC1 suggest that low pH "primes" the protein for insertion into membranes.[33] These two environmental modulators of CLIC1 may point to its possible *in vivo* physiological function. The localization

of CLIC1 and CLIC4 to acidified intracellular vesicles and endosomes may imply a coupling of CLIC Cl^- channel activity to the acidification by a proton pump reminiscent of CLC5 or CFTR. A link between CFTR and CLIC1 is supported by work done by Edwards,[30] who demonstrated in *Xenopus* oocytes that the co-expression of CFTR and CLIC1 lead to a synergistic increase in cAMP-activated current, part of which was IAA-94 sensitive. A similar regulator relationship between CLIC1 and CFTR could be even further enhanced in the acidic environment of endosomes, where more of the CLIC1 protein would form Cl^- channels. As genetic tools continue to evolve, a number of mouse knockout models have been developed to test the physiological role of CLIC *in vivo*. Both the $CLIC1^{-/-}$ and $CLIC4^{-/-}$ showed very slight phenotypes; however, a study of the intracellular vesicles of the $CLC4^{-/-}$ mice revealed that the large intracellular vesicles were less acidic than wild-type, although the endosomes demonstrated no change in acidification.[129] The potential redundancy of the CLICs may have masked many phenotypic changes from single CLIC knockouts. To further grasp the role of the CLICs specifically in the intracellular vesicles, multiple knockout models are needed.

ANION CHANNELOPATHIES OF THE KIDNEY

Thus far, only a single anion channelopathy has been described in human kidney, dysfunction of ClC-Kb which causes type III and IV Bartter's syndrome. Recent evidence has shown that ClC-5 is a Cl^-/H^+ exchanger, and thus has removed Dent's disease from the ranks of anion channelopathies, so it will be discussed elsewhere. In fact, the dearth of anion channelopathies in the kidney does not suggest that Cl^- conductances are not important in the nephron, but perhaps instead is illustrative of our limited knowledge of Cl^- channels' functional roles. The physiological functions of the newly identified TMEM16 Cl^- channel family are only beginning to be understood, and the missing molecular identities of the vast collection of volume-sensitive Cl^- channels still represent a significant hole in our understanding. Learning more about Cl^- channels in the kidney will undoubtedly teach us more about the cause of human diseases and how to treat them.

Bartter's Syndrome

Bartter's syndrome is a collection of kidney diseases that result in mishandling of salts in the thick ascending limb (TAL), and result in renal salt-wasting, hypokalemic metabolic alkalosis, elevated rennin and aldosterone levels, normal or low blood pressure, and hypercalciuria.[50] Traditionally, Bartter's was divided into two classes based on the age of the onset of symptoms: either neonatal or classic Bartter's. More recent genetic analysis of Bartter's patients revealed that mutations in five separate genes could cause the symptoms associated with Bartter's, prompting a further division into five classes, each demonstrating a separate dysfunction in the NaCl absorption pathway of the TAL[55] (Figure 31.7). Na^+, K^+, and Cl^- anions are imported across the apical membrane from the tubule lumen in the cells of the TAL via the NKCC2 co-transporter; mutations causing dysfunction in the NKCC2 co-transporter result in type I Bartter's syndrome. The K^+ leaves the cell via apical ROMK K^+ channels to return to the lumen; mutations in the ROMK K^+ channels result in type II Bartter's. The Cl^- exits the cell across the basolateral membrane through the ClC-Kb/Barttin channel complex; mutations in the ClC-Kb channel cause type III Bartter's, and mutations in the ClC-Kb channel subunit Barttin cause type IV.[55] Type V Bartter's syndrome results from gain-of-function mutations in the calcium sensing receptor protein, CaSR, a member of the G-protein receptor superfamily.[50] CaSR is activated by high extracellular Ca^{2+}, and in turn inhibits salt transport, thus overactive CaSR inappropriately inhibits salt absorption, resulting in symptoms typical in Bartter's syndrome.[49]

Interestingly, type III and type IV Bartter's does not result in the same phenotype, which would be expected if only the ClC-Kb–Barttin complex was being affected. Patients with mutations in the Barttin subunit have more severe salt-wasting than those with type III, in addition to sensorineural deafness. The deafness is now known to be caused by dysfunction of both ClC-Ka and ClC-Kb channels in the inner ear (see previous CLC section), demonstrating that Barttin is a required subunit for both ClC-Ks. In humans, the increased severity of type IV Bartter's therefore suggests a role of ClC-Ka in salt absorption in the TAL, although dysfunction in ClC-Ka alone is not associated with any renal disease phenotype.[61]

Polycystic Kidney Disease

Unlike type III and IV Bartter's syndrome, autosomal dominant polycystic kidney disease (ADPKD) is not a Cl^- channelopathy; however, the progress of ADPKD depends directly on an inappropriate increase in Cl^- channel function. ADPKD is the most common genetic disorder found in humans, effecting 1 out of 800 births.[137] It results in the slow and progressive accumulation of fluid filled cysts in the kidney and the liver, which by adulthood can result in renal failure and necessitate kidney transplantation or result in patient death.[137] Two genes have been causally associated with ADPKD, the two polycystin genes, PKD1

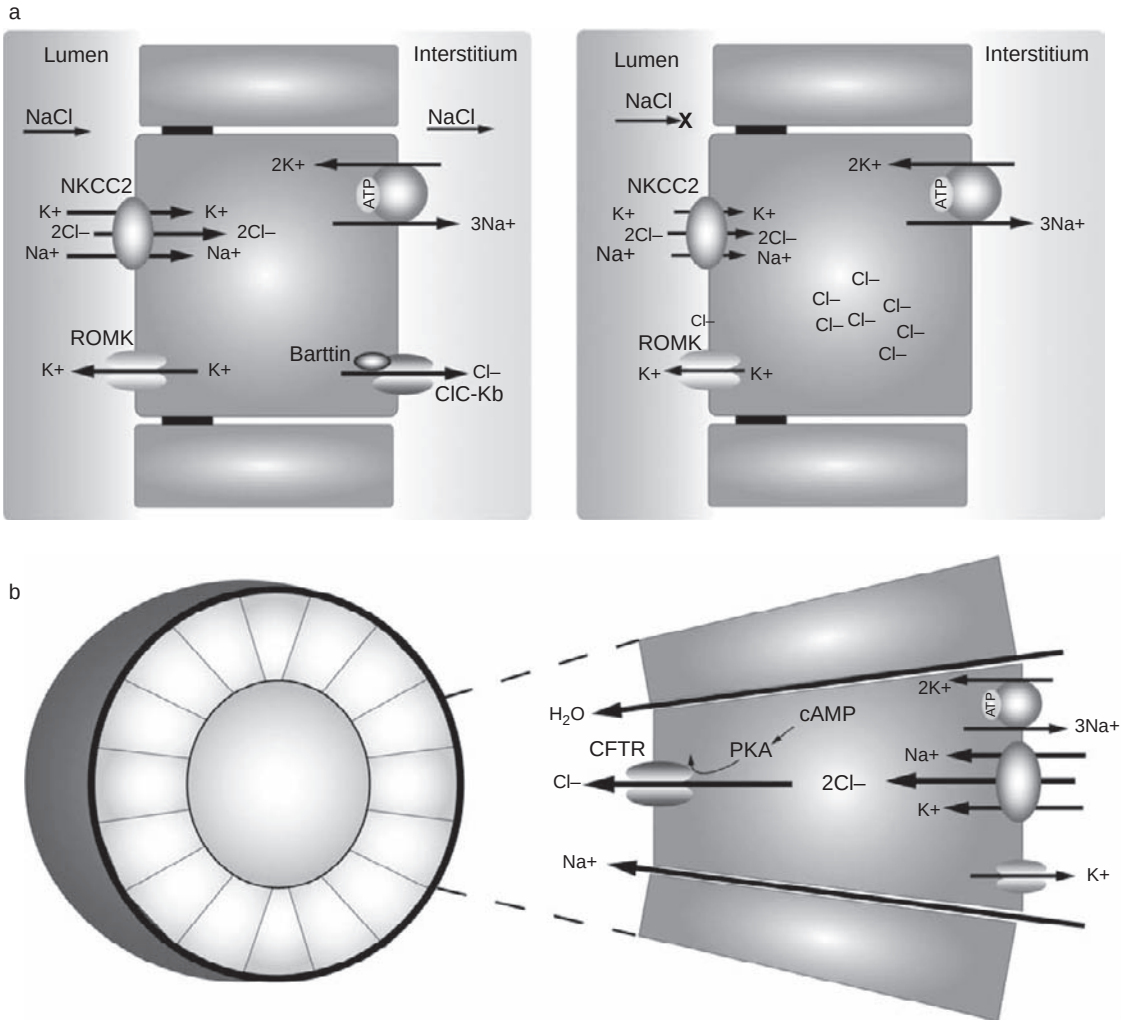

FIGURE 31.7 **Anion channelopathies of the kidney.** (a) Bartter's syndrome type III and IV. In normal cells of the thick ascending loop (TAL), NaCl is absorbed from the lumen and moved into the interstitium, a process that requires the transport of K^+, $2Cl^-$, and Na^+ across the apical membrane (NKCC2), and the subsequent efflux of Na^+ (Na^+/K^+-ATPase) and Cl^- (ClC-Kb) across the basolateral membrane. When either the ClC-Kb or its barttin subunit is dysfunctional, Cl^- builds within the cell, slowing apical transport of Na^+, Cl^-, and K^+. Without NaCl absorption in the TAL potentially severe salt-wasting will occur. (b) Mutations of either PKD1 or PKD2 genes causes tubule epithelial cells to form cysts and not tubules. Cyst growth and expansion, however, relies on fluid secretion into the cyst lumen driven by an apical CFTR Cl^- conductance that pulls paracellular Na^+ and H_2O along with it.

and PKD2[137]; how mutations in these genes and their gene products, PC1 and PC2/TRPP2 respectively, lead to cyst development remains unclear. PC1 is a large membrane protein that includes an extensive extracellular domain and may be part of focal adhesion complexes at the plasma membrane,[60] but it has also been shown to cleave into numerous functional products including P100, which has been shown to inhibit the ER Ca^{2+} sensor protein STIM1.[141] PC1 may also regulate the function of PC2. PC2 is a calcium channel that may reside on either the ER or plasma membranes. PC2 has been shown to be a key regulator of ER Ca^{2+} stores and ATP-mediated Ca^{2+} release.[60,69] A PC1–PC2 complex on an extended non-motile cilium has been proposed to detect intertubule flow, a key developmental signal during tubulogenesis. Under this hypothesis, a dysfunction in flow directionality may lead to abnormal tubule growth and the creation of cysts.[148] Alternative hypotheses have PC1 and PC2 playing key roles in regulating proliferation and apoptosis, both key elements in normal tubulogenesis, and being co-opted for cyst development.[121]

Although the mechanism that begins cytogenesis is not yet understood, the mechanisms contributing to cyst growth and enlargement are better understood. The development of ADPKD cysts requires the proliferation of epithelial cells and fluid accumulation within the cyst cavity.[67] Both of these are accelerated by the

cAMP signal transduction pathway.[68] In studies of primary cultures of ADPKD cells, apical cAMP-activated Cl^- conductances were identified using the patch-clamp technique. These currents were sensitive to glibenclamide and DPC, but not DIDS, and had a selectivity sequence of $Br^- > Cl^- > I^-$; these are all hallmark characteristics of the CFTR Cl^- channel.[44] Immunohistochemistry showed CFTR to be in the apical membranes of ADPKD cells and in cyst linings of ADPKD kidneys.[44] The movement of fluid, therefore, is believed to be facilitated by Cl^- secretion into the lumen of the cysts by apical CFTR channels, pulling both Na^+ and water along with it via paracellular pathways (Figure 31.7). This model of CFTR-mediated secretion is very similar to the role of CFTR in the airway, where it maintains the airway surface liquid (ASL). The apical Cl^- secretion in cyst epithelia is made possible by the accumulation of cytosolic Cl^- via the basolateral NKCC1 co-transporter, which transports in two Cl^- for every Na^+ and K^+ ion.[65] More recent work has also confirmed a more direct connection between CFTR and the polycystin proteins. Ikeda et al.[51] demonstrated in a MDCK model system that the expression of PC1 downregulated the amount of apical CFTR expression, concluding that mutant PC1 would promote increased CFTR plasma membrane expression, and increased Cl^- and fluid secretion into the cyst lumen. Thus, the increased function of CFTR may lead to fluid accumulation in the cysts; perhaps demonstrating better than any of the numerous experiments mentioned earlier in the CFTR section that CFTR is in the kidney and it functions there just as it does elsewhere: facilitating salt and fluid secretion.

To test the role CFTR plays in cyst growth in humans, researchers looked specifically at families with members who suffered from both ADPKD and CF. Although very few of these individuals have been studied, it does appear that ADPKD patients who also suffer from CF have fewer and smaller renal and hepatic cysts than do their age-matched siblings with ADPKD but not CF.[143] However, in another study where a single CF (Δ508CFTR) patient with ADPKD was compared to non-siblings with ADPKD but no CF, there appeared to be no difference in kidney volume or renal function.[94] Obviously, in humans it will require further accumulation of the very rare occurrence of families with both ADPKD and CF before we can really know whether CF patients receive some renal protection. Surprisingly, $CFTR^{-/-}$ knockout mice have not been crossed with any ADPKD mouse models to see if cytogenesis or cyst growth is diminished; this type of experiment could increase our understanding of CFTRs role in ADPKD.

Recent work has focused on CFTR as a target for a therapeutic approach to control ADPKD-mediated cyst growth and expansion using specific, high-affinity CFTR inhibitors. MDCK cells with endogenous CFTR and low levels of PC1 will form cysts when grown in a collagen matrix and given the cAMP agonist forskolin, but cyst growth is inhibited with the application of the specific CFTR inhibitor CFTRinh-172.[67] Similarly, when CFTR inhibitor compounds CFTRinh-172 and Ph-GlyH-101 were used to treat embryonic cystic mouse kidneys in a 4 day culture model system, they reduced cyst number and growth by more than 80%. Further, direct treatment of PKD1 knockout mice with the CFTR inhibitor slowed the normally fast development of kidney cysts and preserved kidney function.[144,131] These studies strongly support targeting CFTR as a therapy for ADPKD patients that may prove efficacious in decreasing cyst size and preserving kidney function.

SUMMARY

Recent years have marked an exciting time in the field of Cl^- channel research. More and more of the molecular identities of the functional Cl^- channel groups have been discovered, and this new knowledge has given us an expanded view of the importance of Cl^- channels in both kidney physiology and human physiology. So, too, we must acknowledge the shifting landscape that has redefined many anion channels as exchangers, and accept that perhaps that the characteristics that separate the two groups are far less significant than previously believed. But what hasn't changed is the importance of anion channels in kidney function. Each year increases our understanding of their role in secretion of waste, water retention, ionic balance, blood pressure regulation, and the recapture of essential solutes. We can now add the TMEM16 and SLC26a gene families to those expressed in the kidney that conduct anions, and look forward to what these newly discovered Cl^- channels can tell us. But not all recent discoveries have been on the large-scale, many incremental but significant discoveries have also been made that slowly progress our understanding of human diseases like Bartter's Syndrome and PKD, and bring us one step closer to developing more effective therapies. The same questions persist: how do anion channels work in the context of the human kidney? How does their dysfunction lead to human disease? Can we develop new or more effective pharmacologic therapies for human kidney disease? But we now have even greater tools, knockout animals, siRNA, vast drug libraries, and the ability for large-scale molecular screens with which to answer these fundamental questions.

CHAPTER

32

Physiology and Pathophysiology of the NaCl Co-Transporters in the Kidney

Gerardo Gamba

Molecular Physiology Unit, Department of Nephrology and Mineral Metabolism, Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, and Instituto de Investigaciones Biomédicas, Universidad Nacional Autónoma de México, Mexico City, Mexico

INTRODUCTION

There are four types of electroneutral co-transporter systems that have been identified: (1) the sulfamoylbenzoic (or bumetanide)-sensitive Na^+-K^+-$2Cl^-$ co-transporter; (2) the sulfamoylbenzoic (or bumetanide)-sensitive Na^+-Cl^- co-transporter; (3) the benzothiadiazine (or thiazide)-sensitive Na^+-Cl^- co-transporter; and (4) the dihydroindenyloxy-alkanoic acid (DIOA)-sensitive K^+-Cl^- co-transporter. All these possibilities are encoded by members of the family of solute carriers SLC12, according to the classification of the Human Genome Organization.[1] Two genes of this family, SLC12A1 encoding the apical Na^+:K^+:$2Cl^-$ co-transporter, NKCC2 (also known as BSC1), and SLC12A3, encoding the Na^+:Cl^- co-transporter, NCC (also known as TSC1), are particularly relevant to kidney physiology, pharmacology, and pathophysiology. NKCC2 and NCC play a key role in salt reabsorption of the thick ascending limb of Henle's loop and distal convoluted tubule, respectively, with consequent effects in potassium, calcium, and acid–base homeostasis. They also serve as receptors for the loop diuretics (furosemide, bumetanide, ethacrinic acid) and thiazide-type diuretics (chlortalidone, hydrochlorothiazide, metolazone), respectively, that are heavily used in the management of patients with arterial hypertension or edematous states, such a cardiac failure, chronic liver disease, chronic renal disease or nephrotic syndrome. Inactivating mutations of NKCC2 cause Bartter syndrome type I, and of NCC cause Gitelman's syndrome. Additionally, dysregulation of NCC is implicated in the genesis of pseudohypoaldosteronism type II, and it is proposed that both co-transporters belong to the hypertension susceptibility genes. In this chapter we will discuss the cation-coupled chloride co-transporters, with particular emphasis on NKCC2 and NCC.

The SLC12A family was identified in the early 1990s with the cloning of the thiazide-sensitive Na^+-Cl^- co-transporter,[2,3] followed by two genes encoding the Na^+-K^+-$2Cl^-$ co-transporters,[3–6] and is composed of nine related genes.[7,8] Later, the four genes encoding K^+:Cl^- co-tranporters that were named KCC1,[9] KCC2,[10] KCC3,[11,12] and KCC4[12] were identified.

Figure 32.1 depicts a phylogenetic tree of all members of the SLC12 family for which functional properties are known, as well as the chromosome to which each gene has been mapped in humans, the inherited disease that results from inactivating mutations of the gene, and the consequence of knocking-out each gene in the mouse. Two branches within the family are clearly identified. The Na^+-driven branch encompasses three genes: *SLC12A1* and *SLC12A2* encode the Na^+:K^+:$2Cl^-$ co-transporters, NKCC2 and NKCC1, respectively. NKCC2 is a kidney-specific gene, with expression restricted to the apical membrane of the thick ascending limb of Henle's loop (TAL).[3,5,13,14] In contrast, NKCC1 is a ubiquitously expressed protein that is located at the basolateral membrane of secretory epithelial cells, as well as in many non-epithelial cells (neurons, fibroblasts, erythrocytes, etc.).[15,16] *SCL12A3* is the third gene of the Na^+-driven branch, and encodes the thiazide-sensitive Na^+:Cl^- co-transporter,

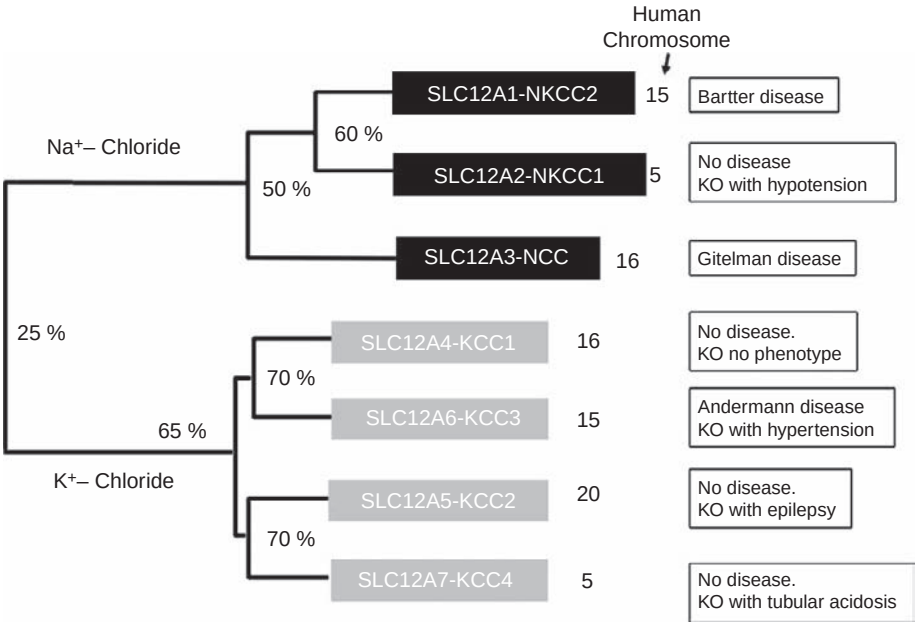

FIGURE 32.1 SLC12 phylogenetic tree. The family is divided in two branches: the Na-coupled and the K-coupled co-transporters. The degree of identity between members is shown in percentages. Chromosome location, inherited diseases, consequences in corresponding knockout mice, and the tissue specific expression is shown.

NCC.[2,3,17] It is mainly expressed in the apical membrane of the distal convoluted tubule (DCT). Initially it was thought that NCC is a gene with restrictive expression in the kidney; however, later it was demonstrated to be expressed at the protein level along the gut,[18] in bone,[19] and in the lens.[20] Although a thiazide-sensitive Na^+-Cl^- co-transporter has been postulated to exist in other tissues,[21] blood vessels,[22] pancreas,[23] peripheral blood mononuclear cells,[24] gallbladder[25] and heart,[26] its presence at the molecular level has not been demonstrated. In bone, NCC activity is associated with the rate of bone formation. Many clinical studies have shown that thiazide diuretics in elderly subjects promote an increase in bone mineral density and help to prevent pathological fractures.[27,28] Consistent with this beneficial effect of thiazides, NCC is expressed in osteoblasts of rat and human bones, and addition of thiazides to osteoblasts in culture increases the formation of mineralized nodules. This effect of thiazides was not present after NCC expression was reduced by transfecting cells with an NCC antisense plasmid.[19]

The degree of identity at the protein level between NKCC1 and NKCC2 is ~60%, and between NCC and the NKCCs is ~50%. The degree varies, however, within specific domains of the co-transporters. It is >80% in some of the central hydrophobic membrane spanning domains, ~50% in the carboxyl terminal domain, and <10% in the amino terminal domain and most of the interconnecting loops that are oriented toward the extracellular side.

The K^+-driven branch is composed of four genes, SLC12A4 to SLC12A7, encoding the K^+:Cl^- co-transporters KCC1 to KCC4, respectively. KCC1 is ubiquitously expressed, while KCC2 is only present in neurons. KCC3 and KCC4 are expressed in several tissues, including the kidney.[7,8,29] Along the nephron KCC3 has been shown to be present only in the proximal tubule, while KCC4 is also expressed in the basolateral membrane of TAL and the intercalated cells of collecting duct (CD).[30–32] The degree of identity is about 60% between KCCs and about 25% with the members of the Na^+-driven branch.

Two additional genes are classified within the SLC12A family (not shown in Figure 32.1) due to a degree of identity of ~20% with either the Na^+-driven or the K^+-driven branches. SLC12A8 gene (human chromosome 3) encodes a protein of 714 amino acid residues that has been identified as a psoriasis susceptibility gene by two independent groups.[33,34] One report suggests that this protein may translocate polyamines and amino acids across the plasma membrane.[35] SLC12A9 (human chromosome 7) encodes a 918 residue protein originally named as co-transporter interacting protein (CIP) for its ability to modulate the activity of NKCC1.[36] Its topological similarity and the 25% identity with other members of the family suggest that it is likely that CIP transports substrates that have not been identified.

THE PHYSIOLOGY OF NaCl CO-TRANSPORTERS IN THE KIDNEY

The electroneutral cation–chloride co-transporters translocate Cl^- ions together with a cation, which can be Na^+, K^+ or both, maintaining the requirement of

electroneutrality: $1Na^+$-$1Cl^-$, or $1K^+$-$1Cl^-$ or $1Na^+$-$1K^+$-$2Cl^-$ stoichiometry. The direction of the transport process is defined by the cation gradient. Therefore, NKCC1, NKCC2, and NCC move ions inward across the plasma membrane, while KCCs move ions outward. Because Na^+ and K^+ are returned to the steady-state by the Na^+:K^+-ATPase, the activity of the SLC12A co-transporters is considered to be primarily regulation of the intracellular chloride concentration $[Cl^-]_i$, a role that is critical to some physiological processes. One of these is cell volume regulation. During cell shrinking, due to increased osmolarity of the extracellular medium, the regulatory volume increase response stimulates transport mechanisms to enhance the intracellular osmolarity, including activation of NKCC1 > NKCC2 > NCC. In contrast, during cell swelling, the regulatory volume decrease promotes the activation of KCCs to reduce intracellular osmolarity. Because basically every cell expresses NKCC1 and KCC1, this cell volume regulatory mechanism is universal.[37]

Another major function of electroneutral cation–chloride co-transporters is the setting of the intraneuronal chloride concentration, either above or below its electrochemical equilibrium potential. For this reason, the activity of these co-transporters is critical in determining the polarity and magnitude of the effect of neurotransmitters that gate Cl^- channels in postsynaptic membranes, such as GABA.[16,38] It is known that before birth GABA behaves mostly as an excitatory neurotransmitter, in neurons in which intracellular chloride is above the electrochemical equilibrium due to more prominent expression of NKCC1 than KCC2. After birth, however, GABA becomes predominantly an inhibitor transmitter, due to the inversion of NKCC1/KCC2 ratio of expression that lowers intracellular chloride below equilibrium.[39]

A third major role of the SLC12A co-transporters that will occupy our interest for the rest of this chapter is the transepithelial movement of ions. NCC and NKCC2 are polarized to the apical membrane of DCT and TAL, respectively, where they participate in renal salt reabsorption. NKCC1 is expressed in the basolateral membrane of several chloride-secreting epithelia, where its activity is critical to provide the cell with chloride ions to be secreted in the apical membrane. The K^+:Cl^- co-transporters are also involved in epithelial movement of ions. One example is KCC4 that is expressed in the intercalated cells of the CD, where it plays a role in the chloride efflux required to maintain hydrogen secretion and thus, acid–base homeostasis.[31]

The Thiazide-Sensitive Na^--Cl^- Co-Transporter

NCC is the major salt transport pathway in the apical membrane of mammalian DCT cells[40–44] which mediates reabsorption of 5–10% of glomerular filtrate. In the early DCT (DCT1) NCC is fully in charge of salt reabsorption, while in the late DCT (DCT2) it shares the responsibility with the sodium channel ENaC.[45–49] This is an important difference, since DCT1 is not considered to be part of the aldosterone-sensitive distal nephron, due to the lack of 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which prevents illicit occupation of the mineralocorticoid receptor by cortisol.[46,49–52] Thus, NCC is susceptible to aldosterone regulation only in DCT2 cells. The molecular mechanism of salt reabsorption in DCT is illustrated in Figure 32.2. The Na^+ gradient that drives transport from the lumen to the interstitium is generated and maintained by the intense activity of Na^+/K^+-ATPase that is polarized to the basolateral membrane.[53] Potassium entering the cell through the Na^+/K^+ pump is secreted by the luminal membrane via K^+ channels[54] and by an apical K^+-Cl^- co-transporter.[55] Thus, potassium secretion rate is determined, at least in part, by the rate of Na^+-Cl^- reabsorption. In addition, NCC modulates magnesium and calcium reabsorption, the latter in an inverse relationship with sodium reabsorption. The lower the sodium reabsorption, the higher the calcium reabsorption, and *vice versa*.[42] As shown in Figure 32.2, NCC is the target for thiazide-type diuretics (metolazone, hydrochlorothiazide, chlortalidone, bendroflumethiazide).[3,43,56] Because thiazides are recommended for the treatment of arterial hypertension, some edematous states, and renal stone disease,[57,58] this group of drugs are among the most commonly prescribed medicines in the world.

The Loop-Diuretic-Sensitive Na^+-K^+-$2Cl^-$ Co-Transporter 2 (NKCC2)

NKCC2 is the major salt transport pathway in the apical membrane of the mammalian TAL, a nephron segment where 15–20% of glomerular filtrate is reabsorbed.[59–64] In addition to its role in salt reabsorption, NKCC2 activity also serves to keep the countercurrent multiplication mechanism by promoting salt concentration in the renal medulla and thus, the renal ability to concentrate urine. Divalent cation (Ca^{2+} and Mg^{2+}) and ammonium (NH_4^+) reabsorption in the TAL also requires the activity of NKCC2 (for reviews see [64–66]). As shown in Figure 32.2, in the case of Ca^{2+} and Mg^{2+} this is due to the fact that simultaneous

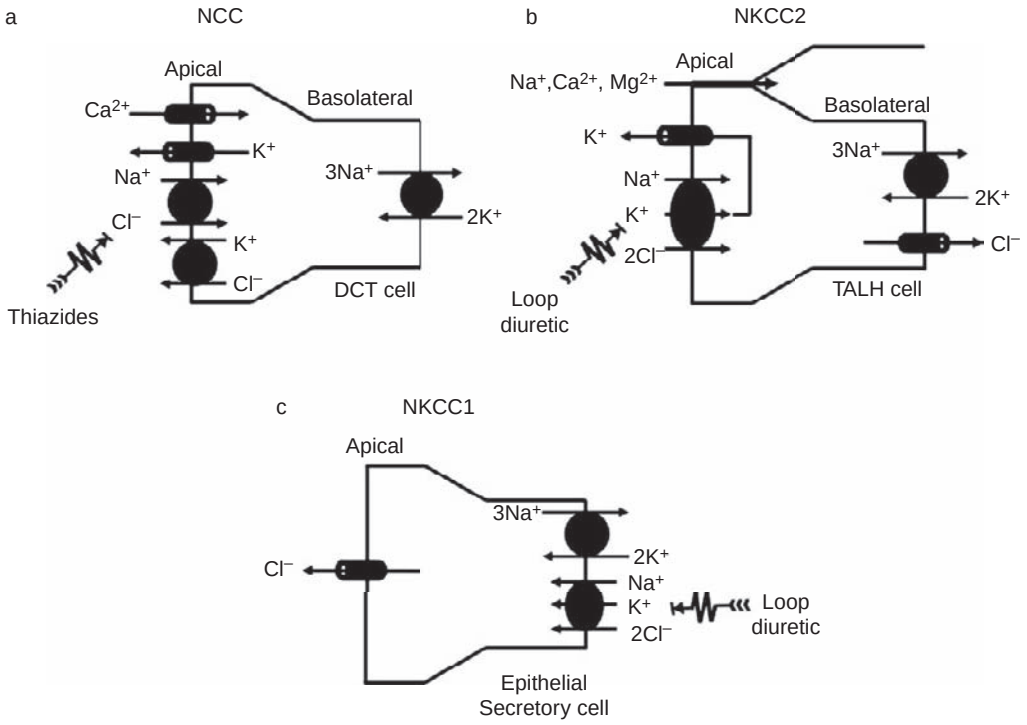

FIGURE 32.2 **Transepithelial ion transport by NCC, NKCC2, and NKCC1.** (a) Distal convoluted tubule. Expression of NCC is polarized towards the apical membrane. (b) Thick ascending limb of Henle's loop. NKCC2 expression is located to the apical membrane. (c) An example of secretory epithelial cell that could be from trachea, gills, intestine, salivary gland, etc. NKCC1 present in the basolateral membrane provides the cell with the chloride to be secreted through the apical membrane.

operation of NKCC2 with the basolateral chloride channels CLC-KB, the Na^+/K^+-ATPase, and the apical inwardly rectifying K^+ channel known as ROMK, promotes the generation of positive voltage within the TAL lumen, which in turn drives the reabsorption of a second cation via a paracellular pathway, which could be Na^+, Ca^{2+} or Mg^{2+}. Thus, in contrast to what occurs in DCT, in the TAL reducing salt reabsorption is associated with reducing calcium reabsorption. Because of this, loop diuretics are often used in the clinical setting for the management of life-threatening hypercalcemia. In the case of ammonium, this is due to the fact that NH_4 can use potassium transport pathways for its translocation through the plasma membrane. Thus, NKCC2 can also operate as the Na^+:NH_4^+:$2Cl^-$ co-transporter.[67,68]

NKCC2 is an important target in cardiovascular and renal pharmacology, because inhibition of this co-transporter is the base of the loop diuretic actions that are the most potent natriuretic agents available for clinical use (furosemide, ethacrinic acid, bumetanide). Loop diuretics decrease the salt reabsorption in TAL, producing significant natriuresis and diuresis. Because loop diuretics reduce interstitial osmolarity of the renal medulla, another mechanism of action is to reduce the concentration capacity of the kidney. Any increase in salt delivery to the macula densa is expected to be compensated by reducing the glomerular filtration rate due to the tubuloglomerular balance.[69] This compensation is absent, however, in the presence of loop diuretics, because the salt-sensing protein in macula densa is also NKCC2.[70] Since the B variant of NKCC2 is the most abundant variant in macula densa cells,[71] and it is not expressed in shark kidney, which also lacks a macula densa,[72] it has been proposed that NKCC2B is the Cl^- sensor in TAL cells. It has been difficult to prove this hypothesis because the variant-specific knockout mice lacking NKCC2B developed a compensatory increase in NKCC2A expression in the TAL cells, and only exhibited a very slight shift to the right of the tubuloglomerular feedback curve.[73] Similarly, the isoform-specific null mice for NKCC2A variant also showed slight changes in tubuloglomerular feedback.[74] These observations suggest that both isoforms working together compose the Cl^- sensor in the macula densa.

Increasing net NaCl reabsorption in TAL by hormones generating cAMP via Gs-coupled receptors such as vasopressin, glucagon, parathyroid hormone, β-adrenergic, and calcitonin is a fundamental mechanism for regulating salt transport in this nephron segment.[75,76] Of these hormones, the most important is the antidiuretic hormone vasopressin, which increases NaCl absorption by TAL through a mechanism that appears

to involve trafficking of NKCC2 to the apical plasma membrane.[77–79] Supporting this proposal it has been observed in medullary TAL that most NKCC2 protein is located in intracellular vesicles, and that addition of cAMP increases the expression of NKCC2 in the apical membrane by activating the exocytosis, rather than by inhibiting the endocytosis of NKCC2-containing vesicles.[80,81] Additionally, long-term increases in vasopressin are associated with increased expression of NKCC2 and maximal urinary concentration ability.[82,83]

The Loop-Diuretic Sensitive Na^+-K^+-$2Cl^-$ Co-Transporter 1 (NKCC1)

NKCC1 is the Na^+-K^+-$2Cl^-$ co-transporter that is present in secretory epithelium, as well as in many non-epithelial cells. At the cellular physiology level, NKCC1 is very important for cell volume and $[Cl^-]_i$ regulation.[7,15,37,84] The diverse phenotypes of NKCC1 knockout mice illustrate the role of this transporter in numerous physiological processes.[85-87] NKCC1 knockout mice feature deafness due to both disrupted epithelial secretion in the labyrinth and a sensorineural defect, infertility due to a deficiency in spermatocyte production, cecum bleeding and blockade of the colon due to impaired intestinal secretion, salivation impairment, and low blood pressure due to vascular and renal effects.[88] Blood pressure in NKCC1 null mice is decreased due to reduced vascular tone.[86,88–90] In this regard, the loop diuretic bumetanide decreased blood pressure in normal mice by inhibiting the activity of NKCC1 in vascular beds, and reduced the vascular smooth muscle cells' myogenic tone. Both effects are not present in the NKCC1 null mice, strongly suggesting that are the results of inhibiting NKCC1 in blood vessels.[91,92] Of note, however, one study using telemetry to monitor blood pressure day and night for several days failed to confirm hypotension in the NKCC1 knockout mice, and suggested a salt-sensitive component because a significant increase in blood pressure was produced by a high-salt diet.[93] Finally, NKCC1 is expressed in the basolateral membrane of the macula densa cells,[94] where it has been suggested that it modulates renin secretion.[95]

MOLECULAR BIOLOGY OF THE SODIUM-DEPENDENT CHLORIDE CO-TRANSPORTERS

The Thiazide-Sensitive Na^+-Cl^- Co-Transporter

Following an expression cloning strategy using the functional expression system of *Xenopus laevis* oocytes, NCC cDNA was first identified at the molecular level from the winter flounder (*Pseudopleuronectes americanus*) urinary bladder.[2] This clone was named as TSC (for thiazide-sensitive co-transporter), and later changed to NCC. The flounder's transcript produced a 3.7 kb cDNA clone containing a 3609 bp open reading frame that predicted a 1023 amino acid residues protein with a core molecular mass of 112 kDa. The computer-based analysis hydrophobicity/hydrophylicity[96] suggested the putative basic topology of the Na^+-coupled-Cl^- co-transporters shown in Figure 32.3a. The short amino terminal domain is followed by a central hydrophobic domain containing what appear to be 12 α-helices compatible with transmembrane-spanning segments. A long carboxyl terminal domain follows this. The amino and carboxyl terminal domains are predicted to be located within the cell. The long loop between transmembrane segments 7 and 8 is glycosylated in NCC[97,98] and NKCC2,[99] and thus presumably in all members of the SLC12A family. In flounder, a shorter 3.0 kb transcript due to alternative splicing is expressed in several tissues including the brain, eye, heart, intestine, gonads, and skeletal muscle.[2] The functional consequence of this variant remains elusive.[100] After the cloning of NCC from the flounder urinary bladder, cDNAs encoding NCC from a variety of mammalian sources were isolated, including rat (*Rattus norvegicus*),[3] mouse (*Mus musculus*),[177] rabbit (*Oryctolagus cuniculus*),[101] and human (*Homo sapiens*).[102,103] Additionally, the NCC cDNA sequence has been deposited in gene databases for at least another 10 species, mostly mammalians and one birth.[104] The degree of identity between mammalian NCCs is ~90%, and of any mammalian with flounder is ~60%. Molecular identification of putative NCC sequences in eel suggests the existence of two different NCC genes.[105] NCCα is expressed only in eel kidney, while NCCβ was observed in many tissues, but more abundantly in intestine. The amino acid residues of NCCα and NCCβ are 1027 and 1043, respectively. No functional expression was analyzed, but the extend of identity of NCCα or NCCβ with any NCC, NKCC1 or NKCC2 supports the proposition that these eel sequences probably correspond to NCC, since degree of identity of NCCα or NCCβ with any NCC sequence is higher than with any NKCC1 or NKCC2. In mammals, rabbit and human NCC is longer than other species due to the presence of 17–26 amino acid residues in the carboxyl terminal domain. These extra residues were shown to be encoded in humans by a separate exon (exon 20) which is not present in rodents.[7,104] It is noteworthy that in humans, there is a putative protein kinase A (PKA) site (RPS) within the extra fragment. No functional significance for this extra exon in humans has been reported, but an extensive proteomic analysis of human urinary

FIGURE 32.3 **Molecular physiology of the Na^+-K^+-$2Cl^-$ co-transporter, NKCC2.** (a) Proposed topology (similar to NCC and NKCC1), transport mode, and immunolocalization of the long isoform of NKCC2 (L-NKCC2). The intracellular short amino-terminal domain is followed by 12 transmembrane segments and a long carboxyl terminal domain. The long hydrophilic loop between TM segments 7 and 8 is gylcosylated.[97,99] Several threonines/serine residues in the amino-terminal domain are known to be critical for the regulation of the co-transporters. The mutually exclusive cassette exons A, B, and F are shown in red. (b) Proposed topology, transport mode, and immunolocalization of the short isoform of NKCC2 (L-NKCC2). Location of the mutually exclusive cassette exons is shown in red, and the unique 55 piece at the end is shown in orange. In the picture the white arrows points to positive cells. (c) Sequence and alignment of the exon cassettes A, B, and F. Swapping the red or green residues between B and F isoforms switches their ion transport kinetics between each other (TM-2: transmembrane domain 2; ICL: interconnecting segment between TM2 and TM3). The 55 unique fragment of the short NKCC2 is shown. Positively charged residues are shown in blue. (d) Distribution of L-NKCC2 and S-NKCC2, as well as exons A, B, and F along the limb of Henle, as stated. (e) Ion transport kinetics and capacity of transport for L-NKCC2 A, B, and F variants, as informed by Plata et al.[77] *(Modified from ref. [64].)*

exosomes revealed, among may proteins found, the presence of several fragments of NCC, some of which have the serine 811 phosphorylated, that correspond to the putative protein kinase A site RPS contained by the human exon 20.[106] The expression of NCC protein has been confirmed using specific antibodies in intestine,[18] bone cells,[19] and lens.[20] Additionally, *in silico* analysis of NCC expression revealed that NCC transcripts are abundantly present in sensory ganglia, such as trigeminal and dorsal root ganglion.[104] No report has confirmed the presence of NCC protein in this tissue, and its functional significance is unknown.

The Loop-Diuretic-Sensitive Na^+-K^+-$2Cl^-$ Co-Transporter 2 (NKCC2)

The product of SLC12A1 is the Na^+-K^+-$2Cl^-$ co-transporter known as NKCC2, and it has been located exclusively in the apical membrane of the TAL. Two groups simultaneously identified the cDNA encoding both Na^+:K^+:$2Cl^-$ co-transporter isoforms. Hebert and co-workers cloned the cDNA encoding NKCC2/BSC1 from rat renal outer medulla, and then NKCC1/BSC2 from a mouse inner medullary collecting cells cDNA library,[6] while Forbush and co-workers first identified NKCC1/BSC2 cDNA from a shark rectal gland cDNA library,[4] and later NKCC2/BSC1 from rabbit renal outer medulla.[5] Later, human and mouse NKCC2 sequences were reported.[14,107] Isolated cDNA clones were about 4.5 kb in size, with an open reading frame of 3285 bp encoding a 1095 residue protein. The predicted NKCC2 topology (Figure 32.3A) is highly similar to NCC, featuring the central hydrophobic domain with 12 putative membrane-spanning segments that is flanked by the predominantly hydrophilic amino terminal domain (~165 amino acids) and carboxyl terminal domain (~450 residues). Functional expression

analysis in *Xenopus laevis* oocytes demonstrated that NKCC2 encodes a bumetanide-sensitive Na^+-K^+-$2Cl^-$ co-transporter.[3] It was observed, in a tissue distribution analysis using Northern blot, that NKCC2 transcripts are exclusively present in the renal outer medulla. All other tissues were negative and, until today, no study has confirmed the presence of NKCC2 protein in any other tissue or culture cell. It was proposed that this is due to the presence of a tissue-specific promoter.[108] Interestingly, however, as shown for NCC, *in silico* distribution analysis suggests the existence of NKCC2 transcripts in the sensory ganglia, such as trigeminal and dorsal root ganglion.[104]

SLC12A1 gives rise to a number of alternative splicing variants. At least six isoforms have been suggested to be present in the mouse kidney. Two independent alternatively splicing mechanisms are responsible[7,13,109] (Figure 32.3a,b). One splicing event was first observed in rabbit,[5] and later also in mouse,[14] rat,[110] and human[107] kidney. Three isoforms or variants arise from this splicing mechanism that involve the existence of three mutually-exclusive cassette exons nominated as A, B, and F (Figure 32.3a). These cassettes are composed of 96 bp encoding a 32 amino acid that is part of the second part of the transmembrane segment 2 and the first part of the intracellularly-located interconnecting segment between TM2 and 3 (Figure 32.3c). Thus, three NKCC2 proteins are produced differing only in the 32 amino acid residues, and all three are present in the mammalian NKCC2s known to date.[104] Only variants A and F have been identified from *Squalus acanthias* (shark) kidney.[72]

Another splicing of *SLC12A1* gene that was observed in the mouse kidney is due to the presence of a poly-adenylation site located in the intron between exons 16 and 17, resulting in a shorter C-terminal domain with an extra 55 amino acid residues, not present in the long isoform (Figure 32.3b).[13] Thus, two NKCC2 proteins are produced. These are identical from the first residue in the amino terminal domain to residue 74 of the carboxyl terminal domain. After this point, the longer isoform contains 383 residues not present in the shorter isoform, while the shorter contains 55 residues not present in the longer variant (Figure 32.3c). The existence of the shorter isoform in mouse kidney was demonstrated by a specific polyclonal antibody directed against the 55 unique piece of the shorter isoform.[13] By means of RT-PCR, it was shown that mouse kidney exhibits transcripts of the three isoforms A, B, and F, combined with both possibilities for the carboxyl terminal domain, suggesting that both splicing mechanisms are independent of each other and thus, that a total of six isoforms are predicted to be produced in mouse kidney: three long NKCC2 isoforms (A, B, and F), and three short NKCC2 isoforms (A, B and F).[13] The possible functional significance of spliced isoforms is discussed below.

The Ubiquitous Bumetanide-Sensitive Na^+-K^+-$2Cl^-$ Co-Transporter (NKCC1)

The SLC12A2 gene encodes the ubiquitously expressed Na^+-K^+-$2Cl^-$ co-transporter. NKCC1 is expressed in the plasma membrane of both epithelial and non-epithelial cells. In the first case, it is limited to the basolateral membrane in which the activity NKCC1 serves to provide the cell with the potassium or chloride ions to be secreted through the apical membrane. The only exception is the choroid plexus, in which both the Na^+-K^+-ATPase and NKCC1 are expressed in the apical membrane.[111] NKCC1 has been identified at the molecular level in several species, including mouse,[6] rat,[112] human,[113] *Bos taurus* (bovine),[114] shark,[4] *Anguilla anguilla* (eel),[115] and *Dicentrarchus labrax* (sea bass),[116] and even from the plant *Arabidopsis thaliana*.[117] The existence of one alternatively-spliced isoform of NKCC1 has been suggested.[118] This is a slightly shorter splice variant present in mouse brain total RNA due to the lack of 48 bp corresponding to the entire exon 21. This exon contains a potential PKA phosphorylation site. The existence of a splice transcript was supported by an RNAse protection assay. Distribution analysis within the brain showed that an NKCC1 transcript lacking exon 21 is present in all areas examined except in the choroid plexus, where only the full-length isoform containing exon 21 is expressed. Functional expression in heterologous systems revealed that the shorter variant behaves as a Na^+-K^+-$2Cl^-$ co-transporter.[119] Interestingly, it was recently shown that exon 21 of NKCC1 is implicated in differential sorting in polarized epithelial cells.[120]

Genes, Promoters, and Phylogenetic Analysis

The location of *SLC12A1*, the gene encoding NKCC2 in humans is within chromosome 15,[107] in rat within chromosome 3,[121] and in mouse within chromosome 2.[122] *SLC12A1* is composed of more than 80 kb and 26 exons have been clearly described to encode for the full length 1095 amino acid residue protein.[104] Mouse is the only species from which the *SLC12A1* promoter region has been cloned.[108] The NKCC2 transcript starts with the first exon of 34 bp that is non-coding, followed by a first intron of 1101 bp and a second exon containing the translation start codon. The promoter is composed of 2255 bp. There is a TATA box located at position -29 and consensus recognition sites for several transcription factors, of which the most interesting could be a binding site for HNF-1 at -211 bp. In developing mouse

kidney, the expression of HNF-1 precedes the expression of NKCC2.[123] HNF-1 has been implicated in the regulation of tissue-specific expression of genes in liver, pancreas, kidney, and intestine. Deletion of −2255 to −1529 bp of the promoter resulted in a ~three-fold increase in gene transcription rate, suggesting the presence of negative regulatory elements in this segment. No further effect was observed by deleting −1529 to −469 bp, but a significant reduction in gene expression was obtained by elimination from −469 to −190, suggesting that this region contains positive regulatory elements. An HFN-1-binding site is located in this region. A cAMP response element-binding protein is located at nucleotide −1111, and this could be of major importance because it is known that NKCC2 expression is stimulated by vasopressin.[75,82,124]

The gene *SLC12A2* encodes NKCC1 and is located to chromosome 5q23 in humans,[113] and to chromosome 18 in mouse.[6] The complete gene encompasses a region of 75 kb[118] and is made up of 28 exons. Significant luciferase activity was produced by transfection of mouse IMDC3 cells with a 2063 bp promoter region, together with a luciferase reporter gene. Deletions of >1 kb that reduced the promoter region to 702 or 516 bp resulted in a significant increase in luciferase activity, suggesting the existence of silencer sequences in the deleted bases. Additional deletions resulted in progressive reduction of luciferase activity, suggesting the presence of enhancer elements. Expression of NKCC1 in vascular smooth muscle cells has been suggested to be associated with the development of hypertension in rat models of hypertension. In this regard, a recent report showed that SLC2A2 gene promoter hypomethylation upregulates NKCC1 expression in aorta and heart of spontaneously hypertensive rats.[125,126]

SLC12A3, the gene encoding the thiazide sensitive Na^+-Cl^- co-transporter, is located in humans to chromosome 16q13,[102,103] in rat to chromosome 19p12-14,[127] and in mouse to chromosome 8.[128] Human *SLC12A3* is 55 kb long and contains 26 exons.[102] Transcription initiation is confined to an area from -18 to -6 bp upstream of the translation start codon. The promoter activity observed in the mouse distal convoluted cell line (MDCT),[129] with a construct containing 1019 bp of the 5′ flanking region was reduced only 25% by eliminating the first 885 bp. Sequence analysis of the promoter revealed the presence of a TATA element, two Sp-binding sites, and potential binding sites for NF-1/CTF or NY-I/CP-I. Interestingly, the promoter activity of the rat NCC gene is inhibited by acidosis. This is consistent with a marked fall in renal cortical abundance of NCC protein assessed by Western blot,[130] and by [^{3}H] Metolazone-binding to plasma membranes from the renal cortex[131] of rats exposed to chronic NH_4Cl-loading.

FUNCTIONAL PROPERTIES

The member of the family that has been more extensively characterized is NKCC1. This is because it is expressed in many different cell types that, on one hand, made it accessible for functional characterization, even before the cDNA was identified, and on the other hand, it attracted the interest of many groups of researchers in a variety of fields such as neuroscience, cell volume regulation, red blood cell, and epithelial transport mechanism (for an in-depth review see [15]). In contrast, before identification of the corresponding genes, functional characterization of NKCC2 and NCC was relatively scarce,[57,132,133] and most of the knowledge came from analysis of renal outer medulla or cortical plasma membrane-binding of tracer [^{3}H] Bumetanide or [^{3}H]Metolazone, respectively.[134–136] With the cloning of cDNAs encoding the SLC12A co-transporter proteins and several variants, in-depth characterization of their major functional, pharmacologic, and some regulatory properties has been made possible.

The Thiazide-Sensitive-Na^+-Cl^- Co-Transporter

Heterologous expression of teleost, rat, mouse, and human NCC has been achieved in *Xenopus laevis* oocytes.[2,3,137–140] Oocytes are not epithelial cells; however, this expression system is a useful tool for robust and reproducible NCC expression. Unfortunately, expression of NCC in mammalian cells transfected with NCC cDNAs has been almost impossible to achieve, and so far has been reported only by two independent groups in MDCK[141] and HEK-293.[142] However, in both cases, the level of NCC expression was low, and not sufficient for that required to define the functional properties of the co-transporter. Thus, *Xenopus laevis* continued to be the best cells to assess NCC activity, and basically all of what is known today regarding the functional properties and regulation of NCC activity comes from studies performed in oocytes. Recent reports from Hoover and co-workers[143,144] showed that a subcloned version of the immortal mouse DCT cell line originally produced by Gesek, Friedman and co-workers[145] exhibit what appears to be a robust expression of endogenous NCC, promising an excellent tool for NCC functional analysis in a mammalian cell system.

As shown in Table 32.1, a number of interesting differences have been observed between fish (flounder) and mammalian (rat and mouse) NCC. The affinity for Na^+ and Cl^- in rat[137] or mouse NCC proteins[139] is significantly higher than the affinity observed in the

flounder NCC.[146] In addition, the Km values for Na^+ and Cl^- in mammalian NCCs are similar, whereas in flounder the Km value for extracellular Cl^- is lower than the value for Na^+. NCC activity is inhibited by thiazide-type diuretics with the following profile: polythiazide > metolazone > bendroflumethiazide > trichloromethiazide > chlorthalidone. However, for all thiazides, flounder's NCC exhibited lower affinity. At a concentration of 100 μM, the thiazides with lower potency, trichloromethiazide and chlorthalidone, reduced flounder NCC activity by only 68 and 46%, respectively,[146] whereas the same concentration of all thiazides inhibited rat NCC by >95% .[137]

Two proposals for the order of ion-binding to NCC have been suggested. By assessing the [^{3}H]metolazone-binding to membranes extracted from rat renal cortex, Tran and collaborators[147] observed that Na^+ increased tracer-binding to the putative thiazide-sensitive transport protein. In contrast, Cl^- decreased the affinity for metolazone. Thus, the model that was proposed included two binding sites within the thiazide receptor: one selective for Na^+; and the other that recognizes either Cl^- or metolazone in a competitive fashion. In this model, occupation of the Na^+ site increases the affinity of the second site for either Cl^- and/or metolazone.[148]

The second model was based on observations of functional properties of NCC as expressed in *Xenopus laevis* oocytes. Monroy et al.[137] observed that affinity for Na^+ or Cl^- changed as a function of counterion concentration. The lower the extracellular Na^+ concentration, the lower the Cl^- affinity, a relationship that supports the initial conclusions of Tran et al.[147] However, it was also observed that lower extracellular Cl^- concentrations coincided with lower Na^+ affinity. In addition, it was observed that the IC_{50} for metolazone inhibition increased when the thiazide dose–response curves were measured in lower Na^+ or Cl^- conditions, suggesting that both ions compete with metolazone for binding to the co-transporter. Thus, the proposed model included a random order of binding, with both ions affecting affinity for the counterion and competing with thiazide diuretics.[137] Supporting this model, data produced later that is discussed below suggest that affinity-defining domains or residues for Cl^-- and thiazide-binding are located in different parts of the protein.[98]

TABLE 32.1 Ion Transport and Thiazide-Sensitive Kinetics of Mammalian and Flounder NCC Expressed in *Xenopus laevis* Oocytes

	Rat NCC[98,137]	Mouse NCC[139]	Flounder NCC[98,137]
Na^+ Km (mM)	5.5 ± 1.0	7.2 ± 0.4	30.0 ± 6.0
Cl^- Km (mM)	2.6 ± 0.6	5.6 ± 0.6	15.2 ± 2.0
Metolazone IC_{50} μM	0.3 ± 0.001	0.4 ± 0.001	4.0 ± 0.08

The Loop-Diuretic-Sensitive Na^+-K^+-2Cl^- Co-Transporter 2 (NKCC2)

Several NKCC2 splice variants in different species have been analyzed at tissue-specific expression and functional level, including shark,[72] rat,[3] mouse,[78] rabbit,[5] and human.[149] As previously discussed, there are three variants of NKCC2 named A, B, and F (Figure 32.3c). The three variants from mouse perform as Na^+-K^+-2Cl^-, suggesting that the difference between variants could be in the kinetic properties for ion transport and/or bumetanide affinity.[78] This hypothesis was supported by intrarenal localization studies that demonstrated axial distribution of these variants along TAL.[5,14,110] As shown in Figure 32.3d, the A isoform is present in both cortical and medullary TAL. In contrast, the B isoform is present only in cortical TAL, and the F variant is expressed only in the inner stripe of the outer medulla. Early studies[150–152] demonstrated that the NaCl transport rate in mTAL is significantly more rapid than in the cTAL, but with greater diluting power in the later segment. Thus, the possibility for heterogeneity of the transport process was suggested. Evidence supporting this hypothesis was obtained simultaneously by Plata et al. [153] and Gimenez et al.[71] using mouse and rabbit NKCC2 variants, respectively (Figure 32.3e). NKCC2F exhibits the lowest affinity for co-transported ions, and is more sensitive to changes in extracellular osmolarity. As shown in Figure 32.3d, NKCC2F is predominantly expressed in the inner stripe of the outer medulla, where the salt concentration is very high, and where greater changes in extracellular osmolarity occur. NKCC2A exhibits the highest transport capacity and is expressed along all TAL. Finally, NKCC2B, the variant that is expressed only the cTAL where ion concentration of the tubular fluid has decreased to values even below those in plasma, is the variant with the highest affinity for the co-transported ions. Thus, the dilution power along TAL is explained by the presence of three alternatively-spliced variants of NKCC2 with distinct functional characteristics. The NKCC2 influx data from Plata et al.[153] were later used to construct a mathematical model for the NKCC2 co-transporter isoforms.[154]

As discussed above, a shorter variant containing 55 amino acid residues at the end that are not present in the longer NKCC2 isoform has been described

(Figure 32.3b,c). This variant is only present in mTAL, not in cTAL[13] and performs as a K^+-independent, but nevertheless, loop diuretic-sensitive Na^+-Cl^- co-transporter that is activated by hypotonicity and inhibited by cAMP.[155] Therefore, the shorter NKCC2 variant may provide a molecular explanation for previous physiological studies that suggested a switch from Na^+-Cl^- to Na^+-K^+-Cl^- co-transporter mode in TAL by extracellular osmolarity or by the presence of vasopressin. Eveloff and co-workers[156,157] observed, in rabbit TAL cells, the existence of a K^+-independent, furosemide-sensitive Na^+-Cl^- co-transporter in hypotonic conditions that became K^+-dependent, constituting the Na^+-K^+-$2Cl^-$ co-transporter, when cells were changed to isotonic medium. In addition, Sun et al.[158] found that in mouse TAL cells, vasopressin (i.e., cAMP) shifts the mode of apical co-transport from Na^+-Cl^- (in its absence) to Na^+-K^+-$2Cl^-$ (in its presence). Consistent with these studies, the large NKCC2 is a Na^+-K^+-$2Cl^-$ co-transporter that is activated by increased tonicity or the presence of vasopressin, while the shorter NKCC2 is a Na^+-Cl^- co-transporter that is activated in hypotonicity or by inhibition of protein kinase A activity.

The shorter variant also exerts a dominant-negative effect upon the activity of the longer NKCC2 that can be abrogated by cAMP.[78] Using confocal microcopy, in oocytes injected with both the long (NKCC2F) and the short variant of mouse NKCC2, Meade et al.[79] observed that the short NKCC2 reduced the activity and surface expression of the long NKCC2. This effect could be prevented by cAMP, and correlated with the observation that the short NKCC2 variant prevented co-transporter trafficking and surface membrane expression of the long NKCC2. These studies thus suggested that in mouse medullary TAL, activation of Na^+-K^+-$2Cl^-$ co-transporter by hormones that increase intracellular cAMP (e.g., vasopressin, PTH) requires the presence of the short NKCC2 protein. The absence of cAMP allows the short form of NKCC2 to reduce co-transporter activity, whereas in the presence of cAMP, the negative effect of the short isoform on NKCC2 is inhibited. In this regard, Mount and collaborators[13] observed that expression of the short NKCC2 is axially distributed along TAL, as cortical TAL appears to lack this isoform. This heterogeneity may explain the observation that in mouse the vasopressin effect is present only in the medullary TAL.[63] Interestingly, the short isoform is also expressed in the thin ascending limb (Figure 32.3d), but its significance in this region is not known.

STRUCTURE–FUNCTION RELATIONSHIPS

The proposed topology for the Na-coupled chloride co-transporters NKCC1, NKCC2, and NCC is shown in Figure 32.3. There is only one study that has addressed the topology at the biochemical level. Gerelsaikhan and Turner[159] used an *in vitro* translation experiment with a variety of human NKCC1 constructs with the carboxyl-terminal reporter sequence containing multiple N-linked glycosylation sites located after each of the putative transmembrane domain. The authors concluded that the amino- and carboxyl-terminal domains are located intracellulary and flank the central hydrophobic domain in which the first eight TM segments are easily identifiable, exhibiting the classical ~20 residue α-helices. It was impossible to differentiate between TMs 9 and 10, and between TMs 11 and 12, and thus it was proposed that probably there are only two large TMs of ~36 residues in length that form tight hairpin-like structures in the membrane or take up either a non-helical or a partial-helical structure.

Ion or Diuretic Affinity Modifier Domains or Residues

Several attempts to begin to understand structure–function relationship issues in the Na^+-coupled Cl^--co-transporters have been made on NKCC1 (for review see [160]), NKCC2,[71,153,161–163] and NCC.[98] In most cases, functional differences in NKCC1 or NCC between fish and mammalian orthologs have been exploited to design chimeric proteins to begin to define domains, regions or individual residues that are defining the ion transport or diuretic-binding affinities and/or specificity. In the case of NKCC2, most of the structure–function information available comes from the functional analysis of alternatively spliced variants.

The identity degree between shark and human NKCC1 is 74%, and interesting functional differences occurs between these orthologs (Table 32.2). Several chimeric constructs were studied by interchanging fragments of NKCC1 between human and shark cDNAs. First, the amino- and carboxyl-terminal domains between both species were swapped, providing evidence that residues located within the central hydrophobic core define ion affinity.[164] Then, a variety of chimeras were constructed and analyzed by in-depth kinetic analysis.[164–166] The chimeric design took into account the transmembrane segments that are identical in NKCC1 of both species. According to the results,[160] the three TM segments playing an important

TABLE 32.2 Ion Transport Kinetics and Bumetanide Affinity of the Na^+-K^+-$2Cl^-$ Co-Transporter NKCC1 from Human and Shark

role in ion transport kinetics in NKCC1 are TM2, TM4, and TM7. TM2 is involved in Na^+ and Rb^+ kinetics, TM 4 in Rb^+ and Cl^- kinetics, and TM7 in Na^+, Rb^+, and Cl^- kinetics. Interestingly, the behavior of several chimeric proteins with respect to bumetanide inhibition was completely different from that observed in ion transport kinetics. In the case of bumetanide, data suggested that TM segments 2–6 and 10–12 play a role in defining affinity for loop diuretics. Thus, results from studies using shark and human NKCC1 chimeric co-transporters argued against a previous hypothesis that loop diuretics and Cl^- compete for the same binding site.[167]

Analysis of the spliced variants A, B, and F of NKCC2 revealed a clear role of the segments encoded by these exons (TM2) in transport kinetics properties, not only for Na^+ and Rb^+, but also for Cl^- and bumetanide[71,153] (Figure 32.3). Further studies[72] showed that NKCC2 variants A and F, but not B, are present in the shark kidney, and that also in shark, the affinity for transported ions of the NKCC2A variant is higher than the NKCC2F variant. Additional chimeric proteins were constructed: chimera A/F contained the TM2 sequence of variant A followed by an interconnecting sequence of variant F, and *vice versa*.[168] The results suggested that Cl^- transport affinity-defining domains between isoforms A and F were located within the predicted interconnecting segment between TM2 and TM3, rather than within the TM2 segment. The chimeras' behavior with respect to bumetanide affinity was opposite to that of Cl^- affinity, suggesting that residues located within TM2, and not within the TM2–TM3 interconnecting segment, play a role in defining bumetanide affinity. The most recent study regarding structure–function relationship on the NKCC2 variants included a series of single or multiple point mutations of rabbit NKCC2 variants B and F or A and B, in order to switch one or few residues between variants.[162] The results demonstrated that replacement of six residues in NKCC2B resulted in a variant with Na^+ and Cl^- affinities identical to those of NKCC2F. Interestingly, three of these residues are located within the TM2 segment (ATG in B isoform were switched to TAY), and the other three within the interconnecting segment between TM2 and TM3 (SVT in B isoform were changed to MCV). The six mutations (ATG-TAY/SVT-MCV) turned NKCC2B into the F variant (Figure 32.3c), suggesting that the interconnecting loop between TM2 and TM3 might actually be part of a membrane-embedded domain.

The domains or residues defining the affinity for co-transporter ions or inhibitors may not be the same as the residues critical for the specificity for certain ions or inhibitors. All studies discussed above were performed in native, chimeric, and/or mutant NKCC1 or NKCC2 that were expected to behave as Na^+-K^+-$2Cl^-$ co-transporters. Thus, no information was obtained concerning structural requirements to define specificity for ions or diuretics. In this regard, the short isoform of NKCC2 in mouse perform as a K^+-independent, but loop diuretic-sensitive, Na^+-Cl^- co-transporter,[155] suggesting that sequences within the carboxyl-terminal domain could be critical to endow NKCC2 with K^+ transport ability. However, a study in which chimeras were constructed by swapping the amino- and carboxyl-terminal domains between NCC and NKCC2F[161] showed that chimera with the central hydrophobic domain of NKCC2, flanked by amino- and carboxyl-terminal domains of rat NCC, exhibit NKCC2 behavior. That is, as a bumetanide-sensitive Na^+-K^+-$2Cl^-$ co-transporter, indicating that the residues that endow rat NKCC2F with its functional properties should be located within the central hydrophobic domain. Thus, the explanation on how the short NKCC2 variant performs as a bumetanide-sensitive Na^+-Cl^- co-transporter remains elusive. The unique 55 amino acid segment at the end of this isoform contains several negatively-charged residues, suggesting that this fragment could interact with the co-transporter core to prevent K^+ translocation, like the ball and chain mechanism proposed for some membrane channels.[169]

Similar chimera construction and directed point mutation approaches have been used to gain insight into the structure–function relationships of NCC. It was first observed that rat[137] and mouse[139] NCCs exhibit similar functional properties that are, however, significantly different from those shown for flounder NCC.[146] Differences in functional properties and primary sequences between rat and flounder NCCs were

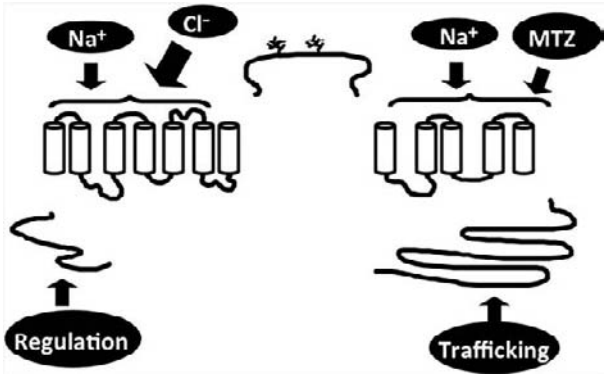

FIGURE 32.4 **Affinity modifying domains in the thiazide-sensitive Na^+-Cl^- co-transporter, NCC.** *(Modified from ref. [98].)*

exploited to define affinity-modifying domains and residues.[98,170] Figure 32.4 depicts what is known regarding the structure–function relationship of NCC. By means of silent restriction sites, NCC cDNAs from rat and flounder were divided into five fragments: amino terminal domain; TM segments 1–7; extracellular glycosylated loop; TM segments 8–12; and the entire carboxyl-terminal domain, and then fragments were swapped between them to obtain a variety of combinations. The results first indicated that the central hydrophobic domains define functional characteristics of NCC. Chimeras in which the TM segments 1–7 were interchanged between flounder and rat NCCs demonstrated that affinity-defining residues for Cl^- are located within these segments. Similarly, affinity-defining residues for thiazide inhibition are located within TM segments 8–12. The observation that Cl^- affinity is defined by residues located within TM segments 1–7 is supported by another study, in which functional consequences of single nucleotide polymorphisms (SNP) located within the exons of the human *SLC12A3* gene changed the primary structure of NCC.[171] The results revealed that a highly-conserved glycine within the fourth transmembrane domain plays a critical role in defining the level of co-transporter activity and the affinity for Cl^-. Accordingly, it was observed that a glycine-to-alanine SNP at position 264 resulted in decreased activity of the co-transporter by 50%, with increased affinity for Cl^- by one order of magnitude. Based on these observations, it was later observed that this SNP on NCC increases the response of humans to loop diuretics, probably because of the reduced capacity of DCT to compensate for the effect of inhibiting salt reabsorption in TAL.[172] The information that thiazide affinity-defining residues were located within TM8 to TM12 was further explored by site directed mutagenesis, revealing that a single residue in rNCC and flNCC is responsible for the differences in affinity for thiazides between mammalian and fish co-transporters. The serine 575 in rat NCC corresponds to the cysteine 576 in flounder NCC. By changing this residue, the affinity for thiazides can be transformed from mammalian to fish affinity, and *vice versa*.[170] It is worth noticing that the NCC mutants that changed the affinity for thiazides had no effect upon the co-transporter affinity for Cl^-, arguing against the proposal that thiazide diuretics and Cl^- compete for the same binding site.[147]

Analysis of the putative glycosylation sites in rat NCC by means of mutagenesis revealed that glycosylation itself is another component of the co-transporter that affects thiazide affinity. In one study, eliminating the glycosylation sites located within the extracellular loop between TM segments 7 and 8 has remarkable consequences in NCC transport activity and properties.[97] Elimination of one site (either N204 or N242) resulted in a 50% reduction of NCC activity, and elimination of both sites was associated with a 95% reduction. Interestingly, prevention of glycosylation was associated with increased affinity for extracellular Cl^- and metolazone. This effect of glycosylation on thiazide affinity seems to be unique to rat NCC, since it was not observed after preventing glycosylation of flounder NCC[98] or rat NKCC2F.[99] In this last co-transporter, elimination of glycosylation by means of site directed mutagenesis was associated with increased affinity for extracellular chloride, but no effect was observed on the affinity for the loop diuretic bumetanide.

The carboxyl terminal domain appears to have an important role in maturation and trafficking of the co-transporters. A region of 77 amino acid residues of NKCC2 (amino acid 708–884), that is not present in NKCC1, seems to be required for driving NKCC2 to the apical membrane in polarized cells,[120] while there is a dileucine motif NKCC1, not present in NKCC2, that directs this co-transporter to the basolateral membrane.[173] A LLV motif in NKCC2 was identified as an ER retaining signal.[174] A protein known as SCMP2 influences NKCC2 expression through recycling endosomes and interfering with its exocytotic trafficking.[175]

The Na-Coupled Chloride Co-Transporters Form Homodimers

Moore-Hoon and Turner[176] used rat parotid plasma membrane to analyze NKCC1 using the reversible chemical cross-linker DTSSP (3,3′-dithiobis-[sulfosuccinimidyl propionate]). They observed that NKCC1 migrates at ~335 kDa. After protein denaturation, single monomers of approximately ~170 kDa were obtained, in which the investigators were unable to detect the presence of any additional protein. Similar

results were later observed on human NKCC2 by Starremans et al.,[177] and on NCC by De Jong et al.[178] These studies were performed in *Xenopus laevis* oocytes injected with *in vitro*-transcribed cRNA from FLAG- and/or HA-tagged wild-type co-transporters and concatamer constructions. These experiments revealed that FLAG-NKCC2 and HA-NKCC2 are physically linked.[177] Similar observations were obtained for FLAG-NCC and HA-NCC constructs.[178] Thus, NKCC1, NKCC2, and NCC are able to form homodimers, and might be functional in this conformation. Because dimers are sensitive to reducing agents such as β-mercaptoethanol, it is likely that disulfide bonds between cysteines are involved.[170] Additionally, some data suggest that members of the *SLC12A* family can build heterocomplexes comprised of different members of the family. For example, an orphan gene of the family known as CIP appears to inhibit transport activity of NKCC1[36] or activate KCC2.[179] However, it does not affect the activity of other family members, raising the possibility that CIP may form an activating heterocomplex specifically with NKCC1.[36] A recent study has shown, by means of yeast two-hybrid and pull down assays, that K^+-Cl^- co-transporter isoforms can interact among themselves, and even with NKCC1.[180]

REGULATION OF SODIUM CATION-COUPLED CO-TRANSPORTERS

The activity of the sodium−cation coupled chloride co-transporters, as occurs with many other ion transport proteins, can be modulated at multiple levels. One is the level of expression of the protein, which in turn can be due to increase in the rate of gene transcription, in the stability of the messenger RNA or post-translationally by affecting the turnover rate of the protein. This level of regulation requires activation/deactivation of synthesis/degradation mechanisms that usually take time to install, and thus are preferred with increased or decreased activity of the co-transporters required for longer periods of time. Another level of regulation is the balance between endocytosis and exocytosis of the co-transporter containing vesicles into the plasma membrane, as only the fraction of co-transporters inserted in the membrane are able to translocate ions. Finally, a co-transporter that is already in the membrane can be regulated to increase or decrease its turnover rate due to conformational changes that affect their activity. The presence of a co-transporter in the cell surface and its intrinsic level of activity are often modulated by phosphorylation/dephosphorylation processes and thus, are subjected to a rapid regulation through cascades of second messengers induced by a variety of hormonal signals.

With the availability of cDNA probes, primers, and high-quality polyclonal antibodies against NCC or NKCC2, several strategies have been implemented to study patterns of these co-transporters abundance, and changes under several physiological and pathophysiological circumstances.[7,181] Discussion of each model is beyond the scope of this chapter, but Tables 32.3 and 32.4 summarize the several experimental, physiological or pathophysiological conditions in which the level of NCC or NKCC2 protein and/or mRNA expression has been analyzed. In general, increased expression of either NCC or NKCC2 is observed in models in which salt retention is induced, while decreased expression is observed by salt-wasting stimuli.

The knowledge of the cation-coupled chloride co-transporters regulation by phosphorylation/dephosphorylation processes has expanded enormously in the last few years, thanks to the discovery of a kinase network that works in conjunction to modulate the ion transport mechanisms. It is well-known that activity of NKCC1/2 and NCC is tightly regulated by means of phosphorylation/dephosphorylation processes, and several lines of evidence suggest that intracellular chloride concentration $[Cl^-]_i$ is a common pathway of NKCCs regulation. When $[Cl^-]_i$ falls, the co-transporters become phosphorylated and activated, whereas when $[Cl^-]_i$ rises, the co-transporters are dephosphorylated and inhibited.[182,183] These effects of $[Cl^-]_i$ on co-transporter activity have been demonstrated for NKCC1,[182,184,185] NKCC2,[186] and NCC.[142,187] In all cases, it was observed that activation of the co-transporter by intracellular Cl^- depletion is associated with increased phosphorylation of the co-transporter in several conserved threonine residues located within the amino-terminal domain.

A great tool to advance in our understanding of NKCC1, NKCC2, and NCC regulation came from the discovery that certain threonine/serine residues in the amino-terminal domain become phosphorylated in association with activation of the co-transporters. The first evidence was obtained for activation of the NKCC1 with phosphorylation of a threonine residue by Lytle and Forbush,[188] in suspensions of shark rectal gland tubules. The peptide FGHNTIDAVP, which became phosphorylated, was isolated and corresponds to amino acid residues 184−194, which are located within the amino-terminal domain of NKCC1.[4] It was later demonstrated by mass spectrophotometry that in phospho-acceptor amino acid sites within the co-transporter amino-terminal domain threonines located at positions 184, 189, and 202 of NKCC1 become phosphorylated in associated with the co-transporter's activation.[184] Of these, threonine 189 is absolutely required for NKCC1 to be functional. Then, analysis *in vivo* was performed using a specific antiphospho-NKCC1

antibody named R5, which was raised against a synthetic peptide of the amino-terminal domain containing threonines 212 and 217 of human NKCC1 (corresponding to threonines 184 and 189 of shark NKCC1).[185,189] The results demonstrated that activation of NKCC1 by intracellular Cl^- depletion is associated with phosphorylation of these threonines.

The same R5 phospho-antibody was used to demonstrate that activation of NKCC2 or NCC by cell volume changes or intracellular Cl^- depletion is associated with phosphorylation of the conserved threonines 96–101 in rat NKCC2 and 53–58 in rat NCC.[186,187,190] Later, specific phospho-antibodies for these and other threonine/serines in the amino-terminal domain were raised against each rat or human co-transporter, confirming the role of the residues detected by R5 antibody and suggesting other sites within the amino-terminal domain as potential residues to be involved.[142,191] Similar to NKCC1, threonine 60 of human NCC (corresponding to 189 from shark NKCC1) is required for NCC to be functional,[187] and when activated by phosphorylation it appears that T60 is the first to be phosphorylated; this opens the possibility to phosphorylate nearby threonine/serine residues.[191] None of these phospho-acceptor sites are individually required for NKCC2 to be functional, because elimination of each one at a time reduces, but does not prevent, the activity of the co-transporter.[186]

Figure 32.5 shows an alignment analysis of a region of the amino-terminal domain of NCC, NKCC2, and NKCC1 highlighting the conserved threonine/serine phosphorylation sites among species that have been implicated in activation of the co-transporters in different studies. Tables 32.5 and 32.6 contain detailed information on all the works in which phosphorylation of specific site or sites on NCC or NKCC2 have been studied. Several works *in vitro* and *in vivo* have shown that some of the amino-terminal domain phosphorylation

residues are involved in activation of NCC by intracellular chloride depletion,[142,187] low-salt diet,[192,193] vasopressin,[194,195] angiotensin II[196,197] or aldosterone[193,198]; and NKCC2 by hypertonicity,[199] intracellular chloride depletion,[186,200] vasopressin,[77] and growth hormone.[201] Thus, NKCC1, NKCC2 or NCC are activated by phosphorylation of particular amino-terminal domain threonine/serine residues by different stimuli and intracellular cascades such as Gαs receptor-cAMP-PKA (vasopressin), Gαq receptor-IP3-PKC (angiotensin II), tyrosine kinase-associated receptor (growth hormone) or activation of an intracellular soluble kinase by $[Cl^-]_i$ or changes in cell volume (see below). These data suggest that different cascades probably combine in activation of a particular kinase pathway that is responsible for the phosphorylation of these particular sites.

The kinase cascade that has been shown to be involved in the phosphorylation of the amino terminal threonine or serine residues of NKCC1, NKCC2 or NCC is the WNK-SPAK pathway. The WNK family of serine/threonine kinases is closely related to MAP kinases. Members of this family lack the conserved catalytic lysine (K) present in subdomain II of all the other serine/threonine kinases, hence the name WNK for "with no lysine (K)".[202] The crystal structure of the WNK1 catalytic domain later revealed that the catalytic lysine is present in subdomain I.[203] The family is

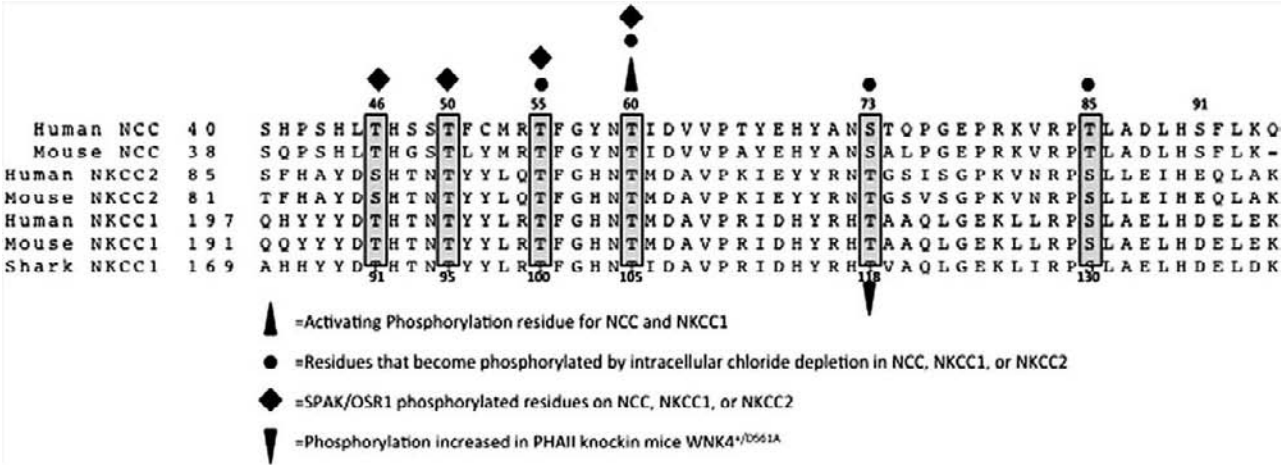

FIGURE 32.5 **Sequence alignment of a region of the amino-terminal domain containing the conserved residues (highlighted in gray) that have been associated with phosphorylation/activation of the co-transporters.** Numbering above alignment indicates residues in NCC. Numbering below alignment indicates numbering in NKCC2.

composed of four members, known as WNK1 to WNK4,[204] each containing a serine/threonine kinase domain of 294 residues flanked by a short amino-terminal domain (146 to 220 amino acid residues) and a long carboxyl terminal domain (796 to 1888 residues) exhibiting two coiled-coil domains for protein interaction, and a conserved auto-inhibitory motif shown to inhibit autophosphorylation in WNK1.[202,205] The degree of conservation among the four isoforms is high within the kinase domain ($>80\%$), but low within the amino- or carboxyl-terminal domains ($<15\%$).

The importance of WNKs to renal physiology and pathophysiology was highlighted by the demonstration that intronic deletions of WNK1 or missense mutations in an acidic conserved region of WNK4 are the cause of a human form of an inherited syndrome featuring arterial hypertension, hyperkalemia, and metabolic acidosis known as pseudohypoaldosteronism type II (PHAII), Familiar Hyperkalemic Hypertension (FHH) or Gordon's disease.[206–208] Because PHAII is a mirror image of Gitelman's disease and it is treatable with low doses of thiazides (see below), it was suspected that activity of NCC was implicated in the pathophysiology of the disease. This was first demonstrated using the heterologous expression system of *Xenopus laevis* oocytes.[209,210] WNK4 inhibits the activity of NCC, and this effect is prevented by either eliminating the catalytic activity of WNK4[209,211–213] or by the introduction of one of the PHAII-type mutations in WNK4,[209,213] thus suggesting that the activity of NCC in PHAII patients is increased due to elimination of the WNK4-induced inhibition of NCC. The activation/phosphorylation of NCC as the major mechanism for hypertension and hyperkalemia was confirmed in two animal models of PHAII[214,215] (Table 32.5). The mechanism for PHAII in families with intronic deletion of WNK1 is less-understood. WNK1 does not seem to have a direct effect upon NCC. Instead, it has been observed that WNK1 prevents the WNK4-induced inhibition of NCC.[210] Thus, if WNK1 expression is increased, as is suggested to occur as a consequence of WNK1 intronic 1 deletion,[206] the WNK4 inhibitory effect upon NCC will be prevented and thus, NCC activity will increase. Interestingly, there is a shorter variant of WNK1, lacking the entire amino and kinase domain that is exclusively expressed in the kidney, specifically in DCT.[216–218] The short WNK1 prevents the WNK1 effect on WNK4.[219] Thus, it is postulated that under physiological conditions the expression of the short WNK1 in DCT modulates the interaction between WNK1 and WNK4, regulating NCC activity. In PHAII, however, increased expression of the long WNK1 surpasses the regulatory capacity of short-WNK1, thus inhibiting WNK4 with the consequent activation of NCC. This model, however, awaits definitive confirmation by *in vivo* models.[220–222]

Two kinases related to the yeast Ste-20p family known as SPAK (Ste20p-related proline-alanine rich kinase) and OSR1 (oxidative stress response 1) have been shown to be located downstream of WNKs, at least for their effects on the cation-coupled chloride co-transporters.[223,224] The first evidence of the WNK-SPAK/OSR1 interaction was obtained in a study in which the K-Cl co-transporter, KCC3, was shown to interact with SPAK/OSR1 in a two-hybrid yeast system. The co-transporter interacting with SPAK/OSR1 using a specific binding domain was determined to be RFx(V/I).[225] One such binding site is located in the amino-terminal domain of NCC and NKCC2, two are present in NKCC1, and two or three sites in each

WNKs support the interaction between WNKs and co-transporters with SPAK.[142,225,226] In fact, among all proteins in the human proteome, WNK1 and NKCC1 are the ones with higher numbers of SPAK-binding domains.[227] Functional and biochemical studies using NKCC1 demonstrated that both WNK1 or WNK4, as well as SPAK or OSR1, must be present to induce amino-terminal domain phosphorylation and activation of the co-transporter.[190,223,228] It was shown that WNKs lie upstream of SPAK/OSR1, and that WNK phosphorylates SPAK/OSR1 on two specific threonine and serine residues (T243 and S383 in SPAK), inducing activation of the kinase.[192,223] Thus, it is believed that SPAK/OSR1 are the kinases that actually phosphorylate the amino-terminal threonine residues of NKCC1, NKCC2 or NCC, and that WNKs modulate this effect by activating SPAK/OSR1.[191,229–232]

The interaction between SPAK and NCC has been confirmed, and also the requirement for the amino-terminal domain SPAK-binding site of NCC.[142,191,226] To find out the importance of the interaction and phosphorylation between SPAK and NCC *in vivo*, Rafiqui et al.[192] generated a mice knockin model by eliminating the threonine residue of the T-loop in SPAK (T243A) or OSR1 (T185A) that is phosphorylated by WNK1 or WNK4. The $OSR1^{185A/185A}$ mice died on embryonic

day 17.5, while the $SPAK^{234A/234A}$ mice were viable, grew normally and thus were further analyzed. Along the nephron, SPAK is specifically expressed in TAL and DCT. The blood pressure of $SPAK^{234A/234A}$ mice is reduced and consistent with reduction in salt reabsorption as the mechanism of hypotension; blood pressure was normalized after feeding the $SPAK^{234A/234A}$ mice with a high-salt diet for several days. In fact, $SPAK^{234A/234A}$ mice developed a Gitelman-like syndrome, with hypomagnesemia and hypocalciuria. Hypokalemia was not observed in a normal-sodium diet, but became apparent with a low-sodium diet. Using specific phosphoantibodies for NCC amino-terminal threonine residues, it was shown that in $SPAK^{234A/234A}$ mice expression of NCC in the kidney was reduced by 30% and phosphorylation at residues T53, T58, and S89 were reduced by about 80% (Tables 32.3 and 32.5). Similar observations were obtained using specific antibodies against NKCC2 (Tables 32.4 and 32.6). All these observations together indicate that absence of SPAK activity resulted in decreased activity of NKCC2 and/or NCC. Because the phenotype resembles Gitelman's rather than Bartter's disease, it was suggested that the effect of SPAK inactivation upon NCC was stronger. Crossing the PHAII knockin mice generated by Yang et al.[215] with the $SPAK^{234A/234A}$ mice[192] demonstrated that hypertension and the whole PHAII syndrome were prevented, indicating the major role of SPAK-induced regulation of NCC in this syndrome.[233] Thus, the SPAK knockin mice model provided compelling evidence of the key role of SPAK in modulation of NKCC2 and NCC activity.

Interestingly, the complete elimination of SPAK in a SPAK knockout model also resulted in decreased expression and phosphorylation of NCC, but in contrast to the $SPAK^{234A/234A}$ mice, resulted in increased phosphorylation of NKCC2[234] (Tables 32.4 and 32.6). In contrast, a recent study in which a kidney tissue-specific elimination of OSR1 was achieved (KS-$OSR1^{-/-}$ mice) resulted in an incomplete form of Bartter's syndrome, with decreased expression and phosphorylation of NKCC2, together with increased expression of SPAK and NCC phosphorylation[235] (Tables 32.4 and 32.6). Thus, it is possible that NKCC2 is preferentially under the control of OSR1, while NCC is under the control of SPAK. Several SPAK splicing isoforms are expressed in the kidney that could serve to explain the different regulation of NKCC2 and NCC under different circumstances.[236]

WNK2 and WNK3 also exert effects on the cation-coupled chloride co-transporters that are of interest. WNK3 is expressed along the entire nephron, as well as in several epithelial and non-epithelial cells outside the kidney,[232,237] and strongly activates NKCC1, NKCC2, and NCC, while it inhibits all four KCCs.[238–240] Thus, WNK3 activates chloride influx pathways and inactivates chloride efflux pathways. Activation of NKCC1, NKCC2, and NCC by WNK3 is associated with phosphorylation of the same amino-terminal domain threonines in the several models discussed above[226,238,239] (Tables 32.5 and 32.6). WNK3 activation of NCC is associated with increased expression of NCC on the cell surface, suggesting that it promotes the trafficking of NCC vesicles into the plasma membrane.[239] One study suggests that the effect of WNK3 and WNK4 on NCC can be achieved by the carboxyl-terminal domain of the kinase alone, that is, in the complete absence of the kinase domain.[241] Other studies, however, have shown that the effect of WNK3 and WNK4 on NCC are kinase-dependent,[209,212,213,239,241] and unlike what occurs with WNK1 variants[216,217] there is no evidence that such truncated variants of WNK3 or WNK4 are expressed in the DCT. One study in which chimeric proteins between WNK3 and WNK4 domains were constructed suggested that the type of effect of WNK3 or WNK4 upon NCC resides within the amino-terminal domain.[211]

The WNK3-induced activation of NKCCs or inhibition of KCCs occurs even during cell swelling, which is a well-known inhibitor of NKCCs and activator of KCCs.[3,137,199] WNK3 catalytic activity can be prevented by the substitution of D294A. By doing this, the effect on the co-transporters is not only prevented, indicating the requirement for catalytic activity, but additionally, catalytically inactive WNK3 becomes an inhibitor of NKCC1, NKCC2, and NCC, and an activator of KCCs, even in isotonic conditions in which KCCs are non-functional. Because activation of KCCs by WNK3-D294A can be prevented with calyculin A and/or cyclosporine A, it is likely due to a catalytically inactive WNK3-induced activation of protein phosphatases.[240] Because the effect of WNK3 upon the sodium-coupled chloride co-transporters is associated with phosphorylation of the SPAK phospho-acceptor sites in the co-transporter's amino-terminal domain, it is likely that WNK3 also lies upstream of SPAK/OSR1 for its effect on the SLC12A co-transporters. Supporting this possibility, the positive effect of WNK3 on NKCC2 or NCC can be prevented by elimination of SPAK-binding sites located in WNK3.[186,226] Thus, WNK3 modulates the activity of all members of the SLC12 family and, in doing so, bypasses the changes in cell volume and/or intracellular chloride concentration that are usually required for their activation or inhibition. It is believed that WNK3/SPAK is the intracellular kinase pathway sensitive to cell volume and/or intracellular chloride concentration.[184,232,242] WNK2 is preferentially expressed in the central nervous system, and is apparently absent in kidney. Its effects on NKCC1 and KCCs are similar to those of WNK3.[243]

THE ROLE OF THE SODIUM-COUPLED CATION CHLORIDE CO-TRANSPORTERS IN INHERITED DISEASE

Given the major roles that NCC and NKCC2 play in renal physiology, it is of no surprise that inactivating mutations of these co-transporter genes are associated with monogenic disease, such as Gitelman's and type I Bartter's diseases, respectively. In addition, by affecting the modulation of NCC by certain kinases, increased activity of this co-transporter (and other ion transport protein in the distal nephron) is the mechanism behind another monogenic disease known as PHAII.

Gitelman's Disease

Gitelman's disease is an autosomal recessive monogenic disease featuring hypokalemic metabolic alkalosis, arterial hypotension, hypocalciuria, and hypomagenesemia. The clinical presentation usually becomes evident by the second decade of life. All these manifestations are due to a lack of salt transport capacity of the DCT, and resemble the clinical consequences of thiazide diuretic intoxication. Because of this, NCC became a strong candidate for the cause of the disease, and links between Gitelman's disease and the locus for *SLC12A3* in human chromosome 16 was found by several groups.[102,244–246] At present, nearly 350 different mutations of NCC have been reported to be associated with Gitelman's disease or with low blood pressure in an open population (see the human gene mutation data base at www.hgmd.or). Supporting the studies on genomic associations, phenotypes resembling Gitelman's disease have been obtained in mice by targeted disruption of NCC.[247,248] Interestingly, total knockout of NCC produces an incomplete Gitelman syndrome, while substituting the serine residue at the position 707 by a stop codon completely expunges the disease. Functional analysis of human or rat NCC containing some of the reported point mutations revealed that mutant NCC proteins are non-functional.[138–140]

Although Gitelman's disease is an autosomal recessive disorder, surprisingly, not all patients have shown mutations in both SLC12A3 alleles. About 30% of the Gitelman patients have been diagnosed with mutations in only one allele, another 45% are compound heterozygous; that is, they exhibit mutations in both alleles, but the mutation is different for each one, and near 20% are homozygous.[7,102,249–254] Because inheritance of Gitelman's disease is clearly recessive, and heterozygous relatives of patients with Gitelman's disease are clinically and metabolically asymptomatic, it is likely that undetected mutations in the other allele also exist. Most of the studies usually search for mutation within exons, but it is possible that mutations within the promoter or even in some introns or in the 3′ untranslated region affect expression of the protein. Most of the Gitelman's mutations are single point mutations in residues that are highly-conserved from fish to humans, and the mechanisms by which mutations reduce or abolish transporter activity are several, including impairment of protein synthesis, impairment of protein processing, impairment of insertion of an otherwise functional protein into the plasma membrane, impairment of functional properties of the co-transporter, and acceleration of protein removal from the membrane or degradation. Initial reports of missense mutations reported along the NCC protein revealed that the co-transporter is not glycosylated and thus, is not present at the plasma membrane.[138] It is known that preventing NCC glycosylation remarkably reduces the activity of the co-transporter due to deficient insertion into the plasma membrane.[97] Later studies of more mutants of NCC[139,140] showed that some missense mutations in NCC causing partially functional proteins are explained by a defect in the trafficking of the co-transporter to the plasma membrane which possesses normal functional and kinetic properties, but in which insertion into plasma membrane is seriously impaired.

Bartter's Disease

The characteristic clinical picture of Bartter's syndrome includes a salt-wasting state with low blood pressure due to dehydration, metabolic alkalosis with hypokalemia, hypercalciuira, hypereninemia, and secondary aldosteronism.[255] This picture is clearly due to a reduction in the salt transporting capacity of the TAL. The disease is usually apparent at birth or even earlier, due to excessive accumulation of amniotic fluid (polyhydramnios). A striking difference with Gitelman's disease is that Bartter's patients exhibit hypercalciuria and some develop nephrocalcinosis (Table 32.7), while in Gitelman's syndrome the expected presentation is hypocalciuria. Although Bartter's disease is monogenic, it is heterogeneous, because mutations in five different genes expressed in TAL can produce a very similar disease. Of these, three are directly involved in salt reabsorption in TAL and two other genes modulate the activity and/or trafficking of salt transporters. Thus, Bartter's disease is classified into five types. Types I to IV (Table 32.7) are the consequence of inactivating mutations of NKCC2 (type I), the potassium channel ROMK (type II), the basolateral Cl^- channel CLC-KB (type III), and the CLC-KB chaperon protein Barttin (type IV).[66,107,256–258] The absence of ROMK prevents NKCC2 activity, because recycling of potassium to the TAL lumen is prevented. Reduction of CLC-KB activity, due to mutations on the channel or because of the absence of barttin, probably decreases the activity of NKCC2, because the co-transporter is sensitive to intracellular chloride concentration.[186] Bartter's disease type V is the result of activating mutations in the calcium sensing receptor located in the basolateral membrane.[64,259–261] The

TABLE 32.7 Clinical Presentation of Patients with Bartter's Disease According To Genomic Classification in Types I to IV

	Type I	Type II	Type III	Type IV
Affected gene	SLC12A1	KCNJ1/ROMK	ClCNKB	BSND
Age of onset	Neonatal	Neonatal	First decade	Neonatal
Polyhydramnios	Yes	Yes	No	Yes
Sensorineural deafness	Rare	Rare	No	Yes
Poliuria	Yes	Yes	Uncommon	Yes
End-stage renal disease	No	No	No	Yes
Hypokalemia	Severe	Severe	Moderate	Severe
Metabolic alkalosis	Moderate	Moderate	Mild	Moderate
Nephrocalcinosis	Yes	Yes	No	Yes

stimulation of the calcium sensing receptor by extracellular calcium activates a second messenger cascade within the TAL that inhibits NKCC2 and ROMK. This way, an increase in extracellular calcium reduces salt reabsorption in the TAL that is followed by a reduction in calcium reabsorption, thus increasing calciuria. In patients with active mutations of the calcium sensing receptor, the receptor is activated with normal extracellular calcium concentration inducing a permanent reduction in NKCC2/ROMK activity. Bartter's disease in this case is usually a mild syndrome.

At present, nearly 75 different mutations of NKCC2 have been reported to be associated with Bartter's disease or with low blood pressure in an open population (see the human gene mutation data base at www.hgmd.or). It is possible to suggest the molecular nature of Bartter's syndrome just by analyzing the clinical picture, although a confirmation by specific gene sequencing is desirable (Table 32.7). For instance, all patients present hypokalemia and metabolic alkalosis, which are less severe in type III patients. Antenatal presentation and polyhydroamnios are much more often seen in Bartter's type I, II, and IV than in type III disease. Patients with type III disease do not develop nephrocalcinosis. Type IV is associated with deafness and development of chronic renal failure.[66,262] Therefore, age of clinical presentation and certain features such as nephrocalcinosis, deafness, and chronic renal failure help the clinician to identify of the appropriate molecular target.

Pseudohypoaldosteronism Type II/Familial Hypekalemia Hypertension

PHAII/FHH is the mirror image of Gitelman's disease. It is an autosomal dominant inherited disease featuring arterial hypertension with hyperkalemia, despite a normal glomerular filtration rate, and hyperchloremic metabolic acidosis as a consequence of decreased urinary H^+ excretion.[207,208] In addition, while Gitelman's patient's develop hypocalciuria, PHAII patients develop hypercalciuria.[263] This is translated into bone, because the first exhibit is increased bone mineral density,[264,265] whereas later a significant decrease in bone density develops.[266] As shown above, Gitelman's disease is the consequence of inactivating mutations of NCC. In contrast, all clinical features in PHAII patients are corrected by treatment with low dose, thiazide-type diuretics,[208,266] suggesting that increased activity of NCC is required for PHAII. No significant linkage was found between PHAII and the *SLC12A3* locus on chromosome 16,[267] eliminating the possibility that activating mutations of NCC are behind the development of this syndrome. Instead, four different genes have been shown to be the cause of PHAII. As discussed above, the gene responsible in families linked to chromosomes 12 and 17 have been observed to be WNK1 and WNK4, respectively.[206,268–274] Two other genes can be the cause of the disease: Kelch-like 3 (KLHL3) and cullin 3 (CUL3).[275] While KLHL3 mutations can be dominant or recessive, CUL3 are dominant and most of them are *de novo* mutations.

Extensive work has been done with WNKs regarding NCC modulation. Nothing is known yet regarding KLHK3 and CUL3 modulation of NCC activity. However, because most of the pathophysiology of PHAII seems to be explained by increased activity of NCC,[17,191,276,277] it is highly likely that these proteins modulate the activity of NCC. KLHL3 and CUL3 together form a protein complex that provides a RING-type of E3-ubiquitin ligase.[278] It has been demonstrated that the HECT-type of E3-ubiquitin ligase known as Nedd4-2 modulates NCC activity.[279] Thus, it is possible that the KLHL3–CUL3 complex regulates either NCC, some of the WNKs, or SPAK by ubiquitination or another known or unknown associated protein that in turn affects the activity of NCC.

WNK4 has been proposed to be a negative regulator of NCC activity that becomes a positive regulator when it harbors PHAII-type mutations.[209,210,212,213] A PHAII syndrome develops in BAC transgenic mice containing two wild-type WNK4 alleles and two PHAII-type mutant alleles,[214] indicating that haploinsufficiency does not explain the disease, because this model contains two wild-type WNK4 alleles. The disease is also present in a knockin mouse harboring WNK4 with a PHAII type mutation.[215] In these models, PHAII clinical features were rescued by treatment of mice with a thiazide-type diuretic, by crossing the mouse with the NCC null mice or with the SPAK knockin mice,[214,215,233] highlighting the importance of SPAK-NCC in producing the disease. Thus, it is possible that under certain conditions WNK4 inhibits NCC activity and in patients with PHAII mutations this inhibition is not present, leading to a chronic increase in the activity of NCC that produces arterial hypertension and hyperkalemia. One study proposed that PHAII mutations in WNK4 reconstitute the effect of angiotensin II upon the WNK4-SPAK-NCC cascade, suggesting that PHAII is a gain-of-function disease producing a state of hyperactivity of angiotensin II in the DCT.[17,196] There are, however, other proposals. One is that NCC activation is the result of altered interactions between the NCC activating WNK3 and the inhibitory WNK4.[241] The other, based on observations on hypomorphic WNK4 mice, is that WNK4 could be an activator of NCC that increases its potency by PHAII mutations.[280]

POTENTIAL ROLE IN POLYGENIC DISEASES

The physiological roles of sodium–chloride co-transporters and the diseases that are produced by their inactivating mutations or misregulation by WNKs support that they are implicated in the development of complex polygenic diseases, such as arterial hypertension. This is a highly prevalent disease (>20% of the adult population) with an important genetic component. NCC and NKCC2 are genes that clearly play a role in defining blood pressure levels, since inactivation of these transport proteins is associated with hypotension. Inhibition of NCC with thiazides is the base of the most recommended first line therapy for arterial hypertension.[281] Supporting the role of NCC or NKCC2 in defining blood pressure levels in an open population, a work based on genetic analysis of the Framingham Population Study sequenced the NCC, NKCC2, and ROMK genes in 3125 subjects. It was observed that 49 out of the 3125 exhibited a rare mutation in one allele of one these genes. This is 1.5% of the studied population. Subjects harboring such mutations have lower blood pressure, a reduced risk for developing hypertension, and a reduced risk of death due to cardiovascular disease.[282] Although several of the mutations detected in this study were not reported previously as causing Gitelman's or Bartter's disease, it was later shown that they indeed reduced the activity of NCC[283] or NKCC2.[283,284] A genome-wide association study in an Amish population revealed that SPAK or STK39 is a hypertension risk gene.[285] Thus, genome studies are beginning to reveal the role of SLC12A co-transporter genes in essential hypertension.

Osteoporosis is a polygenic disease of the skeleton that is secondary to a decrease in bone mineral density, with a disruption of the normal bone architecture and a consequent increase in the risk of fractures. Due to the functional interaction of NCC with calcium-transport mechanisms, this co-transporter is involved in renal calcium absorption. Inactivating mutations of NCC in Gitelman's disease are associated with high bone mineral density,[264,265] whereas activation of NCC in PHAII subjects is accompanied by decreased bone mineral density.[266] In addition, there is strong epidemiological evidence that hypertensive patients treated with thiazides are at a lower risk for osteoporosis.[27,28,286–288] In this regard, it has been shown that the NCC protein is expressed in osteoblasts in rat and human bones, and that addition of thiazides to osteoblast cells in culture increases the formation of mineralized nodules by a mechanism that may involve NCC.[19] Therefore, it is likely that osteoporosis is another polygenic disease in which this co-transporter could be implicated.

Acknowledgments

This chapter is dedicated with endless gratitude to the memory of my mentor Steven C. Hebert MD for his invaluable help and collaboration of over 20 years. Experimental work performed in the author's laboratory has been supported by The Mexican Council of Science and Technology (CONACYT), NIH grants DK36803 and DK064635, the Wellcome Trust, The Foundation Leducq for the Transatlantic Network on Hypertension–Renal Salt Handling in the Control of Blood Pressure.

CHAPTER

33

Sodium and Chloride Transport: Proximal Nephron

Alan M. Weinstein

Department of Physiology and Biophysics, Weill Medical College of Cornell University, New York, NY, USA

INTRODUCTION

The principal function of the proximal tubule is the reabsorption of some two-thirds to three-quarters of the glomerular filtrate. This means, primarily, reabsorption of Na^+, Cl^-, HCO_3^-, and in smaller quantities potassium, phosphate, and various filtered organic compounds. In view of the copious glomerular filtrate, proximal reabsorption plays a crucial role in the maintenance of fluid and electrolyte balance of the body. In particular, modern hypertension research has considered it essential to identify proximal tubule Na^+ transporters, and understand the signals and second messengers that regulate these transporters. Proximal tubular transport is energized by the metabolic reactions within the proximal tubular epithelium, either directly by ATP-driven "ion pumps" (primary active transport) or indirectly by the coupling of solute fluxes to Na-transport (secondary active transport). The workload to this epithelium is prescribed by the glomerular filtration rate (GFR), which can vary several-fold within the course of a day, so that the ensemble of epithelial transport systems are also asked to modulate their function responsively, and in a coordinated manner.

All segments of isolated proximal tubules are capable of reabsorbing the same solutes when perfused *in vitro*. Quantitatively, however, marked differences exist along the tubule; reabsorption of sodium, water, glucose, and bicarbonate in the early proximal tubule is about three-fold greater than that in the mid-portion of the convoluted proximal tubule, and nearly ten times that of the straight segment of the tubule. Furthermore, *in vivo*, the transtubular concentration gradients of the luminal solutes, as well as the electrical potential of the lumen, change as one moves from early- to late-proximal tubule. In the earliest part of the proximal tubule, preferential reabsorption of organic solutes (glucose and amino acids, etc.) and of sodium bicarbonate, lactate, acetate, phosphate, and citrate occurs. Consequently, the luminal concentration of these solutes is reduced in the remaining portion of the proximal tubule. Alterations in solute reabsorption have been inferred in a number of disorders of proximal tubule, and have been of particular interest to workers seeking to understand how changes in urine composition alter the propensity to kidney stone formation.

Historically, *in vivo* micropuncture and microperfusion was the experimental method that delineated proximal tubule transport properties, namely transepithelial fluxes and permeabilities. The next investigative focus was identification of specific transporters within luminal and peritubular cell membranes, and the experimental techniques have been diverse. Assessment of the cellular compartment was first done electrophysiologically, using conventional and ion-selective microelectrodes, and subsequently with pH- or cation-sensitive fluorescent dyes. More direct information about the membrane transporters derived from vesicle preparations enriched in fractions from luminal (brush border) or peritubular cell membranes. Patch-clamp techniques (whole-cell or excised patch) allowed the study of single membrane ion channels, but have had limited application to proximal tubule. A major advance came with molecular identification of the transporters, expressing these transporters in cells that are convenient for study, developing antibodies for location and quantification within tubular cell membranes, and examination of tubules from mice in which the transporter has been knocked-out.

Central to its role in body fluid homeostasis is the responsiveness of proximal tubule sodium transport to changes in GFR, as well as to neural and hormonal signals. In large measure, changes in sodium reabsorption that accompany changes in GFR may be understood in terms of transepithelial oncotic and hydrodynamic forces which impact on the tubule cells or on the paracellular pathway. Neurohumoral regulation of proximal tubule transport begins with a cellular signal, followed by transduction steps, which ultimately produce changes in transporter densities or kinetics within the cell membranes. The signaling pathways for the important neurohumoral regulators have been an object of intense investigation, although the insights have come slowly. This research program has had to contend with a number of cellular second messenger molecules, with a number of kinases and phosphatases, with identification of anchoring proteins that secure the local action of a signal, and with the cytoskeletal elements responsible for transporter traffic. Although much information is available, a facile description of the path from neurohumoral signal to transporter flux is not yet at hand.

The organization of this chapter starts with the description of whole tubule function: fluxes and the associated driving forces; and tubule permeabilities. Historically, this is the section with the oldest data, and the section that has undergone the least revision from earlier chapter versions. The next two sections are devoted to the description of the epithelial components: luminal and peritubular cell membrane transporters; the tight junction; and the lateral intercellular space. In view of the copious transepithelial solute fluxes, special attention will be given to the problem of matching luminal and peritubular transport fluxes, in order to avoid catastrophic perturbation of cell volume and composition. The last section describes the regulation of proximal transport, with emphasis on physical factors, and on the action of the two key regulatory molecules, angiotensin and dopamine.

EPITHELIAL FUNCTION

Net Fluxes

The filtered load of a solute to the proximal tubule is the product of the single nephron glomerular filtration rate (SNGFR) and the ultrafilterable concentration of the solute. For small nonelectrolyte species the ultrafilterable concentration is that in plasma water. For electrolytes, negatively-charged serum proteins produce a Donnan potential, which acts to decrease ultrafilterable Na^+ and increase Cl^- concentration with respect to that of plasma water.[556] In amphibian and mammalian proximal tubules, the net effect of proximal tubule transport is the reabsorption of the luminal solution, resulting in a diminished axial flow rate as one proceeds along the tubules. The systemic infusion of a substance, such as inulin, which is filtered at the glomerulus, not reabsorbed (or secreted) by the proximal tubule, and which may be assayed in aliquots of tubular fluid, permits the calculation of the net volume reabsorption by the tubule from the glomerulus to the point of sampling. Thus, in the rat superficial cortical nephrons, the tubular fluid (TF) inulin concentration at the end of the convoluted proximal tubules is twice that of plasma (P), indicating that half of the filtrate is reabsorbed proximally.[242] In the amphibian, *Necturus*, the TF/P ratio suggests that about one-third of the filtrate is reabsorbed by the proximal tubule,[600] and in certain fish, the net effect of proximal tubule transport is secretion of fluid into the lumen[88]; however, in view of translational considerations, only the mammalian kidney is considered in this chapter.

With micropuncture sampling of fluid from the proximal tubule, if a complete collection of tubule fluid is made, then the absolute transport rate by the nephron segment is known and can be expressed as a flux per unit area of epithelium (Table 33.1). Alternatively, one may perfuse dissected segments of tubule to directly

establish the epithelial fluxes under well-defined luminal and peritubular conditions. One must then obtain an independent measure of SNGFR to estimate the fractional reabsorption. The advantage of this approach is that proximal nephron segments not accessible to micropuncture may be examined. For the data from the perfused proximal convoluted tubule of the rabbit shown in Table 33.1, the measured sodium flux, referred to a 5.4 mm segment of tubule, implies sodium reabsorption of 1.2 nEq/min. With a SNGFR of 20 nl/min, the filtered load of sodium is 2.9 nEq/min, so that the fractional reabsorption is predicted to be about 40%. In the instances of successful micropuncture of rabbit proximal tubule, the observed fractional reabsorption of sodium has been 50[152] and 45%.[762] This type of comparison is particularly important, in that it suggests a reasonably well-maintained transport capacity for tubules examined *in vitro*. When examined carefully, however, conditions *in vitro* can produce subtle differences from the tubule *in vivo*. As might be expected, dissection conditions of isolated rabbit proximal tubules can decrease the peritubular membrane electrical potential and increase cytosolic Na^+ concentration; however, they can also engender a peritubular membrane K^+ channel, not seen *in vivo*, and change the Na^+ :HCO_3^- stoichiometry of the peritubular membrane co-transporter from 3:1 to 2:1.[490,492]

Unfortunately, attempts to present a concise tabulation of proximal transport (Table 33.1) must be tempered by an appreciation of internephron heterogeneity, and the structural changes along the individual tubule. In broad terms, two nephron populations have been identified: those with superficial cortical glomeruli, whose short loops of Henle turn at the outer–inner medullary border (about ⅔ of rat nephrons); and those with juxtamedullary glomeruli, whose long loops of Henle penetrate the inner medulla to variable extents. In many mammalian species, the juxtamedullary glomeruli are larger and have a greater SNGFR than the mid-cortical or superficial cortical nephrons.[556] In the rat, the filtration rate of juxtamedullary glomeruli has been measured by micropuncture collection of Henle limb fluid, and found to be about 1.5- to 2-fold that of superficial glomeruli.[286,344,512] In the rabbit, an indirect technique has given estimates confirming the disparity between superficial and juxtamedullary nephrons (e.g., 43 and 66 nl/min,[36]; 23 and 29 nl/min[43]). Comparisons of transport properties of superficial cortical and juxtamedullary proximal tubules are available.[78] Corresponding to the greater SNGFR of the juxtamedullary nephrons, there is a greater overall rate of volume and sodium reabsorption. Perfused tubule data from rabbit has indicated a relative magnitude of juxtamedullary-to-superficial Na^+ fluxes from 1.2-[341] to 2-fold[364] larger; the relative magnitude of HCO_3^- fluxes is 2-fold larger.[342] Beyond this quantitative distinction, the relative importance of specific transport mechanisms may also differ between the two nephron populations.[342,468,634]

The capacity for volume transport gradually diminishes as one proceeds along the mammalian proximal nephron.[352] This occurs in association with morphologic changes at the electron-microscopic level that have prompted the division of mammalian proximal tubule into three segments[455] (Figure 33.1). The early proximal convoluted tubule, S1, is characterized by tall, densely-packed apical microvilli, numerous mitochondria, and an intricate pattern of folding and

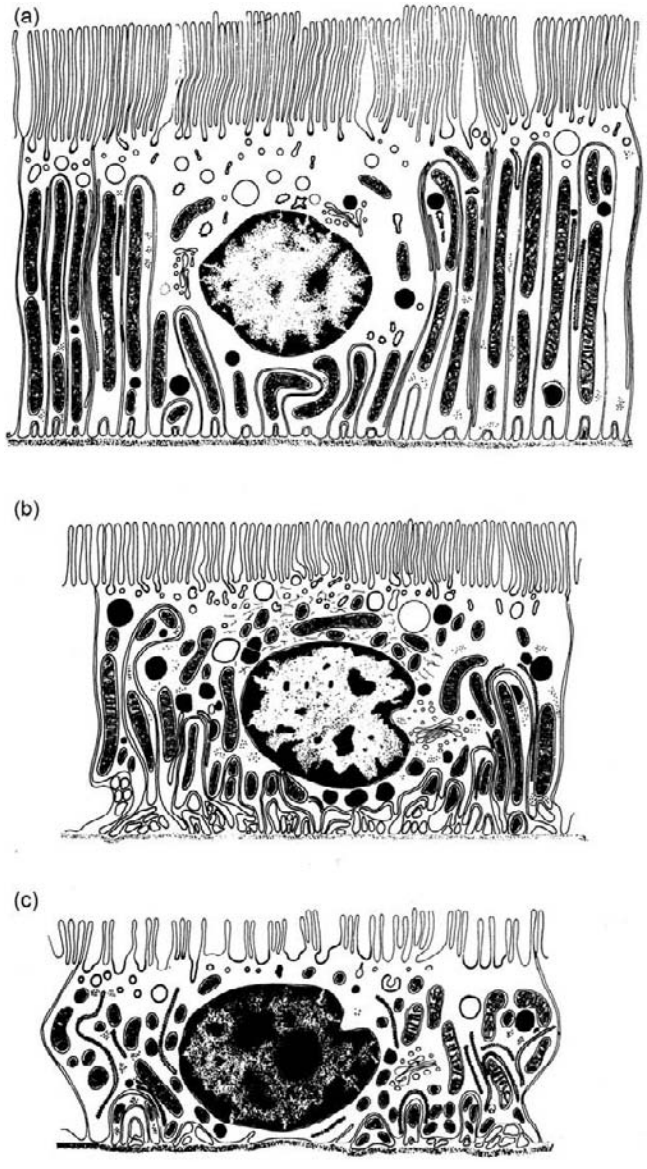

FIGURE 33.1 **Proximal tubule cells within the: (a) S1; (b) S2; and (c) S3 segments of the rabbit nephron.** *(From[352], with permission.)*

interdigitation of the lateral cell membranes.[739] There is a gradual transition to the S2 segment, which comprises the remainder of the proximal convoluted tubule and the very beginning of the proximal straight tubule. Here, there are fewer mitochondria and less amplification of membrane area. Finally, the proximal straight tubule, S3, shows a more cuboidal cell with fewer mitochondria and rare interdigitations. Welling and Welling[738] have compared the cell membrane areas in the S1 and S3 segments of rabbit proximal tubule, and found that for each segment, the apical and basolateral areas are nearly equal. In S1, however, the absorptive area of the cell is increased by membrane folding to 36 cm^2/cm^2 epithelium, whereas in S3 this value is 15 cm^2/cm^2 epithelium. The transport of solutes and water has been measured in dissected perfused segments of rabbit proximal tubule, and the spontaneous transport rate was substantially less in the proximal straight tubule than in convoluted segments[125,388] (Table 33.1). In the rat, microperfusion of proximal tubule segments *in vivo* (with comparable flow rates and luminal fluid composition) has demonstrated a lower volume reabsorption rate for segments more than 1–2 mm from the glomerulus.[165] Serial micropuncture along a single proximal tubule with filtered fluid flowing freely confirmed the sharp decline in reabsorptive flux of volume (sodium) and anions after the first 1–2 mm of tubule[426,427] (Figure 33.2). Comparison of Na^+ transport by perfused proximal straight tubules from superficial and juxtamedullary rabbit nephrons has demonstrated comparable reabsorptive rates. The respective convoluted tubule fluxes are two- and four-fold greater for Na^+,[45,364] with a similar proportionality for HCO_3^-.[708] Proximal convoluted tubule fluxes of glucose may be six-fold greater,[44] and of phosphate three-fold greater than those of proximal straight tubule.[530]

In rat and rabbit kidneys, the Na^+ concentration, and hence the total osmolality, remain relatively constant along the proximal tubule.[255,388] This constancy of tubule fluid osmolality implies "isotonic transport," and poses a special problem for rationalizing the forces at work in water reabsorption (*vide infra*). The fates of chloride and bicarbonate in the mammalian proximal tubule differ, however, in that the chloride rapidly rises to a level above that of the glomerular filtrate and the bicarbonate falls.[125,215,255,685] This shift in anion composition occurs early in the proximal tubule, that is to say, within the S1 segment. This is referred to as "preferential bicarbonate reabsorption," and has received much attention as a clue to transport activity at the cellular level. The key features of the compositional changes in tubular fluid during its passage through the mammalian proximal tubule are illustrated in Figure 33.3.[552] The tubular fluid/plasma (TF/P) concentration ratio of several solutes is plotted as a function of proximal tubular length. TF/P inulin rises to approximately 2.0, indicating water reabsorption. Glucose and amino acids are rapidly reabsorbed so that at 25% proximal tubular length their concentrations decline to some 10% of the filtrate concentration. Preferential bicarbonate reabsorption lowers the bicarbonate concentration of tubular fluid to approximately 5–8 mM. Along the initial portion of the proximal tubule, the chloride concentration is increased by reabsorption of water.[28] In the initial segment, the transepithelial voltage is lumen negative,[46,220] due to the electrogenic nature of co-transport of sodium with glucose or amino acids.[221,387] As the concentration of these solutes declines and that of chloride rises, the polarity of the transepithelial electrical potential difference changes to lumen positive values.[46,220] This voltage is, at least in part, a diffusion potential, generated by the chloride and bicarbonate concentration gradients, and the greater permeability of the tubular wall to chloride than to bicarbonate.

Transport Forces

To attribute mechanisms to epithelial transport, fluxes must be resolved in terms of responsible driving forces, specifically hydrostatic or osmotic pressure, solute concentration gradients, electrical potential or metabolic energy. The transepithelial volume flow, J_v (ml/s · cm^2 epithelium), is a function of hydrostatic and osmotic driving forces:

$$J_v = L_p\left[\Delta p - RT\sum_1^n \sigma_i \Delta c_i\right] = (RTL_p)\left[\frac{\Delta p}{RT} - \sum_1^n \sigma_i \Delta c_i\right]$$
$$= \overline{v}_w P_f\left[\frac{\Delta p}{RT} - \sum_1^n \sigma_i \Delta c_i\right] \tag{33.1}$$

Here the water permeability of the epithelium is represented either by the coefficient L_p (ml/s · cm^2 · mmHg), by RTL_p (ml/s · cm^2 · Osm) or by P_f (cm/s), where RT is the product of the gas constant and absolute temperature (1.93×10^4 mmHg/Osm at 37°C), and $\overline{v}_w$ is the partial molar volume of water (0.018 ml/mmol). In Eq. (33.1) the osmotic effect of any species is incorporated in the reflection coefficient, σ_i, ($0.0 \le \sigma_i \le 1.0$). For $\sigma_i = 1.0$, the species exerts a full osmotic effect, and the epithelium is an ideal semipermeable membrane. When $\sigma_i = 0.0$, the species exerts no osmotic force. To determine the reflection coefficient for a specific solute, the change in the transepithelial volume flow produced by a transepithelial concentration gradient, Δc_i, is compared to the volume flow produced by an equal concentration gradient of an impermeant species. The ratio of these two volume flows is just the reflection coefficient, σ_i.

To represent solute transport, J_i (mmol/s · cm^2), the epithelial flux equation is of the form:

$$J_i = J_v(1-\sigma_i)\,\overline{c}_i + \sum_{j=1}^n L_{ij}\Delta\overline{\mu}_j^c =$$
$$J_v(1-\sigma_i)\,\overline{c}_i + \sum_{j=1}^n L_{ij}[RT\Delta\ln(c_j) + z_jF\Delta\psi] \tag{33.2}$$

in which the first term is a convective flux in which a mean concentration appears:

$$\overline{c}_i = \frac{\Delta c_i}{\Delta\ln(c_i)} \approx 0.5\cdot\left[c_i(l) + c_i(p)\right]$$

in which c_i(l) and c_i(p) designate luminal and plasma concentrations. It is a consequence of thermodynamic theory (Onsager symmetry) that the reflection coefficient, σ_i, from Eq. (33.1) also appears in Eq. (33.2) for convective solute drag. This formalizes the intuitive notion that the smaller solutes, which are least osmotically effective, are more likely to be entrained in the volume flow. The second term in Eq. (33.2) represents electrodiffusive solute flux, namely the flux of solute i as a function of the electrochemical potential differences, $\Delta\overline{\mu}_j^c$, of all of the solutes under consideration. Expansion of this potential is shown in the rightmost expression, in which RT is the product of gas constant and absolute temperature (2.57 J/mmol at 37°C), z_i is the valence of solute j, F is the Faraday (96.5 C/mEq), and $\Delta\psi$ is the electrical potential difference across the epithelium. It is also a consequence of Onsager symmetry that the coefficients $L_{ij} = L_{ji}$ (mmol^2/J · s cm^2). When the coefficient L_{ij} is positive (for i≠j), then a reabsorptive driving force on solute i will also promote reabsorption of solute j, so that this coefficient may be considered to represent co-transport of the two solutes. Such co-transport obviously arises when a common carrier transports the two species, but may also occur as a result of intraepithelial convective flows.[730]

Some of the most precise experimental measurements that can be made are those of electrical

potentials and currents. In the absence of solute-solute interaction, the transepithelial solute flux is written:

$$J_i = J_v(1-\sigma_i)\,\bar{c}_i + L_{ii}\,[RT\Delta\ln(c_i) + z_iF\Delta\psi] = J_v(1-\sigma_i)\,\bar{c}_i + P_i\left[\Delta c_i + \frac{z_iF}{RT}\bar{c}_i\Delta\psi\right] \quad (33.3)$$

where $RTL_{ii}/\bar{c}_i = P_i$ (cm/s) is the conventional solute permeability. Equation (33.3) has generally been the starting point for the application of electrophysiology to characterize proximal tubule. For example, if luminal and peritubular solutions have equal ionic concentrations ($\Delta c_i = 0$), and there is zero volume flow, then application of an electrical potential difference ($\Delta\psi$) produces a change in ionic current:

$$I_i = z_iFJ_i = P_i\left(\frac{z_i^2F^2}{RT}\right)\bar{c}_i\Delta\psi = g_i\Delta\psi \quad (33.4)$$

in which g_i (S/cm^2) is the partial ionic conductance of species i. The total epithelial electrical conductance, $g = \Sigma g_i$, or the epithelial electrical resistance, $R = 1/g$, thus provides a measure of the sum of the ionic permeabilities. When the luminal and peritubular solutions are unequal, the open-circuit potential, in the absence of net transepithelial volume flow ($J_v = 0$), gives useful information about the relative ionic permeabilities. In this case, the sum of all ionic currents is zero ($0 = \Sigma\, I_i$), so that the transepithelial electrical potential is:

$$\Delta\psi = -\sum_{i=1}^{n}\frac{g_i}{g}\frac{RT}{z_iF}\,\Delta\ln(c_i) \quad (33.5)$$

If, for example, the only concentration differences across the epithelium are equal and opposite anion gradients (such as chloride and bicarbonate), Eq. 33.5) shows that the difference in ionic conductances determines the magnitude of the transepithelial "diffusion potential."

Table 33.2 is a compilation of the permeability properties of the proximal tubules of rat and rabbit. Again, the inclination to present such tabulation must be tempered by acknowledgement of variation of the permeabilities along the nephron, and of differences between superficial and juxtamedullary nephrons. With respect to water permeability, it has been suggested that there is a decline in L_p from the S1 to the S2 segment of the rat tubule.[432] Nevertheless, the water permeability remains at least as large in the straight segment as in the convoluted segment.[598] With respect to solute permeabilities, an increase in the electrical conductance of the rat proximal tubule has been observed as one moves from the earliest to the latest accessible segments.[620] Experiments in perfused rabbit tubules suggest that the increase in total conductance is due to an increase in the chloride permeability.[343] Comparison of tubule permeabilities indicates that juxtamedullary proximal convoluted tubules[82,84,164,343] and proximal straight tubules[330,364,708,713] are more cation selective than the superficial proximal tubule segments. Comparison of permeabilities of K^+[764] and of Cl^-,[713] between rabbit juxtamedullary and superficial proximal straight tubules suggests that the increase in cation selectivity derives from an absolute increase in juxtamedullary nephron cation permeability, with little difference in anion permeability.

There is no doubt that proximal tubule metabolism is required for transport to proceed at its normal rate. In the absence of ionic concentration gradients across the epithelium, reabsorption still proceeds and cooling or poisoning with metabolic inhibitors

TABLE 33.2 Permeabilities of Proximal Tubules

abolishes transport. A generally accepted treatment of active transport by the proximal tubule has been that of Frömter[215] in which Eq. (33.2) is extended by inclusion of a term for metabolically driven transport, J_i^a:

$$J_i = J_v(1-\sigma_i)\,\bar{c}_i + \sum_{j=1}^{n} L_{ij}\Delta\bar{\mu}_j^c + J_i^a \qquad (33.6)$$

or in the absence of coupled fluxes

$$J_i = J_v(1-\sigma_i)\bar{c}_i + P_i\left[\Delta c_i + \frac{z_i F}{RT}\bar{c}_i\Delta\psi\right] + J_i^a \qquad (33.7)$$

It may also occur that water flux is linked to metabolic reactions in a way that reabsorption proceeds in the absence of transepithelial driving forces. This flux, J_v^a, has been termed "active water transport," and, by analogy with Eq. (33.6), Eq. (33.1) for transepithelial volume flow has been written[267,731]:

$$J_v = L_p\left[\Delta p - RT\sum_{1}^{n}\sigma_i\Delta c_i\right] + J_v^a \qquad (33.8)$$

A derivation of J_v^a from considerations of the internal structure of the tubule epithelium will be indicated in the section on the paracellular pathway.

THE TRANSCELLULAR PATHWAY

Cytosolic Concentrations

In the foregoing, proximal tubule transport has been treated from the perspective of the epithelium as a homogeneous entity, with reflection coefficients and permeabilities inferred from the transepithelial fluxes produced by changes in luminal and peritubular solutions. Over the last decades, however, a more microscopic view of proximal tubule transport has evolved. Crucial to this perspective were the observations that the intercellular tight junctions could serve as a low resistance route for transepithelial ion permeation.[223,758] This defines a "paracellular pathway" for fluxes, across the tight junction, into the lateral intercellular space, and out across the basement membrane to the peritubular capillaries. The "transcellular pathway" enters the cell cytosol via the luminal membrane and exits across the basal cell surface or across the lateral cell membrane into the lateral intercellular space. To discern solute transport across individual cell membranes, one must be able to monitor changes in intracellular concentrations.[110] Historically, the first estimates of cell ion content derived from chemical analysis of tissue. Difficulties with this method include the inaccuracy associated with the subtraction of the extracellular contribution to the total, as well as the limitation of examining the concentration at only a single point in time. An additional concern arises when one tries to estimate transmembrane chemical potential differences, if some of the cell ion content is bound or sequestered, and thus not available to the "transport pool." Somewhat akin to the chemical assay has been the application of the electron probe to determine cell solutes. With the small beam of this technique, true intracellular sampling can be ensured, although the estimate of cell water is indirect and an important source of uncertainty. Nuclear magnetic resonance (NMR) spectroscopy has been used as a nondestructive method for measuring intracellular sodium of proximal tubules in suspension.[278,396] Unfortunately, only a portion of the cell sodium is "visible" by NMR, and additional steps must be taken to estimate the total pool.[111] One fruitful technique for probing the cell interior has been the use of microelectrodes capable of penetrating the cell membrane, presumably without destroying the functional integrity of the cell. The electrodes may record the electrical potential of the cytosol or, when fashioned with a substance that reacts selectively with an ion, the cytosolic electrochemical potential of the selected ion species. Although technically challenging, these measurements provide precisely the information necessary for establishing the driving forces for ionic fluxes.[219,370] Subsequently, ion-sensitive fluorescent dyes were developed, and these could be loaded into proximal tubule cells and used to monitor continuous changes in pH,[7] calcium[174] or chloride.[329,395]

Despite the technical difficulty of studying the small cells of mammalian proximal tubules, a reasonably complete picture of the intracellular milieu is available (Table 33.3). In the rat, the intracellular potential has been found to be −76 mV.[189] Good agreement has been reported for the cell sodium concentration estimated electrophysiologically (17.5 mmol/l)[782] and with the electron probe (20.3 mmol/l).[61] Potassium is actively accumulated above its electrochemical equilibrium.[141,189]

Although an early investigation suggested passive distribution of chloride across the proximal tubule,[639] subsequent work established cellular chloride uptake against a potential gradient.[139] The mechanism underlying this elevation of cytosolic chloride will be considered below. At this point, it suffices to acknowledge that the potential hill for chloride is linked via several anion exchangers to the bicarbonate potential. In turn, the elevation of cytosolic bicarbonate is regulated and maintained well above the equilibrium value (1.4 mmol/L) by a number of transport processes, including Na^+/H^+ exchange and metabolically driven proton extrusion from the cell (H^+-ATPase).[9,576]

It has also been possible to impale cells of the isolated perfused rabbit proximal tubule. The intracellular potentials of the proximal convoluted and proximal straight tubules were first found to be −51 and −47 mV respectively,[89] and subsequent determinations have been confirmatory (−50 mV[590]; −61 mV,[70]). In the proximal straight tubule, the cell potassium activity is higher than its electrical equilibrium. Both the cell potassium activity and the cell potential fall (depolarize) with ouabain-inhibition of the peritubular Na^+, K^+-ATPase.[90] As in the rat, the chloride activity is elevated above equilibrium, and there is good agreement between the electrophysiologic determination (18 mmol/L)[335] and that found using a fluorescent dye (21 mmol/L).[395] The intracellular pH of rabbit proximal tubules in suspension was first investigated using a radiolabeled weak organic acid. Under control conditions, the cells were found to be alkaline, 7.51, becoming acid with the application of ouabain, 7.42.[96] Subsequent determinations have revealed the pH to be lower (7.22,[590]), and thus more akin to that found in the rat proximal tubule.

Luminal Membrane

General Properties

Important information about membrane permeabilities and species-species interactions has been obtained from studies in vesicle suspensions prepared from proximal tubule brush border. The water permeability of the luminal membrane was assessed by the response of vesicle volume (light scattering) to an osmotic shock.[682,683,688] Corresponding to the approximate doubling of transepithelial water permeability from proximal convoluted tubule to proximal straight tubule of the rabbit (Table 33.2), is the observation of a comparable increase in water permeability of luminal membranes from these two segments.[680] Critical insight into the mechanism of water transport came with the discovery of an integral membrane protein (designated AQP-1), which serves as a water channel, or aquaporin, and is the principal water pathway for luminal and peritubular membranes of proximal tubule (reviewed by [2]). Consistent with the membrane water permeability measurements, the abundance of AQP-1 along the proximal tubule doubles as one moves from S2 to S3 segments.[449] In mice, the importance of AQP-1 for proximal tubule water flux was demonstrated with the study of S2 segments from AQP-1 knockout mice, whose water permeability (P_f) was about 20% that of wild-type mice.[794] Additional vesicle studies indicated that across the luminal membrane, solute−water interaction appears to be minimal, with a reflection coefficient for NaCl of 1.0.[523,681,682] This is consistent with absence of solute permeation through AQP-1, when expressed and studied in oocytes.[2] Thus, in the application of Eq. (33.6) to the luminal membrane, the terms for convective solute flux may be ignored.

Electrophysiological investigation of proximal tubule revealed that luminal membrane electrical resistance (260 ohm · cm^2) is between one and two orders of magnitude greater than the total epithelial resistance[217,218] (Table 33.2). The impact of altering luminal ionic composition on intracellular potential suggested that the potassium permeability of the luminal cell membrane was much greater than the sodium permeability, and that the chloride permeability was negligible.[216] These observations provided strong evidence that sodium entry into proximal tubule cells is coupled to the entry or exit of other solute species. Direct examination of the conductive channels within this membrane using the patch-clamp technique has been possible only to a limited extent. In the first successful attempt, Gögelein and Greger[250] identified a channel in the luminal membrane of rabbit proximal convoluted tubule, which showed a greater conductance to K^+ than to Na^+. Luminal K^+ channels have also been identified in patch-clamp studies of primary culture of rabbit S1 proximal tubule.[471] Additional K^+ channels have been identified immunohistochemically in the luminal cell membrane of mammalian proximal tubule, including the voltage-gated channel KCNA10,[776] and the

voltage-dependent K^+ channel complex, KCNE1/KCNQ1.[678] Both are thought to play a role in stabilizing the membrane potential against the depolarizing effect of Na^+-dependent uptake of glucose and amino acids (*vide infra*). This role for luminal K^+ channels received confirmation in microperfusion and electrophysiological investigation of proximal tubules from homozygous kcnq1 knockout mice.[679]

Luminal membrane sodium channels ($P_{Na}/P_K \geq 19$ and blocked by amiloride) have been found in a patch-clamp study of the rabbit proximal straight tubule.[251] This result anticipated the observation of voltage-sensitive, amiloride-blockable sodium entry across luminal membrane vesicles of this tubule segment,[340] and across the luminal membrane of cultured LLC-PK1 cells.[132] The LLC-PK1 cell line is derived from pig kidney, and is thought to resemble S3 proximal tubule. A later study of the S3 segment of rat proximal tubule demonstrated a luminal membrane conductance which could be inhibited by micromolar concentrations of amiloride, and which could be enhanced by a low-sodium diet or mineralocorticoid injection.[756] Under conditions of enhanced channel expression, the mRNA which encodes for the ENaC sodium channel could be detected in these proximal tubule cells. It is natural to surmise that the capacity of the proximal straight tubule of the rabbit to reabsorb sodium in the absence of a co-transported solute[599] might be a consequence of such channels.

Chloride channels have also been identified within proximal tubule cell membranes. In the mammalian kidney, an interesting finding has been the appearance of a chloride conductance after addition of cyclic AMP[424] or by modulating cytosolic production of cyclic AMP.[425] These observations, made in a preparation of brush border membrane vesicles, were confirmed in a patch-clamp study of the luminal membrane of proximal tubule cells in primary culture,[168,577,653] and parallels observations in other epithelia. Under the cellular conditions of Table 33.3, one would expect such a channel to be a pathway for Cl^- secretion; however, in the presence of a lumen-to-blood chloride gradient, application of cyclic AMP induces a reabsorptive transcellular chloride flux, which can be inhibited by luminal application of a chloride channel blocker.[702] The physiologic role of this chloride channel in proximal tubule function remains to be delineated.

Sodium-Glucose Co-Transport

The first sodium entry pathway to receive intensive study was its coupled transport with glucose. Considerable insight had been derived from intestinal and renal preparations, and the description of co-transport that emerged received confirmation as molecular biology provided expression and study of these transporters in other cells.[305,765,766,767] The co-transport of glucose with sodium was demonstrated in vesicles prepared from luminal membranes of rabbit[23] and rat[372] proximal tubules. In the presence of a sodium gradient (medium to vesicle), vesicle glucose concentration rises to levels above that in the medium, and then slowly equilibrates with the ambient concentration. This glucose uptake, which carries a net positive current, can be enhanced by short-circuiting the vesicle membrane.[62] Conversely, glucose gradients (medium to vesicles) may be used to drive vesicle sodium concentration transiently well above that of the bathing solution.[310] In the intact epithelium, the presence of glucose and sodium in the luminal perfusate depolarizes the luminal cell membrane.[217,452,586] Examining rat proximal tubule *in vivo*, Samarzija et al.[586] observed that the magnitude of luminal membrane depolarization is diminished by lowering either the luminal glucose or sodium concentrations, by depolarizing the luminal membrane, or by elevating the cell glucose concentration. In short, reabsorptive flux of the Na^+-glucose pair is dependent upon the electrochemical potentials for each species across the luminal membrane. These qualitative features of Na^+-dependent glucose flux could be captured using a linear nonequilibrium thermodynamic model of the co-transporter.[729]

Kinetic studies of glucose uptake across luminal membrane have been presented within the framework of carrier-mediated transport, characterized by a maximal transport rate and a luminal glucose concentration for which transport is half-maximal (K_m). When Turner and Silverman examined sodium-dependent uptake of glucose into vesicles prepared from dog renal cortex, their data suggested the presence of two such carrier sites.[671] In their preparation a high-velocity, low-affinity site had a $K_m = 4.5$ mmol/L, while the second site had a low velocity and high affinity ($K_m = 0.2$ mmol/L). The possibility was suggested that these two carriers might correspond to different sites of glucose uptake along the nephron. In pursuit of this issue, Turner and Moran[638,668] prepared vesicles from both the outer cortex and outer medulla of rabbit kidney. Here, the low-affinity carrier localized to the outer cortical region (presumably containing S1 and S2 segments of the proximal tubule), and the high affinity carrier localized to the outer medullary vesicles (presumably containing S3 segments). Corresponding to the affinity difference is the determination of a 1:1 (glucose:Na^+) stoichiometry of the cortical co-transporter,[316,669] and a 1:2 stoichiometry of the high affinity carrier.[670] More direct studies, localizing glucose uptake, were performed in isolated segments of rabbit proximal tubule by Barfuss and Schafer.[44] Their data were compatible with a single high-capacity carrier in the proximal convoluted tubule ($J_{max} = 1800$ pmol/s · cm^2 and $K_m = 1.7$ mmol/L), and

low-capacity, high-affinity transporters in the proximal straight tubule ($J_{max} = 170-270\ pmol/s \cdot cm^2$ and $K_m = 0.35-0.70$). Thus, these experiments presented a coherent picture of a system of proximal glucose transport which would, under normal conditions, deliver only negligible quantities of glucose to the distal nephron. It should be noted that Na^+-glucose co-transport appears in cultured cell systems, and its identification was useful in establishing the similarity of the LLC-PK1 cell line to proximal tubule.[549] As in the straight tubule, the stoichiometry of glucose:Na^+ is 1:2.[417,476] Co-transport was also identified in primary cultures of proximal tubule cells,[153,777] again as high-affinity with 1:2 stoichiometry,[5,584] although electrophysiological study of one preparation suggested a lower affinity transporter.[74]

An important step in the study of Na^+-glucose co-transport came with the cloning of the gene for the intestinal co-transporter, SGLT1 (or, using the Human Genome Organization nomenclature, SoLute Carrier SLC5A1).[304] When this co-transporter was expressed in amphibian oocytes[328] or in mammalian cells,[102] it had high glucose affinity and kinetics indicating 1:2 stoichiometry. Early on, the availability of the intestinal transporter allowed identification of antigenic similarity with renal brush border proteins.[793] Subsequent *in situ* hybridization studies localized SGLT1 to the S3 segment of proximal tubule, precisely the site suggested by the kinetic data.[413] Prior to the cloning of this transporter, a number of detailed mathematical representations of Na^+ co-transport had been developed.[306,367,557,667] In each of these models, the co-transport of glucose and sodium was represented as a series of reactions: substrate binding to carrier; translocation of loaded carrier; unbinding at the opposite membrane face; and cycle completion by translocation of empty carrier. Expression of SGLT1 in oocytes enabled more extensive electrophysiological investigation and reformulation of a more secure model. Steady-state experiments revealed several salient features of the transporter: solute binding affinity is asymmetric, comparing inside and outside of the carrier; translocation of empty carrier is an important rate-limiting step and sensitive to the transmembrane PD; and solute-binding is not sufficiently rapid as to be considered at equilibrium with respect to translocation.[146,521,522] This expression system also enabled time-dependent studies to directly examine individual potential-dependent steps within the transport cycle. These have been useful in confirming charge of the unloaded carrier and identifying similarity in kinetics of SGLT1 from human, rat, and rabbit.[302,437,520] More recently, Loo and co-workers have focused on SGLT1 structure, and specifically characterization of the external sugar-binding domain.[311,439]

The cloning of SGLT1 also yielded insights not suspected from earlier studies, namely that protons could substitute for sodium in the transport of glucose,[312] and that in the translocation of two Na^+ and one glucose, SGLT1 also transports over 200 water molecules.[438,469] This degree of water transport may be important with respect to intestinal function, but in the kidney these fluxes through SGLT1 will be tiny. The discrepancy between the limited abundance of SGLT1 and the high capacity for glucose transport of cortical brush border membrane vesicles was readily apparent.[519] Homology screening revealed a gene which encoded for a second Na^+-glucose co-transporter, SGLT2 (SLC5A2), expressed in kidney, for which the stoichiometry is 1:1 and which, by *in situ* hybridization, localizes to the S1 segment of proximal tubule.[353] More detailed kinetic studies indicated that SGLT2 is the low-affinity, high-capacity system identified in kinetic studies.[784] When SGLT2 is expressed in oocytes and studied electrophysiologically, a kinetic scheme similar to that for SGLT1 could be developed to represent this transporter.[445] While still other sodium-glucose co-transporters have been identified, any significance with respect to renal transport remains to be established.

Sodium/Proton Exchange

From a quantitative perspective, the most important sodium flux across the luminal cell membrane is the Na^+/H^+ counter-transporter.[622] The Na^+/H^+ exchanger was securely established by Murer et al.,[494] using a suspension of vesicles composed predominately of luminal membrane. Their basic observation was that a sodium concentration gradient from suspension medium to vesicle interior resulted in acidification of the medium. This effect required the presence of intact vesicles, but was undisturbed when electrical potential differences between the vesicle interior and the medium were eliminated. Further, a suspension medium alkaline, with respect to vesicle interior, stimulated sodium uptake by the vesicles. These results were confirmed in rabbit proximal tubule vesicles by Kinsella and Aronson (Figure 33.4)[374], who further demonstrated alkalinization of the vesicle interior by the inwardly directed sodium gradient. This counter-transport is reversibly inhibited by amiloride,[375] and proceeds with a Na^+:H^+ stoichiometry of 1:1.[376] Following those early observations, kinetics of the proximal tubule luminal membrane Na^+/H^+ antiporter were studied intensively.[20,270,480] Vesicle preparations revealed a transport site that bound a single Na^+[714] with an affinity roughly one-tenth that of the external Na^+ concentration, and with competitive binding by H^+ or NH_4^+.[24,375] Studies of the antiporter at lower temperatures indicated that Na^+ uptake and H^+ extrusion occurred in a sequential ("ping-pong")

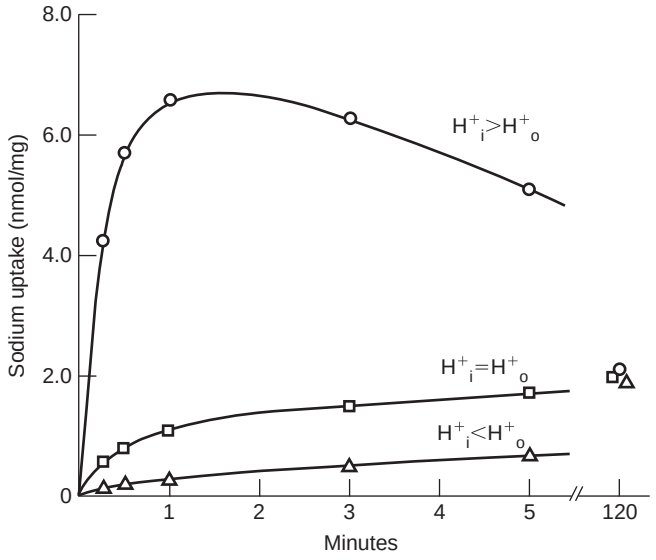

FIGURE 33.4 Effect of proton gradients on sodium uptake by luminal membrane vesicles prepared from rabbit renal cortex. Low internal pH ($H_i^+ > H_o^+$) enhances; and elevated internal pH; ($H_i^+ < H_o^+$) retards sodium entry, relative to the rate of entry in the absence of pH gradients. The vesicles were prepared in sodium-free medium and uptake was measured in solutions containing 1 mM Na^+. *(From[374], with permission.)*

fashion, with H^+ transport likely to be the rate-limiting step.[513,514] The effect of intracellular pH is more complex, with cytosolic alkalosis shutting off Na^+/H^+ exchange more sharply than a simple substrate depletion effect.[22] Cytosolic pH appears to have little impact on the Na^+ affinity of the antiporter,[377] but rather modifies the turnover rate.[514] With respect to the kinetic properties of this transporter, the information gained from renal brush border membrane vesicles has generally received confirmation in studies of isolated proximal tubule cell suspensions,[97,504] and in vesicles prepared from established cell lines[482] or from primary culture of proximal tubule cells.[209,652]

In mammalian proximal tubule, comparison of brush border and basolateral membrane vesicle showed that the Na^+/H^+ exchanger is primarily within the luminal cell membrane.[338] In the intact tubule, Schwartz[616] presented evidence for the direct coupling of Na^+ and H^+ fluxes, showing that ouabain inhibition of the peritubular Na,K-ATPase, presumably raising cell sodium concentration, could run the luminal Na^+/H^+ exchanger in reverse. Examination of vesicles from cortical and outer medullary regions of the kidney indicated that the Na^+/H^+ exchanger is present along both convoluted and straight segments of proximal tubule.[339,483] More direct evidence for the presence of the luminal membrane Na^+/H^+ exchanger in the S3 segment was offered by Kurtz.[400] Using tubules whose cells had been loaded with the pH-sensitive fluorescent dye, BCECF, he found acidification of the cell interior with removal of luminal sodium. Nevertheless, the vesicle studies indicated that the maximal Na^+/H^+ exchange rate was lower in the outer medullary population, suggesting a lower density of the transporter in straight proximal tubules.[339] This also received confirmation by Baum,[52] who perfused both convoluted and straight proximal tubules with BCECF-loaded cells. Comparing the impact of changes in luminal sodium on intracellular pH, he concluded that, relative to the convoluted segment, the straight tubule had a 30% capacity for Na^+/H^+ exchange.

In the molecular era, the Na^+/H^+ exchangers came to be recognized as a family of transport proteins, NHE-, with the luminal membrane exchanger of proximal tubule identified as NHE3 (SLC9A3). The gene for NHE3 was cloned and sequenced,[511,662] and the product identified immunocytochemically in the brush border membrane.[99] Kinetic studies of the NHE3 in expression systems generally confirmed the properties noted a decade earlier in the membrane preparations.[510,663] With respect to the Na^+/H^+ exchange activity of the peritubular membrane, the NHE1 isoform was identified in basolateral membrane vesicles and in immunohistochemical staining of rabbit proximal tubule.[100] Failure to detect NHE3 protein in proximal straight tubule prompted speculation that another NHE isoform may be operative in this segment.[12] More generally, even in tubule segments in which NHE3 was abundant, the magnitude of the Na^+/H^+ flux that actually traversed this isoform was uncertain. Based on the observation that the inhibitor profile of rat brush border vesicle Na^+/H^+ exchange was identical to the inhibitor profile of NHE3 in expression systems, it was concluded that NHE3 was the sole exchanger within the luminal cell membrane.[700] That view was quickly amended with the development of the NHE3 knockout mouse, in which proximal microperfusion revealed rates for Na^+ and HCO_3^- reabsorption of 25% and 40% compared with wild-type.[610] In subsequent *in vivo* microperfusion studies, residual Na^+ reabsorption was found to be slightly greater, 60%[443] and 45%.[703] When the proximal tubules from knockout mice were dissected, loaded with BCECF, and perfused *in vitro*, the magnitude of luminal Na^+/H^+ exchange could be assessed as the change in intracellular pH in response to restoration of luminal Na^+.[151] In those experiments, the Na^+-dependent proton secretion in knockout tubules was about 50% of the wild-type, and completely inhibitable by amiloride. The magnitude of NHE3 flux was also assessed in rat proximal tubules perfused *in vivo*, in which a specific NHE3 inhibitor reduced Na^+ reabsorption by 30%[676] and 40%.[700] These values are likely to be underestimates of

the NHE3 flux, in view of the fact that amiloride inhibition was only 50%.[700] In sum, it seems safe to attribute about half of the luminal membrane Na^+/H^+ exchange to NHE3. With respect to the molecular identity of the residual transport, both NHE2 knockout[151] and specific inhibitor studies[700] have eliminated NHE2 as a candidate. Goyal and co-workers identified NHE8, within kidney cortex[258] and expressed on proximal tubule brush border.[257] Its quantitative role in luminal Na^+/H^+ exchange remains to be defined.

Regarding the functional importance of the luminal membrane Na^+/H^+ exchanger in the proximal nephron, two caveats are in order. It is important to distinguish total HCO_3^- reabsorption from the Na^+-dependent portion of HCO_3^- reabsorption. The luminal membrane contains an H^+-ATPase,[120] and amiloride block of the Na^+/H^+ transporter has been used to identify a significant component of proton secretion via the H^+-ATPase.[41,319,400,537] The second caveat is that total Na^+-dependent proton secretion may be considerably greater than tubular HCO_3^- reabsorption. Preisig and Rector[538] microperfused rat proximal convoluted with a late proximal solution, low in bicarbonate and high in chloride. In this situation, where net bicarbonate absorption was virtually absent, amiloride still inhibited 44% of NaCl reabsorption. These findings were taken as evidence for the importance of parallel pathways through the luminal membrane for Na^+ (via the Na^+/H^+ exchanger) and for Cl^- (via a Cl^- base exchanger) in the net reabsorption of NaCl. The implication of such a scheme is that the net flux of Na^+ across the Na^+/H^+ transporter can well exceed the total reabsorptive bicarbonate flux. The first mathematical model of NHE3 was based on a scheme of Na^+-binding, translocation, and release, H^+-binding, translocation, and release, and also included competing NH_4^+-binding, translocation, and release.[734] In this model, all binding was assumed to be rapid (equilibrium), and affinity coefficients were assumed to be symmetric with respect to internal and external faces of the transporter. With one additional assumption, namely the inclusion of an internal modifier site which enhances translocation in response to cytosolic acidification, the kinetic behavior described in vesicle studies could be represented. When this simulation of NHE3 was incorporated into a mathematical model of rat proximal tubule, Na^+/H^+ exchange functioned directly to reabsorb luminal $NaHCO_3$, and in parallel with a luminal membrane Cl^-/base exchanger, yielded net NaCl reabsorption. An additional prediction of this kinetic model was that Na^+/NH_4^+ exchange via NHE3 is the most important mechanism for ammonia secretion by proximal tubule. This comported with conclusions from tubules *in vitro*, that ammonia secretion from cellular ammoniagenesis could be blocked by inhibition of NHE3.[496] Both experiment and model cast doubt on an earlier scheme of diffusive NH_3 secretion and trapping in acidic luminal fluid. With respect to NHE function, more sensitive experimental techniques have revealed nonlinearities. Fuster et al. used a pH-sensitive electrode to determine bath pH gradient in the immediate neighborhood of proton-transporting cells; from the gradient magnitude and the cell shape, they calculated the transmembrane proton flux.[231] When this methodology was applied to cells expressing NHE1 (and to a lesser extent NHE3), it was found that NHE turnover rate as a function of external Na^+ became sigmoidal.[232] Their observations were consistent with NHE schemes in which two "monomers" functioned cooperatively to yield a functional transport stoichiometry of $2Na^+$ for $2H^+$. The study demonstrated the power of an electrophysiological technique to examine an electroneutral transporter; whether the observations have a physiologic correlate in kidney tubule function, remains uncertain.

Chloride/Base Exchange

To enter the cell across the luminal membrane, chloride must be transported up an electrochemical potential gradient (Table 33.3); either co-transport with luminal Na^+ or exchange for cytosolic base, is energetically feasible. In the rat, Lucci and Warnock[444] found that furosemide inhibited two-thirds of the fluid transport when the luminal perfusion was a high-chloride, low-bicarbonate solution. In view of the ability of a known inhibitor of erythrocyte anion exchange (SITS) to also inhibit proximal volume reabsorption, Lucci and Warnock suggested that NaCl transport occurred via parallel luminal Na^+/H^+ and Cl^-/OH^- (or Cl^-/HCO_3^-) exchangers. Warnock and his colleagues supported this hypothesis with the demonstration of pH-gradient driven, electroneutral Cl^- fluxes across brush border membrane vesicles.[709,711,712] Similar conclusions were drawn by Liedtke and Hopfer,[421] whose study of luminal membrane vesicles from rat small intestine indicated that coupled Na^+-Cl^- co-transport was unlikely. Their work also indicated an inhibitory effect of furosemide on the Cl^-/OH^- exchanger.[422] Absence of Na^+-Cl^- co-transport was also a consistent finding in vesicles prepared from brush border membranes of the mammalian kidney.[493,623] In the straight proximal tubule of rabbit, a Cl^- microelectrode study has failed to detect Na^+-dependent luminal chloride entry.[335] Although a number of reports confirmed the presence of a Cl^-/OH^- exchanger in renal brush border membrane vesicles,[129,144,637] the absence of quantitatively significant flux through such an exchanger was indicated by others.[138,337,580,623] Methodological concerns relating to vesicle experiments were raised on both sides of this issue. When Schwartz[617] perfused rabbit proximal

convoluted tubules with a sodium-free acidic fluid, there was no significant effect of luminal Cl^- on the appearance of bicarbonate within the luminal fluid.

Critical insight into luminal chloride transport came with the work of Karniski and Aronson,[355] who demonstrated a chloride-formate (Cl^-/HCO_2^-) exchanger in brush border membrane vesicles from the rabbit. In their experiments, a formate gradient could drive transmembrane chloride flux, and a chloride gradient could drive formate flux. This process was electroneutral and could be blocked by the anion exchange inhibitor, DIDS. Most significantly, they found (Figure 33.5) that while a pH gradient only slightly enhanced chloride uptake, this same gradient in the presence of a physiologic concentration of formate could drive substantial chloride flux. To account for this formate effect, they suggested that a backflux of formic acid, down its concentration gradient, from the acidic bath to the alkaline vesicle interior, would serve to constantly resupply the Cl^-/HCO_2^- exchanger. Karniski and Aronson proposed that in the intact tubule, the concurrent operation of Cl^-/HCO_2^- and Na^+/H^+ exchangers, along with backdiffusion of formic acid, would yield a net flux of NaCl across the luminal cell membrane. Subsequently,

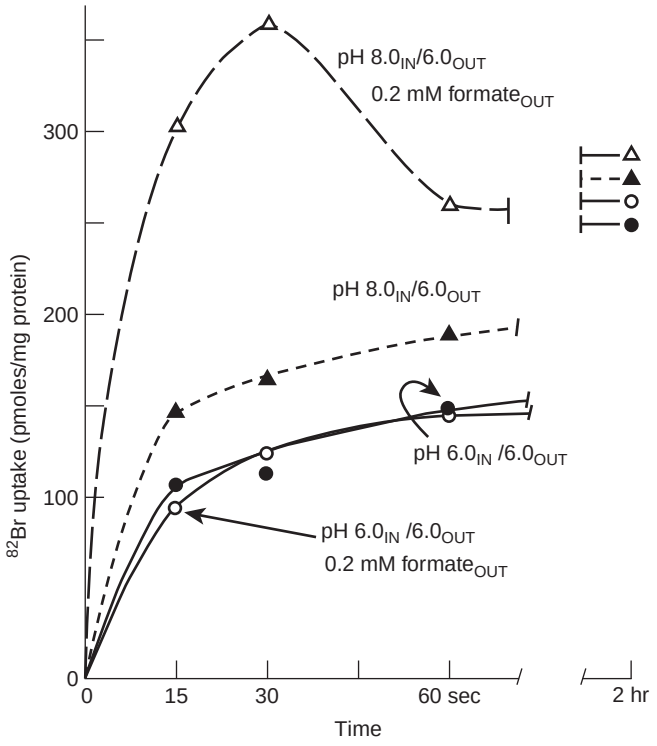

FIGURE 33.5 **Effect of formate and a pH gradient on $^{82}Br^-$ uptake by luminal membrane vesicles prepared from rabbit renal cortex.** While a pH gradient (8.0–6.0) only slightly enhances $^{82}Br^-$ transport, this same gradient in the presence of 0.2 mM formate produces a substantial increase in uptake, with an overshoot above the equilibrium concentration. *(From[355].)*

this mechanism was refined, with the identification of a luminal membrane HCO_2^-/OH^- exchanger, which could recycle secreted formate back into the cell.[585] (By virtue of its inhibitor profile, this anion exchanger is distinct from the Cl^-/HCO_2^- antiporter.) One point of difficulty with the overall scheme was the subsequent finding that the diffusional permeability of the luminal membrane to formic acid was far too low to sustain a flux comparable to the estimated chloride flux.[535] An effort was made to rationalize this discrepancy mathematically, by considering the possibility of formic acid accumulation within an unstirred layer defined by the brush border. It was found, however, that with realistic diffusion coefficients, the microvilli were sufficiently short that no significant differences of formic acid concentration could develop between the bulk luminal solution and that near the cell membrane.[393,394] At this time, the possibility of a microdomain of low pH adjacent to the luminal membrane in which the formic acid to formate concentration ratio is enhanced remains the least secure element of this proposed mechanism.

Acknowledging points of uncertainty, a scheme emerged in which Cl^-/base exchange in proximal tubule is effected by two or more anion exchangers functioning in parallel[21] (Figure 33.6). To pursue this scheme further, a candidate protein for the Cl^-/HCO_2^- antiporter was sought and purified from brush border membrane vesicles.[642] Of uncertain significance was the observation that when reconstituted into phospholipid vesicles, this protein could also mediate direct Cl^-/HCO_3^- exchange.[641] The effect of formate has been examined in intact tubules, with cells containing BCECF, in which luminal chloride is able to acidify the cell in the presence (but not the absence) of formate.[8,51] It must also be acknowledged that one protocol which could detect formate stimulation of Cl^-/base exchange in superficial proximal convoluted tubules failed to detect it in tubules from juxtamedullary nephrons.[634] There has also been the observation of a negative formate effect in a study of proximal straight tubule,[402] again raising the possibility of nephron heterogeneity with respect to the mechanism of chloride entry. In their search for chloride entry mechanisms, Karniski and Aronson[356] also demonstrated a Cl^-/oxalate exchanger within brush border vesicles, on a carrier distinct from that for Cl^-/HCO_2^-. The subsequent finding of luminal membrane pathways for oxalate recycling, either in exchange for SO_4^{2-} or OH^-,[398] supported the possibility that the Cl^-/oxalate exchanger may also be an important route for luminal membrane Cl^- entry (Figure 33.6). Aronson and colleagues[398,698] envisioned the possibility that three carriers in parallel, Cl^-/oxalate and oxalate/SO_4^{2-} antiporters plus the $2Na^+$–SO_4^{2-} co-transporter, would effect luminal entry of NaCl.

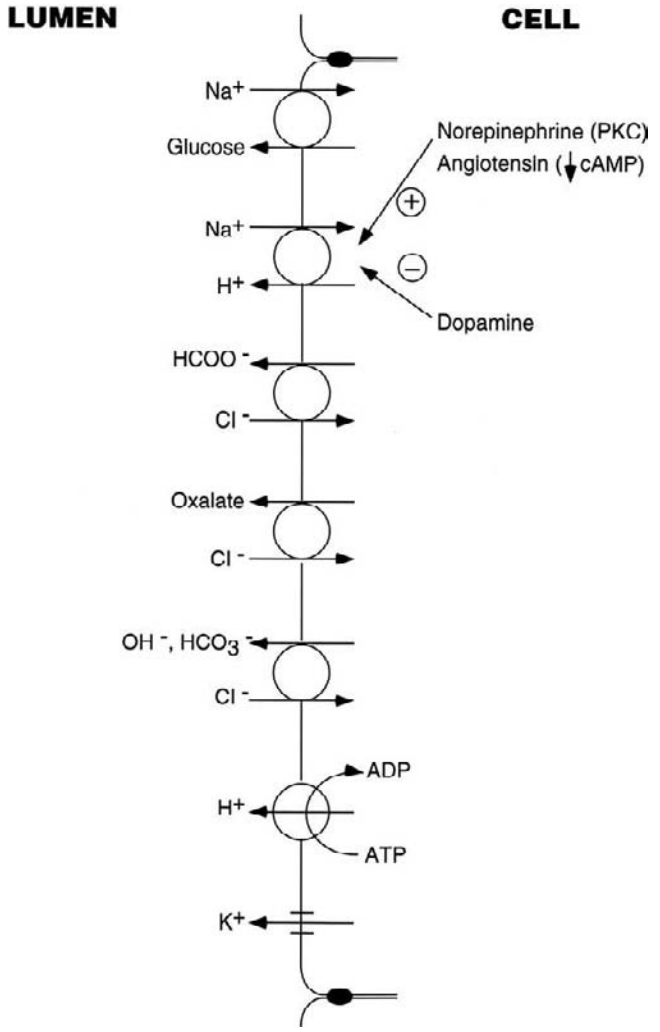

FIGURE 33.6 **Transport pathways across the luminal cell membrane of the mammalian proximal tubule.**

Confirmation of the importance of luminal chloride/base exchangers came with measurements of fluxes in intact proximal tubules. When any segment of rabbit proximal tubule (S1–S3) was perfused with an acidic (high Cl^-, low HCO_3^-) solution, there was a substantial impact of formate to stimulate volume (NaCl) reabsorption[603,604] In perfusions with a relatively alkaline solution (such as an ultrafiltrate of plasma) there was no such enhancement, presumably due to the limited recycling of formate. In reviewing these observations, Berry and Rector[83] pointed out that the pH-dependence of formic acid permeation effectively prioritizes proximal anion reabsorption along the tubule, HCO_3^- taking precedence over Cl^-. The increased volume reabsorption observed with formate was subsequently found to occur in association with an increase in cell volume, thus supporting the transcellular route for the increment in chloride flux.[601] With perfusion of proximal tubules of the intact rat kidney, both luminal formate and oxalate enhance NaCl reabsorption from an acidic, high-chloride, luminal solution.[698,699,706] The ability of a chloride channel blocker, DPC, within the peritubular perfusate, to block the formate and oxalate effects is additional evidence that the increment in NaCl flux is transcellular.

Molecular identification of luminal membrane anion transporters has focused attention on the SLC26 family of anion exchangers.[178,489] Of the members in this family, the SLC26A4 transporter (pendrin) was demonstrated to be a Cl^-/formate exchanger when expressed in *Xenopus* oocytes,[619] and its mRNA was identified in rat kidney cortex.[645] The protein, however, was not detected immunohistochemically in mouse proximal tubule brush border.[381] Furthermore, in pendrin knockout mice, Cl^-/formate exchange in brush border membrane vesicles was normal, and microperfusion of proximal tubules showed normal formate stimulation of volume reabsorption.[357] The transporter SLC26A6 (CFEX, PAT1) could also mediate Cl^-/formate exchange in oocytes, and the protein was expressed in brush border of mouse proximal tubules.[381] Further study of SCL26A6 revealed that it had a broad transport capacity, which included Cl^-/oxalate, Cl^-/HCO_3^-, and Cl^-/OH^-.[148,772] The observation that low concentrations of oxalate could inhibit Cl^-/HCO_3^- exchange led Jiang et al.[345] to surmise that the primary function of SLC26A6 in proximal tubule was as the luminal Cl^-/oxalate exchanger. This prediction was borne out in a study of mice deficient in SLC26A6.[705] The mice had normal serum electrolytes and normal proximal tubule volume reabsorption under control conditions; oxalate stimulation of proximal volume flux was absent. These knockout mice showed only a tendency toward deficient formate stimulation of volume reabsorption, so that at this time, the identity of the Cl^-/formate exchanger(s) remains uncertain.

Suspicion that formate may have other effects on proximal transport, beyond luminal anion exchange, was raised in a mathematical model of rat proximal convoluted tubule which included representation of luminal membrane Cl^-/HCO_2^- exchange.[733] Simulation of formate addition reproduced the observed cell swelling and increase in cytosolic chloride concentration; however, the density of the chloride/formate exchanger had virtually no effect on overall NaCl reabsorption along the tubule. In similar simulations, the density of the Na^+/H^+ exchanger had a powerful impact on NaCl reabsorption, indicating that for the model tubule, sodium reabsorption was rate-limiting for NaCl flux. Subsequent experimental examination of mice deficient in NHE3 found that formate stimulation of proximal sodium (volume) and chloride reabsorption was absent, although oxalate stimulation was entirely preserved.[704] These workers surmised that, in the normal tubule, there

might be a functional coupling between NHE3 and the Cl^-/formate exchanger. A direct study of the formate effect on NHE3 function was undertaken by Petrovic et al.[528] In the absence of CO_2/HCO_3^-, addition of formate to the bath and lumen of mouse microperfused kidney proximal tubule caused intracellular alkalinization, with cell pH increasing from baseline level 7.17 to 7.55. Removal of sodium from the lumen or addition of EIPA completely prevented the alkalinization. It was concluded that formate stimulates the apical Na^+/H^+ exchanger NHE3 in kidney proximal tubule, and that formate stimulation of chloride reabsorption could be indirect and secondary to activation of NHE3. An intriguing possibility is that the Cl^-/formate exchanger may be acting as a formate receptor to modulate NHE3.[528] In a subsequent study, deletion of the Slc26a6 anion exchanger from the S3 mouse proximal tubule diminished NHE3 activity, despite comparable protein abundance.[527]

Peritubular Membrane

General Properties

The cell sodium content reflects the balance among conductive, coupled, and metabolically driven fluxes across both luminal and peritubular cell membranes. In the rat, the potassium-to-sodium permeability ratio is about 20:1,[215] and the electrical resistance of this membrane is 90 ohm · cm^2, roughly a third of the luminal membrane.[217] A similar apportionment of electrical resistance appears in the proximal convoluted tubule of the rabbit, where the peritubular and luminal resistances are 39 and 118 ohm · cm^2.[410] In the straight proximal tubule of the rabbit, Bello-Reuss[70] has found the peritubular sodium conductance undetectable. In the first successful application of a patch pipette to the peritubular membrane of rabbit proximal tubule, only a potassium channel was clearly identified.[250] With respect to convective sodium fluxes across this membrane, all the data are negative with one exception. Welling et al.[740,742] applied an osmotic shock to the peritubular surface of isolated rabbit tubules and recorded the change in cell volume. A comparison of the effect of raffinose and NaCl indicated a reflection coefficient, $\sigma_{NaCl} = 0.5$, suggesting that water flow across this membrane would carry significant quantities of NaCl. This surprising result did not receive confirmation, however, in two subsequent studies of basolateral membrane vesicles. Using either light-scattering[682] or a fluorescent indicator[523] to assess vesicle volume, salt reflection coefficients of 1.0 were obtained. Subsequent experiments in whole tubule preparations, with optical measurement of cell volume[284] or using a fluorescent indicator[635] indicated $\sigma_{NaCl} = 1.0$, implying no NaCl flowed convectively across the peritubular membrane.

Sodium Bicarbonate Co-transport

Co-transport of sodium with bicarbonate is an important pathway for sodium and the principal pathway for bicarbonate exit across the peritubular membrane in both amphibian and mammalian proximal nephron.[9,109,534] The delineation of this coupled transport followed from the careful examination of bicarbonate exit from the salamander proximal tubule by Boron and Boulpaep.[108] Using pH and Na^+-sensitive microelectrodes, they observed that a reduction in peritubular bicarbonate concentration led to a decline in cytosolic pH, a peritubular depolarization, and a decline in cell sodium activity. Further, a reduction in peritubular sodium also led to a decline in cytosolic pH and, in contrast to the expectation from a conductive Na^+ pathway, peritubular depolarization. All of these effects could be blocked by the anion transport inhibitor, SITS. These results suggested the operation of a coupled Na^+ and HCO_3^- co-transporter, with the exit of at least two bicarbonate ions for each sodium. In the salamander, the electrochemical gradient of bicarbonate across the peritubular membrane was sufficient to drive sodium exit from the cell, if the stoichiometry were 2:1 or greater (HCO_3^-:Na^+). Subsequent study of the *Necturus* proximal tubule confirmed the presence of substantial voltage-sensitive HCO_3^- exit across the peritubular membrane,[454] which was later shown to be coupled to Na^+ and HCO_3^- transport.[441] Here, it was suggested that the stoichiometry might well be 3:1. With regard to the issue of HCO_3^-:Na^+ stoichiometry, one interesting set of observations in *Necturus* was the finding that when functioning in the normal reabsorptive direction, this ratio was 3:1, but when bath conditions were changed to reverse the flux direction, the ratio changed to 2:1.[531] This suggested an asymmetry with respect to the affinities of the substrates, perhaps secondary to the conformational changes of the transporter during the translocation step.

In rat proximal tubule, experiments using conventional microelectrodes indicated that elimination of bicarbonate from the perfused peritubular capillaries produced a large instantaneous depolarization.[225] In this early work, the investigators attributed the depolarization to a conductive bicarbonate pathway and estimated (Eq. (33.5)) that nearly half the peritubular membrane conductance might be mediated by bicarbonate. Electrophysiologic study of the perfused straight proximal tubule of the rabbit also disclosed a steady-state depolarization with removal of peritubular bicarbonate.[70,89] In that work, however, the depolarization was attributed to a pH-dependent decrease in peritubular membrane K^+ conductance, and thus

a decreased contribution of the K^+ potential to the overall membrane potential. The rat proximal tubule was then re-examined, and still the results indicated that the immediate depolarization produced by peritubular bicarbonate removal did not depend upon changes in membrane K^+ conductance.[123,124] This depolarization was inhibited by SITS, but a clear implication of Na^+ in the bicarbonate exit step was not confirmed. Within a short period of time, a number of investigators securely established the presence of Na^+—HCO_3^- co-transport in the peritubular membrane of the mammalian kidney. Sasaki et al.[590] using pH-sensitive microelectrodes, demonstrated that in the straight proximal tubule of rabbit, elimination of bath sodium resulted in cellular acidification and peritubular depolarization, an effect that was partially blocked by SITS. Biagi and Sohtell[91,92] used conventional microelectrodes to document a peritubular depolarization with sodium removal in both convoluted and straight proximal segments. The effect was substantially blocked by SITS, and attributed to coupled HCO_3^- transport. Yoshitomi et al.[781] re-examined the rat proximal tubule, now using both Na^+-sensitive and pH-sensitive microelectrodes. Removal of peritubular sodium or bicarbonate led to the expected depolarization, acidification, and decrease in cell sodium activity. When these investigators compared the (SITS-inhibitable) depolarization with either 10-fold reductions of peritubular Na^+ or HCO_3^- (equal changes in chemical potential) they found that the impact of the bicarbonate removal was three-fold greater. They concluded that the HCO_3^-:Na^+ stoichiometry was 3:1. In an independent set of experiments, sudden reduction in peritubular bicarbonate produced peritubular HCO_3^- and Na^+ fluxes (estimated from cell size and buffering power), which confirmed the 3:1 coupling ratio.[781]

The peritubular bicarbonate pathway in the rat proximal tubule was also investigated using fluorescence of intracellular BCECF to monitor changes in cytosolic pH.[7] In this first use of BCECF in the rat, Alpern was able to document SITS-inhibitable acidification of the cell with reduction of peritubular sodium. When BCECF was used to detect pH changes along the nephron, the transporter was identified in the S3 segment, but in clearly reduced capacity compared with S2.[52,238] Abuladze et al.,[1] used BCECF to quantify Na^+—HCO_3^- transport capacity in all three proximal tubule segments from both cortical and juxtamedullary rabbit kidneys. They reported S1 fluxes three- to five-fold greater than those of S2, and S2 fluxes eight-fold greater than those of S3. Examination of isolated basolateral membrane vesicles prepared from rabbit[4,263] and rat kidney[264] permitted the kinetics of the transporter to be studied in relative isolation. By determining driving force equilibrium across this transporter, Soleimani et al.[644] confirmed that three negative charges were carried for each sodium. Subsequently, the co-transported species were identified as one HCO_3^- plus one CO_3^{2-}.[640] Identification of the transported species was also pursued electrophysiologically. In rabbit proximal tubules *in vitro*, under "standard" conditions, the stoichiometry of peritubular HCO_3^-:Na^+ flux through this co-transporter was 2:1, and insensitive to carbonic anhydrase inhibition. However, with perfusion conditions more closely approximating those *in vivo*, the stoichiometry shifted to 3:1, and was sensitive to carbonic anhydrase inhibition. This change in transport was interpreted as a shift of the transported species from $2HCO_3^-$—Na^+ to CO_3^{2-}-HCO_3^-—Na^+, as *in vivo*[490,492,625] Gross and Hopfer[273] studied the Na^+—HCO_3^- co-transporter in a cell line derived from the S1 segment of rat proximal tubule, grown to confluence on filters. When the luminal cell membrane of this artificial epithelium was permeabilized with amphotericin, cytosolic solute concentrations were identified with those of the luminal solution, and the stilbene-sensitive transepithelial current with current through the Na^+—HCO_3^- co-transporter. Data from this preparation indicated a 3:1 flux stoichiometry,[273] and provided information with which to construct a detailed kinetic model for this transporter.[274,275]

The Na^+—HCO_3^- co-transporter (SLC4A4) was cloned first from *Ambystoma* kidney,[573] and then from human[127] and rat kidneys.[128,572] Denoted akNBC, hkNBC, and rkNBC respectively, all three co-transporters are comprised of 1035 amino acids, and structural comparisons have been presented.[571,643] Using antibody developed against rNBC, the protein was demonstrated in rat proximal tubule in an exclusively basolateral pattern, with intense staining in S1, rapid decline in S2, and no detectable staining in S3.[607] Staining in *Ambystoma* proximal tubule was also basolateral, but considerably weaker. Immunohistochemistry at the electron microscopic level confirmed these findings.[460] When rkNBC was expressed in *Xenopus* oocytes, transporter function could be studied electrophysiologically, and the stoichiometry of HCO_3^- to Na^+ fluxes was found to be 2:1.[184,618] It was concluded that the function of this transporter in mammalian cells *in vivo* was clearly different from its function in oocytes. The conundrum was sharpened with experiments in artificial epithelia derived from mouse proximal tubule or collecting duct, each deficient in NBC. In these two mammalian cells, transfected kNBC showed 3:1 or 2:1 stoichiometry for proximal and collecting duct cells, respectively.[271] Important insight came from, Müller-Berger et al.[491] who examined rkNBC in oocytes electrophysiologically, and found that with elevation of cytosolic calcium concentration, there was a relatively slow (30 second) activation of

the NBC conductance, plus a shift in stoichiometry from 2:1 to 3:1. They understood that such events in the proximal tubule *in vivo* would constitute a switch from zero (or secretory) peritubular HCO_3^- flux to brisk HCO_3^- reabsorption. This switch was deciphered by Gross et al.,[272] working with the artificial mouse proximal tubule epithelium transfected with kNBC. They found that addition of cAMP caused a shift in stoichiometry from the basal 3:1 to 2:1, and this was PKA-dependent. Replacing the single PKA phosphorylation site of the transfected transporter eliminated the stoichiometric shift.

Chloride Transporters

In early electrophysiologic investigation of both amphibian[276,636] and mammalian[70,124,133] proximal tubules, peritubular chloride conductance appeared to be virtually absent or at least negligible. In proximal convoluted tubules of the rabbit, perfused *in vitro*, peritubular application of a chloride channel blocker had no effect on NaCl reabsorption.[53] Welling and O'Neil[744] found that in rabbit proximal straight tubule the conductive chloride pathway in peritubular membrane could account for about 6% of the total membrane conductance. However, after cell swelling induced by a 150 mOsmol hypotonic osmotic shock, the chloride conductance increased to 20% of the total peritubular membrane conductance. Using quantitative video microscopy, the volume of rabbit proximal convoluted tubules was unaffected by changes in peritubular chloride concentration. However, prior hypotonic cell swelling rendered the cell volume sensitive to peritubular chloride concentration, and this effect was eliminated by application of a chloride channel blocker.[602] Peritubular chloride channel blockers have also been effective in blunting the changes in the membrane electrical potential following a change in peritubular chloride concentration.[626] Further electrophysiologic study of rabbit convoluted tubule during osmotic shock estimated the fractional chloride conductance to increase from 3% to a maximum of 16%, with relaxation to 8%. During these same experiments, the fractional conductance of the $Na^+-3HCO_3^-$ pathway declined from 41 to 16%, with little change in the absolute conductance through this pathway. Data from such experiments provide enough information to estimate the reabsorptive flux of chloride through the peritubular channels. If one assumes that the peritubular membrane has an electrical resistance of 100 ohm $\cdot$ cm^2,[410] equivalently a conductance of 10 mS/cm^2, then the conductance of the $Na^+-3HCO_3^-$ pathway is about 5 mS/cm^2, as is the maximal chloride conductance after the osmotic shock. With reference to Table 33.3b, the cytosolic chloride electrochemical potential across this channel is about 2 J/mmol or 20 mV. Multiplication by the steady-state chloride conductance of the swollen cell, 2.5 mS/cm^2, yields a chloride current of 50 nA or 0.5 nmol/s $\cdot$ cm^2. This estimate may be compared with the overall transepithelial sodium flux of late proximal convoluted tubule at 4.5 nmol/s $\cdot$ cm^2. Thus, the conductive chloride flux is not insignificant, and yet it cannot be the whole story. Further, concern over the magnitude of the osmotic shocks used in these experiments prompted re-examination with smaller perturbations by Breton et al.[117] When the cell volumes increased by only 20–25%, the peritubular chloride conductance increased by only 3–4-fold from control. Another important observation from the study of Breton et al.[117] was that the time course of chloride channel activation was delayed with respect to the time course of cell swelling, suggesting perhaps a chemical modification of the channel, rather than an immediate stretch-activated response. As in the luminal membrane, increases in cytosolic cAMP also activate a chloride channel within the peritubular membrane of rabbit[627,628] and rat.[702]

From the considerations above, peritubular chloride fluxes must also occur as electroneutral-coupled transport with other ions. Guggino and associates[277,436] examined chloride transport across the peritubular membrane of *Necturus* proximal tubule, using Cl^-- and pH-sensitive microelectrodes. They found that following either removal of peritubular Cl^- or increase of cytosolic Cl^-, exit of chloride from the cell was substantially blunted by removal of either peritubular Na^+ or HCO_3^-. This chloride exit was inhibited by SITS. In view of the electroneutral nature of the process, they proposed a coupled transport mechanism in which intracellular Cl^- was exchanged for Na^+ and 2 HCO_3^- from the peritubular side (Figure 33.7). Such coupled transport systems had been established in invertebrate neurons.[576] Other studies of chloride permeation of the peritubular membrane of amphibian proximal tubule suggested a Cl^-/HCO_3^- exchanger that was independent of sodium,[188,783] although such a transporter would mediate chloride uptake by the cell. In the mammalian proximal tubule, peritubular Cl^-/HCO_3^- exchange had been suspected from peritubular capillary perfusion studies in the rat.[119,673] More convincing evidence for the presence of Na^+-dependent Cl^-/HCO_3^- exchange in the peritubular membrane of rat proximal tubule came from experiments of Alpern and Chambers.[10] In these tubules loaded with BCECF, restoration of peritubular capillary chloride produced cellular acidification. This acidification did not occur in the absence of ambient (luminal and peritubular) Na^+, and was blocked by SITS. Consistent with these findings was the observation[264] that in basolateral membrane vesicles from rat renal cortex, an oppositely directed Cl^- gradient (inside to outside) stimulated

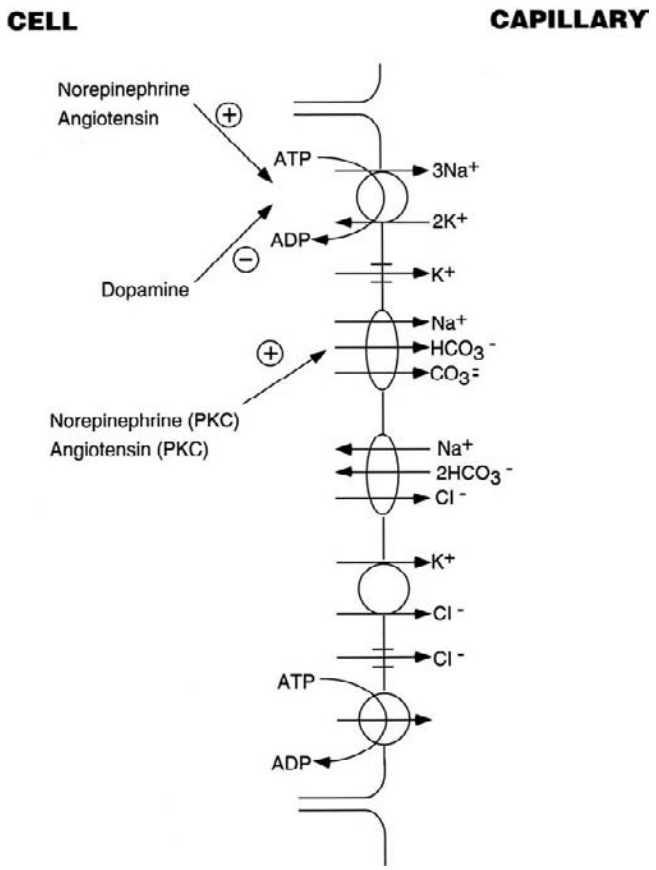

FIGURE 33.7 **Transport pathways across the basolateral cell membrane of the mammalian proximal tubule.**

HCO_3^--dependent Na^+ uptake. In vesicles from the rabbit, in which Cl^- uptake was assayed, it was found to be enhanced by an outwardly directed HCO_3^- gradient, and further stimulated by the addition of a Na^+ gradient.[145] In a Cl^- microelectrode study of rabbit proximal convoluted tubule, Ishibashi et al.[333] found that removal of either HCO_3^- or Na^+ from the peritubular bath increased cytosolic Cl^-, an effect inhibited by SITS, and which was interpreted as confirmation of Na^+-dependent Cl^-/HCO_3^- exchange. A subsequent examination of the rate of decline of cell Cl^- following perturbations of the peritubular bath suggested that this transporter was the dominant pathway for peritubular Cl^- exit.[334]

Examination of the straight proximal tubule of the rabbit has not yielded consistent findings regarding the Na^+-dependence of Cl^-/HCO_3^- exchange. Sasaki and his associates, using pH-sensitive microelectrodes, first found a small cellular alkalinization with the removal of peritubular chloride.[591] Subsequent study with a Cl^--sensitive electrode demonstrated a substantial increase in intracellular chloride with reduction of peritubular bicarbonate, an effect that was blunted by the complete removal of sodium and blocked by SITS.[593] Using straight proximal tubules containing BCECF, Kurtz[401] found a peritubular Cl^-/HCO_3^- exchanger that could function in the absence of Na^+. A basolateral Cl^-/HCO_3^- exchanger in this segment was also identified by Nakhoul et al.,[500] but its Na^+-dependence could not be defined. A microelectrode study of the S3 segment of the rabbit was performed by Kondo and Frömter,[390] who observed that removal of bath Cl^- decreased intracellular Cl^-, alkalinized the cell, and produced no change in cytosolic Na^+. This effect was blocked by peritubular SITS. Further, reduction of peritubular HCO_3^- increased cell Cl^-, so that a strong case was advanced for the presence of a Na^+-independent Cl^-/HCO_3^- exchanger in the peritubular membrane. With reference to Table 33.3b, this exchanger must mediate chloride uptake by the cell. A cycle of this exchanger in association with a cycle of a luminal or peritubular Na^+/H^+ transporter would yield net cellular uptake of NaCl, and could increase the volume of the tubule cell. Indeed, the peritubular Cl^-/HCO_3^- exchanger has been implicated in the recovery of cell volume after shrinkage in a hyperosmolar medium.[434,435,570]

Electrically silent chloride exit across the peritubular membrane may also occur as co-transport of KCl.[710] This transport mechanism had been proposed in connection with studies of *Necturus* gallbladder by Reuss and his associates[559,560] as a means of rationalizing the necessary Cl^- exit with the low membrane chloride conductance, and was confirmed with the demonstration that intracellular chloride activity could be made to vary with variation in the basolateral potassium concentration.[163,558] With respect to the mammalian proximal tubule, beyond the need for Cl^- exit, the brisk influx of K^+ via the Na-K-ATPase mandates substantial peritubular K^+ exit. For the rat proximal tubule, it was estimated that the conductive pathway was inadequate to account completely for this exit, so that in the construction of a mathematical model of this epithelium a peritubular KCl co-transporter was incorporated.[727] The first evidence for the proximal tubule KCl co-transporter came with the experiments of Eveloff and Warnock[198] on rabbit renal basolateral membrane vesicles. Here, K^+ or Cl^- gradients drove uptake of the other species in a voltage-independent manner. These findings received support with observations of furosemide-sensitive cell volume decrease in rabbit proximal straight tubule,[743] and furosemide-sensitive K^+ exit in proximal tubule suspensions.[30,391] In proximal straight tubule, Sasaki et al.[589] used both K^+- and Cl^--sensitive microelectrodes to demonstrate the mutual interaction of K^+ and Cl^- across the peritubular membrane. This interaction was independent of membrane electrical potential, and independent of Na^+. These findings received confirmation in the proximal convoluted tubule, examined with Cl^--sensitive microelectrodes by Ishibashi et al.,[333] although

in this work, coupled KCl exit appeared to be insensitive to furosemide. A subsequent electrophysiological investigation also failed to detect furosemide-sensitive coupled K^+ and Cl^- fluxes.[626] At the molecular level, four KCl co-transporters have been identified within the SLC12 family (SLC12A4-7), also known as KCC1-4.[303,487] Cloning and expression of KCC1 was achieved by Gillen et al.,[246] who reported that it was widely expressed; KCC3 and KCC4 were cloned by Mount et al.,[488] who noted a more selective expression, including kidney for both.

Na,K-ATPase

Metabolically driven sodium extrusion from the cell and potassium uptake are effected by the Na,K-ATPase situated exclusively within the peritubular cell membrane.[358,403] The biophysical properties of this pump were a key focus of early investigations of epithelial transport.[249,348–350] The functional transport unit of the Na,K-ATPase consists of an alpha-subunit bound to cytoplasmic structural proteins[485] and an externally protruding beta-subunit. Although there are three isoforms for the alpha-subunit, only a single isoform (α_1) appears to be expressed in proximal tubule.[467,666] The beta-subunit appears to function as a molecular chaperone, targeting insertion of the transporter.[237] Together the alpha–beta unit spans the peritubular membrane and contains, within its interior, cation-binding sites. A gamma-subunit to the Na,K-ATPase exists within kidney, and has been identified as one member of the FXYD family of proteins with wide ranging organ distribution.[27,234,237] The role of the gamma-subunit remains uncertain, although it has been suggested that it may function to limit transport during hypoxia or other tissue stress.[25,26] The most widely held scheme[350] for the operation of the pump envisions a cycle which begins with an E1 state, in which ATP is bound to the alpha-subunit and the cation-binding sites are open to the cytoplasmic surface for the binding of 3-Na^+ ions. With the binding of Na^+, ADP is released, leaving a phosphorylated unit in which the cations are initially inaccessible to either membrane face (occluded). A conformational change in the transport unit brings it to the E2 state, in which the cationic-binding sites are open to the external surface. At this point the release of Na^+ is followed by the binding of 2 K^+ ions, and with hydrolysis of the phosphate bond, these K^+ ions are occluded. Binding of ATP is associated with the conformational transition back to the E1 state, and release of K^+ into the cytoplasm. Stoichiometry of the Na,K-ATPase was first established in nonrenal systems,[249,379,503] and this was confirmed in oxygen utilization experiments in whole kidney[371] or in tubule suspensions.[298,299] A suspension of rabbit renal cortical tubules was examined, using NMR to monitor Na^+ transport from the cell and a K^+-electrode in the suspending medium to determine K^+ uptake, and it was demonstrated that over nearly an order of magnitude of Na,K-ATPase turnover, the Na:K stoichiometry remained 3:2.[29] By virtue of this stoichiometry, the Na,K-ATPase generates a net outward current across the peritubular membrane; pump inhibition with ouabain induces prompt depolarization of the peritubular membrane in rat proximal tubule.[222]

Development of a microassay system for Na, K-ATPase by Schmidt and Dubach[605,606] permitted the first estimate of enzyme activity within individual tubule segments. Subsequently, Morel and his colleagues developed a simpler assay and identified the distribution of Na,K-ATPase along the nephron.[180,360] They found comparable distribution in rat, rabbit, and mouse, with substantially greater concentration of ATPase in proximal convoluted tubule than in the straight segment. Garg et al.[233] found Na,K-ATPase activities of the S1, S2, and S3 segments of rabbit proximal tubule to be 17.5, 6.7, and 3.8 pmol ATP/s · cm tubule. Under conditions of the assay, maximal hydrolytic activity of the enzyme was determined, so that maximal Na^+ transport is three times these values. Corresponding to the transport activity of the Na, K-ATPase, there is a free energy change of 28.6 J/mmol (Table 33.3) or 6.8 cal/mmol, a figure compatible with the free energy of hydrolysis of ATP of 13–14 cal/mmol.[686] El Mernissi and Doucet[195] quantified ouabain-binding sites of rabbit PCT, and found 0.109 pmol/cm or 25×10^6 sites/cell. Thus, the ATPase activity of 10 pmol/s · cm would correspond to about 100 cycles/s of a single Na,K-ATPase unit. The actual rate of sodium transport by the Na,K-ATPase is usually less than maximal enzyme activity, and is dependent upon the levels of intracellular Na^+, peritubular K^+, and intracellular ATP. Of these three factors, in proximal tubule *in vivo*, cytosolic Na^+ concentration is the most important regulator of pump activity.[348,359] The half-maximal enzyme activation occurs at 31 mmol/l,[249,647] a level which is comparable to normal intracellular chemical concentrations. The physiological correlate to this biochemical data is the observation in *Necturus* proximal tubule that the rate of sodium transport responds to variations in the cytosolic sodium concentrations (Figure 33.8).[650] This suggested that under normal conditions the luminal cell membrane is the rate-limiting step for sodium transport. With respect to peritubular K^+, half-maximal ATPase activation occurs at concentrations under 1.0 mmol/l.[249,647] In lysed membrane preparations, the half-maximal saturation of ATPase activity, with respect to ATP, occurs at 0.4 mmol/l.[348,648] Thus, at normal levels of intracellular ATP (1–3 mmol/l) there should be little change in the rate of hydrolysis with variation of

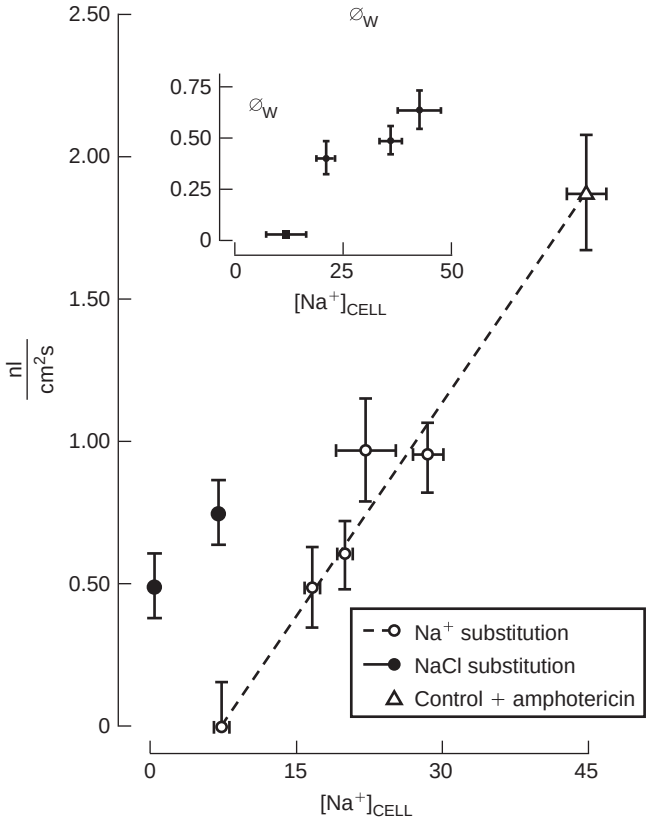

FIGURE 33.8 **Transepithelial water flow, Φ_w, (or, equivalently, transepithelial sodium flux) is plotted as a function of intracellular sodium concentration in *Necturus* proximal tubules. Intracellular sodium is decreased from the control value (30 mM) by substitution of luminal Na^+ with tetramethylammonium (or substitution of luminal NaCl with mannitol – see inset); sodium is increased above control by the luminal application of amphotericin.** *(From[650], with permission.)*

the ATP concentration. Nevertheless, in the intact tubule, partial inhibition of mitochondrial respiration produced proportional declines in cellular ATP and transport.[279] In a more extensive study, Soltoff and Mandel[646,648] found a linear correlation between cellular respiration and ion transport spanning a range of cellular ATP concentrations of 0–4 mmol/l. Thus, in the intact cell, it appears that ATP concentration can serve as an intermediary between transport and metabolism.

Coordination of Entry and Exit

Under normal circumstances, there may be several-fold variations in glomerular filtration rate to which the proximal tubule responds with nearly proportional changes in sodium reabsorption (*vide infra*). Although the mechanism underlying this glomerulotubular balance is not completely understood, the wide swings in the transcellular fluxes of sodium and bicarbonate pose a threat to the proximal tubule cell, with respect to maintaining a viable cell volume and pH. Such challenges are not unique to proximal tubule, but threaten all transporting epithelial cells, particularly the gastrointestinal epithelia, which experience swings in sodium-dependent glucose and amino acid uptake. In part, the kinetic response of Na,K-ATPase to cell Na^+ concentration will increase Na^+ exit (Figure 33.8), but this is generally insufficient to provide cellular homeostasis. Schultz and associates have emphasized the need for peritubular exit pathways to keep pace with luminal entry in order to preserve the integrity of cell composition and cell volume.[611,612,613] Beyond this, considerable attention has focused on the positive correlation between the potassium permeability of the peritubular membrane and the rate of epithelial sodium transport.[66,169] Increasing peritubular potassium conductance beyond enhancing potassium exit, should be expected to hyperpolarize the membrane, thus enhancing chloride and bicarbonate exit as well. The critical experimental observations were made in the epithelium of the small intestine of *Necturus*, from recordings with conventional and K^+-selective microelectrodes.[262,280] It was found that with the addition of alanine to the luminal solution there was a prompt depolarization of the cell interior in association with a doubling of sodium reabsorption. Over a period of several minutes the K^+ conductance of the basolateral membrane increased, repolarizing the cell and further enhancing sodium transport. The parallel response of peritubular K^+-conductance with reabsorptive Na^+ flux was subsequently documented in frog proximal tubule, following the application of phenylalanine to the tubule lumen,[473,474] and in the mammalian proximal tubule with luminal application of glucose and alanine.[67,408,409] Direct examination of the K^+ channel of the peritubular membrane via patch-clamp has shown that the increase in K^+-conductance with luminal application of organics is the result of an increase in the open probability of this channel.[65] Thus, attention focused on identifying the signal by which luminal solute entry could activate these channels. The two principal candidates for modulators of peritubular exit have been cell volume and coupling of the Na, K-ATPase activity with K^+-channel open probability (pump-leak parallelism) via cytosolic ATP concentration. The signaling and transport effectors for cell volume regulation have been extensively reviewed.[406,407]

Examination of *Necturus* small intestine indicated that both increased sodium transport and hypotonic cell swelling had similar impact on the basolateral membrane. These observations led to the proposal that a transport-associated increase in cell volume might mediate the enhanced K^+-conductance found with increased Na^+ reabsorption.[412] It had been known

since the experiments of MacRobbie and Ussing[446] that frog skin epithelium could volume-regulate. When the skin was placed in a hypotonic bathing solution, the initial swelling of the epithelial cells was followed by a gradual restoration of cell volume, presumably with the loss of cell solute. A critical observation was that hypotonic swelling of the toad urinary bladder was associated with increased basolateral membrane conductance.[210] In his analysis of cell volume regulation, Ussing[675] articulated the hypothesis that cell swelling was associated with the appearance or activation of both K^+ and Cl^- channels within the basolateral cell membrane, and loss of KCl via these pathways. With respect to proximal tubule, there has been considerable attention focused on the response of the peritubular membrane to increases in cell volume.[197,481,692] It was first noted in proximal tubules from the rabbit that exposure to a hypotonic solution was followed by a "volume regulatory decrease" (VRD).[170] This VRD was associated with a loss of cytosolic potassium.[261] In both *Necturus*[440] and rabbit tubules[378] cell swelling enhances peritubular K^+-conductance. Further, Kirk et al.[380] made the important observation that proximal tubule VRD occurred during isotonic swelling, where cell volume increased as a result of enhanced luminal Na^+ entry (rather than a hypotonic shock).

Proposed mechanisms of volume-induced K^+-conductance have included the direct effect of stretch on the K^+ channel or a volume-driven increase in cytosolic Ca^{2+}, with secondary channel activation. Patch-clamp studies have demonstrated stretch-activated K^+ channels within the peritubular membrane of amphibian proximal tubule,[362,582] as well as stretch-activated nonselective cation channels, which are permeable to Ca^{2+}.[207,208] In frog proximal tubule cells subjected to Na^+-alanine uptake, there is also evidence for stretch-activated anion channels.[475,567] In the mammalian tubule, stretch-activated K^+ channels have not been identified; however, it was observed that hypotonic cell swelling resulted in a rise in cytosolic calcium concentration.[462–464] This finding, in association with the appearance of Ca^{2+}-activated K^+ channels during hypotonic shock,[363] supplied a plausible mechanism for the increase in peritubular membrane K^+ permeability. In these studies (proximal straight tubules of the rabbit), blocking the rise in cytosolic calcium eliminated the hypotonic VRD. Questions were raised, however, by experiments in proximal convoluted tubule,[116] which indicated that VRD persists despite elimination of the rise in cell calcium. Most germane to the problem of coordinating entry and exit is the observation that when proximal convoluted tubules are exposed to luminal glucose and alanine, there is no significant increase in cytosolic calcium.[63] The importance of this result is the demonstration of differences in the cellular response to hypotonic swelling, and that due to enhanced luminal entry. Indeed, even in amphibian tubules, differences between hypotonic and isotonic VRD have been discerned, with Na^+-coupled alanine uptake the VRD is independent of external Ca^{2+}.[486] Critical insight into the coupling of transport to peritubular K^+ permeability came with the discovery that the peritubular K^+ channel open probability was decreased by increases in cytosolic ATP concentration in the physiological range.[664] With application of luminal glucose and alanine to rabbit proximal convoluted tubule, sodium transport increased, cytosolic ATP decreased, and peritubular K^+ conductance increased in proportion to the decrease in ATP.[64,664] When ATP was applied exogenously, this effect of luminal organics to increase peritubular K^+ conductance was eliminated.[664] Conversely, application of an inhibitor of the Na,K-ATPase increased cytosolic ATP concentration, and thus decreased the open probability of the peritubular K^+ channel.[322]

One question which received relatively little attention in these investigations, was whether the observed changes in peritubular membrane K^+ permeability were sufficient to rationalize the observed volume homeostasis. Contributing to this homeostatic effect is the impact of increased K^+ permeability to hyperpolarize the peritubular membrane, and thus augment chloride and bicarbonate exit. These events are complicated by the fact that peritubular hyperpolarization will also enhance luminal entry via the Na^+-glucose cotransporter, and cytosolic acidification (increased peritubular HCO_3^- exit) will enhance luminal entry via the Na^+/H^+ exchanger. The quantitative issue of the sufficiency of the documented pump-leak parallelism to maintain cell volume was examined in a mathematical model of proximal tubule.[735] In those calculations, it was found that with realistic bounds on the electrical conductance of the peritubular membrane, variation of K^+ permeability by itself does not provide adequate homeostasis for proximal tubule. Satisfactory volume regulation was achieved, however, when the activity of the peritubular $Na^+-3HCO_3^-$ co-transporter was allowed to vary directly in response to changes in the rate of luminal Na^+/H^+ exchange. Evidence for the coordination of these two transporters will be considered below. There are data regarding the anion lost in association with K^+ during cell swelling, and it appears to show some variability among species. In *Necturus*[440] and mouse tubules,[691] omission of bicarbonate impairs VRD and cell swelling is associated with enhanced peritubular HCO_3^- conductance.[690] In the straight proximal tubule of rabbit, however, removal of chloride impaired VRD, while omission of bicarbonate or the application of SITS had no inhibitory effect.[743] In the proximal convoluted tubule of the rabbit, hypotonic swelling increases both K^+-conductance and Cl^--conductance of

the peritubular cell membrane.[744,745] An intriguing examination of cell volume was undertaken in primary culture of mouse proximal tubule cells, comparing wild-type with knockouts of the peritubular K^+ channel, KCNE1.[47] The wild-type cells showed VRD with the appearance of swelling-induced K^+ and Cl^- channels; the knockouts showed neither K^+ nor Cl^- currents during swelling. When knockout cells were transfected with KCNE1, both swelling-activated K^+ and Cl^- currents were restored. These experiments demonstrated a close functional linkage between the two channels allowing a coordinated response to a volume challenge.

THE PARACELLULAR PATHWAY

The Lateral Intercellular Space

It had long been recognized that certain epithelia, such as gallbladder or small intestine, could transport water from lumen to blood against an adverse osmotic gradient. Curran[167] and Durbin[185] hypothesized that metabolically-driven salt transport into an intraepithelial compartment could drive transepithelial water flow, if the membranes bounding this compartment had suitable permeability properties. Subsequently, several groups of investigators[244,674,746] proposed that the space between the basolateral cell membrane and the basement membrane qualifies as the "middle compartment" within the epithelium. Salt transport into the interspace across the lateral cell membrane would induce an osmotic water flow across this membrane. Accumulation of salt and water within the interspace would then generate local hydrostatic pressure, sufficient to drive this solution out across the permeable basement membrane and connective tissue. This proposal identifies the lateral intercellular space as part of the pathway for the bulk of transepithelial water flow. Morphologic observations on gall bladder,[366,660] intestine,[752] *Necturus* proximal tubule,[76,456,457] and the isolated perfused rabbit proximal tubule[659] have all been confirmatory, showing interspace dilatation with reabsorptive flow and interspace collapse with cessation or reversal of flow.

It is also a secure finding that along the length of the proximal tubule the luminal sodium concentration differs little, if at all, from that in peritubular blood. This means that water reabsorption must occur in a constant proportion to sodium reabsorption. Windhager et al.[759] demonstrated that in *Necturus* proximal tubule the sodium flux drives the net water reabsorption. These investigators introduced into the tubule lumen solutions isosmotic with plasma, but with varying sodium concentration, in order to obtain a wide range of values for the sodium flux. Over the course of the experiment, the luminal osmolality did not change, indicating a negligible external driving force in the passive movement of water. Nevertheless, a plot of the net water flux as a function of the net sodium flux shows a line, the slope of which indicates that transport occurred isotonically (Figure 33.9a). A similar series of experiments was performed in rat proximal convoluted tubule by Morel and Murayama.[484] They again verified

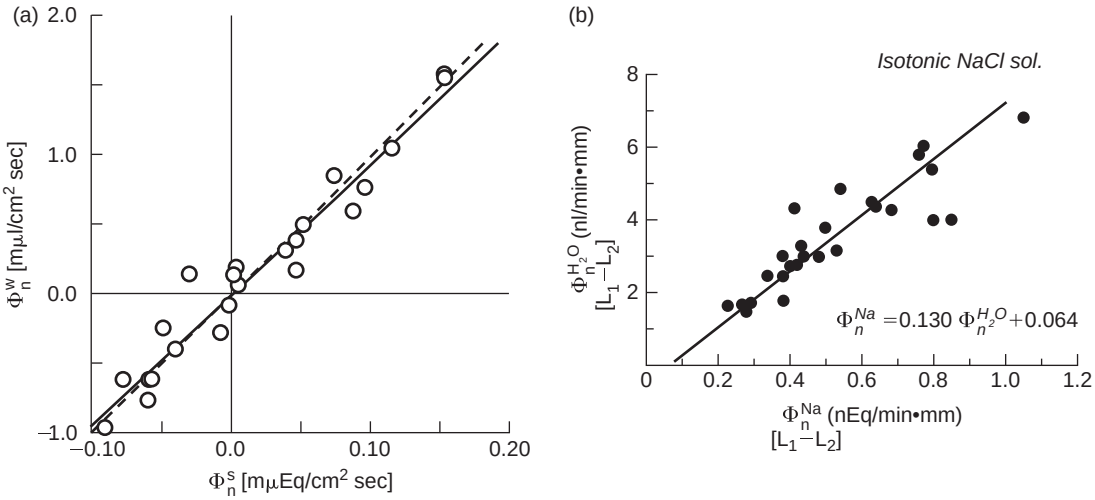

FIGURE 33.9 **(a) Correlation of net solute flux, Φ_n^s, and net water flux, Φ_n^w, across the perfused proximal tubule of *Necturus*. The least squares line of regression for the data points (solid line) is not statistically different from the line through the origin (dashed line), whose slope is that for isotonic water reabsorption. *(From[759], with permission.)* (b) Correlation of net sodium flux, Φ_n^{Na}, and net water flux, Φ_n^{H20}, occurring between two collection sites (L1 and L2) of a perfused rat proximal tubule. The line of regression for the data points (solid line) indicates isotonic transport of sodium.** *(From[484], with permission.)*

over a wide range of luminal sodium concentrations (and sodium fluxes) that the flux of sodium determined the flow of water. Further, the water flow occurred so as to maintain the lumen isotonic to plasma (Figure 33.9b).

The dependence of isotonic water reabsorption on sodium reabsorption has been referred to as "coupled water transport" to distinguish it from water flux referable to a demonstrable transepithelial osmotic gradient. This coupled water transport has been rationalized in an analysis of the lateral intercellular space as an intraepithelial middle compartment.[731,736,737] As in Figure 33.10, the lateral interspace is represented with a tight junction (J_A), basement membrane (J_B), and lateral cell membranes (J_L). A reference osmolality, C_0, is assumed (such as that of the blood), and the osmolalities of the interspace, $C_0 + C_E$, of the lumen and cell interior, $C_0 + C_M$, and of the peritubular solution, $C_0 + C_S$, are written in terms of increments above or below the reference. Each membrane, α, (α = A, B or L) has water and solute permeabilities $L_{p\alpha}$ and H_α, and a reflection coefficient σ_α. Transmembrane fluxes for volume and solute are denoted by $J_{v\alpha}$ and $J_{s\alpha}$. Assumptions may be made which simplify the analysis, but which maintain most of the important features of the lateral interspace model: (1) the tight junction is relatively impermeable, $L_{pA} = H_A = 0$; (2) the lateral cell membrane is relatively solute impermeable, $H_L = 0$, and $\sigma_L = 1$; but (3) there is fixed solute transport across the lateral membrane at a rate, N; and (4) the reflection coefficient for the interspace basement membrane and underlying tissue is zero, $\sigma_B = 0$. With these assumptions the transport equations for each membrane may be written, for volume and solute flows:

$$J_v = J_{vL} = L_{pL}[(P_M - P_E) + RT(C_E - C_M)] = J_{vB} = L_{pB}[(P_E - P_S)] \tag{33.9}$$

$$J_s = J_{sL} = N = J_{sB} = J_{vB}C_0 + H_B(C_E - C_S) \tag{33.10}$$

where P_M, P_E, and P_S are the hydrostatic pressures in the respective compartments. The equalities, $J_v = J_{vL} = J_{vB}$ and $J_s = J_{sL} = J_{sB}$, reflect the fact that in the steady-state, mass entry across the lateral membrane must be equal to that leaving the channel mouth. It may be noted that an additional approximation has been introduced into Eq. (33.10), in which the reference concentration, C_0, is identified as the mean basement membrane concentration.

When the mass balance relations are used to eliminate the unknowns P_E and C_E, from Eqs (33.10) and (33.11), one obtains an expression for transepithelial volume flow:

$$J_v = L_p(P_M - P_S) + RTL_p\left(C_S - C_M + \frac{N}{H_B}\right) \tag{33.11}$$

in which the epithelial water permeability, L_p, is given by the expression:

$$L_p = \frac{L_{pLB}H_B}{H_B + RTL_{pLB}C_0} \quad \text{where} \quad L_{pLB} = \frac{L_{pL}L_{pB}}{L_{pL} + L_{pB}} \tag{33.12}$$

Equation (33.12) describes the volume flow of the whole epithelial model in terms of the permeability parameters of the component membranes. It shows the volume flow to be a linear function of the pressure and osmolality of the bathing solutions. When there are exactly equal bathing media ($C_M = C_S = P_M = P_S = 0$), there is still transepithelial volume flow:

$$J_v^a = RTL_p\frac{N}{H_B} = RTL_p\hat{C} \tag{33.13}$$

This "active water transport," referenced in Eq. (33.9), thus arises naturally as a component of volume flow driven by intraepithelial solute–solvent coupling, i.e., the empirically described "coupled water transport." It increases with larger rates of solute transport and decreases when there is little solute trapping by the basement membrane (large H_B). The virtual concentration, $\hat{C} = N/H_B$, represents the strength of transport of the epithelium, in that volume flow just ceases when the osmolality of the luminal solution is raised by this amount. For a proximal tubule model one must also verify isotonic transport. In approximate terms, this means that only a small decrement in luminal osmolality is required for the reabsorbate tonicity to be equal to that of the peritubular fluid. Formally, one seeks the osmotic deviation, C*, such that if

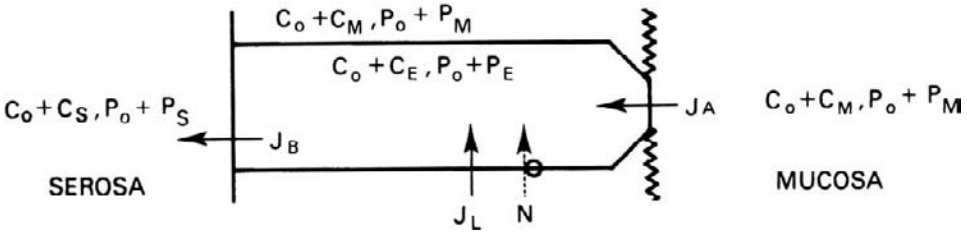

FIGURE 33.10 **Schematic representation of the lateral intercellular space**. The cell and mucosal medium are assumed to be at the same osmolality and pressure. *(From[736], with permission.)*

$C_S \approx C_0$, and $C_M \approx C_0 - C^*$, then $J_s/J_v \approx C_0$. This corresponds to solving the equation:

$$C_0 = \frac{J_s}{J_v} = \frac{N}{RTL_p(\hat{C} + C_s - C_M)} = \frac{N}{RTL_p(\hat{C} + C^*)} \quad (33.14)$$

which has the solution:

$$C^* = \frac{N}{RTL_{pLB}C_0} \quad (33.15)$$

When the luminal osmolality is decreased by the amount C*, transport is isotonic to plasma. Provided C* is at most a few mOsm/l, there will be no experimentally-detectable difference between lumen and blood. Transport is generally considered isotonic if C* is within 2% of C_0. It should also be noted that isotonic transport depends only upon the water permeabilities of the epithelial membranes. The notion of solute trapping within the interspace, which was crucial to uphill water transport, is really unimportant in the dynamics of isotonic transport.

Perhaps one of the confusing features of transport isotonicity is that the relevant membrane permeabilities may be quite different from the whole epithelial water permeability that is actually measured. The expression for L_p (Eq. (33.12)) shows that both water permeabilities and solute trapping effects are involved. Intuitively, this corresponds to the fact that water flow across the lateral membrane, driven by a hypotonic lumen, will tend to dilute the interspace and hence, negate some of the osmotic flow. The interspace dilution will be smaller for larger basement membrane permeabilities. This "intraepithelial solute polarization" effect is an inescapable feature of the lateral interspace. The expression for L_p may be rewritten:

$$\frac{L_p}{L_{pLB}} = \frac{1}{1 + \hat{C}/C^*} \quad (33.16)$$

which shows that to the extent that an epithelium can transport against a gradient (large $\hat{C}$), and yet reabsorb water isotonically (small C*), the observed epithelial L_p must be substantially smaller than the cell membrane water permeabilities.

In Table 33.4, this model is applied to the data of Tables 33.1 and 33.2 for proximal tubules of rat and rabbit. The upper panel shows rates of isotonic reabsorption, along with the measured water permeabilities. For the rat, two values for L_p are given, corresponding to the older[672] and later determinations.[536] A value for the equilibrium deviation from isotonicity (C*) has been assumed to be at 2% of the ambient osmolality. At least in the rat, this is comparable to experimental determinations.[265,432] The quantities in the lower panel of the table are derived from the experimental data using the model equations. The estimate of cell membrane water permeability required for isotonic transport, RTL_{pLB}, is just J_v/C^*. If the value of RTL_{pLB} computed for the rabbit tubule is referred to the luminal and lateral cell membranes in series, each of 36 cm^2/cm^2,[738] then one obtains a unit membrane water permeability, consistent with direct estimates, using rapid video techniques.[136,741] In theory, the AQP1 knockout mouse, deficient in water channels from both luminal and peritubular cell membranes, provides a pure decrease in the parameter RTL_{pLB}. The experimental observations in this knockout were an overall epithelial water permeability (L_p) about 22% that of wild-type (Schnermann et al., 1998), and luminal hypotonicity (C*) about four-fold greater than wild-type.[677] In terms of the model developed here, and with the assumption that active Na^+ transport is little changed in the knockout mouse, the change in C* should reflect a 78% reduction in L_{pLB}. The fact that the fractional change in overall L_p is comparable indicates that in the mouse, one would expect little intraepithelial solute polarization, and thus little capacity for water reabsorption against an adverse osmotic gradient. The discrepancy between the overall epithelial water permeability and that of the cell membranes in series, allows the calculation of the strength of transport, $\hat{C}$ in Eq. (33.13).

Williams and Schafer[754] have emphasized that the middle compartment need not be the true lateral interspace, but could actually be the cortical interstitial space. In their model of rat proximal tubule, the salt permeability of the peritubular capillary corresponds to the term H_B used here. With estimates of cell membrane water permeability and capillary solute permeability comparable to those of the first column in Table 33.4, they also predicted that solute polarization would reduce the epithelial L_p to about 50% of that of

TABLE 33.4 Application of the Interspace Model to Proximal Tubule

		Rat PCT	Rat PCT	Rabbit PCT
J_s	($nOsm/s \cdot cm^2$)	19	19	9.0
J_v	($nl/s \cdot cm^2$)	65	65	30
$RTL_p \times 10^4$	($cm/s \cdot Osm$)	44	22	63
P_f	(cm/s)	0.24	0.12	0.35
c*	(mOsm/L)	6	6	6
$RTL_{LB} \times 10^4$	($cm/s \cdot Osm$)	105	105	50
$\hat{c}$	(mOsm/L)	8	23	–

$H_B \times 10^4$	(cm/s)	24	8.3	–

the cell membranes. For the rat, the discrepancy between L_p and L_{pLB} requires that active water transport be substantial, i.e., from 55–80% of the isotonic flux (Table 33.4). In the more detailed models of proximal tubule epithelium which have been developed there is considerable disagreement in the estimates of coupled water flux, ranging from predominant[323,324,583,657] to negligible.[14,595,707,753] In a simulation of the rat proximal tubule, in which both isotonic transport and the whole epithelial L_p were reproduced faithfully, coupled water flux was estimated to be about two-thirds of the isotonic transport rate.[727] This corresponded to a strength of transport of 23 mOsm/l of NaCl. There are few experimental studies examining uphill water transport by the proximal tubule. Bomsztyk and Wright[105] reported that in rat tubules, microperfused with a low bicarbonate (10 mEq/l) luminal solution, an additional 30 mmol/L of mannitol was required within the lumen to nullify volume reabsorption. Although the interpretation of this experiment was complicated by the presence of several forces favoring water reabsorption (anion gradients and protein oncotic forces), the findings suggested a substantial component of solute-linked water reabsorption by the rat proximal tubule. Green et al.[267] examined the doubly perfused rat proximal tubule, specifically with the aim of determining the presence of active water transport. Using low bicarbonate solutions in both tubule and capillary perfusions, an isotonic luminal solution yielded reabsorptive water flux of 1 nl/mm · min. Varying only the luminal NaCl concentration allowed the determination of volume flux as a linear function of the transepithelial salt gradient (Figure 33.11). Regression analysis indicated that a luminal osmolality between 13 and 29 mosm/l (depending on peritubular protein concentration) greater than in peritubular blood would be required to null volume reabsorption. These experiments document active water transport by rat proximal tubule, quantitatively close to model predictions, and thus provide support for solute–solvent coupling within the lateral intercellular space.

The interspace outlet permeability, H_B, is a parameter of critical importance. It directly determines the strength of transport (Eq. (33.13)), and when this solute permeability is sufficiently small ($H_B < RTL_{pLB}C_0$) it is dominant in determining the epithelial L_p (Eq. (33.12)). Persson and Spring[525] examined the subepithelial tissue of *Necturus* gallbladder and found that it has only about twice the resistivity of free solution. They argue, therefore, that any important limitation to solute exit from the interspace must derive from the small area of the lateral interspace as it abuts the basement membrane. More recent experiments using photoactivation of caged fluorescent dyes have indicated that solute

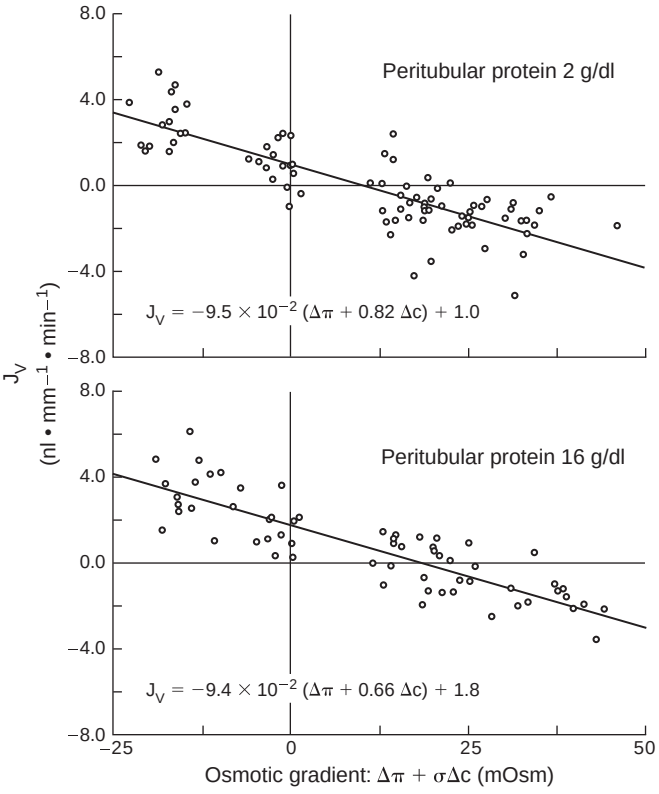

FIGURE 33.11 **Volume flux as a function of transepithelial osmotic driving force in rat proximal tubules, in which both lumen and peritubular capillaries have been perfused**. Each point corresponds to a single tubule perfusion. The abcissa is the transepithelial osmotic driving force, $\Delta\pi + \sigma\Delta C$; the ordinate is the measured volume flux, J_v. For each protein concentration, the line shown is the graph of Eq. (33.1), so that the ordinate intercept, J_v^a, is the coupled water transport (water flux in the absence of a transepithelial driving force.) The abcissa intercept is the concentration of the luminal impermeant required to null volume reabsorption. *(From[267], with permission.)*

diffusion within the lateral interspace is comparable to that in free solution.[770] Such had been the assumption in analytical estimates of the electrical resistance of the interspace fluid of proximal tubule from ultrastructural data. Mathias,[453] using data from the rabbit[739] estimated interspace resistance at about 4% that of tight junction, and Maunsbach and Boulpaep[458] calculated 4–21% of epithelial resistance may be attributed to the interspace. Welling et al.[740] have indicated that beyond the limitations of interspace width, interdigitating cellular elements at the base of the interspace may provide the most important barrier to mass exit. With reference to Table 33.4, Eq. (33.13) defines the outlet permeability required by the model ($H_B = N/\hat{C} = J_s/\hat{C}$). For the rat, H_B is predicted to be $8.3–24 \times 10^{-4}$ cm/s. When interpreted as an electrical resistance (Eq. (33.4)), this is 0.4–1.1 ohm · cm^2, and is not incompatible with the whole epithelial resistance of 5–10 ohm · cm^2.

The Tight Junction

The tight junction of the proximal tubule provides a low resistance pathway between the luminal solution and the lateral intercellular space. Morphologically, the tight junctions have been identified with the "zonula occludentes," visualized in electron microscopy, in which there is no detectable space between the epithelial cells. Freeze-fracture techniques indicated the fibrillar structure of these junctions, with relatively few fibrils present in the junctions of the proximal tubule.[156,539] In epithelia with greater electrical resistance, there are, correspondingly, a greater number of fibrils.[155,156] The TJ strands may be viewed as chains of particles, with typical spacing of these particles, as seen in freeze-fracture electron micrographs, being in the order of 20 nm.[509] The structural composition of these strands has been deciphered slowly.[477,608] Occludin was the first of the transmembrane proteins to be associated with the tight junction,[228] and to be implicated in a functional role in junctional permeability.[461] An important advance came with the identification of claudin-1 and claudin-2 within the junctional strands.[226,229] When claudin-2 was introduced into the Madin–Darby canine kidney (MDCK) cells, a conversion from a very "tight" junction to a "leaky" junction was observed.[227] This suggested that claudin-2 could be responsible for the leakiness of the MDCK epithelium and the formation of pores between apposing TJ strands. Indeed, when the claudins expressed in MDCK cells are selectively modified, the paracellular conductance of small electrolytes can be modulated, including the anion/cation selectivity preference.[159] The sodium conductance of tight junctions containing claudin-2 can also be modulated by changes in ambient calcium concentration.[785,786] Claudin-2 exists throughout the proximal tubule, and in a contiguous early segment of the thin descending limb of long-looped nephrons in mouse kidney.[196] In mice with deletion of the claudin-2 gene, the proximal tubules have a 2.5-fold increase in electrical resistance, due to a decrease in tight junctional Na^+ permeability.[495] Although these mice have normal renal function, they do excrete a Na^+ infusion more rapidly than wild-type mice. Of note, the high Na^+ permeability of proximal tubules appears as a maturational event, and is not present in the neonatal period in which natriuresis figures prominently.[57,546] Apparently, claudin-2 expression of proximal tubule is subject to modulation by changes in metabolic status, and in the rat is downregulated during metabolic acidosis.[37] If the impact of decreased claudin-2 is to increase distal NaCl delivery, this might be expected to enhance the distal nephron functions of K^+ and net acid excretion.

Like proximal tubule, other leaky epithelia (gallbladder, small intestine) also transport large volumes of salt solutions isotonically, and this encouraged speculation as to the function of the tight junction in isotonic water transport. A number of mathematical simulations of proximal tubule addressed this issue,[323,324,583,651,657,736,737] but have simply not provided an answer as to why electrical leakiness should correlate with the ability to transport isotonically. The fraction of reabsorptive water flow which actually traverses the tight junction is also unknown. Arguments in favor of transjunctional water flow in proximal tubules have included: substantial solvent drag of ionic species[16,106,224,266,308,361,596]; the appearance of streaming potentials with the application of an impermeant osmotic agent[164,221,661]; and ionic permeabilities roughly in proportion to their mobility in free solution.[392] None of these findings, however, provides proof of tight junctional water flow. Either streaming potentials or solvent drag can come as the result of a solute polarization effect within the interspace. With solute polarization, water flux across the cell and through the lateral interspace alters interspace ion concentrations, thus promoting either a diffusion potential or diffusive flux across the tight junction. For a true streaming potential, water flux across the tight junction must be present and carry either an anion or cation preferentially. This issue was addressed by Tripathi and Boulpaep[661] in their measurements of streaming potentials across the proximal tubule of *Ambystoma*. With the application of peritubular sucrose, a lumen-positive potential appeared, consistent with either a streaming potential or interspace NaCl depletion (and an anion-selective junction). When ambient chloride was replaced by cyclamate, the junction became cation-selective and its total conductance substantially decreased. Repeat application of peritubular sucrose produced the same lumen-positive potential, now inconsistent with a diffusion potential. With respect to the solvent drag measurements, it is undisputed that intraepithelial solute polarization may produce an overall reflection coefficient that is substantially less than that of the cell and tight junction, taken in parallel. The question is thus a quantitative one, as to whether one could construct a model of proximal tubule with just the right solute polarization to yield realistic reflection coefficients as well as a proper L_p. So far, this does not appear possible. For the rat, the data of Frömter et al.[224] were used to determine composite interspace models for this epithelium.[730] It was found that all of the acceptable interspace models required substantial tight junction convective chloride flux.

An apparently direct argument for tight junctional water flux in rabbit tubules came from Whittembury and associates,[135,253,748] whose estimate of the water permeability of the peritubular cell membrane

indicated a transcellular water permeability less than the overall epithelial L_p. The unit membrane water permeability obtained with this technique has received confirmation in a vesicle preparation,[687,689] although higher values have also been obtained.[683] Strong evidence for tight junction water flow was also obtained in the rat, with observation of substantial convective entrainment of sucrose, despite relatively small diffusional flux.[747] The small diffusive component effectively rules out interspace solute polarization as a confounding factor. Nevertheless, an objection had been raised by Rector and Berry,[80,553] who presented calculations based on pore theory which indicated that the tight junctions were not large enough to allow passage of a significant fraction of transepithelial water flow. Subsequently, Preisig and Berry[536] measured the permeation of sucrose and mannitol across the rat proximal tubule. Applying the Renkin equations to their data, they computed the dimensions of the "sucrose pore," and indicated that it could be responsible for at most 2% of the tubule water permeability. It was acknowledged, however, that a smaller paracellular pore that did not admit the sucrose molecule could account for up to one-third of the water permeability. An important contribution to this discussion came with the suggestion of Fraser and Baines[213] that the tight junction might be more realistically represented as a fiber matrix, rather than as a collection of pores. The critical feature of the fiber matrix equations is that for a given solute permeability, the water permeability can be substantially greater than that predicted from the Renkin equations. It was demonstrated that this formulation was compatible with the known permeabilities of rat proximal tubule.[213] Alternatively, Guo et al.[281] reproduced a pore-theoretic representation of the tight junction, utilizing two pores to fit the mannitol and sucrose data of Preisig and Berry.[536] In this model, the two pores were given anatomic correlates: the small pore was referred to gaps in the apposition of claudins molecules, while the large pore corresponded to breaks within a strand, occupying about 2% of its length. With these dimensions, tight junction water permeability was predicted to be about 21% of transepithelial water permeability.

With the tight junction established as a route for reabsorptive solute flux, a hypothesis was advanced that the junction might be an important site for the regulation of proximal sodium reabsorption. Lewy and Windhager found that in rats, both with and without acutely elevated renal venous pressure, there was a direct correlation between single nephron filtration fraction and proximal tubule sodium reabsorption.[418] Given that lower filtration fractions would result in reduced protein oncotic pressure within the peritubular capillaries, they surmised that this would lead to reduced capillary uptake of fluid from the renal interstitium and lateral intercellular space and, hence, elevated interspace pressure. This, in turn, would result in increased backflux of the sodium, already transported into the interspace, that is, backflux across the tight junction into the lumen. At the time of this proposal, attention had focused on intrarenal mechanisms responsible for the natriuresis of extracellular fluid volume expansion with saline.[187,383,384] Dirks et al.[173] had shown that proximal tubule sodium reabsorption was depressed following saline expansion. In the dog, the ability to reverse the natriuresis with infusion of hyperoncotic albumin indicated that peritubular oncotic pressure could influence sodium reabsorption, and Earley and his associates[186,451] had proposed that renal interstitial pressure might be an intermediate variable. Subsequent micropuncture experiments in the rat documented enhancement of proximal sodium reabsorption by peritubular protein.[113,114,385] In particular, the depression of proximal tubule sodium reabsorption which occurs with saline infusion could be reversed by perfusion of the efferent arteriole with a solution whose protein concentration is comparable to that under control conditions.[115,649] It has been well-documented that changes in the ambient protein concentration alter sodium reabsorption by the perfused proximal tubule. In the isolated perfused rabbit proximal tubule, Imai and Kokko found enhancement of sodium reabsorption with increasing concentrations of protein in the bathing solution.[331] In the absence of peritubular colloid, the permeability of the tubule to sucrose was increased. In the rat kidney, Green et al.[269] studied proximal tubule volume reabsorption when albumin was present in varying concentrations in luminal or peritubular capillary perfusates. Figure 33.12 shows the asymmetry (luminal versus peritubular protein) and the non-linearity of the reabsorptive enhancement by peritubular colloid. This implies that the colloid effect is not a simple oncotic force, such as might be reckoned using Eq. (33.1) and the known water permeability. It does suggest that the increase in peritubular capillary albumin changes the "state" of the epithelium to make active sodium transport more efficient at driving volume reabsorption. A comparable asymmetric effect of protein on salt reabsorption was also documented in rabbit proximal convoluted tubule *in vitro*.[332]

It is a tenet of the backflux hypothesis that the action of peritubular protein is mediated through an effect on renal interstitial pressure and hence, pressures within lateral intercellular spaces. In substantiation of this point, decreases in peritubular capillary oncotic pressure, which occur with saline volume expansion, result in increases in renal interstitial pressure (as least as assessed by renal subcapsular pressures).[515,516,548,629]

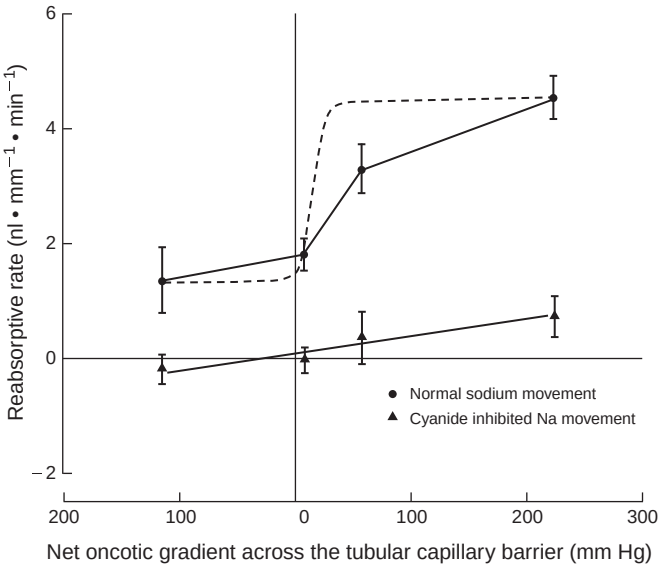

FIGURE 33.12 **Effects of transtubular oncotic pressure gradients on volume reabsorption by rat proximal tubule**. Both tubule lumen and peritubular capillaries are perfused with identical Ringer's solutions to which variable amounts of albumin have been added. In the tubules perfused with cyanide (lower curve) spontaneous sodium reabsorption has ceased and the effect of oncotic pressure is blunted. *(From[269], with permission.)* The dashed curve represents the prediction of an interspace model in which the tight junction is compliant. *(From[732].)*

Prevention of this rise in interstitial pressure by applying a renal artery clamp also prevents the fall in absolute proximal reabsorption associated with saline expansion.[212,327] Further, the deliberate increase of renal interstitial pressure by the instillation of fluid decreases proximal sodium reabsorption and produces a natriuresis.[260,287] Morphologic examination of the proximal tubule of the rat[75,140] has shown progressive dilation of the lateral intercellular space, as well as opening of the interspace at the tubule basement membrane, with increments of saline volume expansion. The precise mechanism of sodium "backflux" across the tight junction remains to be delineated. One possibility is that with increased interstitial pressure there is junctional widening and diffusion of sodium from interspace to lumen. A small decrease in epithelial electrical resistance has been documented with saline-loading in the rat.[621] In the rat, mannitol injected into the proximal tubule does not permeate and is completely recovered in the urine. However, with massive saline diuresis, as with renal venous constriction or elevated ureteral pressure, a significant fraction of the mannitol traversed the tubular epithelium into the systemic circulation.[442] Similarly, sucrose infused into the systemic circulation may permeate the proximal tubule epithelium during periods of renal vein constriction.[42] Perhaps the strongest objection to the view that sodium diffuses back across widened junctions is that, at least in the rat proximal tubule, the electrodiffusive force on sodium is likely to be in the reabsorptive direction. A second possibility is that backflux of sodium across the tight junction occurs by convective flow. The tight junctions of the leaky epithelia are very sensitive to hydrostatic pressures applied from the contraluminal side. In rabbit gallbladder[684] and *Necturus* proximal tubule,[259,301] contraluminal pressures drive substantially greater volume flow across the epithelium than an equal luminal pressure. In *Necturus*, volume expansion decreases the proximal tubule NaCl reflection coefficient.[77] In these experiments, it is likely that junctional structure is distorted, forming relatively large pores with negligible sieving of solute, as both salt and water return to the lumen. Indeed, in the meticulous study of van Os et al.[684] on the rabbit gallbladder, serosal pressures drove water back into the lumen at a rate 30-fold greater than would have been predicted from the osmotic water permeability of this epithelium. This occurred with little change in diffusional solute permeability. These investigators suggested that their results were most compatible with a serosal pressure effect of opening up relatively large water channels at a small number of junctional loci. Convective backflux across the tight junction of rat proximal tubule has been invoked by Ramsey et al.[550] to explain their observation that the luminal appearance of lanthanum deposited within the renal interstitium is enhanced during saline volume expansion.

The mathematical model of the lateral interspace, set out in the previous section, cannot represent the peritubular oncotic effects on sodium reabsorption considered above.[728] However, when this model is extended by inclusion of a compliant tight junction, a regulatory effect of peritubular Starling forces can be simulated.[732] In this case, tight junction "compliance" signifies that both junctional salt and water permeability increase, and the salt reflection coefficient decreases in response to small pressure differences from lateral interspace to tubule lumen. Although these compliance properties were completely empirical, they provided a model in which decreases in peritubular protein (which increased interspace hydrostatic pressure) opened the tight junction, and produced a secretory salt flux. This backflux was a combination of both diffusive and convective terms, and did not specifically require either component to dominate. When this model was used to simulate the experiments of, Green et al.[269] the model predictions were consistent with the observed reabsorption. The predicted fluxes appear as the dashed curve in Figure 33.12. In this model of the tight junction, once the interspace pressure falls below that of the lumen, the junction is closed and junctional properties are fixed. The consequence of junction closure in

the simulation of Figure 33.12 is that beyond a certain value of peritubular protein, one expects little influence of peritubular Starling forces on volume reabsorption. In this light, it is not surprising that a number of investigators found no significant influence of peritubular protein on proximal reabsorption,[40,161,315] and even interstitial Starling forces could correlate poorly with sodium transport.[103,472,665] Consistent with this view are the observations by Ott et al.[516] that in the dog, hyperoncotic albumin infusion increased proximal reabsorption only in the previously volume-expanded group. In the isolated perfused proximal tubule of the rabbit, several reports have indicated a lack of effect of peritubular bath protein on paracellular permeability.[79,82,410] Pirie and Potts[529] explored the influence of pressure gradients in this preparation. They found that elevations in intraluminal hydrostatic pressures abolished the effect of peritubular protein to enhance sodium reabsorption. Although they did not offer a specific explanation for their data, the present considerations might suggest that with higher luminal pressures, the tight junction always stayed closed.

REGULATION OF PROXIMAL NaCl TRANSPORT

Convergence on NHE3

Considerable attention has been given to understanding proximal sodium reabsorption in relation to neural and hormonal signals, and to changes in glomerular filtration rate. The luminal membrane Na^+/H^+ exchanger is responsible for both $NaHCO_3$ reabsorption and a substantial component of NaCl reabsorption. This, along with the fact that luminal entry is rate-limiting for transcellular sodium flux, renders the antiporter ideally suited as a regulatory site for proximal reabsorption. Indeed, a coherent picture has emerged in which every signal that regulates proximal Na^+ reabsorption converges on NHE3. A remarkable diversity of pathways has been identified as proximate modifiers of the antiporter.[176,177,243,270,300,478,717] Regulatory signals to NHE3 converge on the carboxy-terminal tail of the transporter, and Donowitz and Li[176] have organized the NHE3 binding partners and signals anatomically, according to their position on this tail (Figure 33.13). Of these, the most important is inhibition by cAMP-dependent phosphorylation of the antiporter by protein kinase A (PKA).[351,479,722] Liu and Cogan[430] examined bicarbonate reabsorption by the S1 segment of rat proximal tubule following a variety of maneuvers designed to affect cellular cAMP concentration. When luminal appearance of cAMP is used as a measure of cytosolic concentration, the correlation with bicarbonate transport over nearly a 10-fold range is striking (Figure 33.14). The acute nature of these experimental maneuvers must be emphasized, since the impact of chronic stimulation by cAMP is different.[131] Beyond cAMP effects, NHE3 activity is also phosphorylated acutely by the calcium−phospholipid-dependent protein kinase, PKC,[354,470,720,721,750] by direct signals from G-proteins,[6] and perhaps by a tyrosine kinase.[247] Beyond transporter phosphorylation, rapid regulation of sodium reabsorption via NHE3 is achieved through cellular machinery that makes NHE3 physically available within the brush border membrane, including insertion and retrieval of transporter from subapical vesicle pools.[104,199,307,790] Ultimately, chronic NHE3 regulation must be referable to the protein synthetic machinery.[317,130,248]

Of the signals that impact NHE3 flux, the first to be studied was the decrease in Na^+/H^+ exchange via cAMP-dependent phosphorylation, initially as a consequence of parathyroid hormone (PTH)-binding. This signal pathway is critical to the action of angiotensin II and dopamine, and will be considered below. The PTH effect was documented in isolated perfused proximal tubules,[171,293] and paralleled the effect of cAMP when examined in tubule suspensions[174] or brush border membrane vesicles.[351] A major advance came with the identification of a protein cofactor, NHERF-1 (NHE regulatory factor), which is required for cAMP phosphorylation of NHE3.[723,726,792] Ultimately, a number of such regulatory proteins have been identified whose role has come to be recognized as scaffolding molecules, for which transporter-binding occurs by virtue of their tertiary structure, termed PDZ domains.[93,175,176,716] The OK cell is a proximal tubule cell line from opossum kidney that expresses NHE3 and NHERF-1, and which displays cAMP-dependent inhibition of NHE3. This cell served as a preparation in which to demonstrate the physical link between NHE3 and NHERF-1, as well as a link between NHERF-1 and ezrin.[405] Ezrin is a protein kinase A (PKA) anchoring protein, as well as a linking molecule to the actin cytoskeleton. The scheme that emerged was that of a multiprotein signal complex, in which NHERF and ezrin brought PKA and NHE3 into proximity[718,724] (Figure 33.13). Supporting this picture in the intact kidney was immunocytochemical co-localization of NHE3, NHERF-1, and ezrin within the brush border of rat proximal tubule.[693] Although mice with homozygous deficiency of NHERF-1 show normal electrolytes, brush border membrane vesicles from these mice showed no effect of cAMP to inhibit NHE3 activity, despite normal protein levels of NHE3, PKA, and ezrin.[632,725] Cultured proximal tubule cells from these mice display absent regulation of NHE3 by

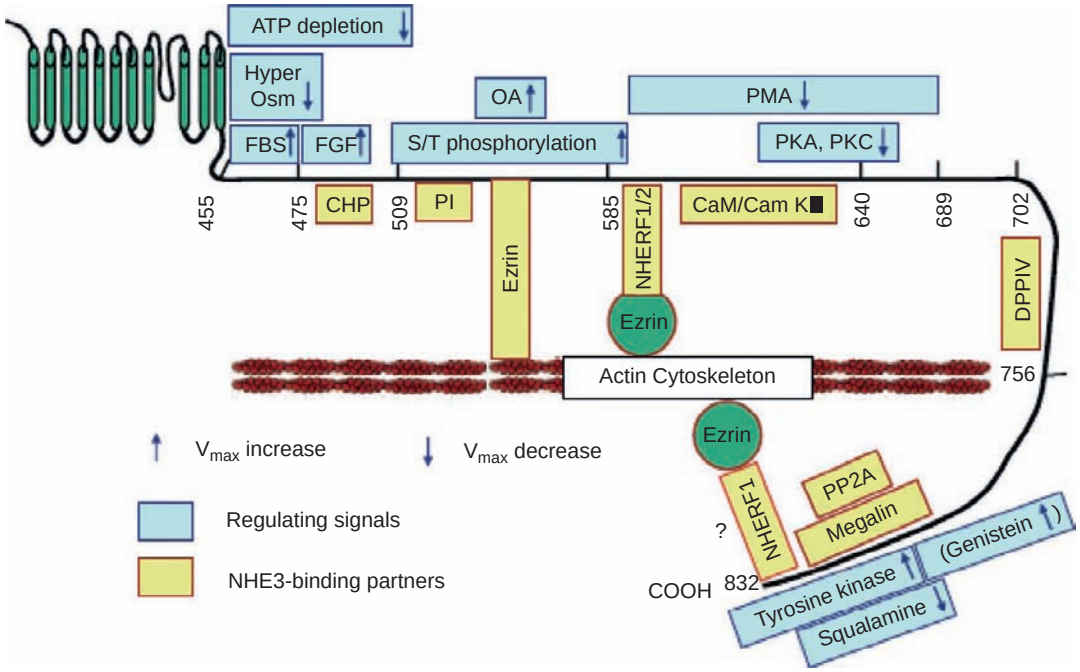

FIGURE 33.13 **NHE3 organization, including COOH-terminal domains involved in acute regulation and binding partners**. Shown above the COOH terminus in blue are sites of action of regulatory stimuli defined by the truncations, which abolish the specific regulatory effects. The direction of the arrow indicates acute stimulation or inhibition of NHE3 activity. Below the COOH terminus in yellow are listed associating proteins and the areas of their binding sites on NHE3. *(From[176].)*

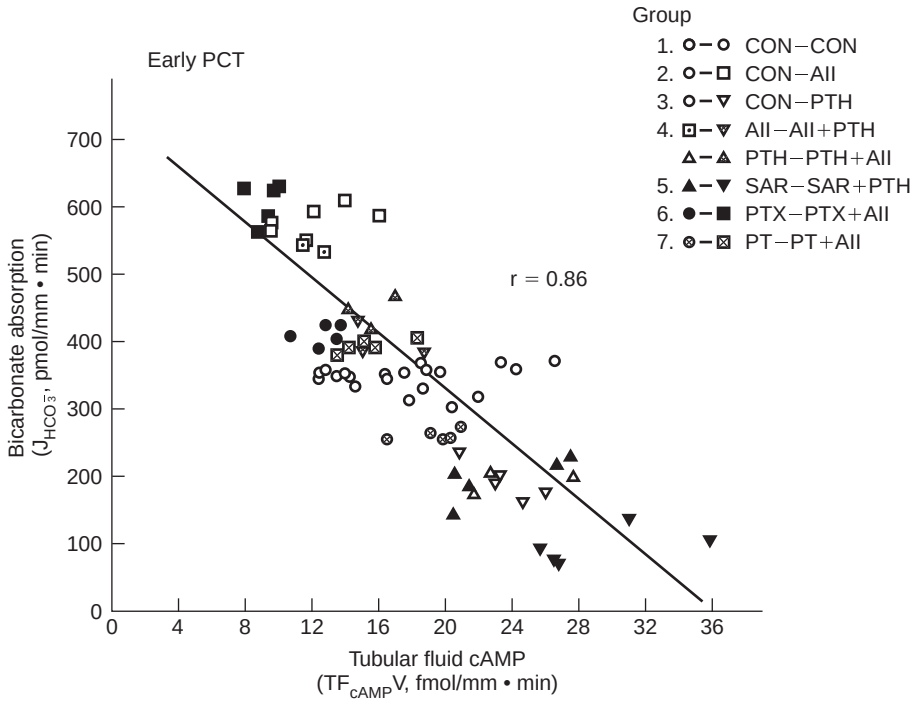

FIGURE 33.14 **Relationship of bicarbonate absorption to tubular fluid cAMP delivery in the early S1 segment of PCT**. A variety of maneuvers have been used to alter cellular content of cAMP, including parathyroidectomy (PTX) or infusion of angiotensin II (AII), parathyroid hormone (PTH), saralasin (SAR) or pertussis toxin (PT). *(From[430].)*

PTH, which could be restored via transfection with adenovirus containing the gene for NHERF-1.[166] Although NHERF-1 binds to the proximal tubule luminal membrane Na^+-phosphate co-transporter, NaPi-2a, and although NaPi-2a is downregulated by PTH, the NHERF-1 role in this context may be quite different from its NHE3 paradigm. In the case of NaPi-2a, NHERF-1 affects trafficking,[632] but there is no evidence that NHERF-1 is involved in the PTH-induced cAMP-dependent phosphorylation of this transporter.[93,94]

Beyond chemical modification of a fixed contingent of microvillous Na^+/H^+ exchangers, there is regulation of the NHE3 density within the luminal membrane.[466,633] An early observation in cultured proximal tubule cells was that PTH perturbed actin filament structure and caused microvillous shortening, events not replicated with application of cAMP alone.[252] Subsequently, density-gradient centrifugation of cell homogenates permitted examination of distinct membrane vesicle populations from rat proximal tubule suspension. It was found that PTH treatment resulted in migration of Na^+/H^+ exchange activity from one fraction to another, and then disappeared.[307] With the availability of NHE3-specific antibody, the distinction between Na^+/H^+ activity and NHE3 abundance could be made. Using vesicles prepared from the kidneys of parathyroidectomized rats treated acutely with PTH, it was found that within minutes of treatment Na^+/H^+ activity decreased, and phosphorylated NHE3 appeared. Over the course of hours, brush border NHE3 antigen declined, and this could be blocked by pretreating the animals with colchicine.[199] The ability of PTH to couple to adenylate cyclase appears to be critical to its ability to provoke NHE3 redistribution.[790] Events *in vivo* were mimicked in OK cells in which PTH induced a rapid phosphorylation of membrane-bound NHE3 and a parallel decrease in function, and then a slower retrieval of the cell surface transporter into an endocytic pathway.[160] Disruption of the actin cytoskeleton in proximal tubule suspension produced an increase in NHE3 abundance in luminal membrane vesicles prepared from these tubules.[142] A precise role, however, for the actin cytoskeleton in the regulation of NHE3 function has been elusive. Beyond transporter retrieval, the state of cellular actin fibers has been implicated in modulation of PKA phosphorylation of NHE3, consistent with its physical association with the NHERF–ezrin complex.[399,654] An additional complication is that the retrieval destination of apical transporters may be transporter-dependent. Whereas PTH *in vivo* produces transfer to endosomes of the luminal membrane sodium–phosphate transporter, the destination of NHE3 appears to be a reserve compartment at the base of the microvilli.[774] In addition, NHE3 is also internalized in association with megalin to a distinct vesicle compartment[98,101]; this appears to be critical to the action of the proximal tubule to reabsorb and process luminal proteins in OK cells and in mouse.[240,241] The kinetics of insertion and retrieval of NHE3 are clearly altered in consequence to demands for proximal Na^+ conservation (see below), although precise mechanisms remain uncertain, due in part to the uncertainty of extrapolation from cell culture preparations to tubules *in vivo*.

Modulation of the Na,K-ATPase

All of the regulatory signals that impact on the luminal Na^+/H^+ exchanger also modulate the Na,K-ATPase.[204] Early study of the action of PTH in OK cells identified the release of inositol triphosphate (IP3) and diacyl glycerol, along with an increase in cytosolic Ca^{2+}. In intact proximal tubule cells and basolateral membrane vesicles, it was possible to confirm the IP3 release.[320] With this information, it was natural to focus on the role of protein kinase C (PKC) in mediating the PTH-induced decrease in proximal Na^+ reabsorption. Baum and Hays[55] were first to examine the effect of PKC activation on PCT transport, and demonstrated inhibition of bicarbonate, chloride, and glucose transport by rabbit tubules *in vitro*. This global effect on multiple solutes was consistent with inhibition of the Na,K-ATPase, and this was the finding of Bertorello and Aperia,[85] who determined maximal Na,K-ATPase activity in rat proximal tubules preincubated with a PKC activator. The logical connection of these portions of the story was the demonstration that PTH inhibited maximal Na,K-ATPase activity in tubules in which cytosolic Na^+ was elevated by the ionophore, monensin.[562] This stimulation also occurred when a truncated PTH analog was used, which had no PKA activity, so that the Na,K-ATPase inhibition was dissociated from cAMP generation. These observations were supported by the finding in intact tubules that the PTH effect on Na,K-ATPase is eliminated by inhibition of PKC with staurosporine[594] or with calphostin.[508] Interest has focused on the structural correlates of Na,K-ATPase regulation, and these have been depicted by Feraille and Doucet[204] (Figure 33.15). The first observation is that regulatory phosphorylation occurs on the alpha-subunit, which can be phosphorylated by both PKA and PKC.[86] There is a single PKA phosphorylation site at a serine within the last cytoplasmic loop, while PKC phosphorylation occurs on the N-terminal cytoplasmic tail.[68,205] The rate of alpha chain phosphorylation by PKC was influenced by the ionic environment, enhancing with K^+ and diminishing with Na^+, suggesting preference for the E2 over the E1 conformation.[205] The converse of this observation has also been reported, namely that PKC phosphorylation impacts on the conformational equilibrium of the enzyme, favoring the E1-Na state.[433] Although an inhibitory effect of PKC phosphorylation had been reported[86], Feschenko and Sweadner[206] found no effect of alpha-subunit phosphorylation on Na,K-ATPase kinetics, neither on maximal velocity nor Na^+ affinity. They concluded that the regulatory impact of PKC must derive from the cellular environment, and other signals.

One complicating aspect of the PTH effect on proximal tubule Na,K-ATPase is the interaction with the

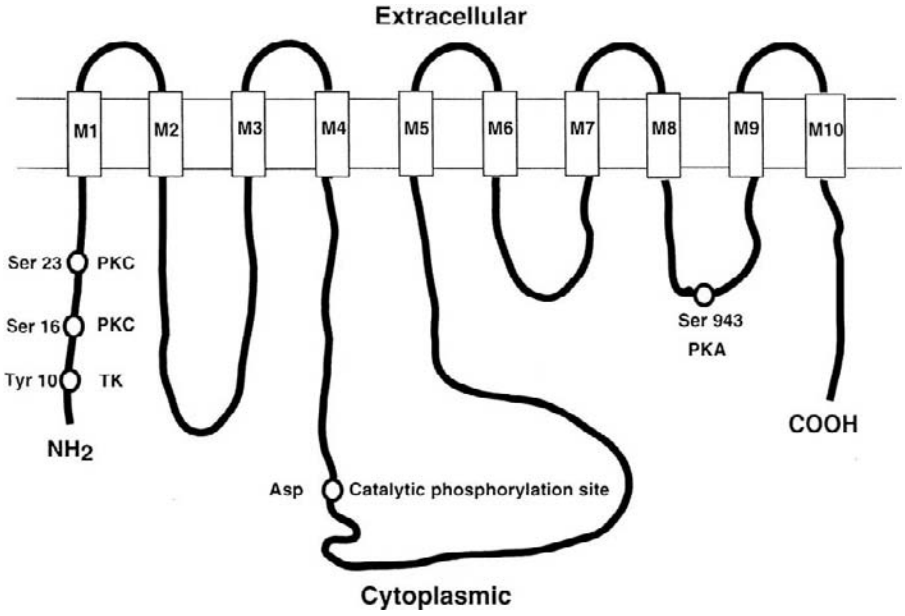

FIGURE 33.15 **Transmembrane looping of the alpha subunit of the Na, K-ATPase, with localization of phosphorylated amino acids**. The PKA site is located at serine-943; PKC sites are on the NH_2 cytoplasmic tail. The aspartate residue within the M4–M5 loop is phosphorylated during the catalytic cycle of the pump. *(From[204].)*

cytochrome P450 pathway. Ribeiro et al.[561] demonstrated that PTH released arachidonic acid in proximal tubule suspension, that a specific inhibitor of P450 prevented the inhibitory effect of PTH on the Na, K-ATPase, and that the effects of 20-hydroxyeicosatetraenoic acid (20-HETE) and PTH on the Na,K-ATPase were not additive. These observations were extended by Ominato et al.[508] working with rat proximal tubules, who showed that inhibition of cytochrome P450 not only blocked the PTH effect, but also Na,K-ATPase inhibition by activators of PKC, as well as inhibition by a PKC catalytic fragment. These workers drew the conclusion that the P450 product was an effector for PKC on the Na,K-ATPase. A slightly different conclusion was reached by Nowicki et al.[506] working in a cultured cell line (COS cells), who observed that 20-HETE had no effect on Na,K-ATPase in the absence of PKC, and that inhibitors of PKC (or mutation of the PKC catalytic site) eliminated the 20-HETE effect. These workers drew the conclusion that the P450 product was an effector for PKC on the Na,K-ATPase. A second complicating aspect of the regulation of Na,K-ATPase is the interaction with the cell's endocytic machinery. In proximal tubule cells in suspension, dopamine treatment caused phosphorylation of the alpha-subunit of Na,K-ATPase, decreasing its activity and resulting in its appearance in endosomes.[150] Dopamine-induced phosphorylation was blocked by PKC inhibition. In OK cells, phosphorylation of the alpha-subunit and its uptake into endosomes could be prevented with either PKC inhibition or by transfection with an alpha-subunit lacking the PKC phosphorylation site.[150]

Complexity of PKC modulation of the Na,K-ATPase became apparent with microperfusion studies of rat proximal tubules by Liu and Cogan, and their observation that Na^+ and HCO_3^- reabsorption was stimulated by PKC activation and depressed by PKC inhibition.[431] Wang and Chan[697] sharpened this picture with their report of a time-dependent effect of PKC activation on microperfused rat proximal tubules, with early stimulation (0 to 10 minutes) yielding to late inhibition after 25 to 35 minutes of perfusion. In rat proximal tubule cells in suspension, Feraille et al.[203] examined the effect of PKC activation on Na,K-ATPase activity, and reproduced prior observations that with standard incubation conditions PKC activation inhibited Na,K-ATPase activity. However, the thrust of their report was that in a well-oxygenated preparation, PKC was stimulatory due to an increase in Na^+-affinity. Enhancement of the transport activity occurred in parallel with phosphorylation of the alpha-subunit of the Na,K-ATPase.[137] In contrast to the findings of Chibalin et al.[150], Efendiev et al.[191] reported that in OK cells, PKC activation increased Na,K-ATPase activity by recruiting new transporters to the cell membrane. With regard to the inhibitory or stimulatory effect of PKC on the Na,K-ATPase, Efendiev et al.[192] have focused attention on cytosolic Na^+ concentration to act as a switch. Working in OK cells, they manipulated cell Na^+ using the ionophore monensin, and used rubidium uptake to assay Na,K-ATPase activity in intact tubules. They found that PKC activation stimulated the pump at low cell [Na^+], had no effect at estimated [Na^+] around 12 mM, and was inhibitory at cell [Na^+] greater than 16 mM. The inhibition, but not the stimulation, was abrogated with P450 inhibition. This work was extended by experiments in rat proximal tubules in which the phosphorylation of the PKC site of the

alpha-subunit was measured.[326] It was found that at the normally low cell Na^+, the sites were largely phosphorylated, and only at abnormally high cell Na^+ were they dephosphorylated and susceptible to the action of PKC. In more recent studies in OK cells, fluorescence microscopy of tagged alpha-subunits has demonstrated an impact of increased cytosolic Na^+ to traffic Na,K-ATPase to endosomes adjacent to the cell membrane.[154] Whether this represents trafficking of transporter to or from the plasma membrane may depend upon other neuro-humoral factors.

Neural and Humoral Factors

Renal Nerves

Renal sympathetic nerves have long been known to modulate proximal tubule sodium transport, and are perhaps the most important regulator.[172,256] Denervation of the rat kidney reduced proximal reabsorption by 40% in the absence of any change in single nephron glomerular filtration.[71] Stimulation of the sympathetic nerves can increase reabsorption by 30%, again without change in filtration.[73] In the isolated perfused convoluted proximal tubule of the rabbit (but not the straight portion) both alpha and beta catecholamines enhance sodium transport.[69] Similar stimulation by both adrenergic agonists is observed in the doubly microperfused rat tubule.[719] In the perfused mammalian tubule, norepinephrine increases both bicarbonate and chloride transport.[60] Nord and his associates[505] found that in a suspension of tubule cells from the rabbit, sodium uptake was enhanced by alpha agonists and blocked by ethylisopropylamiloride, thus suggesting alpha stimulation of brush border Na^+/H^+ exchange. Subsequently, Wong et al.[761] demonstrated that in the microperfused S1 segment of rat proximal tubule, both acute renal denervation or acute alpha-1 blockade reduce chloride reabsorption by 40%, while manipulation of alpha-2 activity had little impact. The effect of alpha-1 blockade could be eliminated by pre-activation of PKC, suggesting that the calcium–phospholipid-dependent kinase was the important signaling pathway for renal sympathetic activity. In view of the increase in cellular cAMP with beta adrenergic agonists, the mechanism by which beta agonists enhance proximal sodium reabsorption must be indirect, and the evidence implicates NHERF: activated beta-2 receptor binds NHERF, and thus prevents cAMP-dependent downregulation of NHE3. When binding was prevented with a mutated beta receptor, the PKA-dependent decrease in NHE3 flux was also prevented.[292] A coordinated effect of sympathetic activity on luminal and peritubular cell membranes was suggested by the observation that PKC activation also enhanced activity of the peritubular $Na^+-3HCO_3^-$ co-transporter.[578] Of greater significance with respect to luminal-peritubular coordination is the observation that norepinephrine also increases the activity of the Na,K-ATPase.[60,87] The effect on the sodium pump, however, is more likely mediated by a phosphatase, since PKC is inhibitory here.[19,314,419]

Angiotensin

Angiotensin II has been intensely studied as a regulator of proximal sodium transport.[158,295,296,541,614] In the intact animal, selective blockade of angiotensin II is diuretic, so it appears that under normal conditions there is tonic stimulation of the proximal tubule.[771] In physiologic doses, it enhances Na^+ reabsorption in rat[297] or rabbit tubules,[615] and the stimulatory effect appears to be more pronounced in the S1 segment.[429] Specific receptors for angiotensin exist on both luminal[121] and peritubular membranes,[122] and the hormone effect may be achieved from either side of the cell.[429] Distinguished on the basis of inhibitor binding, several distinct receptor types have been identified on proximal tubule, each with affinity for angiotensin in the nanomolar range.[181,190] In intact rat tubules, the most prominent effect of angiotensin, in picomolar concentrations, is the stimulation of $NaHCO_3$ reabsorption via Na^+/H^+ exchange,[429] and this is mediated by binding to AT1 receptors.[543,763] In a suspension of proximal tubule cells, angiotensin II enhances both Na^+ uptake and cell pH recovery after an acid-load.[581] The increase in tubular reabsorption due to angiotensin is correlated with the inhibition of cAMP generation,[430] and these findings are reproduced in cultured proximal tubule cells transfected with the AT1 angiotensin receptor.[656]

While systemic angiotensin concentrations may be in the 0.01–0.1 nM range, luminal concentrations are 100-fold higher[624] due to tubular synthesis and secretion of angiotensin.[112,532] Microperfusion studies, combining luminal perfusion of angiotensin with simultaneous inhibition of local synthesis, have confirmed the stimulation of transport starting in the picomolar range.[58,540] However, over a broad range of luminal concentrations (0.01–10.0 nM) these workers found the stimulatory effect of luminal angiotensin to be relatively flat. With respect to the peritubular action of angiotensin, inhibition of Na^+ transport becomes apparent at concentrations above 0.1 nM as an attenuation of the stimulation seen at lower doses. Inhibition may dominate at concentrations greater than 100 nM,[296] and may involve binding to an AT2 receptor.[291] *In vivo*, AT1 blockade has been used to reveal an effect of peritubular angiotensin II, metabolized to angiotensin III, which then binds to the AT2 receptor to decrease Na^+ reabsorption.[517,518] Pursuit of the signaling pathway underlying the inhibitory effect of angiotensin has

indicated formation (via phospholipase A2) of an epoxygenase metabolite of arachidonic acid.[181,294,318,448,575]

Microperfusion experiments have also revealed a coordinated action of luminal angiotensin and renal nerve activity. In volume-contracted animals, proximal reabsorption is brisk, additional luminal angiotensin adds little, and luminal AT1 antagonism has a dramatic inhibitory effect on reabsorption; in volume-expanded animals, there is only a small impact of luminal AT1 inhibition, while luminal angiotensin sharply increases volume reabsorption.[542] Quan and Baum[544] made the observation that when renal nerves were cut luminal perfusion of an angiotensin converting enzyme inhibitor (enalaprilat) failed to decrease proximal volume reabsorption, although the tubule remained sensitive to the stimulatory effect of directly applied luminal angiotensin. Conversely, stimulation of renal nerves conferred enalaprilat-sensitivity to proximal reabsorption.[545] These studies suggested that renal nerves amplified their signal to enhance proximal sodium reabsorption by switching on the local angiotensin synthetic machinery. A mysterious aspect of luminal angiotensin signaling is the luminal angiotensin concentration maintained well above that needed for maximal stimulation. One explanation that has been advanced is that in such a system, regulation of transport might be determined by AT1 receptor density.[389] Indeed, metabolic acidosis increases proximal tubule AT1 expression, and thus increases the effect of angiotensin to stimulate proximal ammoniagenesis.[498] In OK cells, both AT1 receptor expression[39] and NHE3 activity[230] are increased by insulin. The significance of the proximal AT1 receptor to total body Na^+ balance is suggested by the demonstration of Gurley et al.[283] that mice with AT1 knockout restricted to proximal tubule have decreased proximal tubule Na^+ reabsorption and are relatively hypotensive.

With respect to specific proximal tubule transporters, angiotensin is pleiotropic. Beyond the effect of decreasing cAMP to increase NHE3 flux, there is evidence that angiotensin can act to increase NHE3 membrane density in intact tubules.[415] It is likely that the increase in NHE3 activity contributes to the observed increase in NH_4^+ secretion by perfused mouse proximal tubule, although the increased NH_4^+ production in perfused S3 segments is evidence for a more global angiotensin action.[497] Within proximal tubules of rats with renovascular hypertension, there is increased expression of the Na^+-glucose co-transporter (SGLT2), which is blunted by AT1 inhibition.[59] Additionally, angiotensin augments proximal acidification by the luminal membrane H^+-ATPase, at least in part through transporter insertion.[694] Indeed *in vivo*, ACE inhibition produces translocation of an array of luminal transport proteins, including NHE3, NHERF, ezrin, and the H^+-ATPase, from tip to base of brush border microvilli,[414] and this translocation is reversed by direct infusion of angiotensin II.[564] In the picomolar to nanomolar concentration range, angiotensin stimulates HCO_3^- exit via the peritubular $Na^+-3HCO_3^-$ co-transporter,[162,193,239] perhaps via a pathway which activates PKC,[579] and perhaps by increasing the membrane content of this transporter.[565] Within the concentration range of angiotensin that stimulates proximal reabsorption, there is increased peritubular Na, K-ATPase[235]; this occurs promptly and with changes in the phosphorylation of the Na,K-ATPase.[778] There is also increased peritubular K^+ conductance.[162] Despite enhancement of peritubular exit pathways, the net effect of angiotensin on cytosolic Na^+ concentration is an increase.[555]

Dopamine

The proximal tubule is also the target of natriuretic signals, and dopamine is the most important.[17,134,787] Among the key early observations were findings that urinary dopamine could derive from circulating L-DOPA,[34] that on balance, the whole kidney synthesized dopamine (consuming DOPA), with tubular secretion providing the bulk of urinary dopamine,[38] and that proximal tubules could be a source for this excreted dopamine.[35] Within proximal tubule, conversion from DOPA to dopamine is due to the enzyme L-amino acid decarboxylase (L-AADC), and the importance of the local generation of dopamine was underscored by the demonstration that maximal L-AADC activity was modulated by dietary salt intake.[631] In mice, in which proximal tubule AADC has been knocked-out, urinary dopamine is dramatically reduced, and the animals show elevated blood pressure (compared with wild-type) when on a normal- or high-salt diet.[791] Proximal tubules are a target for the locally generated dopamine. Dopamine inhibits sodium reabsorption in the isolated perfused straight tubule,[72] and in tubule suspensions.[411] In proximal convoluted tubules (*in vitro*), however, dopamine decreased sodium reabsorption only in tubules in which transport had been stimulated by norepinephrine,[56] consistent with the observation *in vivo* that a DA-1 agonist is not natriuretic in a denervated kidney.[325] RNA message for the DA-1 dopamine receptor was demonstrated in proximal tubule,[773] and subsequently the protein was identified on both luminal and peritubular cell membranes.[507]

As with angiotensin, dopamine impacts on transporters of both luminal and peritubular cell membranes, most notably but not exclusively NHE3 and the Na, K-ATPase. Studies of dopamine action via the DA-1 receptor have implicated a number of second messenger systems, but principally cAMP-PKA targeting

NHE3 and Ca^{2+}-PKC targeting the Na,K-ATPase.[17] When renal cortical tissue was incubated with dopamine or DA-1 agonists, Na^+/H^+ exchange in brush border membrane vesicles decreased, and this could be blocked by inhibition of either adenylate cyclase or PKA.[200] Use of OK cells permitted direct demonstration that dopamine (via DA-1) and PKA phosphorylated NHE3 on identical sites.[749] In large measure, the decrease in Na^+/H^+ exchange reflects a dopamine-mediated decrease in NHE3 within the luminal cell membrane.[32] This conclusion was based on experiments in which mouse cortical slices were treated with dopamine, and brush border membrane vesicles assayed for NHE3 activity and antigen. A prior observation had been made in OK cells that dopamine produced endocytosis of NHE3 in a PKA-dependent manner.[321] Development of antibodies recognizing NHE3 phosphorylated at PKA target sites, confirmed the effect of dopamine to increase phosphorylation at those sites, and permitted the observation that in the rat *in vivo*, NHE3 phosphorylation shifted from microvilli to a subapical location.[386] With respect to other luminal transporters, dopamine also induces internalization of the Na^+-phosphate co-transporter,[31] and this effect involves participation of NHERF.[715] The impact of dopamine on the Na,K-ATPase was demonstrable as a decrease of enzyme activity in microdissected tubules[18] or as a decrease in oxygen consumption by proximal tubules in suspension in which cell Na^+ was kept high by nystatin permeabilization.[630] The dopamine-mediated decrease in proximal tubule cellular Na,K-ATPase activity has been shown to occur in association with endocytosis of the enzyme, and blocking the endocytosis with an actin stabilizer eliminated the decrease in enzyme activity.[149] An early event in the endocytic process is PKC-dependent phosphorylation of the alpha-subunit of the Na,K-ATPase.[150] An early observation in rat proximal tubule was that, like ouabain, dopamine produced an increase in tubule diameter.[18] Subsequent study of rabbit PST with Na^+-sensitive fluorescent dye demonstrated a prompt rise in cell Na^+ in response to dopamine.[397] This indicates that with inhibition of both Na^+ entry and exit pathways, on balance, the effect of dopamine on the Na,K-ATPase dominates. In an electrophysiologic study, dopamine also blunted peritubular HCO_3^- exit via the Na^+—$3HCO_3^-$ co-transporter.[397]

The DA-1 receptor density is regulated, and consistent with the physiology, there is an inverse relationship with AT1 angiotensin receptor density. Early observations included the findings that in cell culture (LLCPK) dopamine recruits its own DA-1 receptor to the cell membrane[118]; and in rats, dopamine downregulates the AT1 receptor.[147] In a primary culture of rat proximal tubule cells, application of a dopamine agonist increased DA-1 density, decreased AT1 density, and eliminated the angiotensin-elicited increase in cytosolic Ca^{2+} (Figure 33.16).[368] In these same cells, angiotensin decreased the DA-1 density, and blunted the dopamine-agonist-induced increase in cAMP. The dopaminergic decrease in AT1 density was also observed in a primary culture of human proximal tubule cells.[245] Complementing these observations, the proximal tubule AADC knockout mouse showed increased renal AT1 mRNA expression.[791] Another aspect of dopamine receptor physiology, which may have direct translational impact, is "desensitization" of the DA1 receptor by phosphorylation.[201] In proximal tubule, the G-protein-coupled receptor kinase 4 (GRK4) is the principal kinase to phosphorylate the DA1 receptor, thus diminishing the dopamine effect. The critical observation is that in primary cultures of human proximal tubule, cells derived from hypertensive patients show decreased responsiveness to dopamine agonists and increased DA-1 phosphorylation.[587] These observations may be understood in light of the later demonstration that cells from hypertensive patients have substantially greater GRK activity.[202] Furthermore, a GRK4 mutation identified in human hypertension produced hypertension in a transgenic mouse.[202] Renal interstitial infusion of GRK4 antisense oligonucleotides decreased GRK4 expression, decreased DA-1 phosphorylation, and mitigated the blood pressure rise of spontaneously hypertensive rats.[588]

Nitric Oxide (NO)

Nitric oxide provides a paracrine signal from renal nerves or renal endothelial cells to affect proximal tubule Na^+ transport.[420] Due to its short half-life and difficulty in measurement, the impact of NO has been assessed indirectly, in experiments in which NO synthase (NOS) has been inhibited or NO donors have been infused, so that renal tubular dose—response for NO is not available. In whole animals, infusion of a NOS inhibitor at a dose which does not increase arterial blood pressure or glomerular filtration, leads to a reduction in sodium excretion.[404,450] Majid et al.[450] found that with NOS inhibition, urinary Na^+ excretion failed to increase as a function of renal perfusion pressure, and this prompted them to propose that NO may be a mediator of the pressure-natriuresis response (see below). When the NO donor, sodium nitroprusside (SNP), was added to tubule lumen or to peritubular capillaries, it decreased proximal Na^+ reabsorption.[194] Wu et al.[768] added the observation that when NOS inhibition increased proximal sodium reabsorption, the effect could be abrogated by transection of renal nerves; the NOS inhibition effect was reproduced with specific inhibition of neuronal NOS. With renal nerve stimulation, proximal Na^+ reabsorption increased, but

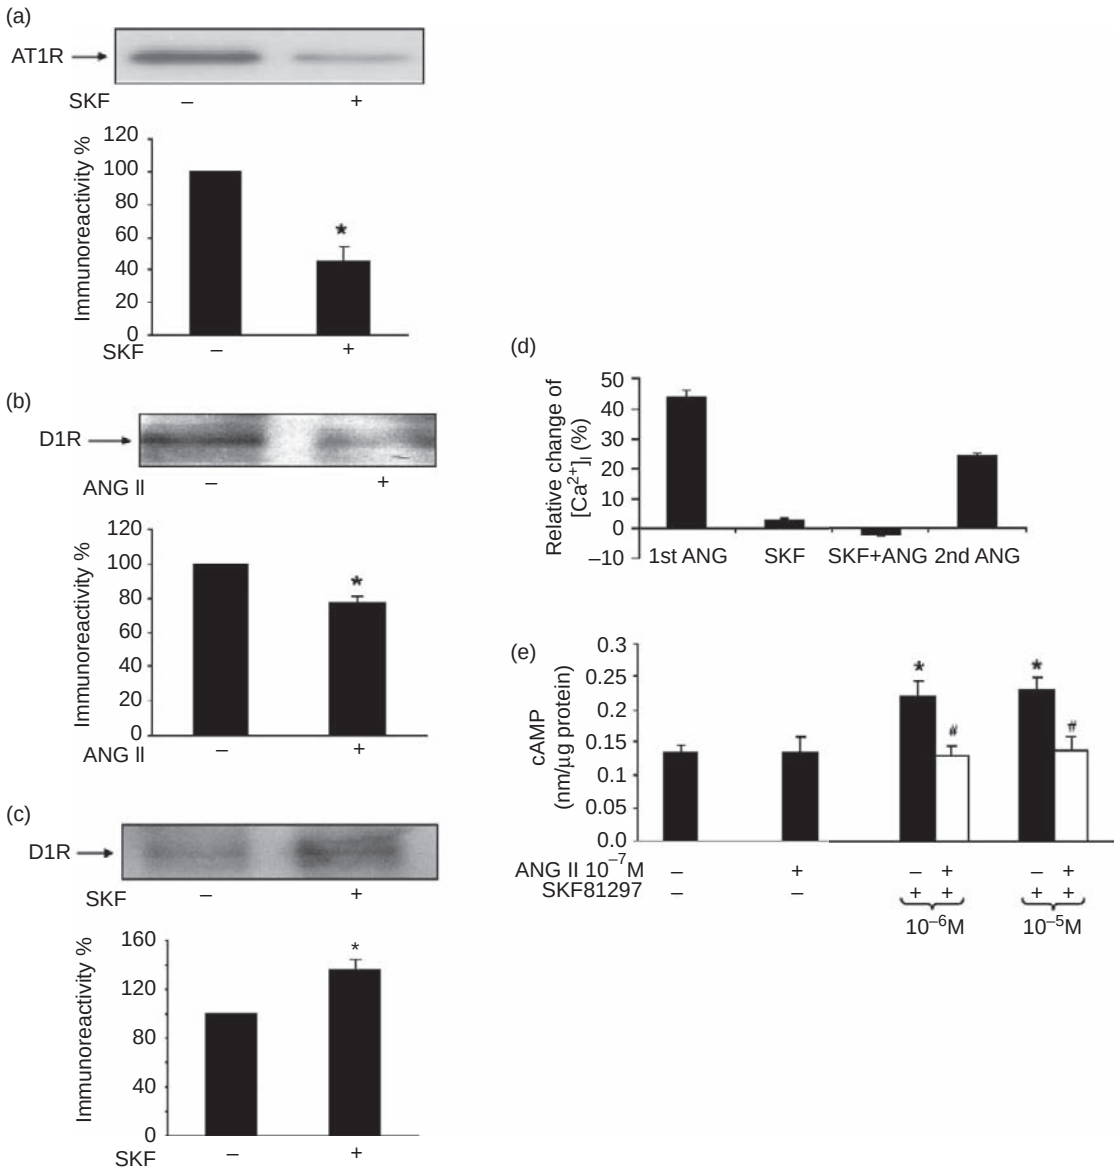

FIGURE 33.16 **Effects of ANG II and the DA-1 receptor (D1R) activating ligand, SKF81297, acting singly and in combination on renal proximal tubule (RPT) cells in culture**. (a)–(c): Cell surface expression of receptors was studied using biotinylation and densitometric quantification of bands. (a) Effect of SKF81297 on the abundance of cell surface membrane angiotensin receptor (AT1R); (b) effect of ANG II on the abundance of cell surface membrane D1R; (c) effect of SKF81297 on the abundance of cell surface membrane D1R. (d)–(e) SKF81297 abolishes the ANG II-mediated calcium response and ANG II abolishes the SKF81297-mediated cAMP response. (d) Treatment-induced change in the $[Ca^{2+}]$i level was calculated as the percent change in the $[Ca^{2+}]_i$ value before and after each treatment. (e) Renal cortical slices were exposed to ANG II alone or SKF81297 alone or pretreated with ANG II and then treated with both ANG II and SKF81297 and cAMP levels were measured in the tissue lysates. (*P 0.05 vs. control. #P 0.05 vs. respective SKF81297-treated groups.) *(From[368].)*

not in the presence of neuronal NOS inhibition.[769] At apparent odds with the natriuretic effect of NO are rat micropuncture findings that NOS inhibition decreased proximal sodium reabsorption (an effect blocked by renal nerve transection or infusion of an alpha 2 adrenergic blocker)[658] or the observation that peritubular capillary perfusion with agents promoting NO release increased Na^+-dependent luminal proton secretion.[13] Consistent with these results, mice with deficient neuronal NOS showed defective proximal $NaHCO_3$ reabsorption.[701] Pertinent to such discordant findings are the observations of Wang,[696] who observed a dose-dependent effect of tubule perfusion with SNP, in which low dose increased and high dose decreased proximal Na^+ and HCO_3^- reabsorption; perfusion with a NOS inhibitor decreased reabsorption, consistent with the enhancing effect of low-dose SNP. One possible reconciliation has been the suggestion that the

variable impact of NO on proximal tubule Na^+ transport may be contingent on cytosolic cAMP concentration.[236]

With respect to mechanism, proximal tubule epithelial cells do not contain RNA message for constitutive nitric oxide synthases (endothelial or neuronal NOS), but have abundant message for guanylate cyclase.[655] In primary culture, rat proximal tubule cells showed little cGMP production in response to NO inducers, but co-incubation with bovine pulmonary endothelial cells rendered the cells sensitive, and resulted in a sharp increase in cGMP, a decrease in Na,K-ATPase activity, and a decrease in vectorial Na^+ transport from apical to basal surfaces.[423] Carey and associates have offered the perspective that renal interstitial cGMP mediates the action of NO. Infusion of cGMP into the renal interstitium produces natriuresis in the whole kidney; infusion of an NO donor increases the interstitial cGMP concentration, and blocking the production of cGMP by administration of a soluble guanylate cyclase inhibitor completely blocked the natriureteic effect of NO.[346] In a follow-up to this observation, human proximal tubule cells in culture were found to contain soluble guanylate cyclase, and it was demonstrated that stimulation by NO produced cGMP that was secreted into the culture medium.[592] Of interest, in these experiments application of an NO donor resulted in a decrease in cell Na^+ content, consistent with a dominance of an inhibitory effect on Na^+ entry pathways.[592] A recent study has implicated a tyrosine kinase (Src) as a downstream mediator of the cGMP effect.[501]

Volume Expansion and Pressure Natriuresis

The influence of physical factors on the paracellular pathway does not preclude important effects of volume expansion on the cell itself. This was the supposition of, Robson et al.[566] who reported depression of glucose reabsorption in the kidney of the volume-expanded rat. This view found support in a whole organ tracer study, which failed to discern increased glucose backflux during volume expansion.[309] Proximal micropuncture documented decreased capacity for glucose reabsorption during volume expansion,[33] and a correlation of sodium and glucose reabsorption under the influence of albumin infusion.[365] The microperfusion study of Boonjarern et al.[107] demonstrated decreased reabsorptive flux of labeled glucose in the presence of volume expansion. The case for a cellular effect of peritubular protein has also been presented by Berry and associates, working with isolated tubules, and finding depression of chloride reabsorption with removal of bath protein.[81] The evidence was strengthened in subsequent experiments in which transepithelial concentration gradients were adjusted to virtually eliminate electro-diffusive forces across the epithelium. In that study, the increase of peritubular protein from 6 to 10 gm/dl still produced a 42% increase in NaCl reabsorption.[54] Consistent with these findings, micropuncture of the volume-expanded rat has also indicated a greater depression of proximal reabsorption of NaCl than $NaHCO_3$.[95,157] Pursuing this issue in another coupled transport system, Pitts et al. found that prior volume expansion of the rabbit depressed phosphate transport in straight proximal tubule removed and perfused over 90 minutes.[530] In the same study, prior volume expansion also depressed Na^+-coupled phosphate transport in brush border membrane vesicles.

There has been considerable effort to define the cellular impact of volume expansion. Electron probe analysis of rat kidney suggested that cell Na^+ concentration increases following saline infusion.[285] When the kidney from the volume-expanded rat is protected from physical factors using an arterial snare, the increase in cell Na^+ is eliminated.[554] These findings were interpreted as most consistent with a decrease in Na,K-ATPase activity during volume expansion. "Pressure natriuresis," in which systemic arterial pressure is increased, has been an important model with which to examine the acute impact of physical factors on proximal sodium reabsorption.[502,574] In these animals, renal autoregulation maintains a relatively constant renal blood flow and glomerular filtration rate, but renal sodium excretion increases in association with an increase in renal interstitial hydrostatic pressure.[369] In prior studies, Kinoshita and Knox[373] had shown that the decrease of proximal sodium reabsorption that normally follows increased renal interstitial pressure could be eliminated by blocking prostaglandin synthesis. In pressure natriuresis during block of prostaglandin synthesis with indomethacin, renal interstitial hydrostatic pressure still increases, but sodium and lithium reabsorption are no longer decreased.[254] Complementing this observation is the finding that with a directly applied increase in interstitial hydrostatic pressure, treatment with indomethacin eliminated the increase in tight junctional lanthanum permeability.[551] Although physical factors are involved, these results are best rationalized by an impact on the cell, rather than a direct tight junction effect.

To delineate cellular events following volume expansion, membrane fractions were obtained from kidneys undergoing pressure natriuresis, and examined for content of NHE3 and Na,K-ATPase.[789] This study revealed that acute hypertension prompted the retrieval of luminal membrane transporters (change in membrane fraction in which transport activity appeared), and a sharp reduction in the the activity of Na,K-ATPase. The retrieval of NHE3 was prompt

(within 5 minutes of acute hypertension), reversible (within 20 minutes), and concurrent with the acute changes in lithium clearance.[788] With respect to the Na, K-ATPase, the decrease in activity was not accompanied by any loss of immunoreactivity of its subunits within the membrane fractions. Immunohistochemical staining of NHE3 plus confocal microscopy permitted the visual demonstration that with acute hypertension NHE3 redistributed from the brush border into the base of the microvilli, confirming the inference from the membrane fraction analysis (Figure 33.17). Complementing these structural changes, functional changes in luminal membrane Na^+/H^+ exchange could be identified *in vivo*. When proximal tubule cells were loaded with BCECF, cytosolic pH could be monitored continuously during luminal microperfusion, specifically the time course of cellular acidification following luminal Na^+ removal. Within 20 minutes of acute hypertension, the Na^+-dependent change in cytosolic pH was reduced 52% from control.[780] When brush border membrane vesicles were examined both for NHE3 protein and for Na^+/H^+ exchange activity, it was found that despite retrieval (change in membrane fraction), the activity per transporter remained constant.[774] Thus, in contrast to the changes in Na, K-ATPase activity, the reduction in Na^+/H^+ activity could not be attributed to kinetic modification of the NHE3 transporter. The chronic analog to pressure natriuresis is a high-salt diet, and in this model there was reduction in Na,K-ATPase activity, with no change in α1-subunit density.[524] Following 3 weeks of high salt, young rats showed retrieval of luminal membrane NHE3 and NaPi2 and peritubular membrane Na,K-ATPase.[775] With acute volume contraction, however, transporter kinetics do appear to change, since the increase in lithium reabsorption is not accompanied by the appearance of new NHE3.[416] Over time, however, chronic volume contraction does increase NHE3 message in proximal tubule.[211] McDonough[465] has provided a summary scheme of the impact of extracellular fluid volume or blood pressure on proximal tubule transporter expression (Figure 33.18).

The signals from interstitium to tubule have also been pursued in more detail, and there is evidence that arachidonic acid metabolites of cytochrome P450 are implicated. Acknowledging the prior identification of eicosanoids (specifically 20-hydroxyeicosatetraenoic acid, 20-HETE) as inhibitors of Na,K-ATPase, Zhang et al.[788] sought evidence for their role as mediators of pressure natriuresis. They examined pressure natriuresis in rats pretreated with cobalt chloride to blunt cytochrome P450 metabolism, and found that this treatment blocked the pressure-associated increase in lithium clearance. This occurred in association with failure of NHE3 retrieval from brush border vesicles, and failure of Na,K-ATPase activity to decrease within its membrane fraction.[788] These findings received support with the observation that proximal convoluted tubule contains abundant cytochrome P450 4A isoforms.[336] Furthermore, rabbit proximal straight tubules in suspension produce 20-HETE, and when 20-HETE production is inhibited in an isolated perfused tubule, volume reabsorption is enhanced.[547] Using a specific inhibitor of eicosanoid formation, Dos Santos et al.[179] re-examined pressure natriuresis in pretreated rats. In these animals, 20-HETE excretion was nearly eliminated, and the pressure-induced increase in sodium excretion and lithium clearance was substantially blunted. This occurred in association with blunted retrieval of NHE3 from brush border and blunted decrease in Na,K-ATPase activity.[179] A more specific inhibitor of 20-HETE formation reproduced these results, although it was emphasized that about half of the increase in pressure-induced Na^+ excretion persisted.[755] It must be acknowledged that this work leaves unanswered the identity of the signal from

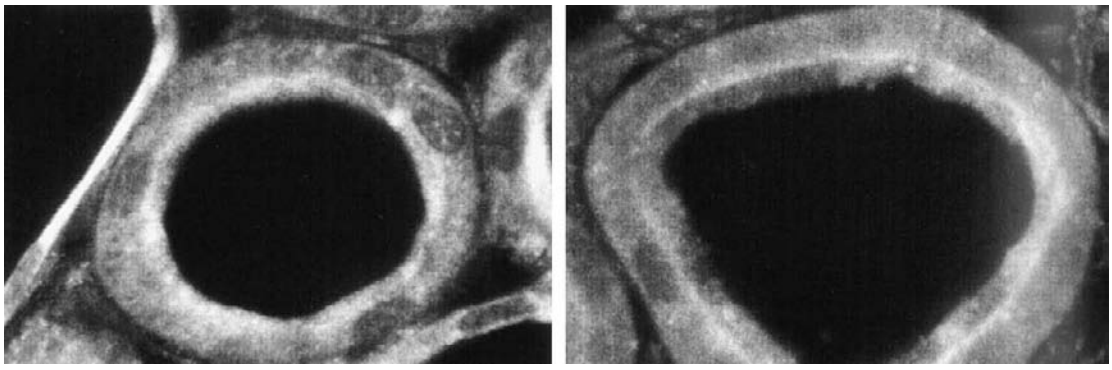

FIGURE 33.17 **Effect of acute hypertension on NHE3 distribution in rat proximal tubules**. Panels show NHE3 immunofluoresence under control conditions (left), and after 20 minutes of acute hypertension. Under control conditions, NHE3 appears along microvilli; with pressure natriuresis, there is redistribution of the exchanger to base of the brush border. *(From[779].)*

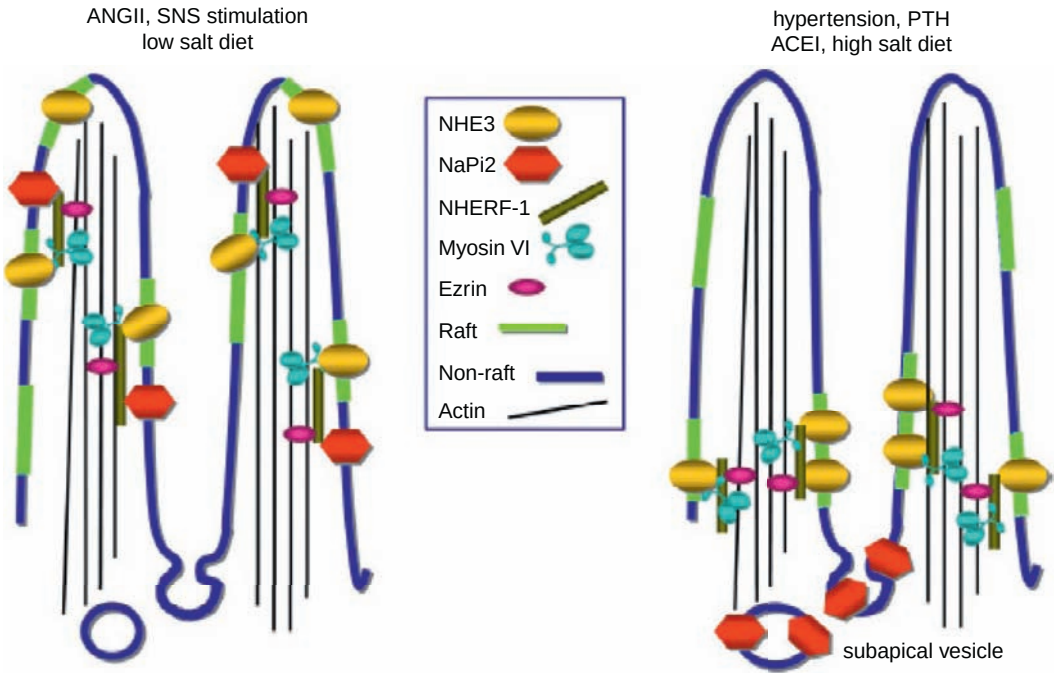

FIGURE 33.18 **Schematic representing response of renal PT sodium transporters NaPi2 and NHE3 to natriuretic and antinatriuretic stimuli**. With ANG II and sympathetic nerve stimulation, both NaPi2 and NHE3 are located in the body of the microvilli, NHE3 along with NHERF-1 and ezrin. With elevated perfusion pressure, ACEI or PTH, NHE3, and NaPi2 are translocated out of the body of the microvilli; NHE3 remains in a domain at the base of the microvilli, while NaPi2 moves to subabpical endosomes. *(From[465].)*

interstitial hydrostatic pressure to cell. A role for NO was examined in the rat, but NOS inhibition blunted transmission of renal perfusion pressure to the interstitium, so that the failure to observe pressure natriuresis may simply have been a consequence of low interstitial pressure.[499] More recently, renal interstitial cyclic GMP concentration was found to increase with renal perfusion pressure, and guanylyl cyclase inhibition blunted the pressure-associated decrease in proximal Na^+ reabsorption.[347] Leaving cGMP systhesis intact, but blocking cellular secretion of cGMP with intrarenal probenecid, also eliminated pressure natriuresis.[3] This action of extracellular cGMP to decrease Na^+ transport appeared to be tonic, in the sense that intrarenal infusion of phosphodiesterase decreased renal Na^+ excretion.[3]

Glomerulotubular Balance

In response to spontaneous variations in glomerular filtration rate, the rate of proximal tubule reabsorption varies proportionally. This "glomerulotubular balance" was apparent in the first micropuncture examination of mammalian kidney,[695] and was demonstrated elegantly by Schnermann et al.,[609] with their finding that over a four-fold change in GFR, the accessible rat proximal tubule reabsorbed roughly 40% of the filtered load (Figure 33.19). Although glomerulotubular balance may

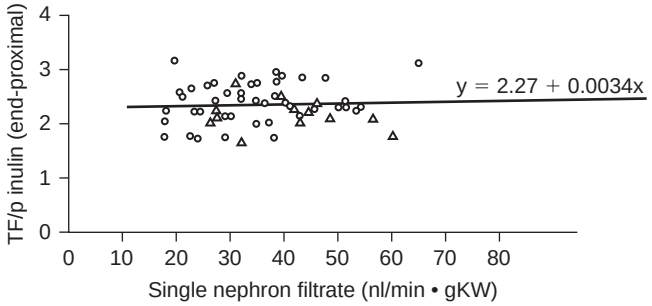

FIGURE 33.19 **End-proximal tubular fluid was sampled from rat nephrons and plotted as a function of SNGFR**. With spontaneous variation in SNGFR over a four-fold range there is virtually no change in the fractional water reabsorption. *(From[609], with permission.)*

prevent solute loss following GFR increases, perhaps its most important effect is to preserve distal delivery of sodium (permitting distal regulation of acid and potassium excretion) in times of low GFR. The mechanisms underlying balanced tubular reabsorption include both peritubular capillary effects and luminal factors.[242,290,751] Peritubular oncotic forces are generally recognized as a major force in the maintenance of balanced tubular reabsorption.[187] Any increase in filtration fraction must result in an increased peritubular protein concentration, and thus, enhanced proximal reabsorption. Experimental maneuvers which distort this oncotic force (such as saline infusion or albumin

administration) disrupt glomerulotubular balance. Nevertheless, in a mathematical model comprised of glomerulus, proximal tubule, peritubular capillary, and interstitium, simulation of only the filtration fraction effect on tubular transport failed to reproduce glomerulotubular balance.[732] In simulations of glomerular arteriolar resistance changes, it was found that fractional changes in proximal sodium reabsorption were smaller than the fractional changes in GFR. This derived from the fact that the variation in GFR came as a result of changes in glomerular plasma flow, as well as in filtration fraction. In order to achieve glomerulotubular balance, there must be a mechanism by which alterations in plasma flow, independent of peritubular Starling forces, can influence proximal reabsorption.

Perhaps the most important factor underlying perfusion–absorption balance is a direct effect of axial flow velocity on reabsorption.[751] Such "perfusion–absorption balance" has been found to influence the transport of glucose,[382] bicarbonate[11,143,428] and chloride.[268,760] One of the best illustrations of this phenomenon is the micropuncture data of Chan et al.[143] shown in Figure 33.20, in which a three-fold increase in luminal perfusion rate (with trivial changes in luminal HCO_3^- concentration)

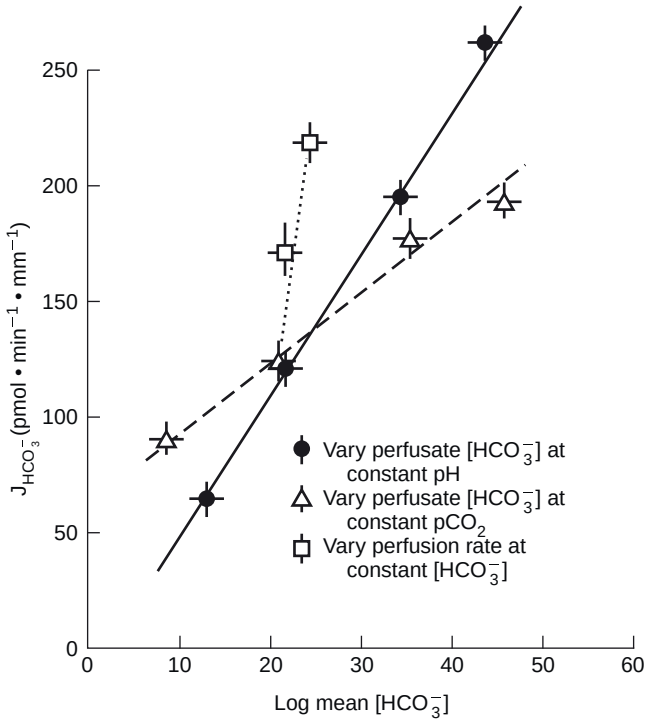

FIGURE 33.20 **Net bicarbonate reabsorption, J_{HCO3}, by perfused rat proximal tubule as a function of mean luminal bicarbonate concentration**. At a constant pCO_2, bicarbonate transport varies linearly with the transepithelial concentration gradient (dashed line). Elevation of pCO_2 enhances, and depression of pCO_2 diminishes, bicarbonate reabsorption (solid line). There is a steep dependence of J_{HCO3} on luminal flow rate. *(From[143], with permission.)*

produced a doubling of the rate of bicarbonate reabsorption. More pronounced effects have been reported with "native" tubular fluid, in comparison with artificial microperfusion solutions, suggesting the presence of a filtered, transport-promoting factor.[49,288] It may also be the case that reductions (rather than increases) in luminal flow are more faithfully followed by proportional changes in transport.[48,289,526,569] Nevertheless, the range over which modulation of luminal flow produces proportional changes in proximal reabsorption is broad.[568] The underlying mechanism for flow-dependent reabsorption has been a point of controversy. One perennial consideration is an unstirred layer effect within the brush border.[563] Morphological observations of Maunsbach et al.[459] demonstrated that lower tubule flow rates are associated with diminished tubule distention and a compaction of the brush border microvilli. Nevertheless, model calculations indicate it unlikely that there is any appreciable convective stirring within this pile,[50] neither should the diffusion barrier between the bulk luminal fluid and the cell membrane pose any significant hindrance to Na^+/H^+ exchange.[394] An intriguing mechanism for flow-dependent transport gained support from two studies, using very different methodologies, which both suggested that increases in axial flow velocity recruit new transporters into the luminal membrane. Preisig[533] loaded rat proximal tubule cells with the pH-indicator BCECF and examined recovery from an acute acid-load *in vivo* (ammonium pulse). With increases in luminal flow rate, the pH recovery mediated by Na^+/H^+ exchange was enhanced. Maddox et al.[447] subjected rats to acute changes in vascular volume in order to obtain hydropenic, euvolemic, and volume-expanded groups, with respective grouping according to decreased, normal, and increased GFR. When brush border membrane vesicles were prepared from each of these groups, and Na^+/H^+ kinetic parameters assessed, it was found that the V_{max} determinations stratified in parallel with GFR.

Guo et al.[282] proposed that the brush border microvilli serve as the sensor for axial flow along the proximal tubule. In that hypothesis, the drag force on each microvillus produces torque on an actin filament core, and this force is transmitted to the underlying cytoskeleton. The close spacing and uniform height of the microvilli allowed a precise calculation of that torque, and using the known bending moment for an actin filament, the Young's modulus for a microvillus was estimated. This yielded the prediction that for microvilli 2.5 μm in height, the tip deflection under axial flows of 30 nl/min would be about 4 nm, in effect depicting the microvilli as a set of stiff bristles that would retain their configuration through the physiological range of flows.[282] In a subsequent analysis, a simplified equation for microvillous torque was derived which has

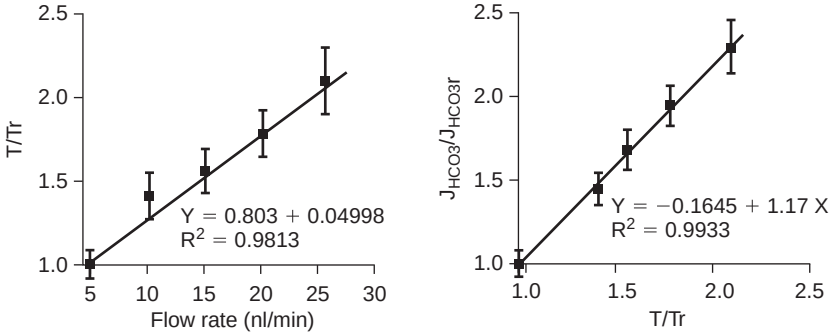

FIGURE 33.21 **Impact of luminal flow rate on bicarbonate reabsorption (J_{HCO3}) in mouse proximal tubules perfused *in vitro*.** The panel on the left shows the computed microvillous torque, T, at each flow, relative to the torque when perfusion is at 5 nl/min (T_r.) In the right panel, the observed J_{HCO3} is plotted as a function of the relative torque. *(From [183], with permission.)*

been useful for assessment of experimental data.[182] The essence of that derivation was identifying microvillous drag with the force on the tubular fluid:

$$D \cdot N = \frac{dp}{dz} \cdot \pi \cdot R^2 \tag{33.17}$$

where D is the drag per microvillus, N is the number of microvilli per unit length of tubule, p is luminal hydrostatic pressure, z is axial length, and R is the tubule radius from center-line to microvillus tip. Assuming Poiseuille flow:

$$\frac{dp}{dz} = 8\mu Q/\pi R^4 \tag{33.18}$$

where Q is luminal flow rate and μ is the tubule fluid viscosity. This provides the estimate of microvillous drag:

$$D \cdot N = 8\mu Q/R^2 \tag{33.19}$$

and for a microvillus of height, L, the torque, T, is:

$$T \cdot N = 8\mu QL/R^2 \tag{33.20}$$

Since the number of microvilli, N, is not easily obtained, Eq. (33.20) is most useful in comparing two experimental trials in which flow is varied and the assumption is made that neither N nor L change with the experimental conditions:

$$\frac{T}{T_r} = \left[\frac{\mu Q}{\mu_r Q_r}\right] \cdot \left[\frac{R_r^2}{R^2}\right] \tag{33.21}$$

in which the subscript "r" denotes a reference flow. This equation reveals the microvillous torque to vary directly with luminal flow and fluid viscosity, and inversely as the square of the luminal radius.

Du et al.[182] applied a slightly more detailed version of Eq. (33.21) to analyze the first experimental study of flow-dependent volume reabsorption, J_v, in isolated perfused mouse proximal tubules. The key finding of that work was that fractional changes in perfusion were greater than the fractional changes in J_v, but when changes in luminal diameter were included in the calculation, the fractional change in microvillous torque and J_v were identical. Furthermore, luminal fluid viscosity increased J_v at constant perfusion rate. And finally, disruption of the cytoskeleton with cytochalasin D eliminated the perfusion-dependent increase in J_v. Du et al.[183] subsequently re-examined flow-dependent transport in mouse proximal tubule, with measurement of HCO_3^- reabsorption, J_{HCO3}. Over a five-fold variation of luminal perfusion rate, there was a predicted two-fold variation in microvillous torque, which scaled identically with the reabsorption (Figure 33.21). Du et al.[182] also reconsidered the data of Burg and Orloff,[126] widely cited as a negative effect of flow on proximal sodium reabsorption in isolated perfused rabbit proximal convoluted tubule. Burg and Orloff had observed that a three-fold increase in tubule perfusion rate produced a 37% increase in volume reabsorption, a value that did not achieve statistical significance. However, they also noted that with the highest flow, there was a 41% increase in tubule diameter. Du et al. estimated that these changes of flow and diameter would yield a 43% increase in microvillous torque, certainly compatible with the observed impact on J_v. In sum, it appears that rabbit proximal tubules were more distensible than mouse tubules, so that perfusion-dependent changes in luminal diameter precluded large deviations in microvillous torque. At present, the cellular signals from torque to Na^+/H^+ exchange remain to be delineated.

PERSPECTIVE

Sodium reabsorption along the proximal tubule refers to a multiplicity of processes, occurring in series and in parallel along a heterogeneous epithelium. Sodium transport cannot be considered out of context of the secretion of protons or the reabsorption of chloride, bicarbonate, potassium, calcium, and organic solutes. Furthermore, the precise interrelationship of these coupled transport processes depends upon the location along the proximal tubule, as well as upon physiologic parameters external to the nephron, such as plasma composition or extracellular volume status of the organism.

One focus of this chapter has been on the biophysics of transport, namely identification of the transporters and the driving forces for their fluxes. The feasibility of such an approach was due to the development of experimental technology, which permitted examination of cell membranes and recording of intracellular composition. With these tools, the first order of business had been definition and localization of the transporters. More recent molecular methods enhanced this aspect of tubule physiology by providing means to visualize a transporter within proximal tubule, and to distinguish biochemical modifications or changes in membrane density. The ability to clone and express transporters in high density in otherwise quiet systems (in which flux through the pathway of interest dominates) has yielded advances in the definition of transport kinetics.

The second order of business has been identifying important regulatory factors. This means an understanding of how changes in cell volume or composition translate into alterations of sodium reabsorption, and of the key neurohumoral signals and physical factors which modulate transport. The complexity of this task is in part technical, insofar as cellular transport machinery may involve an assembly of interacting proteins that are not fully recovered in convenient expression systems. Furthermore, the overall impact on sodium transport by one hormone may depend upon the state of activation of the other systems. Nevertheless, one recurring theme in descriptions of transport regulation has been the targeting of both luminal and peritubular membranes in a coordinated fashion.

Enrichment of our perspective of proximal tubule function must ultimately confer a quantitative understanding of its roles in pathologic states of the organism. Traditionally, this has focused on secondary renal response to disorders of extracellular volume homeostasis, such as edema forming states. It is entirely likely, however, that a role for proximal tubule may come to be identified in primary pathogenesis, as perhaps in volume-dependent hypertension. One anticipates, as a consequence of such information, that therapeutic intervention, which seeks to alter renal sodium transport, will be achieved with greater accuracy and greater safety.

INTRODUCTION

In this chapter we review the transport of ions by the loop of Henle, distal convoluted tubule, the connecting tubule, and the collecting duct. We will place special emphasis on the cellular and molecular mechanisms responsible for Na^+ transport in these regions, as well as the factors that regulate Na^+ transport.

ANATOMIC CONSIDERATIONS

The mammalian loop of Henle contains the descending thin limb, the ascending thin limb, and the thick ascending limb. The thin descending segment begins in the outer medulla after a gradual transition from the pars recta, and ends at the hairpin turn at the tip of Henle's loop. The thin ascending limb begins at the tip of Henle's loop and ends with its abrupt transition to the thick ascending limb. Loops of Henle that arise from superficial or midcortical nephrons may lack a thin ascending limb. In these short loops, thick limbs generally begin at, or slightly before, the hairpin turn (for a detailed discussion see Chapter 20).

The thick ascending limbs of Henle (TAL) of long looped nephrons begin at the boundary between the inner and outer medulla. The TAL of short looped nephrons does not extend as far into the medulla and may, in fact, be entirely cortical. The TAL extends up into the cortex, where it abuts the glomerulus of origin for that nephron and forms the macula densa part of the juxtaglomerular apparatus. The TAL is composed of two parts: a medullary portion and a cortical portion. The ratio of medullary to cortical TAL for a given nephron is a function of the depth of the glomerulus of the nephron such that superficial nephrons have primarily cortical thick limbs, while juxtamedullary nephrons possess primarily medullary thick limbs.

The distal nephron is divided into three segments: the distal convoluted tubule (DCT); the connecting tubule (CNT); and the collecting duct (CD). These segments are clearly delineated in the rabbit, but in many species the transition between segments is gradual. Therefore, distal tubule segments are most accurately defined by their respective cell types. The DCT begins about 50–100 μm beyond the macula densa, and is lined by a single type of cell: the DCT cell. Na^+-K^+-ATPase activity is particularly high in the basolateral membrane of this segment. The CNT forms a transition zone between the DCT and the cortical CD (CCD). In superficial nephrons, a single CNT drains the DCT into the collecting duct. The CNTs of deep nephrons, however, form arcades that ascend through the cortex draining several DCTs into a CCD. The CNT contains two types of cells: the CNT cell, exclusive to the CNT; and the intercalated cell, also found in the CD.

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00034-3

The collecting duct begins at or slightly before the confluence of two or more connecting tubules, and may be divided into three main parts: the CCD; the outer medullary collecting duct (OMCD); and the inner medullary collecting duct (IMCD). The CCD consists of at least three cell types: principal cells, responsible for Na^+ and K^+ transport; and two types of intercalated cells, responsible for H^+ and HCO_3^- transport. In the rabbit, principal cells account for 65–75% of cells in the CCD. The OMCD can be divided into two regions based on location: the outer stripe and the inner stripe. Approximately 80–90% of cells within the OMCD are principal cells. However, as will be discussed later, the functional properties of principal cells in the OMCD differ from those of the CCD. The IMCD extends from the junction between the inner and outer medulla to the tip of the papilla. The IMCD has been divided into three subsegments based on functional differences, including Na^+ transport. Intercalated cells account for about 10% of all cells in the initial portion of the IMCD, but are absent from the terminal IMCD.

Na^+ TRANSPORT IN THE LOOP OF HENLE

The loop of Henle is responsible for absorbing 25 to 40% of the filtered sodium load. Moreover, the dissociation of salt and water absorption by the loop of Henle is ultimately responsible for the capacity of the kidney either to concentrate or to dilute the urine. The active absorption of NaCl in the water-impermeable TAL serves both to dilute the urine and supply the energy for the single effect of countercurrent multiplication.

Salt Transport by Thin Descending and Thin Ascending Segments

There is morphologic and functional evidence of interspecies and inter- and intranephron heterogeneity in the thin loop segments. The morphologic characteristics of the loop of Henle are covered in detail in Chapter 20 of this volume. Generally, loops of Henle can be divided into two groups: long loops and short loops.[150] The thin descending limb of short loop nephrons is a simple, flat epithelium with few organelles and deep junctional complexes. The thin descending limbs of long loop nephrons are heterogeneous. The upper segment of these thin limbs has a larger diameter and thicker epithelium than short loops. The cells in this region have complicated basolateral interdigitations and apical microvilli, but shallow junctional complexes consist of a single junctional strand. These characteristics are most pronounced in rodents, while in rabbits and humans the upper portion of the thin descending limb has a simpler organization with less extensive interdigitation and deeper junctional complexes.

The lower portion of the thin descending limb consists of flat, noninterdigitating cells with a few apical microvilli and with junctional complexes of intermediate depth. There is little interspecies variability in this portion of the descending limb. The thin ascending limb, present only in long loop nephrons, consists of very flat cells connected by very shallow junctional complexes.

According to the passive models for urinary concentration (see Chapter 40), the thin descending limb should have very high water permeability such that the tubular fluid is concentrated by water abstraction rather than solute entry. *In vitro* microperfusion studies have confirmed that upper and lower portions of mammalian descending limbs are very permeable to water[149,150,176,219] (Table 34.1). The passive models also require the thin ascending limb to be rather impermeable to water, highly permeable to sodium chloride, and only modestly permeable to urea. As indicated in Table 34.1, *in vitro* microperfusion studies of thin ascending limb segments have demonstrated that these requirements are, in fact, satisfied.

The permeability of thin descending limb segments to sodium and chloride has been measured in hamsters, rats, and rabbits. In hamsters and rats, the upper portion of long looped descending limbs has a higher sodium permeability and higher P_{Na}/P_{Cl} ratio than do descending limbs of short looped nephrons. In contrast, there is little difference in P_{Na}/P_{Cl} between long and short loop nephrons in rabbits.[149,150] These results are consistent with the morphologic evidence of greater heterogeneity in rats and hamsters than in rabbits. The pathways for transepithelial movement of sodium and chloride in the descending limb are not defined.

The formation of dilute urine begins in the thin ascending limb of Henle. Fluid from the thin ascending limb is more dilute than fluid obtained from the descending limb at the same level. The decrease in osmolality is due primarily to a fall in the NaCl content of the luminal fluid. The mechanism for NaCl transport across the thin ascending limb epithelium is incompletely understood. Measurements of salt dilution potentials in microperfused thin ascending limb segments reveal them to be chloride selective, with P_{Cl}/P_{Na} ratios of 2.2 to 3.5 in rats and hamsters; segments perfused and bathed with symmetric solutions do not generate a spontaneous transepithelial voltage and do not show net transport of solute (reviewed in [150]). These observations have been interpreted to indicate that salt transport *in vivo* results from passive electrodiffusion rather than active transport. Although driven by passive electrochemical gradients, Cl^- movement across the TAL proceeds through a transcellular, and regulated, pathway. $^{36}Cl^-$ flux ratios and salt dilution voltages indicate that the Cl^- pathway discriminates among anions and is saturable.[150]

NaCl Absorption in Thick Ascending Limb

General Features

Rocha and Kokko[257] and Burg and Green[33] first demonstrated the salient characteristics of salt absorption in rabbit medullary and cortical TAL segments, respectively. First, net salt absorption resulted in a lumen-positive transepithelial voltage (Ve, mV), which could be abolished by furosemide, and in dilution of the luminal fluid. Second, the transport of Cl^- under these circumstances occurred against both electrical and chemical gradients, and hence involved an active transport process. Third, both net chloride absorption and the transepithelial voltage depended on (Na^+, K^+)-ATPase activity, present in large amounts along the basolateral membrane of this segment. A final curious feature of the TAL is that this segment is a "hybrid epithelium" possessing a very low permeability to water, yet a high ionic conductance (Table 34.2). The ionic conductance determined from the fluxes of $^{22}Na^+$ and $^{36}Cl^-$ is approximately 20–50 mS/cm^2, and is cation selective ($P_{Na}/P_{Cl} = 2–6$). This high electrical conductance is unusual among epithelia with low water permeabilities.

Table 34.2 presents a summary of the important transport properties of the rabbit, mouse, and rat TAL which are relevant to the concentrating and diluting functions of this nephron segment. A low permeability to water is required for the TAL to function as a diluting segment. Hebert et al.,[138,140] and subsequently Hebert[132] demonstrated that the apical cell membrane constitutes the major barrier to transcellular water flow in this segment.

Studies of the electrophysiologic (Table 34.3) and biochemical properties of intact, isolated, perfused thick limb segments, and of apical and basolateral membranes of thick limb cells have provided insights into the specific transport mechanisms involved in salt absorption, and the origin of the lumen-positive transepithelial voltage in this nephron segment.[107,108,110–113,135,138–140] A model for salt absorption by the TAL, which integrates the results of these studies, is shown in Figure 34.1. Net Cl^- absorption by the TAL is a secondary active transport process. Luminal Cl^- entry into the cell is mediated by an electroneutral Na^+-K^+-$2Cl^-$ co-transport process driven by the favorable electrochemical gradient for sodium entry. More specifically, the net driving force for the entry of Cl^- into the cell is determined by the sum of the chemical gradients for Na^+, K^+, and Cl^-. Since the Na^+ gradient is maintained by the continuous operation of the basolateral membrane (Na^+,K^+)-ATPase pump, apical entry of Cl^- via the co-transporter ultimately depends on the operation of the basolateral (Na^+,K^+)-ATPase. Accordingly, maneuvers that inhibit ATPase activity, such as removal of K^+ from or addition of ouabain to, peritubular solutions leads to dissipation of the Na^+ gradient and subsequent inhibition of apical membrane Cl^- entry.[138,257]

In contrast to the electroneutral entry of Cl^- across the apical membrane, the majority of Cl^- efflux across the basolateral membrane proceeds through conductive pathways.[135,142,276] A favorable electrochemical gradient for Cl^- efflux through dissipative pathways has been demonstrated by Greger et al.[110] in the rabbit cTAL. In this study, an intracellular Cl^- activity of 22 mM, measured using single Cl^--selective microelectrodes, was substantially above the equilibrium value (5 mM) predicted from the intracellular voltage. Intracellular Cl^- is maintained at concentrations above electrochemical

equilibrium by the continued entry of Cl^- via the apical Na^+-K^+-$2Cl^-$ co-transporter. Blocking Cl^- entry through this pathway with furosemide or substitution of extracellular Cl^- by gluconate, caused the intracellular Cl^- activity to fall to a value close to its equilibrium.[110] In addition to electrodiffusive efflux of Cl^- across the basolateral membrane, a component of electroneutral KCl co-transport has been proposed in some species,[112] and the the K^+-Cl^- co-transporter, KCC4, has been shown to be present at the TAL basolateral membrane.[25]

In addition, according to the model in Figure 34.1, the potassium that enters TAL cells via the Na^+-K^+-Cl^- co-transporter recycles, to a large extent, across the apical membrane by way of a K^+ conductive pathway. This apical K^+ recycling serves several purposes. First, it ensures a continued supply of luminal potassium in order to sustain Na^+-K^+-Cl^- co-transport. Without recycling, the luminal K^+ concentration would fall rapidly as a consequence of K^+ entry via Na^+-K^+-Cl^- co-transport, and would limit net NaCl absorption. Second, the apical membrane potassium current provides a pathway for net potassium secretion by the TAL, which is an active process, ultimately driven by the (Na^+,K^+)-ATPase, proceeding in the face of a lumen-positive transepithelial potential. Third, under open circuit conditions, the transcellular and paracellular pathways form a current loop in which the currents traversing the two pathways are of equal size but opposite direction. The potassium current from cell to lumen polarizes the lumen and causes an equivalent current to flow from lumen to bath through the paracellular pathway.[113] Since the paracellular pathway is cation-selective ($P_{Na}/P_{Cl} = 2–6$), the majority of the current through the paracellular pathway is carried by sodium moving from the lumen to the interstitium. This paracellular absorption of sodium increases the efficiency of sodium transport by the TAL. With reference to Figure 34.1, for each

Na^+ transported through the cell – and requiring utilization of ATP – one Na^+ is transported through the paracellular pathway without any additional expenditure of energy. Finally, the apical K^+ current satisfies the continuity requirement imposed by a high degree of conductive Cl^- efflux across basolateral membranes.[135,214] A small component of sodium transport by the TAL (5–10%) is accounted for by sodium bicarbonate absorption.[105] Sodium bicarbonate absorption is thought to be mediated by an apical membrane amiloride-sensitive Na^+/H^+ exchanger and a basolateral membrane electrogenic $3Na^+/(HCO_3^-)$ co-transporter.[105] The following sections will describe the individual components of the mechanism for TAL salt transport (Figure 34.1) in greater detail.

Apical Na^+-K^+-Cl^- Co-Transport

The predominant mode for Cl^- entry into the TAL cell is via a Na^+-K^+-$2Cl^-$ co-transporter.[107,135,138] A characteristic feature of this transporter is its sensitivity to inhibition by furosemide, bumetanide, and other 5-sulfamoylbenzoic acid derivatives.[253] The first demonstration of dependence on luminal sodium for Cl^- absorption was reported by Greger in isolated perfused rabbit cortical TAL segments.[107] Moreover, a requirement for luminal potassium has been demonstrated for sodium and chloride absorption in both mouse medullary[135] and rabbit[111] cortical thick ascending segments perfused *in vitro*. As a result of these studies, it is now recognized that Cl^- absorption in the TAL generally depends on the simultaneous presence of Na^+ and K^+ (or NH_4) in the lumen.

Measurement of isotope flux into TAL cells or membrane vesicles prepared from the inner stripe of outer medulla have delineated further the ionic requirements and stoichiometry of $1Na^+$-$1K^+$-$2Cl^-$ co-transport.[34,171,174] There is a general agreement that the co-transporter in the thick ascending limb conforms to this stoichiometry under most experimental conditions. However, under certain circumstances, which will be discussed below, apical membrane NaCl entry may be independent of luminal potassium. Early work suggested differences in apparent affinity constant for chloride along TAL[71,108,147,174] which suggested axial heterogeneity in the properties of the Na^+-K^+-$2Cl^-$ co-transporter, because Greger,[108] and Hus-Citharel and Morel[147] examined the cortical TAL, while Koenig et al.[174] and Burnham et al.[34] prepared membranes from the medulla. An axial heterogeneity in the regulation of co-transporter activity as the thick limb ascends from the medulla into the cortex might be anticipated. This is explained by differences in affinity constant for ions of axially distributed along TAL of alternatively spliced variants of the Na^+-K^+-$2Cl^-$ co-transporter.

SLC12A1 gene encodes for the absorptive form of the co-transporter, referred to as BSC1 or NKCC2, located exclusively at the apical membrane of TAL, simultaneously cloned by Gamba et al.[94] and Payne et al.[241] Molecular biology of this gene is extensively discussed in Chapter 32. Inactivating mutations in the *SLC12A1* gene is the cause of Bartter syndrome type I. This syndrome, characterized by hypokalemia, metabolic alkalosis, hyperaldosteronism, and low blood pressure, results from a defect in salt absorption by the TAL, providing strong support for the conclusion that NKCC2 is responsible for apical Na^+-K^+-$2Cl^-$ co-transport in the thick ascending limb.[92] The NKCC2 cDNA encodes a protein containing ~1100 amino acids and having a predicted molecular weight of 115–120 kDa.[92] The observed molecular weight, however, is approximately 150 kDa due to extensive glycosylation. Hydropathy analysis of the amino acid sequence predicts a protein having 12 putative transmembrane spanning domains (TM). Six isoforms of NKCC2 have been identified that are results of alternative splicing in the 5′ and 3′ regions of the NKCC2 gene. Three 5′ splice products, termed A, B, and F, are expressed in all mammalian species.[92] These variants differ only in a 96 bp region, which encodes the amino acids forming half of the second TM and interconnecting segment between TM2 and 3. The isoforms show differential expression within the thick ascending limb. Using RT-PCR, Yang et al.[345] examined

the distribution of NKCC2 isoforms in single nephron segments. The A isoform was found in both the cortical and medullary TAL, the B isoform was restricted to the cortical TAL, while the F isoform was present in the medullary, but not cortical, TAL and, to a lesser extent, in the outer medullary collecting duct. Altough the three variants mediate Na^+-K^+-$2Cl^-$ co-transport, they have different transport properties. The A and B isoforms have higher affinities for Na^+, K^+, and Cl^- than the F isoform. The A isoform appears to have a greater transport capacity than the other isoforms[244] (see Figure 32.3 of Chapter 32). Thus, the presence of the A and F isoform in the medullary thick ascending limb could account for the observed high rates of NaCl transport relative to the cortical segment (Table 34.2), while the expression of the A and B isoforms in the cortical thick ascending limb may subserve the ability to achieve lower luminal NaCl concentrations in that segment. As discussed with detail in Chapter 32, difference in affinity for ions among the NKCC2 variants B and F has been attributed to only six residues within these exons.

There is experimental evidence that the apical co-transporter in TAL might operate as a simple NaCl symporter under certain conditions. Eveloff and coworkers have reported potassium-independent, furosemide-sensitive NaCl transport in isolated rabbit TAL cells and membrane vesicles prepared from TAL cells.[71] Potassium dependence of the co-transporter might be subject to physiologic regulation. Eveloff and Calamia[72] have shown that under isotonic conditions the chloride-dependent, furosemide-sensitive component of sodium uptake is independent of potassium, but that under hypertonic conditions the sodium uptake becomes K^+-dependent. Sun et al.[301] have also reported that, in perfused mouse medullary TAL segments, basal sodium chloride transport was K^+-independent, but that upon stimulation of salt transport by ADH NaCl transport became dependent on luminal K^+. The NKCC2 variants at the carboxyl terminal domain help to explain this discrepancy. Alternative splicing at the 3′ end of NKCC2 produces additional isoforms with either long (C9) or short (C4) carboxy-termini.[221] Under isotonic conditions, the truncated (C4) isoforms do not mediate Na^+-K^+-$2Cl^-$ co-transport. Under hypotonic conditions, however, the C4 isoforms mediate K^+-independent NaCl co-transport, which is inhibited by cAMP[243] and may account for the K^+-independent NaCl transport noted in earlier studies.[72,301] Of note, the C4 isoform inhibit the transport activity of the full-length (C9) isoforms when the two are co-expressed,[245] and this inhibition is relieved by cAMP.[245] The inhibition of C9 NKCC2 isoforms by C4 isoforms suggests a physical interaction between these proteins. Biochemical studies have established that NKCC2 exists as a dimer.[295] Thus, it is possible that different combinations of NKCC2 isoforms within the dimer could produce transporters with a wide variety of functional properties. Moreover, the subunit composition of the dimers may be a point of physiologic regulation. Alternatively, the C4 isoform could alter membrane trafficking or stability of the C9 isoform. The C4 isoform resides predominantly in subapical vesicles rather than the cell membrane.[245] Meade et al.[209] found that co-expression of the C4 isoform reduced the abundance of C9 isoform in *Xenopus* oocyte membranes. The reduction in cell surface C9 isoform was reflected by a commensurate reduction in bumetanide-sensitive Rb uptake. The inhibitory effect of C4 on C9 cell surface localization could be prevented by cAMP or by disruption of microtubules, suggesting that C4 alters the trafficking of C9 in or out of the apical membrane.

Evidence for a model of two distinct binding sites for Cl^- with differing affinities follows from studies of Forbush and Palfrey[80] on ^{3}H-bumetanide binding to renal medullary membranes. In these studies, Na^+, K^+, and Cl^- were all required for bumetanide to bind to canine renal medullary membranes. The K_a values for sodium and potassium were 2 mM and 1 mM, respectively. The effect of Cl^- concentration on bumetanide binding was biphasic. At low concentrations (<5 mM), Cl^- enhanced ^{3}H-bumetanide-binding. These data are consistent with a model in which the binding of Cl^- to a high-affinity site exposes a second lower-affinity site that may be occupied either by bumetanide or by the second Cl^-. However, functional studies using chimeras constructed between the ubiquitously expressed Na^+-K^+-$2Cl^-$ co-transporter NKCC1 encoded by *SLC12A2* gene and NKCC2, as well as in wild-type and mutant variants A, B, and F of NKCC2, revealed that changes in chloride affinity are not paralleled by changes in bumetanide affinity, and *vice versa*, questioning the competition of chloride and bumetanide for a single-binding site (see Chapter 32 on NaCl co-transporters).

The binding of ions to the co-transporter is thought to be ordered and cooperative.[185] Thus, sodium binds to the co-transporter first, and promotes binding of a Cl^- and then K^+. Binding of K^+ to its site, in turn, promotes binding of the second Cl^- to the co-transporter. Once fully occupied, the co-transporter–ion complex translocates to the internal surface of the cell membrane, where debinding occurs in the same order. The full reaction sequence of binding and debinding results in inward $Na^+/K^+/2Cl^-$ transport. Partial reactions permit K^+/K^+ and Na^+/Na^+ exchange.

Apical Potassium (K) Channels

Studies of isolated, perfused, thick limb segments have established that the predominant, and perhaps

only, conductance across the apical membrane is to potassium.[113,136] Blockade of the apical K conductance by luminal barium in mouse medullary thick ascending limb (mTAL) decreases the transepithelial electrical conductance (G_e) by roughly 50%, while increasing the apical-to-basolateral membrane resistance ratio (Ra/Rb) from 1.9 to 12.9.[135] Moreover, changes in the luminal K^+ concentration produce essentially Nernstian changes in the apical membrane electrical potential.[135] Electrophysiological studies demonstrated that the apical membrane K^+ conductance is sufficient to recycle the potassium uptake via the Na^+-K^+-$2Cl^-$ co-transporter.

The properties of the apical membrane K^+ conductance have been studied in plasma membrane vesicles prepared from outer renal medulla.[34,252] Conductive K^+ fluxes in these vesicles can be measured by loading the vesicles with a high concentration of potassium, and then removing the potassium from the external solutions. Tracer amounts of $^{86}Rb^+$ are then added to the extravesicular solutions to begin uptake. Under these conditions, the outwardly directed K^+ gradient creates an inside-negative diffusion potential that drives $^{86}Rb^+$ uptake into the vesicles. Burnham et al.[34] and Reeves et al.[252] were thus able to demonstrate barium-sensitive $^{86}Rb^+$ flux in membranes from rabbit outer medulla. The Rb^+ flux was conductive as judged by its inhibition via collapse of the intravesicular voltage or by measurement of intravesicular voltage using voltage-sensitive dyes. The $K_{0.5}$ value for barium inhibition of Rb^+ flux was 50−100 μM.[34] The barium-sensitive Rb^+ flux was also dependent on the calcium activity within the vesicles.[34] Moreover, in reconstituted proteoliposomes prepared from porcine outer medulla, the calcium dependence of the K^+ conductance was modulated by a high-affinity ($K_{0.5}$ = 0.1 nM) calmodulin-binding site.[173]

The patch-clamp technique has identified two types of apical K^+ channels in the TAL, a low-conductance (35 pS) K^+ channel and an intermediate-conductance (70 pS) K^+ channel in the apical membrane of the TAL. The 35 pS K^+ channel is observed in the apical membrane of rabbit,[327] rat,[325] and mouse.[202] Moreover, exposure of the cytoplasmic surface of the patch to ATP inhibited channel activity. In addition to the 35 pS K^+ channel, Bleich et al.[23] and Wang[325] described an intermediate conductance (60−70 pS) K^+ channel in rat TAL segments. Like the low conductance K^+ channel, the 70 pS K^+ channel was inhibited by ATP and barium.[325] In addition, the channel activity was voltage-dependent with depolarization increasing its activity; the channel could be blocked by quinine, verapamil, and diltiazem, and was inhibited at low cytosolic pH. The activities of both the intermediate and low conductance K^+ channels are increased by high dietary potassium.[200] An overview regarding regulation of

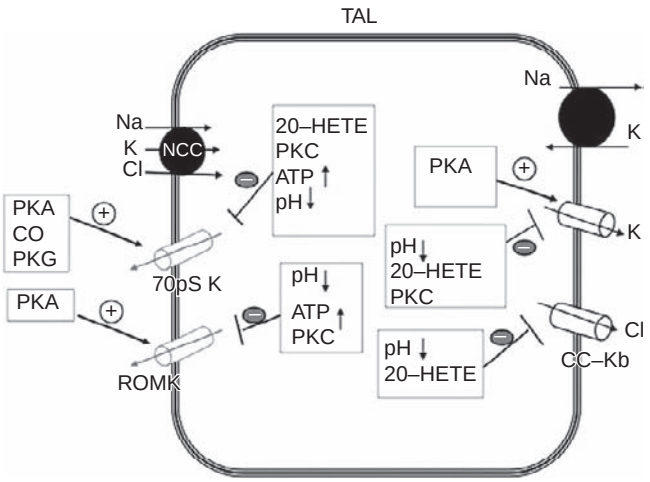

FIGURE 34.2 **A cell scheme illustrating the inhibitory and stimulatory factors for regulation of apical and basolateral ion channels.**

apical K^+ channels in the TAL is summarized in Figure 34.2, and detailed information can also be found in the review articles.[141,329]

An ATP-dependent K^+ channel was cloned from rat kidney by Ho et al.[143] This channel, termed ROMK (Renal Outer Medullary K^+ channel), is the prototype for a large family of inward rectifying K^+ channels (K_{IR} channels). K_{IR} channels have two transmembrane spanning domains, intracellular N- and C-termini, and an extracellular helical domain between the two transmembrane domains. Structural studies of other K_{IR} channels have established that the channels exist as heteromers of four K_{IR} subunits.[230,231,307] The extracellular helical domain appears to form the outer vestibule and selectivity filter of the channel, while the second transmembrane domain lines the pore cavity.

$ROMK^+$ channels have three alternatively spliced forms and they are ROMK2 (Kir1.1b), ROMK3 (Kir1.1c),[26,350] and ROMK6 (Kir1.1d).[178] The encoded ROMK proteins differ at the beginning of the N-terminus; ROMK2 has the shortest N-terminus[177] and splicing adds either 19 or 26 amino acids for ROMK1 or ROMK3, respectively. Relative ROMK mRNA abundance measured by competitive PCR has shown that ROMK2 and ROMK3 are much more abundant than ROMK1 or ROMK6 in rat kidney.[17] Moreover, single-nephron PCR analysis indicated that ROMK1 is expressed in the collecting duct, while both ROMK2 and ROMK3 are expressed in the medullary and cortical thick ascending limb.[26] Immunolocalization of ROMK proteins, using antibodies that recognized all three isoforms, revealed apical membrane localization in the medullary and cortical thick ascending limb, the late distal tubule, the connecting tubule, and the cortical collecting duct.[210,341] Oddly, the expression of ROMK in the thick limb was

heterogeneous, with some cells lacking demonstrable staining. In contrast, the expression of the Na^+-K^+-$2Cl^-$ co-transporter was uniform within the TAL.[341] This implies that apical K^+ recycling by the ROMK-positive cells may be sufficient to supply K^+ for Na^+-K^+-$2Cl^-$ transport in the ROMK-negative cells.

The 35 pS channel conductance of ROMK corresponds to the low conductance K^+ channel described by Wang et al.[325] The current−voltage relations exhibit weak inward rectification, which is due to blocking of the channel by intracellular Mg^{2+} or polyamines.[177] The activity of this channel is modulated by intracellular pH and by intracellular ATP, through both phosphorylation-dependent and phosphorylation-independent pathways.[141] The maintenance of $ROMK^+$ channel activity requires protein kinase A (PKA)-mediated phosphorylation and deletion of any two of three PKA-phosphorylation sites inactivates ROMK.[203] Phosphorylation of ROMK affects both channel activity (P_o) and the number of functional channels in the plasma membrane.[346] In addition, PKA-induced phosphorylation of ROMK enhances the sensitivity of the $ROMK^+$ channel to phosphatidylinositol phosphates (PIP2).[189]

Nucleotides have both inhibitory and stimulatory effects on ROMK activity. At micromolar concentrations, ATP stimulates ROMK activity via PKA-mediated phosphorylation and production of PIP_2.[329] Millimolar concentrations of ATP inhibit ROMK activity.[326,328] The inhibition by ATP can be relieved by increasing concentrations of ADP or by PIP_2.[198] Certain other members of the K_{IR} family are also inhibited by ATP. The ATP sensitivity of these channels—for example, $K_{IR}6.2$—is endowed by the association of regulatory subunits.[51] These regulatory subunits, such as the sulfonylurea receptor (SUR) and CFTR,[3,151] belong to the ABC gene family which is characterized by nucleotide-binding domains. The sulfonylurea receptor, together with $K_{IR}6.2$, forms the glibenclamide-sensitive, ATP-sensitive K^+ channel that controls insulin secretion by pancreatic β-cells.[151] The K_{IR}/SUR channels are more sensitive to inhibition by ATP than those of heterologously expressed $ROMK^+$ channels. In addition, the native 35 pS K^+ channel, but not the heterologously expressed $ROMK^+$ channel, is inhibited by glibenclamide.[324] These observations have prompted the search for regulatory subunits for the $ROMK^+$ channel. Both SUR2B[18] and CFTR[216] are expressed in the thick ascending limb and collecting duct, making them candidates for ROMK regulation. In transfection studies, co-expression of ROMK with either SUR2B[305] or CFTR[208,264] dramatically increases both the nucleotide dependence and glibenclamide sensitivity of ROMK. Immunoprecipitation studies confirmed that one of the ROMK isoforms, ROMK2, physically interacts with SUR2B.[305] The role of CFTR in regulating the native $ROMK^+$ channels has been further suggested by the finding that PKA-induced regulation of ATP sensitivity of the native 35 pS K^+ channel is compromised in CFTR knockout mice.[199] Figure 34.3 is a cartoon illustrating the current view regarding the composition of the native ATP-sensitive K^+ channel in the apical membrane of the TAL.

The electrophysiologic properties of the ROMK channels have strongly suggested that ROMK is the native 35 pS K^+ channel expressed in the thick ascending limb.[47,233,329] In support of this view, no low-conductance K^+ channels were detected by patch-clamp analysis in ROMK knockout mice.[201] Moreover, deleting the gene product encoding ROMK also abolished the expression of intermediate conductance K^+ channels in the thick ascending limb.[200] It has been proposed that the intermediate conductance channel may be a heteromeric protein containing ROMK and other, as yet unidentified, subunits. The notion that one of the ROMK channels is the predominant channel responsible for apical K^+ recycling in the thick ascending limb is strongly supported by the finding of mutations in the ROMK gene in some families with Bartter syndrome.[290] Thus, the presence of ROMK mutations as a cause of Bartter syndrome indicates the important role of ROMK in net salt absorption by the thick ascending limb.

Basolateral Potassium (K) Channels

Basolateral K^+ channels in the TAL play an important role in the regulation of transepithelial transport.[98,141] They are responsible for generating basolateral membrane potential which is essential for Cl diffusion across the basolateral membrane in the TAL. Activation of basolateral K^+ channels in the TAL is expected to hyperpolarize the basolateral cell membrane, thereby augmenting the driving force for Cl exit across the basolateral membrane. In contrast, decreasing basolateral K^+ channel activity depolarizes the cell membrane potential, thereby diminishing the driving force for Cl^- exit across the basolateral membrane. Consequently, inhibition of Cl^- exit leads to an increase in intracellular Cl^- concentration which decreases the activity of NKCC2, probably via inhibiting WNK3-SPAK.[247]

The physiological importance of the basolateral K^+ channels in maintaining transepithelial membrane transport in the TAL and distal nephron is best demonstrated in SeSAME disease (Seizures, Sensorineural deafness, Ataxia, Mental retardation, and Electrolyte imbalance). This disease is the result of defective gene product encoding KCNJ10, an inwardly-rectifying K^+ channel,[281] which is also expressed in the basolateral membrane of TAL and distal nephron.[183] The renal phenotypes of SeSAME disease are hypokalemia, metabolic alkalosis, and hypomagnesemia. Presumably, defective basolateral K^+ channels cause membrane potential depolarization,

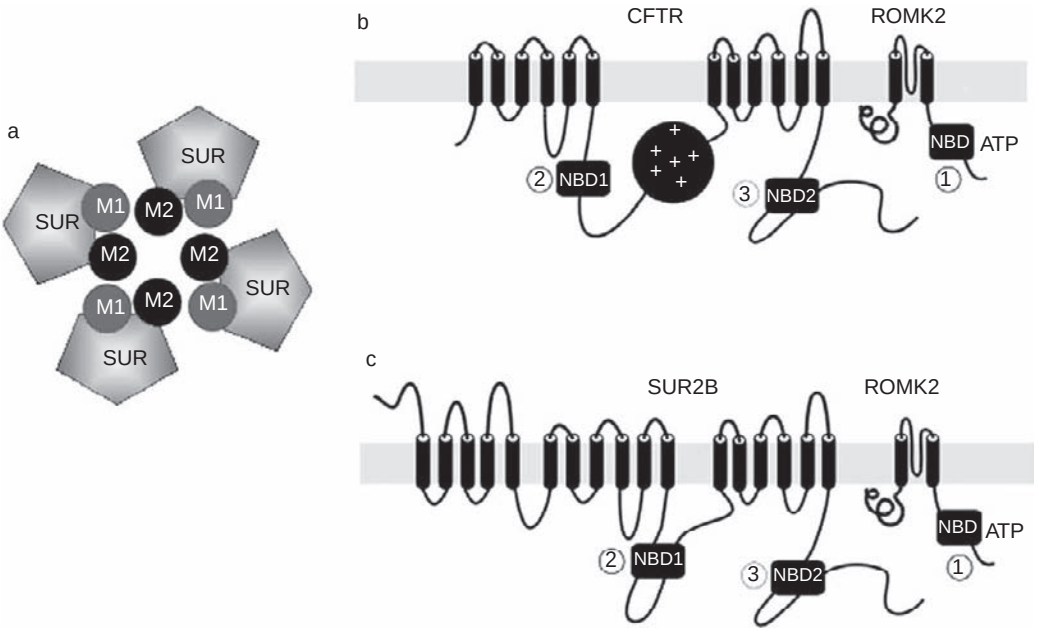

FIGURE 34.3 Assembly of the native ATP-sensitive K channels in the TAL with ATP-binding cassette [ABC] proteins. (a) The proposed hetero-octameric complex forming the native ATP-sensitive K channels in the TAL with four K_{IR} subunits and four sulfonylurea receptor [SUR] subunits. (b) The topology of CFTR and ROMK channels proposed to form kidney K_{ATP} channels. A single nucleotide-binding domain [NBD, 1] is present on the C-terminus of ROMK while two NBDs [numbered 2 and 3] are found on CFTR. (c) The topology of the sulfonylurea receptor, SUR2B, and ROMK proposed to form kidney K_{ATP} channels.

thereby decreasing Cl^- diffusion across the basolateral membrane. Consequently, an increase in intracellular Cl^- concentrations results in the inhibition of the apical Na entry through NKCC2, thereby suppressing Na absorption and diminishing the lumen-positive potential in the TAL. A decrease in the lumen-positive potential results in inhibition of magnesium absorption through the paracellular pathway in the TAL.[134] Also, the inhibition of Na absorption in the TAL increases Na delivery to the distal nephron, accordingly stimulating Na absorption in the expanse of K^+ in the connecting tubule and causing K^+-wasting. Therefore, an alteration in the basolateral K^+ channel activity in the TAL has a significant effect on transepithelial transport not only in the TAL, but also in the distal nephron segment.

Patch-clamp experiments demonstrated that an inwardly-rectifying 50 pS K^+ channel[119,238] and a Na^+ and Cl^- activated 140−180 pS K^+ channel[240] are present in the basolateral membrane of the TAL. The 50 pS K^+ channel is highly-expressed, and may be the main K^+ channel in the basolateral membrane of the TAL. The regulation of the 50 pS K^+ channels has been intensively studied and several factors, including protein kinase A (PKA), 20-hydroxyeicosatetraenoic acid (20-HETE), and external Ca^{2+}, have been identified to modulate the 50 pS K^+ channels (Figure 34.2). Arachidonic acid inhibits the basolateral 50 pS K^+ channels in the TAL through the CYP-omega-hydroxylase-dependent metabolism, and 20-HETE mediates the effect of arachidonic acid on the K^+ channel.[115,119] Also, raising the external Ca^{2+} inhibited the basolateral 50 pS K^+ channels in the TAL by a PKC-dependent mechanism.[179] Two lines of evidence suggest that the effect of the external Ca^{2+} on the basolateral 50 pS K^+ channels was the result of stimulating the Ca^{2+}-sensing receptor (CaSR) which is expressed in the TAL[133]: (1) the inhibitory effect of raising the external Ca^{2+} on the 50 pS K^+ channels was observed only in cell-attached patches, but not in excised patches; (2) the effect of raising external Ca^{2+} on the 50 pS K^+ channel was absent in the presence of the CaSR antagonist. It is possible that the CaSR might directly interact with the basolateral 50 pS K^+ channels in the TAL. This speculation is supported by reports from several studies. First, the basolateral 50 pS K^+ channels in the TAL might represent heterotetramers made of Kir4.1/Kir5.1, because the basolateral K^+ channels in the distal tubules with similar biophysical properties to those of the 50 pS K^+ channel in the TAL are composed of Kir4.1 and Kir5.1.[183,197] Second, immunostaining experiments demonstrated that Kir4.1 and Kir5.1 were expressed in the basolateral membrane of the TAL.[254,306] Finally, the study using immunoprecipitation performed in the cells transiently transfected with Kir4.1 and the CaSR has demonstrated that Kir4.1 was associated with the CaSR.[144] The regulation of the basolateral 50 pS K^+ channel by the external Ca^{2+} should play a role in the

modulation of transepithelial Na transport and concentrating ability in the TAL. Since the active reabsorption of $NaCl^-$ in the water-impermeable TAL is essential for urinary concentrating mechanism, inhibition of $NaCl^-$ reabsorption in the TAL should result in a decrease in concentrating ability. Indeed, it has been reported that hypercalcemia impairs urinary concentrating ability.[99]

Because the activity of the basolateral K^+ channels is regulated by the external Ca^{2+}/Mg^{2+} concentrations at a physiologically relevant range (1 to 2 mM), the CaSR-mediated regulation of the membrane transport in the TAL is mainly through controlling the basolateral K^+ channel activity. Figure 34.4 is a cell scheme illustrating the role of basolateral K^+ channels in mediating the effect of stimulation of the CaSR on Na^+ and divalent cation transport in the TAL. Under physiological conditions, the basolateral K^+ channels maintain the cell membrane potential such that it could sustain a constant Cl^- diffusion across the basolateral membrane. An increase in the external Ca^{2+} (hypercalcemia) activates the CaSR, thereby inhibiting basolateral K^+ channels and decreasing the driving force for Cl^- diffusion across the basolateral membrane. Inhibition of Cl^- exit is expected to lead to hyperpolarization of transepithelial voltage (V_{te}). A less positive V_{te} would diminish the reabsorption of Na^+ and divalent cations such as Ca^{2+} and Mg^{2+}. Indeed, it has been reported that an increase in plasma Ca^{2+}/Mg^{2+} level enhanced urinal Ca^{2+}/Mg^{2+} excretion.[249,250]

Basolateral Membrane Cl^- Channel and Transporter

Cl^- CHANNEL

Cl^- exit across the basolateral membrane of TAL cells is largely conductive, proceeding down its electrochemical gradient through Cl^--selective channels in the basolateral membrane. The notion that basolateral Cl^- transport is electrogenic first derived from observations that, in the mouse medullary TAL and rabbit cTAL,[138] net Cl^- absorption accounts for about 90% of the equivalent short-circuit current. Measurements of the basolateral membrane voltage by Greger and Schlatter[112] confirmed that reductions in bath chloride concentration depolarized the basolateral membrane, while reductions in intracellular chloride concentration produced by blocking Cl^- entry with furosemide hyperpolarized the basolateral membrane. Both sets of observations are consistent with the presence of a Cl^- conductance in the basolateral membrane. Consistent with the view that basolateral Cl^- transport is via chloride channels, a variety of compounds known to block Cl^- channels also inhibit salt absorption in TAL segments. Wangemann et al.[121] have catalogued the electrophysiologic effects, relative potencies, and structure–function relations of over 200 such compounds. The major effects of these agents, when present in the peritubular bathing solutions, are inhibition of transepithelial voltage, inhibition of the equivalent short circuit current, and hyperpolarization of the basolateral membrane.

Application of the patch-clamp technique to the TAL has established that Cl^- channels are present in the basolateral membrane of TAL cells. Paulais and Teulon detected a 40 pS anion selective channel ($P_{Cl}/P_{Na} = 20$) in the basolateral membrane of collagenase treated mouse cortical TAL segments.[121] The I–V relations of the channel were linear in both the cell-attached and excised configurations. The open probability of the channel in the cell-attached state was voltage-dependent, increasing as the membrane was depolarized. In the excised patch configuration, the open probability was no longer voltage-dependent. Greger et al. described a Cl^- channel in the basolateral membrane of rat TAL segments.[109] This channel also has a conductance of about 40 pS, but rather than having a linear I–V relation, this channel exhibits outward rectification. The open probability increases with depolarization in both the cell-attached and -excised patch configuration. A low conductance Cl^- channel (8–10 pS) having linear I–V relations has also been detected in the basolateral membrane of TAL cells.[121,120,118] The activity of this channel is

increased following incubation with cAMP-dependent protein kinase and ATP,[120] and is inhibited by 20-HETE acid, a Cyp-ω-hydroxylase-dependent metabolite of arachidonic acid.[118]

Evidence for Cl^- channels in the TAL also comes from studies of Cl^- flux in renal medullary membrane vesicles. Since TALs comprise approximately 70% of the volume in the inner stripe of outer medulla, vesicles prepared from this region should be predominantly derived from this segment. $^{36}Cl^-$ flux into vesicles from rabbit outer medulla[16] is electrogenic, cation-independent, inhibitable by chloride channel blockers, and has a low activation energy ($E_a = 6.4$ kcal/mole), characteristic of transport through a channel. Moreover, when vesicles from rabbit outer medulla were incorporated into planar lipid bilayers, chloride channel activity was demonstrated.[251] These channels were anion selective ($P_{Cl}/P_K = 10$) and had a single-channel conductance of 80−90 pS in 320 mM KCl solution. The I−V relations in symmetric solution were linear, and in asymmetric solutions the I−V relations conformed to the Goldman−Hodgkin−Katz equation. The open probability of this channel was voltage-dependent, increasing activity with depolarizing voltages. These channels are also seen in vesicles made from highly purified suspensions of mouse thick ascending limb.[337]

Molecular cloning has demonstrated the basolateral Cl^- channels are composed of ClC-K1 and ClC-K2,[2,166,311] members of a large number of the ClC family of channels.[155] ClC-K1 and ClC-K2 are expressed exclusively within the rat kidney. In the human, the two corresponding channels are denoted hCLC-Ka and hCLC-Kb, and are located contiguously on chromosome 1.[265] Due to the high degree of sequence similarity between hCLC-Ka and hCLC-Kb, it is not certain which of the human channels correspond to CLC-K1 versus CLC-K2, although the distribution of ClC-K2 along the nephron most closely matches that of hClC-Kb.[304] Zimniak and colleagues[351] have cloned cDNA from rabbit renal outer medulla, named rbClC-Ka, which shares 80% homology to the rat CLC-K1 and CLC-K2. The distribution of rbClC-Ka along the nephron resembles that of CLC-K2 rather than ClC-K1.[351] Several lines of evidence support the view that CLC-K2 (or the probable human homolog hCLC-Kb) is the channel that mediates chloride efflux across the basolateral membrane of the thick ascending limb. First, using polymerase chain reaction amplification of single tubule segments, the ClC-K2 and rbClC-Ka channels were shown to be expressed primarily in the thick ascending limb and the collecting duct.[2,351] Second, immunohistochemical studies using an antibody against the rbClC-Ka channel revealed predominantly basolateral staining in the medullary and cortical thick ascending limb.[338] Similar results were obtained by Vandewalle and colleagues using an antibody that recognized both CLC-K1 and CLC-K2.[314] Finally, and most compelling, is the identification of mutations in hCLC-Kb in patients with neonatal Bartter syndrome.[289] Thus, as was the case for the NKCC2 and ROMK proteins, linkage of ClC-Kb to Bartter syndrome establishes the importance of its gene product in transepithelial NaCl transport. Activating mutations of CLC-Kb have also been reported.[153] Specifically, substitution of threonine by serine at position 481 of CLC-Kb results in a dramatic increase in Cl^- currents, without a change in channel selectivity or cell surface expression. The T481S polymorphism is relatively common in the general population, particularly in African populations. Among Caucasians, the presence of the T481S polymorphism was associated with higher systolic and diastolic blood pressures, and a higher prevalence of hypertension.[154] Thus, ClC-Kb is an attractive candidate gene for certain forms of essential hypertension, particularly salt-sensitive hypertension. Additional studies in different populations will be required to determine the significance of these ClC-Kb polymorphisms.

To form functional Cl^- channels in thick ascending limb requires not only CLC-K2/hCLC-Kb, but also a subunit, named barttin.[21] Lost function of mutation of barttin is responsible for a form of Bartter syndrome accompanied by sensorineural deafness.[21] Barttin is believed to act, at least in part, by increasing the cell surface expression of ClC-Kb.[70]

KCl SYMPORTER

Some uncertainty remains regarding the role of basolateral electrochemical KCl symport in net Cl^- efflux across that membrane. In the rabbit cortical TAL, Greger and Schlatter[239] concluded that KCl symport accounted for about one-third of basolateral Cl^- efflux. This conclusion is based on the following observations: an increase in the K^+ concentration or decrease in the Cl^- concentration of the basolateral solution depolarized the basolateral membrane; bath barium depolarized the basolateral membrane and abolished the K^+-induced changes in V_bl; and barium had no discernible effect on the transepithelial resistance or fractional resistance of the basolateral membrane. The lack of an effect of barium on resistance persuaded the investigators to propose that a barium-sensitive KCl co-transporter was present.[112] Alternatively, these data are compatible with parallel conductive pathways for K^+ and Cl^-. The absence of a barium effect on transepithelial resistance could be due to an offsetting increase in basolateral Cl^- conductance or to changes in basolateral membrane resistance below the experimental limits of detection. A cloned KCl co-transporter, KCC4, is present in the basolateral

membrane of the thick ascending limb.[316] However, its physiologic role in thick ascending limb function is not known.

Synchronous Na^+/H^+: Cl^-/HCO_3^- Exchange

An additional form of apical membrane NaCl entry has been observed in the mouse cTAL. Friedman and Andreoli[83] found that net Cl^- absorption and the transepithelial voltage were doubled when CO_2 and HCO_3^- were added to the external solutions bathing cTAL segments. Since the (CO_2 HCO_3^-)-stimulated rate of NaCl absorption did not result in net CO_2 transport, and could be abolished by the lipophilic carbonic anhydrase inhibitor ethoxyzolamide or by the luminal addition of the anion exchange inhibitor SITS or DIDS, it was proposed that the apical membrane of the mouse cTAL contains parallel, near-synchronous Na^+/H^+: Cl^-/HCO_3^- exchangers in addition to a Na^+-K^+-Cl^- co-transporter. Subsequent studies have shown that, like the mouse mTAL, the apical membrane of the mouse cTAL contains a potassium conductance, and that both the (CO_2 HCO_3^-)-dependent and (CO_2 HCO_3^-)-independent components of NaCl absorption require luminal potassium.[84,82] Thus, the cation exchange process may proceed as (Na^+, K^+)/2 H^+. Both the (CO_2 HCO_3^-)-dependent and -independent components of NaCl absorption in mouse cTAL segments were equally susceptible to inhibition by luminal bumetanide ($K_i = 5-8 \times 10-7$ M).[82] Addition of CO_2 and HCO_3^- to the bathing solutions has no effect on net NaCl transport in either rabbit cTAL or mouse mTAL. Both the rat and mouse mTAL do contain Na^+/H^+ exchangers in their apical membranes. However, in these segments, Na^+/H exchange plays a role in net HCO_3^- transport and cell pH regulation, rather than transcellular NaCl absorption.[104,168]

Bicarbonate and Ammonium Transport

Medullary and cortical TAL segments from the rat absorb bicarbonate and acidify the luminal fluid.[105] The rates of bicarbonate absorption measured in *in vitro* perfused TAL segments account for most of the filtered bicarbonate that is reabsorbed by the loop of Henle *in vivo*.[104] The rate of sodium bicarbonate absorption in the rat TAL is, however, only a small fraction (5–10%) of total sodium absorption by this segment. Thus, while bicarbonate transport by the TAL may play an important role in urinary acidification in some species, bicarbonate transport has little impact on net salt balance or free water excretion. There is considerable species variation in the rates of bicarbonate absorption by the TAL. No significant bicarbonate transport was detected in mouse and rabbit TAL.[83,105] In the rabbit, this correlates with the absence of carbonic anhydrase activity in the TAL.[95]

The mechanism of bicarbonate absorption by the rat TAL has been reviewed.[105,38] Transcellular bicarbonate absorption results from proton secretion across the apical membrane and bicarbonate reabsorption across the basolateral membrane. The apical proton secretion occurs primarily by NaH exchange. Evidence for functional apical Na^+/H^+ exchange has been presented for the rat[104,180] and mouse TAL.[83,167] In these segments, acidification of luminal fluid is sodium-dependent and amiloride-sensitive. Moreover, removal of luminal sodium or luminal amiloride results in cytoplasmic acidification. As noted above, the NHE3 isoform of the Na^+/H^+ exchanger is expressed in the apical membrane of the thick ascending limb.[6] NHE3 expression in the TAL is increased by chronic metabolic acidosis, providing a mechanism for enhanced HCO_3^- absorption in this setting. An apical membrane H-ATPase may also contribute to bicarbonate absorption in the TAL.[105] Inhibition of the Na^+-K^+-Cl^- co-transporter by furosemide stimulates bicarbonate absorption in the rat TAL. Thus, this transporter is not directly involved in bicarbonate absorption. Rather, the reduction in cell Na^+ activity that attends inhibition of Na^+-K^+-Cl^- co-transport provides a greater driving force for apical Na^+/H^+ exchange.

Krapf[180] has demonstrated that base efflux across the basolateral membrane of perfused rat TAL segments occurs as $Na^+(HCO_3^-)$ co-transport. This process is electrogenic (probable stoichiometry $1Na^+:3HCO_3^-$), sodium-dependent, Cl^--independent, and SITS-sensitive. $Na^+(HCO_3^-)$ co-transport has been demonstrated in mouse medullary TAL as well. In the mouse, the apical Na^+/H^+ exchanger and basolateral $Na^+(HCO_3^-)$ co-transporter play a role in cell pH regulation, rather than transcellular bicarbonate transport.

Origin of Transepithelial Voltage

The spontaneous, lumen-positive transepithelial potential that accompanies net NaCl absorption is, in principle, the sum of at least two terms: an electrogenic voltage arising from rheogenic cellular pathways; and a zero-current dilution voltage referable to salt accumulation in intercellular spaces during salt absorption. Given the cation selectivity of the paracellular pathway (P_{Na}/P_{Cl} ~2–6), an accumulation of Na^+ in the lateral intracellular space mediated by the (Na^+, K^+)-ATPase could create a lumen-positive diffusion potential across the junctional complex. As discussed earlier, the lumen-positive potential arising from rheogenic cellular transport serves to drive a proportion of net sodium reabsorption through the paracellular pathway.

However, this paracellular sodium absorption will be diminished by the extent to which paracellular diffusion potential accounts for the spontaneous transepithelial voltage, V_e. Thus, it is pertinent to consider the relative contributions of both electrogenic and diffusion potentials to the total transepithelial voltage.

Hebert and Andreoli[136] assessed the possible contributions of a paracellular diffusion potential to V_e in the mouse TAL. The conductance of the paracellular pathway, G_s, was measured by blocking the transcellular conductance with 20 mM Ba^{2+} in the lumen. The junctional complexes were then disrupted by the imposition of large osmotic gradients produced by the addition of urea to the luminal perfusate. Using the value of G_s in the presence of 800 mM luminal urea as an estimate of the ionic conductance of the lateral interspace, exclusive of the junctional complex, Hebert and Andreoli[136] calculated that, during net NaCl transport, the maximal rise in NaCl concentration in the lateral interspace was 10 mEq/liter, and that the resulting dilution potential was less than 1 mV. These results are consistent with the notion that virtually all of the transepithelial voltage is the result of rheogenic transcellular processes.

Specifically, because the apical membrane is exclusively conductive to potassium, and because the $Na^+K^+2Cl^-$ co-transporter is electroneutral, the apical membrane voltage, V_a, will approximate the K^+ equilibrium voltage, E_K. The basolateral membrane voltage, V_{bl}, in contrast, is a function of several conductive pathways; examples include K^+ and Cl^- channels, $Na^+HCO_3^-$ symport, (Na^+, K^+)-ATPase. Of these, Cl^- is likely the most important conductive species across the basolateral membrane. V_{bl}, therefore, will be greater than E_{Cl}, but less that E_K, and hence less than V_a (Table 34.3). The lumen-positive V_e then is the result of differing conductance characteristics of the apical and basolateral membranes. The exact value of V_e will be determined by the relative magnitude of the basolateral K^+ and Cl^- conductances, and the currents passing through the apical and basolateral membranes.

According to these arguments, the electrogenic nature of V_e should allow for a significant fraction of net sodium absorption to proceed via the paracellular pathway. Indeed, for a constant stoichiometry of the Na^+K^+-$2Cl^-$ entry, the ratio of net Cl^- absorption to paracellular sodium absorption should have a value of 2. The rate of net paracellular Na^+ absorption depends on a variety of factors, such as V_e, G_s, and P_{Na}/P_{Cl}, which vary considerably from tubule to tubule. When each of these variables was measured in the same tubule, however, the ratio of net Cl^- absorption to paracellular Na^+ absorption was reasonably constant at 2.4 ± 0.3.[136] Thus, the stoichiometry of Na^+K^+-$2Cl^-$ entry may be constant under those experimental conditions, that is, ADH stimulated mTAL segments, and the variables G_e, G_s, and P_{Na}/P_{Cl} are related in a given tubule in such a way as to maintain the net Cl^- to paracellular Na^+ ratio at 2.

Coupling of Substrate Utilization to Ion Transport

Transepithelial NaCl absorption accounts for the single largest expenditure of energy by TAL cells. Inhibition of the (Na^+,K^+)-ATPase by ouabain reduces O_2 consumption by rabbit,[42,71] rat,[309] and mouse[168] TAL segments by 50%. The effect of ouabain on O_2 consumption can be mimicked by either furosemide or by removal of Na^+ or Cl^- from the bath solutions.[42,71] This suggests that about one-half of the total cellular ATP supply is consumed by the basolateral membrane (Na^+,K^+)-ATPase pump, and that this pump operates almost exclusively for the purpose of transepithelial NaCl transport.

TAL segments utilize a variety of metabolic substrates including D-glucose, D-mannose, butyrate, β-OH-butyrate, acetoacetate, lactate, acetate, and pyruvate to support the high ATP requirement imposed by salt transport.[339] Uchida and Endou[310] determined the ability of various substrates to maintain cellular ATP concentrations in microdissected mouse TAL segments. In mTAL segments, glucose, lactate, and β-hydroxybutyrate all conserved cellular ATP content equally well. In the cTAL, lactate and β-hydroxybutyrate increased cellular ATP more than did glucose. Wittner et al. reported that in the absence of exogenous substrate, NaCl transport fell by 73% in 10 minutes in rabbit cTAL.[339] Chamberlin and Mandel[43] assessed the ability of various endogenous and exogenous substrates to support oxidative metabolism in suspensions of rabbit mTAL segments. Unlike the findings in rabbit cTAL, the mTAL suspensions maintained 85% of their basal O_2 consumption in the absence of exogenous substrates. Inhibitors of glycolysis, fatty acid oxidation, and amino acid oxidation reduced O_2 consumption, indicating that glucose, fatty acids, and amino acids all serve as endogenous substrates capable of supporting oxidative metabolism when the availability of exogenous substrate is limited.[43]

Therefore, the TAL, particularly the medullary portion, relies almost exclusively on oxidative metabolism as its source of energy. However, the mTAL resides in an oxygen-poor environment. The oxygen tension in the outer medulla is about 10 mmHg.[186] Apparently, like the cTAL, the O_2 affinity of the mTAL is sufficiently high that oxidative metabolism is maintained even at low oxygen pressures. Nonetheless, the high oxygen requirement in an oxygen-poor environment

might predispose the mTAL to injury if oxygen delivery falls or salt transport requirements increase. Brezis and co-workers have shown that the medullary TAL is, in fact, exquisitely susceptible to hypoxic injury.[30] Maneuvers that diminish TAL salt transport, such as furosemide, exert a marked protective effect against hypoxic injury.[31]

Regulation of Salt Absorption in TAL

The rate of salt absorption by the thick ascending limb is modulated by physical factors, such as luminal flow rate and the composition and osmolality of luminal and peritubular fluids, and hormones, such as vasopressin and glucagon, which exert their effects through interactions with specific cellular receptor proteins. The regulation of TAL salt transport is characterized by considerable interspecies variation, as well as intranephron heterogeneity. It is worth noting, again, that the cortical and medullary portions of the TAL have different transport properties (Table 34.2) and subserve different functions. Salt absorption in both segments creates luminal fluid dilution and the potential for free water excretion; however, only salt absorption by the medullary TAL enriches the medullary interstitial osmolality and enhances urinary concentrating power. Given these differences, it is not surprising that the rates of transport in the medullary and cortical TAL are modulated quite differently. A good example of both species and intranephronal heterogeneity is the effect of antidiuretic hormone on TAL transport.

Antidiuretic Hormone

The ADH affects NaCl absorption in the ascending limb of Henle, and thereby regulates the countercurrent multiplication process. Support for this contention was provided by the demonstration, in some species, of an ADH-induced increase in adenylate cyclase activity[40,55] and protein kinase activity[65] in the medullary, but not cortical, portions of the TAL.

Table 34.4 summarizes the effects of ADH on salt transport in *in vitro* microperfused medullary TAL segments of mouse, rat, and rabbit. Hall and Varney[123] established that ADH increased the lumen-positive transepithelial voltage and the net rate of tracer Cl^- absorption in the mouse medullary TAL. Several laboratories have confirmed these effects of ADH on the transepithelial voltage and unidirectional Cl^- flux in the mouse, and have demonstrated that the effect of ADH on NaCl transport was restricted to the medullary portion of this segment.[138,270,276,338] Moreover, the maximal stimulation of the transepithelial voltage in the mouse medullary TAL occurred at hormone concentrations of approximately 20 pg/ml or 10 μU/ml, found during states of antidiuresis.[138] A similar increase in transepithelial voltage can be obtained in the mouse medullary TAL, but not the cortical TAL, by the addition of cAMP analogs or forskolin, a nonhormonal activator of adenylate cyclase to the peritubular media.[138] In contrast, ADH, even at peritubular concentrations of 250 μU/ml, has no effect on V_e in the mouse cortical TAL.[138] Taken together, these results indicate that the mouse medullary TAL and cortical TAL are functionally heterogeneous with respect to the effect of ADH on net NaCl absorption, and that stimulation of net NaCl absorption in the mouse medullary TAL by ADH is mediated by cAMP. The effect of ADH in TAL does not seem to be contant in all species. ADH causes a variable increase in cyclic AMP production in the rabbit TAL, but pharmacologic concentrations of ADH had no effects on either the transepithelial voltage or tracer Cl^- efflux in this species.[270] ADH or the V_2 selective analog dDAVP increased NaCl absorption from the TAL on homozygous Brattleboro (central diabetes insipidus) rats.[340] In humans evidence is limited. Studies in pump-perfused human kidneys rejected for transplantation have shown ADH-sensitive adenylate cyclase activity in collecting ducts, but not in TAL segments.[40,263] Since the ability of humans to elaborate concentrated urine is limited compared to the mouse, the failure of ADH to increase cAMP in the human TAL is consistent with Morel's suggestion that the response of medullary TAL segments to ADH correlates directly with urinary concentrating ability.[217]

TABLE 34.4 Effects of ADH on NaCl Transport by Thick Ascending Limb Segments

Species	ADH	V_e (mV)	J_{NaCl} (pmol/sec/cm^2)
Mouse	−	5	2600
	+	11	10,800
Rat	−	2.4–3.3	4825
	+	3.6–4.7	7770
Rabbit	−	3–7	6400
	+	3–7	Unchanged

Table from Reeves, W. B., and Andreoli, T. E. (2008). Sodium chloride transport in the loop of Henle, distal convoluted tubule, and collecting duct. In "The Kidney: Physiology and Pathophysiology," 4th edn, 849–888, Alpern, R. J., and Hebert, S. C. (eds.). Elsevier.

Mechanisms of ADH Affect on TAL

The mechanism whereby ADH stimulates salt transport in the medullary TAL has been studied most extensively in the mouse. The effects of ADH in this segment are mediated predominantly through interaction of the hormone with the vasopressin V_2 receptor coupled to adenylate cyclase. Thus, ADH stimulates

adenylate cyclase activity in the TAL,[217] and cAMP analogs and forskolin[139] mimic the effects of ADH on transport in this segment. Cholera toxin stimulates salt transport in the TAL, indicating that the V_2 receptor is coupled to the catalytic subunit of adenylate cyclase by a stimulatory guanine nucleotide-binding protein, G_s. The catalytic subunit of adenylate cyclase may, in turn, be influenced by calmodulin. Takaichi and Kurokawa[302] have shown that calmodulin inhibitors inhibited ADH-sensitive cAMP production in isolated mouse medullary TAL segments. Likewise, Ausiello and Hall[13] showed that the addition of exogenous calmodulin stimulated ADH-sensitive cAMP production by LLC PK_1 cells.

Table 34.5 lists the effects of ADH on several electrophysiologic parameters of mouse medullary TAL segments perfused *in vitro*. The approximate doubling of the equivalent short-circuit current results from an increase in the transepithelial voltage[135,138,214] and an increase of roughly 20% in the transepithelial conductance. Moreover, the ADH-induced increase in transepithelial conductance, G_e, is referable to an increase in the barium-sensitive or transcellular conductance, Gc. ADH has no effect on the magnitude or permselectivity of the paracellular conductance, G_s (Table 34.5).

ADH increases both the apical and basolateral membrane conductance.[135,214] The apical membrane of TAL cells is, as noted previously, predominantly K^+ conductive. In the presence of luminal furosemide to block K^+ uptake via the Na^+-K^+-$2Cl^-$ co-transporter, mouse TAL segments exhibit net K^+ secretion that is increased by ADH.[135] Because the electrochemical driving force for K^+ secretion is presumably constant in the presence of furosemide, it was suggested that the increase in K^+ secretion was due to an increase in apical membrane K^+ conductance.[135] In support of this notion, using membrane vesicles prepared from rabbit outer medulla, Reeves et al.[252] demonstrated that *in vitro* exposure to cAMP-dependent protein kinase and ATP specifically enhanced barium-sensitive rates of $^{86}Rb^+$ uptake. This finding has been confirmed in subsequent work that examined the effects of phosphorylation on the activity of ROMK channels. ROMK is phosphorylated by cAMP-dependent protein kinase at a number of sites,[342] and this phosphorylation increases the activity of the channel.[208]

The ADH-induced increase in transepithelial NaCl absorption can be blocked by luminal furosemide, and therefore represents an increase in apical Na^+-K^+-$2Cl^-$ co-transport activity. The mechanism whereby ADH increases apical co-transport activity is unclear. Sun et al.[301] demonstrated that in isolated perfused mouse TAL segments, ADH changed the stoichiometry of NaCl entry from $1Na^+$:$1Cl^-$ to $1Na^+$:$1\ K^+$:$2Cl^-$. This change in stoichiometry, accompanied by apical K^+ recycling, could create a lumen-positive potential to drive Na^+ reabsorption via the paracellular pathway. Phosphorylation of the cloned Na^+-K^+-$2Cl^-$ co-transporter NKCC2 by cAMP-dependent protein kinase does not appear to directly increase co-transporter activity. However, phosphorylation may influence co-transporter activity by modulating the interactions between NKCC2 isoforms. As noted above, an isoform with a truncated C-terminus, denoted C4, can inhibit the activity of the full-length NKCC2.[245] However, the inhibition by the C4 isoform can be relieved by phosphorylation by cAMP-dependent protein kinase.[245,209] Thus, ADH may increase apical Na^+-K^+-$2Cl^-$ entry by releasing NKCC2 from tonic inhibition by truncated isoforms. Of note, the short C4 variant is expressed in medullary TAL, but not in cortical TAL,[221] providing a potential explanation for the lack of ADH effect on cortical TAL discussed above. Chronic exposure to ADH may increase apical Na^+-K^+-$2Cl^-$ entry by increasing the abundance of NKCC2.[64]

The predominant portion of the ADH-induced increase in cellular conductance is accounted for by an increase in the basolateral membrane Cl^- conductance.[135,214] Two mechanisms have been suggested for the hormone-dependent increase in basolateral Cl^- conductance. Schlatter and Greger[276] proposed that the ADH-induced increase in intracellular cAMP results in a direct increase in chloride channel activity. Such a mechanism has been amply demonstrated in Cl^- secreting epithelia, such as the trachea and intestine. In support of their proposal, Schlatter and Greger demonstrated that cAMP and ADH elicited a fall in the fractional resistance of the basolateral membrane in mouse medullary TAL segments, even when cell Cl^- activity was kept at low levels by blocking apical Cl^- entry with furosemide.[276] Likewise, using patch-clamp analysis, Paulais and Teulon[239] found that preincubation of mouse cortical TAL segments with forskolin or cAMP analogs increased the number of Cl^-

TABLE 34.5 Effects of ADH on Electrophysiologic Parameters in Mouse Medullary TAL Segments

ADH (μU/ml)	V_e (mV)	G_e (mS/cm^2)	G_c (mS/cm^2)	G_s (mS/cm^2)	V_a (mV)	V_{bl} (mV)	R_a/R_b
0	5.6	103.7	45.1	58.6	54.4	− 50.7	1.2
250	10.3	121.3	60.2	61.0	47.3	− 38.9	2.2

Table from Reeves, W. B., and Andreoli, T. E. (2008). Sodium chloride transport in the loop of Henle, distal convoluted tubule, and collecting duct. In "The Kidney: Physiology and Pathophysiology," 4th edn, 849–888, Alpern, R. J., and Hebert, S. C. (eds.). Elsevier.

channels observed in basolateral membrane patches. It is now known that NKCC2 is sensitive to intracellular chloride concentration: chloride depletion activates the co-transporter by inducing phosphorylation of key amino terminal domain threonines of the co-transporter by a pathway involving the soluble kinases WNK3 and SPAK.[247] Additionaly, elimination of TAL basolateral chloride channels in Bartter's type III and IV reduces salt reabsorption by TAL, producing the disease. Thus, one mode of regulation of NKCC2 can be achieved by modulating intracellular chloride concentration in TAL.

Alternatively, ADH might enhance Cl^- conductance indirectly by increasing apical membrane Cl^- entry.[135] According to this proposal, an ADH-dependent activation of apical membrane Na^+-K^+-$2Cl^-$ co-transporter and K^+ channels leads to an increase in intracellular Cl^- activity, and a subsequent increase in basolateral Cl^- conductance. In support of this view, Molony et al.[214] found, also in mouse medullary TAL, that the ADH-dependent rise in cellular and basolateral conductance were much lower when Cl^- entry was inhibited by furosemide than in control conditions. Studies of Cl^- channels incorporated from basolaterally enriched renal medullary membrane vesicles into planar lipid bilayers have demonstrated several properties of these channels that may account for an intracellular Cl^- concentration-dependent rise in basolateral Cl^- conductance.[251,336] First, the activity of the Cl^- channels is increased with membrane depolarization evidently due to the basolateral membrane depolarization that follows ADH stimulation of TAL segments.[251] Second, Cl^- channels in the vesicles behave like Goldman rectifiers, so that increases in intracellular Cl^- cause an increase in the outward single-channel conductance.[251] Third, channel activity is dependent on the intracellular Cl^- concentration, such that increases in Cl^- over the range 2−50 mM result in large increases in the open time probability of these Cl^- channels.[336] In this respect, it should be recognized that the time-averaged conductance of a basolateral Cl^- channel is given by the product $g_{Cl}P_o$, where g_{Cl} is unit channel conductance and P_o is open time probability.

Thus, an ADH-dependent increase in apical Cl^- entry could stimulate basolateral Cl^- conductance to a far greater extent than expected from simple Goldman rectification. In that connection, at least two laboratories have found, in mTAL segments, that reducing intracellular Cl^- with luminal furosemide produced a three-fold reduction in basolateral Cl^- conductance.[214,276]

Modulation of ADH Effect on TAL Segments

Several factors, such as prostaglandins, peritubular calcium concentration, and peritubular osmolality, have been demonstrated to modulate the actions of ADH on NaCl absorption in the TAL (see the review articles by Hebert and Molony).[135,212] In isolated mouse and rabbit TAL segments, increases in peritubular osmolality, induced by adding urea or impermeant solutes such as mannitol, rapidly and reversibly inhibit the ADH-stimulated rate of net Cl^- absorption. Peritubular hypertonicity results in a prompt reduction in the transepithelial voltage and in the cellular conductance.[213] Molony and Andreoli determined that hypertonicity inhibits the basolateral membrane chloride conductance.[212] The antagonizing effect on ADH-induced stimulation of net Cl transport is not due to decreasing cAMP, because application of either ADH or cAMP is unable to reverse the hypertonicity-mediated effect. Thus, increasing the absolute magnitude of interstitial osmolality provides a negative feedback signal that can reduce ADH-dependent salt absorption by the mTAL.

PGE_2 also plays a role in modulating the effect of ADH on NaCl absorption in the mTAL (see Molony's review article [212]). In the mouse mTAL, PGE_2 abolished the effect of ADH on transepithelial voltage and on net NaCl absorption, while it had no effect on NaCl salt absorption in the absence of ADH. Likewise, reported biochemical studies in the mTAL[226] indicate that PGE_2 has no effect on cellular cAMP concentrations in the absence of ADH, and that PGE_2 markedly inhibits the ADH-dependent stimulation of cytosolic cAMP concentrations. The TAL, particularly in the macula densa, expresses COX-2.[130] COX-2 expression in these cells may be coupled to renin secretion. Thus, COX-2 expression is increased by salt restriction, diuretics, and in Bartter syndrome all conditions characterized by hyperreninemia.[46] In addition to PGE_2, 20-HETE may also modulate the effect of cAMP on Na^+ transport in the TAL. McGiff and co-workers[207] demonstrated that 20-HETE inhibits NaCl transport in the TAL by a mechanism involving inhibition of the apical K^+ channel[323] and the Na^+-K^+-$2Cl^-$ co-transporter.[69] Moreover, high 20-HETE concentration inhibits the effect of cAMP on the apical K^+ channels in the rat TAL.[116]

Hypercalcemia often results in an ADH-resistant urinary concentrating defect, that is, nephrogenic diabetes insipidus. At least part of this concentrating defect results from the inhibition of ADH-stimulated cAMP production in the TAL by calcium. Takaichi and Kurokawa demonstrated that high ambient calcium inhibited cAMP production stimulated by forskolin, indicating that the inhibition probably involved the catalytic subunit of adenylate cyclase. Preincubation of tubule segments with pertussis toxin abolishes the effect of hypercalcemia on cAMP generation, indicating that the inhibition of cAMP generation is mediated through activation of G_i.[303] The effects of hypercalcemia on cAMP production are mediated by a G-protein-coupled CaSR present on the basolateral membrane of

TAL cells.[133] As discussed above, stimulation of CaSR also inhibits the apical 70 pS and basolateral 50 pS K channels.[117,179] Consequently, activation of CaSR is expected to alter NaCl absorption, thereby affecting the concentrating mechanism.[137]

Intracellular Mechanisms for NKCC2 modulation in TAL

The physiological pathways for NKCC2 regulation have begun to be uncovered. The rate of salt reabsorption by TAL depends on the amount of NKCC2 protein expressed in the apical membrane at any given time; that is, the protein half-life in the plasma membrane. As shown in Figure 34.5, the amount of NKCC2 is the result of a dynamic process involving exocytosis and endocytosis mechanisms. Stimulators of NKCC2, such as cAMP (vasopressin, PTH, glucagon or β-adrenergic stimulation) promote exocytosis over endocytosis. Electron microscopy analysis of mouse TAL[100] and biotinylation of rat TAL apical membrane[232] demonstrated that only between 3–5% of total NKCC2 is present in the apical membrane in basal conditions. Vasopressin stimulates trafficking of NKCC2 towards the plasma membrane in *Xenopus* oocytes,[209] in mouse TAL,[100] and in rat TAL,[232] by a process that is modulated by the vesicle-associated membrane proteins VAMP2 and VAMP3. Exocytosis of NKCC2 is a continuous dynamic process that is further activated by cAMP, via protein kinase A (PKA).[9] Because PKA inhibition does not completely prevent cAMP-induced increase of NKCC2 presence in the apical membrane, it is possible that cAMP also inhibits endocytosis. Two amino acid residues of NKCC2 become phosphorylated by PKA, Ser126 and Ser874, but the exact consequence of this is not known.[122] Endocytosis of NKCC2 occurs also constitutively in TAL. A fraction recycles toward the apical membrane and another fraction undergoes degradation. Inhibition of endocytosis by cholesterol depletion completely block NKCC2 retrieval from the membrane, increasing NKCC2 presence and chloride transport by TAL.[9] Supporting this view, it has been shown that part of NKCC2 is associated with lipid rafts.[331]

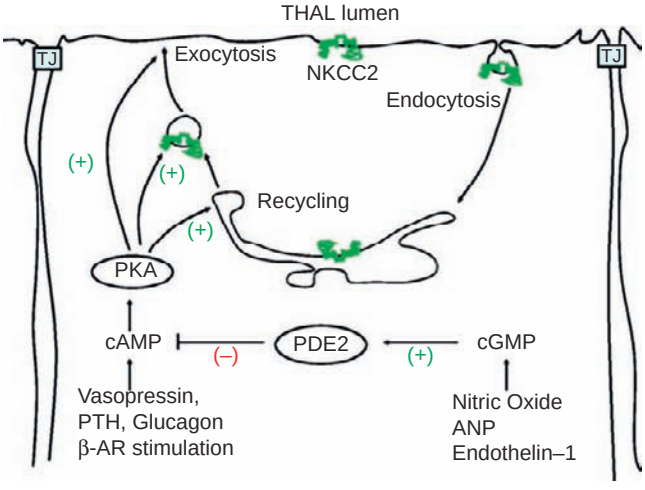

FIGURE 34.5 **Physiological regulatory pathways of NKCC2 in thick ascending limbs of Henle's loop (TALs).** *From ref. [8].*

Inhibitors of NKCC2 such as nitric oxide, through the eNOS synthase,[246] atrial natriuretic peptide, and endothelin affect trafficking of the co-transporter, mainly through a cGMP-dependent activation of phosphodiestarese 2 (PDE2) that in turn degradates cAMP (Figure 34.5). The intracellular mechanism for other NKCC2 inhibitors such as 20-HETE and PGE_2 is not extensively known,[8] but can be achieved at least in part by modulating the ADH effect in TAL. PGE_2 for instance, in the *in vitro* mouse mTAL PGE_2 has no effect on NaCl salt absorption when ADH is absent.[246] In the presence of ADH, PGE_2 reduces the ADH-dependent values for transepithelial voltage and net NaCl absorption to ADH-independent values, by what appears to be inhibition of ADH-stimulated generation of cAMP in the mTAL by activating G_i. Hypercalcemia reduces TAL salt reabsorption by a calcium-induced inhibition of NKCC2 and ROMK vía calcium sensing receptor activation of G_i.[93]

Adrenergic Agents

Adenylate cyclase activity stimulated by β-adrenergic receptors is present in the rat, but not rabbit, TAL.[41] Likewise, β-adrenoceptors have been detected along the rat TAL by autoradiographic localization. The physiologic effects of adrenergic agents have been tested in micropunctures and *in vitro* microperfusion studies. DiBona and Sawin[58] demonstrated an enhancement of loop NaCl absorption during low-frequency renal nerve stimulation. Acute renal denervation, on the other hand, depressed NaCl absorption by the loop of Henle.[19]

Mineralocorticoids

There is controversy regarding mineralocorticoid effects on TAL. Some evidence suggests that aldosterone influences NaCl transport in the TAL (reviewed in [59]). First, clearance studies indicate that aldosterone increases free water clearance in adrenalectomized animals, consistent with an increase in NaCl absorption by the TAL. Second, nuclear mineralocorticoid receptors are present in both the medullary and cortical portions of the TAL of rat and rabbit, although it is known that the presence of mineralocorticoid receptors is no guarantee of being a specific target site of aldosterone. The mechanisms of aldosterone actions are discussed in Chapter 35. Third, aldosterone appears to modulate the

activity of certain transport-related enzymes in the TAL. Specifically, adrenalectomy reduces the activity of (Na^+,K^+)-ATPase in the rabbit TAL. The activity of these enzymes can be restored to almost normal by aldosterone, but not by dexamethasone. In the adrenal-intact mouse, pharmacologic doses of mineralocorticoid increased (Na^+,K^+)-ATPase activity of mTAL segments by 25%. Finally, *in vivo* and *in vitro* microperfusion studies have demonstrated effects of aldosterone on TAL sodium transport. Adrenalectomy inhibited loop of Henle sodium absorption by 33−50%. Aldosterone, but not dexamethasone, increased sodium transport to control levels. Also in the rat medullary TAL, adrenalectomy decreases $NaHCO_3$ absorption by 33%. However, other studies have failed to show an effect of mineralocorticoids on (Na^+,K^+)-ATPase activity in the TAL (also reviewed in [59]). Additionally, a recent study shows that aldosterone administration on adernalectomized rats had no effect on NKCC2 expression.[313]

Na^+ TRANSPORT IN DISTAL CONVOLUTED TUBULE

General Characteristics

The DCT absorbs roughly 10% of the filtered sodium load.[255] Fluid enters the DCT with a sodium concentration of 25−30 mM, but salt is added along the initial 20% of the DCT, so that the sodium concentration averages 50 mM at a point 200−300 μm from the macula densa. From there, tubular sodium concentration decreases along the DCT to a value of approximately 30 mM at the end.[279] Tubular fluid to plasma sodium ratios as low as 0.10 have been observed during stationary microperfusion.[255] This finding, together with the presence of the lumen-negative potential difference (see subsequent discussion), establishes clearly the active nature of sodium absorption in this segment.

Sodium absorption by the DCT is load-dependent. That is, over a wide range of delivery rates, the proportion of sodium absorbed by the DCT remains constant at 80%.[255] At high tubular fluid flow rates, the fall in luminal sodium concentration along the tubule is attenuated; thus, more sodium is available to distal sodium absorptive sites at high flow rates than at low flow rates. Sodium absorption in the rat DCT has been reported to be 25−30 pEq/mm^2/sec, that is, about one-third of the rate occurring in the PCT. However, rates comparable to those in the PCT have been reported in isolated perfused DCT.[52,53,66]

Electophysiologic Considerations

The electrophysiologic and transport properties of the DCT and CNT are summarized in Table 34.6. The transepithelial voltage in the earliest loops of the DCT, measured with fine tip electrodes, ranges from 9 to 19 mV, lumen-negative. Small lumen-positive voltages, 3.7 to 5.7 mV, have been measured both in micropuncture experiments, by using low resistance micropuncture electrodes, and in isolated, perfused early DCT segments (reviewed in [255]). When the composition of the luminal perfusate resembled distal tubular fluid, i.e., having a low NaCl concentration (see earlier discussion), the lumen voltage tended to be slightly positive, whereas when tubules were perfused with solutions resembling plasma, i.e., high NaCl concentration, the lumen voltage was negative. The lumen-negative potential measured with high NaCl solutions was abolished by luminal amiloride, an inhibitor of epithelial sodium channels. The positive voltage under *in vivo* conditions is a salt dilution potential arising from the differential permeability of the DCT to Na^+ and Cl^-, while the lumen-negative potential under symmetric solutions reflects active Na^+ reabsorption via amiloride-sensitive sodium channels (see subsequent discussion).

The transepithelial electrical potential in the late DCT of rats measured *in vivo* ranges from 37 to 60 mV. Values in isolated rabbit DCT and CNT segments perfused with symmetric solutions are less negative, 5 to 30 mV.[114,286,347] The voltage can be inhibited by peritubular ouabain or luminal amiloride,[347] and is quite sensitive to changes in perfusion pressure and flow rate, decreasing with high pressures or flow rates.

The transepithelial resistance of the rat DCT decreases from 337 Ω-cm^2 in the early DCT to 135 Ω-cm^2 in the late DCT.[255] Hypotonic luminal fluids increase, and hypertonic perfusates decrease, the transepithelial resistance with respect to isotonic luminal fluid. Somewhat lower electrical resistances have been found in isolated perfused rabbit DCT[114,347] and CNT.[4]

Intracellular microelectrode analysis of rabbit DCT cells has yielded conflicting results. Yoshitomi et al.[347] found evidence for both K^+ and Na^+ conductive pathways in the apical membrane and K^+ and Cl^- conductive pathways in the basolateral membrane. The apical membrane accounted for 80% of the total cellular resistance. In contrast, Velazquez et al.[319] found the apical membrane to comprise over 99% of the cellular resistance, and could not detect any Na^+ or K^+ conductances in that membrane. Perhaps some of this discrepancy could have arisen from the examination of different portions of the DCT in the two laboratories. Ellison et al. have demonstrated that sodium reabsorption in the early DCT is largely mediated by a thiazide-sensitive, neutral NaCl co-transporter, while sodium absorption in the late DCT involves an amiloride-sensitive electrogenic pathway.[66] Thus, Yoshitomi et al.[347] may have described the late DCT and Velazquez et al.[319] the early DCT.

TABLE 34.6 Electrophysiologic and Transport Properties of DCT

	V_t (mV)	Rt ($\Omega - cm^2$)	V_{bl} (mV)	fRa	J_{Na} (pmol/mm/min)	J_{Cl} (pmol/mm/min)
Rat DCT	+8 to −19	81–382	−57 to −65		128–258	285
Rabbit DCT	−2 to −40	22–116	−78 to −84	0.78–0.99	82	
Rabbit CNT	−4 to −27	29–31	−71 to −83		62–121	405

(eds.). Elsevier.*

Mechanism of Na^+ Absorption

The available evidence permits the delineation of certain facets of Na^+ absorption in the DCT. A general model for these mechanisms is presented in Figure 34.6. Central among these are the characteristics discussed in the following subsections.

APICAL NaCl CO-TRANSPORT

The absorption of sodium and chloride in the early DCT is mutually dependent.[319] Sodium absorption is a function of the luminal chloride concentration, and chloride absorption is a function of the luminal sodium concentration. The half-maximal concentrations of both sodium and chloride are 10 mM.[319] Furthermore, the intracellular Cl^- activity is above its electrochemical equilibrium, such that Cl^- entry into the cell must involve active transport. The early distal tubule is the site of action of thiazide diuretics.[53,66,286]

A thiazide-sensitive neutral NaCl co-transporter (TSC) was cloned from the flounder urinary bladder using an expression cloning strategy.[95] A homologous transporter, NCC (SLC12A3) was subsequently cloned from the mammalian kidney.[94] NCC and NKCC2 are members of the same family of solute transporters and share considerable sequence homology (see Chapter 32). NCC transports NaCl with a 1:1 stoichiometry, is K-independent, and is inhibited by thiazide diuretics.[215] NCC is expressed in the apical membrane of early DCT cells (or DCT1) and extends, in most species, into the late DCT (or DCT2) (reviewed in [92,255,278]). In addition, mutations in the NCC gene are the cause of Gitelman syndrome that mimics the effects of thiazide diuretics.[92] Full discussion on NCC molecular physiology is presented in Chapter 32.

APICAL CONDUCTIVE SODIUM CHANNELS

The entry of sodium into the late rat DCT cell[52] is inhibited by amiloride, a sodium channel blocker. A sodium channel in the apical membrane would serve to depolarize the membrane and create the observed lumen-negative transepithelial potential. This transepithelial voltage, in turn, is a driving force for passive chloride reabsorption. Sodium channel subunits have been found by immunolocalization in the late DCT in mouse and rat kidney.[255,278]

BASOLATERAL ELECTROGENIC Na^+ PUMP

The voltage (V_{bl}) across the basolateral membrane of the *Amphiuma*[333] and rabbit[114,347] DCT is 60 to 90 mV. A reduction in the luminal sodium concentration causes V_{bl} to depolarize, while increases in the sodium concentration hyperpolarize V_{bl}. In addition, V_{bl} depolarizes after ouabain treatment. These observations are consistent with the notion that apical sodium

entry stimulates the electrogenic (Na^+,K^+)-ATPase system in the basolateral membrane.

BASOLATERAL POTASSIUM CHANNELS

The basolateral membrane of DCT cells contains a large, barium-sensitive potassium conductance.[114] Patch-clamp studies of the basolateral membrane of DCT cells have identified three different potassium channels. Two of the channels have similar conductances (50−60 pS) and kinetics, and both are blocked by barium. The third channel is seen less frequently, has a conductance of 80 pS, and is not blocked by barium. A basolateral potassium channel Kir4.1/KCNJ10 which has been localized to the basolateral membrane of DCT when mutated causes the SeSAME/EAST syndrome characterized by epilepsy, ataxia, sensorineural deafness, and renal salt-losing nephropathy similar to Gitelman's disease.[254,281] Inactivating mutations of this channel prevent the K^+ efflux of the basolateral membrane, presumably increasing the intracellular K^+ concentration that inhibits the basolateral Na^+,K^+-ATPase.

BASOLATERAL CHLORIDE CHANNELS

Microelectrode studies by Yoshitomi et al.[347] provided evidence for a chloride conductive pathway in the basolateral membrane of rabbit DCT cells. Likewise, Gesek and Friedman[97] found evidence for basolateral membrane Cl^- channels in cultured mouse DCT cells. Specifically, inhibition of apical Cl^- entry with thiazide diuretics resulted in a fall in intracellular Cl^- activity and a hyperpolarization of the membrane voltage.[97] The thiazide-induced hyperpolarization could be abolished by either a reduction in the extracellular Cl^- concentration or by NPPB, a Cl^- channel blocker,[97] suggesting that a Cl^- channel accounts for the basolateral Cl^- conductance. The single-channel properties of Cl^- channels in DCT cells have not been reported, but now it is known that CLC-Kb chloride channels are present in DCT basolateral membrane.[283] The basolateral Cl^- conductance was increased by parathyroid hormone, presumably acting via cAMP.[97]

Regulation of NaCl Transport in DCT

Na^+ DELIVERY

As noted earlier, NaCl reabsorption in the DCT is dependent on the delivered load of NaCl. Chronic increases in the delivery of NaCl to the DCT can be achieved using furosemide to inhibit NaCl reabsorption in the thick ascending limb. The DCT responds to such a maneuver with an increase in the capacity for NaCl transport,[67] and increased expression of NCC,[1] as well as marked ultrastructural changes in the DCT cell. These morphologic changes include an increase in the size of the DCT cell, an increase in the basolateral membrane surface area, and an increase in the size of mitochondria.[67,159] Hypertrophy of DCT is also seen in Bartter's mice due to knockout of ROMK,[37] and in BAC transgenic mice harboring two alleles of WNK4 containing the pseudohypoaldosteronism type II (PHAII) type mutation Q562E.[184] Thus, it is likely that DCT hypertrophy is due to either an increase in sodium entry into the DCT cell or activation of the renin−angiotensin system (see discussion below). In addition, an increase in dietary sodium alone, which increases distal NaCl delivery but not distal Na^+ absorption or activation of the renin−angiotensin−aldosterone system, does not, in the rat, result in an increase in cell height.[67] Moreover, inhibition of NaCl entry into DCT cells with chronic thiazide treatment resulted in a loss of cell height, loss of normal polarity, and apoptosis of the DCT cells.[191]

STEROID HORMONES

The presence of both mineralocorticoid and glucocorticoid receptors in the DCT has been demonstrated by immunohistochemistry and by hormone-binding. In addition, adrenalectomy resulted in a decrease in (Na^+,K^+)-ATPase activity in the DCT.[59] Microperfusion studies of superficial distal tubules (containing both DCT and CNT), however, demonstrated an increase in sodium transport in animals receiving aldosterone infusions.[59,317] Both the thiazide-sensitive and thiazide-insensitive components of sodium transport were increased by aldosterone.[317] The former may reflect neutral NaCl co-transport in the DCT, while the latter reflects electrogenic sodium absorption in the late DCT or CNT. Aldosterone infusion also resulted in large increases in NCC protein,[1,169,258,317] and phosphorylation in amino-terminal domain regulatory threonines[313] (see Chapter 32). These findings establish NCC as an aldosterone-regulated transporter, a situation that occurs in DCT2 that is considered to be part of the aldosterone sensitive distal nephron.[11] Aldosterone increases of NCC expression do not seem to be due to an increased transcription rate of the SLC12A3 gene encoding NCC.[1,218] Instead, it has been observed that NCC expression in the plasma membrane is regulated by ubiquitylation via the HECT-E3 ubiquitin ligase Nedd4-2, which in turn is modulated by phosphorylation by the serum glucocorticoid kinase 1 (Sgk1),[10] similar to what occurs with ENaC. Thus, aldosterone regulation of NCC appears to be, at least in part, through the Sgk1-Nedd4-2 pathway. Interestingly, in some families with PHAII, an inherited form of salt-sensitive hypertension in humans also known as Familial Hyperkalemic Hypertension or Gordon's syndrome, it results from mutations in Cullin 3 and KLHL3 proteins, which are part of a RING-type E3 ubiquitin ligase complex which presumably modulates NCC activity by ubiquitilation processes.[29,196]

Glucocorticoids increase (Na^+,K^+)-ATPase activity following adrenalectomy in the DCT. This effect was not blocked by spironolactone, a mineralocorticoid receptor antagonist, suggesting that glucocorticoids were acting via glucocorticoid receptors rather than mineralocorticoid receptors.[59] In addition, dexamethasone infusions increased thiazide-sensitive NaCl transport and [^{3}H]metolazone-binding sites in adrenalectomized rats.[317] Nonetheless, the role of glucocorticoids in the physiologic regulation of sodium transport in the DCT remains unclear.

Gonadal steroid hormones may also influence NaCl transport in the DCT. Chen et al.[45] first reported gender differences in the density of thiazide receptors, and in the natriuretic response to thiazides in rats. Female rats had higher levels of thiazide-binding sites in the renal cortex than males. The levels in females fell following ovariectomy, while levels rose in males following orchiectomy. Moreover, the increase in urinary sodium excretion caused by thiazides was greater in females than in males, suggesting that the differences in thiazide-binding sites were reflective of differences in thiazide-sensitive salt transport *in vivo*. Likewise, using antibodies against the cloned thiazide-sensitive NaCl co-transporter (NCC), Verlander et al.[320] found that estrogen treatment increased NCC expression in the DCT. These results are consistent with the view that male sex hormones (e.g., testosterone) may downregulate NCC expression and salt transport, while estrogens increase NCC expression and salt transport in the DCT.

PROTEIN KINASES

Studies of PHAII have yielded additional insights into the regulation of NCC function. PHAII is the phenotypic opposite of Gitelman syndrome, and is characterized by hypertension, hyperkalemia, and metabolic acidosis. The disorder is largely corrected by thiazide diuretics. These features suggested that an increase in NCC activity may be involved in the pathogenesis of PHAII. Positional cloning demonstrated that PHAII in some families is caused by mutations in either of two serine-threonine kinases, WNK1 and WNK4,[334] and more recently the whole exomes sequencing strategy revealed that Cullin 3 and KLHL3[29,196] are responsible for the disease in WNK-negative families. Subsequent studies have shown that WNK4 acts to inhibit NCC-mediated NaCl transport, likely by reducing cell surface expression of NCC[35,334,343] and that effect of WNK4 turns into activation by the PHAII type mutations,[184,334,344] resulting in higher rates of NaCl transport. It has been observed that a switch of WNK4 from inhibiting to activating NCC can be achieved by angiotensin II,[266] suggesting that NCC activation by angiotensin II,[267] which is independent of the presence of aldosterone,[313] is a WNK4-dependent process. In this regard, it has been shown that WNK4-induced phosphorylation of the downstream kinase SPAK/OSR1 is modulated by calcium concentration,[225] and that phosphorylation of SPAK and NCC in the presence of a low-salt diet or angiotensin II infusion is abrogated in WNK4 total knockout mice,[39] supporting the proposal that angiotensin II signaling via the $G\alpha_q$-coupled AT1 receptor that increases intracellular calcium could be a modulator of the WNK4 type of effect on NCC. WNK4 also affects the activity of apical ROMK channels: wild-type WNK4 inhibits ROMK and the PHAII mutant WNK4 further reduces the activity of the channels, helping to explain the hyperkalemia of PHAII patients.[157] Recent observation also shows that angiotensin II-induced inhibition of ROMK channels[330] is at least in part dependent on the presence of WNK4.[349] Thus, it is possible that PHAII type mutations in WNK4 are of the gain-of-function type, mimicking the effect of angiotensin II on NCC and ROMK activity on DCT-CD. WNK4 also affects the Cl^- permeability of the paracellular pathway.[156] The mechanism whereby WNK1 produces PHAII is less well-defined. Yang et al.[343] found that WNK1 does not directly affect NCC activity, but modulates the inhibition of NCC by WNK4. They propose that mutations that increase the activity of WNK1 prevent WNK4 from inhibiting NCC-mediated transport. Although not causing disease, WNK3 is also a powerful modulator of NCC activity. Wild-type WNK3 activates NCC, while the catalytically inactive WNK3 inhibits NCC.[256] Activity of NCC is also modulated by protein phosphatase 4.[101] (For an extensive review on NCC regulation see Chapter 32.)

Na^+ TRANSPORT IN THE CONNECTING TUBULE AND COLLECTING DUCT

The transport of Na^+ in the connecting tubule and the collecting duct is responsible for the final adjustments of renal Na^+ excretion. These tubular segments share in common an electrogenic Na^+ transport mediated by the epithelial sodium channel (ENaC), and sensitivity to aldosterone.

The Connecting Tubule

The connecting tubule connects the distal convoluted tubule (DCT) with the cortical collecting duct (CCD). Developmentally, the DCT originates from the metanephric blastema, whereas the CCD arises from the ureteric bud. The origin of the CNT is not clear, since the CNT shares some transport characteristics with both the late DCT and the downstream CCD.[14] This suggests that the CNT is a hybrid tubular segment

that develops at the border of the two adjoining segments, the DCT and the CCD.[278] The transition between the late distal convoluted tubule (DCT2) and the CNT is gradual in the mouse, rat, and human kidney.[190] In the mouse kidney, the CNT represents more than 8% of the fractional renal tubular volume, compared to 12% for the DCT and 4% for the CCD.[194]

The distal convolutions of superficial nephrons comprising the late DCT, the CNT, and the initial collecting tubule, are accessible by micropuncture. The importance of the CNT in Na^+ absorption was evaluated in a number of *in vivo* experiments. Microperfusion studies of the late distal convoluted tubule show that more than 90% of the Na^+ delivery in the DCT is reabsorbed in the DCT2 and the CNT by an amiloride-sensitive Na^+ transport.[52,205] In the rabbit isolated and perfused CNT, Na^+ absorption measured by net ^{22}Na fluxes is 3–4-fold higher than in the CCD under similar conditions.[4] Furthermore, patch-clamp studies in microdissected CNTs from the cortical labyrinth show that the amiloride-sensitive current was 4–5-fold higher than that measured in the CCD of the same animal.[88] From these experiments it was estimated that the maximal Na^+ transport capacity of the CNT allows the reabsorption of 10% of the filtered load of Na^+. Thus, the CNT represents a major site for the regulation of distal Na^+ reabsorption. Recent genetic experiments using homologous recombination in the mouse to invalidate ENaC specifically in the DCT2 and the CNT, provided direct evidence that the CNT plays a critical role for the maintenance of the Na^+ and K^+ homeostasis.[50]

In the CNT, a significant fraction of Na^+ absorption is associated with K^+ secretion. Patch-clamp and immunolocalization studies identified the presence of the inward rectifier Kir1 channel ROMK at the apical membrane as the major channel.[87,210,318] The density of active ROMK channels was found to be higher in the CNT compared to CCD, consistent with the idea that the CNT is an important site for K^+ secretion in the distal nephron. However, the density of active ROMK channels in the CNT was independent of the K^+ diet. This suggests that the increased K^+ secretion under a high-K^+ diet is primarily due to an increase in the driving force for K^+ efflux across the apical membrane, due to the upregulation of the apical Na^+ conductance.

The connecting tubule contains CNT-specific cells and intercalated cells; the specific CNT cells represent 70–80% of the epithelial lining in the CNT, and are the site for Na^+ absorption and K^+ secretion; the remainder of the epithelial lining consists of the intercalated cells that mediate acid–base balance.[61,158,170,204] Under a standard Na^+ diet, the epithelial sodium channel (ENaC) is detected by immunohistochemistry at the apical membrane of CNT specific cells.[193] ENaC is highly selective for Na^+ ions with a $P_{Na}/P_K > 100$, and a single channel conductance g_{Na} of 4 to 5 pS.[36] ENaC is blocked by submicromolar concentrations of amiloride, and by triamterene at higher concentrations. ENaC is expressed in other epithelial tissues such as the lungs, the colon, salivary glands, and sweat ducts. The channel is constitutively open; analysis of the ENaC gating kinetics suggests two different gating modes, one with a high (> 0.75), the other with low (< 0.25) open probability.[236] Transitions between these gating modes are influenced by factors such as membrane voltage or Na ions; hyperpolarization or a low extracellular Na favors the high open probability gating mode. By contrast, an acute increase in extracellular or intracellular Na^+ reduces the ENaC openings and channel current.[234,235,236] These regulatory mechanisms, termed self-inhibition and feedback inhibition respectively, are likely important to prevent a massive entry of Na^+ ions into the cell when luminal Na^+ concentration is high.[7,48] Other intracellular factors associated with cellular stress such as a decrease in pH, an increase in oxidative stess or a rise in Ca^{2+} ions decrease channel open probability.[48,162,234] ENaC is not mechanosensitive.[236]

Cloning by functional expression revealed that the ENaC channel consists of three homologous α-, β-, and γ-subunits that all are required for the full expression and activity of the channel at the cell surface.[36] The ENaC subunits share 30% homology at the amino acid level; each subunit is made of two transmembrane α helices and a large extracellular domain that represents more than half of the mass of the protein; the amino- and carboxy-termini are facing the cytosolic side of the membrane. The recent crystalization of an ortholog of ENaC, the Acid Sensing Ion Channel 1 (ASIC1), confirms this membrane topology and provides a high-resolution structure of the homologous subunits that constitute the channel core.[152] Based on homology models and functional data, the second transmembrane α helix is lining the ENaC pore and comprises important functional domains controlling ion flux through the pore: they include sequentially from outside, an extracellular gate, the amiloride- and triamterene-binding site, and further downstream the selectivity filter.[102,163,164,165] The cytosolic N-terminus of ENaC comprises a functional domain made of conserved cysteines that control ENaC gating; the C-terminus of ENaC subunits is characterized by conserved proline residues involved in ENaC interactions with cytosolic regulatory proteins.[242,296]

ENaC is activated by soluble proteases including trypsin, chymotrypsin, kallicrein or elastase. In addition, ENaC activity is significantly increased *in vitro* when co-expressed with membrane-attached serine proteases, such as the GPI-anchored proteases CAP-1

(an ortholog of the human prostasin) or CAP-2 (an ortholog of the human transmembrane protease serine 4 (TRPMSS4)).[49,129,312,322] In heterologous expression systems and in the kidney, the α and the γ ENaC subunit are found as a high and a low molecular weight forms, the latter resulting from ENaC cleavage by endogenous proteases.[89,68,89,129,145,206] The active α and γ ENaC at the cell surface is predominantly in its cleaved form. The α and γ ENaC have both canonical cleavage sequences for furin-like proteases in their extracellular domain. Furin is an endoprotease, a member of the subtilisin-like proprotein convertase family that cleaves precursor proteins along their secretory pathway from the trans-Golgi network to the apical surface. The molecular mechanism of ENaC maturation and activation by endoproteases is not yet completely understood.

The ROMK are expressed at the apical membrane of specific CNT cells.[15,87,210] Big K channels (BK channels) or maxi-K channels have been shown to account for K^+ secretion in the late distal tubule; the co-expression of these high-conductance Ca^{2+}-activated K channels (BK channels) with ENaC in CNT cells remains controversial.[15] From patch-clamp studies it seems that BK channels are restricted to the apical membrane of the intercalated cells.[237]

At the basolateral membrane, the Na/K-ATPase is responsible for pumping Na^+ out of the cell in exchange with K^+; the Na/K-ATPase activity as measured by pump current and ATP hydrolysis is higher in the CNT than in the CCD, consistent with the idea that the CNT transports more Na^+ and K^+ than the downstream segments.[161]

These membrane transporters provide a transcellular route for electrogenic Na^+ reabsorption and K^+ secretion in the CNT cells. ENaC at the apical membrane represents the entry step for Na^+ ions along a favorable electrochemical gradient; the resulting depolarization of the apical membrane provides a favorable driving force for K^+ secretion. The electrical coupling in the Na^+ and K^+ transport across the apical membrane, and the direct coupling of the Na^+ and K^+ transport by the basolateral Na/K pump, indicates that Na^+ absorption in the CNT directly affects K^+ secretion, and that these two ion transports are closely linked.

The Collecting Ducts

THE CORTICAL COLLECTING DUCT

The Na^+ and the K^+ transports in the CCD have been largely studied and differ from those in the CNT, more quantitatively than qualitatively. Table 34.7 summarizes the electrophysiologic and transport properties of CCD. The electrogenic Na^+ absorption mediated by ENaC generates a lumen-negative transepithelial voltage (V) in the CCD that varies widely according to the mineralocorticoid status of animals.[106,269] This lumen-negative voltage in mammalian CCD segments is abolished by ouabain,[106,125] luminal amiloride,[300] and luminal sodium deletion.[300] However, the lumen-negative transepithelial potential in the rabbit CCD is seven times less negative compared with the CNT.[148]

The membrane transporters involved in Na^+ absorption and K^+ secretion in the CCD principal cells are essentially the same as in the CNT cells (see Figure 34.7). Immunohistochemical studies have shown that, under standard salt diet, the abundance of ENaC at the apical membrane decreases from the late DCT and CNT to the CCD, further supporting the idea that the CNT is a major site for ENaC-mediated Na^+ absorption in the aldosterone distal nephron.[192,193] By contrast to the CNT, the selective invalidation of ENaC in the mouse CCD using homologous recombination does not result in any alteration in Na^+ and K^+ homeostasis, even under restricted dietary Na^+ intake.[261] This suggests that the absence of ENaC in the CD can be compensated, at least in part, by an increase in ENaC activity in the CNT.

From isolated and perfused rat CCD, the major fraction of Na^+ absorption in the CCD is electrogenic and mediated by ENaC; no evidence was found supporting the contribution of a thiazide-sensitive electroneutral NaCl co-transport in Na^+ absorption.[260] Recent studies, however, have reported that a significant fraction of Na^+ absorption in the mouse and rat CCD is electroneutral, insensitive to luminal amiloride, but sensitive to thiazides.[187] Microperfusion studies in different

genetically-engineered mouse models under a low-Na^+ diet concluded that this electroneutral Na^+ and Cl^- absorption results from the parallel operation of two bicarbonate transporters, a Na^+-dependent Cl/HCO_3^- exchanger and the anion exchanger pendrin. This amiloride-insensitive Na^+ transport pathway likely occurs through the intercalated cells.

THE OUTER MEDULLARY COLLECTING DUCT

The transport properties of the outer medullary collecting duct (OMCD) have been studied by *in vitro* perfusion of isolated tubule segments. The functional properties of the OMCD differ depending on the location of the segment within the outer medulla. Table 34.8 summarizes the electrophysiologic and transport properties of OMCD. Segments within the outer stripe of the outer medulla ($OMCD_o$) exhibit electrophysiologic properties resembling those of the cortical collecting duct, with an electrogenic apical Na^+ entry and a lumen-negative transepithelial voltage.[175] Compared to the CCD, the $OMCD_o$ displays a less-negative transepithelial voltage, much lower ionic permeabilities, and a lower rate of active reabsorption of Na^+.[298,299] In the collecting ducts extending into the medulla, principal cells that mediate Na^+ and K^+ transport in the CCD are progressively replaced by cells with electrical properties similar to intercalated cells of the CCD lacking a demonstrable Na^+ or K^+ conductance in the apical membrane.[175] Within the inner stripe of outer medulla ($OMCD_i$), principal cells are virtually absent and no net Na^+ absorption occurs.[298,299]

THE INNER MEDULLARY COLLECTING DUCT

The analysis of salt transport by the IMCD has been confounded by problems of axial tubule heterogeneity, species variability, and differences in experimental approaches. Studies examining IMCD function *in vivo* have yielded markedly different results than *in vitro* studies of isolated perfused tubules. Table 34.9 summarizes the electrophysiologic and transport properties of IMCD. *In vivo* microcatheterization studies and microperfusion studies have demonstrated that the IMCD reabsorbs about 80% of the sodium delivered to it[182,293] while, with one exception,[182] little sodium transport could be observed in IMCD tubules perfused *in vitro*.[268,294]

ENaC AND THE MAINTENANCE OF Na^+ BALANCE

ENaC represents the main transport pathway for Na^+ absorption in the CNT and the collecting duct. The role of ENaC in the maintenance of Na^+ homeostasis and extracellular body fluid is supported by genetic studies of rare monogenic diseases that identified functional mutations of ENaC associated with changes in Na^+ and K^+ balance, in plasma levels of aldosterone, and in blood pressure.

The pseudohypoaldosteronism type 1 (PHA-1) is characterized in the first week of life by severe dehydration, hyponatremia, hyperkalemia, and acidosis.[44] There are two clinically distinct forms of PHA-1: an autosomal recessive form that affects multiple organs (systemic form), including kidneys, colon, salivary glands, and sweat ducts (but not the skin or inner ear, for instance); and an autosomal dominant form that is restricted to the kidneys. Patients with the systemic form of PHA-1 have mutations in α, β, and γ ENaC subunits.[44] Mutations in the α, β or γ ENaC genes include nonsense, frameshift or missense mutations leading to different degrees of channel loss-of-function; the severity of the syndrome correlates usually with the extent to which ENaC activity is reduced. The autosomal dominant form of PHA-1 is caused by mutations of the mineralocorticoid receptors.[96] A variety of genetic mouse models recapitulate PHA-1 in which the constitutive inactivation of the genes encoding either the α, β or γ ENaC subunits leads to a severe renal phenotype of increased sodium excretion, hyperkalemia, metabolic acidosis, and elevated plasma aldosterone levels.[146]

Pseudoaldosteronism or Liddle's syndrome is an autosomal dominant form of salt-sensitive hypertension with early onset of elevated blood pressure during adolescence; the elevated blood pressure is usually associated with hypokalemia, metabolic alkalosis, low plasma aldosterone, and suppressed plasma renin activity.[28] The elevated blood pressure in Liddle's

syndrome can be normalized under salt restriction and amiloride treatment. Based on these clinical evidences, G.W. Liddle postulated that the syndrome was "*a disorder in which the renal tubules transport ions with such abnormal facility that the end result simulates that of a mineralocorticoid excess*".[188] The mutation identified in the index case is a 45 amino acid deletion in the cytosolic C-terminus of the β ENaC subunit.[287] Subsequent genetic analysis of other Liddle's syndrome families revealed corresponding missense or deletion mutations in the C-terminus of the γ ENaC subunit, but none in the α-subunit.[127,128] These mutations allowed the identification of a conserved proline-rich motif (a canonical PxxY motif) in the C-termini β and γ ENaC subunits as the common target for the mutations causing Liddle'syndrome.[275,292]

ENaC channels carrying mutations associated with Liddle's syndrome exhibit an increased ENaC activity *in vitro* and *in vivo*, consistent with Liddle's hypothesis.[12,54,274] These ENaC gain of function mutations result in both, an increased number of active channels at the cell surface, and a higher open probability.[79]

REGULATION OF Na^+ TRANSPORT

The regulation of Na^+ absorption mediated by ENaC is quite similar in the CNT and the collecting duct. Factors that directly modulate ENaC activity at the cell surface include extracellular or intracellular Na^+, membrane potential, serine proteases, as already mentioned. Certainly the most relevant ENaC regulation for the fine tuning of Na^+ absorption in the CNT and CCD is the control of ENaC activity by hormones such as aldosterone and vasopressin.

ALDOSTERONE

The effects and the mechanisms of action of aldosterone are reviewed in detail in Chapter 35, and are discussed here briefly. The major renal target for aldosterone action is ENaC in the DCT2, in the CNT-specific cells, and in the principal cells of the CCD.[62,75] The DCT2, CNT, and CCD are renal tubular segments that share the expression of the mineralocorticoid receptor (MR) and the enzyme 11β-steroid dehydrogenase type 2 (11βHSD2).[14,181,332] Aldosterone, but also glucocorticoids like cortisol, bind[5] with high affinity the cytoplasmic mineralocorticoid receptor. *In vivo* the specificity of aldosterone versus cortisol for the mineralocorticoid effects is due to the selective degradation of glucocorticoids, but not mineralocorticoids, by the 11βHSD2.[91] Which is high in CCD segments, and protects the MR from being activated by glucocorticoids[27,227] (see Figure 34.8). Illustrating the important role of this enzyme in preventing the activation of the mineralocorticoid receptor by glucocorticoids, the genetic deficiency of 11βHSD2 produces a syndrome of apparent mineralocorticoid excess (AME), which resembles hyperaldosteronism (hypertension, hypokalemia, metabolic alkalosis), except for the fact that aldosterone levels are low.[222,335] The clinical manifestations result from the stimulation of mineralocorticoid receptors by circulating cortisol.

Aldosterone increases the rates of Na^+ absorption and K^+ secretion in these nephron segments[269,273,282] (see Figure 34.8). An increase in the Na^+ permeability of the apical membrane occurs within a few hours of exposure. In the aldosterone-sensitive distal nephron (DCT2, CNT) and the CCD, aldosterone increases the

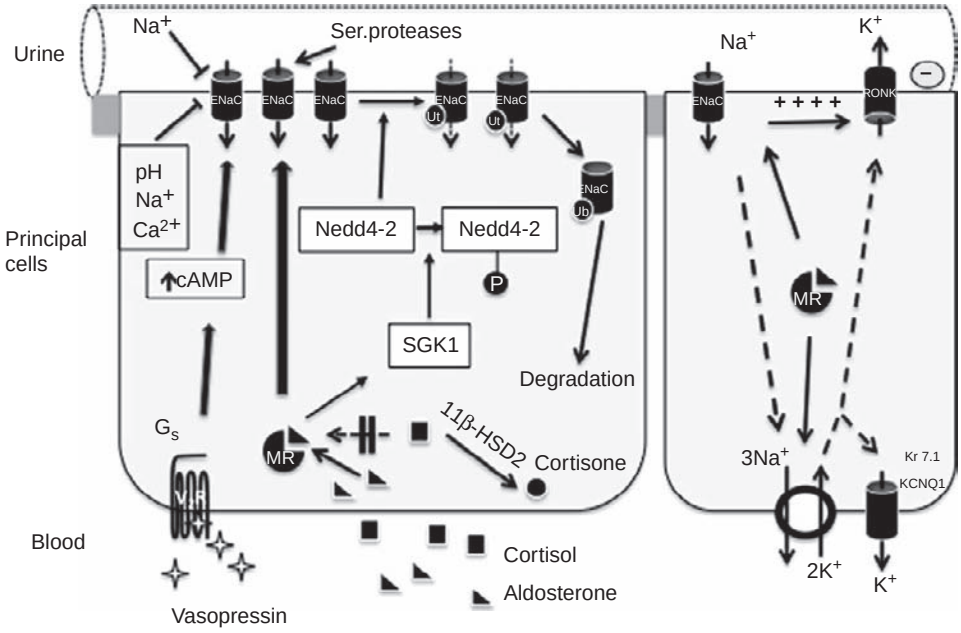

FIGURE 34.8 **ENaC regulation and Na^+ absorption in the connecting tubule and the collecting duct.** Na^+ absorption and K^+ secretion mediated by ENaC and ROMK, respectively, are coupled electrically at the apical membrane, and by the Na/K-ATPase at the basolateral membrane. Aldosterone regulates both ENaC and the Na/K-ATPase. Aldosterone and vasopressin increase the number of newly synthesized ENaC at the cell surface. The ubiquitin ligase Nedd4-2 controls the stability of ENaC at the cell surface. ENaC is activated by serine proteases.

biosynthesis of αENaC whereas the β and γ ENaC subunits are constitutively expressed.[86,195] The upregulation of the synthesis of αENaC by aldosterone leads to an increase in the expression of active, cleaved forms of ENaC channels at the cell surface.[85]

It is not clear whether the increase in the biosynthesis of αENaC is sufficient for triggering the trafficking of the multimeric αβγ ENaC channels at the cell surface or whether specific aldosterone-induced regulators of ENaC trafficking and stabilization at the apical membrane are required. For a constitutively active channel such as ENaC, the stability and the density of active channels at the cell surface is the most important determinant in the regulation of Na^+ absorption in the distal nephron. Measured by patch-clamp techniques in the amphibian distal nephron cell line A6, the half-life of ENaC activity at the cell surface was estimated at around three hours.[348] The molecular determinants of the ENaC half-life at the cell surface are not completely understood. Ubiquitylation is an important post-translational modification that determines ENaC stability at the cell surface. Ubiquitylation is a general process that labels proteins with ubiquitin to target the ubiquitylated proteins for endocytosis and/or degradation. Nedd4-2 is a protein ubiquitin ligase that catalyses the monoubiquitylation of β and γ ENaC subunits after binding specifically of the enzyme to conserved PY motifs in their cytosolic C-terminus of ENaC[259,296] (see Figure 34.8). The ubiquitylated ENaC at the cell surface undergoes clathrin-mediated endocytosis and degradation. *In vitro*, Nedd4-2 efficiently suppresses ENaC activity. Mutations in the cytosolic PY motifs of ENaC subunits are associated with Liddle's syndrome and prevent the interaction between Nedd4-2 and ENaC; the resulting defect in ENaC ubiquitylation leads to the retention of active channels at the cell surface.[274,79] Deubiquitylation enzymes such as Usp2-45 increase ENaC activity *in vitro*.[262]

In vitro experiments support the idea that aldosterone stabilizes ENaC at the cell surface by inhibiting ENaC ubiquitylation and endocytosis.[297] A number of ENaC regulatory proteins are induced by aldosterone, such as the phosphatidylinositide 3′-kinase(PI3K)-dependent kinase SGK-1 (serum- and glucocorticoid-regulated kinase 1) or the 14-3-3 scafolding protein.[56,73] The SGK-1 kinase (serum- and glucocorticoid-regulated kinase 1), increases the abundance of the active ENaC at the cell surface.[321,346] SGK-1 was shown to phosphorylate Nedd4-2, promoting the interaction between Nedd4-2 and the 14-3-3 scafolding protein; this interaction prevents the Nedd4-2 dependent ubiquitylation of ENaC[56] (Figure 34.8). These studies, performed *in vitro* in heterologous expression systems or in cortical collecting duct cell lines, identify Nedd4-2 as a critical convergence point for the regulation of ENaC at the cell surface. In addition to the SGK1/Nedd4-2 pathway, a number of kinases have been reported to

modulate ENaC activity *in vitro*. Activation of the Raf-1-MAPK/ERK kinases inhibits the cell surface expression of ENaC by stimulating the interaction between Nedd4-2 and ENaC.[74,229,284]

Mouse models in which genes contributing to the aldosterone-signaling pathway have been invalidated, only partially confirm the data obtained *in vitro* in heterologous expression systems. Mice deficient in the mineralocorticoid receptor (MR) have a normal prenatal development, but die soon after birth from dehydration and hyperkalemia. This severe PHA-1 phenotype confirms the roles of the MR, and the Na^+ transporters ENaC and NCC, in maintaining Na^+ and K^+ homeostasis.[20] However, the severity of the MR knockout phenotype contrasts with the mild renal phenotype of the mice lacking the aldosterone-induced protein SGK1.[76] The SGK1 deficient mice show a higher natriuresis compared to wt mice only under a low-Na^+ diet, and this higher natriuresis is not related to decreased ENaC activity.[76] Furthermore, under chronic aldosterone treatment, ENaC activity is identical in the SGK1 deficient mice and the wt littermates. This suggests that *in vivo* SGK1 is not central for the long-term regulation of ENaC by aldosterone; in addition, SGK1 could regulate other Na^+ transporters such as NCC located upstream of ENaC.[10]

Mice carrying Liddle's mutation in the SCNN1B gene encoding a deletion of the C-terminus of β ENaC recapitulate Liddle's syndrome under a high-salt diet.[248] These mice with a defective interaction between ENaC and Nedd4-2 represent an informative model to evaluate the contribution of Nedd4-2 in the regulation of ENaC by aldosterone. In addition to the Liddle's phenotype including hypervolemia, elevated blood pressure, hypokalemia, metabolic alkalosis, these mice retain their ability to respond to aldosterone.[54] The knockout of the Nedd4-2 gene in mice results in an elevated blood pressure associated with low plasma aldosterone levels; these effects correlate with an increase in the expression of α and β ENaC, but also NCC.[24,285] These mice also remain sensitive to aldosterone. From these *in vivo* data it appears that neither SGK1 nor Nedd4-2 appear to be limiting in the signaling pathway of aldosterone for stimulating ENaC at the cell surface.

VASOPRESSIN

Exposure of rat CCD *in vitro* to antidiuretic hormone results in a sustained stimulation of a apical electrogenic Na^+ transport,[272] as shown by the increase in the transepithelial potential, a depolarization of the apical membrane, and an increase the apical Na^+ conductance of the tubule.[277] These changes are entirely reversed by luminal amiloride, consistent with Na^+ absorption mediated by ENaC. These effects of ADH on ENaC are mediated by binding to vasopressin type 2 receptors (V2R) expressed in the CCD and CNT, activation of the adenylate cyclase, and by the generation of intracellular cAMP[32,77,220,224,272] (see Figure 34.8). In humans, a reduction in renal Na^+ excretion starts to be observed when the urine osmolality reaches a certain threshold.[223] This suggest that the effect of vasopressin on Na^+ reabsorption likely requires higher concentrations than for the effect on water reabsorption.[273] The effects of ADH on Na^+ transport in the rat CCD are synergistic to aldosterone.[131]

It is not clear how vasopressin and the generation of intracellular c-AMP upregulate ENaC and stimulate ENaC-mediated Na^+ absorption *in vivo* in the CCD. *In vivo* ADH increases both the number of active channels and the open probability.[32] In MDCK cells, c-AMP increases the amiloride-sensitive short-circuit current (I_{SC}) proportionally with the number of ENaC channels at the cell surface, indicating that an increase in active ENaC density can account for the upregulation of the ENaC-mediated Na^+ absorption by vasopressin.[220] In COS cells, c-AMP-dependent phosphorylation and inhibition of Nedd4-2 could be demonstrated that would lead to an increased ENaC stability at the cell surface.[291] Of course, the Nedd4-2 pathway mediating both the vasopressin and aldosterone effects on ENaC cannot explain their synergistic stimulation of Na^+ transport in the distal nephron and the collecting duct.

In addition to its short-term regulation of water and Na^+ absorption in the CCD, vasopressin has long-term transcriptional effects. Chronic vasopressin treatment increases the expression of β and γ ENaC expression in the CCD, with a concommittent increase in Na^+ transport.[63,228] However, no detectable change in the surface expression of the ENaC subunits could be observed.[271] An increase in the Isc and Na^+ transport could be demonstrated after long-term treatment with vasopressin, which was only partially inhibited by amiloride.[60] Thus, the contribution of ENaC in mediating the chronic effects of vasopressin remains unclear, and probably does not simply result from effects on ENaC transcription or trafficking at the cell surface.

INSULIN

The direct effects of insulin on renal Na^+ excretion is difficult to evaluate, because of its secondary effects on plasma glucose or potassium that are difficult to control precisely.

In humans and rats maintained euglycemic, insulin decreased urinary Na^+ excretion.[57,172] This effect on Na^+ excretion was abrogated when K^+ was infused to correct for hypokalemia.[81] Using a euglycemic insulin-clamp technique, insulin does not change renal Na^+ excretion[258] in rats when both plasma glucose and K^+ levels are precisely controlled.

However, insulin and IGF-1 receptors are expressed in the mammalian renal tubular system including the collecting duct.[124] The effect of insulin on Na^+ transport appears tissue-specific. Insulin stimulates ENaC-mediated Na^+ transport in the frog skin,[280] toad urinary bladder[288] or *in vitro* in A6 cells[22] or in a mammalian CCD cell line.[103] In mammalian isolated and perfused CCD, insulin failed to increase Na^+ transport.[315] IGF-1 is under the control of growth hormone (GH). Both GH and IGF-1 induces fluid and Na^+ retention in humans.[126,211] In acromegalic rats, evidence supports that the IGF1-induced increase amiloride-sensitive Na^+ absorption accounts for renal Na^+ retention.[160]

Insulin increases Na/K-ATPase pump activity.[78] Evidence supporting upregulation of ENaC-mediated Na^+ absorption after acute insulin treatment has been reported.[308] However, a patch-clamp study failed to demonstrate an effect of insulin on whole cell amiloride-sensitive Na^+ conductance in rat CCD, whereas ROMK conductance and Na^+-pump current were clearly increased.[90] It is conceivable that under both euglycemic and normokalemic conditions insulin primarily increases K^+ secretion via ROMK; the resulting hyperpolarization of the apical membrane increases the driving force for Na^+ absorption through ENaC channels. This effect is expected to be small and can be compensated by other Na^+ transporters along the nephron so that Na excretion remains unchanged.
