The transfer of water across the principal cells of the collecting ducts is now known at such a detailed level that billions of molecules of water traversing the membrane can be represented; see useful teaching tools at http://www.mpibpc.gwdg.de/abteilungen/073/gallery.html and http://www.ks.uiuc.edu/research/aquaporins. The 2003 Nobel Prize in chemistry was awarded to Peter Agre and Roderick MacKinnon, who solved two complementary problems presented by the cell membrane: how does a cell let one type of ion through the lipid membrane to the exclusion of other ions; and how does it permeate water without ions? This contributed to a momentum and renewed interest in basic discoveries related to the transport of water, and indirectly to diabetes insipidus.[50,51] The first step in the action of AVP (synthesized by du Vigneaud, Nobel Prize in Chemistry 1955)[52] on water excretion is its binding to arginine vasopressin type-2 receptors (hereafter referred to as V2 receptors) on the basolateral membrane of the collecting duct cells (Figure 46.7). The human *AVPR2* gene that codes for the V2 receptor is located in chromosome region Xq28, and has three exons and two small introns.[53,54] The sequence of the cDNA predicts a polypeptide of 371 amino acids with seven transmembrane, four extracellular, and four cytoplasmic domains. The activation of the V2 receptor on renal collecting tubules stimulates adenylyl cyclase via the stimulatory G-protein (Gs) (1994 Nobel Prize in Physiology and Medicine to Rodbell and Gilman for signal transduction and G-proteins), and promotes the cyclic adenosine monophosphate (cAMP)-mediated incorporation of water channels into the luminal surface of these cells.[55] E. Sutherland and T. Rall isolated cyclic adenosine monophosphate in 1956, and Sutherland was awarded the Nobel Prize in Physiology or Medicine in 1971.[56] There are two ubiquitously expressed intracellular cAMP receptors: (1) the classical protein kinase A (PKA) that is a cAMP-dependent protein kinase; and (2) the recently discovered exchange protein directly activated by cAMP that is a cAMP-regulated guanine nucleotide exchange factor. Both of these receptors contain an evolutionally-conserved cAMP-binding domain that acts as a molecular switch for sensing intracellular cAMP levels to control diverse biological functions.[57] Several proteins participating in the control of cAMP-dependent AQP2 trafficking have been identified; for example, A-kinase anchoring proteins tethering PKA to cellular compartments; phosphodiesterases regulating the local cAMP level; cytoskeletal components such as F-actin and microtubules; small GTPases of the Rho family controlling cytoskeletal dynamics; motor proteins transporting AQP2-bearing vesicles to and from the plasma membrane for exocytic insertion and endocytic retrieval; SNAREs inducing membrane fusions, hsc70, a chaperone important for endocytic retrieval. These processes are the molecular basis of the vasopressin-induced increase in the osmotic water permeability of the apical membrane of the collecting tubule.[58–60]

AVP also increases the water reabsorptive capacity of the kidney by regulating the urea transporter

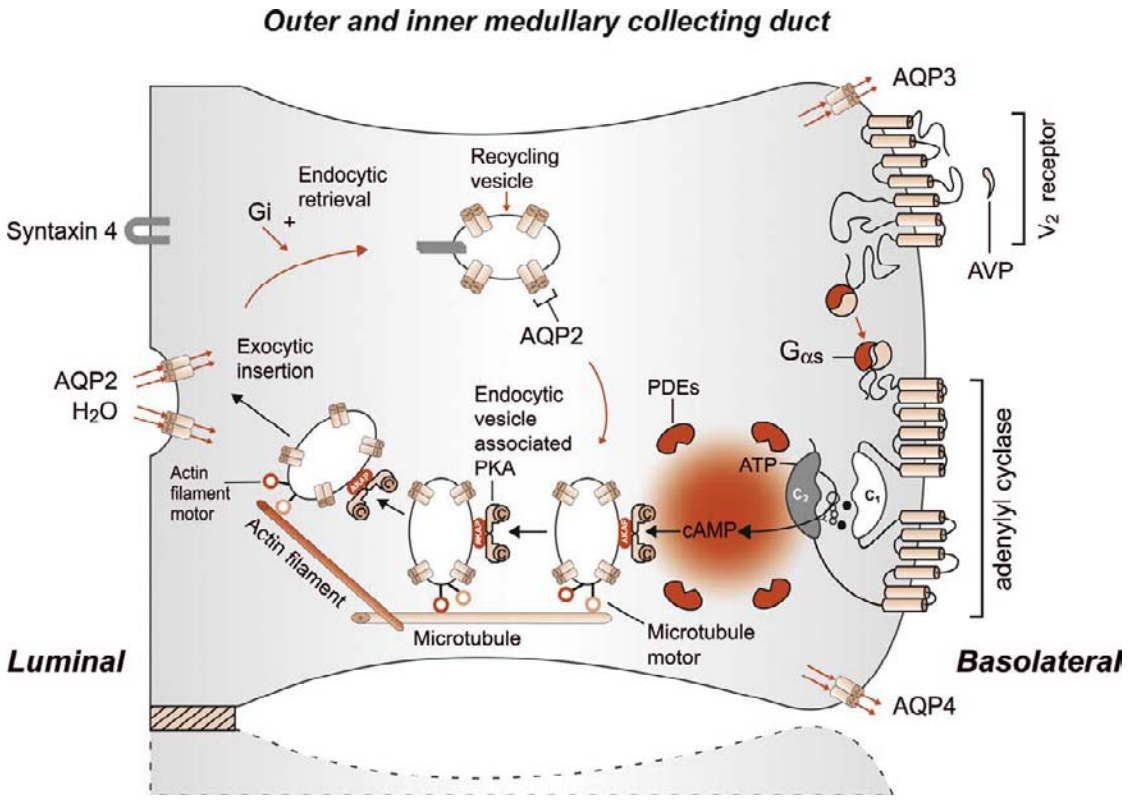

FIGURE 46.7 **Schematic representation of the effect of vasopressin (AVP) to increase water permeability in the principal cells of the collecting duct.** AVP is bound to the V2 receptor (a G-protein-linked receptor) on the basolateral membrane. The basic process of G-protein-coupled receptor signaling consists of three steps: a hepta-helical receptor that detects a ligand (in this case, AVP) in the extracellular milieu; a G-protein ($G_{\propto s}$) that dissociates into a subunits bound to GTP and bg subunits after interaction with the ligand-bound receptor; and an effector (in this case, adenylyl cyclase) that interacts with dissociated G-protein subunits to generate small-molecule second messengers. AVP activates adenylyl cyclase, increasing the intracellular concentration of cAMP. The topology of adenylyl cyclase is characterized by two tandem repeats of six hydrophobic transmembrane domains separated by a large cytoplasmic loop, and terminates in a large intracellular tail. The dimeric structure (C_1 and C_2) of the catalytic domains is represented. Conversion of ATP to cAMP takes place at the dimer interface. Two aspartate residues (in C_1) coordinate two metal co-factors (Mg^{2+} or Mn^{2+}, represented here as two small black circles), which enable the catalytic function of the enzyme. Adenosine is shown as an open circle and the three phosphate groups (ATP) are shown as smaller open circles. Protein kinase A (PKA) is the target of the generated cAMP. The binding of cAMP to the regulatory subunits of PKA induces a conformational change, causing these subunits to dissociate from the catalytic subunits. These activated subunits (C) as shown here are anchored to an aquaporin-2 (AQP2)-containing endocytic vesicle via an A-kinase anchoring protein. The local concentration and distribution of the cAMP gradient is limited by phosphodiesterases (PDEs). Cytoplasmic vesicles carrying the water channels (represented as homotetrameric complexes) are fused to the luminal membrane in response to AVP, thereby increasing the water permeability of this membrane. The dissociation of the A-kinase anchoring protein from the endocytic vesicle is not represented. Microtubules and actin filaments are necessary for vesicle movement toward the membrane. When AVP is not available, AQP2 water channels are retrieved by an endocytic process, and water permeability returns to its original low rate. Aquaporin-3 (AQP3) and aquaporin-4 (AQP4) water channels are expressed constitutively at the basolateral membrane.

variants UT-A1/3, which are present in the inner medullary collecting duct, predominantly in its terminal part.[61] AVP also increases the permeability of principal collecting duct cells to sodium. In summary, as stated elegantly by Ward and colleagues,[62] in the absence of AVP stimulation, collecting duct epithelia exhibit very low permeabilities to sodium urea and water. These specialized permeability properties permit the excretion of large volumes of hypotonic urine formed during intervals of water diuresis. In contrast, AVP stimulation of the principal cells of the collecting ducts leads to selective increases in the permeability of the apical membrane to water (P_f), urea (P_{urea}), and Na (P_{Na}).

The actions of vasopressin in the distal nephron are possibly modulated by prostaglandin E2, nitric oxide,[63] and by luminal calcium concentration. PGE_2 is synthesized and released in the collecting duct, which expresses all four E-prostanoid receptors (EP1−4). Both EP2 and EP4 can signal via increased cAMP. Olesen et al. hypothesized that selective EP receptor stimulation could mimic the effects of vasopressin, and demonstrated that, at physiological levels, PGE_2 markedly increased apical membrane abundance and phosphorylation of AQP2 *in vitro* and *ex vivo*, leading to increased cell water permeability.[64] In their experiments, both EP2 and EP4 selective agonists were able to mimic

these effects. Furthermore, an EP2-agonist was able to positively regulate urinary-concentrating mechanisms in an animal model of nephrogenic diabetes insipidus where AVPR2 receptors were blocked by Tolvaptan, a non-peptide V2-antagonist. These results reveal an alternative mechanism for regulating water transport in the collecting duct that has major importance for understanding whole body water homeostasis, and provide a rationale for investigations into EP receptor-agonist use in X-linked nephrogenic diabetes insipidus treatment.

THE BRATTLEBORO RAT WITH AUTOSOMAL RECESSIVE NEUROGENIC DIABETES INSIPIDUS

The animal model of diabetes insipidus that has been most extensively studied is the Brattleboro rat. Discovered in 1961, the rat lacks vasopressin and its neurophysin, whereas the synthesis of the structurally-related hormone oxytocin is not affected by the mutation.[65] Its inability to synthesize vasopressin is inherited as an autosomal recessive trait. Schmale and Richter[66] isolated and sequenced the vasopressin gene from homozygous Brattleboro rats, and found that the defect is due to a single nucleotide deletion of a G residue within the second exon encoding the carrier protein neurophysin (Figure 46.8). The shift in the reading frame caused by this deletion predicts a precursor with an entirely different C-terminus. The messenger RNA (mRNA) produced by the mutated gene encodes a normal AVP, but an abnormal NPII moiety[66] which impairs transport and processing of the AVP-NPII precursor and its retention in the endoplasmic reticulum of the magnocellular neurons where it is produced.[67,68] Homozygous Brattleboro rats may still demonstrate some V2 (*vide infra*) antidiuretic effects, since the administration of a selective non-peptide V2-antagonist (SR 121463 A, 10 mg/kg i.p.) induced a further increase in urine flow rate (200 to 354 ± 42 mL/24 h) and a decline in urinary osmolality (170 to 92 ± 8 mmol/kg).[69] This decline in urine osmolality following the administration of a non-peptide V2 receptor antagonist could also be secondary to the "inverse agonist" properties of SR121463A: the intrinsic activity or "tone," of the V2R would be deactivated by the SR121463A compound (for the inverse agonist properties of SR121463A see [70]). There is also an alternative explanation to this relatively high urine osmolality of 170 since, in Brattleboro rats, low levels of hormonally-active AVP are produced from alternate forms of AVP preprohormone. Due to a process called molecular misreading, one transcript contains a 2 bp deletion downstream from the single nucleotide deletion that restores the reading frame, and produces a variant AVP preprohormone that is smaller in length by one amino acid and differs from the normal product by only 13 amino acids in the neurophysin II moiety.[71] Oxytocin, which is present at enhanced plasma concentrations in Brattleboro rats, may be responsible for the antidiuretic activity observed.[72,73] Oxytocin is not stimulated by increased plasma osmolality in humans.

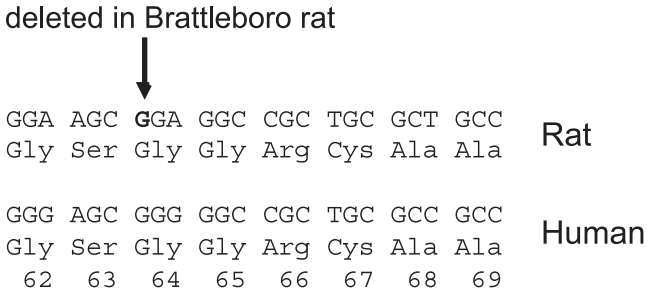

FIGURE 46.8 **Neurophysin II genomic and amino acid sequence showing the 1 bp (G) deleted in the Brattleboro rat.** The human sequence (GenBank entry M11166) is also shown. It is almost identical to the rat prepro sequence. In the Brattleboro rat, G1880 is deleted with a resultant frameshift after 63 amino acids (amino acid-1 is the first amino acid of neurophysin II).

KNOCKOUT MICE WITH URINARY CONCENTRATION DEFECTS

A useful strategy to establish the physiological function of a protein is to determine the phenotype produced by pharmacological inhibition of protein function or by gene disruption. Transgenic knockout mice deficient in AQP1, AQP2, AQP3, AQP4, and CLCNK1, NKCC2, NFAT5, AVPR2 or AGT have been engineered.[74–83] Angiotensinogen (AGT)-deficient mice are characterized by both concentrating and diluting defects secondary to a defective renal papillary architecture.[80] The *Aqp3*, *Aqp4*, *Clcnk1*, and *Agt* knockout mice have no identified human counterparts. Of interest, *AQP1*-null individuals have no obvious symptoms.[84] Yang et al.[85] have generated an AQP2-T126M "conditional knock-in" model of NDI, to recapitulate the clinical features of the naturally occurring human AQP2 mutation T126M.[86] The conditional knock-in adult mice showed polyuria, urinary hypoosmolality, and ER retention of AQP2-T126M in the collecting duct. Screening of candidate protein folding "correctors" in AQP2-T126M-transfected kidney cells showed increased AQP2-T126M plasma membrane expression with the Hsp90 inhibitor 17-allylamino-17-demethoxygeldanamycin (17-AAG), a compound currently in clinical trials for tumor therapy. 17-AAG increased

urine osmolality in the AQP2-T126M mice (without effect in AQP2 null mice), and partially rescued defective AQP2-T126M cellular processing. These proof-of-concept findings suggest the possibility of using existing drugs for therapy in some forms of NDI.

Mice lacking the AVPR2 receptor failed to thrive and died within the first week after birth due to hypernatremic dehydration.[83] Li et al.[87] generated mice in which the *Avpr2* gene could be conditionally deleted during adulthood by administration of 4-OH-tamoxifen. Adult mice displayed all characteristic symptoms of X-linked NDI, including polyuria, polydipsia, and resistance to the antidiuretic actions of vasopressin. Gene expression analysis suggested that activation of renal EP4 PGE_2 receptors might compensate for the lack of renal V2R activity in X-linked NDI mice, and both acute and chronic treatment of the mutant mice with a selective EP4 receptor agonist greatly reduced all major manifestations of XNDI. This beneficial effect is likely secondary to the intracellular generation of cAMP at the principal cell level by EP4 PGE_2 receptors.

As reviewed by Rao and Verkman,[88] extrapolation of data in mice to humans must be made with caution. For example, the maximum osmolality of mouse (< 3000 mOsm/kg H_2O) is much greater than that of human urine (1000 mOsmol/kg H_2O), and normal serum osmolality in mice is 330 to 345 mOsmol/kg H_2O, substantially greater than that in humans (280−290 mOsm/kg H_2O). Protein expression patterns, and thus the interpretation of phenotype studies, may also be species-dependent. For example, AQP4 is expressed in both proximal tubule and collecting duct in mouse, but only in collecting duct in rat and human.[88]

Ethylnitrosourea-mutagenized mice heterozygous for the F204V mutation in the *Aqp2* gene have been described,[89] and mice from the Jackson Laboratory with congenital progressive hydronephrosis bear the S256L mutation in *Aqp2* which affects its phosphorylation and apical membrane accumulation.[90,91]

QUANTITATING RENAL WATER EXCRETION

Diabetes insipidus is characterized by the excretion of abnormally large volumes of hypoosmotic urine (< 250 mmol/kg). This definition excludes osmotic diuresis, which occurs when excess solute is being excreted, as with glucose in the polyuria of diabetes mellitus. Other agents that produce osmotic diuresis are mannitol, urea, glycerol, contrast media, and loop diuretics. Osmotic diuresis should be considered when solute excretion exceeds 60 mmol/hour. The quantification of water excretion (free water clearance, osmolar clearance, free electrolyte water reabsorption, effective water clearance) is described elsewhere in this textbook.

CLINICAL CHARACTERISTICS OF DIABETES INSIPIDUS DISORDERS

Neurogenic Diabetes Insipidus

Common Forms

Failure to synthesize or secrete vasopressin normally limits maximal urinary concentration and, depending on the severity of the disease, causes varying degrees of polyuria and polydipsia. Experimental destruction of the vasopressin-synthesizing areas of the hypothalamus (supraoptic and paraventricular nuclei) causes a permanent form of the disease. Similar results are obtained by sectioning the hypophyseal hypothalamic tract above the median eminence. Sections below the median eminence, however, produce only transient diabetes insipidus. Lesions to the hypothalamic−pituitary tract are frequently associated with a three-stage response in experimental animals and in humans[92]: (1) an initial diuretic phase lasting from a few hours to 5 to 6 days; (2) a period of antidiuresis unresponsive to fluid administration (this antidiuresis is probably due to vasopressin release from injured axons and may last from a few hours to several days; because urinary dilution is impaired during this phase, continued water administration can cause severe hyponatremia); and (3) a final period of diabetes insipidus. The extent of the injury determines the completeness of the diabetes insipidus and, as already discussed, the site of the lesion determines whether the disease will be permanent.

Twenty-five percent of patients studied after transsphenoidal surgery developed spontaneous isolated hyponatremia, 20% developed diabetes insipidus, and 46% remained normonatremic. Normonatremia, hyponatremia, and diabetes insipidus were associated with increasing degrees of surgical manipulation of the posterior lobe and pituitary stalk during surgery.[93] Central diabetes insipidus observed after transphenoidal surgery is often transient, and only 2% of patients need long-term treatment with dDAVP.[94]

The causes of central diabetes insipidus in adults and in children are listed in Table 46.1.[95−98] Rare causes of central diabetes insipidus include leukemia, thrombotic thrombocytopenic purpura, pituitary apoplexy, sarcoidosis[99] and Wegener granulomatosis, xanthoma disseminatum,[100] septooptico dysplasia and agenesis of the corpus callosum,[101] metabolic anorexia nervosa, lymphocytic hypophysitis,[102] and necrotizing

TABLE 46.1 Etiology of Hypothalamic Diabetes Insipidus in Children and Adults

	Children (%)	Children and Young Adults (%)	Adults (%)
Primary brain tumor[a]	49.5	22.0	30.0
Before surgery	33.5		13.0
After surgery	16.0		17.0

infundibulo-hypophysitis.[103] Maghnie et al.[97] studied 79 patients with central diabetes insipidus: additional deficits in anterior pituitary hormones were documented in 61% of patients, a median of 0.6 years (range, 01–18.0 years) after the onset of diabetes insipidus. The most frequent abnormality was growth hormone deficiency (59%), followed by hypothyroidism (28%), hypogonadism (24%), and adrenal insufficiency (22%). Seventy-five percent of the patients with Langerhans cell histiocytosis had an anterior pituitary hormone deficiency that was first detected a median of 3.5 years after the onset of diabetes insipidus.[97] None of the patients with central diabetes insipidus secondary to *AVP* mutations developed anterior pituitary hormone deficiencies.

Rare Forms

AUTOSOMAL DOMINANT AND RECESSIVE NEUROGENIC DIABETES INSIPIDUS

Lacombe[104] and Weil[105] described a familial non-X-linked form of diabetes insipidus without any associated mental retardation. The descendants of the family described by Weil were later found to have autosomal dominant neurogenic diabetes insipidus.[106–108] Hereditary neurogenic diabetes insipidus (OMIM 125700)[109] is a well-characterized entity, secondary to mutations in *AVP* (OMIM 192340).[109] Patients with autosomal dominant neurogenic diabetes insipidus retain some limited capacity to secrete AVP during severe dehydration, and the polyuropolydipsic symptoms usually appear after the first year of life,[110] when the infant's demand for water is more likely to be understood by adults. In hereditary neurohypophyseal diabetes insipidus, termed familial neurohypophyseal diabetes insipidus (FNDI), levels of AVP are insufficient, and patients show a positive response to treatment with dAVP. Growth retardation might be observed in untreated children with autosomal dominant FNDI.[111]Over 60 mutations in the prepro-arginine-vasopressin-neurophysin II *AVP* gene located on chromosome 20p13 have been reported in dominant FNDI (adFNDI). Knock-in mice heterozygous for a nonsense mutation in the AVP carrier protein neurophysin II showed progressive loss of AVP-producing neurons over several months correlated with increased water intake, increased urine output, and decreased urine osmolality. The data suggest that vasopressin mutants accumulate as fibrillar aggregates in the endoplasmic reticulum and cause cumulative toxicity to magnocellular neurons, explaining the later age-of-onset.[112,113] To date, recessive FNDI, with early polyuric manifestations, has only been described in three studies.[114–116] Very early (first week of life) polyuric states are usually nephrogenic, but we and others have observed autosomal recessive central diabetes insipidus patients with early polyuria, dehydration episodes responding to dDAVP with specific mutations of the AVP gene.[114–117] A study by Christensen[118] examined the differences in cellular trafficking between dominant and recessive AVP mutants, and found that dominant forms were concentrated in the cytoplasm, whereas recessive forms were localized to the tips of neurites. The expression of regulated secretory proteins such as granins and prohormones, including pro-vasopressin, generates granule-like structures in a variety of neuroendocrine cell lines due to aggregation in the trans-Golgi.[119] Co-staining experiments unambiguously distinguished between these granule-like structures and the accumulations by pathogenic dominant mutants formed in the ER, since the latter, but not the trans-Golgi granules, co-localized with specific ER markers.[112] As studies concerning both dominant and recessive FNDI accumulate, it is becoming evident that FNDI exhibits a variable age-of-onset, and this may be related to the cellular handling of the mutant AVP. This progressive toxicity, sometimes called a toxic gain-of-function, shares mechanistic pathways with other neurodegenerative diseases, such as Huntington's and Parkinson's.

Of interest, errors in protein folding represent the underlying basis for many inherited diseases[120–122] and are also pathogenic mechanisms for *AVP*, *AVPR2*, and *AQP2* mutants. Why AVP-misfolded mutants are cytotoxic to AVP-producing neurons is an unresolved issue. Protein misfolding, an "unfolded protein response" in cells, and the accumulation of excess misfolded protein leading to apoptotic cell death are well-documented for autosomal dominant retinitis pigmentosa.[123]

WOLFRAM SYNDROME

Wolfram syndrome, also known as DIDMOAD, is an autosomal recessive neurodegenerative disorder accompanied by insulin-dependent diabetes mellitus and progressive optic atrophy. The acronym DIDMOAD describes the following clinical features of the syndrome: *d*iabetes *i*nsipidus, *d*iabetes *m*ellitus, *o*ptic *a*trophy, and sensorineural *d*eafness. An unusual incidence of psychiatric symptoms has also been described in patients with this syndrome. These included paranoid delusions, auditory or visual hallucinations, psychotic behavior, violent behavior, organic brain syndrome typically in the late or preterminal stages of their illness, progressive dementia, and severe learning disabilities or mental retardation or both. Patients with Wolfram syndrome develop diabetes mellitus and bilateral optical atrophy mainly in the first decade of life, the diabetes insipidus is usually partial and of gradual onset, and the polyuria can be wrongly attributed to poor glycemic control. Furthermore, a severe hyperosmolar state can occur if untreated diabetes mellitus is associated with an unrecognized posterior pituitary deficiency. The dilatation of the urinary tract observed in the DIDMOAD syndrome may be secondary to chronic high urine flow rates and, perhaps, to some degenerative aspects of the innervation of the urinary tract. The gene responsible for Wolfram syndrome, located in chromosome region 4p16.1, encodes a putative 890 amino acid transmembrane protein referred as *wolframin*. Wolframin is an endoglycosidase H-sensitive glycoprotein, which localizes primarily in the endoplasmic reticulum of a variety of neurons, including neurons in the supraoptic nucleus and neurons in the lateral magnocellular division of the paraventricular nucleus.[124,125] Disruption of the *Wfs1* gene in mice cause progressive β-cell loss and impaired stimulus-secretion coupling in insulin secretion, but central diabetes insipidus is not observed in $Wfs^{-/-}$ mice.[126] Miner1, another endoplasmic reticulum protein, is causative in Wolfram syndrome 2[127] and WFS1 negatively regulates a key transcription factor involved in ER stress signalling.[128]

SYNDROME OF HYPERNATREMIA AND HYPODIPSIA

Some patients with the hypernatremia and hypodipsia syndrome may have partial central diabetes insipidus. These patients also have persistent hypernatremia that is not due to any apparent extracellular volume loss, absence or attenuation of thirst, and a normal renal response to AVP. In almost all the patients studied, the hypodipsia has been associated with cerebral lesions in the vicinity of the hypothalamus. It has been proposed that in these patients there is a "resetting" of the osmoreceptor, because their urine tends to become concentrated or diluted at inappropriately high levels of plasma osmolality. However, using the regression analysis of plasma AVP concentration versus plasma osmolality, it has been shown that in some of these patients the tendency to concentrate and dilute urine at inappropriately high levels of plasma osmolality is due solely to a marked reduction in sensitivity or a gain in the osmoregulatory mechanism.[129] This finding is compatible with the diagnosis of partial central diabetes insipidus. In other patients, however, plasma AVP concentrations fluctuate in a random manner, bearing no apparent relationship to changes in plasma osmolality. Such patients frequently display large swings in serum sodium concentration, and frequently exhibit hypodipsia. It appears that most patients with "essential hypernatremia" fit one of these two patterns (Figure 46.9). Both of these groups of patients consistently respond normally to nonosmolar AVP release signals, such as hypotension, emesis, hypoglycemia or all three. These

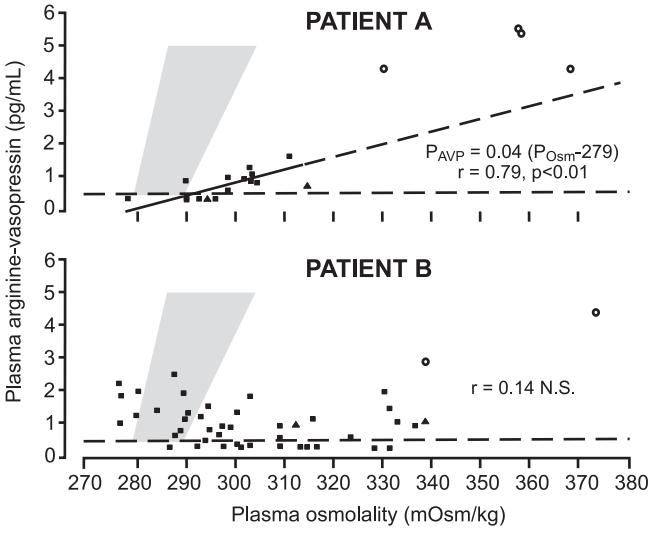

FIGURE 46.9 **Plasma arginine vasopressin (PAVP) as a function of "effective" plasma osmolality(P_{Osm}) in two patients with adipsic hypernatremia.** Open circles indicate values obtained on admission; filled squares indicate those obtained during forced hydration; filled triangles indicate those obtained after 1 to 2 weeks of ad libitum water intake; gray areas indicate range of normal values. *(From ref. [245].)*

observations suggest that: (1) the osmoreceptor may be anatomically, as well as functionally, separate from the nonosmotic efferent pathways and neurosecretory neurons for vasopressin, and a hypothalamic lesion may impair the osmotic release of AVP while the nonosmotic release of AVP remains intact; and (2) the osmoreceptor neurons that regulate vasopressin secretion are not synonymous with those that regulate thirst.

Hereditary Nephrogenic Diabetes Insipidus

In nephrogenic diabetes insipidus (NDI), the kidney is unable to concentrate urine despite normal or elevated concentrations of the antidiuretic hormone arginine vasopressin. In congenital NDI, the obvious clinical manifestations of the disease, that is polyuria and polydipsia, are present at birth and need to be immediately recognized to avoid severe episodes of dehydration. It is clinically useful to distinguish two types of hereditary NDI: a "pure" type characterized by loss of water only; and a complex type characterized by loss of water and ions. Patients who have congenital NDI and mutations in the *AVPR2* or *AQP2* genes have a pure NDI phenotype with loss of water but normal conservation of sodium, potassium, chloride, and calcium. Patients with inactivating mutations in genes (*SLC12A1*, *KCNJ1*, *CLCNKB*, *CLCNKA*, and *CLCNKB* in combination or *BSND*) that encode the membrane proteins of the thick ascending limb of the loop of Henle have a complex polyuropolydipsic syndrome with loss of water, sodium, chloride, calcium, magnesium, and potassium. Most (>90%) of pure congenital NDI patients have mutations in the *AVPR2* gene, the Xq28 gene coding for the vasopressin V2 (antidiuretic) receptor. In less than 10% of the families studied, congenital NDI has an autosomal recessive inheritance, and mutations have been identified in the *AQP2* gene located in chromosome region 12q13, that is, the vasopressin-sensitive water channel. When studied *in vitro*, most *AVPR2* mutations lead to receptors that are trapped intracellularly, and are unable to reach the plasma membrane. A minority of the mutant receptors reaches the cell surface, but is unable to bind AVP or to trigger an intracellular cAMP signal. Similarly, *AQP2* mutant proteins are trapped intracellularly and cannot be expressed at the luminal membrane. AVPR2 and AQP2-trafficking defects are correctable by chemical chaperones.

LOSS-OF-FUNCTION MUTATIONS OF *AVPR2*

X-linked NDI (OMIM 304800)[109] is secondary to *AVPR2* mutations, which result in a loss-of-function or dysregulation of the V2 receptor.[130] Males who have an *AVPR2* mutation have a phenotype characterized by early dehydration episodes, hypernatremia, and hyperthermia as early as the first week of life. Dehydration episodes can be so severe that they lower arterial blood pressure to a degree that is not sufficient to sustain adequate oxygenation to the brain, kidneys, and other organs. Mental and physical retardation and renal failure are the classical "historic" consequences of a late diagnosis and lack of treatment. Heterozygous females exhibit variable degrees of polyuria and polydipsia, because of skewed X-chromosome inactivation.[131,132]

Clinical Characteristics

The historic clinical characteristics include hypernatremia, hyperthermia, mental retardation, and repeated episodes of dehydration in early infancy.[133–136] Mental retardation, a consequence of repeated episodes of dehydration, was prevalent in the Crawford and Bode study,[133] in which only nine (11%) of 82 patients had normal intelligence. Early recognition and treatment of X-linked NDI with an abundant intake of water allows a normal lifespan with normal physical and mental development.[137] Two characteristics suggestive of X-linked NDI are the familial occurrence and the confinement of mental retardation to male patients. It is then tempting to assume that the family described in 1892 by McIlraith,[138] and discussed by Reeves and Andreoli[139] was an X-linked NDI family.

Crawford and Bode[133] clearly describe the early symptoms of the nephrogenic disorder and its severity in infancy. The first manifestations of the disease can be recognized during the first week of life. The infants are irritable, cry almost constantly and, although eager to suck, will vomit milk soon after ingestion unless prefed with water. The history given by the mothers often includes persistent constipation, erratic unexplained fever, and failure to gain weight. Although the patients characteristically show no visible evidence of perspiration, increased water loss during fever or in warm weather exaggerates the symptoms. Unless the condition is recognized early, children experience frequent bouts of hypertonic dehydration, sometimes complicated by convulsions or death; mental retardation is a frequent consequence of these episodes. The intake of large quantities of water, combined with the patient's voluntary restriction of dietary salt and protein intake, lead to hypocaloric dwarfism beginning in infancy. Frequently, lower urinary tract dilatation and obstruction, probably secondary to the large volume of urine produced,[140] develop in affected children. Dilatation of the lower urinary tract is also seen in primary polydipsic patients, and in patients with neurogenic diabetes insipidus.[141,142] Chronic renal insufficiency may occur

by the end of the first decade of life, and could be the result of episodes of dehydration with thrombosis of the glomerular tufts.[133]

History

In 1989, we observed that the administration of dDAVP, a V2-receptor agonist, increased plasma cAMP concentrations in healthy subjects, but had no effect in 14 male patients with X-linked NDI.[143] Intermediate responses were observed in obligate carriers of the disease, corresponding to half of the normal receptor response. On the basis of these results, we predicted that the defective gene in these patients with X-linked NDI was likely to code for a defective V2 receptor.[143] Since that time, a number of experimental results have confirmed our hypothesis: (1) the NDI locus was mapped to the distal region of the long arm of the X-chromosome[144–147]; (2) the V2 receptor was identified as a candidate gene for NDI[148]; (3) the human V2 receptor was cloned[53]; and (4) 214 putative disease-causing mutations have now been identified in the V2 receptor, and the list of mutations is still expanding[149,150] (Figure 46.10).

Population Genetics of *AVPR2* Mutations

X-linked NDI is generally a rare disease in which the affected male patients do not concentrate their urine after administration of AVP.[151] Because this form is a rare, recessive X-linked disease, female individuals are unlikely to be affected, but heterozygous female individuals can exhibit variable degrees of polyuria and polydipsia because of skewed X-chromosome inactivation. In Quebec, the incidence of this disease among male individuals was estimated to be approximately 8.8 in 1,000,000 male live births.[131] A founder effect of two particular *AVPR2* mutations,[152] one in Ulster Scot immigrants (the Hopewell mutation, W71X), and one

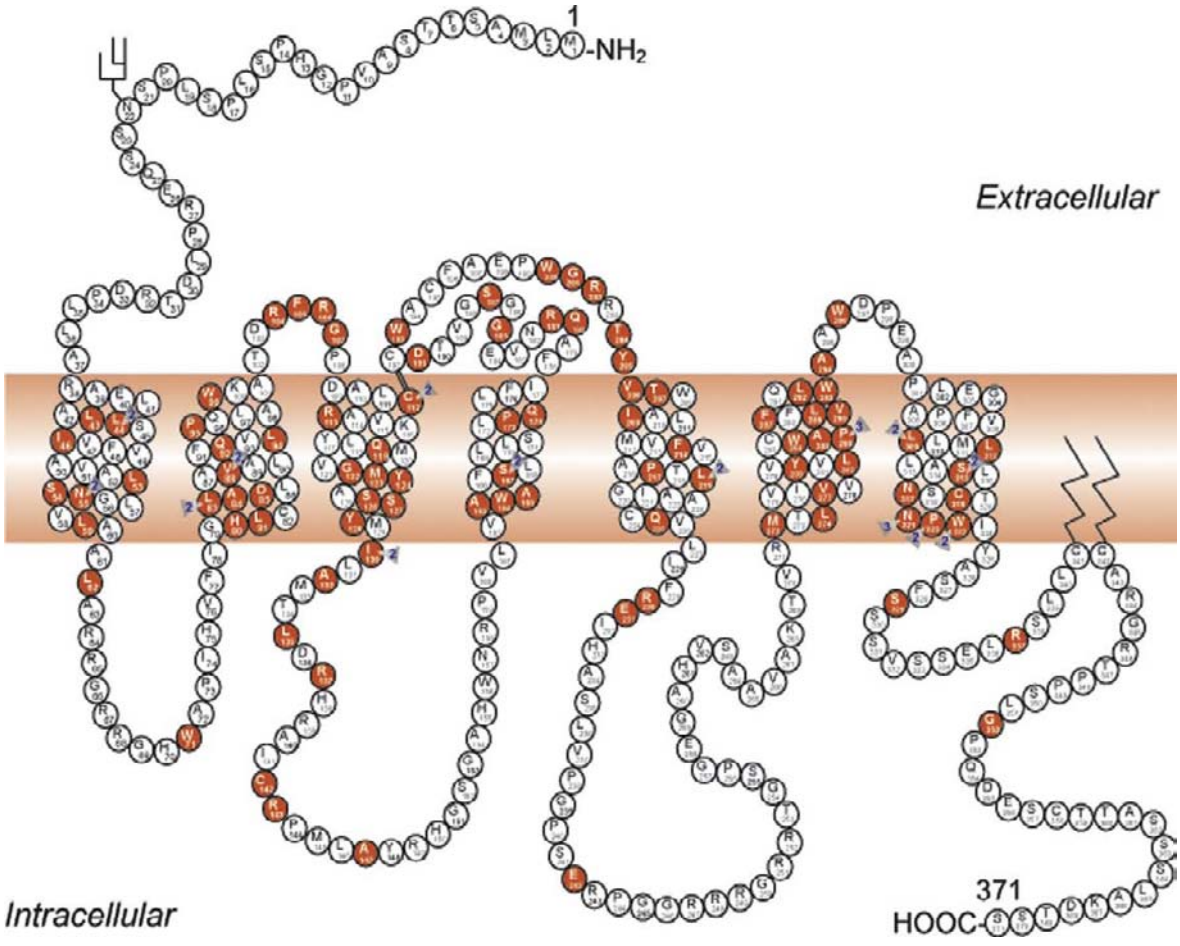

FIGURE 46.10 **Schematic representation of the V2 receptor and identification of 193 putative disease-causing AVPR2 mutations.** Predicted amino acids are shown as the one-letter amino acid code. A solid symbol indicates a codon with a missense or nonsense mutation; a number indicates more than one mutation in the same codon; other types of mutations are not indicated on the figure. There are 95 missense, 18 nonsense, 46 frameshift deletion or insertion, 7 inframe deletion or insertion, 4 splice-site, and 22 large deletion mutations, and one complex mutation.

in a large Utah kindred (the Cannon pedigree), result in an elevated prevalence of X-linked NDI in their descendants in certain communities in Nova Scotia, Canada, and Utah, United States.[117] These founder mutations have now spread all over the North American continent. We have identified the W71X mutation in 42 affected male individuals who reside predominantly in the Maritime Provinces of Nova Scotia and New Brunswick, and the L312X mutation in eight affected males who reside in the central United States. We know of 98 living affected male individuals of the Hopewell kindred, and 18 living affected male individuals of the Cannon pedigree.

We propose that all families with hereditary diabetes insipidus should have their molecular defect identified. The molecular identification underlying X-linked NDI is of immediate clinical significance, because early diagnosis and treatment of affected infants can avert the physical and mental retardation that results from repeated episodes of dehydration. Affected premature male infants may experience less severe polyuric symptoms, and may need only increased hydration during their first week without a need for hydrochlorothiazide treatment. Water should be offered every 2hours day and night, and temperature, appetite, and growth should be monitored. Admission to hospital may be necessary for continuous gastric feeding. The voluminous amounts of water kept in patients' stomachs will exacerbate physiological gastrointestinal reflux in infants and toddlers, and many affected boys frequently vomit. These young patients often improve with the absorption of an H_2 blocker, and with metoclopramide (which could induce extrapyramidal symptoms) or with domperidone, which seems to be better-tolerated and efficacious. As mentioned previously, all polyuric states (whether neurogenic, nephrogenic or psychogenic) can induce large dilatations of the urinary tract and bladder,[133,141,142] and bladder function impairment has been well-documented in patients who bear *AVPR2* or *AQP2* mutations.[153,154] Of interest, in mice with congenital progressive hydronephrosis (cph) homozygote for the S266L mutation (*Aqp2*) the congenital obstructive uropathy is likely a result of the polyuria.[90] Chronic renal failure secondary to bilateral hydronephrosis has been observed as a long-term complication in these patients. Renal and abdominal ultrasound should be done annually, and simple recommendations, including frequent urination and "double voiding" could be important to prevent these consequences.

Expression Studies

Classification of the defects of naturally occurring mutant human V2 receptors can be based on a similar scheme to that used for the LDL receptor. Mutations have been grouped according to the function and subcellular localization of the mutant protein whose cDNA has been transiently transfected in a heterologous expression system.[155] Using this classification, type 1 mutant V2 receptors reach the cell surface, but display impaired ligand binding and are consequently unable to induce normal cAMP production. The presence of mutant V2 receptors on the surface of transfected cells can be determined pharmacologically. By carrying out saturation-binding experiments using tritiated AVP, the number of cell surface mutant V2 receptors and their apparent binding affinity can be compared with that of the wild-type receptor. In addition, the presence of cell surface receptors can be assessed directly by using immunodetection strategies to visualize epitope-tagged receptors in whole-cell immunofluorescence assays.

Type 2 mutant receptors have defective intracellular transport. This phenotype is confirmed by carrying out, in parallel, immunofluorescence experiments on cells that are intact (to demonstrate the absence of cell surface receptors) or permeabilized (to confirm the presence of intracellular receptor pools). In addition, protein expression is confirmed by Western blot analysis of membrane preparations from transfected cells. It is likely that these mutant type 2 receptors accumulate in a pre-Golgi compartment, because they are initially glycosylated but fail to undergo glycosyl-trimming maturation.

Type 3 mutant receptors are ineffectively transcribed and lead to unstable mRNA, which are rapidly degraded. This subgroup seems to be rare, since Northern blot analysis of cells expressing mutant V2 receptors showed mRNA of normal quantity and molecular size.

Most of the *AVPR2* mutants that we and other investigators have tested are type 2 mutant receptors. They did not reach the cell membrane, and were trapped in the interior of the cell.[156–159] Other mutant G-protein-coupled receptors[160] and gene products that cause genetic disorders are also characterized by protein misfolding. Mutations that affect the folding of secretory proteins, integral plasma membrane proteins or enzymes destined to the endoplasmic reticulum, Golgi complex, and lysosomes result in loss-of-function phenotypes irrespective of their direct impact on protein function, because these mutant proteins are prevented from reaching their final destination.[161] Folding in the endoplasmic reticulum is the limiting step: mutant proteins which fail to correctly fold are retained initially in the endoplasmic reticulum and subsequently often degraded. Key proteins involved in the urine countercurrent mechanisms are good examples of this basic mechanism of misfolding. *AQP2* mutations responsible for autosomal recessive NDI are characterized by

misrouting of the misfolded mutant proteins, and are trapped in the endoplasmic reticulum.[162] Mutants that encode other renal membrane proteins that are responsible for Gitelman syndrome,[163] Bartter syndrome,[164,165] and cystinuria[166] are also retained in the endoplasmic reticulum.

The *AVPR2* missense mutations are likely to impair folding and to lead to rapid degradation of the misfolded polypeptide, and not to the accumulation of toxic aggregates (as is the case for AVP mutants), because the other important functions of the principle cells of the collecting duct (where *AVPR2* is expressed) are entirely normal. These cells express the epithelial sodium channel (ENaC). Decreased function of this channel results in a sodium-losing state.[167] This has not been observed in patients with *AVPR2* mutations. By contrast, another type of conformational disease is characterized by the toxic retention of the misfolded protein. The relatively common Z mutation in a_1-antitrypsin deficiency not only causes retention of the mutant protein in the endoplasmic reticulum, but also affects the secondary structure by insertion of the reactive center loop of one molecule into a destabilized b sheet of a second molecule.[168] These polymers clog up the endoplasmic reticulum of hepatocytes and lead to cell death and juvenile hepatitis, cirrhosis, and hepatocarcinomas in these patients.[169]

If the misfolded protein/traffic problem that is responsible for so many human genetic diseases can be overcome, and the mutant protein transported out of the endoplasmic reticulum to its final destination, these mutant proteins could be sufficiently functional.[120] Therefore, using pharmacological chaperones or pharmacoperones to promote escape from the endoplasmic reticulum is a possible therapeutic approach.[121,156,161] We used selective nonpeptide V2 and V1 receptor-antagonists to rescue the cell-surface expression and function of naturally occurring misfolded human V2 receptors.[158] Because the beneficial effect of nonpeptide V2 antagonists could be secondary to prevention and interference with endocytosis, we studied the R137H mutant previously reported to lead to constitutive endocytosis.[170] We found that the antagonist did not prevent the constitutive b-arresting-promoted endocytosis.[156] These results indicate that, as for other *AVPR2* mutants, the beneficial effects of the treatment result from the action of the pharmacological chaperones. These studies were confirmed *in vitro* with the use of non-peptide V2 agonists.[171] In clinical studies, we administered a nonpeptide vasopressin antagonist SR49059 to five adult patients who have NDI and bear the del62-64, R137H, and W164S mutations. SR49059 significantly decreased urine volume and water intake and increased urine osmolality whereas sodium, potassium, and creatinine excretions and plasma sodium levels were constant throughout the study.[156] This new therapeutic approach could be applied to the treatment of several hereditary diseases resulting from errors in protein folding and kinesis.[120,121]

Because most human gene-therapy experiments using viruses to deliver and integrate DNA into host cells are potentially dangerous,[172] other treatments are being actively pursued. Schöneberg and colleagues[173] used aminoglycoside antibiotics, because of their ability to suppress premature termination codons.[174] They demonstrated that geneticin, a potent aminoglycoside antibiotic, increased AVP-stimulated cAMP in cultured collecting duct cells prepared from E242X mutant mice. The urine concentrating ability of heterozygous mutant mice was also improved.

LOSS-OF-FUNCTION MUTATIONS OF AQP2 (OMIM 222000, 125800, 107777)

On the basis of desmopressin infusion studies and phenotypic characteristics of both male and female individuals who are affected with NDI, a non-X-linked form of NDI with a postreceptor (post-cAMP) defect was suggested.[109,175–177] A patient who presented shortly after birth with typical features of NDI, but who exhibited normal coagulation and normal fibrinolytic and vasodilatory responses to desmopressin, was shown to be a compound heterozygote for two missense mutations (R187C and S217P) in the *AQP2* gene.[178] To date, 46 putative disease-causing *AQP2* mutations have been identified in 52 NDI families (Figure 46.11). The oocytes of the African clawed frog (*Xenopus laevis*) have provided a most useful experimental system for studying the function of many channel proteins. This convenient expression system was key to the discovery of AQP1 by Agre,[179] because frog oocytes have very low permeability and survive even in freshwater ponds. Control oocytes are injected with water alone; test oocytes are injected with various quantities of synthetic transcripts from AQP1 or AQP2 DNA (cRNA). When subjected to a 20 mOsm osmotic shock, control oocytes have exceedingly low water permeability, but test oocytes become highly permeable to water. These osmotic water permeability assays demonstrated an absence or very low water transport for all of the cRNA with *AQP2* mutations. Immunofluorescence and immunoblot studies demonstrated that these recessive mutants were retained in the endoplasmic reticulum.

AQP2 mutations in autosomal recessive NDI, which are located throughout the gene, result in misfolded proteins that are retained in the endoplasmic reticulum. In contrast, the dominant mutations reported to date are located in the region that codes for the carboxyl-terminus of AQP2.[180–182] Dominant AQP2

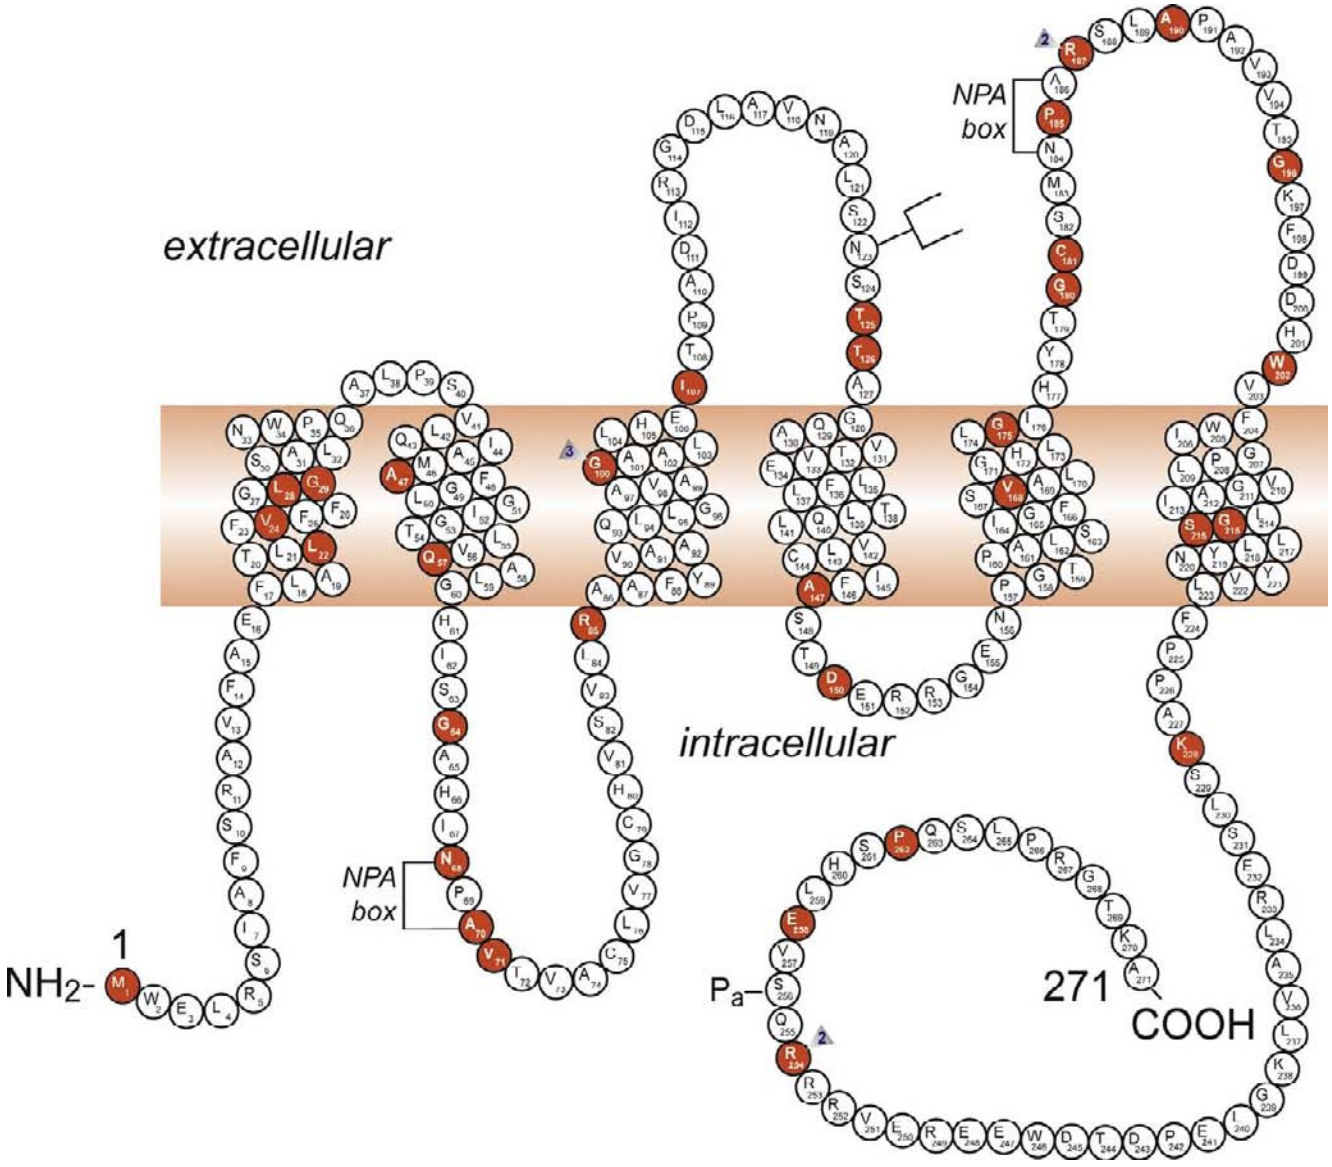

FIGURE 46.11 **A representation of the AQP2 protein and identification of 46 putative disease-causing AQP2 mutations.** A monomer is represented with six transmembrane helices. The location of the PKA phosphorylation site (Pa) is indicated. The extracellular, transmembrane, and cytoplasmic domains are defined according to *Deen, P. M., et al. (1994)*.[178] Solid symbols indicate the location of the mutations (for references, see Table 46.1): M1I; L22V; V24A; L28P; G29S; A47V; Q57P; G64R, N68S, A70D; V71M; R85X; G100X; G100V; G100R; I107D; 369delC; T125M; T126M; A147T; D150E; V168M; G175R; G180S; C181W; P185A; R187C; R187H; A190T; G196D; W202C; G215C; S216P; S216F; K228E; R254Q; R254L; E258K; and P262L. GenBank accession numbers—AQP2: AF147092, exon 1; AF147093, exons 2 through 4. NPA motifs and the N-glycosylation site are also indicated.

mutants form heterotetramers with wild-type AQP2 and are misrouted. Patients bearing these dominant mutations have a less severe phenotype compared to patients who are compound heterozygotes or homozygotes for recessive mutations: the patient and her daughter first described to bear the AQP2-E258K dominant mutation increased their urine osmolality to 350 mOsm/kg H_2O following dDAVP.[183] Also, the patient with a detailed phenotype described by Robertson and Kopp[184] increased her urine osmolality to 220 mOsm/kg H_2O during a mildly hypertonic dehydration, to 258 mOsm/kg H_2O after dDAVP, and to 305 mOsm/kg H_2O after hydrochlorothiazide and indomethacin. This patient was found to be heterozygous for the R254Q mutation, possibly interfering with the S256 phosphorylation site.[185] In the mutant AQP2 (763–772) knock-in mice, Sohara et al. demonstrated a slight increase in urine osmolality following dehydration, but a marked increase after the administration of Rolipram, a phosphodiesterase 4 inhibitor.[186]

COMPLEX POLYUROPOLYDIPSIC SYNDROME

In contrast to a pure NDI phenotype, with loss of water but normal conservation of sodium, potassium, chloride, and calcium, in Bartter syndrome, patients' renal-wasting starts prenatally, and polyhydramnios often leads to prematurity. Bartter syndrome (OMIM 601678, 241200, 607364, and 602522) refers to a group of autosomal recessive disorders caused by inactivating mutations in genes (*SLC12A1*, *KCNJ1*, *CLCNKB*, *CLCNKA*, and *CLCNKB* in combination or *BSND*) that encode membrane proteins of the thick ascending limb of the loop of Henle (for review see [187,188]). Although Bartter syndrome and Bartter mutations are commonly used as a diagnosis, it is likely, as explained by Jeck et al.,[189] that the two patients with a mild phenotype originally described by Dr. Bartter had Gitelman syndrome, a thiazide-like, salt-losing tubulopathy with a defect in the distal convoluted tubule.[189] As a consequence, salt-losing tubulopathy of the furosemide-type is a more physiologically appropriate definition.

Thirty percent of the filtered sodium chloride is reabsorbed in the thick ascending limb of the loop of Henle through the apically expressed sodium–potassium–chloride co-transporter NKCC2 (encoded by the *SLC12A1* gene), which uses the sodium gradient across the membrane to transport chloride and potassium into the cell. The potassium ions must be recycled through the apical membrane by the potassium channel ROMK (encoded by the *KCNJ1* gene). In the large experience of Seyberth and colleagues,[190] who studied 85 patients with a hypokalemic salt-losing tubulopathy, all 20 patients with *KCNJ1* mutations (except one) and all 12 patients with *SLC12A1* mutations were born as preterm infants after severe polyhydramnios. Of note, polyhydramnios is never seen during a pregnancy that leads to infants bearing *AVPR2* or *AQP2* mutations. The most common causes of increased amniotic fluid include maternal diabetes mellitus, fetal malformations and chromosomal aberrations, twin-to-twin transfusion syndrome, rhesus incompatibility, and congenital infections.[191] Postnatally, polyuria was the leading symptom in 19 of the 32 patients. Renal ultrasound revealed nephrocalcinosis in 31 of these patients. These patients with complex polyuropolydipsic disorders are often poorly-recognized, and may be confused with pure NDI. As a consequence, congenital polyuria does not suggest automatically *AVPR2* or *AQP2* mutations, and polyhydramnios, salt-wasting, hypokalemia, and nephrocalcinosis are important clinical and laboratory characteristics that should be assessed. In patients with Bartter syndrome (salt-losing tubulopathy/furosemide-type), the dDAVP test will only indicate a partial type of NDI. The algorithm proposed by Peters et al.[190] is useful, since most mutations in *SLC12A1* and *KCNJ1* are found in the carboxyl-terminus or in the last exon and, as a consequence, are amenable to rapid DNA sequencing.

Polyuria, polydipsia, electrolyte imbalance, and dehydration may also been seen in cystinosis, nephronophthisis, and apparent mineralocorticoid excess. Polyuria may be as mild as persistent enuresis and as severe as to contribute to death from dehydration and electrolyte abnormalities in infants with cystinosis who have acute gastroenteritis.[192] Nephronophthisis and apparent mineralocorticoid excess are also associated with low urine osmolality unresponsive to vasopressin.[193]

ACQUIRED NEPHROGENIC DIABETES INSIPIDUS

Acquired NDI is much more common than congenital NDI, but it is rarely as severe. The ability to produce hypertonic urine is usually preserved, even though there is inadequate concentrating ability of the nephron. Polyuria and polydipsia are therefore moderate (3–4 l/d).

The more common causes of acquired NDI are listed in Table 46.2. Lithium administration has become the most frequent cause; 54% of 1105 unselected patients on chronic lithium therapy developed NDI.[194] Nineteen percent of these patients had polyuria, as defined by a 24hour urine output exceeding 3 liters. The mechanism whereby lithium causes polyuria has been extensively studied. Lithium inhibits adenylyl cyclase in a number of cell types, including renal epithelia.[195,196] The dysregulation of aquaporin-2 expression is the result of cytotoxic accumulation of lithium which enters via the epithelial sodium channel (ENaC) on the apical membrane, and leads to the inhibition of signaling pathways that involve glycogen synthase kinase type 3 beta.[197] The concentration of lithium in urine of patients on well-controlled lithium therapy (i.e., 10 to 40 mOsmol/L) is sufficient to exert this effect. For patients on long-term lithium therapy, amiloride has been proposed to prevent the uptake of lithium in the collecting ducts, thus preventing the inhibitory effect of intracellular lithium on water transport.[198]

Primary Polydipsia

Primary polydipsia is a state of hypotonic polyuria secondary to excessive fluid intake. Primary polydipsia was extensively studied by Barlow and de Wardener in 1959[199]; however, the understanding of the

TABLE 46.2 Causes of Nephrogenic Diabetes Insipidus.

Narrow definition of NDI: water permeability of the collecting duct not increased by AVP
Congenital (idiopathic)
Hypercalcemia
Hypokalemia
Drugs:
Lithium
Nonpeptide vasopressin receptor (V2) antagonists
Demeclocycline
Amphotericin B
Methoxyflurane
Diphenylhydantoin
Nicotine
Alcohol
Broad definition of NDI: defective medullary countercurrent function
Renal failure, acute or chronic (especially interstitial nephritis or obstruction)
Medullary damage:
Sickle-cell anemia and trait
Amyloidosis
Sjögren syndrome
Sarcoidosis
Hypercalcemia
Hypokalemia
Protein malnutrition
Cystinosis

Modified from ref. [246]

pathophysiology of this disease has made little progress. Barlow and de Wardener[199] described seven women and two men who were compulsive water drinkers; their ages ranged from 48 to 59 years, except for one patient who was 24 years old. Eight of these patients had histories of previous psychological disorders, which ranged from delusions, depression, and agitation to frank hysterical behavior. The other patient appeared normal. The consumption of water fluctuated irregularly from hour to hour or from day to day; in some patients, there were remissions and relapses lasting several months or longer. In eight of the patients, the mean plasma osmolality was significantly lower than normal. Vasopressin tannate in oil made most of these patients feel ill; in one, it caused overhydration. In four patients, the fluid intake returned to normal after electroconvulsive therapy or a period of continuous narcosis; the improvement in three was transient, but in the fourth it lasted two years. Polyuric female subjects might be heterozygous for *de novo* or previously unrecognized *AVPR2* mutations, may bear *AQP2* mutations, and may be classified as compulsive water drinkers.[200] Therefore, the diagnosis of compulsive water drinking must be made with care, and may represent our ignorance of yet undescribed pathophysiological mechanisms. Robertson[200] has described under the name "dipsogenic diabetes insipidus" a selective defect in the osmoregulation of thirst. Three studied patients had, under basal conditions of *ad libitum* water intake, thirst, polydipsia, polyuria, and high-normal plasma osmolality. They had a normal secretion of AVP, but osmotic threshold for thirst was abnormally low. These dipsogenic diabetes insipidus cases might represent up to 10% of all patients with diabetes insipidus.[200]

Diabetes Insipidus and Pregnancy

Pregnancy in a Patient Known to Have Diabetes Insipidus

An isolated deficiency of vasopressin without a concomitant loss of hormones in the anterior pituitary does not result in altered fertility, and with the exception of polyuria and polydipsia, gestation, delivery, and lactation are uncomplicated.[201] Patients may require increasing dosages of dDAVP. The increased thirst may be due to a resetting of the thirst osmostat.[202]

Increased polyuria also occurs during pregnancy in patients with partial NDI.[203] These patients may be obligatory carriers of the NDI gene[204] or may be homozygotes, compound heterozygotes or may have dominant AQP2 mutations.

Syndromes of Diabetes Insipidus that Begin during Gestation and Remit after Delivery

Barron et al.[205] described three pregnant women in whom transient diabetes insipidus developed late in gestation and subsequently remitted postpartum. In one of these patients, dilute urine was present despite high plasma concentrations of AVP. Hyposthenuria in all three patients was resistant to administered aqueous vasopressin. Because excessive vasopressinase activity was not excluded as a cause of this disorder, Barron et al. labeled the disease vasopressin-resistant, rather than NDI.

A well-documented case of enhanced activity of vasopressinase has been described in a woman in the third trimester of a previously uncomplicated pregnancy.[206] She had massive polyuria and markedly

elevated plasma vasopressinase activity. The polyuria did not respond to large intravenous doses of AVP, but responded promptly to dDAVP, a vasopressinase-resistant analog of AVP. The polyuria disappeared with the disappearance of the vasopressinase. It is suggested that pregnancy may be associated with several different forms of diabetes insipidus, including central, nephrogenic, and vasopressinase mediated.[203,207,208]

Polyuria and Nocturia in Diabetes Insipidus, Nocturnal Polyuria in Enuretic Children

Polyuria could be constant during the day but also present at night: the urine is normally most concentrated in the morning due to lack of fluid ingestion overnight and increased vasopressin secretion during the late sleep period.[209] Neurons in the suprachiasmatic nucleus, the brain biological clock, send axonal projections toward the supraoptic nucleus, one of the hypothalamic nuclei producing vasopressin,[5] providing a possible anatomical substrate for the circadian modulation, an osmoregulatory gain during the late sleep period.[209] As a result, the first manifestation of a mild-to-moderate loss of concentrating ability is often nocturia. However, nocturia is not diagnostic of a defect in concentrating ability, since it can also be caused by other factors such as drinking before going to bed or, in men, by prostatic hypertrophy, which is characterized by urinary frequency rather than polyuria. Psychogenic polydipsic patients tend to ingest large amounts of fluid during the day but not at night, therefore nocturia is rarely seen in primary polydipsic patients.[199] The pattern of nocturnal polyuria in enuretic children is similar to that observed in acute sleep deprivation, and enuresis in children might be related to the failure of sleep to cause a reflex reduction in arterial pressure and urine production.[210,211]

INVESTIGATION OF A PATIENT WITH POLYURIA

Plasma sodium and osmolality are maintained within normal limits (136−143 mOsmol/l for plasma sodium; 275−290 mOsmol/kg for plasma osmolality) by a thirst−AVP−renal axis. Thirst and AVP release, both stimulated by increased osmolality, is a "double-negative" feedback system.[212] Even when the AVP component of this double-negative regulatory feedback system is lost, the thirst mechanism still preserves the plasma sodium and osmolality within the normal range, but at the expense of pronounced polydipsia and polyuria. Thus, the plasma sodium concentration or osmolality of an untreated patient with diabetes insipidus may be slightly greater than the mean normal value, but these small increases have no diagnostic significance. Polyuric patients should be asked about their thirst and their way to quench it: cold water will quench thirst more effectively in severely polyuric and dehydrated patients, irrespective of their etiology (central versus nephrogenic). Primary polydipsic patients may tend to absorb large quantities of water, ice-cold or not. Glucose-induced osmotic diuresis is more frequent than any cause of non-osmotic polyuria. High plasma glucose levels with polyuria could also be observed in brain-dead patients with diabetes insipidus receiving glucose infusions at a rate exceeding 500 ml/hour, which corresponds to the maximum (25 g/hour) possibility for glucose metabolism. The polyuria observed in post-obstructive diuresis is appropriate, representing an attempt to excrete the fluid retained during the period of obstruction.[213]

Excepting the context of brain trauma, brain surgery or long-term lithium administration, where the diagnosis of polyuria is obvious, a logical approach to the patient with polyuria is to search for arguments supporting known causes of polyuric states. Such arguments may be: (1) morphological (brain magnetic resonance imaging), including the presence of a hypothalamic tumour or mass related to a granulomatous or inflammatory process; (2) hormonal, suggesting that the posterior pituitary involvement is not isolated, but rather is associated with other signs of anterior pituitary deficits; (3) systemic, with the presence of a generalized inflammatory process or pituitary metastasis; (4) hereditary, with other members of the family affected with central or nephrogenic diabetes insipidus.

An abrupt onset of polyuria in an adult would suggest acquired central diabetes insipidus. Magnetic resonance imaging of the hypothalamic structures and of the posterior pituitary should be obtained to assess the posterior pituitary normal "bright spot," a possible surrogate of the posterior pituitary vasopressin content, and any accompanying lesions. Clinical and biochemical indices of associated anterior pituitary/hormone deficiency should also be obtained,[97] since additional deficits in anterior pituitary hormones were documented in 61% of patients, a median of 0.6 years after the onset of diabetes insipidus. The most frequent abnormality was growth hormone deficiency (59%), followed by hypothyroidism (28%), hypogonadism (24%), and adrenal insufficiency (22%). Seventy-five percent of the patients with Langerhans cell histiocytosis had an anterior pituitary hormone deficiency that was first detected a median of 3.5 years after the onset of diabetes insipidus.

In this context, the dehydration test is rarely necessary, and is only recommended for patients with isolated polyuria, a normal pituitary stalk and hypothalamic region on magnetic resonance imaging, and

with no familial history of polyuria. If plasma osmolality and/or sodium concentration under conditions of *ad libitum* fluid intake are above 295 mmol/kg and 143 mmol/L, the diagnosis of primary polydipsia is excluded.[214]

If severe polyuric symptoms and signs are documented, water should be restricted to only two to four hours during day time in infants, plasma sodium should be available every two hours during testing and should not exceed 145–148 in children and adults, since a maximal endogenous vasopressin stimulation (more than 3.5 pg/mL) should occur at this level with a maximal urine osmolality response (higher than 800 mOsm/kg H_2O). If delays of more than 60minutes are encountered to obtain plasma sodium or urine osmolalities during dehydration tests, these tests should be done in other institutions where almost immediate laboratory reports are obtained after blood samplings.

Theoretically, it should be relatively easy to differentiate between neurogenic diabetes insipidus, NDI, and primary polydipsia by comparing the osmolality of urine obtained during dehydration with that of urine obtained after the administration of dDAVP. Patients with neurogenic diabetes insipidus should reveal a rapid increase in urinary osmolality, whereas it should increase normally in response to moderate dehydration in patients with primary polydipsia. However, for several reasons, these distinctions may not be as clear as one might expect.[215] First, chronic polyuria resulting from any cause interferes with the maintenance of the medullary concentration gradient, and this "wash-out" effect diminishes the maximum concentrating ability of the nephron. The extent of the blunting varies in direct proportion to the severity of the polyuria. Hence, for any given basal urine output, the maximum urine osmolality achieved in the presence of saturating concentrations of AVP is depressed to the same extent in patients with primary polydipsia, neurogenic diabetes insipidus or NDI (Figure 46.12). Second, most patients with neurogenic diabetes insipidus maintain a small, but detectable, capacity to secrete AVP during severe dehydration, and urinary osmolality may then increase to greater than the plasma osmolality. Third, patients referred to as partial diabetes insipidus (either neurogenic or nephrogenic) and patients with acquired NDI have an incomplete response to AVP, and are able to concentrate their urine to varying degrees in a dehydration test. Finally, all polyuric states (whether neurogenic, nephrogenic or psychogenic) can induce large dilatations of the urinary tract and bladder.[141,142] As a consequence, the urinary bladder of these patients has an increased residual capacity, and changes in urinary osmolality induced by diagnostic maneuvers might be difficult to demonstrate.

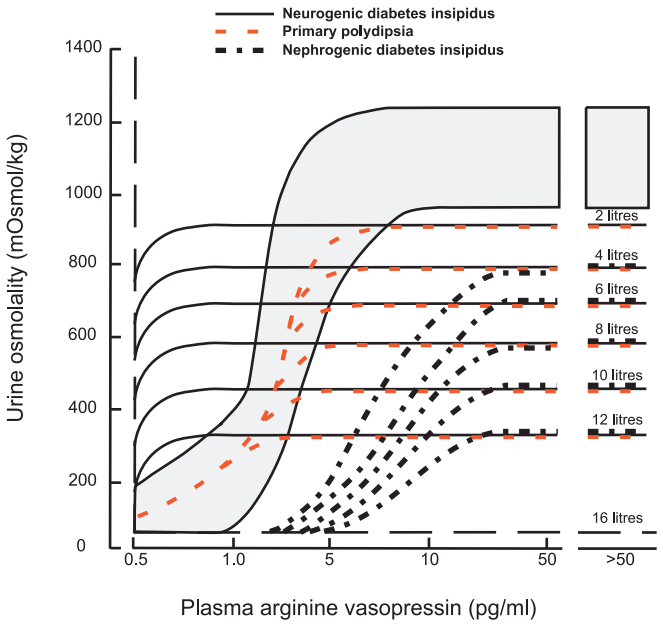

FIGURE 46.12 **Schematic diagram of the relationship between urine osmolality and plasma vasopressin in patients with polyuria of diverse cause and severity.** The shaded area represents the normal range. For each of the three categories of polyuria, the relationship is described by a family of sigmoid curves that differ in height. These differences in height reflect differences in maximum concentrating capacity due to "wash-out" of the medullary concentration gradient. They are proportional to the severity of the underlying polyuria (indicated in liters at the right-hand side of each plateau), and are largely independent of the cause. The three categories of diabetes insipidus differ principally in the submaximal or ascending portion of the dose–response curve. In patients with neurogenic diabetes insipidus, this part of the curve lies to the left of normal, reflecting increased sensitivity to the antidiuretic effects of very low concentrations of plasma vasopressin. In contrast, in patients with neurogenic diabetes insipidus, this part of the curve lies to the right of normal, reflecting decreased sensitivity to the antidiuretic effects of normal concentrations of plasma vasopressin. In primary polydipsia, this relationship is relatively normal. *(From ref. [215].)*

Indirect Tests for Diabetes Insipidus

The measurement of urinary osmolality after dehydration and dDAVP administration is usually referred to as "indirect testing," because AVP secretion is indirectly assessed through changes in urinary osmolalities.[32] The patient is maintained on a complete fluid-restriction regimen until urinary osmolality reaches a plateau, as indicated by an hourly increase of less than 30 mOsmol/kg for at least 3 successive hours. After measuring the plasma osmolality, 2 mg dDAVP are administered subcutaneously. Urinary osmolality is measured 30 and 60minutes later. The last urinary osmolality value obtained before the dDAVP injection, and the highest value obtained after the injection, are compared. In patients with severe neurogenic diabetes insipidus, urinary osmolality after dehydration is usually low (< 200 mOsmol/kg) and increases more than

50% after dDAVP administration. In patients with severe NDI, urinary osmolality after dehydration is also low (<200 mOsmol/kg), but does not increase after dDAVP administration (<20%). Urinary osmolality increases to variable degrees (10% to 50%) after dDAVP administration to patients with partial neurogenic or partial nephrogenic diabetes insipidus. In patients with primary polydipsia, maximum urinary osmolality will be obtained after dehydration (>295 mOsmol/kg) and does not increase after dDAVP administration (<10%).

Alternatively, plasma sodium and plasma and urinary osmolalities can be measured at the beginning of the dehydration procedure and at regular intervals (usually hourly) thereafter, depending on the severity of the polyuria.[216] For example, an 8-year-old patient (body weight 31 kg) with a clinical diagnosis of congenital NDI (later found to bear an *AVPR2* mutation) continued to excrete large volumes of urine (300 ml/h) during a short 4hour dehydration test. During this time, the patient suffered from severe thirst, his plasma sodium was 155 mOsmol/l, plasma osmolality was 310 mOsmol/kg, and urinary osmolality was 85 mOsmol/kg. The patient received 1 mg of dDAVP intravenously and was allowed to drink water. Repeated urinary osmolality measurements demonstrated a complete urinary resistance to dDAVP. It would have been dangerous and unnecessary to prolong the dehydration further in this young patient. Thus, the usual prescription of overnight dehydration should not be used in patients, and especially children, with severe polyuria and polydipsia (more than 30 ml/kg body weight per day). Great care should be taken to avoid any severe hypertonic state, arbitrarily defined as plasma sodium greater than 155 mOsmol/l.

Direct Tests of Diabetes Insipidus

The two approaches of Zerbe and Robertson are used,[217] although they are expensive, time-consuming, and difficult to do on young patients. In the first approach, during the dehydration test, plasma is collected hourly and assayed for AVP. The results are plotted on a nomogram depicting the normal relationship between plasma sodium or osmolality and plasma AVP in normal individuals (Figure 46.6a). If the relationship goes below the normal range, the disorder is diagnosed as neurogenic diabetes insipidus.

In the second approach, NDI can be differentiated from primary polydipsia by analyzing the relationship between plasma AVP and urinary osmolality at the end of the dehydration period (Figure 46.6b). However, definitive differentiation might be impossible, because a normal or even supranormal AVP response to increased plasma osmolality occurs in polydipsic patients. None of the patients with psychogenic or other forms of severe polydipsia studied by Robertson showed any evidence of pituitary suppression.[215]

In a comparison of diagnoses based on indirect versus direct tests of AVP function in 54 patients with polyuria of diverse cause, Robertson[215] found that the indirect test was reliable only for patients with severe defects. Three patients with severe NDI, and 16 of 17 patients with severe neurogenic diabetes insipidus were accurately diagnosed. However, the error rate of the indirect test was about 50% in diagnosing partial neurogenic diabetes insipidus, partial NDI or primary polydipsia in patients who were able to concentrate their urine to varying degrees when water-deprived. The benefits of combined direct and indirect testing of AVP function have been discussed by Stern and Valtin.[218] The diagnosis of primary polydipsia remains one of exclusion, and the cause could be psychogenic[199] or inappropriate thirst.[200,219] Psychiatric patients with polydipsia and hyponatremia have unexplained defects in urinary dilution, the osmoregulation of water intake or the secretion of vasopressin.[148]

Therapeutic Trial of dDAVP

In selected patients with an uncertain diagnosis, a closely monitored therapeutic trial of dDAVP (10 mg intranasally twice a day for 2 to 3 days) may be used to distinguish partial NDI from partial neurogenic diabetes insipidus or primary polydipsia. If dDAVP at this dosage causes a significant antidiuretic effect, NDI is effectively excluded. If polydipsia and polyuria are abolished and plasma sodium does not go below the normal range, the patient probably has neurogenic diabetes insipidus. Conversely, if dDAVP causes a reduction in urine output without reduction in water intake and hyponatremia appears, the patient probably has primary polydipsia. Since fatal water intoxication is a remote possibility, the dDAVP trial should be closely monitored. The methods of differential diagnosis of diabetes insipidus are described in Table 46.3.

Carrier Detection, Perinatal Testing, and Early Treatment

The identification of mutations in the genes that cause hereditary diabetes insipidus allows the early diagnosis and management of at-risk members of families with identified mutations. We encourage physicians who follow families with autosomal neurogenic, X-linked, and autosomal NDI to recommend mutation analysis before the birth of an infant, because early diagnosis and treatment can avert the physical and mental retardation associated with episodes of

TABLE 46.3 Differential Diagnosis of Diabetes Insipidus.

1. Measure plasma osmolality and/or sodium concentration under conditions of *ad libitum* fluid intake. If plasma osmolality is >295 mOsmol/kg and sodium is >143 mOsmol/l, the diagnosis of primary polydipsia is excluded and the work-up should proceed to step (5) and/or (6) to distinguish between NDI and neurogenic diabetes insipidus. *Otherwise*:
2. Perform a dehydration test. If urinary concentration does not occur before plasma osmolality reaches 295 mOsmol/kg and/or sodium reaches 143 mOsmol/l, the diagnosis of primary polydipsia is again excluded and the work-up should proceed to step (5) and/or (6). *Otherwise*:
3. Determine the ratio of urine to plasma osmolality at the end of the dehydration test. If it is <1.5, the diagnosis of primary polydipsia is again excluded and the work-up should proceed to step (5) and/or (6). *Otherwise*:
4. Perform a hypertonic saline infusion with measurement of plasma AVP and osmolality at intervals during the procedure. If the relationship between these two variables falls below the normal range, the diagnosis of neurogenic diabetes insipidus is established. *Otherwise*:
5. Perform a dDAVP infusion test. If urine osmolality increases by <150 mOsmol/kg above the value obtained at the end of the dehydration test, the diagnosis of NDI is established. *Alternatively*:
6. Measure urine osmolality and plasma AVP at the end of the dehydration test. If the relationship falls below the normal range, the diagnosis of NDI is established.

Data from ref. [219].

dehydration. Diagnosis of X-linked NDI was accomplished by mutation testing of cultured amniotic cells ($n = 7$), chorionic villus samples ($n = 10$) or cord blood obtained at birth ($n = 57$) in 74 of our patients. Thirty-five males were found to bear mutant sequences, 22 males were not affected, and nine females were not carriers. These affected patients were immediately given abundant water intake, a low-sodium diet, and hydrochlorothiazide. They never experienced episodes of dehydration, and their physical and mental development is normal. Gene analysis is also important for the identification of nonobligatory female carriers in families with X-linked NDI. Most females heterozygous for a mutation in the V2 receptor do not have clinical symptoms: few are severely affected.[131,220,221] Mutation detection in families with inherited neurogenic diabetes insipidus provides a powerful clinical tool for early diagnosis and management of subsequent cases, especially in early childhood, when diagnosis is difficult and the clinical risks are the greatest.[222]

Neurogenic diabetes insipidus (central or Wolfram) is easily treated with dDAVP.[223] All complications of congenital NDI are prevented by an adequate water intake. Thus, patients should be provided with unrestricted amounts of water from birth to ensure normal development. In addition to a low-sodium diet, the use of diuretics (thiazides) or indomethacin may reduce urinary output. This advantageous effect has to be weighed against the side-effects of these drugs (thiazides: electrolyte disturbances; indomethacin: reduction of the glomerular filtration rate and gastrointestinal symptoms).

RADIOIMMUNOASSAY OF AVP AND OTHER LABORATORY DETERMINATIONS

Radioimmunoassay of AVP

Three developments were basic to the elaboration of a clinically useful radioimmunoassay for plasma AVP[224,225]: (1) the extraction of AVP from plasma with petrol-ether and acetone and the subsequent elimination of nonspecific immunoreactivity; (2) the use of highly-specific and sensitive rabbit antiserum; and (3) the use of a tracer (^{125}I-AVP) with high specific activity. These same extraction procedures are still widely used,[161,198,213,216] and commercial tracers (^{125}I-AVP) and antibodies are available. AVP can also be extracted from plasma by using Sep-Pak C18 cartridges.[226–228]

Blood samples collected in chilled 7 ml lavender-stoppered tubes containing ethylenediaminetetraacetic acid are centrifuged at 4°C, 1000 g (3000 rpm in a usual laboratory centrifuge), for 20minutes. This 20minute centrifugation is mandatory for obtaining platelet-poor plasma samples, because a large fraction of the circulating vasopressin is associated with the platelets in humans.[229,230] The tubes may be kept for 2hours on slushed ice before centrifugation. Plasma is then separated, frozen at − 20°C and extracted within 6 weeks of sampling. Details for sample preparation (Table 46.4) and assay procedure (Table 46.5) can be found in writings by Bichet and colleagues.[229,231] An AVP radioimmunoassay should be validated by demonstrating: (1) a good correlation between plasma sodium or osmolality and plasma AVP during dehydration and infusion of hypertonic saline solution (Figure 46.6); and (2) the inability to obtain detectable values of AVP in patients with severe central diabetes insipidus. Plasma AVP immunoreactivity may be elevated in patients with diabetes insipidus following hypothamic surgery.[232]

In pregnant patients, the blood contains high concentrations of cystine aminopeptidase, which can (*in vitro*) inactivate enormous quantities (ng mL^{-1} min^{-1}) of AVP. However, phenanthrolene effectively inhibits these cystine aminopeptidases (Table 46.6).

Aquaporin-2 Measurements

Urinary AQP2 excretion could be measured by radioimmunoassay[233] or quantitative Western analysis,[234] and could provide an additional indication of the responsiveness of the collecting duct to AVP.

TABLE 46.4 Arginine Vasopressin Measurements: Sample Preparation.

4°C – Blood in EDTA tubes
Centrifugation 1000 g × 20 min.
Plasma frozen – 20°C
Extraction:
2 mL acetone + 1 mL plasma
1000 g × 30 min 4°C
Supernatant + 5 mL of petrol-ether
1000 g × 20 min 4°C
Freeze – 80°C
Throw nonfrozen upper phase
Evaporate lower phase to dryness
Store desiccated samples at – 20°C

TABLE 46.5 Arginine Vasopressin Measurements: Assay Procedure

Day 1	Assay set-up 400 μL/tube (200 μL sample or standard + 200 μL of antiserum or buffer). Incubation 80 hours, 4°C
Day 4	^{125}I-AVP 100 μL/tube 1000 cpm/tube. Incubation 72 hours, 4°C
Day 7	Separation dextran + charcoal

0.1 mL/10 mL of blood

Plasma Sodium, Plasma, and Urine Osmolality

Measurements of plasma sodium, plasma, and urinary osmolality should be immediately available at various intervals during dehydration procedures. Plasma sodium is easily measured by flame photometry or with a sodium-specific electrode.[235] Plasma and urinary osmolalities are also reliably measured by freezing point depression instruments with a coefficient of variation at 290 mmol/kg of less than 1%.

At variance with published data,[229,217] we have found that plasma and serum osmolalities are equivalent (i.e., similar values are obtained). Blood taken in heparinized tubes is easier to handle, because the plasma can be more readily removed after centrifugation. The tube used (green-stoppered tube) contains a minuscule concentration of lithium and sodium, which does not interfere with plasma sodium or osmolality measurements. Frozen plasma or urinary samples can be kept for further analysis of their osmolalities, because the results obtained are similar to those obtained immediately after blood sampling, except in patients with severe renal failure. In the latter patients, plasma osmolality measurements are increased after freezing and thawing, but the plasma sodium values remain unchanged.

Plasma osmolality measurements can be used to demonstrate the absence of unusual osmotically active substances (e.g., glucose and urea in high concentrations, mannitol, ethanol).[236] With this information, plasma or serum sodium measurements are sufficient to assess the degree of dehydration and its relationship to plasma AVP. Nomograms describing the normal plasma sodium/plasma AVP relationship are equally as valuable as classic nomograms describing the relationship between plasma osmolality and effective osmolality (i.e., plasma osmolality minus the contribution of "ineffective" solutes: glucose and urea).

MAGNETIC RESONANCE IMAGING IN PATIENTS WITH DIABETES INSIPIDUS

Magnetic resonance imaging (MRI) permits visualization of the anterior and posterior pituitary glands and the pituitary stalk. The pituitary stalk is permeated by numerous capillary loops of the hypophyseal–portal blood system. This vascular structure also provides the principle blood supply to the anterior pituitary lobe, because there is no direct arterial supply to this organ. In contrast, the posterior pituitary lobe has a direct vascular supply. Therefore, the posterior lobe can be more rapidly visualized in a dynamic mode after administration of gadolinium (gadopentate dimeglumine) as contrast material during MRI. The posterior pituitary lobe is easily distinguished by a round, high-intensity signal (the posterior pituitary "bright spot") in the posterior part of the sella turcica on T1-weighted images. Loss of the pituitary hyperintense spot or bright spot on a T1-weighted MRI image reflects loss of functional integrity of the neurohypophysis, and is a non-specific indicator of neurohypophyseal diabetes insipidus regardless of the underlying cause.[97,237] It is now considered that the bright spot represents normal AVP storage in the posterior lobe of the pituitary, that the intensity is correlated with the amount of AVP, and that after 60 years of age the signal is often less intense, with irregularities in the normally smooth convex edge.[238,239] MRI is reported to be the best technique with which to evaluate the pituitary stalk and infundibulum in patients with idiopathic polyuria. A thickening or enlargement of the pituitary stalk may suggest an infiltrative process destroying the neurohypophyseal tract.[240]

TREATMENT

In most patients with complete hypothalamic diabetes insipidus, the thirst mechanism remains intact. Thus, hypernatremia does not develop in these patients, and they suffer only from the inconvenience associated with marked polyuria and polydipsia. If hypodipsia develops or access to water is limited, then severe hypernatremia can supervene. The treatment of choice for patients with severe hypothalamic diabetes insipidus is dDAVP, a synthetic, long-acting vasopressin analog with minimal vasopressor activity, but a large antidiuretic potency. The usual intranasal daily dose is between 5 and 20 mg. To avoid the potential complication of dilutional hyponatremia, which is exceptional in these patients as a result of an intact thirst mechanism, dDAVP can be withdrawn at regular intervals to allow the patients to become polyuric. Aqueous vasopressin (Pitressin) or dDAVP (4.0 mg/1 ml ampule) can be used intravenously in acute situations, such as after hypophysectomy or for the treatment of diabetes insipidus in the brain-dead organ donor. Pitressin tannate in oil and nonhormonal antidiuretic drugs are somewhat obsolete and now rarely used. For example, chlorpropamide (250–500 mg daily) appears to potentiate the antidiuretic action of circulating AVP, but troublesome side-effects of hypoglycemia and hyponatremia do occur.

The treatment of congenital NDI has been reviewed by Knoers and Monnens.[176] An abundant unrestricted water intake should always be provided, and affected patients should be carefully followed during their first years of life. Water should be offered every 2 hours day and night, and temperature, appetite, and growth should be monitored. The parents of these children easily accept setting their alarm clock every 2 hours during the night. Hospital admission may be necessary to allow continuous gastric feeding. A low-osmolar and low-sodium diet, hydrochlorothiazide (1–2 mg/kg/d) alone or with amiloride, and indomethacin (0.75–1.5 mg/kg) substantially reduce water excretion, and are helpful in the treatment of children. Many adult patients receive no treatment.

Acknowledgments

The Molecular Biology of Renal K^+ Channels

WenHui Wang[1] *and Chou-Long Huang*[2]

[1]Department of Pharmacology, New York Medical College, Valhalla, NY, USA
[2]University of Texas, Southwestern Medical Center, Dallas, TX, USA

INTRODUCTION

Renal epithelial transport depends on the coordinated function of potassium channels with ion transporters (co-transporters, channels, and exchangers) and ion pumps in apical and basolateral membranes of distinct cell types along the nephron of the mammalian kidney. Potassium (K^+) channels are key members of this integrated transport system in renal epithelial cells. First, renal K^+ channels participate in generating cell membrane potential; since numerous transporters are electrogenic, changes in cell membrane potential could alter the transport rate of a given substance. Second, renal K^+ channels are involved in the volume regulation that is essential for preventing cell swelling or shrinking in the hypotonic or hypertonic environment. Third, renal K^+ channels play an important role in K^+ recycling which is essential for maintaining the function of several transport proteins, such as Na^+-K^+-ATPase. Finally, renal K^+ channels are extremely involved in K^+ secretion in the aldosterone-sensitive distal nephron (ASDN). Figure 47.1 is a scheme providing an overview regarding the role of K channels in different renal segments.

Since K^+ channels play such an important role in kidney function, understanding the structure and regulation of renal K^+ channels is essential to gaining insights into the molecular mechanisms of kidney potassium handling. In the past decades, the development of molecular biology and patch-clamp techniques has had a significant impact on the exploration of the molecular identity of some renal K^+ channels. This chapter summarizes our current understanding of the molecular identity of renal K^+ channels, and will specifically focus on the ROMK (Kir1; *KCNJ1*) channel. We will discuss similarities, as well as certain differences, in the properties of cloned K^+ channels compared to native K^+ channels expressed in the different nephron segments.

THE MOLECULAR BIOLOGY OF ROMK, A DISTAL K^+ SECRETORY CHANNEL

Structure of Inward Rectifying K^+ Channels and ROMK

The K^+ channel, *ROMK* (Kir1; *KCNJ1*[1]), belongs to a growing family of inwardly rectifying K^+ (Kir) channels[2] that are functionally characterized by high potassium selectivity and by either weak or strong inward rectification. To date, 16 Kir genes have been identified and classified into seven subfamilies (Kir1.x to Kir7.x). All Kir channels have a membrane topology consisting of two membrane-spanning domains (M1 and M2), an intervening H5 pore-forming region, and cytoplasmic amino (NH_2-) and carboxyl (COOH-)-terminal domains (Figure 47.2[3–5]). This membrane topology corresponds to the last two membrane spanning segments of the voltage-gated K^+ channels, suggesting a common ancestral origin.[6–8] The N- and C-terminal cytoplasmic regions of Kir channels provide regulatory domains (Figure 47.2) that can be phosphorylated by kinases,[9] and that interact with protons,[10–12] nucleotides,[13] and phosphoinositides.[14,15]

The three-dimensional structure of ROMK is not available, but it can be inferred from X-ray crystallographic structures of bacterial and eukaryotic K^+ channels. The first crystal structure of K^+ channel

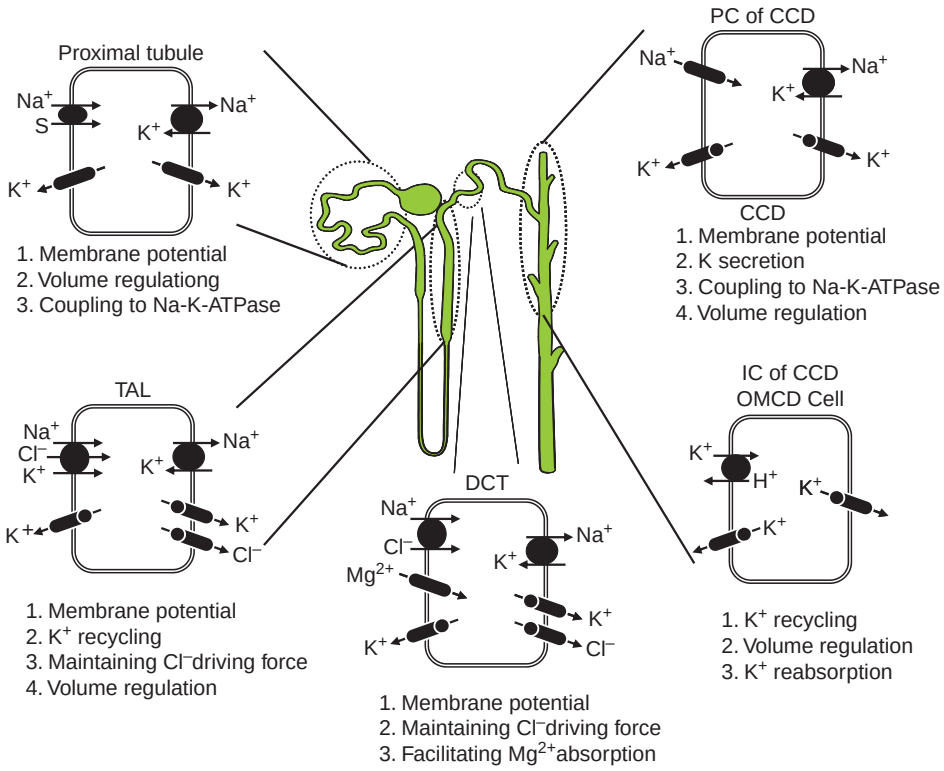

FIGURE 47.1 A cell model demonstrating the role of K channels in different renal segments.

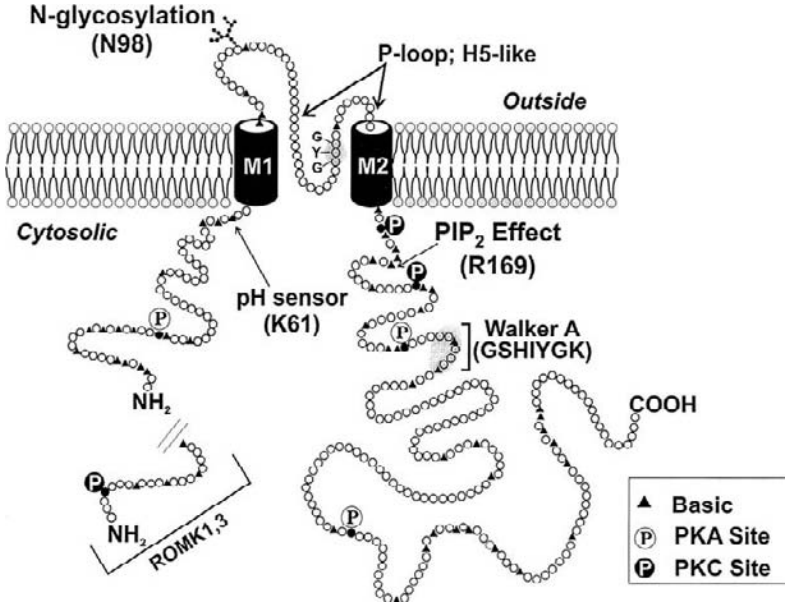

FIGURE 47.2 Topology of ROMK (Kir1.1) K^+ channel. M1 and M2 represent the two membrane-spanning domains characterizing the inward-rectifier family of potassium channel. Some important functional sites are indicated. A short amphipathic segment in the M1-M2 linking segment in ROMK forms the pore-forming (P-loop) or H5 region. The canonical T-X-G-Y-G amino acid sequence found in all K^+ channels is shown in the H5 segment. Numbering is based on amino acid sequence of ROMK2 (Kir1.1b).

determined is from *Streptomyces lividans* (KcsA).[16] Although not an inward rectifier K^+ channel, KcsA shares the same membrane topology with Kir channels with two membrane-spanning M1 and M2 segments, a H5 pore-forming region, and N- and C-terminal cytoplasmic domains. The amino acid sequence of KcsA is similar to the corresponding region of other K^+ channels, including vertebrate and invertebrate voltage-gated K^+ channel, inward rectifier, and calcium-activated K^+ channels. The crystal structure of KcsA reveals a tetramer with four identical subunits that encircle a central ion conduction pathway with four-fold symmetry (Figure 47.3). The M1 and M2 segments of each subunit form α-helices and are inserted into the

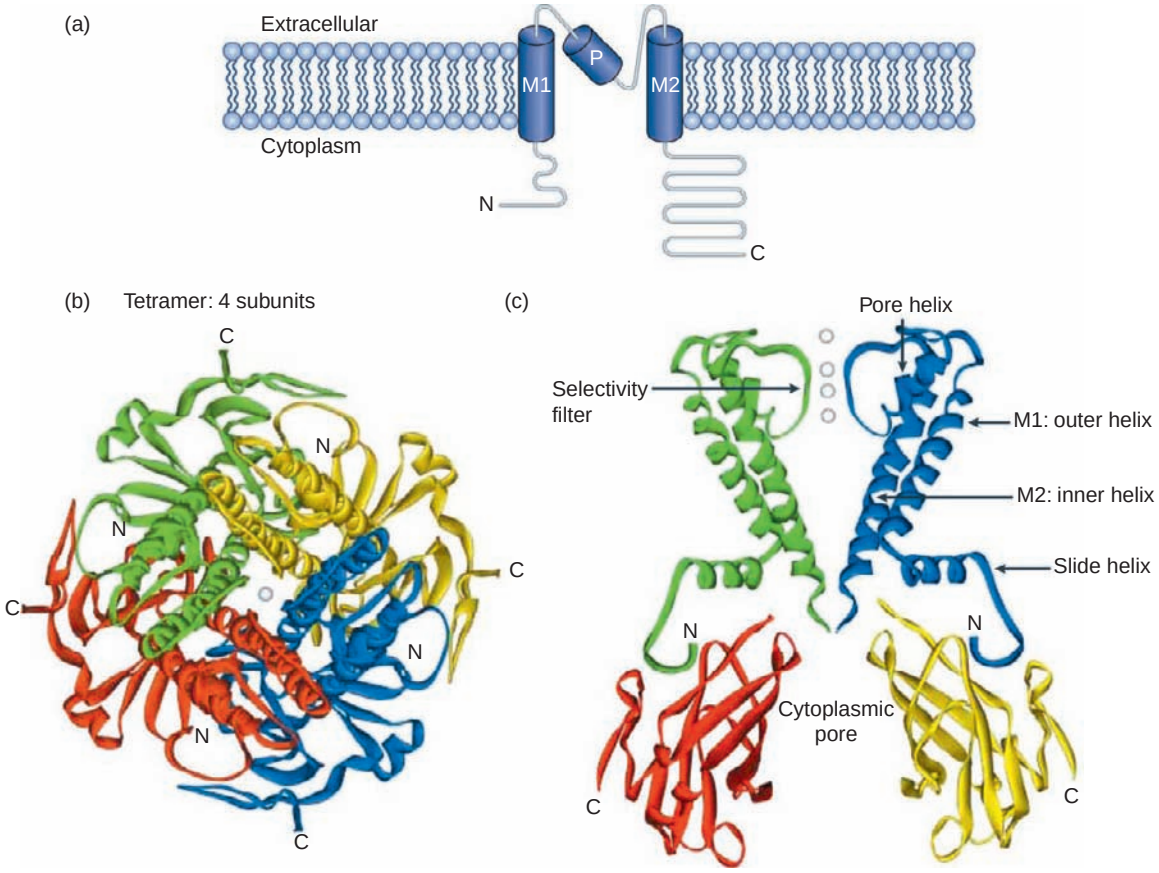

FIGURE 47.3 **Architecture of inwardly rectifying K (Kir) channels 276.** (a) A scheme of Kir channels: each subunit contains two transmembrane helices (M1 and M2), a channel pore (P), and both N- and C-termini. (b) The tetrameric structure of the KirBac1.1 channel4 (PDB ID:1P7B) viewed from the extracellular side. Each monomer is marked by red, green, yellow, and blue, respectively. The conduction pathway is indicated by a K ion (white). (c) Side view of two subunits of the KirBac1.1 illustrating the transmembrane domain (green and blue), the C-terminal domains of their neighbouring subunits (red and yellow) and K ions (white) in the selectivity filter. See color section at the back of the book.

tetramer such that M2 faces the central ion conduction pathway (termed inner helix), and M1 faces the lipid membrane (outer helix). Amino acids connecting M1 and M2 (from N to C) form the turret, a tilted pore helix that runs half-way through the membrane, and the selectivity filter bearing the Thr-X-Gly-Tyr-Gly (X is any amino acid) signature sequence of all K^+ channels. The inner helices are tilted with respect to the membrane, so that the subunits open like the petals of a flower facing the outside of the cell. Furthermore, the four inner helices pack against each other as a bundle near the intracellular aspect of the membrane, giving the appearance of an inverted teepee.

The ion conduction pathway (pore) of KcsA can be functionally divided into three parts that (from the outside of the cell) consist of the selectivity filter, a water-filled wide cavity near the middle of the membrane (the central cavity; ~10Å across), and the internal part of the pore made up of the anti-lipid facing amino acids of four inner helices. The selectivity filter (~12Å in length) is the narrowest part of the pore, and is lined by four evenly spaced layers of carbonyl oxygen atoms from amino acids X-Gly-Tyr-Gly, and a single layer of hydroxyl oxygen atoms from amino acid threonine. K^+ ions dehydrate and enter the selectivity filter in single file. The five layers of oxygen atoms form four consecutive K^+ ion-binding sites to stabilize dehydrated K^+ ions in the filter, which compensates for the energy required for dehydration. Due to repulsion between closely spaced ions, K^+ ions occupy only two of the four binding sites at a given time, in either 1,3 or 2,4 configuration. These unique structural and energetic features contribute to the extremely high selectivity (~1000 to 1 for K^+ over Na^+) yet fast conduction rate (up to ~10^8ions/sec) of K^+ channels for K^+ ions.

The crossing of four inner helices of KcsA as a bundle near the intracellular aspect of the membrane creates a point of structural constraint between the membrane pore and the cytoplasm, referred to as bundle crossing. Structural comparison of KcsA with

Mthk, a bacterial calcium-activated K^+ channel,[17] provides insights into how bundle crossing might function as an activation gate for K^+ channels. In KcsA, the inner helices are straight and the diameter of bundle crossing is about 3.5Å, suggesting that the crystal structure of KcsA is in closed conformation. In contrast, the crystal structure of Mthk, which is solved in the presence of high (Ca^{2+}), thus likely in the open conformation, reveals that inner helices are bent at a hinge point and splayed open so that the bundle crossing does not form a barrier to the flow K^+ ions between the central cavity and the cytoplasm. Thus, KcsA and Mthk structures likely represent closed and open pore conformations of many different K^+ channels, including ROMK. Conservation of a glycine residue at the inner helix hinge point in most K^+ channels supports this conclusion.

The structural studies of KcsA and Mthk do not include the cytoplasmic N- and C-terminal domains. The crystallographic structure of the bacterial inward rectifier K^+ channel KirBac1.1, including the transmembrane and cytoplasmic domains, provides the first insight into the intracellular domains of Kir channels.[18] The structures of the intracellular domains of eukaryotic Kir channels are determined in two ways. One uses only the N- and C-terminal cytoplasmic domains connected by an artificial kinker for crystallographic studies.[19] The other determines the structures of cytoplasmic domains, together with the transmembrane domains, using either a chimeric channel containing the outer three quarters of the membrane domains of KirBac3.1 and the inner one quarter of the membrane domain and the intracellular N- and C-terminal domains of Kir3.1[20] or the native form of inward rectifier K^+ channel from chicken (Kir2.2).[21] Overall, these studies reveal that the N-terminal cytoplasmic domain of one subunit interacts with the C-terminus of the adjacent subunit, and together form predominantly β-sheet structures. The four sets of associated N- and C-terminal domains assemble into a tetramer surrounding a water-filled cytoplasmic pore that extends coaxially from the transmembrane pore domain. Thus, the cytoplasmic pore extends the ion permeation pathway to ~60Å, nearly twice the length of the transmembrane pore. The apex of the cytoplasmic pore abutting the transmembrane domain is formed by a loop referred to as the "G-loop." In the crystal structures, the G-loops are in either a constricted or dilated conformation, likely representing closed and open states of the cytoplasmic pore, respectively.[19–21] Thus, Kir channels contain two regions along the length of ion conduction pathway that can adopt constricted or dilated conformation and function as the gates. One is the inner helix bundle crossing, and the other is the apex of the cytoplasmic pore formed by the G-loops.

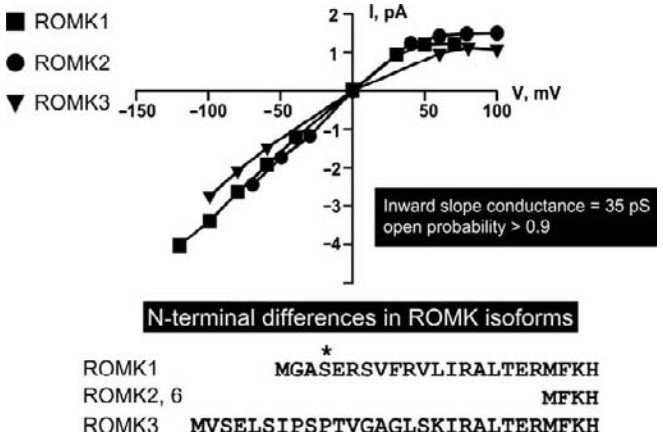

FIGURE 47.4 **The ROMK splice variants.** Current-voltage relationships for ROMK1, 2, and 3 are shown. Each of these variants has a similar I–V curve and calculated single channel conductance of ~35 pS. The open probability of these three channels is also similar and >0.9. ROMK1, 2, 3, and 6N-terminal amino acid sequences are shown using the single letter notation for residues. ROMK2 and 6 have an identical amino acid sequence. ROMK1 and ROMK3 have 19 and 26 additional N-terminal amino acids, respectively, compared to ROMK2 or 6. The asterisk in the ROMK1 sequence indicates a functional PKC phosphorylation site.

Interestingly, the plasma-membrane facing surface of the cytoplasmic pore contains many positively charged amino acids known to be important for binding to membrane phosphatidylinositol-4,5-bisphosphate (PIP_2)[4,22] (see section on "Regulation of ROMK by PIP_2" below). Interaction between these amino acids and membrane PIP_2 may alter the conformation of the G-loop and the inner helix bundle crossing to activate the channel.[19,20]

ROMK Channel Isoforms

Following the cloning of ROMK1 (Kir1.1a) from rat kidney,[3] three additional alternatively spliced forms of this channel were isolated (Figures 47.2 and 47.4), and named ROMK2 (Kir1.1b), ROMK3 (Kir1.1c)[23,24] and ROMK6 (Kir1.1d).[25] The encoded ROMK proteins differ at the beginning of the N-terminus – ROMK2 (also rat ROMK6, which has the same amino acid sequence as ROMK2; Figure 47.4[25]) has the shortest N-terminus, and splicing adds either 19 or 26 amino acids for ROMK1 or ROMK3, respectively (see Figures 47.2 and 47.4). Relative ROMK mRNA abundance measured by competitive PCR has shown that ROMK2 and ROMK3 are much more abundant than ROMK1 or ROMK6 in rat kidney.[26] In addition, a novel set of ROMK proteins, about one-third the size of native ROMK, has been suggested to be formed from alternative splicing of the ROMK core exon.[27] The significance of these putative

smaller channel proteins remains unclear. Six splice variants[28–30] have been identified in the human ROMK gene, *KCNJ1*, located on chromosome 11q24.[28] These six human transcripts apparently encode only three distinct polypeptides, two of which are similar to rat ROMK1 and ROMK2.[28] A rat homolog of the third human ROMK isoform has not been identified. Two ROMK homologs have also been cloned from human kidney, but their roles in renal function are unknown.[31]

ROMK Channel Localization

Rat ROMK1-3 are differentially expressed along the nephron from the thick ascending limb of Henle, TAL, to the outer medullary collecting duct, OMCD, (Figure 47.5[23,32]). The rat TAL and distal convoluted tubule, DCT, express ROMK2 and ROMK3 messenger RNA, while principal cells in the cortical collecting duct, CCD, express ROMK1 and ROMK2 transcripts (see Figure 47.5). The outer medullary collecting duct cells appear to express only ROMK1 transcripts. The general single channel properties of the ROMK1, 2, and 3 isoforms are similar, e.g., single channel conductance and open probability (Figure 47.4). Although the specific functional/regulatory consequences of the different isoforms have not been fully-elucidated, a serine at the fourth position in the extended N-terminus in ROMK1 has been shown to be required for sensitivity to arachidonic acid (Figures 47.2 and 47.4)[33] and protein kinase C[34] (see section on ROMK function below). Thus, ROMK1 may add distinct functional characteristics to ROMK channels. No specific role for the extended N-terminus of ROMK3 has yet been identified. Whether tetrameric ROMK channels are formed of different subunits (e.g., heterotetramers of ROMK2 and ROMK1 in the cortical collecting duct) or exist only as homotetramers is not known. Finally, ROMK transcripts are present in some other tissues,[3] including the early gravid uterus.[35] Roles for ROMK in these tissues have not been determined.

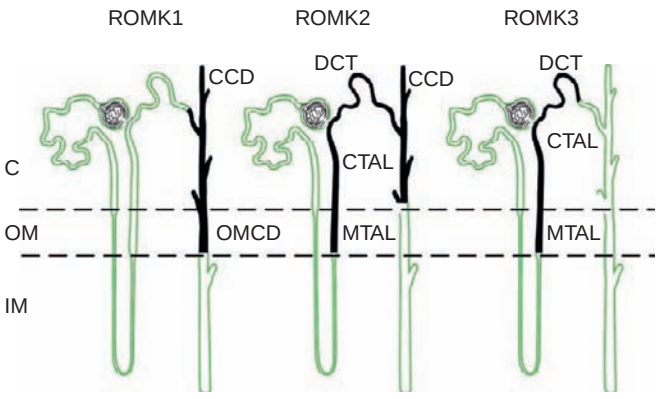

FIGURE 47.5 **The distribution of the ROMK 1, 2, and 3 isoforms along the rat nephron.** The shaded regions indicate the localization of ROMK transcripts and protein (CCD: cortical collecting duct; CTAL: cortical thick ascending limb; DCT: distal convoluted tubule; MTAL: medullary thick ascending limb; OMCD: outer medullary collecting duct). In the CCD and OMCD, ROMK is expressed only in principal cells.

Antibody generated to sequences of ROMK shared by all isoforms has demonstrated an apical pattern of channel protein expression in rat TAL (including macula densa cells), DCT, and early CNT cells, and principal cells of the CCD and OMCD.[36–39] This localization is consistent with the ROMK channel providing a K^+ secretory pathway in these renal epithelia.

ROMK Channel Properties are Similar to the Distal (SK) K^+ Secretory Channel

The single channel characteristics and regulatory properties of ROMK channels expressed in *X. laevis* frog oocytes are virtually identical to those of the native ATP-sensitive, small conductance (SK) channels in TAL cells[40,41] (Figure 47.6) and principal cells in the CCD[42–48](Figure 47.7). Similar kinetic characteristics of K^+, NH_4^+, and Tl^+ have been observed in the native secretory K^+ channel in the rat CCD and ROMK2 channels expressed in *X. laevis* oocytes,[49,50] leading Palmer and co-workers to conclude that the native SK and cloned ROMK channels were identical. A further characteristic of the low conductance secretory K^+ channel found in principal cells is a lack of sensitivity to external TEA^+.[42]

The general properties of ROMK channels expressed in *Xenopus* oocytes include: (1) weak inward rectification (Figure 47.4) that is dependent on the binding of cytosolic Mg^{2+} or other polyvalent cations to the channel pore[51–56]; (2) activation by protein kinase A-dependent phosphorylation processes[9,39,57,58]; (3) inhibition by high concentrations of MgATP[13]; (4) inhibition by slight reductions in cytosolic pH[59,60]; and (5) inhibition by arachidonic acid and protein kinase C.[33,34] When coupled with gene expression and protein localization studies, these functional similarities strongly suggest that ROMK makes up the pore-forming subunit of the renal distal SK potassium channel.[46,50]

Characteristics of the ROMK Channel Pore

CHANNEL KINETICS

ROMK channels are characterized by a high open probability (P_o) of greater than 0.9 for inward K^+ flux.[3,49,57,61] The high open probability results from one open state and two closed states. One closed state is very short (~1 ms; 99% frequency), and the other is longer (~40 ms) but very infrequent (~1%).[57,61] The infrequent closed state is due to blocking by divalent cations, as it can be abolished by EDTA.[61] Choe and

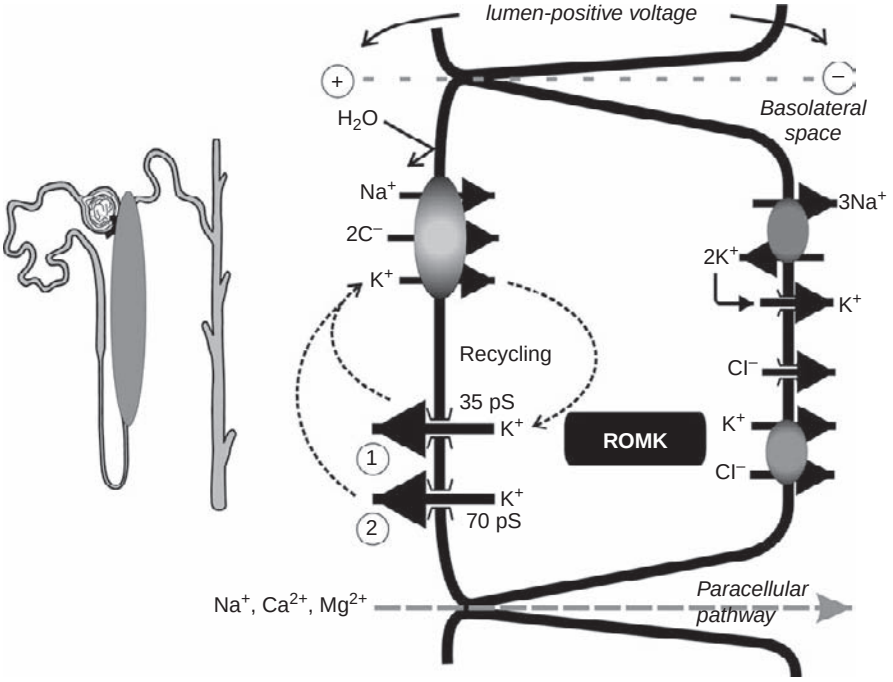

FIGURE 47.6 **Model for ion transport in the thick ascending limb.** The two types of apical K^+ channels are shown; 35 pS (also called the small K^+ or SK channel) and 70 pS channels. ROMK and SK functional and regulatory characteristics are essentially identical. It has been proposed that the 70 pS channel is also formed by ROMK in association with another channel subunit, but this remains to be demonstrated.

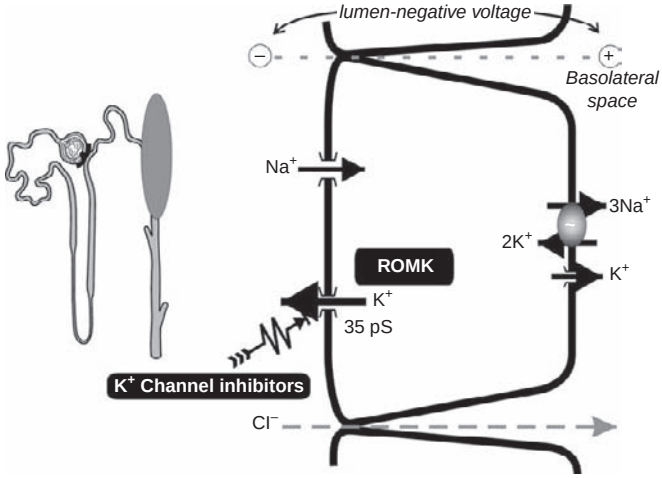

FIGURE 47.7 **Model for ion transport by the principal cell in the collecting duct.** The apical K^+ secretory channel in this cell is ROMK.

co-workers[61] have also suggested that the closed state of ROMK results from K^+ ions transiently blocking its own pathway. Such a model would not require large molecular motions, but rather small molecular oscillations.

CHANNEL RECTIFICATION

One of the fundamental characteristics of ROMK, as well as all Kir channels is inward rectification, the property of passing current more easily in the inward than in the outward direction (see Figure 47.4). Although this seems to be contrary to the role of ROMK in K^+ secretion, the inward rectification observed with ROMK, and with the kidney K^+ secretory channel, is "weak." The term "weak" rectification refers to the ability of ROMK to actually pass outward current, albeit to a lesser extent than inward current. Many of the other Kir channels are "strong" rectifiers, and characteristically pass little outward current. The very high open probability of the ROMK channel, usually >0.9, may help make up for the rectification effect on K^+ secretion. In other words, although the outward conductance (ease of passing K^+ secretory current) is less than the inward conductance, the channels are open most of the time, and thus are able to secrete large amounts of K^+. We now know that inward rectification of ROMK is due to blocking of the channel pore by Mg^{2+}[55] or polyamines like spermine or spermidine from the intracellular side.[52,53] Thus, it is possible that variations in the cytosolic concentrations of these inorganic and organic cations could provide an important mechanism regulating outward (i.e., K^+ secretory current. It was suggested that the inhibition of outward K^+ fluxes through ROMK by Mg^{2+} may contribute to K^+-wasting in the setting of Mg^{2+} deficiency.[62] A subsequent study by Yang et al.[63] examining the regulation of ROMK expressed in *Xenopus* oocytes and the native channel by intracellular and extracellular Mg^{2+} supports this idea.

Kinetic studies of inward rectification by Mg^{2+} and polyamines indicate that the effect is voltage-dependent and depends on the extracellular

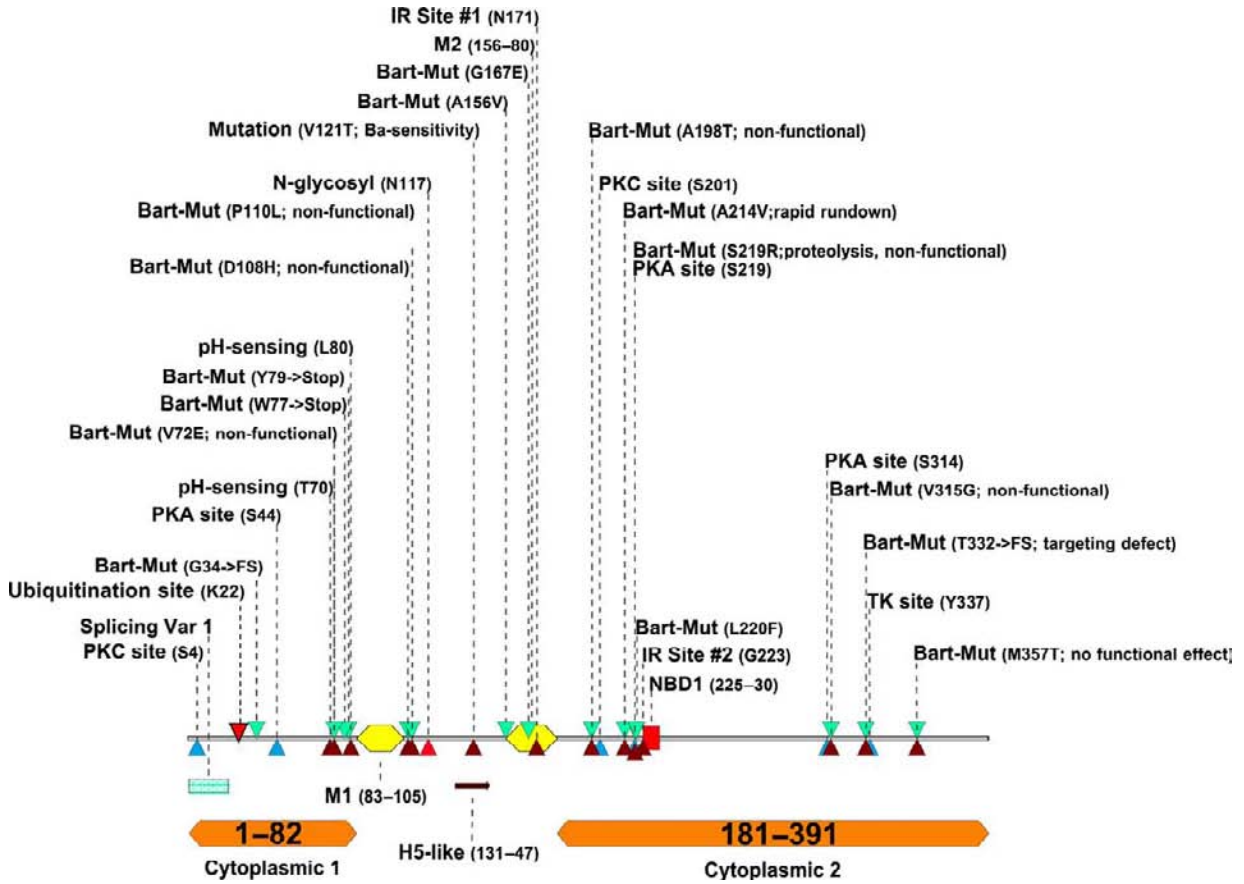

FIGURE 47.8 **The major functional and regulatory sites, and the Bartter's mutations are shown in this schematic representation of ROMK1, Kir1.1a** (see text for discussion).

concentration of K^+ (thus varies with the K^+ reversal potential in the constant intracellular (K^+)).[54,55,61,64,65] These findings suggest an interaction between permeant and blocking ions, and the presence of a variable energy well within the channel pore. The crystal structure of Kir revealing a long channel pore with multiple binding sites for K^+ and blocking ions is consistent with this idea.[19–21]

Electrophysiological studies have demonstrated the importance of the M2 segment and COOH-termini in determining the inward rectifying characteristics of inwardly rectifying K^+ channels.[54,56,66,67] Two residues are particularly important in determining whether the rectification is strong or weak. In strong inward rectifiers like IRK1 (Kir2.1),[5] a negatively charged residue, aspartic acid (D172 in IRK1), in the M2 membrane segment has been shown to be critical for strong inward rectification.[54,56] In ROMK the aspartate residue is replaced by asparagine (see Figure 47.8, IR Site #1, N171 in ROMK1), consistent with the weak rectification of this channel. A second residue located in the C-terminus has also been shown to be an important contributor to strong rectification in IRK1.[67] This glutamate residue (E224 in IRK1) is replaced by a glycine residue in ROMK (see Figure 47.8; IR Site #2). This C-terminal glycine residue in ROMK is a part of the Walker A site that contributes to the nucleotide-binding interactions (see Figure 47.1, and IR Site #2 in Figure 47.8) in the nucleotide-binding domain (NBD; Figure 47.8), and thus serves a different gating function in ROMK. As expected from this model, exchange of the ROMK C-terminus with that on IRK1 produces strong rectification in oocytes injected with the mutant ROMK channel.[66] Consistent with the electrophysiological results, the crystal structure of Kir2.2 reveals that the inner helices line the central cavity and the internal half of the membrane pore, and the side chain of D172 points to the center of the central cavity.[21] The binding sites for Mg^{2+} in the crystal structure of Kir2.2 were examined by soaking the crystal with 10 mM Sr^{2+}, an electron dense mimic of Mg^{2+}. Three density peaks due to Sr^{2+} are observed in the crystal of Kir2.2: one in the central cavity corresponding to the position of D172 and two in the cytoplasmic pore, referred to as the upper ring and lower ring of charges, respectively. The upper ring of charges consists of E224 of IRK1 and

an additional glutamate residue E229 from each of four subunits. The lower ring of charges consists of four D255, one from each subunit.[21]

Finally, two different extracts of venom have been suggested to specifically inhibit ROMK channels.[68,69] Both the snake toxin, δ-dendrotoxin,[68] the honey bee venom extract, tertiapin, and the modified compond, tertiapin-Q[69,70] appear to block ROMK activity by interacting with channel pore. Tertiapin-Q specifically blocks ROMK and Kir3.1, but not other Kir channels such as Kir4 and Kir5, and has been explored to estimate the density of ROMK channels in the CCD and CNT in response to dietary K^+ intake.[71] A study, however, indicates that tertiapin-Q can also block MaxiK (or BK, *hSlo1*) Ca^{2+}-activated K^+ channels.[72] Thus, caution should be exercised when utilizing tertiapin-Q to define ROMK activity under the condition in which MaxiK channels are activated by flow.

Regulation of the ROMK K^+ Channel

ROMK channel activity, like that of the native SK channel in TAL and principal cells, is regulated by a variety of factors that either activate or inhibit channel activity (Figure 47.9). The molecular mechanisms for these alterations in channel function are rapidly being identified.

PROTEIN KINASE A (PKA)

PKA-dependent phosphorylation processes activated by receptor-mediated events or alterations in cytosolic second messengers (e.g., cyclic AMP, cAMP) play important roles in regulating the native SK channel in principal cells of the CCD (Figure 47.10[45–48,73]). Phosphorylation-dephosphorylation processes also modulate the activity of the cloned ROMK K^+ channel.[9,33,34,57,58] K^+ channel activity in excised inside-out

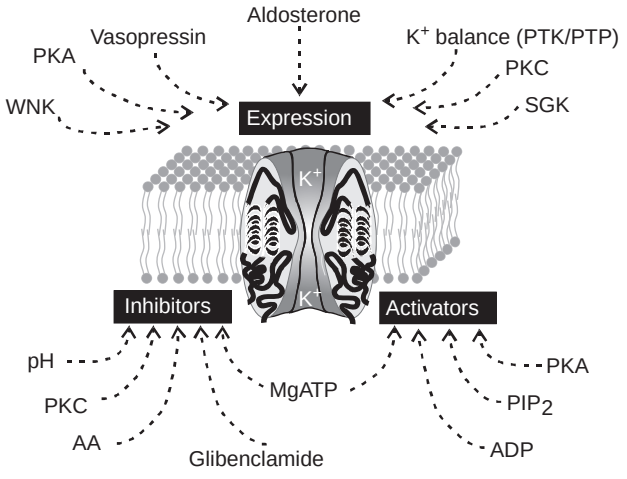

FIGURE 47.9 **The major identified regulators of ROMK channels.**

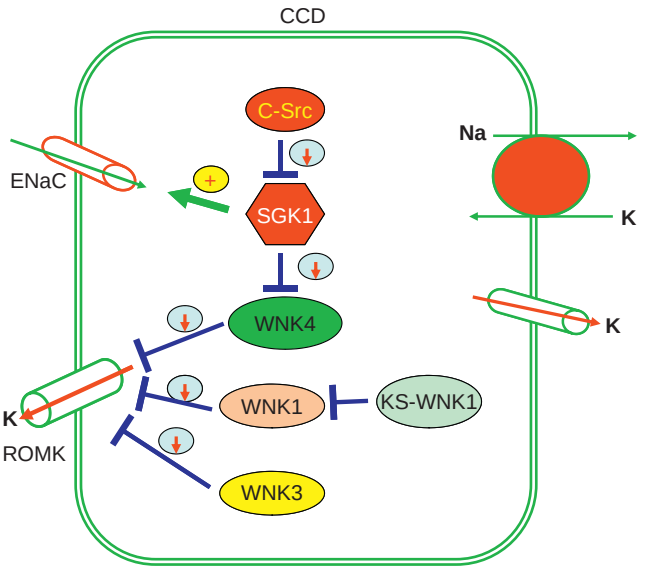

FIGURE 47.10 **A cell model illustrating the mechanism by which ROMK channel activity is regulated by the interaction among c-Src, SGK1, and WNKs in the CCD.**

patches of oocytes expressing ROMK requires activation by PKA-dependent phosphorylation processes.[58] Rundown or loss of ROMK channel activity in these patches occurs whenever phosphatase-mediated dephosphorylation activity is greater than phosphorylation (see also section on PIP_2 below for role of protein versus lipid kinases and phosphatases in the process of rundown and reactivation by MgATP).

The critical PKA phosphorylation sites are on the channel protein itself (see Figure 47.2). This has been demonstrated by several observations. First, ROMK protein expressed in HEK-293 cells can be phosphorylated by PKA.[9] Phosphopeptide analysis and mapping have shown three serine residues phosphorylated by PKA (one residue on the N-terminus (serine 25 in ROMK2) and two residues on the C-terminus (serine 200 and serine 294 in ROMK2)). Mutation of any single PKA phosphorylation site on ROMK2 reduces whole cell K^+ currents by 35–40% in oocytes; mutation of two or more of the three sites produces non-functional channels.[9] This is consistent with the critical role of PKA phosphorylation in channel activation. Second, at the single channel level the N-terminal and C-terminal PKA phosphorylation sites alter the channel activity, albeit differently.[57] None of the mutations with serine residues replaced by alanine alters the single channel conductance. Each of the C-terminal PKA phosphorylation site mutations, however, reduces open probability (P_o) by about 40%, due to the appearance of a new long closed state. This reduction in P_o is sufficient to account for the observed reduction in whole oocyte currents.[9] Replacing the N-terminal serine with alanine

does not change P_o, but does reduce the probability of finding functioning channels by about 60%. The mechanism for this reduction in active channels is not known at present. The mechanism by which PKA increases ROMK channel activity may include stimulation of surface expression and enhance the effect of PIP_2 on ROMK channels. It has been shown that stimulation of PKA increases the sensitivity of ROMK channels to PIP_2 in *Xenopus* oocytes.[74] Also, a recent study demonstrates that mutation of serine residue 44 to aspartate increases the surface delivery of ROMK1 channels.[75] One of the fundamental characteristics of SK channels in principal cells and in the TAL is their activation by Gs-coupled receptors or by the addition of cyclic AMP.[46] AKAPs are A-Kinase Anchoring Proteins that bind PKA holoenzyme (catalytic plus regulatory subunits), and maintain the enzyme at specific intracellular sites.[76,77] Wang and co-workers reported that ROMK1 channels expressed in *X. laevis* oocytes could not be activated by cyclic AMP unless expressed with an isoform of AKAP, AKAP79.[78] On the other hand, findings that ROMK channels carrying PKA site mutations exhibit reduced current in *Xenopus* oocytes in the absence of AKAP79 suggests that ROMK can be phosphorylated without AKAP79.[78] The role of AKAP in the native tissue is not determined. Some studies suggested that the Na/H exchange regulatory protein 2 (NHERF-2) might act as an AKAP, because NHERF-2 interacts with ROMK channels[79] and facilitates the stimulatory effect of SGK1 on ROMK channels.[80]

ARACHIDONIC ACID (AA)

Like the native SK channel in the CCD,[81] ROMK1 channels expressed in *Xenopus* oocytes are sensitive to arachidonic acid (AA[33,34]). The effect of AA is specific, since other fatty acids failed to mimic the effect of AA.[33] However, AA has little-to-no effect on the other two ROMK family members, ROMK2 and ROMK3.[34] Since the amino acid sequences of the ROMK channels are identical, with the exception of the N-terminus, the role of the N-terminus in mediating the effect of AA is strongly suggested. This is supported by the demonstration that deletion of the initial 37 aa of ROMK1 abolished the effect of AA. Moreover, a serine residue at the fourth position within the N-terminus of ROMK1 has been shown to play a crucial role in the AA-mediated inhibition of ROMK1, since mutation of this serine residue to alanine abolished the effect of AA (Figures 47.1 and 47.3[34]). Since this serine residue is a putative PKC phosphorylation site,[3] and AA has been shown to activate PKC, the effect of AA may depend on stimulation of a membrane-bound PKC.

PROTEIN KINASE C (PKC)

Activation of PKC phosphorylation processes inhibits the apical SK channel in the CCD.[48] ROMK1, which is exclusively expressed in collecting ducts, has three potential PKC phosphorylation sites involving serine residues: one on the N-terminus; and two on the C-terminal end. ROMK2 and ROMK3 only have the two C-terminal PKC phosphorylation sites (see Figures 47.2 and 47.4). Using an *in vitro* phosphorylation assay, it was observed that serine residue 4 in the N-terminus and serine residue 201 in the C-terminus are two major PKC-induced phosphorylation sites. The effect of PKC on ROMK channels is complex. It was demonstrated that phosphorylation of either serine residue 4 or 201 is essential for ROMK1 export to the plasma membrane.[18] On the other hand, stimulation of PKC *in vivo* has been shown to inhibit ROMK channel activity. The N-terminal serine residue at the fourth position appears to be most important to PKC-mediated K^+ channel inhibition of ROMK1. Interestingly, this is the same residue critical for the inhibitory effect of arachidonic acid (see Figure 47.4). However, it is possible that PKC-induced inhibition of ROMK channels may be indirect, resulting from a decrease in PIP_2 content. It was demonstrated that stimulation of PKC decreases the PIP_2 level in the plasma membrane.[82] Because PIP_2 is essential for maintaining ROMK channels in the open state, decreases in PIP_2 levels may contribute to the PKC-induced inhibition.

WNKS (WITH NO LYSINE KINASE)

WNKs are a family of four serine/threonine protein kinases named WNK1–4.[83,84] Among them, WNK1, 3, and 4 are expressed in the distal nephron.[85–87] The discovery that mutations in WNK1 and WNK4 cause the autosomal-dominant hypertension and hyperkalemia known as pseudohypoaldosteronism type 2 (PHA2) led to extensive characterization of their properties and function.[88] Evidence indicates that the WNK family plays an important role in the regulation of ROMK channels.[22,87,89–92] WNK1, 3, and 4 inhibits the ROMK channel activity (Figure 47.10), and the effect of WNKs on ROMK is mediated by stimulation of clathrin-dependent endocytosis.[22,89] Intersectin, a scaffold protein containing two Eps15 homology domains and four or five tandem SH3 domains, interacts with WNK1 and 4, which is required for the regulation of clathrin-mediated endocytosis of ROMK by WNKs.[93] In addition, a clathrin adaptor protein, Autosomal Recessive Hypercholesterolemia (ARH), has been shown to interact with ROMK, and the interaction may be involved in the stimulation of endocytosis of ROMK by WNK1.[16] Dysregulation of ROMK by

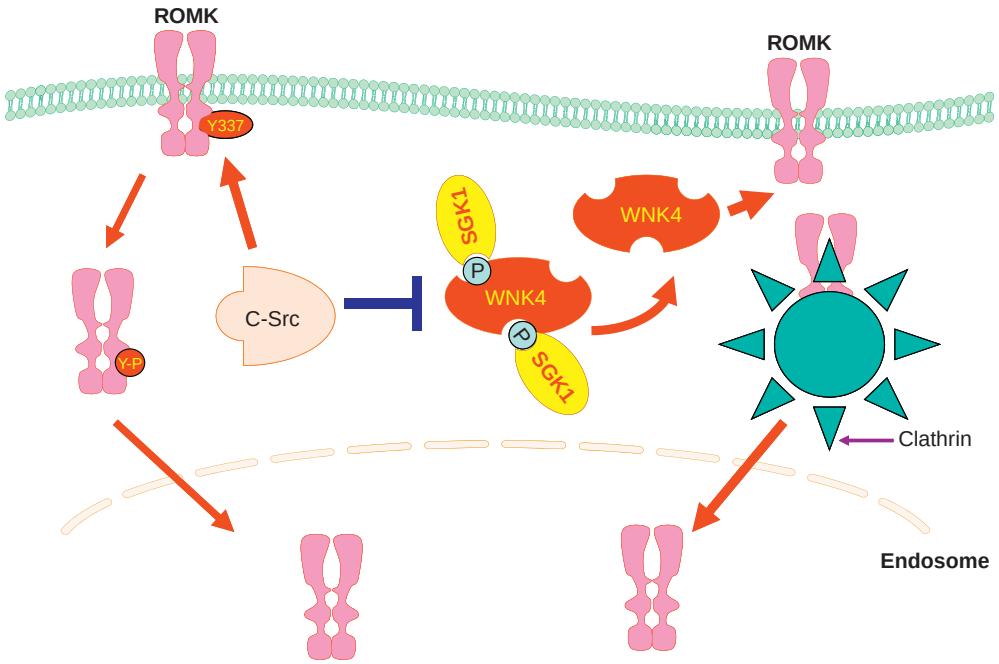

FIGURE 47.11 **A cell model demonstrating the regulation of ROMK1 channel in the CCD by Src-family PTK, SGK1, and WNK4.**

WNK1 and 4 may contribute to the hyperkalemia in PHA2.[94]

A kidney-specific splice form of WNK1 (KS-WNK1), in which an alternative 5′ exon replaces the first four exons of WNK1, is expressed in the distal nephron.[95] Unlike the long form of WNK1, KS-WNK1 lacks kinase activity and, by itself, does not regulate ROMK channels. However, KS-WNK1 antagonizes the inhibitory effect of WNK1 on ROMK.[90,92] It has been reported that high K^+ intake increases, whereas low K^+ intake decreases, the expression of KS-WNK1, and that increased KS-WNK1 expression attenuates the inhibitory effect of WNK1 on ROMK channels.[90,92] Thus, the alteration of the ratio between the long and short form of WNK1 may be an important mechanism by which a dietary K^+ intake regulates ROMK channel activity.

PROTEIN TYROSINE KINASE (PTK)

The ROMK channel is a substrate of PTK, and tyrosine residue 337 in the C-terminus of ROMK1 has been demonstrated to be a PTK phosphorylation site[95,97] (Figure 47.8). Tyrosine phosphorylation of ROMK is regulated by dietary K^+ intake: a low K^+ intake increases, whereas a high K^+ intake decreases, tyrosine phosphorylation.[98] The regulation of tyrosine phosphorylation of ROMK by K^+ diet is partially achieved by modulating the expression of Src family PTK in response to a dietary K^+ intake. Low K^+ increases, whereas a high K^+ suppresses, the expression of Src family PTK.[99] Immunostaining has also demonstrated that c-Src, the most ubiquitously distributed member of Src family PTK, is present in the thick ascending limb, connecting tubule, and cortical collecting duct.[96] Also, CD63, a tetra-spanning protein, increases c-Src activity by stimulating c-Src phosphorylation in tyrosine residue 416, thereby enhancing the c-Src-induced inhibition of ROMK channels.[100]

Although the fate of tyrosine phosphorylated ROMK is not completely understood, the stimulation of tyrosine phosphorylation of ROMK1 facilitates channel internalization (Figure 47.11[97]). Because ROMK1 is exclusively expressed in the connecting tubule and CCD, this mechanism should play an important role in K balance during K restriction. However, the upstream signaling which stimulates PTK is still not known. K restriction has been shown to stimulate renin and the angiotensin II system.[101–103] Moreover, micropuncture studies have revealed that luminal perfusion of angiotensin II inhibited K secretion in the distal nephron.[104] Patch-clamp experiments have further demonstrated that angiotensin II downregulates ROMK channels in the CCD, and that such inhibition could be demonstrated only in the CCD from K-restricted rats.[105] In addition, two lines of evidence indicate that superoxide is a mediator of the effect of K diet on the Src family PTK: (1) low K intake stimulates superoxide anion levels; and (2) incubation of M-1 cells, a cultured mouse CCD principal cell, with hydrogen peroxide increases the expression of c-Src.[106] The notion that superoxide anion could serve as a second messenger of low K intake on the Src family PTK is also supported by the finding that suppression of superoxide anion

attenuates the effect of low-K intake on c-Src expression, and diminishes the tyrosine phosphorylation of ROMK. Thus, superoxide and PTK pathway play important roles in maintaining K homeostasis.

ALDOSTERONE AND SERUM-GLUCOCORTICOID-INDUCED KINASE (SGK)

SGK1 has been reported to stimulate ROMK1 channels by facilitating the phosphorylation of ROMK channels at serine residue (Ser) 44, thereby enhancing the export of ROMK channels from the ER.[107,108] SGK1 also suppresses the effect of WNK4 on ROMK channels (Figure 47.10) through the phosphorylation of WNK4 at Ser 1169[91] and 1196.[109] Thus, the C-terminus containing Ser 1169 and 1196 was called the "switch-domain" for renal K secretion. Moreover, WNK1 has also been reported to stimulate SGK1 through PI3 kinase.[110] WNK1-induced activation of SGK1 could also play a role in mediating the effect of a high-K intake on K secretion. A large body of evidence suggests that SGK1 mediates, at least in part, the effect of aldosterone on renal K secretion.[91,111–113] For instance, the phenotype of SGK1 deletion is similar to MR knockout mice, and displays compromised renal K secretion in response to a high dietary K intake.[111] However, it is still not known whether the stimulatory effect of SGK on renal K secretion is the result of increased ENaC activity which in turn augments the electrochemical gradient for K secretion or due to a direct stimulation of ROMK channel insertion. It has shown that ROMK expression in the apical membrane of the TAL and CCD is actually increased rather than decreased in SGK null mice.[114] This suggests that the role of SGK in stimulating ROMK insertion may not be essential or can be replaced by other kinases, such as cAMP-dependent protein kinase A. A possible role of SGK in regulating renal K secretion by a daily dietary K intake has been suggested by the report that a high dietary K intake for 12hours stimulates SGK expression in the kidney.[115] Moreover, ROMK channel activity increased significantly in the CCD from rats on a high-K diet for only 6hours. Thus, SGK may regulate ROMK channel activity in the CT and CCD in response to a daily variation of dietary K intake.

INTERACTION OF PTK, SGK1, AND WNK4

As discussed above, WNK4 inhibits ROMK channels and K secretion in the CNT and the CCD. SGK1 reversed the inhibitory effect on ROMK channels by stimulation of WNK4 phosphorylation in serine residues 1169 and 1196. However, Wang and his associates have demonstrated that Src family PTK modulates the effect of SGK1 on WNK4, and abolishes the SGK1-induced phosphorylation of WNK4. Figure 47.11 is a model illustrating the role of the interaction among c-Src, SGK1, and WNK4 in regulating ROMK channels and K secretion. Activation of c-Src inhibits the SGK1-mediated phosphorylation of WNK4, thereby restoring the inhibitory effect of WNK4 on ROMK channels and K secretion.[116] The c-Src-dependent modulation of SGK1-WNK4 interaction may play a key role in preventing K loss during volume-depletion, and in stimulating K secretion during a high-K intake. Both volume-depletion and K secretion are expected to increase SGK1 expression. However, a high-K intake has been shown to suppress PTK activity, whereas volume-depletion does not inhibit PTK expression. Consequently, although a volume-depletion stimulates SGK1 activity, a high PTK activity blocks the effect of SGK1 and prevents K loss.

UBIQUITINATION

Ubiquitination plays an important role in the regulation of protein degradation and recycling by attaching ubiquitin molecules to lysine residues of substrate protein. Ubiquitination can further be classified into mono-ubiquitination by adding only one or two ubiquitin molecules to the substrate protein or polyubiquitination by attaching more than four ubiquitin molecules. The polyubiquitinated protein is subjected to degradation, whereas monoubiquitinated proteins are targeted to internalization and possibly recycling to the cell membrane. ROMK1 channel activity could be regulated by monoubiquitination, and the ubiquitin-binding site is on Lysine residue 22 on the N-terminus of ROMK1[117] (Figure 47.8). The physiological importance of monoubiquitination in the regulation of ROMK channel is still not clear. Because ROMK channel activity in the CCD decreases in response to stimulation of PTK, it would be interesting to determine whether monoubiquitination is required for the PTK-induced internalization of ROMK1 in the CCD. POSH (plenty of SH3) is an E3 ubiquitin ligase, and expression of POSH enhances the ubiquitination of ROMK, suggesting that POSH is involved in ubiquitination of ROMK channels.[118]

NUCLEOTIDES, THE CYSTIC FIBROSIS TRANSMEMBRANE CONDUCTANCE REGULATOR (CFTR), AND SULFONYLUREA RECEPTOR (SUR) PROTEINS

MgATP both activates and inhibits ROMK channels (Figure 47.9), with the net effect of nucleotide action being the integration of these opposite and complex events. Activation occurs by stimulation of PKA-mediated phosphorylation (see section on PKA, above) or by altering the generation of PIP_2 (,[15] and see section on regulation by PIP_2, below). These processes modulate channel-gating or plasma membrane channel density (e.g., by regulating trafficking of the channel to the

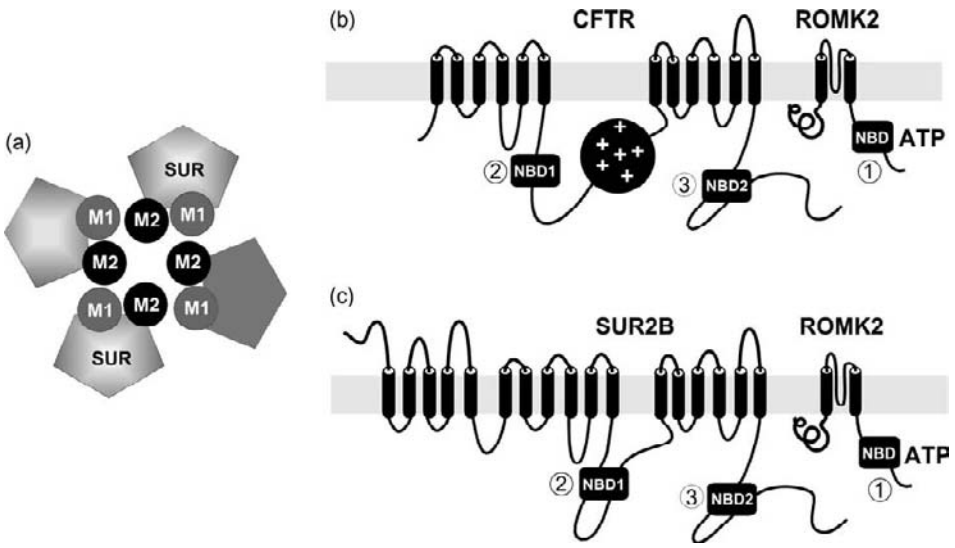

FIGURE 47.12 **Assembly of K_{ATP} and ROMK channels with ATP Binding Cassette (ABC) proteins.** (a) The proposed hetero-octameric complex forming ATP-sensitive (K_{ATP}) channels with four K_{IR} subunits and four sulfonylurea receptor (SUR) subunits. The M1 and M2 membrane segment arrangement is as shown in Figure 47.2a, with the M2 membrane segments lining the channel pore. (b) The topology of CFTR and ROMK channels proposed to form kidney K_{ATP} channels. A single nucleotide-binding domain (NBD, 1) is present on the C-terminus of ROMK, while two NBDs (numbered 2 and 3) are found on CFTR. (c) The topology of the sulfonylurea receptor, SUR2B, and ROMK proposed to form kidney K_{ATP} channels.

apical plasma membrane for the endoplasmic reticulum[75]). Inhibition of the SK secretory channel in CCD by MgATP[45] identifies this channel as belonging to a subgroup of Kir channels, referred to as ATP-sensitive or K_{ATP} channels (the classical K_{ATP} channels, Kir6.x; and Kir1.1 or ROMK channels[43,119]). The renal SK or K_{ATP} channel is somewhat less sensitive to ATP than the pancreatic β-cell or other K_{ATP} channels. As observed with other K_{ATP} channels,[119,120] addition of MgADP to MgATP-inhibited ROMK channels relieves the ATP block.[13] Thus, changes in the cytosolic MgATP concentration or in the MgATP/ADP ratio, as may occur with alterations in the activity of Na^+-K^+-ATPase, could modulate ROMK channel activity. This may provide one mechanism for coupling basolateral Na^+-pump activity with apical K^+ secretion in the principal cells of the CCD.

Channel inhibition by Mg-ATP is incompletely understood; however, the mechanism likely involves both direct binding of MgATP to the ROMK protein at an unconventional nucleotide-binding site (NBD; Figure 47.2b) and interaction with CFTR. The direct binding of ATP to K_{ATP} channels is supported by cross-linking of azido-ATP compounds to the channel proteins.[51,121,122] In addition, recent biochemical observations using fluorescent ATP analogs have shown that Mg-ATP can bind directly to K_{ATP} channels, including ROMK.[51,123,124] Both N- and C-terminal segments form the nucleotide-binding site which is situated at a region modeled to be involved in channel gating.[61,125,126] The crucial N-C-terminal interaction occurs between adjacent subunits; in other words, the nucleotide-binding site is intermolecular. As observed with other K_{ATP} channels,[119,120] addition of ADP to ATP-inhibited ROMK channels relieved the ATP block.[13]

Only a few studies have found that ATP can inhibit ROMK when expressed alone in *X. laevis* oocytes,[12,13,127] suggesting that direct binding of MgATP to ROMK is insufficient for channel inhibition. Several studies have demonstrated that ROMK channels may interact with CFTR or sulfonylurea receptor type 2B (SUR2B) (Figure 47.12a), and that such interaction is required for ATP sensitivity.[128–130] Moreover, a characteristic of K_{ATP} channels, including the renal SK channel, is their sensitivity to inhibition by sulfonylureas like glibenclamide.[119,131] The pancreatic β-cell K_{ATP} channel is formed by two subunits; a pore-forming polypeptide, Kir6.2; and the sulfonylurea-binding protein, SUR1 (an ABC (ATP-Binding Cassette) protein family member like CFTR[132–134]) in a 4:4 ratio (see Figure 47.12a[135–137]). Kir6.2 provides the K^+ channel permeation pathway and ATP binding-inhibition site, while SUR is required for sulfonylurea binding, and for certain aspects of regulation by nucleotides (e.g., ADP effects[133,138,139]). Two lines of evidence suggest that CFTR-ROMK interaction may play a key role for the sensitivity of ROMK to sulfonylurea agents: (1) CFTR is expressed in the same apical regions as ROMK channels in the CTAL and CCD,[140] and a functional

truncated hemi-CFTR is also expressed in the MTAL[141]; (2) glibenclamide- and Mg-ATP-sensitive whole cell K^+ currents in *X. laevis* oocytes are only observed when ROMK is co-expressed with CFTR.[127,142] In the kidney, glibenclamide induces natriuresis in rats,[143,144] and patch-clamp experiments have shown that 200 μM glibenclamide inhibits the apical SK channel in the rat TAL by about 60–70%.[40,145] The sensitivity of the SK channel in TAL to sulfonylureas is, however, much less than in other K_{ATP} channels.[43] Thus, the ability of glibenclamide to inhibit the K^+ secretory channels in renal distal tubule suggests that a SUR-like protein is associated with this channel, and is involved in the sulfonylurea effect (Figure 47.12C). However, the role of CFTR in regulating ATP-sensitivity of ROMK channels is still not completely understood.[146] Because the regulation of ROMK channels by ATP required PKA-dependent phosphorylation of CFTR, ATP-sensitivity of ROMK might be the result of the PKA-phosphorylation state of CFTR, rather than direct ATP regulation.[146]

INTRACELLULAR pH AND EXTRACELLULAR K

Small reductions in cytosolic pH reversibly inhibit ROMK channel activity expressed in *X. laevis oocytes*,[10–12,60,147] and the SK channel in TAL and CCD.[45,47,48,148] Lysine at position 80 on the N-terminus of ROMK1 (K61 on ROMK2; see Figures 47.2 and 47.8) is primarily responsible for conferring this pH-sensitivity, as mutation of this residue abolished pH-dependency[10,11,149]; although later studies have suggested an alternative role of lysine-80 in the pH regulation of ROMK1.[150,151] The pH-dependent gating of ROMK is rapidly reversible as long as the exposure to low pH (6.0–7.0) is short. Longer exposure to low pH results in "irreversibility." Schulte and co-workers have recently provided an explanation for the latter. The pH-dependent conformational change in ROMK apparently exposes N- and C-terminal cysteine residues forming disulfide bridges that lock the protein in a closed conformation. The disulfide bridges can be broken by DTT (dithiothreitol), resulting in channel reopening.

Cytosolic pH can also alter ROMK channel activity in another way. The $K_{1/2}$ for inhibition of ROMK channel activity is not fixed, but can be modulated by altering cytosolic side pH. McNicholas and co-workers[12] found that decreasing the pH from 7.4 to 7.2 on the cytosolic face of excised patches from oocytes expressing ROMK2 reduced the $K_{1/2}$ for MgATP inhibition from about 2.5 mM to $<$0.5 mM, almost a 10-fold increase in affinity with this small acidification. This effect appears to be independent of the lysine residue implicated in pH-dependent regulation of ROMK channel activity,[10,11] indicating that another pH sensor may be present on ROMK. This notion is supported by the report that the residues on the N-terminus of ROMK and the helix bundle crossing near the cytoplasmic end of the transmembrane pore have also been shown to modulate sensitivity to pH.[10,152] Relevant to the existence of multiple internal pH sensors is the finding that pH-dependent gating of ROMK1 is associated with conformational changes in both N- and C-termini.[147] The pH sensitivity of ROMK channels is controlled by extracellular K^+[153,154]. It has been shown that removal of extracellular K^+ inactivates ROMK channels which are closed by internal acidic pH. In the absence of extracellular K^+, intracellular alkalization fails to reactivate ROMK channels, and adding extracellular K^+ is required to reactivate ROMK channels. It has been suggested that internal pH-gating and external K^+-gating might act in the same amino acid (leucine residue 160 of ROMK2).[155] Acidification induces conformation changes, preventing K^+ access to the transmembrane pore from the cytoplasm.[152]

Not only affecting ATP sensitivity, change in pH also modulates the effect of polyamine block of ROMK channels. A negatively-charged glutamic acid residue in this C-terminal region (e.g., E224 in Kir2) has been shown to modulate block by Mg^{2+} or polyamines.[67] In addition, a histidine residue in Kir6.2 (H216, see Figure 47.2[156]) in a region corresponding to the Walker A site in ROMK, has been shown to mediate pH-dependent modulation of polyamine block of this K_{ATP} channel. Thus, this region of the C-terminus of Kir channels is involved in a variety of different gating functions (ATP, pH, polyamines).[157]

PHOSPHOINOSITIDES

Phospholipids, particularly PIP_2, have been shown to modulate Kir channels including ROMK1.[14,15,158] Exposure of inside-out patches from oocytes expressing Kir6.2 to PIP_2 reduces the ATP-sensitivity of this K_{ATP} channel, apparently by reducing the probability of ATP-binding to its receptor site.[158] Consequently, increasing concentrations of PIP_2 increase K_{ATP} channel activity. PIP_2 interacts with the pore-forming subunit rather than the SUR subunit of K_{ATP} channels, since PIP_2 modifies the ATP sensitivity of the C-terminal truncated Kir6.2 channel in the absence of SUR1.[158] ROMK, like many Kir channels, contains a high density of positively-charged amino acids just C-terminal to M2 (see Figure 47.2). Huang and co-workers[15] have shown that labeled phospholipid vesicles bind to a recombinant ROMK1 C-terminal fusion protein. These investigators implicated arginine 186 in the ROMK1 C-terminus (see Figure 47.2), as mutation of this residue to glutamine modified PIP_2 effects. Since PIP_2 is generated by ATP-dependent lipid kinases, Huang and co-workers have suggested that the stimulatory effect of MgATP may be due to the generation of PIP_2 by lipid

kinases.[15] Interaction with PIP_2 in the membrane is likely a general mechanism for activating Kir channels (see section on the structure of Kir and ROMK above).

REGULATION OF ROMK EXPRESSION IN KIDNEY (K^+ INTAKE, MINERALOCORTICOIDS, VASOPRESSIN, Klotho)

Since K^+ homeostasis is mainly controlled by aldosterone and the potassium-load, it is not surprising that ROMK mRNA expression in rat kidney is regulated by aldosterone, K^+ adaptation, and vasopressin (see Figure 47.9). It is well-established that rats fed a high-K^+ diet adapt by upregulating renal K^+ secretion and excretion.[159] This results, at least in part, from an increase in the SK channel density in CCD.[160] Wald and co-workers[161] found that K^+ deficiency reduces ROMK mRNA expression in both cortex and medulla, while K^+-loading increases ROMK transcript slightly only in medulla. Moreover, several studies have shown that K^+ deficiency decreased ROMK expression in the plasma membrane of the collecting duct,[162,163] presumably by stimulating internalization including clathrin and syntaxin-1A-dependent endocytosis.[164,165] The specific ROMK isoforms that changed with potassium were not assessed. Moreover, Frindt and co-workers[166] found that ROMK transcript abundance by *in situ* hybridization in the CCD was not affected by a high-K^+ diet. Thus, the high-K^+ diet-induced increase in density of active SK channels in principal cells in the CCD is not due to increased abundance of ROMK mRNA. Rather, changes in ROMK protein abundance, channel activation or ROMK channel translocation to the membrane are potential mechanisms to account for the high-K^+ adaptation effect on SK channels in the principal cells.

Mineralocorticoids also regulate ROMK abundance. Adrenalectomy decreased ROMK mRNA abundance in cortex, but increased transcript abundance in the medulla.[161] In this latter study, K^+ deficiency in adrenalectomized rats reduced ROMK mRNA to control levels, suggesting that the hyperkalemia associated with adrenalectomy was the cause for the increased ROMK message in medulla. In another study, White and colleagues[26] showed that aldosterone administration by minipump to adrenal intact rats increased ROMK transcripts in whole kidney. In the latter study, the ROMK2, 3, and 6 isoforms were increased by the mineralocorticoid. This latter study would be consistent with mineralocorticoid-mediated regulation of ROMK mRNA abundance in cortex. However, the glucocorticoid-responsive element responsible for transcriptional regulation of ROMK by mineralocorticoid has never been identified in the promoter region of the RMOK gene, *KCNJ1*.

Vasopressin, via cyclic AMP, stimulates K^+ secretion in principal cells,[47] and activates the apical K^+ channels in TAL cells[40,167] (see Figure 47.6). Although the activation of PKA by cAMP would phosphorylate ROMK (or the SK channel), it remains to be shown whether this is sufficient to account for the stimulation of K^+ channel activity or whether additional mechanisms, such as channel insertion into the membrane, are required. As discussed above, PKA-anchoring proteins appear to be required for cAMP activation of ROMK currents in oocytes[78] (see Figure 47.10).

Klotho is an aging-suppressing protein which is expressed in several organs, including the kidney. The application of the Klotho's extracellular domain increases the surface expression of ROMK1, and enhances urinary K^+ excretion.[168] The mechanism by which Klotho increases the expression of ROMK in the plasma membrane is by eliminating terminal sialic acids from N-glycan of ROMK. Consequently, underlying disaccharide galactose-N-acetylglucosamine is exposed and binds to galectin-1, a ubiquitous galactoside-binding lectin. Binding of ROMK to galectin-1 inhibits the clathrin-dependent endocytosis of ROMK. The physiological role of endogenous Klotho in K^+ homeostasis is unknown.

Lessons from Bartter's Syndrome

Bartter's syndrome[169] comprises a set of autosomal recessive renal tubulopathies characterized by hypokalemic metabolic alkalosis, salt-wasting, hyperreninemia, and hyperaldosteronsim.[170–173] Antenatal Bartter's syndrome is the most severe form of the inherited disorders, and is characterized by hyperprostaglandinemia (PGE_2). Antenatal Bartter's syndrome is genetically heterogeneous, resulting from mutations in one of five genes.[174] Three of the Bartter's genes encode the major Na^+, K^+, Cl^- transporters in the TAL: the *SLC12A1* gene encoding the apical Na-K-2Cl co-transporter[175,176]; the *CLCKB* basolateral Cl^- channel[177]; and the *KCNJ1* apical K^+ recycling channel, ROMK (see mutations in Figure 47.8[178–180]). Mutations in two other genes also produce the Bartter's phenotype – barttin and the extracellular calcium-sensing receptor (CaSR). Barttin is a membrane protein that is required for trafficking of the ClCKb channel to the basolateral membrane of TAL cells, and loss-of-function mutations in barttin result in the absence of basolateral Cl^- channel activity.[181] Gain-of function mutations in the CaSR result in inhibition of Na,K-ATPase, NKCC2, and apical 70 pS K channel activity.[174,182,183]

The effect of loss-of-function mutations in ROMK on TAL function can be understood, since apical K^+ recycling is crucial both to supplying K^+ to the Na-K-2Cl

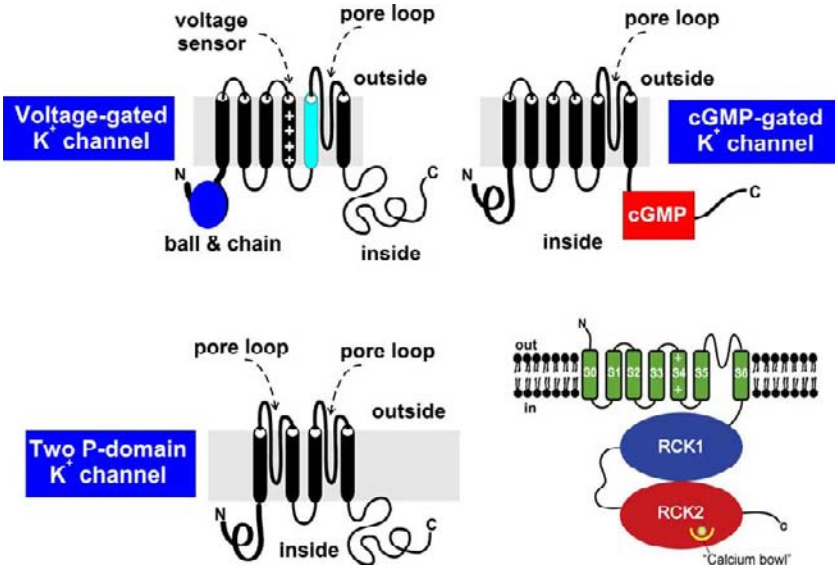

FIGURE 47.13 **Proposed topologies of the voltage-gated, cyclic nucleotide-gated, two-P-domain K^+ channel and Ca^{2+}-activated BK channels expressed in mammalian kidney.** The pore loops are indicated in each channel. Note the two pore loops for the two-P channel.

co-transporter, and to generation of the lumen-positive transepithelial voltage that drives 50% of the reabsorbed sodium through the paracellular pathway.[184,185] ROMK channels with some of the Bartter's mutations express either no or little function in *X. laevis* oocytes,[186–188] consistent with mutations in *KCNJ1* in Bartter's syndrome resulting in ROMK loss-of-function. Based on the location of the amino acid residue altered with certain KCNJ1 mutations (e.g., at or near phosphorylation sites or the nucleotide-binding site), the resultant ROMK channels would be expected to exhibit altered gating (see discussion above on "Regulation of the ROMK K^+ Channel"). A ROMK-deficient mouse has been developed and exhibits a Bartter's-like phenotype.[189,190]

While both human and mouse studies clearly demonstrate the importance of ROMK in TAL function, several questions regarding the resulting Bartter's phenotype remained. First, two types of apical K^+ channels have been observed in the rat TAL,[40] an SK channel with characteristics typical of ROMK and an intermediate conductance (~70 pS) channel that is similar only in some properties with ROMK. In rat TAL cells, however, the 70 pS channel predominates, so that mutations in the ROMK gene that generate inactive SK channels would only be expected to have minimal effect on the apical K^+ conductance of TAL cells. This has suggested that the intermediate conductance channel requires ROMK for function (e.g., either as a subunit or as a regulator). This possibility has been established by the absence of 70 pS K^+ channels in the TAL from ROMK null mice.[191] Second, ROMK comprises the apical K^+ secretory channel in principal cells of the CCD. Yet, Bartter's individuals with *KCNJ1* mutations are hypokalemic. This is due to the impairment of NaCl and fluid reabsorption in TAL which leads to increased NaCl and fluid delivery to the distal nephron, which stimulates K^+ secretion via the alternative flow-stimulated Maxi-K channel[94] (see section on "Maxi-K Channel" below).

OTHER RENAL POTASSIUM CHANNELS

Several other K^+ channels have been cloned from kidney-derived cell lines or are found in mammalian kidney (Figure 47.13). Physiological roles for these channels are less-defined than that for ROMK.

Ca^{2+}-Activated Big-Conductance K^+ Channels (BK, Maxi-K Channel)

The BK channel is composed of a pore-forming α-subunit (*Slo* 1), and an accessory β-subunit.[192,193] BK channel activity has been detected at the apical membrane of both principal cell (PC) and intercalated cell (IC), basolateral membrane of PC in the CNT and CCD[194,195] and in the podocytes where the BK channels may be involved in regulating glomerular filtration rate.[196]

BK IN THE APICAL MEMBRANE

Microperfusion experiments have demonstrated that BK channels are involved in mediated K^+ secretion during increased dietary K^+ intake.[197] However, the observation that the deletion of the BK channel α-subunit does not affect the net K^+ excretion in mice fed with a high-K^+ diet suggests that HK-induced stimulation of

ROMK channel expression and high plasma aldosterone level can compensate for deleting BK channels on K^+ secretion.[198] Although the role of BK channels in mediating flow-stimulated K^+ secretion has been firmly established,[198–201] it is still not completely-understood whether IC or PC is responsible for mediating the BK-dependent K^+ secretion. Patch-clamp experiments have demonstrated that apical BK channel activity is higher in IC than those in PC.[195] However, because IC has a low Na-K-ATPase activity, it is still arguable whether BK channels in IC significantly contribute to K^+ secretion in the collecting duct.[202] A recent study performed in *Kcnmb4*$^{-/-}$ mice in which the BK β4-subunit is deleted suggests the role of BK channels in IC in mediating flow-dependent K^+ secretion. Holtzclaw et al. have demonstrated that renal K^+ excretion was compromised in response to a HK intake in mice lacking the BK β4-subunit which is expressed in the apical membrane of IC in the CNT and CCD.[203] Furthermore, immunocytochemical staining shows that a high-K^+ intake decreased IC size in wild-type, but not in *Kcnmb4*$^{-/-}$, mice. Moreover, the flow rate speed was higher in knockout mice than those of wild-type mice. It is suggested that the BK channel in IC plays a role in K^+ secretion through decreasing IC size and increasing luminal volume of the CNT and the CCD, thereby creating conditions more favorable for K^+ secretion.

BK CHANNEL IN THE BASOLATERAL MEMBRANE

Immunocytochemical staining shows that BK α- and β1-subunits are expressed in the basolateral membrane of PC in the CNT and CCD, and their expression is stimulated by Na^+ restriction. The physiological function of basolateral BK channels in PC is possibly responsible for hyperpolarizing the basolateral membrane, thereby increasing the driving force for Na^+ absorption. The notion is supported by the observation that BK-β1($^{-/-}$) mice (*Kcnmb1*$^{-/-}$) have a higher Na^+ clearance than those of wild-type mice in response to low Na^+ intake.[204] The impaired function of basolateral BK channels in PC also affects the renal K^+ secretion in *Kcnmb1*$^{-/-}$ mice in response to a high-K^+ intake.[205] *Kcnmb1*$^{-/-}$ mice on a high-K^+ diet are hypertensive, volume-expanded, and have reduced urinary K^+ and Na^+ clearances, an effect which can be treated with mineralocorticoids receptor antagonist. This suggests that the impaired K^+ secretion results from high aldosterone levels which stimulate Na^+ transport in *Kcnmb1*$^{-/-}$ mice.

Regulation of BK Channels

DIETARY K^+ INTAKE

Real-time PCR analysis has demonstrated that a high K^+ intake stimulates the mRNA transcription of BK α-, β2-, and β4-subunits, but not β1, in the rabbit CCD.[206] Because a low-Na^+ intake, which increases aldosterone levels, fails to mimic the effect of a high-K^+ intake on the mRNA level of BK α- β2-, and β4-subunits, it excludes the role of aldosterone in regulating BK channel expression.[207] Also, the patch-clamp experiments demonstrated that a high-K^+ intake stimulates the BK channel activity in PC of the CCD.[194] Since inhibition of P38 and ERK activates BK channels in PC, and a high-K^+ intake suppresses both MAPK,[194] p38, and ERK, MAPK may be involved in mediating the effect of a high-K^+ intake on BK channels.

PKA AND PKC

Patch-clamp study has demonstrated that PKA and PKC inhibit BK channel activity in the PC of the CCD.[208] The role of PKA and PKC in regulating the flow-stimulated BK-dependent K^+ secretion in the CCD is also shown in the isolated perfused rabbit CCD. PKA induced a tonical inhibition of BK channels or an associated regulatory protein in PC. However, PKA has no inhibitory effect on BK channel in IC. It is possible that BK channels in PC and IC may be the results of different splice variants which respond to PKA in different ways.

CYTOCHROME P450 (CYP) EPOXYGENASE

BK channels in the PC are activated by CYP-epoxygenase-dependent metabolism of arachidonic acid, an effect which is also mimicked by 11,12-epoxyeicosatrienoic acid (11,12-EET), a main product of CYP-epoxygenase-dependent metabolism in the kidney.[209] Because a high-K^+ intake increased 11,12-EET levels in the CCD and stimulated the expression of CYP2C44 homolog, a main CYP-epoxygenase in the kidney, 11,12-EET may play a role in stimulating BK channel-dependent K^+ secretion during a high-K^+ intake. This notion is also supported by the finding that inhibition of CYP-epoxygenase abolished the flow-stimulated and BK-dependent K^+ excretion in the isolated rabbit CCD.[209]

Other 6-TM Renal K^+ Channels

The voltage-gated K^+ (Kv) channels are expressed in the kidney, and their function in regulating epithelial transport is well-documented.

KCNQ1 CHANNEL

KCNQ1 forms a small conductance (2–10 pS) Kv channel in kidney, existing as a heteromultimeric complex with KCNE1 (minK). MinK has a single transmembrane segment and is highly-expressed at the apical membrane. KCNQ1 and KCNE1 have been

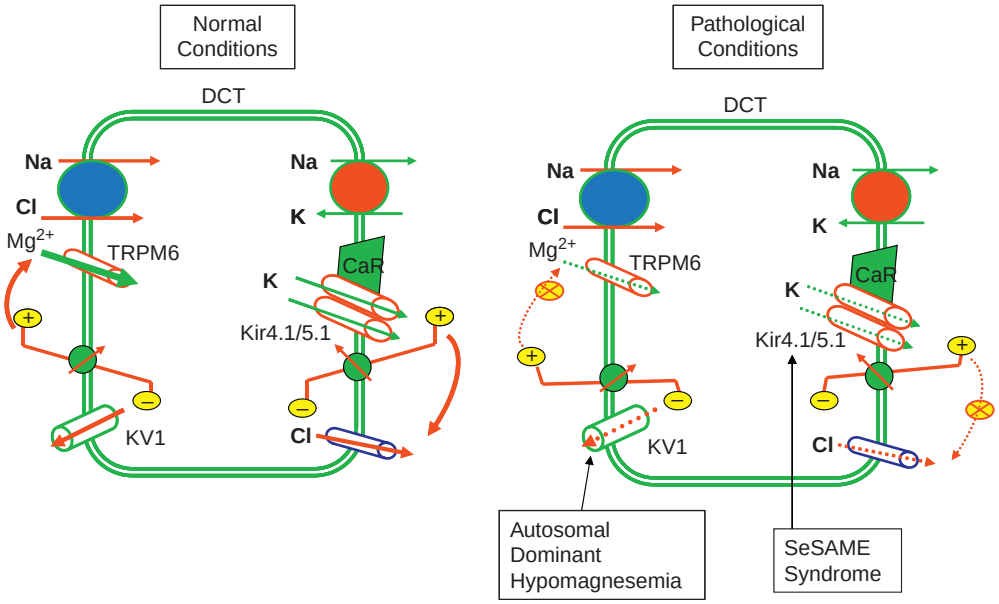

FIGURE 47.14 **A cell model illustrating the role of Kv1 and Kir4.1/5.1 in regulating Mg^{2+} transport and transepithelial Cl^- transport in the DCT.** SeSAME syndrome (for seizures, sensorineural deafness, ataxia, mental retardation and electrolyte imbalance).

extensively characterized in heart, where they play crucial roles in cardiac repolarization.[210–212] Mutations of these genes cause long QT syndrome. Immunostaining has demonstrated that voltage-gated K channels, such as ERG1 and KCNQ1, are expressed in the apical membrane of DCT and collecting duct.[213,214] The voltage-gated K^+ channels may prevent the membrane depolarization that occurs following stimulation of electrogenic Na^+-coupled transport of glucose or amino acids.[215] Accordingly, KCNE1 deficient mice exhibit a reduction in glucose and amino acid uptake, and defective volume regulation in the proximal tubule.[216] However, additional Kv channels and BK may also participate in stabilizing proximal tubule membrane potential during electrogenic Na^+ uptake.

KCNA1 FAMILY CHANNEL

A genetic study has revealed that voltage-gated K^+ channels (Kv1.1; KCNA1), which are expressed in the apical membrane of the DCT, play a role in regulating Mg^{2+} transport in the DCT.[217] A missense mutation in the Kv1.1 voltage-gated K channel caused human autosomal dominant hypomagnesemia. Figure 47.14 is a model illustrating the possible role of Kv1.1 in regulating Mg^{2+} transport in DCT. The activation of voltage-gated K channels is expected to hyperpolarize the apical membrane, thereby increasing the driving force for Mg^{2+} absorption through transient receptor potential cation channel 6 (TRPM6). Defective Kv1.1 channel function would impair the hyperpolarization of apical membrane potential, thereby decreasing the driving force for transepithelial Mg^{2+} transport through TRPM6.

KCNA10 is found at the apical membrane of the proximal tubule.[218] The *KCNA10* gene is located on 1p11–13, and transcripts are expressed in kidney, heart, and aorta. KCNA10 has 58% amino acid identity with Kv1.3, which also resides at 1p11–13.[219] The predicted secondary structure is identical to that of other Shaker-related K^+ channels, including intracellular N- and C-termini, 6 transmembrane segments, a voltage sensor (S4), and a pore (P) region. Unlike Shaker proteins, however, KCNA10 contains a putative cyclic nucleotide (CN)-binding domain at the C-terminus, suggesting that protein function is regulated by cyclic nucleotides (Figure 47.13).

2-TM Renal K^+ Channel (Non-ROMK)

Kir4.1 (KCNJ10), Kir4.2 (KCNJ15), AND Kir5.1 (KCNJ16) CHANNELS

Heteromeric Kir4.1/Kir5.1 and/or Kir4.1/Kir5.1 channels form the basolateral small conductance K^+ channel in distal nephron segments.[220] The inward rectifier K^+ channel, Kir4.1, was originally identified from rat brain, and exhibits 53% amino acid identity to ROMK1.[221,222] The kidney also expresses Kir4.1 mRNA, and the channel protein has been immunolocalized to the basolateral membrane of distal nephron segments, including DCT, CNT, and CCD.[223] Internal protons decrease Kir4.1 K^+ current by reducing open probability, however, internal protons also increase

channel conductance.[224] Mice with deletion of the Kir4.1 gene (KCN10) have been generated[225] but, due to early lethality in the neonatal stage, renal phenotype has not been examined.

Kir4.2 was originally cloned from human kidney and called Kir1.3.[31] While this study reported that Kir4.2 channels were not functional in *X. laevis* oocytes,[31] subsequent studies have shown that this protein forms inward rectifying K^+ channels that are inhibited by protein kinase C and internal protons.[220,226] Kir4.2 mRNA is found in human[31] and mouse[220] kidney, and in the latter species, specifically in the DCT.

The inward rectifier K^+ channel, Kir5.1, was also cloned from rat brain, but does not form functional K^+ channels by itself when expressed in *X. laevis* oocytes.[221] Kir5.1 mRNA is present in kidney,[221,227] and channel protein is abundantly expressed in PT, and in DCT and CCD segments,[228] where Kir4.1 is also expressed.[223] Recent studies have demonstrated that Kir4.1 or Kir4.2 can form heteromeric inward rectifying K^+ channels with Kir5.1 with distinct properties in the heterologous expression systems,[220,227,229] as well as in the native kidney.[227] The heteromeric interaction of Kir5.1 with other Kir K^+ channels is specific for Kir4.x channels, and requires a small region in the proximal COOH-terminus of Kir4.1.[229]

Patch-clamp experiments, immunocytochemical and molecular biological methods have confirmed the expression of several inwardly-rectifying K channels in the basolateral membrane.[204,230–233] Two lines of evidence suggest that Kir4.1/5.1 heterotetramers are the main type of K channels in the basolateral membrane in the ASDN: (1) the Kir4.1 protein is detected in the basolateral membrane of the DCT and the CCD[220,232]; and (2) the patch-clamp experiments have shown that Kir4.1/Kir5.1 channels form the major K channels in the basolateral membrane of principal cells (PC) in the CCD.[232] The most dramatic and specific effect of the Kir4.x-Kir5.1 assembly on K^+ channel function is the shift in the pKa for inhibition by internal protons from 6.0 to the physiologically relevant pKa of 7.4.[227,228,234,235] Internal pH sensitivity of Kir4.1-Kir5.1 is modulated by PIP_2,[236] similarly to Kir1.1 (ROMK).[237]

Kir4.1 has been shown to interact with Ca^{2+}-sensing receptor which inactivates the K channels.[238] Because Kir4.1 participates in generating the cell membrane potential, activation of Ca^{2+}-sensing receptor is expected to depolarize the membrane potential, thereby inhibiting transepithelial Na/Cl transport in the DCT. The importance of Kir4.1 in regulating membrane transport in the DCT is best demonstrated in patients with EAST (for epilepsy, ataxia, sensorineural deafness, and tubulopathy)[239] or SeSAME syndrome (for seizures, sensorineural deafness, ataxia, mental retardation and electrolyte imbalance).[240] The disease is caused by defective gene product encoding KCNJ10 (Kir4.1), which is expressed in a variety of tissues including in the basolateral membrane of the ASDN. The renal phenotypes of EAST/SeSAME syndrome are hypokalemia, metabolic alkalosis, and hypomagnesemia.[239,240] Figure 47.14 is a cell model illustrating the role of Kir4.1/5.1 in regulating NaCl transport in the DCT. Activation of Kir4.1/5.1 is expected to increase the negativity of basolateral membrane, thereby providing the driving force for Cl^- exit across the basolateral membrane. In contrast, defective Kir4.1 depolarizes the basolateral membrane, thereby diminishing the driving force for Cl^- exit across the basolateral membrane. Consequently, delivery of NaCl to the CNT and CCD is increased and leads to enhanced Na absorption in the CNT and CCD at the expense of K^+-wasting, resulting in hypokalemia and metabolic alkalosis. It was suggested that decreased basolateral membrane potential impairs Mg^{2+} absorption in the DCT, due to a compromised driving force for Mg^{2+}.[44]

Kir2.3 (KCNJ4) CHANNEL

In cortical collecting duct principal cells the maintenance of the negative membrane potential depends, at least in part, on the activity of an inwardly rectifying 18 pS K^+ channel. This basolateral K^+ channel has been suggested to be the inwardly rectifying K^+ channel, Kir2.3.[241] The kidney Kir2.3 was cloned from a mouse CCD cell line and its expression in kidney confirmed by Northern analysis.[241] When the MDCK cells were transfected with Kir2.3, the channel is expressed in the basolateral membrane,[242] and a basolateral sorting signal was identified at the COOH-terminal tail.[243,244] Kir 2.3 shares some biophysical properties with the native 18 pS K^+ channel, such as high open probability and channel conductance, 14.5 pS.[241]

Kir6.1 (KCNJ8) CHANNEL

Kir6.1 was originally cloned from a rat pancreatic islet cell cDNA library using Kir3.1 as a probe,[245] and belongs to the Kir6.x (ATP-sensitive; K_{ATP}) subfamily of inwardly rectifying K^+ channels.[2,246] Exogenous expression of Kir6.1 channels in *X. laevis* oocytes form ATP-sensitive channels only when co-expressed with a sulfonylurea receptor protein.[246,247] Although this inward rectifier is predominantly found in brain, heart, and vascular tissue, expression in kidney has been documented.[245,248] Kir6.1 has been localized to both mitochondria[249] and plasma membranes.[249,250] Upregulation of Kir6.1 mRNA has been observed following ischemic injury in rat kidney, consistent with the proposed role of K_{ATP} channel activation in protection from ischemic damage (e.g., in the heart[251]). Recently, Kir6.1 was cloned from rabbit proximal

tubule cDNA library, and expression of Kir6.1, SUR2A, and SUR2B in rabbit proximal tubule confirmed by PCR.[250] Functional studies in *X. laevis* oocytes suggested that Kir6.1 may form the basolateral ATP- and taurine-sensitive K^+ channel involved in the basolateral K^+ conductance of proximal tubules.[250] Adenylate kinase, which promotes phosphoryl transfer between ATP and ADP and associates with K_{ATP} channels,[252] has been cloned from the rabbit proximal tubule library,[253] and may associate with Kir6.1 in these cells to promote metabolic sensing.

Kir7.1 (KCNJ13) CHANNEL

The inward rectifier K^+ channel, Kir7.1, was originally cloned from human brain cDNA libraries after searching the GenBank expressed sequence Tag (EST) database using Kir1.1 and Kir6.2.[254,255] The Kir7.1 K^+ channel displays unusual K^+ permeation properties, with a low single channel conductance of 50 fS, low sensitivity to blocking by external Ba^{2+} or Cs^+, and very low dependence of conductance on external K^+.[254–256] PCR and Western blot analyses have identified Kir7.1 transcripts and protein, respectively, in rat, guinea pig, and human kidney.[254,255,257,258] Expression of Kir7.1 along the rat nephron was demonstrated by Western blots of microdissected nephron segments,[258] which showed K^+ channel protein in TAL, DCT, CNT, CCD, OMCD, and IMCD.[258] Immunostaining localized Kir7.1 to basolateral membranes of DCT and principal cells.[258] In the guinea pig, Kir7.1 protein is expressed in basolateral membranes of proximal tubule and TAL cells.[257] In the CCD, Kir7.1 is expressed in principal cells, but not intercalated cells. The unique pore properties of Kir7.1 and its localization close to Na-K-ATPase suggested that this K^+ channel may be functionally coupled to Na-K-ATPase, and involved in K^+ recycling across basolateral membranes.[258,259]

The Two-Pore K^+ Channels (K_t)

In CNT and CCD, a double-pore K channel (KCNK1) is expressed in the apical membrane.[38,260–262] However, the physiological function of the two-pore K channels in the CNT or CCD is still not clear. The most recently-discovered class of K^+ channels is characterized by a topology containing two pores or P-loops. These channels are also appropriately referred to as the "two pore domain" (or K_t, two-P, TWIK-related) K^+ channels (e.g., see [263]). K_t channels exhibit four membrane spanning domains consisting of two Kir-like domains that are linked in a single subunit (see Figure 47.13[263–269]). Structurally similar channels have been identified in the *C. elegans* genome project and represent the most abundant class of K^+ channels in this species.[270] The TWIK-related channels, including TWIK-1,[263,264,266–269,271] TWIK-2,[265] TREK-1,[263,272,273] TASK-1,[263,274] and TASK-2,[263] are all expressed in mammalian kidney.[263]

Both TWIK-1[267] and TWIK-2[265] express weakly inward-rectifying K^+ channels that are inhibited by intracellular acidification. Transcripts for TWIK-1 are expressed in rabbit cortical TAL and collecting duct,[269] and TWIK-1 protein has been localized to the brush border of proximal convoluted tubules, intracellular and apical border of intercalated cells in the CCD, and in cortical and medullary TAL cells.[266] TREK-1 gives rise to mechanosensitive outward-rectifying K^+ currents that are activated by arachidonic acid and are inhibited by protein kinases A and C.[272,275] TASK channels exhibit noninactivating outward-rectifying K^+ currents that are very sensitive to external pH.[263,274] While the properties of TWIK-related K^+ channels do not fit with any of the known native K^+ channels in kidney, their widespread expression in mammalian and other organisms (e.g., *C. elegans*) suggests either that they have been missed in patch-clamp recording or that they associate with other (unidentified to date) subunits to produce pores with native channel properties.

SUMMARY AND CONCLUSIONS

While we have gained significant insights into the structural diversity of K^+ channels expressed in the mammalian kidney, many new channels will likely be identified in the near future. Likewise, electrophysiological studies continue to expand our database of physiologically and pharmacologically distinct K^+ channels. The exciting challenge is to identify which channel genes encode which native channels. Given that many K^+ channels are probably comprised of more than one subunit (e.g., the K_{ATP} channels), this challenge is somewhat daunting, and will require many more years of investigation. Finally, we expect that new inherited disorders due to mutations in some of these channel genes (channelopathies) will be identified. These channelopathies will not only provide new insights into the physiological roles of K^+ channels, but will likely raise new questions as it has for ROMK mutations in Bartter's syndrome.

Extrarenal Potassium Metabolism

Vaibhav Sahni, Aleksandra Gmurczyk, Robert M. Rosa

The Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Internal potassium homeostasis is defined as the regulation of potassium distribution between the intracellular and extracellular fluid compartments, as distinct from the net gain or loss of potassium from the body. While the kidney plays the predominant role in maintaining external potassium balance, nonrenal tissues, especially muscle and liver, are quantitatively the most important organs involved in the regulation of internal potassium balance.

The ratio of potassium between intracellular and extracellular fluids is critically important, not only to the behavior of electrically excitable cells, such as muscle and nerve, but also to the vital processes of all living cells. The reason for this is that a major regulator of cell function is the transmembrane potential. The determinants of this membrane potential are described by the Goldman–Hodgkin–Katz equation, the most important term of which is the logarithm of the ratio of internal to external ionic activity of potassium.

Of the 3500 mEq of potassium found in the body of a 70 kg human, about 98% is confined to intracellular water (Figure 48.1). Of this, 80% is contained in muscle cells, at a concentration of about 150 mEq/liter. The remaining 2% of total body potassium (about 70 mEq) is located in the extracellular fluid (about 14 liters), where the normal concentration is 3.5–5.5 mEq/liter. The chief biological mechanism responsible for maintaining this 30-fold potassium gradient between cell water and extracellular fluid is the Na,K-ATPase pump, situated in the plasma membrane of all animal cells. A minor role is played by the inward transport of potassium coupled with sodium and chloride, via the Na–K–2Cl transporter in the plasma membrane of some cells. Transcellular distribution of potassium is also modulated by hormonal factors, such as insulin and catecholamines, by hydrogen ion balance, plasma osmolality, intracellular potassium content, and by factors that affect the passive movement of potassium through membrane channels, such as the level of intracellular calcium and pH (Table 48.1). Some of these factors, such as the activity of Na,K-ATPase and the distribution of hydrogen ions, may concurrently affect the potassium content of cells of the distal nephron, and thereby influence the external balance of potassium.

From a practical standpoint, a key determinant of transmembrane potential is the plasma potassium. Since the concentration of potassium inside cells far exceeds extracellular concentration, percentile changes in intracellular potassium are relatively small, even during extreme degrees of total body potassium surfeit, deficit or internal redistribution. The changes in extracellular potassium seen in diseased states are therefore much more likely to alter the membrane potential of cells than are concomitant changes in intracellular potassium. For this reason, a variety of mechanisms have evolved to preserve the extracellular concentration of potassium within the normal range.

If a moderate load of potassium (0.5 mEq/kg) is administered intravenously over 1 hour, about 40% of it is excreted into the urine at the end of that time. Within 3 hours, renal excretion is complete and the serum potassium, which initially increases by about 0.6 mEq/liter, returns to baseline.[1,2] The ability of the normal human kidney to excrete all of an oral load of potassium is more sluggish; while potassium excretion increases 6-10-fold within a few hours,[3–5] only about half of the load is excreted during the first 3–6 hours after it is ingested.[5–9] Of considerable interest, however, is recent evidence that is consistent with the existence of an unidentified "gut" and/or "hepatoportal factor" that senses potassium ingestion, and

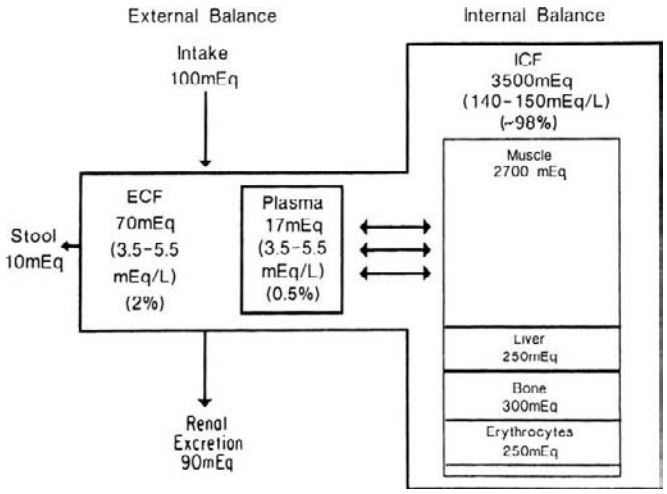

FIGURE 48.1 **Internal potassium homeostasis in a 70 kg person.** The potassium concentration in the extracellular fluid (ECF) depends on both the external balance (intake and output) and the internal balance (distribution between extracellular and intracellular fluid, ICF). Factors affecting internal balance are listed in Table 48.1. Note that the large ICF pool exists at a far greater K concentration than the small ECF pool; the ECF pool will therefore change more dramatically with changes in total body K or K distribution.

TABLE 48.1 Factors Affecting Internal Potassium Homeostasis

Factor	Effect on Potassium
Insulin	Enhanced cell uptake
β-Catecholamines	Enhanced cell uptake
α-Catecholamines	Impaired cell uptake
Acidosis	Impaired cell uptake and enhanced efflux[a]
Alkalosis	Enhanced cell uptake and reduced efflux[a]
External potassium balance	Loose correlation
Drugs	See text
Hyperosmolality	Enhance cell efflux

[a]*Degree varies with disturbance.*

rapidly initiates the process of renal potassium excretion in the absence of a significant change in plasma potassium concentration.[10,11]

Consumption of only 35 mEq of potassium by a 70 kg adult during an average meal (an amount equivalent to 1% of total body potassium) would, if confined exclusively to the extracellular space, raise the plasma potassium by 2.5 mEq/liter – enough to have pronounced effects on neuromuscular function. It is well-established, however, that a potassium load given to a normal human or dog has an apparent volume of distribution of 70–80% of body weight, somewhat greater than total body water,[6,12] instead of the 20% that represents extracellular fluid. In other words, only a small portion (about one quarter) of the 35 mEq of ingested potassium will normally remain in the extracellular compartment, raising the concentration of potassium in plasma by only about 0.6 mEq/liter. In contrast, a similar load of potassium administered to patients with deranged extrarenal potassium homeostasis may produce serious hyperkalemia.[13]

The cells also buffer plasma potassium during potassium depletion. In states of progressive potassium deficiency, as depletion worsens, a greater amount of potassium is lost from within cells to lessen the fall in external concentration, and to minimize the alteration in its intracellular to extracellular ratio.

These examples of potassium surfeit or deficit emphasize the critical role of internal potassium homeostasis in mitigating potentially dangerous changes in the plasma potassium. Disorders of the factors that mediate this adjustment thus may have substantial clinical importance and are the primary topic of this chapter.

POTASSIUM DEPLETION AND REPLETION

In many conditions, such as vomiting, diabetic ketoacidosis, and chronic renal failure, abnormalities of internal and external potassium homeostasis coexist. Just as internal potassium homeostasis can affect potassium uptake and excretion by the kidney, so changes in external potassium balance, by altering cellular potassium content, can independently influence internal potassium homeostasis.

Potassium Depletion

The idealized curvilinear relationship between total body potassium and the serum potassium concentration illustrated in Figure 48.2 is derived from several measurements in hypokalemic patients with positive potassium balance during replacement therapy,[14–16] and from unpublished data on hyperkalemic humans and animals.[17] In the early stages of depletion, extracellular potassium loss is proportionately greater than the loss of cellular potassium.[18] Nonetheless, since only a small fraction of total body potassium is extracellular, the quantity of potassium lost from the extracellular compartment is much smaller than that lost from inside cells.

In the early phases of hypokalemia (>2.5 mEq/liter), patients tend to display an almost linear relationship between total body potassium and the serum

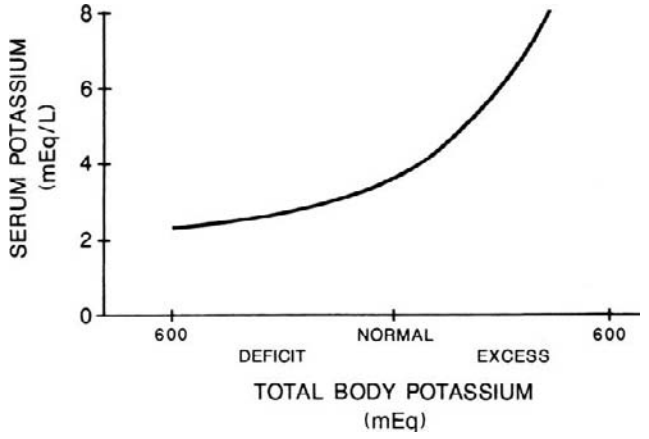

FIGURE 48.2 **Idealized relationship between the serum potassium concentration and the body potassium content.** *Reprinted with permission from ref. [17].*

potassium concentration. It has been observed that a change of 100–200 mEq in total body potassium (about 5%) is required to lower the serum potassium by 1.0 mEq/liter.[17] In such a situation, the extracellular potassium concentration would be expected to fall proportionately more (e.g., 4.0 to 3.0 mEq/liter) than the intracellular concentration (e.g., 140 to 133 mEq/liter). Because of the relationship of cell membrane potentials to the ratio of internal to external ionic activity of potassium, excessive extracellular potassium loss would be expected to hyperpolarize cells (resting membrane potential is increased). This expectation has been confirmed in studies of early potassium deficiency in both dogs[19] and humans.[20]

When potassium depletion becomes more severe, so that serum levels fall below about 2.5 mEq/liter, a further 1.0 mEq/liter fall will represent a much larger 200–400 mEq decrement in total body potassium (greater than 10%), reflecting a greater degree of potassium loss from within the cells[17,21] than occurred in the early phases of depletion. Decreased cell potassium content has, in fact, been observed in several tissues during severe hypokalemia.[15,22,23]

In severe potassium depletion cells tend to depolarize (resting membrane potential is decreased), at least in dogs[19] which, like humans, then develop weakness and muscle paralysis. Under conditions of chronic hypokalemia, however, there is also upregulation of the colonic form of H,K-ATPase (HKα2), which leads to enhanced potassium reabsorption from the gut.[24]

Potassium Repletion

During potassium repletion for severe hypokalemia, cellular potassium uptake is enhanced both in animals[25,26] and in humans[27]; that is, the administered potassium has an increased volume of distribution; as potassium is gained by the body and the stores become higher, the cellular uptake of potassium decreases. In anuric humans, for example, the cellular uptake of a potassium-load decreases as total body potassium increases.[27] Extracellular potassium then tends to rise and membrane potential decreases.[28] The important therapeutic caveat in the late phases of correction of potassium depletion is that less potassium administration is required than in earlier phases to increase serum potassium, which may rise suddenly to unexpected, dangerously hyperkalemic levels.[29]

As reviewed extensively by Sterns et al.,[27] the serum potassium alone is, at best, an extremely rough guide for estimating potassium replacement therapy, presumably because other factors, such as acid–base status, influence it. A low serum potassium value (e.g., 3.0 mEq/liter) may be associated with a range of total body deficits spanning a few hundred millequivalents (Figure 48.2).

The exact mechanisms that produce this curvilinear relationship are uncertain. They may stem in part from impairment of the electrogenic sodium pump.[19,30,31] During potassium depletion in rats, skeletal muscle potassium loss is associated with a reduced capacity for Na-K pumping and a reversible decrease in the number of [^{3}H] ouabain-binding sites.[32] A possible mechanism for suppression of the Na-K pump during potassium depletion is enhanced stimulation of alpha-adrenoreceptors[33] (see "Catecholamines"). In addition, even modest dietary potassium restriction provokes resistance to insulin-mediated cellular potassium uptake (see "Insulin").

INSULIN

The effect of insulin on potassium homeostasis was first demonstrated two years after its purification by Banting and Best. Harrop and Benedict,[34] and Briggs and Koechig[35] described the fall in serum potassium coincident with lowering of blood sugar when insulin was administered to diabetic patients, as well as in the non-diabetic human, dog, and rabbit. Later, there were reports of severe hypokalemia in insulin-treated patients with ketoacidosis who developed paralysis.[36]

Cellular Mechanism

The hypokalemic action of insulin derives from its capacity to cause net potassium uptake in skeletal muscle,[37–39] adipose tissue, and hepatic cells,[40–42] as well as other extrarenal sites.[43] This effect was formerly assumed to occur to preserve electrical neutrality when

insulin-mediated glucose uptake produced intracellular anionic sugars[44,45] and deposited potassium as an accompaniment of glycogen in the liver.[46]

This classical hypothesis did not explain the clinical observation that sudden lowering of serum potassium could precede the fall in blood sugar in insulin-treated diabetic coma. Zierler[47] first noted that insulin's effect on potassium movement in rat muscle occurred even in the absence of glucose; its known effect to increase sodium efflux *in vitro* also occurred without glucose.[48] Furthermore, enhancement of potassium disposal in the intact animal was separable temporally from glucose uptake[49,50] and occurred at plasma insulin concentrations having no measurable influence on uptake of glucose *in vivo*.[51] Different receptor mechanisms for potassium and glucose transport appear to exist.[45]

In vitro, insulin is known to stimulate both potassium uptake[52,53] and sodium efflux[37,54] in frog and rat muscle preparations. Similar effects have been reported in rat adipose tissue,[55] hepatocytes,[56] and other cells.[57] Considerable evidence[45] suggests that following binding to cell surface receptors,[58] insulin accelerates monovalent cation transport by stimulating Na,K-ATPase, the sodium-potassium pump. Most convincing is the fact that both insulin-stimulated net sodium efflux and potassium influx are blocked by ouabain.[37,52,54,59] *In vitro*, addition of insulin to purified plasma membrane of skeletal muscle increases the activity of the Na,K-ATPase.[60] Little evidence is currently available on whether insulin affects potassium permeability or potassium channels in skeletal muscle cells. Insulin activation of sodium−hydrogen exchange sensitive to amiloride[61] does not appear to be important to sodium-pump-mediated potassium uptake.[62] In adipocytes, insulin-stimulated uptake of K^+ and Rb^+ is inhibited by bumetanide and by removal of Cl^- from the extracellular fluid, suggesting a primary action of insulin on the Na−K−2Cl co-transporter.[63] On the other hand, in skeletal muscle, insulin does not appear to activate the co-transport of K^+ with Na^+ and Cl^-.[64] There is evidence, however, that the serum and glucocorticoid-inducible kinase SGK1 participates in the different signaling pathways that mediate the hypokalemic effect of insulin.[65]

Stimulation of active sodium−potassium transport by Na,K-ATPase could be due to a *de novo* increase in the number of sodium pump sites or to allosteric activation of existing sites. The latter theory is consistent with the rapid activation of transport that occurs,[66] as well as with the lack of new ouabain-binding sites[67,68] after exposure to insulin *in vitro*.

At least three molecular forms of the Na,K-ATPase catalytic subunit have been identified, designated alpha1, alpha2, and alpha3. In both rat and human skeletal muscles, insulin mediates the Na,K-ATPase alpha1- and alpha2-subunit translocation into the plasma membrane via a phosphatidylinositol 3-kinase-dependent mechanism.[69] In liver, the effect of insulin can be accounted for by increased intracellular sodium concentration.[56] Insulin also activates a KCl co-transporter uptake system in a cultured cell line resembling skeletal muscle.[70]

It should be noted that insulin is known to produce hyperpolarization of cellular membranes, not only in skeletal muscle,[71,72] but in a variety of other tissues.[73,74] This rapid effect appears to precede measurable increases in intracellular potassium.[39] Although stimulation of Na,K-ATPase could account for insulin's hyperpolarizing effect,[75] failure of ouabain to block it, at least in some studies, suggests that changes in ion permeability may be responsible. The role of hyperpolarization in mediating insulin effects on cation transport is uncertain. The effect of insulin to stimulate active sodium and potassium transport in skeletal muscle is mimicked by insulin-like growth factor I (IGF-I).[76]

In Vivo Effects

Abundant evidence therefore exists that insulin increases net uptake of potassium ions by several tissues *in vitro*. Since skeletal muscle is well-documented to respond to insulin and is the major body reservoir for potassium, it is most likely the dominant site for insulin-stimulated extrarenal potassium disposal *in vivo*. Human forearm muscle (and adipose tissue) increases potassium uptake during arterial infusion[51] of insulin.

Wilde[77] noted over half-a-century ago that injected potassium rapidly disappeared from the blood of cats, but was followed by a secondary rise in serum potassium. Recent investigation suggests that, at least during insulin infusion, hepatic disposal plays an important role in potassium homeostasis in the first hour of exposure to insulin in humans.[78] Splanchnic uptake accounted for two-thirds of the fall in plasma potassium during euglycemic hyperinsulinemia. In the second hour, net splanchnic uptake reversed, and peripheral tissues became the dominant site of potassium disposal.

That the effect of insulin on extrarenal potassium homeostasis is dose related is well-established[79,80] (Figure 48.3). In normal subjects, neither intramuscular nor subcutaneous administration of insulin, which achieved plasma insulin levels of about 50 μU/ml, decreased the plasma potassium.[81] Intravenous insulin injection, by comparison, produced 40-fold greater insulin levels, which were accompanied by a steady-state reduction in plasma potassium, with a maximal effect of about 30% occurring 50 minutes after insulin injection.

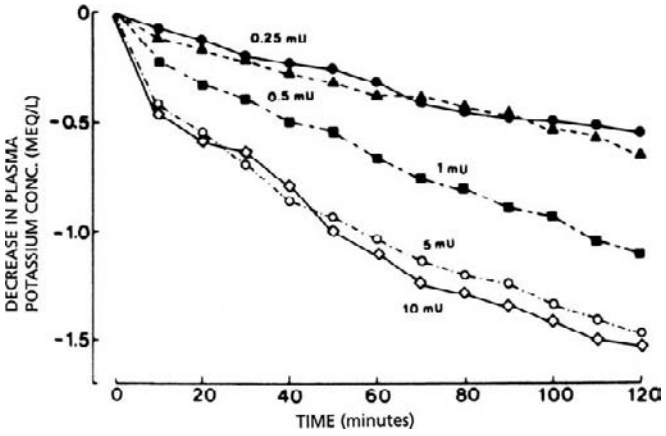

FIGURE 48.3 **Dose-related effect of euglycemic hyperinsulinemia on plasma potassium concentration.** Infusion of insulin at the doses shown produced plasma insulin levels of approximately 25, 50, 100, 500, and 1000 μU/ml above basal values. *Reprinted with permission from ref. [79].*

On the other hand, much smaller increments of insulin, about three-fold above basal values, either during constant venous[78,82] or intra-arterial infusion[49,51,83] also appear capable of augmenting potassium uptake *in vivo*.[27] Under conditions of prolonged potassium depletion, however, the expression of skeletal muscle Na,K-ATPase α2 isoform is decreased, which allows for enhanced efflux of potassium from muscle to the extracellular space.[84] Of particular interest is the observation that even modest dietary potassium restriction leads to a decrease in insulin-mediated cellular potassium uptake in rats in the absence of a fall in plasma potassium concentration.[85]

Clinical Implications

The relevance of these findings to a given clinical situation of exogenous potassium challenge will depend on the magnitude of potassium-load requiring disposal, and the elevation of insulin accompanying it. Following carbohydrate feeding, for example, increased liver uptake of potassium occurs.[46] Since peripheral venous insulin levels for 2 hours following oral glucose loading are elevated five-fold,[86] well within the range capable of augmenting potassium uptake, it seems likely that insulin contributes to the transient decrease in potassium that occurs after feeding.[87] Even basal circulating insulin levels may be essential to disposal of an acute potassium-load, since disposal is impaired when basal levels are decreased 50% by somatostatin.[88] The effect of carbohydrate meals to blunt or prevent hyperkalemia may be particularly important in anuric patients dependent on extracorporeal dialysis.[89]

During exogenous potassium challenge, the importance of insulin to potassium disposal by the intact organism deprived of endogenous insulin[90–93] or resistant to the actions of insulin[94] is well-established. As expected, supraphysiologic doses of exogenous insulin are capable of improving potassium tolerance.[92] Thus, for emergency treatment of hyperkalemia, the intravenous administration of insulin together with glucose is indicated, unless the patient is already hyperglycemic from diabetes in which case additional glucose is not warranted.

The ability of potassium-loading to stimulate the release of pancreatic insulin directly, in amounts sufficient to contribute to disposal of that potassium, is less clear. In pancreatic B-cells, ATP-sensitive K channels link cellular membrane potential to hormone secretion.[95] These channels control the transmembrane potential, and thereby the calcium channels that trigger glucose-induced insulin secretion.[96] Depolarization of the cell membrane (as expected with hyperkalemia) induces an increase in insulin secretion.[97] In humans[98] and intact dogs,[99–101] minor increments in blood potassium appear capable of triggering pancreatic insulin secretion. Since elevations in portal venous insulin far exceed those in the peripheral circulation when insulin release is stimulated,[100,102,103] it seems reasonable to conclude that, under conditions of significant hyperkalemia, induction of insulin release to promote potassium uptake does constitute a homeostatic feedback control system.

GLUCAGON

The effect of glucagon on extrarenal potassium disposal has been difficult to isolate, because the hormone also influences the secretion of insulin, epinephrine, and aldosterone. Administration of glucagon to cats does appear to mobilize potassium from the liver and produce a transient rise in arterial potassium levels.[104] In humans, the hyperkalemic response to the hormone appears to be only partly due to an epinephrine-like effect of glucagon to increase liver glycogenolysis.[105]

For example, aortic injection of glucagon in humans, which results in hepatic vein glucagon levels within the pathophysiologic range, causes a transient increment in hepatic vein potassium concentrations, but this precedes the slow rise in glucose in hepatic venous blood.[106] The specific source of the modest rise in hepatic venous potassium under these conditions has not been determined. Previous *in vitro* investigations using perfused rat liver suggest that glucagon releases potassium directly from the liver.[41,107] The effect would not appear to be due to diminished Na−K pump-mediated potassium uptake, since isolated rat hepatocytes

exposed to glucagon actually undergo stimulation of this cation pump.[108]

Systemic infusion of glucagon to physiologic levels tends to elevate plasma potassium slightly by an extrarenal mechanism, at least when glucagon-induced insulin secretion is suppressed by somatostatin, both in normal subjects[105] and in diabetic subjects.[109] It is unclear whether hyperglucagonemia, which occurs in decompensated diabetes mellitus,[110] uremia,[111] and exhausting exercise[112] affect potassium homeostasis. In the dog, potassium-stimulated insulin release appears to be accompanied by a modest rise in circulating glucagon.[92,112]

CATECHOLAMINES

The observation of D'Silva[113] in 1934 that epinephrine lowers the serum potassium in cats has since acquired important physiologic and clinical relevance.[114–116] Although D'Silva emphasized the rapid rise in the serum potassium that followed a bolus injection of epinephrine (now felt to be a consequence of transient hepatic discharge of potassium by alpha-adrenergic stimulation),[117–119] of greater significance was the sustained "after-fall" in serum potassium that he observed. This secondary decrease in potassium was found to persist throughout a 1 hour infusion of epinephrine.[120]

Since epinephrine inhibited the renal excretion of potassium,[121,122] its late hypokalemic action was attributed to net uptake of potassium by extrarenal tissues. Indeed, *in vivo* limb studies in dogs[123] and humans,[124,125] as well as tissue analysis and ion flux studies, supported accelerated uptake of potassium, primarily in skeletal muscle,[126] but also in liver[126] and heart,[127] in response to epinephrine. *In vitro*, epinephrine was demonstrated to stimulate potassium uptake, as well as sodium efflux, by isolated skeletal muscle in both rats[128,129] and humans.[128] A similar effect was present in rat diaphragm,[130] cat cardiac muscle,[131] and frog sartorius muscle.[132]

Because epinephrine may influence insulin secretion, it was necessary to show that its hypokalemic effect was independent of insulin.[133,134] Independence from renin-mediated aldosterone release was established by the lowering of potassium despite nephrectomy.[135,136] Since extrarenal potassium disposal was impaired when nephrectomized rats were subjected to adrenalectomy or to chemical sympathectomy,[93] both circulating adrenomedullary epinephrine, as well as peripheral sympathetic nervous activity, appeared to be important sources of sympathetic influence on potassium.

Beta-Adrenergic Effects

Epinephrine stimulates both alpha- and beta-adrenergic receptors.[137] The conclusion that its hypokalemic action was a result of beta-adrenergic stimulation derived from experiments many years later employing beta-agonists and beta-antagonists.[119,123] Isoproterenol, a nonspecific beta-agonist, reproduced the prolonged hypokalemia earlier observed by D'Silva, and this effect was reversed by the beta-adrenergic-antagonist propranolol; likewise, epinephrine's effects on cation flux were blocked by beta-antagonists.[1,114]

Beta-agonists and -antagonists have been used to establish that the stimulating effect of catecholamines on potassium uptake is mediated by the beta2-receptor subtype.[138,139] Epinephrine's effect on potassium is prevented by the presence of nonselective beta-antagonists such as propranolol[1,115,123,131,141–143] and timolol,[144] as well as by the nonspecific alpha-beta blocker labetalol.[145] Less reversal occurs with the partially beta1-selective-antagonists metoprolol[146] and atenolol.[144] No effect on potassium appears to be produced by the more specific beta1-antagonist practolol.[131,147] In addition, the selective beta2-antagonists butoxamine[138,148] and ICI-118551[149,150] are able to block the hypokalemic action of beta-agonists.

Numerous studies of beta-agonists have revealed that several beta2-agonists, including salbutamol,[151–155] terbutaline,[136,156–158] fenoterol,[159] and ritodrine[156] lower potassium levels, unlike the beta1-agonist ITP,[131] which has no effect. These pharmacologic studies therefore provide strong support for beta2 mediation of adrenergic effects to enhance potassium disposal.

Mechanism of Action

The specific cellular mechanism by which cell surface beta2-receptor stimulation augments transcellular potassium uptake in affected tissues has been evaluated in detail. Compelling evidence exists to support the proposal of Clausen[114] that beta2-stimulation initiates cyclic AMP formation,[160] which leads to activation of the sodium pump (Na,K-ATPase), and therefore electrogenic sodium efflux accompanied by potassium uptake.[161] Beta receptors are known to stimulate adenylate cyclase,[38,160,162] enhancing conversion of intracellular ATP to cyclic AMP.[163] Linkage of beta receptors and cyclic AMP is supported by the ability of theophylline to potentiate the effect of epinephrine on cation transport and membrane potential,[114] as well as by the increase in membrane potential that dibutyryl cyclic AMP and theophylline produce in rat diaphragm muscle.[164] Epinephrine, in stimulating cation transport, is well known to produce hyperpolarization of membranes in skeletal muscle.[114]

The sodium pump of muscle cells and lipocytes is activated by cyclic AMP. For example, Na,K-ATPase activity in smooth muscle membrane fragments is enhanced by exposure to cyclic AMP.[165] The most compelling evidence that catecholamine-mediated potassium influx involves the beta-adrenergic system through activation of the sodium pump, however, are the demonstrations in a series of experiments that potassium influx occurs as active movement of the cation against its electrochemical gradient[166]; ouabain blocks the ability of epinephrine to promote potassium influx in rat soleus muscle[129]; epinephrine markedly increases the ouabain-sensitive 22Na efflux by stimulating the Na−K pump in frog skeletal muscle, and this effect is blocked by propranolol[167]; epinephrine produces membrane hyperpolarization and transient decreases in extracellular potassium and intracellular sodium, which is blocked by ouabain, in isolated rat soleus muscle and human intercostal muscle[128]; and isoproterenol directly stimulates the Na−K pump in isolated rabbit myocytes.[168] While the specific sequence of events linking beta-adrenergic stimulation to sodium pump activity has not been delineated, phosphorylation of some portion of the sodium pump after beta2-receptor stimulation is presumably involved.[166] Beta-adrenergic agents also stimulate the cellular uptake of potassium via the Na−K−2Cl transporter in the skeletal muscle membrane of rats.[64]

There are numerous clinical examples showing that enhanced exogenous or endogenous beta-adrenergic stimulation augments extrarenal potassium uptake in humans. Whether high potassium levels can stimulate secretion of endogenous adrenomedullary epinephrine, and thereby form a homeostatic feedback loop, remains unresolved. Supraphysiologic levels of potassium *in vitro* can cause the release of catecholamines from isolated chromaffin cells[169] and perfused adrenal glands,[170] possibly related to the membrane depolarizing effect of a high potassium level. Induction of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis,[171] by extremely high levels of potassium has also been observed. Reports that intra-arterial injections of KCl augment catecholamine release in cats[172] and in the dogfish shark[173] suggest a potential role for potassium as a catecholamine secretagogue *in vivo*.

Although specific stimulation of catecholamine release by potassium is not yet established, it is clear that physiologic elevations of endogenous catecholamines do enhance potassium uptake. Similar to the pharmacologic doses of epinephrine used in earlier animal reports of its protective effect during potassium-loading,[120,131,174] as well as its ability to lower basal potassium,[175] relatively small doses[1,140] have also been shown to enhance extrarenal disposal of an acute potassium-load. It has also been established that ambient potassium may be lowered when sustained epinephrine infusions[176] (Figure 48.4) elevate plasma concentrations of epinephrine to levels no higher than those observed in stressful conditions, such as myocardial infarction,[177] surgical stress,[178] and diabetic ketoacidosis.[179] By comparison, acute beta blockade does not appear to elevate fasting potassium levels,[176] suggesting that basal beta-adrenergic tone plays a limited role in potassium homeostasis in normal fasted individuals at rest.

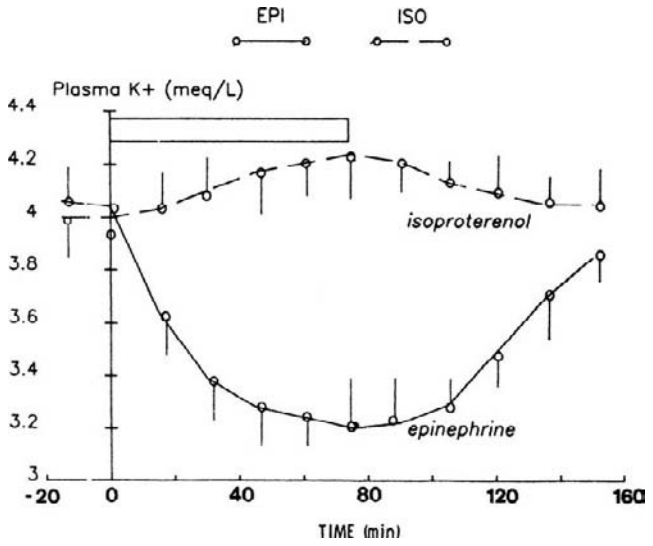

FIGURE 48.4 **Effect of epinephrine and isoproterenol infusions (long box) on the plasma potassium concentration.** The contrasting effects of the two beta-agonists probably are due to the relative beta2 selectivity of epinephrine at the dose given. Plasma epinephrine concentrations achieved by infusion were similar to those known to occur in myocardial infarction and other disorders. *Reprinted with permission from ref. [176].*

It has recently been appreciated, however, that there are two common physiologic circumstances in which endogenous catecholamines could act to defend against increments in extracellular potassium concentration. The first of these is postprandial disposal of dietary potassium. Feeding is now known to be associated with stimulation of the sympathetic nervous system.[180] Since only half of the potassium ingested in a meal is normally excreted within 6 hours,[7] enhanced beta-adrenergic-mediated extrarenal potassium disposal may help to limit elevations of serum potassium in the immediate postprandial period. In conjunction with enhanced potassium uptake due to insulin release, this mechanism would be particularly important in subjects at risk for hyperkalemia for any reason.

The second circumstance is the dramatic effect of catecholamine release during vigorous exertion to moderate the acute physiological hyperkalemia of

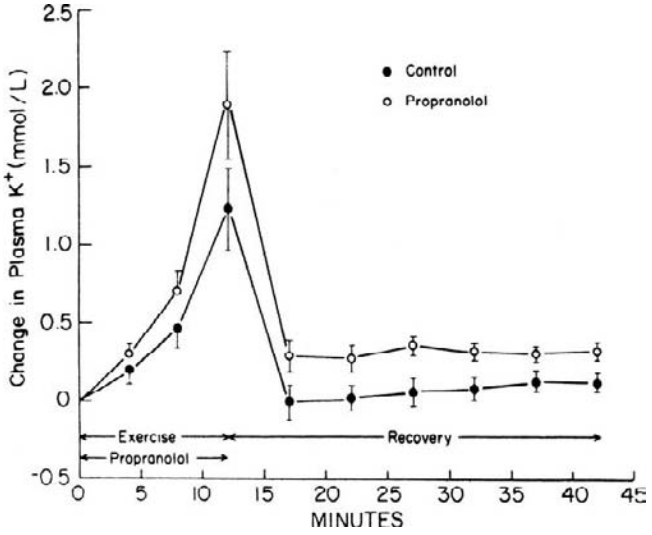

FIGURE 48.5 **Effect of adrenergic blockade on the plasma potassium concentration during vigorous exercise and recovery.** Beta-blockade with propranolol potentiated the rise of plasma potassium at peak exercise and prolonged its elevation during recovery. In the same subjects, alpha blockade with phentolamine was shown to lower the peak plasma potassium level, as well as the overall potassium curve. *Reprinted with permission from ref. [182].*

exercise. Catecholamines circulate at high levels during vigorous exercise, and the associated short-term elevation of potassium that is released into the circulation from working muscles is exaggerated by beta blockade[181,182] (Figure 48.5), suggesting that endogenous beta-adrenergic activity does protect against extreme hyperkalemia during exhaustive exercise. In this context, it is of particular interest that training leads to upregulation of the content of the Na,K-ATPase,[183] which serves to mitigate the rise in extracellular potassium concentration relative to the work performed.[184] Another mechanism that might mitigate the rise in extracellular potassium seen during exercise is AMP-activated protein kinase. This cellular enzyme, which is normally stimulated by exercise or ischemia, has been demonstrated to produce a decrease in plasma potassium when stimulated chemically in the rat.[185] This decrease does not appear, however, to be mediated by the Na,K-ATPase, and may instead be secondary to diminished efflux of potassium from the intracellular compartment.

Alpha-Adrenergic Effects

The fact that opposing alpha- and beta-adrenergic influences have in the past been reported on smooth muscle tone,[186] glucoregulatory hormones,[187] presynaptic membrane receptors,[188] and changes in intracellular second messengers[160,189] suggests the role of alpha-adrenergic agonists in potassium homeostasis. As noted previously, the early rise in extracellular potassium emphasized by D'Silva in 1934[113] was later attributed to alpha-mediated hepatic potassium release by the mixed alpha- and beta-agonist epinephrine.[119] This initial rise in potassium could be prevented by alpha blockade.[119] In addition, phenylephrine, a pure alpha-agonist, was observed to cause a sustained increase in potassium in dogs.[119,190]

When phenylephrine was infused into normal human subjects who were challenged with an intravenous potassium-load, the overall rise in plasma potassium was augmented by about 50%,[2] despite no change in insulin, renin, aldosterone or urinary potassium. In separate studies, addition of the alpha-antagonist phentolamine blocked the phenylephrine effect on potassium disposal. Neither alpha stimulation nor blockade appeared to affect the concentration of potassium in the absence of potassium-loading.

Other evidence suggests that the alpha effect might directly contribute to potassium homeostasis in certain circumstances. Alpha-receptor stimulation during vigorous exercise contributes to the acute rise in potassium that is maximal at peak exercise, and limits the dramatic fall due to potassium re-uptake during recovery.[182] Furthermore, during potassium depletion in rats, the sodium–potassium pump of skeletal muscle is suppressed by an increase in alpha-adrenergic activity mediated by nerves, an action that would mitigate the expected fall in plasma potassium concentration.[33] It is therefore speculated that enhanced alpha-agonist activity might act to preserve potassium similarly during a variety of acute illnesses, such as myocardial infarction[176] or delirium tremens,[191] where catecholamine stimulation of both beta- and alpha-receptors may coexist. Unopposed stimulation of alpha receptors may contribute to the impairment of potassium disposal caused by beta-receptor blockade.

Dopamine

The infusion of dopamine is known to augment glomerular filtration rate, renal plasma flow, osmolar clearance, sodium excretion,[192] and potassium excretion[193] in normal humans and animals. Levodopa, the metabolic precursor of dopamine, has also been reported to enhance renal potassium excretion,[194,195] and an increase in endogenous dopamine produced by protein feeding has been associated with augmented kaliuresis.[196] On the other hand, the dopamine antagonist metoclopramide also increases potassium excretion, an action ascribed to its blockade of tonic dopaminergic inhibition of aldosterone release.[197] Whether the dopaminergic system plays a role in extrarenal potassium homeostasis remains uncertain. Both dopamine and dobutamine lower plasma potassium

when infused into anesthetized dogs, but only by a few tenths of a mEq per liter.[198]While some studies demonstrate enhanced extrarenal potassium uptake into cells following administration of metoclopramide,[199–201] others demonstrate no such effect of either metoclopramide[202–204] or the dopamine agonist bromocriptine.[202,203,205] The discrepancy between these studies may well be attributed, at least in part, to the fact that metoclopramide is a nonspecific antagonist of dopamine.[206] The determination of the role, if any, of the dopaminergic system in extrarenal potassium homeostasis must await studies employing specific dopamine antagonists.

Clinical Implications

The clinical significance of epinephrine-induced hypokalemia is underscored by reports of hypokalemia occurring during acute illnesses, such as myocardial infarction, as well as during medical treatment with beta-agonists.[207] Struthers et al.[144] discovered that when epinephrine infusion produced circulating epinephrine levels similar to those found after myocardial infarction, the serum potassium fell from 4.06 to 3.22 mEq/liter in normal volunteers. This ability of small doses of epinephrine to diminish potassium levels was confirmed by Brown et al.[176] In this context, the frequency of hypokalemia during acute myocardial infarction has been observed to be 8 to 30%.[208–211] Concomitant therapy with diuretics may further increase the frequency of hypokalemia during myocardial infarction,[212,213] as it appears to do in normal subjects who are experimentally infused with epinephrine.[214]

Because several studies have suggested that hypokalemia is an independent risk factor for cardiac arrhythmias in patients with acute myocardial infarction, these observations may have clinical relevance. A higher incidence of atrial fibrillation[215] and ventricular arrhythmias are reported in hypokalemic compared with normokalemic patients during infarction.[209,216] In one report,[210] ventricular tachycardia or fibrillation increased three-fold (to 35%), and hospital mortality doubled in hypokalemic patients with myocardial infarction.

It must be appreciated, however, that the hypokalemia reported during earlier studies of epinephrine infusion occurred when high concentrations of plasma epinephrine were sustained by infusion. Whether elevations of plasma epinephrine during acute myocardial infarction are similarly sustained, rather than transient,[177] is uncertain. The contribution of circulating epinephrine to the hypokalemia that may occur during this form of acute illness therefore remains hypothetical. Nonetheless, pharmacologic data do suggest that such acutely ill patients may be protected from the hypokalemia that is sometimes associated with myocardial infarction by the use of beta blockers.[142,143,217] Whether the beneficial effect of beta blockade reported in this setting is due to diminution in hypokalemia-related arrhythmias is not known. That hypokalemia is not more prevalent in the setting of acute myocardial infarction may, in part, be a consequence of a simultaneous elevation in plasma norepinephrine, suggesting alpha-receptor stimulation that might antagonize the effect of epinephrine on potassium homeostasis.

Transient lowering of potassium levels has also been reported in other acute medical conditions[218–221] in which catecholamines might stimulate beta-adrenergic receptors capable of increasing cellular uptake of potassium. Pharmacologic therapy employing beta2-agonists such as terbutaline, ritodrine, and salbutamol to prevent premature labor[151,155,156,158,222] may produce a substantial degree of hypokalemia. Administration of salbutamol and albuterol in the treatment of bronchospasm[153,223] may also produce unwanted hypokalemia. In this context, it is important to appreciate that administration of inhaled beta2-agonists to healthy volunteers in doses similar to those used by asthmatic patients during an acute attack has produced decrements of plasma potassium by as much as 0.9 mEq/liter.[159] These observations raise the disturbing possibility that such usage of these agents may be the explanation for the high incidence of sudden death in adolescent asthmatics.[224] Hypokalemia in this setting might be further exaggerated by the concomitant use of theophylline[225] or other methylxanthines.[226,227] Theophylline not only increases the level of circulatory catecholamines, but also enhances catechol stimulation of adenylate cyclase by blocking inhibitory adenosine receptors. Hypokalemia associated with elevated levels of epinephrine has also been reported in patients admitted for trauma,[228] and in normal subjects who received endotoxin.[229] Sepsis induced in rats, moreover, increases the activity of Na,K-ATPase.[230]

The clinical significance of the adrenergic nervous system in potassium balance is also evident in the well-established effect of beta-antagonists to elevate extracellular potassium concentration. An example is the acute effect of propranolol to exaggerate the hyperkalemia of vigorous exercise.[182] Some,[231–233] but not all,[234,235] investigators have reported a 10–15% increase in ambient plasma potassium during chronic beta blockade with nonselective agents. In addition, one study suggests that the serum potassium may rise above 6 mEq/liter in patients on nonselective beta-blockers at the time of open heart surgery.[236] Transient hyperkalemia has been reported after cyclosporine

administration in patients on beta-blocking agents, but not when these are omitted.[237] Patients receiving succinylcholine anesthesia may also be at risk for the development of hyperkalemia.[238] Patients with end-stage renal failure on dialysis, moreover, regularly exhibit an increase in predialysis potassium of about 1 mEq/L when treated with propranolol.[239] Despite the clinical relevance of these studies describing an increase in extracellular potassium concentration in a variety of clinical conditions in patients receiving beta-blockers, it is important to realize that beta-blockers are unlikely to produce any significant increment in potassium concentration in subjects in whom the other mechanisms of potassium homeostasis are intact.

Since some studies do substantiate the anticipated absence of effect on potassium of cardioselective beta1-antagonists,[236,240,241] selected groups of patients at risk for hyperkalemia might be protected from significant elevations in potassium due to beta blockade by the use of such selective agents. Such patients include those with diabetes mellitus, hypoaldosteronism, and renal failure.

THYROID

Thyroid hormones enhance the activity of Na, K-ATPase in muscle cells,[242] accelerating the extrarenal disposal of potassium.[243] A portion of this effect can be ascribed to upregulation of beta-adrenergic receptors and an increase in beta-adrenergic responsiveness, but there appears to be a direct effect on cellular Na, K-ATPase as well.[243] Hypokalemic paralysis occasionally complicates thyrotoxicosis; in such cases urinary excretion of potassium is always low, reinforcing the hypothesis that the low serum potassium reflects a shift of potassium from the extracellular to the intracellular compartment rather than urinary losses of potassium. The hypokalemia and paralysis respond to the administration of beta-adrenergic-blocking agents.[244] This syndrome has been reported many times in Orientals, but is extremely rare in Caucasians and Blacks. It is not, moreover, associated with the inherited mutations in the calcium and sodium ion channels reported to cause familial hypokalemic periodic paralysis, but may in some cases be associated with a mutation in a channel mediating potassium efflux.[245] Hyperkalemia has been reported in hypothyroid dogs after exercise, but not in humans with hypothyroidism.[246]

ACID–BASE

Although acid–base balance affects potassium excretion by the kidney, shifts of potassium in and out of body cells are the initial way in which acid–base disturbances alter serum potassium. These movements are influenced by a variety of factors, including the changes in extracellular and intracellular pH, the degree of cellular buffering, the nature of the anion accompanying H^+, and the associated changes in hormonal and neural regulators of potassium uptake, including insulin and catecholamines.

The concentration of potassium in plasma tends to vary in the same direction as that of free hydrogen ions,[27,247–249] so that acidosis promotes hyperkalemia and alkalosis promotes hypokalemia. Since approximately 40% of the acid buffering capacity of the body is provided by intracellular proteins, largely in muscle cells,[250] and since potassium is the chief intracellular cation of muscle, the release of intracellular potassium is to be expected as a consequence of the intracellular buffering of hydrogen ions. Conversely, with repair of acidosis or during alkalosis, potassium will tend to move into cells. This exchange of K^+ for H^+ is not necessarily equimolar, and the routes across the plasma membrane that are responsible for such transfers have not been completely delineated. A simple reciprocal exchange of K^+ and H^+ via a single plasma membrane transporter has not been described in muscle cells.

Hydrogen Ion

The importance of pH in affecting internal potassium distribution during acidosis was demonstrated in early studies.[251–254] Fenn and Cobb[247] reported in 1934 that potassium exited from skeletal muscle *in vitro* when the bath pH was lowered, and moved into the tissue when blood at physiologic pH was substituted for acidic medium. They invoked the Donnan equilibrium to account for similarity in the intracellular to extracellular ratios of hydrogen and potassium ions, so that a decrease in that ratio produced by acidosis would be associated with a decrease in the ratio for potassium – that is, an increase in extracellular K^+. *In vivo* as well, an approximately linear relationship appears to exist between the potassium gradient and the pH gradient across muscle cell membranes, as predicted by the Donnan effect.[255,256] Nevertheless, the shifts in potassium observed in experimental situations are not always fully explained, either by the Donnan effect or by changes in membrane potential.[256,257]

Since the ratio Ki/Ke for skeletal muscle is approximately 30, the maintenance of a similar hydrogen ion ratio between intracellular and extracellular fluid would require an intracellular pH of approximately 5.92. However, intracellular pH is actually in the range of 6.9–7.0, so that the intracellular to extracellular proton ratio is only approximately 3 rather than 30. The

major reason for this is the operation of the amiloride-sensitive Na^+–H^+ antiporter, which transports H^+ out of cells by a secondary active mechanism that ultimately derives its energy from ATP via the Na,K-ATPase of plasma membranes.

Moreover, the direction of the movement of potassium during acute acid–base disorders is not uniform among various tissues.[257] During acute respiratory acidosis, potassium moves out of the cells in muscle and liver, but into cardiac muscle. Yet, in both skeletal and cardiac muscle, the ratio of intracellular to extracellular hydrogen ion concentration falls. As will be seen subsequently, powerful evidence has been adduced under both *in vitro* and *in vivo* conditions suggesting that, in some circumstances, the ionic ratios of hydrogen and potassium can be dissociated and transmembrane fluxes of potassium change in the face of a stable pH gradient.

Inhibition of the sodium–potassium pump of plasma membranes by an acid pH contributes importantly to the relationship between acidosis and plasma potassium. In every case in which it has been measured, an increase in plasma potassium associated with systemic acidosis is accompanied by a fall in intracellular potassium. The optimal pH for mammalian Na,K-ATPase is 7.5–7.6, whereas intracellular pH of muscle is 6.9–7.2.[258] The effect of pH on the activity of the sodium–potassium pump is exerted from the intracellular, rather than the extracellular, side of the membrane.[259,260] In bladder epithelial cells, for example, a reduction of intracellular pH by 0.3 units, from pH 7.2 to 6.9, reduced pump activity to about 70% of that at pH 7.2. On the other hand, alkalinizing the cell interior to pH 7.5 led to a 35% increase in sodium-pump activity.[260]

In addition to a direct effect of pH on the sodium–potassium transport enzyme, an indirect mechanism might involve the linked operation of the Na-H antiporter and the Na,K-ATPase. An attractive mechanism to explain the shift of potassium out of cells that occurs in acidosis involves the linked operation of these two transporters. Both of these transporters are present in the plasma membranes of most cells, including skeletal muscle. Acidification of the extracellular fluid would be expected to slow the rate at which hydrogen ions leave the cell and sodium ions enter, via the Na-H antiporter. The resultant decrease in intracellular sodium concentration would slow the Na-K pump, reduce active uptake of potassium by cells, and increase the concentration of potassium in extracellular fluid. A prediction of this hypothesis is that amiloride, which blocks the Na-H antiporter, would prevent the hyperkalemia produced by acidosis. It is not yet known whether this is the case, but amiloride does block the extracellular acidosis produced by KCl infusions.[261]

Finally, intracellular acidosis appears to open ATP-sensitive potassium channels in skeletal muscle by reducing the degree of channel inhibition by ATP, an action that might accelerate efflux of K^+ from muscle cells during anoxia or extreme acidosis.[262]

Mineral Acids

Acute mineral acidosis, produced by infusing HCl or NH_4Cl, elevated plasma potassium by an average of 0.7 mEq/liter per 0.1 unit decrease in blood pH, in 14 different studies summarized by Adrogue and Madias.[257] The results of these studies were extremely variable, however, ranging from 0.24 to 1.67 mEq/liter per 0.1 pH unit.

One reason for the variability in these reports is that the effect of mineral acid infusions on plasma potassium depends on the duration of the acidosis.[27,254,263,264] Immediately following an acute acid infusion there is a marked fall in extracellular pH and bicarbonate, followed by a gradual rise over the next 2 hours or so, as tissue buffering and respiratory compensation moderate the initial changes in blood pH.[249,250,254,264] Plasma potassium begins to rise early in the course of the infusion and increases progressively as buffering takes place, so that its concentration does not change in parallel with the change in pH. Late in the course of an acute acid-load, when cell buffers have been exhausted and intracellular pH drops sharply, plasma potassium rises more steeply.

It might be expected that the hyperkalemic response to an acid-load would be influenced by the state of muscle potassium. Experimental potassium depletion induced by DOCA (mean plasma K^+ 1.9 mEq/liter) did indeed attenuate the increase in plasma potassium produced by metabolic acidosis, but did not prevent it, and the percentage rise in plasma potassium from baseline induced by NH_4Cl acid-loading was not significantly different from that of controls.[265]

Clinical observations on the endogenous mineral acidosis of uremia, due to retention of sulfate and phosphate, suggest that the change in potassium that is observed when acidosis is corrected is of the magnitude expected in experimental mineral acidosis.[17,266]

Organic Acids

That changes in acidity are not the sole determinant of the kalemic response to acidosis is indicated by the disparate effects which mineral acidosis and nonmineral acidosis have on potassium. In humans and animals, infusion of organic acids such as acetic, lactic or beta-hydroxybutyric acid produce far smaller elevations of potassium than hydrochloric acid.[264,267–270]

The prevailing hypothesis is that the anions of organic acids, either by readily penetrating the intracellular compartment,[257] by entering cells as intact molecules[271] or by being formed endogenously within cells,[272] minimize the necessity for potassium cations to leave cells in exchange for hydrogen ions.[273] The addition of HCl to rat diaphragms *in vitro* results in a loss of potassium from the muscle,[253] whereas when extracellular pH is lowered by addition of acetic acid, beta-hydroxybutyric acid or lactic acid, no shift of potassium out of the cell is observed.[271]

For similar degrees of clinical severity, less elevation of serum potassium occurs with endogenous organic acidosis encountered in ill patients than with mineral acidosis, although the correlation of pH and serum potassium in clinical states of organic acidosis is further complicated by prior total body potassium depletion, oliguric renal failure, hypercatabolism, and other factors.[273] Ketone acids, for example, stimulate the secretion of insulin by the normal pancreas, while suppressing the secretion of glucagon. Infusions of hydrochloric acid, on the other hand, do not stimulate insulin secretion, but enhance plasma glucagon,[102] which in turn tends to elevate the serum potassium. The sympathoadrenal system, which is strongly activated in most clinical states accompanied by organic acidosis (e.g., diabetic or alcoholic ketoacidosis, and the lactic acidosis of circulatory shock), plays an important role in minimizing hyperkalemia, because of the hypokalemic action of beta-adrenergic stimulation. Moderately severe potassium depletion (as occurs in diabetic ketoacidosis) itself attenuates the increase in plasma potassium induced by metabolic acidosis.[265]

Untreated severe diabetic ketoacidosis is characterized by marked deficits (200−300 mEq) in total body potassium,[274] owing primarily to coincident potassium losses from the gastrointestinal tract or kidneys. Despite these losses, hypokalemia is uncommon, present in only 4% of episodes in one series,[275] probably because of concomitant acidosis. Serum potassium is usually normal or elevated at presentation,[276] but falls during successful treatment. Hypokalemia during recovery from diabetic ketoacidosis is most prominent in patients who initially received sodium bicarbonate.

Since insulin plays a significant role in cellular shifts of potassium, lack of insulin is presumably important in promoting hyperkalemia during diabetic ketoacidosis,[277] as it is in patients with hyperosmolar nonketotic coma, who may have severe hyperkalemia without acidosis.[278]

Similar to uncontrolled diabetes, several factors in lactic acidosis complicate the effect of acidemia *per se* on serum potassium. These include volume-depletion, prerenal azotemia, hypercatabolism, concomitant diabetes, catecholamine effects, and external potassium imbalance.[279] Although severe hyperkalemia is unusual in lactic acidosis, Perez et al.[273] have pointed out the absence of detailed studies on potassium in this varied disorder. In experimental lactic acid infusion in animals,[270] and in uncomplicated post-seizure lactic acidosis in humans,[272,280,281] potassium does not increase with the appearance of acidosis. However, in other forms of lactic acidosis, such as those earlier encountered due to phenformin therapy in diabetes,[276] and in other forms not associated with tissue hypoxia, mild elevation of potassium may occur.[272] Renal insufficiency may be a contributing factor in such patients. Most patients with alcoholic ketoacidosis have a normal extracellular potassium concentration,[282,283] although there is significant variability. The effects of rarer forms of organic acidosis on internal potassium homeostasis have been reviewed elsewhere in detail.[273]

Respiratory Acidosis

The effect of acute respiratory acidosis in elevating plasma potassium is, in general, smaller in magnitude than that of metabolic acidosis, though some effect can usually be detected.[248,255,284,285] A rise varying from 0.06 to 0.3 mEq K^+/liter per 0.1 pH unit was detected in 22 studies of mild to moderate respiratory acidosis.[257] More severe experimental acidosis, provoked by inhaled concentrations of CO_2 as high as 30%, induce more pronounced hyperkalemia.[257] In anephric dogs, the initial effect on potassium is small, but after 2 hours respiratory acidosis may increase to the range observed in metabolic acidosis.[27] On the other hand, in *in vitro* experiments, when the extracellular medium bathing isolated rat diaphragms was acidified by raising the ambient CO_2 from 2 to 10%, no shift in potassium was observed,[271] consistent with the ability of carbonic acid to permeate cells, as do other organic acids. Chronic respiratory acidosis produced in dogs was not attended by hyperkalemia.[285]

The increase in serum potassium induced by severe respiratory acidosis in intact rats could be roughly approximated from the decrease in $(H^+)_i/(H^+)_o$, and was attributed to the importance of the Donnan effect in producing these changes.[255] In addition, it is very likely that sympathoadrenal stimulation plays a major role in modulating serum potassium during respiratory acidosis *in vivo*, since it is well-established that acute hypercapnia results in an intense sympathetic discharge and an increase in the plasma concentration of epinephrine.[257,286] Glycogenolysis induced by epinephrine probably contributes to the initial release of glucose and potassium from the liver with hypercapnia, noted by Fenn and Asano,[287] and the hypokalemic effect of beta-adrenergic stimulation is likely to blunt the movement of potassium out of skeletal muscle that

would otherwise accompany acidosis. Probably for this reason, mild respiratory acidosis induced acutely in anesthetized patients was not found to elevate the plasma potassium,[288] although beta-adrenergic blockade produced marked hyperkalemia in hypercapneic animals.[289]

Bicarbonate

It has been suggested that the serum bicarbonate concentration, even at constant or "isohydric" pH, alters extrarenal potassium distribution and might account in part for the weak correlation between pH and serum potassium in many studies. Under conditions of constant blood pH, infusion of sodium bicarbonate appears to lower serum potassium,[257,290,291] and during acidosis in rats, potassium may correlate better with serum bicarbonate than with blood pH.[292] A similar correlation can be found in patients with hyperkalemia of diverse etiologies,[293] as well as in experimental acute ammonium chloride acidosis.[294] This has been taken to indicate that bicarbonate therapy, in addition to beneficially raising pH, corrects hyperkalemia directly, perhaps via intracellular transfer with the potassium cation.

Another explanation of the same data is that it is the quantity of acid buffered by cells, rather than the arterial pH, that governs the release of intracellular potassium. This would account for the fact that extracellular bicarbonate, rather than arterial pH, sometimes seems to exert an independent controlling influence on extracellular potassium. Effective buffering of an acid-load by intracellular and extracellular buffers, so as to produce a low serum bicarbonate and a normal arterial pH, involves the liberation of substantial amounts of potassium cations from intracellular proteins.[295] It can be inferred from the foregoing that alkali treatment of hyperkalemia should be most effective when the plasma bicarbonate is low and acidosis marked, and less so when plasma bicarbonate and pH are normal; this is indeed the case.[296] This result is also inherent in the finding that the changes in plasma potassium produced by metabolic alkalosis are smaller than those seen in metabolic acidosis.

Alkalosis

Metabolic and respiratory alkalosis are commonly associated with hypokalemia. In both, renal losses are important in initiating and perpetuating hypokalemia, but extrarenal adjustments are also involved. Acute alkalosis induced by infusions of sodium bicarbonate usually leads to a decrement in plasma potassium concentrations. The $\Delta(K)p/\Delta pH$ slope is usually smaller than that commonly observed in acute mineral acidosis, although the reported range is wide, from -0.09 to -0.42 mEq/liter per 0.1 pH unit.[257,297,298] The initial change is not attributable to kaliuresis. Acute respiratory alkalosis produces a comparable decrease in plasma potassium, although during voluntary overbreathing this fall may be counteracted by an increase in circulating norephinephrine which, as noted earlier, tends to increase plasma potassium.[299] It should be pointed out that most studies of extrarenal effects of metabolic alkalosis have involved the infusion of hypertonic solutions of sodium bicarbonate. Since hypertonicity itself promotes a rise in plasma potassium, this would tend to counteract any hypokalemic effect of alkalosis *per se*.

An intuitively appealing explanation for the extrarenal effect of alkalosis is replacement of H^+ associated with cellular buffers by potassium, in the reverse of the sequence discussed earlier by which acidosis releases intracellular potassium ions. Enhanced exchange of intracellular H^+ for extracellular Na^+ via the amiloride-sensitive Na^+-H^+ antiporter would accelerate cellular potassium accumulation by stimulating the Na, K-ATPase pump. In addition, intracellular alkalosis probably stimulates the sodium–potassium pump directly, as discussed earlier.

The combined effects of respiratory alkalosis on renal and extrarenal potassium handling commonly produce mild hypokalemia (around 3.0 mEq/liter) resistant to potassium replacement in hypocapneic patients who are artificially ventilated. Extreme hypocapneic alkalosis and hypokalemia, as seen in recently intubated patients who are overventilated, may produce serious cardiac arrhythmias.[300]

ALDOSTERONE

In addition to its action on the kidney to increase potassium excretion, aldosterone enhances potassium secretion into intestinal fluids and saliva. Aldosterone-induced colonic potassium secretion appears to occur through increased expression of luminal BK channels.[301] In chronic renal insufficiency, moreover, the colonic secretion of potassium is greatly enhanced.[302] In that sense, its effect on serum potassium can be said to have an extrarenal component. Aldosterone also has an independent action to accelerate renal acid excretion, and the consequent alkalosis itself has a secondary effect on cellular uptake of potassium. Apart from these mechanisms, there is no convincing evidence for a direct action of aldosterone to increase potassium uptake by muscle cells. For example, incubation of isolated rat diaphragms with

aldosterone results in a loss, rather than a gain, of intracellular potassium.[303,304]

An extrarenal action of aldosterone has been suggested in the past, because of several lines of evidence. First, in experimental animals, hyperkalemia after adrenalectomy seemed not to be entirely accounted for by a positive balance of potassium.[305] Furthermore, the fall in plasma potassium accompanying the administration of mineralocorticoids was not necessarily associated with an increase in potassium excretion.[306–308] Interpretation of such data is complicated, because of the effect of adrenal medullary hormones on extrarenal potassium uptake, and the renal action of mineralocorticoids to retain sodium and excrete acid, resulting in expansion of extracellular fluid volume and alkalosis, both of which might secondarily lower serum potassium.

Long-term treatment of dogs by Young and Jackson[308] with high doses of aldosterone altered the relationship between plasma potassium and total body exchangeable potassium, so that at any level of exchangeable potassium, plasma potassium was lower than in untreated animals. In these experiments, however, mean plasma bicarbonate was significantly higher in aldosterone-treated dogs than in controls, leaving open the possibility that aldosterone-induced alkalosis influenced potassium distribution.

Bia et al.[135] gave intravenous potassium loads to adrenalectomized and nephrectomized rats, and found that the acute administration of aldosterone prior to infusing potassium blunted the hyperkalemia. The differences they observed, however, were small, and could have been completely accounted for by a modest increase in the potassium concentration of gastrointestinal secretions (e.g., an increase of 20 mEq/liter in 1 ml of intestinal fluid) caused by the known action of aldosterone to increase intestinal potassium secretion.

The role of mineralocorticoids in the disposition of an oral potassium-load was studied in anephric humans by Sugarman and Brown.[309] Anephric patients were given 0.5 mEq/kg of KCl after 72 hours of either mineralocorticoid treatment (10 mg DOCA daily) or spironolactone (300 mg daily). The rise in serum potassium was delayed by DOCA, but the difference from control experiments with spironolactone was most marked at 1 hour, much less pronounced at 2 and 3 hours, and not present at 24 hours, suggesting that the mineralocorticoid had delayed absorption of potassium from the gastrointestinal tract. Chronic administration of high doses of mineralocorticoids is said to diminish serum potassium slightly in anuric patients, perhaps because of an increase in stool potassium.[310]

Finally, Alexander and Levinsky[311] reported that chronic potassium-loading improved extrarenal disposal of an acute potassium-load given after a night's fast, an effect abolished by adrenalectomy and restored by chronic (but not acute) high-dose mineralocorticoid replacement. They postulated that chronic hyperaldosteronism acts directly by enhancing cellular uptake of an acute potassium-load.[311] Another interpretation was offered by Spital and Sterns.[26] These investigators showed that, when dietary potassium is withdrawn from rats previously fed a high-potassium diet, high rates of potassium excretion persist and "overshoot," causing these animals to become progressively more depleted of potassium than controls. This "paradoxical potassium depletion" is responsible, at least in part, for extrarenal potassium adaptation, by creating a sink of potassium-hungry cells that avidly take up potassium, and thereby blunt the increment in plasma potassium after an acute potassium-load. Hyperaldosteronism magnifies urinary potassium losses during fasting, and thus promotes potassium depletion, which in turn facilitates the uptake into muscle of an acute potassium-load.[312]

In summary, aldosterone and other mineralocorticoid hormones do accelerate the disposal of potassium, but probably not by a direct effect on muscle. The changes observed can be accounted for by the known actions of aldosterone on the renal and gastrointestinal transport of sodium and potassium, and the separate action of aldosterone to produce systemic alkalosis by enhancing acid excretion.

RENAL FAILURE

In states of mild-to-moderate chronic renal failure, the ability to excrete potassium is well maintained by an adaptive increase in the rate of fractional potassium excretion to levels near the maximal for subjects with normal renal function.[313,314] As renal function declines further, however, so does the ability to excrete potassium in a timely manner.[315] With advanced renal failure, potassium is retained longer[5] and dependence on extrarenal disposal becomes more critical.

Whether extrarenal potassium disposal is enhanced, normal or impaired in the setting of uremia remains controversial.[316] Studies in which an oral potassium load was given found that patients with chronic renal failure excreted only one quarter[9] to one-half[7,8] the amount of potassium excreted by subjects with normal renal function over a comparable period of time. Nonetheless, an exaggerated rise in serum potassium did not always occur.[7,9] Reports of impaired extrarenal disposal of an oral potassium-load in patients with chronic renal failure might be criticized, either because the patients had higher basal serum potassium concentrations or might have

been more acidotic than the control subjects.[8,317,318] Another study that concluded that extrarenal potassium disposal was impaired in patients with chronic renal failure involved chronic rather than acute potassium-loading.[319] A more general criticism of studies administering oral potassium that might account for some of the discrepant conclusions, however, is the inherent difficulty of estimating the rate of gastrointestinal absorption of potassium in the setting of renal failure. With intravenous potassium-loading, however, most,[101,135,320] but not all[321] animal studies appear to show a discernible defect in extrarenal potassium disposal in the setting of renal failure. With rare exceptions,[320,322] however, these studies examined extrarenal potassium homeostasis immediately after acute nephrectomy, rather than in the uremic state.

If extrarenal potassium disposal is impaired in uremia, it cannot be a consequence of increased cellular potassium content or high total body potassium, since both are normal or low in this state.[323–328] Nor does there appear to be peripheral resistance to insulin-mediated potassium uptake,[329] despite the known resistance to the action of insulin on glucose metabolism in renal failure.[330] The chronic hyperinsulinemia of end-stage renal failure may afford some protection against hyperkalemia. Renin production, which might be expected to be suppressed in patients with end-stage renal disease, is normal or elevated in many patients. Furthermore, both hyperkalemia[27,331] and salt restriction[332] appear to stimulate aldosterone production adequately in the setting of chronic renal failure (in patients who do not have hyporeninemic hypoaldosteronism), and a lowering of the plasma potassium suppresses aldosterone secretion normally.[333]

Catecholamines circulate at increased levels in most,[334,335] but not all,[336] patients with renal failure. While it is likely that much, if not all, of this increase is a consequence of decreased renal excretion, the pressor and pulse responses to norepinephrine infusion have been reported to be impaired in renal failure.[334,336] Both intravenous[337] and inhaled[338] albuterol appear, however, to be effective and rapid therapeutic modalities to treat hyperkalemia in patients with advanced renal failure. If beta-adrenergic-mediated extrarenal potassium homeostasis is blunted in renal failure when compared with normal subjects,[339] it may well be in those whose endogenous plasma epinephrine levels are chronically elevated[340] or who are more acidemic. Contrarily, it should be appreciated that the administration of drugs that possess beta2-antagonist properties can produce significant hyperkalemia in patients with renal failure on dialysis.[239]

Impaired extrarenal disposal of potassium in uremia might conceivably be caused by high circulating levels of parathyroid hormone. Infusion of parathyroid hormone appears to impair extrarenal disposition of a potassium-load in nephrectomized rats,[341] an action ascribed to the enhancement of potassium efflux from cells produced by increasing intracellular calcium. Potassium tolerance in partially nephrectomized rats with chronic renal failure is improved by parathyroidectomy, and by administration of the calcium channel-blocker verapamil.[342]

Metabolic acidosis can impair cellular potassium uptake (see "Acid–Base"), and alkalinization has been demonstrated to reverse this effect in anuric patients.[318] Part of this effect of acidosis may be to diminish the activity of Na,K-ATPase, which has a pH optimum in the range of 7.5–7.6 in mammalian tissue.[258]

That the activity of the Na-K pump is impaired in the erythrocytes of some uremic subjects has been well-established.[343–349] The impairment is correlated with an increase in intracellular sodium of red blood cells. Also, the diminished pump activity is reversed when the red blood cells of uremic patients are incubated in normal plasma[344] or when the patients are dialyzed,[343,345,348,350] and the impairment is reproduced when normal erythrocytes are incubated in uremic plasma.[344,351] These studies suggest the presence of a circulating inhibitor of the Na-K pump in some uremics. Other investigators have reported a decrease in the number of pump sites, estimated by ouabain-binding, rather than in the activity of the pump (defined as the ion turnover rate per pump site) in the red blood cells of certain uremic patients.[352,353] Experimental uremia in rats decreases the Na,K-ATPase activity of skeletal muscle,[354] an effect reproduced by incubating normal muscle cells with uremic serum.[354] The excessive rise in plasma potassium exhibited by patients with chronic renal failure undergoing exercise is consistent, moreover, with an impairment in skeletal muscle Na,K-ATPase in humans with this condition,[355] although a higher baseline potassium concentration or a more acidotic state can be confounding variables in such studies.

MAGNESIUM

In a variety of clinical states, potassium-depletion accompanies magnesium-depletion. Among patients with hypokalemia, the coincidence of magnesium deficiency may range from less than 10%[356] to over 40%.[357,358] Clinical conditions with a high incidence of combined deficiencies in potassium and magnesium, such as diuretic administration, alcoholism, and diabetic ketoacidosis, generally involve a defect in renal conservation of potassium. Along with interest in the relationship between extrarenal magnesium and

potassium balances[359] has come information on the relationship of their movements in and out of cells.[360]

Because potassium and magnesium are the principal intracellular cations, it is not surprising that an important physiologic relationship might exist between them. For each, reduced intracellular concentrations may exist in certain states of depletion, out of proportion to the reduction in serum levels.[361,362] Furthermore, a high correlation is found between magnesium and potassium concentrations in extrarenal tissues, such as skeletal muscle.[363] A deficiency of magnesium evokes potassium-depletion in animals and humans. In rats, however, serum potassium remains normal,[364] whereas in human subjects, hypokalemia is often observed.[357,361]

A specific effect of magnesium-depletion on potassium homeostasis can be deduced from experimental magnesium deficiency states in which magnesium deficiency is associated with renal potassium-wasting.[365] One proposed mechanism is of importance to their internal homeostasis, insofar as it would involve a direct effect of magnesium depletion on the ability of both renal and extrarenal cells to preserve their potassium.[359,366] It is known that experimental dietary magnesium depletion in rats results in loss of cellular potassium in cardiac as well as skeletal muscle.[367] Furthermore, during magnesium depletion in both animals[368] and humans,[365] the intracellular deficiency of potassium cannot be restored by provision of potassium alone; correction of the magnesium deficiency is required. Clinical combined depletion may play a role in cardiac arrhythmias seen in patients with alcoholism or on diuretics,[357,369] underscoring the importance of magnesium replacement in the correction of refractory hypokalemia and cellular potassium-depletion.

Two extrarenal mechanisms have been suggested: reduced Na,K-ATPase activity; and increased cell membrane permeability to potassium. Cellular potassium-depletion due to diminished active potassium uptake mediated by Na,K-ATPase might occur because this cation pump requires cellular magnesium.[258] Animal studies have shown that magnesium-depletion is associated with a reduced concentration of Na−K pump units in rat skeletal muscle.[370] Reduced ouabain-binding, indicative of a decreased number of Na−K pumps, has also been found in humans treated with diuretics who developed low muscle potassium concentrations associated with hypomagnesemia.[371] Additional data suggest that magnesium-depletion may also exert its effect on intracellular potassium through an impairment of the activity of the sodium-potassium pump *per se*, rather than on the number of pump sites per cell.[372]

The second proposed mechanism of potassium loss would involve effects of magnesium on membrane potassium channels. In mammalian heart cells and in a cultured insulin-secreting cell line investigated by the patch-clamp technique, physiologic concentrations of intracellular magnesium block outward current by inhibiting the opening of ATP-sensitive potassium channels.[373,374] Magnesium may therefore play an important role in the low conductance of the outward potassium current through these channels[375] under normal conditions. Such a direct effect of magnesium on potassium channels might result in cellular potassium-depletion during magnesium deficiency.

DRUGS

Medications are the primary etiologic factor in as many as one-third of cases of clinically significant hyperkalemia,[376−379] and are contributing factors in more than 60% of hyperkalemic episodes in hospitalized adults.[380] Potassium supplements, angiotensin-converting enzyme inhibitors, angiotensin-II receptor-antagonists, potassium-sparing diuretics, trimethoprim, pentamidine, heparin, and prostaglandin-suppressing drugs that induce hyporeninemic hypoaldosteronism account for most of these cases; relative to those, hyperkalemia due to drugs that alter internal potassium distribution would appear to be uncommon.[377,381] As is true for drug-induced hyperkalemia in general, the risk of significant hyperkalemia is substantially increased in patients with diabetes mellitus, renal insufficiency, hypoaldosteronism, and in the elderly. In most other cases, the rise in potassium is mild.[377]

Impaired Extrarenal Disposal

Hyperkalemia due to beta-adrenergic-blockers, the most common class of medications that elevate potassium by extrarenal mechanisms, was discussed in an earlier section. A small, transient increase in serum potassium usually occurs in patients given depolarizing muscle relaxants, such as succinylcholine.[382−385] Exaggerated increments, however, may occur in patients with central nervous system diseases, spinal cord injury, increased intracranial pressure, and a variety of other ailments.[379] In such pathological states, the acetylcholine receptors may be increased beyond the junctional area.[386] Because potassium efflux from muscle end plates occurs during normal depolarization, massive efflux of the cation from such sensitized muscle can account for the hyperkalemia noted in patients with neurologic motor deficits, tetanus or muscle damage.[387] Succinylcholine-induced hyperkalemia may also be seen with neuroleptic malignant syndrome[388]

and skeletal muscle metastasis of a rhabdomyosarcoma.[389] Why burn patients and those with intracranial lesions not involving upper motor neurons[384] are also at risk is less apparent. In patients at risk, succinylcholine should be used with caution and in the smallest dose possible, and with pretreatment by nondepolarizing muscle relaxants.[387]

Muscle cell breakdown may also result in hyperkalemia in patients who develop myositis due to the HMG-CoA reductase inhibitor, lovastatin.[390] Such reactions are more likely when lovastatin is administered in combination with gemfibrozil, cyclosporine, and nicotinic acid.[391] HMG-CoA reductase inhibitors are commonly used in patients already predisposed to hyperkalemia due to diabetes mellitus or renal insufficiency.

Arginine HCl, in doses used for the correction of metabolic alkalosis, may increase serum potassium.[392] When this cationic amino acid is taken up by cells, potassium is displaced into the extracellular fluid. Hyperkalemia is more likely in patients with renal failure[393] who are unable to excrete this endogenous potassium-load, and in those with liver failure who are unable to metabolize the administered arginine normally.[394] The magnitude of potassium rise in normal subjects is under 1 mEq/liter[392]; it is not closely correlated with pH, and may occur in patients before correction of the alkalosis is accomplished.[394] Lysine HCl may also increase serum potassium levels. The antifibrinolytic agent epsilon aminocaproic acid (Amicar) has been reported to cause hyperkalemia as well,[395] although the mechanism underlying this effect is unclear.

Trivial increments in potassium may also occur at therapeutic or mildly toxic levels of cardiac glycosides.[396,397] Blockade of Na,K-ATPase-mediated potassium uptake with normal doses of digitalis has minimal effect on the serum potassium, since glycoside binding to skeletal muscle, the major body reservoir of potassium, is limited. At toxic concentrations of digitalis, however, such as following massive overdose, marked hyperkalemia is well-described and indicates a poor prognosis.[398,399] The toxic concentration of digitalis also prevents standard treatment of the hyperkalemia with calcium. Although no significant effect to retard potassium disposal in normal subjects with therapeutic digitalis levels has been published, it is likely that such an effect may exacerbate hyperkalemia in patients at risk. In patients with renal failure, for example, even modest digoxin toxicity resulting from therapeutic doses is reported to cause hyperkalemia.[400] In fact, of drugs known to induce hyperkalemia, digoxin was the most frequently encountered among patients with hyperkalemic episodes,[380] and nearly one quarter of these had toxic digoxin levels.

Nonsteroidal anti-inflammatory drugs produce hyperkalemia best attributed to their antikaliuretic effect, which results in positive potassium balance.[401,402] No impairment of extrarenal potassium homeostasis has been directly demonstrated.[380,403,404]

Lithium intoxication in animals is associated with a progressive elevation in serum potassium and electrocardiogram abnormalities characteristic of hyperkalemia. However, only at concentrations of plasma lithium (>10 mEq/liter) many times the therapeutic lithium levels (1 mEq/liter) attained in manic-depressive patients[405] do these changes occur. Increments in serum potassium of under 1 mEq/liter have been reported during chronic lithium therapy,[406] but frank hyperkalemia is rarely observed.[407] Lithium may displace intracellular potassium from human red blood cells and from skeletal muscle.[406] Amphotericin B (including the liposomal formulation) can cause severe hyperkalemia due to potassium released from the intracellular compartment when the dose is excessive, the rate of infusion is rapid or renal function is impaired.[408]

Enhanced Extrarenal Disposal

Drug-induced lowering of serum potassium by exogenous insulin and beta-adrenergic-agonists was described in detail earlier. Increased circulating catecholamine levels, as well as enhancement of catechol stimulation of adenylate cyclase, also appear to mediate in part the effect of methylxanthine derivatives such as theophylline. Hypokalemia due to beta-adrenergic stimulation may occur with severe theophylline toxicity[409] in humans. Propranolol is reported to block hypokalemia due to theophylline toxicity in the dog.[409] Whether therapeutic levels of aminophylline are important in acutely lowering serum potassium in humans is unclear.[410] Other methylxanthines, such as caffeine, might also be expected to decrease potassium concentrations,[227] not only by stimulating release of catecholamines, but also by their blockade of high-affinity (A1) adenosine receptors, which normally act to inhibit adenylate cyclase.

Several clinical studies have reported minor decreases in serum potassium levels in patients treated with calcium-antagonists, sometimes associated with increased urinary potassium losses.[411] Severe hypokalemia with heart block may complicate overdosage of verapamil.[412] Enhanced extrarenal potassium disposal has been demonstrated with the calcium channel-blockers verapamil, nifedipine, and nitrendipine.[413–415] In one study,[415] pretreatment with either verapamil or nifedipine reduced by about 40% the increment in plasma potassium produced over 1 hour by the

infusion of KCl in nephrectomized rats. The effect was not mediated by changes in pH, bicarbonate, insulin, aldosterone or the alpha- or beta-adrenergic systems. Diltiazem has been shown to reduce the interdialytic rate of increase in plasma potassium in patients with end-stage renal disease.[416] Diminished calcium-mediated potassium efflux from cells may be responsible, since increased intracellular calcium enhances potassium permeability *in vitro* (the Gardos effect)[417] in erythrocytes and other cells.[418] While this action would lower plasma potassium, the net effect of calcium channel-blockers in clinical practice is complicated by the fact that these agents also inhibit secretion of aldosterone,[419,420] which in turn would tend to produce potassium retention.

The increased use of thiopental infusions to achieve therapeutic barbiturate coma has been associated with extreme degrees of hypokalemia secondary to enhanced cellular uptake of potassium. Serious rebound hyperkalemia has ensued, moreover, following the administration of potassium to correct the hypokalemia and discontinuation of the thiopental.[421,422] The mechanism responsible for the hypokalemia is unknown, but could involve inhibition of voltage-dependent neuronal potassium currents. Overdosage of the antimalarial chloroquine has also been associated with hypokalemia, presumably from enhanced cellular uptake, but such cases are often confounded by concomitant administration of other medications.[423] High-dose intravenous methotrexate has been associated with the rapid development of tetraparesis and marked hypokalemia in one patient that appeared to be caused by enhanced extrarenal disposal of potassium.[424]

OTHER FACTORS

Two other factors that may clinically elevate serum potassium levels by affecting extrarenal potassium homeostasis are hyperosmolarity and cellular necrosis. Less well-described are the effects of barium, cesium, and body hypothermia to lower serum potassium levels by extrarenal shifts. A sudden increase in cell mass produced by rapid proliferation, moreover, may sequester potassium intracellularly and result in hypokalemia.

Hyperosmolarity

Hypertonic potassium-free solutions administered to normal human subjects fail to lower plasma potassium, despite expanding the extracellular fluid compartment.[425] This observation suggests that plasma potassium is maintained during the infusion by movement of potassium out of cells, impelled by an increase in its intracellular concentration, because of contraction of the intracellular volume. Potassium levels are maintained even when dilutional acidosis is prevented by incorporating bicarbonate into the hypertonic infusion.[426]

A modest rise in plasma potassium concentration (0.3−0.6 mEq/liter) can be produced in normal subjects by moderate increases in tonicity (10 mOsm/kg).[427] The effect is of clinical importance chiefly in diabetics, in whom plasma tonicity can be raised by 40−50 mOsm/kg during hyperglycemia, and who lack insulin-mediated potassium uptake. Glucose-induced hyperkalemia is more pronounced in diabetics deficient in aldosterone secretion[428] or during treatment with captopril,[429] but it may also be observed in diabetics with normal aldosterone responses. The standard 100 g oral glucose tolerance test produced an average increment of 1.3 mEq/liter in plasma potassium in four such patients.[430] The effect of hyperosmolarity on potassium homeostasis may also be present in patients with cerebral edema or with renal insufficiency when treated with large quantities of hypertonic mannitol.

Cellular Necrosis

When renal excretion and extrarenal disposal of potassium are exceeded, release of intracellular potassium into the extracellular compartment during cellular necrosis will result in hyperkalemia. The most common sources are muscle, tumor cells, and erythrocytes.

Traumatic muscle injury, due to motor vehicle accidents, alcoholism, cocaine abuse[431] or other etiologies, may produce life-threatening hyperkalemia, usually during rhabdomyolytic renal failure. Catabolic states, such as sepsis, compound fractures, burns, major surgery or overwhelming infections, result in protein breakdown to meet increased energy demands. Skeletal muscle, the source of protein loss, may release sufficient potassium to cause severe hyperkalemia, if renal excretory mechanisms are compromised.

Accelerated breakdown of a large leukemic tumor burden, especially during induction of chemotherapy, produces kaliuresis and may cause symptomatic hyperkalemia. Burkitt's lymphoma, a rapidly growing neoplasm, while not causing hyperkalemia even in azotemic patients prior to chemotherapy,[432] may result in hyperkalemia within hours of treatment, even in the absence of renal insufficiency. Fatal hyperkalemia has also been reported after initial tumor lysis therapy in acute lymphocytic leukemia, chronic lymphocytic

leukemia, and lymphosarcoma. The tumor lysis syndrome is only rarely reported after treatment of non-lymphomatous solid tumors.[433] Intensive supportive therapy probably accounts for the absence of hyperkalemia reported in some series.[434]

Transient hyperkalemia, in the absence of renal failure, occasionally occurs during hemolytic states such as congenital or acquired hemolytic anemia, hemoglobinopathy or transfusion reactions. Conversely, plasma potassium may fall during the rapid proliferation of erythrocytes and their precursors when severe pernicious anemia is successfully treated.[435–437]

Barium

Barium is a well-known inhibitor of potassium exit channels in muscle at concentrations of 1–5 mM.[438] *In vitro*, Ba^{2+}-treated muscle develops flaccid paralysis and depolarization secondary to this change in potassium permeability.[439] Hypokalemia is therefore a feature of barium poisoning, as are cardiac arrhythmias and skeletal muscle paralysis,[440] associated with depolarization of muscle fibers.[438] Barium poisoning is thought to be responsible for "Pa Ping paralysis" reported in Chinese patients who had eaten salt or drunk wine with a high content of barium salts.[441,442]

Cesium

Cesium chloride has been marketed as part of an alternative therapy for malignancy. Cesium appears in the periodic table below rubidium and potassium with a positive valence of 1; its salts are extremely toxic, causing hypokalemia, cardiac arrhythmias, prolonged Q-T interval, and torsade de pointes, probably like barium, by blocking potassium exit channels.[443]

Fluoride

Exposure to toxic levels of inorganic fluoride can produce hyperkalemia that is refractory to standard measures to increase cellular uptake of potassium such as glucose, insulin, and bicarbonate. The mechanisms appear to be decreased potassium influx due to impairment of Na,K-ATPase, further aggravated by a subsequent increase in intracellular calcium that enhances potassium efflux via the Gardos effect.[444]

Hypothermia

Acute transient hypokalemia has been described in patients with hypothermia associated with accidental trauma or following surgery.[445,446] When body temperature returns to normal, the hypokalemia disappears. Post-operative hypothermia (<36.5°C) was found in 40% of patients undergoing gastrointestinal and vascular surgery. Low serum potassium levels coincided with post-operative hypothermia in over half of these, whereas no patients with normothermia became hypokalemic. Urinary potassium losses did not account for the differences.[445] The hypokalemia of experimental hypothermia is not prevented by beta-adrenergic blockade.[447] It may be related to the alkalosis that regularly accompanies hypothermia because of the effect of lowered temperature to reduce the dissociation of carbonic acid.[448]

Race

The extrarenal disposal of an intravenous load of KCl is delayed in normal young African-Americans as compared with Caucasians, perhaps attributable to a racial tendency to lower Na,K-ATPase activity in the cells of African-Americans.[449]

OVERVIEW OF K^+ DISTRIBUTION AND EXCRETION—INTERNAL AND EXTERNAL BALANCE

As the most abundant cation in intracellular fluid, K^+ plays an important role in a variety of cell functions. High K^+ concentration in cells and low K^+ concentration in extracellular fluid is essential for many cellular processes, including determining the electrical properties of cell membranes in both excitable (nerve, muscle) and nonexcitable (transporting epithelia) tissues.[514,515] Cell K^+ also contributes importantly to the effective osmolality of intracellular fluid, and thus to the regulation of cell volume.[316,514,515,568] Changes in cell K^+ modify intracellular acidity, and thereby indirectly influence a variety of metabolic processes.[4,274] These important functions depend on the coordinated action of a variety of regulatory mechanisms that serve to maintain total K^+ content (50–55 mmol/kg body weight) and distribution.[4,154,274]

INTERNAL K^+ BALANCE

Figure 49.1 schematically shows several features of the distribution of K^+ in the body. More than 98% of body K^+ resides within cells, principally in skeletal muscle, whereas only 2% of total body K^+ is located in the extracellular fluid space. Maintenance of K^+ homeostasis is challenging, because the daily dietary intake of K^+ in the adult (~70 mEq) typically approaches the total K^+ content normally present within the extracellular fluid space (~70 mEq in 17 L of extracellular fluid, with a K^+ concentration averaging ~4 mEq/l). To maintain zero balance in the adult, dietary intake of K^+ must be matched by its elimination, a task performed primarily by the kidney.

Ingested potassium enters the extracellular fluid by reabsorption from the small intestine, a process not subject to specific regulation.[264] K^+ that enters the extracellular fluid must temporarily and rapidly be translocated into cells to prevent dangerous increases in plasma K^+ levels. The buffering capacity of the combined cellular storage reservoirs, which includes muscle, liver, and red blood cells, is vast compared with the extracellular pool and is capable of sequestering large amounts of K^+. The biochemical and hormonal factors that influence the internal balance of K^+, typically by altering Na-K-ATPase activity, are listed in Figure 49.2.[7,259,479,480] Racial differences in K^+ distribution have also been reported.[495]

The steep K^+ concentration gradient across the cell membrane depends on the regulated interplay between active uptake by Na^+,K^+-ATPase and passive backleak through K^+ channels and carrier-mediated transport processes[514,515,568] (Figure 49.1b). When K^+ enters the extracellular fluid, active Na^+,K^+-ATPase-mediated K^+ uptake into cells occurs rapidly, and buffers against fluctuations of K^+ in the extracellular fluid. This process is efficient, and plasma K^+ concentration is kept

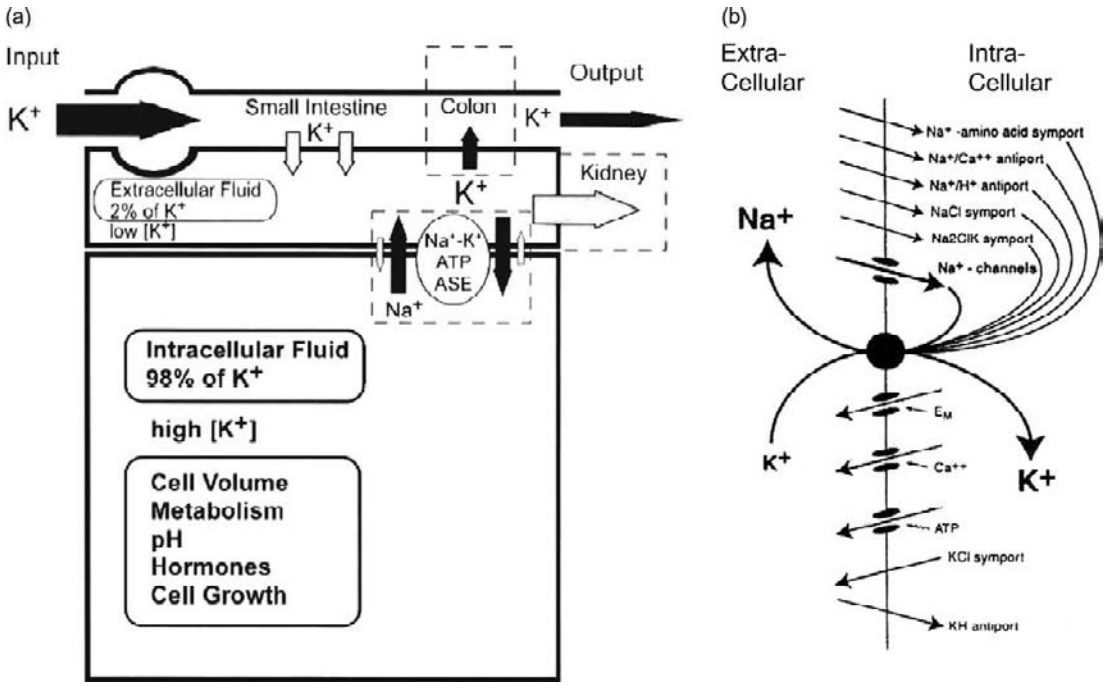

FIGURE 49.1 (a) Distribution of K^+ in the body and pathways of K^+ entry and exit. (b) Transporters involved in the distribution of K^+ and Na^+ across cell membranes. The activity of the Na^+,K^+-ATPase in cell membranes is opposed by several symporters, antiporters, and ion channels. *(From Giebisch, G. (2002). A trail of research on potassium. Kidney Int.* ***62****, 1498–1512, with permission.)*

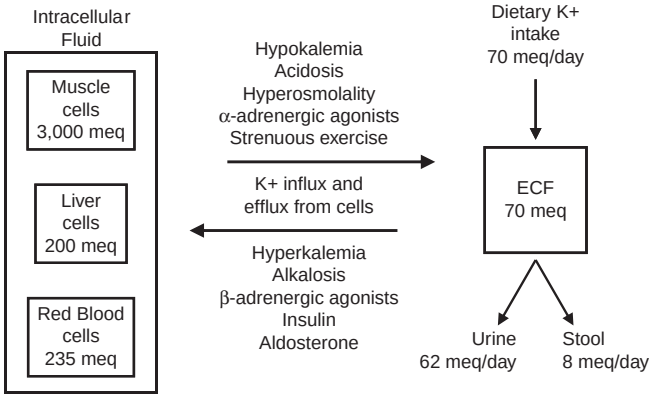

FIGURE 49.2 **Distribution of K^+ between the intracellular and extracellular (ECF) fluid compartments.** Only ≈2% of the total body K^+ is present in the ECF, with most of the remainder in intracellular fluid, here represented by three of the largest cellular compartments. The distribution of K^+ represents a balance between active uptake into cells by the Na^+,K^+-ATPase and the passive leak of K^+ out of cells. This balance is influenced by the K^+ concentration of the ECF, as well as by the factors listed above and below the two arrows. A typical daily K^+ intake of 70 meq/d is matched by the sum of a small excretion in the stool and the regulated excretion of K^+ by the kidneys. *(From Giebisch, G. (2002). A trail of research on potassium. Kidney Int.* ***62****, 1498–1512, with permission.)*

remarkably constant in the range from 3.5 to 5.0 mM.[53–55,97,98,102,478,479] Variations in K^+ intake are matched within hours by parallel adjustments in K^+ excretion, most of which is mediated by the kidney.[49,177–185,473,579–583] However, during exercise and ischemia, extracellular K^+ may quickly rise significantly. To minimize cell ATP decrease and loss of K^+ production of AMP-activated protein kinase (AMPK), under these conditions, is stimulated by an increase in intracellular AMP-to-ATP ratio favoring translocation of K^+ into cells in states of exercise and ischemia.[591,602] Although overshadowed by the kidney, the colon also excretes K^+ and responds to stimuli calling for a change in excretion rate.[29,30,151,216]

EXTERNAL K^+ BALANCE: THE ROLE OF THE KIDNEY

To accomplish excretion of the variable quantity of K^+ ingested daily, the kidney must first extract K^+ from blood in which K^+ circulates at a rather low concentration. Indeed, dietary K^+ may approximate that of sodium (80–120 mM/day), but the concentration of K^+ in plasma, and therefore the rate at which it is filtered by glomeruli, is only one-thirtieth of that of sodium. Nevertheless, the glomerular filtration rate (GFR) is normally high enough so that K^+ could be excreted by filtration alone. However, if the GFR is reduced to 10 to 15% of normal, as occurs with chronic renal failure, filtration alone would not be able to keep up with the normal dietary intake. Even if the GFR were reduced

TABLE 49.1 Main Features of Potassium Transport, Based on Clearance Experiments

1. K^+ secreted by renal tubules (excreted K^+ > filtered K^+)
2. K^+ excretion can be dissociated form the rate of glomerular filtration
3. Reabsorption of K^+ along the nephron precedes K^+ secretion
4. Secretion of K^+ occurs by exchange for Na^+
5. K^+ tolerance: Increased K excretion at relatively low K^+ in plasma
6. Reciprocal relation between urinary excretion of K^+ and H^+, carbonic anhydrase inhibitors induce kaliuresis
7. Adrenal steroids stimulate K^+ secretion

only by half, because not all filtered K^+ can escape reabsorption, it is likely that renal excretion would be inadequate and K^+ would be retained. Furthermore, even when GFR is normal, an excretion mechanism relying solely on filtration would have a limited capacity for adaptive increase, and could not achieve the 20-fold increase in K^+ excretion that has been observed in animals exposed to increased intake of K^+ by diets high in K^+ or parenteral infusions containing K^+. Indeed, net urinary K^+ excretion reflects not only glomerular filtration, but also tubular reabsorption and secretion. Clearance studies from as early as the 1940s revealed that the kidney is capable of secretion enabling the transfer of K^+ from plasma to tubule fluid.[48–52,177–186,187,292,330,345–347,379,473,474,583] Table 49.1 summarizes the main features of renal K^+ transport based on these studies.

A simplified but generally adequate view of renal K^+ handling is that proximal nephron segments between the glomerulus and the distal convoluted tubule (DCT) reabsorb a rather fixed fraction (80–90%) of the filtered K^+, whereas distal tubules and collecting ducts either secrete a variable quantity of K^+ into tubule fluid[49,177–187,221,320–324,379,485] or effectively reabsorb K^+.[119,179,325,371] By varying the rate and even the direction of K^+ transport, the distal nephron is able to respond homeostatically to changes in dietary K^+ intake or to changes in extracellular K^+ caused by other gains (parenteral administration, release from cellular pools) or losses (from the GI tract or skin). In people ingesting $\approx$70 mmol/day K^+, the usual rate of K^+ excretion in the postabsorptive period between meals is approximately 10–15% of the rate of K^+ filtration. In the hours following ingestion of K^+-rich meals, the rate of urinary excretion of K^+ can increase greatly to approach or even exceed the rate at which it is filtered. Such increments in K^+ excretion can be attributed to an increase in the quantity secreted by distal nephron segments. Increased secretion may not entirely account for increases in K^+ excretion in all cases, however, and variations in reabsorption by tubule segments, either proximal or distal to the main secretory sites, may become important in some circumstances.

If K^+ intake is reduced or eliminated (or if the body is depleted of K^+ by prior renal or nonrenal losses), urinary K^+ excretion declines rapidly as the deficit in total body K^+ increases. Within a few days K^+ excretion can be reduced to very low levels,[179,322–324] but K^+ conservation is less complete than that of sodium.[179]

General Aspects of K^+ Transport Along the Nephron

The generalization that filtered K^+ is largely reabsorbed by proximal nephron segments and that excreted K^+ is secreted by distal segments provides a useful framework for integrating information about renal handling of K^+, but a closer look at the cytologically distinct subdivisions of the nephron and the way each handles K^+ reveals a more complicated picture. K^+ is not continuously reabsorbed from all tubule segments proximal to the secretory sites in the distal tubules and collecting ducts. The rather constant fractional delivery of K^+ (10–20% of the filtered quantity) that has been found by collecting and analyzing samples of fluid from the earliest portion of the superficial DCT accessible to micropuncture is achieved by a sequence of reabsorption, secretion, and reabsorption as the glomerular filtrate travels through the proximal tubule and the loop of Henle.[179,322,323,324,325,466,470,471,473,579,583] Secretion of K^+ into loops of Henle has been documented only for the juxtamedullary nephron population[104,250,252,531]; however, it seems likely that the more superficial nephrons behave similarly.

Figures 49.3 and 49.4 represent schematic representations of the renal elements responsible for K^+ excretion. The location and naming of the subdivisions generally follow the scheme outlined by Kriz and Bankir.[281] Some features that distinguish superficial and deep nephrons are pictured. K^+ is filtered and reabsorbed from proximal convoluted tubules (PCT) of both superficial and deep nephrons. As the proximal straight tubule (PST) enters the outer medulla, the direction of K^+ transport reverses, and K^+ is secreted into the third proximal segment (S3) and the thin descending limb of the loop of Henle.[250–252] Higher K^+ concentrations are attained in loops of deeper nephrons that penetrate further into the inner medulla.

K^+ can be reabsorbed by thick ascending limbs (TALs), and net reabsorption probably occurs in both medullary and cortical TALs of both deep and superficial nephrons.[198,201,218] The portion of the distal tubule beyond the macula densa where each ascending limb contacts its parent glomerulus comprises several segments that are cytologically distinguishable. The DCT, extending beyond the

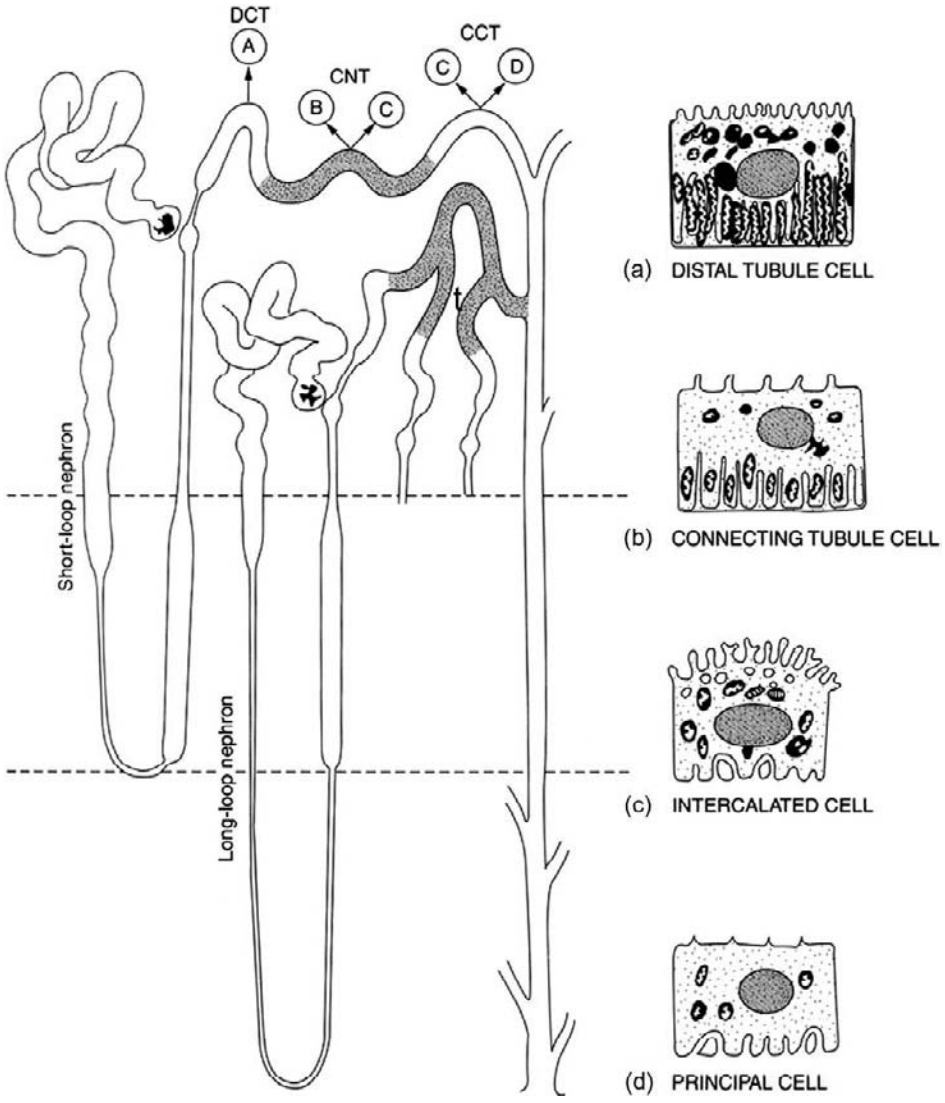

FIGURE 49.3 **Schematic illustration of the distal nephron segments** (CCT: cortical collecting tubule; CNT: connecting tubule; DCT: distal convoluted tubule). *(From ref. [244], with permission.)*

macula densa, is functionally distinct from the TAL segment, and probably contributes modestly to K^+ excretion.[451]

The next segment of the distal tubule – the connecting tubule (CNT), and the segment following it, the cortical collecting duct (CCD) – are major sites of K^+ secretion. In superficial nephrons, epithelium characteristic of the CCD appears some distance proximal to the first confluence of two distal tubules. This region has also been referred to as the late distal tubule or the initial collecting tubule (ICT).[28] In deeper nephrons, the CNTs frequently join to form arcades before flowing into the collecting duct. The separate segments of the distal tubule are discussed subsequently in more detail. K^+ is secreted into the collecting duct throughout the cortex, and probably in the outer stripe of the outer medulla as well.[485,486] However, in the inner stripe of the outer medulla, K^+ reabsorption appears once again and contributes to K^+ accumulation in the medullary interstitium. Both secretion and reabsorption of K^+ have been described along the terminal portions of the inner medullary collecting duct.[402,403,452,463,485–488]

K^+ Transport by Individual Nephron Segments

Glomerulus

K^+ ions that are free in plasma water pass across the glomerular capillary membrane with little hindrance. Nonfilterable proteins in plasma may bind a small fraction of K^+[294] and restrict filtration. The net negative charge on these plasma proteins tends to reduce K^+ concentration in glomerular filtrate relative to plasma water (Donnan equilibrium), but the concentration of

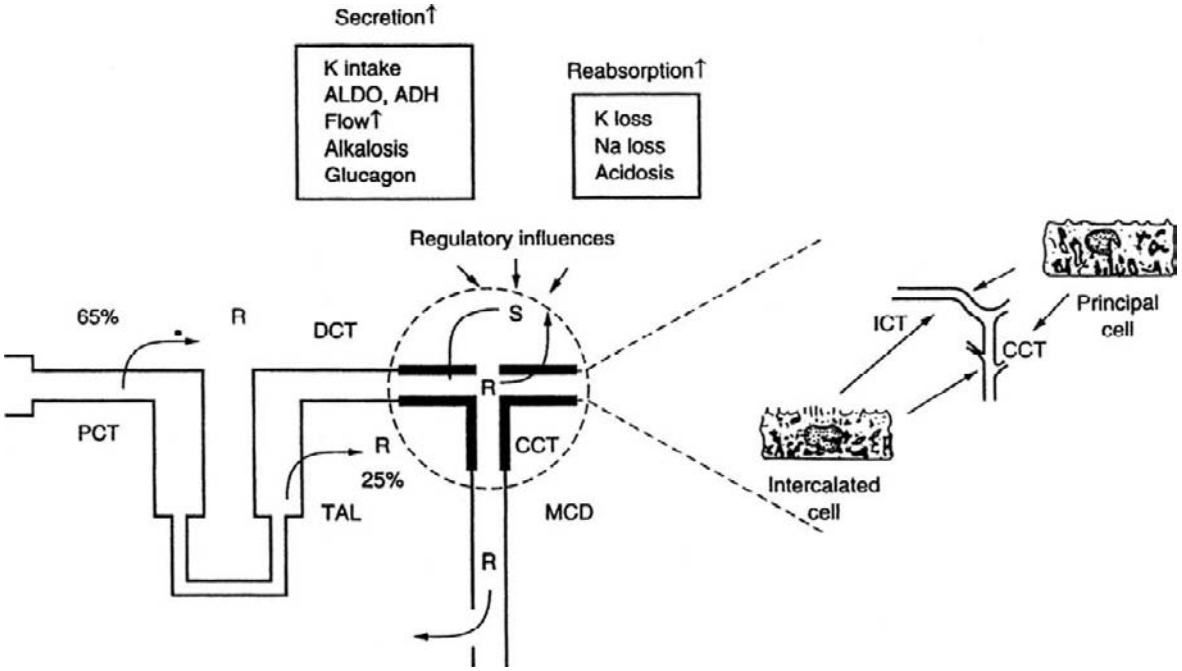

FIGURE 49.4 **Overview of K^+ transport along the nephron.** Secretion (S) largely determines the excretion of K^+ during normal and high K^+ intake; reabsorption (R) determines the excretion of K^+ in K^+ depletion. Note the cell heterogeneity in the distal nephron (see Figure 49.3) (ADH: antidiuretic hormone; ALDO: aldosterone; CCT: cortical collecting tubule; DCT: distal convoluted tubule; MCD: medullary collecting duct; PCT: proximal convoluted tubule; TAL: thick ascending limb of Henle). *(From Giebisch, G. (2002). A trail of research on potassium. Kidney Int.* ***62****, 1498–1512, with permission.)*

K^+ in plasma is approximately 6% lower than in plasma water. These factors tend to cancel each other out, and the concentrations of K^+ in glomerular filtrate and in plasma or serum, are approximately equal.

Although variations in GFR do cause proportional variations in the rate of K^+ filtration, they do not usually result in large changes in K^+ excretion, because mechanisms promoting glomerulotubular balance tend to stabilize the rate of K^+ delivery out of the proximal tubule and the loop of Henle. In the 1950s, when renal clearance methods were first applied systematically to the study of K^+ regulation by the kidney, it was observed that rates of glomerular filtration and final K^+ excretion could be varied independently of one another.[49,100,346,347] However, if GFR is reduced enough to decrease sodium and water excretion, the rate of K^+ excretion will also decrease.[49,100]

Proximal Convoluted Tubule: Direction, Magnitude, and Mechanism of Transport

Transepithelial K^+ Transport

Information about the direction and magnitude of K^+ transport processes along the nephron was obtained in the 1960s by *in vivo* micropuncture techniques.[193] The main features of K^+ transport in various nephron segments are summarized in Figure 49.4. Collections of tubular fluid samples showed that about 50% of filtered K^+ reaches the last accessible surface segment of the PCT.[322] Collections from sites close to the glomerulus showed that reabsorption of K^+, which occurs over most of the accessible proximal tubule,[59,179,322,325,399,553] may be preceded by a small K^+ leak into the lumen.[516] The downstream reabsorption of K^+ along the proximal tubule, like that of sodium, generally proceeds without developing a large concentration difference across the proximal tubule as a roughly similar fraction of water is also absorbed. Although K^+ concentration has been reported to increase slightly[40] or to remain unchanged[109] along the proximal tubule, a few studies have provided evidence that proximal reabsorption of K^+ can proceed against an electrochemical gradient, and that tubular fluid K^+ concentration may decline (by about 10%) between early and late proximal segments in rat kidneys.[61,268]

Three mechanisms participate in K^+ reabsorption by the proximal tubule: solvent drag; diffusion; and apparent active transport. First, the consistently observed association between K^+ transport and fluid transport suggests that a fraction of proximal K^+ absorption depends on the simultaneous rate of fluid

absorption.[61,62] This dependence of K^+ transport on net fluid transport, and the finding of low reflection coefficients of K^+,[550] support the notion of direct coupling of K^+ and fluid through the same transport pathway: a solvent drag mechanism.

Second, diffusion of K^+ from luminal to peritubular fluid may also occur because fluid absorption may raise the K^+ concentration in the proximal tubule, thus creating a concentration difference favoring K^+ absorption. *In vivo* microperfusion experiments show that proximal K^+ transport is very sensitive to changes in luminal K^+ concentration and transepithelial voltage.[61,62,550] The high K^+ permeability in the proximal tubule,[270] and the dependence of K^+ transport on the transepithelial electrochemical potential difference is consistent with diffusive movement through a paracellular pathway. However, barium, a potent K^+ channel-blocker, has been shown to block a significant fraction of K^+ reabsorption, implying possible participation of a transcellular route for reabsorption of K^+.[270,528] However, little is known about this pathway.

Third, the direction of the electrochemical driving force for K^+ in at least part of the proximal tubule, and the special microenvironment of the paracellular compartment between proximal tubule cells, provides theoretical support for apparent active K^+ absorption. Such movement of K^+ ions against an electrochemical potential gradient in the early proximal tubule is implied by experimental findings demonstrating both a concentration of K^+ in the tubule lumen below that in arterial plasma, and a lumen-negative transepithelial potential.[162,268,518] Moreover, dissociation between sodium-driven fluid movement and K^+ transport has also, albeit rarely, been observed. Micropuncture studies provide evidence that channel-dependent K^+ fluxes mediate a secretory component of K^+ movement into the early proximal tubule,[11,268,518] but K^+ reabsorption further downstream exceeds such secretory K^+ fluxes. Direct measurements of the electrochemical driving force for K^+ across the apical cell membrane in amphibian proximal tubules also support active K^+ reabsorption.[11,164] However, there is no evidence that K-H-ATPase activity identified in the apical membrane of mammalian proximal tubules[112,117] contributes to K^+ reabsorption.[538a,592]

A cell model summarizing the complex mechanisms involved in proximal tubular K^+ transport is pictured in Figure 49.5. It includes a sodium-K^+ exchange pump (Na^+,K^+-ATPase) in the basolateral membrane, a K^+ conductance in the apical membrane, and a pathway for K^+ transport between cells. Two pathways for K^+ exit across the basolateral membrane are shown: a conductive channel and a K-Cl co-transporter.[18,551] Note also that the transepithelial potential along the tubule changes from lumen-negative values in the early PCT to lumen-positive values in the late PCT.[162]

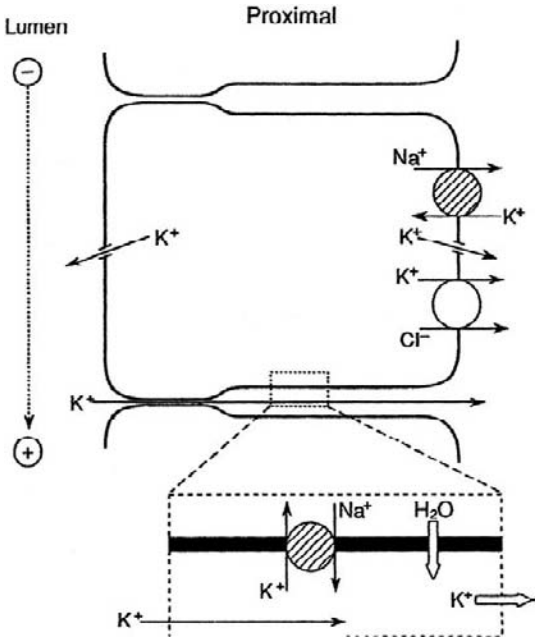

FIGURE 49.5 **Model of proximal tubule cell.** Transepithelial voltage is lumen-negative in S_1, and becomes lumen-positive in S_2. Enlargement of lateral membrane and the intercellular and extracellular spaces illustrates a postulated mechanism permitting absorption of potassium against a concentration gradient.

Weinstein has suggested that the apparent reabsorptive movement of K^+ against an electrochemical driving force does not require an active, directly energy-driven reabsorptive maechanism for K^+ in the apical cell membrane.[559] Given that Na^+,K^+-ATPase-driven uptake of K^+ does occur in the cell membranes lining the paracellular compartment between cells, such transport could deplete this compartment of K^+, particularly if the diffusion resistance to K^+ across the basolateral exit was low. A situation could then develop in which the luminal fluid equilibrates with the low-K^+ fluid in the interspace, effectively decreasing the K^+ concentration in the lumen below peritubular plasma levels. Exit of K^+ ions from the interspace into the peritubular fluid would be driven by bulk movement of fluid and K^+ along the hydrostatic pressure gradient that normally develops along the interspace from its luminal to basolateral end.

In the later part of the PCT, the transepithelial potential difference becomes lumen-positive, providing an additional driving force for net K^+ reabsorption.[162] It is likely that K^+ movement driven by the transepithelial voltage occurs through the paracellular shunt pathway. *In vivo* microperfusion experiments using mannitol to vary tubular fluid osmolarity reveal that the direction of net K^+ transport is

dependent on that of net fluid transport.[61,62] Previous observations had already shown that inhibition of proximal sodium and water transport would also block K^+ reabsorption,[59,181,234,579,581] an effect consistent with entrainment of K^+ ions by sodium-dependent fluid reabsorption.

Transepithelial electrochemical gradients of K^+ demonstrate the effect of changes in the electrical potential difference on tubule K^+ concentration.[456] Marked differences were observed between K^+-replete and K^+-depleted animals: whereas a lumen-positive potential was recorded in replete animals, the transepithelial potential difference was reversed in K^+-depleted animals, and the K^+ concentration ratio across the late proximal tubule was significantly elevated. These data support the view that diffusion along an electrochemical gradient can play a critical role in transport of K^+ across the proximal tubule.

Cell K^+ Transport

In proximal tubule cells, steady-state levels of cell K^+ depend on the balance between active uptake from interstitial fluid and passive leakage from the cytosol, either to the interstitium or to the tubule lumen. K^+ ions are actively taken up by the ATP-driven Na^+-K^+ exchange pump located in the basolateral membranes. Microelectrode measurements of basolateral membrane voltage and of K^+ activities show that the electrical potential difference across cell membranes of both amphibian and mammalian tubule cells is too small to account for the measured intracellular K^+ activity by passive distribution. Also, inhibitor studies indicate that ATPase-driven accumulation of K^+ is responsible for high cell K^+ concentrations. Inhibition of Na^+,K^+-ATPase activity reduces intracellular K^+ concentrations and content.[48,49,83,124,233,284,420,421,514,515]

The basolateral sodium-K^+ pump operates in an electrogenic mode: the rate at which sodium ions are pumped out of the cell exceeds the rate at which K^+ ions are taken in. The contribution of such an electrogenic cation exchange to the steady-state voltage across the basolateral membrane is probably small; however, sudden activation of the pump, either by raising cell sodium, by increasing extracellular K^+ from low levels or by warming tubules previously cooled, leads to rapid hyperpolarization of the basolateral cell membrane to levels that can exceed the equilibrium potential that could be generated by passive diffusion of K^+ ions.[48,49,83,124,148,150,233,390,420,421]

Figure 49.6 illustrates additional transporters in the basolateral membranes of proximal tubule cells. K^+ channels are present in both cell membranes, and serve several functions. They generate the cell-negative electrical potential which constitutes an important driving force for the entry of positively-charged solutes and the basolateral exit of negatively-charged solutes. Sodium-coupled electrogenic glucose and amino acid transport across the apical membrane of proximal tubule cells is facilitated by the cell-negative potential. Chloride diffusion, electrogenic Na^+-HCO_3 cotransport and Ca^{2+}/Na^+ exchange are also modulated by the magnitude of the K^+-dependent basolateral membrane potential.[513–515]

K^+ channels are also involved in volume regulation of proximal tubule cells.[237,419] Both apical and basolateral K^+ channels are activated by cell swelling, either directly by stretching of the membrane or indirectly, by volume-dependent Ca^{2+} entry through non-selective cation channels.[150,381,419] Apical K^+ channels are also sensitive to changes in membrane voltage, with depolarization leading to increased activity. Apical K^+ channels in the proximal tubule are critical in stabilizing the cell-negative potential, especially during depolarizing Na^+-coupled transport (i.e., with glucose or amino acids). The K^+ channel KCNQ1 and the accessory protein KCNE1 have been localized to the brush border of the mid-to-late proximal tubule.[516] They have been proposed to play a role in net K^+ secretion in the early proximal tubule, and in polarizing the brush border membrane to maintain the electrical driving force for Na^+-coupled transport. In support of this view, mice lacking KCNE1 exhibit increased renal excretion of Na^+ and glucose, and signs of volume-depletion.[516]

Basolateral K^+ channels are inhibited by an increase in cell ATP, by a fall in pH, by cyclic AMP and taurine,[217] and they have been implicated in renal cell damage by hypoxia.[400]

Coupling Between Sodium Transport and Basolateral K^+ Channels

The constancy of intracellular K^+ in the presence of large changes in transepithelial net sodium transport depends on appropriate modulations of the basolateral K^+ conductance.[453,454] Because a major pathway for sodium reabsorption is transcellular and involves the basolateral sodium-K^+ exchange pump, large changes in the rate of basolateral sodium extrusion necessarily cause large changes in K^+ uptake. However, by varying the magnitude of the basolateral-leak conductance in proportion to changes in pump rate, cells in renal[35–39,56,57,79,241,290,561,564] and other transporting epithelia[194] are able to maintain cytosolic K^+ activity, and cell volume, within narrow limits.

Pump-Leak Coupling

Transport-related changes in the coupling between active sodium extrusion across the basolateral membrane and apical and basolateral K^+ conductances are depicted in Figure 49.7a and 49.7b. Changes in cell

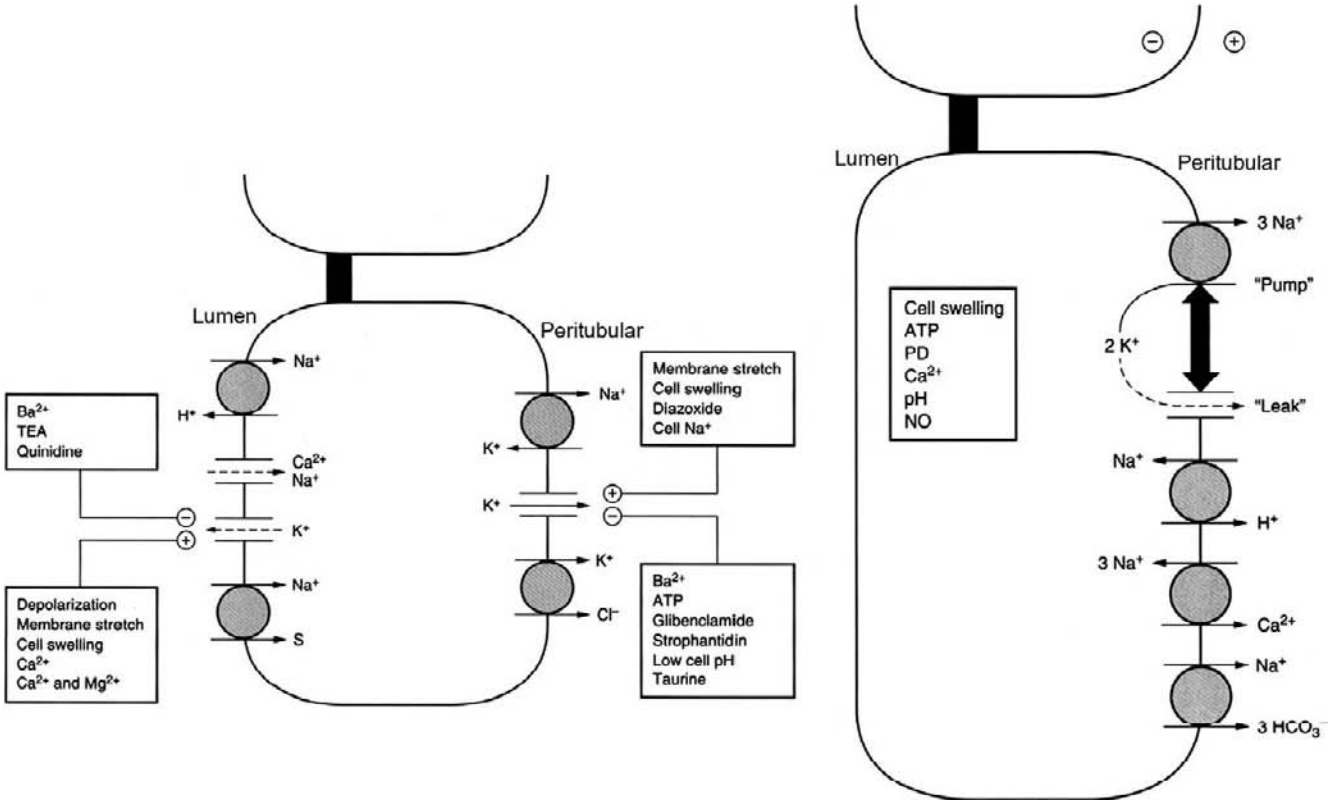

FIGURE 49.6 **Models of proximal tubule cells, including the main transport pathways and the apical and basolateral K^+ channels** (ATP: adenosine triphosphate; TEA: tetraethylammonium; NO: nitric oxide). Left: Model of a proximal tubule cell. Right: Relationship between the activity of basolateral Na,K-ATPase and the leak through K channels. The two-headed arrow indicates linkage between the pump and K channels; as K uptake increases, permeability to K increases, and *vice versa*. Factors that regulate transport pathways (left) and mediate the pump-leak coupling (right) are indicated in individual boxes. Basolateral transporters that may alter these variables are also shown (ATP: adenosine triphosphate). *(From Malnic, G., Bailey, M. A. and Giebisch, G. (2004). Control of renal potassium excretion. In "The Kidney," 7th ed., Vol. 1, 453–496, Brenner, B. (ed.). WB Saunders, Philadelphia, with permission.)*

volume and pH have a significant effect on K^+ channels, alkalosis increasing and acidosis decreasing the open probability.[35,210,282,286,362,446] During substrate-induced stimulation of proximal sodium transport, cell pH rises with a time-course that matches the observed increase in basolateral K^+ conductance.[38]

Changes in the concentration of Ca^{2+} in tubule cells, especially those correlated with fluctuations in cell volume and nitric oxide, may also couple basolateral Na^+, K^+-ATPase activity to K^+ permeability. Alterations in basolateral cell potential have also been implicated, since stimulation of electrogenic Na^+,K^+ pump activity hyperpolarizes tubule cells. Such membrane voltage changes are known to activate voltage-sensitive K^+ channels.[543]

Renal K^+ channel activity, including that of channels in the basolateral membrane of proximal tubule cells,[241,508] is also sensitive to alterations in cellular ATP.[35,36,508] Small amounts of ATP are required for the activity of some K^+ channels in the renal tubule, but millimolar concentrations inhibit K^+ channel activity. This effect is reversed by ADP,[217] and points to the involvement of the ATP/ADP ratio in the control of K^+ channel activity. It appears that transport-related changes in cell ATP levels modify cell K^+ conductance. Thus, stimulation of sodium transport in proximal tubules results in a significant fall in cell ATP, whereas inhibition of sodium transport increases cell ATP levels. This cross-talk mechanism, linking apical sodium transport to basolateral K^+ channel activity, is shown in Figure 49.7.[241,508,561] Thus, transport-related changes in the basolateral membrane potential of tubule cells may be involved in coupling the K^+ conductance to the pump activity. Measurements of the basolateral conductance of tubule cells,[233] as well as patch-clamp studies, in which the open probability of basolateral K^+ channels was examined as a function of the membrane potential,[343] show an increase in K^+ conductance with cell hyperpolarization. To the extent that stimulation of basolateral ATPase activity elevates the cell-negative potential, K^+ conductance would also be expected to increase interaction between basolateral and apical membrane transport.

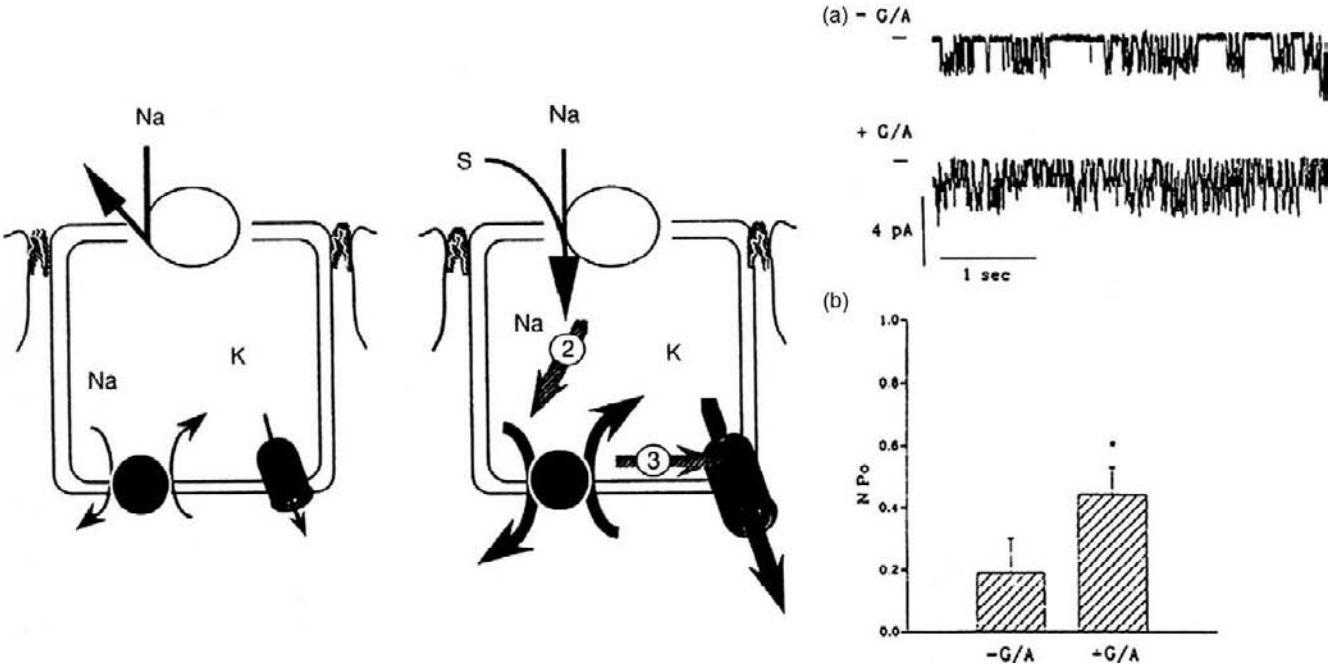

FIGURE 49.7 Left: Coupling between Na^+,K^+-ATPase activity and K^+ recycling in the basolateral membrane of proximal tubule cells.[36,37,198,512] Net rate of sodium transport was stimulated by addition of organic substrates (S; i.e., glucose or amino acid) to the lumen. Thus: (1) apical Na entry via Na-dependent substrate co-transporters is stimulated in the presence of substrates; (2) the Na^+, K^+-ATPase subsequently revs up so that active efflux of Na into the interstitium matches passive apical sodium entry; (3) ensuring that the increased active uptake of K^+ via the Na^+,K^+-ATPase will be efficiently recycled back across the basolateral membrane, K^+ channel activation ensues. *(Kidney Int. 1995; **48**, 1017–1023.)* Right: (A) Patch-clamp analysis of basolateral K^+ channel activity in isolated perfused proximal tubule. (B) Effect of luminal addition of glucose and alanine on single-K channel open probability (NP_o). $p < 0.02$. *(Am. J. Physiol. Renal 1993; **264**, F760–764.)*

Schultz has drawn attention to an additional relationship between transport events in the luminal and basolateral membrane of epithelial cells that involves changes in the pump-related K^+ conductance.[453,454] In leaky epithelia, such as the proximal tubule, stimulation of co-transport of sodium ions with organic solutes such as glucose or amino acids augments sodium entry across the apical membrane. Since the co-transporter carries positive current into the cell, the cell-negative electrical potential is reduced.[518] In tight epithelia, such as the CCD, mineralocorticoids increase apical sodium conductance, and thus bring about depolarization of the apical cell membrane.[64,65,275–277,356,358,361] The increase in K^+ conductance that occurs with stimulation of sodium pumping across the basolateral membrane also provides an important transport-sustaining feedback loop. The rise in potassium conductance hyperpolarizes the basolateral membrane and renders net transport more effective. An essential feature of these effects is that maneuvers that increase sodium transport tend to curtail further sodium entry, because the depolarization of the apical cell membrane reduces the electrochemical driving force for further sodium transport into the cell.

Loop of Henle: K^+ Recycling, Direction, Magnitude, and Mechanism of Transport

In vivo micropuncture and microperfusion studies show net reabsorption of K^+ between the last accessible segment of surface proximal tubules and the first accessible segment of surface distal tubules.[101,249,250,252,511–513] Thus, only a modest fraction, some 5–10% of the filtered K^+, reaches the early distal tubule (see Figure 49.4). As shown in Figure 49.3, this portion of the nephron comprises several morphologically and functionally distinct segments: the third segment of the proximal tubule (S3); the thin descending and thin ascending limbs; and the medullary and cortical thick ascending limbs of the loop of Henle.

The K^+ concentration in the loop of Henle fluid near the tip of the papilla can be as much as 10 times higher than the K^+ concentration in systemic plasma.[101,108,248–252] de Rouffignac and Morel[101] suggested that K^+ is added to tubule fluid along the descending limb of Henle's loop after being absorbed from the ascending limb and collecting duct. The phenomenon constitutes K^+ recycling (Figure 49.8). Jamison and coworkers further showed that K^+ delivery to the end of

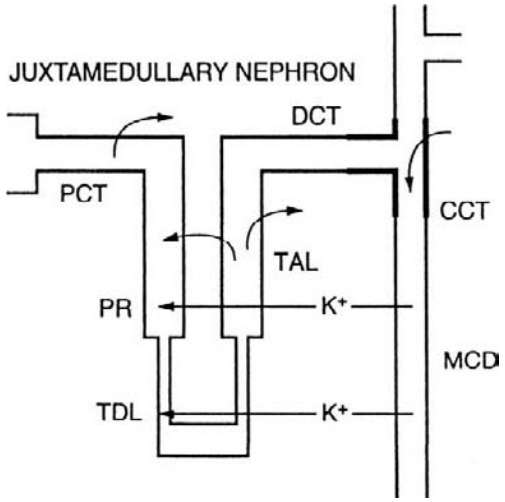

FIGURE 49.8 **Sites of K^+ movement into and out of the nephron.** The diagram emphasizes the movement of K^+ from the collecting ducts to the descending limbs of the loop of Henle via the medullary interstitium (CCT: cortical collecting tubule; DCT: distal convoluted tubule; MCD: medullary collecting duct; PCT: proximal convoluted tubule; PR: pars recta; TAL: thick ascending limb; TDL: thin descending limb). *(Field, M. J., and Giebisch, G. (1989). Mechanisms of segmental potassium reabsorption and secretion. In "The Regulation of Potassium Balance," 139–156, Seldin, D. W., and Giebisch, G. (eds.). Raven Press, New York, with permission.)*

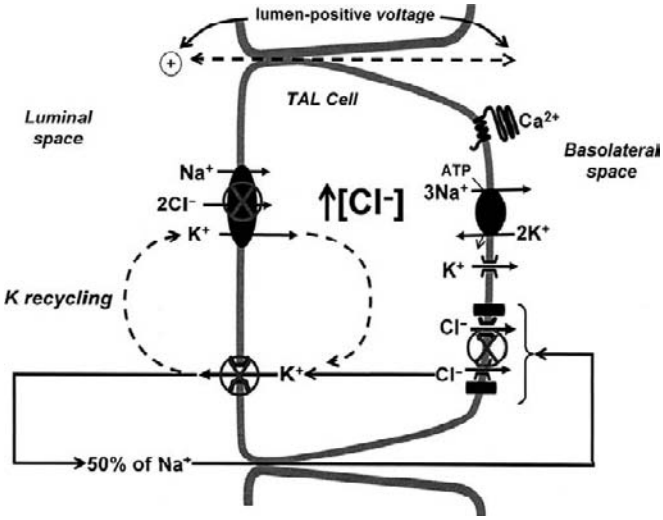

FIGURE 49.9 **Model of a thick ascending limb cell, including the main transport pathways and the apical and basolateral ion channels.** Potassium may also leave the cell across the basolaterall membrane by KCl co-transport (not shown). Note that the lumen-positive transepithelial potential difference drives cation reabsorption through the paracellular pathway (AA: arachidonic acid; ATP: adenosine triphosphate; CaR: extracellular calcium-sensing receptor; cGMP: cyclic guanonine monophosphate; 20-HETE: 20-hydroxyeicosatetraenoic acid; NO: nitric oxide; PKA: protein kinase A; PKC: protein kinase C; TALH: thick ascending limb of Henle; V_2: receptor for arginine vasopressin). *(From Malnic, G., Bailey, M. A. and Giebisch, G. (2004). Control of renal potassium excretion. In "The Kidney," 7th ed., Vol. 1, 453–496, Brenner, B. (ed.). WB Saunders, Philadelphia, with permission.)*

the descending limb of deep nephrons could equal the rate of K^+ filtration in normal rats,[252] and exceeded it in rats either fed a high-K^+ diet[32] or infused acutely with K^+.[15] The observation that isolated thin limbs of Henle lack a mechanism of active K^+ secretion[245,246] supports the view that K^+ enters the descending limb passively. If K^+ is also secreted into the proximal straight tubule of superficial nephrons,[552,578] and the delivery of K^+ to the DCT of deep nephrons is substantially less than the filtered quantity, then K^+ must be reabsorbed by ascending limbs in both populations of nephrons. Thus, K^+ is trapped in the medulla by countercurrent exchange between the ascending and descending limbs of the loop of Henle. Studies of isolated TAL perfused *in vitro* show that these segments are capable of absorbing K^+.[74]

As originally postulated by Jamison et al.[249] and shown in Figure 49.8, the main pathway by which K^+ can reach the renal medulla is absorption from the medullary collecting duct. Stokes[483–485] has shown that the outer medullary collecting duct is adequately permeable to both sodium and K^+, and therefore could permit K^+ reabsorption to occur passively. K^+ secretion by cells of the distal tubule and the cortical collecting duct into the tubular fluid provide the source of K^+ that accumulates in the renal medulla. Accordingly, more K^+ recycles with stimulation of secretion, whereas suppression of secretion attenuates the deposition of K^+ in the renal medulla. Thus, K^+ is secreted into tubule fluid in (at least) two sites along the nephron (see Figure 49.8), first into a proximal part of the nephron (the end-proximal tubule and descending limb), and second into a more distal region (the CT and CCD). When K^+ intake is suddenly increased after a period of K^+ deprivation, renal K^+ excretion, distal K^+ secretion, and K^+ recycling[110,129,130,214,223,249,494] all increase. Stokes also proposed that rising medullary K^+ concentrations inhibit NaCl and water absorption by the loop of Henle, and thus increase the flow rate and sodium concentration of fluid entering the distal tubule, providing optimum conditions for the distal segments to secrete K^+.[484] Medullary recycling is thus responsible for maintaining high concentrations of K^+ in the renal medulla. Such trapping of K^+ is also expected to limit reabsorptive loss of K^+ from the terminal collecting ducts.[579]

Thick Ascending Limb (TAL) Cell Transport Mechanisms

Studies of isolated mammalian TALs and amphibian (*Amphiuma*) early distal tubule have provided similar K^+ transport models (Figure 49.9). The primary driving

force for net K^+ reabsorption is again ATP-driven active Na^+-K^+ exchange across the basolateral membrane, which generates the steep sodium gradient for the entry of Na^+ across the apical cell membrane.

Apical Membrane

Entry of Na^+ is primarily mediated by an $Na^+ - 2Cl^- - K$ (or under certain conditions, Na,Cl) co-transport mechanism inhibited by the potent "loop" diuretics.[74–76,201–204,218,251,363,365–367,444] Also present in the apical membrane is a second pathway for sodium entry into cells, the Na-H exchanger (not shown in Figure 49.9). Conductive pathways for K^+ are found in both the apical and basolateral membranes.[201–204,218–220,363,365] The K^+ concentration gradient across the apical membrane favors K^+ secretion, which permits recycling of K^+ ions back to the tubule lumen. This back-diffusion provides a continuous luminal supply of K^+ for co-transport with sodium and chloride. The K^+ leak in the luminal membrane is also responsible for net K^+ secretion under those conditions in which the activity of the reabsorptive co-transport mechanism has been impaired.

Evidence supporting the operation of the $Na^+ - 2Cl^- - K^+$ co-transporter in the apical membrane includes the mutual dependence of these ions for transport. Net reabsorption of Na^+, K^+, and Cl^-, and the lumen-positive potential are abolished in the luminal absence of any of the three ions.[198,200–204] In addition, luminal application of furosemide also eliminates transport of all three ions, and collapses the transepithelial potential.[76,198,200,201,444] Interference with the co-transport system, either by appropriate luminal ion substitution or by administration of furosemide, lowers cell chloride and sodium activity, thereby supporting the view that the co-transport system is the main apical pathway for entry of these ions into the cell. Additional evidence for the requirement of a steady supply of luminal K^+ to safeguard $Na^+ - 2Cl^- - K^+$ co-transport in the cortical TAL is the observation that sodium reabsorption decreases sharply following the depletion of K^+ from the lumen or following the administration of K^+ channel-blockers.[537,538] These maneuvers also attenuate tubuloglomerular feedback.[519]

Morphological and electrophysiological criteria suggest the presence of at least two cell types in TALs, each with different permeability properties of the apical and basolateral cell membranes.[243,244,246] In the cortical TAL the K^+ permeability in the apical membrane exceeds that of the basolateral membrane, whereas the converse relationship was observed in the medullary TAL. These permeability differences may be associated with functional disparities, K^+ secretion being the prevalent transport mode in the cortical TAL, and reabsorption in the medullary TAL.[509]

Patch-clamp techniques have identified at least two K^+ channels in the apical membrane that mediate K^+ recycling.[58,217,540,544–547,548] The open probability of these apical K^+ channels is high, and they are inhibited by barium, low cell pH, millimolar concentration of ATP, and protein kinase C (PKC). Cell alkalinization and cyclic AMP, as well as NO and cyclic GMP, stimulate K^+ channels. Apical K^+ channels are also activated by furosemide, an effect mimicking the effects of aldosterone.[362,363,365,368] Aldosterone in amphibian early distal tubules, enhances apical Na-H exchange and alkalinizes cell pH. When furosemide is given, apical sodium entry is blocked and the intracellular sodium concentration decreases. As a consequence, the driving force for apical Na-H exchange increases and alkalinizes the cytoplasm. Because apical K^+ channels are stimulated by cell alkalinization, their activity increases.[362,363] This sequence of events explains why the full expression of the aldosterone effect on K^+ permeability depends on an intact Na-H exchange in the apical cell membrane.

A difference between the transport modes of cortical and medullary TAL segments has also been observed regarding the K^+ sensitivity of the apical co-transporter to K^+. Figure 49.10 shows two cell models in which vasopressin switches the apical sodium chloride transporter from a K^+-insensitive mode to one that depends critically on the presence of K^+ in the tubule lumen.[496a]

An interesting effect concerns the sequence of events following an increase in peritubular Ca^{2+}, which has been shown to inhibit both apical K^+ channels and $Na^+ - 2Cl^- - K^+$ co-transport.[217] Patch-clamp studies have demonstrated that the inhibitory effects of Ca^{2+} are mediated through activation of P450 and PKC.[539–542,546,547] It is likely that the extracellular Ca^{2+} ion-sensing receptor (CaSR) present on the basolateral membrane of the TAL[404,405] plays a role in this response. The CaSR is a G-protein-coupled surface receptor that is activated by increases in extracellular Ca^{2+} ion concentrations,[69] and has been shown to inhibit NaCl absorption and K^+ channels in the TAL by eicosanoids and P450 metabolites.[85,172]

Basolateral Membrane

As summarized in Figure 49.9, the basolateral membrane of TAL cells permits diffusion of both K^+ and chloride; however, the chloride conductance is dominant.[198,202,218,540] In addition to the K^+ conductance, $K^+ - Cl$ and the K^+-HCO_3^-[300] co-transport provide additional pathways for K^+ movement from cell to interstitium. Patch-clamp studies have defined a sodium-sensitive K^+ channel in the basolateral

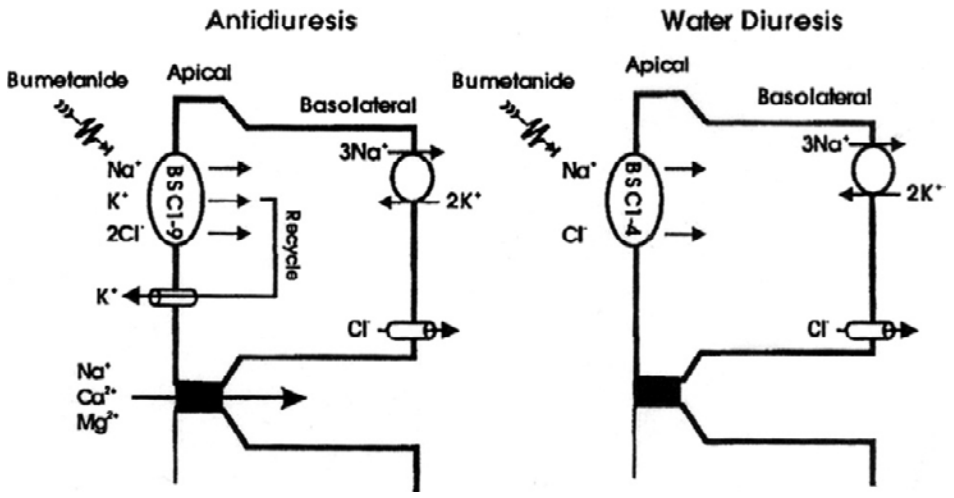

FIGURE 49.10 **Proposed model for thick ascending limb (TAL) function.** (a) Operation during water conservation. (b) Operation during maximal water diuresis. *(Am. J. Physiol. Renal 2001; **280**, F574–F582.)*

membrane.[383] These channels are stimulated by high cell sodium concentrations, providing coupling mechanisms between apical sodium uptake and basolateral ATP-dependent K^+ recycling. The Cl^- concentration gradient across the basolateral membrane favors diffusion of chloride from interstitium into the cell. Thus, both the luminal K^+ conductance and the basolateral Cl^- conductance tend to generate diffusion potentials oriented with the cell interior negative to the extracellular fluids. Because the K^+ concentration gradient across the apical membrane exceeds the Cl^- concentration gradient across the basolateral membrane, the voltage across the apical membrane exceeds the voltage across the basolateral membrane. These unequal electrical potential differences arranged in series generate a lumen-positive transepithelial voltage, which provides a driving force for reabsorption of K^+ and other cations by passive diffusion through the paracellular shunt pathway. The magnitude of passive paracellular K^+ reabsorption is difficult to assess because the transepithelial electrochemical gradient for passive K^+ reabsorption along the cortico–medullary axis is poorly defined.

Overall K^+ reabsorption along the loop of Henle is the result of two opposing events: secretion into the descending limb of Henle's loop as a consequence of K^+ recycling (see Figure 49.8); and K^+ reabsorption along the TAL of Henle's loop. Stimulation of K^+ secretion into the descending limb and enhanced delivery to the tip of Henle's loop have been demonstrated during K^+-loading by puncture of juxtamedullary nephrons.[249,250]

Several factors modulate K^+ reabsorption along the loop of Henle.[511,512] K^+ reabsorption is enhanced by restricting dietary K^+ intake, provided a constant load of fluid and K^+ is delivered into the loop of Henle; administration of a high-K^+ diet has the opposite effect.[511] Reabsorption of K^+ in perfused loops of Henle is stimulated by aldosterone R6TS.[107,465,468,473] However, no reduction in the rate of K^+ transport was observed in studies of perfused thick ascending limbs isolated from adrenalectomized animals.[577] Several factors modulate K^+ recycling and delivery into the distal tubule. Recycling of K^+ between the collecting duct and the descending limb of Henle's loop is enhanced following aldosterone administration in adrenalectomized animals.[223] Calcitonin reduced medullary recycling by inhibition of K^+ secretion into the distal tubule,[130] whereas vasopressin had the opposite effect.[129] Urea recycling increases delivery of fluid to principal cells and stimulates K^+ secretion.[214] Because ammonium ions may substitute for K^+ ions on the apical $Na^+ - 2Cl^- - K^+$ co-transport site, hyperkalemia may inhibit ammonium accumulation in the renal medulla and impede its translocation into the collecting tubule.[121,122]

The amphibian diluting segment normally reabsorbs K^+, but it may secrete K^+ following K^+-loading,[364] administration of loop diuretics,[363,365] alkalinization of the peritubular fluid[436] or administration of aldosterone.[545,567] Aldosterone stimulates both cell K^+ uptake and release into the lumen, an effect that is reversed by exposure to amiloride.[516] Acidosis inhibits the Na-K pump, as well as the K^+ channel.[196,199,209] In contrast, alkalosis stimulates both pump-mediated uptake of K^+ into cells, and passive K^+ efflux from the cells of the diluting segment.[210] Apical K^+ channel activity also increases with cell volume.[210]

Reversal of the direction of K^+ transport, from reabsorption to secretion, frequently follows administration

of loop diuretics. Free-flow micropuncture and loop perfusion studies[234,341] in the mammalian kidney, as well as perfusion of the amphibian diluting segment, show sharply reduced rates of K^+ reabsorption or reversal to net K^+ secretion following the inhibition of the apical $Na^+ - 2Cl^- - K^+$ co-transporter by furosemide,[74,76,511,512] torasemide,[512] ethacrinic acid,[75] and bumetanide.[512,523,524] The secretion of K^+ is the consequence of unopposed K^+ diffusion from the cell into the lumen.

Several experimental studies show that vasopressin enhances net sodium, chloride, and K^+ transport across the thick ascending limb of Henle.[218,220,319] Vasopressin action increases basolateral chloride permeability and accelerates chloride extrusion into the peritubular fluid. Vasopressin also enhances the affinity of the apical co-transporter for K^+ and augments the apical K^+ permeability. This increase in permeability speeds up apical membrane recycling of K^+ and stimulates $Na^+ - 2Cl^- - K^+$ co-transport. Loss-of-function mutations of the apical ROMK K^+ secretory channel can lead to Bartter's syndrome. Interference with recycling of K^+ ions in the apical membrane accounts for diminished sodium and K^+ reabsorption, and explains the urinary loss of sodium and K^+, hypokalemia, and high levels of aldosterone observed in this genetic disorder.[20,218]

Two mechanisms by which inhibition (or absence) of apical K^+ channels curtails sodium chloride and K^+ reabsorption in the TAL[20] are summarized in Figure 49.9. First, diminished K^+ recycling across the apical membrane lowers the turnover rate of $Na^+ - 2Cl^- - K^+$ co-transport. Second, the drastic reduction of the lumen-positive potential compromises the main driving force for passive movement of sodium through the paracellular pathway. Current flow across the basolateral membrane is largely carried by chloride ions which normally leave the cell along a favorable electrochemical gradient through chloride channels. Interference with such chloride exit from the cell is expected to increase its cell concentration and diminish apical activity of $Na^+ - 2Cl^- - K^+$ co-transport. This is illustrated in Bartter's Syndrome types 3, 4A, and 4B, in which either the basolateral chloride channels (CLCKA, CLCKB) or Barttin (BSDN) are mutated.[217]

DISTAL CONVOLUTED TUBULE CELL: DIRECTION, MAGNITUDE, AND MECHANISM OF TRANSPORT

The main pathways contributing to K^+ transport by DCT cells are shown in Figure 49.11. Two conductive pathways in the basolateral membrane allow for K^+ and Cl^- exit. K^+ is also able to exit the cell across the apical membrane, primarily through a K—Cl co-transporter, and, in some preparations, barium-sensitive K^+ channels.[590] The predominant path for sodium entry from the lumen is a Na—Cl co-transporter (slc12a3) that is blocked by thiazide diuretics, but not inhibited by bumetanide.[95,134,135,522–525] Amiloride-sensitive sodium channels may also be present in the apical membrane.[590] The junctional complexes between cells are cation-selective, and may permit diffusion of Na^+ and K^+ through the paracellular pathway from interstitium to lumen.

Evidence for the apical K-Cl co-transporter has come from microperfusion studies in rats.[134,135,522–525] K^+ secretion in this segment is increased when the luminal concentration of either K^+ or chloride is decreased. This increase in K^+ secretion occurs without a change in transepithelial voltage, and is not blocked by barium. Recirculation of chloride ions across the apical membrane is an important element of the mechanism of such K^+ secretion, particularly when luminal chloride concentrations are kept low by the administration of poorly-reabsorbable anions such as SO_4.[526] Under such conditions, thiazide diuretics, by blocking apical chloride entry via NaCl co-transport, inhibit K^+ secretion, consistent with K^+ ions entering the lumen by an electroneutral K-Cl co-transport mechanism.

Single channel analysis has demonstrated the presence of K^+ channels that modulate Na^+ and fluid reabsorption in this nephron segment (Figure 49.12). Of special interest is the function of KCNJ 10 Kir4.1 (KCNJ10), which provides an important pathway for basolateral K^+ recycling, especially by heteromerization with KCNJ 10 (Kir5.1).[287] This heteromeric complex is inhibited by low cell pH, and by activation of

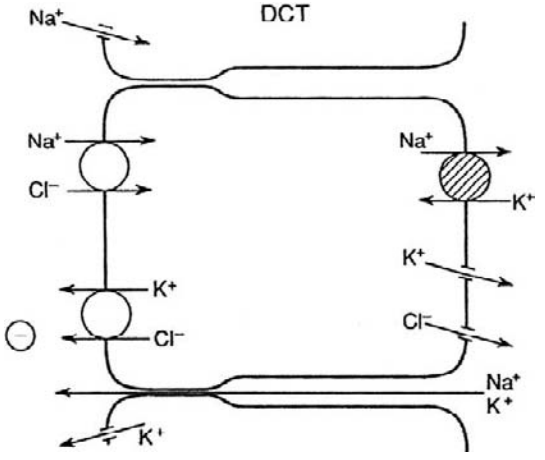

FIGURE 49.11 Model of distal convoluted tubule (DCT) cell. Some observations point to a lack of conductive pathways (channels) in the apical membrane; other studies have found evidence for Na and K conductances.

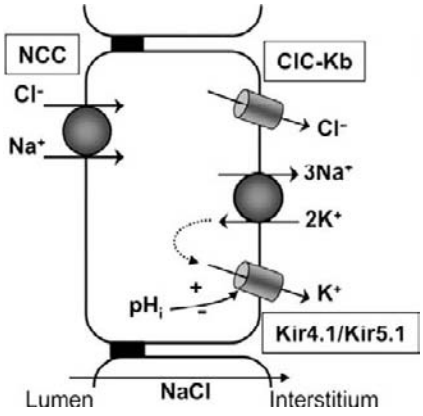

FIGURE 49.12 **Basolateral transport mechanisms in connecting tubule cells.** Note pH-sensitive K channels in the basolateral membrane. *(From ref. [24].)*

Ca^{2+} receptors.[24,287] Genetic dysfunction of this basolateral K^+ channel complex leads to salt-wasting due to diminished basolateral Na/K-ATPases activity, which results in high cell Na and a reduced driving force for passive Na entry across the apical membrane.[383a,401a]

Connecting Tubule and Cortical Collecting Duct Cells: Direction, Magnitude, and Mechanism of Transport

Two morphologically and functionally distinct cell types – principal cells and intercalated cells – determine K^+ transport in these segments, and play a major role in determining the magnitude of final urinary K^+ excretion (Figure 49.13). Principal cells, the most numerous cells in the initial collecting tubule (ICT), connecting tubule (CNT), and the cortical collecting duct (CCD) secrete K^+,[144–149,319–324,379–382,385,464,474] and are the cells subject to the most important regulatory influences. The less numerous intercalated cells also secrete K^+, but are capable of active K^+ reabsorption under certain conditions (dietary K^+ restriction) via an apical ATP-dependent electroneutral transport mechanism that mediates hydrogen ion secretion in exchange for K^+ reabsorption.[91,112,117,138,279,457–460,571,572]

K^+ Secretion

Figures 49.13–49.15 show the processes contributing to K^+ transport in the late DCT, CNT, and CCD. As pointed out above, the late distal convoluted tubule and collecting duct play a key role in K^+ homeostasis, but significant aldosterone-sensitive sodium reabsorption and K^+ secretion also occurs along the CNT. Collecting tubule K^+ secretion appears to become physiologically important whenever transport in the CNT is compromised or its transport capacity overwhelmed during ingestion of a high-K^+ diet.[416,560] Theoretical analysis, based on known morphology and transport parameters, has also supported the importance of CNT-mediated K^+ transport in maintaining K^+ homeostasis.[560]

Figure 49.13 summarizes the main transport processes mediating K^+ secretion in principal (and intercalated) cells. K^+ uptake across the basolateral membrane is again coupled to active sodium extrusion by the Na^+, K^+-ATPase, and provides for coupling between transepithelial sodium reabsorption and K^+ secretion. From the rapid depolarization of the basolateral membrane voltage caused by addition of ouabain to the peritubular bathing solution, it has been concluded that the Na–K^+ exchange pump operates in an electrogenic fashion, particularly following stimulation by desoxycorticosterone (DOC) treatment.[275,276,424,425,436] The basolateral pump responds to several stimuli known to modulate net K^+ transport, such as acid–base disturbances, changes in plasma K^+, and mineralocorticoid hormones.[175,176,184,185,187,276,312,314,356,360,424–427,465–469] Figure 49.13 also indicates the presence of a K^+ conductance in the basolateral membrane which, along with

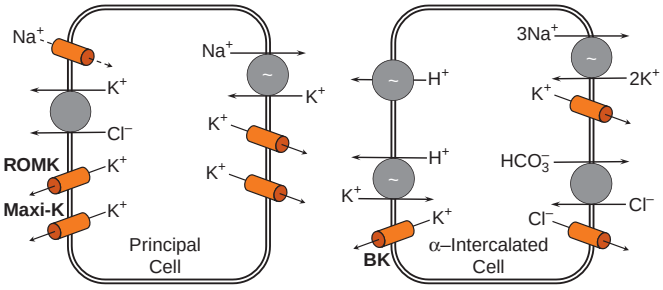

FIGURE 49.13 **Model of principal and intercalated cell, including apical and basolateral transport pathways.** Transcellular Na absorption proceeds through apical Na^+ channels and the basolateral Na^+-K^+ pump. K^+ secretion depends on K^+ uptake by Na^+-K^+ pump and movement through apical K^+ channels or K^+-Cl^- cotransporter. In intercalated cells, K is actively reabsorbed in the apical membrane by K/H-ATPase activity, and leaves cells in the basolateral membrane by K channels.

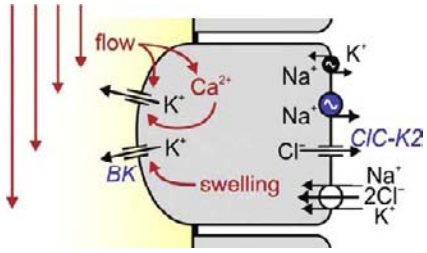

FIGURE 49.14 **Additional basolateral transport mechanisms (Na/2Cl/K transport) in principal and intercalated cells.** Note basolateral Na/2Cl/K transport. This model is consistent with passive paracellular Cl^--secretion.[575]

the high electrochemical gradient for K^+ efflux, is largely responsible for the cell negativity. Stimulation of the electrogenic Na^+-K^+-ATPase by aldosterone may drive the cell negativity to values exceeding the K^+ equilibrium potential, and reverse the direction of K^+ movement through basolateral K^+ channels (see section on adrenal steroids). Microperfusion studies in isolated CCDs have also identified a significant contribution of bumetanide-sensitive K^+ entry across the basolateral membrane of both principal and intercalated tubule cells (Figure 49.14).[310] Such K^+ transport, mediated by Na-K-2Cl co-transport (Slc12a2), is stimulated by high flow rate, and contributes to the well-established increase in K^+ secretion through BK (or maxi-K) channels.[574,575]

The apical membrane has both sodium and K^+ conductances. The sodium concentration gradient between lumen and cell favors diffusion of sodium ions into the cells, reducing the cell-negative voltage across the apical membrane relative to the voltage across the basolateral membrane. This asymmetrical electrical polarization of the apical and basolateral membranes favors diffusive movement of K^+ from cell to lumen, and is the source of the lumen-negative transepithelial potential difference which favors diffusive movement of K^+ from cell to lumen.

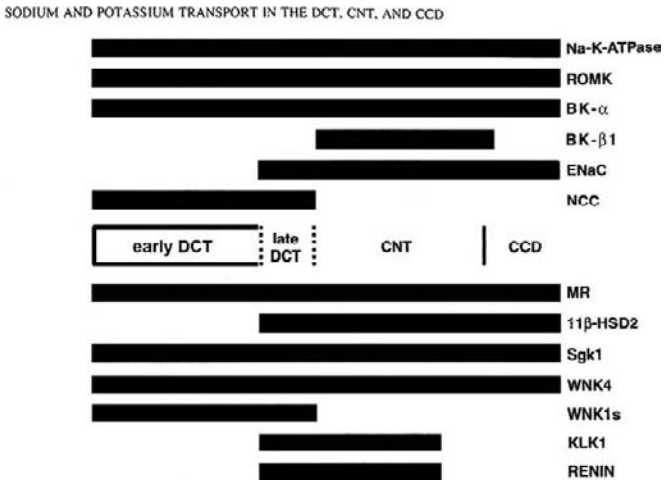

FIGURE 49.15 **Expression patterns of sodium and potassium transport systems and of their regulatory proteins along the distal convoluted tubule (DCT), connecting tubule (CNT), and cortical collecting duct (CCD).** In rat, mouse, and human, the sodium-chloride co-transporter (NCC) characterizes the DCT and co-localizes in the late DCT with the epithelial sodium channel (ENaC), which is also expressed in the CNT and CCD. The inwardly rectifying potassium channel (ROMK) and Na,K-ATPase are localized, respectively, in the apical and basolateral membrane along the aldosterone-sensitive distal nephron. Note that the expression of some regulatory proteins is restricted to the DCT and CNT, and does not extend to the CCD (MR: mineralocorticoid receptor; 11β-HSD2: 11β-hydroxysteroid dehydrogenase type 2; Sgk1: serum and glucocorticoid-inducible kinase; WNK4: with no lysine kinase 4; WNK1s: kidney-specific form with no lysine kinase 1; KLK1: tissue kallikrein). *(From Meneton, P., Loffing, J., and Warnock, D. Sodium entry across the apical epithelial sodium channel (ENaC; see Chapter 7 by Palmer and Sackin) and its electrogenic basolateral extrusion by the Na-K pump play a critical role in regulating apical K^+ transport by their depolarizing effect on the apical membrane potential. In animals fed a normal K^+ diet, K^+ secretion in the CCD is generally dependent on sodium absorption.[155,156,160,161,342,382,489] However, in rats fed a high-K^+ diet for as little as 18 hours, a significant fraction of K^+ excretion becomes amiloride-insensitive, and thus ENaC-independent, an observation consistent with the activation of a non-principal cell-mediated pathway in α-intercalated cells.[161] Diminished K^+ reabsorption in the proximal tubule may further compensate for compromised distal tubule K^+ secretion, as it has been shown that hyperkalemia suppresses proximal fluid and K^+ reabsorption.[67]

The apical membrane voltage of principal cells is depolarized following administration of mineralocorticoids.[179,350,356,359,360] In contrast, amiloride blocks ENaC and hyperpolarizes the apical membrane. The reduction in the driving force for K^+ excretion explains the K^+-sparing effect of this diuretic.[275,357,358,361] The K^+ conductance of the apical membrane is variable and increased by high-K^+ intake,[350,352,356,358,375,376,424–427,437,438,441,443] and vasopressin.[437,438,443] The apical K^+ conductance is reduced by intracellular acidification,[350,472,498] consistent with the K^+-sparing effect of acute acidosis.[470,475] Coupling between basolateral Na^+,K^+-ATPase activity and apical K^+ and sodium channels has also been observed, as evidenced by the coordinated changes of basolateral Na^+-K^+-ATPase activity and apical membrane Na^+ and K^+ conductances.[351]

K^+ Channels in the Aldosterone-Sensitive Distal Nephron (ASDN)

The apical sodium as well as apical and basolateral K^+ channels have been extensively studied by applying the patch-clamp technique to cultured amphibian kidney cells and to cells of isolated mammalian collecting ducts[81,157–161,179,183,187,217,379–382,407,540–548,563] (see also Chapter 47 by Wang and Huang).

Figures 49.15 to 49.17 summarize our present state of knowledge about apical and basolateral K^+ channels in principal and intercalated cells. The apical low-conductance secretory K^+ channel (SK) are highly K^+ selective, and have a high open probability. They are

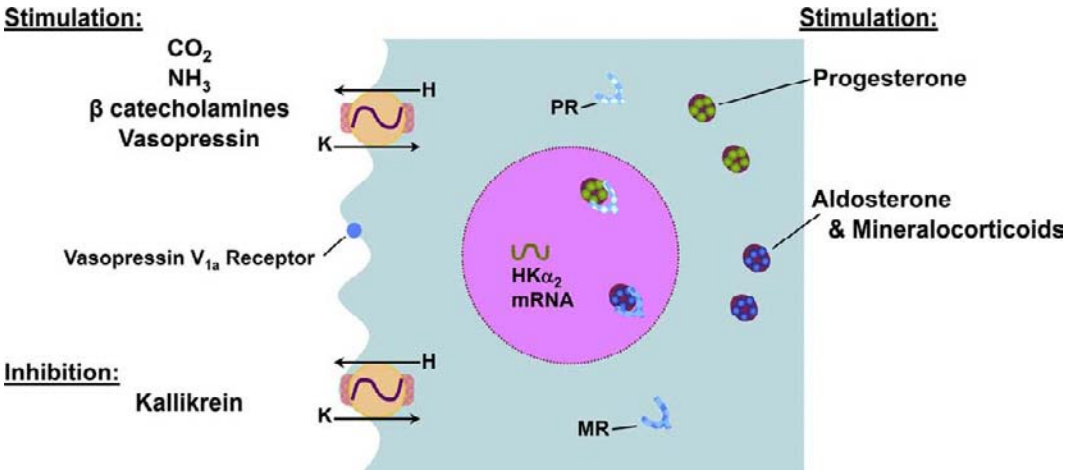

FIGURE 49.16 **Model of acid secreting (A-type) intercalated cells in the ICT and CCD.** These cells are the site of potassium absorption via an H,K-ATPase. Proton secretion is driven by an H-ATPase (not shown). *(Courtesy of Dr. Charles Wingo.)*

stimulated by low concentrations of ATP and cyclic AMP-dependent protein kinase A, as well as by alkalinization of the cytoplasm. They are inhibited by barium, arachidonic acid, Ca^{2+}-calmodulin kinase II, millimolar concentrations of ATP, Ca^{2+}-dependent protein kinase C, and acidification of the intracellular fluid. The channel is sensitive to phosphorylation processes, so that protein phosphatase inhibitors are required to prevent channel "run-down," the decline in channel activity observed following excision of membrane patches. The open probability of the secretory K^+ channel is not markedly voltage-dependent, and Ca^{2+} ions do not directly affect channel activity in excised membrane patches. Increased channel activity is often reflected by recruitment of channels into the active apical membrane pool.[217] The K^+ channel is identical to ROMK (Kir1, KCNJ1), a cloned, inwardly rectifying, low-conductance, ATP-regulated K^+ channel.[157,158,217,227,603]

Whereas the SK/ROMK channel is present solely in connecting and principal cells, high conductance channels with characteristics associated with BK or (maxi-K) channels have been identified in both principal and intercalated cells both functionally,[158,160,195,240,303,385–387,430] and by immunolocalization.[205–208,354] The density of BK channels in intercalated cells exceeds that detected in principal cells in the distal nephron.

The open-probability of BK channels, as defined in split-open, isolated connecting tubules and cortical collecting tubules, is quite low at the resting membrane potential and basal intracellular Ca^{2+} concentration, although their single-channel conductance is about five times that of ROMK.[158,303,377,430,432,440–443] Apical BK channels are activated by membrane depolarization, elevation of $[Ca^{2+}]$, hypoosmotic stress, and/or membrane stretch,[120,160,224,239,377,490,491] and can be selectively blocked by iberiotoxin.[20,78,170] BK channels are generally comprised of pore-forming α-subunit, a member of the *slo* family of K^+ channels originally cloned from *Drosophila*, and a regulatory β-subunit.[17,131]

Cumulative evidence implicates the BK channel in mediating an important fraction of K^+ secretion in the CNT and CCD in response to high urinary flow rates[20,310,386,387,574,575] K^+-loading[20,354,385–387] and application of vasopressin to the lumen fluid,[10] and in the absence of ROMK in Bartter's syndrome.[20] BK channel-mediated K^+ secretion in the CCD is also dependent on a basolateral bumetanide sensitive chloride-dependent transport pathway, proposed to be NKCC1[310] (Figure 49.14). In support of this conclusion is the finding that mice with genetic disruption of NKCC1 exhibit higher serum potassium concentrations, with

inappropriately low urinary potassium excretion, compared to wild-type mice.[334,533]

The density of BK channels in intercalcalated cells exceeds that detected in principal cells in the distal nephron. It remains unsolved as to how intercalated cells maintain a high steady state K concentration for sustained luminal K^+ secretion as there is little immunodetectable[418] and functional[34,44,116,380,434] Na^+-K^+ pump activity in intercalated cells. A K-independent Na-ATPase identified biochemically in kidney[468] and present in CA MDCK may serve as an exit pathway for Na brought in by the apical NBCDE or BL NKCC.

Flow activation of BK channels is associated with an increase in delivery to and reabsorption of Na^+ by the distal nephron.[269,342,574,575] This in turn increases the driving force for passive K^+ efflux by depolarizing the apical membrane potential. High tubular fluid flow rates also lead to an increase in $[Ca^{2+}]_i$, via luminal Ca^{2+} entry and IP3-mediated store release to concentrations sufficient to stimulate Ca^{2+}-sensitive BK channels.[574] It has been suggested that high flow rates along connecting and collecting tubules activates apical Ca^{2+} channels, which in turn stimulate Ca-sensitive maxi-K channels.[574,575]

An unresolved problem concerns the contribution of Ca^{2+}-sensitive BK^+ channels to K^+ secretion under physiological flow conditions. Single channel analysis by patch-clamp techniques is limited to "split-open" tubules in the absence of membrane stretch. This renders evaluation of BK^+ channel activity difficult in conditions mimicking physiological flow rates of tubule fluid.

The basolateral K^+ channels, shown in Figure 49.13, are also K^+ selective. Some are activated by membrane hyperpolarization; all are inhibited by barium. Basolateral K^+ channels are characterized by several factors that distinguish them from their apical homologs.[225,226,315] First, a subpopulation responds to hyperpolarization by increased activity,[543] which contributes to the increase in basolateral membrane K^+ conductance following stimulation of electrogenic Na^+-K^+-ATPase activity. Second, basolateral K^+ channels are stimulated by NO and cGMP.[225,226,315] The evidence for the involvement of NO is the decline in basolateral K^+ channel activity by inhibiting nitric oxide synthase, whereas donors of exogenous NO stimulate these channels. Application of cGMP analogs also activate basolateral K^+ channels, and hyperpolarize the basolateral membrane. This induces an increase in the apical membrane potential through current flow via the paracellular pathway, and stimulates sodium entry across the apical membrane of principal cells.[315] Features shared by these channels are their lack of inhibition by ATP and a biphasic effect of changes in cell Ca^{2+}: whereas low concentrations stimulate basolateral K^+ channels (via activation of cGMP), high levels of Ca^{2+} inhibit K^+ channels.[225,226,315,445]

Apical Co-Transport of KCl

Microperfusion studies of superficial distal tubules in the rat and isolated rabbit CCDs provide evidence for an electroneutral K^+ and chloride co-transport mechanism in the apical membrane,[8,132–135,521–525] also shown in Figure 49.13. The key evidence for this mechanism is that K^+ secretion into the distal tubule is stimulated when the lumen is perfused with solutions with a low chloride concentration. This effect occurs without changes in the transepithelial voltage across the distal tubule wall, and persists in the presence of barium, a K^+ channel inhibitor. K-Cl co-transport may contribute to K^+ secretion when the concentration of chloride in the lumen declines. This may occur with the delivery of poorly reabsorbable anions, such as sulfate, phosphate, and especially bicarbonate into the distal tubule.[8,264] The molecular identity of this KCl co-transporter is not known.

K^+ REABSORPTION

In the distal nephron, intercalated cells mediate K^+ reabsorption (Figure 49.14). They are scattered among the principal cells of the cortical and outer medullary collecting duct, and also among the cells of the distal tubule (infrequently in the distal convoluted tubule, and more commonly in the connecting tubule and initial collecting tubule).[99,255,318] Several types of intercalated cells have been recognized: A-type cells secrete hydrogen ions; and B-type cells secrete bicarbonate ions. A third, "mixed" type, containing both Cl^-—HCO_3^- exchangers in the apical and basolateral membrane, has also been described.[558]

The A-type cells may also be responsible for K^+ reabsorption, as shown in Figures 49.14 and 49.16. Several important differences between intercalated cells and principal cells should be noted. Na^+, K^+-ATPase expression and activity in basolateral membranes of intercalated cells in tubules of the renal cortex is much lower than in principal cells.[258] However, it is possible but not yet proven that lack of this transport is compensated for by a K-independent, ouabain-insensitive Na^+-ATPase.[173,408] Moreover, intercalated cells also have low apical Na^+-conductances, but express large-conductance BK channels.[303,239,377,432]

Several isoforms of K^+-H^+-ATPase, distinguished by variable K^+/Na^+ sensitivities of the exchange processes, and by different sensitivities to inhibitors such as gastric K^+-H^+ blockers and ouabain, are responsible for active K^+ absorption in intercalated cells.[6,112,117,211,457–460,558,571,572] Two types of K^+-H^+-ATPase have been described in rat and mouse

cortical and outer medullary collecting tubules, and they are structurally identical to isoforms of K^+-H^+-ATPases cloned from gastric and colonic mucosa. Their importance is suggested by numerous functional studies.[70,112,117,122] However, a recent study, based on experiments in gastric and colonic K^+-H^+-ATPase knockout mice has provided strong evidence for an as yet unidentified additional transport mechanism for linked K^+ reabsorption and hydrogen ion secretion that is distinct from known K^+-H^+-ATPases.[384a] The importance of this transporter is underscored by its ability to compensate effectively for the loss-of-function of both gastric and colonic K^+-H^+-ATPase. Similar results have also been reported using the mouse cortical collecting tubule. Thus, the contribution of individual K^+-H^+-ATPases and other not-yet-identified transporters to the maintenance of K^+ and hydrogen ion balance is not fully-understood.

Two inhibitors of the gastric K^+-H^+-ATPase, omeprazole and SCH28080, decrease both K^+ absorption and hydrogen secretion in the distal tubule and the outer medullary collecting duct. K^+-H^+ exchange is increased during metabolic acidosis,[404,460] experimental K^+ depletion,[70,112,117,122,457–460,571,572,592] and during administration of a low-sodium diet.[457,458] Increased sensitivity to K^+ depletion was reported in mice lacking the colonic isoform of K^+-H^+-ATPase, although the ability of renal K^+ conservation was quite well-preserved, and most of the loss of K^+ occurred by fecal excretion.[333]

Several factors modulate the activity of apical K-H exchange, and are summarized in Figure 49.16. They include acid–base-related factors such as stimulation by ammonium and CO_2, catecholamines, kallikrein, vasopressin, and adrenal steroids.[571] Moreover, progesterone is also important for effective retention during K^+ deprivation.[125,126] Interference with K-H exchange also compromises effective Na retention.[571]

Morphological studies of the apical cell membrane of intercalated cells in K^+-depleted rats have shown changes in fine structure, such as an increase in the number of rod-shaped particles and amplification of the microplicae.[254–257,481] These alterations in membrane structure are specific for the luminal membrane of intercalated cells. Intercalated cells also undergo marked morphological amplification of their apical membranes following acidification.[110a] These changes suggest that K^+ reabsorption and hydrogen ion secretion are functionally linked.

Medullary Collecting Duct Cells

Several sections of the medullary collecting ducts have been distinguished on the basis of morphological and functional differences. The outer medulla can be grossly separated into outer and inner stripes, and the inner medulla can be subdivided into outer and inner halves. The inner medullary collecting duct is separated into initial and terminal segments. Most of these collecting duct segments participate in the regulation of K^+ excretion.

The medullary collecting duct in the outer stripe resembles the cortical collecting duct. K^+ secretion and sodium reabsorption continue,[485–487] and the cells lining this segment have morphological and functional properties similar to principal and intercalated cells.[255]

The collecting duct in the inner stripe is characterized by a different transport pattern. K^+ secretion is absent when isolated tubule segments are perfused with symmetrical solutions, and the apical cell membrane lacks significant K^+ conductance.[464] However, when transepithelial K^+ gradients are applied, significant K^+ movement occurs, presumably via the paracellular transport route.[459,464,570] K^+ depletion increases the passive K^+ permeability.[464] The generation of electrical potentials also activates passive K^+ movement. For instance, a lumen-positive potential, generated by electrogenic hydrogen ion secretion, induces signficant K^+ reabsorption. This coupling between K^+ and hydrogen movement may explain why augmented proton secretion is frequently associated with enhanced K^+ reabsorption.

An active K^+-hydrogen exchange mechanism has also been detected in collecting ducts isolated from the inner stripe of the outer medulla in K^+-depleted rabbits. Activation of this transporter also contributes to the stimulation of K^+ reabsorption and hydrogen ion secretion that is observed in K^+ depletion.[569]

Both reabsorption and secretion of K^+ have been observed in the inner medullary collecting duct. Figure 49.17 summarizes some of the known transport properties of inner medullary collecting duct cells.[410] An important feature of inner medullary collecting duct cells is a nonspecific cation channel in the apical membrane.[305] Depending on the apical transmembrane electrochemical driving forces, this channel may mediate both sodium reabsorption and K^+ secretion. At very high lumen K^+ concentrations, passive reabsorption of K^+ may also take place. The presence of a furosemide-sensitive Na^+-2Cl-K^+ co-transporter in the basolateral membrane of inner medullary collecting duct cells has also been reported.[90a,209,410]

CONTROL OF RENAL K^+ TRANSPORT

General Aspects of Regulation of Renal K^+ Transport

Figure 49.18 illustrates the difference between two distinct K^+ mechanisms involved in renal K^+

homeostasis. First, feedback control of K^+ excretion depends on changes in plasma K^+ concentration which, either directly or by modulating aldosterone release, alters renal K^+ secretion. A second mechanism, feed-forward control of K^+ excretion, depends on the local increase of K^+ concentration in the gastrointestinal tract, the liver, and possibly the cerebral circulation.[591] Such feed-forward control of extracellular K^+ homeostasis minimizes changes of plasma K^+ concentrations, and may account for the rapid response of the kidney to changes in gastrointestinal K^+ uptake.[89,369,591] The nature of the intestinal and cerebral K^+ receptor and the signaling mechanisms effecting changes in renal K^+ excretion are not known. Attention should also be drawn to evidence that the central nervous system participates in controlling renal K^+ excetion. Examples include the rapid increase in K^+ excretion following unilateral nephrectomy, diurnal fluctuations of K^+ excretion, and aldosterone-independent changes in K^+ balance in hypo- and hyperkalemic conditions.[392–397] Figure 49.19 summarizes known agents modulating K^+ secretion.

Proximal Tubule

The proximal tubule is the main site of K^+ reabsorption, but does not play an important role in the physiological regulation of K^+ excretion.[179] K^+ transport is largely dependent on sodium and fluid movement, and changes with variations of proximal tubule sodium and fluid reabsorption. Increased delivery of K^+ into the loop of Henle occurs during osmotic diuresis and inhibition of proximal tubule sodium and fluid transport.

Secretory potassium entry into the proximal straight tubule has been reported[250,252] (Figure 49.8). Such secretory transport has been demonstrated *in vitro*,[260,261] but it is likely that modest K^+ secretion also occurs *in vivo*. Given the increase in medullary K^+ concentration along the corticomedullary axis, K^+ ions may enter the tubule lumen by diffusion as part of the process of medullary recycling.[248,249]

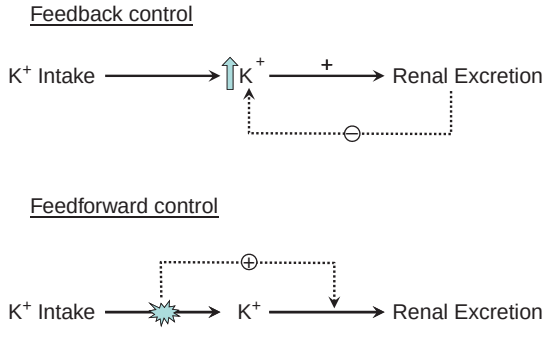

FIGURE 49.18 **The main control mechanisms safeguarding K homeostasis.[591]**

Thick Ascending Limb of Henle, Distal Convoluted Tubule, Connecting and Collecting Tubules

The TAL normally reabsorbs a significant fraction of filtered and recycled K^+. However, reabsorption may be significantly reduced or even replaced by net secretion, following inhibition of Na-2Cl-K co-transport or interference with apical K^+ recycling.[20,217,512] Diminished reabsorption of K^+ in the TAL may thus contribute to enhanced urinary excretion whenever TAL function is compromised.[20,234]

Modest rates of K^+ secretion have also been observed along the mammalian DCT, but changes in tubule flow rate and dietary K^+ intake do not affect K^+ secretion.[451] *In vivo* micropuncture and microperfusion experiments indicate that the DCT is the main site of action of thiazide diuretics.[94,95,522–525] An interesting relationship between sodium chloride and K^+ transport has been observed in microperfusion experiments. When apical sodium entry was stimulated by raising the Na concentration in the tubule lumen, K^+ secretion increased. It is likely that enhanced chloride entry increased cell chloride and stimulated K-Cl co-transport from cell to lumen.[521] Thus, recycling of chloride appears to play a significant role in K^+ secretion in DCT cells.

The CNT, ICT, and CCD are the main nephron sites that control K^+ excretion.[177–186,465,470,473,474,483–487,579–583,585] Information on the transport function of the ICT has been obtained by either free-flow or *in vivo* microperfusion studies. The CCD has also been investigated by *in vitro* microperfusion techniques. These tubule segments are distinguished by marked cell heterogeneity, and net transport of K^+ results from varying components of secretion and reabsorption of K^+. The most important systemic changes that affect these factors include K^+ intake, adrenal steroids, salt and water balance, and acid–base balance. Figure 49.19 summarized the main factors modulating K_r transport in DCT, CNT, and CCD.

Changes in K^+ Intake

Both increases and decreases in K^+ intake, as well as acute loading with K^+-containing fluids, initiate appropriate adjustments in renal K^+ excretion. Increases in K^+ intake tend to raise plasma K^+ concentration, which both affects the kidney directly and stimulates the adrenal glands to secrete aldosterone.[31,66,118] Decreases in K^+ intake or losses of K^+ that exceed intake tend to reduce total body K^+ content, plasma K^+ concentration, and aldosterone secretion.

K^+-Loading

Potassium secretion along the ICT rises sharply with parenteral administration of K^+-containing solutions.[179,182,185,473,474,491,579,583,585] The stimulation of K^+ secretion after acute K^+-loading has been demonstrated in both free-flow and microperfusion studies. Factors contributing to increased rates of secretion include increases in plasma K^+,[474,593] aldosterone levels,[66,118,145–147,166,482,487,585] and distal flow rate.[179,266,285,319,322] The independent and separate effects of these variables have been explored in microperfusion experiments in which flow rate, luminal ion concentrations, and the levels of both mineralocorticoids and glucocorticoids could be controlled.[121,123,154,155,416] Chronic K^+-loading increases the secretory capacity of the distal nephron so that at a given plasma K^+ level, renal K^+ excretion is significantly accelerated.[2,48,49,50,52,345–348,466] Figure 49.20 illustrates relationships between plasma K^+ concentration and either renal K^+ excretion or distal K^+ secretion in control animals, and in animals fed a high-K^+ diet, and Figure 49.21 provides an overview of the cell messengers involved. Pretreatment with the high-K^+ diet leads to powerful stimulation of K^+ secretion and a more rapid onset of kaliuresis.[228,352,585] This stimulation of K^+ secretion at normal or only slightly elevated plasma K^+ levels following chronic elevation of K^+ intake is a clear example of an adaptive change in renal function, and occurs even when plasma aldosterone is kept constant.[352] Full adaptation, though, does require an increase in mineralocorticoid levels.[140–147,381,382] Along with an enhanced rate of K^+ uptake by nonrenal cells,[7,53] the increased secretory capacity of distal tubule cells promotes K^+ tolerance – the ability of animals fed a high-K^+ diet to survive an acute K^+-load that would otherwise be fatal. As summarized in Figure 49.22, elevation of plasma K^+ also inhibits proximal fluid absorption, thereby increasing the delivery of fluid and Na into the distal nephron.[67]

A further example of K^+ adaptation is the ability of a reduced number of nephrons – such as in chronic renal failure – to sharply increase K^+ secretion and to maintain K^+ balance.[176] In addition to aldosterone, angiotensin II also increases ROMK activity, but only in animals fed a high-K diet.[556] A high-K diet increases not only the apical surface expression of ROMK, but also that of ENaC and of BK channels in both principal and intercalated cells in the CCD.[157] In contrast, NaCl co-transport expression in distal convoluted tubules was found to be decreased. Such redistribution of sodium reabsorption from NCC to nephron sites

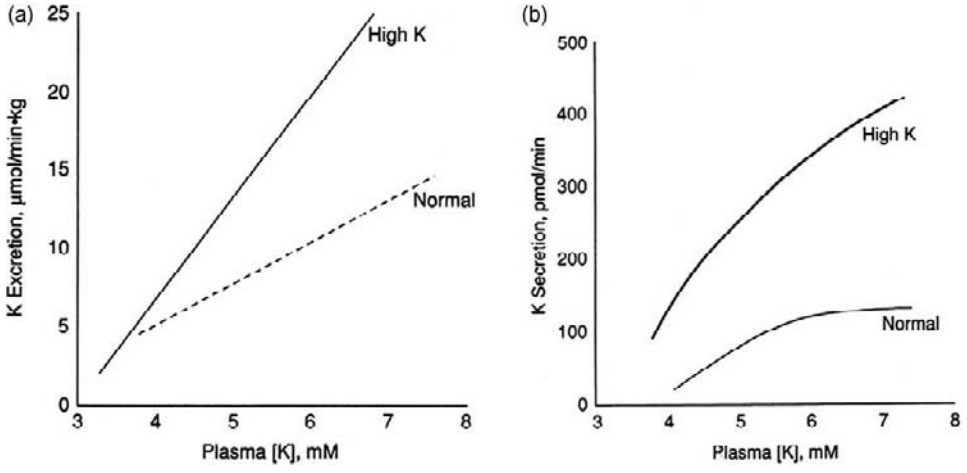

FIGURE 49.20 **(a) Relation between plasma K^+ concentration and renal K^+ excretion in rats on a control and high-K diet; and (b) distal tubule K^+ secretion.**

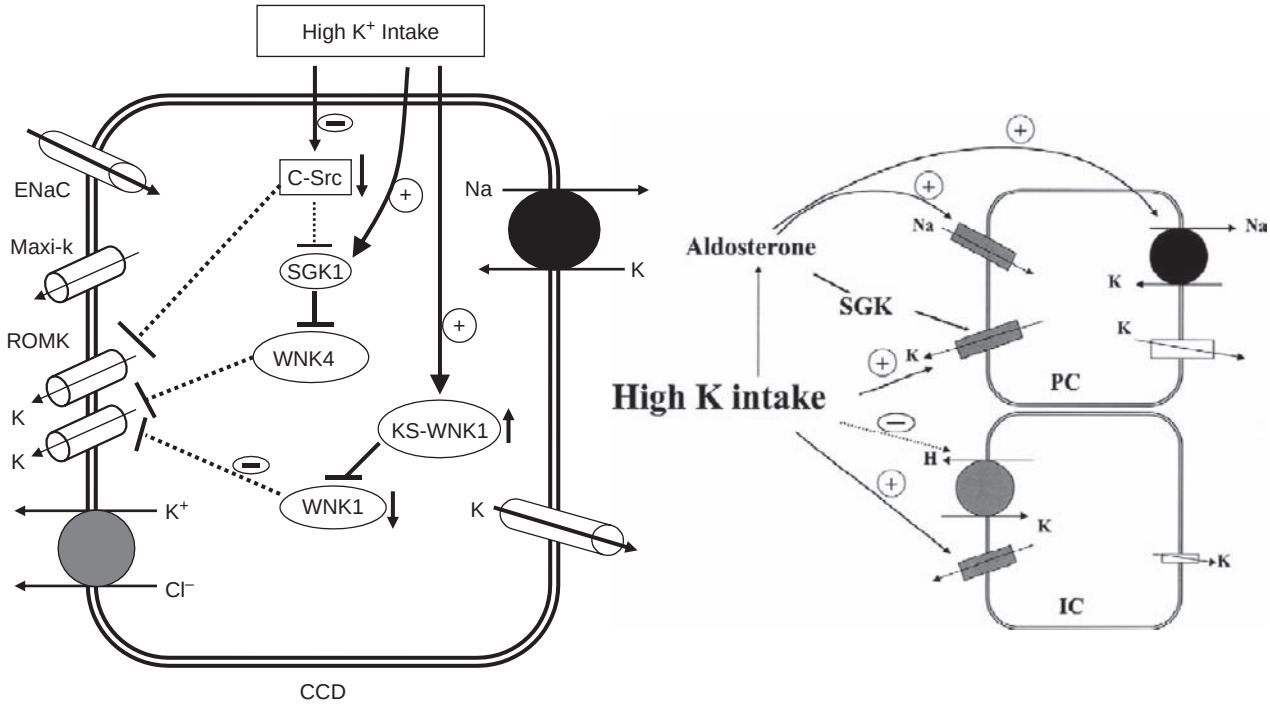

FIGURE 49.21 **Model of CCD cells illustrating the mechanisms by which high-K^+ diet increases K^+ secretion.** High-K^+ intake stimulates aldosterone secretion, which in turn activates ENaC and Na^+,K^+-ATPase in principle cells. Increased ENaC activity augments the driving force for K secretion, whereas stimulation of Na^+,K^+-ATPase can indirectly activate ROMK channel activity by a cross-talk mechanism. In addition, high K^+ intake can increase ROMK channel activity via modulation of the WNK pathway (see section on WNKs).

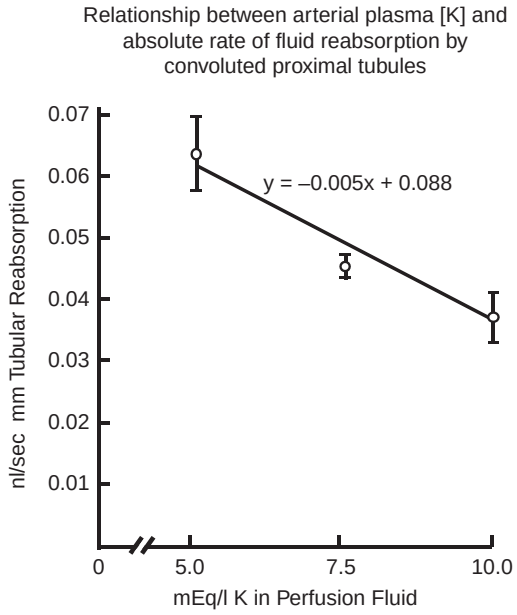

FIGURE 49.22 **Summary of the effects of changing peritubular K^+ concentration on proximal tubule fluid absorption.**[67]

with high ENaC expression provides an increase in the electrogenic driving force of K^+ secretion by the principal cell, and optimizes urinary K^+ excretion in hyperkalemic conditions.

Adaptive changes of K^+ transport have clear morphological and biochemical correlates in the distal tubule and CCD.[255–257,466,467,470] Proliferation of the basolateral cell membrane is highly significant in K^+-adapted animals, and is closely associated with a sharp increase in Na^+,K^+-ATPase.[113,114,156,163,254,296] Hyperkalemia and mineralocorticoids independently initiate the amplification of the basolateral membrane and the attendant increase in ATPase activity.[469] Thus, changes in basolateral membrane area, Na^+,K^+-ATPase content, and K^+ secretory rates are tightly coupled.[466,471,476] Morphological changes are apparent after 24 hours of increased K^+ intake and increase for about another week before a plateau is reached.[476] Increased K^+ excretion may continue beyond cessation of a high-K^+ intake.[348]

Principal cell basolateral membrane amplification also occurs with increased delivery of fluid and sodium ions to the ICT which occurs as a consequence of decreased proximal fluid absorption in hyperkalemic conditions[134,136,256,296,398] (Figure 49.22). The underlying mechanism appears to be stimulation of sodium reabsorption, which is linked to K^+ secretion. Another example is that chronic administration of furosemide to animals in which fluctuations of aldosterone and changes in electrolyte balance were prevented still leads to a sharp increase of K^+ secretion and sodium reabsorption.[469] Similar adaptation is observed in

unilaterally nephrectomized animals: K^+ balance is maintained by redistribution of Na^+ reabsorption from proximal to distal nephron sites and increased delivery of fluid into the distal nephron of the remaining nephron population.[109,467] Again, amplification of the basolateral membrane occurs predominantly in the principal cell population.

High-K^+ feeding also increases the pool of active ROMK in principal cells by diminishing apical removal of channels by endocytosis[157,161,539,544,546,548] and redistributing BK channels from an intracellular pool to the plasma membrane.[354] Figure 49.21 summarizes the change in cell messenger activity in response to increased K^+ intake. An important element responsible for stimulation of K^+ secretion is an increase in aldosterone release.[354] However, the effect of dietary potassium on stimulation of ROMK and BK channel activity is not due a direct hormonal effect, but reflects the mineralocorticoid-induced increase in apical ENaC and basolateral Na-K-ATPase activity, leading to enhancement of the electrochemical gradient favoring potassium secretion. The contribution of the BK channel towards excretion of a dietary potassium-load has been underscored by the finding that mice with genetic ablation of the β1-subunit of the BK channel exhibit, at baseline, low urinary potassium and sodium clearances, conditions that are exacerbated when the animals are fed a high-K^+ diet.[205–208]

In animals fed a normal K^+ diet, K^+ secretion in the CCD is completely dependent on sodium absorption.[342,483,489] However, distal potassium secretion may occur via a sodium-independent pathway in animals loaded with potassium for as little as 18 hours.[156,382] Moreover, basolateral sodium uptake via the Na/H exchanger has been proposed to be able to sustain basolateral pump activity in principal cells and potassium secretion in the CCD in the absence of significant sodium absorption.[353]

Dietary-induced stimulation of K^+ secretion is mediated not only by the aldosterone-dependent mechanisms described above, albeit indirectly, but also by aldosterone-independent mechanisms, a notion suggested by microperfusion studies that reveal that a high-K^+ diet stimulates potassium secretion in CCDs isolated from adrenalectomized rabbits.[352] A high-K^+ diet stimulates the expression of renal CYP2C23, a major CYP-epoxygenase, and increases the concentration of 11,12-epoxyeicosatrienoic acid (EET), a product of CYP-epoxygenase-dependent arachidonic acid metabolism in the CCD, which in turn stimulates BK channel activity,[497] CYP-epoxygenase-dependent arachidonic acid metabolism has been proposed to mediate regulation of renal K^+ secretion in response to dietary K^+ intake.[547]

A high-K^+ diet may not only diminish K^+ reabsorption by lowering H-K exchange,[569] but also by enhancing apical recycling of K^+ in intercalated cells by BK channels.[380]

K^+-Deprivation

Renal K^+ excretion drops sharply after withdrawal of K^+ from the diet and aldosterone secretion is suppressed. Concurrently, distal tubule K^+ secretion is markedly depressed or disappears altogether[142,175,177,371] to be replaced by net reabsorption.[119,322,371] K^+ reabsorption involves both active and passive transport mechanisms. Active K-H exchange is significantly increased in cortical and medullary collecting tubule segments.[70,112,117,571] An increase in passive K^+ permeability in the OMCD has been reported in states of K^+-depletion, and could favor accelerated K^+ reabsoprtion if the electrochemical gradient were favorable.

Figure 49.23 provides an overview of some of the transport changes that take place following administration of a low-K^+ diet.[539,540,546] Tyrosine phosphorylation of ROMK by Src initiates the endocytotic removal of apical K^+ channels. Specific tyrosine phosphorylation on the C-terminus of ROMK is critical, and superoxide production is closely associated with the low-K^+ response.[546] Notably, the reduction of apical K^+ channel density in response to K^+-depletion is independent of aldosterone, and consistent with previous findings of a direct effect of K^+ intake on K^+ excretion.[352]

Interestingly, upregulation of Na^+,K^+-ATPase activity has also been observed in tubules following K^+-depletion.[72,113] The original hypothesis that Na,K-ATPase was relocated to the apical membrane to facilitate K^+ reabsorption was not supported by immunological studies.[258] Thus, increased Na^+,K^+-ATPase-mediated K^+ uptake across the basolateral membrane requires increased backleak through basolateral K^+ channels.[113] It is well-established that K^+-depletion stimulates renal growth, a condition in which Na^+, K^+-ATPase might be expected to increase, but this relationship requires further exploration.[254]

K^+-depletion also involves changes in the distribution of H-K ATPases in cortical and outer medullary collecting ducts.[12,231,259] As shown in Figure 49.24, the ouabain-insensitive isoform of H-K-ATPase (type I) is downregulated in K^+-depletion and replaced by the type III isoform that is sensitive to inhibition by ouabain, and less selective for K^+ compared to sodium.[70,106a,117] Furthermore, remodeling of H-K-ATPases in K^+-depletion involves their targeting to principal cells,[117] instead of intercalated cells.

Since ammonium can substitute for K^+ on both Na-K-ATPase and Na-2Cl-K transporters, changes in extracellular K^+ exert a significant effect on acid excretion.[175,176,534] The interactions between K^+ and

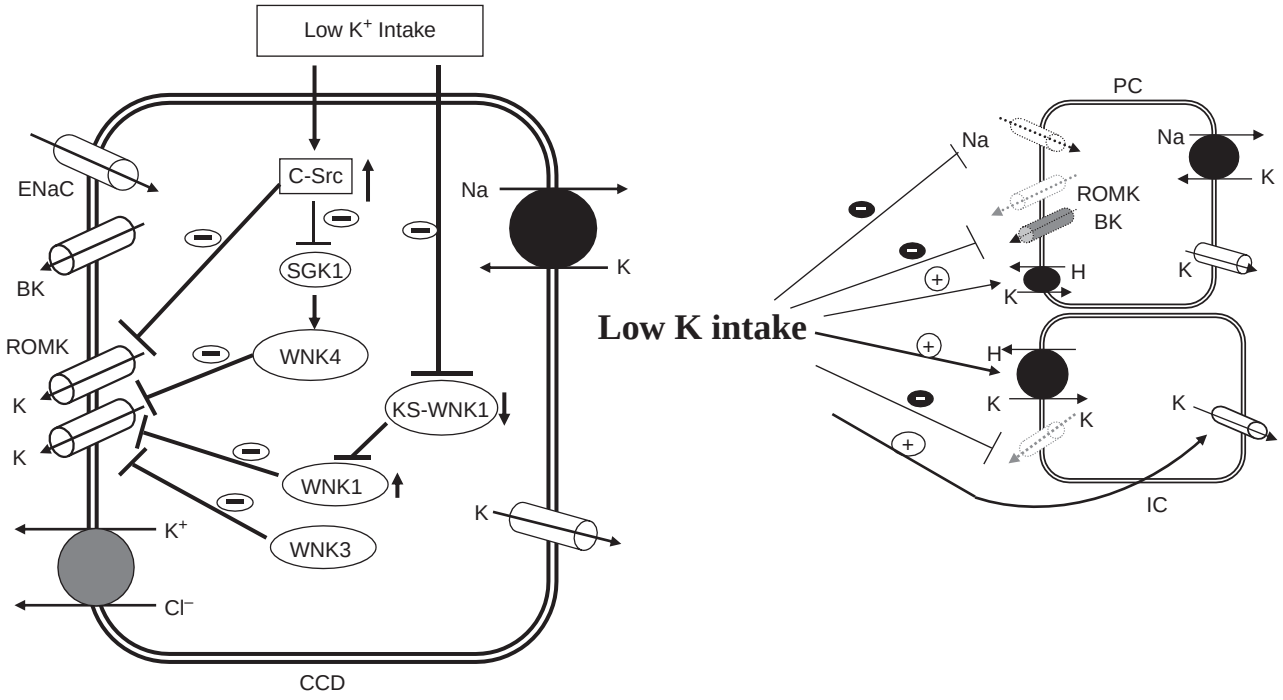

FIGURE 49.23 Model of CCD cells illustrating the mechanism by which low-K^+ diet decreases K^+ secretion. Low-K^+ intake reduces ROMK channel activity and thus K^+ secretion in principle cells via modulation of the WNK pathway and enhances apical H-K-ATPase activity in intercalated cells.

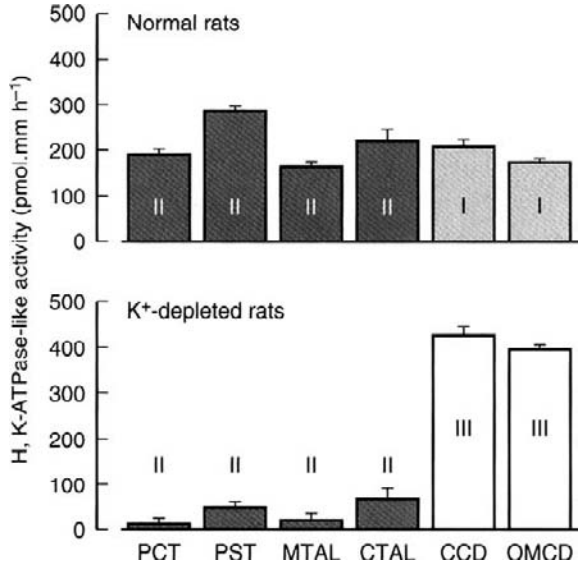

FIGURE 49.24 Distribution of three subtypes of H+,K+-ATPase-like activities, defined in the lower panel, along the nephron of normal rats and potassium-depleted rats.[117] All H-K-ATPase isoforms are sensitive to Sch28080. However, type I is insensitive to millimolar concentrations of ouabain whereas type III is sensitive to ouabain. Type II is inhibited by ouabain but is restricted in expression to the proximal tbule and thick ascending limb (TAL). Type III can be further distinguished from type II by its sensitivity to sodium and upregulation in response to K^+ depletion.[70,106a,117]

ammonium are summarized in Figure 49.25. Under conditions of K^+-depletion, the interstitial concentration of K^+ declines, and Na^+-K^+-ATPase-mediated uptake of ammonium in inner and outer MCD increases. Enhanced supply of cell hydrogen ion increases apical secretion, in part through the H-K exchange mechanism, thus stimulating K^+ reabsorption. Net K^+ secretion decreases further, since tubule trapping of ammonium blocks ROMK.[215] Hyperkalemia has the opposite effect. K^+ ions replace ammonium on Na^+,K^+-ATPase and the Na^+,K^+-2Cl co-transporter, which leads to diminished cell acidification and hydrogen ion availability for apical secretion. As a consequence, hyperkalemia may induce metabolic acidosis.[176]

Changes in aldosterone modulate, but are not fully responsible for, the renal response to K^+-deprivation. This mineralocorticoid modulates the urinary loss of K^+, but K^+ excretion continues to diminish when animals are put on a low-K^+ diet with clamped circulating aldosterone.[348–349]

In addition to aldosterone, progesterone has also been identified to be involved in the adaptive response to low-K intake.[126] Plasma concentrations of progesterone increase during K^+ restriction, and the efficiency of K^+ retention involves the stimulation of colonic H-K-ATPase in tubule cells.

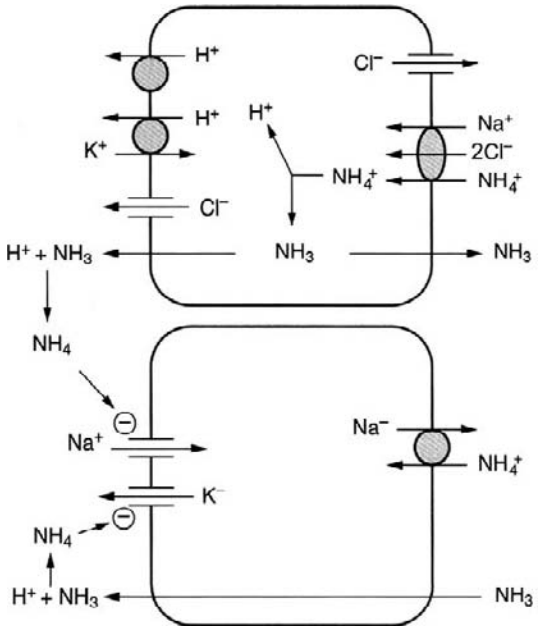

FIGURE 49.25 **Interaction between intercalated and principal cells.** Active K^+ reabsorption in the intercalated cell of the outer medullary collecting duct (OMCD) during K^+ depletion. Note that NH_4 can bind to the extracellular K^+ site of basolateral Na^+K^+-ATPase and the Na^+-Cl^--K^+ co-transporter and thereby stimulate H^+ secretion and K^+ reabsorption. Diffusion trapping of NH_4 in the tubule lumen directly inhibits K^+ secretion. *(From Malnic, G., Bailey, M. A., and Giebisch, G. (2004). Control of renal potassium excretion. In "The Kidney," 7th ed., Vol. 1, 453–496, Brenner, B. (ed.). WB Saunders, Philadelphia; and Wall, S. M. (2000). Impact of K^+ homeostasis on net acid secretion in rat terminal inner medullary collecting duct: Role of the Na-K-ATPase. Am. J. Kidney Dis. **36**, 1079–1088, with permission.)*

Finally, angiotensin II also plays a role in the tubule response to changes in K^+ intake. K-deprivation reduces apical ROMK activity, and patch-clamp experiments provide evidence for the involvement of AT1R receptor activation during inhibition of ROMK channels in rats given a low-K diet.[539,548]

Ultrastructural changes in medullary collecting ducts during K^+-depletion are largely confined to the intercalated cell population, and include a marked increase in the length of the apical cell membrane, an increase in the number of rod-shaped particles in the apical membrane, and a fall in the number of subapical cytoplasmic vesicles.[471] These morphological observations suggest an increase in the number of apical K^+ transporters, most likely the K,H-ATPase.

Interactions Between K^+ Channels and Magnesium

Changes in magnesium metabolism affect the kidney's ability to maintain normal K^+ balance. Magnesium deficiency tends to prevent restoration of K^+ balance following K^+ loss,[235] and recent evidence

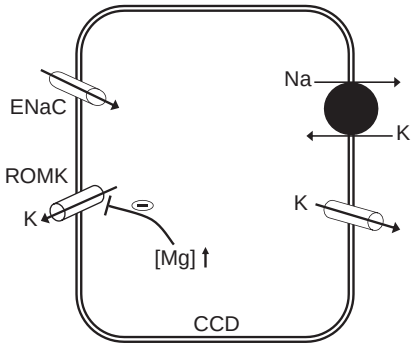

FIGURE 49.26 **Effect of changes in intracellular magnesium on ROMK channels in principal cells.**

has implicated involvement of apical ROMK channels in principal cells of the outer medulla[587]: a decrease in cell magnesium, during magnesium depletion, relieves K^+ channel inhibition and promotes enhanced K^+ secretion and kaliuresis whereas a rise in cell magnesium inhibits ROMK activity (Figure 49.26). Infusion of Mg decreases excretion of K^+ in the human kidney.

Adrenal Steroids

Mineralocorticoids have long been known to stimulate sodium reabsorption and, under appropriate conditions, enhance K^+ secretion. Figure 49.27 demonstrates the effects of aldosterone treatment on K^+ excretion.[594] Results from experiments in which mineralocorticoids were administered for prolonged periods of time until a steady-state was reached are shown. Aldosterone significantly enhances the efficiency of K^+ excretion, as evidenced by the fact that at each plasma K^+ concentration, more K^+ was excreted by animals with higher aldosterone levels. Expressed differently, as the aldosterone level rises, the same amount of K^+ can be excreted at progressively lower plasma K^+ levels. The direct stimulatory effect of mineralocorticoids on K^+ secretion by the distal tubule and CCD has been amply demonstrated.[55,93,145–148,222,356] Enhanced uptake of K^+ into extrarenal tissues has also been reported.[53,55,595]

The mechanism of aldosterone release from the adrenal glomerulosa involves two well-defined stimuli: cell depolarization by either an increase in extracellular K^+ or angiotensin II.[90] Both maneuvers enhance Ca^{2+} entry and aldosterone-synthase activation.[90] Recent evidence reveals that K^+ channel mutations characterized by diminished K^+ selectivity (increased Na permeability) result in cell depolarization and enhanced aldosterone production.[90]

The effects of mineralocorticoids on cell K^+ transport mechanisms of principal collecting duct cells are summarized in Figures 49.28a, 49.29 and 49.30. The effects of mineralocorticoids depend on the antecedent

hormonal condition, the duration of hormone treatment, and the modifying effects of sodium ions on K^+ transport.[96,146] Key aldosterone-sensitive transport mechanisms include the basolateral Na-K exchange pump, apical Na channels, and K^+ channels in both apical and basolateral membranes. Mineralocorticoid hormone action occurs in several steps summarized in Figure 49.29b. They include binding of aldosterone to cytoplasmic receptors to form the aldosterone–receptor complex, activation of the gene to initiate transcription, synthesis of new aldosterone-induced proteins, and actions on apical and basolateral transport operations. This process can be divided into early and late phases.

In the early phase, mineralocorticoids activate the apical sodium conductance, and thus stimulate sodium entry. With this increase in sodium entry and cell sodium activity, the basolateral pump turnover increases and K^+ secretion rises.[13,113,115,259,356,468,469] Enhanced sodium entry *per se* leads to rapid insertion of Na^+-K^+-ATPase units into the basolateral membrane from an enzyme pool whose magnitude depends on the antecedent aldosterone levels.[26,27,113,115,349] Thus, the acute effects of aldosterone include significant stimulation of Na^+,K^+-ATPase involving increased activity of individual pumps, and insertion of additional units.[115,259] Continued exposure to elevated mineralocorticoid levels results in late phase changes, including an additional increase in both K^+ and sodium transport rates, insertion of additional basolateral Na-K pump units, and further enhancement of the apical sodium and K^+ conductances.[153,276,356,424–427]

Also occurring in the late phase of mineralocorticoid administration are significant morphological changes in principal cells.[466–471,530,531] Mineralocorticoids have a direct effect on basolateral membrane amplification, independent of changes in K^+ balance and plasma K^+ levels.[469] However, sodium ions are required for full

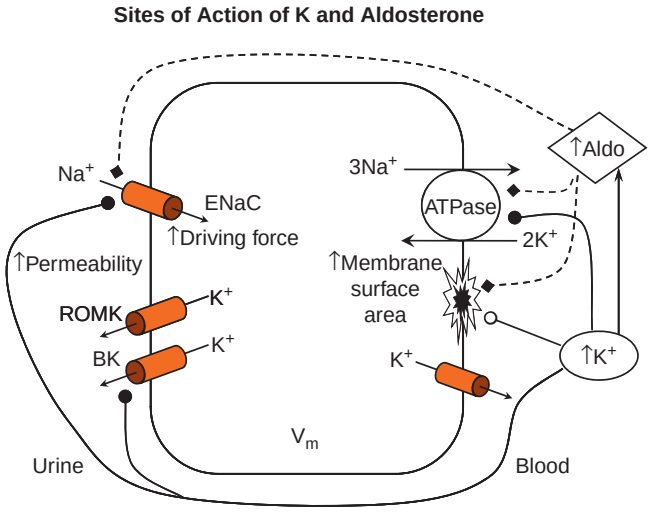

FIGURE 49.28 **Factors involved in the regulation of K^+ transport by aldosterone and peritubular K^+.** (1) Changes in peritubular K^+ increase apical K^+ and Na^+ channel activity, stimulate Na^+,K^+-ATPase activity, and augment the basolateral membrane area. High K^+ also activates the release of aldosterone. (2) Changes in aldosterone stimulate apical Na^+ channels but enhance K^+ channel activity only during chronic hyperkalemia. Similar to high K^+, aldosterone stimulates Na^+,K^+-ATPase activity and increases the basolateral membrane area and Na^+, K^+-ATPase activity. *(From ref. [150], courtesy of S. Hebert.)*

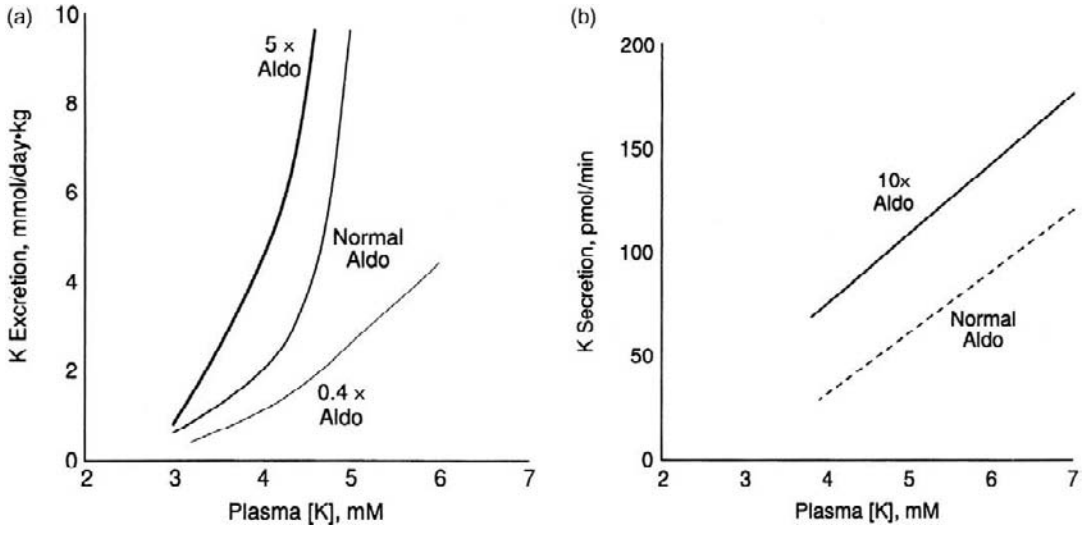

FIGURE 49.27 **Relation between K excretion and plasma K at different levels of aldosterone.** The relationship between plasma K^+ concentration and renal K^+ excretion (a) (*from ref. [415]*), and distal K^+ secretion (b) (*from ref. [416]*) is affected by circulating aldosterone. Effects of increased and decreased aldosterone are shown with respect to normal levels.

mineralocorticoid effects: morphological changes fail to develop fully during administration of a low-sodium diet.[476] In contrast to the changes observed in principal and connecting tubule cells, significant changes in basolateral membrane area fail to occur in intercalated cells during either diet- or hormone-induced stimulation of tubular K^+ secretion.[467,471]

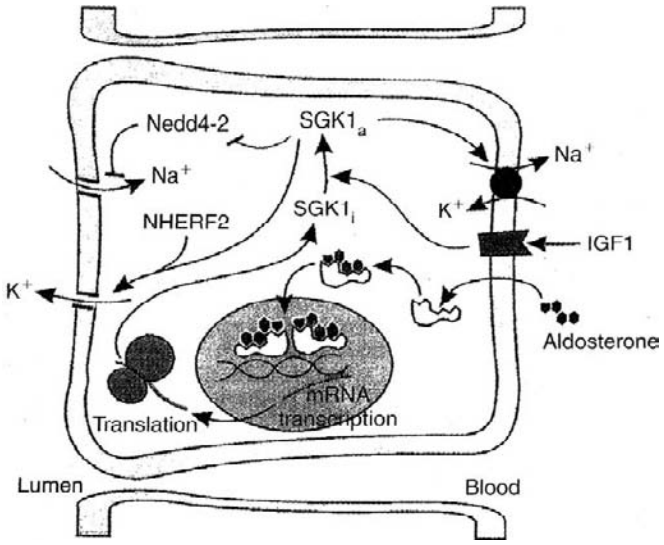

FIGURE 49.29 Effects of hormones on principle cell transport pathways. Aldo stimulate K^+ secretion via pathways shown in this cell model.

The electrophysiological consequences of high-K^+ and chronic mineralocorticoid administration are shown in Figure 49.30. The basolateral membrane voltage may hyperpolarize, and the direction of passive K^+ transport may reverse.[276,324] The mineralocorticoid-induced increase in the basolateral electrogenic Na-K exchange and basolateral K^+ conductance accounts for the rise in membrane potential above the K^+ equilibrium potential. The increase in membrane voltage provides a driving force for K^+ uptake into principal cells. This sequence of events suppresses the backflux of K^+ from cell to peritubular fluid, and increases the efficiency of K^+ secretion.

Measurements of proximal cell K^+ levels in tubules harvested from chronically mineralocorticoid-treated animals do not show an increase in cell K^+ content or activity.[375] This attests to the precise adjustments of basolateral pump activity to apical K^+ conductance. Possible mechanisms of this interaction between basolateral and apical transport mechanisms are mineralocorticoid-induced changes in cell ATP, Ca^{2+}, and pH levels. Were the stimulation of basolateral Na-K exchange to reduce cell ATP concentrations, apical K^+ channels would be released from inhibition. It is also possible that aldosterone activates basolateral Na-H exchange, alkalinizes the cytoplasm, and

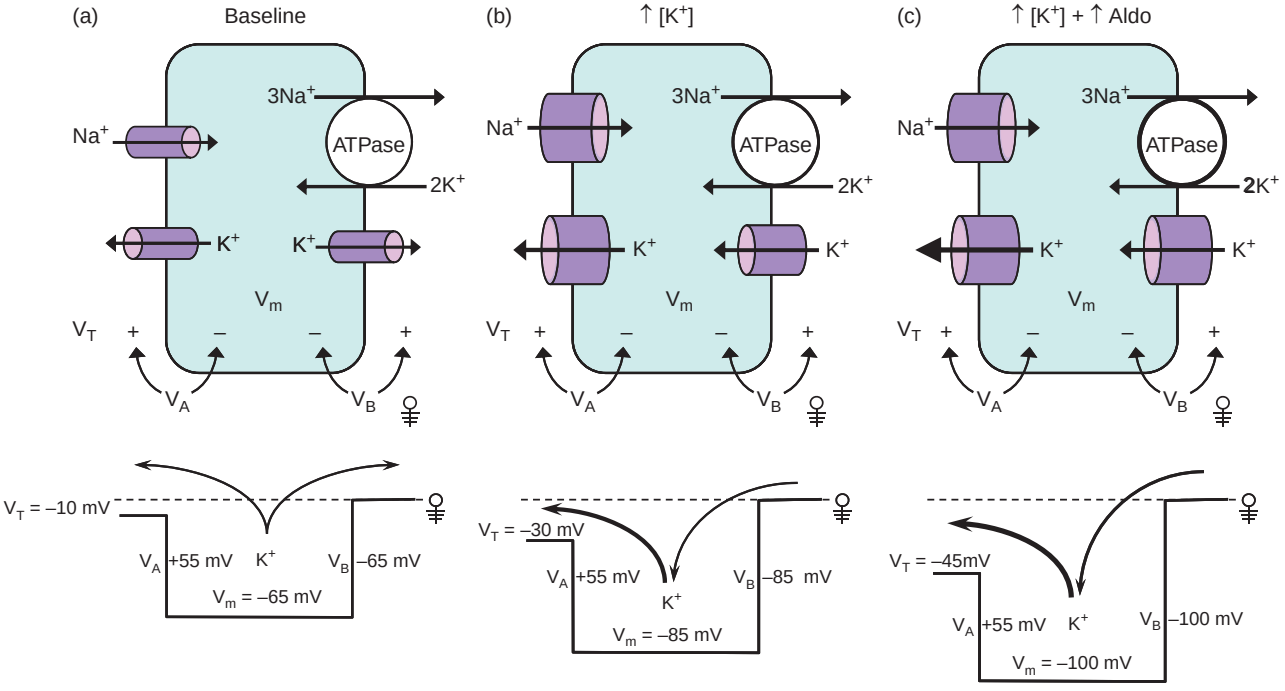

FIGURE 49.30 **Schema of cortical collecting tubule cell with key site of potassium transport.** Depending on the magnitude of the electrical potential difference across the basolateral cell membrane, potassium ions may either leave the cell (recycle) (a) or be taken up into the cell in parallel with pump-mediated potassium transport (b,c).

activates the apical secretory K^+ channels. Principal cells extrude hydrogen ions across the basolateral membrane by Na-H exchange,[86] and because aldosterone accelerates Na-H exchange in cells of the diluting segment,[362,368] this mechanism is an attractive possibility. Finally, cell Ca^{2+} changes could also be involved, owing to the effects of pump-induced alterations of cell sodium concentrations that affect Na^+/Ca^{2+} exchange.[445]

Sodium ions importantly modify the stimulating effect of mineralocorticoids on K^+ secretion. Thus, the kaliuretic effect of chronic desoxycorticosterone (DOC) treatment is effectively abolished by a low-sodium diet, and is amplified by a high-sodium intake.[455] Studies on single CCDs have confirmed the importance of an intact apical sodium entry mechanism, and an adequate lumen sodium supply, for the full stimulation of Na,K-ATPase activity that follows mineralocorticoid administration.[530,531] As pointed out above, switching from a low- to a high-cell-sodium environment induces a rapid increase of ATPase activity in proximal tubule cells.[113] Such prompt activation is consistent with a permissive role for Na in mineralocorticoid action mediated by the stimulating effect of sodium to insert pump units from a latent cytoplasmic pool into the basolateral membrane. Similarly, raising intracellular sodium concentrations enhances the cell surface expression of Na-K-ATPase α-subunit in mammalian cortical collecting duct principal cells. This process involves both c-AMP-dependent and cyclic-AMP-independent pathways.[113,188] Moreover, such activation of Na,K-ATPase is modulated by aldosterone, since cortical collecting ducts from aldosterone-depleted animals have a greatly diminished response to the change in ambient sodium, implying that the size of the cell sodium pool is strongly influenced by mineralocorticoids. In tubules from DOC-treated animals, amiloride significantly attenuates pump stimulation.[357] These results support the view that enhanced apical sodium entry into principal cells is necessary to allow full expression of mineralocorticoid stimulation of Na^+,K^+-ATPase activity. The efficacy of aldosterone-induced kaliuresis is also affected by urine flow rate.[145,147] Microperfusion experiments show that direct effects of aldosterone on K^+ transport are modified by simultaneous modulation of urine flow rate. Thus, although aldosterone enhances K^+ secretion in single distal tubules perfused at a constant rate, the antidiuretic effect of aldosterone may modulate the direct stimulation of aldosterone on K^+ excretion. On the other hand, dexamethasone does not stimulate potassium secretion in tubules perfused at a constant rate, but elicits K^+ transport stimulation through its enhancing effect on tubule flow rate.[147]

Aldosterone may act rapidly (<10 minutes) on renal distal nephron ion transport by a nongenomic mechanism. This is not affected by actinomycin D or spironolactone, and thus is independent of protein synthesis.[527] This nongenomic effect involves, primarily, stimulation of Na^+/H^+ exchange, and is thought to be mediated by specific membrane receptors for aldosterone. Membrane-binding sites of very low (0.1 nM) dissociation constant (Kd) for aldosterone which modulated Na^+/H^+ exchange were first described in human polymorphonuclear leucocytes. Such sites have no affinity for dexamethasone, corticosterone, ouabain, amiloride, and 18-hydroxyprogesterone.[140,505] Similar receptors for aldosterone were also found in pig kidney, but these had higher values of Kd for desoxycorticosterone acetate and corticosterone. These membrane receptors are different from the classical cytoplasmic mineralocorticoid receptors (MR), since MR knockout mice still display the nongenomic effect of aldosterone.[174] Activation of the nongenomic mechanism via membrane receptors includes a signaling path involving G-protein, inositol triphosphate, Ca^{2+}, and protein kinase C, as well as MAP-kinase.[527] ENaC-mediated current in isolated rabbit CCD is stimulated by nongenomic action of aldosterone.[527] Inasmuch as these nongenomic actions involve apical sodium channels, they could also have significant indirect effects on K^+ secretion.

Glucocorticoids

Abnormal function of the hypothalamic–pituitary–adrenal axis is often associated with deranged K^+ homeostasis.[63,123] In patients with low circulating levels of glucocorticoids, the excretory response to K^+-loading is blunted, even if aldosterone is normal. Glucocorticoid excess, in contrast, can be associated with kaliuresis and hypokalemia. The effect of glucocorticoids on urinary K^+ excretion largely reflects secondary stimulation of K^+ secretion in the distal nephron following glucocorticoid actions in proximal nephron segments. Glucocorticoids increase GFR, and also the delivery of sodium and fluid to the distal nephron[33]: these latter effects are strongly kaliuretic. Microperfusion experiments also support an indirect effect, since acute intravenous dexamethasone does not increase distal K^+ secretion when fluid and salt delivery are constant.

Nevertheless, studies suggest that chronically elevated glucocorticoids exert a direct mineralocorticoid-like effect on the distal nephron. Mineralocorticoid target genes are activated by glucocorticoid excess, even when aldosterone is normal, and patients with familial glucocorticoid receptor haploinsufficiency or apparent mineralococticoid excess are hypokalaemic despite low circulating aldosterone. These conditions

of corticosteroid cross-talk reflect the inherent affinity of the mineralocorticoid receptor for glucocorticoids.[16] As shown in Figure 49.31, the enzyme 11β-hydroxysteroid dehydrogenase type II (11βHSD2) converts active glucocorticoids to inactive metabolites. In the principal cell, 11βHSD2 brings mineralocorticoid receptor target proteins, such as ENaC, under the control of aldosterone.[16,22,280]

The 11βHSD2 barrier can be attenuated by mutations in the encoding gene or pharmacological inhibition of enzyme function: the hypokalemic hypertension of apparent mineralocorticoid excess or that following excess licorice consumption reflects glucocorticoid action in the distal nephron.[21,41] Micropuncture studies in rats confirm this,[23] and mice lacking 11βHSD2 maintain robust K^+ excretion despite severe hypokalemia.[22] Much of the K^+ excretion is amiloride-sensitive and is likely mediated by ROMK. However, kaliuresis is maintained after sodium handling is normalized and becomes resistant to amiloride. It is likely that such persistent K^+ excretion reflects BK-mediated K^+ secretion: 11βHSD2 null mice are severely polyuric and the increase in urine flow would activate BK channels.[20]

Some evidence suggests that glucocorticoids may also influence K^+ secretion by glucocorticoid receptor (GR) activation.[21,41] GR is expressed in the aldosterone-sensitive distal nephron of the rat, and it is this receptor, not MR, that translocates to the nucleus in response to physiological variations in aldosterone.[1,47] The physiological meaning of this is not resolved, but in mice with reduced levels of 11βHSD2 a high-salt diet causes hypokalemia and inappropriately high K^+ secretion in the distal nephron. The deranged K^+ homeostasis was prevented by GR blockade, and spironolactone was without effect.[41] In summary, there is strong evidence that chronic exposure to elevated glucocorticoids may directly influence K^+ secretion at this site, an effect above and beyond the kaliuresis triggered by rapid-onset events in more proximal segments.

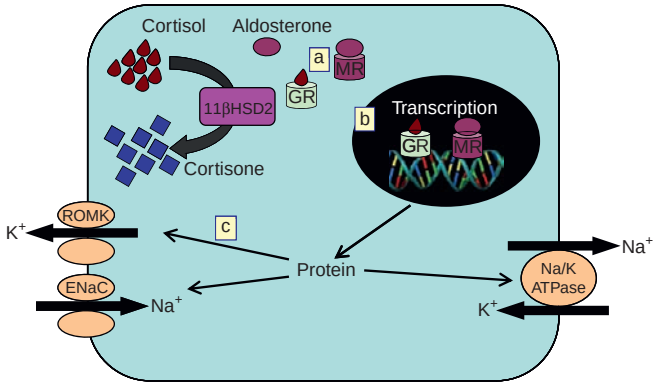

FIGURE 49.31 **The enzyme 11β hydroxysteroid dehydrogenase type 2 (11βHSD2) is co-expressed with the mineralocorticoid receptor (MR) in aldosterone target tissues, such as the principal cell of the collecting duct.** The enzyme converts cortisol, which is an agonist of the mineralocorticoid receptor (MR) to cortisone, which is not. This confers aldosterone-specificity on MR, placing transcription of aldosterone-induced proteins, such as ENaC, ROMK, and the basolateral Na/K-ATPase, under the control of the renin–angiotensin system. Recent data challenge the conventional view of corticosteroid action in the aldosterone-sensitive distal nephron, which expresses both the mineralocorticoid and glucocorticoid receptor (GR). As shown in (a), 11βHSD2 may also govern ligand access to GR, and GR translocation to the nucleus (b) is influenced by physiological changes in circulating aldosterone, and plays a permissive role in regulation of ENaC by aldosterone. Direct regulation of ROMK by GR is suggested (c) but the kaliuretic effects of glucocorticoids may also reflect activation of ENaC. *(Figure courtesy of Dr. Louise Evans.)*

WNKs (With No Lysine Kinase)

WNKs are serine/threonine protein kinases, and WNK1, 3, and 4 are expressed in the DCT and CCD.[127,229,253,331,562,598,604] A large body of evidence indicates that the WNK family plays an important role in the regulation of Na absorption and K^+ secretion. WNK4 suppresses the expression of the Na-Cl cotransporter (NCC) in the plasma membrane of the DCT, thereby inhibiting Na absorption.[253] In contrast, WNK1 stimulates NCC activity indirectly by antagonizing the inhibitory effect of WNK4. WNK1, 3, and 4 inhibit ROMK channel activity, and the effect of WNK on ROMK is mediated by stimulation of clathrin-dependent endocytosis. The inhibitory effect of WNK4 on ROMK1 does not require the kinase activity, because co-expression of the inactivated WNK4 inhibits expression of ROMK1 in *Xenopus* oocytes. The mutated gene products encoding inactivated WNK1 or WNK4 causes pseudohypoaldosteronism type II, a disease with characteristics of hypertension and low aldosterone levels. A kidney-specific splice form of WNK1 (KS-WNK1), in which an alternative 5′ exon replaces the first four exons of WNK1, is expressed in the DCT and CCD.[291] Unlike the long form of WNK1, KS-WNK1 lacks kinase activity and does not block ROMK channels. Moreover, KS-WNK1 can antagonize the inhibitory effect of WNK1. A high K^+ intake increases the expression of KS-WNK1, and accordingly attenuates the inhibitory effect of WNK1 on ROMK channels (Figure 49.32).[291,312] Thus, alteration of the ratio between the long and short forms of WNK1 may be an important mechanism by which a high-K intake stimulates ROMK channel activity. K^+ restriction has been reported to decrease the expression of KS-WNK1 and increase the long form WNK1. Consequently, the inhibitory effect of KS-WNK1 on WNK1 is diminished, and WNK1-mediated inhibition of ROMK channels is enhanced, in the CCD from animals fed a low-K diet.[236]

It should be noted that aldosterone is secreted both in the setting of intravascular volume depletion

(hypovolemia) and hyperkalemia. In the face of the hypovolemia, aldosterone promotes Na^+ retention and limits urinary K^+ loss. In hyperkalemia, aldosterone maximizes K^+ loss without Na^+ retention. This "aldosterone paradox" may be explained by changes in the relative expression and activities of WNK family members[127,229,236,253,331,493] (Figures 49.32 and 49.33).

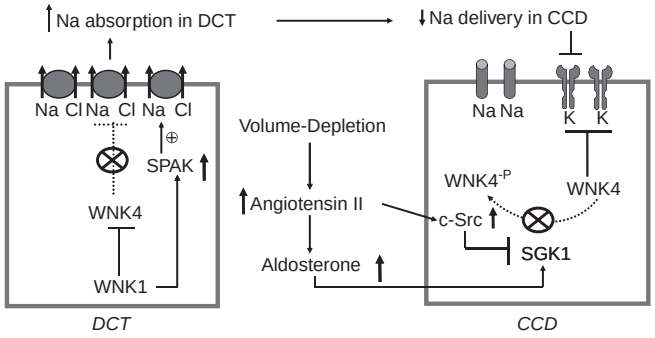

FIGURE 49.32 **A cell scheme illustrates the mechanism by which increasing dietary potassium intake facilitates K secretion.** A high-K intake increases KS-WNK4 expression which inhibits WNK1 function, thereby suppressing WNK1-mediated inhibition of WNK4. Thus, a high-K intake decreases NaCl co-transporter activity, and increases NaCl delivery to the connecting tubule and the CCD. A high-K intake also increases SGK1 activity which phosphorylates WNK4, thereby suppressing the WNK4-mediated inhibition of ROMK. Thus, a high-K intake stimulates K secretion in the connecting tubule and the CCD through increasing Na delivery and apical K^+ channel activity (CCD: cortical collecting duct; SGK1: serum-glucocorticoid-induced kinase 1; WNK: with-no-lysine kinase; KS-WNK1: kidney-specific WNK1).

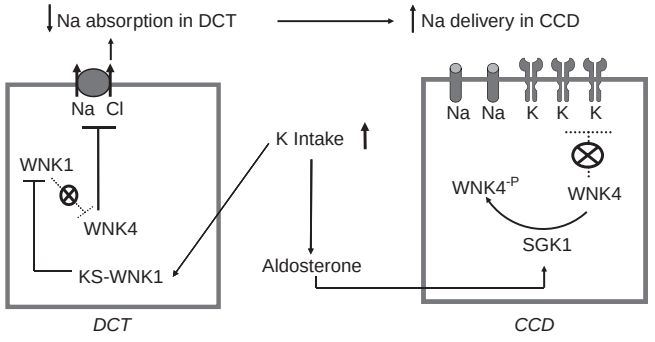

FIGURE 49.33 **A cell scheme illustrating the role of angiotensin II in regulating ROMK channels during volume-depletion.** Volume-depletion abolishes the inhibitory effect of WNK4 on the NaCl co-transporter through stimulation of SGK1-mediated WNK4, thereby increasing Na absorption in the distal nephron. Decreasing the Na delivery to the connecting tubule and the CCD diminishes the driving force for K secretion. In addition, the angiotensin II pathway inhibits SGK1-induced phosphorylation of WNK4 through activation of c-Src family protein tyrosine kinase, and leads to suppression of ROMK channel activity. A dotted line means a diminished effect (CCD: cortical collecting duct; DCT: distal convoluted tubule; SGK1: serum-glucocorticoid-induced kinase 1; WNK: with-no-lysine kinase).

Salt and Water Balance

K^+ excretion generally changes in association with modulation in sodium excretion. On the one hand, interventions that increase salt and water excretion – high-salt intake, extracellular volume expansion, saline infusion, administration of many diuretics acting upstream of the initial collecting tubule, and infusion of sodium salts of poorly-reabsorbable anions – all stimulate K^+ excretion.[59,180–186,234,267,326,399,470,582] On the other hand, maneuvers that diminish sodium excretion – rapid reduction of glomerular filtration rate, sodium-depletion, and volume-contraction – all decrease K^+ excretion. Thus, distal secretion of K^+ depends importantly on the delivery of sodium and tubule fluid to the sites of K^+ secretion.

Figure 49.34 illustrates the effect of different levels of sodium intake on the steady-state relationship between plasma K^+ and urinary K^+ excretion at clamped aldosterone levels.[596] K^+ excretion at a given plasma K^+ level is stimulated by augmenting sodium intake and a given rate of K^+ excretion occurs at lower plasma K^+ levels when sodium intake is elevated. This enhancement of K^+ excretion is thought to depend on increased delivery of fluid and sodium to the distal tubule and CCD.

Studies on single tubules, employing both micropuncture[260] and microperfusion[139,191,192,319] techniques, have fully confirmed that tubule fluid flow rate and luminal sodium concentration independently affect K^+ secretion. Figure 49.35 summarizes the effects of tubule flow rate and fluid sodium concentrations on K^+ secretion along the distal tubule. Increasing flow rate invariably stimulates K^+ secretion. For a given

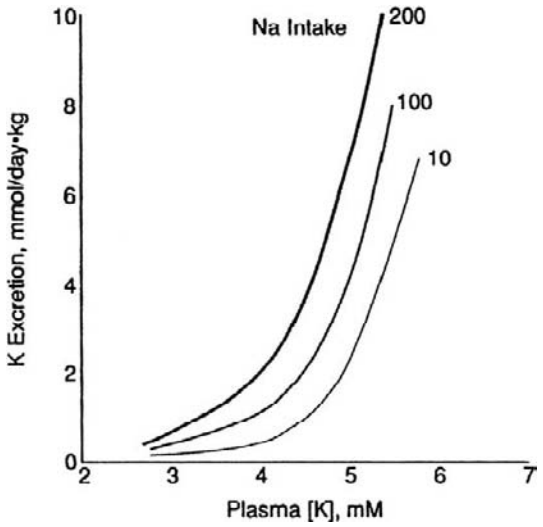

FIGURE 49.34 The relation between plasma K^+ concentration and renal K^+ excretion is affected by dietary Na intake. *(From ref. [596], with permission.)*

flow rate, K^+ secretion is augmented in animals with a high-K intake[266] or after mineralocorticoid administration[123,183]; it is decreased in animals on a low-K^+ diet.[266]

Three separate mechanisms underlie the increase of distal K^+ secretion with enhanced flow rate. The first involves electrophysiological linkage between sodium absorption and K^+ secretion. Increasing fluid delivery into the distal tubule increases the sodium concentration in the lumen, which in turn stimulates sodium absorption[267] and depolarizes the apical cell membrane, thus creating a more favorable electrochemical gradient for K^+ secretion. This effect is of greatest importance when luminal Na concentration shifts from low to high levels.[48,139,192,319,485]

An increase in tubular fluid flow rate also stimulates sodium absorption due to an increase in the open probability of ENaC.[342,433]

Enhanced sodium entry from the lumen into principal cells during augmented delivery of fluid stimulates the basolateral Na,K-ATPase and accelerates K^+ translocation into cells from the peritubular fluid. Thus, as long as basolateral pump activity responds to increased lumen delivery of sodium with increased Na-K exchange, K^+ secretion continues at a high enough rate to either prevent (in the lower range of lumen flow rates) or to curtail (in the higher range of lumen flow rates) a decline in the concentration of K^+ in the tubule lumen. If K^+ concentrations decline less than flow rate increases, K^+ secretion rates increase. Experimental conditions in which lumen K^+ concentrations remain constant during diuretic conditions,[232] and in which the concentration difference between cell interior and lumen remain unaltered despite marked stimulation of K^+ secretion (see Table 24 in [415]), underscore the importance of accelerated and coupled K^+ and sodium transport. By "clamping" the K^+ concentration in the lumen to fairly constant levels over the range of low physiological levels of tubule flow, the connecting and collecting tubule emerge as the major control site of K^+ excretion.[473]

A second mechanism that links increased delivery of fluid to the distal nephron to enhanced K^+ secretion may involve a flow-dependent fall of lumen K^+ concentration,[191,192] which increases the driving force for K^+ exit across the apical membrane. This mechanism permits K^+ secretion to increase under conditions in which increased sodium delivery into the distal tubule fails to stimulate basolateral Na-K-ATPase. Diminished apical sodium uptake and low lumen K^+ concentrations would hyperpolarize the apical membrane potential and tend to reduce the electrochemical driving force, favoring K^+ secretion. The functional state of the basolateral Na^+,K^+-ATPase transport system thus determines the extent to which increased fluid delivery stimulates K^+ secretion.

The third mechanism, illustrated in Figure 49.36, links changes in luminal flow to distal potassium secretion by activation of the BK channel. An increase in luminal flow rate transduces mechanical signals (circumferential stretch, shear stress, hydrodynamic bending moments on the cilium decorating the apical surface of virtually all renal epithelial cells) into increases in intracellular Ca^{2+} concentration, which in turn activate apical BK channels to secrete potassium, thereby enhancing urinary potassium excretion.[557,575]

Although apical sodium channels are a key pathway for entry of sodium into principal cells, K^+ excretion

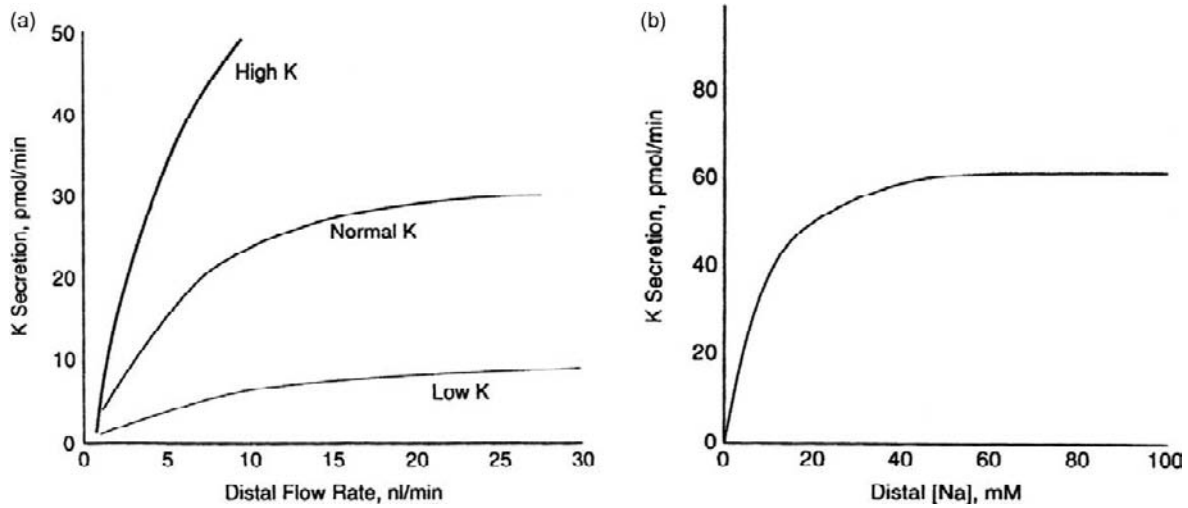

FIGURE 49.35 **(a) Relationship between distal flow rate and distal K secretion as affected by K intake. (b) Distal K secretion requires a luminal Na^+ concentration exceeding 25–35 mM.** The relation between flow rate of tubule fluid in distal tubule and distal K^+ secretion is affected by dietary intake: normal K^+ diet; low- K^+ diet; high- K^+ diet. *(From ref. [269], with permission.)*

appears not to be entirely dependent on apical sodium supply. Animals maintained on a low-sodium diet do respond with kaliuresis to acute K^+-loading,[384] as do animals given the ENaC inhibitior, amiloride.[589] Moreover, humans tolerate very well a diet high in K^+ and low in sodium.[374] An explanation for the apparent dissociation between apical sodium supply and maintained ability for K^+ secretion may be the presence of at least two additional sodium entry pathways in principal cells. These are located in the basolateral membrane, and include Na/H and Na/Ca^{2+} exchange.[86,295] Activity of these basolateral entry pathways may, at least in part, replace apical sodium supply and maintain K^+ secretion under conditions of low distal fluid and sodium delivery, especially under conditions of elevated levels of plasma K^+.[176] K^+ excretion independent of distal amiloride-sensitive Na transport has been confirmed in rats during high dietary K^+ intake.[156] Such Na-channel-independent K^+ excretion develops progressively during prolonged K-loading; it could be mediated, in part, by K^+ secretion in intercalated cells[206,354] and/or by reduced K^+ reabsorption along the proximal tubule and thick ascending limb of Henle's loop as a consequence of high plasma K^+ levels. The latter have been shown to lower proximal tubule Na and fluid reabsorption.[67,302]

Recent evidence, based on distal tubule perfusion studies, suggests a significant component of electroneutral sodium reabsorption (Figure 49.37), resistant to amiloride inhibition but sensitive to hydrochlorthiazide. Mechanistically, the transport process involves the parallel action of sodium-dependent Cl/bicarbonate exchange and sodium-independent chloride-bicarbonate exchange (pendrin). The presence of this transport in ß-intercalated cells is significant, because it would uncouple K^+ secretion from electrogenic sodium transport via Na channels in principal cells.[127,128]

The ability of the distal tubule and CCD to maintain a fairly constant K^+ concentration in the lumen over the physiological range of flow rates has two important consequences. First, the marked flow

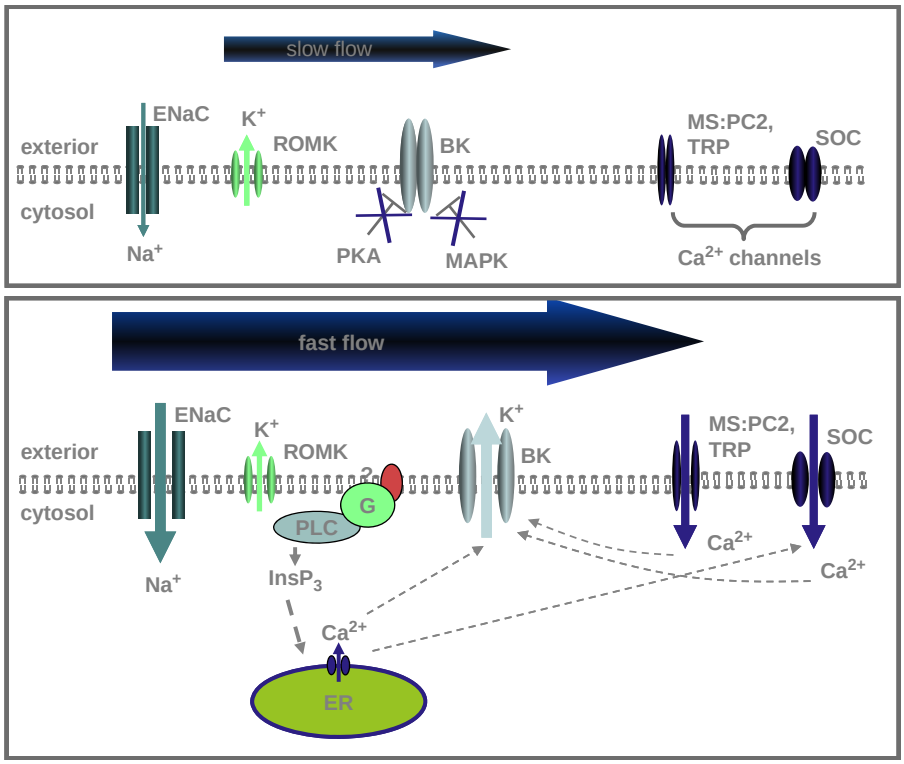

FIGURE 49.36 **Proposed model for the molecular physiology of flow-induced K^+ secretion (FIKS) in the distal nephron.** At slow "physiologic" flow rates, K^+ secretion requires electrogenic Na^+ absorption through ENaC, and is mediated by the SK/ROMK channel. The apical Ca^{2+}- and stretch-activated BK channel is tonically inhibited by PKA and MAPK. A rapid increase in tubular fluid flow rate associated with circumferential stretch of the CCD leads to shear or hydrodynamic impulses at the cilium or apical membrane and an increase in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$), due to luminal Ca^{2+} entry and internal store release. These hydrodynamic forces are associated with an increase in net Na^+ absorption and K^+ secretion, the latter mediated by Ca^{2+}-dependent activation of the BK channel. FIKS further requires microtubule integrity and possibly release of tonic channel inhibition. Mechanosensitive (MS) Ca^{2+} channels identified in the apical membrane of the distal nephron include polycystin 2, and the transient receptor vanilloid-4 (TRPV4) channels. Store-operated Ca^{2+} channels (SOC) also contribute to the flow-induced Ca^{2+} response.[574]

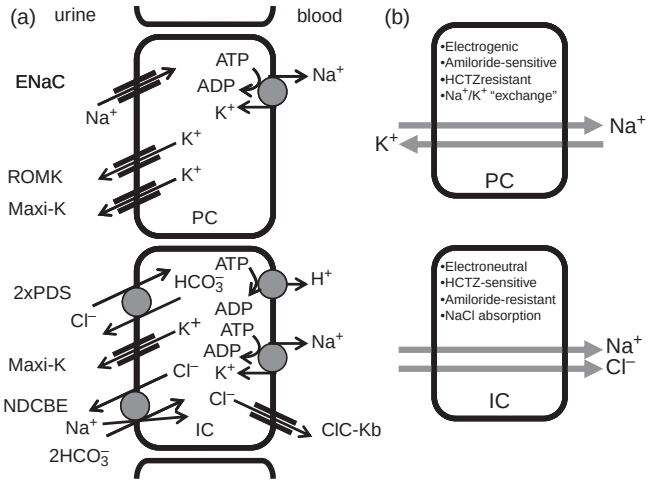

FIGURE 49.37 **Overview of the two major Na^+/* transport pathways in principal and intercalated cells, depicting electrogenic and electroneutral transport mechanisms.** *(From ref. [128].)*

dependence of K^+ secretion in the distal tubule and CCD endows the process of K^+ secretion with great sensitivity to changes in the delivery of sodium and fluid. This tubule segment is thus responsible for the enhanced rate of K^+ excretion that follows inhibition of sodium and fluid reabsorption upstream of the distal tubule and collecting duct ([234]; see "Diuretics" section below). Second, the ability of the distal nephron segments to "clamp" the K^+ concentration has implications for the physiological importance of those components of K^+ secretion that occur upstream during K^+ recycling. K^+ secreted upstream of the ICT determines the amount of K^+ secreted along the DCT and ICT as the tubule fluid approaches the "late" distal tubule. Hence, with stimulation of medullary K^+ recycling, the concentration of K^+ in the early distal tubule rises and approaches the "clamped" concentration across the initial collecting tubule. Thus, a smaller fraction of excreted K^+ is then contributed by distal secretion. Conversely, when medullary recycling of K^+ is minimal, and the concentration of K^+ in the fluid entering the distal tubule is low, a larger fraction of excreted K^+ has to be secreted by the distal tubule and the CCD.

A non-invasive method for evaluation of the transtubule gradient of K^+ (TTKG) in the CCD has been described.[565,566] Such estimates have been used to evaluate the effects of hormones, diuretics, and acid–base disturbances in patients. The method allows distinction between modulation of urine K^+ excretion by changes in flow rate and/or direct effects on K^+ secretion in principal cells. This approach has also shown that urea recycling, by enhancing flow rate in the cortical collecting tubule, provides a mechanism for aiding K^+ excretion.[214]

Chronic enhancement of sodium delivery into the distal nephron, for instance during treatment with loop diuretics, leads to both functional and morphological adjustments in the downstream tubule segments; these changes increase the capacity for sodium absorption and K^+ secretion in cells of the distal nephron.[136,257,296,344,466,467] Prolonged increased entry of sodium into cells of the distal tubule must be responsible for transport stimulation, because the functional and morphological changes persist when plasma aldosterone, vasopressin, and K^+ are held constant.[466,470] Increased transport in collecting duct segments following chronic treatment with diuretics that act on the loop of Henle or the distal convoluted tubule may curtail sodium excretion as well as promote K^+ secretion.[136] An increase in amiloride-sensitive K^+ secretion has been observed following uninephrectomy, and is linked to an initial increase in plasma K^+ concentration, and increased distal tubule fluid and sodium delivery.[25,46,109]

Renal sympathetic nerve activity affects renal K^+ excretion, most likely mediated by changes in glomerular filtration rate (GFR) and sodium excretion.[422] Renal denervation was shown to increase GFR, accompanied by enhanced sodium excretion, significant kaliuresis, and lowering of plasma K^+ concentration. Renal denervation lowers proximal sodium reabsorption, and the ensuing kaliuresis is best explained by enhanced sodium delivery to distal K-secreting nephron segments. An interesting observation concerns the relationship between distal tubule sodium reabsorption and K^+ secretion in a rat model of nephrotic syndrome. Although displaying high rates of sodium reabsorption in collecting ducts, K^+ secretion was not enhanced in tubules from such nephrotic rats. Inhibition of ROMK secretory K^+ channels was traced to the presence of high albumin in the tubule lumen. Moreover, nephrotic rats were shown to be less able to excrete K^+ when given a high-K^+ diet, an observation consistent with compromised apical K^+ channel activity.[149]

Non-chloride sodium salt also affects urinary K^+ excretion. Thus, the kaliuretic effects of sulfate, phosphate, and bicarbonate are well-established. Prolonged fasting and the enhanced excretion of short-chain fatty acids and organic acid radicals also promote K^+ loss.[306] Interestingly, infusion of sodium bicarbonate is more kaliuretic than similar amounts of sulfate.[80] It is generally assumed that the stimulating effect of poorly-reabsorbable anions on K^+ secretion is mediated by their effects on the lumen-negative potential.[321] Although there is evidence that the transepithelial potential difference effectively alters K^+ secretion,[179] it is unlikely that the effects of poorly-reabsorbable anions are solely mediated by changing the

transepithelial potential, because sulfate-induced enhancement has been shown to continue in the presence of effective blockade of sodium and K^+ channels. This suggests that stimulation of K^+ secretion in the presence of sulfate is mediated by low tubule chloride, which stimulates electroneutral K^+ chloride co-transport.[526] Perfusion studies also provide support for the notion that lumen alkalinization and bicarbonate directly stimulate K^+ secretion through augmenting electroneutral secretory K^+ chloride co-transport.[8]

Acid–Base Balance

Acid–base derangements have long been known to affect the excretion of K^+, and losses of K^+, particularly in states of alkalosis, are well-documented.[14,48–52,68,176,179,182,320,470,472] Figure 49.38 shows the striking dependence of renal K^+ excretion and distal K^+ secretion on blood pH. It is apparent that alkalosis stimulates, and acidosis depresses, K^+ excretion.

Clearance, stop-flow, micropuncture, and microperfusion studies indicate that the DCT and CCD are the main nephron sites where acid–base changes affect K^+ secretion. The right panel of Figure 49.38 shows results of a microperfusion study in which tubule flow rate and solute composition of luminal fluid were kept constant. Metabolic acidosis caused distal K^+ secretion to decrease, whereas metabolic alkalosis had the opposite effect. Direct effects of acid–base disorders on K^+ transport in these nephron segments can be distinguished from indirect effects that include changes of: (1) distal flow rate; (2) composition of fluid reaching the distal tubule; and (3) aldosterone levels.[472] Changes in plasma K^+ cannot be held responsible for acid–base related changes in K^+ excretion, because hyperkalemia is frequently associated with acidosis, whereas hypokalemia is commonly observed in alkalosis.[4,14,51,176,320]

The direct effects of acid–base disorders, summarized in Figure 49.39, involve modifications of both basolateral and apical transport functions in principal and intercalated cells. With regard to the basolateral membrane, alkalosis stimulates active K^+ uptake and increases the permeability to K^+ ions (Figure 49.40). The permeability increase in alkalosis shifts the membrane potential close towards the K^+ equilibrium potential, and minimizes K^+ loss from cells into the peritubular fluid. Acidosis has the opposite effect, including direct inhibition of basolateral Na^+,K^+-ATPase activity (Figure 49.41).[350] Acid–base related changes in the apical cell membrane are also observed and involve a striking sensitivity of both K^+ and sodium channel activity to cytosolic pH. Over a narrow and physiological pH range, acidosis (pH 7.0) suppresses and alkalosis (pH 7.4) stimulates sodium and K^+ channel activity.[158,159,217,544,546]

Additional stimuli modulating K^+ secretion in acid–base disturbances involve the delivery of tubule fluid with high Na^+ bicarbonate and low chloride concentrations to the distal nephron in metabolic alkalosis (Figure 49.42). Bicarbonate and other poorly-permeant anions act as osmotic diuretics and increase distal tubule flow rate and, as mentioned above, low lumen chloride concentration stimulates apical K-Cl secretion in distal convoluted and principal cells.[132,521,526] Bicarbonate also appears to activate K^+ excretion directly.[8,306] Figure 49.42 shows the results of *in vivo*

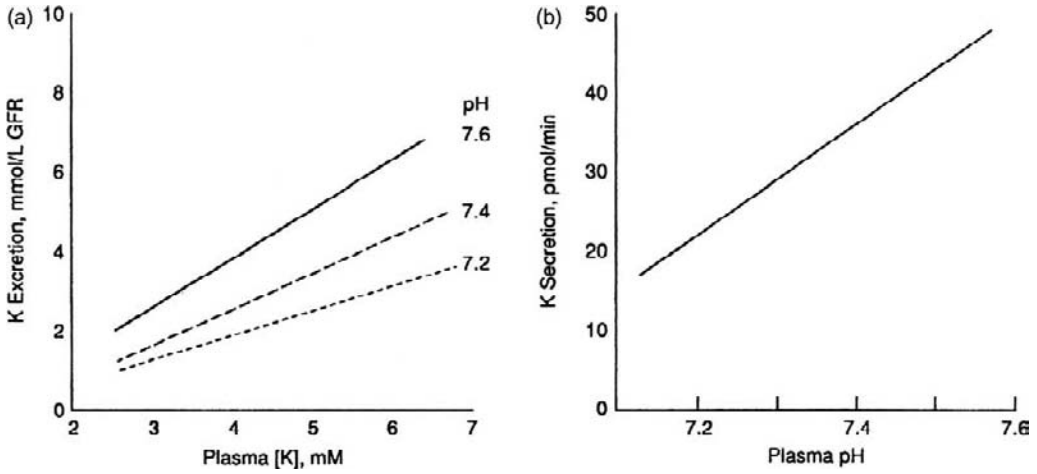

FIGURE 49.38 **(a) The relationship between plasma K^+ concentration and renal K^+ excretion is affected by plasma pH.** (*From Stanton, B. A., and Giebisch, G. (1991). Renal potassium transport. microperfusion experiments in which luminal chloride was replaced with sulfate. Reducing luminal Cl concentration below 20 mM stimulates K^+ secretion into the distal tubule without changing the transepithelial voltage. Unidirectional flux measurements show that the increase in K^+ secretion occurs because the cell-to-lumen flux is enhanced. This enhanced secretory flux is not blocked by barium in the lumen.

Opposing effects of metabolic acidosis on K^+ excretion are summarized in Figure 49.41; metabolic acidosis may either inhibit or stimulate K^+ secretion. Direct actions of acidosis involve inhibition of K^+ secretion in distal nephron segments. In addition, indirect effects enhance K^+ secretion by elevating distal delivery of sodium-containing fluid following diminished proximal tubular bicarbonate transport. When flow rate along single distal tubules is kept constant, acidosis depresses K^+ secretion.[472] However, under free-flow conditions in intact tubules, K^+ secretion may rise as a consequence of increased fluid flow rate thought to result from inhibition of proximal transport during acidosis.[14] Such an increase in distal fluid and sodium delivery stimulates K^+ secretion during loading with ammonium chloride, in diabetic acidosis, and in proximal tubular acidosis. Taken together, it is clear that the effects of acid–base disturbances on K^+ excretion are mediated by two major components: direct effects related to pH, and secondary effects relating to the rate of delivery and composition of fluid entering the distal nephron. Increased aldosterone, possible related

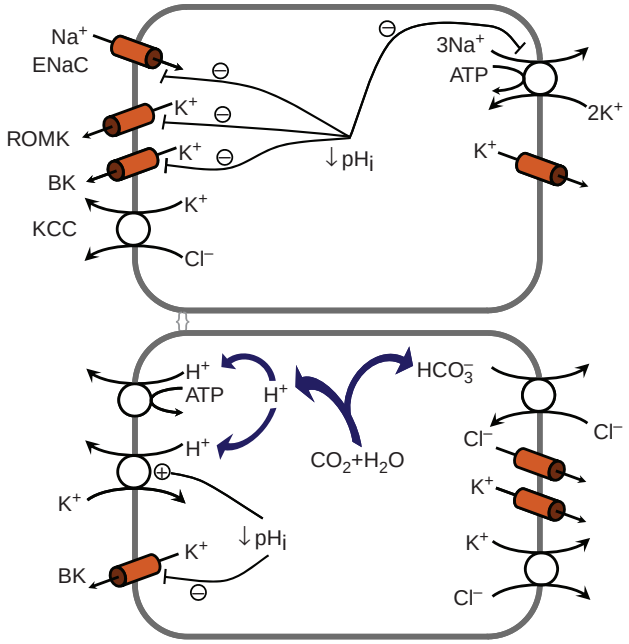

FIGURE 49.39 **Effects of pH changes on K^+ transport in principal (top) and intercalated (bottom) cells.** *(From ref. [14].)*

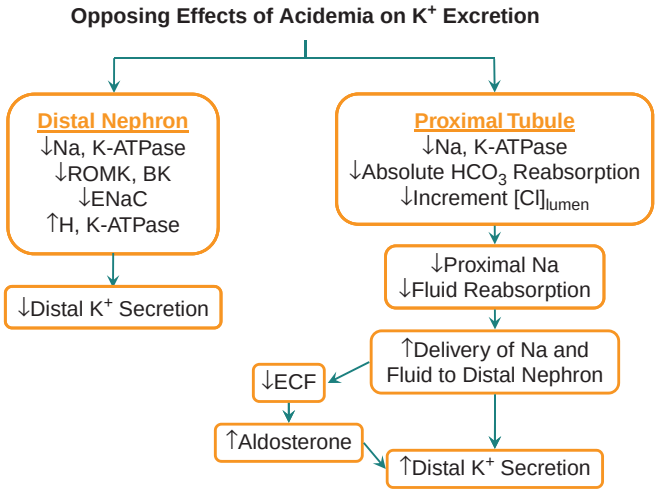

FIGURE 49.41 **Complex effects of acidemia on proximal and distal tubule potassium transport.**[14]

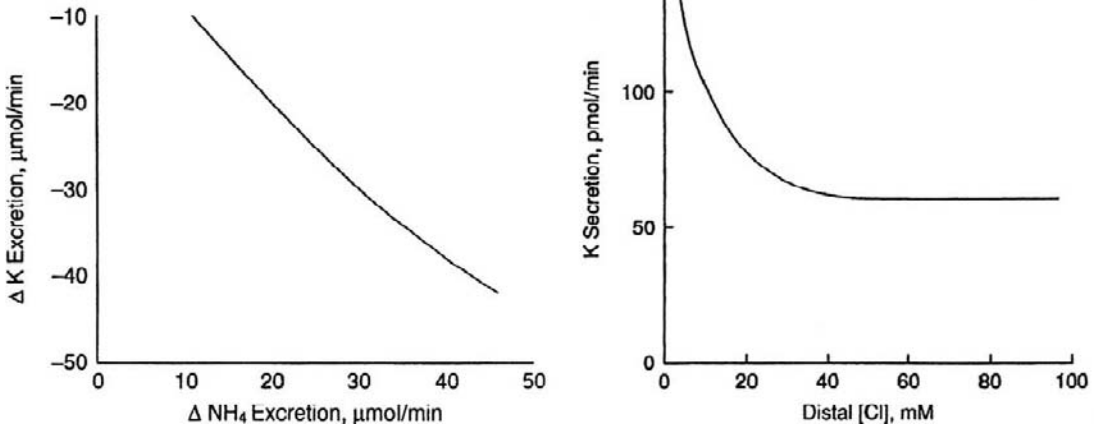

FIGURE 49.40 **Effects of acute alkalemia on K^+ excertion.**

to ECFV contraction, also contributes to kaliuresis during acidosis; K^+ excretion is reduced in acidosis when aldosterone levels are not allowed to increase.[473]

Metabolic alkalosis increases K^+ secretion by several mechanisms, both as a result of direct stimulation of K^+ secretion in principal cells and diminished K^+ reabsorption by K-H-ATPase in intercalated cells (Figure 49.40). Additionally, high delivery rates of bicarbonate-containing fluid into the distal tubule further promote K^+ secretion.[8,80,306]

It should be noted that the effects of respiratory acid–base disturbances on renal K^+ excretion are milder than those observed in metabolic acid–base disturbances.[14] In respiratory acidosis, the maintenance of significantly higher plasma bicarbonate concentrations sustains proximal tubule fluid reabsorption, and renal compensation of chronic respiratory acidosis restores plasma pH to normal more effectively than in metabolic acidosis.[14] Kaliuresis in respiratory alkalosis is also milder than that observed in metabolic alkalosis.

K^+ transport across the outer medullary collecting duct is also affected by changes in electrogenic hydrogen ion transport. Acidosis enhances electrogenic hydrogen secretion and tends to increase the lumen-positive potential, whereas alkalosis has the opposite effect. Passive K^+ reabsorption would thus be increased during acidosis and depressed in alkalosis. Independent of these indirect effects, metabolic acidosis has been shown to stimulate the activity of the apical K^+-H^+-ATPase in isolated rabbit CCDs.[458]

Renal production of ammonium is important not only to renal acid excretion, and therefore to maintenance of acid–base balance, but also to renal K^+ excretion. Tannen has drawn attention to the inverse relationship between urinary K^+ and ammonium excretion shown in Figure 49.42.[501,502] Studies in *in vivo* and isolated perfused kidneys have demonstrated that K^+ excretion is depressed when ammonium excretion is enhanced, an effect that has been localized in micropuncture studies to tubule sites beyond the ICT.[247] Studies of isolated perfused kidneys have systematically evaluated acid–base and endocrine factors modulating principal cell function.[445,446] The cell mechanism of the inhibitory effect of ammonium on K^+ excretion may involve competition between K^+ and ammonium at the K^+-binding site of the Na^+,K^+-ATPase in the basolateral membrane of principal tubule cells.[534]

Other Hormones

Vasopressin stimulates the secretion of K^+ ions across the distal tubule and CCD.[146,148,437,438,443,447] *In vivo* perfusion of the distal tubule and electrophysiological studies of K^+ transport in principal cells indicate that activation of K^+ secretion reflects an increase in apical sodium permeability.[443] Besides this effect on the driving force of K^+, patch-clamp studies have shown that vasopressin also increases the density of K^+ channels in the apical membrane of principal tubule cells.[82] The effects of vasopressin on K^+ secretion in cortical collecting ducts are sharply augmented by mineralocorticoid pretreatment.[438]

Luminal vasopressin also stimulates K^+ secretion via activation of V1 receptors.[10] This effect differs from the basolateral action, in that the V1 receptor is coupled to the phospholipase-IP3, Ca^{2+}-PKC signaling pathway, rather than cyclic AMP (Figure 49.43). A key role of Ca^{2+} was established by showing that chelators such as BAPTA abolished the luminal effects of vasopressin.

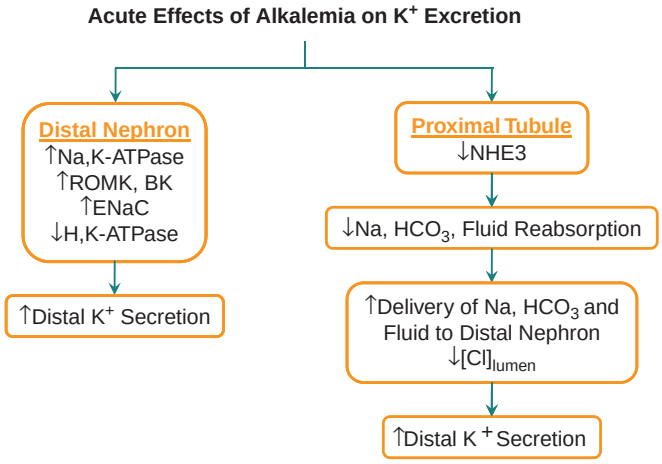

FIGURE 49.42 **Relation between luminal NH_4 (left) and Cl^- (right) concentration and K^+ secretion.** Distal K^+ secretion is inhibited by the presence of Cl^- in the tubule lumen and is stimulated when Cl^- concentration falls below 20 mM. *(From Velazquez, H., Ellison, D. H., and Wright, F. S. (1987). Chloride-dependent potassium secretion in early and late distal tubules. Am. J. Physiol. Renal* **253**, *F555–562, with permission.)* Changes in renal potassium excretion are negatively correlated with changes in ammonium excretion. *(From ref. [501,502], with permission.)*

B., Musa-Aziz, R., Mello-Aires, M., and Malnic, G. (2004). Signaling path of the action of AVP on distal K^+ secretion. Kidney Int.* ***66****, 696–704, with permission.)*

These observations strongly suggest that Ca^{2+}-sensitive B channels mediate the luminal effects of vasopressin. In contrast, the basolateral effects of vasopressin involve V2 receptors and the cAMP–PKA cascade which modulate ROMK channels.[82] The inhibitory effects on K^+ secretion of angiotensin and prostaglandins are similarly mediated by the phospholipase A-arachidonic acid pathway.[217]

Klotho, ATP, Catecholamines, Insulin, Glucagon, Kallikrein, and Guanilyn

Klotho, an age-suppressing agent, is expressed in distal tubule cells and regulates expression of ROMK channels in the kidney.[84] It not only increases ROMK abundance in HEK cells (human embryonic kidney cells), but also increases urinary K^+ excretion when given intravenously to rats. Diminished Klotho production associated with reduced renal mass and renal failure could contribute to impaired K^+ excretion. It is of interest that angiotensin II infusions curtail Klotho expression in the kidney. K^+ restriction activates the angiotensin II system, and its inhibitory effect on Klotho could account for diminished K^+ excretion during K-deprivation.[84]

Purinergic receptors and *ATP* affect K^+ transport in the kidney. Apical ATP reduces not only amiloride-sensitive Na transport,[128,297,298] but also decreases apical ROMK channel activity.[316] Consistent with inhibition of K^+ secretion by luminal ATP is the observation that mice lacking P2Y2 receptors display facilitated K^+ excretion accompanied by lower plasma K^+ concentrations.[406] A paracrine element of ATP-dependent regulation of tubule transport in collecting ducts has also been suggested: decreased Na reabsorption and diminished K^+ secretion as well as lowering of urinary ATP excretion result from ablation of renal purinergic receptors that are normally activated in intercalated tubule cells by enhanced tubule flow rate.[228a]

Both α- and β-adrenergic agonists affect K^+ transport by distal nephron segments. Care must be taken, however, to distinguish direct tubule effects from extrarenal effects, because epinephrine activates K^+ uptake in liver and muscle, and lowers plasma K^+ levels.[53,55] Nevertheless, when plasma K^+ levels are prevented from declining after epinephrine administration by infusion of K^+-containing fluids, renal K^+ excretion still falls. The epinephrine effect to suppress K^+ secretion or to enhance K^+ reabsorption has been localized to nephron sites beyond the initial collecting tubule.[104] Treatment with adrenergic agonists has been shown to reduce the lumen-negative voltage and chloride absorption in cortical collecting ducts.[242]

Insulin plays an important role in the regulation of extrarenal K^+ homeostasis,[53,103] but its renal effects are both modest and complex.[60,167,415] Insulin administration has been observed to reduce K^+ excretion,[104] but the role of changes of plasma K^+ and other hormones have proved difficult to resolve. In one clearance study, in which efforts were made to maintain constant K^+ levels in the blood, insulin modestly increased K^+ excretion.[415] In contrast, microperfusion of isolated CCDs with insulin *reduced* K^+ secretion.[167]

Glucagon has also been shown to have a significant effect on K^+ excretion. Its infusion induces a prompt increase in K^+ excretion, and it has been suggested that the effective excretion of K^+ following food intake may be related to glucagon release.[5]

Kallikrein is synthetized in distal connecting tubule cells,[87,128] and its release into the tubule fluid following a dietary K-load modulates downstream K^+ and Na transport.[137] Figure 49.44 illustrates its mode of action and that of other luminal agents. Following a dietary load of K, kallikrein is released into the tubule lumen and exerts its downstream action by inhibiting K^+ reabsorption by K/H exchange in intercalated cells. It also stimulates apical sodium channels in principal cells, depolarizing the apical membrane and enhancing the driving force for K^+ secretion. It is noteworthy that

the prompt kaliuresis following food intake was not associated with increased urinary aldosterone excretion.[87]

Guanylin and *uroguanylin* are peptides found in the gut and urine, and renal function studies demonstrate their ability to promote an increase in sodium and fluid excretion.[9] Perfusion studies in single rat distal tubules show that these peptides also inhibit K^+ secretion, most likely by modulating the activity of maxi-K channels. It is possible, but not certain, that guanilyn and uroguanylin are involved in the signaling between the gastrointestinal tract and the kidney with respect to changes in K^+ balance.

Diuretics

Diuretic drugs, used primarily to promote excretion of salt and water, also affect renal K^+ excretion.[73,134,135,171,181,186,201,234,345,524] Figure 49.45 illustrates the primary renal sites of action of compounds representative of three classes of diuretic drugs that act from the luminal side of tubule cells. Loop diuretics, such as furosemide, act mainly on the Na-K-2Cl co-transporter in the apical membrane of thick ascending limb cells.[74–76,198,201,234] Thiazide diuretics have their primary action on an Na-Cl co-transporter in cells of the distal convoluted tubule.[95,234,522–524] Loop and thiazide diuretics are both capable of increasing K^+ excretion. K^+-sparing diuretics, exemplified by amiloride and triamterene, block Na channels in principal cells of the ICT and CCD.[19,73,119,232,357] Renal K^+ excretion depends primarily on secretion by principal cells in the ICT and CCD. Amiloride targets these cells by a blocking ENaC, reducing the transepithelial potential difference and diminishing the driving focrce for K^+ secretion. Luminal Ca^{2+} also blocks ENaC, and has similar inhibitory effects on K^+ secretion.[372]

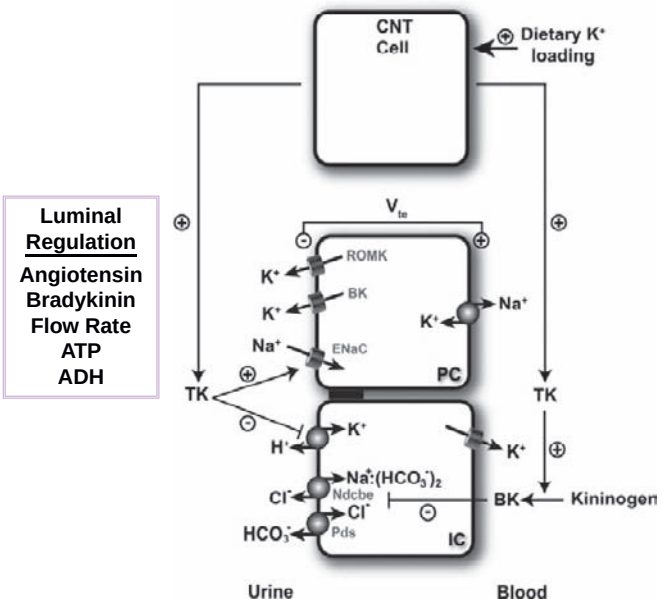

FIGURE 49.44 Regulation of distal tubule function by messengers. *(From ref. [128].)*

Loop diuretics increase renal K^+ excretion, in part by direct effects on TAL cells, and also by secondary effects on principal cells in the ICT and CCD. Thus, furosemide inhibition of the Na-K-2Cl co-transporter leaves the cell-to-lumen K^+ flux through apical membrane channels unopposed, resulting in either greatly reduced K^+ absorption or even reversal to produce net K^+ secretion, along the TAL.[201,511,512] The inhibition of Na and Cl absorption in the TAL also reduces medullary interstitial osmolality and results in decreased fluid absorption along the descending limb. Thus, loop diuretics not only decrease K^+ reabsorption in the thick ascending limb but, in addition, increase the rate of fluid delivery out of the loop of Henle and provide a flow rate stimulus to K^+ secretion along the distal tubule and collecting duct. Different degrees of kaliuresis have been observed in animal studies with furosemide and piretanide. The latter is less potent in promoting loss of K^+, owing to stimulation of bradykinin production which curtails sodium entry into collecting duct principal cells.[71]

Thiazide diuretics also promote renal K^+ excretion, largely via inhibition of the apical Na-Cl co-transporter in the DCT.[135,523–526] A likely explanation for the effect of thiazides to promote K^+ excretion is the increase in distal sodium and fluid delivery through inhibition of sodium chloride co-transport. By decreasing carbonic anhydrase-dependent sodium and bicarbonate reabsorption in the proximal tubule, thiazides also tend to increase the flow rate of fluid into the distal nephron.[234,522]

Osmotic diuretics exert their kaliuretic action largely by increasing fluid and sodium delivery into the distal tubule following proximal tubule transport inhibition. As described above, poorly permeant anions such as sulfate, phosphate bicarbonate, ferrocyanide, and hippurate not only augment distal fluid and sodium delivery, but also facilitate K^+ secretion by lowering lumen Cl^--concentration, thus stimulating K^+-chloride co-transport.[8,132] It should be noted, though, that with increased fluid loads delivered to the distal nephron, larger fractions of K^+ also enter the distal nephron. Additional mechanisms favoring K^+ loss during administration of diuretic agents also involve hormonal effects. As extracellular volume shrinks owing to urinary loss of sodium chloride, aldosterone and vasopressin release stimulate K^+ secretion.

Maturation of K^+ Transport

Somatic growth after birth is associated with a predictable increase in total body potassium content[77,152] and maintenance of a state of positive potassium balance.[106,111,496] Renal potassium clearance is low in newborns, even when corrected for the low glomerular filtration rate prevailing early in life.[106,430,496] Although infants, like adults, can excrete urinary potassium at a rate that exceeds its glomerular filtration, reflecting the capacity for net tubular secretion, they are unable to excrete an exogenously administered potassium load as efficiently as the adult.[313,330,510] Micropuncture studies in young (2-week-old) rats[299] and clearance studies in saline-expanded dogs[271] provide additional evidence for a limited secretory and enhanced reabsorptive capacity of the distal nephron to potassium early in life.

The physiologic processes contributing to net urinary potassium excretion in the neonate are similar to those already described in the fully-differentiated kidney, and include glomerular filtration, reabsorption (predominant) along the proximal tubule and loop of Henle, and bidirectional transport in the distal nephron. The fraction of the filtered load of potassium reabsorbed along the proximal tubule of suckling (2-week-old) rats is similar to that reabsorbed along the same segment in the adult.[299,462] In contrast, the TALH appears to undergo a significant developmental increase in its capacity for potassium reabsorption and diluting capacity, as evidenced by the findings in rats of significant increases in the: (1) fractional reabsorption of potassium along this segment, expressed as a percentage of delivered load, between the second and sixth weeks of postnatal life;[299] and (2) osmolarity of early distal fluid between the second and fourth weeks of life.[605] Molecular studies identify postnatal increases in abundance of mRNA encoding NKCC2 and Na-K-ATPase in rodent kidney, and in particular, in the medulla,[450,588] and Na-K-ATPase activity in rabbit TALH.[448]

Potassium secretion in the distal nephron, and specifically in the mammalian cortical collecting duct

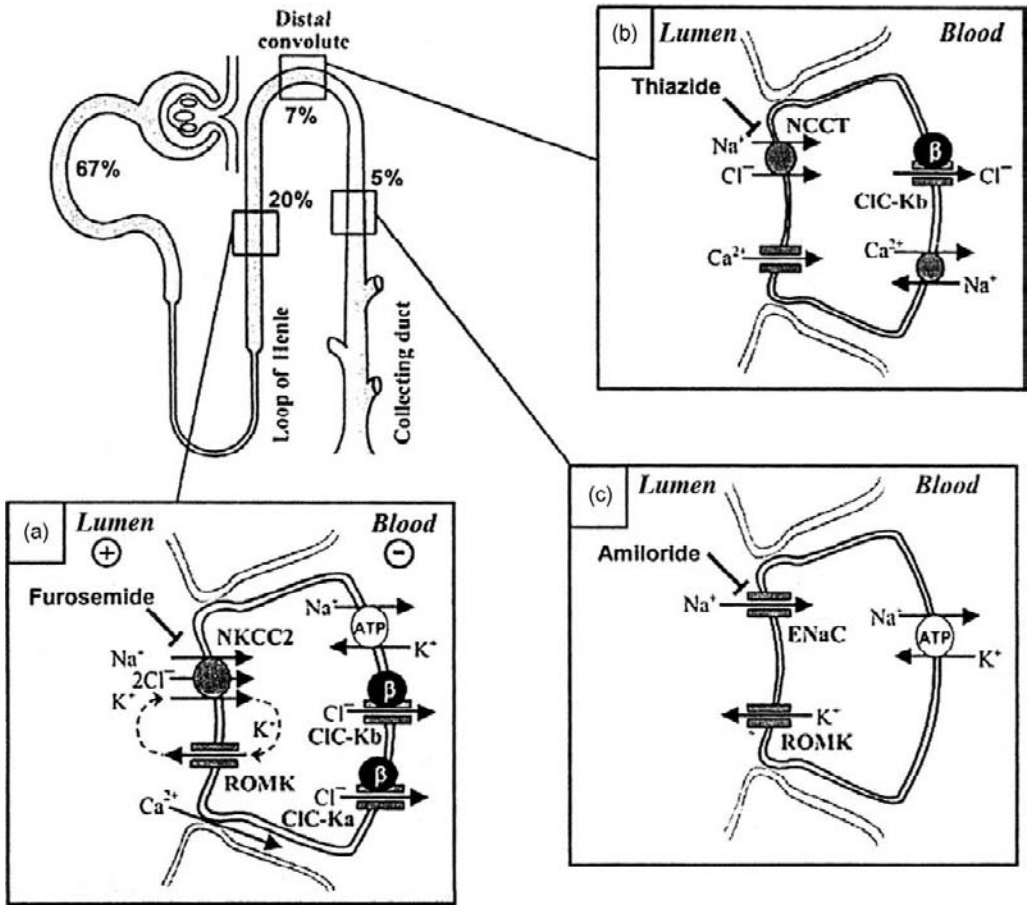

FIGURE 49.45 Distribution of NKCC2, ROMK, the CIC-ß-sub-unit Barttin, CIC-Kb, and NCCT along the nephron and site of action of the classic diuretic agents: (a) furosemide; (b) thiazide; and (c) amiloride. *(Acta Physiol. Scand. 2004, 181, 513–521.)*

(CCD) microperfused *in vitro*, is low early in life, and cannot be stimulated by high tubular (urinary) flow rates (Figure 49.46).[429,430] Indeed, basal potassium secretion cannot be detected in the rabbit CCD until after the third week of postnatal life, with potassium secretory rates increasing thereafter to reach adult levels by six weeks of age.[429] The limited capacity of the distal nephron for potassium secretion is due primarily to a paucity of apical conducting SK/ROMK channels in principal cells early in life.[431] The postnatal increase in apical channel activity reflects a developmental increase in number of channels, due to an increase in transcription and translation of channel proteins,[45,606] and not open probability which remained constant for all channels identified after the second week of life.[431] The electrochemical gradient favoring potassium secretion does not appear to be limiting early in life, as Na-K pump activity and the rate of net sodium absorption in the rabbit CCD at two weeks of age are 50–60% of that measured in the adult.[92,429,448] *In vivo* measurements of the sodium concentration in distal tubular fluid generally exceed 35 mEq/l both in healthy adult and suckling rats and thus should not restrict distal sodium secretion.[192,299,605]

Flow-induced potassium secretion, which is mediated by the Ca^{2+}- and stretch-activated BK channel, is a relatively late developmental event, first appearing in the rabbit CCD in the fifth week of postnatal life.[430,575] The detection of flow-induced potassium secretion coincides with the appearance of apical immunodetectable maxi-K channel α-subunit protein in this segment.[575] The absence of flow-induced potassium secretion early in life is not due to a limitation in the ability of the distal nephron to respond to an increase in luminal flow rate with an increase in net sodium absorption and/or intracellular Ca^{2+} concentration, responses required for flow-stimulated net potassium secretion; these flow-induced responses in CCDs from young animals are equivalent to those detected in the adult by the second week of postnatal life.[575]

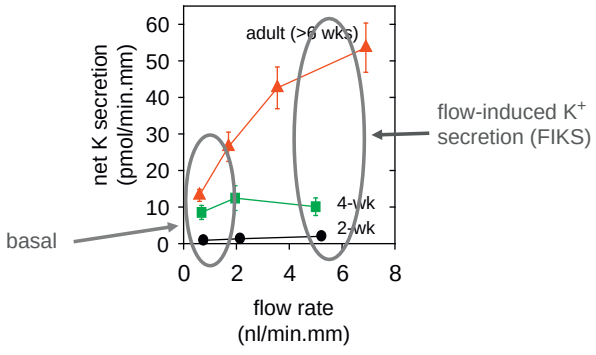

FIGURE 49.46 **Developmental changes in basal and flow-induced (FIKS) K^+ secretion in microperfused rabbit CCDs.** The maturing rabbit CCD is characterized by the relatively early appearance of basal K^+ secretion, mediated by SK/ROMK channels, at ~2 wks of age and, after the 4th week of postnatal life, BK channel-mediated FIKS. *Modified from ref. [429].*

The paucity of apical potassium secretory channels and relatively robust basolateral Na-K-ATPase activity prevailing in the CCD early in life requires that potassium translocated into the cell by the Na-K pump be recycled back into the interstitium via basolateral potassium channels to maintain a constant intracellular potassium concentration. Thus, the postnatal increase in transepithelial potassium secretion likely requires not only activation of apical potassium channels, but also modification of the magnitude of basolateral potassium recycling. Little is known about the developmental expression and regulation of renal basolateral potassium channels. Immunodetectable Kir7.1, which co-localizes with Na-K-ATPase at the basolateral membrane of distal nephron and principal cells of the fully differentiated CCD,[374a] is first observed in the cortical and medullary TAL by the end of the first postnatal week in rat, appearing in the DCT and CCD at three weeks of age.[497a] As the postnatal appearance of Kir7.1 coincides with that of ROMK in the CCD, Kir7.1 is not a likely candidate for basolateral potassium recycling in the early postnatal period. Kir7.1 has been proposed to contribute to urinary potassium excretion in response to potassium-loading by generating a transepithelial potential difference for sodium reabsorption which, in turn, provides the driving force for potassium secretion.[497a]

While the distal nephron is limited in its capacity for potassium secretion early in life, clearance studies suggest that newborn dogs absorb 25% more of the distal potassium load than their adult counterparts.[313] Functional assays of apical H-K-ATPase in rabbit collecting duct reveal that pump activity in neonatal intercalated cells is equivalent to that measured in mature cells.[91] Although these data alone do not predict transepithelial potassium absorption under physiologic conditions, the high distal tubular fluid potassium concentrations measured *in vivo* in the young rat may[299] facilitate H-K-ATPase-mediated potassium absorption in this part of the nephron.

Circadian Rhythm

Renal K^+ excretion varies during the 24-hour day.[337–339] Some of this variation occurs because of spacing between meals or other episodes of K^+ intake. However, even when K^+ ingestion is spread evenly throughout the day and night, a pattern of lower rates

of K^+ excretion at night and in the morning, and higher rates in the afternoon emerges.[337–339,397] Figure 49.47 shows the response of human subjects to an intravenous K^+ load, given either starting at midnight or midday. The relationship between plasma concentration and rate of renal K^+ excretion at different times of the day–night cycle is also summarized. It is apparent that the kaliuretic response was significantly diminished at night. Thus, higher concentrations of K^+ were required at night to effect K^+ excretion.

These daily fluctuations of K^+ excretion have not been fully explained. As with other circadian rhythms, the periodicity is entrained by the light–dark cycle, and depends on both central and peripheral pacemakers.[337–339] Notably, the DCT and CCD express several regulatory "Clock" genes, indicating operation of a local, intrarenal, pacemaker.[607] ENaC-, aquaporin 2-, and vasopressin-receptors have marked circadian rhythms which could indirectly influence the excretion of K^+. Also, it is likely that the changes in K^+ excretion are produced by changes in distal secretion. It has been reported that changes in aldosterone are not required,[393–397] but that the higher K^+ excretions during daytime may be related to enhanced bicarbonate loss in the urine.[477]

Integrated Regulation of K^+ Homeostasis

Renal K^+ excretion is regulated by multiple factors acting at several transport sites in response to influences originating outside the kidney. The final rate of excretion of K^+ is determined by the net effect of mechanisms that may be cooperating or competing. In some situations the individual regulatory factors may act together, while in other cases they may change in directions that tend to cancel one another. Reasonable predictions of the rate of K^+ excretion can be derived from knowledge of expected changes of individual factors.

Model calculations of tubule K^+ transport have provided interesting insights between water and K^+ transport. It was suggested that the increase in K^+ concentration along both the water-permeable connecting and collecting tubule was not only mediated by net secretion in principal cells, but also by vasopressin-dependent fluid equilibration.[560] Indeed, it becomes apparent that the initial K^+ concentration in both nephron segments may reach such high concentrations that they exceed the maximal transepithelial K^+ gradient that can be achieved by K^+ secretion in principal cells. As a consequence, both the CNT and CCD can become sites of modest, albeit significant, reabsorption of K^+. Calculations based on these cell models also allowed an assessment of the interactions between axial flow rate along the CNT and CCD, the sodium-load,

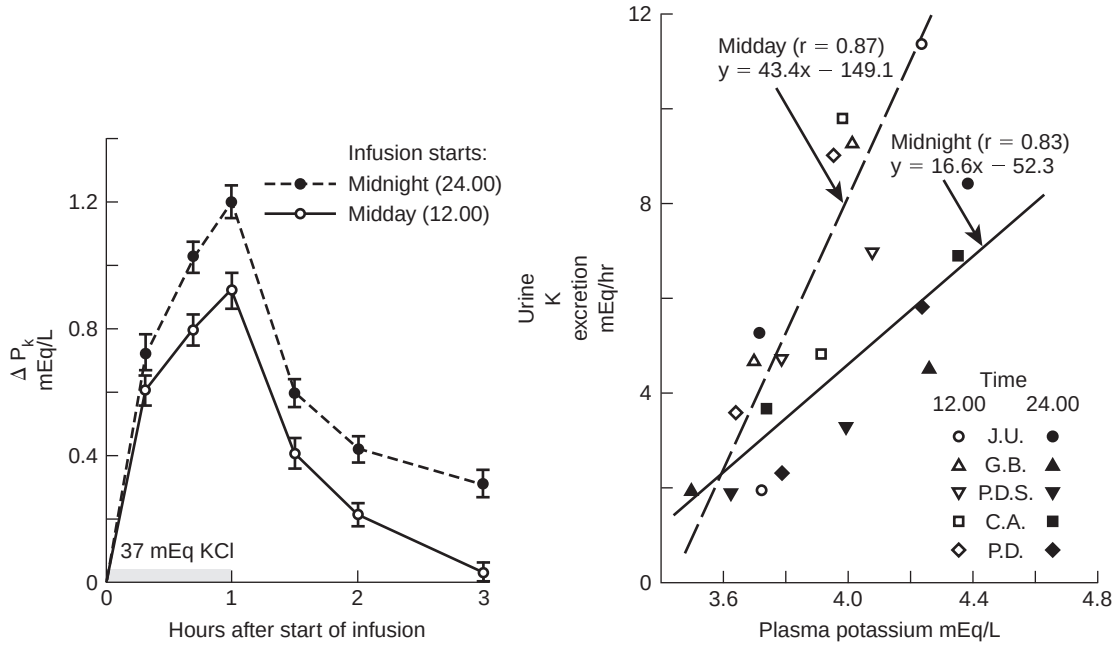

FIGURE 49.47 Left: Response of plasma potassium concentration (PK) in human subjects to intravenous infusion of 37 mEq of potassium chloride solution in 250 ml of water provided over 1 hour either starting at midnight (dashed line) or midday (solid line). Right: Relationship between plasma potassium concentration and rate of renal potassium excretion in human subject at midnight (dashed line) or midday (solid line). *(Am. J. Physiol. 1986, **250**, R735–R752.)*

transepithelial potential difference, and water permeability. It has also made possible an analysis of the factors leading to the typical kaliuresis produced by thiazides.[560]

An example of cooperative factors modulating K^+ transport is seen in the renal response to a high-K^+ intake. As noted previously, the increase in plasma K^+ concentration promotes K^+ uptake by K^+-secreting cells. It also stimulates the adrenal gland to secrete aldosterone, which in turn promotes K^+ secretion by cells of the distal nephron. Increased plasma K^+ concentration also inhibits sodium and fluid reabsorption by the proximal tubule, and thus increases flow rate into the distal nephron.

Evidence of the involvement of such factors in response to a change in K^+ intake was also obtained in a careful study employing human subjects.[391] Dietary K^+ was increased from 100 to 400 mmol/day. Renal K^+ excretion progressively increased so that external K^+ balance was restored within three days. During the first two hours after each meal, plasma K^+ rose by approximately 0.5 mM and then subsided, returning to the normal range before the next meal. Plasma aldosterone also increased after meals. The changes in plasma aldosterone (from 400 to 900 pM) were proportionately larger than the 10–20% increase in plasma K^+. Evidence that distal flow and sodium delivery increased after meals as well came from the observation that sodium excretion increased from 50 to 200 μmol/min. Thus, the concerted actions of multiple regulatory mechanisms improve the defense against the danger of hyperkalemia.

The effectiveness of aldosterone to stimulate K^+ secretion in principle cells is modulated by SGK1 (serum- and glucocorticoid-regulated kinase 1). This kinase affects several renal transport processes. Inspection of Figure 49.28 shows that the stimulation of apical sodium and K^+ channels, as well as of basolateral Na^+,K^+-ATPase through aldosterone, involves participation of SGK. Transcription and translation of SGK is upregulated by aldosterone,[89a,289,354a] and co-expression experiments in heterologous expression systems of SGK with Na^+ or K^+ channels, and with Na^+,K^+-ATPase, indicate increased activity of these transporters. It is significant that both the reabsorption of sodium, as well as the secretion of K^+, is impaired in SGK knockout mice. Compromised upregulation of urinary K^+ excretion during chronic K^+-loading was also demonstrated by maintenance of K^+ balance, but at elevated aldosterone levels.[520] SGK has been shown to enhance abundance of ROMK in the membrane of oocytes, a process that also involves the cooperative effect of NHERF (Na-H exchange regulating factor).[589a,589b] Increased activity of ROMK is also mediated by a significant shift in pH-sensitivity of the channel.[289]

Derangements in the regulation of aldosterone regulation can have important consequences for the maintenance of K^+ balance. The hypokalemia that appears in primary hyperaldosteronism has long been recognized.[175,176] Experimental administration of excess mineralocorticoid hormone (DOC) or aldosterone produces the effects seen in patients with adrenal overproduction of aldosterone. Sodium excretion falls initially, but within a few days it then increases until balance between intake and output is restored. Plasma sodium concentration does not change; however, arterial blood pressure is increased. The "escape" from the sodium-retaining effect of mineralocorticoid excess has been attributed to inhibition of Na reabsorption by factors related to extracellular fluid volume expansion,[213,273] and thiazide-sensitive Na-Cl co-transport has been defined as the key tubule transport that is downregulated during mineralocorticoid escape.[549] In contrast to sodium, K^+ excretion rises to levels exceeding K^+ intake, continues for a longer period, and results in hypokalemia. This continued stimulation of distal K^+ secretion appears to be related to the same volume-related inhibition of sodium reabsorption that limits the period of sodium retention. Inhibition of proximal sodium and fluid absorption leads to increased distal delivery of sodium and fluid, and therefore to a flow rate stimulus to K^+ secretion. Protective mechanisms, activated by the progressively increasing K^+ depletion, involve stimulation of K^+ reabsorption by H^+-K^+-ATPase which progressively restrains further K^+ loss.

It should be noted that some investigators are not satisfied that all stimuli acting to promote increased K^+ excretion have been identified. Rabinowitz and others have argued that increases in K^+ excretion after ingestion of K^+ are not fully-explained by changes in plasma K, circulating aldosterone or distal delivery of fluid and sodium.[105,168,393] These observations have recently been confirmed and extended, and it has been suggested that sensors in the gastrointestinal tract, the liver or the brain are involved in regulating K^+ homeostasis.[392–397] A gastrointestinal or hepatic K^+ sensor would explain the observation that a K^+-load given by infusion into the portal vein is more kaliuretic compared to the same amount of K^+ injected intravenously into the systemic circulation.[369] Moreover, by restricting the initial rise of K^+ to the hepatic circulation, kaliuresis could be induced without larger and potentially harmful fluctuations of K^+ in the general circulation.[89,343,369] Hepatic afferent nerve activity has been reported to increase with K^+ injection into the portal vein, but the mechanism modulating tubule transport of K^+ needs exploration.

When K^+ intake is restricted, reductions in plasma K^+ and circulating aldosterone withdraw the stimulus

to K^+ secretion, and renal K^+ excretion tends to fall. However, in some circumstances the integrated actions of all factors, because of competing priorities, fail to maintain K^+ balance. For example, if K^+ intake is being restricted along with other food because an individual has just undergone an abdominal operation, stress-related stimulation of aldosterone secretion may put high aldosterone levels in competition with low plasma K^+ levels, and cause the rate of K^+ excretion to exceed the rate of intake. Furthermore, if saline infusions are maintaining extracellular fluid volume and urine flow, a high flow rate of tubule fluid may further compromise the ability of the kidney to retain K^+.

In other circumstances, competition among the regulatory factors may actually serve the cause of K^+ homeostasis. Changes in sodium intake are a relevant example. Although changes in sodium intake lead to changes in circulating aldosterone and extracellular fluid volume, they do not result in important deviations from K^+ balance. Lack of sodium enhances proximal fluid reabsorption, and may decrease distal flow rate and diminish K^+ excretion. However, the simultaneous stimulation of the renin–angiotensin–aldosterone system acts to promote K^+ excretion. Similarly, with deprivation of water alone, competition among regulatory factors may also act to stabilize K^+ excretion. The K^+-retaining influence of low luminal flow rate is opposed by the stimulatory influence on K^+ secretion of increased circulating vasopressin.

Finally, in some acid–base disturbances, the net result of several influences on K^+ secretion may cause the kidney to excrete K^+ at rates exceeding K^+ intake, and thus to deplete body K^+. In metabolic alkalosis, plasma K^+ concentration tends to be low because cell uptake of K^+ is enhanced. Aldosterone levels are often elevated and also tend to promote K^+ secretion. Increased distal delivery of bicarbonate, associated with increased distal flow, and high luminal bicarbonate concentration permits the distal Cl concentration to fall to low levels, and thus further favor K^+ secretion of KCl co-transport.

In acute metabolic acidosis, decreased uptake of K^+ by distal cells tends to reduce K^+ secretion. However, as acidosis proceeds, proximal fluid absorption is increasingly inhibited and distal flow rate begins to increase. An additional factor favoring K^+ secretion is the elevation of aldosterone that has been observed in chronic metabolic acidosis. Taken together, it is important to recognize that renal K^+ excretion has multiple determinants, and that they may not always be responding only to changes in K^+ balance.

Acknowledgments

We are grateful to Dr. Fred Wright, who was a major contributor and co-author of previous chapters in the earlier issues. Ms. Leah Sanders and Mr. Duncan Wong have also contributed by careful editing of the manuscript and preparation of the figures.

We dedicate this chapter to Steve Hebert. He was an inspiration to all of us.

CHAPTER

50

Physiopathology of Potassium Deficiency

Francesco Trepiccione, Miriam Zacchia and Giovambattista Capasso

Chair of Nephrology, Department of Internal Medicine, Faculty of Medicine, Second University of Naples, Italy

INTRODUCTION

Hypokalemia is a common clinical disorder that can be the end-result of: (1) potassium (K^+) redistribution between plasma and intracellular fluid (ICF); (2) insufficient K^+ intake; (3) disproportionate K^+ excretion. It is commonly defined as a plasma K^+ concentration less than 3.5 mmol/L, but this level infrequently causes trouble unless it has fallen rapidly: patients are usually symptomatic when plasma K^+ is lower than 2.5 mmol/L. Major muscle weakness have a tendency to occur at plasma K^+ less than 2 mmol/L.

The average K^+ intake in a typical western diet is roughly 70 mmol.[1] The intestine absorbs almost all of the ingested K^+; only negligible quantities of K^+ are excreted in the feces. The kidney plays an important role in K^+ balance, which is the result of glomerular filtration, extensive proximal tubule reabsorption, and highly regulated secretory/reabsorbtive processes located along the distal tubule and the collecting duct (CD).[2] Total body K^+ is roughly 55 mmol/kg of body weight, with 98% distributed to the intracellular fluid (primarily in muscle, liver, and erythrocytes) and 2% in the extracellular fluid. Na/K-ATPase actively pumps K^+ into the cell and preserves the electrochemical gradient between the intra- and extracellular pool.

NEW CONCEPTS ON THE INTEGRATIVE CONTROL OF K^+ HOMEOSTASIS

Feedback Control of K^+ Homeostasis

A large increase in plasma K^+ concentration triggers aldosterone release from the adrenal glands. Aldosterone, in turn, stimulates the activity and synthesis of both Na/K-ATPase and luminal K^+ channels in CD principal cells, thus promoting K^+ excretion.[3] In addition, aldosterone enhances K^+ secretion in the distal colon, which can exert an essential role when renal function is reduced.[4]

On the other hand, if plasma K^+ concentration decreases as a consequence of reduced K^+ intake or increased K^+ excretion, then feedback regulation redistributes K^+ from ICF to plasma. At the same extent, skeletal muscle becomes insulin-resistant to K^+ (but not glucose) uptake, blocks the entry of K^+ from plasma into the cell. Hypokalemia also causes a decreased expression of skeletal muscle Na/K-ATPase 2 isoform, thus allowing a leak of K^+ from ICF to the plasma.[5] The low plasma K^+ concentration suppresses adrenal aldosterone release so that the kidney reduces urinary K^+ excretion.

Feedforward Control of K^+ Homeostasis

However, besides the classic feedback control, some findings suggest a feedforward control.[6] It is clear that plasma K^+ stimulates aldosterone secretion only at supra-physiological levels, with little effect within the physiological range.[7] Indeed, it has been shown that, in sheep, a meal intake produced a substantial kaliuresis in the absence of changes in plasma aldosterone concentration.[8] From these experiments it was concluded that the increased renal K^+ excretion following a meal cannot be explained by changes in aldosterone concentration, but it may be dependent on the existence of a kaliuretic reflex arising from *sensors* in the splanchnic bed (i.e., gut, portal circulation, and/or liver) (Figure 50.1).

One of the potential effectors of the feedforward control of serum K^+ is glucagon. Glucagon secretion is definitely stimulated after a protein-rich meal, and intraportal glucagon infusion produces significant increases in renal blood flow and glomerular filtration

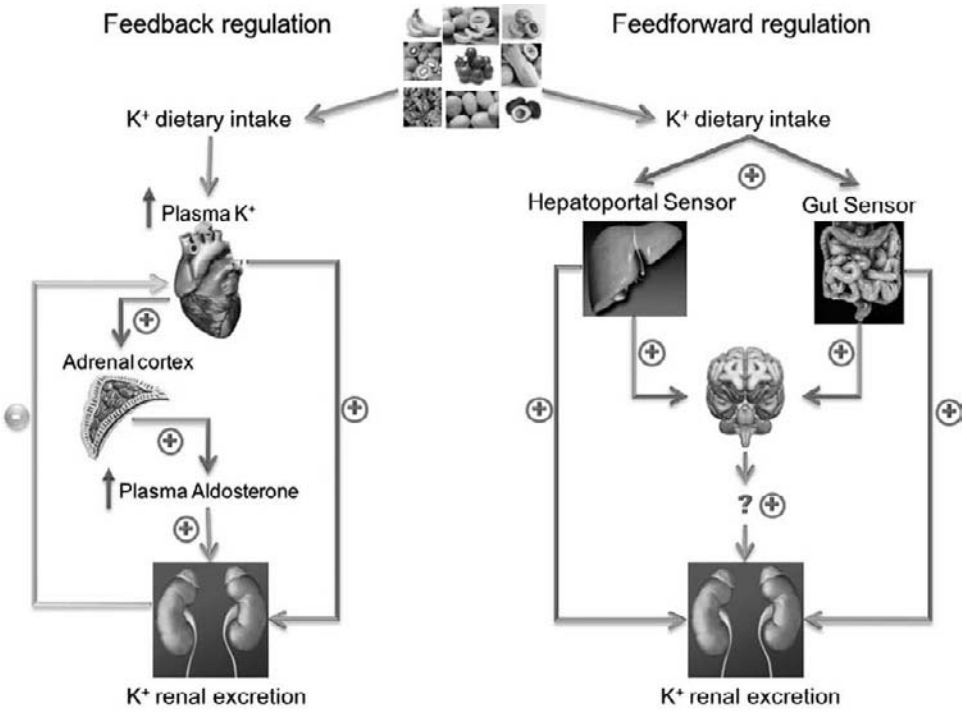

FIGURE 50.1 **Schematic diagram illustrating feedback versus feedforward control of K^+ homeostasis.** Left: In feedback control, an increase in ECF [K^+] is the signal that stimulates urinary K^+ excretion. Right: In feedforward control, an increase in [K^+] in the gut is sensed during K^+ intake and stimulates urinary K^+ excretion independently from a rise in ECF [K^+].

rate (GFR), suggesting the existence of a hepatorenal axis.[9]

The feedforward regulation may act through three different mechanisms: (1) insulin release rapidly stimulates cellular K^+ uptake into insulin-responsive tissues; (2) glucagon, through cAMP released from the liver, quickly increases renal K^+ excretion after a protein-rich meal; (3) a yet-unidentified gut factor senses K^+ ingestion and enhances renal K^+ excretion. When plasma K^+ level increases despite these layers of control, feedback regulation is activated. Aldosterone acts only after a certain time, it is not involved in rapid control of K^+ homeostasis, but it can chronically increase K^+ secretion until plasma K^+ is normalized.[6]

Assessment of Urinary K^+ Excretion

Several urine parameters are used to identify whether hypokalemia is dependent on renal loss. Renal K^+ excretion can be assessed with a 24 hour urine collection or a spot urine test determining the K^+: creatinine ratio. A 24-hour urinary K^+ excretion lower than 15 mEq or a K^+ (mmol)/creatinine (mmol) ratio <1 suggests an extrarenal cause of hypokalemia.

In the clinical practise, as an initial test to address the origin of K^+ losses, a random urine K^+ is used. However, this approach is hampered by the effect of renal water handling on urine K^+ concentration. Determining the transtubular K^+ gradient (TTKG) is still an accepted way to assess renal K^+ handling:

$$\text{TTKG} = [\text{uk}/(\text{uOsmolality}/\text{sOsmolality})]/\text{sk}$$

Tubular fluid K^+ concentration in the last part of the CD is mainly dependent on aldosterone, because most K^+ secretion takes place in the CD. Thereafter, urinary K^+ concentration increases as a consequence of water reabsorption. The TTKG reflects the tubular fluid K^+ concentration at the end of the cortical CD, by accounting for water reabsorption that takes place distal of where K^+ secretion has ended.

However, there are few limitations to the clinical use of this formula.[10] First, the calculation assumes that there is no significant solute transport and only water reabsorption along the medullary CD. Any Na^+ or urea reabsorption in this segment would tend to lower urine osmolality and cause the TTKG to overestimate the gradient for K^+ secretion in the upstream CD. Second, there must be optimal conditions for K^+ secretion at the time that the TTKG is measured. In this regard, urinary Na^+ should be no less than 25 mEq/L, to guarantee that Na^+ delivery to the CD is not rate-limiting in K^+ secretion. In addition, urine osmolality should be equal to or higher than the plasma. A higher urine osmolality indicates increased vasopressin

release, which is known to stimulate K^+ secretion in the CD.

Hypokalemia Associated With Intracellular Shift

The regulation of K^+ distribution between the intracellular and extracellular space is known as internal K^+ balance. Even though the kidney is in charge of the preservation of total body K^+, factors that adjust internal balance are central to the removal of acute K^+-loads. A large K^+ intake could potentially double extracellular K^+ concentration in the absence of a rapid shift into the cells. This process is mainly regulated by insulin and catecholamines, with a minor role of metabolic and respiratory alkalosis.

Hypokalemic periodic paralysis is a rare disorder characterized by muscle weakness or paralysis as a result of the sudden movement of K^+ into cells. Measurement of the TTKG at the time of the attacks typically shows values of <1. The attacks may be triggered by exercise, stress, intake of large quantities of carbohydrates, and increased release of catecholamines or insulin.[11]

This disorder is classified as primary, due to a genetic defect or acquired, due to drugs or glandular diseases. The genetic forms are associated with mutations in genes encoding for subunits of muscular sodium, calcium, and potassium channels. Mutations in the α-subunit of the calcium channel [dihydropyridine (DHP)-receptor] (CACNA1S) gene and the α-subunit of the sodium channel (SCN4A) have been described. Loss of function mutations of CACNA1S reduce current density. A mutation in the KCNJ2 gene encoding for the inward-rectifying potassium channel Kir2.1 causes Andersen-Tawil syndrome, characterized by the triad of periodic muscle weakness, cardiac arrhythmias, and multiple dysmorphic features (short stature, hypertelorism, micrognathia).[12] Whether hypokalemia determines the attack is not well-established. The onset of attacks occurs generally between 15 and 35 years of age; the severity of the clinical manifestations range from rare episodes in a lifetime to daily and severe attacks. The attacks can be triggered by all conditions which favor hypokalemia, such as physical exercise, a carbohydrate-rich meal, alcohol, and cold. Myalgia after the attack is a frequent complaint. The acquired form is mainly associated with thyrotoxicosis. Excess thyroid hormone may predispose to paralytic episodes by increasing Na/K-ATPase activity. The activity of this pump is further induced by catecholamines, which are typically increased in this setting. The underlying cause of thyrotoxicosis is most commonly Graves disease, but it can also be a solitary thyroid adenoma (Plummer disease).[13] The acute attacks of hypokalemic periodic paralysis are best treated with intravenous KCl and propranolol.

It is important to administer KCl in non-dextrose-containing solutions, because glucose will stimulate insulin release, potentially exacerbating K^+ shift into the cells. Propranolol (a nonspecific adrenergic β-blocker) blocks the effects of catecholamines, and inhibits the peripheral conversion of T4 to T3.

Extrarenal K^+ Loss from the Body

Diarrhea is a common cause of hypokalemia due to gastrointestinal loss. Secretory diarrhea may be the consequence of two processes that can occur either alone or together. First, it may be related to inhibition of active intestinal NaCl and $NaHCO_3$ reabsorption and, second, it may be dependent on increased active secretion of Cl^- coupled to passive secretion of an identical quantity of Na^+ in order to maintain the electrochemical balance. Under both circumstances, the stool electrolyte composition is analogous to plasma with a high concentration of NaCl and a much lower K^+ concentration. Despite the low K^+ concentration in the stool, large K^+ losses can take place in the setting of large fecal fluid volume.

Hypokalemia may also be associated with infectious diarrhea. In particular, malaria and leptospirosis may cause alterations in fluid and electrolyte balance. Hypokalemia is particularly frequent in children with severe malaria, and may arise within several hours of initiation of therapy. Hypokalemia develops in about one-third of patients with leptospirosis. Such patients are at risk of both gastrointestinal and renal losses. In the outer membrane of the organism there is a substance that has an inhibitory effect on the Na/K-ATPase within the nephron. It has been hypothesized that this inhibitory effect reduces Na^+ reabsorption along the proximal tubule, thus increasing distal Na^+ delivery, resulting in kaliuresis.[14] Hypokalemia may also be associated with watery diarrhea and achlorhydria, a condition secondary to hypersecretion of vasoactive intestinal polypeptide (VIP). In adults, this syndrome is most commonly a complication of pancreatic islet cell tumors, and sometimes of bronchogenic carcinoma, medullary thyroid carcinoma or retroperitoneal histiocytoma. There are now few reports describing chronic watery diarrhea and hypokalemia due to adrenal pheochromocytoma containing immunoreactive VIP.[15]

A recent report describes five consecutive patients with acute or subacute colonic pseudo-obstruction suffering a typical secretory diarrhea characterized by very high fecal K^+ concentrations (over 100 mEq/kg)

and low Na^+ concentration (Ogilvie syndrome). These elevated fecal concentrations of K^+ in large volume diarrhea induced important outputs of K^+ salts responsible for profound hypokalemia and decreased urinary excretion of K^+.[16]

RENAL K^+-LOSING SYNDROMES

Bartter Syndrome (BS)

BS results from a defect in any of the major components of NaCl reabsorbtive machinery along the TAL. So far, mutations of five genes have been described. The defect determines renal loss of water and electrolytes resulting in hypovolemia, with a compensatory increase in renin and aldosterone levels.

Genetic and Molecular Biology

BS type I is sustained by mutations of the SLC12A1 gene, encoding the kidney-specific furosemide-sensitive NKCC2.[17] A number of point mutations have been described in homozygosis or compound heterozygosis, mostly frameshift and non-conservative missense mutations. To date, over 30 mutations in the SLC12A1 gene have been reported[18]; phenotypic variability among patients with SLC12A1 mutations may be due to the effect of genetic mutations on protein function, and milder phenotypes may correlate with residual NKCC2 function.[19]

BS type II depends on inactivating mutations of the KCNJ1 gene, encoding the K^+ channel ROMK.[20] These channels are the main renal K^+ secretory channels. Along the TAL, ROMK mediates K^+ efflux to the lumen, which is critical for supporting Na/K-2Cl absorption via NKCC2. At this level of the nephron, ROMK channels contribute to the generation of the lumen-positive transepithelial voltage which allows paracellular calcium and magnesium absorption. An inactivating mutation of ROMK is thought to inhibit salt reabsorption along the TAL. Over 35 genetic mutations have been described, such as missense mutations, frameshift mutations, and stop codons which result in a truncated protein.[21] The majority of these mutations reduces or eliminates ROMK surface expression, as a consequence of misfolding and/or mistrafficking; others compromise K^+ permeation and channel regulation. Besides the TAL, ROMK channels are also expressed along the apical membrane of principal cells in the cortical CD, where they mediate K^+ secretion into the lumen. A defect in ROMK results in the classical BS phenotype, including the presence of hypokalemia. This finding brought attention to its role in K^+ secretion. Subsequent studies have demonstrated that, in the absence of functional ROMK channels, K^+ secretion is guaranteed by the upregulation of flux-sensitive Maxi-K channels along the CD in mice.[22]

BS type III depends on the mutation of the kidney-specific Cl^- channel, CLC-K. Two genes belonging to the CLC family are involved in Cl^- efflux across the basolateral membrane, CLCNKA and CLCNKB. Their products are nearly identical at protein level, and both channels are associated with the Barttin subunit, essential for their insertion on plasma membrane and their activity. These channels differ only in their distribution along the nephron, with CLC-Ka expressed predominantly along the TAL, while CLC-Kb is expressed along the DT.[23] CLCKNB defects are associated with a Bartter phenotype in humans; a high rate of deletions encompassing the entire gene has been described,[24] together with frameshift and splice-site mutations. These mutations are supposed to disrupt the protein, altering its function. The predominant location of CLCKb along the DT explains why this variant of BS is less commonly associated with a defect in concentrating mechanism, and with hypercalciuria. There is no evidence CLCKNA mutations may generate a Bartter like syndrome. ClCk1 (the ortholog of CLC-Ka)-deficient mice show a phenotype of nephrogenic diabetes insipidus.[25] However a combination of defects in both CLCNKA and CLCNKB genes result in a phenotype of antenatal BS.[23]

BS type IV refers to the mutations in the BSND gene product. In contrast to other BS variants, the gene does not encode for an ion channel or transporter, but for an accessory subunit of CLC-Ka and CLC-Kb, defined as Barttin. CLC-K/Barttin Cl^- channels also localize in the cochlea, along the basolateral membrane of marginal cells of the stria.[26] Barttin has been found mutated in patients suffering from BS; different mutations generate phenotypes of varying severity. In heterologous expression, CLC-K channels do not yield currents in the absence of a functional Barttin subunit, suggesting that Barttin is essential for their function. As in the TAL, CLC-K channels participate in Cl^- reabsorption in the inner ear. Recent studies have shown that the Barttin subunit is essential for the generation of endocochlear potential; in the absence of Barttin, the degeneration of cochlear outer cells and the collapse of endolymphatic space may contribute to the pathogenesis of deafness in this BS subtype.[27]

BS type V depends on the activating mutation of the calcium-sensing receptor (CaSR). The protein is expressed in the parathyroid and in the kidney, and it is mainly involved in calcium and magnesium homeostasis. Along the TAL the CaSR is expressed on the basolateral membrane and it can inhibit salt absorption. A case report showed that activating mutations of the CaSR gene associated with a BS phenotype inhibit ROMK, explaining the inhibition of salt absorption at

this site.[28] A number of gain-of-function mutations of the CaSR gene have been identified as causing an inherited form of hypocalcemia/hypoparathyroidism (autosomal-dominant hypoparathyroidism). Whether those disarrangements lead to a different phenotype is still unknown.

Mutations in these five genes do not explain all cases of BS, and many patients do not get a genetic diagnosis. It is presumable that other genes are involved in the pathogenesis of this syndrome. Recently a role has been proposed for claudins, a family of transmembrane proteins expressed within the tight junction. Mutation in claudin-16 is associated with familiar hypomagnesemia with hypercalciuria and nephrocalcinosis. A single nucleotide substitution has been found in the extracellular domain of claudin-8 in four African-American BS patients.[29] The effect of the mutation on protein function has not yet been addressed.

Pathophysiology

The defective NaCl absorption along the TAL caused by mutations in any of these five genes leads to an increased salt delivery to the distal nephron. The subsequent volume-depletion leads to a compensatory hyper-reninemia. Mice models of BS type I and II show early onset of polyuria, metabolic alkalosis, increased calcium and magnesium urinary excretion, and hyperprostaglandinemia, a phenotype which resembles the abuse of loop diuretics. The activation of RAAS leads to a compensatory increase in Na^+ absorption along the PT and the aldosterone-sensitive segments of the nephron. The latter favors K^+ secretion along the CD, enhancing the kaliuretic effect of the increased Na^+ delivery. Clinical differences among BS subtypes depend on the specific physiological role of the causative gene in the kidney and in other organs.

Type II BS is characterized by relatively mild hypokalemia compared with type I, and by the dual role of ROMK in the kidney in controlling NaCl absorption along the TAL (through K^+ recycling) and K^+ secretion along the CD. The presence of hypokalemia is ensured by the activation of the flux-sensitive Maxi-K channels which mediate urinary K^+ secretion along the distal nephron. However, newborn infants suffering from type II BS show transient hyperkalemia before developing normohypokalemia later in the infancy. This effect may be due to the delay in BK-dependent K^+ secretion, which later is responsible for urinary K^+ excretion.[30]

The widespread distribution of CLC-K channels along the distal nephron and the compensatory activation of Cl^- absorption through other channels explains why CLCKNB mutations may result in a pure BS phenotype, GS phenotype or a combination of these.[23] Hypercalciuria and nephrocalcinosis are typical signs of type I and II BS, but are rare in type III[24]; however, a broad spectrum of phenotypes has been associated with mutations of the CLCNKB gene, ranging from antenatal BS to classic BS and Gitelman-like syndrome, without any correlation with the type of genetic mutation. Additional studies are needed for a better understanding of the phenotypic variability.

The presence of deafness is a hallmark of type IV BS. Barttin, as pointed out above, is necessary for CLC-K channels trafficking to the membrane. ClCK-barttin complex is expressed in the kidney and in the inner ear. Mice lacking a functional CLC-Ka have a phenotype resembling nephrogenic diabetes insipidus, with high vasopressin plasma levels, and low osmolality of renal papilla even after water restriction, suggesting a role in the urinary concentrating mechanism. CLCKB-null mice show the classic form of BS, whereas only a defect of Barttin determines deafness. In the inner ear CLC-K/Barttin channels participate in Cl^- transcellular extrusion across the basolateral membrane. It is possible that the absence of CLC-Kb could be compensated by the CLC-Ka-Barttin in the inner ear, while the absence of Barttin equals a double defect in CLC-k a and b, leading to deafness.[23] Hypercalciuria and nephrocalcinosis are the main features of type V BS. Activating mutation of the CaSR leads to autosomal dominant hypoparathyroidism, characterized by hypocalcaemia and hyperphosphoremia, with low-normal PTH levels.[31]

Clinical Presentation

Clinically, BS is divided into antenatal and classic BS with or without deafness.

Antenatal BS, or *hyper-prostaglandin E BS*, is the most severe form, characterized by polyhydramnios for excessive urinary output and premature birth. It is sustained by type I and II, and sometimes type III. After birth, patients have a life-threatening clinical course, with fever, vomiting, and lethargy. Biochemical analysis shows the presence of metabolic alkalosis, hypokalemia, isohypostenuria, and hypercalciuria. Nephrocalcinosis is frequent. High urinary prostaglandin excretion of E2 or its metabolites is typical of the antenatal form, and high levels of renin and aldosterone are secondary to volume-depletion. The reason for the high urinary and plasma prostaglandin levels is still unknown, but it seems to be secondary to the defect of NaCl absorption along the TAL.

Classic BS is sustained more often by type III BS. Clinical appearance occurs during infancy or childhood, in the absence of polyhydramnios and prematurity. The clinical course is milder than the antenatal subtype; patients manifest polyuria, polydipsia, vomiting, and dehydration. Nephrocalcinosis is an

infrequent sign, and a less severe defect in urinary concentrating mechanism is present.

BS with sensorineural deafness. The presentation of patients with type IV BS shows remarkable variation, ranging from prenatal diagnosis with severe polyhydramnios and prematurity to late diagnosis.[32]

Gitelman Syndrome

Gitelman syndrome (GS) differs from BS because of the presence of hypocalciuria and hypomagnesaemia. It is often diagnosed in adulthood.

Genetics and Molecular Biology

The syndrome correlates with mutations of the SLC12A3 gene located on chromosome 16q, encoding the thiazide-sensitive sodium-chloride co-transporter (NCC). The transporter is expressed on the apical membrane of distal tubule, and represents the major NaCl transport pathway in this segment. More than 140 mutations have been described; the majority of mutations are missense substitutions, but frameshift and splice-site mutations have also been described.[33] Heterozygous subjects show a tendency for low blood pressure, while the complete GS phenotype occurs only in homozygosis. De Jong et al. have performed, in *xenopus laevis* oocytes, functional and immunohistochemical analysis of mutant human NCC of GS subjects.[34] This study has found class I mutants, characterized by the absence of significant metazolone-sensitive Na^+ uptake with undetectable protein distribution on the membrane, and class II mutants, which exhibited significant, albeit low, metazolone-sensitive Na^+ uptake, while NCC staining was equally present in plasma membrane and cytoplasm. These findings suggest that some mutations compromise NCC abundance in plasma membrane (class I), leading to a defect in protein activity; other mutations only partly impair NCC routing to the membrane, as suggested by the presence of mutant NCC both on plasma membrane and cytoplasm. However, different mechanisms are involved in the impaired trafficking for the two classes of mutations, and the precise mechanism has still to be established. Previous studies suggest the role of defective post-translational changes, such as protein glycosylation, which seems to be required for proper folding and trafficking to plasma membrane.[35] A minority of patients with GS phenotype show mutations in the CLCNKB gene, which is also responsible for BS type III.

Pathophysiology

Both NCC and CLC-Kb dysfunction result in decreased Na^+ and Cl^- absorption along the DT. The volume-contraction resulting from defective NaCl absorption determines a compensatory activation of RAAS, which promotes electrogenic Na^+ absorption along the CD through ENaC. The latter enhances K^+ and H^+ secretion along the CD, favoring hypokalemia and metabolic alkalosis. The pathogenesis of hypocalciuria and hypomagnesemia refers to a not yet completely-elucidated mechanism. Micropuncture experiments have demonstrated an increased Ca^{2+} absorption along the proximal tubule (PT) after chronic administration of thiazides, whereas DT calcium absorption was unaffected.[36] This hypothesis is supported by the presence of thiazide-induced hypocalciuria in a mouse model lacking the calcium channel (TRPV5) along the DT. These findings demonstrate that increased calcium absorption parallels a compensatory increased Na^+ absorption along the PT secondary to volume-contraction. Other studies suggest that enhanced calcium absorption along the DT participates in the generation of hypocalciuria. In a mouse model of GS, the expression of TRPV5 and TRPV6 were increased, and TRPV5 is also overexpressed in renal tissue from patients with GS.[37]

Hypomagnesemia, another hallmark which distinguishes GS from BS, has a controversial origin. Magnesium is freely filtered by the glomerulus, and it is reabsorbed in a small fraction along the PT. The majority of Mg^{2+} is reabsorbed along the TAL, via paracellular pathway, and DT, via transcellular pathway. In the latter, Mg^{2+} reabsorption is mediated by the transient receptor potential cation channel, TRPM6. In NCC knockout mice a downregulation of TRPM6 in DT has been shown.[36] This effect could explain the defective Mg^{2+} absorption, and the subsequent hypomagnesemia.

The clinical phenotype in CLCNKB mutations is extremely variable; several reports have described subjects with phenotypic features of GS without any defect in SLC12A3 gene, carrying homozygous mutations of CLCNKB gene[38] or mixed BS-GS phenotype.[39]

Clinical Presentation

GS is characterized by an extreme inter- and intrafamilial phenotype variability, varying from mild or undiagnosed forms to severe conditions complicated by growth retardation, ventricular arrhythmias, and neuromuscular symptoms. In most cases the diagnosis occurs in adulthood. The patients suffer from tetany, especially during conditions which determine further Mg^{2+} loss, like vomiting or diarrhea. Some patients experience fatigue which compromises daily activities, in relation to the degree of hypokalemia. In contrast with BS, those patients do not manifest polyuria and growth retardation. Chronic K^+ and Mg^{2+} deficiency may predispose to a higher risk for ventricular

arrhythmias. However, lethal arrhythmias have been reported rarely in GS patients, and may be related to underlying triggering mechanisms besides hypokalemia. Riviera et al. have described a subgroup of GS patients with severe phenotype, characterized by early onset, and severe neuromuscular and cardiac symptoms.[40] Almost all patients of the subgroup were male, and showed a higher incidence of splicing mutation leading to a truncated transcript compared with mild and classic GS. This study suggests that male gender and splicing mutations, resulting in a severe protein dysfunction, may account for the clinical severity of GS. Biochemical analysis shows hypocalciuria, hypokalemia, and hypomagnesemia. Although hypocalciuria and hypomagnesemia have been considered necessary for the diagnosis of GS, recently a report of a GS patient with a proven mutation in the GS gene did not manifest those signs. Plasma renin and aldosterone levels are only slightly increased compared with BS.

Liddle Syndrome

Liddle syndrome (LS) is an autosomal dominant disease leading to hypertension. Besides the early onset of hypertension, it is characterized by hypokalemic metabolic alkalosis, with downregulation of RAAS. In the last 10 years the Lifton group has identified several mutations mapping in β- and γ-ENaC subunits, resulting in the expression of a higher number of channels in the plasma membrane.

Genetic and Molecular Biology

ENaC is comprised of three subunits, α, β, and γ, which are assembled at stoichiometry α2βγ. Several studies have suggested that also αβ and αγ are functional channels. The first description of Liddle syndrome (LS) in literature was correlated with the mutation in the gene encoding the β-ENaC subunit, resulting in a premature stop codon which leads to the loss of the last amino acids of the C-terminus.[41] Genetic screening of subjects suffering from LS has showed that the syndrome also segregates with mutations of the gene encoding for the γ-subunit. The expression of either truncated γ- or β-ENaC subunit increases amiloride-sensitive Na^+ uptake in oocytes.[42] These findings suggest that the C-terminus of β- and γ-subunits is a crucial region for the activity of the channel. Different investigations have found that most mutations resulting in LS phenotype are mapped on a highly-conserved PPPXY sequence (PPY motif) of the C-terminus in β and γ; disruption of the motif preserves the channel from inhibitory stimuli.

Pathophysiology

The amiloride-sensitive ENaC is an ion channel which mediates Na^+ absorption along the distal segment of CNT and CD. ENaC channels are positively regulated by aldosterone and vasopressin. In mice, aldosterone has been shown to activate ENaC via the ser/thr kinase Sgk1. This kinase induces ENaC activation partly through the inhibition of ENaC downregulation by the E3 ubiquitine ligase, Nedd4-2, which targets ENaC to degradation in cultured cells.[43] Sgk1 phosphorylates Nedd4-2 to an inhibitory site, thus preventing ENaC removal from the plasma membrane.[44] Mutations in β- and γ-subunits of ENaC in LS result in a constitutive activation of ENaC activity.[45] These mutations impair the PY motif in the C-terminus, which is required for Nedd4-2-mediated ENaC ubiquitination. In the absence of the binding site, Nedd4-2 fails to target the channel for degradation. However, these mutations increase the overall ENaC expression at the apical membrane, contributing to increased Na^+ absorption. The resulting volume-expansion explains the suppression of RAAS. Interestingly, mice bearing a LS deletion revealed normal aldosterone response.[46] Consistently, in cultured cell, aldosterone, vasopressin, and Sgk1 are still able to increase ENaC surface abundance in the presence of LS causative mutations,[47] suggesting that Nedd4-2 is not necessary for aldosterone-dependent increased ENaC activity. However, in LS patients, constitutive increased ENaC activity leads to volume-expansion, high blood pressure, and suppressed RAAS.[48] As a consequence of increased channel activity along the CD, patients do manifest hypokalemia and metabolic alkalosis. Mice bearing LS become hypertensive only when fed a high-salt diet.[49]

Clinical Presentation

LS was first described in 1963 as a condition resembling hyperaldosteronism, because of the coexistence of hypertension, hypokalemia, and metabolic alkalosis. However, due to the low/normal levels of plasma aldosterone this condition is described as pseudohyperaldosteronism of the second type. Hypertension usually develops at an early age in affected individuals, and worsens throughout the lifetime. Recently, Tapolyia *et al*. have proposed the presence of serum bicarbonate over 25 mmol/L, K^+ levels lower than 4 mEq/L, plasma renin activity lower than 0.35 μU/ml/h, and plasma aldosterone levels lower than 15 ng/dl as screening criteria for LS. Based on these criteria, this group found a prevalence of 6.7% patients that satisfied the criteria for likely LS in a cross-sectional investigation of 149 hypertensive patients with hypokalemia and metabolic alkalosis.[50] Hypertension is usually refractory to common antihypertensive drugs, while it is responsive to the use of the ENaC inhibitor, amiloride.

RENAL CHANGES IN K^+ DEFICIENCY

Morphology

Experimental Studies

Hypokalemic states are associated with several renal morphological alterations. The severity and exposure time to hypokalemia are fundamental to the development of renal injuries. Mild hypokalemia ranging among 3.6±0.2 is not associated with significant glomerular or tubular abnormalities in Sprague-Dawley rats.[51] Renal hypertrophy is a universal finding in studies of K^+-depletion (KD) since the early report by Schraeder et al. in 1937. This renal growth has distinct morphologic characteristics. The increase in kidney mass is not uniform, being more prominent in the outer medulla, as reflected in the relative contribution of the different zones to total kidney weight in K^+ deficient rats.[52]

The growth process consists of both hyperplasic and hypertrophic components. Despite the fact that hypokalemic mice present a different metabolic behavior (metabolic acidosis), they develop morphological abnormalities of CD similar to rats and humans. K^+ deficient mice show morphological alterations in outer medulla CD (OMCD) after three days of a low-K^+ diet. CD epithelial cells from K^+ deficient mice have a higher proliferation rate than control mice. Intercalated cells show PCNA positive staining (proliferation marker) more than principal cells. No signs of cellular hypertrophy are detected at this time point in CD epithelial cells, despite IC already display an enlargement of the apical membrane domain. After 14 days of a low-K^+ diet both principal and IC cells appear hypertrophic as evaluated at EM level. In hypokalemia-induced morphologic alteration of OMCD, hyperplasia precedes the development of cellular hypertrophy. Transcriptome analysis of OMCD suggests Gdf15 (growth differentiation factor 15) increases significantly from day 3 to day 14 of the low-K^+ diet. It could be a potential candidate in driving the switch from hyperplasia to hypertrophy. Gdf15 belongs to the TGFβ superfamily, and it could be a growth-stop signal in OMCD.[53]

The growth-promoting effect of K^+ deficiency is not limited by the state of the organ. It occurs in intact, as well as in previously damaged, kidneys. Peterson *et al*.[54] have shown that institution of K^+ deficiency in a model of remnant kidney (5/6 nephrectomy) led to an increase in renal mass and RNA content beyond that expected of the surgical ablation alone.

CD is the main nephron site where morphologic alterations occur in K^+ deficiency. Glomerular and vascular lesions have rarely been observed in pure K^+ deficiency, and changes in proximal convoluted tubules have been limited to vacuolar degeneration. While several studies demonstrate the occurrence of morphologic changes in individual CD cells, conflicting statements have been made regarding the proportion of cell types and number. Hansen *et al*.[55] observed extensive swelling of the epithelium of the CD involving both principal and intercalated cells along the OMCD (Figure 50.2). No changes were observed in either principal or intercalated cells of the initial CD.[56] Intercalated cells in the MCD segment develop extensive microplicae over the entire luminal surface with increased luminal surface boundary length,[55] whereas no change was observed in basolateral membrane length or in the luminal or basolateral aspects of principal cells[57] (Figure 50.3). This increased luminal surface could be due to the fusion of the cytoplasmic vesicles with the apical membrane domain. A large number of rod-shaped structures are opened in the lumen in this way. This event is thought to be useful for H^+ secretion and K^+ reabsorption through H^+-ATPase or H^+-K^+-ATPase activity, respectively. There are conflicting findings about the proportion of intercalated and principal cells in any part of the CD in K^+ deficiency. Evidences indicate the development of morphologic changes in individual cells as well as an increase in cell number.

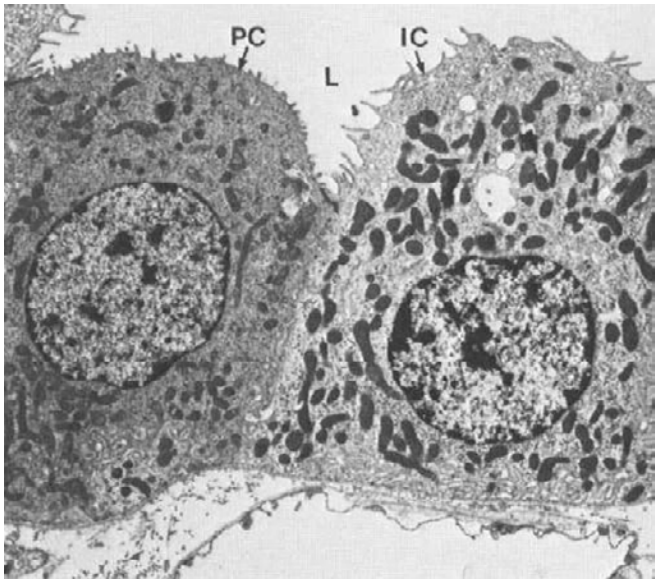

FIGURE 50.3 **Electron microscopy of rat medullary collecting duct, showing a representative picture of hypokalemia-induced morphological changes in both principal and intercalated cells.** *(With permission from Stetson, D. L. et al. [57])*

Recently, progressive capillary loss has been identified in hypokalemic nephropathy. This injury was first observed in the ISOM after 2 weeks of a K-restriction diet, expanded to the OSOM at 4 weeks, and then to the cortex by week 12. Capillary loss significantly correlated with local macrophage infiltration and low endothelial cell proliferation rate, an effect probably secondary to a decrease of VEGF and eNOS expression.[58]

The most remarkable ultrastructural change is the accumulation of cytoplasmic droplets in tubular cells of the medulla. The appearance of droplets starts from the CD at the tip of the papilla, and then extends upward into the outer medulla until the corticomedullary junction. The extension depends on the duration of K^+ deficiency. Besides epithelial cells, interstitial and other cells in the medulla also show cytoplasmic droplets, with considerable enlargement of cell volume. With K^+ repletion, the droplets reversed progressively.[59] The droplets are believed to be the consequence of phospholipids dysregulation,[60] and their lysosomal origin is suggested by the presence of hydrolytic enzymes. It has been suggested that increased ammonia production secondary to hypokalemia may contribute to vacuolation of nucleated cells in KD.[61] In fact, ammonia has been shown to induce vacuolization of lysosomes, inhibition of endocytosis, and lysosomial protein degradation. Another hypothesis is that the cytoplasmic droplets could be related to a cellular autophagy phenomenon. Lipid droplets share common protein with the autophagosome in hepatocytes and cardiac myocytes,[62] and those organelles may be an expression of autophagy. Ureteral ligation in K^+ deficient rats is followed by resolution of droplets, presumably because of increased renal medullary K^+ content.[63] The severity of droplet formation depends on the method of induction of K^+ deficiency, with minimal droplet formation developing with DOCA-induced compared with dietary deficiency.[64]

Tubular and interstitial apoptosis is observed during K^+ deficiency. Apoptotic cells are located mainly in the outer medulla. Bcl-2 protein distributed in the tubules of the outer medulla is significantly decreased in KD rats, while immunoreactivity for Bax protein tends to increase above control levels. These results suggest that apoptosis is associated with progression of cellular proliferation in hypokalemic nephropathy, and a decrease in bcl2 may be involved in promoting this apoptotic process.[65]

Human Studies

Unlike experimental studies where K^+ deficiency can be induced selectively, clinical observations are frequently based on complex conditions where K^+ deficiency is complicated by numerous other alterations, including Na^+ and acid–base homeostasis. The issue is even more complex if we consider additional factors like duration of disease, and therapeutic interventions that may substantially alter histopathologic manifestations in humans. Finally, clinical data are usually limited to cortical biopsies, and sampling of medullary and papillary structures may be lacking. An important observation comes from autopsy studies in healthy Thai adults who died of vehicular accidents. K^+ deficiency prevails among the healthy population of northeast Thailand. In this study, none of the patients had renal histopathological change compatible with a diagnosis of focal or diffuse interstitial nephritis, and there were minimal renal tubulo-interstitial changes.[66]

Glomerular changes consisted mostly of a reduction in capillary surface and Bowman capsule areas, and an increase in the mesangial space. The glomerular shrinkage was not associated with any alterations in cellular constitution of the tuft.[67] Of note is the increase in juxtaglomerular complex size in many of the patients to levels comparable to, or even exceeding, those observed in BS. Such findings underscore the non-specificity of this change, which is likely secondary to defective Cl^- absorption in the thick ascending limb, rather than a characteristic feature of BS. Tubular vacuolization was not a frequent or pathognomic observation, although it was considered characteristic by Conn and Johnson, who coined the term kaliopenic nephropathy in 1956. More important for the prognosis of these patients is the occurrence of degenerative changes such as tubular atrophy, dilatation, epithelial

flattening, and thickening of the basement membrane.[68] Again, these alterations are non-specific, and reflect evidence of chronic injury. Increased interstitial surface area and lymphocytic cellular infiltration were frequent. PAS-positive granules have been observed in some of these patients in all medullary cells when available in the specimen.

Taken together, these observations suggest that many of the renal changes seen in K^+ deficient animals have their counterparts in clinical cases. Some of these changes (glomerular shrinkage, tubular atrophy, interstitial fibrosis) indicate irreversible renal damage, and the occurrence of renal insufficiency in this group of patients has been convincingly demonstrated.[69] Indeed, in some young women the condition has led to end-stage renal disease.[70] Elements of the kaliopenic nephropathy mixed to morphological changes secondary to hypertension are also found in patients with primary aldosteronism. The apparently additive insults of hypertension and K^+ deficiency are illustrated in the study of 18 patients with primary aldosteronism by Danforth *et al*.[71] Moderate to severe hypertensive changes (fibrous thickening of small vessels and glomerular hyalinization) and kaliopenic lesions (vacuolization and degeneration of tubular epithelia) were observed in 14 (78%) and 16 (89%) patients, respectively. The hypertensive changes appeared to be more severe in this group than in subjects with primary hypertension of similar severity, suggesting a possible synergistic effect of K^+ deficiency.

Tubular Function

A heterogeneous pattern of structural and functional changes occurs along the nephron, with a progressive increase from proximal to distal segments.

Proximal Convoluted Tubule

SODIUM CHLORIDE

Transport along the proximal tubule has been extensively studied in both acute and chronic K^+ deficiency models with micropuncture and isolated tubule techniques. An acute change in K^+ concentration in the perfusion bath below 2.5 mM inhibits NaCl transport in isolated and perfused PT from rabbit.[72] Decrements in NaCl reabsorption, as evidenced by decreased net fluid absorption in this segment, have also been observed during capillary microperfusion with hypokalemic solutions in rats.[73] Studies in K^+ deficient animals show a different pattern of alterations in transport. Walter *et al*.[74] performed micropuncture studies on anesthetized rats which had been kept on a K deficient diet for 2 weeks. In these animals total glomerular filtration rate (GFR) and single-nephron filtration rate were significantly lower than controls. Fractional reabsorption by the proximal convoluted tubule was enhanced, and end proximal fluid delivery was markedly reduced. These observations are in line with other studies showing reduced fractional excretion of lithium in K^+ deficiency,[75] presumably a surrogate measurement for enhanced proximal Na^+ reabsorption.

Chronic K^+ deficiency, but not an acute luminal exposure, leads to increased NaCl reabsorption. K^+ deficiency increased the expression of both the adrenergic receptor $alfa_{2B}$,[76] and AT1 (angiotensin II receptors)[77] in rat PT. These changes are coupled with an increase in renin and angiotensin II level, as demonstrated in many species. The higher Na^+ reabsorption could be in part transcellular, mainly driven by several Na^+ transporters upregulated in hypokalemia (*vide infra*).

Hypokalemic rats have an increased expression of Na-H exchanger 3 (NHE3) in membrane fractions of renal cortex and outer stripe of the outer medulla (OSOM). Immunohistochemistry confirms that NHE3 labeling is increased in the luminal membrane domain of the PT of hypokalemic rats.[78] However, Wang *et al*.[79] found no change in the expression of NHE3 mRNA and its cognate protein after 6 and 14 days in rats on a low-K^+ diet. The mRNA levels for NHE1, NHE2, and NHE4 also remained unchanged at 6 and 14 days of the low-K^+ diet. These apparent inconsistencies between protein expression and mRNA levels could be due to a posttranslational level of regulation of NHE3, as recently found in hypertensive models.[80] In parallel with Na^+ reabsorption, NHE3 promotes proton extrusion. This mechanism is functional for net bicarbonate reabsorption through the PT.

BICARBONATE

Chronic K^+ deficiency is associated with metabolic alkalosis and an increase in bicarbonate reabsorption, as demonstrated by free-flow micropuncture and microperfusion studies in rats.[81] In contrast, acute exposure of proximal tubules to ow (K^+ 2 mM) in capillary microperfusion experiments had no effect on bicarbonate reabsorption.[73] The mechanism of enhanced bicarbonate reabsorption is mediated by stimulation of NHE3 and the basolateral $Na/3HCO_3$-co-transporter.[75] In OKP cells, low-K medium causes a decrease in intracellular pH, which leads to increased NHE3 activity.[82] Accordingly, NHE3 total protein abundance and immunostaining along the apical membrane of PT and TAL were dramatically increased in hypokalemic rats.

The bicarbonate basolateral exit pathway from the PT cells is mediated by the sodium bicarbonate

co-transporter (NBC1). During K^+ deficiency states both the activity and mRNA expression of NBC1 are increased.[83] It is not clear if the upregulation of NBC1 causes the lowering intracellular pH or whether it is a consequence of the higher bicarbonate reabsorption.

Angiotensin II could promote bicarbonate reabsorption in the PT. In fact, angiotensin II is found to increase NBC1 expression in rat PT, while it is debated whether it also regulates NHE3 function.[84]

AMMONIUM

Metabolic alkalosis developing during K^+ deficiency is also sustained by increased bicarbonate generation from the ammoniagenesis pathway in the PT. Chronic hypokalemia is associated with increased ammonium excretion in humans as well.[85] K^+ deficiency leads to a three-fold increase in ammonia production in the S1, and to a two-fold increase in S2 segments of PT.[86] No changes in ammonia production were observed in the S3 segment (pars recta) or in the thick ascending limb or distal convoluted tubule. The increased ammonia production in S1 occurred in both superficial and juxtamedullary nephrons, with a greater extent in the former. The primary mechanism by which K^+ deficiency stimulates renal ammonia production is not precisely known. Increased renal ammonia production and excretion, despite the simultaneous presence of metabolic alkalosis, suggest that intracellular factors, rather than extracellular pH, modulate renal ammonia metabolism. Intracellular acidosis that occurs in K^+ deficiency may initiate the adaptive response in ammoniagenesis. Both mitochondrial (glutamine transaminase activity) and cytosolic (phosphoenolypyruvate carboxykinase, PEPCK) enzymes involved in glutamine catabolism and gluconeogenesis are increased in the hypokalemic state.[87] This pathway induces a net gain of new bicarbonate production. K^+ repletion leads to prompt decreases in ammonia production.[88] Although mice present a species-different acid–base adaptation to hypokalemia, namely metabolic acidosis, they share a high urinary ammonium excretion with rats. Hypokalemic mice show an increase of glutamine transporter SNAT3. SNAT3, normally located in the S3 segment of the PT, spreads to S1 and S2 segments during K^+ deficiency, supporting the increase ammoniagenesis in the PT[89] (Figure 50.4).

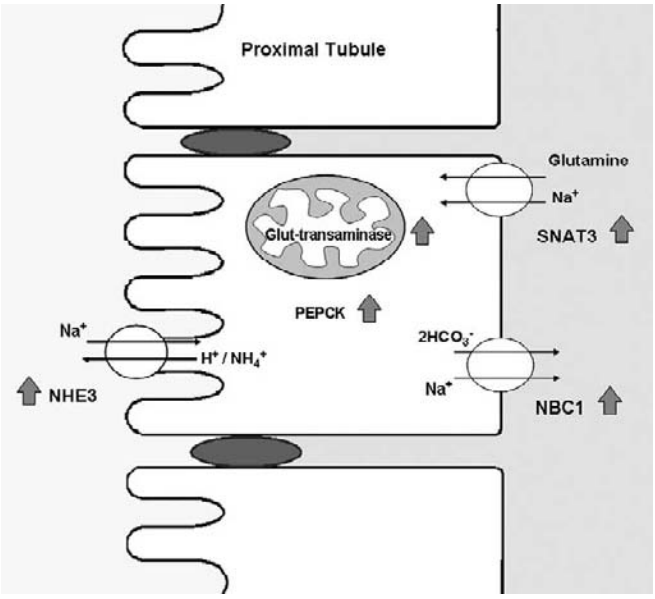

FIGURE 50.4 **Hypokalemia increases ammoniagenesis in proximal tubule cells.** Hypokalemia-induced ammoniagenesis is proved by an increased expression of PEPCK and glutamine transaminase.[87] Therefore, hypokalemic mice present an upregulation of SNAT-3, the sodium-coupled glutamine importer along the whole proximal tubule.[89] These effects are coupled to upregulation of NHE3[78] and NBC-1[145] transporters involved in proximal tubule bicarbonate reabsorption.

PHOSPHATE

Chronic K^+ deficiency is associated with low serum phosphate (Pi) and an increase urinary Pi excretion in rats and mice. Key regulators of renal Pi excretion are the Na dependent co-transporter NaPi IIa and NaPi IIc, expressed almost exclusively in the kidney. Another group of Pi transporters, Pit-1 and Pit-2, have been described.[90] In hypokalemia, a phosphaturic phenotype is associated with a differential regulation of the different NaPi transporters. NaPi IIa protein abundance in brush border membranes (BBM) and protein targeting to the apical membrane are increased, while NaPi IIc and PiT2 are decreased in animals fed with a low-K diet. In addition, NaPi IIc relocates from the apical membrane domain to cytoplasmic vesicles.[91] The downregulation of NaPi IIc seems to sustain the hypokalemia-induced urinary phosphate loss.

OTHER PROXIMAL TUBULE DYSFUNCTION

Chronic K^+ deficiency causes hypocitraturia. Urinary citrate excretion is mainly a function of citrate absorption along the proximal tubule, a process mediated by the Na-dicarboxilate co-transporter NaDC1, and citrate metabolism. Levi *et al.*[92] have shown an increased NaDC1 activity on renal cortical BBM from K^+ deficient rats. Hypokalemia may also participate in proximal tubular dysfunctions observed in children with primary distal renal tubular acidosis. Indeed, in these patients, correction of hypokalemia ameliorates low molecular weight proteinuria, phosphaturia, and generalized aminoaciduria.

Loop of Henle

SODIUM CHLORIDE

Eknoyan *et al*.[93] were the first to suggest that a defect in Na^+ transport by the thick ascending limb (TAL) could explain the concentrating defect of K^+ deficiency. Micropuncture and microperfusion studies showed diminished net Cl^- reabsorption between the latest proximal and earliest distal segment, as well as increased luminal Cl^- concentration at the latter site. These findings were consistent with impaired TAL absorption, and the defect was only partially corrected with indomethacin. Gutsche *et al*.,[94] using the micro stop-flow technique, have provided evidence for defective Na^+ transport in the TAL of K^+ deficient rats. The severity of the defect correlated with the decrease in plasma K^+ concentration, and was rapidly reversed with acute K^+ administration. In addition, net NaCl transport is inhibited by reduction in bath K^+ concentration in isolated perfused TAL.[95]

A more recent study has uncovered the molecular basis of the observed defects in electrolyte reabsorption in the TAL. In rats, NKCC2 mRNA expression in medulla is decreased about 56 and 51% after 6 and 14 days of K^+ restriction diet respectively. Functional studies in tubular suspensions of medullary TAL from K^+ deficient rats demonstrated a 45 and 37% decreased NKCC2 activity at 6 and 14 days, respectively. NKCC2 protein abundance of membrane fraction from renal ISOM is downregulated in rats fed for 4 days on a K^+ restricted diet. Immunohistochemical localization confirms a lower expression of NKCC2 in mTAL.[78] Na/K-ATPase plays a key role in the Na^+-dependent transport in this nephron segment. Despite the increase in the number of Na/K-ATPase units, the transport capacity of the Na/K pump, determined by ouabain-sensitive Rb uptake, was reduced in mTAL from K^+ deficient rats. Inhibition of the Na/K pump was the consequence of a reduced affinity for Na.[96]

BICARBONATE AND AMMONIUM

Basolateral and apical Na-H exchangers (NHEs) in TAL are involved in NH_4^+ and HCO_3^- absorption, respectively. The NH_4^+ absorption rate in Henle's loop is increased in K^+ deficiency, which may be secondary to the increased NH_4^+ concentration in luminal fluid and/or to an increased NH_4^+ absorptive capacity of TAL. HCO_3^- absorptive capacity in Henle's loop is unchanged in K^+ deficiency, despite the presence of metabolic alkalosis. The effects of K^+ deficiency on the expression of basolateral NHE-1 and the expression of apical NHE3 in TAL have been examined by Laghmani *et al*.[97] NHE1 protein abundance was similarly increased (approximately 90%) at 2 and 5 weeks of K^+ deficiency, while NHE1 mRNA amount in TAL cells was increased at 2 weeks, and returned to normal values by 5 weeks. NHE3 protein abundance and mRNA remained unchanged after 2 weeks of K^+ deficiency. NHE3 mRNA was reduced by approximately 50% at 5 weeks. In K^+ deficiency, the increased NHE1 expression may support an increased TAL NH_4^+ absorptive capacity. The lack of change in NHE3 expression, despite the presence of metabolic alkalosis, is in agreement with the unchanged HCO_3^- absorptive capacity of Henle's loop. Recently, an electro-neutral, Na-dependent HCO_3^--co-transporter (NBCn1) has been cloned and localized at the basolateral side of the mTAL. Several results show NBCn1 is fundamental for NH_4^+ reabsorption in the TAL. NH_4^+ entering the mTAL cell via the furosemide-sensitive NKCC2 transporter dissociates into H^+ and NH_3. The NH_3 leaves the cell via non-ionic diffusion preferentially through the basolateral membrane. The remaining proton may either be transported directly via a basolateral NHE1 and/or could be buffered by basolateral import of HCO_3^- through NBCn1. During hypokalemia, NBCn1 protein abundance is strongly upregulated in ISOM. In addition, *in vitro* perfusion of isolated mTAL shows hypokalaemia induced a three-fold upregulation of Na-coupled HCO_3^- influx[98] (Figure 50.5).

Distal Tubule

SODIUM CHLORIDE

Along the DT downregulation of the main Na^+ transporter has been reported. Rats fed a low-K^+ diet for 4 days present a downregulation of sodium chloride co-transporter (NCC) in the membrane fraction of cortex and OSOM. Immunoistochemistry confirms the reduced expression of NCC in the convolute distal tubule cells.[78]

BICARBONATE

In DT, the rate of bicarbonate absorption is not altered in K^+ deficiency, despite a lower delivery rate and the presence of a greater lumen-to-plasma bicarbonate concentration difference due to the higher plasma and lower luminal levels.[99] Micropuncture experiments have demonstrated that bicarbonate reabsorption along the distal tubule of K^+ deficient rats was increased when delivery rates of bicarbonate reached levels similar to those in controls. In the DT, bicarbonate reabsorption is relatively insensitive to peritubular alkalinization, and the systemic alkalosis does not affect acid secretion.[100] The mechanism, therefore, is not self-limiting, and no "braking" of the enhanced bicarbonate reabsorption occurs. This is due to enhanced electrogenic proton secretion (H^+-ATPase) as demonstrated by *in vivo* microperfusion of the superficial distal tubule in K^+ deficient animals.[101]

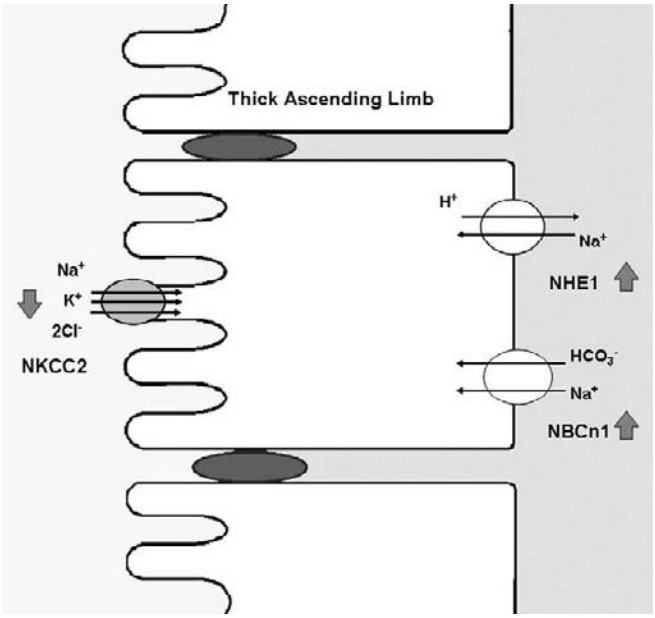

FIGURE 50.5 **Hypokalemia impairs sodium chloride absorption in the TAL, mainly inhibiting both the activity and expression of the NKCC2.**[78] The reduction of sodium chloride absorption in the TAL contributes to the urinary concentrating defect. Ammonium absorption is increased along the TAL, sustained by the upregulation of basolateral NHE1[97] and NBCn1.[98]

POTASSIUM

K^+ secretion in the segments of the distal nephron accessible to micropuncture (the early distal convoluted tubule, the connecting tubule, and the initial collecting tubule), is reduced to near zero in K^+ deficiency.[56]

Collecting Duct

This segment is the site of major structural changes in K^+ deficiency, and the alterations in its transport functions are primarily responsible for metabolic alkalosis and defective urinary concentrating ability.

SODIUM

Along the connecting tubule, as well as the cortical, outer, and inner medullary CD, Na^+ uptake occurs through the luminal amiloride-sensitive epithelial Na^+ channel (ENaC), and it is driven by the electrogenic potential induced by the basolateral Na/K-ATPase. During hypokalemic states, all ENaC subunits (α, β and γ) are downregulated in renal samples from cortex-OSOM, and in whole kidneys as well. This has been ascribed to the hypokalemia-induced inhibition of aldosterone secretion.[78] Despite this finding, K^+ deficiency produces a striking, time-dependent increase in Na/K-ATPase activity, mainly in the CD in ISOM. After 3 weeks of a K-free diet, Na/K-ATPase activity was over four-fold higher than control animals.[102] The increased protein activity was larger than the extent of tubular volume or protein content, indicating that it is not merely a reflection of the concomitant hypertrophy observed in this region of the nephron. Na/K-ATPase activity returned to baseline after 7 days of K^+ repletion.[102] In association with the increased activity, it has been described that two weeks of K^+ deficiency induced a marked increase in the α1- and β1-subunits of Na/K-ATPase in medullary, but not in the cortical portion of the CD.[103] These observations are interesting, because enhanced activity of Na/K-ATPase would likely promote K^+ secretion and urinary loss, thus exacerbating the hypokalemia. Because the ISOM segment of the CD plays an important role in K^+ homeostasis, the upregulation of the Na/K-ATPase has been associated with a potential kaliferic function. To reconcile these observations, Hayashi and Katz[102] proposed that the induced Na^+ pumps were localized to the luminal domain, thus facilitating active K^+ reabsorption instead of secretion. Further evidence is needed to support this hypothesis. During a hypokalemic state, in the medullary interstitium a lower K^+ and an increased NH_4^+ concentration develop (see below). NH_4^+ and K^+ compete for the same transport site of the Na/K-ATPase. Upregulation of the Na/K-ATPase in the IMCD promotes ammonium uptake, primarily from the reduced interstitial K^+ concentration.[104] This phenomenon could be another explanation for the paradox of the Na/K-ATPase upregulation.

Proton Secretion

The development of metabolic alkalosis in sustained by the increased bicarbonate absorption and generation along the PT, as well as the enhanced proton secretion along the CD. Physiologically, the proteins responsible for proton secretion are mainly the H-ATPase and H/K-ATPase.

The effects of K^+ deficiency on the activity and distribution of the H-ATPase in the Sprague-Dawley rat were assessed by Bailey *et al.*[101] K^+ deficiency increased electrogenic H-ATPase activity in rat distal tubule, with an increased insertion of pumps into the apical membrane.[105] These findings were confirmed and expanded by Silver *et al.*[106] The rate of pH(i) recovery in intercalated cells (ICs) in response to an acute acid-load (a measure of plasma membrane H-ATPase activity) was three times larger after K^+ deficiency as compared to controls. This was associated with a change in the distribution of membrane-bound proton pumps in the IC population of cortical CD from K^+ deficient rats. Immunocytochemical analysis of rats CDs showed that K^+ deficiency increased the number of ICs with tight apical H-ATPase staining, and

decreased the number of cells with diffuse basolateral H-ATPase staining. Taken together, these data indicate that chronic K^+ deficiency induces a marked increase in plasma membrane H-ATPase activity in individual ICs.

The ability of A-ICs to secrete protons into the lumen is strictly coupled to bicarbonate extrusion on the basolateral side, and it is blocked when an impairment of bicarbonate extrusion occurs. The latter is mainly mediated by the anion exchanger-1 (AE-1) and other members of this family. During K^+ deficiency, protein abundance of AE-1 increases in cortex and OSOM, and this is coupled with a strong upregulation of another anion exchanger, SLC26A7.[107] In MDCK cells, SLC26A7 was found to translocate from the endosomal compartment to the basolateral membrane in response to a low-K^+ media.[108]

H/K-ATPase promotes luminal acidification and K^+ reabsorption. Two isoforms, H/Kα1 (gastric) and H/Kα2 (colonic), are expressed along the entire length of the CD from the early connecting tubule to the inner medullary CD. This localization is consistent among species. In rat CD, H/K-ATPase is expressed mainly in intercalated cells.[109] Chronic K^+ deficiency (3 weeks) led to a generalized increase in H/K-ATPases activity along the CD segments, with the greater increments occurring in CNT > CCD > MCD. This is in contrast to the morphologic changes that occur in the CD in K^+ deficiency, which display a hypertrophic response with the hierarchy: MCD > CCD > CNT.[102] Studies from single H/Kα1 and H/Kα2 knockout mice show an impairment in acid secretion during normal diet, confirming the crucial role of this transporter in renal acid–base balance. Data from H/Kα2 null mice demonstrated increased fecal K^+ loss, without significant differences in K^+ urinary excretion. A compensatory activation of the H/Kα1 subunits might be responsible for K^+ secretion in the absence of functional H/Kα2-subunits. Investigation of double H/Kα1 and H/Kα1,2-null mice on a K^+ deficient diet will provide insight into the functional importance of H/K-ATPases in K^+ deficient conditions.[109]

Pendrin belongs to a superfamily of Cl/anion exchangers, and has been localized in the apical side of non-type-A IC of the cortical CD. Reduced bicarbonate secretion was demonstrated in a pendrin knockout mouse model. In chronic K^+ deficiency, known to elicit a metabolic alkalosis, pendrin protein levels are decreased and pendrin expression is shifted to an intracellular pool with the relative number of pendrin positive cells reduced. These results are in agreement with a potential role of pendrin in bicarbonate secretion and regulation of acid–base transport in the cortical CD.[110] These adaptations occurring during K^+ deficiency are similar to those observed in chronic metabolic acidosis. Considering that metabolic alkalosis suppresses distal acidification, the stimulation by K^+ deficiency overcomes the effect of the alkalemic state. K^+ deficiency thus exerts a primary, aldosterone and Na^+-independent, stimulatory effect on hydrogen ion secretion in the CD, most likely at the level of the putative proton pump (Figure 50.6).

POTASSIUM

K^+ deficiency results in a decrease in urinary K^+ excretion of variable magnitude, depending on the species. In all species, however, the decline in K^+ excretion does not match the reduced intake, and a persistently negative K^+ balance is observed. In humans, short-term dietary K^+ deprivation (intake of less than 1 mEq/day) induces a decline in urinary K^+ excretion which is still higher than intake, with a gradual adaptation reaching a maximum within 5 to 7 days. In rats fed a low-K diet, urinary K^+ excretion falls promptly and parallels intake by 72 to 96 hours after the institution of a K^+ deficient diet.[111] The conservation of K^+ can be conceived as being due to attenuation of kaliuretic mechanisms, in part by resistance to normally kaliuretic influences, and in part by activation of kaliferic ones. Both phenomena have to be examined in the context of renal and systemic adaptations to K^+ deficiency, with differences in short-term and

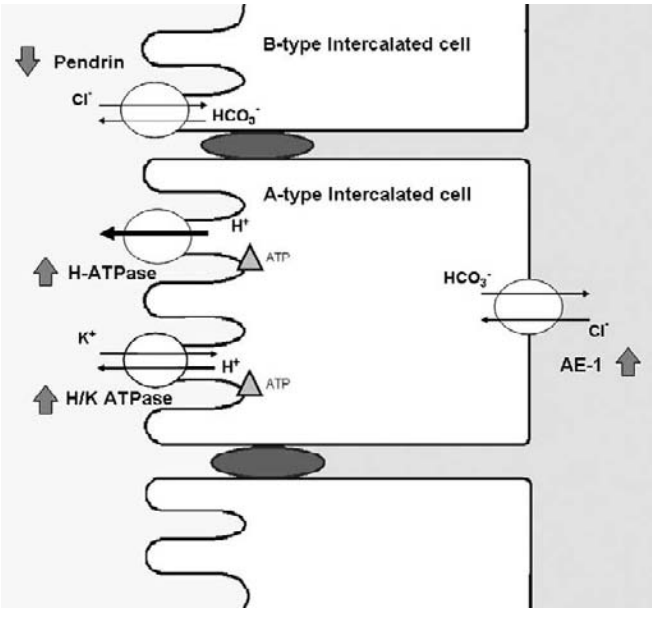

FIGURE 50.6 **Hypokalemia led to a metabolic alkalosis in rats and humans.** In addition to a proximal tubule effect, an increased acid secretion has been described in type-A-intercalated cells. Both H^+-ATPase[106] and H^+/K^+-ATPase[146] showed increased expression, along with an upregulation of AE-1.[107] B-type-intercalated cells showed a reduced expression of the bicarbonate secreting transporter, pendrin.[110] This latter finding supports K^+ depletion also impairing urinary bicarbonate secretion.

long-term K^+ deficiency. K^+ secretion in the CCD is markedly attenuated, but may not cease even with profound degrees of K^+ deficiency.[112] The reduced level of K^+ secretion is coupled with a decreased response to kaliuretic factors. Malnic *et al*.[112] have shown that K^+ deficient rats maintain their ability to increase K^+ secretion in response to increments in tubular flow, albeit at a much lower level. Finally, K^+ deficient humans are resistant to the kaliuretic influence of high urine flux, osmotic diuresis, and metabolic alkalosis. It has been suggested that an "escape" from kaliuretic influences may occur in K^+ deficient conditions, a concept which resembles the escape from the Na^+-retaining effects of chronic mineralocorticoid administration. Thus, no kaliuretic response is observed in rats when DOCA is administered 72 hours after initiation of K^+ deficiency.[111] In contrast, resistance to the kaliuretic effects of mineralocorticoids does not appear in short-term (7–10 days) K^+ deficient humans, in whom administration of DOCA is associated with a kaliuresis, despite the presence of hypokalemia and a large negative K^+ balance.

K restriction suppresses renal K^+ secretion and enhances its absorption.[113] This is achieved by both inhibiting apical K^+ channels in principal cells and stimulating K^+ absorption in intercalated cells. In CCD a molecular mechanism has been proposed to explain the inhibition of ROMK channels during severe and moderate hypokalemia. Low-K^+ intake increases renal superoxide anion generation, which stimulates PTK (protein tyrosine kinase) activity and MAPK (mitogen-activated protein kinase) phosphorylation. PTK inhibits ROMK activity through a tyrosine-mediated phosphorylation. MAPK can inhibit the activity of the ROMK-like SK and BK channels. Moreover, MAPK and PTK may have a positive feedback on each other. Since activation of PTK and MAPK inhibits the apical K-secretory channels, renal K^+secretion is suppressed during K^+ restriction states[114] (Figure 50.7).

The decline in aldosterone levels and the increase of angiotensin II that accompany K^+ deficiency contribute to renal K^+ conservation. It has been proven that angiotensin II has an inhibitory effect on ROMK channels and, on the other hand, antagonists of the AT-1 receptor abolish the renal ability of K^+ conservation during K-restricted diet by preventing the tyrosine phosphorylation of the ROMK channels.[115] In K^+ deficiency states, the ratio of long versus kidney-specific Wnk1 isoforms represents a novel K-saving mechanism along the aldosterone-sensitive segments of the nephron (*vide infra*).

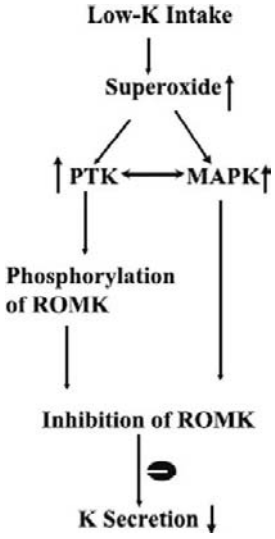

FIGURE 50.7 **Cascade of events leading to the K^+-sparing effect in the CD during K^+ depletion states.** Low extracellular K^+ stimulates an inactivating phosphorylation of ROMK channels through PTK and MAPK kinases.[114]

UREA

The concentrating defect of K^+ deficiency occurs in association with a reduced osmolality of the medullary interstitium. Urea uptake in the kidney is mediated by a family of transporter proteins that include the renal urea transporter UT-A, and the erythrocyte urea transporter UT-B. UT-A1 and UT-A3 are localized in the distal part of the IMCD, and UT-A2 is localized in the descending thin limb of Henle's loop, while UT-B is localized in vasa recta. K^+ deficiency is associated with reduced expression of UT-A1, UT-A3, and UT-B, but with increased expression of UT-A2. These data suggest that the impairment of urea absorption in the terminal IMCD (UT-A1 and -A3), and the impairment of the vasa recta urea recycling, could play a key role in lowering the medullary osmolality of K^+ deficient mice.[116]

WATER

The concentrating defect of K^+ deficiency is manifest primarily as a limitation of maximal urinary concentrating ability, rather than persistent hyposthenuria. K^+ deficiency also results in polydypsia, thus accentuating polyuria independent of the urinary concentrating defect. In humans, thirst is a prominent symptom of experimental K^+ deficiency.[117] In rats, the increased water intake precedes the development of the urinary concentrating defect, and restriction of fluid intake in the initial phase attenuates the polyuria; however, it does not prevent the development of the urinary concentrating defect.[118]

In humans, the concentrating defect has been observed in pathologic and experimental K^+ deficiency. The degree of K^+ deficiency also relates to the severity of the urinary concentrating defect in the rat. The rat,

however, is still capable of generating a maximally-concentrated urine for the first week,[118] while by 2 weeks the concentrating defect is fully established.[119]

Hypokalemic rats keep the basal water permeability at control level, whereas the response to vasopressin is significantly diminished.[120] These results are coupled with *in vitro* experiments where extracellular K^+ has been explored in rat renal papillary CD cells in culture.[121] Exposure of these cells to a K^+-free medium for more than 24 hours was associated with an attenuated cellular cAMP response to both vasopressin and forskolin. Hypokalemia results in decreased aquaporin-2 (AQP2) expression in principal cells of rat CD (cortical and medullary), in parallel with the development of polyuria. K^+ repletion is associated with normalization of AQP2 expression and urine output.[122]

Whether prostaglandin (PG) synthesis interferes with the action of vasopressin and the AQP2 system is not univocal among species. In rats, neither PGE_2 excretion nor papillary tissue content[118,123] is affected by K^+ deficiency. On the same line, indomethacin failed to reverse the concentrating defect, despite effective inhibition of medullary tissue prostaglandin synthesis.[118] The concentrating defect in K^+ deficiency is likely multifactorial; reduction in vasopressin response and in medullary interstitial osmolality are contributing mechanisms acting in a complementary fashion. Impaired NaCl reabsorption in the TAL and alteration in urea recycling limits the establishment of a hypertonic interstitium. The latter is a prerequisite for urine concentration, and it may be amplified by polydypsia and the consequent medullary washout. In addition, an impaired response of the CD to vasopressin contributes to the concentrating defect. Recently a tonicity-responsive enhancer-binding protein (TonEBP) has been identified as a transcriptional factor activated by hypertonicity. TonEBP, among other functions, plays a critical role in protecting renal medullary cells from the deleterious effects of hypertonicity. It is a key regulator of urinary concentration through the regulation of AQP2 and UT-A transcription, in a vasopressin-independent manner. K^+ deficiency conditions are associated with a downregulation of TonEBP in both inner and outer medullary CD and TAL. In the descending thin limb, TonEBP translocates from the nucleus to the cytoplasmic compartment where it is inactive. Lower interstitial osmolality occurring during K^+ deficiency could reduce TonEBP expression, and so contribute to the downregulation of AQP2 and UT-A[124] (Figure 50.8).

There is also evidence in K^+ deficiency for a decrease in inner medullary organic osmolytes which might precede the renal concentrating defect. Aldose-reductase (an osmoregulatory protein) mRNA abundance was reduced in K^+ deficiency.[125]

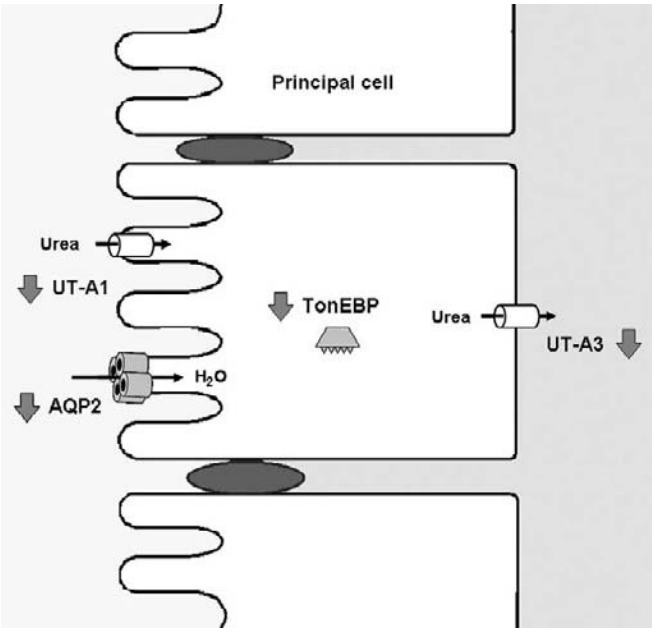

FIGURE 50.8 **A model of the urinary concentration impairment during K^+ deficiency.** In addition to a TAL-dependent low interstitial tonicity generation, principal cells along the CD play a key role. It has been described that K^+ deficiency downregulates AQP2 expression, mainly in cortical and OSOM CD.[122] In a mice model of K^+ deficiency, UT-A1 and UT-A3 are dowregulated.[116] TonEBP could promote the downregulation of urea transporters and AQP2.[124]

System Biology Approach to Hypokalemia

Since the discoding of the human genome, a novel scientific approach has been widely diffuse in health science: so-called systems biology. Systems biology aims to observe any biological system in an holistic way. It examines multiple components of a biological system *simultaneously* through high-throughput techniques (transcriptomics, metabolomics, and proteomics), and integrates the data with mathematical models. Systems biology methods produce a vast amount of data to generate hypotheses on how the observed system works. It offers new opportunities to understand complex systems.

The OMCD transcriptome of hypokalemic mice has been compared with one from mice treated with an NH_4Cl-load. Data were determined by using the serial analysis for gene expression (SAGE) microassay; a cluster analysis of changed tags has been reported in this study. Hypokalemic mice showed overexpression of tags belonging to the cluster of proliferation and apoptosis, while tags of the transport cluster were predominant in NH_4Cl-induced acidotic mice. Several transcripts have been identified in these clusters, and they are listed in the study from Cheval *et al.*[126]

The proteome of kidneys from mild and severe hypokalemic mice has been examined by Thongboonkerd

et al.[127] Chronic (8 weeks K^+ deficient diet) hypokalemic mice were compared with normokalemic mice. Two-dimensional gel-based MALDI-MS and/or Q-TOF MS/MS techniques were carried out on whole kidney samples. Thirty-three proteins induced by K^+ deficiency were identified. They are mainly metabolic enzymes and cytoskeletal proteins. Some of them are involved in the osmoregulatory process of the papillary interstitium, such as aldose reductase. A complete list of the altered proteins is also available.

SYSTEMIC EFFECTS OF K^+ DEPLETION

Healthy individuals may well tolerate short periods of mild K^+ deficiency; however, high K^+ deficiency may induce severe renal, cardiac, and neurologic injuries, and glucose intolerance. Indeed, reduced K^+ intake correlates directly with higher blood pressure in both normotensive and hypertensive individuals.

K^+ and Hypertension

Hypertension is a major health problem in developed countries. It has been extensively demonstrated that the occurrence of hypertension is associated with salt (NaCl) intake. There is evidence that dietary K^+ intake may participate in determining sensitivity to salt-induced hypertension.

Compared with our Paleolithic ancestors, the common Western diet contains a larger amount of Na^+ (150 versus 20 mmol per day), the majority (approximately 75%) is added to food products by manufacturers. While salt intake has been growing dramatically since the Paleolithic period, K^+ intake has been lessening (50 versus 320 mmol per day). This drop in K^+ intake is a consequence of reduced intake of fruits and vegetables in the diet. Epidemiologic studies have demonstrated that dietary K^+ is inversely related to the occurrence of hypertension, independently of salt intake.[128] An international study of electrolyte excretion and blood pressure performed on a large cohort of subjects, distributed in various countries, demonstrated that K^+ excretion is negatively and independently correlated with blood pressure.[129] Furthermore, K^+ supplementation (60 mmol KCl per day) decreased blood pressure in hypertensive patients with diuretic-induced hypokalemia.[130]

The role of dietary K^+ in controlling blood pressure has been assessed by the Dietary Approaches to Stop Hypertension (DASH) trial.[131] Slightly hypertensive individuals were arbitrarily assigned to either a control diet or to the DASH diet (a diet rich in vegetables, fruits, and low-fat dairy products); subgroups of participants on each diet were divided to ingest either low, intermediate or high amounts of Na^+ (approximately 50, 100, and 150 mmol, respectively, per day). The DASH diet markedly reduced blood pressure, independent of Na^+ intake (Figure 50.9). According to a Scientific Statement issued by the American Heart Association, the beneficial blood pressure-lowering effect of the DASH diet is largely a function of its high K^+ content (about 120 mmol/day in the 2100 Kcal DASH diet versus approximately 60 mmol/day in the control diet).[132] The effect of K^+ supplementation on blood pressure was further confirmed in a meta-analysis of 33 clinical trials.[133]

The mechanisms by which low dietary K^+ intake increases blood pressure have been investigated.[134] It has been shown that the hypertensive effect of K^+ deficiency is prevented by lowering daily Na^+ intake. K^+ deficiency seems, at least partially, to enhance renal Na^+ reabsorption. This mechanism could be sustained by WNK1.[135]

New Physiologic Concepts in Aldosterone-Dependent Sodium and K^+ Handling

Aldosterone is an important regulator of the final composition of urine through its effects on the distal

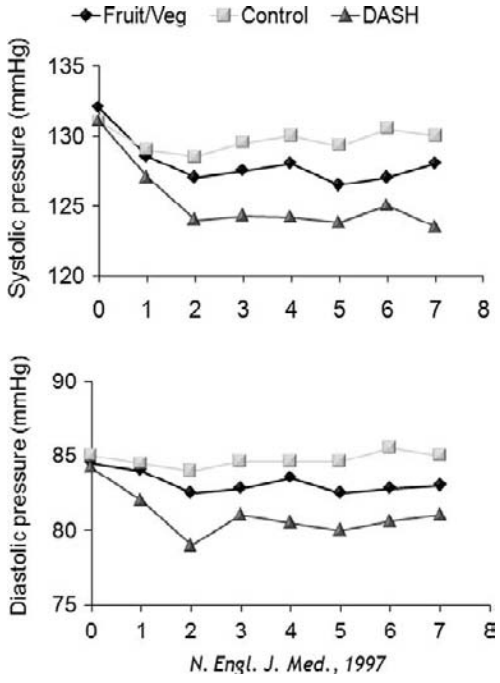

FIGURE 50.9 **Progression of weekly blood pressure measurements during control diet, fruit- and vegetable-enriched diet and DASH diet.** Control diet was typical of the diets of a substantial number of Americans with a K^+ content about 25th percentile of US consumption. The fruits- and vegetables-diet provided potassium and magnesium at levels close to the 75th percentile of consumption. The DASH diet had a K^+ content about 75th percentile of US consumption, and a reduced amount of saturated fat, total fat, and cholesterol. *(Adapted from Appel et al. [131])*

nephron. ENaC are activated by aldosterone, thus creating a lumen-negative potential. The luminal electronegativity supplies the driving force for Cl^- reabsorption through the paracellular pathway and K^+ and H^+ secretion. In such a way, Na^+ and K^+ homeostasis are finely tuned together. Aldosterone secretion is extremely sensitive to extracellular fluid volume depletion and hyperkalemia. In volume-depletion conditions, aldosterone increases salt reabsorption restoring extracellular fluid volume without generating hypokalemia. During hyperkalemia, aldosterone increases renal K^+ excretion, without concomitant renal salt retention.

The ability of the kidney to respond to increased aldosterone with two different physiologic adaptations (salt retention without K^+ secretion during volume-depletion states, and K^+ secretion without salt retention during hyperkalemia) is still a subject of debate. Recent data suggest a potential implication of the WNK kinase.[136] WNK (with no lysine) kinases are a novel family of large serine/threonine protein kinases that are conserved in multicellular organisms.[137] At present, there are four known mammalian WNK family members: WNK1, WNK2, WNK3, and WNK4. WNK4 is widely-expressed in epithelial tissues. Full-length WNK1 is ubiquitous, and is also known as long WNK1 (L-WNK1); an alternatively spliced WNK1 isoform is specifically expressed in the kidney and is, therefore, known as kidney-specific WNK1 (KS-WNK1). KS-WNK1 is an antagonist of L-WNK1.[138] L-WNK1 has been demonstrated to enhance the activity of both ENaC[139] and NCC; the latter occurs through the inhibition of WNK4, which in turn is capable of inhibiting NCC. Both L-WNK1 and WNK4 inhibit ROMK. Interestingly, KS-WNK1 antagonizes L-WNK1 with respect to its effects on ROMK, NCC, and ENaC. Therefore, a positive ratio of L-WNK1 to KS-WNK1 increases the rate of Na^+ reabsorption via ENaC and NCC, and decreases the rate of K^+ secretion by inhibiting ROMK. However, these effects uncouple Na^+ reabsorption from K^+ secretion. These mechanisms may be central to enlighten the hypotensive effect of K^+ supplementation in salt-sensitive hypertension. Indeed, high K^+ stimulates aldosterone secretion, which would be predicted to stimulate a hypertensive, rather than a hypotensive, effect. The abundance of ROMK in the apical membrane of distal nephron is regulated by dietary K^+ intake.[140] It has been reported that high- and low-K^+ intake increases and decreases KS-WNK1 expression, respectively. Low-K^+ intake also increases the expression of L-WNK1 in the kidney. The ratio of L-WNK1 to KS-WNK1 in the kidney is, therefore, increased when K^+ intake is low, and reduced when intake is high. So, by increasing the ratio of L-WNK1 to KS-WNK1, the kidney simultaneously conserves K^+ and Na^+ during K^+ deficiency (Figure 50.10). This effect could be implicated in the pathogenesis of salt-sensitive hypertension, and explain the positive action of high-K^+ intake on blood pressure.

K^+ Depletion and Glucose Intolerance

Insulin controls both K^+ and glucose homeostasis. It is possible that there is a common pathway between the two systems. Insulin-resistance is usually correlated with hyperinsulinemia, because pancreatic β-cells raise insulin secretion to balance insulin resistance.[141] The resulting hyperinsulinemia may induce hypokalemia from excessive cellular K^+ uptake, if the effect of insulin on K^+ uptake is not similarly reduced. In fact, a weakened insulin effect on K^+ fluxes in obesity and diabetes has been demonstrated,[142] which are both correlated with insulin resistance with respect to glucose metabolism.

There are data indicating that there are two distinct varieties of insulin resistance: resistance to cellular glucose uptake observed in type 2 diabetes; and resistance to cellular K^+ uptake observed during K^+ deficiency or fasting.

The molecular mechanisms involved in the differential regulation of glucose versus K^+ cellular uptake by insulin are not known. It is highly probable that these pathways are related to post-binding actions of insulin to its receptor, which is a common step in the regulation of K^+ and glucose uptake. The resistance of

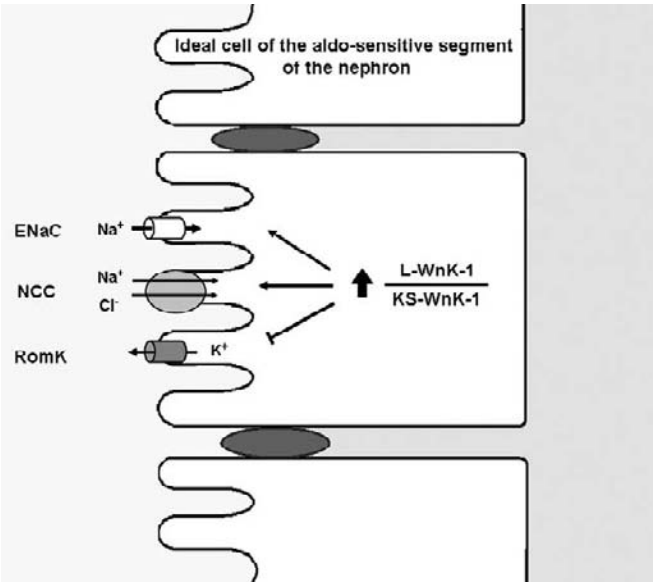

FIGURE 50.10 **The role of WNK in Na^+ and K^+ handling along the aldosterone-sensitive segments.** Hypokalemia induces an increase in the ratio of L-WNK1 to KS-WNK1 in the kidney, which decreases renal K^+ secretion in order to conserve K^+; however, this also causes reabsorption of Na^+ via ENaC and NCC.[140]

muscle cell glucose uptake during insulin resistance is attributed to an impairment of insulin signaling at the level of PI3-kinase, which involves GLUT4 trafficking.[143] Insulin has been suggested to trigger cellular K^+ uptake by activating the Na^+ pump.[144] It has also been anticipated that activation in the kidney, during K^+ deprivation, of NADPH oxidase, superoxide anion production, and PTK activities may affect insulin stimulation of K^+ cellular uptake.

Hypokalemia may play a role in the well-known association between the use of thiazide diuretics and the development of diabetes. It has been estimated that a decrease of 1 mEq/L K^+ may cause an approximately 10 mg/dl increase in glucose. These data are confirmed by the observation that glucose levels can be normalized after K^+ repletion in patients who have hypokalemia. The mechanism of thiazide-induced hyperglycemia is thought to be the consequence of decreased insulin released from the pancreatic beta cell. ATP-sensitive K^+ channels link cell metabolism to electrical activity, thereby playing an important role in the control of insulin secretion.

INTRODUCTION

Hyperkalemia is a common electrolyte disorder that may have detrimental effects, the most serious of which is a cardiac arrhythmia.[1] There is large variability among patients in the absolute concentration of potassium (K^+) ions in plasma (P_K), which leads to electrocardiographic changes and cardiac toxicity of hyperkalemia. From a diagnosis of the cause of hyperkalemia perspective, the basis of hyperkalemia will be a shift of K^+ out of cells if the time course for its development is short and/or if there is little K^+ intake. On the other hand, chronic hyperkalemia implies that there is a defect in the regulation of the excretion of K^+ by the kidney.

Basic Concept for the Movement of K^+ Ions Across Cell Membranes

K^+ is the principal cation in cells. The movement of K^+ ions across cell membranes has two requirements; first, there must be a driving force; second there must be an open K^+ channel in a cell membrane.

Driving Force

K^+ are kept inside the cell by an electrical force; the cell interior has a negative voltage. It follows that a more negative cell voltage is required to shift K^+ into cells. The negative voltage in cells is generated by the activity of the electrogenic cation pump, the Na^+, K^+ ATPase (Na-K-ATPase). This pump exports three sodium (Na^+) ions while importing only two K^+ ions; hence there is a net export of {1/3} of a positive charge per Na^+ that exits from cells via the Na-K-ATPase (Figure 51.1). Because, intracellular anions are largely macromolecular phosphates such as RNA, DNA, and phospholipids, which remain inside the cell, a negative intracellular voltage is generated when Na^+ exits the cell via the electrogenic Na-K-ATPase.

There are three ways to acutely increase ion pumping by the Na-K-ATPase: First, a rise in the concentration of its rate-limiting substrate—intracellular Na^+; second, an increase in the affinity for Na^+ or in the V_{max} of the existing Na-K-ATPase units in cell membranes; third, an increase in the number of active Na-K-ATPase pump units in the cell membrane by recruitment of new units. A chronic increase in Na-K-ATPase pump activity requires the synthesis of new pump units as occurs with exercise training.[2]

The driving force for the secretion of K^+ by principal cells in the late distal convoluted tubule, the connecting segments and the cortical collecting duct (the abbreviation CCD is used in this Chapter to indicate all these nephron segments) is a lumen-negative voltage. This lumen-negative voltage is generated by the electrogenic reabsorption of Na^+ (reabsorption of more Na^+ ions than of their accompanying anion, chloride (Cl^-) ions).

Ion Channels for K^+

There are several different types of channels that permit the diffusion of K^+ through cell membranes.[3,4] Some of these channels are regulated by voltage, others by ligands such as calcium ions (Ca^{2+}), and yet others by metabolites such as adenosine di-phosphate

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00051-3

(ADP)—the latter are called K_{ATP} channels. Because K^+ ions do not reach diffusion equilibrium, control is exerted not only by modulating the number but also the conductance and gating of these channels.

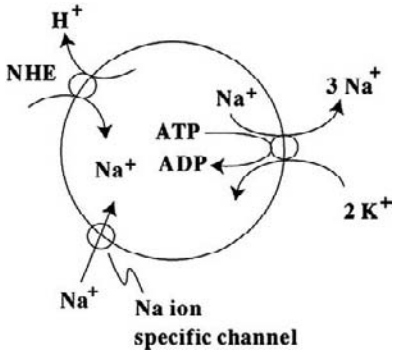

FIGURE 51.1 Na-K-ATPase activity and the export of positive voltage. The Na-K-ATPase generates the electrical driving force for K^+ entry into cells providing that the source of Na^+ pumped out is either Na^+ that existed in cells or Na^+ that entered cells in an electroneutral fashion via NHE. If the source of Na^+ pumped were Na^+ that entered cells via a Na^+ ion channel, the voltage in cells would become less negative. While K^+ channel conductance does limit the rate of K^+ exit, a higher concentration of K^+ in the ICF compartment that resulted from ion pumping by the Na-K-ATPase can still cause the electrogenic exit of K^+. *Reproduced with permission (224).*

The major K^+ channel that adjusts the intracellular voltage is the K^+_{ATP} channel.[5] It is a misnomer to call these channels K^+_{ATP} as the concentration of ATP in cells does not change sufficiently to provide a signal for regulating these channels. The signal that regulates these channels may be the result of a change in the concentration of a related nucleotide, ADP. When the concentration of ADP rises, K^+_{ATP} channels will open; conversely, when the concentration of ADP falls, K^+_{ATP} channels will close. This regulation of K^+_{ATP} channels adjusts the negative voltage in cells, which in turn regulates other ion channels. The best example is the voltage-gated Ca^{2+} channel, which is opened by a less negative voltage in cells. Ionized Ca^{2+} is a major signal for regulation of a number of intracellular processes.

Example: Regulation of the K^+_{ATP} channel by ADP plays a critical role in the release of insulin.[6] When the concentration of glucose in plasma ($P_{Glucose}$) is high, a metabolic signal is generated in ß-cells of the pancreas to cause the release of insulin (Figure 51.2). When the rate of oxidation of glucose rises in ß-cells, the concentration of ADP in these cells falls. This lower concentration of ADP causes the K^+_{ATP} channels to close and thus the ICF compartment becomes less negative because fewer K^+ ions (positive charges) exit ß-cells. This less negative voltage in ß-cells increases the conductance of voltage-gated Ca^{2+} channels and hence the

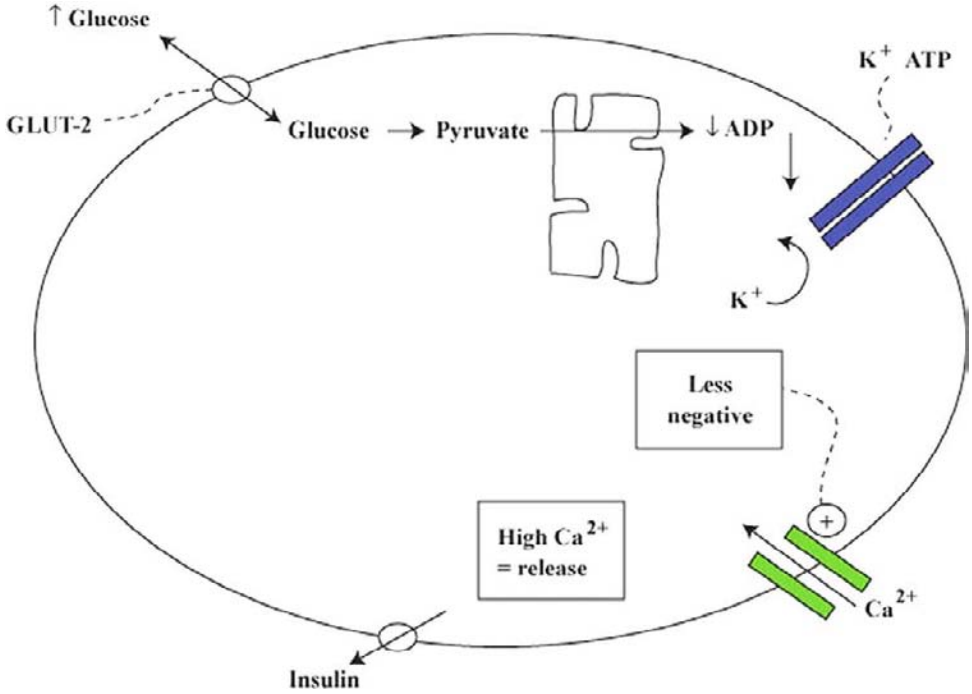

FIGURE 51.2 Signal system to release insulin from ß-cells of the pancreas. The large oval represents a ß-cell of the pancreas. When the $P_{Glucose}$ rises, the $ICF_{Glucose}$ rises to the same extent because of the type of glucose transporter (GLUT-2) in these cells. When glucose is oxidized, the concentration of ADP falls, and this permits K_{ATP} channels to be closed. As a result, less K^+ and positive voltage exits, which causes the ICF compartment to become less negative. This opens voltage-gated Ca^{2+} channels and hence the ionized Ca^{2+} concentration in their cytosol increases. A higher ionized Ca^{2+} in these cells causes the release of insulin.

intracellular concentration of ionized Ca^{2+} rises—this provides the signal to release insulin from ß-cells (Figure 51.2).

A similar logic can be used to deduce how the blood flow to exercising muscle may be controlled using intracellular Ca^{2+} as the signal[7] (Figure 51.3). During a sprint, L-lactic acid is released from skeletal muscle cells. When lactic acid enters vascular smooth muscle cells, H^+ and/or lactate anions lead to the opening of the K^+_{ATP} channels. As a result, K^+ exit and the voltage in these cells become more negative. This causes closure of voltage-gated Ca^{2+} channels and less entry of Ca^{2+} into cells and hence vasodilatation.

Several types of K^+ channels including renal outer medullary K^+ channels, ROMK ($K_{ir}1.1$) (which have similar biophysical prosperities and regulatory mechanism as that of the small conductance K^+ channels identified in mouse and rat CCD), a Ca^{2+} activated big-conductance K^+ channel (BK) and the double-pore K^+ channel, are expressed in the apical membrane of principal cells in CCD.[8,9] ROMK are the K^+ channels most important for the secretion of K^+ in CCD.[9,10] Big K^+ conductance "BK" or maxi-K^+ channels are activated by a rise in intracellular Ca^{2+} and are thought to play an important role in flow dependent K^+ secretion.[11,12] Although these channels likely mediate K^+ secretion in patients with Bartter's syndrome that is due to a loss of function mutation in ROMK,[13] their role in physiological regulation of renal excretion of K^+ is not clear. BK channel activity has been detected in both principal cells and intercalated cells in CCD. It is difficult to explain the contribution of BK located in intercalated cells to K^+ secretion as these cells have low Na-K-ATPase pump content. BK channel activity is increased in the CCD from rats on a high K^+ diet.[14] Furthermore, in BK-α subunit knocked mice, increase in flow failed to stimulate K^+ secretion in distal nephron.[15] Notwithstanding, deletion of BK-α subunit does not affect net K^+ excretion in mice fed a high K^+ diet. It is important to recall that the role of these channels was examined in laboratory rodents which consume 10-fold more K^+ per kg body weight and close to three-fold more Na^+ per kg body weight compared to human subjects consuming a typical Western diet. Therefore, it is possible that the BK channel may provide a way for a "speedy" K^+ excretion if there is a large intake of K^+ and if flow through CCD were augmented. Although, the same limitations imposed by the magnitude of the lumen negative voltage on the rate of secretion of K^+ by these channels will apply, it is possible that "conductance" through ROMK may be rate limiting when there is a need for a high rate of excretion of K^+ over a short period of time.

REGULATION OF K^+ HOMEOSTASIS

Regulation of K^+ homeostasis has two important aspects:

1. Control of the trans-cellular distribution of K^+, which is vital for survival because it limits acute changes in the P_K.

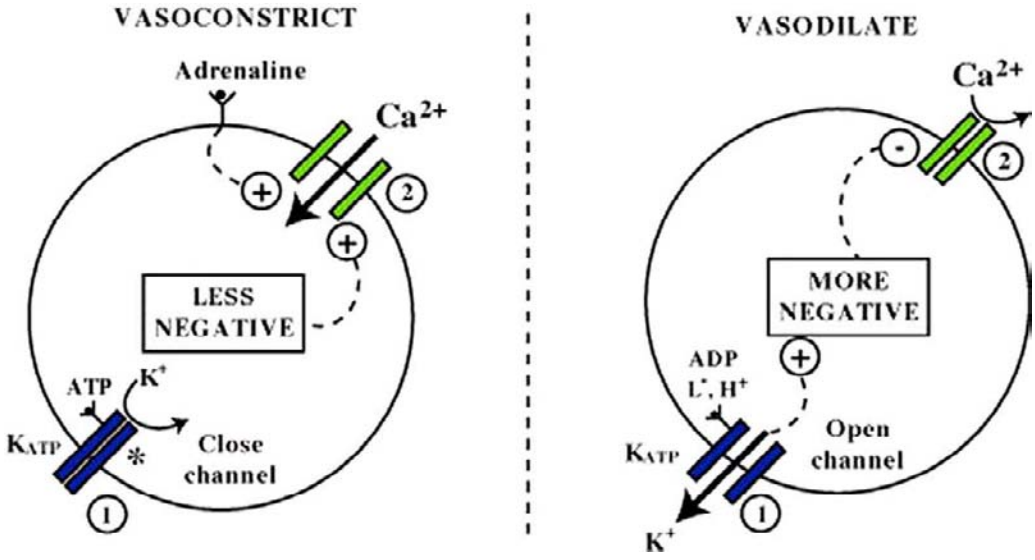

FIGURE 51.3 Vasoconstrictor tone in vascular smooth muscle cells. The circles represent vascular smooth muscle cells. When the ICF has a less negative voltage because its K^+_{ATP} channels (shown in blue) are closed, the voltage-gated Ca^{2+} channels (shown in green) can be maintained in an open configuration permitting a rise in the ICF [Ca^{2+}]. Hence there will be an increase in vasoconstriction (shown to the left of the dashed line). In contrast, during a sprint, K^+_{ATP} channels will open because of a high concentration of L-lactate anions (L^-) and H^+. This will lead to a more negative ICF voltage and closure of their voltage-gated Ca^{2+} channels and thereby vasodilatation and increase in blood flow to muscles.

2. The regulation of K^+ excretion by the kidney, which maintains overall K^+ balance; nevertheless, this is a much slower process.

Acute Control of the Plasma K^+

Distribution of K^+ between the ECF and ICF Compartments

THE Na-K-ATPase

The activity of the Na-K-ATPase is higher when the concentration of its substrate, Na^+ in cells rises. The impact of this increase in the net exit of Na^+ on the trans-membrane voltage, however, depends on whether the Na^+ entry step into cells is electroneutral or electrogenic.

Electroneutral Entry of Na^+ into Cells: This occurs when Na^+ ions enter cells in exchange for hydrogen ions (H^+) via the Na^+/H^+ exchanger-1 (NHE-1) (Figure 51.4, left side).[16] The NHE-1 is normally inactive in cell membranes, as can be deduced from the fact that the concentrations of its substrates (Na^+ in the extracellular fluid (ECF) and H^+ in the intracellular fluid (ICF) compartment) are considerably higher than that of its products (Na^+ in the ICF compartment and H^+ in the ECF compartment) in steady state. The two major activators of NHE-1 are a higher concentration of H^+ in the ICF compartment near NHE -1[17] and insulin.[18] Monocarboxylic acids (e.g., L-lactic acid) enter cells on the monocarboxylic acid cotransporter (M-CT)[19,20] (Figure 51.4). If the M-CT is located in close proximity to NHE in a cell membrane, the release of H^+ from these acids may cause a high concentration of H^+ in the local area of NHE-1, which activates NHE-1 and hence increases the electroneutral entry of Na^+ into cells (Figure 51.4, left side).[21]

Electrogenic entry of Na^+ into Cells: The Na^+ channel in cell membranes is normally gated by voltage. When open, one cationic charge enters the cell per Na^+ transported. Since only 1/3 of a charge exits per Na^+ ion that is exported out of the cell via the Na-K-ATPase (Figure 51.1); the net effect would be to diminish the degree of intracellular negative voltage and this leads to net exit of K^+ out of cells. This explains a rise in the P_K during intense exercise.[22,23] It could explain the development of hyperkalemia in patients with hyperkalemic periodic paralysis.[24,25]

Hormones that Affect the Distribution of K^+

Catecholamines: FXYD1 (phospholemman) interacts with the catalytic α subunit of the Na-K-ATPase and modulates its activity. Un-phosphorylated FXYD1 binds to the α subunit and this inhibits the pump activity by decreasing its affinity for Na^+ and/or its V_{max}. ß-$_2$ adrenergic agonists activate adenalyate cyclase and this leads to stimulation of the conversion of ATP to cAMP. This second messenger, in turn, activates protein kinase-A, which induces phosphorylation of the FXYD1; this disrupts its interaction with α subunit of the Na-K-ATPase and results in an increase in the affinity of the Na-K-ATPase for intracellular Na^+.[26,27] The increase in export of pre-existing intracellular Na^+ (Figure 51.1) increases the negative voltage in cells and causes a shift of K^+ into cells.

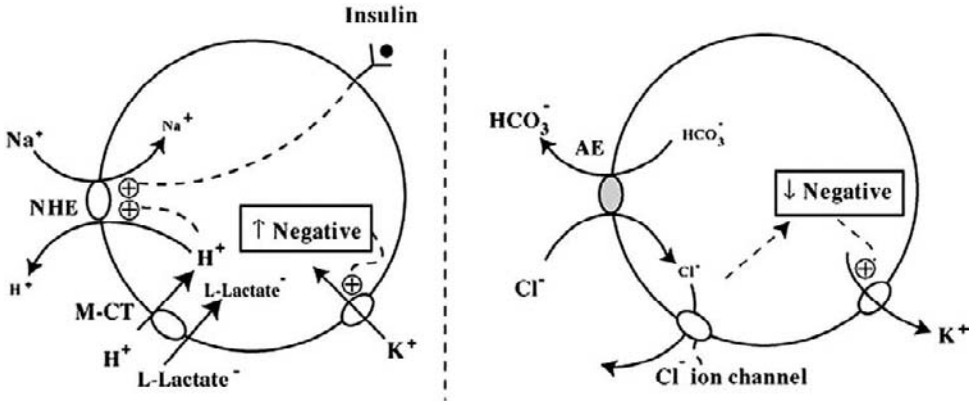

FIGURE 51.4 **Role of NHE-1 and AE in the shift of K^+ across cell membranes.** The circle represents a cell membrane. NHE and the AE are normally *inactive* in cell membranes. As shown to the left of the dashed vertical line, there are two major activators of NHE, insulin and a higher concentration of H^+ in the ICF compartment. Monocarboxylic acids (e.g., L-lactic acid) enter cells on the monocarboxylic acid cotransporter (M-CT). If the M-CT is located in close proximity to NHE-1 in cell membrane, the release of H^+ from these acids may cause a high concentration of H^+ in the local area of NHE-1, which activates NHE-1. Activation of NHE-1 increases the electroneutral entry of Na^+ into cells. As Na^+ exit via the electrogenic Na-K-ATPase, the net effect is a more negative intracellular voltage and the entry of K^+ into cells. As shown on the right, when the AE is activated and there are favorable concentration differences, HCO_3^- will be exported and Cl^- enter cells. The intracellular negative voltage will drive the exit of Cl^-; from cells through their specific ion channel. This latter step will lead to the export of negative voltage from cells and the subsequent exit of K^+.

An acute shift of K^+ into cells and hypokalemia is observed in conditions associated with a surge of catecholamines (e.g., patients with a subarachnoid hemorrhage, myocardial ischemia, and/or an extreme degree of anxiety).[28] ß$_2$-agonists may be used to induce a shift of K^+ into cells in patients with hyperkalemia in an emergency setting. Non-specific ß-blockers are being used for therapy of the subtype of hypokalemic periodic paralysis associated with hyperthyroidism.[29,30]

Insulin: Insulin increases the activity of the Na-K-ATPase and its expression in the plasma membrane through a phosphoinositide 3-kinase, atypical protein kinase C (aPKC), and extracellular signal regulated kinases 1 and 2 (ERK1/2). ERK1/2 kinase phosphorylation of the Na-K-ATPase α subunit promotes translocation of Na-K-ATPase from an intracellular pool to the cell membrane.[31,32] aPKC phosphorylation of FXYD1 leads to an increase in the V_{max} of the Na-K ATPase.[27] Insulin may also have an effect in augmenting the electroneutral entry of Na^+ into cells via NHE-1.[18] This, in conjunction with increasing the number and activity of the Na-K-ATPase on the cell surface, causes the voltage in cells to become more negative (Figure 51.4, left side). Notwithstanding the glucose transporter, GLUT4 and Na-K-ATPase do not co-localize to the same skeletal muscle intracellular vesicles and hence, the effect of insulin to shift K^+ into cells is separate from its effect on glucose entry into these cells.[33]

Insulin has been utilized clinically in the treatment of patients with an emergency due to the adverse cardiac effects of hyperkalemia. In contrast, in patients with diabetic ketoacidosis, a lack of action of insulin results in a shift of K^+ out of cells and the development of hyperkalemia despite a total body deficit of K^+.

Acid–Base Influences

When an acid is added to the body, most of the H^+ are buffered in the ICF compartment.[34] Monocarboxylic acids (e.g., L-lactic acid) enter cells on the M-CT,[19,20] and, as mentioned above, release of their H^+ near NHE-1 may activate NHE-1 and increase the electroneutral entry of Na^+ into cells and hence, in the presence of insulin, may cause a shift of K^+ into cells.[21]

A shift K^+ out of cells may occur in patients with metabolic acidosis due to acids that are not transported on MC-T (e.g., metabolic acidosis due to a gain of HCl acid owing to loss of $NaHCO_3$ in a patient with diarrhea, ingestion of citric acid[35]). A possible mechanism to explain how this may occur is illustrated in (Figure 51.4, right side**)**. Activation of the Cl^-/bicarbonate (HCO_3^-) anion exchanger (AE) will cause HCO_3^- to exit and Cl^- to enter cells.[36] Since cells have Cl^- channels in their membrane,[37] the rise in the concentration of Cl^- in the ICF in conjunction with the usual negative voltage forces Cl^- to exit. As this exit of Cl^- is electrogenic, it causes a less negative voltage in cells and K^+ will exit from cells.

Several clinical implications follow from this analysis:

1. If hyperkalemia is present in a patient with metabolic acidosis due to accumulation of monocarboxylic organic acid, other causes for hyperkalemia than the acidemia should be sought (e.g., lack of insulin in patients with diabetic ketoacidosis, tissue injury, and a lack of ATP to drive the Na-K-ATPase in patients with L-lactic acidosis due to hypoxia[38–40]).
2. Metabolic acidosis due to inorganic acids (addition of HCl) causes a shift of K^+ out of cells. Patients with chronic hyperchloremic metabolic acidosis (e.g., patients with chronic diarrhea or those with renal tubular acidosis (RTA)) however, usually have a low P_K because of excessive loss of K^+ in the diarrhea fluid in the former[41] or the urine in the later.[42]

Respiratory acid–base disorders, on the other hand, cause only small changes in the P_K as there is little movement of Na^+ or Cl^- across cell membranes in these disorders.[43,44]

Tissue Catabolism

Hyperkalemia may be seen in patients with crush injury or those with tumor-lysis syndrome.[45] In these patients, factors that compromise the ability of the kidney to excrete K^+ are usually present as well. Patients with diabetic ketoacidosis, have a total body K^+ depletion but hyperkalemia is commonly present due to a shift of K^+ from cells secondary to a lack of insulin. The corollary is that during therapy, complete replacement of the deficit of K^+ must await the provision of cellular constituents (phosphate, amino acids, Mg^{2+}, etc.) and the presence of anabolic signals.

LONG-TERM REGULATION OF K^+ HOMEOSTASIS

Control of the renal excretion of K^+ maintains overall daily K^+ balance. Although the usual intake of K^+ in adults eating a typical western diet is close to 1 mmol of K^+/kg body weight, the rate of excretion of K^+ can match an intake of more than 200 mmol/day with only a minor rise in the P_K.[46]

Control of K^+ secretion occurs primarily in the CCD.[47,48] Two factors influence the rate of excretion of K^+ in CCD; the flow rate in the terminal CCD, and the net secretion of K^+ by principal cells in the CCD which raises the luminal concentration of K^+ ($[K^+]_{CCD}$).

K^+ Secretion

The secretory process for K^+ by principal cells in the CCD, has two elements. First, a trans-epithelial lumen negative voltage must be generated by electrogenic reabsorption of Na^+ via epithelial Na^+ channels (ENaC) (Figure 51.5). Second, open ROMK channels must be present in the luminal membrane of principal cells.[49]

Aldosterone actions lead to an increase in the number of open ENaC units in the luminal membrane of principal cells in CCD[50] (Figure 51.5). The steps involved include binding of aldosterone to its receptor in the cytoplasm of principal cells, entry of this hormone-receptor complex into the nucleus, and then the synthesis of new proteins including the serum and glucocorticoid regulated kinase-1 (SGK-1).[51,52] SGK-1 increases the expression of ENaC in the apical membrane of principal cells. The mechanism seems to be related to the effect of SGK-1 to phosphorylate and inactivate the ubiquitin ligase Nedd-4-2.[53] Nedd-4-2 ubiquinates ENaC subunits, leading to their removal from the cell membrane and degradation in proteasomes. Therefore, inhibition of the Nedd-4-2 induced endocytosis of ENaC leads to increased expression of ENaC in the luminal membrane, which increases the transport of Na^+.[54,55] Another mechanism by which aldosterone activates ENaC involves proteolytic cleavage of the channel by serine proteases. Aldosterone induces production of "channel activating proteases" (CAP 1–3).[56] These proteases activate ENaC by increasing their open-probability, rather than by increasing their expression in the luminal membrane.

The driving force for Na^+ reabsorption in the CCD is a higher concentration of Na^+ in the lumen of CCD than that in principal cells (~10–15 mmol/L) and a negative voltage inside cells, owing to the actions of the Na-K-ATPase at the basolateral membrane of these cells. The concentration of Na^+ in luminal fluid is limited by the presence of urea osmoles and that the osmolality of luminal fluid in CCD will be equal to plasma osmolality in the presence of vasopressin. The rate of electrogenic Na^+ reabsorption is limited by constraints on the magnitude of luminal negative voltage that can be generated in CCD because of limitations on transport of Cl^-. At a trans-epithelial lumen negative voltage of −61 mV and a plasma Cl^- of 100 mmol/L, the minimum luminal Cl^- concentration would be 10 mmol/L. Therefore, under most circumstances, the concentration of Na^+ in luminal fluid is sufficient for the activity of ENaC. Variations in the luminal concentration of Na^+ in the CCD do not regulate the net secretion of K^+.[57]

The reabsorption of Na^+ in the CCD can be electroneutral, if the rate of reabsorption of its major accompanying anion Cl^- matches its rate of reabsorption, or electrogenic, if more Na^+ than Cl^- are reabsorbed in CCD (Figure 51.5). The pathway(s) for the reabsorption of Cl^- in the CCD is (are) not well defined, but it is thought that paracellular pathways play an important role.[58,59] Recently an electroneutral, thiazide-sensitive and amiloride-resistant Na^+-Cl^- transport was identified in the intercalated cells of the cortical collecting duct in mice.[60,61] This seems to be mediated by the parallel activity of the Na^+-dependent Cl^-/HCO_3^- exchanger (NDCBE), which promotes the electroneutral exchange of one intracellular Cl^- with one Na^+, two HCO_3^- and the Na^+ independent Cl^-/HCO_3^- exchanger (pendrin). This transport mechanism is apparently responsible for as much as 50% of Na^+-Cl^- transport in CCD of the mouse while mineralocorticoids act. To play a role in modulating the rate of K^+ secretion, this mechanism of electroneutral NaCl reabsorption needs to be expressed in the late DCT and the connecting tubule.

An increase in the concentration of HCO_3^- and/or an alkaline luminal fluid pH seem to increase the amount of K^+ secreted in the CCD. It was suggested that this

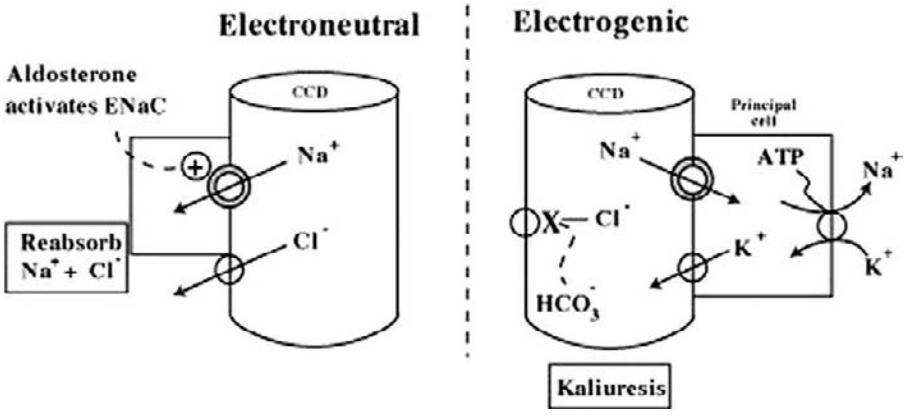

FIGURE 51.5 Electrogenic and electroneutral reabsorption of Na^+ in the CCD. The barrel-shaped structures represent the CCD and the rectangles represent principal cells. Na^+ is reabsorbed via ENaC; this reabsorption is increased by aldosterone (the shaded enlarged circle). Net secretion of K^+ occurs through its specific ion channel (ROMK). Electroneutral reabsorption of Na^+ is shown on the left and an example of electrogenic reabsorption of Na^+ (the presence of HCO_3^- or an alkaline luminal pH) is shown to the right of the dashed vertical line. *Reproduced with permission (224).*

may be due to a decrease in the apparent permeability of Cl^-[62] and/or an increase in ROMK open probability in this nephron segment. It is also possible that the increase in luminal HCO_3^- concentration in CCD, inhibits the Cl^-/HCO_3^- exchanger (pendrin), and hence the NDCBE and the electroneutral NaCl reabsorption,[60] perhaps leading to a higher rate of electrogenic reabsorption of Na^+.

If the rate of reabsorption of Na^+ in CCD is not appreciably higher than the rate of reabsorption of Cl^-, a large lumen-negative voltage cannot develop. The hyperkalemia in patients with the syndrome of "Familial Hyperkalemia with Hypertension" (also known as type II pseudohypoaldosteronism or Gordon's syndrome) may be an example for this pathophysiology.[58,63] Two factors are important to achieve this near-equal rate of ion transport in the CCD. First, low delivery of Na^+ and Cl^- to the CCD occurs because the reabsorption of Na^+ and Cl^- is augmented in the distal convoluted tubule because of increased activity of Na^+-Cl^-cotransporter (NCC). Second, effective arterial blood volume expansion suppresses the release of aldosterone; this leads to fewer numbers of open ENaC in the luminal membrane of principal cells in CCD. Hence the rate of reabsorption of Cl^- in the CCD may match that of Na^+.

ROMK channels are abundant and have a high open-probability on a K^+-rich diet.[9,64] Therefore ROMK channels do not seem to be rate-limiting for net secretion of K^+ unless the P_K falls to the mid-3 mmol/L range in rats.[65] Dietary K^+ intake is an important regulator of ROMK channels. Low K^+ intake decreases, whereas a high K^+ intake increases the number of ROMK channels in the luminal membrane of principal cells.[66] The membrane trafficking of ROMK is modulated by phosphorylation of tyrosine in the channel protein, such that phosphorylation of tyrosine stimulates endocytosis and de-phosphorylation of tyrosine induces exocytosis. K^+ depletion increases the expression and activity of the protein tyrosine kinase and tyrosine phosphorylation of ROMK channels results in their endocytosis.[67] Angiotensin II (ANG_{II}) inhibits ROMK activity in K^+-restricted rats, but not in rats on a usual K^+ diet.[68] The effect of ANG_{II} may be mediated via activating NADPH oxidase II and the production of superoxide anions, which increases the expression of protein tyrosine kinase.[69–71] The WNK (*With No Lysine*) kinases seem to play a role in modulating K^+ secretion. There are two isoforms of WNK1; a ubiquitous full-length WNK1 (WNK1-L) and a kidney-specific, short WNK1 lacking the kinase domain (WNK1-S).[72] WNK1-L induces endocytosis of ROMK[73] whereas WNK1-S inhibits this effect of WNK1-L. The ratio of WNK1-S to WNK1-L transcripts is reduced by K^+ restriction (more endocytosis of ROMK) and is increased by K^+ loading (less endocytosis of ROMK).[74,75]

Flow Rate in the CCD

When vasopressin acts and aquaporin-2 water channels (AQP2) have been inserted in the luminal membrane of principal cells, the late distal nephron is permeable to water, the osmolality of fluid in the terminal CCD is equal to the plasma osmolality and hence is relatively fixed. Therefore, the flow rate in terminal CCD is determined by the number of osmoles in the luminal fluid.

The osmoles that are present in the lumen of the terminal portion of CCD are largely urea, NaCl, and K^+ with an accompanying anion. While there is little reabsorption or secretion of electrolytes in the nephron segments distal to terminal CCD, and hence the number of electrolyte osmoles in terminal CCD is close to their rate of excretion in the urine, this is not the case for urea. A quantitative analysis of the process of intra-renal urea recycling reveals that the amount of urea delivered to the early DCT is about two-fold larger than the quantity of urea that is excreted in the urine. In the following paragraphs, we shall illustrate that urea recycling aids the excretion of K^+; this process is especially important in subjects with disorders or those who are taking drugs that lead to a less lumen-negative voltage in the CCD.[76]

Urea Recycling, Process and Quantitative Analysis

For simplicity, we shall begin with the absorption of urea in the inner medullary collecting duct (MCD) (Figure 51.6). This absorption requires the presence of urea transporters in the luminal membrane of cells of the inner MCD (vasopressin phosphorylates and causes the insertion of urea transporters UT-A1 in the luminal membrane of cells in this nephron segment[77]), and a higher concentration of urea in the luminal fluid in the inner MCD than that in the interstitial fluid in the inner medulla. This later requirement is achieved because all the segments of the distal nephron that are upstream to the inner MCD, are likely to be impermeable to urea, but most of the water delivered to the early DCT is reabsorbed in the CCD and MCD owing to the insertion of AQP2 into the luminal membranes of principal cells. The concentration of urea rises to higher than 600 mmol/L in the luminal fluid that is delivered to the inner MCD (Figure 51.6).

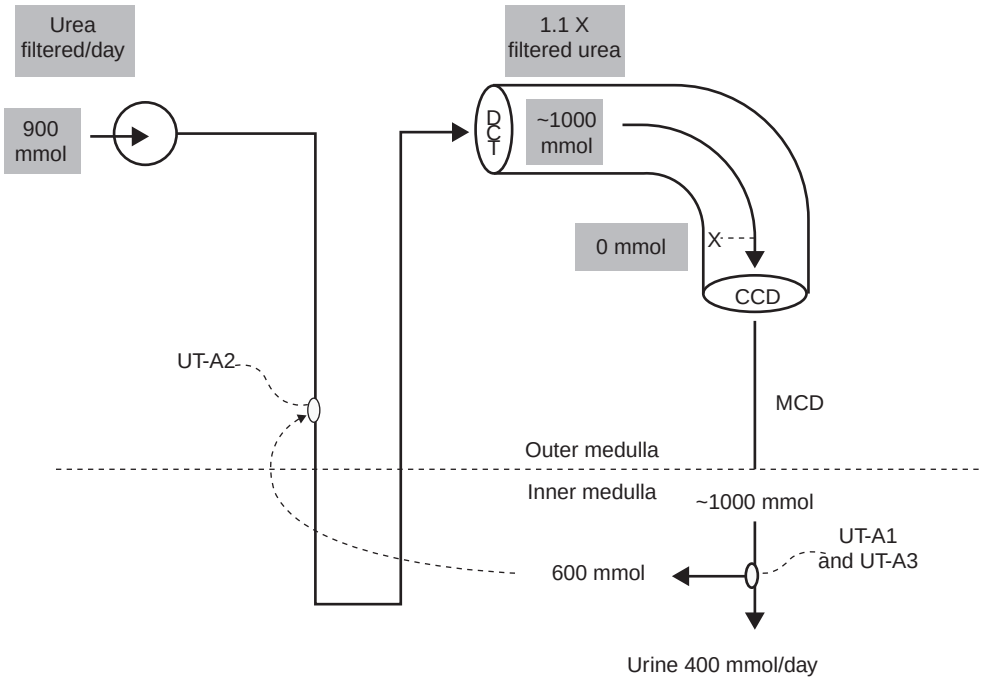

FIGURE 51.6 An overview of intra-renal urea recycling. In micropuncture studies in rats, the amount of urea in luminal fluid in early distal tubule was 1.1 times the amount that was filtered. Extrapolated to adult human with a GFR of 180 L/day and a plasma urea of 5 mmol/L, 1000 mmol of urea would be delivered to early CCD per day. Since ~400 mmol of urea are excreted daily in an adult human subjects who consumes a typical Western diet, then ~600 mmol of urea are reabsorbed down stream from the DCT and recycled back to DCT. Based on the presence of urea transporters, it is likely that the urea is reabsorbed in the inner MCD and added into the luminal fluid in the descending thin limbs of the loop of Henle of superficial nephrons that have their bends deeper in the medulla via UT-A2.

The bulk of the urea that is reabsorbed in the inner MCD leaves the inner medulla via the ascending vasa recta, because it has UT-A2 and, as a result, is permeable to urea. Once in the deep outer medulla, most urea will enter the luminal fluid of the descending thin limbs (DtL) of the loop of Henle of superficial nephrons that have their bends deep in the outer medulla, as they possess the UT-A2 and the concentration of urea is higher in the interstitial compartment than in the luminal fluid of the DtL, which allows for a high rate of delivery of urea to the early DCT.[78,79]

To obtain a quantitative estimate of the amount of urea that is recycled, one needs an estimate of the amount of urea that is delivered to the early DCT and the amount of urea that is excreted in the urine over a given period of time. Since the amount of urea delivered to the early DCT cannot be measured in human subjects, it is essential to use data from experiments using the micropuncture technique in the early DCT in fed rats. In these studies,[80] the amount of urea in the early DCT was 1.1 times the amount of urea that was filtered. Extrapolated to a human adult with a GFR of 180 L/day, and a plasma urea concentration of 5 mmol/L, a reasonable estimate of the daily delivery of urea to the early DCT is approximately 1000 mmol/day. Since subjects eating a typical Western diet excrete close to 400 mmol of urea per day, the amount of urea that recycles would be approximately 600 mmol per day.

Importance of Urea Recycling for the Excretion of K^+

This process of urea recycling adds an extra 2 L to the flow rate in terminal CCD (600 mosmol divided by a luminal fluid osmolality that is equal to that in plasma or ~300 mOsm/L). A reasonable estimate of the number of liters of fluid that exit the terminal CCD per day is close to 5 L (1500 mosmol/day in the terminal CCD (1000 mosmol of urea/day and 500 mosmol/day of electrolytes) divided by 300 mosmol/L). This means, in quantitative terms that 40% of the flow rate in terminal CCD is the result of this process of recycling of urea.

Implications for the Patient with Hyperkalemia

Patients who develop chronic hyperkalemia have a renal defect that is characterized by an inability to

generate a sufficiently large trans-epitheleal (TE) lumen-negative voltage in the CCD to secrete all their daily intake of K^+ while maintaining a normal P_K. These patients, however, will achieve a steady state in which they will excrete all the K^+ they ingest and absorb that is not lost via non-renal routes. To understand how this steady state is achieved, we shall consider how a K^+ load of 70 mmol/day is handled in normal subjects and a patient with an electrical defect that leads to a diminished ability to raise the concentration of K^+ in the lumen of terminal CCD ($[K^+]_{CCD}$) (Figure 51.7).

Normal subjects have a much larger capacity to secrete K^+ in their CCD compared to the usual daily intake of K^+; they excrete most of their daily intake over a relatively short period of time close to noon. This likely reflects an increase in the lumen negative voltage in CCD owing to a larger delivery of $NaHCO_3$ to the CCD at the time of the alkaline tide in urine pH. If a normal subject has a P_K of 4 mmol/L and a TE voltage in the CCD of -61 mvolts, the $[K^+]$ in luminal fluid in CCD would be 10 times the P_K or 40 mmol/L. If this voltage could be maintained while 1-L of fluid exits the CCD, 40 mmol of the 70 mmol of K^+ would be excreted in this time period (approximately five hours). For the next 19-hours, if 4-L of fluid would exit the terminal CCD with a concentration of K^+ of only close to 8 mmol/L, the remaining 30 mmol of K^+ can be excreted to achieve K^+ balance.

Let us now consider a patient who has a large defect that leads to a lumen negative TE voltage in the CCD of only −29.1 mvolts (Table 51.1 and Figure 51.7). At this TE voltage, the K_{CCD}/P_K can rise to a value of only three. At a P_K of 4.7 mmol/L, the $[K^+]_{CCD}$ will be close to 14 mmol/L; hence at the usual flow rate in terminal CCD of 5-L/day, this patient could excrete 70 mmol of K^+ daily and maintain a normal P_K. The point to emphasize is that this precise balance is dependant on intra-renal urea recycling and thereby maintaining the daily flow rate in the terminal CCD of 5-L. Therefore, if this patient were to be put on a protein restricted diet (decrease the number of osmoles of urea in the terminal CCD), a smaller number of liters of fluid will exit the CCD per day and hyperkalemia may develop. To put this in a quantitative perspective, if the number of liters exiting the CCD per day were 4-L instead of 5-L, and if the K_{CCD}/P_K were three, while this patient continued to consume 70 mmol of K^+/day, in steady state, the P_K will need to rise to 5.8 mmol/L to maintain K^+ balance and only if this maximum rate of K^+ secretion is maintained throughout the 24 hours period. To further emphasize this point, consider a patient who may

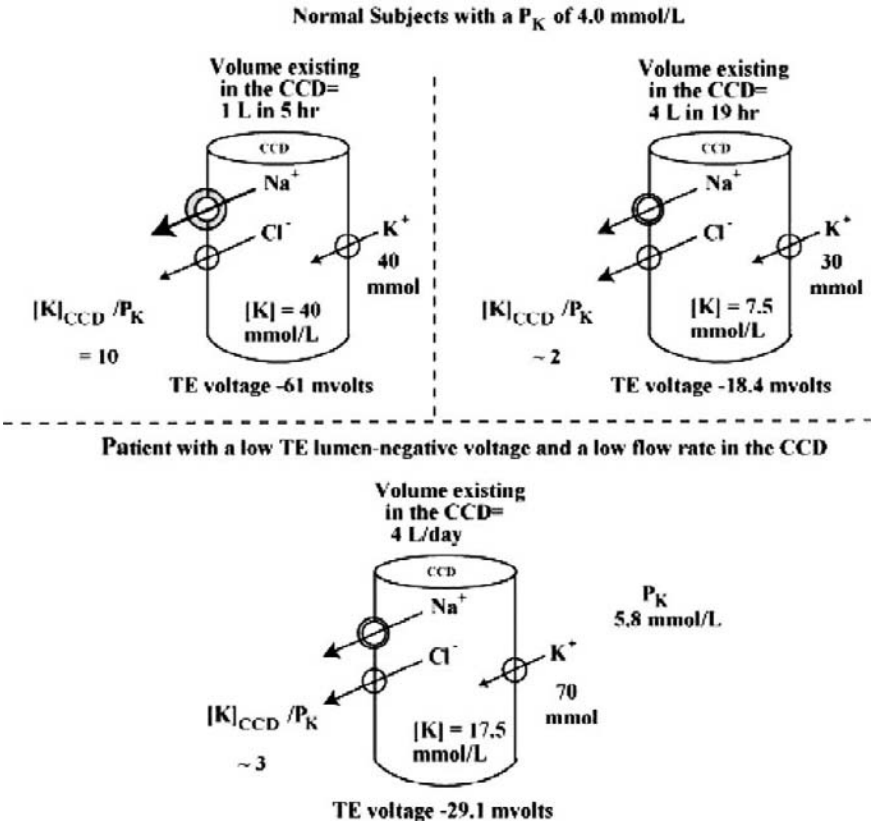

FIGURE 51.7 Excretion of K^+ in normal subjects and in patients with chronic hyperkalemia. The barrel-shaped structures represent the CCD. Over the 24-hour period, both the normal subject and the patient with a low TE voltage reabsorb 70 mmol more Na^+ than Cl^-; and hence excrete 70 mmol of K^+, as they are in balance for K^+. The top portion of the figure describes normal subjects (P_K 4.0 mmol/L). The left section of the top portion illustrates the excretion of K^+ when it is at its usual maximum rate (close to noon) whereas its right portion illustrates this secretory process when K^+ excretion usually declines. In the bottom portion is a patient with a disorder that leads to a lower TE lumen negative voltage in CCD. At TE voltage of −29.1 mvolts, $K^+_{CCD}/P_K = 3$. If the flow rate in terminal CCD declines to 4 L/day, K^+ balance can be maintained but his P_K will rise to 5.8 mmol/L.

TABLE 51.1 Interaction Between the Transepithelial (TE) Voltage, the P_K and Rate of Flow, on the Rate of Secretion in the CCD

TE Voltage (mvolts)	$[K]_{CCD}/P_K$	P_K (mmol/L)	$[K]_{CCD}$ (mmol/L)	Flow Rate$_{CCD}$ (L/day)	$K_{Excretion}$ (mmol/day)
−29.1	3	4.7	14.4	5	70
−29.1	3	5.8	18	4	70
−29.1	3	7.8	24	3	70
−18.4	2	7.2	10	5	70

The $[K^+]_{CCD}/P_K$ is calculated from the TE voltage using the Nernst equation. The numbers are the P_K and the flow rate in terminal CCD per day that are required to achieve a rate of K^+ excretion of approximately 70 mmol/day at a reduced voltage in CCD. Note that even with a large decrease in TE voltage in CCD to −29.1 mvolts, K^+ balance is achieved without a large rise in P_K if the flow rate in terminal CCD is at its usual value of 5 L per day. If the flow rate in terminal CCD were to decrease to 4 L per day, the P_K must rise to 5.8 mmol/L to excrete the daily intake of 70 mmol of K^+ and remain in K^+ balance.

have markedly impaired urea recycling due to a disease that involves the inner medulla (perhaps an example may be a patient with sickle cell disease). This patient may have a flow rate in the terminal CCD that is only 3-L/day rather than 5-L/day. If such a patient has a disease that leads to a reduced ability to generate a high lumen negative TE voltage in the CCD, a more severe degree of hyperkalemia will develop unless K^+ intake is markedly reduced. In quantitative terms, if the TE voltage in the CCD is −29.1 mvolts, the $[K]_{CCD}$ will be three-fold higher than P_K. Therefore, if the volume of filtrate that exits the terminal CCD is only 3-L/day, the P_K would have to be close to 8 mmol/L to excrete 70 mmol of K^+/day.

Integration of the Response to Dietary K^+ Intake: A Paleolithic Perspective

Virtually all our major control mechanisms developed in Paleolithic times; the important ones provided an advantage for survival. There have been no pressures in modern times that have enough control strength to over-ride these control mechanisms. The diet of our most ancient ancestors consisted mainly of fruit and berries; a diet that provides sugar, K^+ and organic anions, but little NaCl. In addition, this intake of K^+ was episodic, but large at times. Therefore, there was a need to have a mechanism in place to rapidly shift K^+ into the liver before it reaches the heart to avoid the risk of cardiac arrhythmia. Furthermore, the renal response needed to be orchestrated to switch from a NaCl conservation mode to a K^+ excretion mode. It is important in this regard to note that aldosterone can be a NaCl retaining or a kaliuretic hormone, in what has been dubbed as the "aldosterone paradox". In more detail, when aldosterone acts, it causes the insertion of a larger number of open ENaC units in the luminal membrane of principal cells in CCD, which permits both NaCl retention or K^+ secretion. Thus, there must be another signal to select one of these possible effects. Of note, the secretagogue for aldosterone is ANG_{II} when its release is in response to a low effective arterial blood volume. On the other hand, a higher P_K directly stimulates the release of aldosterone, however, ANG_{II} in this setting, will be suppressed.

Shift of K^+ into Hepatocytes

While it is well known that there is a rise in the $P_{L\text{-lactate}}$ in portal venous blood after absorption of dietary glucose,[81] the physiological importance of this high $P_{L\text{-lactate}}$ was not evident when viewed solely in metabolic terms. We suggested that a possible function of this high portal $P_{L\text{-lactate}}$ is to prevent hyperkalaemia in hepatic venous blood following the absorption of K^+ from the diet.[21] The process begins by increasing the rate of aerobic glycolysis in enterocytes; as a result of performing more work by intestinal cells and thereby the generation of more ADP, the other substrate (beside glucose) for glycolysis. This extra metabolic work occurs because the sodium linked glucose transporter (SLGT) in this location is SLGT-1. Hence, when 1 mmol of glucose is absorbed, 2 mmol of Na^+ must be absorbed; therefore more ATP will be converted to ADP to absorb a given quantity of glucose.[82] Should glycolysis occur at a faster rate than that of pyruvate oxidation, L-lactate will released into the portal vein. In the liver, the uptake of L-lactic acid on the M-CT could lead to a rise the concentration of H^+ in the sub-membrane region of hepatocytes and hence activation of NHE-1. This electroneutral entry of Na^+ into hepatocytes and its subsequent exit via Na^+/K^+-ATPase in an electrogenic fashion, will lead to a higher negative intracellular voltage and hence the retention of K^+ in hepatocytes. This mechanism requires the presence of insulin,[21] which is released in response to the dietary sugar load with the

ingestion of fruit and berries. Perhaps, because of its effect, to cause the translocation of more Na^+/K^+-ATPase units to the cell surface of hepatocytes, insulin is required for this effect of L-lactic acid to cause a shift of K^+ into hepatocytes.

Integration of the Renal Response to Dietary K^+ Intake

WNK Kinases

Available evidence indicates that this complex network of with-no-lysine kinases (WNKs); WNK4 and WNK1, via effects on NCC and ROMK normally function as a switch to change the aldosterone response of the kidney to either conserve Na^+ or excrete K^+, depending on whether the release of aldosterone is induced by a change in dietary Na^+ or dietary K^+ intake.[83,84]

WNK4 is thought to inhibit NCC activity by reducing its plasma membrane abundance, by diverting post-Golgi NCC to the lysosome for degradation.[85] The expected kaliuresis owing to increased delivery of NaCl to CCD is prevented because WNK4 inhibits ROMK, an effect that involves clathrin-mediated endocytosis.[86,87] SGK-1, when ANG_{II} is suppressed as in conditions of high K^+ intake, phosphorylates WNK4 and reverses its inhibition of ROMK.[88] ANG_{II} has been shown to inhibit ROMK activity in K^+-restricted rats, but not in rats on their usual dietary K^+ intake.[68] The effect of ANG_{II} may be mediated via activating NADPH oxidase II and the production of superoxide anions, which increases the expression of protein tyrosine kinase such as c-Src.[69–71] Src family protein tyrosine kinase phosphorylates ROMK and results in their endocytosis.[89,90] Therefore, ANG_{II} release due to low Na^+ intake or a K^+ restricted diet inhibits ROMK directly via protein tyrosine kinase or indirectly via blocking SGK-1 mediated WNK4 phosphorylation, which restores WNK4 inhibition of ROMK.

ANG_{II} signaling through the ANG_{II} receptor phosphorylates and converts WNK4 from an inhibiting mode to an NCC-activating kinase form. The activating form of WNK4 induces a phosphorylation cascade, whereby WNK4 phosphorylates the intermediary kinases, STE 20/SPS 1-related proline, alanine-rich kinase (SPAK) and perhaps also the oxidative stress responsive protein type 1 (ORS1). Phosphorylated-SPAK/ORS1 in turn phosphorylates and activates NCC.[91] Since the release of aldosterone in states of hypovolemia (or low salt intake) is mediated by ANG_{II}, but not when the stimulus of the release of aldosterone is due to hyperkalemia, this may provide a mechanism to signal the need of actions of aldosterone as a NaCl retaining hormone. In this setting, the effect of ANG_{II} to inhibit ROMK prevents kaliuresis in response to the release of aldosterone and SGK-1. Although SGK-1 phosphorylates WNK4, this does not mimic the stimulatory effects of ANG_{II}.[92] The dual requirement for both SGK-1 and ANG_{II} signaling to switch WNK4 from being an inhibitor to an activator of NCC would provide a mechanism to integrate the effects of high aldosterone and ANG_{II} for appropriate activation of NCC in hypovolemia. It would also explain why high aldosterone and SGK-1 activation induced by a high-K diet does not stimulate NCC transport, in which case ANG_{II} is not elevated.

In response to a large intake of K^+, in the absence of ANG_{II}, WNK4 will be in its NCC inhibiting mode and hence more NaCl will be delivered downstream. Aldosterone, acting via SGK-1, increases the number of open ENaC subunits in the luminal membrane of principal cells in CCD and hence the electrogenic reabsorption of Na^+. Nevertheless, for this result in kaliuresis, ROMK channels in an open configuration must be present in the luminal membrane of principal cells. When ANG_{II} is suppressed, SGK-1 mediated phosphorylation of WNK4 reverses WNK4 effect to inhibit ROMK.

As mentioned above, alternative promoter usage of the WNK1 gene produces a kidney-specific short form of WNK1, called WNK1-S, and a more ubiquitous long form, called WNK1-L.[72] WNK1-L inhibits ROMK by inducing endocytosis of the channel protein; WNK1-S isoform inhibits this effect of WNK1-L. The relative abundance of the WNK1 isoforms is regulated by dietary K^+. The ratio of WNK1-S to WNK1-L transcripts is reduced by K^+ restriction (greater endocytosis of ROMK) and increased by K^+ loading (reduced endocytosis of ROMK).[74,75] WNK1-L up-regulates NCC by blocking the inhibitory form of WNK4 or directly via phosphorylation of SPAK/ORS1.[93] WNK1-L has also been reported to activate SGK-1 through PI3 kinase.[94] WNK1-S, on the other hand, antagonizes the effects of WNK1-L and therefore indirectly inhibits NCC.

Modulation by the Delivery of HCO_3^- to the CCD

An increased delivery of HCO_3^- and/or a rise in the pH of luminal fluid in CCD may provide a signal to augment the secretion of K^+.[62,95] The effect may be due to a decrease in the electroneutral component of Na^+ reabsorption in the CCD, which would increase the magnitude of the luminal negative voltage, if accompanied by an increase in electrogenic Na^+ reabsorption. Alternatively, or in addition, luminal alkalinization may increase the number of open ROMK in the luminal membrane of principal cells in the CCD.

In Paleolithic times, the major source of dietary K^+ was from fruit and berries. The anions ingested along with this K^+ were a family of organic anions that can be metabolized to neutral end products plus HCO_3^-. In addition, a higher P_K is associated with alkalinization in the cells of the proximal convoluted tubule (PCT), which leads to inhibition of the reabsorption of HCO_3^-.[96] The end result is the delivery of more HCO_3^- to the CCD, which promotes aldosterone to exert its kaliuretic effect.[97] On the other hand, ANG_{II}, which mediates the release of aldosterone in response to decreased effective circulating volume, is a potent activator of Na^+/H^+ exchanger-3 (NHE-3) and the reabsorption of HCO_3^- in the cells of the PCT.[98] Therefore, there will be diminished delivery of HCO_3^- to the CCD, which will allow for more electroneutral rather than electrogenic reabsorption of Na^+ in this nephron segment and hence more NaCl retention and less kaliuresis.[97]

Medullary Recycling of K^+

The Paleolithic diet provided little NaCl. Nevertheless, there is a need to deliver one mmol of Na^+ to the CCD to secrete one mmol of K^+. Therefore, there must be a mechanism to increase the delivery of Na^+ to the CCD when there is a need to excrete a large K^+ load. Notwithstanding, it is also essential to minimize the excretion of Na^+ and Cl^- to stay in salt balance.

To increase distal delivery of Na^+, the kidney must make an investment.[99] By this we mean that, the kidney must reabsorb some of the $KHCO_3$ delivered to the MCD to increase the medullary interstitial concentration of K^+.[100,101] While it may seem counter-productive to have active reabsorption of K^+, when a high rate of excretion is needed, this process in fact increases the rate of excretion of K^+ by increasing the distal delivery of Na^+. In more detail, a rise in the medullary interstitial concentration of K^+ will lead to depolarization of cells of the medullary thick ascending limb of the loop of Henle. This will diminish the exit of Cl^- from these cells, as this is an electrogenic process, which carries a negative charge out of the cell. The subsequent increase in intracellular Cl^- concentration inhibits the reabsorption on Na and Cl in the medullary thick ascending limb of the loop of Henle and hence increases their delivery to the distal nephron.[102] This reabsorption of $KHCO_3$ could be achieved via the K^+/H^+-ATPase, which is likely to be present in the luminal membrane of cells in the MCD because of a prior state of depletion of K^+ before the large intake of K^+ occurred.[103] As the rise in P_K is sustained, there will be less K^+/H^+-ATPase units in the luminal membrane of MCD cells. Hence, the medullary interstitial concentration of K^+ will fall and a large natriuresis is avoided.

Intra-Renal Urea Recycling

The second source of dietary K^+ is from ingestion of animal organs (e.g., muscle and liver, which are rich in RNA). The principal anions that accompany this K^+ load are organic phosphates (which are ultimately metabolized to inorganic monovalent phosphate ($H_2PO_4^-$)) or sulfate anions. The key point here, is that unlike HCO_3^-, $H_2PO_4^-$ and sulfate anions do not augment the secretion of K^+ unless the concentration of Cl^- in luminal fluid in the CCD is very low.[57] There is, however, a symbiotic relationship with another constituent in the diet, protein, because when its constituent amino acids are oxidized, urea is produced.[104] The process of urea recycling aids the excretion of K^+ because it increases the number of liters of fluid that exit the terminal CCD.[76] Owing to the process of urea recycling, as calculated above, the flow rate in terminal CCD is increased by about 2-L per day.

CLINICAL TOOLS TO ASSESS THE CONTROL OF THE RENAL EXCRETION OF K^+

Examine the Rate of Excretion of K^+: There is no normal rate of K^+ excretion. Normal subjects in steady state excrete all the K^+ they eat and absorb from the GI tract. Therefore to assess the renal response in a patient with hyperkalemia, we use the expected rate of K^+ excretion in normal subjects who were given a K^+ load; these subjects could augment their rate of excretion of K^+ to greater than 200 mmol/day—this was achieved with only a minor increase in P_K.[46,105] Notwithstanding, to develop chronic hyperkalemia, there must be a defect in the renal excretion of K^+. Nevertheless, in the steady state, these patients will excrete all the K^+ they ingest and absorb that is not lost via non-renal routes. Therefore, a patient with chronic hyperkalemia and a rate of excretion of K^+ that is higher than the 'usual', has a defect in renal K^+ excretion; in addition, a large K^+ intake contributes to the degree of hyperkalemia in this patient.

To assess the rate of excretion of K^+, a 24-hr urine collection is not necessary. One can use the ratio of the concentrations of K^+ and creatinine in a spot urine sample ($U_K/U_{Creatinine}$) despite the diurnal variation in K^+ excretion.[95] This analysis is predicated on the fact that creatinine is excreted at a near-constant rate throughout the day.[106] Moreover, a $U_K/U_{Creatinine}$ in spot urines provides more relevant information because the stimulus to drive K^+ excretion (e.g., P_K) can be known at that time. The expected value in a patient with hyperkalemia is >20 mmol K^+/mmol creatinine (>200 mmol K^+/g creatinine).

The Transtubular K^+ Concentration Gradient (TTKG)

The TTKG was developed to provide a semi-quantitative reflection of the driving force to secrete K^+ in the CCD.[107,108] The lynch pin in this calculation was to adjust the concentration of K^+ in the urine (U_K) for the amount of water that is reabsorbed in downstream nephron segments (i.e., the MCD) to estimate the concentration of K^+ in the luminal fluid in the terminal CCD ($[K_{CCD}]$). To calculate the $[K_{CCD}]$, one divides the U_K by the ratio of urine osmolality (U_{Osm}) to the plasma osmolality (P_{Osm}) (i.e., U_{Osm}/P_{Osm}), as the P_{Osm} should be equal to the osmolality in the luminal fluid in the terminal CCD when vasopressin acts and AQP2 are present in the luminal membranes of the CCD.

The assumption made when using the U_{Osm}/P_{Osm} ratio to adjust for the amount of water that was reabsorbed in the MCD is that the majority of the osmoles delivered to the MCD were not reabsorbed in this nephron segment.[95] While, in the absence of a marked degree of contraction of the effective circulating volume, the amount of electrolytes reabsorbed in the MCD should not pose a problem, this is, however, not true for urea because of intra-renal urea recycling.[76] As estimated above, $\approx$600 mmol of urea are reabsorbed downstream from CCD per day. Therefore, the calculated $[K^+]_{CCD}$ obtained from $U_K/(U_{Osm}/P_{Osm})$ is likely to be appreciably higher than the actual value *in vivo* (same amount of K^+ but a larger volume of water in the terminal CCD). While adjustments in the calculation of the TTKG can be made to account for this error in subjects in whom the rate of excretion of urea is close to the usual (400 mmol/day), if the rate of excretion of urea deviates appreciably from its usual rate of excretion, one does not know the amount of urea that is recycled relative to the amount that is excreted, and hence an adjustment in the calculation to estimate $[K^+]_{CCD}$ is not possible. Furthermore, other factors may affect this process of urea recycling (e.g., vasopressin, ANG_{II}) which further complicates the interpretation of the TTKG. Therefore, we do not use the TTKG in the clinical assessment of patients with a dyskalemia, we think the $U_K/U_{Creatinine}$ provides the clinician with the information needed to assess the renal response in these patients.

CLINICAL APPROACH TO THE PATIENT WITH HYPERKALEMIA

A list of causes of hyperkalemia is provided in Table 51.2. The steps in the clinical approach to the patient with hyperkalemia are illustrated in Flow Charts 51.1–51.3.

Address Emergencies

It is imperative to recognize when hyperkalemia represents a medical emergency because therapy must take precedence over diagnosis. One must also anticipate the dangers associated with each mode of therapy and take steps to prevent them from occurring.

Hyperkalemia constitutes a medical emergency, primarily due to its effect on the heart.[109–111] To understand the effects of hyperkalemia on cardiac myocytes, we start from phase 4 of the action potential, the resting phase (associated with diastole). Since the cell membrane is most permeable to K^+ and relatively impermeable to other ions during this phase of action potential, the resting membrane potential (RMP) is determined by the K^+ equilibrium potential across the

TABLE 51.2 Causes of Hyperkalemia

- High intake of K^+
  - Only if combined with low excretion of K^+
- Shift of K^+ out of cells
  - Tissue breakdown (e.g., rhabdomyolsis), exhaustive exercise
  - Na/K-ATPase problem
    - Tissue hypoxia
    - Lack of a stimulus (e.g., inhibition of insulin release by α–adrenergic surge, use of non selective ß-blockers (small effect if only factor))
    - Inhibition of Na/K-ATPase (e.g., by drugs e.g., digoxin)
  - α-adrenergic surge
  - Hyperosmolality (e.g., administration of mannitol)
  - Metabolic acidosis due to acids that can not be transported on the nonocarboxylic acid cotransprter (e.g., HCl , citric acid)
  - Increase K^+ efflux from cells (administration of succinylcholine, floride intoxication)
  - Rare causes (e.g., hyperkalemic periodic paralysis)
- Diminished K^+ loss in the urine
  - Advanced chronic renal insufficiency
  - Low $[K^+]_{CCD}$ (diminished electrogenic reabsorption of Na^+ in the CCD)
    - Primary decrease in flux of Na^+ through ENaC
      - Very low delivery of Na^+ to the CCD
      - Low levels of aldosterone (e.g., Addison's disease,
      - Blockade of the aldosterone receptor (e.g., spironolactone)
      - Low ENaC activity (Type I pesudohypoaldosteronism)
      - Blockade of ENaC (e.g., amiloride, triamterene, trimethoprim-like drugs)
    - Cl^- reabsorbed at a similar rate as Na^+
      - Increased reabsorption of Na^+ and Cl^- in the distal convoluted tubule (e.g., Familial Hypertension with Hyperkalemia (WNK 4 or WNK1 mutations), drugs (e.g., calcineurin inhibitors), some patients with diabetic nephropathy and hyporeninemic hypoaldosteronism).
      - Increased electroneutral reabsorption of Na^+ and Cl^- in CCD due to Cl^- shunt in the CCD or parallel activity of the Cl/HCO_3 exchanger (pendrin) and the Na dependent Cl/HCO_3 exchanger (NDCBE) (e.g., some of the causes of hyporeninemic hypoaldosteronism)

FLOW CHART 51.1

INITIAL STEPS IN THE PATIENT WITH HYPERKALEMIA

The initial step in the clinical approach to the patient with hyperkalemia is to determine if there is an emergency that demands urgent therapy.

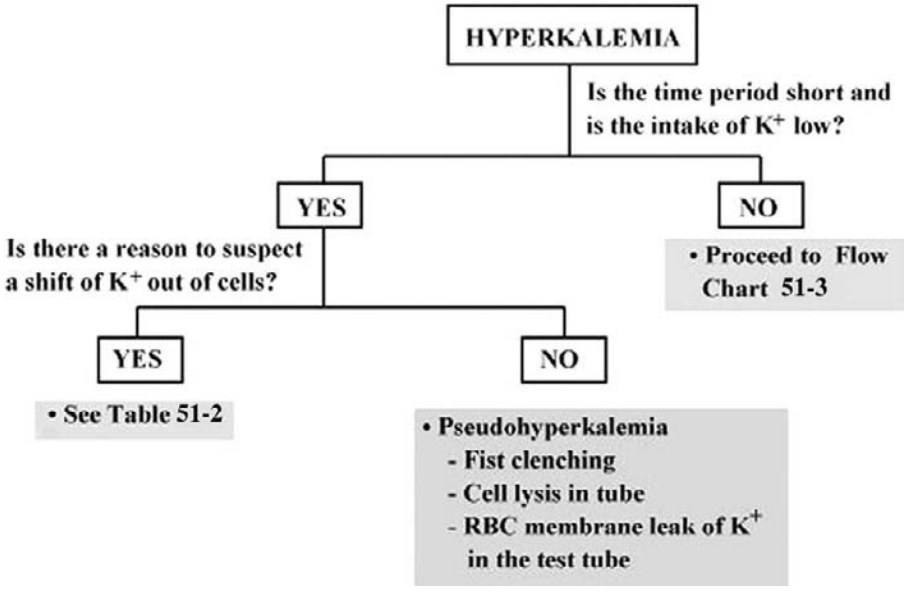
FLOW CHART 51.2

DETERMINE IF THERE IS A SHIFT OF K^+ OUT OF CELLS

Determine if a shift of K^+ out of cells is likely by assessing the time course for the rise in the P_K and whether there was little intake of K^+. If there is no reason to suspect a shift of K^+ out of cells, pseudohyperkalemia should be ruled out.
Source: Reproduced with permission (224).

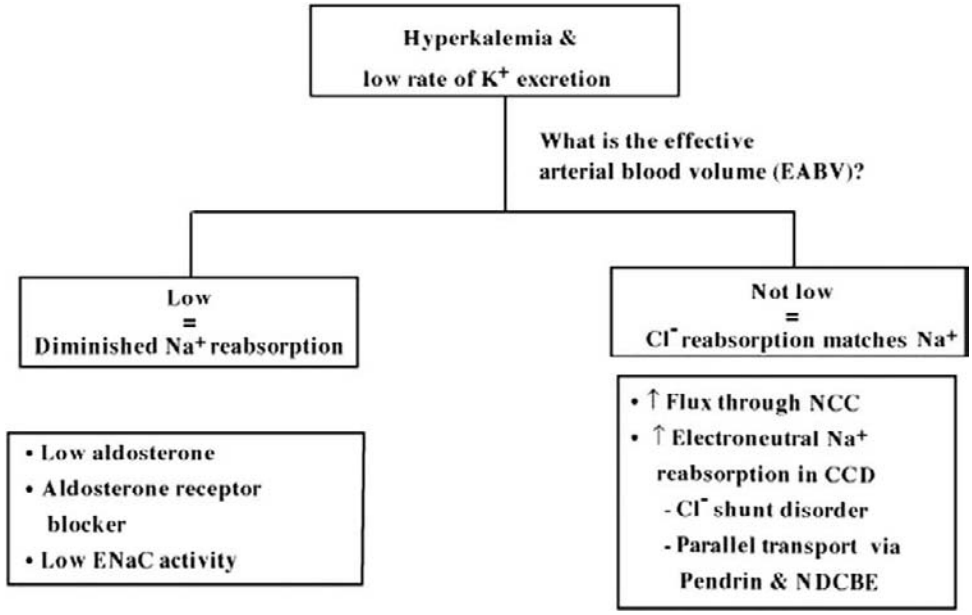


cell membrane. During hyperkalemia, the ratio of K_{in} to K_{out} will be reduced, the RMP will become less negative (i.e., the cell membrane will become depolarized). Stage 0 of action potential is the rapid depolarization phase. This phase is due to opening of the fast Na^+ channels causing a rapid increase in membrane conductance to Na^+ and thus a rapid influx of Na^+ ions into cells. The magnitude of Na^+ inward current

FLOW CHART 51.3

BASIS FOR THE LOW RATE OF EXCRETION OF K^+

Patients with chronic hyperkalemia can be divided into two groups based on their effective arterial blood volume. In this analysis, we assumed that there is an adequate distal delivery of Na^+.



determines the rate of rise of action potential upstroke (Vmax), which determines the speed of impulse propagation. The ability of the cell to open the fast Na^+ channels during phase 0 is related to the membrane potential at the onset of depolarization. If RMP is less negative, fewer Na^+ channels become activated during depolarization, thus the magnitude of the inward Na^+ current and the V_{max} of the action potential diminishes. The decrease in V_{max} results in a reduction in myocardial conduction, with progressive prolongation of the P wave, PR interval, and QRS complex. V_{max} is greatest when RMP is about -75 mV, RMP that is associated with 50% reduction in V_{max} is -65 mV (a rise in plasma K from 4–5 mmol/L to 8–10 mmol/L).

The rapid delayed rectifier K channel (I_{Kr}) is mostly responsible for the efflux of K^+ seen during phase 3 of the cardiac action potential; the rapid repolarization phase. For reasons that are not well understood, the I_{Kr} current is sensitive to extracellular K^+ levels; as extracellular K^+ rises, K^+ conductance through these channels increases, so that more K^+ leave the myocytes in a given time period. This leads to shortening of the repolarization time, which is thought to be responsible for some of the electrocardiographic manifestations observed with a modest degree of hyperkalemia such as ST-T segment depression, peaked T waves and QT shortening.

The earliest ECG manifestations of hyperkalemia include the appearance of narrow based, peaked "tent shaped" symmetrical T waves. These T waves are of relatively short duration, which help distinguish them from the broad T waves typically seen in patients with myocardial infarction or intra-cerebral accidents.[112] Peaked T waves are usually seen at K^+ concentration of >5.5 mM.

As serum K^+ increases to >6.5 mM, the manifestations of slow cardiac conduction become apparent: broad flat P wave (delayed sino-atrial conduction), prolonged PR interval (delayed atrioventricular conduction), wide QRS complex (delayed intra-ventricular conduction). The QRS complex may take the appearance of right or left bundle branch block. A clue that these electrocardiographic changes are due to hyperkalemia and not bundle branch disease is that in hyperkalemia the conduction delay persists throughout the QRS complex and not just in the initial portion (as in left bundle branch block) or in the terminal portion (as in right bundle branch block). Also, the width of T wave is close to that of QRS complex. In intraventricular conduction abnormalities due to other

causes or in ventricular ectopic rhythm, the T wave is much wider than the QRS complex.

As K^+ levels reach 8–9 mmol/L, there are absent P waves indicating atrial arrest. The QRS complex continues to widen and eventually blends with the T wave producing the classical sine wave. The SA node may continue to stimulate the ventricle without evidence of atrial electrical activity producing a sino-ventricular rhythm. As hyperkalemia worsens and the K^+ level reaches 10 mEq/L, sino-ventricular conduction no longer occurs, ventricular fibrillation and asystole are imminent.

It is important to note that this correlation between the absolute level of P_K and the ECG changes is based largely on experiments with the acute infusion of K^+ in animals. There is large variability among patients in the absolute P_K leading to ECG changes and cardiac toxicity of hyperkalemia.[113] Variables include the rapidity of the onset of hyperkalemia,[111,114] underlying cardiac disease, and the presence or absence of hypocalcemia, acidemia, and/or hyponatremia. In a retrospective review of the frequency of ECG changes in patients with hyperkalemia,[115] the ECG had poor sensitivity for diagnosing hyperkalemia, with only 55% of patients with plasma K^+ >6.8 mmol/L manifested peaked T waves. Notwithstanding, 14 out of 90 patients in this case series developed cardiac arrhythmia or cardiac arrest, a number of them did not have any ECG changes on their initial presentation. Therefore, it is our view that severe hyperkalemia, i.e., P_K >7.0 mmol/L should be treated as an emergency with maneuvers to induce a shift of K^+ into cells; even in the absence of ECG changes, and perhaps at even lower P_K (e.g., >6.5 mmol/L) in the presence of hypocalcemia, acidemia and/or hyponatremia.

Determine if the Cause of the Hyperkalemia is a Shift of K^+ out of Cells *In Vivo* or *In Vitro*

Is the time period short and/or has the intake of K^+ been low?

If the answer is yes, there are three options to consider:

There Is Destruction of Cells in the Body

In this case, the diagnosis is usually obvious (e.g., crush injury).

There Is a Shift of K^+ out of Cells in the Body

This may occur in conditions in which there is a less negative voltage in cells. This may be due to tissue hypoxia affecting the Na-K-ATPase (conditions causing hypoxic lactic acidosis), lack of a stimulus for Na-K-ATPase (e.g., lack of insulin in patients with diabetic ketoacidosis, α-adrenergic surge causing inhibition of the release of insulin or directly causing a shift of K^+ out of cells, β_2-adrenergic blockade especially under conditions of α-adrenergic surge). A shift of K^+ may also occur in conditions of metabolic acidosis due to non- monocarboxylic acids, i.e., acids that can not be transported on M-CT (e.g., metabolic acidosis due to a gain of HCl acid owing to loss of $NaHCO_3$ in a patient with diarrhea, ingestion of citric acid[35]). Digoxin inhibits Na-K-ATPase, digoxin overdose can result in hyperkalemia.[116] Bufadienolide, a structurally similar glycoside, is present in high concentration in the skin and venom gland of the toad *Bufo marinus*. The ingestion of such toads or their extracts can result in fatal hyperkalemia.[117] Several cases of hyperkalemia have been reported after the ingestion of certain herbal aphrodisiac pills containing large amounts of toad venom. The stems, leaves, flowers and roots of yellow oleander contain high concentration of cardiac glycosides, ingestion of yellow oleando for deliberate self-harm has been reported especially in South Asia.[118] Acute hyperkalemia may occur during exhaustive exercise or status epilepticus.[119] Severe hyperkalemia has been described as a complication of the administration of mannitol for the treatment or prevention of cerebral edema.[120,121] Succinylcholine depolarizes muscle cells, resulting in the efflux of K^+ through acetylcholine receptors in conditions that may lead to up-regulation of acetylcholine receptors.[122] Floride can open the Ca^{2+} sensitive K^+ channel,[123] floride intoxication can lead to fatal hyperkalemia.[124] A positive family history for acute hyperkalemia suggests that there may be a molecular basis for this disorder (e.g., hyperkalemic periodic paralysis).

Pseudohyperkalemia May Be Present

Pseudohyperkalemia is caused by the release of K^+ during or after venipuncture.[125] Excessive fist clenching during blood sampling may increase K^+ release from local muscle and thus raise the measured P_K.[126,127] Pseudohyperkalemia can be present in cachectic patients because the normal T-tubule architecture in skeletal muscle may be disturbed. This permits more K^+ to be released into venous blood, even without excessive fist clenching during blood sampling. Thrombocytosis (especially megakaryocytosis),[128] leukocytosis (especially due fragile leukemia cells)[129,130] and/or erythrocytosis may cause pseudohyperkalemia due to release of K^+ from cells.[131,132] Cooling of blood prior to the separation of cells from plasma is a recognized cause of pseudohyperkalemia.[133] There are several hereditary subtypes of pseudohyperkalemia, caused by an increase in the passive K^+ permeability of erythrocytes. The P_K increases in blood samples from these patients that have been left at room temperature. Interestingly, eleven pedigrees of

patients with autosomal dominant hemolysis and pseudohyperkalemia were found to have single point mutations in the anion exchanger, AE1.[134] These mutations reduce anion transport in red cells and convert AE1 to a non-selective cation channel.

Is the Rate of Excretion of K^+ High Enough in a Patient with Hyperkalemia?

In a patient with chronic hyperkalemia, pseudohyperkalemia should be first ruled out. To assess the renal response in a patient with hyperkalemia, we use the expected rate of K^+ excretion in normal subjects who were given a K^+ load; these subjects could augment their rate of excretion of K^+ to greater than 200 mmol/day—this was achieved with only a minor increase in P_K.[46,105] Patients with chronic hyperkalemia have a defect in K^+ excretion (i.e., they excrete much less than 200 mmol K^+/g creatinine or 20 mmol K^+/mmol creatinine in their urine).

In a Patient with Chronic Hyperkalemia, Determine the Basis for the Low $U_K/U_{Creatinine}$

There are two possible mechanisms for a lower than expected U_K/U_{Cr} in a patient with hyperkalemia. First, the most common mechanism is a less negative voltage in the lumen of the CCD due to a lower rate of electrogenic reabsorption of Na^+ in the CCD (Figure 51.5). Second, even if a lumen-negative voltage could be generated, the secretion of K^+ might still be low if there were too few ROMK channels with a high open-probability in the luminal membrane of the CCD. While no diseases have been directly attributed to this pathophysiology, we must still include it in the differential diagnosis.

There are two major categories of disorders that lead to a low lumen-negative voltage in CCD: Disorders that lead to a diminished rate of reabsorption of Na^+ via ENaC, and disorders that lead to reabsorption of Na^+ and of Cl^- in CCD occurring at near equal rates.

Diminished Reabsorption of Na^+ via ENaC in the CCD

The first subgroup with this pathophysiology consists of patients who have a marked decrease in the effective arterial blood volume; these patients may have a sufficiently very low delivery of Na^+ to the CCD to limit the rate of secretion of K^+. The hallmark for this diagnosis is the excretion of urine with a very low concentration of Na^+. The second subgroup consists of patients who have lesions that lead to a diminished number of open ENaC units in the luminal membrane of principal cells in the CCD. Accordingly, the reabsorption of Na^+ cannot occur at high enough rate to generate a large lumen-negative voltage in the CCD. The basis of this lower rate of reabsorption of Na^+ includes low $P_{Aldosterone}$ levels (e.g., adrenal insufficiency), blockade of the aldosterone receptor in principal cells, molecular defects that diminish the number of ENaC units in the luminal membrane of the CCD, the presence of cationic compounds in the lumen of the CCD that block ENaC (e.g., the use of the potassium-sparing diuretics amiloride or triamterene or cationic antimicrobial agents such as trimethoprim). These patients have a low effective arterial blood volume and a higher than expected rate of excretion of Na^+ and Cl^- in the presence of a low effective arterial blood volume, and a high $P_{Renin\ mass}$ (with the exception of the patients with hyporenenimic hypoaldosteronism due to decreased production of renin). The $P_{Aldosterone}$ is helpful to determine the reason for the diminished Na^+ reabsorption via ENaC in the CCD.

Reabsorption of Na^+ and Cl^- at Near-Equal Rates in the CCD

In one subgroup of patients with this pathophysiology, the site of the lesion might be in the early DCT where there is enhanced electroneutral reabsorption of Na^+ and Cl^- via NCC. Accordingly, the delivery of Na^+ and Cl^- to the CCD is not sufficiently large to permit the rate of reabsorption of Na^+ to exceed the rate of reabsorption of Cl^- in the CCD by an appreciable amount. In addition, there is a diminished number of open ENaC units in the luminal membranes of principal cells in CCD because of the suppression of release of aldosterone by an expanded effective arterial blood volume. These patients are expected to have a rise in K^+ excretion with the administration of a thiazide type diuretic.

In another subgroup of patients, the defect might be due to enhanced electroneutral reabsorption of NaCl in CCD. The term "chloride shunt disorder" has been coined to describe this pathophysiology, implying that perhaps there is increased permeability for Cl^- through the paracellular pathway.[135] Given the large concentration difference for Cl^- and the relatively small transepithelial voltage difference, if there were increased paracellular permeability for Cl^-, perhaps the movement of Cl^- would be into instead of out of the lumen of the CCD. The defect could also be one of increased electroneutral reabsorption of NaCl by the parallel activity of the Na^+-dependent Cl^-/HCO_3^- exchanger (NDCBE) and the Na^+ independent Cl^-/HCO_3^- exchanger; pendrin.[60] Nevertheless, this transport mechanism has been detected in the cortical collecting duct; to play a role in modulation of K^+ secretion it needs to be expressed in the late

distal tubule and/or the connecting segment. Patients with this pathophysiology of enhanced electroneutral reabsorption of NaCl in the CCD, are expected to have a rise in K^+ excretion with increasing the delivery of HCO_3^- to CCD, e.g., induced with administration of acetazolamide.

SPECIFIC CAUSES OF HYPERKALEMIA

A list of the causes of hyperkalemia based on their possible underlying pathophysiology is provided in Table 51.2 and a list of drugs that may cause hyperkalemia is shown in Table 51.3.

Chronic Renal Insufficiency

Hyperkalemia occurs frequently in patients with advanced, chronic kidney disease and it is due to a diminished ability to excrete K^+. There are two major reasons that lead to a diminished rate of excretion of K^+. First, decreased flow rate in the terminal CCD. In more detail, flow rate in terminal CCD is directly related to the number of luminal osmoles in the lumen of terminal CCD when vasopressin acts.[95] The major osmoles in terminal CCD are urea and $Na^+ + Cl^-$. The number of osmoles of $Na^+ + Cl^-$ in the terminal CCD may be diminished because of dietary salt restriction and/or the use of diuretics that may induce decreased effective arterial blood volume. The number of urea osmoles in the terminal CCD may be decreased because of dietary protein restriction and also diminished intra-renal urea recycling owing to medullary interstitial disease involving the inner MCD. The second reason for diminished rate of excretion of K^+, is a low $[K^+]_{CCD}$. Two factors may contribute to this low $[K^+]_{CCD}$. Although the flow rate in the CCD may be decreased, as there is a very large reduction in the number of residual functioning nephrons in these patients, the flow rate through each remaining CCD segment may be very high. When the flow rate per CCD is high, the ability to reabsorb more Na^+ than Cl^- in the CCD is diminished and the lumen-negative voltage may not be high enough to raise the $[K^+]_{CCD}$ sufficiently. In addition, these patients may be taking drugs that compromise the ability to excrete K^+. Prominent on the list are drugs that diminish the secretion of aldosterone (ACE-inhibitors or angiotensin II receptor blockers) and aldosterone receptor blockers (e.g., spironolactone). The degree of hyperkalemia will obviously be more severe when the intake of K^+ is particularly high, due for example to the intake of salt substitutes that contain KCl or the ingestion of a large volume of fruit juice.[136]

TABLE 51.3 Drugs that can Cause Hyperkalemia

- **Drugs containing K** (only increase P_K if K^+ excretion is compromised)
  - KCl tablets, salt substitutes
- **Drugs causing a K shift from ICF to ECF**
  - Cell depolarizers such as succinylcholine
  - Drugs that inhibit Na/K ATPase e.g., digitalis overdose
  - Chemotherapy causing tumor lysis
  - Drugs impairing insulin release from β-cells such as α-adrenergic agonists, octreiode
  - β_2-adrenergic receptor blockers
- **Drugs which interfere with K excretion in the urine:**
  - Drugs that cause acute renal failure or interstitial nephritis
  - Drugs that inhibit the release of renin e.g., NSAIDs
  - Drugs that inhibit the release of aldosterone (e.g., heparin)
  - Drugs that interfere with the renin- ANG_{II} axis (e.g., direct renin blockers, converting enzyme inhibitors and ANG_{II} receptor blockers)
  - Aldosterone receptor blockers (e.g., spironolactone)
  - Drugs that block ENaC in the CCD (e.g., amiloride, trimethoprim)
  - Drugs the interfere with activation of ENaC via proteolytic cleavage (e.g., nafamostat mesylate)

Addison's Disease[137]

The most common cause of this disorder used to be bilateral adrenal destruction due to tuberculosis, but now autoimmune disease either as an isolated disorder or as part of polyglandular endocrinopathy accounts for the majority of cases.[138] HIV is now the most important infectious cause of adrenal insufficiency,[139] with CMV the most likely cause in this setting. Nevertheless, the list includes other infectious diseases including disseminated fungal infections. Additional causes of Addison's disease include adrenal infiltration by amyloidosis, metastatic carcinoma or lymphoma, adrenal hemorrhage or infarction, as may occur in patients with the anti-phospholipid antibody syndrome,[140] and drugs that impair the synthesis of aldosterone (e.g. heparin, ketoconazole[141] and possibly fluconazole).

Patients with chronic primary adrenal insufficiency may present with chronic malaise, fatigue, anorexia, generalized weakness, and weight loss. Salt craving is a distinctive feature in some patients. Hyperpigmentation is evident in nearly all patients. In most patients, the blood pressure is low and postural symptoms of dizziness and syncope are common. The P_K is usually close to 5.5 mmol/L, unless a significant degree of intravascular volume depletion diminishes the flow rate in CCD, leading to a more severe degree of hyperkalemia. Nevertheless, hyperkalemia is not seen on presentation in approximately one third of the cases.[142] The absence of hyperkalemia in such a large percentage of patients is probably due to a low dietary K^+ intake. Other possible abnormal laboratory findings

include hyponatremia, hyperchloremic metabolic acidosis, hypoglycemia, and eosinophilia. Some patients may present with acute adrenal crisis and shock.

The diagnosis can be established by finding a low $P_{Aldosterone}$ and $P_{Cortisol}$, high $P_{Renin\ mass}$, and a blunted cortisol response to the administration of ACTH.

Adrenal crisis is an emergency that requires immediate restoration of the intravascular volume with administration of intravenous saline and correction of the cortisol deficiency with the administration of dexamethasone or hydrocortisone. Beware of raising the P_{Na} too rapidly if hyponatremia is present because of the risk of osmotic demyelination in a catabolic patient.[143] The administration of cortisol can lead, indirectly, to a fall in the circulating level of vasopressin.[144] We prefer to give dDAVP at the outset of therapy to avoid a large water diuresis that could result in a sudden and excessive rise in the P_{Na}.

Patients with chronic adrenal insufficiency should receive replacement therapy with both a glucocorticoid and a mineralocorticoid. For the former, 25 mg of hydrocortisone (15 mg in the morning and 10 mg in the afternoon) is usually given. For mineralocorticoid replacement, fludrocortisone in a single dose of 50 to 200 μg is usually used. Dose adjustments are made based on patients' symptoms, ECF volume status, the blood pressure and the P_K.

Hyperkalemia Due to Inherited Disorders of Aldosterone Biosynthesis

The inherited enzymes deficiency involved in aldosterone biosynthesis include 21-hydroxylase, 3-hydroxysteroid dehydrogenase, cholesterol desmolase and aldosterone-synthetase deficiency. Except for aldosterone-synthetase deficiency, the other three disorders (also called congenital adrenal hyperplasia) are combined with glucocorticoid deficiency because the cortisol biosynthesis is also affected in these three disorders.[145] Salt wasting, hyponatremia, hyperkalemia and hypotension are common features. Among them, 21-hydrolyase deficiency is the most common, and more easily recognized in affected females who usually have masculine-type genitalia at birth due to excess secretion of fetal adrenal androgen. The diagnosis is confirmed by the findings of elevated serum 17-hydroxyprogesterone, the substrate for the absent enzyme. Patients with 3-hydroxysteroid dehydrogenase and cholesterol desmolase deficiency usually have the signs of sex steroid deficiency, which distinguishes them from patients with 21-hydrolyase deficiency who have manifestations of androgen excess. In patients with aldosterone-synthetase defects, aldosterone synthesis is decreased but corticosterone secretion is enhanced and its concentration in serum is elevated. Aldosterone-synthetase defects can be divided into two types: Type I corticosterone methyl oxidase (COMI) defect and type II corticosterone methyl oxidase (COMII) defect.[146] Serum 18-hydroxycorticosterone is deficient in patients with COMI defect, but increased in patients with COMII defect.

Pseudohypoaldosteronism Type I

The underlying pathophysiology in patients with pseudohypoaldosteronism type 1 (PHA-1) resembles "closed" ENaC in the luminal membrane of principal cells in the CCD. There are two different forms of this disorder with two different modes of inheritance.

Autosomal Dominant Disorder: This is due to loss of function mutations involving the mineralocorticoid receptor.[147] The clinical disorder is usually mild and often remits with time.

Autosomal Recessive Form: This results from various mutations involving all the three subunits of ENaC.[148] Unlike the autosomal dominant form of PHA-1, the disease is permanent, and does not improve in adulthood. Patients usually present in the neonatal period with renal salt wasting, hyperkalemia, metabolic acidosis, failure to thrive, and weight loss. ENaC activity is also impaired in the lung and this leads to excessive airway fluid and recurrent lower respiratory tract infections.

Patients fail to respond to exogenous mineralocorticoids and their $P_{Aldosterone}$ and $P_{Renin\ activity}$ are markedly elevated. Treatment includes supplementation with NaCl and inducing the loss of K^+ through the GI tract. Dialysis may be required for treatment of life-threatening hyperkalemia.

Syndrome of Hyporeninemic Hypoaldosteronism

Patients with this syndrome represent a heterogeneous group with regard to the pathophysiology of their disorder.

A Group with Low Capability of Producing Rennin: The basis of this group of disorders may be destruction of, or a biosynthetic defect in the juxtaglomerular apparatus, that leads to a low $P_{Renin\ mass}$ and thereby to a low $P_{Aldosterone}$.[149,150] Accordingly, there is a less negative luminal voltage in CCD due to less ENaC activity and hence a lower rate of reabsorption of Na^+ in CCD. These patients will tend to have low effective arterial blood volume. Patients with this disorder are expected to have a significant rise in their U_K/U_{Cr} with the administration of exogenous mineralocorticoids.

A Group with Low Stimulus to Produce Rennin: A subset of these patients are those with "Familial

Hyperkalemia with Hypertension" (also known as Pseudohypoaldosteronism type II (PHA-II) or Gordon's syndrome). Patients with this disorder behave like a gain-of-function in the thiazide-sensitive NCC with enhanced reabsorption of Na^+ and Cl^- in DCT;[58] the molecular defects leading to this disorder are discussed below.

This enhanced upstream reabsorption of Na^+ and Cl^- results in a low delivery of Na^+ and Cl^- to the CCD, which compromises the ability of this nephron segment to reabsorb more Na^+ than Cl^-, and thereby leads to a diminished excretory capacity for K^+. ECF volume expansion is a hallmark of the pathophysiology and it results in a low $P_{Renin\ mass}$, and thereby a lower than expected $P_{Aldosterone}$ given the hyperkalemia. Accordingly, these patients are not expected to have an appreciable rise in their U_K/U_{Cr} with exogenous mineralocorticoids, but their hyperkalemia should resolve with the administration of thiazide diuretics (higher Na^+ and Cl^- delivery to the CCD, and more reabsorption of Na^+ than Cl^- in CCD if more ENaC are open due to release of renin and aldosterone as the intravascular volume becomes less expanded).

A similar set of clinical findings to those described above but without a known molecular lesion may occur in other patients, most commonly patients with diabetic nephropathy.[149] Support is given to the hypothesis that suppression of renin release in these patients is the result of volume expansion by the findings that circulating atrial natriuretic peptide blood levels are elevated in these patients,[151] and many will respond to either $NaCl^-$ restriction or to furosemide with an increased P_{Renin} activity.[151,152] A similar pathophysiology (i.e., that suppression of renin release is due to intravascular volume expansion) has been suggested in patients with chronic renal failure[153] and patients with lupus nephritis with hyperkalemia and hyporeninemic hypoaldosteronism.[154] The basis of the disorder remains to be established. It is possible that the reabsorption of Na^+ and Cl^- may be augmented in the DCT akin to patients with "Familial Hyperkalemia with Hypertension". Interesting in this regard with respect to patients with type II DM, who may have hyperinsulinemia and the metabolic syndrome, is that chronic insulin infusion in rats is associated with the retention of NaCl due to its enhanced reabsorption in different nephron segments including the DCT and with less WNK4 expression in the renal cortex.[155] Furthermore, Obese Zuker rats were shown to be more sensitive to thiazides than their lean counterparts with a greater natriuresis , kaliuresis and drop in BP on thiazides.[156] Reduced renal cortical expression of WNK4 was also observed in this model. It is also interesting to note that work in cell culture indicates the involvement of PI3-kinase in activating WNK-1.[89] As mentioned above, WNK1 up-regulates NCC by blocking the inhibitory form of WNK4 or via phosphorylation of SPAK/ORS1.

It is also possible that ECF volume expansion and hyperkalemia in these patients may reflect an increased electroneutral NaCl reabsorption in CCD, perhaps a "Cl shunt" disorder[135]or possibly increased electroneutral reabsorption of NaCl by the parallel activity of the Na^+-dependent Cl^-/HCO_3^- exchanger (NDCBE) and the Na^+ independent Cl^-/HCO_3^- exchanger; pendrin[60] Patients with this pathophysiology of enhanced electroneutral reabsorption of $Na^+ + Cl^-$ in the CCD, are expected to have a rise in K^+ excretion with induction of bicarbonaturia (e.g., administration of acetazolamide).

Differentiation between these two groups of patients with hyporeninemic hypoaldosteronism has implications for therapy. The use of exogenous mineralocorticoids (9 α-fludrocortisone) is of benefit for the first group of patients as it results in both a kaliuresis and re-expansion of the intravascular volume due to retention of Na^+. Diuretic therapy would pose a threat to these patients because it would cause a more severe degree of decreased effective arterial blood volume. In contrast, mineralocorticoids may aggravate the hypertension in those who have excessive reabsorption of Na^+ and Cl^- in the DCT. In this group of patients, the administration of a thiazide diuretic to inhibit NCC should enhance the kaliuresis and lower the blood pressure. The administration of diuretics to patients with enhanced electroneutral Na^+ and Cl^- reabsorption in the CCD may increase their rate of excretion of K^+ by increasing the flow rate in the CCD. The activity of K^+ secretion may be increased by inducing bicarbonaturia; loss of HCO_3^- may have to be replaced to avoid the development of metabolic acidosis.

Familial Hyperkalemia with Hypertension

The term pseudohypoaldosteronism type II (PHAII) is misleading from a physiologic perspective because patients with this syndrome have salt retention and hypertension, findings associated with more rather than with less aldosterone effect.

The cause for increased reabsorption of Na^+ and Cl^- in the DCT in this disorder has been clarified recently.[58] Major deletions in the gene encoding for WNK kinase-1 and missense mutations in WNK4 were reported in these patients. When activated by ANG_{II}, WNK4 normally causes an increased luminal NCC phosphorylation and thus activity through SPAK/OSR1 (Figure 51.8).[157] PHAII-WNK4 mutants activate NCC *in vivo* by enhancing the SPAK/OSR1-NCC phosphorylation signaling,[158] an effect which is not further augmented by ANG_{II}, consistent with gain-of-function

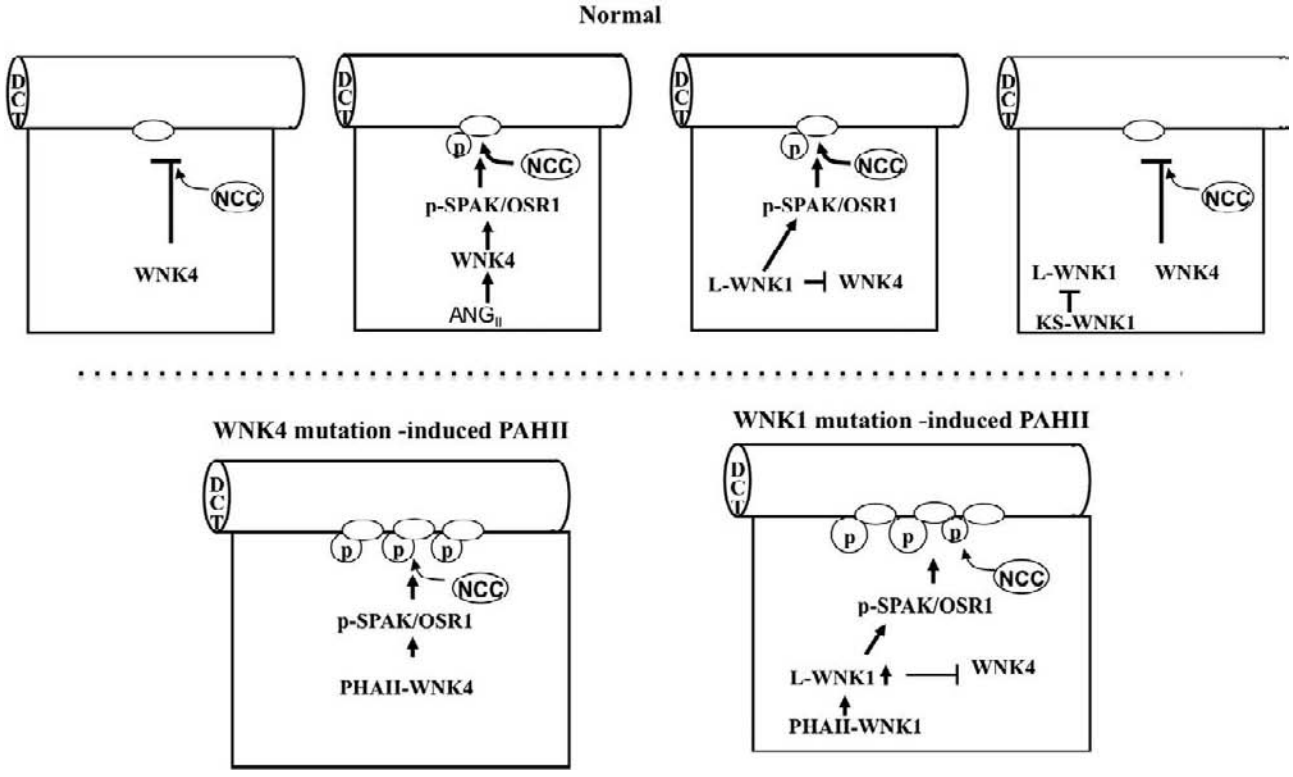


FIGURE 51.8 **Mutations in WNK kinases causing "Familial Hyperkalemia with Hypertension".** WNK4 is thought to inhibit NCC activity by reducing its plasma membrane abundance, by diverting post-Golgi NCC to the lysosome for degradation. When activated by ANG_{II}, WNK4 normally causes an increased luminal NCC phosphorylation and thus activity through SPAK/OSR1. WNK1-L up-regulates NCC by blocking the inhibitory form of WNK4 or by phosphorylation of SPAK/ORSI. WNK1-S has a dominant-negative effect on WNK1-L. PHAII-WNK4 mutants activate NCC *in vivo* by enhancing the SPAK/OSR1- NCC phosphorylation signaling, an effect which is not further augmented by ANG_{II}, consistent with gain-of-function mutations resulting in constitutive activation of the signaling pathway. When the intron1 of WNK1 gene is deleted, both WNK1-L and WNK1-S are increased in DCT and the imbalance of the WNK1-L/WNK1-S ratio leads to an activation of the NCC.

mutations resulting in constitutive activation of the signaling pathway. Thus, reabsorption of Na^+ and Cl^- by NCC in the DCT will be augmented.

The molecular defect in WNK1 is a removal of intron bases that leads to NCC activation (gain of function). There are two isoforms of WNK1; a ubiquitous full-length (WNK1-L) and a kidney-specific, WNK1 lacking the kinase domain (WNK1-S).[159] WNK1-L has an antagonistic effect on the inhibitory form of WNK4, and can also activate SPAK/OSR1-NCC signaling pathway.[93] WNK1-S has a dominant-negative effect on WNK1-L. When the intron 1 of WNK1 gene is deleted, both WNK1-L and WNK1-S are increased in DCT and the imbalance of the WNK1-L/WNK1-S ratio leads to an activation of the NCC.

The higher activity of the thiazide-sensitive NCC could explain the hypertension, hyperkalemia, and the suppressed $P_{Renin\ mass}$ that are common features in this disorder. Because of the enhanced reabsorption of Na^+ and Cl^- via NCC in the DCT, the delivery of Na^+ and Cl^- to the CCD is not sufficiently large to permit the rate of reabsorption of Na^+ to exceed the rate of reabsorption of Cl^- in the CCD by an appreciable amount. In addition, there is a diminished number of open ENaC units in the luminal membranes of principal cells because of the suppression of release of aldosterone by an expanded effective arterial blood volume. The overall result is to cause low luminal negative voltage in the CCD and the development of hyperkalemia. The increased NCC activity in these patients accounts for the marked fall in blood pressure in some patients who are treated with thiazide diuretics.[160]

Hyperkalemic Periodic Paralysis

The defect in this disorder seems to be in the regulation of a specific population of Na^+ channels (the tetrodotoxin sensitive Na^+ channels) in the cell membrane. This syndrome has an autosomal dominant inheritance

and is the result of a mutation in the α-subunit of the skeletal muscle Na^+ channel gene ($Na_v1.4$ encoded by *SCN4A gene*).[24] When the muscle is stimulated to contract, Na^+ influx depolarizes the cell. As the resting membrane potential approaches -50 mV, normal Na^+ channels close. In patients with hyperkalemic periodic paralysis, these defective Na^+ channels fail to close, the persistent Na^+ influx leads to membrane depolarization and drives an outward efflux of K^+ into the ECF compartment, causing hyperkalemia. Depending on the absolute voltage, lesser changes may result in myotonia, while larger changes can cause paralysis. Weakness is triggered by a variety of circumstances including rest after exercise, K^+-rich food, cold environment, emotional stress and fasting. Acute attacks of hyperkalemic periodic paralysis can be treated by inducing a shift of K^+ into cells with ß$_2$-adrenergics.[161] Inducing a large K^+ loss should be avoided. Acetozolamide seems to be effective in prevention of recurrence of attacks, though its mechanism of action is not clear.

Drugs Associated with Hyperkalemia

In general, drugs that cause hyperkalemia can be classified into those that affect the shift of K^+ into cells and those that impair the renal excretion of K^+.

Drugs that Affect Cellular Redistribution of K^+

Non-selective ß-adrenergic blockers may diminish the ß$_2$-adrenergic mediated shift of K^+ into cells.[162] In general, only a minor rise in the P_K is observed. Nevertheless, more significant degrees of hyperkalemia may develop after vigorous exercise[163] or the intake of drugs that may impair the excretion of K^+ by the kidney.

Digitalis overdose may be accompanied by hyperkalemia as a result of the inhibition of the Na-K-ATPase pump.[164,165]

The use of depolarizing agents such as succinylcholine during anesthesia may cause a shift of K^+ from cells and cause hyperkalemia.[122] The hyperkalemic effect of succinylcholine is more pronounced in patients with conditions that may lead to up-regulation of acetylcholine receptors in skeletal muscles such as neuromuscular injury (upper or lower motor neuron lesion), immobilization, muscle inflammation, muscle trauma or burn injury.[166]

Arginine hydrochloride used in the treatment of hepatic coma and severe metabolic alkalosis[167,168] and epsilon-aminocaproic acid,[169] a synthetic amino acid structurally similar to lysine and arginine used to treat severe hemorrhage also causes an efflux of K^+ from cells, resulting in life-threatening hyperkalemia, especially in patients with impaired renal function.

Hyperkalemia may also result from inhibition of insulin secretion by the somatostatin agonist octreotide.[170]

Impaired K^+ redistribution via the activation of the K^+ channel by fluoride poisoning[171,172] leads to life-threatening hyperkalemia and may be ameliorated by the administration of quinidine and amiodarone.[173]

Drugs that Interfere with Renal K^+ Excretion

Drugs that Inhibit the Release of Renin; Non-Steroidal Anti-Inflammatory Drugs (NSAIDS): Secretion of renin by cells in the afferent glomerular arterioles and by cells of the macula densa in the early DCT appears to be mediated in part by locally produced prostaglandins via COX-2.[174] As a result, prostaglandin synthesis inhibition can lead to low $P_{Renin\ mass}$ and low $P_{Aldosterone}$.[175,176] NSAIDs also blunt the adrenal response to hyperkalemia, which is at least partially dependent on prostaglandins. It is not surprising that COX-2 inhibitors produce identical effects to those of non-selective NSAIDS.[177,178] The rise in the P_K is small in normal subjects, but a significant degree of hyperkalemia may develop in the presence of certain diseases or with the intake of drugs that may impair the renal excretion of K^+.

Drugs that Interfere with the Renin-Angiotensin-Aldosterone Axis

Direct Renin Blockers, Angiotensin Converting Enzyme (ACE) Inhibitors and Angiotensin II Receptor Blockers: The two major stimuli for the release of aldosterone are ANG_{II} and an increase in the P_K. The effect of hyperkalemia to stimulate the release of aldosterone acts in concert with ANG_{II} that is generated locally within the adrenal glomerulosa.[179] Blocking both of these actions is expected to reduce aldosterone secretion and thereby impair the renal excretion of K^+. Of note, however, aldosterone levels are not fully suppressed in patients on chronic therapy with ACE inhibitors.[180] Furthermore, there are no reported studies that examined the effect of exogenous mineralocorticoids on the renal excretion of K^+ in patients who develop hyperkalemia while on drugs that block the renin-angiotensin-aldosterone system (RAAS).

Notwithstanding, as show in Table 51.1, hyperkalemia will likely not occur, even if there is a large reduction in TE voltage in the CCD unless there is decreased flow rate in the terminal CCD. A deficiency of actions of ANG_{II} may diminish intra-renal urea recycling by reducing urea reabsorption in the inner MCD as A_{II} stimulates the transport of urea in the inner MCD in the presence of vasopressin,[181] or

possibly by decreasing vasoconstrictor tone to blood vessels that descend into the renal medulla, and thereby wash urea out of the deeper region of the outer medulla as a result of diminishing the driving force for urea entry into the descending thin limbs of superficial nephrons. Hence, the hyperkalemia seen in some patients on ACE inhibitors or ARBs may be due to a combination of diminished electrical driving force for the net secretion of K^+ in the CCD and a diminished rate of flow in the terminal CCD due to a decrease in urea recycling.

In patients with hypertension without risk factors for hyperkalemia, the incidence of hyperkalemia with RAAS inhibitor mono-therapy is low (<2%), whereas rates are higher with dual RAAS blockade (5%).[182] The incidence of hyperkalemia is also increased in patients with congestive heart failure or chronic kidney disease (5% to 10%). However, these estimates are based on data from patients in a study setting and hence may not reflect the incidence of hyperkalemia in an outpatient setting. The rise in the P_K is less than 0.5 mmol/L in patients with relatively normal renal function. In contrast, more severe hyperkalemia may be seen in patients with chronic kidney disease, concurrent use of a drug that impairs renal K^+ excretion such as a potassium-sparing diuretic or a non-steroidal anti-inflammatory drug, and in the elderly patients.

Drugs that Inhibit Aldosterone Synthesis; Heparin: Aldosterone synthesis is selectively reduced in patients who are treated with heparin.[183–185] This seems to be due to an effect of heparin that leads to a reduction in the number and affinity of adrenal ANG_{II} receptors. It has been estimated that hyperkalemia occurs in about 7% of patients receiving heparin. Both unfractionated and low-molecular weight heparin can cause hyperkalemia. Hyperkalemia due to prophylactic subcutaneous unfractionated heparin (5000 units twice daily) has also been reported. Nevertheless, the degree of decrease in the $P_{Aldosterone}$ may not be of sufficient magnitude to affect the renal excretion of K^+ in many patients who receive this drug. Severe hyperkalemia occurs only if some other disorder that leads to impairment in K^+ excretion is present such as renal insufficiency or if the patient is taking an ACE inhibitor, or a potassium-sparing diuretic.

Aldosterone Receptor Antagonists; Spironolactone and Eplerenone: Hyperkalemia is of particular concern in patients on the non-specific mineralocorticoid receptor antagonist, spironolactone,[186] or the selective mineralocorticoid receptor antagonist eplerenone, especially given the increasing indications to combine spironolactone or eplerenone with ACE-inhibitors and/or ARBs in patients with renal and cardiac disease. Heart failure, diabetes, and chronic kidney disease increase the risk of hyperkalemia from these agents. The prevalence of hyperkalemia associated with the combined use of mineralocorticoid receptor antagonists and ACE-inhibitors/ARBs appears to be much higher in clinical practice (~10%) than what has been reported in large clinical trials, perhaps in part due to the use of higher than recommended doses. The incidence of hyperkalemia is dose dependent with detectable effects even at doses of 25 mg spironolactone per day, at higher doses, the risk of severe hyperkalemia increases. Juurlink et al.,[186] in a population-based study of computerized drug prescription records and hospitalizations in Ontario, Canada, studied the correlation between the rate of spironolactone prescription for patients with heart failure on ACE-inhibitors, following the publication of "The Randomized Aldactone Evaluation Study" with hyperkalemia and associated morbidity. The frequency with which spironolactone was prescribed to patients with heart failure who were taking an ACE inhibitor rose significantly after the publication of RALES (from 30 prescriptions per 1000 patients in early 1999 to 149 prescriptions per 1000 patients by late 2001). Over the same interval, there were significant increases among these patients in the rates of hospital admissions for hyperkalemia (from 4.0 to 11.0 per 1000) and of in-hospital death from hyperkalemia (from 0.7 to 2.0 per 1000). Notwithstanding, a study from the United Kingdom found a similar increase in spironolactone use after the publication of RALES, but without an increase in hyperkalemia or admissions to hospital for hyperkalemia.[187]

Drugs that Block ENaC; Trimethoprim and Pentamidine: The cationic form of trimethoprim and pentamidine causes hyperkalemia and salt wasting by blocking ENaC in the lumen of the CCD.[188] Patients with HIV and pneumocystis carinii pneumonia treated with trimethoprim not infrequently develop hyperkalemia.[189–191] Although this was attributed to the use of high doses of trimethoprim in these patients, trimethoprim may cause a rise in P_K when used in conventional doses. In a study of hospitalized patients treated with standard doses of trimethoprim,[192] significant hyperkalemia occurred in greater than 50%, with severe hyperkalemia (>5.5 mmol/L) in 21% of these patients. Risk factors for hyperkalemia due to usual-dose of trimethoprim include renal insufficiency, hyporeninemic hypoaldosteronism, and concomitant use of ACE-inhibitors and ARBs.[192]

Another factor that may explain the observed high incidence of hyperkalemia in patients with HIV and pneumocystis carinii pneumonia treated with trimethoprim is the low flow rate in the terminal CCD. Because the dietary intake in this group of patients is likely very poor, the number of osmoles (urea and NaCl) in terminal CCD will be low and hence a lower number of liters of fluid will exit CCD. If protein intake is low

delivery of urea to the inner MCD will be diminished and hence intra-renal urea recycling will be decreased. In addition to its effect to diminish the rate of excretion of K^+, a low flow rate in terminal CCD also increases the concentration of trimethoprim in the lumen of the CCD for a given amount of this drug (same quantity of trimethoprim is now in a smaller volume). Hence the ability of trimethoprim to block ENaC in principal cells in the CCD will be enhanced.[193] This also may be a contributing factor to the development of hyperkalemia in patients receiving conventional doses of trimethoprim.

If hyperkalemia develops over a short period of time or in the absence of a large intake of K^+, its most likely cause is a shift of K^+ out of cells. For example, a shift of K^+ from cells may occur due to suppression of the release of insulin by α-adrenergics released in response to contracted effective arterial blood volume owing to the effect of trimethoprim to block ENaC and cause renal salt wasting.[194]

With regard to therapy, loop diuretics may help by lowering the concentration of trimethoprim in the luminal fluid in the CCD. Enough NaCl must be given to re-expand the effective arterial blood volume. Because only the protonated form of trimethoprim blocks ENaC,[188] increasing the delivery of HCO_3 to the CCD should cause less trimethoprim to be in its cationic form and hence minimize its ENaC blocking effect. Inducing bicarbonaturia with acetazolamide is a rationale therapeutic option when continuation of trimethoprim is necessary and blockade of ENaC is likely. Enough alkali would need to be given to avoid the development of metabolic acidosis.

Calcineurine Inhibitors (Cyclosporin, Tacrolimus): Hyperkalemia develops in some patients receiving cyclosporin or tacrolimus following organ transplantation. The pathophysiology of hyperkalemia and the clinical signs in these patients resembles that of "Familial Hyperkalemia with Hypertension".[195] In a recent study, Hoorn et al.[196] demonstrated that in wild-type mice tacrolimus caused salt-sensitive hypertension and increased the abundance of phosphorylated NCC and the NCC-regulatory kinases WNK3, WNK4 and SPAK. Hydrochlorothiazide reversed tacrolimus-induced hypertension. Tacrolimus treated mice developed hyperkalemia when they consumed a high K^+ chow. Kidney transplant recipients treated with tacrolimus had a greater fractional excretion of Cl^- in response to bendroflumethiazide, a drug that blocks NCC, than individuals not treated with tacrolimus; renal NCC abundance was also greater in these patients.

Nafamostat Mesylate Interferes With Activation of ENaC Via Proteolytic Cleavage: Activation of ENaC by aldosterone involves proteolytic cleavage of the channel by serine proteases such as CAP1. These proteases activate ENaC by increasing the open probability of the channel rather than by increasing its expression at the cell surface. Nafamostat mesylate is a potent serine protease inhibitor that has been widely used in Japan for the treatment of acute pancreatitis, disseminated intravascular coagulation and as an anticoagulant in hemodialysis.[197] It can cause hyperkalemia primarily by decreasing urinary K^+ excretion.[198] The mechanism is related to the metabolites of nafamostat that inhibits these aldosterone-inducible, membrane-associated, channel activating proteases.[199]

THERAPY OF HYPERKALEMIA

Medical Emergencies

The major danger of a severe degree of hyperkalemia is a cardiac arrhythmia. Because mild ECG changes may progress rapidly to a dangerous arrhythmia, any patient with an ECG abnormality related to hyperkalemia should be considered as a medical emergency. Because some patients may develop cardiac arrhythmia or even cardiac arrest in the absence of changes associated with hyperkalemia in the initial ECG, it is our view that severe hyperkalemia, i.e., P_K >7.0 mmol/L, should be treated as an emergency with maneuvers to induce a shift of K^+ into cells even in absence of ECG changes, and perhaps at even lower P_K, e.g., >6.5 mmol/L, in the presence of hypocalcemia, acidemia and or hyponatremia. Notwithstanding, those who develop hyperkalemia after extreme exercise (the super-marathon[200]), most patients on chronic hemodialysis, and infants seem to tolerate even severe hyperkalemia without adverse effects.

Antagonize the Cardiac Effects of Hyperkalemia

In cells in which the rate of rise of action potential upstroke (V_{max}) is dependant on the inward Na^+ current, administration of calcium alters the relation between the V_{max} and the RMP at the onset of depolarization such that V_{max} is greater at less negative RMP, and hence conduction velocity is increased.[109]

A 10 ml of a 10% solution of calcium chloride contains about three times the amount of elemental calcium compared to calcium gluconate. Calcium gluconate, however, is preferred because of less risk of tissue necrosis if it extravasates. The usual dose of Ca gluconate is 1000 mg (10 ml of a 10% solution) infused over 2–3 minutes. The effect of IV calcium occurs in one to three minutes but lasts for only 30–60 minutes. This dose can be repeated in five minutes if ECG changes persist, or if they recur. Extreme caution

should be exerted in patients on digitalis because hypercalcemia may aggravate digitalis toxicity. It is recommended that Ca be given in hyperkalemic patients on digitalis only if there is loss of P wave, or a wide QRS complex. In this case calcium gluconate should be diluted in 100 ml of D5W and infused over 20–30 minutes to avoid acute hypercalcemia. The administration of digoxin-specific antibody fragments is the preferred therapy in these patients.

Induce a Shift of K^+ into the ICF

Insulin: A number of studies support the use of insulin to treat acute hyperkalemia.[201–205] The effect of insulin on plasma K^+ levels is independent of its hypoglycemic effect, which may be impaired in patients with end stage renal disease. The usual recommended dose of insulin is 10 units of regular insulin given as intravenous bolus. The insulin regimen, however, that was shown in studies to achieve close to a 1 mmol/L fall in P_K at 60 minutes, was the infusion of about 20 units of regular insulin over that period of time. This seems to achieve and maintain the supra-physiological levels of insulin in plasma that are required for a maximal shift of K^+ into cells. Hypoglycemia is definitely a risk. In the study by Blumberg et al.,[201] giving this dose of insulin and 20 g of glucose, 50% of their patients developed hypoglycemia. Hypoglycemia was avoided when the same dose of insulin was used but 60 g of glucose were infused over the one hour period.

ß$_2$-Adrenergic Agonists: ß$_2$-adrenergic stimulation lowers the P_K in patients with renal failure.[202–204,206–211] Albuterol (Salbutamol), a selective β_2-agonist, as inhaled/nebulized or IV is the most widely studied and used; only the inhaled form however, is available in the United States and Canada. Allon et al.[209] observed a decline in the P_K 1.0 mmol/L that lasted for two hours with 20 mg of albuterol given by nebulizer. There was a minimal increase in heart rate and a notable absence of cardiovascular side effects. However, since 20 to 40% of patients with ESRD are resistant to this therapy and it is not possible to predict non-responders, we do not recommend β_2-agonist as a sole emergency therapy. Moreover, we are concerned about the safety of these drugs in the doses used for the treatment of hyperkalemia, which are four to eight times that prescribed for the treatment of acute asthma. It is to be noted that in many of the studies using these agents, patients were selected for the study and patients on β-blockers (who are likely to have cardiac disease) were excluded. In some studies, patients with angina, myocardial infarction within six months, and patients with unstable heart rhythm were excluded.

The combination of nebulized ß$_2$-agonists and insulin was reported to produce a greater fall in P_K (1.2 mmol/L) compared with either drug alone (~0.65 mmol/L).[202] One should note however that only 10 units of regular insulin as an intravenous bolus was given in this study and the magnitude of the fall in P_K was lower than that observed in other studies using higher doses of insulin as an infusion.[201,203] Thus, it remains uncertain whether ß$_2$-agonists would have a P_K lowering effect additive to that of higher doses of insulin.

$NaHCO_3$: A number of studies have found $NaHCO_3$ therapy to be ineffective as the sole treatment of hyperkalemia.[201,212,213] It is noteworthy that these studies were performed in stable hemodialysis patients who did not have significant acidemia (i.e., NHE-1 was presumably inactive). Studies that examined the combined use of $NaHCO_3$ with insulin also have conflicting results.[203,205] Thus the question remains, "Would $NaHCO_3$ be effective in patients with a more significant degree of acidemia?" There are no data in the literature to answer this question definitively.[214] Given this uncertainty, we only use $NaHCO_3$ in addition to other therapies to treat emergency hyperkalemia in patients with a significant degree of acidemia. Caution is warranted because an excessive administration of $NaHCO_3$ has the risk of inducing hypernatremia, ECF volume expansion, carbon dioxide retention, and hypocalcemia.

Non-Medical Emergency

Removal of K^+ From the Body

It is important to appreciate that a very much less K^+ loss is needed to lower the P_K from 7.0 to 6.0 mM than to lower it from 6.0 to 5.0 mM.[215] Hence creating a modest K^+ loss can be very important when there is a severe degree of hyperkalemia.

Enhancing the Excretion Of K^+ in the Urine

While a number of maneuvers may be suggested to increase the excretion of K^+ in the urine, there are no data to support their efficacy, particularly in the acute setting. The administration of a loop diuretic may induce kaliuresis by increasing the flow rate in the terminal CCD. One should avoid intravascular volume depletion as this may lead to the opposite effect of decreasing flow in the terminal CCD. Kaliuresis may be also enhanced by giving a mineralocorticoid (e.g., 100–300 μg florinef) and possibly by inducing bicarbonaturia with a carbonic anhydrase inhibitor. $NaHCO_3$ may need to be given to replace the HCO_3^- lost in the urine.

Cation Exchange Resins

Sodium polysterene sulfonate (SPS) is a cross linked polymer to which reactive sulfonic groups are attached, and preloaded with a the cation, Na^+. When SPS is placed in a solution, its reactive sulfonate group exchange their bound Na^+ for another cation in the solution. SPS has been long used by clinicians for the treatment of hyperkalemia with the assumption that it exchanges its bound Na^+ with K^+ in the lumen of GI tract and hence causes the loss of K^+ in stool.

SPS contains 4 mEq of Na^+ per gram, which could be available for exchange for K^+ in the lumen of the GI tract. Based on the affinity of SPS to Na^+ and K^+,[216] and if one considers the measured concentrations of Na^+ and K^+ at different sites in the lumen of the gastrointestinal tract, it seems that the only favorable site for this exchange to take place is in the lumen of the rectum (or perhaps the entire colon). Notwithstanding, other cations such as NH_4^+, Ca^{2+} and Mg^{2+} will compete with K^+ for this exchange with Na^+. But even if the exchange of Na^+ for K^+ were to occur in the colon, there is only a small amount of K^+ in the lumen of the colon to bind the resin. The amount of K^+ excreted via the GI tract in normal subjects is about, 9 mmol/day. It has been suggested that patients with ESRD have an enhanced colonic excretion of K^+. Balance data are conflicting and the bulk of evidence would suggest that uremic patients may excrete a few extra mmol of K^+ than normal subjects in their stool.[217]

One possible theoretical benefit to the use of cation exchange resins is if they were to bind K^+ and lower its concentration in luminal water, this may enhance the net secretion of K^+ by the recto-sigmoid colon. While the administration of several doses of SPS over a number of days may increase the loss of K^+ via the GI tract, the question is how to achieve a large loss of K^+ from the GI tract over a short period of time if this to be used to achieve the loss of K^+ in a patient with moderately severe hyperkalemia? The limiting factor for a large K^+ loss via the GI tract is stool volume. As shown by Emmett et al.,[216] the administration of 60 g of sorbitol, an osmotic cathartic, to normal subjects, the mean stool weight was 788 g over 12 hours and the total K^+ output was 26 ± 2 mmol over that time period. The addition of resin did not add much in terms of K^+ loss, as the total K^+ output was 30 ± 6, mmol over 12-hour period.

Two studies are commonly quoted to support the use of SPS in the treatment of hyperkalemia. In the study by Flinn et al.[218] SPS was given four times per day and the results for the P_K were reported on day five. Importantly, patients were given sufficient amount of sorbitol to produce a "satisfactory" diarrhea. Although the number of patients was rather small, one group of patients was treated with sorbitol alone, and had an average reduction by day five of treatment in P_K that was larger than patients treated with both resin and sorbitol.

Scherr et al.[219] treated 30 patients with hyperkalemia and oliguria with SPS, most patients did not require laxatives as constipation occurred only occasionally. The mean fall in the P_K in the group that received SPS orally was 0.9 ± 0.1 mmol/L in the first 24 hours. K^+ excretion in stool was not measured, so there is no evidence that the administration of resin caused a fecal loss of K^+ sufficient to account for the fall in P_K. In fact, some patients had quite impressive falls in P_K in the first 24 hours. For instance, one patient had a fall of 2.8 mmol/L, after oral resin 40 grams. The results are difficult to explain if SPS has a K^+ binding capacity *in vivo* of about 1 mmol per gram.

An increasing concern with the use of SPS in sorbitol is the development of intestinal necrosis, which usually involves the ileum and the colon. While the incidence of this complication is not exactly known and is likely to be rather low considering the frequency with which it is used, it is however, frequently fatal. Most cases were reported initially in patients in the post-operative period (e.g., post renal transplant) or in critically ill patients given resin enema.[220,221] Recently however, McGowan et al.[222] reported 11 cases of intestinal necrosis over a period of nine years that were temporally related to the use of SPS in sorbitol, four of which were fatal. All patients received oral SPS, only two of them were postoperative (both of them had orthopedic surgery) and only four had ESRD that required dialysis. The harm has generally been attributed to the use of 70% sorbitol.[223] There does seem to be some concern however that the resin itself may be involved.[222] In September of 2009, the FDA recommended against the "concomitant use of sorbitol" with Kayexalate® powder because of concerns about the risk of colonic necrosis and other gastrointestinal side effects. This warning however did not apply to premixed sodium polystyrene sulfonate in 33% sorbitol. There is concern however, that at least some of the more recent reports of colonic necrosis followed use of premixed preparation containing 33% sorbitol.[220]

In patients with life-threatening hyperkalemia, there is no role for the use of resins or attempting to induce K^+ loss via the intestinal tract. In a patient with moderately severe hyperkalemia in whom the decision is made not to start dialysis, to induce K^+ loss in stool, the goal of therapy should be to induce diarrhea. The addition of resin adds little in terms of K^+ loss to the induction of diarrhea alone. If the patient does not develop diarrhea, this treatment is not likely to be effective. Since there is concern about the use of

sorbitol 33%, the role of other cathartics need to be explored. Since, it seems that the most K^+ loss is achieved with the use of cathartics that induce secretory diarrhea, drugs like bisacodyl may be considered.

Dialysis

Hemodialysis is more effective than peritoneal dialysis for removing K^+. Removal rates of K^+ can approximate 35 mmol/hr with a dialysate bath K^+ concentration of 1−2 mM. A glucose-free dialysate is preferable to avoid the glucose-induced release of insulin and the subsequent shift of K^+ into cells, lessening the removal of K^+. For the same reason, one should consider discontinuing the insulin/glucose infusion once hemodialysis is initiated.

Because virtually every biological process is sensitive to changes in pH (for reviews, see refs.[1,2,3]), acid–base homeostasis is of critical importance to cells and organisms, and has attracted considerable attention. Until relatively recently, acid–base homeostasis, for both clinicians and basic scientists, has been synonymous with pH regulation in the two most easily accessed compartments, blood and cerebrospinal fluid (CSF). The pH in these extracellular compartments (pH_o) is certainly important for organisms. For example, alterations in pH_o may affect various extracellular biochemical reactions (e.g., hemostasis, complement fixation) and influence binding of various substances (e.g., hormones, metals, therapeutic agents) to plasma proteins or cell surface receptors. Moreover, certain ion channels[4,5] as well as transporters that move solutes across cell membranes are sensitive to pH_o changes. Nevertheless, the number of processes sensitive to changes of extracellular pH pales in comparison with the myriad processes sensitive to alterations in intracellular pH (pH_i). Thus, pH_i homeostasis should be a matter of central importance not only for individual cells, but also for the organism composed of these cells.

Although cellular metabolism can modulate pH_i, the regulation of pH_i is the province of membrane proteins that transfer acid–base equivalents across the plasma membrane. In addition, transporters that carry acid–base equivalents across organellar membranes can transiently modify pH_i or can participate in the buffering of cytoplasmic H^+.

Since the last edition of this book, the field of pH_i regulation has continued to advance in the following broad areas: (1) the multiplicity of transport pathways responsible for pH_i regulation, and (2) molecular mechanisms by which these pathways operate.

Elucidating the multiplicity of transport pathways in pH_i regulation: A common theme is that patterns of pH_i regulation in particular cell types is characteristic of the cell and complex. As a result, without previous knowledge of a cell's physiology, it may be impossible to predict its response to a particular maneuver. For example, switching the extracellular buffer from a non-CO_2/HCO_3^- buffer to CO_2/HCO_3^- usually causes an abrupt fall in pH_i, due to influx of the highly permeant CO_2. On the other hand, some cell membranes show no evidence whatsoever of being permeable to gases such as CO_2[6] or NH_3.[7,8,6] In fact, some of the CO_2 permeability of membranes may require "gas" channels.[9,10,11,12] For cells with CO_2-permeable membranes, the response to the initial CO_2-induced acidification may—depending on the cell type and initial pH_i —be a pH_i recovery that is totally absent,[13] partial,[14] complete,[15] or even excessive.[16–23]

Underlying the diversity of pH_i regulation is its complexity. Thus, a particular cell type may possess numerous plasma-membrane transporters that regulate pH_i, each with its own unique properties. For example, five genes encode Na^+-coupled HCO_3^- transporters, and these generally have multiple variants, each of which has a characteristic expression profile that depends on cell type and developmental stage, and susceptibility to regulatory mechanisms. Since the last edition of this book, investigators have described many new variants of transporters and have clarified the roles that they play in pH_i regulation.

pH_i regulation is also complex in that Na^+–H^+ exchangers, Na^+-coupled HCO_3^- transporters, and other

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00052-5

acid–base transporters may be under the concerted control of humoral agents[20,24–28] or other environmental influences, such as acidosis[29] or hypertonicity (see ref. [30]). In the case of pH_o changes, certain G-protein-coupled receptors can detect extracellular H^+.[31] In addition, charges in the basolateral concentration of $[CO_2]$ and $[HCO_3^-]$ per se—independent of basolateral pH—are powerful regulators of acid–base transport in the proximal tubule.[32]

Given the complexity and diversity of patterns of pH_i regulation, one must examine pH_i physiology anew for each previously unexplored cell type.

Understanding the molecular mechanisms of pH_i regulation: Since the last edition of this book, the field has seen further major advances in the molecular physiology of acid–base transporters. Many of these carriers are discussed in greater detail in Chapter 53 on Na^+-coupled HCO_3^- transporters, Chapter 54 on anion exchangers, and refs. [167,713,714] on Na^+-H^+ exchangers. The reader may also consult a review on Na^+-coupled HCO_3^- transporters.[33]

Scope of this chapter: In this chapter, we shall first consider the methodologies available for making pH_i measurements. We shall then examine the factors that contribute to changes in pH_i: the thermodynamic forces acting on hydrogen ions (H^+) and other charged acids/bases; the permeation of the cell membrane by electrically neutral acids and bases; the buffering power of the intracellular fluid; and transporters that regulate pH_i by moving H^+, bicarbonate ions (HCO_3^-) and/or other weak acid/bases across the plasma membrane. Because space does not permit us to summarize the vast array of acid–base transporters, we will focus on transporters that play a major role in pH_i regulation. Emerging from this discussion will be a model of pH_i regulation. Finally, in light of this model, we will consider several factors that fundamentally alter pH_i regulation: alterations in pH_o; temperature changes; metabolic inhibitors and hypoxia; cell shrinkage; hormones, growth factors, and oncogenes.

METHODS FOR MEASURING pH_i

Of the techniques available for measuring pH_i, we shall consider the four that are currently of greatest utility. These techniques differ from one another in terms of their theoretical foundations, the precise cellular properties that they measure, as well as in their accuracy and sensitivity.

pH-Sensitive Microelectrodes

In the mid 1990s, it was beginning to look like the use of pH microelectrodes might become a dying art, except for their restricted use for measuring pH_i in large invertebrate cells. However, the emergence of the *Xenopus* oocyte expression system and the cloning of numerous acid–base transporters over the past couple of decades have breathed new life into an old technology.

When a pH electrode and an indifferent reference electrode are placed in a solution, the voltage difference between the electrodes (E_X) is linearly related to the solution pH (pH_X):

$$pH_X = pH_S + (E_X - E_S)\frac{F}{RT \ln 10} \qquad (52.1)$$

pH_S is the pH of a standard solution, E_S is the voltage difference in this standard, and F/(RT ln 10) is the theoretical slope (~58 mV per pH-unit change at 22°C) of the line relating pH to voltage. The actual slope is determined empirically.

Although the pH sensor can be any of several materials (e.g., platinum-hydrogen, antimony, tungsten, or a liquid membrane), the most reliable remains pH-sensitive glass. Glass has the advantages of long lifetime, long-term stability, as well as insensitivity to cations other than H^+ (at physiological pH), redox reactions, and various gases. Several styles of glass pH-sensitive microelectrodes are available, including Hinke's exposed-tip design,[34] Roger Thomas' recessed-tip design,[35] and Roger Thomas' eccentric design.[36,37] Glass electrodes are particularly well suited to measure pH_i of relatively large cells (e.g., squid axons), or to measure pH_o. However, because it is difficult to fabricate glass microelectrodes that are small enough to be used with small cells, glass electrodes generally have been abandoned in favor of electrodes with liquid-membrane sensors, which are easier to make, but have a much shorter lifetime, are less stable, and are sometimes sensitive to drugs and other parameters.

Ideally, the pH and reference microelectrodes must impale a single cell. An acceptable alternative may be to place them in two identical cells, or in cells that are electrically coupled. Another solution is to employ a double-barreled electrode.[38,39] Unfortunately, for each barrel, there is a trade-off between tip size and electrode performance. The larger the two barrels of a double-barreled electrode, the better the electrode performance, but the greater the cell damage caused by impalement. The performance of liquid-membrane electrodes can be improved by using a concentric design in which a saline-filled pipette is threaded into the column of a liquid-membrane sensor, thereby reducing the overall longitudinal resistance between the sensor at the electrode's tip and the electrical contact in the electrode's barrel.[40–43] Fedirko et al.[40] have described a simplified approach for implementing this concentric design for H^+- and Ca^{2+}-selective microelectrodes, permitting rapid measurements of extracellular pH and Ca^{2+} transients in rat hippocampal brain slices.

pH-sensitive electrodes, particularly those with glass sensors, remain the method of choice for monitoring pH_i in relatively large cells. Not only are these electrodes highly sensitive (< 0.01 pH units), they are probably more precise and accurate than dyes. Moreover, the microelectrodes report pH and cell voltage simultaneously, and in real time. The "pH_i" that they report is almost certainly that of the bulk cytoplasm (i.e., the fluid in direct contact with the plasma membrane), uncontaminated by the pH of organelles. Disadvantages of using microelectrodes for measuring pH_i include the time and skill required for making and using them. In addition, one can only use conventional microelectrodes on cells large enough to sustain the impalement.

Although small mammalian cells generally do not easily tolerate impalement, pH-sensitive microelectrodes placed near the extracellular side of the plasma membrane of a mammalian cell can be used to measure H^+ fluxes due to acid–base transporter activity. Using an elegant "self-referencing" pH microelectrode technique with Chinese hamster ovary (CHO) fibroblasts, Fuster et al.[44] measured the continual extracellular H^+ gradient when a cell-attached patch pipette was repetitively positioned close to and away from an extracellular pH electrode. H^+ fluxes due to altered Na^+–H^+ exchanger activity were quantitated from changes in the extracellular H^+ gradient elicited by altering the cytoplasm via pipette perfusion. Electrodes with relatively large tips (15–20 μm) have been used to monitor surface pH transients in oocytes and glean important information about the permeability to CO_2 and NH_3 in the study of gas channels.[45–48]

Distribution of Weak Acids and Bases

Cell membranes are generally far more permeable to neutral molecules than to charged ones of similar shape and size. Thus, if a cell is exposed to a monoprotic weak acid HA ($HA \rightleftarrows H^+A^-$), the neutral molecule rapidly enters the cell (Figure 52.1). Assuming for the moment that A^- cannot penetrate the membrane, the entry of HA continues until HA is in equilibrium across the cell membrane, that is, when the concentration of HA inside the cell ($[HA]_i$) is the same as that outside ($[HA]_o$). Because entering HA dissociates to H^+ and A^-, the equilibration of HA across the membrane is necessarily accompanied by a fall in pH_i. This principle underlies the pH_i changes caused by neutral weak acids and bases that we will discuss below in the Section on "Effects of Weak Acids and Bases on pH_i". Provided that the dissociation constant ($K = [H^+] \times [A^-]/[HA]$) is the same both inside and outside the cell, then, at equilibrium,

$$\frac{[H^+]_i}{[H^+]_o} = \frac{[A^-]_o}{[A^-]_i} \tag{52.2}$$

Because the transmembrane distribution ratios of A^- and H^+ are inversely related, we can use Equation 52.2 to compute pH_i.

The weak acid most commonly used to calculate pH_i is 5,5-dimethyl-2,4-oxazolidinedione (DMO), employed as ^{14}C-DMO; benzoic acid has also been used.[49,50] Regardless of the weak acid used, the amount of radioactivity in the intra- or extracellular fluid is proportional to the total concentration of the probe ($[A^-] + [HA]$). pH_i is computed from the following equation, which must include the concentrations of the total probe because it is impossible to measure $[A^-]$ directly:

$$pH_i = pK + \log\left[\frac{([A^-]_i + [HA]_i)}{([A^-]_o + [HA]_o)}(10^{pH_i - pK} + 1)\right] \tag{52.3}$$

One can use a similar approach to compute pH_i from the distribution of a permeant weak base, such as methylamine.[51] Reviews by Waddell and Butler[52] and by Roos and Boron[3] contain more detailed descriptions and discuss potential difficulties of the weak-acid/base method.

The major advantages of the weak-acid/base method include its technical simplicity and applicability to even very small cells. The parameter actually measured is not the pH of the cytoplasm, but rather a volume–weighted mean pH of all intracellular compartments in which the weak acid or base is distributed. The practical sensitivity of this approach is 0.03–0.05 pH units—considerably less than the microelectrode technique. The major disadvantage of the weak-acid/base approach is that continuous pH_i measurements are not possible.

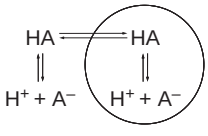

FIGURE 52.1 The distribution of a monoprotic weak acid across the cell membrane. When placed in the external solution, HA passively enters the cell, where it dissociates to form H^+ and A^-. Once $[HA]_i = [HA]_o$, the equilibrium $HA \rightarrow H^+ + A^-$ holds in both the intracellular and extracellular fluids.

pH-Sensitive Dyes

Absorbance

Molecules with an absorbance, fluorescence excitation, and/or fluorescence emission spectrum sensitive to pH may be convenient probes for measuring pH_i. When exposed to light, pH-sensitive dye molecules may absorb some of the light as electrons make the

transition to a higher-energy state. From the intensities of incident light (I_o) and the light transmitted through the solution (I), we can compute the absorbance (A):

$$A = \log \frac{I_o}{I} \tag{52.4}$$

According to the Beer-Lambert law, A at a particular wavelength (A_λ) is proportional to both the length of the light's path through the solution (l) and the concentration of the dye (C):

$$A_\lambda = \varepsilon_{\lambda,pH}\, lC \tag{52.5}$$

where the proportionality constant $\varepsilon_{\lambda,pH}$ is the dye's extinction coefficient at a particular wavelength and pH. The wavelength dependence of $\varepsilon_{\lambda,pH}$ defines the shape of the absorbance spectrum, and the pH dependence of $\varepsilon_{\lambda,pH}$ defines how this shape is affected by changes in pH. However, A_λ depends not only upon pH, but also upon l and C. Although l and C are extremely difficult to ascertain in a live cell, we can obtain the absorbance data at two wavelengths (λ_1 and λ_2), and compute the absorbance ratio ($A_{\lambda 1}/A_{\lambda 2}$):

$$\frac{A_{\lambda 1}}{A_{\lambda 2}} = \frac{\varepsilon_{\lambda 1,pH}\, lC}{\varepsilon_{\lambda 2,pH}\, lC} = \frac{\varepsilon_{\lambda 1,pH}}{\varepsilon_{\lambda 2,pH}} \tag{52.6}$$

Thus, because the l and C terms cancel out, the absorbance ratio in Equation 52.6, depends only on pH. By choosing two wavelengths such that $\varepsilon_{\lambda 1,pH}/\varepsilon_{\lambda 2,pH}$ varies considerably with pH, one can obtain sensitive pH measurements. Experimenters using fluorescein derivatives typically use the peak absorbance wavelength (~510 nm), and the isosbestic wavelength (~440 nm), where ε is insensitive to pH changes. Monitoring dye absorbance at the isosbestic wavelength is attractive because one can determine the extent of dye loss during the experiment, assuming l is constant.

An advantage of absorbance for measuring pH_i is that it tends to be extremely stable and sensitive. On the other hand, because absorbance is proportional to l and C, a relatively high intracellular dye concentration is required, even for thick preparations (e.g., renal tubules).

Fluorescence

After absorbing a photon, most molecules return to the ground state by gradually losing energy through a series of random collisions with other molecules (see ref.[53]). Some dyes, however, can lose a quantum of energy from an excited singlet state by emitting a photon (i.e., fluorescing). The intensity of emitted fluorescent light (I_{emit}) can be measured with a photomultiplier tube (e.g., see ref.[19]) or an intensified [CCD] television camera, which provides imaging data (e.g., see ref.[54]). At most wavelengths, I_{emit} is sensitive to pH, but at all wavelengths, I_{emit} is sensitive to dye concentration as well as other parameters (e.g., position of cell in the incident light beam). Therefore, one usually employs a ratio technique to generate a parameter more uniquely related to pH. With the *fluorescence-excitation ratio* approach, commonly used with fluorescein dyes such as BCECF, one alternately excites at two wavelengths while monitoring I_{emit} at one wavelength. With the *fluorescence-emission ratio* approach, commonly used with some rhodamine dyes such as SNARF-1, one excites at one wavelength, while monitoring I_{emit} simultaneously at two wavelengths. By analogy with the absorbance ratio approach, one chooses three wavelengths to optimize the pH sensitivity of the ratio. A strength of the fluorescence-emission ratio approach is that the simultaneous capture of I_{emit} at two wavelengths improves temporal resolution (see below).

Fluorescence measurements offer the advantage of being extremely sensitive. Thus, it is possible to quantitate the fluorescence from small amounts of dye, even in a microdomain within a single cell. In addition, one can use fluorescence with two-dimensional imaging, confocal microscopy, and multi-photon microscopy. Because fluorescence is more sensitive than absorbance to the environment of the dye molecule, fluorescence measurements are in principle more prone to artifact.

Bleaching and Photodynamic Damage

Excessive illumination can photolyse (i.e., bleach) dye molecules, causing a progressive decrease in the concentration of native dye. Among the photolysis products may be free radicals that react with cellular components and injure the cell ("photodynamic damage"). Excessive illumination can also cause a time-dependent shift in the apparent intracellular calibration curve of the dye,[19] presumably due to bleaching-induced generation of dye-related products with spectral characteristics slightly different than those of the parent compound.

Bleaching can be particularly problematic during experiments on single cells, where the number of dye molecules and thus the number of emitted photons is low. The problem is that the limiting signal-to-noise ratio (S/N) is proportional to the square root of the number of photons measured. One can increase the number of emitted photons by increasing the intensity of the excitation light source, but at the expense of exacerbating the bleaching and photodynamic damage. The damage can be minimized either by illuminating continuously with low-intensity light for longer, or by limiting the duty cycle of high-intensity exciting light.[19] Thus, one must sometimes trade off pH_i resolution (i.e., S/N) against time resolution. In imaging experiments, where a cell may be represented by thousands of picture elements (pixels), the photon emission rate per pixel is exceedingly low. Here, one must trade off pH_i resolution, time resolution, and

spatial resolution (i.e., the number of pixels that must be grouped to compute pH_i values).

More recent advances in fluorescence microscopy have helped to minimize the predicament of good pH_i vs. spatial/temporal resolution. For example, two-photon excitation laser scanning microscopy is a relatively new imaging technique that has allowed investigators to reduce photobleaching of ion-sensitive fluorescent dyes, even while acquiring high spatial and temporal resolution recordings.[55,56] Multiphoton imaging technology is based on the general quantum principle that a molecule can exhibit fluorescence after absorbing two photons simultaneously when excited by high-intensity light of twice the wavelength necessary for single-photon absorption. Excitation at the higher wavelengths (and thus lower energies) reduces overall photobleaching of the dye. Two-photon microscopy has been particularly useful in measuring intracellular Ca^{2+} transients with excellent spatial resolution in tissues and cellular microdomains (see[57–60]). The technique has also been used with pH-sensitive dyes.[61] For example, intracellular pH has been measured with BCECF in microdomains of the epidermis,[62] and with SNARF-4 in villous enterocytes *in vivo*.[63]

Calibration

SIMULTANEOUS MICROELECTRODE MEASUREMENTS

Because dyes interact with cytoplasmic components, the spectroscopic properties of an intracellular dye differ, sometimes markedly, from those of the same dye examined in a cuvette. Therefore, intracellular dye calibration is essential. One calibration approach is to use a second, independent method for measuring pH_i in either the same cell, or another cell under similar conditions. For example, simultaneous measurements with a pH-sensitive microelectrode have confirmed that the absorbance indicator dimethylcarboxyfluorescein in salamander proximal-tubule cells,[64] and the fluorescence indicator BCECF in leech glial astrocytes[65] yield reasonable values.

NIGERICIN APPROACH

The most popular approach has been to monitor intracellular absorbance or fluorescence while using the high-$[K^+]_o$/nigericin technique[66] to clamp pH_i to predetermined values. Nigericin is a carboxylic ionophore that exchanges K^+ (and to a lesser extent Na^+) for H^+ across cell membranes. If one is successful in choosing $[K^+]_o$ to match $[K^+]_i$, then pH_i should equal pH_o. Thus, by altering pH_o, one can measure the dye's spectral properties over a range of pH_i values. A detailed calibration spanning a wide pH_i range can be obtained for each experiment. Alternately, one can perform the detailed calibration on one set of cells, and routinely perform only a single-point calibration.[19] Potential problems with the high-$[K^+]_o$/nigericin technique have been discussed in some detail.[67]

In using nigericin-containing solutions for dye calibration, one must be careful to cleanse the perfusion system completely after each calibration procedure. Even trace amounts of nigericin can interfere with the assessment of pH_i-regulating mechanisms, by mimicking a K^+-H^+ exchanger and by increasing "background acid loading[a]" through nigericin-mediated exchange of internal K^+ for external H^+.[17,68]

NULL-POINT APPROACH

A novel calibration technique, originally proposed for microelectrodes by Szatkowski and Thomas,[69] but applied to dyes by Eisner et al.,[70] involves sequentially exposing the cell to a permeant weak acid and weak base. As discussed below, the size of a pH_i change elicited by a weak acid/base depends on the initial pH_i. It is thus possible to compute the initial pH_i from the magnitude of the change of the pH_i indicator. Eisner et al.[70] have extended this approach by introducing an elegant null-point technique, in which one experimentally determines a combination of weak-acid and weak-base concentrations that produces no change in the measured fluorescence. The null-point approach can be particularly useful in assessing the validity of other dye-calibration procedures, particularly the high-$[K^+]_o$/nigericin technique.[71–73]

Choice of Dyes

BCECF

The most popular dye for fluorescence measurements of pH_i is the fluorescein derivative BCECF,[74] which has four negatively-charged carboxylate groups and a phenolic -OH moiety that is titrated by pH changes. The dye can be directly loaded into large cells (e.g., *Xenopus* oocytes) with an injection pipette, or into small mammalian cells by diffusion from a patch pipette during whole-cell recordings.[75,76] However, BCECF is usually loaded into cells as an uncharged acetoxymethylester (AM) precursor that easily permeates most plasma membranes. Intracellular esterases hydrolyze BCECF-AM to yield four or five formaldehyde molecules for each charged BCECF molecule trapped inside the cell. The time required for dye loading can vary greatly among cell types, from 1 minute to tens of minutes. Less conventional methods for dye loading—including scrape loading, osmotic lysis, and electroporation—are examined in more detail in

[a]We define "acid loading" as any process that causes pH_i to fall. Examples include the uptake of H^+, the loss of HCO_3^-, or the metabolic production of H^+.

Giuliano and Taylor.[77] BCPCF, with carboxypropyl groups, is a derivative of BCECF that can be used as a dual-emission pH indicator.[78]

OTHER DYES

Both pyranine-based[79] and rhodamine-based dyes[80,81] have also been used for monitoring pH_i. Rhodamine dyes such as the seminaphthorhodafluor (SNARF) dyes are excited and emit at longer wavelengths than the fluorescein derivatives. An advantage of SNARF is that its fluorescence-emission spectrum is pH sensitive, in addition to its absorbance and fluorescence-excitation spectra. Thus, the dye can be used in the dual-emission mode, and is therefore more useful than fluorescein derivatives for confocal microscopy, in which one typically excites at only one wavelength. Dual-emission dyes also enable the user to sample more frequently, and to avoid the delay in alternating between two excitation wavelengths. SNARF-1 can be used simultaneously with Fura-2 for monitoring both pH_i and $[Ca^{2+}]_i$.[82] In general however, one should be cautious in using multiple ion-sensitive dyes simultaneously to avoid quenching artifacts.[83]

MEASUREMENT OF pH IN ORGANELLES

pH-sensitive fluorescent dyes with lower pK values are available (e.g., from Life Technologies™/Molecular Probes®) for pH measurements in acidic organelles such as lysosomes. Some of these dyes include the weak-base LysoSensor probes,[84,85] the aminorhodamine dye pHrodo,[86] and the fluorinated fluorescein dye Oregon Green.[87,88] These probes can be targeted to appropriate organelles by a cell's own endocytic pathway.

Investigators have also developed ingenious methods for targeting pH-sensitive probes to organelles. As reviewed by Maxfield and Yamashiro,[89] pH-sensitive indicators can be targeted to the endocytic pathway following pinocytosis or receptor-mediated endocytosis. Kim et al.[90] have measured Golgi pH with either a rhodamine- or fluorescein-labeled β subunit of verotoxin, which accumulates in the Golgi complex after receptor-mediated endocytosis and retrograde transport. Grinstein's group has also measured pH in the endoplasmic reticulum[91] and the *trans*-Golgi network[92] by creating chimeric proteins with organelle-specific retrieval signals, and subsequently tagging them with pH-sensitive fluorophores before internalization. A similar approach has been used to measure the pH of recycling endosomes.[93,94] The Machen group has examined pH regulation in the secretory pathway by targeting biotin-labelled pH probes to organelles expressing avidin-chimera proteins.[95–97] Seksek et al.[98] have used a different technique to measure the *trans*-Golgi pH of fibroblasts. They injected the cells with 70-nm liposomes containing membrane-impermeable pH-sensitive fluorophores; the liposomes then fused with the *trans*-Golgi. As described in the next section, investigators have also measured the pH of organelles by fusing pH-sensitive green fluorescent protein (GFP) variants or associated biosensors to organellar localization signals.

GREEN-FLUORESCENT PROTEIN (GFP)

Another fluorophore that has become useful in the pH field is GFP, which is a natural product of the jellyfish *Aequorea victoria*, and typically used to label proteins expressed in cells.[99,100] Several researchers have engineered GFP mutants such as pHluorins[101] that are sensitive to pH changes in the physiological range, and can be targeted to the cytosol or organelles.[102–108] Wild-type or mutant fluorescent proteins such as GFP and YFP can also be fused together to create ratiometric pH biosensors, and subsequently target the biosensors to organelles such as the mitochondria.[109] Tantama et al.[110] have recently engineered—from the red fluorescent protein mKeima—a pH-sensitive, dual-excitation/ratiometric variant called pHRed. This variant would be particularly useful during simultaneous measurements requiring the use of other more blue-shifted fluorescent probes. Moreover, upon two-photon, single-wavelength excitation, pHRed exhibits modest pH-sensitive changes in fluorescence lifetime that could be used to obtain rough estimates of pH_i.

Compared to more traditional pH indicators, pH-sensitive GFP mutants are advantageous in displaying a low rate of photobleaching while remaining trapped inside of cells. pHluorins linked to markers of synaptic vesicles (synaptopHluorins) undergo marked changes in fluorescence upon exocytosis at synaptic terminals and have therefore been used to characterize synaptic vesicle cycling associated with presynaptic activity.[101–112] Such vesicular cycling has been examined in transgenic mice expressing synaptopHluorin.[113] It is intriguing to speculate on the potential applicability of pH-sensitive GFPs to examine cellular pH physiology. Indeed, pHluorin constructs have been used to measure pH_i of fungi, plants, and yeast,[114–116] as well as transiently transfected HEK293 cells and astrocytes (Liu and Bevensee, unpublished). One could perform *in vivo* pH_i measurements on targeted cells that are induced by a specific promoter to express a pH-sensitive GFP. Metzger et al.[117] successfully measured pH_i in cerebellar slices from a generated transgenic mouse expressing a pH- and chloride-sensitive yellow-green variant of GFP (EYFP) under the control of a neuronal potassium channel promoter.

Differential Dye Loading

One can exploit differential dye loading in preparations to target dyes to specific cells or locations. For

example, intercalated cells in the cortical collecting tubule of the kidney incorporate BCECF-AM much more rapidly than the neighboring principal cells.[118] In a somewhat different application, Chu et al.[119] found that mouse colonic crypt cells exclude SNARF, which can then be used to measure extracellular pH changes in the intact epithelium. Also, a probenecid-sensitive organic-anion transporter can extrude BCECF from some cells including thyroid cells,[120] and epithelial kidney and intestinal cells.[121,122] In an elegant study, Harris et al.[123] used BCECF to measure the pH of the lateral intracellular space (LIS) of MDCK cell monolayers by first loading the cells with BCECF, and subsequently allowing organic transporters to move the dye into the LIS.

BCECF generally stains the cytoplasm rather uniformly, although in some cells the nuclear region is more intense than peripheral areas.[124] Working on Ehrlich ascites tumor cells, Thomas et al.[66] found that 6-carboxyfluorescein is confined to the cytoplasm, but fluorescein is distributed in both the mitochondria and cytoplasm. Furthermore, Slayman et al.[125] found that BCECF can accumulate in vacuoles of the fungus *Neurospora* when the cells are exposed to BCECF-AM.

One can evaluate a dye's intracellular compartmentalization by monitoring the fluorescence loss elicited by selectively permeabilizing different compartments with detergents. For example, most of the BCECF loaded into rat hippocampal CA1 neurons appears to be in the cytoplasm because 0.01% saponin reduces the fluorescence signal by ~96%.[126] Both absorbance- and fluorescence-derived estimates of pH_i can be influenced by dye in compartments other than the cytoplasm, depending upon each compartment's volume, dye concentration and pK, and pH.

Nuclear Magnetic Resonance

Certain atomic nuclei, among them ^{31}P and ^{19}F, possess a quantum mechanical property termed "spin," and behave as tiny bar magnets with magnetic moments. When an atomic nucleus of this type is placed in an external magnetic field, the magnetic moment precesses with a characteristic frequency about the axis of the applied field. The nucleus can be excited to a high-energy state by irradiating it with an oscillating magnetic field of the same frequency (i.e., resonance frequency) as the precession frequency. The resonance frequency depends not only on the identity of the atomic nucleus (e.g., ^{31}P), but also on its chemical environment, which influences the strength of the magnetic field at the nucleus. Thus, the resonance frequencies for ^{31}P in $HPO_4^{=}$ and HPO_4^{-} are slightly different because of the different chemical environments of the ^{31}P. Because the exchange rate of ^{31}P between individual $HPO_4^{=}$ and HPO_4^{-} ions is very rapid, nuclear magnetic resonance (NMR) detects only a single inorganic phosphate peak, the location of which depends on $[HPO_4^{-}]/[HPO_4^{=}]$. Because the dependence of this ratio on pH is described by a modified pH-titration curve ($H_2PO_4^{-} \rightleftarrows HPO_4^{=} + H^+$; $pK_a' = \sim 6.8$), the position of the inorganic phosphate peak is a good index of pH_i.

A major advantage of ^{31}P-NMR is that, in addition to providing nearly continuous measurements of pH_i, it can also be used to monitor levels of a variety of phosphorus-containing compounds, such as ATP. The pH_i value derived from NMR measurements is predominantly the pH of the cytoplasm. However, the inorganic phosphate peak for the cytosol may overlap with the inorganic-phosphate peaks from other intracellular compartments, as well as the extracellular space. The mitochondrial inorganic phosphate peak can in some cases[127] be resolved from that of the cytoplasmic peak. NMR measurements have been made on whole organs, whole small animals, and human limbs.[128]

pH_i can also be measured by NMR with ^{19}F-labeled probes having pK values in the physiological range.[129] As discussed by Deutsch,[130] ^{19}F-labeled probes are advantageous over ^{31}P in that background signals are low, and the fluorinated probes are highly visible and sensitive to the environment. Commonly used probes such as fluoroanilines, derivatives of fluoroisobutyric acid, and fluorinated pyridoxins are generally introduced into cells as methyl esters, similar to the approach used for pH-sensitive dyes. Aside from cost and the need for technical expertise, the major disadvantage of NMR is its relatively low sensitivity. Thus, a considerable mass of ^{31}P or ^{19}F is required for detection, precluding the use of the technique with single cells. For reviews, see refs[128,131,132].

As reviewed by Gallagher et al.,[133] related approaches for estimating pH_i include a comparison of ^{13}C signals for CO_2 and HCO_3^{-}, the use of ^{89}Y-labeled compounds, and pH-sensitive exchange of ^1H_2O between bulk water and water bound to a gadolinium complex.

FORCES AFFECTING THE PASSIVE MOVEMENT OF H^+ AND OTHER CHARGED ACIDS AND BASES

Forces Affecting H^+

Until the 1930s, it was generally assumed that hydrogen ions were in electrochemical equilibrium across the cell membrane, as defined by the Nernst equation:

$$V_m = \frac{RT}{F} \ln \frac{[H^+]_o}{[H^+]_i} \qquad (52.7)$$

Here, V_m is the voltage difference across the plasma membrane (the unit is the volt), R is the universal gas content (8.31 joules • $^{\circ}K^{-1}$ • equivalent^{-1}), T is absolute temperature, F is Faraday's constant (96,486 coulombs • equivalent^{-1}), and the subscripts *o* and *i* refer to extracellular and intracellular, respectively. In terms of pH, the foregoing equation becomes

$$V_m = (0.0585\ V) \times (pH_i - pH_o) \qquad (52.8)$$

assuming a temperature of 22°C. Thus, if H^+ were in equilibrium, then pH_i would be one unit lower than pH_o for each −58.5 mV of membrane potential. However, such a situation would present severe problems for the cell, inasmuch as V_m changes would shift the equilibrium distribution of H^+, and thus alter pH_i and pH_i-sensitive processes. It was not until the mid-1930s that Fenn and colleagues,[134,135] in experiments on frog skeletal muscle, demonstrated that pH_i is higher than expected for H^+ to be in electrochemical equilibrium. The authors, in effect, estimated V_m from the ratio $[K^+]_o/[K^+]_i$, and measured pH_i using the weak-acid method.

Nowadays, both V_m and pH_i can be measured directly, and for nearly all cells studied, pH_i is well above the equilibrium pH_i. In vertebrate skeletal muscle, for example, V_m is ∼ −90 mV and pH_i is ∼7.1[3]. Given a pH_o of 7.4, Equation 52.8 predicts an equilibrium pH_i of ∼5.9, far lower than the actual pH_i. Rather than calculating equilibrium pH, one could equally well compute equilibrium potential for H^+, that is, the membrane voltage required for H^+ to be in equilibrium across the membrane (E_H). In skeletal-muscle example introduced above ($pH_i = 7.1$, $pH_o = 7.4$), the E_H computed from Equation 52.7 or Equation 52.8 is ∼ −18 mV. Because the actual V_m (−90 mV) is more negative than E_H, H^+ is drawn into the relatively negative cell, driven by an electrochemical gradient of 90−18 or 72 mV. Thus, there is a substantial electrochemical gradient (1.2 pH units or 72 mV) favoring the passive influx of H^+. If the cell membrane were permeable to H^+, then the resultant H^+ influx would represent a *chronic intracellular acid load* (i.e., an acid load imposed on the cell for an indefinite period) that would tend to lower pH_i.

In the above discussion, we made no assumptions about the mechanism of the hypothetical influx of H^+. It had generally been thought that H^+ flux across the plasma membrane occurs via nonspecific pathways. However, as extensively reviewed by DeCoursey,[136,137] voltage-activated, Zn^{2+}-inhibited H^+ currents were first described in snail neurons,[138] and have subsequently been characterized in numerous other cell types, including epithelial cells (e.g., kidney cells), connective tissue, skeletal muscle, lymphocytes, macrophages, granulocytes, and microglia. Ramsey et al.[139] and Sasaki et al.[140] independently identified the first cDNA encoding a Zn^{2+}-sensitive, voltage-gated proton channel, termed H_v1 (also known as VSOP). As first shown by Meech and Thomas, the channel is closed at normal V_m levels, when the H^+ electrochemical gradient favors the passive influx of H^+. However, strong depolarization not only reverses the H^+ gradient—now favoring the passive efflux of H^+—but also opens the channels. Thus, as reviewed by Capasso et al.,[141] as long as the cell is highly depolarized, this channel functions as an H^+-efflux pathway that can contribute to acid extrusion, defined below in our discussion of pH_i regulation. Murphy et al.,[142] used the NH_4^+-prepulse technique to acid load rat alveolar epithelial cells, and computed the acid-extrusion rate from the subsequent pH_i recovery. They observed similar Zn^{2+}-sensitive acid extrusion, regardless of whether the cells were depolarized with high-K^+ solutions, and concluded that H_v1 channels must have been contributing to the pH_i recovery. However, it is not clear whether—under conditions of 'normal' membrane voltage—the H^+ electrochemical gradient would be outward and the H_v1 channels would be open. In the absence of data showing that the Zn^{2+} effects are reduce/eliminated by the knockdown/knockout of H_v1, one must entertain the hypothesis that Zn^{2+} had nonspecific effects and that H_v1 did not contribute to pH_i regulation.

The depolarization threshold for channel activation is lowered by increasing the pH_o-to-pH_i gradient. Although the single-channel conductance is low for H_v1, high protein expression in cells account for macroscopic H^+ currents that can exceed K^+ currents.

It has become clear that H_v1 is functionally coupled to NADPH oxidases (NOX), and plays a critical role in removing the protons formed as byproducts during the generation of O_2^-[143–145]; for reviews, see refs[137,146]. This H_v1 activity is important during neutrophil phagocytosis,[147] signaling in immune cells, as well as in spermatozoa activation (see ref. [141]).

Forces Affecting Charged Weak Acids/Bases

In general, the passive fluxes of ionic weak acids (e.g., NH_4^+) and bases (e.g., HCO_3^-) also impose a chronic intracellular acid load. As noted earlier (see Equation 52.2), whenever a neutral weak acid (HA) is equilibrated across the cell membrane ($[HA]_i = [HA]_o$), the transmembrane distribution ratio for H^+ is the reciprocal of the distribution ratio for the anionic conjugate weak base (A^-). Consider, for example, the CO_2/HCO_3^- buffer system. If (1) $[CO_2]_i$ equals $[CO_2]_o$, (2) CO_2 is in equilibrium with H^+ and HCO_3^- both

inside and outside the cell, and (3) the equilibrium constant is the same inside and outside the cell, then:

$$\frac{[H^+]_i}{[H^+]_o} = \frac{[HCO_3^-]_o}{[HCO_3^-]_i} \quad (52.9)$$

That is, the electrochemical gradient for HCO_3^- (and that for any other monovalent anion that can be described by a similar equation) is equal to but opposite to the gradient for H^+. Inasmuch as H^+ normally leaks into cells, HCO_3^- and other anionic weak bases tend to leak out, also decreasing pH_i. In crayfish muscle, the transmitter GABA opens Cl^- channels that are also permeable to HCO_3^-.[148] The resultant HCO_3^- efflux can reduce pH_i by as much as 0.4. A similar $GABA_A$-activated HCO_3^- conductance is present in cells from turtle cerebellum[149] and rat hippocampus.[150,151] This $GABA_A$-activated HCO_3^- conductance can be inhibited by antagonists of $GABA_A$ receptors such as picrotoxin. In a similar fashion, HCO_3^- movement through glycine-activated Cl^- channels alters pH_i.[75] Other anionic weak bases that seem to penetrate at least some cell membranes include the DMO anion,[152] formate,[153] propionate,[154] and salicylate.[153]

We can make a similar analysis for cationic weak acids ($HB^+ \rightleftarrows H^+ + B$). If the electrically neutral conjugate weak base (B) is equilibrated across the cell membrane (i.e., $[B]_i = [B]_o$), if the equilibrium $HB^+ \rightleftarrows H^+ + B$ holds on both sides of the membrane, and if the equilibrium constant is the same on both sides of the membrane, then:

$$\frac{[H^+]_i}{[H^+]_o} = \frac{[HB^+]_i}{[HB^+]_o} \quad (52.10)$$

That is, the electrochemical gradient for HB^+ is in the same direction as that for H^+. Thus, similar to H^+, cationic weak acids such as NH_4^+ tend to enter the cell and produce a chronic intracellular acid load.

Energetics of pH_i Regulation

The preceding analysis shows that, under the conditions that normally prevail in most cells (e.g., $pH_i \cong 7.1$, $V_m \cong -60$), the electrochemical gradients affecting H^+ and charged monovalent weak acids/bases (provided the neutral species equilibrates across the membrane) generally favor fluxes that would lower pH_i. Note that the above thermodynamic analysis addresses only the net *direction* of these passive fluxes, and does not address the *rate* of intracellular acid loading. These passive fluxes are depicted for a model cell in Figure 52.2. Additional acid-loading mechanisms include carrier-mediated transport of H^+ into or HCO_3^- out of cells, as well as metabolism that generates acidic byproducts. Acid-loading mechanisms such as passive fluxes, carrier-mediated transport, and metabolism are "chronic" because they act continuously to lower pH_i. Maintaining a normal pH_i requires that acid loading be matched by a comparable—and continuous—extrusion of acid. By definition, this acid extrusion[b] must be an active (i.e., energy-requiring) process. Acid extrusion can be accomplished either by the active uptake of alkali (e.g., OH^- or HCO_3^-) and/or the active removal of acid (e.g., H^+).

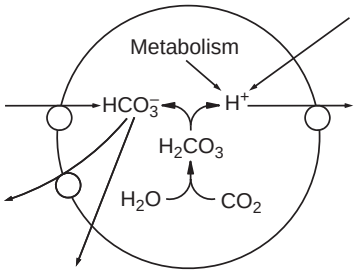

FIGURE 52.2 Factors affecting cellular H^+ balance. In a typical mammalian cell, membrane potential (V_m) might be −60 mV (inside negative) and extracellular pH (pH_o) approximately 7.4. In order for H^+ to be in electrochemical equilibrium, pH_i would have to be approximately 6.4. This is far lower than typical values, which range from 6.8 to 7.6, depending upon the cell type. Thus, H^+ tends to enter the cell passively (*inward arrow*). The same gradient that drives H^+ into the cell would also tend to drive HCO_3^- out (*outward arrow*), thereby lowering pH_i. The cell would also be acidified by any transporters that mediate the efflux of HCO_3^- (*curved arrow*), and perhaps by the metabolic generation of acid (*arrow*). In order for pH_i to be kept at its normal, relatively alkaline value, transporter(s) must actively remove acid from the cell, or accumulate an alkali such as HCO_3^-. Together, such active processes are referred to as "acid extrusion."

EFFECTS OF WEAK ACIDS AND BASES ON pH_i

Effects of CO_2 and Other Neutral Weak Acids

In the section above on "Distribution of Weak Acids and Bases" for measuring pH_i, we discussed the flux of neutral weak acids and bases across the cell membrane. In general, solutions containing the weak acid HA always contain the conjugate weak base A^-. However, because membranes are usually far more permeable to HA than to A^-, HA fluxes generally have a greater effect on pH_i.

Flux of the Neutral Weak Acid

When a cell is exposed to a neutral weak acid, HA enters and dissociates into A^- and H^+, thereby causing pH_i to fall:

[b]We define "acid extrusion" as any process that causes pH_i to rise. Examples include the efflux of H^+ and the uptake of HCO_3^-.

$$HA \rightarrow A^- + H^+ \quad (52.11)$$

This movement of the neutral weak acid (or a neutral weak base such as NH_3, discussed below) has been termed non-ionic diffusion. This process continues until $[HA]_i$ equals $[HA]_o$. Subsequently, there should be no further change in pH_i, provided there is no flux of A^- and no change in the rates of acid–base transporter activity. Although CO_2 is often regarded as a weak acid, it is not an acid at all. Only after reacting with H_2O does CO_2 yield the true weak acid, H_2CO_3, which then dissociates (as described above for the idealized weak acid HA):

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow HCO_3^- + H^+ \quad (52.12)$$

These two reactions can be combined into a single one with an overall apparent equilibrium constant ($K_a' = [HCO_3^-][H^+]/[CO_2]$). The enzyme carbonic anhydrase (CA) greatly accelerates the formation of HCO_3^- from CO_2 by catalyzing the reaction:

$$CO_2 + OH^- \xrightarrow{CA} HCO_3^- \quad (52.13)$$

which generates H^+ by virtue of consuming OH^-. The mechanism by which CA catalyzes this reaction is examined in more detail by Liljas et al.[155] In the absence of CA, the reaction can also occur, particularly under alkaline conditions (i.e., pH >8).

In the example of Figure 52.3, a cell is successively exposed to solutions equilibrated with 1, 2 and 5% CO_2 (constant $[HCO_3^-]_o = 10$ mM). Each time, CO_2 produces a rapid and sustained fall of pH_i. The period during the CO_2 exposure in which pH_i is relatively stable is termed the *plateau phase*. The magnitude of the CO_2-induced acidification is inversely related to the intracellular buffering power (β; see below). The magnitude of the pH_i decrease also increases with $[CO_2]_o$. The degree of dissociation is governed by the relationship between pH_i and pK_a', which, in logarithmic form, is the familiar Henderson-Hasselbalch equation:

$$pH_i = pK_a' + \log \frac{[HCO_3^-]_i}{[CO_2]_i} \quad (52.14)$$

where pK_a' is ~6.1 at 37°C. Therefore, if pH_i is 7.1, 10 molecules of incoming CO_2 dissociate into H^+ plus HCO_3^- for each molecule of CO_2 that remains CO_2. If the initial pH_i is only 6.1, then this ratio falls to 1:1, and fewer incoming CO_2 molecules dissociate. There are two practical consequences of this rule. First, the lower the initial pH_i, the smaller the magnitude of acidification elicited by the subsequent exposure to the CO_2. Second, as one raises $[CO_2]_o$ by fixed increments, the magnitude of the acidification is not proportional to the successive $[CO_2]_o$ increment. Thus, in Figure 52.3, the ΔpH_i produced by 2% CO_2 is less than twice as large as that produced by 1% CO_2, and that produced by 5% CO_2 is substantially less than five times that produced by 1% CO_2.

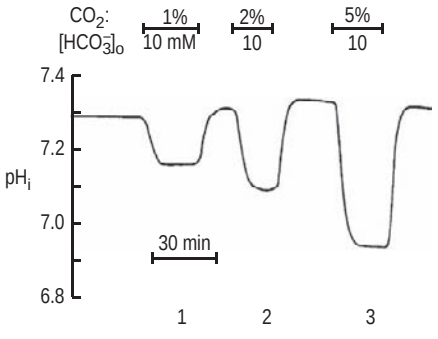

FIGURE 52.3 Effect of CO_2 on pH_i. A giant barnacle muscle fiber was exposed to CO_2 at three different levels: 1% ($pH_o = 7.5$), 2% ($pH_o = 7.2$), and 5% ($pH_o = 6.8$). After its entry into the cell, CO_2 is rapidly hydrated to H_2CO_3, which in turn dissociates into H^+ and HCO_3^-, causing pH_i to fall. Removing CO_2 reverses these processes. pH_i was measured with an exposed-tip pH-sensitive microelectrode, of the design of Hinke.[621] *(Reproduced from ref. [165].)*

Although investigators have long believed that all gases penetrate all membranes simply by dissolving in the membrane lipid, Waisbren et al.[6] demonstrated the first membrane with negligible permeability to a dissolved gas (i.e., CO_2 and NH_3). Moreover, Nakhoul et al.[11] and Cooper and Boron[9] identified the first gas channel—AQP1, which is permeable to CO_2. Later work showed that AQP1 is also permeable to NH_3[48] and that rhesus (Rh) proteins can be permeable to both CO_2[156] and NH_3.[157–159] In human erythrocytes, AQP1 and the Rh complex, together, are responsible for ~90% of the CO_2 permeability.[160,46] Thus, at least two families of proteins can function as gas channels. Furthermore, just as ion channels display ion selectivity, the AQPs and Rh proteins display gas selectivity. Based on CO_2- or NH_3-mediated changes in the surface pH of oocytes expressing AQP or Rh-family members, the sequence of CO_2/NH_3 selectivity is AQP4 ≅ AQP5 > AQP1 > AmtB > RhAG.[47]

Weak acids such as acetic acid,[161] lactic acid,[162] and DMO[152] can also elicit intracellular acidifications, which have $[HA]_o$ and pH_i dependencies similar to those described for CO_2. Aside from the dissolved gases discussed in the previous paragraph, many nonvolatile neutral weak acids and bases may move through plasma membranes—at least in part—via protein pathways (e.g., channels, transporters) in addition to any traffic through the lipid phase of the membrane. In a general sense, all such fluxes can be thought of as non-ionic diffusion, regardless of the mechanism. CO_2

is unusual, however, in that $[CO_2]_o$ is easily controlled, independent of $[HCO_3^-]_o$, either by the experimenter (who can equilibrate solutions with a known CO_2 mixture) or by the intact organism (which can alter its external respiration). Of course, the price one pays for varying $[CO_2]$ at constant $[HCO_3^-]$ is that—at equilibrium—pH must vary as well, as predicted by Equation 52.14. In the laboratory, it is possible to overcome this limitation by using out-of-equilibrium CO_2/HCO_3^- solutions (see below) to change only one of the three parameters (pH, CO_2, or HCO_3^-) at a time. For nonvolatile weak acids, the experimenter can only manipulate the total concentration of extracellular buffer ($[TA]_o = [HA]_o + [A^-]_o$) and pH. When $[TA]_o$ is fixed, changes in pH_o produce reciprocal alterations in $[HA]_o$ and $[A^-]_o$, so that the magnitude of the HA-induced pH_i decrease is very pH_o sensitive.

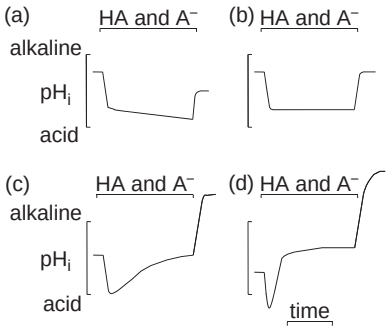

FIGURE 52.4 Hypothetical responses of a cell to the application of a neutral weak acid (HA) and its conjugate weak base (A^-). In all cases, the initial effect is a rapid fall in pH_i, due to the influx and partial dissociation of HA. The decrease in pH_i halts once $[HA]_i = [HA]_o$. The subsequent course of pH_i depends on the balance among (1) the passive efflux of A^- (which will lower pH_i), (2) transporters (e.g., $Cl^- - HCO_3^-$ exchanger) that lower pH_i, and (3) transporters (e.g., $Na^+ - H^+$ exchanger) that raise pH_i. a: Acid loading exceeds acid extrusion, and pH_i falls during the plateau phase. When external HA/A^- is removed, the recovery of pH_i falls short of the initial value. b: Acid loading exactly balances acid extrusion, and pH_i is stable during the plateau phase. When external HA/A^- is removed, pH_i returns to its initial value. c: Introducing HA/A^- does not fundamentally alter either acid loading or acid extrusion. pH_i returns to exactly its initial level by the end of the plateau phase. When external HA/A^- is removed, pH_i overshoots its initial value. d: Introducing HA/A^- promotes acid extrusion more than acid loading. During the plateau phase, pH_i recovers to a value that is higher than the initial pH_i. When external HA/A^- is removed, pH_i overshoots its initial value by even more than in case C.

Flux of the Anionic, Conjugate Weak Base

In the preceding discussion, we assumed that the movement of the uncharged weak acid HA was the only factor affecting pH_i. In other words, we excluded the possibilities that: (1) the charged species A^- can traverse the cell membrane and significantly affect pH_i, and (2) acid–base transporters as well as metabolic processes that generate acid–base equivalents can alter the overall balance between acid extrusion/loading. In the absence of these complicating effects, applying and withdrawing HA/A^- would produce the pH_i changes illustrated in Figure 52.4b.

What would happen if A^-, as well as HA, were able to cross the membrane passively? At the instant a cell is exposed to a solution containing HA and A^-, the electrochemical gradient for A^- would be inward (assuming that the initial $[A^-]_i$ were sufficiently low). Initially then, both HA and A^- would enter, the HA tending to lower pH_i, and the A^- tending to raise pH_i. A significant permeability of the membrane to A^- would reduce the initial rate of the HA-induced acidification. Eventually, however, the generation of A^- from incoming HA, as well as the influx of A^-, would raise $[A^-]_i$ to such a level that A^- would tend to exit the cell passively, as described earlier. In addition, a transporter might move A^- out of the cell; for example, a $Cl^- - HCO_3^-$ exchanger normally moves HCO_3^- out of the cell. Subsequently, the efflux of A^- would lower pH_i, both during the initial HA-induced acidification and during the later plateau phase, as illustrated in Figure 52.4a. This A^- efflux represents what might be termed a "semi-chronic" acid load, inasmuch as the pH_i decrease would continue until $[A^-]_i$ was so low that A^- was equilibrated across the membrane. Removing external HA/A^- would elicit a rapid rise in pH_i due to the efflux of HA from the cell. Note, however, that pH_i would rise to a value less than the initial pH_i. The magnitude of the shortfall would be directly related to the net acid loading due to A^- efflux. The pH_i changes illustrated in Figure 52.4a, presumably due to permeability of the membrane to the A^- form of a weak acid, have been observed in snail neurons exposed to salicylic acid.[153]

Acid-extrusion mechanisms can also influence the pH_i changes of a cell exposed to HA/A^-. In practice, the effects described below are due to one or more acid-extruders that outstrip acid loaders. These transporters are described in more detail later, as are their effects on the dynamics of pH_i regulation. We introduce these transporters here only to complete our consideration of pH_i transients elicited by HA/A^-. Consider a cell that is permeable to HA, but not to A^-, and that has an acid-extrusion mechanism that is unaffected by A^- (e.g., $Na^+ - H^+$ exchange). Applying HA/A^- would acutely acid load the cell, due to the influx of HA, and subsequent formation of A^- and H^+. However, an acid-extruder stimulated by the pH_i decrease would remove this acute acid load and return pH_i to exactly its starting value (Figure 52.4C). Note that removing HA/A^- causes pH_i to overshoot its

initial value by a substantial amount. The magnitude of the overshoot is directly related to the net amount of acid extruded during the HA/A^- exposure. This pattern of pH_i changes, including a complete recovery of pH_i during the plateau phase, is observed in snail neurons acid loaded by exposure to CO_2/HCO_3^-.[15] Other examples have been reported in which the plateau-phase pH_i recovery is incomplete.

As illustrated in Figure 52.4d, exposing a cell to HA/A^- may cause the pH_i during the plateau phase to rise to a value even greater than the initial pH_i. For example, if the cell had an acid extruder that is stimulated either by HA or A^-, then the influx of HA would initially acidify the cell. However, the stimulated acid extruder would not merely return pH_i to its initial value, as in Figure 52.4c, but increase pH_i beyond the initial value, as in Figure 52.4d. We can provide two such examples in which A^- stimulates acid extrusion and thereby elicits pH_i changes similar to those in Figure 52.4d: (1) exposing renal mesangial cells to CO_2/HCO_3^- stimulates a Na^+-driven HCO_3^- uptake mechanism,[19,163] and (2) adding acetic acid/acetate to the lumen of a rabbit S3 proximal tubule stimulates a Na^+/acetate cotransporter.[161,164] HA can also stimulate acid extrusion. In the rabbit proximal tubule, CO_2 per se appears to stimulate Na^+-H^+ exchange and H^+ pumping.[22]

Effects of NH_3 and Other Neutral Weak Bases

Solutions containing the neutral weak base B also contain its conjugate weak acid HB^+. Because membranes are usually far more permeable to B than to HB^+, B fluxes tend to have a greater effect on pH_i.

Flux of the Neutral Weak Base

When a cell is exposed to a neutral weak base, B enters and associates with H^+ to form HB^+, causing pH_i to rise:

$$B + H^+ \rightarrow HB^+ \qquad (52.15)$$

This process continues until $[B]_i$ equals $[B]_o$. Subsequently, there should be no further change in pH_i, provided there is no flux of HB^+ and no change in the rates of acid–base transporter activity. Removing external B reverses the reaction as written in Equation 52.15, and B passively diffuses out of the cell. pH_i should then return to exactly its initial level. An example of the effect of the weak base NH_3 is shown in Figure 52.5. Applying 20 mM total ammonium (i.e., $[NH_3]_o + [NH_4^+]_o$) causes pH_i first to rise, and then stabilize (segment ab, pulse 1). Removing the NH_3/NH_4^+ elicits a fall in pH_i to a value somewhat lower than the initial one (compare points a and c). The reason for this

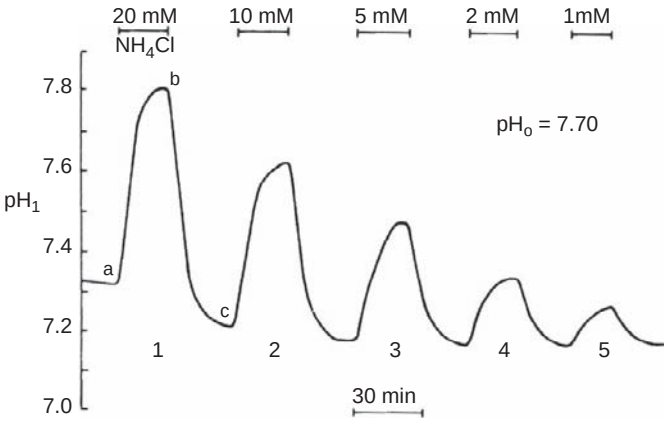

FIGURE 52.5 Effects of brief exposures to NH_3 on pH_i. A giant barnacle muscle fiber was exposed to NH_3 at five different levels of $[NH_3] + [NH_4^+]$: 20, 10, 5, 2, and 1 mM. Because pH_o was 7.70 throughout, $[NH_3]_o$ was approximately 312, 156, 78, 31, and 16 μM, respectively, in the five pulses. After its entry into the cell, NH_3 rapidly combines with H^+ to form NH_4^+. The resulting rise in pH_i continues until $[NH_3]_i = [NH_3]_o$. Removing external NH_3/NH_4^+ reverses these processes. Between NH_3/NH_4^+ pulses, the external solution was buffered with 5-mM HEPES to pH 7.5. pH_i was measured with an exposed-tip pH-sensitive microelectrode, of the design of Hinke.[621] *(Reproduced from ref. [165].)*

small pH_i undershoot will become clear below. As discussed above for HA-induced acidifications, the magnitude of the NH_3-induced alkalinization depends upon intracellular buffering power, $[NH_3]_o$, and the degree to which entering NH_3 is protonated. The last is governed by the relation:

$$pH_i = pK_a' + \log \frac{[NH_3]_i}{[NH_4^+]_i} \qquad (52.16)$$

where pK_a' (~9.2 at 22°C) is the acid dissociation constant. Thus, at the initial pH_i of 7.3 (point a), approximately 99.4% of entering NH_3 is protonated to form NH_4^+, whereas at a pH_i of 7.8 (point b), only approximately 98% is protonated. The dependence of the protonation of NH_3 on the difference $(pK_a' - pH_i)$ has two consequences, analogous to the two discussed earlier for CO_2. First, the higher the initial pH_i, the smaller the magnitude of the alkalinization elicited by the subsequent exposure to the NH_4^+. Second, as one raises $[NH_3]_o$ by fixed increments, the magnitude of the alkalinization with each successive $[NH_3]_o$ increment does not increase in proportion. Thus, in Figure 52.5, the alkalinization produced by 10 mM total NH_4^+ is less than twice as great as that produced by 5 mM total NH_4^+.

In Figure 52.5, the magnitude of the NH_4^+-induced alkalinization actually depends more on $[NH_3]_o$ than on $[\text{total } NH_4^+]_o$. Thus, the NH_4^+-induced alkalinizations will be identical for solutions in which $[\text{total } NH_4^+]$ and pH_o are varied reciprocally so as to keep

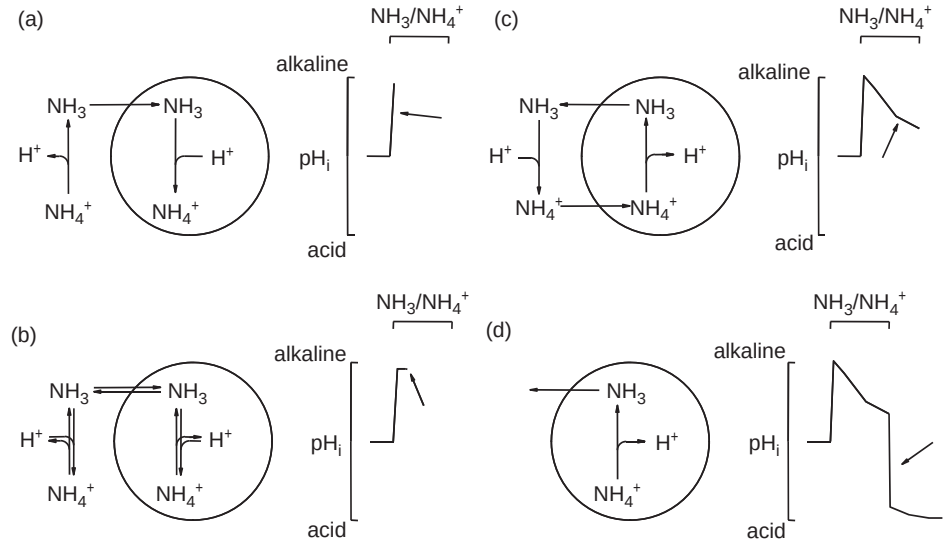

FIGURE 52.6 The NH_4^+ prepulse technique. a: When a cell is first exposed to a solution containing NH_4^+ and NH_3, there is a rapid increase in pH_i, due to the influx of NH_3. This rise in pH_i is blunted if NH_4^+ can also enter the cell. b: Eventually, $[NH_3]_i$ rises to the point where $[NH_3]_i$ transiently equals $[NH_3]_o$. Here, NH_4^+ is in equilibrium with NH_3 and H^+, both inside and outside the cell. pH_i is transiently stable. c: During the plateau phase, the entry of NH_4^+ leads to the formation of intracellular NH_3, which then exits the cell. This sets up a shuttling system for carrying H^+ into the cell. The NH_4^+ may enter via a simple conductive pathway, or be transported by a carrier such as the Na^+–K^+ pump or $Na^+/K^+/Cl^-$ cotransporter. Other acid loading processes (e.g., Cl^-–HCO_3^- exchange or metabolism) could also contribute to the plateau-phase acidification. d: Upon removing external NH_3/NH_4^+, most of the intracellular NH_4^+ gives up its H^+ and exits the cell as NH_3. Because NH_4^+ had accumulated in the cell during the plateau (either because of NH_4^+ uptake per se or other acid-loading processes), pH_i undershoots its initial value and the cell is acid loaded.

$[NH_3]_o$ constant.[165] Neutral weak bases such as lidocaine,[166] procaine,[166] and methylamine[51] also elicit intracellular alkalinizations that have $[B]_o$ and pH_i dependencies similar to those described for NH_3.

As noted above, the bacterial protein AmtB, an Rh homolog, functions as a gas channel permeable to NH_3.[47,48,157–159] In addition, aquaporins 1, 4, 5,[47] and AQP8[168] are permeable to NH_3.

It is possible to target the weak base NH_3 and selectively raise the pH of a specific intracellular compartment. For example, Carraro-Lacroix et al.[169] raised the pH of lysosomes by first endocytotically targeting urease to the lysosome compartment, and then exposing the cells to urea. The urease—now in the lysosomes—catalyzed the hydrolysis of the urea to produce one molecule of CO_2 but two of the weak base NH_3. Both because of the 2:1 stoichiometry of generated NH_3:CO_2 and the low initial lysosomal pH, the NH_3 dominates and the net effect is the NH_3-driven consumption of H^+ to form NH_4^+, thereby selectively alkalinizing the lysosome.

Flux of the Cationic, Conjugate Weak Acid

When one exposes a cell to a weak base, the dominant effect on pH_i generally reflects the influx of the highly permeant neutral weak base (e.g., NH_3). However, the flux of the conjugate weak acid (e.g., NH_4^+) may produce pH_i decreases that are substantial or even dominant. The effects on pH_i of applying and withdrawing NH_3/NH_4^+ can be separated into four steps. When a cell is exposed to NH_3/NH_4^+, the rapid influx of NH_3 leads to an initial rise in pH_i (Figure 52.6a). However, this alkalinization is actually blunted by the simultaneous, although smaller, influx of NH_4^+. The most general mechanism of NH_4^+ influx is the passive diffusion of NH_4^+,[170] although the carrier-mediated transport of NH_4^+ into cells can be substantial. For example, NH_4^+ can enter cells by substituting for K^+ on the Na^+–K^+ pump[171] and/or the $Na^+/K^+/Cl^-$ cotransporter.[7] Although most of the entering NH_4^+ remains NH_4^+, a small fraction (governed by the differences between pK_a' and pH_i) dissociates to form NH_3 and H^+. When external NH_3/NH_4^+ is removed, the NH_4^+ that previously entered, but failed to dissociate, now dissociates into NH_3 (which rapidly leaves the cell) and H^+ (which is trapped within the cell). As a consequence, the final pH_i (point c in Figure 52.5) is slightly lower than the initial value (point a).

The acidifying effect of NH_4^+ is much more evident when the NH_3/NH_4^+ exposure lasts beyond the initial influx (Figure 52.6a) and equilibration of NH_3 (Figure 52.6b). During an extended plateau phase, the continuing net influx of NH_4^+ produces a plateau-phase acidification, as illustrated in Figure 52.6c. In cells with a Cl^-–HCO_3^- exchanger (e.g., sheep cardiac

Purkinje fibers), this plateau-phase acidification may be augmented by efflux of HCO_3^- in exchange for Cl^-.[172] When the external NH_3/NH_4^+ is eventually withdrawn, the pH_i undershoot is greatly exaggerated (Figure 52.6d). The magnitude of the undershoot reflects the previous influx of NH_4^+. The longer the exposure to NH_3/NH_4^+, the more extensive the plateau-phase acidification, and the larger the undershoot. This undershoot represents an acute intracellular acid load. Indeed, the NH_4^+-prepulse technique is widely used for acid loading cells in studies of pH_i regulation.[170]

If the NH_4^+ electrochemical gradient is reversed during the plateau phase, in a cell for which the dominant mechanism of NH_4^+ entry is a passive flux, then pH_i rises during the plateau phase and the pH_i undershoot is converted to a shortfall.[165]

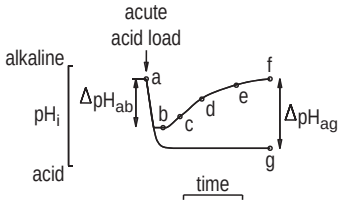

FIGURE 52.7 Determination of intracellular buffering power (β_i) in an intact cell from the pH_i change produced by an acute acid load. β_i is defined as the amount of strong acid injected (mmole/liter of cytoplasm) divided by the negative of the resultant fall in pH_i. Injecting acid, however, causes a biphasic change in pH_i: a rapid fall (segment ab), followed by a slower recovery (*bcdef*). The latter is due to extrusion of acid from the cell by one or more active transport processes. The true β_i must be computed from the pH_i change (ΔpH_{ag}) that would have occurred had all acid extrusion been blocked (segment ag). If the ΔpH_i instead is computed from the pH_i at points b, c, d, e or f, the computed β_i will be, at best, artifactually high (in the case of ΔpH_{ab}) and, at worst, will approach infinity (in the case of $\Delta pH_{af} = 0$). If the acid load is applied by exposing the cell to CO_2, then the active transport of HCO_3^- into the cell can sometimes cause the pH_i at point f to be greater than the pH_i at point a. In this case, ΔpH_{af} is <0, and the computed β_i will be negative.

INTRACELLULAR BUFFERING

Role of Buffering in pH_i Regulation

In the broadest sense, a pH buffer is any system that moderates the effects of an acid load by reversibly consuming H^+, or of an alkali load by reversibly releasing H^+. As we shall see, buffering in the intracellular fluid (e.g., the cytosol) is considerably more complex than in the blood and extracellular fluids. One can determine the buffering power (β) of either the extra- or intracellular fluid by applying an acute acid or alkali load, and measuring the resultant change in pH. β is defined as the amount of strong base (or strong acid) required to raise (or lower) pH by a given amount. Strictly speaking, the definition is given in differential notation. However, if the amount of base added (ΔB, given in mM) and the resultant pH increase (ΔpH) are sufficiently small, then β is approximated by:

$$\beta = \frac{\Delta B}{\Delta pH} \qquad (52.17)$$

This definition was originally proposed in slightly different form by Koppel and Spiro in 1914[173,174] and later modified to its present state independently by Michaelis[175] and Van Slyke.[176] Note that β is always a positive number; for a strong acid, ΔB and ΔpH are both negative. β is usually reported in mM per pH unit.

Among the several methods available for applying acid and alkali loads to the cytoplasm, the most direct is by injection of acid[151,77] or alkali into the cell with a micropipette. Such an acute acid load produces an abrupt fall in pH_i (see Figure 52.7, segment ab), the extent of which is determined by the amount of acid injected, the intracellular buffering power, and the ability of pH_i-regulatory mechanisms to blunt the pH_i decrease. As discussed in later sections, these pH_i-regulatory mechanisms can actively extrude acid from the cell and thereby return pH_i to its initial value (segment b–f). If we were to calculate β blindly, then we would see that the apparent β depends critically on the time of the ΔpH_i measurement following the acid load. For example, the apparent β is relatively low at point b and rises to infinity at point f, where ΔpH_i is zero.

An approach for avoiding the above ambiguity is to define intracellular buffering power (β_i) under conditions in which we completely block pH_i regulation. In this case, pH_i would follow the trajectory indicated by ag in Figure 52.7, the observed ΔpH_i at "infinite" time would be relatively large, and the computed β would be smaller than any of the possibilities described above. There are three justifications for excluding acid–base transport processes from the definition of β_i: *(a)* As we have just seen, excluding cellular transport processes makes the calculated β_i time independent (provided we allow enough time for pH_i to fall). *(b)* As we shall see later, transport of acid and/or base can generally be distinguished from buffering mechanisms by applying transport inhibitors or performing ion substitutions in the extracellular fluid. *(c)* Generally, these transport processes are not fully reversible. The buffering mechanisms included in our definition of β_i fall into three categories: *(a)* weak acids and bases (i.e., chemical buffers), *(b)* biochemical reactions consuming or releasing H^+, and *(c)* transport of acids or bases across organellar membranes. These mechanisms, which will be discussed in more detail later, can be justifiably grouped because there is presently no practical basis for distinguishing among them

when examining cytosolic pH regulation. Furthermore, they proceed very rapidly compared to the time currently required to measure pH_i.

Buffering mechanisms abate pH_i changes produced by acute acid and alkali loads that otherwise could damage the cell. However, these mechanisms cannot prevent a change in pH_i, only reduce its magnitude. Furthermore, buffering mechanisms cannot restore pH_i to its initial value following an acid or alkali load. Such recoveries are brought about by transport of acid and/or base across the cell membrane. As an illustration, consider the response of the cell to an acute intracellular acid load, as in Figure 52.7. Cellular buffers respond very rapidly, typically consuming more than 99.99% of the applied acid and limiting the initial fall in pH_i (*ag*). Active transport mechanisms respond more slowly, extruding acid from the cell and returning pH_i toward normal (b–f). During the transport-mediated pH_i recovery, H^+ previously taken up by the buffering mechanisms is now released and extruded from the cell. By the time pH_i returns to its initial level (f), the entire acid load has been extruded from the cell, and cellular buffering mechanisms have been returned to their pre-acid-loading state (a). Buffering mechanisms play no role in the steady state; in this case, acid loading exactly balances acid extrusion, and the state of cellular buffers is unchanged.

Mechanisms of Intracellular Buffering

The total intracellular buffering power (β^T) is the sum of chemical (i.e., weak-acid/base equilibria), biochemical, and organellar buffering powers.

Chemical Buffering

A weak base (B) of valence *n* reacts with H^+ to produce its conjugate weak acid (HB) of valence n + 1:

$$B^n + H^+ \rightarrow HB^{n+1} \tag{52.18}$$

This equilibrium is described by the relation:

$$K_a' = \frac{[B^n][H^+]}{HB^{n+1}} \tag{52.19}$$

where K_a' is the apparent acid dissociation constant. This relation can also be expressed in logarithmic form, whereupon it takes the form of Equation 52.16. Starting with the definition of β (Equation 52.17) and the statement of chemical equilibrium (Equation 52.19), one can express β as a function of $[H^+]$, K_a', and total buffer concentration.[173,175]

$$\beta = \frac{2.3K_a'[H^+]}{(K_a' + [H^+])^2}[TB] \tag{52.20}$$

where 2.3 approximates ln(10), and [TB] is the concentration of total buffer (i.e., $[TB] = [B^n] + [HB^{n+1}]$). By obtaining the derivative of β with respect to $[H^+]$ (i.e., $d\beta/d[H^+]$) and setting this equal to zero, one can show that β is maximal when $[H^+]$ equals K_a'.[173] This maximal buffering power (β^{max}) is simply:

$$\beta^{max} \cong 0.58\,[TB] \tag{52.21}$$

Although the pH of maximal buffering power is in general unique to the buffer, all buffers have the same molar buffering power ($\beta^{max}/[TB]$), and the same dependence of β on the difference $pH - pK_a'$. If more than one buffer is present, then β^T is simply the sum of the individual buffering powers, each computed from Equation 52.20.

The foregoing equation describing β was derived by taking the partial derivative of $[B^n]$ with respect to pH at a fixed [TB]. That is, the analysis applies only to buffers in a closed system, in which [TB] is constant. Closed-system buffers include a solution of a nonvolatile buffer (e.g., inorganic phosphate) in a beaker, a solution of a volatile buffer (e.g., CO_2/HCO_3^-) in a capped syringe, and an impermeant buffer (e.g., a protein) in the cytoplasm of a cell. In such a closed system, β for CO_2/HCO_3^- would be rather low at normal pH_i values, because pH_i (~7.0) is far higher than the pK_a' of 6.1. However, cells are generally not a closed system with respect to CO_2/HCO_3^-. Rather, CO_2 usually freely exchanges with the extracellular fluid (ECF) so that the total intracellular CO_2 (i.e., $[CO_2]_i + [HCO_3^-]_i$) can change appreciably during intracellular acid–base disturbances. For example, when H^+ is added to cytoplasm containing CO_2/HCO_3^-, H^+ combines with HCO_3^- according to the reactions:

$$H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow H_2O + CO_2 \tag{52.22}$$

The cytoplasmic CO_2 so formed is lost to the ECF. Thus, it is $[CO_2]_i$ that remains constant, while $[HCO_3^-]_i$ and [total CO_2]$_i$ both fall. Because there is no buildup of CO_2 within the cell, the extent of the reaction in Equation 52.22 is limited only by the availability of HCO_3^-. The amount of H^+ absorbed (i.e., buffered) by the CO_2/HCO_3^- system exactly equals the amount of HCO_3^- that disappears. That is:

$$\beta^{CO_2} = \frac{\Delta[HCO_3^-]}{\Delta pH} \tag{52.23}$$

where β^{CO_2} is the CO_2 buffering power. When this equation, in differential form, is combined with the Henderson-Hasselbalch equation, it can be shown that:

$$\beta^{CO_2} = 2.3\,[HCO_3^-] \tag{52.24}$$

when $[CO_2]$ is held constant. At very high pH values, when the equilibrium $H^+ + CO_3^{2-} \rightleftarrows HCO_3^-$ cannot be

ignored, the term 4.6 $[CO_3^{2-}]$ must be added to the right-hand side of Equation 24. This equation describes the buffering power of CO_2/HCO_3^- in an open system, such as a solution in a beaker equilibrated with gaseous CO_2. Because most cell membranes are highly permeable to CO_2, this gas rapidly equilibrates across membranes and stabilizes $[CO_2]_i$, provided the ECF behaves as an infinite reservoir for CO_2. Thus, an isolated cell *in vitro* behaves as an open system for CO_2/HCO_3^-. Because the intact organism has mechanisms (e.g., alveolar ventilation in higher vertebrates) for stabilizing $[CO_2]$ in the ECF, CO_2/HCO_3^- behaves as an open-system buffer *in vivo*, both in the extra- and intracellular spaces.

In an open system, the CO_2/HCO_3^- buffer pair generally makes a substantial contribution to β^T. For example, at a pH_i of 7.1, the buffering power of all non-CO_2 buffers in rat renal mesangial cells is only about 10 mM,[19] whereas the computed β^{CO_2} is nearly 29 mM when the cell is equilibrated with 5% CO_2. Thus, β^{CO_2} accounts for nearly 75% of the β^T of 39 mM/pH unit.

It is essential to distinguish clearly between open- and closed-system buffers of a cell. The cell is a closed system for intracellular buffers that do not readily cross the cell membrane (e.g., inorganic phosphate and the imidazole groups of proteins). Thus, these buffers are influenced by the attributes of the cell (e.g., volume, temperature, and metabolic state), and not those of the extracellular fluid. These are termed *intrinsic buffers*.[165] Biochemical and organellar buffering mechanisms (*vide infra*) are also intrinsic, and the total intrinsic buffering power (β^I) is the sum of biochemical, organellar, and intrinsic chemical buffering powers.

The cell is an open system when one member of the buffer pair readily crosses the cell membrane. The buffering power of such a buffer pair is very sensitive to extracellular conditions. As noted earlier, β^{CO_2} is proportional to $[HCO_3^-]_i$, which in turn is completely determined by pH_i and the extracellular P_{CO_2} (assuming that CO_2 equilibrates across the cell membrane). The cell also behaves as an open system for buffers other than CO_2/HCO_3^-. These are generally conjugate pairs of which one member is a small, neutral molecule. Examples include NH_3/NH_4^+ and acetic acid/acetate. Regardless of whether the charged species is a cation or an anion, the intracellular buffering power of an open-system buffer pair is always $2.3 \times [\text{charged species}]_i$, provided the neutral species is equilibrated across the cell membrane. Thus, the intracellular buffering power of such a buffer pair is sensitive not only to the total amount of the buffer in the ECF (i.e., $[TB]_o$), but also to pH_o. As with CO_2/HCO_3^-, these other open-system buffers can sometimes be the dominant component of β^T. For example, β^I in squid axons is $\sim$9 mM.[170] When these axons are exposed to a pH_o–7.7 NH_3/NH_4^+ solution containing only 10 mM total ammonium, $[NH_4^+]_i$ rises to 10 mM. The computed β^{NH_3} is 23 mM, nearly 70% of β^T. Because the buffering power of such open-system buffers is so sensitive to factors external to the cell (e.g., pH_o), these buffers are termed *extrinsic*.[165] The total chemical buffering power of a cell is the sum of the buffering powers of the individual conjugate acid/base buffer pairs, be they intrinsic (closed system) or extrinsic (open system).

Biochemical Buffering

Because certain biochemical reactions consume or release H^+ and are pH_i sensitive, they can act as H^+ buffers.[3] Examples include hydrolysis of ATP (which releases H^+) and hydrolysis of phosphocreatine (which consumes H^+). During the Cori cycle, the liver converts lactic acid into glucose, whereas skeletal muscle breaks down the glucose to produce ATP and more lactic acid. Also, H^+ buffering can arise when reactions induce a change in the pK_a' of an ionizable group. A classic example is the buffering reactions of oxygenated versus deoxygenated hemoglobin.

A well studied example of biochemical buffering are reactions involving intermediary metabolites in rat brain.[179] Cells that are acutely acid loaded with an increase of P_{CO_2} in the ECF respond by reducing intracellular levels of several acid metabolic intermediates (i.e., the acids of lactate, pyruvate, citrate, α-ketoglutarate, malate, glutamate, and aspartate), while raising those of glucose and glucose-6-phosphate. These observations are consistent with the hypothesis that reducing pH_i inhibits a step in the glycolytic pathway, possibly the phosphofructokinase reaction. Indeed, mouse muscle phosphofructokinase is markedly sensitive to pH changes[180]; reducing *in-vitro* pH from 7.2 to 7.1 produces more than a 90% inhibition. Rat-brain cells respond in the opposite fashion to acute intracellular alkali loads. Increases in pH_i induced by lowering the P_{CO_2} in the ECF lead to increased levels of lactate and pyruvate.[181] Thus, the biochemical machinery of these cells seems to respond appropriately to pH_i changes, consuming H^+ in response to intracellular acid loads and releasing H^+ in response to alkali loads. The extent to which such biochemical reactions contribute to overall buffering power can be computed from changes in steady-state metabolite levels, provided that such changes are reciprocally linked to the production or consumption of neutral and/or readily diffusible molecules. For example, the consumption of one citrate molecule removes three H^+, whereas malate removes two, and pyruvate, one. From data on rat brain,[182] the buffering power of biochemical reactions amounts to about half that provided by all non-CO_2 physicochemical buffers. Biochemical buffering power can be defined and quantitated in a manner analogous to

chemical (*vide supra*) and organellar (*vide infra*) buffering powers [see Equation 52.17]. The biochemical buffering reaction can be written as:

$$R^n + q\ H^+ \rightleftarrows P^{n+q} \tag{52.25}$$

where R is the reactant, P is the product, n is the valence, and q is the H^+ stoichiometry ($q > 0$). The biochemical buffering power is thus:

$$\beta = \frac{\Delta[R^n]\cdot q}{\Delta pH} \tag{52.26}$$

As noted above, biochemical and organellar (*vide infra*) buffering mechanisms, in addition to closed-system chemical buffers, comprise the intrinsic buffers.

Organellar Buffering

H^+-transport systems have been identified or implicated in many intracellular organelles,[3,183] including mitochodria,[184–191] lysosomes,[192] sarcoplasmic reticulum,[193] Golgi network,[92,90] endosomes,[194–198] chromaffin granules,[199,192] and zymogen granules.[200] In addition, three of the cloned Na-H exchangers (NHE6, 7, and 9) are found in organellar membranes where they may contribute to organellar pH regulation.[167,713] For reviews of vesicular H^+ pumps, see refs.[201,202] It would be reasonable to expect decreases in cytoplasmic pH to stimulate H^+ uptake and/or inhibit H^+ extrusion by at least some organelles, and increases in pH_i to produce the opposite effects. Such buffering would lead to a net transfer of H^+ into these organelles following intracellular acid loads, and a net movement of H^+ into the cytoplasm following alkali loads. A transfer of acid or base across organellar membranes would constitute a *de facto* buffer mechanism for the bulk intracellular fluid. Although the extent to which such hypothetical organellar buffering mechanisms contribute to β^T is not established, it can be inferred from published data that changes in extraorganellar pH can produce at least small changes in the intraorganellar pH of mitochondria,[127] lysosomes,[192] and sarcoplasmic reticulum vesicles.[193] Organellar buffering power can be defined and quantitated in a manner analogous to that for physicochemical and biochemical buffering [see Equation 52.17]. The organellar buffering reaction is written:

$$\text{organelle}() + H^+ \rightleftarrows \text{organelle}(H^+) \tag{52.27}$$

where the parentheses refer to organellar contents. Organellar buffering power is thus:

$$\beta = \frac{\Delta[\text{organelle}()]}{\Delta pH_i} \tag{52.28}$$

Organellar buffers, along with the biochemical and closed-system chemical buffers, comprise β^I.

Measurement of Intracellular Buffering Power

Titration of Cell Homogenates

The easiest method for estimating β_i is to homogenize a tissue sample and titrate the homogenate. The slope of the pH titration curve is the buffering power of the homogenate. However, some disadvantages limit the accuracy of this technique. First, homogenization may disrupt cellular organelles and thus obscure the organellar buffering contribution. Second, homogenization-induced changes in metabolism must be prevented, for example by quick-freezing the sample before homogenization,[203] and then performing the titration either at low temperature[203] or in the presence of an inhibitor such as fluoride.[182] Blocking metabolism will reduce biochemical buffering, and reducing temperature generally increases pK_a' values, thereby altering chemical buffering.

Microinjection

The most straightforward approach for estimating β_i in an intact cell is to microinject a known amount of acid or base into a cell and monitor the resultant change in pH_i. The microinjection can be achieved either by iontophoresis[15] or by pressure injection.[177] This technique enables one to compute the total β_i (i.e., sum of physicochemical, biochemical, and organellar buffering) of the cell. For small neurons incubated in a CO_2-free solution, the iontophoresis and pressure-injection methods give β_i values of 10.8 mM/pH unit[15] and 10.3 mM/pH unit,[177] respectively. Disadvantages of this direct *in-vitro* titration approach include the necessity of using cells that (1) are large enough to withstand the microelectrode impalements, and (2) have a sufficiently compact geometry to permit rapid equilibration of the injected acid or base throughout the cell.

Weak-Acid and Base Methods

An approach that, at least in principle, is applicable to cells of all shapes and sizes, is measurement of the pH_i change produced by exposing the cell to a neutral weak acid HA ($HA \rightleftarrows H^+ + A^-$), or weak base B ($HB \rightleftarrows H^+ + B$). As discussed earlier, exposing a cell to a neutral weak acid leads to a decrease in pH_i as HA enters the cell and partially dissociates into H^+ and A^-. The entry and dissociation halt once $[HA]_i = [HA]_o$. The extent of the dissociation depends on the weak acid's pK_a', as well as the initial pH_i. Virtually all of the released H^+ is consumed by intracellular buffers (Figure 52.8A and B); the remaining fraction is responsible for the accompanying pH_i decrease. Although HA/A^- is a buffer, it does not participate in buffering the acid load imposed by the intracellular dissociation of HA. Similarly, a B/BH^+ buffer

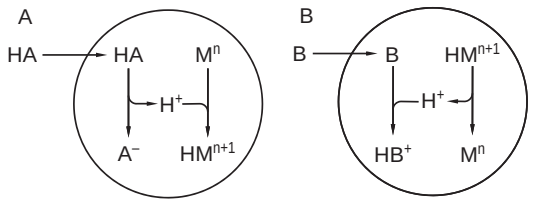

FIGURE 52.8 Measurement of intracellular buffering power by exposure to a neutral weak acid or base. A: When a cell is exposed to a neutral weak acid (HA), HA enters the cell, where some of it dissociates into H^+ and A^-. Virtually all of this H^+ is taken up by buffers (M; valence = n) that are titrated to their conjugate weak acids (HM; valence = n + 1). Thus, for each A^- formed, almost exactly one H^+ is consumed by non-HA/A^- buffers. $\beta = -\Delta[A^-]_i/\Delta pH_i$. B: When a cell is exposed to a weak base, B, the base enters the cell, where some of it combines with H^+ to form HB^+. Virtually all of this H^+ is derived from buffers (HM; valence = n + 1) that are titrated to their conjugate weak bases (HM; valence = n). Thus, for each HB^+ formed, almost exactly one H^+ is released by non-B/HB^+ buffers. $\beta = -\Delta\,[HB^+]_i/\Delta pH_i$.

system can not buffer changes in pH_i caused by the entry (or exit) of B. Because the dissociation of HA leads to the formation of one A^- for each H^+, the magnitude of the intracellular acid load is $\Delta[A^-]_i$. This amount of added acid is the additive inverse of the amount of base added (ΔB) in the preceding definition of β:

$$\beta_i = \frac{\Delta B}{\Delta pH_i} = \frac{-\Delta[A^-]_i}{\Delta pH_i} \qquad (52.29)$$

Note that β_i is the non-HA/A^- buffering power of the cell. It is the sum of chemical, biochemical, and organellar buffering. ΔpH_i is directly measured, and $\Delta[A^-]_i$ is calculated from final and initial values of pH_i and $[HA]_o$. In the simplest case, the initial $[A^-]_i$ is zero, and final $[A^-]_i$ is given by:

$$[A^-]_i = [HA]\cdot 10^{pH_i - pK_a'} \qquad (52.30)$$

assuming $[HA] = [HA]_i = [HA]_o$. A commonly used weak acid for measuring β_i is CO_2, for which:

$$\beta_i = \frac{\Delta B}{\Delta pH_i} = \frac{-\Delta[HCO_3^-]_i}{\Delta pH_i} \qquad (52.31)$$

β_i is the non-CO_2/HCO_3^- or intrinsic buffering power, β_i^I. Once β_i^I is known, the total intracellular buffering power (β_i^T) can be obtained by computing the open-system CO_2 buffering power:

$$\beta_i^T = \beta_i^I + \beta_i^{CO_2} \qquad (52.32)$$

where $\beta_i^{CO_2}$, the CO_2 buffering power, is given by $2.3 \times [HCO_3^-]_i$, as outlined above.

There are as many as three major drawbacks of using the weak-acid method to measure β. First, $[HA]_i$ may not exactly equal $[HA]_o$. In rapidly metabolizing cells for instance, $[CO_2]_i$ may exceed $[CO_2]_o$. Second, the pH_i decrease elicited by the entry of HA may stimulate acid-extrusion mechanisms (i.e., pH_i-regulating systems described below). Thus, the actual ΔpH_i may be smaller than if all acid–base transport had been blocked (Figure 52.7). By underestimating ΔpH_i, one will overestimate β_i. This error should in principle be eliminated by blocking the pH_i-regulating systems.[165] One can also minimize the error by extrapolating the pH_i-versus-time curve back to a point at which acid extrusion is judged to have had no effect on pH_i.[17,204–206] For example, in the hypothetical experiment of Figure 52.7, one could extrapolate the pH_i recovery (i.e., bcdef) back to the time of the acid load. A third potential drawback of the weak-acid method is that the weak acid could indirectly alter pH_i by modifying cellular metabolism. Thus, it is critical that the weak acid affect pH_i only by entering and dissociating into H^+ and A^-. Otherwise, any other effect on pH_i will lead to an error in the calculation of β_i.

The intrinsic intracellular buffering power can also be determined by exposing a cell to a neutral weak base, B (Figure 52.8B). As described in the preceding section, exposing a cell to B leads to a pH_i increase as most of the entering B combines with H^+ to form HB^+. The entry of B and the alkali loading of the cell continues until $[B]_i = [B]_o$. Almost all of the entering H^+ that is converted to HB^+ is derived from cellular buffers. The minute amount that comes from the pool of free H^+ is responsible for the rise in pH_i. Thus, the change in $[HB^+]_i$ is equivalent to the amount of strong base added to the intracellular fluid:

$$\beta_i = \frac{\Delta B}{\Delta pH_i} = \frac{\Delta[HB^+]_i}{\Delta pH_i} \qquad (52.33)$$

In the simplest case, the initial $[HB^+]_i$ is zero, and the final $[HB^+]_i$ is calculated from the statement of chemical equilibrium:

$$[HB^+]_i = [B]\cdot 10^{pK_a' - pH_i} \qquad (52.34)$$

assuming that $[B] = [B]_i = [B]_o$. The most commonly used weak base is NH_3:

$$\beta_i = \frac{\Delta B}{\Delta pH_i} = \frac{\Delta[NH_4^+]_i}{\Delta pH_i} \qquad (52.35)$$

$[NH_4^+]_i$ is determined in a manner analogous to that outlined earlier for $[HCO_3^-]_i$. Note that β_i in this case is the non-NH_3/NH_4^+ buffering power (i.e., the buffering power of all buffers other than NH_3/NH_4^+). If the NH_3 titration is performed in the absence of CO_2/HCO_3^-, then the measured β_i is β_i^I. If CO_2/HCO_3^- is present, then the measured β_i is $\beta_i^I + \beta_i^{CO_2} = \beta_i^T$. An approach commonly used with NH_4^+ is to compute β from the pH_i decrease caused by decreasing or withdrawing

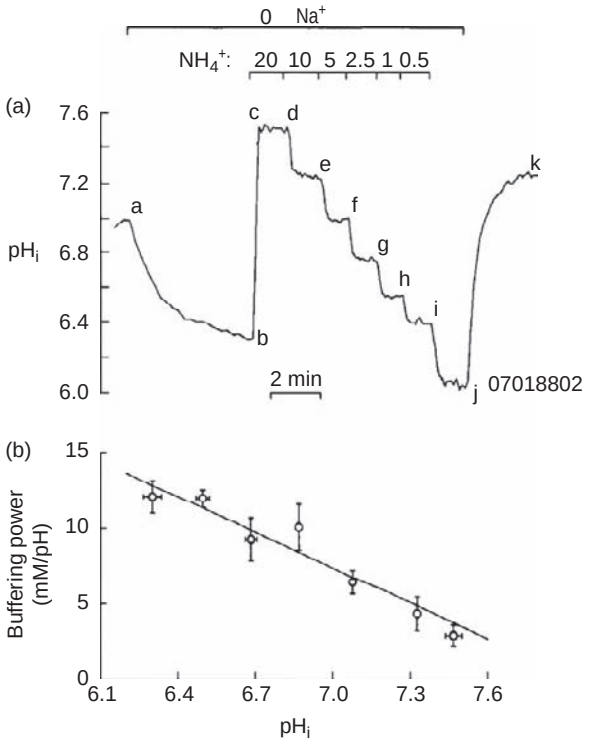

FIGURE 52.9 The dependence of intrinsic intracellular buffering power on pH_i. a: The effect on pH_i of stepwise reductions in $[NH_4^+]_o$ in the absence of CO_2/HCO_3^-. Na^+ was removed to block acid-extruding mechanisms. The subsequent reduction in $[NH_4^+]_o$ from 20 to 10 to 5 to 2.5 to 1 to 0.5 to 0 mM produced discrete acid loads. This experiment was performed on a single renal mesangial cell, the pH_i of which was measured using BCECF and a microscope-based fluorometry system. b: Computation of β_i. The acid load imposed by each stepwise reduction in $[NH_4^+]_o$ was computed from the change in $[NH_4^+]_i$. The latter was calculated from $[NH_4^+]_o$, pH_o and pH_i. The mean buffering power in the pH_i range covered by the stepwise fall in pH_i was computed as $\beta_i = \Delta[NH_4^+]_i/\Delta pH_i$. *(Reproduced from ref. [19].)*

external NH_4^+. During such experiments, one usually blocks acid-extrusion mechanisms (e.g., by removing external Na^+) that would likely counteract the acidification. By reducing $[NH_4^+]_o$ in a stepwise fashion (Figure 52.9a), one can compute β_i as a function of pH_i (Figure 52.9b), as has been done in mesangial cells[19] and gastric parietal cells.[207] An alternate approach one can use with NH_4^+ is to compute β_i from the pH_i increase that accompanies stepwise increases of external NH_4^+.[17]

ACID–BASE TRANSPORT SYSTEMS

Acid–base transporters can be divided into two groups: acid loaders and acid extruders. Acid loaders move H^+ into, or base equivalents (e.g., OH^- or HCO_3^-) out of, cells and generally contribute to the recovery of pH_i from acute intracellular alkali loads. In contrast, acid extruders move H^+ out of, or base equivalents into, cells and generally contribute to the recovery of pH_i from acute intracellular acid loads. In the remainder of this section, we discuss major acid–base transporters in each of these two categories. For each transporter, we will examine at least the following three issues: (1) general function and molecular identity, (2) energetics and role in pH_i regulation, and (3) effects of pharmacological agents. Please consult the following relevant chapters in this book on the molecular biology of Na^+-coupled HCO_3^- transporters (Chapter 53) and anion exchangers (Chapter 54), as well as refs.[167,713,714] on Na^+–H^+ exchangers.

Acid-Loading Mechanisms

Introduction

As noted above, passive fluxes of H^+, monovalent cationic acids (e.g., NH_4^+), and monovalent anionic bases (e.g., HCO_3^-) are governed by the electrochemical gradient for the ion in question, and normally tend to acidify the cell. In principle, such passive transport processes could be exploited for protecting the cell against alkaline loads. Nevertheless, such passive processes generally do not appear to have a substantial impact on pH_i. A notable exception discussed above is the $GABA_A$-activated Cl^- channel at the crayfish neuromuscular junction[148] and in cells from turtle cerebellum[149] and rat hippocampus.[150,151] This Cl^- channel can conduct HCO_3^- and thus mediate a substantial HCO_3^- efflux that lowers pH_i. For the most part, however, major acid-loading transport pathways are HCO_3^- transporters—the most common ones being Cl^-–HCO_3^- exchange and Na^+/HCO_3^- cotransport.

Cl^-–HCO_3^- and Cl^-–OH^- Exchangers

GENERAL FUNCTION AND MOLECULAR IDENTITY

Found in a wide variety of animal-cell membranes, Cl^-–HCO_3^- exchangers normally couple the influx of Cl^- to the efflux of HCO_3^- (Figure 52.10a–h). Na^+-independent Cl^-–HCO_3^- exchangers (to distinguish them from the Na^+-dependent Cl^-–HCO_3^- exchangers discussed later) are thought to serve two major functions in non-epithelial cells: regulation of intracellular pH (pH_i), and regulation of intracellular $[Cl^-]$. The erythrocyte exchanger is known as the "band 3 protein" because of its position on SDS-polyacrylamide gels (for review, see ref.[208]) Band 3 has also been termed AE1 because it was the first "anion exchanger" to be cloned and sequenced[209]). As described in greater detail in Chapter 54, the AE gene subfamily comprises at least three related genes AE1, AE2, and AE3. The AE gene

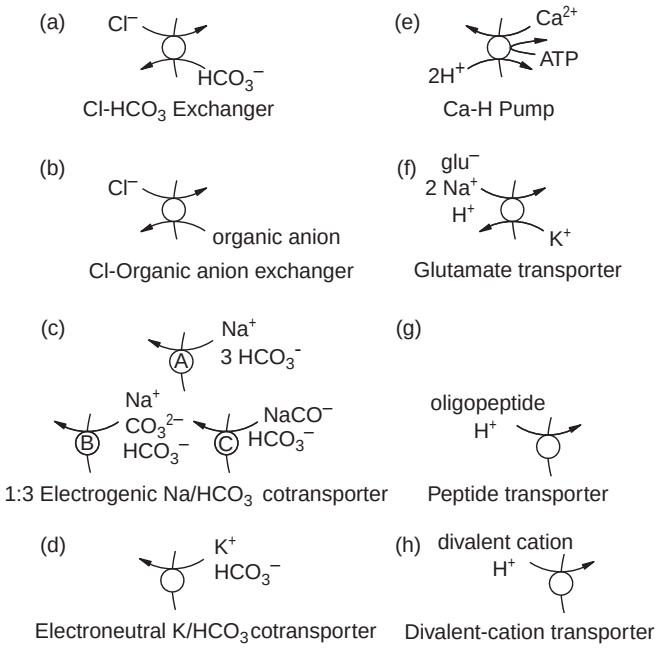

FIGURE 52.10 Acid-loading mechanisms. A: Cl^-—HCO_3^- exchanger. B: Cl^--organic anion exchanger. C: 1:3 Electrogenic N^+/HCO_3^- cotransporter. The electrogenic Na^+/HCO_3^- cotransporter present in the basolateral membranes of epithelial cells has a stoichiometry of 3 HCO_3^- equivalents for each Na^+. Three alternative models are shown. D: Electroneutral K^+/HCO_3^- cotransporter. E: Ca^{2+}—H^+ pump. F: Glutamate transporter. G: Peptide transporter. H: Divalent-cation transporter.

subfamily is a branch of the bicarbonate-transporter (SLC4) family that includes the Na^+-coupled HCO_3^- transporter subfamily (see Chapter 53). Several members of the SLC26 family can also mediate Cl^-—HCO_3^- exchange.[210,211] However, unlike the AE family, which virtually always exhibits a Cl^-: HCO_3^- stoichiometry of 1:1, the SLC26 family can exhibit stoichiometries of 1:2, 1:1, or 2:1[212–214]; for review, see ref.[211].

INVOLVEMENT OF Cl^- AND HCO_3^-/OH^-; ENERGETICS

Red cell AE1 mediates electroneutral homo- or hetero-exchange of monovalent anions with a 1:1 stoichiometry, exhibiting a substrate preference of $Cl^- \sim HCO_3^- \sim NO_3^- > Br^- > F^- > I^-$ > divalent oxyanions.[215,216] Sulfate is cotransported with H^+.[217] Monovalent anion exchange can be reasonably well modeled by a ping-pong kinetic scheme, thought to reflect the alternation of an anion binding site between one side and the other of the membrane.[218–221] Because the Cl^-:HCO_3^- stoichiometry is 1:1, the transporter is electroneutral. Thus, the direction of net transport is determined by the sum of the chemical gradients for Cl^- (i.e., $[Cl^-]_i/[Cl^-]_o$) and HCO_3^- (i.e., $[HCO_3^-]_i/[HCO_3^-]_o$). Because the inward Cl^- gradient is generally greater than the inward HCO_3^- gradient in cells other than erythrocytes, the former dominates, driving HCO_3^- out of the cell. The transporter is easily reversed, however, by inverting the sum of the Cl^- and HCO_3^- gradients. Indeed, a classic pH_i assay for Cl^-—HCO_3^- exchange activity involves removing external Cl^- that evokes a rapid pH_i increase.[222,223] In some cell types, the transporter can also be reversed by lowering $[HCO_3^-]_i$, as would occur during severe intracellular acid loads. The exchanger operating in reverse then becomes an acid extruder, moving HCO_3^- into the cell and contributing to the pH_i recovery from the acid load.

Some Cl^-—HCO_3^- exchangers have a very high affinity for HCO_3^- and transport can take place with low levels of HCO_3^- ($\sim$100 μM) in a nominally HCO_3^--free solution. For example, removing external Cl^- from the solution bathing rat osteoclasts can elicit a dramatic DIDS-sensitive pH_i increase, even in the nominal absence of CO_2/HCO_3^-.[224] However, vigorously bubbling the solutions with 100% N_2 gas greatly reduces the pH_i increase.

Sun et al.[225] reported the presence of a Cl^-—OH^- exchanger (or H^+/Cl^- cotransporter), which operates in parallel with a "conventional" Cl^-—HCO_3^- exchanger, in guinea-pig ventricular myocytes. The putative Cl^-—OH^- exchanger is Cl^- dependent; it is activated by low pH_o[225] and also by high pH_i.[226] The evidence that it is a Cl^-—OH^- exchanger—rather than a Cl^-—HCO_3^- exchanger—is that it functions as an acid loader in the presence or absence of CO_2/HCO_3^-, and is insensitive to DIDS.[225] The activation of the exchanger by lowering pH_o is unaffected by a CO_2-free, 100% N_2 atmosphere.[227] As attractive as it is to conclude that the transporter is a Cl^-—OH^- exchanger, it is difficult to rule out the possibilities that: (1) ambient and metabolically produced CO_2/HCO_3^- have not been totally eliminated, and (2) the transporter has an exceedingly high affinity for HCO_3^-. Putative Cl^-—OH^- exchange activity also contributes to NaCl reabsorption in intestinal epithelial cells.[228]

Based on experiments on rat-brain synaptosomes, Martínez-Zaguilán et al.[229] have concluded that a H^+/Cl^- cotransporter is responsible for (1) the pH_i increase elicited by removing extracellular Cl^-, and (2) the faster pH_i recovery from an acid load in the absence of extracellular Cl^-. However, it is generally difficult to distinguish H^+ transport in one direction from OH^- and/or HCO_3^- transport in the opposite direction.

The CLC gene family encodes proteins that are either Cl^- channels or Cl^-—H^+ exchangers.[230] While ClC1, ClC2, ClC-Ka, and ClC-Kb are plasma-membrane Cl^- channels, ClC3 through ClC7 are thought to be vesicular Cl^-—H^+ exchangers. Although these ClCs are primarily expressed intracellularly, low levels of ClC4, ClC5, and ClC6 expression are observed

at the plasma membrane, leading to Cl^-–H^+ exchanger activity at this location.[231,230] The other ClCs in this group (i.e., ClC3 and ClC7) are also likely to be exchangers because each member of the group possesses a key glutamate residue that is necessary for such exchange.

DEPENDENCE ON pH_i

By analogy to acid extruders, which are often stimulated by decreases in pH_i, one might expect acid loaders such as Cl^-–HCO_3^- exchange to be stimulated by increases in pH_i. Indeed, Cl^-–HCO_3^- exchange activity in many cells including Vero and L-cells,[232] mesangial cells,[163] and lymphocytes[233] is low but measurable at pH_i values as low as 6.5, increases to somewhat higher levels in the physiological pH_i range, and then rises very steeply as pH_i increases above ~7.6.

In more recent expression studies, the widely distributed AE2 also appears to exhibit greater activity at more alkaline pH_i values.[234–236] The pH sensor is located somewhere within the C-terminal transmembrane domain,[237,238] and its apparent pK_a is modulated by residues within the N-terminal cytoplasmic domain.[237,239,240] Multiple histidines within the transmembrane domain contribute to AE2 activity, as well as pH_i and pH_o sensitivies.[241] Furthermore, residues within the first putative re-entrant loop of AE2 also contribute to pH_i and/or pH_o sensitivities.[242]

EFFECTS OF PHARMACOLOGICAL AGENTS

The non-erythroid Cl^-–HCO_3^- exchanger is blocked by stilbene derivatives such as DIDS and SITS,[113,243] as well as the noncompetitive inhibitor niflumic acid.[244,245] Some of the more potent AE inhibitors include oxonol dyes at the nanomolar level.[246–249]

Electrogenic Na^+/HCO_3^- Cotransporters

GENERAL FUNCTION AND MOLECULAR IDENTITY

Present in the basolateral membrane of several epithelia, including the renal proximal tubule, is an electrogenic Na^+/HCO_3^- cotransporter[13] that mediates the isodirectional flux of one Na^+ and—in the simplest model—three HCO_3^- ions.[250] In epithelia, the cotransporter normally mediates a net efflux of Na^+ and HCO_3^- (see below), and therefore functions as an acid loader (Figure 52.10C). In the early proximal tubule, Na^+/HCO_3^- cotransport appears to be the major route of HCO_3^- efflux across the basolateral membrane. The transporter thus plays a key role in HCO_3^- reabsorption, and probably makes an important contribution to Na^+ reabsorption as well.

Our understanding of Na/Bicarbonate Cotransporters (or NBCs), as well as other bicarbonate transporters has expanded immensely over the past 16 years with the molecular identification of these proteins. As described in Chapter 53, ten *SLC4* genes encode members of the family of bicarbonate transporters including electrogenic and electroneutral NBCs, the Na-driven Cl^-–HCO_3^- exchanger (NDCBE), and the Na^+-independent anion exchangers (AEs). At the amino-acid level, the transporters share considerable homology to one another, and are therefore predicted to have similar membrane topologies.

INVOLVEMENT OF Na^+ AND HCO_3^-; ENERGETICS

In the salamander proximal tubule, the cotransporter has an absolute requirement for both Na^+ and HCO_3^-.[13] The cotransporter in rabbit proximal convoluted tubules can still function even in the absence of added HCO_3^-,[251] probably due to intracellular formation of HCO_3^- from metabolically-derived CO_2. Removing external HCO_3^- elicits a rapid fall in pH_i and $[Na^+]_i$, and a near-instantaneous depolarization of the basolateral membrane. A similar pattern of changes is caused by removing external Na^+. All effects are fully reversible. The DIDS-sensitive depolarization elicited by removing Na^+, which makes it appear as though Na^+ is moving as an anion, is practically diagnostic of electrogenic Na^+/HCO_3^- cotransport.

A 1:3 stoichiometry is accounted for by any of the schemes outlined in Figure 52.10C.[252] The model in which Na^+ exits together with one CO_3^{2-} and one HCO_3^- (Figure 52.10C, model B) is supported by the observation that SO_3^{2-} stimulates Na^+ uptake by basolateral membrane vesicles,[253] presumably by interacting at a CO_3^{2-} site. However, more recent studies indicate that NBCe1-A—at least as expressed in *Xenopus* oocytes—does not interact with either SO_3^- or HCO_3^-.[254,255] In preliminary work, Grichtchenko and Boron[256] as well as Lee et al.[257] performed a more direct assessment of CO_3^{2-} transport by using extracellular pH electodes to measure NBCe1-induced changes in surface pH (pH_s) of *Xenopus* oocytes expressing both the transporter and extracellular-facing carbonic anhydrase (CAIV). Depolarization-induced activation of the NBC elicited an expected decrease in pH_s as base equivalents were transported into the cell. However, applying a CA inhibitor caused the magnitude of the pH_s decrease to increase rather than to diminish. The larger response is consistent with the hypothesis that NBCe1 mediates CO_3^{2-} transport and that the role of CAIV is to consume H^+ generated as the reaction $HCO_3^- \rightarrow CO_3^{2-} + H^+$ replenishes CO_3^{2-} near the cell surface.

The direction of net cotransport is determined by the combined transmembrane gradients for Na^+, HCO_3^- and voltage. If one focuses on Na^+, then the epithelial cotransporter acts as an auxiliary Na^+ pump. As far as its classification as a primary, secondary or

tertiary active Na^+ transporter is concerned, the cotransporter occupies an unusual niche. The Na^+–K^+ pump directly or indirectly establishes the membrane voltage. This pump also indirectly establishes the Na^+ gradient that energizes the Na^+–H^+ exchanger, which raises pH_i and thereby establishes the HCO_3^- gradient. These voltage and HCO_3^- gradients, directly or indirectly established by the Na^+–K^+ pump, drive the epithelial Na^+/HCO_3^- cotransporter in the direction of the net Na^+ efflux. Thus, this Na^+ extrusion can be viewed as a secondary/tertiary active transport process.

EFFECTS OF PHARMACOLOGICAL AGENTS

Similar to Cl^-–HCO_3^- exchangers, Na^+/HCO_3^- cotransporters are inhibited by stilbene derivatives such as DIDS[13]; for review, see ref.[258]. Cloned NBCe1 expressed in oocytes can also be inhibited by benzamil,[259] the non-steroidal anti-inflammatory drug tenidap,[259,260] niflumic acid,[261] and diBAC oxonol dyes.[261] Recently, the *N*-cyanosulphonamide S0858 has been identified as an NBC inhibitor in renal epithelial cells[262] and ventricular myocytes.[263,264]

Electroneutral K^+/HCO_3^- Cotransporter

GENERAL FUNCTION AND MOLECULAR IDENTITY

A K^+/HCO_3^- cotransporter (Figure 52.10D), presumably electroneutral, has been documented in squid giant axons, where it normally mediates the efflux of one K^+ and one HCO_3^- ion.[265] Because the transporter moves HCO_3^- out of the axon, it functions as an acid loader. A similar transporter has been reported in cells of the medullary thick ascending limb of rat kidney,[266,267] and may exist in cultured cortical astrocytes of rat (Bevensee and Boron, unpublished). In mammalian glia, K^+/HCO_3^- cotransport may contribute to the pH_i decrease following an acute intracellular alkali load.

INVOLVEMENT OF K^+ AND HCO_3^-; ENERGETICS

In the squid giant axon dialyzed with a fluid containing K^+, but lacking Na^+ and Cl^-, the cotransporter moves K^+ and HCO_3^- out of the axon, eliciting a pH_i decrease.[265] Under the appropriate conditions, the K^+/HCO_3^- cotransporter can also operate in the forward direction, moving HCO_3^- into the squid giant axon.[268,269] Exposing axons dialyzed with a fluid devoid of K^+, Na^+, and Cl^- to an artificial seawater containing K^+ and CO_2/HCO_3^- elicits a pH_i decrease (due to CO_2 entry), followed by a pH_i increase (due to K^+/HCO_3^- influx). The HCO_3^- fluxes mediated by K^+/HCO_3^- cotransporter can be enhanced by using out-of-equilibrium CO_2/HCO_3^- solutions to introduce HCO_3^- exclusively to either the inside or outside of the axon.[268,270]

As mentioned above, two independent groups have also reported DIDS-sensitive, K^+-coupled HCO_3^- transport in the medullary thick ascending limb (mTAL), either from tubule suspensions[266] or perfused tubules.[267] In the perfused-tubule study,[267] luminal DIDS increased transepithelial HCO_3^- reabsorption—a finding consistent with DIDS-sensitive K^+-coupled HCO_3^- transport opposing HCO_3^- reabsorption.

EFFECTS OF PHARMACOLOGICAL AGENTS

While the transporter in the mTAL is sensitive to stilbene derivatives such as DIDS, the K^+/HCO_3^- cotransporter in the squid giant axon is not. However, quaternary ammonium ions introduced into the cell inhibit inwardly directed cotransport.[268] The potency of inhibition increases with increasing alkyl chain length of the quaternary ammonium ion. For example, the apparent K_i for phenylpropyltetraethylammonium or PPTEA ($\sim$91 μM) is $\sim$850-fold less than the apparent K_i for tetraethylammonium or TEA ($\sim$78 mM).

Ca^{2+}-$2H^+$ Exchange Pump

GENERAL FUNCTION AND MOLECULAR IDENTITY

The P-type ATPase family includes not only the Na^+-K^+ and H^+-K^+ pumps, but also the Ca^{2+} pumps, of which there are two types—the sarcoplasmic (endoplasmic) reticulum Ca^{2+}-ATPase (SERCA) and the plasma membrane Ca^{2+}-ATPase (PMCA). These Ca^{2+} pumps, along with Na^+/Ca^{2+} exchangers, contribute to Ca_i^{2+} regulation by pumping Ca^{2+} either out of the cells across the plasma membrane (PMCAs) or back into intracellular stores (SERCAs). In both cases, the pumps exchange Ca^{2+} for H^+. Thus, from the standpoint of pH_i, the PMCAs, which take up H^+ as they extrude Ca^{2+} across the plasma membrane, function as acid loaders (Figure 52.10E).

Four PMCAs (PMCA1-4) have been cloned and characterized (for reviews, see refs. [271–274]). The cDNAs encode proteins with $\sim$1200 amino acids. Based on hydropathy analysis, the PMCAs have ten transmembrane α-helices (TM 1-10) with both the N- and C-termini being cytoplasmic. The ATPase catalytic domain lies between TM 4 and TM 5. According to molecular modeling data, PMCAs have a predicted structure similar to the crystallized SERCAs, with the following cytosolic domains: actuator (A), nucleotide-binding (N), and phosphorylation (P).[271] Based on localization studies (for review, see ref. [275]). PMCA1 and PMCA4 are expressed ubiquitously. In contrast, PMCA2 and PMCA3 are found predominantly in the nervous system. mRNA encoding all four isoforms have been found in kidney.[276,277] However, PMCA levels of mRNA and protein are highest in the distal

tubule, particularly in the distal convoluted tubule.[278,279]

INVOLVEMENT OF Ca^{2+}; ENERGETICS

It has been known for some time that the plasma-membrane Ca^{2+} pump in erythrocytes exchanges Ca^{2+} for H^+.[280,281] Schwiening et al.[282] have used Ca^{2+}- and pH-sensitive microelectrodes to demonstrate that the plasma membrane Ca^{2+} pump in snail neurons also exchanges extracellular H^+ for intracellular Ca^{2+}. In this preparation, activation of the Ca^{2+} pump (generated by increasing intracellular Ca^{2+} with depolarization or iontophoretic Ca^{2+} injection) elicits an increase in extracellular Ca^{2+}, and a simultaneous increase in extracellular pH. Both the increase in extracellular Ca^{2+} and pH can be inhibited by the Ca^{2+}-pump inhibitor vanadate. A similar Ca^{2+} pump, present in hippocampal neurons,[283] appears responsible for causing an increase in the extracellular pH of the hippocampal slice elicited by stimuli-induced neuronal activity.[284–286]

Glutamate Transporters

GENERAL FUNCTION AND MOLECULAR IDENTITY

In the mammalian CNS, the predominant excitatory amino acids glutamate and aspartate are transported from the extracellular space back into neurons and glial cells by ion-coupled glutamate transporters in the SLC1 family.[287] Since 1992, cDNAs encoding several of these electrogenic glutamate transporters have been cloned and characterized.[288–296] As reviewed in refs.[290,297,298], these transporters are predominantly expressed in the nervous system, but also in certain epithelial cells. The L-glutamate/L-aspartate transporters EAAT1 (or GLAST1) and EAAT2 (or GLT1) are mainly found in glia, whereas EAAT3 (or EAAC1) and EAAT4 are found predominantly in neurons. EAAT3 is also expressed in liver, as well as the small intestine and kidney where it mediates the uptake of glutamate and aspartate across the apical membrane.[299] EAAT4 is expressed in cerebellum, whereas EAAT5 is predominantly expressed in retina.

INVOLVEMENT OF GLUTAMATE/ASPARTATE, Na^+, AND K^+; ENERGETICS

Using the results from $^{22}Na^+$ and [^{14}C]glutamate uptake studies, as well as pH_i measurements, on *Xenopus* oocytes expressing EAAT3, Kanai et al.[300] concluded that the protein transports 1 glutamate, 2 Na^+ and 1 H^+ into the cell, in exchange for 1 K^+, which moves out of the cell (Figure 52.10F). This stoichiometry, which predicts a net movement of one positive charge into the cell, agrees with that proposed for the glutamate transporter in salamander retinal glia based on kinetic analysis.[301] Adding either glutamate or aspartate to the extracellular fluid causes a steep fall in pH_i,[300] consistent with the influx of H^+ or the efflux of alkali. H^+ appears to be the transported acid–base species because the EAAT3-induced change in pH (but not the transporter current) is inhibited by amino acids with a higher pK (e.g., cysteine) than glutamate—a finding consistent with transport of the amino acid coupled to H^+ as an ion pair, followed by H^+ dissociation and a subsequent drop in pH.[302]

Peptide and Divalent-Cation Transporters

Although most solute exchangers and cotransporters in animal cells are Na^+ driven, some are H^+ coupled (Figure 52.10g and h). The absorption of oligopeptides and peptide-based antibiotics by intestinal and proximal-tubule epithelial cells is mediated by two members of the SLC15 family, H^+/oligopeptide transporters PepT1 (SLC15A1) and PepT2 (SLC15A2; for reviews, see refs. [303,304]). PepT1 and PepT2 transport the same di- and tri-peptides, but with different affinities/capacities.[303] PepT1 exhibits low-affinity, high-capacity transport, whereas PepT2 exhibits the opposite: high-affinity, low-capacity transport. Both transporters are expressed in kidney (among other tissues), with PepT1 found in the S1 segment of the proximal tubule and PepT2 found in the S3 segment.[305,306] Other members of the peptide transporter family include PTH1 (SLC15A4) and PTH2 (SLC15A3), both of which can transport histidine as well as di- and tripeptides in a H^+-coupled manner (for review, see ref.[303]).

The cDNA encoding PepT1 has 707 amino acids with 12 putative membrane-spanning segments.[307] Based on the recent crystal structure of a prokaryotic homologue, PepT proteins possess a large central hydrophilic cavity where peptide binds, and a smaller extracellular one where H^+ binds.[308] In oocytes expressing PepT1, the net transport of dipeptides occurs with a proton:dipeptide stoichiometry of 1:1[309] and causes a steep fall in pH_i.[300,309] For negatively charged dipeptides, one H^+ binds to the cation site of the transporter, whereas another H^+ neutralizes the dipeptide on the peptide site. The net transport stoichiometry of negatively charged dipeptides is therefore 1 proton for 1 neutralized dipeptide.

15 years ago, Gunshin et al.[310] cloned the cDNA encoding a mammalian divalent-cation transporter (DCT1)—now called the divalent metal transporter (DMT)—which mediates intestinal non-heme Fe^{2+} absorption. DMT contains 561 amino acids with 12 putative membrane-spanning domains (see review by Mackenzie and Hediger[311]). By Northern blotting, DMT is ubiquitously expressed; heavily so in the duodenum. In kidney, DMT is expressed at the apical membrane of the thick ascending limb of the loop of Henle, the distal nephron, and collecting ducts, as well

as intracellularly throughout the nephron.[312] DMT is electrogenic, and cotransports any one of a group of metals (e.g., Fe^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Cd^{2+}, Cu^{2+}, Ni^{2+}, Pb^{2+}) together with one H^+. By analogy with the EAATs and PepT1, adding Fe^{2+} to the extracellular fluid of an oocyte expressing DMT leads to a rapid fall in pH_i, consistent with the influx of H^+.

Other Transporters that Carry Strong or Weak Acids or Bases

We have discussed several major categories of transporters that act as acid loaders. Two of these—the Cl^--HCO_3^- exchangers and Na^+/HCO_3^- cotransporters—specifically play a role in regulating pH. However, any transporter that carries a proton or a weak acid or base could affect pH. A quick perusal of the 40^+ families of SLC proteins[313] reveals that about half of these families include members that transport either H^+ or weak acids or weak bases. In addition, several other families of transport proteins (e.g., vacuolar H^+ pump, gastric H^+-K^+ pump) can carry acids or bases. Although most of these transporters do not regulate pH, they can impact pH. The extent of this impact depends on the rate of transport and—for transported substances other than H^+ or OH^-—the pK of the substance, and the pH of the compartments on either side of the membrane across which the transport occurs.

Acid-Extrusion Mechanisms

Introduction

As discussed earlier, acid extrusion, that is, the movement of H^+ (or protonated monovalent weak acids) out of cells, or the movement of OH^- or HCO_3^- (or monovalent weak bases) into cells, generally occurs against a steep energy gradient. Based on their source of energy, acid-extrusion mechanisms can be divided into three groups: primary, secondary and tertiary active transporters (see ref. [314]). Primary active transport mechanisms, also called pumps, derive their energy from electron transport (e.g., the electron transport chain that drives H^+ out of mitochondria) or, as with the transporters such as the H^+ pump considered below, from the hydrolysis of ATP. Secondary active transport systems (e.g., Na^+—H^+ exchange) derive their energy from the electrochemical gradient of an ion (e.g., Na^+)—a gradient that is in turn established by a primary active transporter (e.g., Na^+—K^+ pump). Finally, tertiary active transporters (e.g., the monocarboxylate system) are driven by an ion gradient established by a secondary active transporter.

From the point of view of feedback control, the effectiveness of an acid extruder would be enhanced greatly if decreases in pH_i increased transport. The most productive approach for studying the pH_i dependence of acid extruders in intact cells has been to load cells with acid acutely, as schematized in Figure 52.11A–D. The acid load can be applied by prepulsing with NH_4^+,[170] microinjecting H^+,[177] dialyzing with a low-pH solution,[315] or reducing pH_o in the temporary presence of nigericin.[316] In the model experiment of Figure 52.11A, the pH_i decrease produced by the acid load (segment ab) is followed by a rapid recovery to the initial pH_i (bcd). In the most general case, this pH_i recovery is mediated by one or more acid extruders, but may be opposed by one or more acid loaders. Identifying the component of pH_i recovery that is mediated by a particular transporter requires that the transporter be specifically, instantaneously, and completely inhibited. Such inhibitors exist for two of the acid extruders that we will discuss below, the Na^+-driven Cl^-—HCO_3^- exchanger and the Na^+—H^+ exchanger. Figure 52.11A illustrates three possible outcomes (indicated by broken curves following the

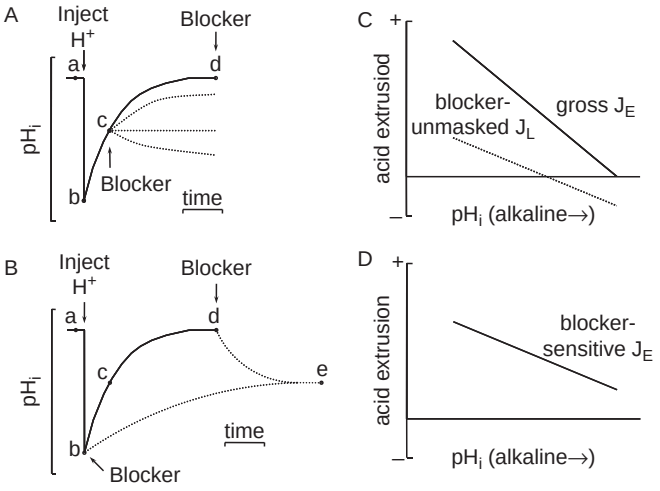

FIGURE 52.11 Determining the pH_i dependence of an acid–base transporter. The pH_i dependence of the Na^+-driven Cl^-—HCO_3^- exchanger. A: Hypothetical experiment illustrating how an inhibitor (e.g., DIDS) can be used to ascertain the component of a pH_i recovery from an acid load that is mediated by an acid extruder such as the Na^+-driven Cl^-—HCO_3^- exchanger. The blocker is applied at the arrow (point c). The broken curves illustrate three possible effects of the blocker on the pH_i recovery. B: Another hypothetical experiment illustrating a different approach for determining the pH_i-dependence of an acid extruder during the pH_i recovery from an acid load. The blocker is applied either at the time of the acid load, or after the pH_i recovery (broken curves). C: The pH_i dependence of "gross" acid extrusion (gross J_E) is calculated from the pH_i recovery in the absence of blocker (bcd) in panel B. The pH_i dependence of "blocker-unmasked" acid loading (blocker-unmasked J_L) is calculated from the pH_i recovery in the presence of blocker (be), or the pH_i decrease elicited by applying the blocker after the pH_i recovery (de) in panel B. D: The pH_i dependence of "blocker-sensitive" acid extrusion (blocker-sensitive J_E) is calculated by subtracting the plot of blocker-unmasked J_L from the plot of gross J_E in panel C.

arrow) of applying such an agent during a pH_i recovery due at least in part to a mechanism sensitive to the blocker. First, applying the blocker may slow but not halt the pH_i recovery. This result indicates that a second, blocker-insensitive acid-extruder also contributes to the pH_i recovery. Second, the blocker may completely eliminate the pH_i recovery, indicating that the entire recovery is due to a blocker-sensitive mechanism(s). However, complete blockade by the blocker does not rule out the possibility that the blocker-sensitive, acid-extrusion process is opposed by a less potent blocker-sensitive, acid-loading process. Third, applying the blocker may not only halt the pH_i recovery, but may also unmask a slow pH_i decline. This result implies that the blocker-sensitive, acid-extrusion process is opposed by at least one blocker-insensitive acid loader.

In any of the above three eventualities, the difference in rates of pH_i change (dpH_i/dt) immediately before and immediately after applying the blocker at point c in Figure 52.11A is the component of the pH_i recovery—at the pH_i value prevailing at point c—that is due to blocker-sensitive transporters. In order to convert this blocker-sensitive dpH_i/dt to a net acid-extrusion rate (J_E), we must multiply this dpH_i/dt by the total intracellular buffering power (β^T) prevailing at the pH_i of the blocker application, as well as the inverse of the surface-to-volume ratio (ρ):

$$J_E = (\beta^T/\rho) \times (dpH_i/dt)_{\text{blocker-sensitive}} \qquad (52.36)$$

Because acid–base transporters are generally sensitive to changes in pH_i, this analysis must be repeated over a range of pH_i values to produce a plot of the pH_i dependence of the blocker-sensitive flux(es).

Rather than repeating the experiment in Figure 52.11A many times, each with a different pH_i at the instant we apply the blocker (i.e., point *c*), we could employ a more practical approach, which requires only three types of experiments. First, we monitor the pH_i recovery—in the absence of blocker—over the entire pH_i range indicated by bcd in Figure 52.11B. At regular pH_i intervals during this recovery, we compute the "gross" dpH_i/dt, from which we compute the gross J_E (Figure 52.11C).

Second, we monitor the pH_i recovery in an experiment in which the blocker is present during the entire pH_i recovery. If the blocker-sensitive transporter is the only acid extruder present in the cell, then pH_i will not recover at all, or may even decline. On the other hand, if other acid extruders are present (as is more often the case), then pH_i will recover slowly and incompletely, as in be in Figure 52.11C. At regular pH_i intervals during this abbreviated recovery, we compute the "blocker-insensitive" dpH_i/dt, from which we compute the blocker-insensitive J_E (Figure 52.11C).

Third, we allow pH_i to recover fully (bcd), and then add the blocker. If, during the steady state indicated by point d, one or more acid loaders oppose the blocker-sensitive acid extruder, as is typically the case, then applying the blocker will cause pH_i to drift downward (de). The initial rate of pH_i decline at point d reflects the rate of acid loading (J_L) at the pH_i at d. At regular pH_i intervals during this pH_i decline, we compute the "blocker-unmasked" dpH_i/dt, from which we compute the blocker-unmasked J_L (Figure 52.11C).

Finally, at each pH_i value, we subtract the blocker-unmasked J_L from the blocker-insensitive J_E in Figure 52.11D. The result is the pH_i dependence of the "blocker-sensitive" J_E (i.e., the flux mediated by the transporter of interest). This approach was first used by Boron et al.[317] to determine the pH_i dependence of the Na^+-driven Cl^-–HCO_3^- exchanger of barnacle muscle, and then by Boyarsky et al.[318] to determine the pH_i dependence of the Na^+–H^+ exchanger of renal mesangial cells. Others extended this approach to study the pH_i dependence of Na^+–H^+ exchange in IEC-6 colonic cells,[319] UMR-106 osteoblastic cells ,[320] osteoclasts,[124] rabbit S3 proximal tubules,[206] ventricular myocytes,[321] rat hippocampal astrocytes,[17] and shrunken mesangial cells.[322] Finally, the approach outlined in Figure 52.11B–D also has been used to determine the pH_i dependence of the Na^+-driven Cl^-–HCO_3^- exchanger in NIH 3T3 cells transformed with the c-H-*ras* oncogene,[323] and the pH_i dependence of the H^+ pump in rabbit S3 proximal tubules[206] and osteoclasts.[124]

H^+ Pumps

GENERAL FUNCTION AND MOLECULAR IDENTITY

An electrogenic vacuolar-type H^+ pump (Figure 52.12A, left) is present in the proximal tubule and distal nephron of the kidney (for reviews, see refs. [201,324,325] and Chapter 56), as well as in macrophages and neutrophils ,[326,327] osteoclasts,[328] tumor cells,[329] and goblet cells of the insect midgut.[330] Similar H^+ pumps are present in clathrin-coated vesicles and other organellar membranes (for reviews, see refs. [201,331,324,325]).

The V-type H^+ pump is composed of two domains, V_0 and V_1. The V_0 domain, which is comprised of at least five different subunits, is involved in translocating H^+ across the membrane. The V_1 domain, which is comprised of at least eight different subunits, is involved in ATP hydrolysis and contains the catalytic nucleotide binding sites. A more complete review of the structure and function of the V_0 and V_1 subunits of the pump are presented in refs. [324,325,332,333]. Similar vacuolar H^+ pumps have been examined in *Neurospora* and plant cells.[334–336]

Immunohistological studies with antibodies raised against various subunits of the H^+ pump have revealed expression of the pump throughout the

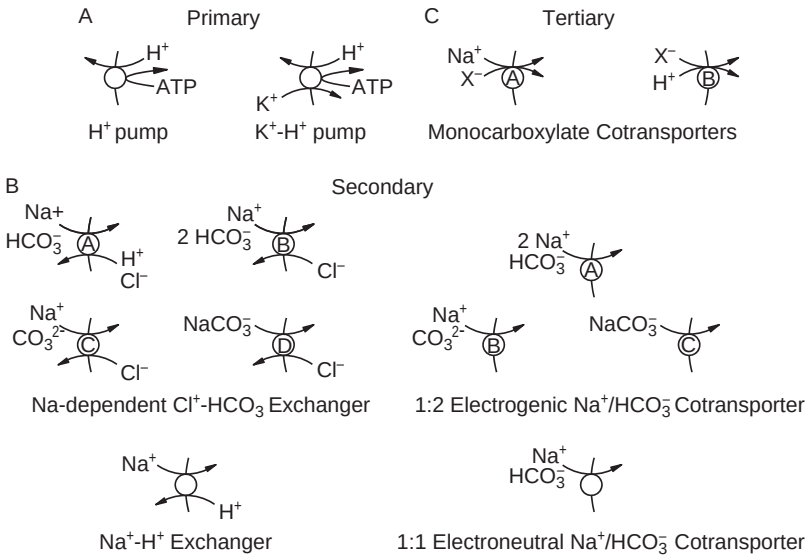

FIGURE 52.12 Acid-extrusion mechanisms. **A**: Primary active transport mechanisms include the electrogenic H^+ pump and the electroneutral K^+—H^+ pump. **B**: Secondary active transporters include the Na^+-driven Cl^-—HCO_3^- exchanger (four models of which are shown), the Na^+—H^+ exchanger, the 1:2 electrogenic Na^+/HCO_3^- cotransporter, and the 1:1 electroneutral Na^+/HCO_3^- cotransporter. **C**: The tertiary active transport system consists of a Na^+/monocarboxylate cotransporter that brings the monocarboxylate (X^-) into the cell, and an H^+/monocarboxylate cotransporter that uses the energy stored in the X^- gradient to drive H^+ out of the cell. In renal proximal tubules, the Na^+/monocarboxylate cotransporter is confined to the luminal membrane.

nephron on both apical and basolateral membranes.[337] In the cortical collecting tubule, the H^+ pump is localized to the apical membrane of α intercalated cells (which secrete acid) and the basolateral membranes of β intercalated cells (which secrete alkali).[338–340] Vacuolar H^+ pumps are also present at the apical membrane of the proximal tubule.[338–340]

ENERGETICS

The extrusion of H^+ by this primary active transporter is not coupled directly to the movement of other ions that might balance electrical charge. Rather, this pump is electrogenic. Because the H^+ pump is driven by the hydrolysis of ATP, which provides a substantial amount of energy, it is capable of generating a large H^+ gradient across the cell membrane. For example, if the voltage across the membrane were zero, then the H^+ pump could establish a pH difference of about three pH units. On the other hand, when compared to other H^+ transporters, H^+ pumps have a relatively low transport rate. Thus, the H^+ pump is expressed in epithelia needing a high-gradient/low-capacity H^+ transporter. An H^+ pump contributes to pH_i regulation in a number of cells, including macrophages and neutrophils,[327] osteoclasts,[124] renal cells,[341,342] glial cells,[343,344] and corneal epithelial cells.[345]

K^+—H^+ Exchange Pumps

GENERAL FUNCTION AND MOLECULAR IDENTITY

As discussed earlier, K^+—H^+ exchange pumps (Figure 52.12A, right) are members of the P-type ATPase family. Both the gastric and non-gastric H^+—K^+ pumps are ATP-driven transporters that exchange intracellular H^+ for extracellular K^+. However, the gastric and non-gastric pumps differ in their molecular biology, localization, functional properties, and pharmacological sensitivities (for reviews, see refs.[346–349] and Chapter 3).

Both the gastric and non-gastric forms of the H^+—K^+ pump are present in the collecting duct of the kidney, where their major role may be in K^+ preservation (for reviews, see refs[346–349]). For example, during K^+ depletion, mRNA and protein levels of the non-gastric form are raised in multiple nephron segments.

INVOLVEMENT OF K^+; ENERGETICS

In using the energy from ATP hydrolysis, H^+—K^+ pumps can establish extremely large pH gradients. For instance, gastric parietal cells (see ref.[350] can produce gastric secretions containing as much as 140 mM HCl (i.e., pH $\sim$0.7). In parietal cells of rabbit gastric glands, applying omeprazole (which blocks H^+—K^+ pumps) reduces pH_i by nearly 0.1 in glands stimulated with histamine and IBMX, though not in resting glands. This result implies that the H^+—K^+ pump contributes to the maintenance of pH_i in stimulated parietal cells.

Functional studies of non-gastric H^+—K^+ pumps have been performed *in vitro* using expression systems such as the *Xenopus* oocyte and HEK-293 cells. In such expression systems, the non-gastric pumps exchange extracellular K^+ for intracellular H^+. However, the pumps may also possess the ability to transport Na^+ (for reviews, see refs.[347,351]).

Na^+-Driven Cl^-—HCO_3^- Exchanger

GENERAL FUNCTION AND MOLECULAR IDENTITY

A secondary active transport system that exchanges external Na^+ and HCO_3^- for internal Cl^- and H^+ (or its equivalent, *vide infra*) was first identified in invertebrate cells such as squid axons[352,353] and snail

neurons.[354] Indeed, the work on the squid axon was the first evidence for the dynamic regulation of pH_i.[170] This transport mechanism makes an important contribution to pH_i regulation in mammalian neurons.[355] Not certain is the precise identity of the transported acid–base equivalents, inasmuch as pH_i measurements cannot clearly distinguish inward movements of HCO_3^-, CO_3^{2-} or $NaCO_3^-$ from one another, or from outward movements of H^+. All four schemes outlined in Figure 52.12B (top left) can account for the data. For simplicity, we shall refer to the transporter as the Na^+-driven Cl^-–HCO_3^- exchanger.

As mentioned earlier and described in greater detail in Chapter 54, investigators have cloned the cDNA encoding the Na^+-driven Cl^-–HCO_3^- exchanger (NDCBE or SLC4A8) and have also examined the transport properties of the protein.[356] When expressed in *Xenopus* oocytes, human NDCBE exhibits all the functional hallmarks of the endogenously expressed transporter. For instance, stimulation of NDCBE activity in oocytes causes an increase in pH_i that (1) requires external Na^+ and HCO_3^-, (2) can be inhibited by stilbenes, and (3) correlates with a decrease in intracellular Cl^-.[356] Using the surface-pH measurement technique described above for examining CO_3^{2-} transport by NBCe1, Grichtchenko and Boron[357] as well as Lee et al.[257] have provided preliminary evidence that NDCBE can also transport CO_3^{2-}.

DEPENDENCE ON pH_i AND CALCULATION OF ACID EXTRUSION RATES

Using the approach outlined above in Figures 52.11B–D, Boron et al.[317] separately determined the pH_i dependence of the Na^+-driven Cl^-–HCO_3^- exchanger of barnacle muscle at pH_o values of 6.8, 7.4, 8.0, and 8.6 (at a fixed $[CO_2]$ of 0.4%). As shown in Figure 52.13, the flux is highest at low pH_i values, and gradually falls toward zero at a pH_i of ~7.4—the threshold for activating the exchanger. This work was the first to demonstrate threshold behavior for an acid extruder; similar work followed on the Na^+–H^+ exchanger (see below). The pH_i sensitivity of acid extrusion in Figure 52.13 is probably not a Michaelis-Menten type of dependence on intracellular H^+, which would translate into a sigmoid (rather than a linear) acid-extrusion-rate-versus-pH_i relationship. The pH_i sensitivity may reflect an allosteric site for intracellular H^+ (*vide infra*).

It is important to recognize that, for two reasons, an analysis of the type shown in Figure 52.13 is far more valuable than a simple plot of the pH_i recovery rate (dpH_i/dt) versus pH_i. First, because the above analysis includes buffering power, the result is a flux rather than merely a rate of change in pH_i. This consideration is important when buffering power changes appreciably

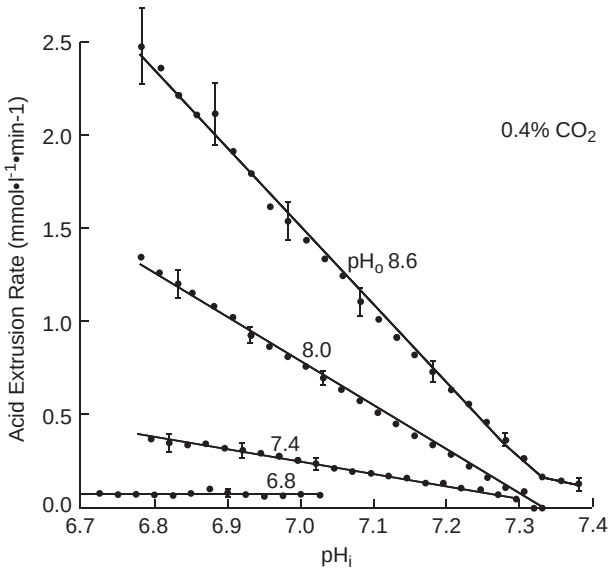

FIGURE 52.13 **The pH_i dependence of the Na^+-driven Cl^-–HCO_3^- exchanger from giant barnacle muscle fibers.** The rate of pH_i recovery from an acid load (NH_4^+ prepulse) was determined over a range of pH_i values, multiplied by the sum of intrinsic and HCO_3^- buffering powers (both of which vary with pH_i), and corrected for an acidification unmasked by applying SITS. *(Reproduced from ref. [317].)*

over the pH_i range in question, or if a transporter is to be compared under conditions when buffering power is expected to vary. Second, the above analysis takes into account processes other than the transporter in question; these other processes may contribute to the pH_i recovery (or lack thereof!). Failing to make this correction can lead to a serious over- or underestimation of the flux due to the transporter of interest.

DEPENDENCE ON pH_O

Although the Na^+-driven Cl^-–HCO_3^- exchange rate is stimulated at low values of pH_i, it is apparently inhibited at low values of pH_o. For example, both in barnacle muscle and squid giant axons, decreases in pH_o—produced by lowering $[HCO_3^-]_o$ at a fixed P_{CO_2}—cause J_E to decrease.[358,359] However, at least for the squid axon, this apparent inhibition at low pH_o may be only illusory: when pH_o is decreased at a fixed $[NaCO_3^-]_o$, the inhibition disappears.[358] Thus, at least in squid axons, the transporter per se may be relatively pH_o insensitive. Most methods of producing acidosis may inhibit Na^+-driven HCO_3^- transport because they simultaneously lower $[NaCO_3^-]_o$.

INVOLVEMENT OF Na^+, Cl^-, AND HCO_3^-

The Na^+-driven Cl^-–HCO_3^- exchanger has an absolute requirement for external Na^+,[15] external HCO_3^-[360] or a related species, and internal Cl^-.[315] Removing any one of these three ions from the appropriate side of the

membrane completely blocks acid extrusion. Moreover, Na^+ and Cl^- are actually transported along with acid equivalents.[15,315] The observed stoichiometry is one Na^+ entering the cell, one Cl^- exiting, and two acid equivalents neutralized intracellularly. This stoichiometry is consistent with all four models presented in Figure 52.12B (top left). The prediction that Na^+-driven Cl^-—HCO_3^- exchange should be electroneutral is supported by the observations that transport neither alters[165,361] nor is altered by V_m.[352]

ENERGETICS

The models of Figure 52.12B (top left) make equivalent energetic predictions, based upon which physiological gradients for Na^+, Cl^-, and HCO_3^- should support Na^+-driven Cl^-—HCO_3^- exchange with no external source of energy.[3] The major predicted energy source is the steep Na^+ gradient, established by the Na^+—K^+ pump. This model of a secondary active transporter, driven only by ion gradients, is supported by the observation that transport can be reversed by reversing gradients for Na^+ and/or HCO_3^-.[317,362,363] Curiously, however, the transporter in squid axons requires ATP; not as an energy source, but probably for an essential phosphorylation event or as an essential cofactor.[364]

THE pH_i THRESHOLD

In barnacle muscle, the activity of the Na^+-driven Cl^-—HCO_3^- exchanger falls toward zero as pH_i approaches a pH_i threshold of ~7.4 (see Figure 52.13). This reduction in transport does not reflect the inavailability of energy, however, which is sufficient to drive pH_i to ~8.0. Threshold behavior is thus probably due to an allosteric effect of H^+ on the transporter or an essential activator. This hypothesis is supported by the observation that the barnacle-muscle Na^+-driven Cl^-—HCO_3^- exchanger, in addition to mediating net acid extrusion, also mediates what appears to be Na^+—Na^+[362] and Cl^-—Cl^-[365] exchange. Like acid extrusion, these ancillary transporter activities are also stimulated by reducing pH_i below the threshold.

SENSITIVITY TO PHARMACOLOGICAL AGENTS

The Na^+-driven Cl^-—HCO_3^- exchanger is blocked by the stilbene derivatives 4-isothiocyano-4′-acetamido-2,2′-stilbene disulfonate (SITS) and 4,4′-diisothiocyano-2,2′-stilbene disulfonate (DIDS). The site of permanent action is apparently a free amino group on the transporter that reacts with the isothiocyano moiety of the stilbene to form an *N,N*-disubstituted thiourea (Edman reaction). However, even stilbene derivatives lacking an isothiocyano group can inhibit the transporter, although the inhibition is often less than complete and is reversible. Thus, 4,4′-dinitro-2,2′-stilbene disulfonate (DNDS), at a concentration of 1 mM, reversibly inhibits the squid-axon transporter by approximately 80%.[366] By analogy to the erythrocyte Cl^-—HCO_3^- exchanger, the Na^+-driven Cl^-—HCO_3^- exchanger probably forms a reversible, ionic complex with each of the aforementioned stilbenes. This interaction presumably involves the negatively charged sulfonate groups on the stilbene and cationic moieties on the transporter. The stilbenes with amino-reactive groups (i.e., SITS and DIDS) subsequently form a covalent bond that eventually blocks transport irreversibly. Interesting, the inhibition of squid-axon Na^+-driven Cl^-—HCO_3^- exchanger by DNDS is apparently competitive with Na^+ as well as with HCO_3^-—a finding that is quantitatively consistent with the hypothesis that DNDS actually competes with the $NaCO_3^-$ ion pair for binding.[366]

Two non-stilbene amino-reactive agents also inhibit Na^+-driven Cl^-—HCO_3^- exchange.[165] The inhibition by *p*-isothiocyanatobenzenesulfonate is irreversible, as is its reaction with free amino groups. The inhibition by pyridoxal phosphate is reversible, as is its reaction with free amines. Na^+-driven Cl^-—HCO_3^- exchange is also reversibly inhibited by relatively high levels (~0.5 mM) of furosemide.[352,365]

Na^+—H^+ Exchangers

GENERAL FUNCTION AND MOLECULAR IDENTITY

Na^+—H^+ exchangers (Figure 52.12B, bottom left) have been identified in the plasma membranes of a wide variety of vertebrate cells (for reviews, see refs.[167,714]). At least two functional classes of Na^+—H^+ exchangers have been identified. The first, which is apparently the most widespread version, are the Na^+—H^+ exchangers of nonepithelial cells[171,316,373–378] as well as the basolateral membranes of many epithelial cells.[64,379] This distribution is characteristic of what have been regarded as "housekeeping" transporters (e.g., Na^+—K^+ pump and Na^+—Ca^{2+} exchanger), which are inhibited by relatively low concentrations of 5-amino-substituted amiloride analogs, (e.g., EIPA). The second class of exchangers is the one characteristically located at the apical membrane of epithelia such as the renal proximal tubule.[164,380–385] It is inhibited by only relatively high concentrations of the aforementioned amiloride analogs. These two pharmacologically distinct Na^+—H^+ exchangers have been identified on the apical and basolateral membranes of LLC-PK1 cells.[386] A third pharmacological class of Na^+—H^+ exchanger is found in rat astrocytes[387] and hippocampal neurons.[205,355,388,389] These cells have a Na^+-driven acid extruder that functions in the nominal absence of HCO_3^-, and is not inhibited even by high levels of amiloride and/or amiloride analogs.

A cDNA encoding a Na^+—H^+ exchanger (NHE1) was first cloned by Sardet et al.,[390] using an expression

strategy. At present, eight additional NHE isoforms (NHE1 to NHE9) have been identified, all members of the SLC9 family.[167,713,714] The sequence comparisons, tissue distributions, and functions of the various NHE isoforms are examined in Chapter 53. In the remainder of this section, we will examine the role of Na^+-H^+ exchange in pH_i regulation.

DEPENDENCE ON pH_i

The first convincing evidence that decreases in pH_i stimulate Na^+-H^+ exchange came from experiments on membrane vesicles, in which low pH_i stimulates amiloride-sensitive Na^+ efflux.[391] This result, analogous to the Cl^--influx and Na^+-efflux data on the Na^+-driven $Cl^- - HCO_3^-$-exchanger, extends the allosteric-H^+-site hypothesis to the Na^+-H^+ exchanger.

One can also determine the pH_i dependence of the Na^+-H^+ exchanger in experiments on intact cells. However, an examination of the literature describing the pH_i dependence of Na^+-H^+ exchangers reveals that many investigators assume that the Na^+-H^+ exchanger is the only factor contributing to the recovery of pH_i from an acute acid load. In support of this conclusion, they point out that the recovery occurs in the nominal absence of HCO_3^- and is inhibited by blockers of the Na^+-H^+ exchanger. However, there is a serious flaw in this line of reasoning. It is true that, after a cell containing a Na^+-H^+ exchanger is acutely acid loaded, there is a more-or-less exponential pH_i recovery (e.g., see bcd in Figure 52.11A) that may be prevented by pretreating with amiloride analogs. However, this result only proves that an intact Na^+-H^+ exchanger is required for the pH_i recovery. Such experiments do not address the issue of how background acid-loading processes influence the rate of the pH_i recovery, and thus can not—by themselves—provide the pH_i sensitivity of the Na^+-H^+ exchanger.

An analysis of the pH_i sensitivity of Na^+-H^+ exchange in intact cells requires that one rule out, or at least account for, background acid-loading processes that oppose the action of the exchanger, as discussed above in connection with Figure 52.11. In experiments on isolated hepatocytes in the nominal absence of HCO_3^-,[392,393] applying amiloride has no effect the steady-state pH_i. This implies that both Na^+-H^+ exchange and background acid loading are inactive at this pH of ~7. During the recovery from an acid load, amiloride analogs block the pH_i recovery, but do not unmask a background acid-loading process. Thus, in these cells, the product of (β^T/ρ) and the gross pH_i recovery rate is the true net Na^+-H^+ exchange rate, which varies with pH_i in a nearly linear fashion (Figure 52.14A and B).

In many other cells, however, applying an amiloride analog causes a sizeable fall in steady-state

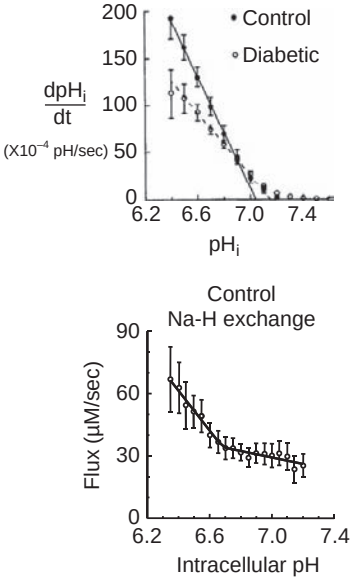

FIGURE 52.14 Two patterns of pH_i dependence of the Na^+-H^+ exchanger. A: The Na^+-H^+ exchanger of rat hepatocytes exhibits true pH_i threshold behavior. Although applying EIPA completely blocks the recovery of pH_i from an acid load, EIPA has no effect on pH_i after the pH_i recovery is completed. Thus, the exchanger is inactive in the normal steady state. The experiments were performed on single freshly disaggregated hepatocytes in the nominal absence of CO_2/HCO_3^-. pH_i was measured using BCECF and a microscope-based fluorometry system. *(Reproduced from ref. [392].)* B: The Na^+-H^+ exchanger in rat mesangial cells is active in the steady state. Applying EIPA in the steady state unmasks a sizeable acidification, indicating that the exchanger is normally active. The experiments were performed on single cells (passage 2–5) in the nominal absence of CO_2/HCO_3^-. *(Reproduced with permission from ref. [318].)*

pH_i,[376,394,395] as indicated by de in Figure 52.11B, implying that both acid loading and Na^+-H^+ exchange were active at the original steady-state pH_i. A similar EIPA-induced pH_i decrease occurs in renal mesangial cells. The pH_i dependence of the true Na^+-H^+ exchange rate thus can be computed only after correcting the gross pH_i recovery rate for EIPA-insensitive acid extrusion and EIPA-unmasked acid loading, as discussed in connection with Figure 52.11B–D. The result for the mesangial cell is the curve shown in Figure 52.14B that indicates that the Na^+-H^+ exchanger is substantially less pH_i sensitive in the physiological range than under conditions of severe acid loading.[318]

DEPENDENCE ON pH_o

The Na^+-H^+ exchanger is inhibited by decreases in pH_o. In intact cells, lowering pH_o decreases the rate at which pH_i recovers from an acid load.[396,397] In crayfish neurons, the pH_i recovery halts completely at the pH_o at which the energy required to move one H^+ out of the cell equals that released by moving one Na^+ in.[397] In brush border membrane vesicles from the renal

cortex, the pH_o dependence of Na^+-H^+ exchange is described by a simple pH titration curve with a pK_a of 7.45.[398] Based on kinetic analyses, external H^+, Na^+, Li^+, and amiloride all compete for a common site on the exchanger (for review, see ref. [367]).

INVOLVEMENT OF Na^+

Acid extrusion by the Na^+-H^+ exchanger in intact cells is blocked by removing extracellular Na^+.[171,396,397] Furthermore, in the presence of extracellular Na^+, acid extrusion is accompanied by a rise in intracellular Na^+ activity[171,396,397] that is blocked when acid extrusion is blocked by lowering pH_o.[396] Reported values of the apparent K_m for external Na^+ vary over a fairly wide range, between ~5 mM and ~40 mM at a pH_o of 7.4.[64,399–403] Accordingly, external Na^+ nearly saturates the transporter at a normal pH_o. The K_m values tend to be inversely related to pH_o, consistent with competition between external Na^+ and H^+ (for review, see ref. [367]). In membrane-vesicle studies, the exchanger can transport Li^+ in place of Na^+.[382] Indeed, Li^+ transport by the exchanger is a key element of the "proton-suicide" technique used to kill cells with a functional Na^+-H^+ exchanger.[404]

EFFECTS OF PHARMACOLOGICAL AGENTS

Amiloride is a K^+-sparing diuretic that inhibits apical ENaC Na^+ channels in tight epithelia; K_i values are in the range 0.1 to 1 μM.[405,406] However, at substantially higher concentrations, amiloride also inhibits certain Na^+-H^+ exchangers (K_i: 3 to 1000 μM; see refs.[407,408]) and Na^+-Ca^{2+} exchange (K_i: 300 to 1100 μM; see refs.[409,410]). The inhibition of Na^+-H^+ exchange by amiloride has generally been found to be purely competitive with respect to external Na^+,[377,400,411,412] although both mixed-type[413] and noncompetitive inhibition[414] have been reported. Because of the competition with Na^+, millimolar levels of amiloride generally are necessary to inhibit Na^+-H^+ exchange at physiological Na^+ concentrations.[171,396,397,411] Structure-function relationships, which have been reviewed in some detail,[406,407,415] indicate that different regions of the amiloride molecule alter the molecule's affinity for the apical Na^+ channel, the Na^+-Ca^{2+} exchanger, or the Na^+-H^+ exchanger. HOE compounds such as HOE694 and HOE642 (cariporide) are relatively new Na^+-H^+ exchange inhibitors that have different affinities for several NHE isoforms, with NHE1 being the most sensitive. Similar to amiloride, the base structure of HOE compounds is guanidinium. However, unlike amiloride and its sister compounds, HOE compounds have an attached benzene ring.

Electroneutral and Electrogenic Na^+/HCO_3^- Cotransporters

As discussed earlier, an electrogenic Na^+/HCO_3^- cotransporter with a Na^+:HCO_3^- stoichiometry of 1:3 is present on the basolateral membrane of proximal tubule cells of the kidney, where it mediates Na^+ and HCO_3^- reabsorption, and therefore functions as an acid loader. A member of the SLC4 family, NBCe1 (SLC4A4) is responsible for HCO_3^- transport in the proximal tubule. A second transporter, NBCe2 (SLC4A5), which is expressed at high levels in hepatocytes, can also mediate electrogenic Na^+/HCO_3^- cotransport with an apparent Na^+:HCO_3^- stoichiometry of 1:3.[416] In mouse choroid epithelial cells, NBCe2 has a Na^+:HCO_3^- stoichiometry of 1:3.[417] However, both NBCe1[418,419] and NBCe2[420] can also operate with a stoichiometry of 1:2, in which case they move Na^+ and HCO_3^- into cells, and therefore function as acid extruders. An electrogenic Na^+/HCO_3^- cotransporter with a Na^+:HCO_3^- stoichiometry of 1:2 (Figure 52.12B, top right) has been documented in both invertebrate and mammalian glial cells (for reviews, see refs.[421–424]).

An electroneutral Na^+/HCO_3^- cotransporter with a Na^+:HCO_3^- stoichiometry of 1:1 (Figure 52.12B, bottom right) has been described in sheep Purkinje fibers,[425] guinea pig myocytes,[426] and vascular smooth-muscle cells.[427] As described in more detail in Chapter 53, two SLC4 members, NBCn1[428,429] and NBCn2 (aka, NCBE)[430] mediate electroneutral Na^+/HCO_3^- cotransport.

Monocarboxylate Transporters

GENERAL FUNCTION AND MOLECULAR IDENTITY OF MCTS

Na^+-independent transport of monocarboxylates such as lactate occurs by a process of cotransport with H^+ (or exchange with OH^-) across the plasma membranes of most cell types (for review, see ref. [431]). The responsible transporters are members of the SLC16 family, which includes 14 members.[432,433] The two best characterized monocarboxylate transporters are MCT1 (SLC16A1)[434] and MCT2 (SLC16A7).[435] However, only MCT1-MCT4 exhibit H^+-coupled monocarboxylate transport. In fact, most of the other family members have yet to be functionally characterized. The sequences of the encoded proteins are predicted to have 12 transmembrane (TM) segments, with a large intracellular loop between TM 6 and 7 and greatest conservation in the predicted transmembrane regions. Although both MCT1 and MCT2 have broad tissue distributions, in the kidney, MCT1 is expressed on the basolateral membrane of proximal tubule cells, and MCT2 is expressed on the basolateral membrane of medullary collecting duct cells.[435]

SUBSTRATE SPECIFICITY AND ENERGETICS OF THE MCTS

MCT isoforms appear to have different affinities for the same substrates. For example, both MCT1 and MCT2 transport lactate and pyruvate,[435] but MCT2 has a much higher apparent affinity for pyruvate.[436]

In all cells examined, H^+/X^- cotransport appears to be electroneutral[162,437] (see ref.[431]). Because MCT-mediated transport of monocarboxylates involves cotransport with H^+, the net driving force depends on the gradients of both monocarboxylate and H^+ across the plasma membrane. Depending on the direction of the net driving force, MCTs can mediate either the influx or efflux of monocarboxylates. As described below, MCT1 on the basolateral membrane of renal proximal-tubule cells acts in conjunction with an apical Na^+/monocarboxylate (Na^+/X^-) cotransporter to facilitate transepithelial lactate reabsorption.

EFFECTS OF PHARMACOLOGICAL AGENTS ON MCTS

MCT1 and MCT2, but not MCT3 and MCT4, are inhibited substantially by α-cyano-4-hydroxycinnamate (CHC).[432,435,438] However, because CHC has yet to be widely tested on other classes of transporters, it is not clear whether this compound is specific for MCTs.

THE Na^+/MONOCARBOXYLATE COTRANSPORTER

The Na^+/X^- cotransporter is rather nonspecific, capable of transporting D- and L-lactate, pyruvate, acetate, and other monocarboxylates. The cotransporter is found in apical membranes of both the proximal tubule and small intestine.[162,439] The Na^+/X^- cotransporter appears to be electrogenic (moving more Na^+ than X^-) in mammals,[198,440–442] but electroneutral in amphibians.[162] Investigators have found that one member of the SLC5 family of "Na^+/glucose cotransporters", namely SLC5A8, encodes an electrogenic sodium-coupled monocarboxylate transporter (SMCT; see refs.[443–446]). In addition, zebrafish SLC5A12 encodes an electroneutral SMCT.[446] As expected, the transporters are relatively nonselective for monocarboxylates, although substrate affinities can vary among the transporters.

INTERACTION OF Na^+/X^- AND H^+/X^- COTRANSPORTERS

Some proximal-tubule cells possess both a Na^+/X^- cotransporter at the apical membrane and an MCT at the basolateral membrane (Figure 52.12C). Acting in concert, these two monocarboxylate transporters can extrude substantial amounts of acid while reabsorbing monocarboxylates.[161,162]

The first step of the acid-extruding process is the coupled entry of Na^+ and X^- across the apical membrane, an example of secondary active transport. Because the pK_a' governing the dissociation of monocarboxylic acids ($HX \rightleftarrows H^+ + X^-$) is generally far below pH_i, very little of the entering X^- can combine with H^+ to form HX, and thus Na^+/X^- cotransport by itself is "pH_i silent". In the second step, X^- entering via luminal Na^+/X^- cotransport rapidly exits across the basolateral membrane via MCT—along with H^+. In this system, basolateral H^+/X^- cotransport is an example of tertiary active transport because the extrusion of H^+ is driven by an X^- gradient that is, in turn, established by the luminal Na^+/X^- cotransporter, a secondary active transporter. The net effect is the transepithelial reabsorption of monocarboxylate from lumen to blood.

Following the coupled uptake of Na^+ and X^- across the apical membrane, the extrusion of Na^+ across the basolateral membrane by the Na^+–K^+ pump contributes to transepithelial Na^+ reabsorption. Indeed, acetate promotes volume reabsorption.[447]

The Regulation of pH_i

INTRODUCTION

In the preceding sections, we have discussed a wide range of factors that influence pH_i. In this and the following section, we will examine how these factors interact to produce transient changes in pH_i and, finally, to establish a steady-state pH_i.

FUNDAMENTAL LAW OF pH_i REGULATION

What determines the stability of pH_i? It is intuitively obvious that pH_i will remain constant as long as the rate of acid extrusion out of the cytoplasm (J_E) is equal to the rate of acid loading into the cytoplasm (J_L)[c]. pH_i will rise if J_E exceeds J_L, and pH_i will fall if J_L exceeds J_E. The rate of pH_i change is proportional to the difference between J_E and J_L, proportional to the surface-to-volume ratio (ρ), but inversely proportional to buffering power:

[c]We define acid-extrusion and acid-loading rates as fluxes (J), with the units of moles per unit area of cell surface, per unit time. In practice, such a definition is practical for calculating values from experiments only if the cell has a very simple geometry (e.g., cylinder in the case of an axon). For most mammalian cells, which have complicated geometries, investigators express acid-loading and acid-extrusion rates in what we would term "pseudofluxes" (φ),[448] with the units of moles per unit volume of cytoplasm, per unit time. In the case of a pseudoflux, the surface-to-volume ratio is folded into the φ value. One must use caution in dealing with φ values, which can change with cell swelling or shrinkage, even without a change in the true underlying acid–base "flux".

$$\frac{d\mathrm{pH}_i}{dt} = \frac{\rho}{\beta}(J_E - J_L) \qquad (52.37)$$

Equation 52.37 makes good intuitive sense. If $J_E = J_L$, then $d\mathrm{pH}_i/d\mathrm{t} = 0$, and the cell is in a steady state with respect to pH_i. Should J_E exceed J_L, pH_i must increase because $d\mathrm{pH}_i/d\mathrm{t}$ will be greater than zero. Furthermore, the rate of this alkalinization is expected to increase as the difference between J_E and J_L increases. If J_E and J_L are unequal, then the rate of pH_i change must be proportional to the surface-to-volume ratio (ρ). Thus, pH_i transients tend to be faster in smaller cells. Finally, the rate of pH_i change must be strongly influenced by β. If β were infinite, then pH_i would be fixed, regardless of J_E and J_L. Conversely, if β approached zero, then even a small difference between J_E and J_L would cause pH_i to change very rapidly.

Factors that Influence the Steady-State pH_i

A Graphical Representation of Equation 52.37

Figure 52.15 is a plot of J_E and J_L as a function of pH_i for a hypothetical cell. The shape of the J_E curve is modeled after that reported for the Na^+–H^+ exchanger of cultured mesangial cells,[318] whereas the shape of the J_L curve is modeled after that reported for Cl^-–HCO_3^- exchange in several cells.[163,232] It is clear from Equation 52.37 that pH_i can be in a steady state (i.e., $d\mathrm{pH}_i/d\mathrm{t} = 0$) only if J_E and J_L are equal. Thus, in Figure 52.15, the steady-state pH_i is determined by the intersection of the J_E and J_L curves. By using the graphical model in Figure 52.15, one can evaluate how steady-state pH_i is altered by either acid–base disturbances, which we will discuss below, or by other factors such as hormones, mitogens, and oncogenes. Some examples will be presented below, from which the following three key concepts will emerge.

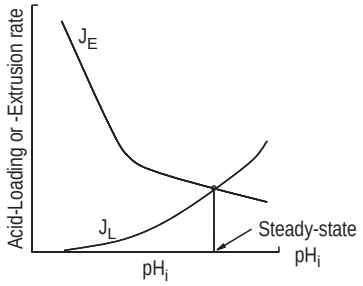

FIGURE 52.15 Dependence of acid-extrusion rate (J_E) and acid-loading rate (J_L) on pH_i for a hypothetical cell. The shapes of the curves are similar to those describing the Na^+–H^+ exchanger and background acid-loading process in renal mesangial cells.

Buffering Power Does Not Influence Steady-State pH_i

Buffering is important for cells because it reduces the magnitude of the pH_i excursions that result from acute (i.e., one-time-only) acid and alkali loads. However, buffering does not prevent pH_i changes; it only minimizes them. Moreover, after an acute acid or alkali load, buffering cannot return pH_i to normal. As we will see in the next paragraph, it is the acid-extruding mechanisms that are responsible for returning pH_i toward normal. According to Equation 52.37, β only influences the rate of pH_i recovery from such an acid load.

Acute Acid or Alkali Loads Do Not Affect Steady-State pH_i

Consider the consequences of an acute acid load (e.g., an injection of H^+ or an influx of a weak acid that leads to the intracellular generation of H^+). The vast majority of H^+ introduced into the cell is neutralized by buffers (the small amount of unbuffered H^+ is responsible for the pH_i decrease). pH_i can return to normal only when the entire acid load—both the additional free H^+ and the added H^+ that is reversibly neutralized by buffers—is extruded from the cell. During such a pH_i recovery, acid extruders remove free H^+ from the cytoplasm, and buffers then partially replenish these extruded protons. Thus, during the pH_i recovery, the added protons move from the buffers to the cytoplasm, from where the acid extruders translocate them to the outside of the cell. If there has been no fundamental change in the properties of the acid loaders and acid extruders, then pH_i will return precisely to its initial value. Thus, by themselves, acute acid and alkali loads produce only transient changes in pH_i.

Only Fundamental Changes in Acid-Extruding and Acid-Loading Processes Can Affect Steady-State pH_i

Consider the consequences of modifying the pH_i dependence of an acid-extruding process in such a way that the intersection of the J_E and J_L curves in Figure 52.15 is altered. Such a change in transporter kinetics would produce a shift in steady-state pH_i. Note that, whereas a change in the J_E and/or J_L curves is required for a shift in steady-state pH_i, the J_E and J_L curves can shift without a change in steady-state pH_i. For example, if there were appropriate offsetting changes in both curves, then it would be possible for the steady-state pH_i to remain unaltered, even though J_E and J_L were modified.

Examples of Intracellular Acid–Base Disturbances

Acute Intracellular Acid Load

Figure 52.16A–F illustrates the time course of pH_i in a hypothetical experiment in which we acutely acid load a cell (segment *ab*) and monitor the subsequent pH_i recovery (*bcd*). Figure 52.16B is reproduced Figure 52.15 and shows the pH_i dependencies of J_E and J_L, as well as J_E and J_L values at different times during segment *abcd* in Figure 52.16A. As described above, the intersection of the J_E and J_L curves at point *a* in Figure 52.16B determines the initial steady-state pH_i, where $dpH_i/dt = 0$.

We could regard the acute acid load as a square-wave increase in J_L. The product of the width (i.e., duration) of the square wave, the height of the square wave, and the surface-to-volume ratio is the amount of acid we are loading into the cell. Dividing this amount by β yields the magnitude of the pH_i decrease, which is represented in Figure 52.16A as an instantaneous fall in pH_i (*ab*). This imposed decrease in pH_i causes J_E to rise (*b* on the J_E curve) and J_L to fall (*b* on the J_L curve). According to Equation 52.37, because J_E now exceeds J_L, pH_i must increase. However, as the pH_i recovery proceeds (*bcd*), J_E gradually falls and J_L rises. Eventually, J_E and J_L come into balance at point *d*, which is identical to point *a*. Thus, as long as an acute intracellular acid load does not produce fundamental changes in the kinetics of either acid extrusion or acid loading, the effect on pH_i is only transitory. Stated differently, if the pH_i dependencies of J_E and J_L in Figure 52.16B are unchanged, then steady-state pH_i also is unchanged. In principle, the precise shape of the pH_i recovery (*bcd*) could be obtained by integrating Equation 52.37. An acute alkaline load will have the opposite effects on pH_i, and can be analyzed in an analogous way.

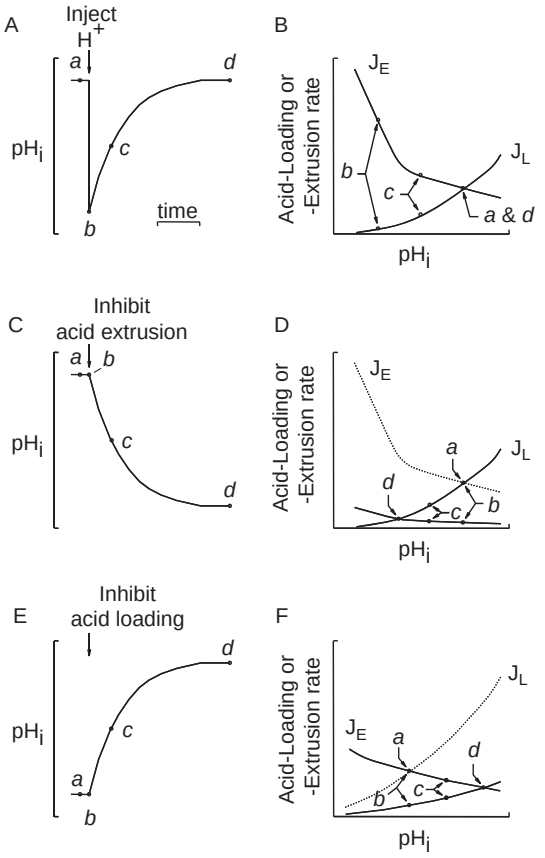

FIGURE 52.16 Response of a hypothetical cell to three insults to intracellular acid–base homeostasis. A and B: An acute intracellular acid load produces no fundamental change in the kinetics of acid extrusion and acid loading. Initially, pH_i is described by point *a* in panel A, and J_E and J_L balance each other, as described by point *a* in panel B. The acid load, which causes pH_i to fall to point b (panel A), also causes J_E to rise and J_L to fall, as described by the *b* points (panel B). Because J_E now exceeds J_L, pH_i recovers (segment *bcd* in panel A). During this recovery, J_E gradually decreases and J_L gradually increases until they reach their original values at point *d* (panel B). C and D: Inhibiting acid extrusion is assumed to reduce J_E by 75% over the entire pH_i range. The original J_E-pH_i relationship is given by the broken curve. Because J_L exceeds J_E immediately after the insult (points *b* in panel D), pH_i declines (panel C). As pH_i declines (*bcd* in panel C), however, J_E slowly increases and J_L decreases until they once again come into balance at point *d* (panel D), which describes the new steady state. E and F: Inhibiting acid loading is assumed to reduce J_L by 75% over the entire pH_i range. The original J_L-pH_i relationship is given by the broken curve. Because J_E exceeds J_L immediately after the insult (points *b* in panel F), pH_i rises (panel E). As pH_i rises (*bcd* in panel E), J_L slowly increases and J_E decreases until they once again come into balance at point *d* (panel F), which describes the new steady state.

Chronic Inhibition of Acid Extrusion

Imagine that our hypothetical cell, initially in a steady state described by point *a* in Figure 52.16C and Figure 52.16D, is treated with sufficient HOE694 (an inhibitor of Na^+–H^+ exchange) to reduce J_E to approximately one eighth of its original level at all pH_i values in Figure 52.16D. Thus, immediately after this reduction in Na^+–H^+ exchange rate, J_L is unchanged (point *b* on the J_L curve), but J_E is greatly reduced (point *b* on the J_E curve). According to Equation 52.37, because J_L now exceeds J_E, pH_i must slowly fall (*bcd* in Figure 52.16C). However, as pH_i declines, J_E rises and J_L falls (e.g., point *c* in Figure 52.16D). Eventually, J_E and J_L come into balance at point *d*, where pH_i now stabilizes. If β does not depend steeply on pH_i, then the rate of pH_i decline during *bcd* will be greatest at point *b*, where the difference (J_L–J_E) is greatest. Thus, a chronic inhibition of acid extrusion causes steady-state pH_i to fall.

Chronic Inhibition of Acid Loading

Imagine that our hypothetical cell, initially in a steady state described by point *a* in Figure 52.16E and Figure 52.16F, is treated with sufficient DIDS (an inhibitor of $Cl^--HCO_3^-$ exchange) to reduce J_L to approximately one fourth of its original value over the entire pH_i range indicated in Figure 52.16F. In Figure 52.16F, the reduced acid loading is represented by shifting the J_L-pH_i curve downward. Thus, immediately after this inhibition of $Cl^--HCO_3^-$ exchange, J_E is unchanged (point *b* on the J_E curve), but J_L is substantially reduced (point *b* on the J_L curve). According to Equation 52.37, because J_L is now much less than the unchanged J_E, pH_i must slowly rise (*bcd* in Figure 52.16E). However, this gradual increase of pH_i causes J_E to fall and J_L to rise (e.g., point *c* in Figure 52.16F). Eventually, J_E and J_L come into balance at point *d*, where pH_i stabilizes. Thus, a chronic inhibition of acid loading causes steady-state pH_i to rise.

FACTORS INFLUENCING pH_i

Interaction of pH_i and pH_o

Introduction

It is well established that changes in pH_o can affect pH_i, and also that changes in pH_i can be accompanied by changes in pH_o.[449,450] Such interactions between intra- and extra-cellular acid–base metabolism are almost certainly mediated by changes in acid–base transport across the cell membrane. We have already discussed several such transport processes, including (1) non-ionic diffusion of weak acids and bases (including metabolites), regardless of whether the transport occurs through the lipid phase of the membrane or via membrane proteins; (2) passive flux of charged weak acids and bases through channels; and (3) acid–base movement via a variety of transporters. In the remainder of this section, we will examine how an alteration on one side of the cell membrane can alter transport and thus produce a pH change on the other side.

Effects of the "Classical" Changes in Extracellular Acid–Base Status on pH_i

One can define at least six simple disturbances of extracellular acid–base status, each of which has a unique effect on pH_i. Four of these are the "classic" extracellular disturbances: metabolic acidosis and alkalosis, as well as respiratory acidosis and alkalosis. The other two extracellular acid–base disturbances, isohydric hyper- and hypocapnia, are unusual in that they produce alterations in pH_i with no change in pH_o.

METABOLIC ACIDOSIS

A sudden extracellular acidification produced by a reduction of $[HCO_3^-]_o$ at a fixed P_{CO_2} is expected to alter pH_i only by mechanisms that we shall describe as "chronic." The reductions in pH_o and/or $[HCO_3^-]_o$ are expected to inhibit acid-extrusion processes, but stimulate acid-loading processes. Such kinetic changes could be produced by alterations in any rate-determining parameter, such as pH_o, $[Na^+]_o$, $[Na^+]_i$, binding constants, or the density of transporters. The net effect is expected to be a gradual but sustained decline in pH_i, similar to that schematized in Figure 52.16C. The modeling of this problem is similar to that described above in Figure 52.16D, except that not only would J_E decrease, but J_L would increase as well. The time course of the pH_i decline depends on β and on the pH_i dependencies of J_E and J_L. The actual value of the new steady-state pH_i would, of course, be independent of β.

The predictions of the foregoing analysis have been confirmed experimentally. Measurements of steady-state pH_i with DMO indicate that metabolic acidosis lowers pH_i in mammalian skeletal and cardiac muscle.[3,451] The time course of this intracellular acidification has also been monitored with pH-sensitive microelectrodes in several vertebrate cells.[13,204,452,453]

METABOLIC ALKALOSIS

A sudden extracellular alkalinization produced by raising $[HCO_3^-]_o$ at a fixed P_{CO_2} is expected to have chronic effects on acid extrusion, acid loading, and pH_i that are opposite to those described above for metabolic acidosis. Metabolic alkalosis generally produces a gradual but sustained pH_i increase, similar to that schematized in Figure 52.16E. The modeling of this problem would be similar to that of Figure 52.16F, except that, not only would J_E increase, but J_L would decrease as well. Steady-state pH_i measurements with DMO in mammalian muscle[451,454] have confirmed the foregoing prediction that pH_i should rise during metabolic acidosis.

RESPIRATORY ACIDOSIS

A sudden extracellular acidification produced by an increase in P_{CO_2} is expected to alter pH_i by both acute and chronic mechanisms. In the laboratory, it is possible to produce a respiratory acidosis in which $[HCO_3^-]_o$ is constant. However, *in vivo*, respiratory acidosis is always accompanied by a rise in $[HCO_3^-]_o$. Regardless of the effect on $[HCO_3^-]_o$, the "acute" effect of respiratory acidosis is produced by the influx of CO_2, which elicits a rapid fall in pH_i. This represents an acute intracellular acid load from which the cell would fully recover if the kinetics of acid-extruding and acid-loading mechanisms were not fundamentally altered

by the accompanying fall in pH_o. The expected "chronic" effects of respiratory acidosis are qualitatively the same as for metabolic acidosis: an inhibition of J_E and a stimulation of J_L. These chronic effects will tend to lower steady-state pH_i, as in metabolic acidosis. Indeed, pH_i determinations by the DMO technique[3,451] show that respiratory acidosis does reduce steady-state pH_i. In principle, the time course of the pH_i decrease could be predicted from our discussion of CO_2-induced acidifications (the acute effect) and from Equation 52.37 (the chronic effect). Thus, β, initial pH_i, initial and final P_{CO_2}, and the kinetics of acid extrusion and acid loading would all influence the time course of acidification. All these parameters except β would also influence the final steady-state pH_i. After the acute effect (i.e., the rapid CO_2-induced pH_i fall), respiratory acidosis could then produce: (1) A slower but sustained pH_i decline (chronic effect), (2) no further pH_i change (i.e., immediate stabilization), or (3) a pH_i recovery that is either partial, complete or—at least in principle—even exaggerated. Which of the three steady-state outcomes we observe depends upon the relationship between J_E and J_L.

RESPIRATORY ALKALOSIS

The pH_i changes produced by respiratory alkalosis, and the mechanisms effecting these changes, are opposite those produced by respiratory acidosis. The effect on acid extrusion is noteworthy because the imposed rise in pH_o is expected to stimulate acid extrusion, whereas the resultant increase in pH_i (caused by the efflux of CO_2) is expected to inhibit or even totally block acid extrusion. Thus, the expected time course of pH_i after its rapid initial rise could be: (1) A further, slower increase to a new steady state, (2) no change, or (3) a decline. Studies with pH-sensitive microelectrodes have demonstrated the first pattern in mouse skeletal muscle,[204] and steady-state pH_i measurements have confirmed that respiratory alkalosis causes a sustained elevation of pH_i.[3,451]

ISOHYDRIC HYPERCAPNIA

Raising P_{CO_2} at constant pH_o (i.e., raising P_{CO_2} and $[HCO_3^-]_o$ proportionally) produces a rapid fall in pH_i,[170,35] due to the influx of CO_2, just as does respiratory acidosis (*vide supra*). However, for at least two reasons, the long-term influences on pH_i can be very different from those produced by respiratory acidosis. First, because pH_o is fixed, one expects no immediate inhibition of acid extrusion or stimulation of acid loading. Thus, the cell should be better able to resist the acute acid load caused by the influx of CO_2. Second, because $[HCO_3^-]_o$ is higher in isohydric hypercapnia than respiratory acidosis, acid loading due to the passive and carrier-mediated efflux of HCO_3^- should be lower than during respiratory acidosis. Third, the aforementioned increase in $[HCO_3^-]_o$ could also stimulate HCO_3^--dependent acid extrusion (e.g., Na^+-driven Cl^-—HCO_3^- exchange). According to recent data, raising $[CO_2]$ per se (i.e., in the nominal absence of HCO_3^-) can stimulate H^+ extrusion from proximal-tubule cells.[32] Thus, although isohydric hypercapnia is expected to elicit the same initial, CO_2-induced fall in pH_i as respiratory acidosis, the final steady-state pH_i should be higher, as has been confirmed in mammalian skeletal muscle.[451]

The time course of pH_i during isohydric hypercapnia depends on the four previously mentioned factors (i.e., β, initial pH_i, initial and final P_{CO_2}, and the kinetics of acid extrusion and acid loading). In salamander proximal-tubule cells, pH_i does not recover from the initial fall, due to the very high HCO_3^- efflux across the basolateral membrane, via NBC.[13] In cells with lesser degrees of HCO_3^--dependent acid loading, pH_i makes a partial or even complete recovery.[455,3,14] Finally, in cells with dominant HCO_3^--dependent acid-extrusion mechanisms, such as smooth muscle[16] and renal mesangial cells,[19] isohydric hypercapnia increases steady-state pH_i. In both dissociated CA1 neurons[355,456] and cultured astrocytes[17] from the rat hippocampus, the degree of this pH_i increase becomes less and less at progressively higher initial values of pH_i. The pH_i increase produced by isohydric hypercapnia in the rabbit proximal tubule[457] may reflect stimulation of apical Na^+—H^+ exchange and H^+ pumping,[206,458] likely involving sensors for basolateral CO_2 and HCO_3^-.[32]

ISOHYDRIC HYPOCAPNIA

Lowering P_{CO_2} at constant pH_o (i.e., lowering P_{CO_2} and $[HCO_3^-]_o$ proportionally) produces an initial rise in pH_i due to CO_2 efflux, as in respiratory alkalosis. The long-term influences on pH_i are the opposite of those described above for isohydric hypercapnia. Thus, the final steady-state pH_i is expected to be somewhat lower in isohydric hypocapnia than in respiratory alkalosis, as confirmed for mammalian skeletal muscle.[459] The time course of changes in pH_i during isohydric hypocapnia has been monitored in several cells, especially during the transition between normal $P_{CO_2}/[HCO_3^-]$ to nominally CO_2/HCO_3^--free conditions. As expected, the reduction in P_{CO_2} at constant pH_o causes an abrupt increase in pH_i (due to CO_2 efflux), followed by a partial return of pH_i toward normal (probably due to inhibition of acid extrusion and stimulation of acid loading at high pH_i). In mesangial cells, the switch from 10% CO_2/50 mM HCO_3^- ($pH_o = 7.4$) to 5% CO_2/25 mM HCO_3^- ($pH_o = 7.4$) causes an abrupt increase in pH_i that represents an acute intracellular alkali load. The subsequent recovery

of pH_i, due primarily to $Cl^--HCO_3^-$ exchange, can then be examined at physiological levels of extracellular CO_2 and HCO_3^-.[25] A similar approach has been used by Ou-yang et al.[460] to examine $Cl^--HCO_3^-$ exchanger activity in neurons cultured from the rat cortex.

Use of Out-of-Equilibrium CO_2/HCO_3^- to make Isolated Changes in Extracellular $[CO_2]$, $[HCO_3^-]$, and pH—One at a Time

In 1995, Zhao et al.[270] introduced a rapid-mixing technique that allows one to create out-of-equilibrium (OOE) CO_2/HCO_3^- solutions with virtually any combination of $[CO_2]$, $[HCO_3^-]$, and pH in the pathophysiological pH range. The approach is to mix the outputs of two syringes—each containing a different combination of equilibrated $[CO_2]$, $[HCO_3^-]$, and pH—and then rapidly (<200 ms) deliver the newly mixed solution to the cells, while continuously sweeping away the solution after it has contacted the cells.

Sensors for Extracellular $[CO_2]$, $[HCO_3^-]$, and pH

Zhou et al.[32] used the powerful OOE approach to alter, systematically, the basolateral (BL) $[CO_2]$, $[HCO_3^-]$, and pH—one at a time—in experiments on isolated, perfused rabbit proximal tubules. They found that increasing $[CO_2]_{BL}$—while holding $[HCO_3^-]_{BL}$ and pH_{BL} fixed—caused an increase in the rate of HCO_3^- reabsorption (measured during a period of $\sim$20 min). This is the appropriate response to the "respiratory" part of acute respiratory acidosis. Conversely, increasing $[HCO_3^-]_{BL}$—while holding $[CO_2]_{BL}$ and pH_{BL} fixed—caused the rate of HCO_3^- reabsorption to decrease. This is the appropriate response to the "metabolic" part of acute metabolic acidosis. Finally, they found that increasing pH_{BL} (which also increased pH_i)—while holding $[CO_2]_{BL}$ and $[HCO_3^-]_{BL}$ fixed—had no effect on the rate of HCO_3^- reabsorption. In other words—at least during acute stresses—the proximal tubule is incapable of responding to changes in pH_{BL} (or pH_i) per se. Rather, the tubule responds to changes in the basolateral concentrations of the two major buffers, CO_2 and HCO_3^-. These data are consistent with the hypothesis that the proximal tubule has some sort of sensor or sensors that detect extracellular levels of CO_2 and extracellular HCO_3^-. The response to increased $[CO_2]_{BL}$ is blocked by nanomolar levels of compounds believed to be specific for the ErbB family of receptor tyrosine kinases, but not by an inhibitor of Src kinases.[461]

Although proximal-tubule cells apparently do not respond to pH_{BL} changes per se, Ludwig et al.[31] identified two G-protein–coupled receptors (GPCRs) that do respond to changes in extracellular pH. The first is the ovarian cancer GPCR (OGR1). Lowering pH_o from 7.8 to 6.8 converts OGR1 from its fully inactivated to its fully activated state, which causes an increase in inositol phosphate formation. According to additional work by Tomura et al.,[462] OGR1 can lead to an increase in $[cAMP]_i$ via phospholipase C and the cyclooxygenase pathway. OGR1 is highly expressed in osteoblasts, lung, intestine, and kidney. The second pH-sensitive GPCR identified by Ludwig et al.[31] is GPR4, which also appears to signal through cAMP. Shortly thereafter, other investigators identified additional pH-sensitive GPCRs with homology to OGR1 and GPR4, including G2A (from G2 accumulation)[463] and T Cell Death-Associated Gene 8 (TDAG8).[464,465] Acid-induced activation of these additional receptors signals through inositol phosphate accumulation for G2A and cAMP accumulation and RhoA activation for TDAG8 (for a review by Tomura et al., see ref. [466]).

In addition to the above GPCRs, several ion channels are pH sensitive. Thus, it is possible that changes in pH_o could signal via changes in membrane potential. The first such channel to be identified was the Na^+-permeable channel ASIC.[467] This channel is activated by large ($\sim$1 pH unit) and rapid pH_o decreases.[468] pH also modulates 2P-domain K^+ channels (TASK, TALK, TREK, & TWIK). TASKs are acidosis inhibited, whereas TALKs are alkalosis activated.[469] TASK-1 (pK $\sim$7.3) is very sensitive to pH_o variations [470] and TASK-3 has a pK of $\sim$6.6.[471,472] For a thoughtful discussion of mechanisms by which kidney cells may sense intra- or extracellular acid–base disturbances, see the review by Brown and Wagner.[473]

Effects of Intracellular pH Changes on pH_o

The pH of the bulk extracellular fluid (pH_{ECF}) is closely regulated by the respiratory and renal systems. Nevertheless, the movement of acids and bases across cell membranes can modify pH_{ECF}. For example, in the central nervous system, where the neurons and glial cells are in close apposition to one another, acid–base transport across the cell membranes can profoundly alter pH_o (for reviews, see refs. [2,474–476]). Acid–base movement across cell membranes can result in either parallel or reciprocal changes in pH_i and pH_o. Parallel decreases in pH_i and pH_o can occur when an increased rate of lactic acid production (which lowers pH_i) leads to the subsequent efflux of lactic acid via H^+/Lac^- cotransport (which lowers pH_o). The efflux of lactic acid minimizes the fall in pH_i. Reciprocal increases in pH_i and decreases in pH_o occur in gall-bladder epithelial cells due to Na^+-H^+ exchange,[449] and in depolarized snail neurons due to a voltage-activated conductance pathway.[450] In both of the above examples, stabilization of pH_i occurs at the expense of pH_o homeostasis.

Role of the Extracellular Fluid in pH_i Regulation

It is well established that changes in pH_o will elicit reciprocal changes in pH_i. A general rule of thumb: the magnitude of a pH_i change will be ~1/3 the magnitude of the pH_o change. However, $\Delta pH_i/\Delta pH_o$ can vary considerably among cells, being as high as 0.7 in mesenteric vascular smooth muscle,[477] carotid-body glomus cell,[478] and CNS neurons.[479] As noted above, extracellular metabolic acidosis causes a sustained fall in pH_i. The overall effect of this acidosis on acid–base transport is therefore a net transfer of acid from the ECF to the ICF of all accessible cells, causing pH_o to increase somewhat toward normal, but at the expense of causing pH_i to decrease throughout the organism. One interpretation of these reciprocal changes in pH_i and pH_o is that cells act as a pH buffer for the ECF, preventing large fluctuations in pH_o. For example, "healthy" cells taking up H^+ minimize the fall in pH_o due to the release of lactic acid by a subpopulation of hypoxic cells. The partial uptake of this acid from the ECF by the healthy cells may thus be viewed as a mechanism for distributing the acid insult among all cells accessible to the ECF, until such time that the renal and respiratory systems can correct the acid–base disturbance.

In the steady state in most animals, there is a net transfer of metabolically generated acid from cells to the ECF, and from the ECF to the urine, as depicted in Figure 52.17. In the kidney, tubules from both the proximal nephron[13,383,380,396] and distal nephron[341,480] are comprised of cells that regulate pH_i much as would nonepithelial cells; they respond to intracellular acid loads by extruding acid. However, these cells are unique in that HCO_3^- efflux, which provides the major intracellular acid load, is limited to the cells' basolateral (or blood-side) membrane.[13,178,481–484] On the other hand, acid extruders (e.g., the Na^+–H^+ exchanger and H^+ pump) are generally most active at the luminal membrane.[164,380,485] Thus, the acid extruded into the ECF from non-renal cells enters renal-tubule cells via basolateral HCO_3^- efflux, lowering renal-tubule pH_i. Presumably stimulated by this pH_i decrease, luminal acid extruders move the acid into the tubule lumen. Thus, the regulation of pH_i by certain renal-tubule cells ultimately leads to acid excretion by the kidney. The renal-tubule cells therefore provide the following final link between pH_i and pH_o: pH_i regulation by renal-tubule cells is responsible for pH_o regulation, which in turn makes possible pH_i regulation by the body's other cells.

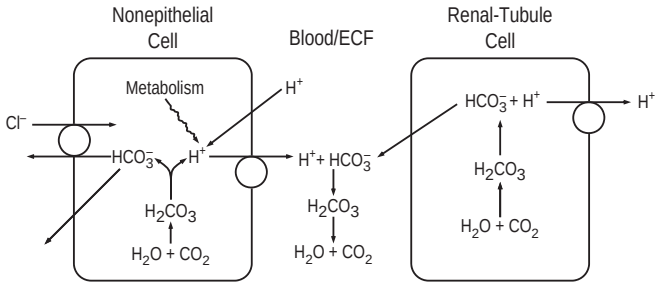

FIGURE 52.17 Schematic representation of factors affecting H^+ balance in the single cell and whole organism. A nonepithelial cell is acid-loaded by metabolic production of acid, by HCO_3^- efflux, and by H^+ influx. pH_i is maintained by a mechanism that extrudes acid from the cell into the ECF and blood. This acid effectively gains entry into certain renal tubule cells by the efflux of HCO_3^- across the renal tubule basolateral membrane. This HCO_3^- efflux, in turn, acid-loads the renal tubule cell and stimulates extrusion of acid across the luminal membrane and into the urine. Thus, the necessity of pH_i regulation by these renal tubule cells brings about pH_i regulation of the blood, which in turn keeps the extracellular pH high enough for nonepithelial cells to regulate their pH_i.

Temperature Changes

Decreasing the temperature generally produces a pH increase in both the blood and intracellular fluid. For reviews, see refs. [3,486]. In principle, a temperature change could alter pH_i in at least three ways: (1) By modifying the pK_a' of pH buffers, (2) by modifying the pK_a' of enzymes or transporters involved in acid–base homeostasis, or (3) by changing the activation energy for an enzymatic reaction or transport process.

Effect of Temperature Changes on the pK_a' of Buffers

The intergrated form of the van't Hoff equation predicts that, in a closed system (i.e., for a fixed total amount of buffer), a buffer's pK should vary inversely with temperature:

$$pK_1 - pK_2 = \frac{\Delta H}{R \ln 10}\left[\frac{1}{T_1} - \frac{1}{T_2}\right] \qquad (52.38)$$

where ΔH is the heat of ionization, R is the universal gas constant, T_1 and T_2 are two absolute temperatures, and the subscripts 1 and 2 refer to pK_a' values at the corresponding two temperatures. If a solution contains only one buffer, then a temperature change will produce parallel shifts in pK_a' and pH. In the case of a solution containing several buffers (e.g., intracellular fluid), the temperature-induced pH shift depends on the sum of the individual pK shifts, each weighted by the buffer's relative contribution to total buffering.[487]

Reeves and Malan[488] have analyzed the pH_i changes produced by temperature shifts in frog muscle *in vivo*. Over the same temperature range, the *in-vivo* pH_i values in these experiments are approximated by the *in-vitro* pH values of a mixture of imidazole, phosphate, and CO_2/HCO_3^-, all at physiological levels.

These frog-muscle data seem consistent with the idea that temperature changes can shift steady-state pH_i by shifting pK_a' of buffers, and thus releasing or consuming H^+. However, this interpretation is inconsistent with the general principle that only alterations in the properties of acid–base transporters can change steady-state pH_i. Consider the example of raising temperature, which would lower the pK_a' values of intracellular buffers, thereby releasing H^+. This represents an acute intracellular acid load, no different in principle from the acid load produced by the injection of H^+. If the only effect of the temperature increase were to lower pK_a' values of buffers, then pH_i would abruptly decrease and subsequently recover to its initial value over the course of a few minutes. The only lasting effect would be subtle changes in the pH_i profile of β. Thus, although there can be little doubt that temperature changes elicit a rapid release or consumption of H^+, we must look to other mechanisms to account for changes in steady-state pH_i.

Effect of Temperature Changes on Enzymes and Transporters

The effects of temperature changes on acid–base transporters and other enzymes affecting pH_i are not well documented. The effects are most likely of two sorts: (1) A temperature-induced shift in the pK_a' of an ionizable group on an enzyme or transport protein could affect the kinetics of the reaction or transport process. (2) Raising the temperature speeds reactions by increasing the energy of the reactants. As far as pK_a' shifts are concerned, a change in temperature would be expected to alter the ionization state of titratable groups on proteins, with effects being greatest for groups with pK_a' values similar to the prevailing pH. For instance, a rise in temperature would lower the pK_a' of an amino group of a protein, thereby reducing the fraction of molecules with a positive charge at that position. Conversely, the fraction of molecules with a negatively charged carboxyl group would rise. Such alterations in ionization could lead to conformational changes that could have major effects on protein function.

As far as direct effects of temperature changes on reaction rates are concerned, enzymatic reaction rates as well as passive and active fluxes of ions all are expected to fall with decreasing temperature, although to varying degrees. In mouse soleus muscle, reducing the temperature from 37°C to 28°C causes the acid-extrusion rate to fall by 65%.[171] Similarly, in cultured astrocytes from rat hippocampus, reducing the temperature from 37°C to room temperature causes the acid-extrusion rate elicited by exposing the cells to CO_2/HCO_3^- to fall by ~40% (unpublished data). In a study on cultured fetal rat hippocampal neurons, Baxter and Church[388] have presented evidence that the Na^+-driven $Cl^- - HCO_3^-$ exchanger contributes to the maintenance of steady-state pH_i at 18°C–22°C, but not at 37°C. In these neurons, increasing temperature may activate the $Na^+ - H^+$ exchanger more than the Na^+-driven $Cl^- - HCO_3^-$ exchanger. In addition to cellular changes brought about by temperature shifts, whole-body physiological changes (e.g., hormone levels, P_{CO_2}, plasma $[HCO_3^-]$) may also influence pH_i.

Metabolic Inhibitors and Anoxia/Hypoxia

Metabolic inhibitors, anoxia/hypoxia and ischemia generally produce slow decreases in pH_i. Metabolic inhibitors have been examined most closely in isolated nerve and muscle preparations using pH-sensitive microelectrodes. Both azide and 2,4-dinitrophenol (DNP) produce two-stage decreases in pH_i:[35,170] an abrupt fall followed by a slower one. The abrupt pH_i decrease is probably due to the influx and dissociation of the protonated weak-acid form of the inhibitor, whereas the slower pH_i decrease may be caused by a net increase in the production of acidic metabolites, confounded perhaps by a decrease in the rate of acid extrusion. Squid axons that are exposed to hydrocyanic acid ($HCN \rightleftarrows H^+ + CN^-$; $pK_a' = \sim 10$) display only a slow decrease in pH_i,[170] the origin of which is likely the same as those of the slow phase of the azide and DNP-induced acidifications. The failure of HCN to produce a rapid pH_i decrease in squid axons is due to its high pK_a'; at physiological pH_i, only a small fraction of incoming HCN dissociates into CN^- and H^+.

Ischemia and anoxia/hypoxia can also elicit decreases in pH_i due to the lactic acid production that results from increased glycolysis in the absence of oxidative phosphorylation (see refs. [489,490]). For example, using ^{31}P-NMR to measure the pH_i of beating rat hearts, Gadian et al.[128] observed that ischemia produced a gradual fall in pH_i from 7.05 to 6.2 in 13 min. However, in hearts previously depleted of glycogen, the pH_i fall triggered by a subsequent episode of ischemia is reduced by ~50%.[491] Similarly, preincubating the hearts in 2-deoxyglucose, which inhibits phosphorylase b and thus glycogen breakdown, reduces the ischemia-induced pH_i decrease by ~25%. Although anoxia/hypoxia might be expected to decrease pH_i by interfering with active-transport processes that extrude acid, the effects of anoxia/hypoxia appear to be more complex and are likely to depend on several factors including the cell type, the experimental preparation (e.g., cells *in situ* vs. cells in culture), duration of anoxia/hypoxia, and the presence vs. the absence of CO_2/HCO_3^-, as well as other parameters that influence the relative activity of various acid–base transporters.

For example, in the isolated turtle heart, anoxia inhibits a DIDS-sensitive, Na^+- and HCO_3^--dependent mechanism by ~50%.[492] In contrast, acute anoxia appears to stimulate a stilbene-sensitive, electrogenic Na^+-coupled HCO_3^- transporter in rat hippocampal neurons.[493] Anoxia/ischemia or subsequent reoxygenation has also been shown to stimulate Na^+–H^+ exchange activity in mammalian neurons and astrocytes,[493–498] and such stimulation can involve kinases such as ERK1/2 and protein kinases A and C.[497,499,500]

Hypoxia-induced changes in acid–base transporter expression are also complex. For example, exposing mice to chronic hypoxia (11% O_2) for two or four weeks decreases the expression of NBCn1 and NBCn2 in cerebral cortex, subcortex, cerebellum, and hippocampus in both neonatal and adult mice.[501] Similar hypoxic results were obtained for NDCBE expression in adult mice, although neonatal animals displayed delayed or absent responses in some of these brain regions.[502] Specific acid–base transporters appear to play important roles in regulating pH_i, ion homeostasis, and perhaps signaling pathways associated with hypoxia-induced cell death.[503] For example, exposing cultured neurons or hippocampal slices to 1% hypoxia for five to seven days causes neuronal damage that is inhibited by the bicarbonate-transport inhibitor DIDS, but exacerbated by NHE inhibitors.[504]

Effects of Cell Shrinkage on pH_i

Effect of Hypertonic Solutions on Na^+–H^+ and Cl^-–HCO_3^- Exchange

In several cell types, including erythrocytes,[505–511] lymphocytes,[374] mesangial cells,[322] glioma cells,[399,512] and barnacle muscle,[513,514] shrinking a cell in a hypertonic medium stimulates the exchange of external Na^+ for internal H^+. In at least *Amphiuma* red blood cells (RBCs), shrinkage in hypertonic solutions also stimulates the exchange of external Cl^- for internal HCO_3^-. Because the H^+ extruded from the cells is derived almost exclusively from buffers, and because the HCO_3^- is derived from the freely diffusible CO_2 and H_2O, these movements of H^+ and HCO_3^- are "osmotically silent." Thus, the net effect of Na^+–H^+ and Cl^-–HCO_3^- exchange is an uptake of NaCl—along with osmotically obligated H_2O—and a recovery of cell volume termed a *volume-regulatory increase* (VRI). As discussed below, shrinkage appears to activate the Na^+–H^+ exchanger directly. However, the stimulation of the Cl^-–HCO_3^- exchanger appears to be indirect, reflecting by the rise in pH_i caused by the activated Na^+–H^+ exchanger.[515]

Interestingly, in lymphocytes, the shrinkage-induced activation of the Na^+–H^+ exchanger is observed only after volume-regulatory decrease that follows a previous cell swelling.[374] Regulation of cell volume per se is discussed in Chapter 5. For other reviews of cell-volume regulation, see refs.[370,371,516–522].

Mechanism by which Shrinkage/Hypertonicity Affects Na^+–H^+ Exchange

Just how cells sense shrinkage is unknown. However, we are beginning to understand more about the signal-transduction processes involved in the acute and chronic responses to shrinkage. Hypertonicity can trigger the rapid dephosphorylation of phosphatidylinositol-5-kinase type I β (PIP5KIβ) that activates the enzyme and increases the rate of PIP_2 synthesis.[523] On a longer time scale, kinases in the Ste20 family, with the subsequent activation of the MAPK pathway, are critical for the chronic response to hypertonic shock in yeast (for reviews, see refs. [524,525]) and mammalian cells (for a review, see ref. [526]).

How does acute cell shrinkage affect one of the key endpoints of the signal-transduction cascade, namely, the Na^+–H^+ exchanger? Most investigators have not observed a hyperosmotic-induced phosphorylation of NHE1,[527] although Rigor et al.[528] have recently reported that the shrinkage of red blood cells from *Amphiuma tridactylum* does activate NHE1 through direct phosphorylation of the C terminus. There is more evidence that the phosphorylation of other proteins is likely to be involved. For example, in work on primary rat astrocytes[529] and confluent C6 glioma cells,[512] Shrode et al. have discovered that shrinkage appears to stimulate Na^+–H^+ exchange through phosphorylation of myosin light chain. Kinases such as tyrosine kinases, MAPKs, and Janus kinase 2 (Jak2) also appear to be involved;[530–533] for a review, see ref. [519]. For example, the general tyrosine kinase inhibitor genistein inhibits both tyrosine kinase-mediated protein phosphorylation and hypertonic-induced stimulation of NHE1 in polymorphonuclear leukocytes.[533]

According to results from an intriguing structure-function study involving chimeras of NHE1 (stimulated by shrinkage) and NHE2 (not stimulated by shrinkage), the extracellular loop between TM domains 1 and 2 of NHE2 is sufficient to inhibit shrinkage-induced activation of the exchanger.[534]

How does acute shrinkage mechanistically alter the Na^+–H^+ exchanger? Shrinkage is thought to increase the transporter's affinity for intracellular H^+.[535] However, Dunham and colleagues[536,537] have reported that cell shrinkage stimulates Na^+–H^+ exchange activity in dog RBCs by reducing the transporter's affinity for external Na^+ at an extracellular inhibitory site.

Other insights into the events linking shrinkage to the acute stimulation of Na^+–H^+ exchange come from work on dog RBCs, lymphocytes, and/or giant-barnacle muscle fibers. First, although Na^+–H^+

exchange appears inactive in these cells under physiological conditions, it can be stimulated by either a decrease in pH_i,[374,538] a decrease in cell volume,[374,508,514] or an increase in $[Li^+]_i$.[538,539] Second, the shrinkage-induced activation of Na^+-H^+ exchange requires Cl^-,[540,508] specifically intracellular Cl^-.[514,541] In rat mesangial cells as well, the shrinkage-induced increase in pH_i is inhibited by preincubating the cells in a Cl^--free solution for a minimum of ~15 min (and presumably decreasing $[Cl^-]_i$ considerably). Third, in barnacle muscle fibers, the shrinkage-induced activation of Na^+-H^+ exchange is inhibited by GDPβS,[513] suggesting involvement of a G protein in the signal transduction system. Consistent with this last observation, Na^+-H^+ exchange is stimulated by either GTPγS, AlF_3, or cholera toxin (CTX).[541] However, the CTX effect is not via a classic G_s pathway, inasmuch as neither cAMP nor cAMP analogs stimulate Na^+-H^+ exchange. It should be emphasized that the data do not prove that CTX stimulates the Na^+-H^+ exchanger by the same signal transduction pathway as does shrinkage. Finally, in barnacle muscle fibers, the Cl^- requirement in the shrinkage-induced activation of the exchanger is at or before activation of the heterotrimeric G protein.[541]

K^+-H^+ Exchange

Cala has observed that an exchange of internal K^+ for external H^+ contributes to the *volume-regulatory decrease* (VRD) that occurs after swelling *Amphiuma* RBCs.[506] This exchange is inhibited in the nominal absence of Ca^{2+}, and is stimulated by applying the Ca^{2+} ionophore A23187, suggesting that increases in $[Ca^{2+}]_i$ may activate K^+-H^+ exchange. Two observations are of special interest. First, increased $[Ca^{2+}]_i$ failed to stimulate K^+-H^+ exchange when Na^+-H^+ exchange was stimulated by shrinkage. Second, if the cells were shrunken (so that Na^+-H^+ exchange should have been stimulated) and then pretreated with amiloride (to block Na^+-H^+ exchange), then swelling failed to activate K^+-H^+ exchange. However, amiloride did not inhibit swelling-activated K^+-H^+ exchange when the drug was applied for the first time to swollen cells. These data led Cala to suggest that Na^+-H^+ and K^+-H^+ exchange may be mediated by the same entity.[542] K^+-H^+ exchange can also be activated by millimolar concentrations of *N*-ethylmaleimide (NEM).[543]

Hormones, Chronic Stress, Growth Factors and Oncogenes

Hormones

A number of hormones modulate transepithelial acid−base transport in various nephron segments (for examples, see refs. [544−547]). In addition, hormones modulate specific acid−base transporters in a variety of cells, including those from the kidney. The Na^+-H^+ exchanger is the transporter that has most often been the subject of these hormone studies—probably reflecting the transporter's popularity rather than its unique sensitivity to hormonal control. Below, we will review some of the hormones that can alter the activity of acid−base transporters, particularly those in the kidney.

GLUCOCORTICOIDS

Elevations in plasma levels of glucocorticoids in response to metabolic acidosis increases acid excretion in the kidney by stimulating Na^+-H^+ exchange, thereby increasing H^+ secretion and HCO_3^- reabsorption. In studies on brush-border membrane vesicles, Na^+-H^+ exchange rates are higher in vesicles obtained from adrenalectomized (adx) animals treated with the glucocorticoid dexamethazone than in adx animals treated with the mineralocorticoid aldosterone, or in adx animals receiving no supplementation.[548,549,550] In proximal-tubule cells isolated from the kidney, Bidet et al.[551] have shown that even a 1-hr treatment with dexamethazone can enhance Na^+-H^+ exchange. The dexamethazone increases the V_{max} of the transporter, and stimulates new protein synthesis. Glucocorticoids exert their effect predominantly on the Na^+-H^+ exchange isoform NHE3. For example, in ileal brush-border membranes from animals injected with methylprednisolone, the glucocorticoid stimulates both the activity and mRNA levels of NHE3, but not of NHE2 or NHE1.[552] In opossum kidney (OKP) cells, glucocorticoids increases both Na^+-H^+ exchange activity[553] and NHE3 mRNA levels.[554] Hydrocortisone raises both the activity and protein level of NHE-3 in OKP cells subjected to acidosis.[555] Data are consistent with a non-genomic component to glucocorticoid-induced activation of NHE3 that involves both the stimulation of protein kinase SGK1 and the presence of the Na^+-H^+ exchanger regulatory factor NHERF2.[556,557] Glucocorticoids can also enhance the stimulatory effect of insulin on NHE3 activity and expression in OKP cells.[558,559]

Glucocorticoids appear to stimulate Na^+/HCO_3^- cotransport as well. For example, removing hydrocortisone from the medium of cultured proximal tubule cells causes a decrease in Na^+/HCO_3^- activity, whereas returning the hydrocortisone or adding dexamethasone increases the activity of the transporter.[560] In addition, both NBCe1 activity and mRNA levels are increased 80−90% in proximal tubules from rats four days after subcutaneous injection with glucocorticoids.[561]

Aldosterone can have both non-genomic (short term) and genomic effects (long term) on Na^+-H^+ exchange. For example, in both renal and non-renal

cells, applying aldosterone elicits a stimulation of the Na^+-H^+ exchanger after a maximum delay of 20 min[562–565] (see ref. [566]), probably due to an alkali shift in the set point of the transporter.[567] However, a 30-min exposure of aldosterone to the frog early distal tubule also stimulates Na^+-H^+ exchange activity, but due to increased expression of the transporter. In this frog-tubule preparation, the stimulation can be inhibited by transcription or translation inhibitors.[568] In a nongenomic fashion, aldosterone also stimulates NHE3 activity in the medullary thick ascending limb of the kidney[569,570] through an ERK-dependent pathway.[571] In immortalized proximal-tubule epithelial cells from the spontaneously hypertensive rat (SHR), aldosterone also stimulates NHE activity through a process requiring H_2O_2 production.[572] As presented in greater detail in Chapter 35, aldosterone also stimulates the V-type H^+ pump in the distal tubule.

CATECHOLAMINES

The catecholamines norepinephrine and dopamine both influence acid–base transporter activity in the kidney. Norepinephrine has been proposed to stimulate Na^+-H^+ exchanger activity in the proximal tubule,[573,574] probably through activation of α_{1A}- and/or α_{1B}-adrenergic receptors.[575] However, in working on the *Ambystoma* proximal tubule, Abdulnour-Nakhoul et al.[576] found that norepinephrine has no effect on Na^+-H^+ exchanger activity, but rather, elicits an increase in pH_i by inhibiting NBC-mediated HCO_3^- efflux. Norepinephrine also increases $Cl^--HCO_3^-$ exchange activity to a greater extent in immortalized proximal-tubule epithelial cells from SHR than normotensive rats, perhaps due to elevated H_2O_2 production.[577] Catecholamines also can influence expression of acid–base transporters. For example, a 15-day whole-animal infusion of norepinephrine increases the expression of both NHE3 and NBCe1 in rat kidney cortex.[578]

Regarding dopamine, it is well established that this catecholamine inhibits Na^+-H^+ exchanger activity in the brush-border membrane of the proximal tubule.[579–584] Such inhibition is mediated through both cAMP/PKA-dependent and -independent events,[579,580,584] and can involve endocytotic removal of NHE3 transporters from the apical membrane.[585] Working on isolated proximal tubules from rabbit, Kunimi et al.[586] have demonstrated that dopamine also inhibits Na^+/HCO_3^- cotransporter activity, although such inhibition was not observed in tubules from hypertensive rats. Dopamine has also been shown to inhibit $Cl^--HCO_3^-$ exchanger activity in immortalized proximal-tubule cells from normotensive, but not hypertensive rats.[587]

Other agents that can influence acid–base activity in the kidney include adenosine, which stimulates Na^+/HCO_3^- cotransporter activity in the proximal tubule,[588] as well as cholinergic agonists that stimulate the cotransporter in proximal-tubule cells.[589,590]

THYROID HORMONES

The effect of thyroid hormone levels on Na^+-H^+ exchange activity has been examined in brush-border vesicles obtained from the renal cortex of hypo-, eu-, and hyperthyroid rats.[550,591–593] Compared to vesicles derived from euthyroid animals, those derived from hypothyroid animals had only half the normal Na^+-H^+ exchange activity, whereas those derived from hyperthyroid animals had twice the normal exchanger activity. In both cases, the altered Na^+-H^+ exchange activity is due to an increase in the V_{max} of the transporter, rather than a decrease in the apparent K_m for Na^+. The effect of thyroid hormones triiodo-L-thyronine (T_3) and L-thyroxine (T_4) on Na^+-H^+ exchange has also been examined in cultured cells. In opossum kidney cells, both T_3 and T_4 stimulate amiloride-sensitive $^{22}Na^+$ uptake,[594] probably by increase the transcription of NHE3.[595]

Thyroid hormone levels also can influence the expression of acid–base transporters. For example, inducing mild hypothyroidism in rats reduces expression of NHE3 and NBCe1 in proximal-tubule brush-border membranes (BBM), but increases expression of AE1 in the distal nephron.[596] Following metabolic acidosis, expression of both NBCe1 in the proximal-tubule BBM and AE1 in the distal nephron are elevated in the hypothyroid vs. control animals. Thyroid hormone also appears to contribute to the developmental switch in expression of NHE8 to NHE3 in the proximal tubule.[597]

PARATHYROID HORMONE, ANGIOTENSIN II, AND CYCLIC AMP

In the renal proximal tubule, HCO_3^- reabsorption is inhibited by PTH,[545,598,599] which increases intracellular levels of cAMP. At the level of brush-border membrane vesicles, PTH and cAMP analogs both reduce Na^+-H^+ exchange activity,[600] whereas parathyroidectomy of the donor animal increases Na^+-H^+ exchange activity.[601] At the cellular level, PTH and cAMP both inhibit Na^+-H^+ exchange in renal epithelial cell lines[602,603] and in rat medullary thick ascending limb (MTAL) tubule suspensions.[604] Based on work by Weinman and colleagues (see ref. [605]), the inhibitory effect of cAMP in the proximal tubule requires the presence of the Na^+-H^+ exchange regulatory factory NHERF-1, which is a PDZ adaptor protein that can bind to the carboxy terminus of NHE3.[606,607] The outcome of PTH stimulation is probably a shift in the pH_i

sensitivity of Na^+-H^+ exchange,[608] likely associated with PTH-induced phosphorylation of NHE3.[609,610] PTH can also have a delayed secondary effect of stimulating internalization of NHE3 from apical membranes.[609,610,611] Long-term PTH exposure also reduces NHE3 expression in OKP cells through a PKA-dependent reduction in NHE3 promoter activity.[612]

PTH and cAMP can also inhibit HCO_3^- transporters. Treatments that raise $[cAMP]_i$ inhibit apical $Cl^-{-}HCO_3^-$ exchange in the *Necturus* gallbladder epithelium,[613] as well as in renal epithelial cells.[614] Similarly PTH appears to inhibit Na^+/HCO_3^- cotransport activity in rabbit renal basolateral membranes via G proteins and a calmodulin-dependent protein kinase.[615] Increases in cAMP and activated Ca^{2+}-dependent protein kinases also inhibit Na^+/HCO_3^- cotransport in these basolateral membranes.[616] As described above for cAMP-mediated inhibition of NHE3, NHERF-1 is also involved in cAMP-mediated inhibiton of NBCe1, although there is no direct association between the two proteins.[617,618]

Low doses of Ang II (e.g., 10^{-11} M in an isolated rabbit proximal tubule, or 10^{-9} M in an anesthetized rat) stimulate Na^+-H^+ exchange and/or Na^+/HCO_3^- cotransport in the proximal tubule,[546,619–627] distal tubule,[628–630] and cortical collecting duct.[631] On the other hand, higher doses of Ang II (e.g., 10^{-9} M or 10^{-6} M in the above preparations) inhibit these transporters.[619,624,627,632,633] Long-term effects of Ang II include regulation of NBCe1 expression in the proximal tubule. For example, expression levels of NBCe1—but not NHE3—in the kidney increase when rats are infused with Ang II, but decrease when infused with the AT1-receptor blocker candesartan.[634] Regarding the signal-transduction pathway, in renal cortical basolateral membrane vesicles[635] and OKP cells,[636] Ang II stimulation of the exchanger involves G-protein activation. Ang II stimulation of Na^+/HCO_3^- cotransporter activity in OKP cells involves activation of Src family tyrosine kinases (SFKs) and the classic MAPK pathway.[637]

In isolated perfused superficial S1 segments of the rabbit proximal tubule, Ang II stimulates both Na^+-H^+ exchange and Na^+/HCO_3^- cotransport,[621] as judged from rates of pH_i change measured at relatively low pH_i values. Interestingly, Ang II has very little effect on steady-state pH_i. Thus, if Ang II indeed stimulates both transporters in the physiological pH_i range, then the combined increase in activities of the acid extruder and acid loader serves to increase transepithelial HCO_3^- reabsorption without altering pH_i. Ang II can also stimulate the Na^+-H^+ exchangers on the apical[638] and basolateral[632] sides of macula densa cells. Recently, Queiroz-Leite et al. have reported that chronic exposure of OKP cells to low levels of Ang II increases NHE mRNA and protein levels through transcriptional activation involving the Sp1/Egr-1 binding site and P450, PI3K, PKA, and MAPK signaling pathways.[639]

Ang II can be internalized by AT_1 receptor–mediated endocytosis through a microtubule-dependent pathway, and subsequently increase NHE3 mRNA levels through direct stimulation of MAP kinases ERK1/2 and increased transcription.[640–642]

Ang II can also stimulate other acid–base transporters. For example, in cat papillary muscles of the ventricular myocardium, Ang II stimulates $Cl^-{-}HCO_3^-$ exchange via activation of a PKC-dependent pathway.[643] However, in cat ventricular myocytes, Ang II stimulates total NBC activity through reactive oxygen species (ROS)-stimulation of ERK,[644] but inhibits electrogenic NBC through p38 kinase.[645] In the kidney, Ang II has been shown to stimulate the H^+ pump in isolated proximal-tubule cells by colchicine-sensitive apical membrane insertion.[342]

Chronic Stresses

CHRONIC METABOLIC ACIDOSIS AND ALKALOSIS

Chronic metabolic acidosis typically increases Na^+-H^+ exchange activity in the kidney, whereas chronic metabolic alkalosis has the opposite effect. For example, brush-border membrane vesicles derived from animals with chronic metabolic acidosis have increased Na^+-H^+ exchange activity,[601] due to an increase in the apparent V_{max}, rather than to a decrease in the K_m for Na^+.[646,550] Increases in the activity of Na^+-H^+ exchange have been observed in other preparations, such as membrane vesicles of rabbit kidney proximal tubules previously incubated in a low-pH solution,[647] and cells from the medullary thick ascending limb (mTAL) of rats subjected to metabolic acidosis.[648] In the mTAL, such activation is paralleled by increases in NHE3 mRNA and protein levels,[648] but not NHE1 mRNA levels.[649] Working with cultured proximal-tubule cells, Alpern et al.[650] found that *chronic* metabolic and respiratory acidosis increases Na^+-H^+ exchange activity via new protein synthesis. This effect, as well as increased expression of NHE3 mRNA, is blocked by overexpressing Csk,[651] a natural inhibitor of Src kinases. Recall that in acute experiments (see above) on isolated perfused proximal tubules, CO_2 appears to signal through a receptor tyrosine kinase, not Src.

Chronic metabolic acidosis/alkalosis can also elicit changes in the activity of other acid–base transporters. For example, the increase in apical Na^+-H^+ exchange activity with metabolic acidosis is paralleled by an increase in basolateral Na^+/HCO_3^- cotransporter activity.[29,647,652] Kwon et al.[653] used semiquantitative immunoblotting and immunohistochemistry to

examine the effect of chronic metabolic acidosis on the expression of three Na^+-coupled HCO_3^- transporters in rat kidney. The acidosis increased NBCn1 abundance in the medullary thick ascending limb and another NBCn1 variant in intercalated cells, but had no effect on NBCe1 abundance in the proximal tubule.

Metabolic acidosis also causes an increase in the activity of apical H^+ pumps in the kidney,[654,655,656] presumably contributing to the increase in HCO_3^- reabsorption. In fact, chronic acidosis stimulates the redistribution of H^+ pumps to the apical surface of collecting-duct intercalated cells, whereas chronic alkalosis stimulates the redistribution to the basolateral surface.[657] *In vitro* chronic acidosis also increases the expression of the H^+-K^+ pump in HEK-293 cells.[658] Finally, Sabolic et al.[657] observed that expression levels of $Cl^--HCO_3^-$ exchange increase in the cortical collecting duct (CCD) of rats subjected to chronic metabolic acidosis (consistent with increased HCO_3^- reabsorption by α intercalated cells), but decrease in animals subjected to chronic metabolic alkalosis. Consistent with this observation is work by the Schwartz group on the rabbit CCD. They found that chronic metabolic acidosis decreases apical Cl^-–base exchange (and pendrin mRNA and protein expression) of the β-intercalated cells, but increases basolateral Cl^-–base exchange (and AE1 expression) of the α-intercalated cells.[659,655] Such expression changes are rapidly reversed with alkali loading for only 6–20 h.[659] In ref.[660], Schwartz and Alexander review the adaptive changes to the pH physiology of CCD intercalated cells subjected to acid–base disturbances.

CHRONIC HYPERCAPNIA

Na^+-H^+ exchange activity is increased in renal brush-border vesicles derived from animals that were chronically hypercapnic.[661] Chronic respiratory acidosis also increases levels of band 3 mRNA in the kidney.[662] Working on either opossum kidney cells or cultures of proximal-tubule cells, Arruda and colleagues have found that 10% CO_2 (i.e., respiratory acidosis) has a biphasic stimulatory effect on NBCe1 activity that initially (within 5 min) involves activation of Src family kinases and phosphatidylinositol 3-kinase and increased membrane insertion of NBCe1.[663–666] Later (24 h), these authors observe increases in mRNA and protein levels. Chronic hypercapnia can also alter the expression of acid–base transporters with dependence on tissue and stage of development. For example, exposing mice to 8 or 12% CO_2 for two weeks increases the expression of: (1) NHE1 and NBCn1 in the brain, heart, and kidney, and (2) NBCe1 in the heart and kidney of neonatal vs. adult mice.[667] Exposing rats to an atmosphere of 8% CO_2 + 13% O_2 for 10 days increases the expression of NBCe1 in the proximal tubule, but decreases the expression of pendrin in connecting tubules and cortical collecting ducts.[668]

RENAL HYPERTROPHY, HIGH PROTEIN DIET AND CHRONIC K^+ DEPLETION

Renal hypertrophy can increase the activity of several acid–base transporters (for review, see ref. [669]). Brush-border membrane vesicles derived from the remnant kidney following a uninephrectomy exhibit increased Na^+-H^+ exchange activity.[326,670] Interestingly, the denervation associated with the uninephrectomy may be the predominant stimulus. Indeed, the hypertrophy-induced activation of Na^+-H^+ exchange elicited by the uninephrectomy can be mimicked by contralateral denervation.[671] Nevertheless, hypertrophy of renal proximal-tubule cells *in vitro* does lead to an increase of Na^+-H^+ exchange activity.[672] In microperfusion studies of rat proximal tubule, Preisig and Alpern[673] demonstrated that the hyperfiltration preceding a decrease in renal mass increases the activities of both Na^+-H^+ exchange and Na^+/HCO_3^- cotransport.

Rats fed a 40% protein diet, rather than a 6% protein diet, also yield cortical brush-border membrane vesicles with enhanced Na^+-H^+ exchange activity, and these effects of uninephrectomy and high-protein diet are additive.[326,670] A high-protein diet in rats promotes distal HCO_3^- reabsorption through endothelin-stimulated activities of the Na^+-H^+ exchanger and H^+ pump.[674] In the case of the H^+ pump, endothelin acts through an increase in aldosterone levels.[675]

Finally, K^+ depletion also can increase the expression and function of renal acid–base transporters, enhancing overall HCO_3^- reabsorption. For example, vesicles derived from K^+-depleted rats exhibit enhanced Na^+-H^+ exchange and Na^+/HCO_3^- cotransport activity due to increases in apparent V_{max} values, with no changes in the apparent K_m values for Na^+.[676] K^+ depletion appears to increase NBCe1 mRNA expression and activity in the proximal tubule, and induce them in the mTAL and inner medullary collecting duct.[677] K^+ depletion also increases expression and activity of K^+-H^+ pumps[346,349] and H^+ pumps in the distal nephron.[678] In the case of the H^+ pumps, Barone et al.[679] present evidence that K^+ depletion increases expression of the H^+ pump on the apical membrane of α-intercalated cells in the collecting ducts and, in these same cells, upregulates SLC26A7 and AE1 on the basolateral membranes.

Growth Factors

CLASSICAL MODEL OF GROWTH-FACTOR EFFECTS ON pH_i

A potential role for pH_i in mitogenesis is suggested by the observation that growth-factor-induced

proliferation of both fibroblasts[680] and mesangial cells[27] is blocked at relatively low pH_i values, and rises sharply as pH_i enters the physiological range. Indeed, there are numerous examples in which adding a mitogen to quiescent cells, in the nominal absence of CO_2/HCO_3^-, causes a sustained increase in pH_i.[24,378,395,681–686] Because the mitogen-induced pH_i increase is prevented either by removing Na^+[681,395] or by pretreating with amiloride or an amiloride analog,[394,395,681] many investigators had deduced that the increase in pH_i is due to stimulation of $Na^+–H^+$ exchange (for more examples, see ref. [351]). Furthermore, in fibroblast mutants lacking $Na^+–H^+$ exchange, mitogens fail to elicit proliferation, or to alkalinize the cells.[404,680] Wang et al.[687] have reported that a P19 embryonal carcinoma cell line lacking $Na^+–H^+$ exchange has a reduced ability to grow and differentiate. The ability to differentiate can be resurrected by reintroducing the exchanger into the cells. These data led to an attractive hypothesis: (1) In quiescent cells, pH_i is too low to sustain proliferation. (2) Mitogens, it addition to affecting other cellular functions, stimulate $Na^+–H^+$ exchange. (3) This stimulation of $Na^+–H^+$ exchange elevates pH_i to a range that is permissive for proliferation. Thus, according to this model, pH_i would play a central role in proliferation.

EFFECT OF MITOGENS ON pH_i IN THE PRESENCE OF CO_2/HCO_3^-

One of the first hints that the mitogen-pH_i model described above might be incomplete was the observation that A431 cells incubated in the presence of CO_2/HCO_3^- do not alkalinize in response to FCS plus EGF.[20] Mesangial cells,[24] fibroblasts,[18] and NIH 3T3 cells[685] also fail to alkalinize. In fact, in mesangial cells, all 13 mitogens or other agents that increased steady-state pH_i in the nominal absence of CO_2/HCO_3^- caused pH_i to decrease in the presence of this physiological buffer.[27] In all four of the aforementioned cell types, the steady-state pH_i in the presence of CO_2/HCO_3^- is substantially higher than observed in the absence of CO_2/HCO_3^-, with or without mitogen. Thus, it seems that, at least for some cells, the pH_i prevailing in the presence of CO_2/HCO_3^- is high enough to put pH_i in a range permissive for proliferation, and that pH_i remains in this permissive range even after a mitogen-induced acidification. Although the pH_i increase elicited by mitogens in the absence of CO_2/HCO_3^- is real, it appears that a change in pH_i is not an intrinsic part of the mitogenic response.

TRANSPORTERS AFFECTED BY MITOGENS IN THE PRESENCE OF CO_2/HCO_3^-

The effect of growth factors on the activity of acid–base transporters of cells incubated in the presence of CO_2/HCO_3^- has been examined in some preparations. In renal mesangial cells, application of arginine vasopressin (AVP)[688,25] or epidermal growth factor (EGF)[688] "activates" all three of the following acid–base transporters known to be present: the $Na^+–H^+$ exchanger, the Na^+-driven $Cl^–HCO_3^-$ exchanger, and the $Cl^–HCO_3^-$ exchanger. The two acid-extrusion mechanisms, assayed at the single pH_i of 6.6, were stimulated by ~100%. The acid loader, assayed at the single pH_i of 7.7, was stimulated to an even greater extent, ~140%. AVP also stimulates both $Na^+–H^+$ and $Cl^–HCO_3^-$ exchange in the A10 vascular-smooth-muscle cell line.[689] It should be emphasized that none of the data discussed thus far address the issue of whether in fact the growth factors stimulated the transporters in the physiological pH_i range (i.e., approximately 7.1–7.3 for these cells).

Growth factors can also have time-dependent effects on pH_i and acid–base transporters. For example, in working on mesangial cells, Ganz et al.[688] observed that both AVP and EGF, which are thought to act through different signal transduction pathways, have similar effects on the time courses of the three aforementioned transporters. Both growth factors elicit an immediate (i.e., within ten min) increase in the activities of all three transporters (assayed at the single pH_i values indicated above). The immediate response is followed within an hour by a fall in the activities of all three transporters, even though the activities remain substantially above control levels. Finally, there is a transient dip in the activities of all three transporters at times corresponding to the period of the maximal rate of increase in cell number (~35–~45 h for AVP and ~12–~20 h for EGF). Growth factors can have "early" and "late" effects on $Na^+–H^+$ exchange in vascular smooth muscle cells (for review, see ref. [690]). The "late" effect can include increased expression of the exchanger.

EFFECT OF GROWTH FACTORS ON THE pH_i DEPENDENCE OF THE $Na^+–H^+$ EXCHANGER

In the past, many investigators believed that the pH_i dependence of the $Na^+–H^+$ exchanger is linear, and that the exchanger is inactive at the physiological (i.e., "threshold") pH_i. Investigators also believed that the mitogen-induced increase in pH_i that is observed in the absence of CO_2/HCO_3^- exclusively reflects stimulation of $Na^+–H^+$ exchange in the physiological pH_i range. According to this view, mitogens cause an alkaline shift and/or an increase in the steepness of the $Na^+–H^+$ exchange activity vs. pH_i relationship, without having other effects on acid extrusion and/or acid loading. Indeed, careful analyses of the pH_i dependence of $Na^+–H^+$ exchanger activity in intact

hepatocytes indicates that Na^+-H^+ exchange activity can vary linearly with pH_i,[392,393] and that a mitogen can shift this line in the alkaline direction.[393] However, as discussed above (pH_i dependence of Na^+-H^+ exchange), it is now clear that the approach often used to reach similar conclusions in other cells (i.e., comparison of pH_i recovery rates with and without amiloride at a single low pH_i) is seriously flawed.

Applying the approach used to generate the pH_i dependence of Na^+-H^+ exchange activity in Figure 52.11A or Figure 52.11B leads to the conclusion that AVP has a complex pH_i- and time-dependent effect on Na^+-H^+ exchange in mesangial cells. At short times (~8 min) after applying AVP, the pH_i dependence of Na^+-H^+ exchange activity (similar to that shown in Figure 52.14A) becomes linear in such a way that the transporter is unaffected at pH_i values below 6.7, but inhibited at higher pH_i values. At longer times (~14 min), the new linearized plot is shifted to more alkaline values. In the new "stimulated" steady state, the Na^+-H^+ exchanger is more active at pH_i values below ~6.9, but less active at higher pH_i values. How can AVP therefore raise pH_i in the absence of CO_2/HCO_3^-, if the Na^+-H^+ exchanger is inhibited in the physiological pH_i range? The answer seems to be that AVP has an even greater inhibitory effect on background acid-loading processes. Thus, AVP causes pH_i to rise in mesangial cells in the absence of CO_2/HCO_3^- not because the growth factor stimulates Na^+-H^+ exchange, but because it inhibits Na^+-H^+ exchange to a lesser extent than it inhibits background acid loading.

Oncogenes

Hagag et al.[691] found that microinjecting the v-H-*ras* p21 gene product into mouse NIH 3T3 cells causes a rapid and sustained pH_i increase that is inhibited by amiloride or low $[Na^+]_o$. Thus, a functional Na^+-H^+ exchanger is required for the *ras*-induced pH_i increase, though these data do not prove that *ras* actually stimulates the exchanger. Doppler et al.[49] took a different approach, transfecting NIH 3T3 cells with the v-*mos* or Ha-*ras* oncogene under the control of the MMTV-LTR promoter. They found that expression of either oncogene, upon addition of a glucocorticoid, elicited an increase in pH_i as well as progression into the S phase of the cell cycle. Expression of the proto-oncogene of Ha-*ras* (i.e., the normal cell product) had no effect on pH_i and was only weakly mitogenic. The pH_i increase associated with expression of the Ha-*ras* oncogene was blocked by dimethylamiloride,[692] demonstrating a requirement for a functional Na^+-H^+ exchanger. In NIH 3T3 cells transformed with the c-H-*ras* oncogene, Kaplan and Boron[323] found that a higher steady-state pH_i—compared to that of the non-transformed cells—was due to an alkali shift of ~0.7 pH unit in the pH_i dependencies of both the Na^+-H^+ exchanger and a Na^+-coupled HCO_3^- transporter.

It is now well established that cancer cells often exist in an acidic environment and that acid extruders help maintain the pH_i of many cancer cells at a relatively alkaline level (for reviews, see refs. [693–695]). Moreover, many cancers exhibit an upregulation of Na^+-coupled HCO_3^- transporters.[696–699] Curiously, cancer cells seem to go out of their way to create the acidic environment in which they exist—a strategy that appears to confer a selective advantage. A key element in creating a low pH_o in solid tumors is the overexpression of hypoxia-inducible extracellular carbonic anhydrases, particularly CAIX and CAXII[700–706] (for review, see ref.[707]). It appears that these enzymes convert the copious amounts of CO_2 exiting from the cells into HCO_3^- and H^+, thereby lowering pH_o but helping the cells maintain a relatively high pH_i.[708–710] Not surprisingly, CAIX has become a therapeutic target.[711,712]

SLC4 Sodium-Driven Bicarbonate Transporters

Ira Kurtz

Department of Medicine, Brain Research Institute, David Geffen School of Medicine at UCLA, Los Angeles, California, USA

The SLC4 (*sol*ute *c*arrier 4) family is a group of a membrane proteins that share sequence homology and in general mediate the transport of bicarbonate. It should be noted that bicarbonate transport is not unique to the SLC4 family. The structurally unrelated SLC26 family has at least three proteins that mediate $Cl^- - HCO_3^-$ exchange. In this chapter, the biology of SLC4 Na^+-dependent bicarbonate transporters will be highlighted. The outlier in the SLC4 family is the SLC4A11 gene product (NaBC1) that lacks the ability to transport bicarbonate and is currently characterized as an electrogenic sodium-borate transporter. Whether SLC4 transporters mediate bicarbonate and/or carbonate transport is unclear and therefore when the word bicarbonate or the chemical symbol HCO_3^- is used throughout the chapter with reference to SLC4 mediated ion transport, it refers to both HCO_3^- and/or CO_3^{2-}.

In this chapter, while extra-renal studies will be highlighted, an emphasis will be placed on the biology of specific sodium-coupled SLC4 proteins in the kidney.

FUNCTIONAL CATEGORIZATION OF THE SLC4 FAMILY

A dendrogram of the SLC4 family of proteins is shown in Fig. 53.1. The 10 different SLC4 gene products can be logically subdivided functionally and structurally into four groups that differ primarily in their Na^+- and Cl^--dependence and electrogenic properties. Although various categorizations have been proposed, the following is a convenient scheme:

Na^+-independent $Cl^- - HCO_3^-$ exchangers: 3 homologous transporters, AE1, AE2, and AE3 (*SLC4A1, -2,-3* respectively) that mediate $Cl^- - HCO_3^-$ exchange have been well characterized. A fourth member, AE4, has also been reported to function as a $Cl^- - HCO_3^-$ exchanger. However, as will be discussed, the amino acid sequence of AE4 is more homologous to sodium-coupled SLC4 transporters.

$Na^+ - HCO_3^-$ cotransporters: There are 3 well-characterized members of the SLC4 family that transport Na^+ and HCO_3^- without concomitant net Cl^-transport. NBCe1 (*SLC4A4* gene) and NBCe2 (*SLC4A5* gene) are sodium bicarbonate cotransporters that are chloride-independent and electrogenic in that their HCO_3^- to Na^+ transport coupling is >1 (2:1, or 3:1). NBCn1 (*SLC4A7* gene) is an electroneutral $Na^+ - HCO_3^-$ cotransporter with a coupling ratio of 1:1.

Na^+-driven $Cl^- - HCO_3^-$ exchangers: Two SLC4 transporters have been reported to mediate $Na^+ - HCO_3^-$ cotransport in exchange for chloride. The literature regarding the functional properties of the first reported mammalian transporter, NCBE (SLC4A10), is somewhat confusing. Although this transporter is reported by several groups to mediate Na^+-dependent $Cl^- - HCO_3^-$ exchange, a separate study in oocytes has shown that chloride is not transported under physiologic conditions, and accordingly the protein was renamed NBCn2 ($Na^+ - HCO_3^-$ cotransporter electroneutral 2). The details of the discrepant findings in this area are discussed below. The second reported transporter in this group, NDCBE (*SLC4A8* gene), is a well-characterized Na^+-driven $Cl^- - HCO_3^-$ exchanger.

Electrogenic Na-borate cotransporter: NaBC1 has been reported to mediate the electrogenic transport of

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00053-7

$Na^+ - BO_4^-$ in the presence of borate, or $Na^+ - OH^-$ cotransport with coupling ratio of Na^+:anion of at least 2 (electrogenic) in the absence of borate. The lack of a clear role for borate transport in various tissues where this transporter is expressed raises questions regarding the actual function of NaBC1 physiologically.

Several SLC4 transporters expressed in the kidney have been localized at the transcript/or protein level in various nephron segments and cell types (Tables 53.1–53.3; Fig. 53.2). Studies involving the expression of SLC4 transcripts in the kidney have been done in several mammalian species including mouse, rat, rabbit and human. In addition to documented known species differences, SLC4 proteins typically have a number of specific variants (due to splicing and/or alternate promoter usage) whose localization in the kidney and functional properties have not been thus far thoroughly investigated. This fact increases significantly the complexity of addressing the actual protein expression pattern and functional characteristics of each SLC4 transporter in various renal cell types.

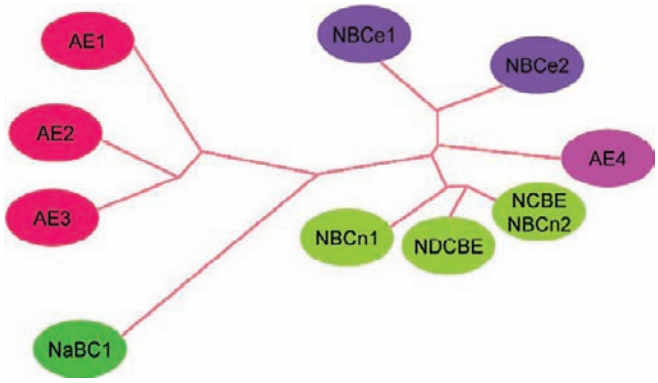

FIGURE 53.1 Dendrogram of SLC4 transporters.

The kidney and brain share the property of having various cell types that express different bicarbonate transporter proteins. Although most SLC4 transporters have in common the property of transporting bicarbonate, cells in the kidney and brain are likely taking advantage of the unique and specific properties of each transporter. The uniqueness of SLC4 proteins stems from the fact that these transporters differ significantly in their ion (Na^+, Cl^-) dependence, coupling ratios, membrane targeting, substrate affinities, developmental expression, regulation by factors pH/phosphorylation, and protein-protein interaction. These differences also account for the fact that functionally, SLC4

transporters have various direct and indirect physiological roles in the kidney including transepithelial bicarbonate transport, intracellular pH regulation, and transport of Cl^-, Na^+ and possibly NH_4^+.

Because SLC4 transporters are expressed not only in the kidney but also in various extrarenal organs and cell types, diseases associated with mutations in these transporters or targeted disruption in mice result in both a renal and extrarenal phenotype (Table 53.4).

SODIUM BICARBONATE COTRANSPORTERS (ELECTROGENIC)

NBCe1 (SLC4A4 Gene)

Structural Variants

Our knowledge regarding the structure of sodium-dependant SLC4 transporters has until recently been extrapolated from the large body of data obtained from studies on the AE1 anion exchanger.[1] More recent studies of NBCe1 reveal very interesting structural and functional differences from AE1.[2] Three variants of the SLC4A5 gene have been well characterized.[3,4] All three NBCe1 variants mediate electrogenic $Na^+ - HCO_3^-$ cotransport, but differ in their N- and C-terminal extremities, regulation, and intrinsic activity. In kidney, NBCe1-A (or kNBC1) is predominantly expressed in S1 and S2 proximal tubule cells where it mediates the basolateral efflux of HCO_3^-, thereby contributing to the reabsorption of ~80% of the filtered bicarbonate load.[5–9] In addition to the proximal tubule, NBCe1-A is also expressed in the eye[10,11] and salivary gland.[12] NBCe1-A transcripts have also been detected in nasal submucosal glands in turbinate mucosa and nasal polyps.[13]

The second NBCe1 variant, NBCe1-B (or pNBC1), which is identical to NBCe1-A except for its unique N-terminus (85 aa replacing the 41 aa in NBCe1-A) was originally cloned from pancreas and is expressed in pancreatic duct epithelial cells where it contributes to basolateral bicarbonate flux from blood to cell, during the process of secretin-evoked pancreatic fluid secretion.[14,15] NBCe1-B is also widely expressed in various other tissues including, colon, skeletal muscle, eye, airway submucosal glands, heart, gall bladder, and nasal mucosa.[10,11,14,16–19] The third variant, NBCe1-C, has a unique C terminus (61 aa replaces 46 in NBCe1-A or B) that ends in a type I PDZ-binding motif.[4] The N-termini of NBCe1-B and NBCe1-C are identical and unlike the N-terminus of NBCe1-A, interact with the IP3 receptor binding protein IRBIT resulting in a stimulation of transport activity.[20,21] More recently additional transcript have been reported.[21A]

Topological and Structural Properties

Of the NBCe1 variants, the structural topology of NBCe1-A has been most thoroughly studied and provides a topologic framework for other Na^+-driven SLC4 bicarbonate transporters (Fig. 53.3). NBCe1-A is an oligomer wherein the predominant oligomeric state of the cotransporter is dimeric.[22] The NBCe1-A monomer is a ~140-kDa glycoprotein containing 1035 amino

acids and is composed of 14 transmembrane regions (TMs).[2,22] The N-terminal transmembrane region has 8 TMs homologous to the SLC4 transporter AE1.[2] Both the extreme N- and C-termini of NBCe1-A are located in cytoplasm, with a large extracellular loop between transmembrane segment (TM) 5 and 6 containing two glycosylation sites.[2,23] Importantly, although NBCe1-A forms a structural oligomer, each monomeric subunit maintains its own independent transport activity.[22]

Previous topological models of NBCe1 were based on the assumption that the cotransporter resembles AE1 which has been extensively studied structurally.[24] The C-terminal transmembrane region of the two transporters share 40% sequence homology but differ structurally. NBCe1-A lacks the two AE1 reentrant loops and extensive substituted cysteine scanning mutagenesis analysis showed that the C-terminal transmembrane region of NBCe1-A is tightly folded unlike AE1 resembling in various aspects the bacterial Na^+-leucine cotransporter, LeuT.[2]

An extensive mutatgenesis study of NBCe1-A has demonstrated several key residues that are critical for its function.[25] Domain swapping studies of the cotransporter have also shed light on its functional properties and have suggested the electrogenicity of NBCe1-A is determined by the interaction of TMs in the lipid bilayer.[24] Arg^{298} in the N-terminus may be involved in constructing a "HCO_3^- tunnel".[26] Residue Thr^{442} in TM 1 is thought to form an external gate for the transported ions.[27] Proposed TM8 has several residues found to be involved in forming the ion translocation pore.[28] Interestingly, substitution of Asp^{555} to glutamic acid in the proposed TM 5 of NBCe1-A induced an outward rectifying Cl^- current and altered the transport substrate selectivity, indicating it plays an important role in HCO_3^- selectivity.[29]

Inhibitors

Asp^{555} is in close proximity of the proposed 4,4′-diisothiocyanatostilbene-2,2′-disulfonate DIDS (a functional inhibitor) binding site of NBCe1-A (Lys^{559}).[29] From the extracellular side, DIDS blocks NBCe1 reversibly by binding to a KKMIK motif at the putative extracellular end of TM5.[30] The apparent affinity of the interaction decreases at more negative voltages possibly due to alterations in the conformation of the cotransporter as the membrane voltage changes.[30,31] DIDS is also capable of blocking the cotransporter from the intracellular side at an unknown site.[32] In addition to DIDS, NBCe1-A is also blocked by the nonsteroidal inflammatory agent Tenidap from the extracellular or intracellular side.[32] NBCe1-B is sensitive to the anion channel inhibitors phloretin, niflumic acid, NPPB, and glybenclamide.[31] NBCe1 is inhibited by the N-cyanosulphonamide compound S0859 however the inhibition is not specific.[33] Benzamil has also been reported to inhibit NBCe1-A.[32]

Familial Proximal Renal Tubular Acidosis: Molecular Mechanisms Involving NBCe1

Patients with autosomal recessive mutations in NBCe1 have an unique phenotype that can be diagnosed clinically that includes severe hyperchloremic acidosis, with extra-renal manifestations including growth and mental retardation, basal ganglia calcification, cataracts, corneal opacities (band keratopathy), glaucoma, elevated serum amylase and lipase, and defects in the enamel consistent with amelogenesis imperfecta.[2,34–43] Regarding the renal phenotype, this "experiment of nature" demonstrates the importance of NBCe1-A in mediating proximal tubule bicarbonate reclamation; the extrarenal manifestations demonstrate the importance of NBCe1- variants in eye (NBCe1-A, NBCe1-B;[10,11]), brain (NBCe1-B, NBCe1-C;[44]), and tooth ameloblasts (NBCe1-B;[45,46]). Thus far,

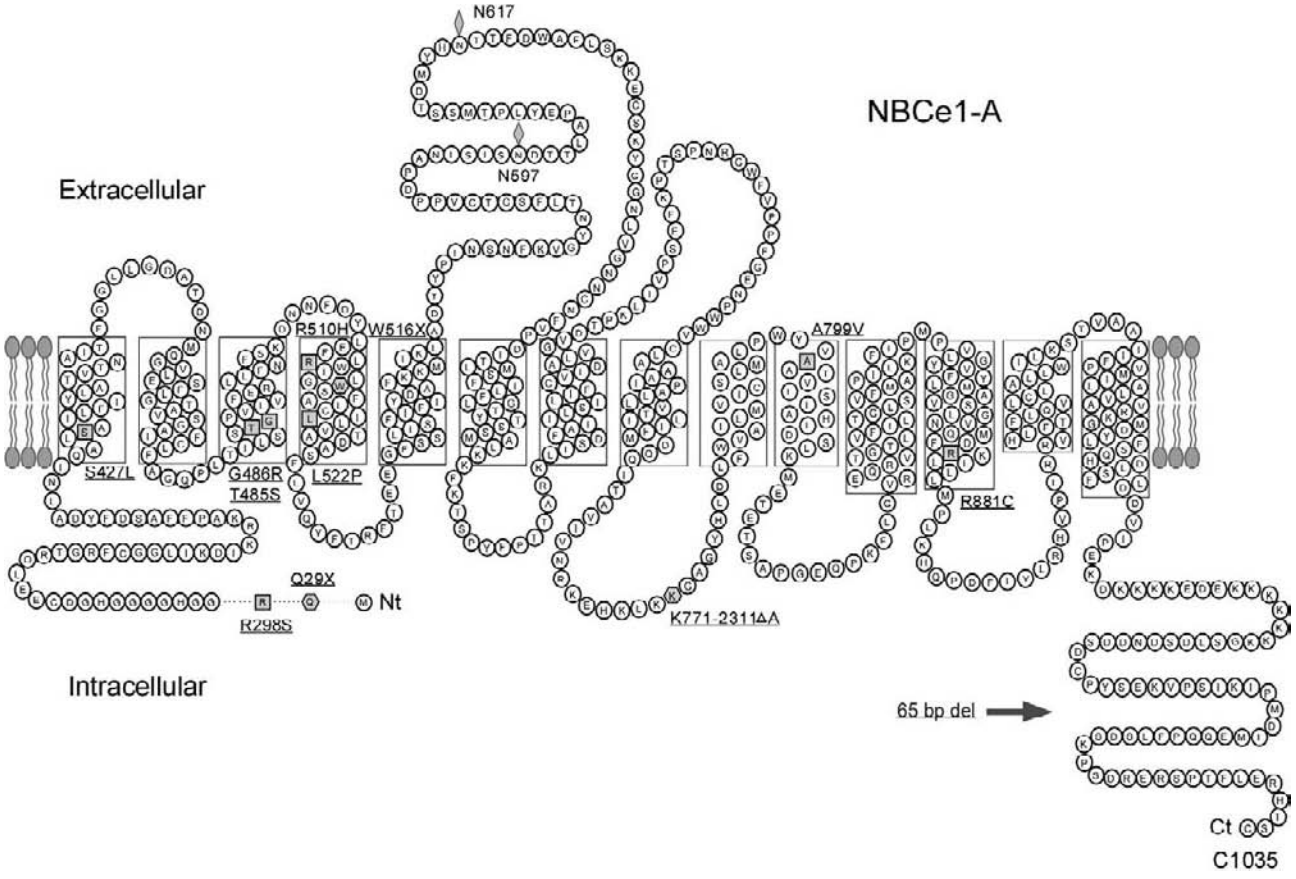

FIGURE 53.3 Topology of NBCe1-A. The transporter has 14 TMs with cystoplasmic N- and C-termini. The location of the known pRTA mutations is depicted. A large extracellular loop between TM5 and 6 typifies the Na^+-driven SLC4 bicarbonate transporters. Note that NBCe1-A lacks the two AE1 (SLC4A1) re-entrant loops.

the following mutants have been described: eight missense mutations (R298S, S427L, T485S, G486R, R510H, L522P, A799V, and R881C), 2 nonsense mutations (Q29X, W516X), a frameshift deletion at nucleotide 2311A, and a C-terminal 65 base-pair deletion from exon 23 to intron 23 predicted to truncate the intracytoplasmic C-terminus (Fig. 53.3, Table 53.5). Other than the NBCe1-A-Q29X mutation which only affects NBCe1-A, the NBCe1-B and -C variants are also mutated resulting in the extrarenal manifestations in this disorder.

The disease causing mechanism of the nonsense/frameshift mutations is due to absence of the full-length NBCe1 protein, whereas the missense mutations result from either reduced transport function and/or impaired plasma membrane processing (R510H, L522P, and R881C; (53, 114, 122)). The functional and targeting defects caused by NBCe1-A pRTA missense mutations have been analyzed in Xenopus oocyte, ECV304 cells, Madin-Darby canine kidney cells, and HEK293 cells with sometimes differing results. In general, mutant membrane transporter proteins are thought to have reduced function as a result of three possible mechanisms that are not mutually exclusive: (1) misfolding of the transporter protein resulting in ER retention; (2) alteration of the ion translocation (permeation) pathway; and (3) impairment of the transporter conformation (static/dynamic) required for substrate translocation.[2]

Missense Mutations

Recent studies have focused on the topologic/structural/functional implications of the residues in NBCe1 that are mutated in pRTA[2]; (Table 53.5). Arg^{298} is located in the cytoplasmic N-terminus of NBCe1-A and resides in a tightly folded aqueous inaccessible conformation based on: (1) homology modeling to the crystallized cytoplasmic domain structure of AE1 and (2) biotin maleimide labeling assays. It has been suggested that Arg^{298} may be involved in constructing a "HCO_3^- tunnel" in NBCe1-A and that mutation R298S disrupts the local structure of the ion permeation pathway thereby impairing the HCO_3^- entry.[2,26] The remaining missence pRTA residues

have recently been localized in the transporter (Fig. 53.3): Ser^{427} to TM 1, Thr^{485}, Gly^{486} to TM 3, Arg^{510} and Leu^{522} to TM 4, Ala^{799} to TM 10, and Arg^{881} to TM 12.[2]

All pRTA residues do not appear to line an ion translocation pore and are likely located in the protein/lipid bilayer complex. Considering the structural change or charge alteration for most of the missense mutations involved in pRTA, it is conceivable that these TM residing mutations would affect protein folding/helix packing in the lipid bilayer, which could lead to significant loss of mutant protein transport function. However, other than R510H, L522P, and R881C, which cause protein intracellular retention, the remaining pRTA causing mutations (S427L, T485S, G486R, and A799V) process to the plasma membrane and retain 10–50% transport function. These findings essentially rule out the possibility that the reduced transport function of the membrane-processed pRTA causing mutations is caused by dramatic protein misfolding.

Mutation of Ser^{427} to leucine induces a failure of the transporter to reverse its direction even at very negative membrane potentials.[35] In addition, the transport is 10% of wild-type NBCe1-A.[35] Ser^{427} has been proposed to be involved in helix interaction and leucine mutation may disrupt NBCe1-A "voltage sensing," affect a Na^+ coordination site, or alter the local conformation required for normal function. Ser^{427} is located in TM 1 adjacent to Ala^{428}, a residue that lines the substrate translocation pore.[27] The bulky side chain of leucine may alter the geometry of the ion translocation pore and impair transport.

The T485S mutation[36] is of interest because of the following considerations: (1) Serine and threonine both belong to the same amino acid category (nucleophilic) and have the same pK_a; (2) structurally, serine closely resembles threonine, but lacks a $-CH_3$ group; (3) mutation of Thr^{485} to serine/cysteine impairs NBCe1-A function by 50%. These observations suggest that the $-CH_3$ group of threonine at position 485 may have a unique role in maintaining the structure of NBCe1-A for normal ion translocation. Valine substitution restored NBCe1-A transport activity to 75% that of the wild-type, despite the fact that it is a hydrophobic amino acid. Moreover isoleucine substitution impaired transport function by 50% also highlighting the potential importance of the $-OH$ group at the 485 position.[2] Based on these findings, it has been proposed that Thr^{485} may reside in a space confined position involving both $-CH_3$ and $-OH$ chemistry that is critical for maintaining NBCe1-A in a conformation required for normal transport function. Indeed, when both $-CH_3$ and $-OH$ groups are removed at this particular amino acid position (alanine substitution), the transport function is decreased to 30% of the wild type.[2] This mechanism may also be applicable to the G486R mutation, which resides adjacent to Thr^{485}.

The L522P mutation causing pRTA is not processed to the plasma membrane in *Xenopus* oocytes, ECV 304, and Madin-Darby canine kidney cells, whereas an L522C mutant does not impair membrane processing.[2,34,43] This suggests that it is the proline residue rather than the loss of leucine that causes intracellular retention of NBCe1-A. Arg^{510} and Leu^{522} both reside in TM 4, a helix that carries signal anchor and stop transfer sequences,[23] and has several residues whose mutation cause protein intracellular retention. TM 4 in NBCe1-A may act as a scaffolding helix that is important for the second stage folding of the transporter. Therefore, it is predictable that a helix disruption mutation (L522P) would significantly misfold the transporter.

The R510H and R881C mutants are also misfolded causing ER retention.[38,47,48] Although R881C was partially expressed on the plasma membrane in the *Xenopus* oocytes and had significant transport activity it was fully retained intracellularly in Madin-Darby canine kidney cells and HEK cells.[2,36,48] Arg^{510} and Arg^{881} are localized to TM 4 and 12, respectively, and do not reside in surface or re-entrant loops as was previously thought.[49] Misfolding of NBCe1-A caused by these two mutations suggests that the arginine at positions 510 and 881 is involved in forming ionic interactions within the TMs to maintain the overall folding of the protein.

Potential Mutant–Specific Therapy in Proximal Renal Tubular Acidosis

In one of the nonsense mutations of NBCe1-A causing proximal RTA, a wt-CAG sequence encoding glutamine has been replaced by a UAG stop codon sequence resulting in premature truncation.[39] Deciphering the rules dictating read-through efficiency is of primary importance for pharmacological treatment of renal tubular acidosis resulting from mutations causing premature stop codons (PSC). Aminoglycosides offer a potential therapeutic approach to treat PSC mutations by inducing ribosomal read-through.[50,51] Aminoglycosides bind to the internal loop of helix 44 of the 16S ribosomal RNA, a region termed the decoding site.[52] In both prokaryotes and eukaryotes, aminoglycosides induce miscoding by mimicking the conformation change in 16S rRNA that would be induced by a correct codon–anticodon pair, thereby compromising the integrity of codon–anticodon proofreading during translation. As a general rule, glutamine is inserted at nonsense UAG or UAA read-through sites, whereas UGA sites miscode to tryptophan.[52]

Recent studies have shown that the NBCe1-A-Q29X mutation can be rescued *in vitro* by treatment with aminoglycoside antibiotics.[53] These findings represent the first evidence that in the presence of the NBCe1-A-Q29X mutation that causes proximal renal tubular acidosis, full-length functional NBCe1-A protein can be produced. In particular these studies offer the opportunity to treat the eye phenotype locally without systemic toxicity. Recently the aminoglycoside derivative NB54 was designed which has significantly less toxicity, with stop-codon read-through potency that is significantly greater than gentamicin likely due to the presence of the flexible N-1-AHB group (*S*)-2-hydroxy-4-aminobutyl group at the N-1 position).[54] In addition non-aminoglycoside compounds such PTC124 may prove efficacious.[55]

Additional Lessons Learned from Mice with Targeted Disruption of SLC4A4

Mice with disruption of the Slc4a4 gene (NBCe1$^{-/-}$ mice) have a more severe (and fatal) phenotype than patients.[56] In addition to severe hyperchloremic metabolic acidosis, they have severe volume depletion, hyponatremia, splenomegaly, intestinal obstructions, and die before weaning. In addition, NBCe1$^{-/-}$ mice also have abnormal dentition as do patients. Paine et al. showed that enamel producing ameloblast cells express AE2a apically and NBCe1-B basolaterally.[45,46] Based on this data, they hypothesized that ameloblasts mediate regulated transcellular bicarbonate secretion during the various phases of enamel formation. Results in NBCe1$^{-/-}$ mice demonstrated that normal enamel development in mammals requires the NBCe1-B variant.[57]

The physiologic importance of NBCe1 in mediating intestinal bicarbonate secretion is exemplified by the intestinal obstruction phenotype in NBCe1$^{-/-}$ mice.[56] NBCe1-B is widely expressed throughout the gastrointestinal tract.[14,58] In the possum ileum, the transporter is predominantly expressed in the mid region of the villi, with lower levels of expression in the crypts,[59] whereas in the murine colon its expression is higher in crypts than in surface cells.[60,61] Although NBCn1 (SLC4A7) is also thought to function as a basolateral bicarbonate uptake mechanism in the intestine,[60–63] NBCe1 is expressed at significantly higher levels than NBCn1,[19] and in addition mice with targeted disruption of SLC4A7 don't have an obvious intestinal phenotype.[64]

Gain of Function

No gain of function mutations have been thus far described.

SYSTEMIC FACTORS AFFECTING NBCe-1 FUNCTION IN THE KIDNEY

Mechanism of enhanced bicarbonate excretion in Na^+ loading. In rats NaCl and $NaHCO_3$ loading reduces the expression of NHE3 and NBCe1 in the proximal tubule potentially contributing to prevention of volume overload and metabolic alkalosis (during bicarbonate loads).[65]

Metabolic alkalosis-potassium depletion: enhanced bicarbonate reclamation: Potassium depletion results in an increase in renal bicarbonate reabsorption proximally and distally.[66–68] Amlal et al. suggested that the upregulation of NBCe1 in the proximal tubule could contribute to the maintenance of metabolic alkalosis.[69] Of note although NBCe1 is normally not expressed in the mTAL and IMCD, the authors reported an increase in the expression of NBCe1 in these nephron segments.

Sympathetic nervous system: norepinephrine: Sonalker reported that long-term (15 days) infusions of noradrenaline (600 ng/min) in rats led to an ~2.5 fold increase in the expression of NBCe1 on Western blotting of rat cortex.[70] The underlying mechanism was not characterized but may have relevance to proximal tubule handling of sodium during alterations in sympathetic outflow to the kidney.

Dopamine: Dopamine decreased the activity of NBCe1 in rabbit and rat proximal tubules but not in spontaneously hypertensive SHR rats.[71] Interestingly, dopamine inhibited the activity of NBCe1 when the cotransporter operated with the 3 HCO_3^-:1 Na^+

stoichiometry.[71] In SHR a defect of DA1 receptor signaling could contribute to the development of hypertension.

PTH: Functional activity of NBCe1 is decreased by PTH in rat tubules *in vivo*.[72] In rabbit tubules perfused *in vivo* under normal conditions, PTH has no effect.[73] In rat tubules pre-incubated in DMEM (Delbecco's modified Eagles medium) + norepinephrine, PTH inhibits the cotransporter possibly via a cAMP dependent mechanism.[71]

Hypertension: In the SHR rat with spontaneous hypertension, Sonalker reported that NBCe1 protein expression was increased ~2 fold in comparison to control WKY rats.[74] However in a separate study, in immortalized proximal tubule SHR cells, NBCe1 activity was reported to be less than normal.[75]

Renal transplant rejection: In a rat model of acute renal transplant rejection, Velic reported down-regulation of NHE-3 but up-regulation of NBCe1-A.[76] These findings may account for changes in proximal tubule bicarbonate transport following renal transplantation.

FK506: The calcineurin inhibitor FK506 has been reported to cause pRTA.[77] Chronic metabolic acidosis per se has no effect on NBCe1-A expression in the kidney.[78] In rats FK506 administration was found to decrease the protein abundance of NBCe1-A in the cortex without a change in acid−base status.

Lithium Toxicity: Chronic lithium toxicity is associated with histologic changes in the kidney and distal renal tubular acidosis.[79] In rats, lithium administration leads to an increase in NBCe1 expression perhaps as a compensatory mechanism.[80]

Ureteral Obstruction: Chronic ureteral obstruction is associated with chronic renal failure and a hyperkalemic distal renal tubular acidosis.[81] In neonatal rats chronic ureteral obstruction resulted in a significant decrease in NBCe1-A expression in the proximal tubule.[82]

Extrarenal Tissues: Role of NBCe-1-B/C in Various Organs and Selective Disease States

Cardiac physiology, ischemia, and reperfusion injury: Several studies have discussed the importance of electrogenic NBC transport in ventricular electrophysiology and function. The data in the literature is sometimes difficult to interpret because NBCe1, NBCe2, and NBCn1 are expressed in the heart and the molecular basis for a given functional effect is not often clearly established. Villa-Abrille showed electrogenic $Na^+ - HCO_3^-$ cotransport modulates resting membrane potential and action potential duration in cat ventricular myocytes.[83] Yamamoto et al. emphasized the functional diversity of electrogenic NBC activity in various species.[84] Schafer et al. demonstrated that following reoxygenation of rat myocytes initially exposed to anoxia, sodium bicarbonate cotransport is responsible for ~50% of the pH_i recovery.[85] DIDS (an NBCe1 and NBCe2 inhibitor) blocked calcium oscillations that cause hypercontracture of the cells.[85] Khandouri et al. have reported an increase in NBCe1-B in myocardium from humans with heart failure.[86] In addition, NBCe1 mRNA and protein was reported to be increased in the rat heart following myocardial infarction.[87] An antibody against NBCe1 significantly improved the post-ischaemic cardiac function.[86] Verdonck hypothesized that the NBCe1-B transporter might contribute to the incidence of arrhythmias in heart failure.[88]

Cystic Fibrosis: NBCe1-B is expressed on the basolateral membrane of pancreatic duct cells in humans.[89,90] In cystic fibrosis pancreatic bicarbonate secretion is decreased and it has been hypothesized that an alteration in basolateral membrane voltage (resulting from defective CFTR transport), impairs NBCe1-B basolateral bicarbonate uptake.[91] IRBIT has been recently shown to be a key coordinator of epithelial fluid and HCO_3^- secretion in murine intralobular pancreatic ducts via independent activation of NBCe1-B and CFTR.[20,21] Interestingly, NBCe1 knockout mice and patients with NBCe1 loss of function mutations do not have a cystic fibrosis phenotype although evidence for pancreatic involvement (elevated amylase or lipase) has been reported in patients.[38,42,56]

Duodenal ulcers: NBCe1-B is expressed in the duodenum, and contributes to transepithelial HCO_3 secretion and potential duodenal cell pHi regulation.[63] Duodenal bicarbonate secretion is thought to protect the duodenal mucosa from acid-related injury.[92] However patients with cystic fibrosis, who have impaired duodenal bicarbonate secretion, paradoxically don't develop duodenal ulcers.[93] Studies in rats support the role of intracellular bicarbonate in the protection of duodenal epithelial cells from ulcer formation.[94]

CNS. Upregulation of NBCe1 (NBCe1-B/C) mediated HCO_3 transport in specific neurons of the brain may prevent excessive extracellular acidosis and inhibit neuronal activity as part of a negative feedback mechanism.[95,96] In seizure-prone gerbils, at 30 minutes postictally, NBCe1 immunoreactivity is substantially elevated in the hippocampus (CA1-, -2, and -3 regions).[97] By three hours, elevated NBCe1 staining is also detectable in the dentate gyrus (and the granule layer).[97]

Molecular Regulation of NBCe1 Function and Membrane Expression

Cytosolic N- and C-terminus: Truncation mutant studies of heterologously expressed NBCe1 variants in

oocytes have shown that unique amino terminus of NBCe1-A stimulates transporter activity (autostimulatory domain (ASD)), whereas the unique amino terminus of the B and C variants inhibits activity.[98] The N-terminus in NBCe1-B and NBCe1-C has accordingly been termed an autoinhibitory domain (AID). The mechanism involved is currently unknown but likely involves interaction(s) between the specific amino terminus and the transport pathway and/or binding to cytosolic factors. In contrast, the carboxy termini affect the plasma membrane expression without affecting cotransporter function.[36,47,98]

In mammalian cells however, Espiru et al. reported that truncation of the N- or C- termini failed to prevent targeting to the plasma membrane (HEK293 cells) or to the basolateral membrane of OK cells.[99] These results differ from Li et al. who showed mistargeting of the C-terminal mutant to the apical membrane with residual basolateral expression in MDCK cells[100] and identified a QQPFLS carboxyl-terminal motif as a basolateral targeting sequence. Horita et al. reported that C-terminal truncation resulted in intracellular NBCe1 localization.[36] Length of truncation, duration of heterologous expression, and cell type may account for these differences. Moreover single point mutation analysis may provide a more informative approach to deciphering the residues that are required for proper folding of the transporter and escape from the ER.[25]

PKA-dependent phosphorylation: Given the prevailing Na^+, HCO_3^- and basolateral membrance voltage in proximal tubule cells, the Nerst equation predicts that for NBCe1-A to mediate the flux of sodium bicarbonate from cell to blood, the ion transport stoichiometry of NBCe1-A is 1 Na^+:3 HCO_3^-.[101–103] Interestingly, the ratio is 1:2 in certain heterologous expression systems such as HEK293 cells and oocytes.[32,104–106] Studies in a mouse proximal and distal tubule cells lines have reported that the stoichiometry of both NBCe1-A and NBCe1-B is cell-type dependent and variable suggesting that unknown cytosolic factors in the proximal tubule interact with NBCe1-A (and NBCe1-B) and modulate the stoichiometry.[107,108] In a proximal tubule cell line, the shift in NBCe1-A stoichiometry from 1:3 to 1:2 is mediated by protein kinase A-dependent phosphorylation of Ser^{982}.[108] Thr^{49} in the unique amino-terminus of NBCe1-B was found to play an important role in modulating the cAMP-induced increase in cotransporter current without altering its stoichiometry.[109] Accordingly, cAMP has also been found to increase intestinal NBCe1-B mediated transport in part via a change in membrane expression.[19,61]

PKC-dependent phosphorylation: ANG II has a biphasic effect on NBCe1 transport in both oocytes and renal proximal tubule cells.[110–114] Studies in oocytes have reported that the ANG II-induced inhibition of NBCe1-A is mediated by the Ca^{2+}-insensitive PKCε isoform that increases its association with NBCe1-A in the membrane, and AII-induced Ca^{2+} mobilization may trigger decreased NBCe1-A surface expression via the AT_{1B} receptor.[113,115] In addition to affecting cell membrane expression, intracellular calcium modulates the stoichiometry of the cotransporter. Specifically, in oocytes expressing NBCe1-A it has been reported that an increase in cytosolic Ca^{2+} shifts the transport stoichiometry from 1:2 to 1:3, possibly via a phosphorylation (PKC) event.[32] Data in a rat parotid cell line suggest that NBCe1-A and NBCe1-B participate in constitutive and stimulated (carbachol) endocytosis regulated by conventional PKCs (PKCαβγ) and by a novel PKCδ.[116] This data may only have relevance in secretory epithelia involving NBCe1-B transport such as salivary duct, ileum, and colon.[19,59,116]

Phosphatidylinositol 4,5-bisphosphate (PIP_2): PIP_2 is noteworthy because in addition to its role as a precursor of the Ca^{2+}-mobilizing inositol triphosphate (IP_3) and the kinase-activating diacylglycerol (DAG), PIP_2 can regulate solute movement.[117] NBCe1 and other members of the SLC4 family have a stretch of C-terminal lysines that may interact electrostically with PIP_2. In voltage-clamped oocytes heterologously expressing NBCe1 (-A, -B, and -C) variants, PIP_2 increased both the B and C variant currents.[118] It has been hypothesized that the NBCe1-A may not respond to exogenous PIP_2 because it may have a higher affinity for endogenous PIP_2 compared to the B and C variants or that a putative autoinhibitory domain in the B and C variants might be masked by PIP_2.[118]

Intracellular Mg^{2+}: When heterologously expressed in oocytes, a phenomenon of NBCe1-A-rundown occurs.[118] The majority of NBCe1-A rundown is likely due to Mg^{2+}-dependent phosphatase (5′-lipid phosphatase) activity because the rundown is largely inhibited by removing bath Mg^{2+}, both in the presence or absence of vanadate and F^-.[118] It has been suggested that the 5′-lipid phosphatase dephosphorylates PIP_2 to PIP.[118] While removing bath Mg^{2+} inhibits NBCe1-A rundown, raising bath Mg^{2+} appears to inhibit NBCe1-A directly.[118] Yamaguchi and Ishikawa reported that intracellular Mg^{2+} inhibits NBCe1-B expressed in mammalian HEK 293 and NIH3T3 cells.[31,119] An N-terminal deletion mutant was less sensitive to Mg^{2+} compared to wild-type NBCe1-B, consistent with the view that the inhibition may be associated, directly or indirectly, with the N-terminal region. Inhibition of NBCe1-mediated transport via an increase in cytosolic Mg^{2+} during ischemia may reduce post-ischemic dysfunction in kidney (NBCe1-A) and heart (NBCe1-B) possibly by keeping the intracellular Na^+

concentration lower and thereby preventing Ca^{2+} overload.

IRBIT: The NBC1-B variant is activated by IRBIT whereas the NBCe1-A is not.[20] IRBIT binds to the N-terminal 1−42 residues of NBCe1-B that are not present in NBCe1-A. Phosphorylation of the PEST (Pro-Glu-Ser-Thr) domain is required for IRBIT binding and activation.[20,120,121] Regulation of NBCe1-B by IRBIT suggests that IRBIT may regulate fluid and HCO_3^- secretion in secretory tissues such as the pancreatic duct.[21]

ATP: In oocytes expressing NBCe1-A, when ATP is applied to the intracellular surface of oocyte membrane patches with low transport activity, the cotransporter current increased.[32] This activation is not due to active ATP-driven transport. The non-hydrolysable ATP analog AMP-PNP does not mimic the effect of ATP.[32] It has been hypothesized that ATP may phosphorylate NBCe1-A by means of an unidentified protein kinase.

Carbonic anhydrase II (CAII): It has been proposed the CAII interacts with an NBCe1 C-terminal a $D^{986}NDD^{989}$ motif forming a transport metabolon that transfers bicarbonate intra-molecularly between the two proteins.[122−124] This hypothesis is of interest given the known expression of CAII in the cytosol of proximal tubule cells.[125] In addition, direct interaction between NBCe1 and membrane bound CAIV has been reported.[126] The data in the literature is both in favor and against the existence of a "transport metabolon;" in part due to difference in techniques employed and the sensitivity/specificity of the measurements utilized.[122,124,127−129] Recently, the question was readdressed using the substituted cysteine accessibility method which showed that the C-terminal tails of the NBCe1-A dimer are highly structured and may sterically prevent CA II binding.[130] Against the quantitative importance of a transport metabolon with CAII is an experiment of nature wherein patients and mice with loss of proximal tubule CAII function do not have as severe proximal renal tubular acidosis as might be predicted; or in comparison to patients with NBCe1 mutations.[131,132] Moreover, neither an alteration in either renal bicarbonate handling or hypobicarbonatemia has thus far been reported in patients or mice with loss of CA IV function.[133−135]

NBCe2: (SLC4A5 Gene)

Structural Variants and Tissue Distribution

NBCe2 (or NBC4) is an electrogenic sodium bicarbonate cotransporter encoded by SLC4A5.[136−139] Interestingly, NBCe2 and $p150^{Glued}$ were originally reported to be encoded by the same locus, DCTN1-SLC4A5, that spans ~230 kilobases on chromosome 2p13 and contains 66 exons.[140] $p150^{Glued}$ is a component of the dynactin heteromultimeric complex of proteins which is required for dynein-mediated vesicle and organelle transport by microtubules.[141] In eukaryotes, it is rare for a single gene to encode two functionally unrelated proteins. More recent studies suggest that SLC4A5 has its own promoter.[142] Six variants have been reported; 4 that are valid splice variants from full-length transcripts (NBCe2-A, -B, -C, and -D;[136,137]) and 2 additional variants[143] that are invalid given they are not found in the SLC4A5 genomic sequence. The most widely expressed variant is NBCe2-C (also called NBC4-C) consists of 1121 aa and is ~145 kDa.[144]

NBCe2 transcripts are expressed in several tissues including brain (human cerebellum, cerebrum, hippocampus, and choroid plexus), heart, kidney, testis, pancreas, muscle, and peripheral blood leukocytes.[58,136,137] At the protein level, NBCe2 has been immunolocalized to the apical membrane of uroepithelial cells and unspecified collecting duct cells in rats.[58,144] In humans, NBCe2 is expressed on the apical membrane of a subset of collecting duct cells in the renal outer medulla.[58] In extra-renal tissues the transporter is expressed in the basolateral membrane of hepatocytes,[144] the apical membranes of cholangiocytes,[143] apical membrane of rat choroid plexus epithelial cells[145] (not detectable in human choroid plexus[58,146]), skeletal muscle,[17] and the basolateral membrane of polarized Calu-cells[16] (suggesting the transporter might be expressed in airway submucosal glands).

Functional Properties

When expressed in mammalian cells NBCe2-C elicits, a Na^+-driven, DIDS-sensitive- bicarbonate flux in the absence of chloride.[138] Similar findings were subsequently reported in oocytes expressing the transporter.[139] NBCe2-C is electrogenic and mediates a hyperpolarization when cells are exposed to bicarbonate and a depolarization when Na^+ is removed. These responses are analogous to those induced by NBCe1. Like NBCe1, NBCe2 appears to function with a Na^+:HCO_3^- stoichiometry of 1:2[139] or 1:3.[138] In mouse choroid plexus epithelial cells, Millar et al. measured a small DIDS-sensitive, Na^+-dependent, HCO_3^--induced outward current.[147] Based on the reversal potential obtained from I-V plots, and the known localization of NBCe2 to the apical membrane of choroid epithelial cells, it was concluded the measured function was mediated by NBCe2 functioning with a 1:3 Na^+:HCO_3^- stoichiometry. Given that the membrane potential of the choroid plexus epithelial cells is −35 mV to −60 mV, NBCe2 would mediate bicarbonate secretion. In a study addressing the potential importance in apical choroid plexus bicarbonate transport, in a mouse model where basolateral bicarbonate influx mediated

by NCBE/NBCn2 (see below) was disrupted, apical NHE activity but not NBCe2 was up-regulated.[148] Moreover, DIDS-sensitive HCO_3^- recovery (presumably assaying NBCe2) in these mice did not function in an inward transport mode. Thus far in native kidney tubules, there are no studies which have addressed the functional contribution of NBCe2 to either transcellular bicarbonate transport and/or intracellular pH regulation.

Hypertension

The Family Blood Pressure Program in 2002 found an association between the *SLC4A5* gene and hypertension.[149] In African Americans 5 SNPs in the *SLC4A5* gene showed significant association with pulse pressure. In Utah pedigrees, at baseline and after a 10-year follow-up period, the association of *SLC4A5* polymorphisms and hypertension was subsequently reported.[150] A meta-analysis of three studies (HyperGEN, HERITAGE, and Family Study and Genetics of Hypertension in Blacks) was done to determine LOD scores for systolic and diastolic blood pressure in African-American and Nigerian families, and linkage evidence showed an association with 2p14−p13.1 where *SLC4A5* is located.[151] In another meta-analysis, the region flanking the *SLC4A5* locus (2p12−q22) was also suggested to be important in whites for blood pressure variation. Finally, *SLC4A5* has been proposed as a promising candidate gene for variations in the blood pressure response to drugs that inhibit the renin-angiotensin system.[152] In a recent analysis, the observed association with resting and submaximal-exercise cardiovascular and metabolic traits in the HERITAGE Family Study were not found to be due variation in the promoter or coding SNPs of the *SLC4A5* gene.[142] Further studies are therefore required to clarify the role of NBCe2 in human hypertension.

Targeted Disruption in the Mouse

Targeted disruption of the Slc4a5 gene results in significant abnormalities in intracerebral ventricle volume, intracranial pressure, and CSF electrolyte levels.[153] In the retina, there is loss of photoreceptors, ganglion cells, and retinal detachment. In a separate study, mice with loss of NBCe2 were shown to have increased blood pressure, a compensated metabolic acidosis and hyporeninemic hypoaldosteronism, elevated fluid intake and urine excretion and an increased glomerular filtration rate.[154] It was suggested that the loss of sodium bicarbonate reabsorption by SLC4A5 initiates compensatory bicarbonate reabsorption via other sodium-bicarbonate transporters.

SODIUM BICARBONATE COTRANSPORTERS (ELECTRONEUTRAL)

NBCn1 (SLC4A7 Gene)

Structural Variants

Pushkin et al. characterized NBC3 (encoded by the SLC4A7 gene), the first electroneutral stilbene-insensitive sodium bicarbonate cotransporter,[155,156] which was subsequently renamed NBCn1.[157] Eight different protein variants (rat and/or human) generated by the SLC4A7 gene have been documented from as many as 16 protein variants that are predicted based on alternative promoter usage and/or splicing.[155,158−159] The documented variants are named NBCn1-(A-H).[158] The first variant characterized from human skeletal muscle cDNA, NBCn1-A (originally NBC3), has 1214 aa and is ~180−200 kDa.[155,160,161] NBCn1 variants have been sub-categorized based on motifs or "cassettes" that they contain. For example, NBCn1-A has an N-terminus that begins with the peptide sequence MERF and contains cassettes I (13 aa) and II (124 aa in human; 123 aa in rat) but lacks a C-terminal cassette III (36 aa). Certain cassettes are homologous to sequences in other Na^+-driven bicarbonate transporters (cassettes I and III), whereas cassette II is unique to NBCn1. Differences in stilbene sensitivity have not been systematically addressed in each of the variants.

Recently, Yang et al. demonstrated the effect of a specific NBCn1 cassette on its function and expression.[162] In NBCn1-A, B, C, and D, cassette II (derived from exon 7 in the SLC4A7 gene) contains multiple putative phosphorylation sites and comprises 20% of the cytoplasmic amino terminus. This cassette has been a focus of attention because it is unique among the SLC4 family in being present only in NBCn1. Transcripts from skeletal muscle,[155] cardiac (apex, atrium and atrioventricular nodes) tissues[163] and embryonic hippocampus neurons[159] express this cassette. Cassette II has been shown to regulate the function and expression of the cotransporter, and may have auto-inhibitory functional activity analogous to the N-terminus of NBCe1-B, -C.[162]

Expression Pattern

Several facts should be considered regarding the expression of NBCn1 variants: (1) Although NBCn1 is expressed in various tissues (transcript and/or protein level) including choroid plexus epithelia, hippocampus, vascular smooth muscle, heart, duodenum, colon, aorta, liver, pancreas, skeletal muscle, spleen, oteoclasts, salivary gland and kidney, the localization of each protein variant in these tissues and in the kidney,[58,62,155,157,161,163−168] has not been

systematically addressed because variant specific antibodies are unavailable. (2) Published findings of the expression of NBCn1 in the kidney are not in uniform agreement potentially due to technical issues, epitope differences being detected, protein-protein interactions *in vivo*, species heterogeneity, and the presence of multiple NBCn1 variants.[78,160–162,167–169] Similarly, differences in NBCn1 choroid plexus expression between species and among mouse strains has been documented.[170]

Despite these complexities, it is currently agreed that the cotransporter is localized to the basolateral membrane of the mTAL in humans and rats.[58,78,161,167,168] In rats but not humans, NBCn1 is expressed on the basolateral membrane of α intercalated cells in the outer medulla.[168] In the rat, inner medullary collecting duct IMCD2 and IMCD3 cells express the cotransporter on the basolateral membrane.[168] Expression of NBCn1 transcripts have also been found by β-galactosidase staining of transgenic mice with a LacZ insertion into the *SLC4A7* gene.[62] This study showed that the cotransporter is located in additional cells types in the mouse kidney including afferent arterioles, glomeruli, arcuate arteries, uroepithelial cells, and urinary bladder.[58,62]

Interaction with PDZ Binding Proteins

Pushkin et al. first showed C-terminal PDZ interacting domain of NBCn1-A (NBC3) can bind to the PDZ-binding protein NHERF-1.[171] Similarly in the eye and inner ear, NBCn1 is organized via PDZ interactions into a supermolecular network of proteins that are mutated in patients with various forms of USHER syndrome;[171A] the most common cause of combined blindness and deafness in humans. NBCn1 per se has not thus far been found to be mutated in this syndrome.

Systemic Factors Affecting NBCn1 Expression in Kidney and Extrarenal Organs

Chronic metabolic acidosis: It has been suggested that countercurrent transfer of NH_4^+ from the medullary thick ascending limb (mTAL) to the outer medullary collecting duct may be modulated by basolateral NBCn1 transport in the mTAL.[167] In keeping with this hypothesis, mTAL NBCn1 expression is upregulated in chronic metabolic acidosis when transepithelial NH_4^+ transport is increased.[167] In cultured mTAL cells, ^{14}C-MA uptake is increased suggesting that acidic conditions increase NBCn1 mediated transport.[172] The upregulation may provide a constant supply of HCO_3^- to the cell and enhance NH_4^+/NH_3 uptake by buffering intracellular H^+ loads. Upregulation of NBCn1 during acidosis is not unique to the kidney and has been demonstrated in neurons where it is associated with glutamate excitotoxicity.[173]

Chronic respiratory acidosis: Studies in mice have shown a developmental and tissue specific effect of chronic respiratory acidosis on NBCn1 expression.[174] The effect of hypercapnia on kidney NBCn1 expression was detected in P2 mice but not neonates or adults. Which cell type in the kidney was involved in the increased expression of NBCn1 was not studied.

K^+depletion: In rats with K^+ depletion, outer medullary collecting duct NBCn1 expression is increased.[175] As in chronic metabolic acidosis, upregulation of the cotansporter may play a role in enhancing countercurrent transfer of NH_4^+ from the mTAL to the outer medullary collecting duct.

Lithium toxicity: Chronic lithium administration induces histologic changes in the kidney associated with dRTA and nephrogenic diabetes insipidus.[79] In rats, lithium administration increased the protein expression of NBCn1 in the inner stripe of the outer medulla ~250%. Presumably, this was due to increased expression on the basolateral membrane of α intercalated cells in the inner stripe of the outer medulla.[168] The relevance to human disease is unclear given that NBCn1 has not been immunolocalized to these cells.[58]

Ureteral Obstruction: Congenital ureteral obstruction is associated with chronic renal failure and a urinary acidification defect.[81] In a neonatal rat model of ureteral obstruction, down-regulation of NBCn1 in medullary thick ascending limbs and outer medullary collecting duct α intercalated cells was detected.[82]

FK506: The calcineurin inhibitor has been shown to decrease the protein abundance of NBCn1 in the rat medulla.[176]

PTH induced hypercalcemia and metabolic alkalosis: Chronic hyperparathyroidism is accompanied by hypercalcemia and mild metabolic alkalosis.[177] Chronic PTH administration in rats led to a decreased expression of NBCn1 in medullary thick ascending limbs and IMCD2 cells in the inner medullary collecting duct.

Hypoxia: In the brain, chronic hypoxia leads to a decreased expression of NBCn1 that is out of proportion to the decrease in brain protein levels.[178] It has been suggested that this effect may reduce energy consumption. Whether this effect is more widespread and a similar decrease in expression of the cotransporter occurs in renal ischemia remains to be determined.

CSF-1-mediated osteoclast survival: NBCn1 is expressed (transcripts and protein) in osteclasts and is thought to play a role in cell survival. The ability of CSF-1 to prolong osteoclast survival requires functional NBCn1.[4]

Functional Properties, Na^+ Current, and Unique Inhibitor Profile

All NBCn1 variants that have been studied thus far have a 1:1 Na^+:HCO_3^- transport stoichiometry and are electroneutral.[155,157,159] In contrast to other members of the SLC4 family, bicarbonate flux mediated by NBCn1 variants are essentially stilbene-insensitive.[155,157,179] Pushkin et al.[155] first suggested that this is due to the replacement of the highly conserved lysine in the conserved putative stilbene-binding motif (K(M/L)XK) by aspartic acid; corresponding to Lys^{542} in human AE1. This may block negatively charged stilbene disulfonates from binding to the transporter. Currently there are no known specific inhibitors of the cotransporter.

NBCn1 produces a steady state ionic current[157,159] that is in part mediated by Na^+, thermodynamically uncoupled to HCO_3^-, and stimulated by stilbenes. The current is not inhibited by amiloride, tetrodotoxin, ouabain, furosemide, or niflumic acid[159] and is possibly generated from the C-terminal transmembrane region of the cotransporter.[24] Using the current to assess the function of the NBCn1-B and D (without casette II) variants, it has been suggested that cassette II may act as an autoinhibitory domain.[162] NBCn1 is inhibited by the N-cyanosulphonamide compound S0859 nonspecifically.[33,180] Whether Tenidap also nonspecifically inhibits the transporter is unknown.

Function in the Kidney

mTAL Transport

Isolated perfused medullary thick ascending limbs have a stilbene-insensitive basolateral sodium driven bicarbonate transport process (electrogenicity has not been studied) thought to be mediated by NBCn1.[167] The expression of NBCn1 and basolateral sodium-driven bicarbonate transport are both increased in chronic metabolic acidosis.[167,172] It has been suggested that NBCn1 mediates basolateral bicarbonate influx to prevent intracellular acidification resulting from apical NH_4^+ influx via NKCC2 coupled to basolateral NH_3 efflux. This hypothesis assumes however that H^+ equivalents released intracellularly from NH_4^+ are not independently transported across the basolateral membrane. Interestingly, mTALs from the NBCn1 KO mouse with normal acid–base status show no difference in transepithelial NH_4^+ transport (Kurtz and Good unpublished observation). Basolateral HCO_3^- uptake mediated by NBCn1 may also function as a regulator of mTAL pHi rather than affecting transepithelial transport.

IMCD Transport

There is little information on the role of NBCn1 in the IMCD. In non-perfused rat IMCD segments adhering to coverslips, a stilbene-insensitive basolateral sodium driven bicarbonate transport process has been reported.[168] Unlike the mTAL, chronic metabolic acidosis has no effect on the expression of NBCn1 in the IMCD. The function of the basolateral transport process has not been examined during chronic metabolic acidosis.

SLC4A7 Gene Disruption in the Mouse

Currently there is no known renal phenotype reported with loss or gain of NBCn1 function. In mice with targeted disruption of NBCn1, a sensorineural phenotype has been described.[64] These mice have visual impairment due to gradual loss of photoreceptors. In addition they have hearing abnormalities due to gradual loss of hair cells, spiral ganglia neurons, and spiral ligament type II and IV fibrocytes.[181] The symptoms are similar to those associated with Usher Syndrome 2B, which maps to chromosome 3p22 (genetic locus of the SLC4A7 gene).[182,183] Given the expression of the transporter in heart and blood vessels, it remains a possibility that subtle change in hemodynamics exist in mammals with loss of NBCn1 function.

Na^+-DRIVEN $Cl^- - HCO_3^-$ EXCHANGER

NDCBE (SLC4A8 Gene)

Structural Variants

The first NDCBE clone was identified (but not functionally characterized) in a screen of 100 cDNA clones from human brain.[184] NDCBE (original name kNBC-3) was then cloned and partially characterized from a human NT-2 cell line,[185] and mouse IMCD cells.[186] The transporter was first shown to function as an electroneutral Na^+-driven Cl^--bicarbonate exchanger by Grichtchenko et al.[187] Human NDCBE (encoded by the *SLC4A8* gene) has been detected by Northern analysis in brain (predominant), testis, kidney, and ovary,[187] and by RT-PCR in human kidney medulla, duodenum, ileum, choroid plexus, hippocampus, and cerebrum.[58] In mouse, transcript expression has been reported to be either highest in testes with less expression in brain;[188] or conversely expressed at high levels in brain.[186] In rat, by RT-PCR, NDCBE transcripts were found in testis, cerebrum, cerebellum, eye, kidney inner medulla, and submandibular gland.[58] Currently, four human NDCBE variants have been characterized functionally and named NDCBE-

A,-B,-C,-D.[187,189] These variants differ in their cytoplasmic N- and C- termini. The longest variant is NDCBE-A composed of 1093 aa and is ~135 kDa.[188,190] In NDCBE-B, the C-terminal 66 aa are replaced by 17 aa that are specific for this variant. NDCBE-C is identical to NDCBE-A except that it is truncated by 53 aa in its N-terminus. Similarly, NDCBE-D is identical to NDCBE-B except that it also is also shortened by 53 aa in its N-terminus. A transcript whose amino acid sequence is identical to NDCBE-D has also been isolated from human heart that differs in its 5′-UTR.[189]

There are no studies with variant specific antibodies that have addressed the localization of the known NDCBE variants in the kidney. In mouse kidney, NDCBE transcripts were reported to be highest in the inner medulla.[186] In a study using an N-terminal antibody (against rat) that would be predicted to detect the NDCBE-A and -B variants, no clear staining of human kidney was detected although transcripts (by PCR) were detected in the medulla (no distinction was made between outer or inner segment) and less so in the cortex.[58] Despite its absence in the kidney, anti-NDCBE immunoreactivity was detected using the same antibody in human hippocampus pyramidal cells.[58] In the rat brain N-terminal antibodies predicted to detect both NDCBE-A and -B variants have localized the transporter to cerebellar Purkinje cells.[58,190] In rat, neurons in the cerebral cortex, CA1-3 and hipoocampal dentate gyrus, substantia nigra, medulla, and cerebellar granular cells express the transporter.[190]

Functional Properties

NDCBE transports $Na^+ - HCO_3^-$ in exchange for Cl^- in an electroneutral fashion. Thermodynamically, 2 HCO_3^-- (or 1 CO_3^{2-}) with 1 Na^+ are exchanged for 1 Cl^- in each transport cycle.[187] This transport stoichiometry is required for the transporter to function electroneutrally. Interestingly, based on ^{36}Cl studies in NDCBE heterologously expressed in xenopus oocyes, the estimated unidirectional Cl^- flux is sevenfold higher than expected and does not occur in the absence of bicarbonate.[187] Therefore, it appears that the majority of Cl^- flux is not being utilized thermodynamically in exchange for $Na^+ - HCO_3^-$ but rather in exchange for Cl^- (i.e. Cl^- self exchange). Removal of extracellular Cl^- impairs ^{36}Cl efflux suggesting that either NDCBE requires that Cl^- bind to an extracellular Cl^- modifier site following removal of Cl^-, or that under these conditions NDCBE mediates electroneutral $Na^+ - HCO_3^-$ cotransport. Regarding the differences in function among the characterized human variants, the unique 17-aa C-terminus of NDCBE-B/D appears to be autoinhibitory in an oocyte expression system.[189]

Hypoxia

In the neonatal mouse brain, chronic hypoxia decreased NDCBE expression in hippocampus and subcortex.[191] In adult mice, expression was also decreased in cerebral cortex and cerebellum. It was hypothesized that changes in expression may adaptively reduce energy expenditure or modulate neuronal pHi.

Function in the Kidney

IMCD Cultured Cells

In a mouse immortalized IMCD cell line acid stress upregulates NDCBE message and a DIDS-sensitive Na^+- and HCO_3^--dependent dependent pH_i recovery.[185] How faithfully these cells mirror the native inner medullary collecting duct is unclear since they also express NBCe1 which is not found in the IMCD *in vivo*.

Targeted Disruption in the Mouse

The role of NDCBE in intercalated cells in the CCD has recently been reported.[188] Approximately 50% of Na^+ absorption in the rat collecting duct is thiazide sensitive and amiloride insensitive.[192] The transporter(s) responsible for this effect in the CCD has been unclear because the known target for thiazides, NCC, is restricted to the distal convoluted tubule.[193] In a recent study, Leviel suggested that NDCBE coupled with pendrin play a role in mediating thiazide-sensitive electroneutral uptake of NaCl in the mouse CCD.[188] Specifically, a Na^+-driven bicarbonate transport process was detected in mouse CCDs that was: (1) absent in mice with targeted disruption of the *SLC4A8* gene, and (2) inhibited by luminal thiazides. Importantly, whether NDCBE is immunolocalized to the apical membrane of CCD intercalated cells has not been determined. Interestingly, thiazides are not able to inhibit NDCBE in an oocyte expression system.[188]

SLC4 TRANSPORTERS WHOSE FUNCTION IS CONTROVERSIAL

NCBE/NBCn2 (SLC4A10 Gene)

Functional Properties

The terminology regarding the name of the SLC4A10 gene product has undergone several revisions in part because of the discrepant functional properties reported in the literature. Wang et al. first cloned the transporter from a mouse insulinoma cell line and named it NCBE (Na^+-driven $Cl^- - HCO_3^-$ exchanger).[194] NCBE was reported by several different

groups to be a Na^+-driven $Cl^- - HCO_3^-$ exchanger.[145,194,195] Subsequently, in the presence of physiologic chloride concentrations, Parker et al. reported that the transporter mediates electroneutral $Na^+ - HCO_3^-$ cotransport similar to NBCn1 and was renamed NBCn2.[196] Interestingly, the transporter simultaneously performed Cl^--self exchange and therefore there was no *net* chloride transport (equal Cl^- flux in both directions) detected under physiological conditions. In the absence of extracellular Cl^- (non-physiologic conditions), the transporter mediated sodium-driven chloride-bicarbonate exchange at a low rate.[196]

Recently, the function of the *SLC4A10* gene product has again been revisited. Damkier et al. reported that *SLC4A10* expressed in stably transected NIH-3T3 cells mediated $Na^+ - HCO_3^-$-cotransport in exchange for Cl^- in an electroneutral fashion (Na^+-driven $Cl^- - /HCO_3^-$ exchange) as Wang et al. originally reported.[197] The authors proposed that the protein be re-named NCBE. Moreover these authors reported that E890, E892, H976, and H980 played an important role in the functional properties of the transporter.

Structural Variants

NCBE/NBCn2-A is composed of 1088 aa and is ~140–150 kDa.[194] The original clone is referred to here as NCBE/NBCn2-A because additional variants have been reported. In general, the mammalian *SLC4A10* gene contains two inserts (cassettes) that account for the known transcripts. Full length cDNAs have been found in mammals for four variants NCBE/NBCn2-A (1088 aa), NCBE/NBCn2-B (originally named rb1NCBE; 1118 aa), NCBE/NBCn2-C (originally named rb2NCBE; 1106 aa) and a partial clone from rat that is possibly NCBE/NBCn2-D (1136 aa).[195,198] At the protein level, evidence for NCBE/NBCn2-D has recently been reported.[198] The transcripts for NCBE/NBCn2-A and NCBE/NBCn2-B contain the 39-bp cassette B that encodes 3 aa and an early stop codon, whereas NCBE/NBCn2-C and NCBE/NBCn2-D contain cassette A (90-bp) in the N-terminus.

Regulation

Although little is known about the regulation of the transporter, Yong-Sun Lee et al. have reported that NCBE/NBCn2-C (originally named rb2NCBE) is inhibited by PKA activation, and that it interacts with EBP50/actin cytoskeleton via a PDZ motif.[199]

Expression in Extrarenal Tissues

NCBE/NBCn2 transcripts are highly expressed in the brain and weakly in rat kidney, testes, ileum, pancreas and pituitary.[194] In mouse, Hubner et al. reported the developmental expression pattern in mouse brain, and that NCBE/NBCn2 is also expressed in stomach, and duodenum.[200] At the protein level the transporter is expressed in the basolateral membrane of choroid plexus cells,[144,190,198,201,202] cerebral cortex,[195,198,201] hippocampus,[195,198,203] cerebellum,[203,195,198] brainstem[198] and lateral superior olive.[198] The most abundant variant is NCBE/NBCn2-A.[198] In the kidney, NCBE/NBCn2 has not been detected at the protein level, however, weak expression has been reported on Northern blotting of human kidney. Although epithelial cells in the kidney do not appear to express the transporter, it is possible that renal nerves in the parenchyma account for the Northern data.

Human Phenotype and Targeted Disruption in the Mouse

As might be predicted from the known expression pattern, loss of NCBE/NBCn2 results in a brain phenotype. Sebat et al. reported a pair of identical twins from a large cohort of patients with autism with chromosomal deletion involving exon 1 of *SLC4A10*.[204] Gurnett et al. described a 13-year-old girl with moderate mental retardation, delayed speech and partial complex epilepsy with a translocation breakpoint of *SLC4A10* on chromosome 2q24.[205] In contrast, mice with targeted disruption of *SLC4A10* have an increased seizure threshold and small ventricles.[201] The latter finding is of interest given the potential importance of NCBE/NBCn2 to transepithelial choroid plexus bicarbonate transport.[144,170] No renal phenotype has thus far been reported.

Electrogenic Na^+–Borate Cotransporter

NaBC1 (SLC4A11 Gene)

The protein encoded by *SLC4A11* was initially called BTR1 (Bicarbonate Transporter Related protein-1) based on sequence homology with other members of the SLC4 family.[206] Motivated by homology with the borate transporter BOR1 in Arabidopsis,[207] Park et al. reported that the transporter was an electrogenic sodium-borate cotransporter and was renamed NaBC1.[208,209] In the absence of borate, the transporter functioned as an electrogenic $Na^+ - OH^-$ cotransporter.[208,209] Questions regarding its functional properties and therefore the appropriate name for the transporter remain, given the lack of documented physiological requirements for borate transport in the tissues expressing NaBC1 in health and disease states.

Expression in the Kidney and Extrarenal Tissues

Studies in human and rat tissues have demonstrated the widespread expression pattern of NaBC1. The

transporter can be localized apically or basolaterally. NaBC1 was originally identified at the protein level in rat kidney, parotid gland, submandibular gland (SMG), pancreas, liver, and spleen.[209] In cornea, NaBC1 is expressed mainly in sensory tissues including endothelial cells with less expression in the epithelial cell layer.[58,210,211] In the inner ear, fibrocytes in the striae vascularis express the transporter.[210,211] In the pancreas NaBC1 is localized to the apical membrane of intercalated ducts.[58] Both the apical membrane of choroid plexus epithelial cells and choroid plexus endothelial cells express NaBC1.[58] In addition, peripheral nerves express the transporter.[58] In kidney, NaBC1 is more widely expressed than any of the SLC4 proteins. These regions include the glomerulus (podocytes), proximal tubule (brush border), nerves near afferent arterioles, basolateral membrane of thin descending limbs in the outer medulla, and basolateral membrane of IMCD cells in the inner medulla.[58] *SLC4A11* transcripts (RT-PCR) have been detected in human stomach and duodenum.

NaBC1 Cell Biology

In knockdown experiments, NaBC1, functioning as a cellular borate influx pathway was reported to be required for cell proliferation.[208,209] In a large scale examination of various intestinal SLC transporter families (including SLC4), administration of various bacteria to mice significantly decreased the expression of intestinal *SLC4A11* (by RT-PCR).[212] The significance of this finding is unknown.

CHED2 Disease and Harboyan Syndrome

Corneal hereditary dystrophy type 2 (CHED2) is caused by mutations in the SLC4A11 gene.[213] Some patients with mutations in the transporter also develop Harboyan syndrome in which perceptive hearing loss and nystagmus are also present.[214] No patients with SLC4A11 mutations have been described with isolated hearing abnormalities. No renal phenotype has been reported in humans despite the widespread localization of NaBC1 in the human kidney.[58]

Targeted Disruption of SLC4A11 in the Mouse

In the first report of targeted disruption of *SLC4A11* in the mouse, sensory tissues were examined.[211] NaBC1 was highly expressed in the corneal endothelial cell layer with less staining in epithelial cells. However unlike humans with mutations in NaBC1, the corneal phenotype was not as severe. Both auditory brain responses and vestibular evoked potential waveforms were abnormal demonstrating the importance of NaBC1 in the visual-auditory-vestibular system. NaBC1 appears be required for generating the inner ear endocochlear potential.[210]

In a second study in mice lacking NaBC1, a renal phenotype was uncovered.[210] LacZ expression and an NaBC1 antibody were used to determine the localization of the transporter in wild-type mice. Unlike the human and rat data, NaBC1 was confined to the thin descending limb at the cortical/outer medullary border. No expression was found in the glomerulus, proximal tubule, nerves or the collecting duct. The urine of the KO mice had a reduced osmolarity, an increased urine volume, increased excretion of sodium, potassium, chloride, and magnesium and a decreased urinary concentration of calcium. It was suggested that NaBC1 in the thin descending limb of Henle is essential for urinary concentration, and that the transporter plays a role in the countercurrent multiplication system. The molecular basis for these findings is still unclear. Further studies are needed to determine its exact transport function.

AE4 (SLC4A9 Gene)

Functional Properties and Expression Pattern in Kidney and Extrarenal Tissues

The function of AE4 is also controversial and there appears to be significant species differences in its kidney expression pattern. AE4 was first cloned from rabbit renal β-intercalated cells and characterized by Tsuganezawa et al.[215] The rabbit transporter is 995 aa and ~110 kDa. Northern analysis of rabbit kidney showed greatest expression in the cortex and the transporter was localized to the apical membrane of rabbit beta intercalated cells. When expressed in oocytes and COS-7 cells AE4 was reported to function as a DIDS-insensitive Na^+-independent $Cl^- - HCO_3^-$ exchanger. Parker et al.[206] and Lipovitch et al.[216] subsequently reported the sequence of the human orthologue. Subsequently, Ko et al. reported that rat AE4 functions as a DIDS-sensitive Na^+-independent $Cl^- - HCO_3^-Cl$ exchanger.[217] In addition, human AE4 expressed in oocytes functioned as a $Cl^- - HCO_3^-$ exchanger. Although AE4 had been reported to function as a Na^++ -independent $Cl^- - HCO_3^-$ exchanger,[215,217,218] its structure closely resembled SLC4 Na^+-dependent transporters (Fig. 53.1). Indeed in a preliminary report, Parker et al. reported that AE4 is an electroneutral $Na^+ - HCO_3^-$ cotransporter.[219]

Although the transporter was initially localized to the apical membrane of rabbit collecting duct β-intercalated cells, subsequent studies have not verified this finding uniformly (Table 53.3). After the initial report, AE4 has been immunolocalized to the apical and lateral membranes of rabbit CCD α-intercalated cells.[217]

A subsequent study showed apical co-localization in rabbit with peanut lectin (a β-intercalated cell marker).[218] In the rat, the transporter was localized to the basal and lateral membrane of CCD α- and β-intercalated cells.[217] In the mouse it is expressed predominantly on the basolateral membrane of cortical collecting duct β-intercalated cells.[220,221]

While northern analysis has shown that AE4 expression predominates in rabbit, human and mouse kidney,[215,216,221] transcripts were also detected in rat stomach and caecum.[217] At the protein level, localization of AE4 was reported in mouse and rabbit gastric surface mucous and duodenal villus cells, and mouse submandibular gland[217] where AE4 is reported to function as an apical $Cl^- - HCO_3^-$ exchanger.[218] However, in a LacZ transgenic mouse, no expression was found in stomach, intestine or colon yet expression in β-intercalated cells was confirmed.[221]

Structural Variants

Multiple splice variants of AE4 have been reported in humans because of selective inclusion/exclusion of part of exons 8, 10, 11, 19 and 20, whereas the use of exons 4–7, 9 and 12–17 appeared constant.[216] It has been suggested that these multiple splice variants may result from inefficient spliceosomal processing.[216] Hentschke et al. in mouse reported 4 different variants resulting potentially from alternative promoter useage.[221] The finding that there are potentially multiple AE4 variants expressed in the kidney cortical collecting duct may account in part for the discrepant immunocytochemistry findings in the literature.

Regulation

In a rat cortical collecting duct cell line (RCCD1 cells), 48 hours of extracellular metabolic alkalosis had no effect on AE4 expression.[222]

Absence of AE4 Expression in the Foxi1$^{-/-}$ Mouse

Mice with targeted disruption of forkhead transcription factor Foxi1$^{-/-}$ develop distal renal tubular acidosis.[220] The cortical collecting ducts of these mice have one cell type that has characteristics of intercalated and principal cells (expression of both AQP2 and CAII). These cells fail to express various acid/base transport proteins including the B_1 subunit of the apical H^+-ATPase, pendrin, and AE4.

Mice with Targeted Disruption of AE4

AE4$^{-/-}$ mice do not have an overt phenotype and have no significant decrease in duodenal upper villous epithelial $Cl^- - HCO_3^-$ exchange activity.[223] Studies of CCD β-intercalated function were not reported.

INTRODUCTION

Optimal function of mammalian cells requires tight control of the acid–base status of intracellular and extracellular compartments. The pH of arterial blood is approximately 7.35–7.45, whereas intracellular pH is normally 7.1–7.3.[1] The CO_2/bicarbonate (HCO_3^-) buffer pair is the body's major pH buffer system for maintenance of pH homeostasis. CO_2 and HCO_3^- also serve as substrates and products in numerous metabolic pathways. Up to fifteen carbonic anhydrase gene products accelerate the slow aqueous equilibration of CO_2 and HCO_3^- inside and outside cells by up to five orders of magnitude. Rapid plasmalemmal HCO_3^- transport across cell plasma membranes by Na^+-dependent and Na^+-independent HCO_3^- transporters is critical for intracellular and extracellular carbonic anhydrases to maintain this equilibrium in the face of changing metabolic demands. At least two gene superfamilies encode Na^+-independent Cl^-/HCO_3^- exchange polypeptides: the SLC4 "bicarbonate transporter superfamily" and the SLC26 "sulfate permease" multi-anion transporter superfamily. Under normal physiological conditions, the Cl^-/HCO_3^- exchangers among the polypeptides encoded by both gene superfamilies are bicarbonate extruders (acid loaders) and Cl^- loaders. Thus, both sets of Cl^-/HCO_3^- exchangers contribute to regulation of intracellular pH (pH_i), cell volume, tonicity, and intracellular [Cl^-].[2–4]

This chapter will focus on the Na^+-independent Cl^-/HCO_3^- exchangers of the SLC4 gene family: AE1/SLC4A1, AE2/SLC4A2, and AE3/SLC4A3. Other members of the SLC4 gene family will also be briefly introduced. The SLC4[2–19] and the SLC26 gene families.[20–26] have been reviewed previously.

The AE Anion Exchangers Among the SLC4 And SLC26 Superfamilies.

The SLC4 bicarbonate transporter superfamily (Fig. 54.1) includes autosomal genes encoding at least three electroneutral Na^+-independent anion exchangers (SLC4A1–3/AE1–3), three Na^+-bicarbonate cotransporters (the electrogenic SLC4A4/NBCe1 and SLC4A5/NBCe2 and the electroneutral SLC4A7/NBCn1), and Na^+-dependent anion exchangers (SLC4A8/NBCDE and SLC4A10/NCBE). The transport mechanisms of three SLC4 proteins remain controversial. SLC4A10, originally described as a Na^+-dependent Cl^-/HCO_3^- exchanger[27,28] has also been described as an electroneutral Na^+-bicarbonate cotransporter NBCn2.[29] SLC4A9 was originally described as a Na^+-independent Cl^-/HCO_3^- exchanger,[30,31] despite the strong phylogenetic prediction of Na^+-dependent transport. The most divergent mammalian member of the family, SLC4A11/BTR1/NaBC1[32] was first reported as an electrogenic Na^+-borate cotransporter important for cell proliferation,[33] but the result has remained unconfirmed despite SLC4A11's phylogenetic proximity to the SLC4 homologs AtBor1 of *A. thaliana* and YNL275w/Bor1 of *S. cerevisiae*, both responsible for maintenance of nontoxic cellular borate levels in the face of elevated environmental borate.[34,35] SLC4 genes are represented in all metazoans, including the fruitfly *D. melanogaster*,[36] the

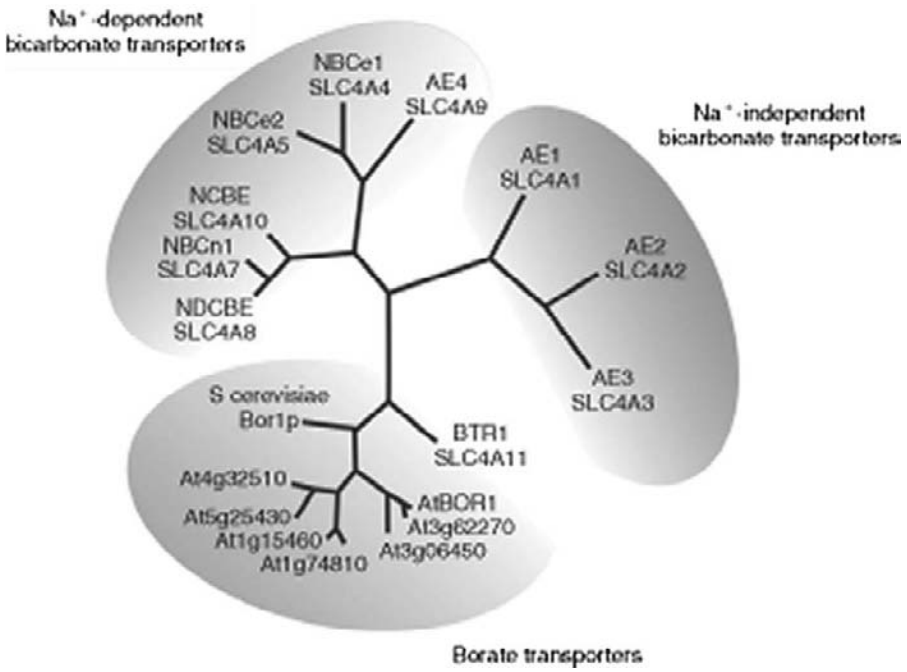

FIGURE 54.1 Phylodendrogram of human SLC4 gene family polypeptides grouped into the three clades of Na^+-independent bicarbonate transporters (red), all Cl^-/HCO_3^- exchangers; Na^+-dependent bicarbonate transporters (blue), including electrogenic and electroneutral Na^+/HCO_3^- cotransporters and Na^+-dependent Cl^-/HCO_3^- exchangers; and borate transporters (green). BTR/SLC4A11 is an electrogenic Na^+-borate cotransporter. The borate transporter clade includes proteins from *S. cerevisiae* (yeast) and *A. thaliana* (plant) of yet undefined transport mechanism. *(Modified from,[579] with permission).*

mosquito *A. aedes*,[37,38] the roundworm *C. elegans*,[39–41] the zebrafish *D. rerio*[42,43] and the pufferfish *T. nigroviridis*,[44] as well as in unicellular eukaryotes.[34,45–47] An SLC4-related gene was also recently reported in a marine prokaryotic genome.[48]

The most extensively studied member of the SLC4 gene family is SLC4A1/AE1 (also known as "band 3"), a Cl^-/HCO_3^- exchanger abundant in erythrocytes of vertebrates and elasmobranchs, but apparently absent from erythrocytes of the jawless fishes.[49] AE1 is also expressed in the Type A intercalated cells of kidney collecting duct in mammals and birds, and at much lower levels in heart and distal colon. Mutations in the SLC4A1/AE1 gene (Table 54.3) are associated with dominant hereditary spherocytic anemia, dominant Southeast Asian ovalocytosis and stomatocytic cation leak syndromes, and dominant and recessive forms of distal renal tubular acidosis.[2–4,13] AE2 is expressed widely among epithelial and other cell types, with highest expression in subsets of epithelial cells including gastric parietal cells, choroid plexus, proximal colonic enterocytes, and thick ascending limb cells. AE3 is expressed at highest levels in brain, heart, and retina, and at lower levels in smooth muscle and epithelial cells. Mutations in the genes encoding SLC4A2/AE2 and SLC4A3/AE3 have not been directly linked to Mendelian human disease, but mutations in the SLC4A4/NBCe1 electrogenic Na^+-bicarbonate cotransporter gene cause the recessive syndrome of proximal renal tubular acidosis, ocular abnormalities, and elevated pancreatic amylase,[50,51] sometimes accompanied by migraine.[52,53] Mutations in the SLC4A11 (nominal Na^+-borate cotransporter) gene are associated with congenital hereditary endothelial dystrophy of the cornea type 2[54,55] associated with vision loss, and with Harboyan syndrome (with added hearing loss). Mouse Slc4 knockout disease models for Na^+-dependent HCO_3^- transporters for which corresponding human genetic diseases remain unidentified are *slc4a5*$^{-/-}$[56] and *slc4a10*$^{-/-}$ mice[57] exhibiting altered choroid plexus function with decreased cerebral ventricular volume; *slc4a7*$^{-/-}$ mice with retinal and cochlear degeneration[58] and mild hypertension resistant to exacerbation by angiotensin II;[59] *slc4a8*$^{-/-}$ mice with coincident absence of Slc26a4/pendrin lack electroneural NaCl reabsorption by cortical collecting duct Type B intercalated cells;[60] and *slc4a11*$^{-/-}$ mice that exhibit, in addition to corneal and auditory abnormalities shared with the corresponding human diseases, polyuria likely related to renal medullary thin limb dysfunction in the countercurrent multiplier mechanism.[61,62]

Cl^-/HCO_3^- exchange and other anion exchange functions are also mediated by SLC26 polypeptides. The SLC26 gene family was identified first among Neurospora sulfate transporters, and subsequently in vertebrates[63,64] and throughout the evolutionary tree,[20] including prokaryotes.[65,66] Polypeptide products of the 11 SLC26 genes transport a wide range of monovalent and divalent anions including sulfate (SO_4^{2-}), chloride (Cl^-), bicarbonate (HCO_3^-), hydroxyl anion (OH^-), oxalate, and formate. Although unrelated in sequence to the SLC4 gene family, at least three of the SLC26 anion exchangers can mediate Cl^-/HCO_3^-

exchange: the congenital chloride-losing diarrhea gene SLC26A3/DRA,[67–69] the Pendred syndrome gene SLC26A4/Pendrin,[70,71] and SLC26A6/Pat-1/CFEX.[72,73] SLC26A7,[74] SLC26A9,[75] and SLC26A11[76,77] also mediate Cl^-/HCO_3^- exchange, but SLC26A7[78] and SLC26A9[79] also appear to function as anion channels. SLC26A2 mediates sulfate/Cl^- exchange[80,81] in chondrocytes, hepatocytes and enterocytes. SLC26A6 and SLC26A1 mediate enterocyte and proximal tubule oxalate/Cl^- exchange.[82,83]

AE DOMAIN STRUCTURE AND ALTERNATIVE TRANSCRIPTS

The AE polypeptide products of the SLC4A1–3 and SLC4A9 genes share a tripartite domain structure as predicted by hydropathy analysis and confirmed by chemical and antibody reactivity studies (Fig. 54.2). A long N-terminal cytoplasmic domain extends for 400–700 amino acids (aa) before the polypeptide chain enters the lipid bilayer. Overall % aa identity of this region among the AE polypeptides is only ~35%, but short stretches within the region are highly conserved (Fig. 54.3). The N-terminal domain of AE1 binds to cytoskeletal proteins, but binding partners of the N-terminal domains of AE2 and AE3 remain less well investigated. The transmembrane domains of ~500 aa in length (Fig. 54.2) are modeled to traverse the bilayer approximately 12–14 times, with at least one large extracellular loop carrying 1,2, or 3 N-glycans. The AE transmembrane domains share a higher overall aa identity of ~65%, with yet greater sequence identity among the putative transmembrane spans (Fig. 54.3). When expressed in *Xenopus* oocytes and in HEK 293 human embryonic kidney cells, the transmembrane domain of AE1 mediates anion transport in the absence of all but the membrane-proximal ~30 aa of the N-terminal cytoplasmic domain.[84–86] The transmembrane domain is followed by a short C-terminal cytoplasmic tail of ~35–40 aa, and harbors a putative binding site for carbonic anhydrase II[87] (but see[14]).

The majority of AE polypeptide variants described to date vary in their N-terminal amino acid sequences (Fig. 54.2). This variation derives from alternative promoter usage resulting in distinct 5′ mRNA exons expressed in tissue-specific and cell type-specific patterns.[88–91] The AE1 and AE3 genes encode two such 5′-variant transcripts encoding proteins with distinct N-terminal aa sequences. The AE2 genes of rat and human express four 5′-variant transcripts, and the mouse gene expresses five such transcripts.[91,92] Two additional transcripts of the AE3 gene encode alternate 3′-transcripts encoding predicted soluble proteins[93] devoid of intrinsic anion transport function. The AE4 gene encodes at least four (Fig. 54.2)[31] and possibly many more variant transcripts.[94] Unusual among the AE genes in its greater sequence similarity with Na^+-dependent than with Na^+-independent SLC4 polypeptides (Fig. 54.1), AE4 may nonetheless function as a Na^+-independent anion exchanger[30,31,95] (but see[7]).

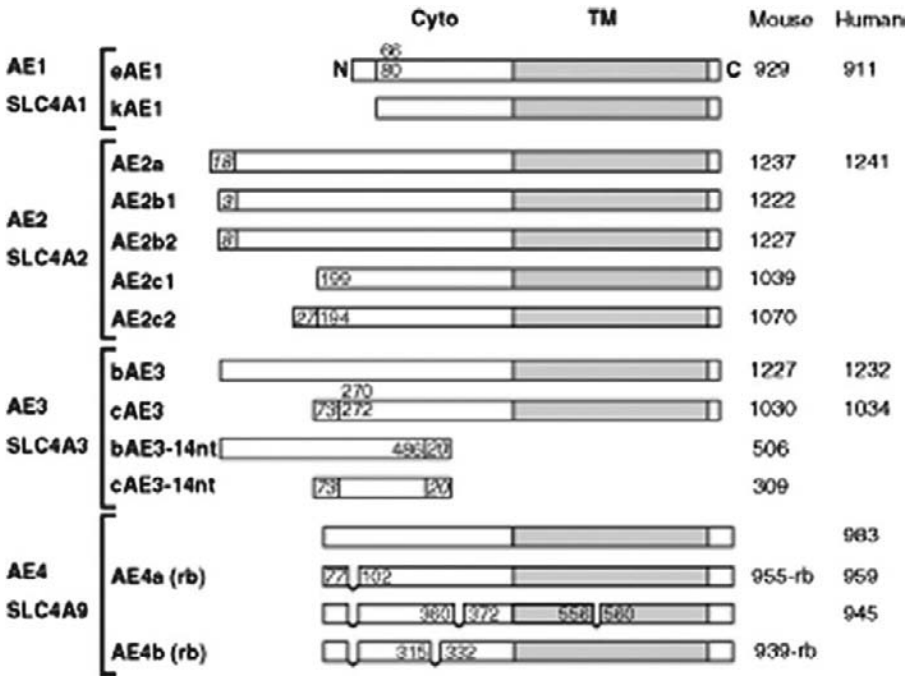

FIGURE 54.2 Schematic of polypeptide variants expressed from the SLC4 Na^+-independent transporters AE1, AE2, and AE3. Also shown are four of the many predicted polypeptide products of the AE4/SLC4A9 gene, found by some but not all to encode Na^+-independent Cl^-/HCO_3^- exchange function, despite their inclusion in the Na^+-dependent clade (Fig. 54.1). Blue indicates predicted transmembrane domains. Total polypeptide lengths (aa) at right. Length (aa) of variant N-terminal domains is indicated within leftmost boxes, and of variant C-terminal domains within rightmost boxes (for the AE3–14nt variants). Aa of junctions indicated in middle boxes. rb, rabbit.

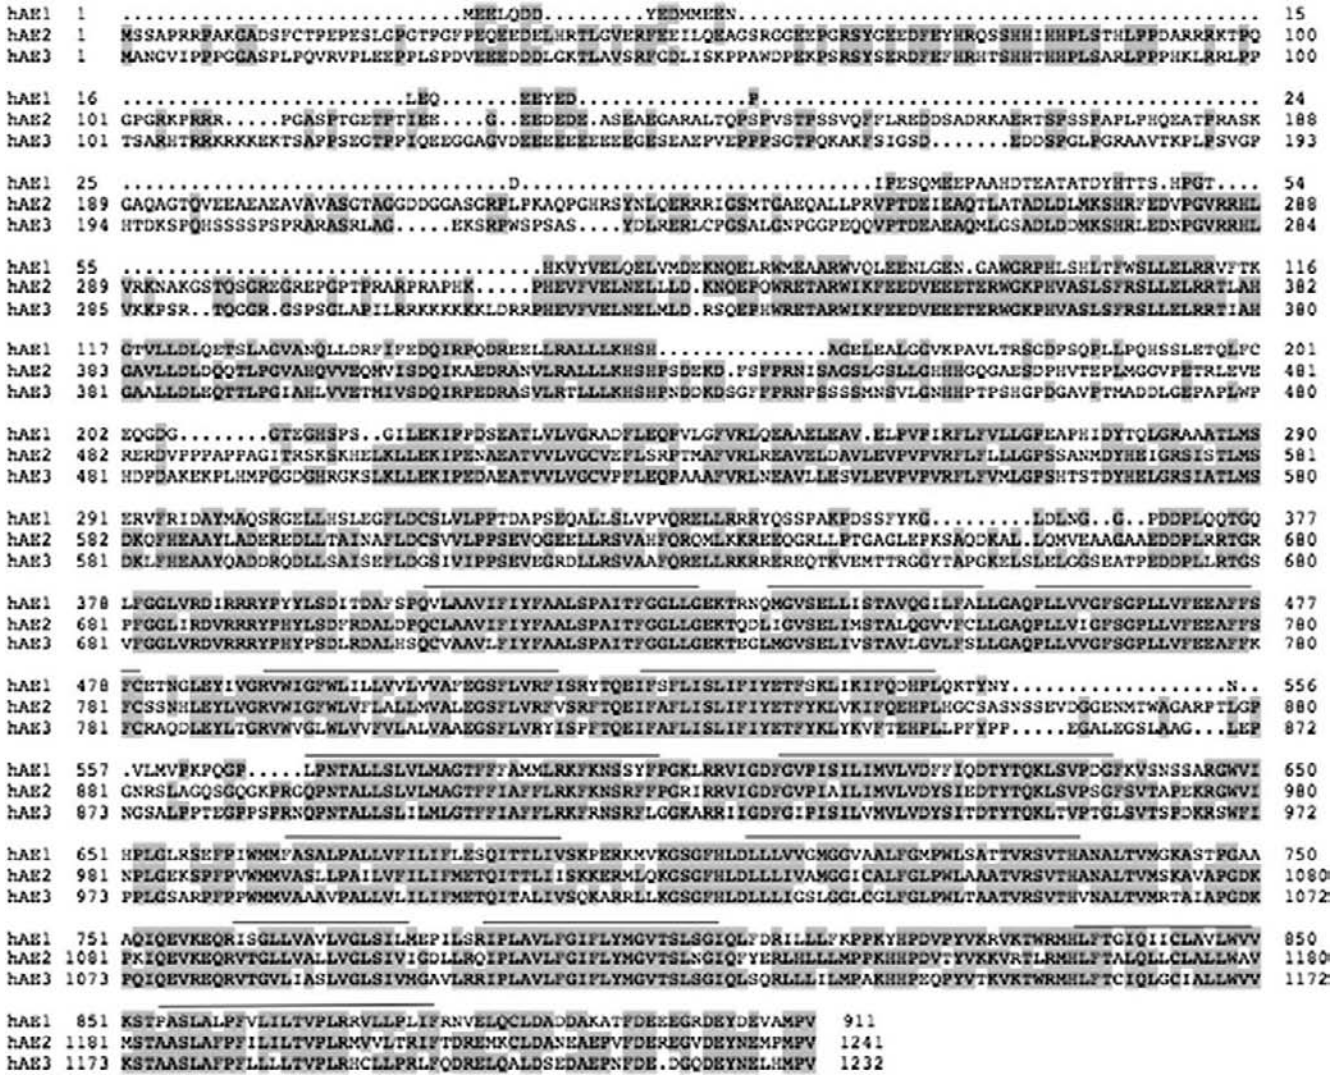

FIGURE 54.3 Amino acid sequence alignment of the Na^+-independent bicarbonate transporter clade of the human SLC4 family, including the Cl^-/HCO_3^- exchanger polypeptides AE1/SLC4A1 (eAE1, NP_000333), AE2/SLC4A2 (AE2a, NP_003031), and AE3/SLC4A3 (bAE3, NP_005061). Alignment was performed with DNAStar software, with manual revision. Conserved residues are highlighted in gray. Putative transmembrane spans are overlined, guided by models of[233] and.[237]

The AE anion exchangers mediate electroneutral, bidirectional exchange of monovalent anions, capable of hetero-exchange and homo-exchange (Fig. 54.4A). They can also mediate cotransport of divalent anions (sulfate and oxalate are the best studied) with a proton in homoexchange or in heteroexchange for monovalent chloride (Fig. 54.4B). Exchange is believed to be via a "ping-pong" mechanism, also known as a "sequential" or an "alternating sites" mechanism (Fig. 54.4C), on the basis of biochemical, kinetic, and spectroscopic changes measured during studies of anion substitution and ligand inhibition.[9,96,97] Extensive functional investigation of AE1 in intact red cells has been accompanied by study of recombinant AE polypeptides in the major expression systems of *Xenopus* oocytes[98] and HEK 293 cells,[85] as well as in CHO,[99] K562,[100] MDCK,[101–103] and Sf9 insect cells,[104] *S. cerevisia*,[105] and *E. coli*.[106]

LOCALIZATION AND FUNCTION OF ANION EXCHANGERS IN TISSUES

AE1 is essential for postnatal survival in humans[107] zebrafish,[43] mice[108,109] and cattle.[110] AE1 is expressed at highest levels in erythrocytes as the eAE1 polypeptide, constituting 25% of total membrane protein and 50% of intrinsic membrane protein. This high density in the red cell membrane is needed for rapid HCO_3^- transport during the sub-second traversal of

pulmonary capillaries (and most other non-sinusoidal capillary beds). Sparingly soluble CO_2 generated by cellular metabolism diffuses across capillary endothelial cells into red cells. There it is converted by erythroid cytoplasmic carbonic anhydrases into highly soluble HCO_3^- and promptly exported by eAE1 in exchange for extracellular Cl^-. The H^+ liberated by the OH^--consuming carbonic anhydrase reaction is buffered by hemoglobin to enhance oxygen release to hypoxic tissues.[111]

In the pulmonary capillaries this process operates in reverse, with entry of extracellular HCO_3^- into the red cell in exchange for cytoplasmic Cl^-. The newly transported intracellular HCO_3^- is used by red cell carbonic anhydrase to generate CO_2, which diffuses down its concentration gradient into the alveolar lumen for exhalation. At the same time, hemoglobin's surrender of H^+ to the OH^- newly generated by carbonic anhydrase enhances hemoglobin binding of O_2 diffusing into the red cell from the alveolus. This reversible Cl^-/HCO_3^- exchange cycle of the red cell, shuttling between hypoxic, hypercarbic peripheral capillaries and hyperoxic, hypocarbic pulmonary capillaries, increases by five- to eight-fold the total CO_2 carrying capacity of the blood[112] (~90% HCO_3^-, 5% free CO_2, and 5% carbamino-hemoglobin and other carbamino-CO_2).[113]

The role of oxygen tension in controlling the rate of mammalian eAE1-mediated anion exchange remains controversial, with reports of both hypoxic stimulation[114] and hypoxic inhibition.[115] eAE1 also mediates H^+-cotransport of sulfate[116] and oxalate[117] in exchange for Cl^-. Elevated erythroid oxalate transport has been correlated with hyperoxaluria and oxalate nephrolithiasis,[117,118] but AE1 polymorphisms have not correlated with oxalate lithiasis. eAE1 has been proposed to contribute to erythroid transport of nitric oxide (NO) or its metabolites as part of red-cell facilitated vasodilation,[119,120] by a nitrite transport-independent mechanism[121] possibly involving AE1 S-nitrosothiolation.[119] However, the stilbene disulfonate-insensitivity of erythroid NO transport, and its undiminished transport by hagfish and lamprey red cells that lack AE1, suggest a dominant AE1-independent NO transport mechanism.[122]

The kidney isoform of AE1 is a truncated form of erythroid AE1, lacking the initial 65 (human) N-terminal amino acids due to transcriptional initiation of kAE1 mRNA from an alternative promoter in exon 3 of the AE gene. kAE1 is expressed in the basolateral membrane of Type A intercalated cells of the mammalian renal collecting duct,[123–125] where it is essential for normal distal urinary acidification.[13,109] AE1 is also expressed at lower levels in glomerular podocytes,[126] heart[127,128] (whether as a tissue-specific transcript variant remains controversial), and in distal colon of rat[129] but not human.[130] Recently, AE1 was localized in the sensory cilia of olfactory neurons.[131]

The AE2/SLC4A2 Cl^-/HCO_3^- exchanger is the most widely expressed of the Na^+-independent SLC4 anion exchangers, and in the mouse is essential for post-weaning survival.[132] In the basolateral membrane of gastric parietal cells,[133] AE2 is required for normal gastric acid secretion.[132] AE2 is required for normal osteoclast activity,[134,135] and for normal male fertility.[136] AE2 is also expressed (Fig. 54.14) in conjunctival epithelium,[137] in odontoblasts and ameloblasts[138,139] in choroid plexus epithelial cells,[140] intestinal enterocytes,[141] respiratory epithelium,[142,143] and in biliary ductular epithelium.[144–146] AE2 is expressed along the length of the nephron (Fig. 54.13), at highest levels in basolateral membranes of medullary thick ascending limb and inner medullary collecting duct.[147–149] AE2 has also been noted in basolateral membrane of macula densa in mouse,[149] rat,[148] and rabbit,[150] where it may possibly contribute to glomerulotubular feedback. The near-ubiquitous distribution of AE2 suggests that AE2 also serves a homeostatic, housekeeping function in the regulation of intracellular pH (pH_i), intracellular chloride concentration and cell volume regulation in renal epithelial cells as well as in other tissues. In some circumstances, as in IMCD cells, AE2 may contribute to transepithelial anion secretion.

AE3 expression is prominent in heart,[151,152] brain,[85,153] retina,[154] adrenal gland,[155] as well as at lower levels in smooth muscle[156] and in epithelial cells of kidney and gut.[153] AE3 can modulate seizure threshold in mice,[155] but its role in renal and cardiac function remains little understood, slowed in part by questionable histochemical specificity of some antibodies as judged by absence of immunostaining in knockout tissue (unpublished results). AE4/SLC4A9 appears apical in gastric surface mucous and duodenal villus cells,[95] but shows species-dependent cell polarity and cell type-specificity in immunostained intercalated cells.[30,31,157] The antibodies may prove unreliable or species-specific, since the AE4 promoter exhibits Type B-intercalated cell specificity.[158] The physiological function of AE4 remains unclear.[159]

AE1 N-TERMINAL CYTOPLASMIC DOMAIN STRUCTURE AND BINDING PROTEINS

Much structural information available for AE anion exchangers derives from study of the abundant erythroid AE1 (eAE1) polypeptide. The N-terminal cytoplasmic domain is attached to and may anchor cytoskeletal protein complexes at the inner face of the erythroid plasma membrane, as shown in Fig. 54.5.

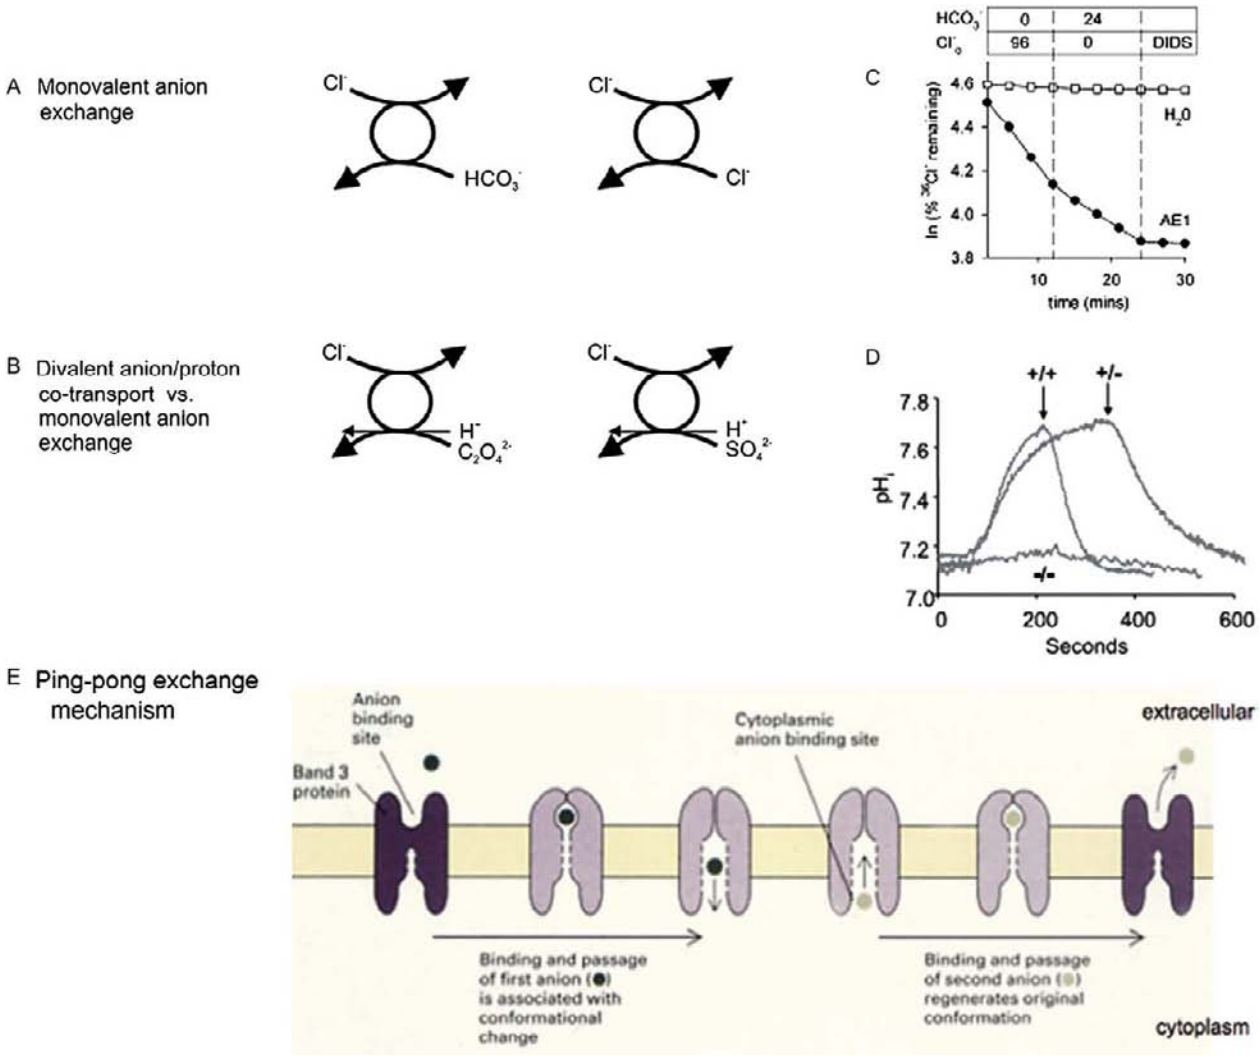

FIGURE 54.4 Anion exchange modes of electroneutral Na^+-independent SLC4 polypeptides. A. Schematic of monovalent anion exchange. B. Schematic of monovalent anion exchange with a divalent anion/proton pair. The spectrum of transported anion substrates is more extensive than portrayed in A and B (see.[229] C. Example of $^{36}Cl^-$ efflux from an AE1-expressing oocyte in exchange for extracellular Cl^- or HCO_3^-, then inhibited by extracellular DIDS. D. Reversible Cl^-/HCO_3^- exchange by BCECF-AM-loaded osteoclasts from wildtype ($^{+/+}$), heterozygous ($^{+/-}$) and homozygous ($^{-/-}$) Ae2(a,b) knockout mice (from[580] with permission). E. The ping-pong (sequential) exchange mechanism is believed applicable to the transport modes portrayed in A and B *(C modified from[581] with permission).*

eAE1 is linked to the spectrin-actin cytoskeleton through its binding of the linker protein ankyrin. Ankryin copy number is ~20% that of eAE1 monomers. eAE1 in the red cell membrane appears to be homodimeric[160,161] or homotetrameric as bound to ankyrin.[162,163] eAE1 also binds tightly to protein 4.2 and glycophorin A, and with lower apparent affinity to protein 4.1, an actin-binding component of the cytoskeletal junctional complex (Fig. 54.5). Less direct interactions have been detected with NH_3 channel RhAG[164] and with water/CO_2 channel AQP1,[165] but see.[166,167] AE1 participates in an erythroid membrane macromolecular complex[164,168] established early during erythropoiesis.[169]

The X-ray structure of the recombinant dimeric N-terminal cytoplasmic domain of eAE1 overexpressed in *E. coli* and crystallized at pH 4.8 has been solved at 2.6 A resolution[106] (Fig. 54.6). The eAE1 monomers are intertwined through "domain swapping" of individual dimerization domains via leucine zipper interactions. The monomers show near two-fold symmetry around an axis at the dimer interface, and the dimers are packed in the crystal as tetramers. The N-terminal 54 amino acids (aa) and the membrane-proximate C-terminal-most 19 aa of eAE1 were disordered in the crystal, and so not visualized. The 20–25 aa immediately preceding entry of the polypeptide chain into the lipid bilayer[170] were omitted from the crystallized

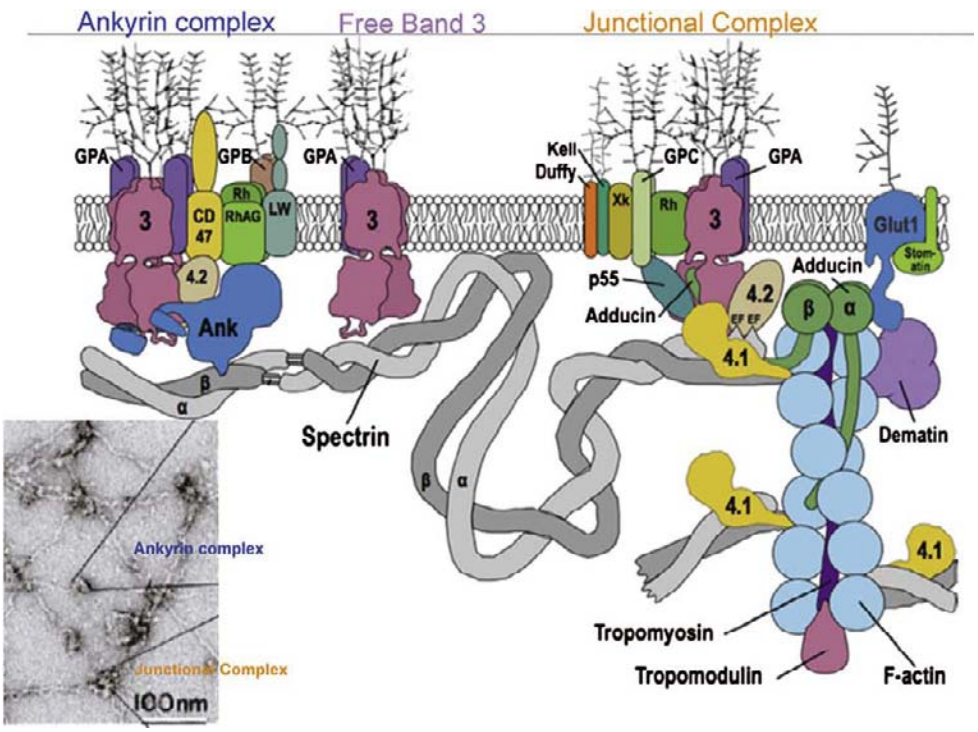

FIGURE 54.5 Three populations of AE1/SLC4A1 (Band 3) envisioned in the the erythrocyte membrane and underlying cytoskeleton: 1) free, unbound AE1 dimers; 2) AE1 tetramers in complex with the ankyrin/spectrin complex (blue in transmission electron micrograph at lower left), associated with AE1-binding proteins glycophorin A (GPA), protein 4.2, and with the RhCDE/RhAG/GPB/CD47/LW complex; 3) AE1 dimers of the spectrin/actin/Protein 4.1 junctional complex (orange in micrograph at lower left) with AE1-binding proteins GPA, adducin and protein 4.2, with associated protein 4.1/p55, GPC, Kell/XK, Duffy, and Glut1/stomatin, all linked to the spectrin/actin/tropomyosin/tropomodulin complex(*Adapted with permission from*[582,583]).

recombinant polypeptide, guided by earlier protease accessibility studies. The absence of this junctional structure renders uncertain the orientation of the AE1 N-terminal cytoplasmic domain with respect to its adjacent transmembrane domain. This eAE1 crystal structure has been used to model the corresponding region of SLC4A2/AE2,[171] and will provide the template for structural analysis of the recently crystallized recombinant N-terminal cytoplasmic domain of the homologous electrogenic sodium bicarbonate cotransporter SLC4A4/NBCe1A.[172]

The soluble eAE1 N-terminal cytoplasmic domain undergoes several structural changes upon pH shift from 6.0 to 10.0, including elongation of the Stokes radius and the axial ratio, increased intrinsic fluorescence, decreased thermal stability, and increased protein segmental motion.[162,173] The crystal structure of the eAE1 N-terminal cytoplasmic domain is more compact than predicted by the domain's solution properties, possibly reflecting the acidic crystallization pH. The crystal structure can be modeled to undergo an alkaline pH-induced elongation in the region of the dimerization domain (Fig. 54.6), leading to separation of the peripheral protein binding domain from the dimerization domain,[173] supported by intradimer luminescence resonance energy transfer (LRET) measurements between Cys201 residues in adjacent monomers.[174] Single particle fluorescence resonance energy transfer (FRET) measurements document two populations of conformers at neutral pH, with inter-Cys201 distances similar to those measured by LRET at extreme pH values. However, this distance is larger when estimated "in situ" in endogenous AE1 present in KI-stripped inside-out red cell vesicles. Moreover, the pH-dependence of that distance differs from that of pure recombinant N-terminal cytoplasmic domain prepared from inside-out vesicles, further suggesting distinct conformations in the two experimental systems,[174] and the potential for considerable plasticity of conformation dependent on local environment and binding partners.

Many functions have been assigned to the N-terminal cytoplasmic domain of eAE1 (Table 54.1). Glycolytic enzymes translocated from cytosol to membrane binding sites[175] where they may form macromolecular complexes to regulate ATP production in concert with metabolic demand. Aldolase binding to AE1 requires two sites within aa 1–23, including aa

Space-filling model of dimer showing interlocking arms of monomeric units. C. Ribbon diagram viewed from a different angle, showing aa 55–65 (dark strand) present in eAE1, but missing in kAE1. D. and E. Reversible conformations of dimeric cytoplasmic domain predicted for pH 6 (D) and pH 10 (E), perhaps explaining the alkalinization-induced Stokes radius increase of 11 A and the doubling of intrinsic fluorescence. *(A–C reproduced with permmission from[106]; D and E reproduced with permission from[173]).*

6–10 and aa 19–23. Glyceraldehyde-3-phosphate dehydrogenase binds to either of two sites located within aa 1–11 or within 12–23. Phosphofructokinase binds to aa 12–23, but AE1 does not contribute the membrane binding sites for lactate dehydrogenase and pyruvate kinase.[176] Thus, organization of the entire glycolytic complex at the red cell membrane requires not only AE1 but additional membrane proteins. Oxygen tension[175] and hemoglobin binding to the eAE1 N-terminal region also contribute to membrane association of glycolytic enzymes. Glycolytic enzymes are largely membrane-localized in inactive form in oxygenated erythrocytes through binding to N-terminal residues of eAE1. Deoxygenation leads to enzyme release and translocation to the cytosol, thus derepressing erythroid glycolytic flux.[177] Glycolytic enzymes of *Ae1*$^{-/-}$ mouse red cells exhibit oxygenation-independent, constitutively cytosolic localization.[178] The eAE1 peptide aa 1–10 bound with low affinity to tetrameric hemoglobin, and decreased hemoglobin cooperativity to the same degree as did the entire N-terminal cytoplasmic domain, or as 2,3-diphosphoglycerate.[179] AE1 N-terminal cytosolic domain mutants with enhanced hemoglobin binding accelerated polymerization of sickle hemoglobin in solution,[180] suggesting a possible point of therapeutic intervention in sickle disease. Conversely, hemoglobin also induced conformational change in AE1.[181–183]

The major human AE1 binding site for erythroid ankyrin is a surface loop comprising aa 175–185.[184] The AE1-ankyrin interaction, although critical for membrane stability, was insensitive to shear stress in

TABLE 54.1 AE1 Residues of Defined Function

Location	eAE1 Residue	Importance/Function	Reference
N-term cytoplasmic	1–11, 12–23	GAPDH binding site	176,446
	12–23	Deoxy-hemoglobin/hemichrome binding site	513,514
	Y8, Y21	p72syk phosphorylation sites, Y8 inhibits binding of glycolytic enzymes	175,515–517
	6–10, 19–23	Aldolase binding site	176
	12–23	Phosphofructokinase binding site	176
	T42	Major casein kinase 1 phosphorylation site	360
	1–54	Disordered in crystal	106
	55–65, 175–185	Required for Ankyrin-1 binding site	184
	Y105, D316	Postulated to contribute inter-monomeric H bond related to pH-sensitive elongation, Trp fluorescence, thermal stability	106
	C201, C317	Able to form inter-monomeric disulfide link	220
	202–211, 357–9	Disordered in crystal	106
	208–225	Contributes to dimer: dimer interface of tetramer	106
	252–261	Contributes to dimer: dimer interface of tetramer	106
	S303	Minor casein kinase 1 phosphorylation site	360
	314–344	Dimerization arm	106
	343–347	Required for Protein 4.1 binding site	189
	K360	Cytoplasmic domain trypsin cleavage site	518
	G381	Deletion abolishes function but maintains surface expression	170
	357–399	Flexible link between N-term cyto and transmembrane domains	106
	Y359	Cytoplasmic domain chymotrypsin cleavage site.	
		Secondary p53/56lyn phosphorylation site, requires prior syk phosphorylation of Y8/Y21; SHP-2 binding to phospho-Y359 allows dephosphorylation of Y8, Y21, Y904.	
		Required for basolateral targeting in polarized MDCK cells	209,479,519
C-term transmembrane	K430	EC1 site of extracellular eosin-maleimide binding, reductive methylation; inhibits function	520
	C479	TM3 site reacts with PCMBS, unreactive with maleimides	235
	K539	EC3 covalent binding site for DIDS/H_2-DIDS, SITS and DNFB; inhibits function	521,522
	K542	EC3 alternate covalent binding site for DIDS (not H_2(DIDS) when K542 mutated	523
	K551, K562	EC3 sites of inter-monomeric crosslinking with BSSS within dimer	218
	M559	Oxidized by Chloramine T (N-chloro-p-toluenesulfoamide)	230
	K590	Inner TM6 covalent binding site for phenyl isothiocyanate and DNFB; inhibits function	521,524,525
	Q630	EC4 extracellular papain cleavage site; inhibits function	526–528
	N642	EC4 N-glycosylation site; glycan not required for trafficking or function	470
	E681	Inner TM8 binding site for extracellular Woodward's Reagent K; inhibits function

TABLE 54.1 (*Continued*)

Location	eAE1 Residue	Importance/Function	Reference
		Reduction by borohydride leads to H + -independent sulfate self-exchange.	254,265
	H734	Intracellular DEPC labeling site, as assigned based on mutagenesis and function in oocytes.	300
	M741	Oxidized by Chloramine T, partially blocked by DNDS and by DEPC.	230
	K743	Intracellular trypsin cleavage site (at low ionic strength)	529,530
	H834	Intracellular DEPC labeling site; modification decreases sulfate affinity, but not substrate-induced conforational change	303,531
	C843	Inner TM13 palmitoylation site	532,533
	K851	Outer TM13 PLP binding site and H_2DIDS intramonomeric crosslinking site; inhibitory	522
	C885	C-term cyto tail NEM labeling site	237
	886–890	Carbonic anhydrase 2 binding site; stimulatory	322
	886–911	Alanine scan mutagenesis reduces V_{max} for sulfate transport in S. cerevisiae.	326
	R901	C-terminal cyto tail site of hydroxyphenylglyoxal binding, reduced in H_2-DIDS-locked outward conformation of AE1. Modification or mutations reduces V_{max} for sulfate transport.	296
	D902EY	Involved in binding GAPDH to kAE1	350
	Y904	Secondary p53/56lyn phosphorylation site, requires prior syk phosphorylation of Y8/Y21	
		Required for basolateral targeting in polarized MDCK cells.	209,479
	M909	Oxidized by Chloramine T	230
	878–911	Binds cytoplasmic N-terminal tail of glycophorin A in vitro and in yeast two hybrid.	347
	893–911	Encodes or activates red cell ghosts glycophorin A protease.	347

resealed red cells.[185] Mouse red cells lacking the corresponding critical Ae1 aa 188–199, despite loss of ability to bind ankyrin *in vitro*, were found to retain 60% of AE1 cytoskeletal binding in red cells that were less destabilized than predicted.[186] The sustained cytoskeletal binding was later attributed in part to interaction with adducin[187] and to the junctional complex. Increased cytoskeletal attachment of AE1 gradually reduces AE1 mobility in the plane of the plasma membrane during erythroid development.[188] Binding of the N-terminal 30 kDa membrane-association domain of protein 4.1R was localized to the LRRRY motif at AE1 aa 343–347 by ligand blot,[189] whereas solution binding methods indicated a predominant role for sites near the far N-terminus of the cytoplasmic domain.[190] ~20% of erythroid protein 4.1 binds to AE1, with larger proportions bound to glycophorin C and to p55/dematin.[191] Phosphatidylinositol-4,5-bisphosphate (PIP2) decreased protein 4.1 binding to AE1 while increasing binding to glycophorin C.[192] Single particle tracking experiments in wildtype and mutant mouse red cells suggest that ~40% of eAe1 is bound to ankyrin, ~33% is bound to adducin, and 27% is unattached to cytoskeletal proteins (Fig. 54.5).[193]

The ribbon diagram of Fig. 54.6C shows as a dark β strand the eAE1 aa 55–65 that are absent from kidney AE1 (kAE1, Fig. 54.2) of renal collecting duct Type A intercalated cells. Absence from kAE1 of this β-strand and the preceeding erythroid-specific residues predicts a structure quite different from that of eAE1, consistent with the inability of kAE1 to bind erythroid ankyrin[194] protein 4.1R, and aldolase.[195] The lack of ankyrin binding by kAE1 corresponds to apparent absence of erythroid ankyrin in Type A intercalated cells.[196] The influence of eAE1-specific aa 1–65 (absent from kAE1) on the conformation of the N-terminal cytoplasmic domain is further suggested by the ability of the common, clinically benign polymorphism K56E (band 3 Memphis, Table 54.3) to retard the SDS-polyacrylamide gel mobility of the N-terminal 60 kDa chymotryptic fragment of erythroid AE1. An additional influence on the structure of the transmembrane domain is suggested by the decreased erythroid transport rate for the (slowly transported putative) substrate, phosphoenolpyruvate.[197]

The erythroid-specific protein 4.2 closely associated with eAE1 during fractionation, and interacted when coexpressed in *Xenopus* oocytes.[198] Genetic deficiency

of AE1 in human hereditary spherocytosis or in knockout animals can be associated with decreased protein 4.2.[199] Conversely, the hereditary elliptocytosis or spherocytosis of protein 4.2 deficiency is associated with partial reduction in abundance of erythroid AE.[200] Incorporation of protein 4.2 into band 3 proteoliposomes slightly reduced anion transport.[201] In contrast, coexpression of protein 4.2 in *Xenopus* oocytes increased AE1-mediated anion transport,[198] whereas some protein 4.2 spherocytosis mutants lacked this phenotype. Protein 4.2 may also link AE1 to the Rh complex via red cell CD47.[202]

Undefined AE1 residues bind to aa 200−211 of protein 4.2, immediately adjacent protein 4.2's ankryin-binding site at aa 187−200.[203] AE1 cleavage at aa 45 and aa 205 by erythroid caspase 3 decreased binding of protein 4.2.[204] Since activated red cell caspase 3 also promotes externalization of phosphatidylserine,[205] a marker and agent of terminal red cell aging[206] and a signal for erythrophagocytosis,[207] the band 3-protein 4.2 interaction may signal erythrocyte removal from the circulation. In HEK-293 cells, AE1 hereditary spherocytosis mutant polypeptides E40K, G130R, and P327R exhibited diminished binding to co-expressed protein 4.2, with decreased protein 4.2. The AE1 transmembrane domain did not interact with protein 4.2.[208]

The tyrosine kinases Syk and Lyn bind to human eAE1 and phosphorylate its N-terminal cytoplasmic domain at Y8, Y21, and Y359. The phosphorylation state of these Tyr residues regulates glycolytic enzyme binding,[175] but likely not anion transport.[117,209] eAE1 tyrosine phosphorylation is increased by malaria parasite invasion, the oxidative stress of sickle disease, thalassemia, G6PD deficiency, and normal cell aging, as well as by hypertonic cell shrinkage. Tyrosine phosphorylation also promotes AE1 dissociation from the cytoskeleton and promotes mobility in the membrane,[210] perhaps adaptive responses to the above stresses.

A calponin homology domain of human kAE1 (aa 27−189, corresponding to aa 92−254 of eAE1) was shown to bind to the C-terminal catalytic domain of integrin-linked kinase in the endoplasmic reticulum, traffic together to the basolateral membrane leading to increased surface expression with proportionately increased transport activity, although without the expected increase in actin cytoskeletal association.[211] The AE1 N-terminal cytoplasmic domain has also been shown to interact with the C-terminal tail of GLUT1.[212] Although the N-terminal cytoplasmic domain of AE2 may bind erythroid ankyrin,[213] others detected no ankyrin binding to N-terminal cytoplasmic domains of kAE1, AE2, or cAE3.[194,214] AE2 binding to the distinct Golgi ankyrin Ank_{195}[215] may contribute to membrane anchoring of the Golgi cytoskeleton.[216] AE3 N-terminal cytoplasmic domain binding proteins have not been reported.

AE1 C-TERMINAL TRANSMEMBRANE DOMAIN STRUCTURE AND BINDING PROTEINS

The C-terminal transmembrane domains of AE1, AE2,[86,217] and AE3[85] suffice to mediate anion exchange in the absence of their corresponding N-terminal cytoplasmic domains. The native or detergent-solubilized transmembrane domains of AE1,[160,218−220] AE2,[221] and AE3[222] are dimers or higher-order oligomers. Figs 54.7A−F shows 18A resolution cryo-electron microscopy images of the dimeric, H_2-DIDS-crosslinked transmembrane domain of solubilized eAE1 in tubular crystals,[223] supporting earlier electron microscopic images of negatively stained two-dimensional crystals.[224,225] Higher resolution (Fig. 54.7A) electron microscopic images of 2D crystals (Fig. 54.7G) revealed outlines of several transmembrane helices,[226] allowing identification of an overall fold with similarities to the Clc Cl^-/H^+ exchanger gene superfamily.[226] This similarity has prompted consideration of an AE1 transmembrane domain model incorporating anti-parallel V-shaped motifs[227] differing from that previously derived from topographically directed mutagenesis and labeling studies (as in Fig. 54.8).

Growth of three-dimensional crystals suitable for high resolution X-ray diffraction has proven difficult for the transmembrane domain of eAE1[228] and for the *S. cerevisiae* SLC4 putative borate transporter polypeptide YNL275w/Bor1p (Fig. 54.1).[34,35,47] This difficulty may reflect in part the conformational flexibility of AE1 required to accommodate a wide range of anion substrate dimensions,[229] and the possibly increased susceptibility of AE1 Met residues to oxidation by peroxides accumulating in polyoxyethylene detergents such as C12E8.[230] Polytopic transmembrane domains of prokaryotic membrane proteins overexpressed in *E. coli* have proven more amenable to crystallization and have provided insight into SLC26-related anion transporter structure.[65,66,231] The recent description of a marine prokaryotic SLC4 anion transporter[48] suggests that this or another route to crystallization and structure determination[46,232] will soon bear fruit for a prototype SLC4 anion transporter transmembrane domain.

In the absence of a high resolution crystal structure, indirect studies of SLC4 transmembrane domain structure have relied upon chemical modification of native or detergent-solubilized erythroid eAE1, and site-directed mutagenesis studies of recombinant AE1 (Table 54.1) and AE2 (Table 54. 2). Fig. 54.8 presents a

topographical model of the secondary structure of eAE1, based on hydropathy analysis[233] updated by scanning cysteine accessibility mutagenesis data[234–238] (but without considering the 2D crystal EM data shown in Fig. 54.7). The model is also informed by proteolytic, glycolytic, and chemical labeling studies (Table 54.1), identification of polymorphic blood group antigen sites recognized by extracellular antibodies (Fig. 54.8 and Table 54.3), and scanning N-glycosylation insertional mutagenesis studies.[239–241] These latter studies suggest that folding of the transmembrane domain in the endoplasmic reticulum (as measured by *in vitro* translation) differs from that in the plasma membrane, and likely undergoes further maturation during transit to the cell surface.[240] The proposal of two flexible re-entrant loop regions suggested by accessibility of introduced Cys residues to impermeant reagents from either side of the cell membrane[237] deviates considerably from earlier models based solely on hydropathy analysis.[233] A model of AE1 transmembrane helix packing was proposed based on groups of two or more complementary subfragments of the AE1 transmembrane domain capable of partial reconstitution of wildtype chloride transport activity.[242–244] Intra- and intersubunit distance constraints have been proposed based upon fluorescence resonance energy transfer (FRET) and luminescence resonance energy transfer experiments (LRET) between inhibitor binding sites or between inhibitor probes and targeted cysteine probes.[174,245,246] FRET experiments have been extended to single dimeric AE1 subdomains on coverslip,[247] allowing measurement of the kinetics of single molecule conformational changes. Intermolecular FRET has also been used to estimate the local pH_i gradient change produced by AE1-mediated Cl^-/HCO_3^- exchange in the immediate intracellular vicinity of the AE1 polypeptide expressed in HEK-293 cells.[248]

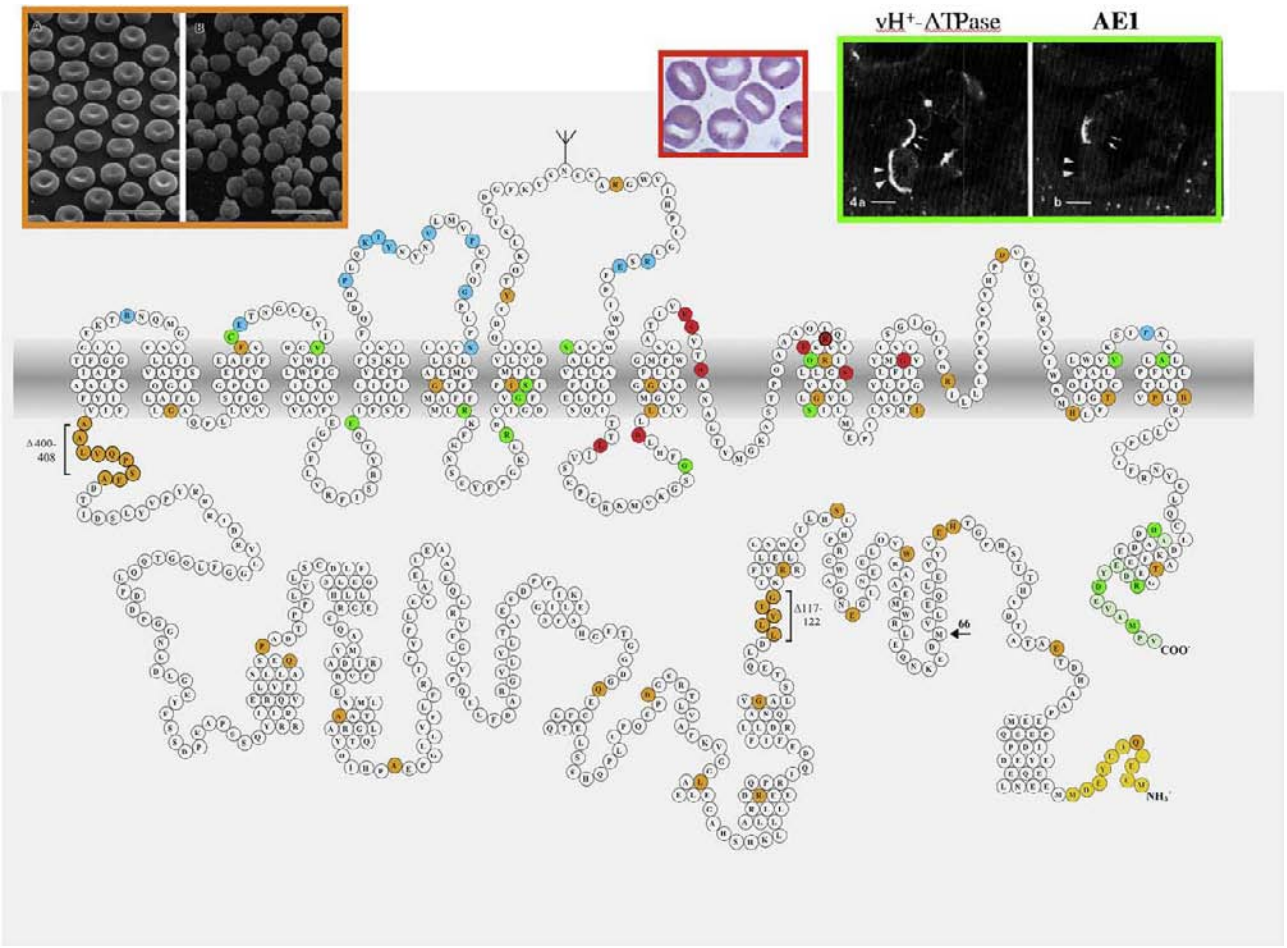

FIGURE 54.8 Proposed topographical model for human AE1/SLC4A1, with natural amino acid variants. Met 66 (arrow) marks start of kidney AE1. Polymorphisms encoding blood group antigens are in blue. Mutations associated with hereditary spherocytic anemia and ovalocytosis are in orange, and include missense, nonsense, splicing, and deletion mutations. Missense mutations associated with hereditary cation-leak stomatocytosis are in red. Mutations associated with dominant and recessive distal renal tubular acidosis are in green. Terminal deletions are in lighter orange and green. Upper left: scanning electron micrographs of bovine wild-type erythrocytes and AE1(−/−) spherocytes (HS, modified with permission from[110]). Upper center, Wright-Giemsa-stained human stomatocytes. Upper right: consecutive semithin sections of rat kidney cortex immunostained for vH^+-ATPase (left) and AE1 (right). Note that only Type A intercalated cell with apical vH^+-ATPase expresses basolateral kAE1 (Modified from[3] with permission). See color plate section at the back of the book.

MECHANISMS OF SLC4/AE ANION TRANSPORT

The anion exchangers AE1, AE2 and AE3 transport monovalent anions (i.e. Cl^- for HCO_3^-) by a mechanism of obligatory one-for-one electroneutral exchange (Fig. 54.4). Each AE1 transport unit in the intact human red cell exchanges Cl^- for HCO_3^- or another Cl^- ~50,000/sec at 37°C.[249] AE1-mediated exchange in the red cell is tightly coupled such that net Cl^- movement driven by the transmembrane electrical potential is at least 10,000 times slower than unidirectional[36] Cl^- flux in the context of homo- or hetero-exchange.[9,250] The tight coupling is reflected in the obligatory trans-anion dependence of unidirectional anion movement. Electroneutral one-for-one monovalent exchange has been rigorously demonstrated for eAE1 expressed in *Xenopus* oocytes.[251] The tight coupling of anion exchange may allow higher anion:cation selectivity than permitted by the pore of an ion channel, with consequent reduction in the metabolic cost of volume regulation.[9] Transport of divalent anions such as sulfate and oxalate requires cotransport with a proton,[116,117] by a mechanism in which divalent anion binding facilitates cis-binding of protons, and proton binding facilitates subsequent binding of divalent anion.[252,253]

Kinetic and other studies generally support a ping-pong mechanism for AE1-mediated anion exchange, in which the substrate binding site faces either the cytosolic compartment (inward conformation) or the

TABLE 54.2 AE2 Residues of Defined Function

extracellular compartment (outward conformation) (Fig. 54.4). Anions may bind and unbind, likely at rates near the diffusion limit, before unbinding is prevented by an initial conformational change sometimes envisioned as closure of an "external gate". This gate closure is coincident with or induces formation of the oppositely directed conformational state sometimes envisioned as opening of an "internal gate". In this state the translocated anion can be released to the other compartment, and the next half-cycle of transport can proceed in the opposite direction. Thus, binding of substrate to one conformational state induces a conformational transition to the other state, accompanied by anion translocation and transport. The conformational transition occurs only upon protein binding of anion on one side.[254,255] The characteristic rank order of anion transport rates by AE1[229] and AE2[256] reflects not binding affinity but rather the extent to which binding of each anion lowers the transition state free energy for the conformational transition. Such a mechanism may allow coexistence of high substrate specificity with the low binding affinities required for anions present at concentrations of 5–150 mM, often with low transmembrane concentration gradients.[257] A postulated short-lived "occluded state" of anion binding hypothesized to accompany the AE1 transition state between inward and outward conformations has not been experimentally detected.

The ping-pong model of completely separate steps for anion exit and entry is supported by several lines of evidence. The strongest evidence is from the "half-turnover" experiments of Jennings,[258] which created conditions to detect the number of $^{36}Cl^-$ anions which rapidly effluxed from resealed red cell ghost membranes into an extracellular medium without permeant trans-anion. This number nearly equaled the number of AE1 polypeptides per red cell, and suggested that each polypeptide had undergone the transition from inward to outward conformation, completing only a half cycle of transport before encountering the absence of rapidly transportable anion in the extracellular medium. Further evidence includes findings that alteration of transmembrane Cl^- gradients controlled the proportion of AE1 polypeptides in the outward conformation (as detected by binding of inhibitors favoring the outward-facing state), that reaction of an outward-binding inhibitors such as DIDS prevented binding of the inward-state inhibitor, NAP-taurine,[259] and that binding of inhibitor to the external side of AE1 blocked Cl^- binding on both sides of the protein, as measured by ^{35}Cl-NMR.[260] In addition, red cell exposure to the external inhibitor H_2DIDS promoted uphill Cl^- efflux,[261] consistent with recruitment of inward-facing AE1-Cl^- complex to the outward facing state where, immediately after Cl^- release, the transporter conformation is frozen by inhibitor binding.

The anion binding sites on the cytoplasmic and extracellular faces of the polypeptide are non-equivalent, with yet undefined binding pockets comprising distinct sets of aa residues on inner and outer faces of AE1 (Fig. 54.8). Thus, whereas symmetrical Cl^- concentrations favor a 6-fold preponderance of the inward conformation of AE1 (reflecting a 6-fold higher relative Cl^- binding affinity vs HCO_3^-), symmetrical HCO_3^- concentrations in the absence of Cl^- favor a 10-fold preponderance of the outward conformation (with its 10-fold higher relative affinity for HCO_3^-.[262] This substrate-specific asymmetry of AE1 affects apparent affinities for substrates and inhibitors. When the carrier is unloaded, the inward facing form (the lower free energy state in Cl^-) is favored over the outward facing form (higher energy state) such that the apparent substrate affinity is higher for external than for internal substrate.[263]

Although the above data support an alternating sites model for AE1-mediated anion transport, evidence for

TABLE 54.3 AE1 Mutations

Band 3	Mutation		Ref
A. SLC4A1 (AE1) MTATIONS ASSOCIATED WITH RED CELL SHAPE CHANGE			
Southeast Asian ovalocytosis	Δ400−408	ovalocytosis (MIM:109270,130600,166900)	453,534,535

a second anion binding site on AE1 detectable at non-physiological conditions shows that a simple ping-pong model cannot suffice to explain the AE1 transport mechanism (summarized by[257]). This alternate Cl^- binding site in human eAE1 appears to interact with E681, believed to constitute part of the main anion translocation pathway.[264,265] Thus, alternating site models of other types have not been ruled out.[266,267] Cysteine scanning and other mutagenesis studies have implicated many residues as potentially contributing primarily or secondarily to the AE1 anion translocation pathway.[235,237,238,268,269] Additional clues have been provided by similar structure-function experiments performed on Na^+-dependent SLC4 anion transporters.

PHARMACOLOGY OF SLC4/AE ANION EXCHANGERS

Anion exchange inhibitors are often of low specificity and low or modest potency, with apparent affinities sensitive to substrate concentration. Use of the inhibitors at effective concentrations may exert "off-target effects" which, though not monitored, may influence the measurement.[270] Thus small molecule inhibitors have proven only moderately helpful in assignment of anion transport in cells or tissues to the action of specific polypeptides. eAE1 in the intact red cell is an exception, due to the combination of its high abundance in the red cell membrane and the absence of other erythroid anion exchangers. Although these small molecule inhibitors are useful in the study of recombinant AE anion exchanger function, Cl^-/HCO_3^- exchange function in intact cells and tissues can be more specifically studied with RNA interference techniques or with comparison of cells from knockout and wildtype mice.

All the SLC4 anion exchangers are inhibited by the stilbene derivatives, SITS, DIDS (4,4′-diisothiocyanostilbene-2,2′-disulfonate) and H_2DIDS.[271] These inhibitors each have two negatively charged sulfonate groups, at least one of which is believed to interact with the anion translocation pathway. The two isothiocyanate groups of DIDS and H_2DIDS and the single group of SITS can slowly react covalently with free amino groups. Inhibition of AE1 by SITS and DIDS occurs initially via rapid, reversible electrostatic ionic interaction, followed by a slower, irreversible covalent reaction. In human AE1 the lysine residue that interacts with the isothiocyanate moiety of stilbene disulfonates is K539, located at the junction of TM5 and the third extracellular loop. A DIDS-reaction motif encompassing this lysine (KLXK, X = hydrophobic residue, e.g., I or Y) is conserved in AE2 and AE3, and in many other SLC4 polypeptides. DIDS inhibits in the rank order of AE1 > AE3 > AE2, with apparently competitive kinetics of non-covalent inhibition.[256,272] Whereas rat AE4 is DIDS-sensitive,[30] rabbit AE4a may be DIDS-insensitive.[31] DIDS sensitivity may be modulated by membrane lipid composition or other factors.[273,274]

Conformation-sensitive reversible inhibitors of AE1 include eosin-maleimide, niflumic and flufenamic acids and other nonsteroidal anti-inflammatory drugs, NAP-taurine, and the oxonol dyes (WW781 and diBA(5)C4), which prefer the outward conformation and are variably sensitive to [Cl^-]. DiBA(5)C4 is among the most potent AE1 inhibitors, with sub-nanomolar potency.[272] Experiments with these AE1 inhibitors have provided additional support for the ping-pong model and for asymmetric disposition of inward and outward conformations.[9] eAE1 anion exchange was also potently inhibited by the non-stilbene blockers NS1652[275] and NS3623.[276] The polyaminosterol MSI-1361 exhibited greater potency against AE2 than AE1 expressed in *Xenopus* oocytes.[277] S20787 inhibited cardiomyocyte

Cl^-/HCO_3^- exchange,[278,279] but tests against the recombinant cardiac anion exchangers AE3 and SLC26A6 remain to be reported. Many additional drugs inhibit AE1 and uncharacterized cellular anion exchange activities at low or moderate potency, including dipyridamole, tenidap, pyridoxal phosphate,[280] topiramate and other carbonic anhydrase inhibitors,[281,282] and others.[270] Cl^-/HCO_3^- exchange activities of intestinal SLC26A3/DRA and renal SLC26A4/pendrin exhibit little or no DIDS sensitivity, in contrast to the DIDS-sensitive SLC26A6 and moderately DIDS-sensitive SLC26A7.[20,23]

THE ANION TRANSLOCATION PATHWAY OF AE1

The anion substrate translocation pathway of AE1 remains undefined. The anion translocation pathway might in principle traverse either a single subunit of the oligomer or the subunit interface. However, a single functional subunit within a dimer appears sufficient to mediate Cl^-/HCO_3^- exchange in red cells[219] and in *Xenopus* oocytes for AE1[283] and for AE2 (Stewart and Alper, unpublished). Moreover, the noncooperative kinetics of monovalent anion transport by the solubilized dimeric polypeptide as well as in intact cells support independent anion translocation pathways within subunits of each oligomer. Nonetheless, numerous studies with fluorescent AE1 ligands such as DBDS[96,264,266] and with mutant-wildtype AE1 heterooligomers[103,284,285] suggest that perturbation of one promoter can alter the conformation of the partner protomer within the dimer/oligomer.

Several regions of the transmembrane domain have drawn particular attention as likely components of or contributors to the anion translocation pathway within the AE1 monomer. Most prominent among these is human AE1 E681 (mouse E699) near the membrane cytoplasmic face, whose modification with the glutamate-reactive Woodward's Reagent K inhibits transport.[286,287] Subsequent borohydride reduction cleaves the adduct and converts the glutamate carboxyl group to an alcohol, creating a norleucine substitution. hAE1 so modified severely inhibits red cell Cl^- exchange, increases Cl^- conductance, and greatly accelerates newly proton-independent sulfate transport[254] as obligatory electrogenic sulfate/Cl^- exchange,[288] demonstrating that tight coupling of anion exchange by AE1 need not be electroneutral. Similar properties were exhibited by the corresponding mouse AE1 mutant E699Q,[268] whereas other substitutions at E699 led to complete loss-of-function. Thus hAE1 E681 appears to be a proton binding site for proton/sulfate cotransport, and likely constitutes part of the gated permeability barrier for the anion translocation pathway. Biophysical modeling predicts the the Cl^- influx half-cycle of electrogenic $sulfate_i/Cl_o$ exchange is accompanied by movement of nearly one positive charge through most of the membrane electric field, with a small negative charge accompanying sulfate on the return cycle.[288] E681 of hAE1 is highly conserved in the SLC4 family, and the corresponding residue of AE2 likely plays a similar role.[289]

Since the anion translocation pathway through the AE1 polypeptide likely includes an external vestibule, the electric field within the translocation pathway may traverse a distance shorter than the thickness of the membrane bilayer. FRET[290] and NMR experiments[291] showing that bound Woodward's Reagent K prevents binding of neither Cl^- nor DIDS to AE1 suggest that the site of DIDS interaction with the AE1 transport pathway resides within the outer half of the electric field. An external vestibule was also consistent with results of scanning Cys accessibility studies of residues surrounding E681 in the Cys-less AE1 transmembrane domain.[234] Some Cys insertion mutants in TM8 external to E681 were nonfunctional at the cell surface. Among the functional Cys insertions preceding and extending beyond E681, those accessible to maleimide reagent labeling defined a surface of the TM8 helix plausibly contributing to the anion translocation pathway.[235] However the functional inhibition produced by the maleimide adducts of these introduced Cys residues was usually modest, unlike the more dramatic inhibition of NBCe1/SLC4A4 by modification of a Cys insertion at L750 (corresponding to hAE1 K677, one putative helical turn above the critical E681).[292] Similar Cys scan experiments in the C-terminal portion of the AE1 transmembrane domain identified hAE1 aa S852-L857 in the putative last extracellular loop as likely contributors to a "charge filter"[238] proposed to impede access of cations to the anion-preferring vestibule. The adjacent acanthocytosis-associated recessive AE1 mutation P868L near the final transmembrane span increased DIDS-sensitive sulfate uptake in intact patient red cells with normal polypeptide abundance.[293] Single Cys substitutions into wildtype AE1 have also contributed to the repetoire of residues that directly or indirectly contribute to the anion translocation pathway.[294]

Covalent modification and mutagenesis studies have highlighted additional C-terminal transmembrane domain amino acid residues important for anion transport. Although some mutations prevented surface delivery of AE polypeptides in heterologous expression systems, others reduced or abolished activity of protein in the plasma membrane. Chemical modification and mutagenesis studies of eAE1 transport suggest that among the Arg residue(s) essential for anion

translocation[295] is R901,[296] mutagenesis or modification of which reduces V_{max} for sulfate transport in *S. cerevisiae*. However, the AE1 distal renal tubular acidosis mutant R901X exhibits apparently normal transport in both human erythrocytes[297] and *Xenopus* oocytes, in which truncation of even 10 additional C-terminal aa retained Cl^-/Cl^- exchange activity.[283] Charge-modifying mutations of R789, R1056, and R1134 attenuated or abolished transport in mouse AE2.[298] Charge-modifying mutations of the Lys residues that bind to and are crosslinked by the isothiocyanate groups of H_2DIDS altered not only reversible antagonist binding, but also apparent sulfate affinity.[299]

His residues have also been implicated in AE-mediated Cl^- transport by the reduced anion transport of mouse AE1 His mutants H721Q, H752S, H837Q, and H852Q.[300] Introduction into these His-to-Gln substitution mutants of the additional mutation K558N (the DIDS isothiocyanate-binding Lys) partially or completely rescued Cl^- transport in *Xenopus* oocytes.[301] In contrast for AE2, only H1029 (corresponding to mAE1 H721) proved critical for AE2-mediated Cl^- transport.[302] Mouse AE1 H752, which alters pH dependence of anion exchange,[301] and human AE1 H834[303] (corresponding to mAE1 H852) have both been proposed as chief targets of inhibitory covalent modification by diethyl pyrocarbonate (DEPC).

ANION CONDUCTANCE ASSOCIATED WITH AE1

The relationship between AE1-mediated anion exchange and the dominant (though small) anion conductance of the human erythrocyte has been a question of long standing. Erythroid anion conductance is considerably larger in nucleated erythrocytes, and often sensitive to activation by hypotonic swelling. AE1 of the nucleated, hormone-regulated trout erythrocyte is unique among AE1 polypeptides in conferring on Xenopus oocytes not only Cl^-/anion exchange function, but also a large anion conductance accompanied by increased taurine transport[274,304] and increased cation conductance.[305] Although expression of so many distinct properties suggests coincident activation of endogenous *Xenopus* permeabilities by heterologous protein overexpression, mutagenesis studies to date[306,307] remain consistent with the hypothesis that trout AE1 can mediate both anion exchange and anion conductance. Thus, defined mutations in TM7 of trout AE1 modified anion conductance magnitude and selectivity without apparent change in the tested anion exchange properties, whereas mutations in more C-terminal regions altered both anion conductance and exchange.[307,308] In contrast oocyte expression of AE1 from skate and from zebrafish[309] and zebrafish AE2[42] was unaccompanied by increased anion conductance.

The parallel inhibition in the human red cell of anion exchange and of ~65% of anion conductance by stilbene disulfonates and other inhibitors suggests this fraction of red cell anion conductance might be mediated by AE1. The conductance mode could represent an infrequent AE1 "malfunction" in which unliganded carrier undergoes the conformational transition between inward and outward states or could represent anion "tunneling" directly through or adjacent to AE1 in the absence of conformational change.[250] AE1-mediated Cl^- conductance is supported indirectly by at least two observations. First, the red cell of the *ae1*$^{-/-}$ mouse[108] lacks both DIDS-sensitive sulfate uptake and DIDS-sensitive anion conductance.[310] The specificity of this observation is tempered by the destabilization of the fragile *ae1*$^{-/-}$ red cell membrane, which is deficient in additional membrane proteins[164,310] among which may be a DIDS-sensitive AE1-independent anion channel, one of several endogenous anion channel activities detectable in human red cells.[311–314] Second, expression in *Xenopus* oocytes of a human eAE1 construct from which the two transmembrane spans 6 and 7 are deleted induced DIDS-sensitive anion conductance, while partially retaining electroneutral anion exchange function. Importantly, the K539A mutation reduced DIDS sensitivity of both exchange and conductance transport modes in this mutant construct.[315]

Expression in *Xenopus* oocytes of AE1 from the nucleated red cell of the skate, *Raja erinaceae* also induced regulated osmolyte permeability and cation conductance properties[316,317] (but see[309]). Interestingly, small cation and osmolyte permeabilities were also associated with deletion of two transmembrane spans in hAE1,[315] reminiscent of the genetic association between reduced Cl^- transport function and low-level cation permeability in stomatocytosis mutants of human AE1.[318] Additional mutations in human AE1 have been reported to produce in oocytes divergent changes in anion exchange and anion conductance.[294,319] Thus, the tightly coupled anion exchange mechanism of AE1 (and of other SLC4 AEs) can apparently be altered in selectivity and in mechanism by single missense mutations.

THE AE1 C-TERMINAL CYTOPLASMIC TAIL: CARBONIC ANHYDRASE BINDING, ANION SELECTIVITY, AND OTHER FUNCTIONS

The final transmembrane span of AE1 terminates in a C-terminal cytoplasmic tail approximately 33–36 aa in length, the N-terminal half of which is required for

AE1 trafficking to the cell surface.[283,320] The moderately well conserved LDADD motif at aa 896−890 of the hAE1 C-terminal cytoplasmic tail binds in some assays to the positively charged N-terminus of carbonic anhydrase II (CAII),[87,321,322] and has been proposed to constitute a bicarbonate transport metabolon.[323,324] CAII co-immunoprecipitated with AE1, and soluble multimeric glutathione-S-transferase (GST) fusion constructs of the AE1 C-terminal tail exhibited saturable binding to immobilized CAII. The carbonic anhydrase inhibitor acetazolamide partially inhibited AE1-mediated Cl^-/HCO_3^- exchange[283,323] without inhibiting Cl^-/Cl^- exchange in *Xenopus* oocytes.[283] Mutation of the LDADD CAII-binding motif of AE1 abolished Cl^-/HCO_3^- exchange in both HEK-293 cells[323] and in oocytes, but failed to reduce Cl^-/Cl^- exchange.[283] Heterologous CAII overexpression failed to stimulate Cl^-/HCO_3^- exchange activity of coexpressed AE1, AE2, or AE3 in HEK-293 cells, but overexpression of catalytically inactive CAII inhibited AE activity. This inhibition was prevented by either missense mutations in the AE1 LDADD motif or by deletion of the 17 N-terminal aa of CAI,[323] both of which prevented CAII binding to the GST-AE1 fusion protein in the solid-phase binding assay without reduction of AE1 surface expression in cells. An AE1-CA2 C-terminal fusion protein did not transport HCO_3^- faster than wildtype AE1 in HEK-293 cells, but was insensitive to inhibition by excess catalytically inactive CA2.[325] In *Xenopus* oocytes, overexpression of heterologous wt but not mutant CAII mildly stimulated AE1-mediated Cl^-/HCO_3^- exchange, but not Cl^-/Cl^- exchange. An intact LDADD CAII-binding motif within a nonfunctional, surface-expressed mutant AE1 polypeptide rescued (within an AE1 heterodimer) Cl^-/HCO_3^- exchange activity in a coexpressed AE1 mutant itself unable to transport HCO_3^- but competent for Cl^-/Cl^- exchange.[283] These data show that residues of the AE1 C-terminal cytoplasmic tail are required for trafficking to the cell surface, can discriminate between transport of Cl^- and HCO_3^-, and can convey that discrimination between subunits within the AE1 dimer. The data are also consistent with the modified sulfate transport caused by mutation of these C-terminal residues.[296,326]

The CAII-binding motif is moderately conserved across the SLC4 gene family. AE2 and AE3 overexpressed in HEK293 cells were each inhibited by coexpressed mutant CA2. Recombinant CAII also interacted with fusion proteins encoding C-terminal tails of recombinant $Na^+-HCO_3^-$ cotransporters SLC4A4 and SLC4A7,[327] Cl^-/HCO_3^- exchanger SLC26A6,[328] and Na^+/H^+ exchanger NHE1.[329,330] SLC4A4 was also activated by CAI and CAII.[331] Acetazolamide treatment or co-expression of catalytically inactive CAII also partially inhibited apparent activity of these transporters.

The ecto-carbonic anhydrase activities of glycosylphosphatidyl-inositol-linked CAIV[332] and transmembrane carbonic anhydrases CAIX[333] interacted with extracellular loops of AE polypeptides, and have been proposed to constitute extracellular components of a bicarbonate transport metabolon assembled on both sides of the plasma membrane.[324] Recombinant CAIV also bound to recombinant fusion protein containing an ecto-loop from NBCe1/SLC4A4,[334] an interaction disrupted by the CAIV missense mutations associated with human autosomal dominant rod-cone dystrophy.[335] CAXIV together with CAIV enhanced AE3-mediated Cl^-/HCO_3^- exchange in hippocampal neurons.[336] CA−AE physical interaction has in some cases been conferred by overexpression pulldown experiments. Carbonic anhydrase coexpression has also been shown to enhance SLC16/MCT-mediated H^+/lactate cotransport,[337] although in part through poorly understood, non-enzymatic effects.[338,339]

Additional data, however, question the bicarbonate transport metabolon hypothesis.[14] Thus, CAII did not bind to free AE1 C-terminal cytoplasmic tail peptide, nor to immobilized GST-AE1 C-terminal peptide fusion protein.[340] Injection of supplemental CAII into oocytes expressing electrogenic SLC4A4/NBCe1 failed to activate $Na^+-HCO_3^-$ cotransport currents in *Xenopus* oocytes even while accelerating intracellular CO_2 hydration in an ethoxazolamide-sensitive[341] or acetazolamide-sensitive manner.[342] $Na^+-HCO_3^-$ cotransport current mediated by a GFP-NBCe1-CAII tripartite fusion protein was no greater in magnitude than that of GFP-NBCe1 without the appended CAII, although the tripartite fusion protein again accelerated ethoxazolamide-sensitive CO_2 hydration.[341] Similarly, CAIV coexpression with NBCe1 increased the extracellular juxtamembrane pH gradient with minimal effect on NBCe1-mediated current.[343] Moreover, a pRTA/migraine mutant of NBCe1 lacking the putative CA2 binding sites expressed normal activity in *Xenopus* oocytes.[342] Thus, in these experimental settings, neither intracellular nor extracellular carbonic anhydrase increased NBCe1 turnover.

Acceleration of HCO_3^- transport by cytoplasmic and ecto-carbonic anhydrases bound closely to the internal and external vestibules of SLC4 HCO_3^- transporters, as proposed by the metabolon hypothesis, suggests that dissociation of translocated HCO_3^-, rather than anion translocation itself, is rate-limiting for anion exchange. Although a rate-limiting anion dissociation step could be consistent with the kinetics of (Woodward's Reagent K-modified) AE1 E681-OH,[265] this condition has not been reported for wild-type AE1. Since bulk intracellular diffusion coefficients of CO_2 and HCO_3^- differ only slightly and are both fast relative to transmembrane anion exchange, and since the oocyte

plasma membrane is not freely permeable to CO_2, then maximizing proximity of carbonic anhydrase activity with HCO_3^- transporters may not enhance rates of SLC4 polypeptide-mediated transmembrane HCO_3^- transport,[341] except perhaps in physiological settings of enhanced intracellular or regional pH gradients.[344,345] Thus, the relationship between HCO_3^- transporters and carbonic anhydrases remains debated.

The short AE1 cytoplasmic C-terminal tail binds additional proteins. The intracellular N-terminal tail of glycophorin A, which facilitates hAE1 trafficking to the surface membrane,[346] binds to the AE1-C-terminal tail.[347] Stabilizing this interaction, the C-terminal ecto-domain of glycophorin A which modulates AE1 anion transport rates[346] interacts via aa R61 with the hAE1 fourth ecto-loop variant E658K to form Wright (a/b) blood group antigens.[348,349] GAPDH binds to the kAE1 C-terminal tail without altered GAPDH activity and in an AE1 phosphorylation-insensitive manner. siRNA knockdown of GAPDH in AE1-expressing MDCK cells increases intracellular retention of AE1, with reduced AE1 at the surface membrane.[350] Several additional candidate binding proteins detected by yeast two hybrid studies using AE C-terminal cytoplasmic tails or larger fragments as bait include the PDZ proteins syntenin and Pick-1[351] (never validated), α-cardiac actin[352] (not validated in native tissue) and the cell-cycle protein p16.[353] The proposed kAE1-specific binding protein kanadaptin[354] was later shown to be a protein of the nucleus and mitochondrion[355,356] unable to bind kAE1.[357] AE2, like AE1, can interact with p16.[358] The C-terminal tail of AE2 also binds GAPDH.[350] AE3-binding proteins have not been described.

ACUTE REGULATION OF ANION EXCHANGERS

Phosphorylation of Anion Exchangers

Human eAE1 is a substrate for serine/threonine kinases and for tyrosine kinases, AE1 phosphorylation does not regulate anion transport rate[265] in the absence of oxidative stress or coincident glucose-6-phosphatase deficiency.[359] Casein kinase I phosphorylated recombinant hAE1 N-terminal cytoplasmic domain at T42 and less completely at S303.[360] Tyrosine kinases p72(syk) and p56/53(lyn) phosphorylated human eAE1 in cells exposed to oxidative[359,361] or hypertonic stress, or subjected to elevated intracellular $[Ca^{2+}]$.[362] Diamide crosslinking and clustering of red cell AE1 was associated with its enhanced tyrosine phosphorylation in the setting of increased phosphorylation and membrane recruitment of p72(syk). These phenomena are irreversible in G6PD-deficient red cells,[363] and lead to release of hemichrome-containing vesicles.[364] In acanthocytic red cells of patients with choreo-acanthocytosis, AE1 was heavily phosphorylated at the Y904, a functional target of p53/56(lyn), but not at Y8, a target of syk.[365] Phosphorylation of eAE1 Y8 and Y21 facilitated secondary phosphorylation of Y359 and Y904 in human red cells,[209] and these residues were susceptible to dephosphorylation by erythroid tyrosine phosphatases PTP1B and SHP-2. Phosphorylation of hAE1 Y8 and possibly also Y21 inhibited binding of glycolytic enzymes to the red cell membrane,[175] associated with hypoxic activation of glycolysis in parallel with glycolytic enzyme dissociation from the membrane,[210] events that may occur during passage through the hypoxic renal medulla. Downregulation of hAE1 tyrosine phosphorylation may regulate red cell vesiculation during the red cell senescence process.[362]

In the skate red cell, hypotonic swelling activated AE1 Tyr phosphorylation in parallel with increased osmolyte permeability, but swelling-activated AE1 tetramerization, altered AE1 binding to ankyrin and protein 4.1, and AE1 trafficking from intracellular lipid raft-containing vesicular fraction to the plasma membrane were all independent of AE1 tyrosine phosphorylation.[366] In human kidney AE1 lacking Y8 and Y21, phosphorylation of Y904 and Y359 is crucial to normal basolateral targeting of kAE1 expressed in polarized MDCK cell monolayers.[367] Tyrosine phosphorylation also contributes to basolateral targeting of chicken kidney AE1,[101] and hAE1 Y904 is conserved in AE2 and AE3.

Rabbit AE2a may be activated by PKC in gastric parietal cell.[90] MEK/MAPK pathway activity during first metaphase leads to Ae2 removal from the mouse oocyte plasma membrane in parallel with reduction in oocyte Cl^-/HCO_3^- activity.[368] Angiotensin II-induced PKC-dependent phosphorylation of rat bAE3 Ser 67 in HEK-293 cells increased Cl^-/HCO_3^- exchange activity without changing surface expression.[369] This phosphorylation event may contribute to hypertrophy of rat cardiomyocytes but not in those of mouse, which express only cAE3 and in which SLC26A6 may be the major Cl^-/HCO_3^- exchanger.[370]

Acute Regulation By pH

The acute regulation of AE2 (and other pH-sensitive SLC4 bicarbonate transporters) requires a "pH sensor(s)" (likely delocalized rather than a unique amino acid residue), is postulated to promote a protein conformational change leading to altered anion transport activity. This regulation is proposed to occur through concerted pH-sensing actions of both N-terminal cytoplasmic and C-terminal transmembrane domains of the protein. The AE anion exchanger gene products differ considerably

in their acute regulation by pH. Native erythrocyte AE1-mediated Cl^-/HCO_3^- exchange[371] and AE1-mediated Cl^-/Cl^- exchange in *Xenopus* oocytes[217,256] both display broad pH versus activity profiles, consistent with the eAE1's role in facilitating CO_2 mobilization from the respiring tissues to the lungs for exhalation.[372] In contrast, the widely expressed, non-erythroid anion exchangers AE2 and AE3 are acutely regulated by changes in pH_i,[373] with activation by alkaline pH consistent with their roles in pH_i recovery from alkaline loads, and inhibition by acid pH appropriate for downregulation of their acid-loading function. Whereas mouse AE1 expressed in *Xenopus* oocytes is relatively insensitive to changes in bath pH between five and nine, mouse AE2 expressed in oocytes[86,217,256] is acutely and independently regulated by pH_o and pH_i, and is also highly sensitive to pH_i when expressed in cultured cells.[99,374] AE3 is also regulated by pH_i when transiently transfected in HEK293 cells[374] or expressed in *Xenopus* oocytes.[373]

In *Xenopus* oocytes, AE2-mediated Cl^-/Cl^- exchange is regulated by intracellular pH_i at constant pH_o and by extracellular pH_o at constant pH_i.[86,373] AE2a-mediated Cl^-/Cl^- exchange is regulated by extracellular pH_o with a pH value at which activity is half-maximal ($pH_{o(50)}$) of 6.9. Structure-function experiments have indicated that regulation of AE2 by changes in pH_o is via a pH sensor(s) that resides within the C-terminal transmembrane domain of AE2[217] and can be regulated/modified by critical amino acid residues in the cytoplasmic N-terminal domain.[86,171,217,373] Removal of the cytoplasmic N-terminal domain acid shifts the $pH_{o(50)}$ of AE2-mediated Cl^- transport and abolishes pH_i regulation of AE2.[86] These findings suggest the presence of a "pH sensor" motif within the AE2 TMD that interacts directly/indirectly with sensor components in the cytoplasmic N-terminal domain to modulate anion exchange activity in responses to changes in pH_i and pH_o. All AE2 N-terminal polypeptide variants displayed similar sensitivity to inhibition by acid pH_i. AE2b1 and AE2b2 resembled AE2a in regulation by pH_o, whereas the gastric parietal cell-specific AE2c1 displayed a significantly alkaline shifted $pH_{o(50)}$ value due to the absence in AE2c1 of AE2a aa 127–134 and aa 145–149.[375]

Additional stretches of non-contiguous residues of the AE2 N-terminal domain present in all five N-terminal variant AE2 polypeptides[92,149] are important for pH regulation of AE2,[171,373] and are predicted by structural modeling to contribute to surface features of the folded cytoplasmic domain.[171] For example, aa 336–347 critical for regulation of AE2 by pH are highly conserved across the entire SLC4 bicarbonate transporter superfamily. Thus, the AE3 Glu residues corresponding to the functionally important E346 and E347 of AE2 are also important for pH_i regulation of cAE3.[373]

The mechanism by which AE2 integrates acute regulation of transport activity by pH_i and pH_o involves both cytoplasmic and transmembrane domains. Attempts to localize the AE2 TMD pH sensor have identified as candidate contributing residues nonconserved histidines,[302] nonconserved charge residues, and other amino acid residues of the TMD.[298] More recently AE1–AE2 chimera studies identified subdomains of AE2 that contribute to different regulatory phenotypes, including regulation by pH.[376] These studies indicated that the Ae2 pH sensor probably did not comprise a single amino acid but rather multiple TMD regions or amino acids interacting to confer on AE2-mediate anion exchange regulation by pH.

Biochemical and cysteine scanning mutagensis studies of AE1 have identified a structure comprising 12–14 TMD including two putative re-entrant loops. The second re-entrant loop and the last two TMD have been proposed to contribute to the AE1 anion selectivity filter. The first re-entrant loop is comprised of ~38 aa, nine of which are not conserved between AE1 and AE2. Mutagenesis studies of these 9 nonconserved amino acids identified single amino acids and regions of charged amino acids including the ^{1075}DKPK^{1078} motif within the AE2 RL1 as crucial components of the pH sensor.[377] Replacement of the AE1 RL1 with the AE2 RL1 or introduction of regions of AE2 RL1 amino acids into the AE1 RL1 failed to confer AE2-like pH sensitivity on AE1. In contrast, introduction of the same AE2 RL1 residues into the RL1 of the pH-insensitive chimera $AE2_{(1-920)}/AE1_{(613-929)}$ conferred AE2-like pH sensitivity to pH_i but not to pH_o.

These data show that H^+ sensing by the pH-sensitive regulatory domain of AE2 likely involves broad conformational change that includes a localized, charged, surface of the cytoplasmic domain and a region of re-entrant loop 1 within the TMD. A role for rapid trafficking events in acute AE2 regulation by pH is likely, but remains inadequately explored.

Acute Regulation by Ammonium and Hypertonicity

All N-terminal AE2 variant polypeptides expressed in *Xenopus* oocytes are activated by hypertonicity[375,378] and by exposure to NH_4Cl.[375,379] AE1 does not share these regulatory properties. Hypertonicity alkalinizes oocyte pH_i through cJNK-dependent stimulation of an unusual Cl^--dependent Na^+/H^+ exchange activity.[380] Thus, activation of AE2 by hypertonicity is consistent, at least in part, with AE2 activation by alkalinization. NH_4Cl activates AE2 despite acidifying the *Xenopus*

oocyte, and so overrides AE2 inhibition by acidic pH_i. Renal medullary and colonic [Na_4^+] are maximal with respect to AE2 stimulation, and so might render endogenous AE2 locally insensitive to inhibition by acidic pH_i.

AE2 stimulation by Na_4^+ and by hypertonicity requires similar regions of both N-terminal cytoplasmic and C-terminal transmembrane domains,[381] but the individual amino acids required differ. Alanine scan of the N-terminal region 336–347 identified single mutations that abolish or attenuate one or both types of stimulation. Chelation of intracellular Ca^{2+} attenuated AE2 stimulation by both Na_4^+ and hypertonicity. Calmidazolium inhibited both basal and stimulated AE2-mediated anion exchange in an apparently CaM kinase-independent manner, via residues in the C-terminal transmembrane domain and independent of the N-terminal cytoplasmic domain.[381]

DEVELOPMENTAL AND CHRONIC REGULATION OF ANION EXCHANGERS

The proximal erythroid promoter regions of AE1 genes have been studied in mouse,[382,383] human,[100] and chicken.[384,385] pH-sensitive repression of chicken AE1 transcription by the vErbA erythroleukemia oncogene contributed to oncogenic block of erythroid differentiation.[386] Newly biosynthesized eAE1 assembled into preformed cytoskeleton during *in vitro* differentiation of chicken erythroid precursors,[387] but appeared to contribute at least temporally to cytoskeletal assembly in murine erythroid precursors.[388]

kAE1 expression in kidney is restricted to collecting duct Type A acid-secreting intercalated cells, but is absent from Type B cells and from non-A non-B cells. Although rabbit primary and immortalized (lectin-defined) Type B intercalated cells in culture can give rise to cells expressing markers of principal cells and of Type A intercalated cells,[389] the developmental relationships among intercalated and principal cells *in vivo* remain unknown. However, mice lacking the transcription factor Foxi1 developed a collecting duct populated by a uniform cell type expressing both the principal cell marker AQP2 and the intercalated cell marker CAII, but lacking expression of immunodetectable vH^+-ATPase, AE1, and AE4.[157] Rescue experiments with Foxi-1 *in vivo* and *in vitro* promise a major advance in understanding of collecting duct and intercalated cell development. The promoter for AE4, preferentially active in Type B intercalated cells,[158] was directly regulated by Foxi1.[390] Foxi1 also regulates development and ion transporter expression in intercalated cell-like dermal ionocytes of *Xenopus*[391] and zebrafish.[392] Zebrafish ionocytes express (kAE1-like) basolateral Ae1b,[393] product of a gene distinct from erythroid Ae1a.[43]

The kAE1 promoter includes intron 3, but the 5′-extent of sequence required for optimal kAE1 transcription remains unknown, as the kAE1 promoter has not yet been tested *in vivo* or in very short-lived primary cultures of GFP-marked murine intercalated cells.[394] AE1 accumulates in increasing numbers of mouse cortical collecting duct intercalated cells between postnatal days three to 18, coordinated with development of HCO_3^- reabsorption and with expression of other acid–base transporters. During the same period pendrin-expressing intercalated cells disappear from the medullary collecting duct.[395] In rabbit collecting duct the balance between Type A intercalated cells and non-A intercalated cells appeared to be regulated by apoptosis.[396] Intercalated cells of rat inner medullary collecting duct proliferated during chronic systemic lithium treatment, but not all new cells expressed AE1.[397]

AE1 mRNA in Type A intercalated cells of adult rat kidney cortex is upregulated in acute[398] or chronic metabolic acidosis[125] and in chronic respiratory acidosis,[399] but down-regulated in acute metabolic alkalosis.[398,400] AE1 upregulation in chronic metabolic acidosis is part of a collecting duct acid–base "regulon" of >25 co-regulated transcripts in mouse kidney.[401] Chronic acidosis-induced increase in AE1 was associated with Type A intercalated cell (and principal cell) proliferation in mouse,[402] but not in rabbit.[400] Chronic lithium treatment led to increased AE1 and intercalated cell proliferation in IMCD, as part of a generalized IMCD remodeling response.[397] Water deprivation of normal rats decreased AE1 mRNA and protein in outer medulla while increasing both mRNA and protein encoding SLC26A7.[403] Similarly, ddAVP administration to Brattleboro rats suppressed collecting duct kAE1 abundance in parallel with increased corticosterone and decreased serum [HCO_3^-],[404] but dramatically upregulated SLC26A7 in outer medullary collecting duct intercalated cells without change in vH^+-ATPase abundance.[405] AE1 mRNA in rat distal colon was upregulated by aldosterone[129] but the aldosterone-increased acidification of the rabbit outer medullary collecting duct[406,407] has not yet been correlated with mineralocorticoid regulation of collecting duct AE1 expression. Rat distal colon AE1 mRNA levels exhibit circadian regulation in tandem with electrolyte absorption and mRNAs of SLC26A3, NHE3, KCC1, and NKCC1, in a feeding-sensitive manner.[408]

AE2 regulation in kidney has been studied in thick limb and in collecting duct. In the rabbit cortical collecting duct principal cell, AE2 mRNA decreased in metabolic acidosis and increased in metabolic alkalosis.[409] AE2 expression in rat thick ascending limb was

regulated by chronic acid−base and NaCl loading.[410] In both cortical (cTAL) and medullary thick ascending limb (mTAL) chronic oral NaCl loading increased basolateral membrane AE2 abundance, whereas NH_4Cl loading increased AE2 expression only in cTAL. Cortical AE2 abundance was unchanged by loading with $NaHCO_3^-$ or KCl, and decreased with $KHCO_3^-$ loading. $NaHCO_3^-$ loading increased AE2 only in outer medulla. AE2b but not AE2a was selectively upregulated in rat cTAL basolateral membrane in response to chronic NH_4Cl loading.[147]

The five 5′-variant transcripts of mouse AE2 (Fig. 54.2) are transcribed from four promoters in the AE2 gene expressed in tissue-specific patterns.[149,375,411] AE2c1 is expressed almost uniquely in stomach, with minor expression in uterus in the mouse.[375] In rabbit stomach, parietal and mucous cells expressed unique proportional distributions of AE2 variant transcripts.[90] The four AE2 promoters of the rat and human genes transcribe only four AE2 mRNAs.[91,92,148,412] The AE2a transcript is expressed at higher abundance than other AE2 isoforms in kidney.[148,149] The mechanisms of differential regulation of AE2 variant polypeptide levels have been little studied, but the human AE2b promoter was selectively regulated by the transcription factor HNF1α expressed in kidney.[413] The human AE2 b1 promoter exhibits a polymorphism of yet unknown significance to transcriptional regulation.[414]

Hormonal regulation of AE2 is developmentally and tissue-specific, but remains little understood. In neonatal rat small intestine, AE2 was downregulated by thyroxine, but was unchanged by dexamethasone.[415] Dexamethasone increased HCO_3^- secretion in bile duct units and intrahepatic cholangiocytes of rat, in parallel with upregulated AE2 protein but unchanged AE2 mRNA.[416] Hepatic AE2 levels were decreased in liver and biliary epithelial cells of primary biliary cirrhosis patients,[417−419] in part likely due to upregulation of miR-506.[420] The combination of ursodeoxycholic acid and glucocorticoids, effective for a subset of patients with primary biliary cirrhosis, selectively activated transcription of AE2b1 and AE2b2 transcripts through enhanced p300-related interactions between HNF1 and the glucocorticoid receptor.[421] Some,[422,423] but not other, association studies[424,425,426] have linked AE2 polymorphisms to either risk, autoimmune phenotype, or ursodeoxycholate responsiveness of primary biliary cirrhosis.

AE2 was decreased in salivary glands of Sjogren's Syndrome patients.[427] Chronic exposure to oxidative stress upregulated AE2 mRNA and protein in human bronchial epithelial cells and in intact rat lung, in parallel with activation of transcription factor AP-1.[428] AE2 expression was regulated by the Von Hippel Lindau gene product, with several-fold increase in AE2 mRNA and protein in non-tumorigenic 786-O-VHL renal cell carcinoma cells despite reduction in Cl^-/HCO_3^- exchange activity, as compared to tumorigenic, VHL-deficient 786-O cells. NHE3 mRNA was similarly elevated, and NHE-mediated recovery from acid load was similarly reduced.[429] Hepatocellular carcinoma samples also exhibited several-fold increased AE2 mRNA levels compared to adjacent normal liver,[430] and anti-sense reduction in AE2 expression induced apoptosis in several hepatocarcinoma cell lines.[431] AE2 overexpression in colon carcinoma cells was transcriptionally regulated by EGR1, and led to extranuclear sequestration of p16 and enhanced ERK phosphorylation. AE2 abundance in clinical colon carcinoma specimens correlated with expression of proliferation markers and with poor prognosis.[358] In contrast, siRNA knockdown of AE2 attenuated high glucose-induced apoptosis in endothelial cells.[432] Ae2 mRNA was greatly decreased in enamel organs of mice deficient in matrix metalloproteinase 20.[433]

The study of regulated AE2 trafficking in polarized epithelial cells remains in early stages. AE2 is exclusively basolateral in most epithelial cells. However, AE2 in human hepatocytes has been localized near or in the apical canalicular membrane in liver,[146] gall bladder and bile duct,[434] and in cultured bile duct epithelial cells.[144] Several AE2 isoforms expressed as C-terminal GFP fusion proteins trafficked basolaterally in polarized MDCK monolayers and apically in primary hepatocyte biliary ductule units,[435] with sorting to either cell pole microtubule-dependent. However, fusion with C-terminal GFP altered trafficking of AE1 in MDCK cells and regulation of AE2 in *Xenopus* oocytes (Stewart, Prabakaran, Alper, unpublished). In addition, AE2 was retained in intracellular vesicular structures in polarized WIF-B cells.[436] The putative AE2-binding, trafficking, and anchoring/scaffolding proteins that might govern the distinct steady-state localizations of AE2 polypeptides in renal and hepatic epithelial cells remain unidentified.

Regulation of renal expression of AE3 or AE4 has not yet been reported. In the developing mouse heart, however, brain AE3 (bAE3) and cardiac AE3 (cAE3) mRNAs are equally abundant, but bAE3 levels decrease dramatically during postnatal cardiac development.[89] In contrast, adult rat and human heart continue to express both bAE3 and cAE3. Stable AE3 expression in adult heart might reflect functional dominance of SLC26A6-mediated Cl^-/HCO_3^- exchange in the adult mouse heart.[370] However, the 2−4-fold higher Cl^-/HCO_3^- exchange activity of SHR rat cardiomyocytes compared with those from WKY rats corresponded to higher levels of bAE3 mRNA and lower cAE3 mRNA levels, suggesting a possible role for bAE3 in this model of hypertensive cardiac

hypertrophy.[437] AE3 is widely expressed in brain, with reduced hippocampal AE3 expression in the *Nhe1*$^{-/-}$ mouse.[438] AE3 is differentially regulated in mouse heart and brain, with chronic hypercapnia decreasing AE3 expression in both neonatal and adult brain, but increasing AE3 expression in neonatal hearts.[439]

AE1 DEFICIENCY DISEASES OF ERYTHROCYTES

Loss-of-function mutations in the human AE1 gene on chromosome 17q22 cause hereditary erythroid and kidney diseases (Table 54.3). Mutations in the human AE2 and AE3 genes have not been directly linked to disease with Mendelian inheritance. The AE1-related erythroid dyscrasias include hemolytic anemias characterized by spherocytosis, ovalocytosis, or stomatocytosis, nearly all caused by dominant heterozygous mutations. AE1-associated distal renal tubular acidosis (dRTA) in the Americas and Europe is caused most often by dominant heterozygous mutations, and in Southeast Asia by recessive homozygous or compound heterozygous mutations. With rare exceptions among the dominant human mutations, and very few among the recessive mutations, the red cell disorders and the kidney diseases are caused by discrete sets of mutations (Fig. 54.8). Homozygosity for the dominant disease mutations is encountered only rarely, and is assumed in most cases to be embryonic-lethal. It is marked by life-threatening hemolytic anemia and severe acidosis, and phenocopied by engineered AE1 knockouts in mouse and zebrafish, and by spontaneous bovine AE1 deficiency.

Hereditary Spherocytosis

Hereditary spherocytic anemia (HS) is characterized by increased osmotic fragility, and reflects a reduced erythroid surface area-to-volume ratio arising from exo- and endo-vesiculation from the unstable membrane of mechanically fragile red cells. Most cases result from dominantly inherited heterozygous deficiency of extrinsic proteins of the erythroid cytoskeleton (β spectrin, ankyrin-1, protein 4.2) but up to 65% of cases exhibit eAE1 deficiency.[440,441] In addition to splenomegaly and jaundice, the more severe hemolytic anemias are accompanied by leg ulcers, hemochromatosis, cholelithiasis, and other problems. The clinical presentation is generally milder in HS associated with AE1 mutations than from other causes,[199,442] and is remarkable for the absence of detectable renal acidification defect.

HS mutations include nonsense, frameshift, and missense mutations (Table 54.3) and are distributed across the entire AE1 coding region (Fig. 54.8). Mutant transcripts are usually absent or of reduced abundance, with moderate compensatory upregulation of the wild-type polypeptide representing increased transcription or post-transcriptional stabilization. Most HS mutant AE1 polypeptides expressed in *Xenopus* oocytes or HEK 293 cells fail to reach the plasma membrane with retention in endoplasmic reticulum or proximal Golgi, and some are misfolded as judged by altered stilbene disulfonate binding.[443] The severe recessive HS caused by the AE1 mutation E40K[444] is accompanied by 90% reduction in erythroid abundance of the AE1-binding protein 4.2. Conversely, the recessive protein 4.2 Nippon mutation is accompanied by 50% reduction in eAE1 abundance.[445] Most HS-associated AE1 mutations are not accompanied by defective distal urinary acidification. The rare exceptions include the severe recessive HS mutation V488M[107] and possibly also Band 3 Neapolis,[446] as well as the unexplained bicarbonaturia reported in HS patients with the heterozygous AE1 mutants S477fs[447] and Q203fs.[448]

BENIGN ERYTHROID PHENOTYPES OF AE1 POLYPEPTIDE VARIANTS

Human AE1 polymorphisms in extracellular loops of the C-terminal transmembrane domain encode minor blood group antigens classified as the Diego blood group system, generally considered of minimal clinical consequence for transfusion compatibility. Recently, however, an acute hemolytic transfusion reaction was associated with AE1-borne Wr(a) incompatibility.[449] Definition of these extracellular polymorphisms (Fig. 54.8) has provided important constraints on evolving models of AE1 topography within the membrane.[10] Anti-AE1 auto-antibodies directed against extracellular epitopes of human AE1 have been proposed either to mediate or to accelerate the complement-assisted removal of aged red cells by reticuloendothelial macrophages.[207] The antigens involved are hypothesized to arise from oxidative modification of AE1, and can target N-glycan carbohydrate antigens.[450] The benign erythroid phenotype of acanthocytosis can be associated with familial central nervous system disease. In one such family the dominant AE1 mutation P868L was associated with elevated erythroid sulfate transport rate and selectively altered red cell binding of H_2-DIDS,[293] consistent with altered conformation at the "second" isothiocyanate binding site at AE1 K851. However, the relationship of this mutation to altered red cell shape and to the neurological disease remains unclear.

Southeast Asian Ovalocytosis (SAO) is an asymptomatic, heterozygous condition associated with several indices of increased red cell rigidity including resistance to plasmodial invasion,[451] and is associated with reduced mortality from cerebral malaria.[452] The AE1 SAO mutant allele encodes a polypeptide with the inframe deletion Δ400−408 that is present in the red cell membrane at normal abundance, but neither transports anions nor binds stilbene disulfonates.[283,453] AE1 SAO is not dominant negative with respect to anion transport,[219] but nonetheless alters the conformation of bound wildtype protein.[170,284]

Cold-stored SAO red cells exhibit a cation leak,[454] and SAO has recently been recognized as a variant of the "hereditary stomatocytosis with cation leak syndromes",[455,456] sometimes presenting clinically as pseudohyperkalemia. In addition to SAO, nine dominant mutations in AE1 have been found to be associated with the red cell cation leak syndromes of cryohydrocytosis, spherocytosis with low temperature cation leak, and shallow slope hereditary stomatocytosis.[318] All stomatocytosis mutations are located in the proximate portion of the second half of the transmembrane domain. These AE1 mutants expressed in *Xenopus* oocytes exhibited moderately-to-severely reduced anion transport accompanied by low magnitude cation fluxes variably sensitive to some inhibitors of wildtype AE1-mediated anion transport. Mutagenesis experiments have supported the hypothesis that the mutations create cation leak pathways through the AE1 polypeptide,[294] but pharmacological results are less supportive. No renal acidification or salt-wasting phenotype has yet been noted in hereditary stomatospherocytosis with cation leak. However, AE1 mutations associated with cation permeability have promoted speculation that oxidatively modified AE1 may contribute to the still unidentified, deoxygenation-activated cation conductance specific to sickle erythrocytes.[457]

AE1 AND DISTAL RENAL TUBULAR ACIDOSIS (dRTA)

Heritable dRTA is caused by mutations in genes encoding components of the Type A intercalated cell acidification mechanism. dRTA is characterized by hyperchloremic metabolic acidosis in the presence of submaximal urinary acidification, usually defined as inability to acidify urine below pH 5.5. Normal proximal tubular function is marked by the absence of bicarbonaturia. The disease is associated with any combination of hypokalemia (severe enough on occasion to provoke weakness and arrhythmia), nephrocalcinosis, nephrolithiasis, growth retardation, rickets, polyuria, nausea and vomiting, and systemic dehydration. "Incomplete dRTA" marked by lack of spontaneous acidosis can be revealed by failure to acidify urine pH below 5.5 in response to standardized acid loading. In humans, dRTA genes of this class identified to date (Fig. 54.9) include the *AE1/SLC4A1* gene encoding the basolateral Cl^-/HCO_3^- exchanger kAE1, the *ATP6V1B1* and *ATP6V1A4* genes encoding B1 and A4 subunits of the apical membrane vH^+-ATPase, and the *CA2* gene encoding the cytosolic carbonic anhydrase CAII (causing mixed proximal-distal RTA).[2,285] dRTA genes described in knockout mice but not yet found in humans include K-Cl cotransporter KCC4/SLC12A7,[458] Cl^-/HCO_3^- exchanger/anion channel SLC26A7,[459] vasopressin-1a receptor,[460] apical ammonia channel RhCG,[461] H,K-ATPase subunits α1 and α2[462] and the matrix protein hensin/muclin/DMBT1[463−465] (but see [466,467]). As some identified familial dRTA cohorts remain without genetic diagnosis, additional dRTA genes will likely be defined as exome and whole genome sequencing becomes more widely available.

AE1-Associated Dominant dRTA

The nine AE1 mutations reported to date in patients with dominantly inherited dRTA are noted in Table 54.3. None of these dominant mutations have been found in the homozygous state, suggesting embryonic lethality. Unlike AE1 HS mutations, all dominant and recessive dRTA mutations of AE1 are missense mutations located in the AE1 transmembrane domain (Fig. 54.8). Dominant dRTA associated with mutant AE1 has been reported with few exceptions in Caucasians, and is unaccompanied by an erythroid phenotype. Erythroid AE1 abundance is normal in patients with heterozygous dRTA-associated AE1 mutations. Thus, whereas presumed AE1 haploinsufficiency in the Type A intercalated cells of HS patients suffices for normal urinary acidification, haploinsufficiency in the setting of dRTA mutations is pathological for the Type A intercalated cell, but inconsequential for the erythrocyte. This suggests a tissue-specific dominant- negative mechanism of disease for AE1-associated dRTA mutations. Two major mechanisms have been described to date (Fig. 54.10): hetero-oligomerization with dominant intracellular retention, and mutant mistargeting to the apical membrane.

In the absence of a robust cultured cell model of differentiated Type A intercalated cells, dRTA-associated AE1 mutant polypeptide function has been studied in *Xenopus* oocytes, HEK-293 cells, and MDCK cells grown on plastic, glass or permeable filter supports. In patient erythrocytes dRTA mutant AE1 polypeptides exhibited wildtype anion transport activity, while in

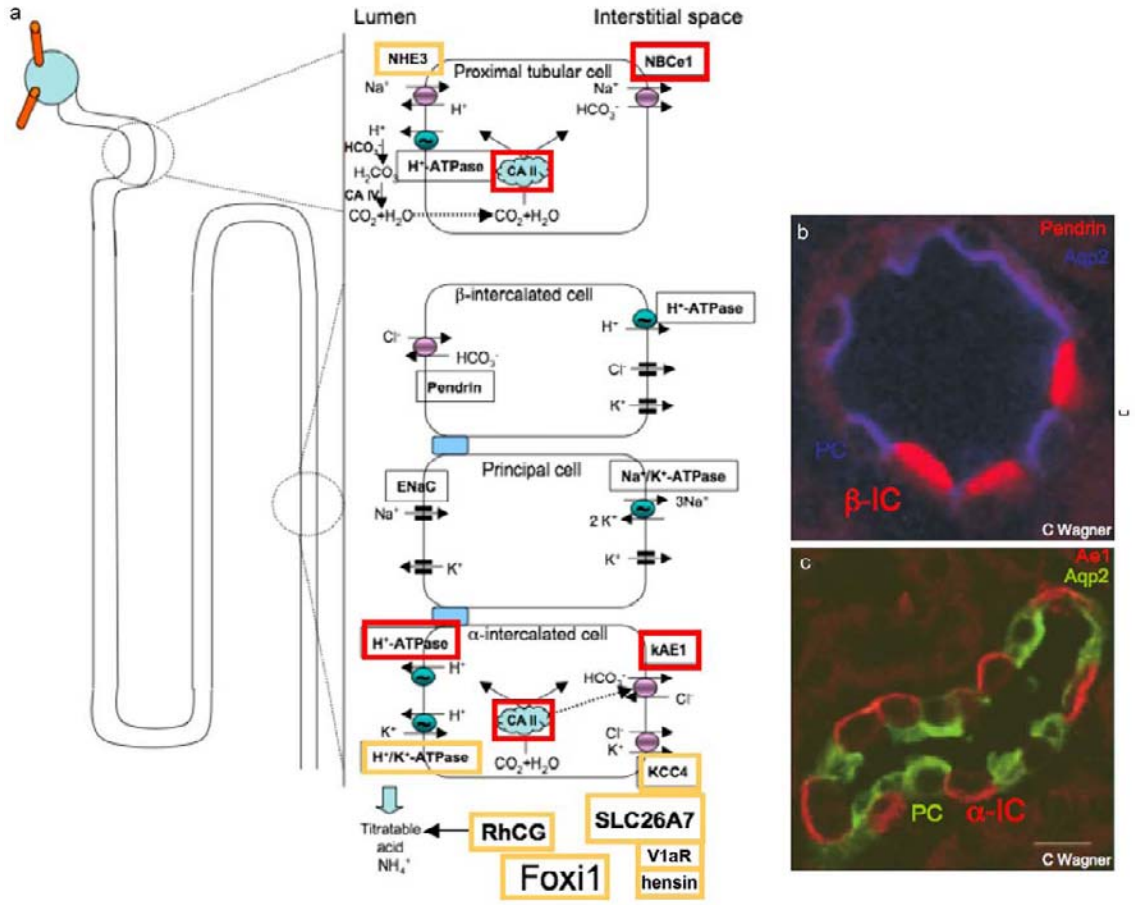

FIGURE 54.9 A. Schematic model of renal acidifying mechanisms: Bicarbonate reabsorption in proximal tubular cells and H^+ secretion in α-intercalated cells of the collecting duct. In the proximal tubule, H^+ is secreted at the apical membrane by the NHE3 Na^+/H^+ exchanger and by the vacuolar H^+-ATPase. Membrane-bound carbonic anhydrase CA IV (not shown) accelerates formation of CO_2 from H_2CO_3 generated by protonation of filtered HCO_3^-. CO_2 enters the tubular cell by diffusion and likely also via AQP1. H_2CO_3 is formed in the presence of cytosolic CA II, and HCO_3^- is transported out of the cell at the basolateral surface by Na^+/HCO_3^- cotransporter NBCe1. In Type A (α)-intercalated cells of the cortical collecting duct, H^+ is transported out of the cell into the lumen by vacuolar H^+-ATPase and, in K^+-depleted conditions, perhaps also by H^+/K^+-ATPase. HCO_3^- generated inside the cells leaves via anion exchanger 1 (kAE1) in exchange for Cl^- entry across the basolateral membrane. Basolateral Cl^- recycling is depicted with KCC4 K^+/Cl^- cotransporter, but may require Cl^- channel(s) in humans. Type B (β)-intercalated cells secrete HCO_3^- in exchange for Cl^- via their apical anion exchanger pendrin. In contrast to α-intercalated cells they can express a basolateral vH^+-ATPase. The principal cells are involved in Na^+ reabsorption and K^+ secretion. (Modified with permission from[285]). Red boxes indicate human dRTA genes. Orange boxes indicate dRTA genes identified in knockout mice, but as yet unassociated with human dRTA. B. Immunofluorescence micrograph of mouse cortical collecting duct showing β-intercalated cells expressing apical pendrin (red) in relation to principal cells expressing apical AQP2 (purple) (Reproduced with permission from[584]). C. Immunofluorescence micrograph of mouse cortical collecting duct showing α-intercalated cells expressing basolateral ae1/slc4a1 (red) in relation to (green) AQP2-expressing principal cells *(Reproduced with permission from[585]).*

Xenopus oocytes they exhibited 50−100% of wildtype anion transport activity[468,469] without a dominant negative phenotype.[468] An explanation for the dominant inheritance of the dRTA was sought in altered AE1 trafficking to the surface of renal epithelial cells. A technical advance enhancing these studies in HEK-293 cells replaced the high-mannose, Endo H-resistant wildtype N-glycan assembled at hAE1 N643 in the fourth exofacial loop with a novel N-glycosylation site in the third exofacial loop in the triple mutant N642D/Y555N/V557T.[470] Additional dRTA mutations could be introduced into this more easily tracked construct without alteration of trafficking attributable to the engineered glycan. Another important approach utilized an ecto-reactive anti-AE1 monoclonal antibody.

Expression of erythroid and of kidney forms of the AE1 dRTA mutant R589H in nonpolarized HEK-293 cells revealed intracellular retention of most kAE1 R589H, in contrast to normal surface expression of eAE1 R589H likely reflecting the different structures

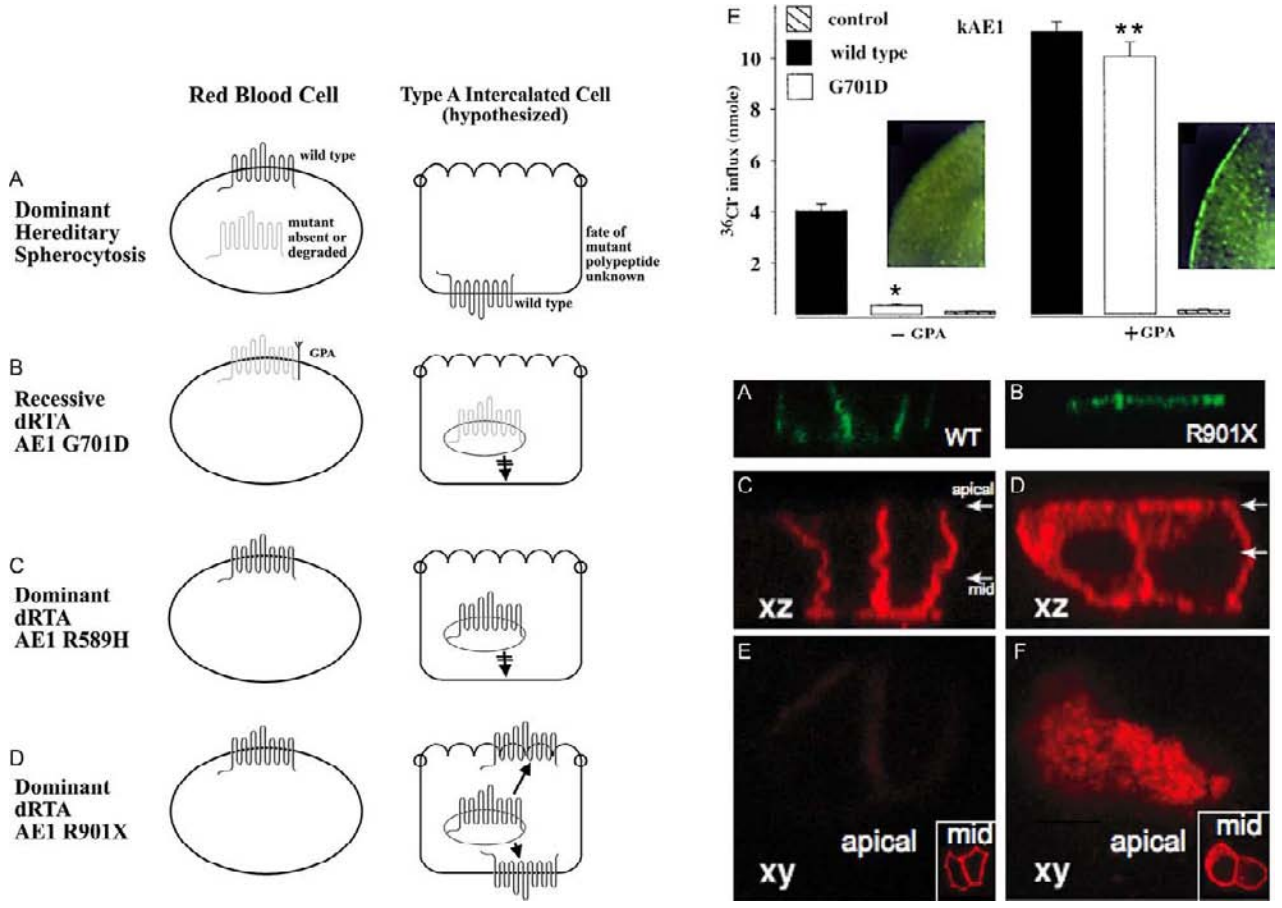

FIGURE 54.10 Pathophysiology of mutant AE1 trafficking in recessive and dominant forms of distal renal tubular acidosis (dRTA). A. Dominant hereditary spherocytosis. In red cells, the mutant erythroid AE1 (eAE1) polypeptide is usually absent or degraded. The wildtype eAE1 polypeptide is at the cell surface at 50−80% of normal level. In Type A intercalated cells, the wt kidney AE1 (kAE1) polypeptide is believed to be at the basolateral surface, but surface abundance and fate of the mutant polypeptide are unknown. B. Recessive dRTA is exemplified by AE1 G701D. In red cells, eAE1 G701D is believed to associate normally with the AE1-binding transmembrane protein, glycophorin A. This association allows normal accumulation and function in the red cell membrane. G701D and other recessive mutants fail to traffic to the surface of the *Xenopus* oocyte and (it is thought) to the surface of the intercalated cell. The coexpression of glycophorin A rescues surface expression and function of kAE1 G701D in the oocyte. The intercalated cell lacks glycophorin A. C. Dominant dRTA is exemplified by AE1 R589H. In the red cell, eAE1 is of normal abundance, surface localization, and function. In *Xenopus* oocytes, AE1 R589H exhibits only mildly diminished function. In the intercalated cell, kAE1 R589H acts as a dominant negative mutant, binding to and preventing surface accumulation of the WT AE1 polypeptide. D. A different mechanism of dominant dRTA is exemplified by AE1 R901X. AE1 901X is of normal abundance and function in red cells, and exhibits near normal function in oocytes. In transiently transfected MDCK cells, kAE1 R901X is present not only in the basolateral membrane, but also at or near the apical surface. In stably transfected cells, the mutant is present only in the apical membrane. The resultant functional short-circuiting of acid secretion could explain the dominant negative clinical phenotype. (Modified with permission from[199]). E. The recessive dRTA mutant AE1 G701D is rescued by coexpression glycophorin A in *Xenopus* oocytes. Bar graphs show $^{36}Cl^-$ influx into oocytes expressing wildtype kAE1 (black) or kAE1 G701D (white) compared with control (water-injected) oocytes (cross-hatched) in the absence (left graph) or presence of co-expressed glycophorin A (right bars). AE1 immunoflorescence shows AE1 G701D expression is absent from the oocyte surface (left inset) whereas coexpression with glycophorin A (right inset) rescues surface expression of kAE1 G701D (modified with permission from[483]). Lower right: AE1 immunoflorescence shows localization of dominant dRTA mutant AE1 901X. Unlike basolateral expression of wildtype kAE1 in stably (A) or transiently transfected, confluent MDCK cells (C, E), the dominant dRTA mutant AE1 R901X accumulates either at the apical membrane in stable transfectants (B) or at both apical and basolateral membranes in transiently transfected cells (D, F). *Modified with permission from*[473]*(A, B) and from*[102]*(C−F).*

and interactions of the N-terminal cytoplasmic domains of eAE1 and kAE1. Wildtype kAE1 surface expression was reduced by transiently coexpressed kAE1 R589H.[471]

MDCK cells offered the advantages of complex processing of the native N-glycan of heterologous AE1 and the possibility of trafficking in a polarized cell system. Low transient transfection efficiency[472] and variable rates of transgene extinction in stable transfectants[473] initially encountered in polarized MDCK cells were overcome by development of recombinant replication-deficient pseudotyped retrovirus,[474]

adenovirus,[103] and lentivirus vectors to boost infection efficiency, modulate toxic overexpression, and increase sensitivity of AE1 transgene immunodetection. Both nonpolarized and polarized MDCK cells overexpressing dominant dRTA kAE1 mutants R589H and S613F retained the mutant polypeptides in endoplasmic reticulum, with some protein also in lysosomes and other structures, and contrasted with basolateral localization of wildtype kAE1. Coexpression of epitope-tagged wildtype kAE1 with kAE1 dominant mutant R589H inhibited surface delivery and accumulation of wildtype protein, and accelerated its degradation.[103] Sections from a heavily scarred kidney resected from a heterozygous AE1 R589H dRTA patient revealed decreased frequency of Type A intercalated cells with reduced apical vH^+-ATPase staining, but AE1 staining was uninformative.[475] However, the well-preserved morphology of a clinically indicated renal biopsy from a dRTA patient heterozygous for AE1 S613F[469] revealed diffuse, decreased AE1 immunostaining with loss of basolateral localization, accompanied by reduced and vH^+-ATPase staining with loss of apical localization in Type A intercalated cells smaller in both number and size than in control kidney.[476] These human data are consistent with the dominant negative trafficking behavior of dominant negative dRTA kAE1 mutations polarized MDCK cells. The dominant dRTA phenotype contrasted with that of a Sjogren's

syndrome patient with dRTA, in which collecting duct immunoreactivity of both vH^+-ATPase and kAE1 was completely absent.[476]

The second trafficking mechanism by which heterozygous AE1 mutations give rise to dominant dRTA is mistargeting to the apical membrane, leading to a postulated apical HCO_3^- secretion that can short-circuit the normal vH^+-ATPase-mediated apical H^+ secretion (Fig. 54.10). AE1 dominant dRTA mutant 901X was expressed normally at the surface of red cells[297] and *Xenopus* oocytes,[283] but was retained in the endoplasmic reticulum of HEK-293 cells, where the mutant also trapped cotransfected wildtype kAE1.[297] kAE1 901X was similarly retained in MDCK cells grown on glass, but in transiently transfected filter-grown MDCK or rat IMCD cells kAE1 was present in both basolateral and apical membranes, in addition to intracellular membranes.[102] However, in stably transfected MDCK cells, AE1 901X accumulated exclusively in the apical membrane with apparent wildtype stability[473] (Fig. 54.12). AE1 dominant dRTA mutant G609R similarly localized in polarized MDCK cells more in the apical than basolateral membrane, in contrast to its normal surface expression in erythrocytes and *Xenopus* oocytes.[477]

Basolateral sorting of kAE1 does not require the sorting protein adaptin AP-1B.[102] A yeast two-hybrid screen recently identified adaptin AP-1A as interacting with the AE1 C-terminal Y904DEV907 sequence. The interaction was validated in HEK-293 cells, and knockdown of endogenous AP-1A reduced surface expression of kAE1.[478] Confirmation of the functional interaction of AP-1A with kAE1 in polarized epithelial cells is awaited. Another potential explanation for

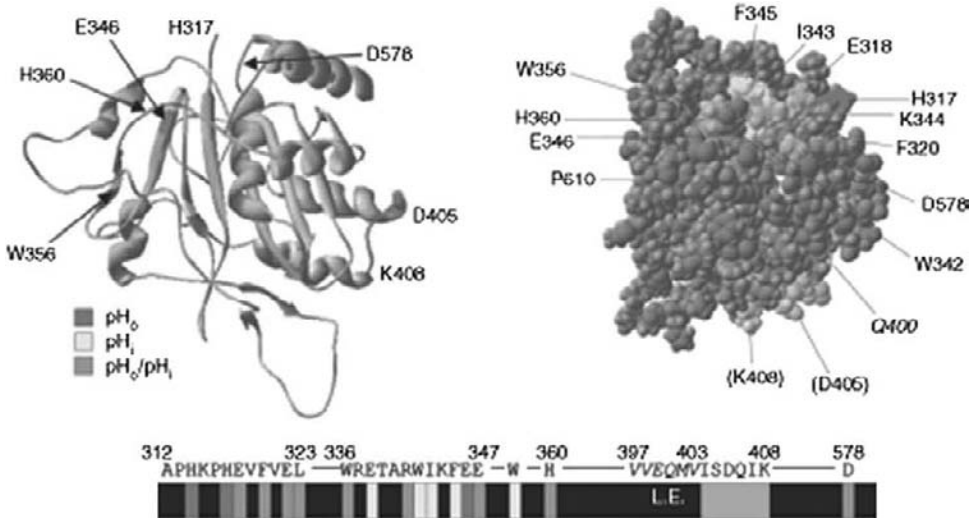

FIGURE 54.13 Amino acid residues of mouse Ae2 N-terminal cytoplasmic domain that contribute to anion transport regulation by extracellular (pH$_o$) and intracellular pH (pH$_i$). A. In each panel, red marks residues in which mutations alter regulation by pH$_o$ only, yellow marks residues in which mutations alter regulation by pH$_i$ only, and orange marks residues in which mutation alters regulation by both pH$_i$ and pH$_o$ *(from,*[171] *with permission).*

apical accumulation of dRTA AE1 mutant R901X is loss of the tyrosine phosphorylation site Y904, required along with Y359 for basolateral accumulation in polarized MDCK cells.[479] Identification of the responsible tyrosine kinase(s) and PTyr-dependent trafficking/scaffolding proteins of the Type A intercalated cell is awaited, and promises to provide more detailed understanding of the altered targeting of dominant dRTA mutant AE1 polypeptides. Whereas Y904 is conserved among AE1 orthologs, and in AE2 and AE3, Y359 is not conserved in AE2 and AE3. A parallel to the N-terminal YVEL motif important in the basolateral trafficking of chicken kidney AE1 variant AE1−4[480] has not been detected in human or mouse kAE1.

Both wildtype kAE1 and dominant negative mutants R589H and R901X are ubiquitinated, then deglycosylated (likely in the cytosol) prior to undergoing proteosomal degradation. The half-life of the mutant polypeptides is shorter than the 15−17 hour half-life of wildtype protein in polarized MDCK cells.[481] The mutant proteins can be partially rescued from ER retention (in the case of mutant R589H or from the apical surface and some ER retention (in the case of R901X) to the basolateral surface of polarized MDCK cells in the context of a mutation that prevents N-glycosylation. Partial basolateral surface rescue was achieved by inhibition of the ER-localized interaction between mutant polypeptides and the ER folding lectin chaperonin, calnexin by castanospermine inhibition of AE1 N-glycan trimming in the ER. Polarized cell exposure to the small molecule chemical chaperones MAL (an Hsc70 modulator) or to C3 or C4 (developed as CFTR ΔF508 correctors) also led to partial rescue of basolateral expression of dominant mutant polypeptides,[481] suggesting possible therapeutic approaches to dominant dRTA caused by AE1 mutations.

AE1-Associated Recessive dRTA

Recessive dRTA has been associated with twelve AE1 mutations found in homozygous or compound heterozygous patients (Table 54.3). Most cases have been reported from Thailand, Malaysia, and Papua-New Guinea, and were frequently accompanied by hematological dyscrasia and (in Thailand) a co-inherited hemoglobinopathy.[482,483] All mutants described to date appear to share a mechanism of intercalated cell-specific intracellular retention[103,483–485] (Fig. 54.10). The first described was AE1 G701D in homozygous patients with normal erythroid eAE1 abundance and anion transport activity.[483] However, both eAE1 and kAE1 forms of the G701D mutant were non-functional in *Xenopus* oocytes due to failure of surface expression. Coexpression in oocytes of the erythroid AE1-binding protein glycophorin A completely rescued functional surface expression of both erythroid and kidney forms of AE1 G701D[483] (Fig. 54.10). As glycophorin A is not expressed in kidney, recessive dRTA mutant AE1 G701D has a conditional recessive

phenotype: normal in the presence of glycophorin A but incapable of normal trafficking in its absence. In contrast, wildtype AE1 surface trafficking does not require glycophorin A, but is potentiated by it.[486]

Expression of kAE1 G701D in HEK-293 cells[487] and in polarized MDCK cells led to its intracellular retention in the Golgi compartment.[103] Consistent with the clinical phenotype of heterozygous family members, coexpressed wildtype kAE1 rescued kAE1 G701D to the basolateral surface of polarized MDCK cells.[103] Additional recessive dRTA AE1 mutants subsequently described[485] (Table 54.3) exhibited similar conditional recessive phenotypes. The anion transport activities of the recessive loss-of-function mutant ΔV850 and the clinically less severe loss-of-function dominant mutant A858D were each potentiated by coexpressed glycophorin A in *Xenopus* oocytes.

Multiple instances of AE1-linked dRTA arise from compound heterozygosity with one rare recessive dRTA allele and one common SAO allele. An example is the AE1 A858D/SAO compound heterozygote with very low erythroid anion transport activity despite half-normal eAE1 polypeptide content. Correspondingly, coexpression in *Xenopus* oocytes of AE1 SAO prevented glycophorin A rescue of AE1 A858D to the surface.[485] kAE1 SAO itself is retained inside polarized MDCK cells.[481] dRTA also results from AE1 compound heterozygosity for two rare dRTA alleles, as in AE1 A858D/ΔV850. AE1 A858D expressed alone in polarized MDCK cells was retarded in exit from endoplasmic reticulum but reached the basolateral membrane, whereas AE1 ΔV850 expressed alone was retained in the endoplasmic reticulum. The coexpressed mutants hetero-oligomerized and, although AE1 A858D slightly enhanced surface delivery of coexpressed *nonfunctional* AE1 ΔV850, ΔV850 decreased surface expression of the coexpressed partially *functional* AE1 A858D.[484]

Glycophorin A rescue experiments for recessive dRTA-associated AE1 mutants R602H, Q759H, and S773P have not been reported. AE1 S773P was discovered in a compound heterozygote dRTA patient with a G701D allele. Although the folding-defective mutant kAE1 S773P was retained and degraded in endoplasmic reticulum in HEK-293 cells,[488] the mutant trafficked at near wild-type levels to the basolateral membrane of polarized MDCK cells. Consistent with clinical phenotype, however, coexpression in MDCK cells of AE1 G701D with the S773P mutant impaired AE1 S773P expression at the basolateral membrane.[103] Neither inhibition of N-glycan processing, genetically engineered prevention of N-glycosylation, nor exposure to small molecule chemical chaperones MAL, C3, or C4 led to detectable rescue of basolateral surface expression for kAE1 SAO or recessive kAE1 mutant G701D.[481]

dRTA With Complete Absence of AE1 and AE1 Knockout Models

Heterozygosity for putative loss-of-function mutation AE1 V488M was diagnosed in a newborn child of two parents, each with mild hereditary spherocytosis due to heterozygosity for the same mutation.[107] The homozygous child was born with life-threatening hydrops fetalis and hemolytic anemia with poikilocytotic red cells devoid of AE1. Renal tubular acidosis was noted at age 3 months, and nephrocalcinosis shortly thereafter. Intensive support with frequent blood transfusion and bicarbonate supplementation allowed survival.

Mouse models of complete AE1 deficiency phenocopy the hydrops fetalis of complete AE1 deficiency in the human. Two engineered *ae1*$^{-/-}$ mouse models showed severe growth retardation, severe hemolytic anemia with spherocytosis and poikilocytosis, severe hypercoagulation syndrome, and death of most mice before weaning.[108,489,490] In red cells from both mouse models, the ultrastructure of the red cell cytoskeleton unexpectedly remained intact in the absence of Ae1, leading to the proposal that the associated membrane fragility arose from destabilization of bilayer lipid in the absence of the membrane's major intrinsic protein.[108,489] The hypercoagulable state was attributed to propensity of the increased fraction of Ae1$^{-/-}$ red cells with externalized annexin V, those likely undergoing premature cell death (eryptosis),[491] to activate the prothrombinase complex,[490] a mechanism apparently not applicable to human red cells.[491] The spontaneous mouse hemolytic anemia mutant *wan* is caused by homozygosity for the AE1 mutation Q85X, and is marked by no survival post-weaning. Decreased clinical severity on mixed strain backgrounds led to the demonstration of modifier genes for the severity of hemolytic anemia,[492] one of which maps near the β-spectrin locus.

The small surviving fraction of *ae1* −/− mice[108] included fertile males. This facilitated subsequent generation of sufficient numbers of weanlings to document at age 12 wks a syndrome of complete dRTA, with spontaneous metabolic acidosis disproportionately exacerbated by an acid load well tolerated by wildtype and heterozygous mice.[109] The acidosis was accompanied by inappropriately alkaline urine pH and by reduced Cl^-/HCO_3^- exchange activity in isolated medullary collecting ducts, with compensatory upregulation of a pharmacologically distinct Cl^-/HCO_3^- exchange activity of unknown identity. Intercalated cells devoid of Ae1 remained present and exhibited reduced abundance of both vH^+-ATPase and of pendrin, but mRNA levels of candidate basolateral Cl^-/HCO_3^- exchangers Ae4 and Slc26a7 were

unchanged. *ae1* −/− mice also exhibited nephrocalcinosis accompanied by hypercalciuria, hyperphosphaturia, and hypocitraturia. An unexpectedly severe urinary concentrating defect with mildly decreased renal function (possibly prerenal) was accompanied by increased inner medullary AQP2 largely retained intracellularly. Possible hypokalemia was masked by hemolysis, and severe renal hemosiderosis may have contributed to the mild renal insufficiency and concentrating defect.[109] Nonetheless, the *ae1*$^{-/-}$ mouse was the first mouse model of complete dRTA with genetic deficiency of a human dRTA gene product. Ongoing attempts to analyze mice with normal eAE1 expression together with selective kAE1 deficiency or kAE1 missense mutations will accelerate future studies of the development, course, and treatment of AE1 mutation-associated dRTA.

Dominantly inherited perinatal hemolytic anemia and apparent renal tubular acidosis in a bovine cohort was associated with the heterozygous mutation AE1 646X.[110] Red cells completely lacked AE1, and coexpressed AE1 R664X suppressed wildtype anion transport in *Xenopus* oocytes. Recombinant bovine AE1 R664X polypeptide and the wildtype/R664X hetero-oligomer in HEK-293 or K562 erythroleukemia cells exhibited endoplasmic reticulum-associated proteosomal degradation, independent of ubiquitination or N-glycosylation and without aggresome formation.[493] Metabolic acidosis in the heterozygous AE1 646X cattle was notably unaccompanied by compensatory respiratory acidosis,[110] consistent with the incomplete respiratory compensation noted in mice with renal tubular acidosis lacking either carbonic anhydrase 2[494] or AE1,[109] and consistent with the coordinate roles of both eAE1 and CA2 in the respiratory disposal of metabolic CO_2. Bovine AE1 R664X represents the most severe dominant negative spherocytosis mutation yet reported, thus far unique in its phenotypic expression in both red cells and kidney.

Ae1 mutations were isolated among chemically mutagenized zebrafish screened for anemia phenotypes. Three recessive loss-of-function alleles of AE1 deficiency in zebrafish with severely reduced erythropoiesis were partially rescued by either zebrafish or mouse *Ae1* cRNAs. The observation of a dyserythropoietic phenotype in Ae1a mutants led to discovery of an Ae1a requirement for normal cytokinesis late zebrafish erythroblasts, with a similar but less prominent effect detectable in bone marrow of the *ae1*$^{-/-}$ mouse.[43] However, dyserythropoietic changes have not been reported in human AE1-associated dominant hereditary spherocytosis, and the clinically distinct human congential dyserythropoietic anemias are unlinked to *AE1*. Neither AE1a nor AE2b[495] are expressed in zebrafish pronephric duct. The systemic physiological functions of zebrafish pronephric duct Ae[42] (Fig. 54.14) remain unexplored.

KNOCKOUT MOUSE MODELS OF DEFICIENCY OF AE2/SLC4A2 AND AE3/SLC4A3

Complete knockout of the *ae2* gene in the mouse allows live births, but severe growth retardation and failure to thrive leads to death before weaning.[132] Gastric mucosal hypoplasia and achlorhydria was associated with reduced numbers of H^+,K^+-ATPase-positive parietal cells with underdeveloped secretory canaliculi lacking AE2. Knockout mice were also deaf (consistent with AE localization in cochlea), ataxic, edentulous,[132] and osteopetrotic[135] consistent with an essential role for AE2 in osteoclast function. A similar, recessive osteopetrotic phenotype is shown by Red Angus cattle with a homozygous large deletion of the AE2 gene region encoding exons 2 and 3.[496] However, genome-wide association studies have not yet implicated human AE2 as a risk modifier for low bone density.

An independently generated AE2 knockout mouse was devoid of AE2a, AE2b1, and AE2b2,[136] but appears to have retained expression of AE2c isoforms and possibly others expressed as a compensatory response ($ae2_{a,b}^{-/-}$ mice). This otherwise grossly healthy mouse model exhibited male infertility, consistent with AE2 localization in epididymis,[497] and osteopetrosis in long bones but not in calvariae.[134] Although basal gastric acid secretion was unimpaired in four month old mice, carbachol/histamine-stimulated secretion was reduced 70%, and was accompanied by increased parietal cell turnover without apoptosis.[498] Thus, the gastric-specific AE2c1 isoform is not sufficient for normal murine gastric acid secretion.

Although modest shRNA suppression of AE2 abundance in normal rat cholangiocytes reduced both unstimulated and secretin-stimulated Cl^-/HCO_3^- exchange,[499] biliary flow and secretion of both HCO_3^- and bile acids were increased rather than decreased in $ae2_{a,b}^{-/-}$ mice compared to wildtype littermates.[500] This observation, parallels the increased pancreatic HCO_3^- secretion observed in mice lacking the apical pancreatic ductal Cl^-/HCO_3^- exchanger slc26a6[501,502] and is consistent with the elevated cAMP levels in $ae2_{a,b}^{-/-}$ murine embronic fibroblasts, which reflect activation of bicarbonate-sensitive soluble adenylyl cyclase by the pH_i elevation secondary to loss of physiological AE2-mediated acid loading.[503] $ae2_{a,b}^{-/-}$ mice exhibit splenomegaly and immune dysregulation, and most develop

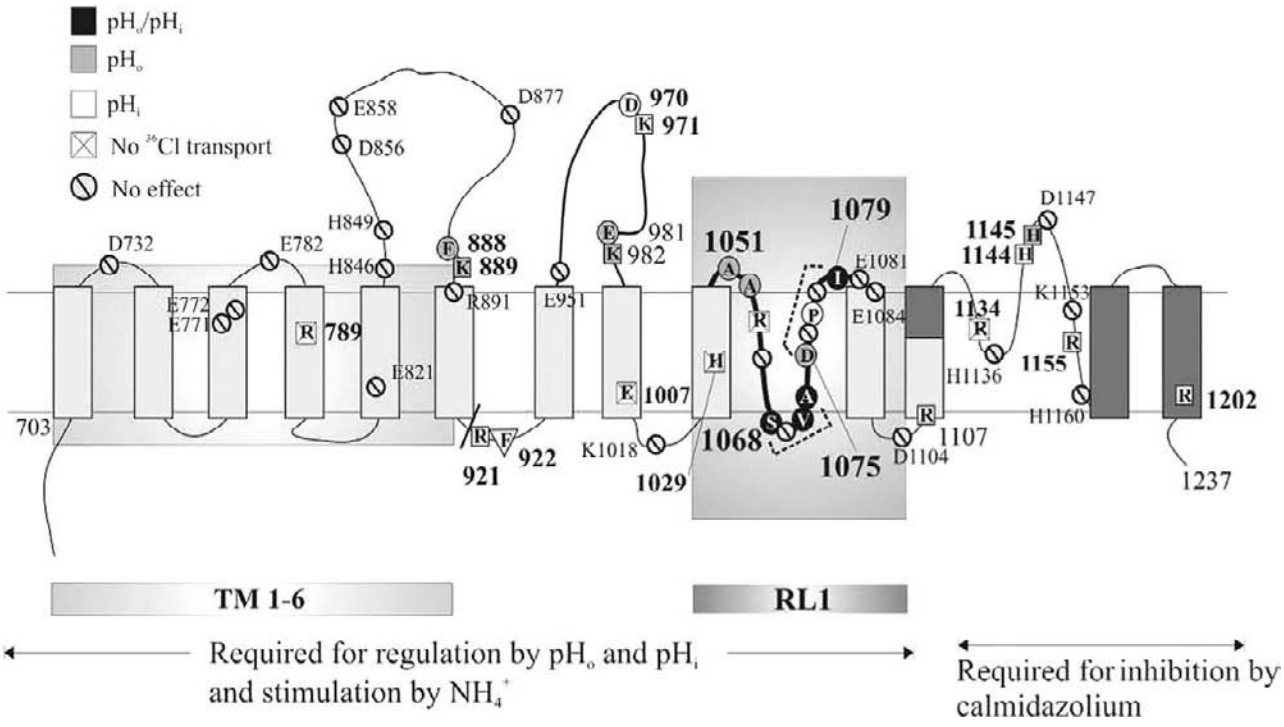

FIGURE 54.14 Mouse Ae2 transmembrane domain (TMD) residues involved in regulation of anion exchange. Re-entrant loop (RL1) in the Ae2 transmembrane domain is important for acute regulation of anion exchange by pH. Shaded areas indicate transmembrane (TMD) subdomains and individual amino acids identified from mutagenesis studies that contribute in a critical way to acute regulation of AE2 by pH, simulation by Na_4^+ and required for inhibition by calmidazolium. The indicated critical amino acids in the RL1 likely interact with as yet unidentified residues in TMD 1−6 or/and in the cytoplasmic N-terminal domain and contribute to the AE2 "pH sensor" function that regulates anion exchange. TMD residues involved in regulation by pH_o are gray, those involved in regulation by pH_i are in white and residues involved in regulation by both pH_o and pH_i are in black. Bisected open circles indicate residues for which mutation did not alter regulation of AE2 by pH. Boxes with X indicate residues for which mutation reduced transport activity below levels required for study of inhibitory regulation *(modified from,[377] with permission).*

anti-mitochondrial antibodies and other auto-immune abnormalities reminiscent of those in human patients. About one third of *ae2*$_{a,b}^{-/-}$ mice develop portal inflamation.[504,505] Proximal colonic epithelium of *ae2*$^{-/-}$ mice shows reduced cAMP-stimulated Cl^- secretion by proximal colonic epithelium,[506] and AE2 knockdown also reduces cAMP-stimulated Cl^- secretion by Calu3 cells.[507] Thus, in some secretory epithelial tissues, Ae2 is the predominant basolateral Cl^- loader. No renal phenotype has yet been reported in either *ae2* knockout mouse strain.

The *ae3*$^{-/-}$ mouse was grossly normal despite wildtype AE3 expression by or before gestational day 11. However, the *ae3*$^{-/-}$ mouse exhibited increased susceptibility to pharmacologically-induced generalized seizures, with increased seizure-associated mortality. The lowered seizure threshold was associated with complete absence of wildtype DIDS-sensitive Cl^-/HCO_3^- exchange activity in CA3 neuronal cell bodies monitored in hippocampal slices,[155] and unaccompanied by compensatory changes in brain mRNA levels of other Slc4 genes, or of Slc26a11, Slc12 Cl^- cotransporters, or Slc9 Na^+/H^+ exchangers. This murine seizure phenotype reinforces the previously documented association of human AE3 polymorphism A867D with seizure history among multiplex families with idiopathic generalized epilepsy.[508] In HEK-293 cells, AE3 A867D exhibited reduced function that was not explained by decreased cell surface abundance.[509]

Ae3-/- mice develop retinal degeneration after four to six months of age,[510] suggesting important homeostatic roles for Ae3 in retinal pigment epithelial cells, muller, and horizontal cells. Late-onset, recessive progressive retinal atrophy in Golden Retriever dogs was recently shown to cosegregate with a frameshift terminator mutation at transmembrane domain residue E868 (661 in cAE3).[511] Although *ae3*$^{-/-}$ mice have not revealed a cardiac phenotype, loss of AE3 expression in the hypertrophic cardiomyopathy transgenic mouse model expressing cardiac α-tropomyosin E180G greatly accelerated cardiac decompensation.[512] No renal phenotype has been reported in the *ae3*$^{-/-}$ mouse.

CONCLUSION

Transmembrane, transepithelial, and systemic transport of HCO_3^- and CO_2 is central to body pH and volume homeostasis. The Na^+-independent, electroneutral Cl^-/HCO_3^- exchangers AE1/band 3 and the related AE2 and AE3 polypeptides of the SLC4 gene family play central roles in these processes, along with Na^+-dependent SLC4 HCO_3^- transporters, and with anion transporters of the SLC26 gene family. The SLC4/AE anion exchangers regulate intracellular pH and, through their polarized localization in renal and other epithelial cells, regulate compartmental and systemic pH. SLC4/AE anion exchangers also regulate cell volume and modulate the cellular equilibrium potential for Cl^-, thus contributing to determination of driving forces for multiple ion transporter pathways. In polarized epithelial cells of kidney and other tissues, anion exchange in concert with cation transport can mediate transepithelial solute secretion or reabsorption.

These physiological functions come to the fore in tissues in which deletion or deficiency of an AE anion exchanger unmasks a lack of functional redundancy. Such is the case with AE1 in the human diseases hereditary spherocytosis, and heritable distal renal tubular acidosis. Hereditary stomatocytosis is an example of mutations that combine loss-of-fnction with gain of novel function (cation permeability). Genetic manipulation of AE2 and AE3 in mice, along with *in vitro* experiments, have suggested human AE2 as a candidate risk modifier gene determining bone density, gastric acidification and differentiation, male fertility, and epithelial secretion, and human AE3 as a candidate risk modifier for seizure disorder, late-onset blindness, and heart failure.

Recent advances in recombinant DNA technology, genome sequencing, model system genetic engineering to modulate gene expression in cultured cells and intact animals, structure determination, and single molecule spectroscopy have each contributed to rapidly accelerating progress in our understanding of the structure and function of SLC4/AE anion exchangers. The coming years should provide atomic-level insight into the structure of an SLC4 transmembrane domain, allowing visualization of the anion translocation pathway(s). Such structure will encourage reevaluation of existing kinetic data, revising mechanistic models that reconcile the requirements of the highest known rates of non-channel ion transport with very high anion:cation selectivity, broad anion specificity, and low substrate anion affinity. Ongoing discovery and characterization of AE-binding proteins will increase understanding of AE regulation. Together, the resulting insights will enhance our growing understanding of the way in which AE anion exchanger function at the cell and organ levels fits into the "systems biology" of cell and organismic pH, Cl^- and volume regulation.

To maintain acid–base balance, the renal tubules secrete hydrogen ions into the lumen at a rate equal to the sum of extrarenal acid generation and bicarbonate filtration. In this chapter we review the cellular mechanisms responsible for transepithelial hydrogen secretion along the nephron and describe the regulators of these processes.

PROXIMAL TUBULE

The fluid entering the proximal tubule is the glomerular ultrafiltrate, which is in Donnan equilibrium with plasma and has a bicarbonate concentration of approximately 25 mEq/L. The proximal convoluted tubule secretes H ions that acidify the luminal fluid leading to the reabsorption of approximately 14 apart from 75% of filtered bicarbonate and decreasing luminal bicarbonate concentration to 5–10 mEq/L and luminal pH from 7.4 to ~6.8. The proximal straight tubule has a smaller capacity for H secretion, but also contributes to bicarbonate reabsorption. With an acidic luminal fluid (relative to the peritubular space) and a relatively small transepithelial voltage [−2 (early proximal tubule) to +2 (late proximal tubule) mV], transepithelial H secretion requires active transport.

The proximal tubule cell voltage is between −50 and −70 mV relative to the peritubular fluid and cell pH of between 7.15 and 7.30.[1–5] Using these values, it can be calculated that protons (hydrogen ions) can enter the cell across the basolateral membrane passively (or equivalently base can passively exit the cell across the basolateral membrane), while H ion secretion across the apical membrane from the cell to the luminal fluid is against the electrochemical gradient, and thus, requires active transport.

Apical Membrane H/HCO_3 Transport Mechanisms

Proton Secretion vs *HCO_3 Absorption*

Net acidification of the tubular fluid may be mediated by apical membrane H secretion or HCO_3 absorption. These two processes, shown in Figure 55.1, have been distinguished using the disequilibrium pH. The mechanisms shown in Figure 55.1 involve two reactions in series. The association/dissociation of H_2CO_3 (carbonic acid) to or from H and HCO_3 (reaction 1) occurs instantaneously, while the association/dissociation of H_2CO_3 to or from CO_2 and H_2O (reaction 2) is very slow. Carbonic anhydrase catalyzes the latter reaction such that in its presence all constituents are at equilibrium. In the absence of luminal carbonic anhydrase, the second reaction will not be at equilibrium and the relative concentrations of the substrates can be used to determine the direction in which the reactions are occurring, and, thus, whether there is direct H secretion or direct HCO_3 absorption.

If carbonic anhydrase is present in the lumen, H_2CO_3 will be in equilibrium with CO_2 and H_2O, and H_2CO_3 concentration will be that calculated from the concentration of CO_2 and the equilibrium constant for the second reaction. Equivalently, using the equilibrium constants for the above reactions, the

concentrations of H, HCO_3 and CO_2 will be those predicted for equilibrium. But, if carbonic anhydrase is absent from the luminal fluid and H secretion is the mechanism by which the tubular fluid is acidified (Figure 55.1a), reactions 1 and 2 will move to the right, but the H_2CO_3 concentration will be greater than that predicted for equilibrium with CO_2, and H and HCO_3 concentrations, while in equilibrium with H_2CO_3, will also be greater than that predicted for equilibrium with CO_2. Conversely, if luminal carbonic anhydrase is absent and HCO_3 absorption is the mechanism by which the tubular fluid is acidified (Figure 55.1b), luminal H_2CO_3, H, and HCO_3 concentrations will all be lower than that predicted for equilibrium with CO_2.

Using slightly different approaches, three groups of investigators have examined this issue.[6–8] All found that under baseline conditions the system is in equilibrium and measured *in situ* pH (H ion concentration) is equal to the predicted equilibrium pH. However, after systemic infusion of a carbonic anhydrase inhibitor luminal pH drops below that predicted for equilibrium (an acid disequilibrium pH), demonstrating secretion of H (Figure 55.1a).

These results provide two extremely important conclusions. First, they demonstrate that the mechanism(s) responsible for luminal fluid acidification involve H secretion rather than HCO_3 absorption across the proximal tubule apical membrane. This conclusion has been confirmed by numerous studies (see below) that have directly identified H rather than HCO_3 transport mechanisms on the apical membrane. The second conclusion of equal importance is that the luminal fluid is normally exposed to carbonic anhydrase. This luminal carbonic anhydrase allows secreted H ions to be buffered quickly, preventing an acid disequilibrium pH that would oppose continued H secretion. This latter point is discussed further below.

Mechanisms of Apical Membrane H/HCO_3 Transport

The discussion below first describes the mechanisms that mediate apical membrane H secretion and then discusses possible backleak mechanisms. The description of the H secretory mechanisms is oriented along lines of coupling to metabolism. The term *primary active transport* describes transport mechanisms directly coupled to the consumption of metabolic energy (ATP), such as the H-ATPase. *Secondary active transport* refers to a transporter that couples the transport of H to that of a second ion, for which a favorable driving force is established by another transporter that is directly coupled to energy consumption. An example of secondary active transport is Na/H exchange. *Tertiary active transport* refers to the presence of three transporters functioning in series, where the first transporter is directly coupled to energy utilization and establishes a favorable electrochemical gradient for molecular species *A*. A second transporter is a coupled transporter that uses the electrochemical gradient for species *A* to establish a favorable electrochemical gradient for species *B*, and the third transporter then uses the electrochemical gradient for species *B* to transport acid or base (species *C*) against its electrochemical gradient. There is now good evidence that all of these mechanisms are present in the proximal tubule. The primary and secondary transport mechanisms play key roles in net acid secretion, while the tertiary transport mechanisms most likely contribute significantly to NaCl reabsorption, and play a minimal role in net acid secretion.

Primary Active Transport: H-ATPase

Five lines of evidence suggest the presence of an apical membrane H translocating ATPase. These include the demonstration of: (1) an H translocating ATPase in apical membrane vesicle preparations, (2) a role of an H-ATPase in the defense of cell pH against an acid load, (3) electrogenic H secretion in the microperfused proximal tubule, (4) apical membrane immunohistochemical labeling with antibodies against purified vacuolar H-ATPase subunits, and (5) a component of HCO_3 absorption that cannot be attributed to secondary or tertiary active H secretion.

Kinne-Saffrin and Kinne were the first to demonstrate the presence of HCO_3-stimulated H-ATPase activity and ATP-dependent H translocation in brush border membrane vesicles.[9–11] This H translocating ATPase is not of mitochondrial origin as it was insensitive to oligomycin.

In the rat proximal tubule microperfused *in vivo* symmetrically with Na-free solutions, Yoshitomi et al. found that cell pH decreases and then returns to control levels.[12] Similarly, Alpern found that rat proximal tubules perfused symmetrically with Na-free solutions develop an alkaline cell pH in the steady state.[1] Both of these observations are best explained by the presence of a Na-independent alkalinizing mechanism in these cells. Kurtz more specifically examined this phenomenon in the S3 proximal tubule perfused *in vitro* utilizing the fluorescent measurement of cell pH.[13] Following an acute intracellular acid load (NH_3/NH_4^+ prepulse), cell pH is rapidly defended in the complete absence of Na. This cell alkalinization is inhibited by luminal dicyclohexylcarbodiimide (DCCD) and N-ethylmaleimide (NEM), two inhibitors of vacuolar H-ATPases. Nakhoul et al. demonstrated that S3 proximal tubules, acidified by removal of luminal and peritubular Na, returned their cell pH to values more alkaline than control cell pH.[14] In these studies, the cell alkalinization was not inhibited by DCCD. All of these studies demonstrate the ability of the proximal tubule cell to transport protons out in response to cell acidification in the complete absence of extracellular Na. Based on our current knowledge of transporters capable of active H efflux from cells, the only Na-independent mechanism that has been identified is the H-ATPase. However, the lack of specificity of the inhibitors, DCCD and NEM, precludes a definitive interpretation from the above studies.

A third line of evidence suggesting the presence of an apical membrane H-ATPase is the demonstration of electrogenic H secretion. Fromter and Gessner first reported that when luminal and peritubular capillaries of rat proximal convoluted tubules are perfused at fast rates with bicarbonate Ringer's solutions (containing no organic components), transepithelial voltage is +1 mV in the early proximal tubule and +0.2 mV in the late proximal tubule.[15] This lumen positive voltage is not affected by ouabain but is inhibited by acetazolamide, a carbonic anhydrase inhibitor.[16] These results demonstrate electrogenic H secretion. While they are consistent with an apical membrane electrogenic H transporting mechanism, they are also consistent with a basolateral membrane electrogenic H/HCO_3 transport mechanism in series with any apical membrane conductance that need not mediate H transport.

Perhaps the best evidence for an apical membrane H-ATPase is the demonstration of the labeling of the apical membrane with antibodies against the purified vacuolar H-ATPase.[17,18] High resolution immunogold labeling demonstrated that the H-ATPase is located at the neck of the apical invaginations between the clathrin-coated domains and the microvilli.[17,19]

Lastly, as will be discussed below (see "Role of Apical Membrane H/HCO_3 Transport Mechanisms in Transepithelial H Secretion"), there is good evidence that a component of proximal tubule HCO_3 absorption exists that is not attributable to secondary or tertiary active transport mechanisms.[20–22]

Based on all of the above, there is strong evidence for the existence of a proximal tubule apical membrane H translocating ATPase of the vacuolar type that contributes to luminal acidification. Its molecular composition was reviewed, this will be described in greater detail later in this Chapter under the "Distal Nephron," and its role in proximal tubule function will be discussed below.[19,23–25]

Secondary Active Transport: Na/H Exchange

The apical membrane Na/H antiporter mediates most of $NaHCO_3$ absorption and all of transcellular NaCl absorption in the proximal tubule.[22,26] Na/H antiporters represent a form of secondary active transport in that they are not directly coupled to metabolism, but rather use the low cell Na concentration established by the ouabain-sensitive basolateral membrane Na,K-ATPase to drive the 'uphill' extrusion of protons. Na/H antiporters are inhibited by amiloride and more potently by amiloride analogs with hydrophobic substitutions at the 5-amino nitrogen atom.[27] Three pieces of evidence are consistent with a Na/H antiporter on the proximal tubule apical membrane.

Murer, Hopfer and Kinne were the first to demonstrate that apical membrane vesicles prepared from rat renal cortex possess Na/H antiporter activity.[28] The antiporter acidifies the external medium in response to an inwardly directed Na gradient, and an outwardly

directed H gradient drives ^{22}Na uptake. The Na/H antiporter is coupled in a 1:1 manner such that transport is electroneutral. Similar results were reported by Warnock et al. and by Kinsella and Aronson.[29,30]

Subsequent studies in vesicles demonstrated that the apical membrane Na/H antiporter displays saturation kinetics with respect to external Na with a K_{Na} of approximately 5–15 mEq/l at pH 7.5.[29,30] External protons compete with external Na for a single site such that increases in external H concentration decrease the apparent affinity for Na, the K_H is 35 nM.[31] The Na/H antiporter is inhibited by amiloride and lithium. Kinsella and Aronson showed that lithium and amiloride compete with Na at the external site and Ives et al. showed that the inhibition by lithium and amiloride involves both competitive and noncompetitive interactions.[32,33,34] As will be discussed below, the Na/H antiporter is exquisitely sensitive to the H concentration on the inside (cytoplasmic side) of the vesicle.[35]

An apical membrane Na/H antiporter has also been demonstrated in the intact tubule by measuring the effect of luminal Na on cell pH. Boron and Boulpaep measured cell pH using a pH-sensitive microelectrode in the *in vitro* perfused salamander proximal tubule and found that following an acid load cell pH recovery is accelerated in the presence of luminal Na, an effect that is blocked by luminal amiloride.[36] Sasaki et al. measured cell pH in the *in vitro* perfused rabbit proximal straight tubule using a pH sensitive microelectrode and showed that luminal Na removal and readdition causes cells to acidify and realkalinize, respectively.[4] Alpern and Chambers measured cell pH in the *in vivo* perfused rat proximal convoluted tubule microfluorimetrically and found similarly that luminal Na removal causes cell acidification and Na readdition causes cell alkalinization.[37] In the studies of Sasaki et al. and Alpern and Chambers, the cell pH change was blocked by amiloride and by amiloride analogs.[37,4]

The last line of evidence supporting the existence of an apical membrane Na/H antiporter is the demonstration of the dependence of HCO_3 absorption on Na transport. In the *in vivo* microperfused rat proximal convoluted tubule and the *in vitro* microperfused rabbit proximal convoluted tubule and proximal straight tubule, HCO_3 absorption is almost entirely inhibited by removal of Na from luminal and peritubular fluids or inhibition of the Na,K-ATPase.[20,38–41] As will be discussed below, these results suggest a role for the Na/H antiporter in HCO_3 absorption, but are complicated by other possible interpretations. A more convincing result is inhibition of HCO_3 absorption by addition of amiloride to the luminal fluid.[20–22]

In summary, the above studies provide strong evidence for an apical membrane amiloride-sensitive, electroneutral Na/H antiporter in the proximal tubule.

Sardet et al. was the first to clone a complementary DNA (cDNA) for a human amiloride-sensitive Na/H antiporter.[42] Based on the sequence, the Na/H antiporter is predicted to be a 99 kDa protein with an amino terminal domain, 10–12 transmembrane spanning regions, and a carboxy terminal hydrophilic region representing a large cytoplasmic tail. Three putative N-linked glycosylation sites (aa 75, 370, and 410) have been identified and the C-terminus possesses several potential phosphorylation sites. The isoform encoded by this cDNA is now referred to as NHE1.

Subsequent studies from multiple labs have identified at least 8 other isoforms, with 3 isoforms (NHEs 1, 3, and 8) expressed in the proximal tubule.[43–46] NHE1 is ubiquitously expressed with few exceptions, and is probably the most important isoform for cell pH and volume defense, cell growth, migration, adhesion, and other 'housekeeping' functions. In the proximal tubule cell, NHE1 is expressed on the basolateral membrane. Haggarty et al. demonstrated that the apical membrane Na/H antiporter of LLC-PK_1 cells (proximal tubule cell line) has an IC_{50} of 13 μM for EIPA (ethylisopropylamiloride) (classified as amiloride-resistant), whereas the basolateral membrane Na/H antiporter has an IC_{50} of 44 nM (amiloride sensitive).[47] The inhibitor sensitivity of the LLC-PK_1 apical membrane transporter is similar to that found in apical membrane vesicles prepared from renal cortex, while the inhibitor sensitivity of the basolateral membrane Na/H antiporter is similar to that of the "housekeeping" isoform.[48–50]

Substantial evidence suggests that NHE3 is the apical membrane Na/H antiporter of the proximal tubule. (1) Immunohistochemical studies have localized NHE3 to the apical membrane of the proximal tubule and thick ascending limb (Figure 55.2).[51,52] (2) NHE3 mRNA is highly expressed in kidney cortex.[53,54] (3) NHE3 is inhibited by amiloride, amiloride analogs, and HOE694, with sensitivities similar to that of the apical membrane Na/H antiporter.[48,49,55](4) In cultured cells and in intact animals, regulation of NHE3 protein and mRNA abundances by glucocorticoids, thyroid hormone, and acidosis parallels regulation of the proximal tubule Na/H antiporter.[56–61] (5) In cultured cells regulation of NHE3 activity (defined as EIPA resistant activity) parallels regulation of the proximal tubule apical membrane Na/H antiporter in that both are stimulated by angiotensin II and endothelin,[62,63] and both are inhibited by parathyroid hormone and protein kinase A.[64] (6) Lastly, mice in which the NHE3 gene has been knocked out develop a mild metabolic

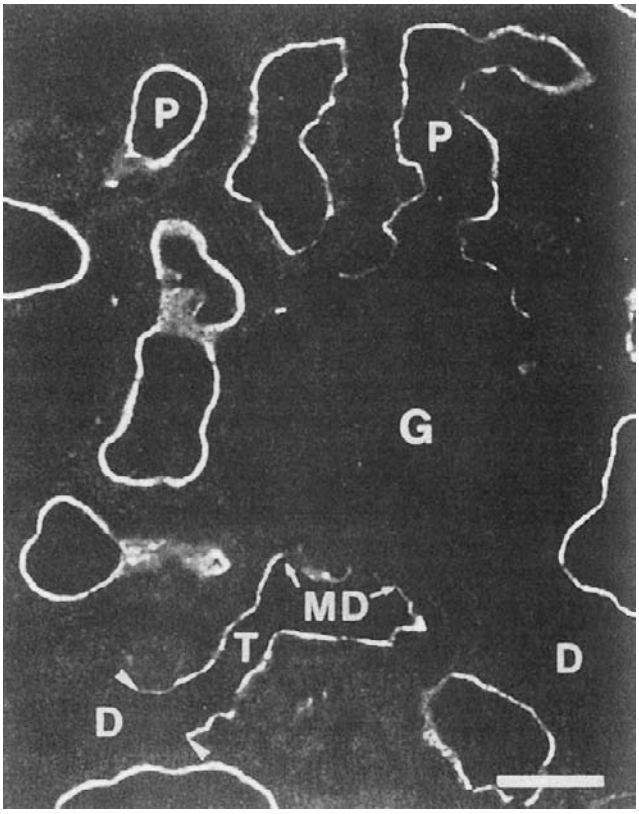

FIGURE 55.2 Immunohistochemical localization of NHE3 in rat kidney cortex. NHE3 is expressed on the apical membrane of the proximal tubule (*P*) and thick ascending limb (*T*), but is not expressed in the distal convoluted tubule (*D*) or glomerulus (*G*). (*From Amemiya M, Loffing J, Lotscher M, Kaissling B, Alpern RJ, Moe OW. Expression of NHE-3 in the apical membrane of rat renal proximal tubule and thick ascending limb. Kidney Int 1995,48:1206-1215, with permission.*)

acidosis and proximal tubule HCO_3 absorption is inhibited by 61%.[65,66]

In NHE3 null mice, about 60% of the remaining HCO_3 absorption is inhibited by bafilomycin, a vacuolar H-ATPase inhibitor, demonstrating a significant role for the H pump in mediating NHE3-independent HCO_3 absorption.[66] The mechanism of H secretion mediation of the remaining 40% of HCO_3 absorption remains controversial. A small EIPA-sensitive component of HCO_3 absorption was observed by some, but not all labs, in mice null for both NHE2 and NHE3, suggesting expression of another Na/H antiporter isoform.[67,66] In support of expression of another NHE isoform, Aronson's group demonstrated expression of an invertebrate NHE isoform (NHE8) in the proximal tubule and localized expression to the apical membrane by *in situ* hybridization, immunoblotting, and immunofluorescence microscopy.[68,69] Apical membrane NHE8 is highly expressed in neonates, likely accounting for much of the NHE activity when apical membrane NHE3 protein expression is scant at this age.[70,71] In both neonatal mice and rats, acid feeding-induced increases in NHE activity are prevented by a dose of EIPA that inhibits NHE8, but not NHE3 activity, and both NHE3 and NHE8 apical membrane protein abundances are increased.[72] With maturation apical membrane expression switches from predominately NHE8 to NHE3 expression, but total cortical NHE8 expression is higher than in the neonatal proximal tubule, suggesting that NHE8 may serve predominantly as an intracellular organelle exchanger in adults.[71] Regulation of this maturational switch appears to be under endocrine control, with both thyroid hormone and glucorticoids being responsible.[71,73,74] However, studies in senile rats provide support for NHE8 contributing to apical membrane Na/H exchange even in the adult by the finding that age-related decreases in proximal acidification occur without changes in NHE3 or H-ATPase expression, but with decreased abundance of both NHE8 mRNA and protein.[75]

Molecular biological studies have provided some characterization of NHE3. The protein has 12 transmembrane domains and a large cytoplasmic C-terminal domain. Transmembrane domain IV is implicated in ion transport, with amiloride inhibition mediated by transmembrane domain IX, and regulation of transporter activity mediated by the C-terminal tail.[76] In the C-terminal tail are binding domains or phosphorylation sites for NHERF [required for cAMP inhibition of NHE3 through EPAC (exchange protein directly activated by cAMP)-dependent and PKA-dependent mechanisms), CHP [(calcineurin homologous protein) involved in ezrin-dependent increases in NHE3 abundance and constitutive function], casein kinase 2 (involved in exocytic and delivery of newly synthesized protein to the membrane surface), PKA phosphorylation sites (which when phosphorylated by PKA do not alter NHE3 activity).[77–81] In addition there is evidence for novel phosphorylation sites that when dephosphorylated by a calyculin A-sensitive phosphatase (likely PP1) stimulate NHE3 activity. It is likely that these sites are functionally significant, but their effect masked by the net contribution of other known phosphorylation sites.

Tertiary Active H Transport

Aronson was the first to propose that active H extrusion could be mediated by tertiary active transport.[82] Siebens and Boron first demonstrated such a process in the Ambystoma proximal tubule perfused *in vitro*.[83] This segment, which contains a basolateral membrane Na,K-ATPase, possesses an apical membrane Na/lactate cotransporter and a basolateral membrane lactate/hydroxyl exchanger (or equivalently an H/lactate

cotransporter). These transporters working in series could effect the active extrusion of protons, but the proton extrusion would be across the basolateral membrane.

Nakhoul and Boron found evidence for such a system in the S3 segment of the rabbit proximal tubule.[14,84] This segment, which contains a basolateral membrane Na,K-ATPase, possesses an apical membrane Na/acetate cotransporter, and pathways for acetic acid movement (equivalent to H/acetate cotransport or acetate/OH countertransport) on the apical and basolateral membranes. The acetic acid pathways may merely represent nonionic diffusion across the lipid bilayer rather than a specific transporter. With this model, the Na,K-ATPase establishes a low cell Na concentration that provides a driving force for the Na/acetate cotransporter, mediating acetate uptake across the apical membrane. The high cell acetate concentration can then drive protons (equivalently as acetic acid nonionic diffusion, H/acetate cotransport, or acetate/OH countertransport) out across the apical or basolateral membrane.

Nakhoul et al. showed that this system participates in the defense of cell pH against an acid load. The role of this system on transepithelial H secretion or transepithelial acetate transport depends on whether the "acetic acid" exits across the apical or basolateral membrane. The contribution of tertiary active transport systems to transepithelial H secretion was addressed by Geibel et al. who demonstrated that in tubules incubated in the absence of CO_2/HCO_3, acetate stimulates transepithelial H secretion, but in tubules perfused in the presence of CO_2/HCO_3, acetate addition inhibits rates of transepithelial H secretion.[85] These data suggest that the acetate tertiary active system does not contribute significantly to transepithelial H secretion under physiologic conditions.

Chloride/Base Exchange

The previous sections have discussed mechanisms responsible for active H extrusion. The proximal tubule also possesses a number of pathways that lead to the net backleak of acid from the lumen into the cell across the apical membrane. These transporters are chloride-dependent and exchange chloride (moving from lumen to cell) for another anion, such as OH, HCO_3, formate, or oxalate (moving from cell to lumen, equivalent to a backleak of acid).[43] Evidence for such transport on the apical membrane has come from several studies.

Lucci and Warnock were the first to suggest the presence of apical membrane anion exchange.[86] In *in vivo* microperfused rat proximal tubule, NaCl absorption is inhibited by luminal addition of disulfonic stilbenes or high doses of furosemide (10^{-3} M), agents that inhibit the red cell Cl/HCO_3 exchanger. Baum also found in the *in vitro* perfused rabbit proximal convoluted tubule that luminal addition of disulfonic stilbenes inhibits Cl absorption.[87]

Using apical membrane vesicles isolated from rabbit renal cortex, Warnock and Yee demonstrated that a pH gradient (inside pH greater than outside pH) drives ^{36}Cl uptake into vesicles.[88] Shiuan and Weinstein found similar results.[89] Both groups found that pH gradients drive Cl uptake even in the presence of a voltage clamp, suggesting direct chemical coupling of Cl and base transport. Burnham et al. found similar results measuring the effect of Cl gradients on proton transport measured by acridine orange.[90] Chen et al. demonstrated Cl/OH exchange using a Cl-sensitive fluorescent dye to measure Cl transport.[91] On the other hand, Seifter et al. showed that when apical membrane vesicles are voltage clamped, pH gradients do not drive Cl uptake.[92] Other investigators have also been unable to demonstrate Cl driven H transport using acridine orange.[93,94] The reason for this discrepancy is not clear, but is most likely due to the low level of Cl/OH exchanger activity. Even those investigators who demonstrated Cl/OH exchanger activity found that it is far less than Na/H antiporter activity. Cl/OH exchange in vesicles is inhibited by disulfonic stilbenes.[89,91]

Karnisky and Aronson showed that formate gradients are able to drive the countertransport of Cl, and Cl gradients are able to drive the countertransport of formate in rabbit renal apical membrane vesicles.[95,96] The rate of this transporter is far greater than that found by other investigators for Cl/OH exchange. Similar evidence was found for a Cl/oxalate exchanger.[95] Based on this they proposed that the physiologically relevant Cl/base exchangers were Cl/formate and Cl/oxalate exchangers.

Measuring cell pH microfluorimetrically in the *in vivo* perfused rat proximal convoluted tubule, Alpern showed that if basolateral cell pH defense mechanisms are inhibited, changes in luminal Cl concentration affect cell pH in a manner consistent with Cl/base exchange.[97] If 1 mM formate is added to luminal and peritubular solutions, the effect of Cl removal and addition increases 3-fold and all effects of luminal Cl substitution are blocked by addition of DIDS to the luminal fluid. Similar results were found by Baum in the *in vitro* perfused rabbit proximal convoluted tubule.[98] Thus, these studies demonstrate Cl/base exchange, and confirm the vesicle results, namely Cl/OH and Cl/formate exchange with Cl/formate exchange activity being greater than Cl/OH exchange activity.

Further support for these anion exchangers is derived from volume flux measurements. The addition of formate or Cl to the luminal fluid increases the

proximal tubule volume and Cl absorption.[99,100] This increase is inhibited by DIDS, an anion exchange inhibitor, suggesting that NaCl absorption is mediated by parallel Na/H and Cl/base exchangers with the H and base recycling. Support for this model comes from the observation that amiloride inhibits Cl absorption in the absence of added formate or oxalate, and that EIPA inhibits the formate-induced stimulation of Cl absorption.[26,87,99] The demonstration that oxalate-dependent Cl transport is not EIPA-sensitive, but is sulfate-dependent, while formate-dependent Cl transport is sulfate-independent, but EIPA-sensitive has lead to a proximal tubule model in which formate-stimulated NaCl absorption is dependent on Na/H exchange, while oxylate-stimulated NaCl absorption is dependent on Na-sulfate cotransport in parallel with sulfate-oxalate exchange.[99,101,102] In the case of formate and OH, stimulation of anion exchange not only increases the rate of NaCl absorption, but inhibits the rate of luminal acidification.

The quantitative role of Cl/base exchangers in proximal tubule/base exchangers in proximal tubule luminal acidification is unclear, but likely to be small. Three studies have been unable to demonstrate an effect of luminal and peritubular Cl removal on net HCO_3 absorption, while one lab found that luminal DIDS stimulates net HCO_3 absorption.[38,40,87,103] Thus, in summary, the Cl/formate, Cl/OH, and Cl/oxalate exchangers appear to function in parallel with Na-dependent transport mechanism to mediate net NaCl absorption from the lumen to cell.[26,87,99,101,102] In circumstances where Na/H exchange is coupled to "base" secretion, net H secretion is reduced. The role of the Cl/base exchangers in proximal tubule function is discussed in more detail in Chapter 33: "Sodium and Chloride Transport: Proximal Nephron."

H Leak

An H leak pathway in the apical membrane, especially in the late proximal tubule, would provide an additional backleak pathway for secreted acid. Reenstra et al. showed that brush border membranes possess a significant H/OH permeability.[104] Ives measured internal buffer capacity of vesicles and was able to calculate an H permeability that is not inhibited by amiloride or DCCD and, thus, is not due to proton movement across the Na/H antiporter or the H-ATPase.[105]

Preisig and Alpern measured apical membrane proton permeability by examining the rate of change of cell pH in response to a rapid luminal pH change.[106] Apical membrane Na- and Cl-coupled transporters were inhibited by perfusing tubules in the absence of luminal and peritubular Na and Cl and rates of change in cell pH were converted to fluxes by measuring buffer capacity. These studies demonstrated an apical membrane proton permeability of 0.52 cm/sec, a value that is in close agreement with that calculated by Ives from vesicle studies when corrected for the surface area of the brush border membrane.[105]

Role of Apical Membrane H/HCO_3 Transport Mechanisms in Transepithelial H Secretion

As shown in Figure 55.3, the proximal tubule apical membrane possesses an H-ATPase, a Na/H antiporter and tertiary active transport mechanisms all capable of effecting active acid extrusion. In addition, possible apical membrane net proton backleak pathways include the Cl/HCO_3, Cl/OH, and Cl/formate exchangers as well as proton diffusion across the membrane. As discussed above, the Cl/base exchangers and tertiary active transport mechanisms probably play a very small, if any, role in proximal tubule acidification, and thus, won't be discussed further.

Using the apical membrane H permeability (see above), Preisig and Alpern calculated that a passive H leak from lumen to cell would be of minor quantitative importance in the early proximal tubule where the luminal pH is close to 7.4 (and cell pH ~7.3). However, in the late proximal tubule with a luminal pH of ~6.8, 1/3 of secreted protons could leak back across the apical membrane.[106]

The role of the Na/H antiporter in mediating transepithelial HCO_3 absorption has been studied in a number of ways. In *in vivo* and *in vitro* perfused proximal

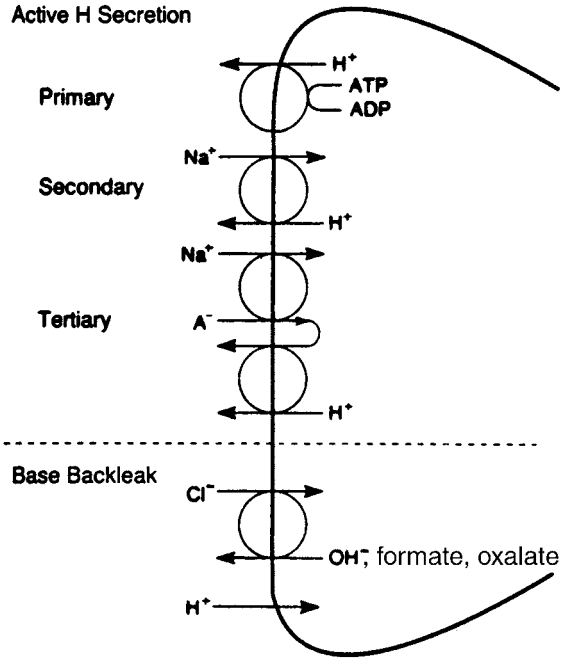

FIGURE 55.3 Apical membrane H transport mechanisms. (*From Alpern RJ. Cell mechanisms of proximal tubule acidification. Physiol Rev 1990,70:79-114, with permission.*)

tubules, either complete Na removal from luminal and peritubular fluids or inhibition of the Na,K-ATPase by peritubular ouabain or peritubular K removal inhibits most of HCO_3 absorption.[20,38–41] While these studies were initially interpreted as demonstrating that all apical membrane H secretion is Na-coupled and utilizes the lumen-to-cell Na gradient established by the Na,K-ATPase, they are equally consistent with a Na-coupled, electrogenic mechanism mediating HCO_3 efflux on the basolateral membrane working in series with a Na-independent H secretory mechanism on the apical membrane, which was demonstrated to be the situation (see below). However, inhibition of the Na,K-ATPase leads to cell depolarization, which inhibits the electrogenic Na/HCO_3 cotransporter on the basolateral membrane, as shown in studies in which inhibition of the Na,K-ATPase in the bullfrog proximal tubule causes a cell alkalinization.[107] This observation is consistent with inhibition of base exit, and not consistent with inhibition of apical membrane Na-independent H secretion, as that would have resulted in cell acidification. Thus, while the effect of both Na removal and Na,K-ATPase inhibition on HCO_3 absorption are consistent with an important role of the Na/H antiporter in HCO_3 absorption, neither can quantify the magnitude of this contribution.

The best approach toward quantifying the contribution of the Na/H antiporter has been to examine the effect of inhibiting the apical membrane Na/H antiporter on HCO_3 absorption. Howlin et al. and Chan and Giebisch demonstrated that luminal amiloride significantly inhibits the rate of HCO_3 absorption in the *in vivo* microperfused rat proximal convoluted tubule.[20,21] However, neither group found the magnitude of inhibition to be as large as expected if the Na/H antiporter mediates all of the H secretion involved in HCO_3 absorption.

To further examine this issue, Preisig et al. looked at the effect of high concentrations of luminal amiloride and t-butyl amiloride (a more potent analog) on transepithelial HCO_3 absorption.[22] In the *in vivo* microperfused tubule, these investigators found that both agents inhibit only 45% of HCO_3 absorption. While one interpretation of this observation is that the Na/H antiporter mediates only a fraction of transepithelial HCO_3 absorption, other interpretations are that the rat Na/H antiporter is insensitive to these agents or that the inhibitor concentration is not consistent along the perfused segment. Preisig et al. then showed that when corrections are made for the measured luminal inhibitor concentration profile (amiloride and its analogs are highly lipophic and diffuse out of the lumen along the length of the perfused segment), and for the luminal [HCO_3] profile, Na/H antiporter activity, assayed as the rate of change in cell pH in response to luminal Na removal or addition, is inhibited by amiloride and t-butyl amiloride as predicted by vesicle studies. Thus, these studies concluded that an amiloride-sensitive Na/H antiporter mediates approximately 65% of transepithelial HCO_3 absorption, with the remaining 35% mediated by an amiloride-insensitive, Na-independent mechanism. This conclusion is supported by the observation that in NHE3 null mice, proximal tubule HCO_3 absorption is inhibited by 61%.[65]

The studies by Preisig et al. were performed in the absence of organic anions in the perfused lumen making it very unlikely that tertiary active transport mechanisms are responsible for the remaining 39% of HCO_3 absorption. Thus, the most likely explanation is that the H-ATPase mediates the remaining 35% of transepithelial HCO_3 absorption. Bank et al. have more directly demonstrated a role of the H-ATPase in HCO_3 absorption by showing that luminal DCCD, an inhibitor of vacuolar H-ATPases, inhibits 21% of proximal tubule HCO_3 absorption.[108]

Basolateral Membrane H/HCO_3 Transport Mechanisms

Because cell pH is above electrochemical equilibrium, basolateral membrane base efflux can occur passively.

Electrogenic $Na/3HCO_3$ Cotransport

Studies have uniformly demonstrated that the key basolateral membrane base efflux mechanism is an electrogenic $Na/3HCO_3$ cotransporter. Evidence for this rests on results that have demonstrated: (1) effects of this transporter on cell pH and cell voltage, (2) the presence of this transporter in basolateral membrane vesicles, and (3) the importance of this transporter in transepithelial HCO_3 absorption.

In intact tubules, initial studies examined the electrogenicity of basolateral membrane H/HCO_3 movement. It was reasoned that if cell pH and HCO_3 concentration are above electrochemical equilibrium, a simple basolateral membrane $H/OH/HCO_3$ conductance could mediate base efflux and transepithelial H secretion. Burckhardt et al. provided evidence for a large basolateral membrane H/HCO_3 conductance in the *in vivo* perfused rat proximal convoluted tubule.[109] When HCO_3 concentration is rapidly decreased from 30 to 3 mEq/L, cells rapidly depolarize and then slowly repolarize. A subsequent increase in peritubular HCO_3 concentration leads to a rapid hyperpolarization followed by a slow depolarization. This basolateral membrane conductance is inhibited by acetazolamide and peritubular SITS. While initial studies had

difficulty demonstrating such a HCO_3 conductance in the *in vitro* perfused rabbit proximal convoluted and straight tubules, improvements in the perfusion technique that permit sufficiently rapid fluid changes, led to confirmation of Burckhardt et al.'s finding.[110]

Further evidence for the electrogenicity of basolateral membrane HCO_3 transport in the intact tubule is the voltage sensitivity of bicarbonate movement. Alpern measured cell pH microfluorimetrically in the *in vivo* perfused rat proximal convoluted tubule and showed that increasing peritubular K concentration from 5 to 50 mEq/L (a maneuver that causes cell depolarization) causes a rapid cell alkalinization that is reversible when peritubular K concentration is reduced back to 5 mEq/L.[1] While these studies suggest the presence of a voltage-sensitive $H/OH/HCO_3$ transport mechanism on this membrane, they were also consistent with a K/HCO_3 cotransporter. To examine this possibility, the studies were repeated in the presence of 2 mM peritubular barium. Barium inhibits the basolateral membrane K conductance, preventing changes in peritubular K concentration from affecting cell voltage.[2,111] In addition, by inhibiting the K conductance, barium itself leads to a cell depolarization.[2,111] Barium addition causes cell alkalinization, and prevents any subsequent effect of changing peritubular K concentration on cell pH.[1] These results are consistent with the presence of a voltage-sensitive $H/OH/HCO_3$ transport mechanism in the proximal tubule cell. While these studies did not specifically address which membrane the transport mechanism is on, the studies by Burckhardt et al. demonstrated a HCO_3 conductance on the basolateral, but not on the apical membrane.

While initially it was felt that Burckhardt et al.'s studies represent a simple HCO_3 conductance on the basolateral membrane, Boron and Boulpaep suggested a more complex transport mechanism.[112] These investigators used ion selective microelectrodes in the *in vitro* perfused salamander proximal tubule and found that lowering the peritubular HCO_3 concentration causes a rapid cell depolarization, indicative of a HCO_3 conductance. However, peritubular acidification also led to cell acidification and a decrease in intracellular Na activity, and lowering peritubular Na concentration causes cell depolarization, cell acidification, and a decrease in cell Na activity. The cell depolarization in response to lowering peritubular Na concentration is in the wrong direction for a Na conductance and is more suggestive of a Na-coupled anion current. In further studies these investigators found that all of the above changes occur in the absence of Cl and are blocked by SITS. Considered together these studies provided the evidence suggesting a directly coupled Na/HCO_3 cotransport mechanism that transports more HCO_3 than Na ions and, thus, is electrogenic.

The first suggestion that such a transport mechanism exists in the mammalian nephron was made by Biagi and Sohtell, who measured cell voltage in the *in vitro* perfused proximal convoluted tubule and proximal straight tubule.[110,113] These investigators found that lowering peritubular HCO_3 or Na concentration leads to a spike depolarization that is blocked by SITS. Once again, the cell depolarization occurring in response to lowering peritubular Na concentration is in the wrong direction for a simple Na conductance.

Subsequent studies performed by Alpern and Yoshitomi et al. measured cell pH in the *in vivo* perfused rat proximal tubule and confirmed the existence of an electrogenic Na/HCO_3 cotransporter.[1,12] Alpern found that decreasing peritubular pH causes cell acidification. Additionally, lowering peritubular Na concentration from 147 to 25 mEq/L (replacing Na with either choline or tetramethylammonium) causes cell pH to decrease by 0.2 pH units, an effect that persists in the complete absence of Cl.[114]

The above studies are consistent with three possible mechanisms of coupling between Na and HCO_3: parallel Na and HCO_3 conductances, amiloride-sensitive Na/H antiport, or SITS-sensitive Na/HCO_3 cotransport. To determine if the results are attributable to parallel Na and HCO_3 conductances, Alpern examined the Na-dependence of basolateral membrane H/HCO_3 permeability.[1] If the HCO_3 conductance were Na-independent, complete Na removal should have no effect on basolateral membrane H/HCO_3 permeability. The results showed that complete removal of Na from luminal and peritubular fluid inhibits basolateral membrane H/HCO_3 permeability by greater than 90%, demonstrating direct coupling between Na and HCO_3. In subsequent studies, SITS, but not amiloride blocked the effect of peritubular Na on cell pH. Lastly, Alpern demonstrated that the effect of cell depolarization (raising peritubular K concentrations) on cell pH was prevented if lumen and peritubular capillaries were perfused with Na-free solutions. Taken together these studies suggest a directly coupled, electrogenic Na/HCO_3 cotransport mechanism similar to that found in the salamander.

Yoshitomi et al. found similar results, measuring cell voltage, pH and Na activity using ion sensitive microelectrodes.[12] Lowering peritubular HCO_3 concentration causes a rapid cell depolarization, a decrease in cell pH, and a decrease in cell Na activity. Decreasing peritubular Na concentration also causes a rapid cell depolarization and a decrease in cell pH. SITS inhibits the effects of both lowering peritubular pH and peritubular Na concentration. Lastly, luminal and peritubular Na removal inhibits the effect of changing peritubular HCO_3 concentration on cell voltage and cell pH. In subsequent studies, Sasaki et al., and

Lopes et al. found similar results in the rabbit proximal straight tubule and the Necturus proximal tubule, respectively.[115,116] Thus, all of these studies consistently demonstrate an electrogenic, SITS-sensitive Na/HCO_3 cotransport mechanism on the proximal tubule basolateral membrane.

This question has also been addressed in basolateral membrane vesicles.[117,118] Akiba et al. found that addition of HCO_3 to the extravesicular fluid increases the rate of ^{22}Na uptake.[117] SITS has no effect on ^{22}Na uptake in the absence of HCO_3, but inhibits the HCO_3-dependent increment. Addition of valinomycin (a K ionophore) in the presence of an inwardly directed K gradient causes an internal positive voltage. This maneuver has no effect on ^{22}Na uptake in the absence of HCO_3, but accelerates the uptake in the presence of HCO_3, an effect that is in the wrong direction for a Na conductance.

Grassl and Aronson demonstrated in rabbit cortical basolateral membrane vesicles that pH gradients drive ^{22}Na uptake.[118] Whereas the effect is small in the absence of exogenous CO_2/HCO_3, it is large in its presence. In addition, a valinomycin-generated positive interior voltage drives ^{22}Na uptake, but only in the presence of HCO_3. Lastly, using acridine orange to measure H transport, Grassl and Aronson found that Na gradients ($[Na]_{in} > [Na]_{out}$) drives HCO_3 out of vesicles leading to acidification of the intravesicular space. ^{22}Na uptake is blocked in a dose-dependent fashion by DIDS and is unaffected by amiloride. In the studies of Akiba et al. and Grassl and Aronson, Cl was absent from all fluids.[117,118] Thus, these studies demonstrate the presence of an electrogenic, stilbene sensitive, Na-coupled HCO_3 transport mechanism. Grassl et al. found similar results in rat cortical basolateral membranes.[119]

Stoichiometry: Based on the electrogenicity demonstrated above, it was concluded that the basolateral membrane Na-dependent HCO_3 transporter carries a greater number of HCO_3 than Na ions. If the free energy for HCO_3 efflux is calculated, it can be predicted that a $Na/2HCO_3$ co-transporter will not be able to function in the HCO_3 efflux mode, unless directly coupled to energy.[120,121] Thus, it was predicted that the stoichiometry is a minimum of 3 HCO_3:1 Na. Yoshitomi et al. directly examined this question by comparing the SITS-sensitive voltage response to a 10-fold reduction in peritubular HCO_3 concentration with the response to a 10-fold reduction in peritubular Na concentration, and found the former to be 2.95-fold greater.[12] They also demonstrated that a reduction in peritubular HCO_3 concentration causes a 3.1-fold greater HCO_3 than Na flux out of the cell. Thus, both studies suggest a stoichiometry of 3 HCO_3:1 Na.

A 3:1 stoichiometry was confirmed by Soleimani et al. in basolateral membrane vesicles by demonstrating that in the presence of valinomycin (to increase K permeability) the HCO_3 and K concentration gradients required for no net Na movement yield a stoichiometry of 1 Na:3 HCO_3:2 negative charges.[122]

Base species transported: Thus far in the discussion this basolateral membrane transporter has been described as a Na/HCO_3 cotransport mechanism, based on a strong transporter dependence on the presence of HCO_3.[117,118] Krapf et al. examined the dependence of the transporter on exogenous CO_2/HCO_3 in the *in vitro* perfused rabbit proximal convoluted tubule utilizing the fluorescent measurement of cell pH.[123] These investigators found that in the absence of exogenous CO_2/HCO_3, the transporter functions at 1/3 of its control rate. While these results could be interpreted as suggesting that the transporter is able to run in the absence of CO_2/HCO_3, it is also possible that metabolism was producing sufficient CO_2 and HCO_3 to run the transporter at a slow rate. In agreement with this latter interpretation, the transporter flux measured in the absence of exogenous CO_2/HCO_3 is completely inhibited by acetazolamide, a carbonic anhydrase inhibitor, or by cyanide, a metabolic inhibitor. There should be no requirement for carbonic anhydrase if the transporter carries H or OH. In addition, the transporter is unaffected by cyanide when studied in the presence of exogenous CO_2/HCO_3. Thus, these results agree with the vesicle studies and suggest that the transporter has an absolute dependence on HCO_3.

Soleimani and Aronson performed further studies that suggest that carbonate (CO_3^{2-}) is also a substrate.[122] They found that with a constant extravesicular HCO_3 concentration, increasing carbonate concentration increases ^{22}Na uptake into basolateral membrane vesicles. Sulfite, a structural analog of carbonate, also stimulates ^{22}Na uptake in the presence of CO_2/HCO_3, but not in the absence of CO_2/HCO_3, an effect that is blocked by the disulfonic stilbene, DNDS. Lastly, using an equilibrium approach similar to that described above, a stoichiometry of 1 Na:1 sulfite:1 HCO_3 was derived, with carbonate and sulfite competing for a similar site. The last issue addressed in these studies was whether three separate binding sites exist or whether Na and carbonate formed a $NaCO_3^-$ ion pair that then interacts with a single site, while HCO_3 interacts at another site. Multiple pieces of evidence are against the ion pair model. First, lithium, which is more likely to form an ion pair with carbonate than is Na, is a less effective substrate for the transporter. Secondly, oxalate and phosphate, anions that participate in ion pair formation with Na, do not interact with the transporter. Lastly, harmaline, an inhibitor of Na transporters, competes with Na on the $Na/3HCO_3$

transporter. Such an interaction would be unlikely if the transporter possessed only two transport sites with both binding negatively charged substrates. Thus, it appears that the transporter is actually a $Na/HCO_3/CO_3$ cotransporter rather than a $Na/3HCO_3$ cotransporter.

Romero et al. cloned the cDNA for the electrogenic $Na/3HCO_3$ transporter from *Ambystoma tigrium*.[124] This cDNA, referred to as NBC1 (*N*a *B*icarbonate *C*otransporter *e*lectrogenic *1*) encodes a 1035 amino acid protein, the same size as and ~80% identical to the human and rat sequence.[125,126] The human and rat mRNAs are larger than the amphibian kidney mRNA, with the human and rat mRNA ~7.5 kb in length and the amphibian mRNA 4.2 kb.[125,126] The difference is due to an extensive 3-prime non-coding region in the human and rat transcript.[126]

Human NBCe1 is highly expressed in both the kidney and pancreas, the two differing only in their N-terminal sequence. The kidney transcript is expressed predominantly in the kidney, while the pancreas transcript is expressed in multiple tissues.[126] In kidney the protein localizes to the basolateral membranes of the proximal tubule.[127] More detailed reviews of HCO_3-coupled transporters have been published and the transporters are discussed in Chapter 54.[128,129]

Na/H Antiporter

Many segments along the nephron possess basolateral membrane Na/H antiporters that likely participate in housekeeping functions. Boron and Boulpaep found that the salamander proximal tubule possesses Na/H antiporters on apical and basolateral membranes.[36] Ives et al. and Sabolic and Burckhardt did not find any Na/H antiporter activity in basolateral membrane fractions from rabbit renal cortex.[130,131] While Grassl and Aronson found some pH-dependent ^{22}Na uptake in the absence of HCO_3, it is not inhibited by amiloride.[118] In the *in vivo* perfused rat proximal convoluted tubule Alpern found that the effect of basolateral Na changes on cell pH is not inhibited by amiloride and in the *in vitro* perfused rabbit proximal convoluted tubule Krapf et al. found similar results.[1,123] Kurtz found an amiloride-sensitive basolateral membrane Na/H antiporter in the S3 proximal tubule and Geibel et al. reported a basolateral membrane Na/H antiporter in S1 and S2 proximal tubule segments dissected from the most juxtamedullary portions of the nephron.[13,132] By immunohistochemistry, Biemesderfer et al. found inhomogeneous labeling of the proximal tubule basolateral membrane with anti-NHE1 antibodies.[133] Taken together these studies suggest that a Na/H antiporter may be expressed on the basolateral membrane of juxtamedullary proximal tubule, but not likely in cortical proximal tubules. More recently evidence for regulation of a basolateral membrane Na/H antiporter in the S3 segment was demonstrated by examining the effect of aldosterone on intracellular pH recovery rate. The basolateral membrane NHE1 appears to be regulated by both genomic (1h via a mineralocorticoid receptor) and non-genomic (2–15 min, likely via a glucocorticoid receptor) mechanisms. At lower concentration ranges (10^{-12} M aldosterone) intracellular [Ca] is increased and NHE1 activity is stimulated, while at higher concentrations (10^{-6} M) intracellular [Ca] decreases and NHE1 activity is inhibited.[134]

Cl/Base Exchange: Na-Dependent and Na-Independent Modes

Edelman et al. first demonstrated the presence of basolateral membrane Cl/HCO_3 exchange in Necturus proximal tubule using Cl-sensitive microelectrodes.[135] Guggino et al. confirmed these results and, in addition, found that the transporter is coupled to Na.[136] Lowering basolateral Cl concentration causes intracellular Cl activity to decrease. Removal of peritubular HCO_3 leads to an increase in cell Cl activity, while changes in peritubular pH in the absence of exogenous HCO_3 have no effect on intracellular Cl activity. When cell pH is modulated by NH_3/NH_4^+ addition and removal, cell Cl activity changes in a manner consistent with Cl/HCO_3 exchange, repeating these maneuvers in the absence of exogenous CO_2/HCO_3 causes a marked decrease in the response of intracellular Cl activity. Lowering peritubular Na concentration leads to an increase in intracellular Cl activity. In addition, cell acidification by NH_3/NH_4^+ addition and removal causes a decrease in Cl activity that is blocked if Na is simultaneously removed from the peritubular fluid. Taken together these findings suggest a $NaHCO_3/Cl$ exchange mechanism. On the basis of other studies that fail to find basolateral membrane electrogenic Cl movement, it was concluded that the transporter is a $Na(HCO_3)_2/Cl$ exchanger.[137,138] A similar transporter has been found in many invertebrate and vertebrate cells and, in these cells, is felt to be an important mechanism responsible for cell pH defense against an acid load.

Alpern and Chambers examined whether such a transport mechanism is present on the basolateral membrane of the rat proximal tubule by studying the effect of peritubular Cl on cell pH.[114] In tubules perfused in the absence of luminal and peritubular Cl, peritubular Cl addition causes cells to acidify by 0.14 pH units, an effect that is blocked by peritubular SITS. In addition, if Cl is added to the peritubular perfusate in the complete absence of luminal and

peritubular Na, cells acidify by only 0.02 pH units. These studies suggest the presence of a small amount of Na-independent and a much larger amount of Na-dependent Cl/HCO_3 exchange activity.

However, the above results are also consistent with a basolateral membrane Cl conductance functioning in parallel with the electrogenic $Na/3HCO_3$ cotransporter. Preisig and Alpern addressed this issue by examining the Cl-dependence of the basolateral membrane H/HCO_3 permeability.[139] If changes in peritubular Cl only affect cell pH by changing voltage and secondarily modifying $Na/3HCO_3$ cotransporter activity, Cl removal should not affect basolateral membrane H/HCO_3 permeability. However, complete removal of Cl from luminal and peritubular solutions leads to a 35% decrease in basolateral membrane H/HCO_3 permeability. Because complete removal of Na from luminal and peritubular fluids leads to a greater than 90% inhibition of basolateral membrane H/HCO_3 permeability, taken together these results suggest that at least 25% of H/HCO_3 permeability is mediated by a Na and Cl-coupled H/HCO_3 transporter.[1,12] The remaining fraction of H/HCO_3 permeability, which is not inhibited by Na removal, may represent a Cl/HCO_3 exchanger. Sasaki and Yoshiyama found similar results using microelectrodes to measure intracellular Cl and pH in the rabbit proximal straight tubule perfused *in vitro*.[140] Decreases in peritubular Cl concentration cause a cell alkalinization and decreases in peritubular pH lead to an increase in cell Cl activity, with both effects inhibited by peritubular SITS. Total Na removal from luminal and peritubular fluids prevents most of the effect of bath pH on cell Cl activity. And, lastly, removal of luminal and peritubular Cl slows the cell pH response to peritubular acidification by 26% and slows the cell pH response to lowering peritubular Na concentration by 19%. These results demonstrate a Na-dependent Cl/HCO_3 exchanger. Kurtz and Nakhoul et al. have reported basolateral membrane Na-independent Cl/HCO_3 exchange in the S3 segment of the rabbit proximal tubule perfused *in vitro*.[141,142]

While studies in the intact tubule seem to consistently demonstrate the presence of a Na-dependent Cl/HCO_3 exchanger, studies in basolateral membranes have been much less consistent. Grassl et al. found that a pH gradient ($pH_{in} > pH_{out}$) can drive ^{36}Cl uptake in rabbit cortical basolateral membrane vesicles.[143] In the presence of CO_2/HCO_3, a similar pH gradient leads to a 6-fold greater accumulation of ^{36}Cl. This effect is not inhibited by voltage clamping the vesicles, but is inhibited by DIDS. Grassl et al. did not find Na-dependence of HCO_3-driven ^{36}Cl uptake. In subsequent studies examining the effect of Cl and Cl gradients on HCO_3-stimulated ^{22}Na uptake, results were not consistent with a $Na(HCO_3)_2/Cl$ exchanger.[118]

In rat basolateral membrane vesicles, Grassl et al. demonstrated that symmetrical Cl addition to the inside and outside of vesicles stimulates HCO_3-dependent ^{22}Na uptake and that a Cl gradient ($Cl_{in} > Cl_{out}$) further stimulates uptake.[119] Chen and Verkman used a Cl-sensitive fluorescent dye to examine the effect of pH gradients on Cl uptake into rabbit cortical basolateral membrane vesicles.[144] These authors demonstrated that pH gradients ($pH_{in} > pH_{out}$) stimulate Cl uptake, an effect that is enhanced by the presence of CO_2/HCO_3 and inhibited by H_2DIDS. Na gradients ($Na_{in} > Na_{out}$) also stimulate Cl uptake, but only in the presence of CO_2/HCO_3.

Based on all of the above data, it appears that the basolateral membrane contains a Cl/HCO_3 exchanger that demonstrates less transporter activity in intact S1 and S2 proximal tubules compared to the S3 proximal tubule. While vesicle studies are clearly consistent with this observation, there is controversy as to the existence of Na-dependent Cl/HCO_3 exchange.

H Leak

Preisig and Alpern measured basolateral membrane H permeability, using an approach similar to that described for apical membrane H permeability.[106] The permeability, 0.67 cm/sec, was similar to that found in the apical membrane.

Role of Basolateral Membrane Transporters

Three types of experiments taken together strongly suggest that the majority of base efflux mediating transepithelial HCO_3 absorption involves the electrogenic, Cl-independent, Na/HCO_3 cotransporter on the basolateral membrane. As mentioned above, such a transporter has a stoichiometry allowing it to run passively in the base efflux direction.[12,122] First, proximal tubule HCO_3 absorption is almost entirely inhibited by removal of luminal and peritubular Na, but is unaffected by removal of luminal and peritubular Cl.[20,38–40,103] Second, and consistent with the above, most of the basolateral membrane H/HCO_3 permeability is Na-dependent and Cl-independent.[1,12,139,140] Third, in studies in which the cell is depolarized by addition of barium to the peritubular fluid, transepithelial HCO_3 absorption is inhibited, implying conductive base efflux.[103] In addition, SITS, an inhibitor of anion exchangers, including the $Na/3HCO_3$ cotransporter, inhibits transepithelial HCO_3 absorption when applied to the peritubular fluid.[145]

The effect of SITS could also implicate involvement of the Na-independent and -dependent Cl/HCO_3 exchangers, however, the observation that peritubular Cl removal does not affect HCO_3 absorption suggests

that these transporters are relatively unimportant in mediating HCO_3 reabsorption.[38,40,103] In addition, the activity of the Na-independent Cl/HCO_3 transporter is very low. And the Na-dependent Cl/HCO_3 exchanger would tend to run Na and HCO_3 into the cell and Cl out of the cell, and thus, would not contribute to transepithelial HCO_3 absorption. This transport could, however, function as a Cl efflux mechanism mediating transepithelial NaCl absorption. It could also function in the defense of cell pH, but Krapf et al. found no effect of Cl removal on cell pH defense in the proximal tubule.[146]

Lastly, while a basolateral H leak could contribute to net basolateral base efflux, Preisig and Alpern calculated that this pathway would be expected to mediate only 2% of base efflux.[106] Figure 55.4 summarizes the basolateral membrane H/HCO_3 transport pathways discussed above.

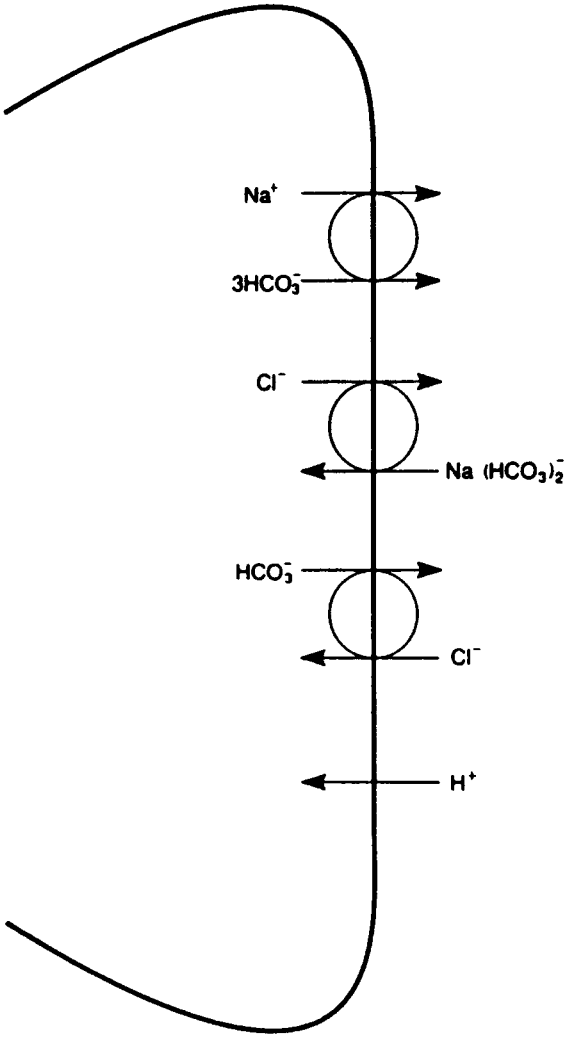

FIGURE 55.4 Basolateral membrane H/HCO_3 transport mechanisms. *(From Alpern RJ. Cell mechanisms of proximal tubule acidification. Physiol Rev 1990,70:79-114, with permission.)*

Leak Pathways

Proton secretion across the apical membrane of the proximal tubule decreases luminal pH and HCO_3 concentration to values below those found in plasma. This sets up gradients for passive back diffusion of base into the lumen. Possible diffusing species include H, OH, HCO_3, and non-HCO_3 buffers. In rabbit proximal convoluted tubules perfused with acidic solutions in the absence of CO_2/HCO_3, in either the absence or presence of luminal organic solutes, the measured transepithelial H permeability is ~ 0.31 cm/sec at 30°C.[147,148] This value agrees well with the transcellular H permeability of 0.3 cm/sec, calculated from individually measured apical and basolateral membrane H permeabilities, suggesting that the majority of transepithelial H diffusion is transcellular.[106] This conclusion is consistent with studies showing that the activation energy for H diffusion is not consistent with diffusion in aqueous solutions.[149]

HCO_3 permeability of the proximal tubule has been measured using two approaches. One approach, using diffusion potentials to measure the ratio of the HCO_3 to Cl permeability combined with a measured tracer Cl permeability, determined a HCO_3 permeability of 1.3×10^{-5} cm/sec in rabbit proximal convoluted tubules.[150] Using a similar approach in the *in vivo* microperfused rat proximal convoluted tubule a slightly higher HCO_3 permeability of 9.8×10^{-5} cm/sec was determined.[151]

A second approach was to measure the rate of net HCO_3 diffusion in response to an imposed HCO_3 gradient in the presence of acetazolamide to inhibit active H secretion and slow the rate of conversion of CO_2 to HCO_3. Although it is impossible to remove H and OH ions and, thus, to prevent their diffusion, the above reported H permeability suggests that transepithelial H/OH diffusion is minimal compared to the HCO_3 flux. Using this approach, measured HCO_3 permeabilities vary between 1.7 and 3.5×10^{-5} cm/sec in the rat proximal convoluted tubule and between 1.4 and 2.0×10^{-5} cm/sec in the rabbit proximal convoluted tubule.[152–155] Measured permeabilities are similar when measured in the lumen to peritubular or peritubular to lumen direction.

Both Schwartz and Hamm et al. found that removal of luminal organic buffers decreases the rate of passive acid efflux from an acidic luminal fluid.[147,148] These results suggest that organic acid efflux could also participate as a passive leak. However, such a flux is unlikely to be of major physiologic importance, as most

organic acids are removed from the luminal fluid early in the proximal tubule before the luminal fluid has been extensively acidified.

Using the above measured permeabilities, passive fluxes can be calculated. In the early proximal tubule these will be insignificant because luminal pH changes little. However, in the late proximal tubule, where the luminal fluid is acidified, passive leaks become more important. Alpern et al. measured a net transepithelial HCO_3 absorption rate in the presence of a late proximal tubule-like fluid of 12 pEq/mm·min.[152] Using the measured HCO_3 permeability, the calculated rate of paracellular HCO_3 backleak is 30 pEq/mm·min, leading to a calculated net transcellular H secretory flux of 42 pEq/mm·min. As discussed earlier under "Apical Membrane Mechanisms," in the late proximal tubule there is a sufficient electrochemical driving force to drive 17 pEq/mm·min of protons from lumen to cell (H "absorption"). Thus, the apical membrane must secrete 59 pEq/mm·min of H in order to effect a net transepithelial H secretory flux (equivalently a transepithelial HCO_3 reabsorptive flux) of 12 pEq/mm·min.

Role of Carbonic Anhydrase

In the proximal tubule carbonic anhydrase is localized to the apical membrane, basolateral membrane, and cytoplasm. The cytoplasmic carbonic anhydrase is type II carbonic anhydrase, while apical and basolateral membrane carbonic anhydrases are type IV. The interested reader is referred elsewhere for an in depth discussion of carbonic anhydrase localization in the proximal tubule.[156–158] In the present chapter we will review evidence establishing a role for carbonic anhydrase in transepithelial H secretion.

A number of investigators demonstrated that carbonic anhydrase plays a role in HCO_3 absorption in the proximal tubule.[159–163] As described at the beginning of the Chapter, luminal carbonic anhydrase facilitates transepithelial H secretion (and HCO_3 reabsorption) by catalyzing the dissociation of HCO_3 to CO_2 and OH, with OH neutralizing secreted H. This prevents the generation of an acid disequilibrium pH (see discussion above), which would secondarily slow the rate of apical membrane H secretory transporters.[6–8] The importance of luminal carbonic anhydrase has been best demonstrated by studying the effect of cell-impermeant luminal carbonic anhydrase inhibitors on HCO_3 absorption. In the presence of these inhibitors HCO_3 reabsorption is inhibited by 80–100%, confirming a key role for luminal carbonic anhydrase in this process.[161,162]

H secretion across the apical membrane generates OH ions within the cell that must exit across the basolateral membrane to have net transepithelial H secretion. While carbonic anhydrase inhibitors confined to the luminal fluid are able to inhibit most of HCO_3 absorption, the effect on luminal pH is different than that observed with inhibitors that can enter the cell. Inhibitors confined to the luminal fluid cause a more profound acid disequilibrium pH compared to cell permeant inhibitors.[161,162] This observation suggests that cell permeant carbonic anhydrase inhibitors block acidification at an additional step. This possible second location could be base diffusion across the cell or base efflux across the basolateral membrane.

Diffusion of H/OH across aqueous solutions is generally a limiting process because of the low H and OH concentrations. Thus, although the diffusion coefficients for H and OH are large, the fact that these entities exist in nanomolar concentrations limits the amount of diffusion. Acid and base diffusion is best accomplished when H/OH combines with buffers existing in millimolar concentrations, and allowing these buffers to then diffuse across the cell.[164,165] Thus, OH generated at the apical membrane can diffuse to the basolateral membrane by combining with CO_2 forming millimolar concentrations of HCO_3 or by combining with non-HCO_3 buffers forming the basic buffer species. The former reaction requires carbonic anhydrase, while the latter process requires mobile buffers within the cell. Measurements of intracellular non-HCO_3 buffer capacity demonstrate significant concentrations of intracellular buffers. Krapf et al. demonstrated that these non-HCO_3 buffers are, in fact, mobile, and thus, that carbonic anhydrase-dependent conversion of OH to HCO_3 is not required for OH diffusion to the basolateral membrane.[123]

Therefore, it appears that the second requirement for carbonic anhydrase is related to base efflux across the basolateral membrane. As described previously in this Chapter, the basolateral membrane base efflux mechanism carries a HCO_3 and a carbonate (CO_3) ion, rather than either OH or H ions. Therefore, OH formed when an H ion is secreted across the apical membrane must be converted to HCO_3 and CO_3 either within the cell or at the basolateral membrane prior to efflux. A number of studies demonstrated that the effect of a peritubular pH change on cell voltage or cell pH is blocked by carbonic anhydrase inhibitors.[109,110,123] This implies that carbonic anhydrase is required to supply HCO_3 and CO_3 to the transporter and/or to allow the HCO_3 and/or CO_3 ions, once they have been transported across the membrane, to react with interstitial buffers on the extracellular side of the basolateral membrane. Alternatively, the carbonic anhydrase inhibitors could have a direct inhibitory effect on the transporter protein. In support of the former, Soleimani and Aronson demonstrated in basolateral membrane

vesicles that the effect of acetazolamide (carbonic anhydrase inhibitor) on Na/3HCO_3 cotransporter activity is due to effects on substrate concentration rather than direct inhibition of the transport protein itself.[166]

In summary, carbonic anhydrase has two roles in proximal tubule transepithelial H secretion. The first is to minimize decreases in luminal pH when H ions are secreted into the lumen by rapidly converting the secreted H to CO_2 and H_2O thereby allowing H secretion to continue at a faster rate. The second role is to facilitate conversion of the cytoplasic OH, formed by the generation of the H that was secreted, to HCO_3 and CO_3 that can then exit across the basolateral membrane. This latter step could be mediated by either cytoplasmic or basolateral membrane carbonic anhydrase. In addition, it is possible, but unproven, that basolateral membrane carbonic anhydrase could further enhance acidification by facilitating conversion of HCO_3 and CO_3 that exit across the basolateral membrane to OH and H, which then can titrate non-HCO_3 buffers in the peritubular interstitium.

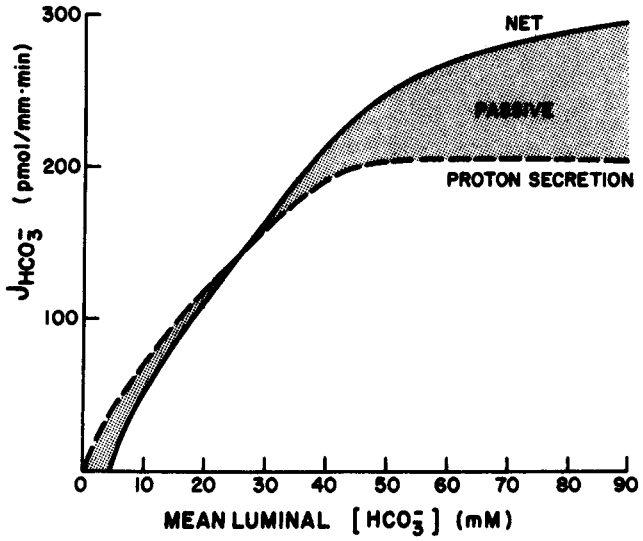

FIGURE 55.5 Dependence of HCO_3 absorption on mean luminal HCO_3 concentration. Solid line indicates net HCO_3 absorption, shaded area indicates passive paracellular HCO_3 flux, and dashed line indicates rate of active transcellular H secretion. *(From Alpern RJ, Cogan MG, Rector FC Jr. Effect of luminal bicarbonate concentration on proximal acidifi cation in the rat. Am J Physiol 1982,243:F53–F59, with permission.)*

Regulation of Acidification

Proximal tubule acidification involves transcellular H secretion in parallel with paracellular HCO_3 backleak. Other leak pathways are relatively minor. Net HCO_3 absorption can be regulated by modification of the transcellular or the paracellular flux, but regulation of the transcellular flux is more frequently observed. Below a number of the important proximal nephron acidification regulatory determinants are discussed.

Luminal HCO_3 Concentration

Malnic and de Mello Aires examined the effect of luminal HCO_3 concentration and pH on the rate of HCO_3 absorption using the split droplet technique.[167] In these classic studies, the pH of a luminal split drop was measured with an antimony electrode and the HCO_3 concentration calculated. It was noted that HCO_3 concentration decreases by first order kinetics, implying that the rate of H secretion is linearly related to luminal HCO_3 concentration. This dependence of H secretion on luminal HCO_3 concentration was confirmed in other split droplet studies and in *in vivo* microperfusion studies.[152,168]

Alpern et al., varying luminal perfusate HCO_3 concentration in the *in vivo* microperfusion setting, showed that the measured rate of HCO_3 absorption increases as a function of mean luminal HCO_3 concentrations below 45 mEq/L [Figure 55.5, solid line (net)].[152] At concentrations greater than 45 mEq/L the rate of HCO_3 absorption tends toward a plateau.

Increases in luminal HCO_3 concentration also increase the rate of passive HCO_3 absorption. Using their measured HCO_3 permeability, Alpern et al. calculated the contribution of passive HCO_3 diffusion to net HCO_3 flux (Figure 55.5, shaded area).[152] When net HCO_3 flux is corrected for the passive HCO_3 flux, the rate of transcellular H secretion can be determined (Figure 55.5, dashed line). As shown, at luminal HCO_3 concentrations above 45 mEq/L, the rate of transcellular H secretion plateaus. At HCO_3 concentrations in the physiologic range (20–25 mM), the major effect of luminal HCO_3 concentration on net HCO_3 absorption is on the rate of proton secretion.

While it is tempting to ascribe the results of Figure 55.5 to a saturable H secretory process, it is important to remember that HCO_3 is not a substrate for the apical membrane transport mechanisms. As discussed above, HCO_3 reabsorption is mediated by H transport mechanisms, and thus, the process is most likely sensitive to luminal H concentration (pH). At high luminal HCO_3 concentrations, large changes in HCO_3 concentration lead to small changes in luminal pH and even smaller changes in luminal H concentration, whereas at low luminal HCO_3 concentrations small changes in HCO_3 concentration can lead to significant changes in luminal pH and even larger changes in luminal H concentration. This would give the appearance that the H secretory process is saturable. This thesis is supported by the direct observations of Aronson et al. who demonstrated that Na/H

antiporter rate is sensitive to external H concentration, with H competing with Na at a single site.[31]

Increases in luminal HCO_3 concentration directly stimulate the apical membrane Na/H antiporter and H-ATPase. In the steady state, the rate of the basolateral membrane $Na/3HCO_3$ transporter must increase to a similar extent as apical membrane H secretion. The most likely signal that increases the rate of the basolateral membrane transporter is an increase in cell pH, resulting from the increased rate of apical membrane H secretion. Alpern et al. demonstrated that increasing luminal pH from 6.6 to 7.3 increases cell pH by only 0.1 pH unit, while a similar increase in luminal pH stimulates transepithelial H secretion three-fold.[37,152] Thus, the basolateral membrane $Na/3HCO_3$ transporter must be exquisitely sensitive to cell pH, such that increases of 0.1 pH unit can increase the rate of the transporter threefold. Apical membrane transporters undergo a similar stimulation in this setting, but in response to a 0.7 pH unit increase in driving force (pH 7.3−6.6). One possible mechanism for the apparent exquisite sensitivity of the basolateral membrane cotransporter is that each turnover of the transporter carries three base equivalents. Thus, kinetically the transporter may be driven by the cube of the OH or HCO_3 concentration. In a proximal tubule mathematical kinetic model based on the ($[HCO_3]$),[3] Verkman and Alpern demonstrated that the $Na/3HCO_3$ cotransporter is sufficient sensitivity to cell pH to explain the experimentally observed changes in transporter rate.[169]

Luminal Flow Rate

When glomerular filtration rate increases, it is important that proximal tubule rates of H secretion increase in proportion. This maintains glomerulotubular balance and prevents increases in GFR from leading to marked bicarbonaturia and development of a metabolic acidosis. Both *in vivo* and *in vitro* microperfusion studies have demonstrated a marked flow dependence of HCO_3 absorption.[145,170,171]

One mechanism by which increases in luminal flow rate can stimulate HCO_3 absorption is by altering the luminal HCO_3 concentration profile.[172,173] Normally, as glomerular ultrafiltrate proceeds down the tubule lumen, HCO_3 concentration progressively decreases because the rate of HCO_3 absorption is proportionally greater than the rate of volume absorption. At faster luminal flow rates (higher GFR), the same rate of HCO_3 absorption would lead to a lesser fall in luminal HCO_3 concentration, which would then stimulate H secretion. Chan et al. and Alpern et al. examined the flow dependence of HCO_3 absorption as a function of mean luminal HCO_3 concentration.[145,170] Both investigators found that while increases in luminal flow rate cause increases in mean luminal HCO_3 concentration, this can account for only a small fraction of the stimulation of HCO_3 absorption. Chan et al. and Wang et al. also showed that changes in luminal flow rate do not affect paracellular HCO_3 permeability, and thus, the effect of flow is on transcellular H secretion.[153,171,174]

To more directly demonstrate this effect of flow rate on transcellular proton secretion, Preisig examined the effect of luminal flow rate on rat proximal tubule cell pH when the basolateral membrane $Na/3HCO_3$ transporter is inhibited.[175] Because cell pH was measured at the site of the perfusion pipette, results are not complicated by changes in the axial luminal HCO_3 concentration profile. Increases in luminal flow rate cause an immediate increase in cell pH that is reversible on decreasing luminal flow rate. This observation proves that increases in luminal flow rate lead to increases in the rate of H secretion. Preisig also showed that the apical membrane H secretory transporter that is stimulated by flow is the Na/H antiporter.[175] Du et al. found a similar flow-dependence of apical membrane proton secretion in the mouse proximal tubule, but concluded that both the Na/H antiporter and H-ATPase were similarly stimulated.[171,174] Consistent with NHE3 being involved in flow-dependent stimulation of H secretion are studies in NHE3-deficient mice, where it was shown that glomerular-tubular balance is significantly reduced.[176]

One possible mechanism for the effect of luminal flow rate on H secretion is a flow-dependent luminal diffusion barrier. According to this theory, a luminal diffusion barrier exists among the brush border microvilli, which impedes diffusion of secreted protons out into the center of the lumen and of HCO_3 from the lumen to the apical membrane. The acid pH in the vicinity of the H transporters in the microvilli then slows the rate of H secretion. Increases in luminal flow rate would decrease the magnitude of the diffusion barrier such that the local pH in the vicinity of the H transporters would increase, and, thus, the driving force for H secretion would increase. In this model, however, one would not expect increases in flow rate to stimulate H secretion if luminal HCO_3 concentration is already in the range where rates of H secretion are insensitive to it (see Figure 55.5, luminal HCO_3 concentration >45 mEq/L). These are the kinetics observed by Alpern et al. when H secretion was examined as a function of mean luminal HCO_3 concentration.[170] Increases in luminal flow rate stimulate H secretion at low luminal HCO_3 concentrations but have no effect on the apparent maximal rate. Similarly, Preisig found no effect of luminal flow rate on cell pH when luminal perfusate pH ($[HCO_3]$) is high.[175]

Wang et al. have proposed another mechanism mediating the flow dependence of H secretion and HCO_3 absorption.[171,174] By modeling the force (torque)

put on the apical membrane microvilli by increases in luminal flow rate, they demonstrated a linear relationship between luminal flow rate and the change in torque and between the change in torque and the change in the rate of HCO_3 absorption. This effect of flow is dependent on an intact actin cytoskeleton. Thus, they concluded that the microvilli serve as sensors of luminal flow rate, and then, in an actin-dependent manner, regulate Na/H antiporter and H-ATPase activity in a proportional manner.

All of the above studies examined the effect of acute changes in luminal flow rate on HCO_3 absorption. Preisig and Alpern created a model of chronic nephron hyperfiltration by combining uninephrectomy with high dietary protein intake.[177] Microperfused rat proximal tubules exposed to chronic hyperfiltration of 12–18 days duration absorbed HCO_3 at faster rates than tubules in control animals (sham operation and normal protein diet). This occurred in spite of the fact that both groups of tubules were microperfused at similar perfusion rates. Thus, there is a chronic adaptation in the capacity for HCO_3 absorption with chronic exposure to higher luminal flow rates.

Harris et al. demonstrated that the flow-induced stimulation of Na/H antiporter activity that occurs secondary to either an increase in dietary protein intake or uninephrectomy appears kinetically as an increase in the V_{max} of Na/H antiporter activity with no change in the Na affinity.[178] Addition of $NaHCO_3$ to the diet (to neutralize the acid load from the high protein diet) did not prevent the stimulation of Na/H antiporter activity. Similar results were found in the remnant kidney model where the stimulation of Na/H antiporter activity is most likely secondary to chronic increases in single nephron glomerular filtration rate.[179,180]

Measuring cell pH fluorescently in the *in vivo* microperfused proximal tubule, Preisig and Alpern demonstrated that both apical membrane Na/H antiporter and basolateral membrane $Na/3HCO_3$ cotransporter activities are increased in parallel by approximately 30 and 100% after 24 hrs and 12–18 days, respectively, of hyperfiltration.[177] Harris et al. found a similar percent stimulation of Na/H antiporter activity after 24 hrs of hyperfiltration.[178]

Peritubular (Extracellular) HCO_3 Concentration, pCO_2, and pH

Acute regulation: Acutely increasing peritubular [HCO_3] inhibits proximal tubule HCO_3 absorption, while decreasing peritubular [HCO_3] stimulates HCO_3 absorption.[145,155,168,181–185] Similarly, acute decreases in pCO_2 inhibit and acute increases in pCO_2 stimulate HCO_3 absorption.[155,182,183,185–188]

Alpern showed that changes in peritubular [HCO_3] do not affect HCO_3 permeability, and have minimal effect on paracellular HCO_3 diffusion.[181] Thus, the major effect of peritubular [HCO_3] is on the rate of transcellular proton secretion. This effect is mediated by a direct effect on basolateral membrane $Na/3HCO_3$ cotransporter activity, and, likely, secondarily affects the rate of apical membrane H transporters through resulting changes in cell pH. Alpern and Chambers demonstrated that a 0.7 pH unit change in peritubular pH causes a 0.3 pH unit change in cell pH.[37] This rather large change in cell pH indicates that cell pH is more responsive to changes in systemic or blood pH than to changes in luminal pH, as decreases in luminal pH of 0.7 pH units result in a 0.1 pH unit change in cell pH. Teleologically, such a system seems reasonable in view of the large variations in luminal pH along the length of the proximal tubule, and the generally small changes in blood pH under physiologic conditions.

In the steady state, net changes in apical and basolateral membrane H transport must be equal, so the change in cell pH reflects the change in driving force required for equal changes in apical and basolateral transport. If cell pH changes by 0.3 pH units in response to a 0.7 pH unit change in peritubular pH, the change in driving force across the basolateral membrane transporter is 0.4 pH units and that across the apical membrane is 0.3 pH units. Thus, in this setting, the transporters seem to be of relatively equal sensitivity. As discussed above, the $Na/3HCO_3$ transporter is exquisitely sensitive to changes in cell pH and may also be very sensitive to changes in peritubular pH. In contrast, the apical membrane Na/H antiporter is relatively insensitive to changes in luminal pH, but most likely more sensitive to changes in cell pH (see below).

The response to changes in pCO_2 is complex. As noted above, increases in pCO_2 stimulate HCO_3 absorption and decreases in pCO_2 inhibit HCO_3 absorption. Because of the high proximal tubule CO_2 permeability, any changes in pCO_2 will have immediate and similar effects on luminal, cell, and peritubular pH. The resulting final pHs will be those required to generate equal changes in apical and basolateral membrane fluxes in the new steady state. Krapf et al. found that changes in extracellular fluid pCO_2 lead a cell pH change that is $^2/_3$rds the magnitude of the change in extracellular fluid pH.[146] Thus, respiratory acidosis (an increase in pCO_2) is associated with equal acidification of luminal and peritubular fluids and a cell acidification that is $^2/_3$rds the magnitude of the extracellular pH change. In the steady state, the larger decrease in peritubular pH compared to cell pH will increase the driving force across the $Na/3HCO_3$ co-transporter in favor of increased transporter activity, and can explain the

increased rate of HCO_3 transport across on the basolateral membrane.

On the apical membrane side, the larger decrease in luminal pH compared to cell pH would decrease the driving force for H secretion. However, respiratory acidosis is associated with an increase in apical membrane H transport, which implies that the apical membrane H secretory mechanisms are more sensitive to changes in cell pH than to changes in luminal pH.

Two possible mechanisms exist for increased sensitivity of Na/H antiporter activity to cell pH compared to its sensitivity to luminal pH. First, when Na/H antiporter activity is examined as a function of internal H concentration, transporter activity is greater at acidic pHs than would be expected for simple substrate interaction, suggesting allosteric regulation.[35] In more convincing studies, these investigators measured the rate of amiloride-sensitive Na efflux when internal pH was lowered. Lowering internal pH would be expected to inhibit Na efflux from vesicles by competition between H and Na for the same site. However, lowering intravesicular pH actually accelerated amiloride-sensitive ^{22}Na efflux, providing definitive demonstration for allosteric up-regulation of Na/H antiporter activity by more acidic internal pHs.

This allosteric activation has been demonstrated for most of the NHE isoforms, and the domains responsible identified by detailed studies of NHE1. Wakabayashi et al. showed that deletion of the C-terminus (amino acids 636-815) of NHE1 has no affect on cell pH regulation of antiporter activity, however, deletion of amino acids 567–635 (also in the C-terminal cytoplasmic domain of NHE1) decreases antiporter sensitivity to cell pH.[189]

A second mechanism that could impart sensitivity to cell pH is regulation of apical membrane NHE3 abundance via trafficking. Proximal tubule endosomes contain both H-ATPases and an amiloride-insensitive Na/H antiporter.[190,191] Schwartz and Al-Awqati demonstrated that rapid cell acidification leads to exocytosis of previously endocytosed fluorescein-labeled dextran, raising the possibility that insertion of endosomal transporters into the apical membrane is another mechanism by which transport capacity increases in acidosis.[192]

In the above discussion, the effects of acute changes in pH, $[HCO_3]$, and pCO_2 on HCO_3 absorption were described. In detailed studies varying pH, $[HCO_3]$, and pCO_2 independently, Boron et al. found that acute regulation of proximal tubule acidification processes is mediated by changes in peritubular $[HCO_3]$ and pCO_2, and not pH per se, and have proposed the existence of HCO_3 and pCO_2 sensors on the basolateral side of the cell.[182,185]

While all of the above described acute effects are large, the changes required to elicit them were also large and frequently non-physiologic. If proximal tubular H/HCO_3 transport processes are to participate in the kidney's defense against physiologic changes in the daily metabolic acid load (primarily determined by the composition of the diet), mechanisms that sense and respond to minimal changes in acid–base parameters are required. These more sensitive mechanisms most likely mediate the chronic adaptations in transporter activity.

Chronic regulation: Using the *in vivo* microperfused rat proximal tubule preparation, Kunau et al. demonstrated that chronic acid feeding causes a marked stimulation in HCO_3 absorption that is greater than was seen by Alpern et al. in an acute metabolic acidosis model, in spite of the fact that the decrease in plasma $[HCO_3]$ in the chronic studies was far less than in the acute studies.[181,193] Similarly, Cogan found that chronic hypercapnea stimulated proximal tubule HCO_3 absorption to a far greater degree than did acute hypercapnea.[194]

Cohn et al. demonstrated that Na/H antiporter activity is increased in apical membrane vesicles prepared from dogs with chronic metabolic acidosis compared to control dogs.[195] In that the increased Na/H antiporter activity persisted *in vitro* when studied under control conditions (pH 7.4), this observation demonstrates a memory effect and not an effect secondary to a change in driving force across the transporter. Tsai et al. and Kinsella et al. found similar results in apical membrane vesicles prepared from rabbit and rat kidney cortex, respectively, and Tsai et al. demonstrated that the effect of acidosis is on the Vmax with no effect on transporter affinity for Na.[196,197]

Similar acid-induced stimulation of the basolateral membrane $Na/3HCO_3$ cotransporter has been found. When compared under the same conditions (pH 7.4), Akiba et al. (using rabbit apical and basolateral membrane vesicles) and Preisig and Alpern (using the *in vivo* microperfused rat proximal tubule) demonstrated parallel increases in apical membrane Na/H antiporter activity and basolateral membrane $Na/3HCO_3$ cotransporter activity when preparations from animals with a chronic metabolic acidosis are compared to preparations from control animals.[139,198] Both studies demonstrated that the increase in activities is due to a memory effect and not merely a change in transporter driving force. Akiba et al. also demonstrated a decrease in $Na/3HCO_3$ cotransporter activity in basolateral membrane vesicles prepared from animals with chronic metabolic alkalosis, and a trend for inhibition of Na/H antiporter activity in apical membrane vesicles prepared from the same animals.

Similar studies have been performed in chronic respiratory acidosis, but with mixed results. Some investigators have found increases in apical membrane Na/H antiporter and/or basolateral membrane Na/3HCO_3 activities, while other investigators have found that a chronic respiratory acidosis has no effect on the activity of either transporter.[199–204] The reason for these discrepancies is not clear, it is possible that hemodynamic changes leading to decreases in GFR in some models are obscuring a stimulatory effect.

Further examination of acid regulation of Na/H antiporter activity demonstrated that NHE3 is the NHE isoform regulated by acidosis, and that the increased activity is associated with an increase in brush border NHE3 protein abundance, with no measurable change in renal cortical NHE3 mRNA abundance.[55,56] While it is not clear *in vivo* whether the increase in apical membrane NHE3 protein abundance is due to trafficking of existing transporters from the cytoplasm to the membrane or requires a simultaneous increase in total cell NHE3 protein, cell culture studies suggest it is the former (see below).

Acid activated signaling pathway: To elucidate the signaling pathway that mediates NHE3-stimulation by extracellular acidity, Amemiya et al. established an opossum kidney (OKP) cell culture model in which cells incubated in control (pH 7.4) or acid media (pH 6.6 to 7.2) demonstrate increased activity of an EIPA-resistant Na/H antiporter (kinetics consistent with NHE3).[57] While the stimulatory effect of media acidification on NHE3 activity is evident within 6 hrs and remains elevated at 24 hrs, NHE3 mRNA and protein abundances are only significantly increased at 12 and 24 hrs, respectively, suggesting that, at least the initial increase in NHE3 activity, is not dependent on increases in whole cell protein abundance (Figure 55.6).[57,205] In support of this conclusion, media acidification increases NHE3 activity in the absence of protein synthesis (cycloheximide).[57] Acid stimulation of NHE3 activity correlates with significant increases in apical membrane NHE3 abundance, which also significantly increases by 6 hrs and persists at 24 hrs, suggesting that the increase in NHE3 activity is mediated by trafficking of protein to the apical membrane (Figure 55.6).[205] Exocytic movement of NHE3 to the apical membrane requires an intact cytoskeleton and the increase in apical membrane abundance is required for acid-induced stimulation of NHE3 activity.[205]

A typical western diet that contains animal protein generates about 0.5–1.0 mEq/kg/day of non-volatile acid through metabolism, which must be excreted mEq-for-mEq by the kidneys to maintain acid–base homeostasis. Through buffering mechanisms, this daily acid addition does not significantly change extracellular pH. Thus, a key biological question is how the body

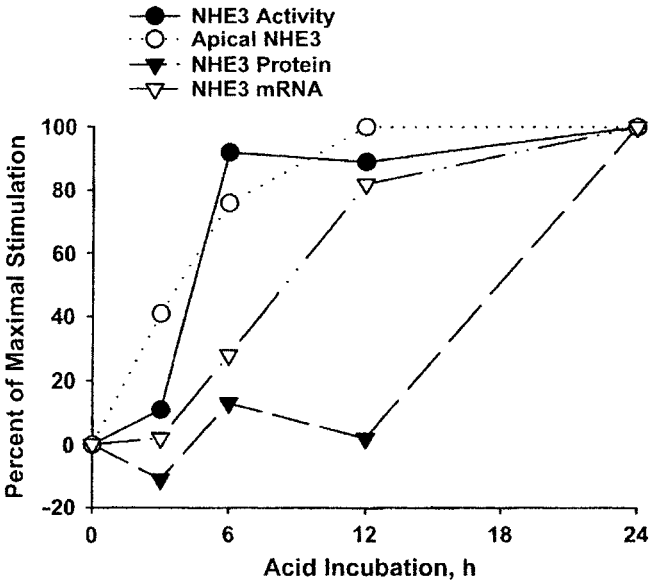

FIGURE 55.6 Time course for the effect of acid on NHE3. NHE3 activity, apical NHE3 protein abundance, total cellular NHE3 protein abundance, and NHE3 mRNA abundance are plotted as the percentage of maximal stimulation *vs* time. *(From Yang X, Amemiya M, Peng Y, Moe OW, Preisig PA, Alpern RJ. Acid incubation causes exocytic insertion of NHE3 in OKP cells. Am J Physiol 2000,279:C410–C419, with permission.)*

responds to the need and senses the precise amount of acid that must be excreted daily. The most likely explanation is that cells respond to "unmeasurable" changes in extracellular pH. If this is the case, sensing mechanisms must be exquisitely sensitive. Ambühl et al. showed that acid feeding increases apical membrane NHE3 protein abundance with changes in extracellular pH of less than 0.1 pH unit.[56] In fact, after seven days of acid feeding plasma pH and HCO_3 concentration are not significantly different from control, while apical membrane NHE3 protein abundance continues to rise (Figure 55.7).[56] Strong evidence suggests that changes in intracellular pH are the signal that initiates the physiological response in that K depletion [extracellular alkalosis and intracellular acidosis (see below)] elicits the same proximal tubule responses as a metabolic acidosis (extracellular and intracellular acidosis).

Endocrine and autocrine pathways have been shown to be involved in mediating the proximal tubule response to an acid load (also see below). In rats, metabolic acidosis is associated with an increase in plasma cortisol levels, and adrenalectomy prevents the acidosis-induced stimulation of Na/H antiporter activity.[197,206,207] In OKP cells, addition of low concentrations of hydrocortisone to the media (that alone do not stimulate NHE3 activity) increase the magnitude of the effect of media acidification on NHE3 activity and whole cell protein abundance, with no effect on

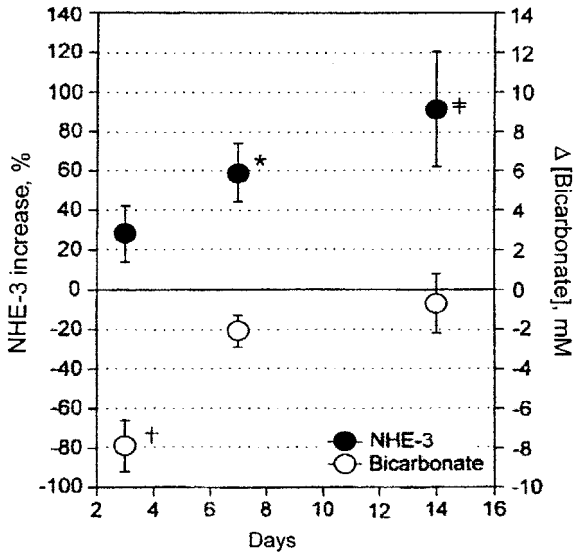

FIGURE 55.7 Acid-induced increase in NHE3 protein abundance (*solid circles*) and decrease in plasma bicarbonate concentration (Δ[bicarbonate], *open circles*) are plotted as a function of duration of treatment. *(From Ambühl PM, Amemiya M, Danczkay M, Lotscher M, Kaissling B, Moe OW, Preisig PA, Alpern RJ. Chronic metabolic acidosis increases NHE3 protein abundance in rat kidney. Am J Physiol 1996,271: F917–F925, with permission.)*

acid-induced increases in NHE3 mRNA abundance.[208] Additional studies demonstrate that the enhanced effect seen in the presence of low dose hydrocortisone is not dependent on protein synthesis, but rather mediated by increased trafficking of NHE3 to the apical membrane.[208] Aldosterone is without effect on NHE3 activity. Taken together, these studies suggest that in the presence of an acid load, low dose glucocorticoids interact synergistically with the acid load to stimulate NHE3 translation and trafficking. Glucocorticoids can also directly increase NHE3 activity, and protein and mRNA abundance, and thus, contribute to the response to an acidosis (see below).

Endothelin also plays a role in acid regulation of NHE3 activitiy. Metabolic acidosis increases renal cortical endothelin levels and endothelin-1 stimulates NHE3 activity (see below).[209,210] In mice in which the ET_B receptor has been knocked out in the kidney, acid feeding does not increase NHE3 activity in renal cortical brush border membrane vesicles, whereas NHE3 activity is significantly increased in vesicles prepared from wild-type mice, demonstrating acid regulation of NHE3 through the ET_B receptor.[211]

Studies elucidating the acid-activated signaling pathway have been performed in OKP cells. In this model, as with *in vivo* models, an intracellular acidification appears to be the key to the adaptation as NHE3 activity is stimulated by both media acidification and exposing cells to weak acids or an NH_4Cl prepulse, maneuvers that acidify the cell but have no effect on extracellular pH.[212] Incubation of OKP cells in acid media activates the non-receptor tyrosine kinases Pyk2 and c-Src and the MAP kinases ERK (extracellular regulated kinase) 1 and 2. Inhibition of Pyk2 kinase [with expression of $pyk2^{K457A}$ (a dominant negative Pyk2) or an siRNA against Pyk2], c-Src kinase [with overexpression of *csk* (*c-Src k*inase, an endogenous inhibitor of Src family kinases), expression of $c\text{-}src^{K295M}$ (a dominant negative c-Src), or expression of $pyk2^{Y402F}$ (a mutant Pyk2 that prevents c-Src binding to Pyk2 and subsequent c-Src activation)], or the ERK 1,2 kinases with PD98059 blocks acid stimulation of NHE3 activity.[212–215] Media acidification also increases transcriptional expression of *c-fos*, *c-Jun*, *junB*, and *egr-1*.[216]

More recent studies have explored the relationship between these acid-activated signaling intermediates and found that downstream of a cell acidification are two parallel pathways.[217,218] One pathway involves Pyk2 and c-Src and the other pathway ERK1 and 2 and the immediate early genes *c-fos* and *c-jun* and their associated increase in activity of the transcription factor AP-1. Following exposure to acid media, Pyk2 is activated within 30 sec, and its activation is required for activation of c-Src kinase, which occurs 90 sec following exposure to acidic media, placing Pyk2 "upstream" of c-Src in the signaling pathway.[213] Studies demonstrating that Pyk2 can be activated by acid in a cell free system over a physiologically relevant pH range (maximal autophosphorylation achieved with a 0.2 pH unit decrease and maximal kinase activity achieved with a 0.4 pH unit decrease) established Pyk2 as the likely proximal tubule cell pH sensor responsible for initiating activation of the acid-activated signaling pathway that mediates the increase in NHE3 activity.[213] Inhibiting acid activation of Pyk2 kinase with the dominant negative $pyk2^{K457A}$ or $siRNA_{Pyk2}$ or inhibiting c-Src kinase with the dominant negative $c\text{-}Src^{K295M}$, while preventing NHE3 activation, do not prevent acid activation of ERK 1 and 2 kinase or the increase in *c-fos* mRNA abundance.[218] These data establish that two parallel pathways are activated by cell acidification and that both are required for acid stimulation of NHE3 activity.

In both cultured OKP cells and *in vivo*, media acidification or acid feeding, respectively, increases endothelin-1 (ET-1) expression.[209,219] The human ET-1 promoter contains an AP-1 binding site between nt -104 and -109. As mentioned above, media acidification increases *c-fos* and *c-Jun* expression and AP-1 activity.[220] Using a luciferase assay, Laghmani et al. showed that acid stimulation of ET-1 transcription is mediated by the above mentioned AP-1 binding site in the ET-1 promoter.[221] Preliminary data from our laboratory suggests that both Pyk2 and c-Src activation are also

required for acid-induced increases in ET-1 transcription, suggesting convergence of the two parallel acid-activated signaling pathways (Figure 55.8).[217] ET-1 stimulation of NHE3 activity is mediated by the ET_B (and not the ET_A) receptor and mediates acid regulation of NHE3 activity.[63,211]

Failure to excrete the daily acid load generated on a typical Western style diet leads to bone demineralization and muscle protein breakdown.[222–224] Described above is the effect of this acid load on NHE3 activity and the acid-activated signaling pathways that likely mediated this effect. However, the renal proximal tubule role in excreting this daily acid load involves more than just stimulation of NHE3 activity. In addition, the apical membrane Na-dependent citrate co-transporter (NaDC-1) and basolateral membrane Na-HCO_3^- (NBC1) activities, NH_3 synthesis, and citrate metabolism are all stimulated. Stimulation of NHE3 activity serves to enhance both proton (H^+) and NH_4^+ secretion, the latter by NHE3 functioning in the Na^+/NH_4^+ exchange mode.[225] Increased NH_3 synthesis involves stimulation of mitochondrial glutaminase (GA) and glutamate dehydrogenase (GDH) activities.[226] Increased citrate metabolism involves stimulation of mitochondrial aconitase (mAcon) (mitochondrial metabolism) and cytoplasmic ATP citrate lyase (ACL) (cytoplasmic metabolism) activities.[227,228] Enhanced citrate reabsorption and metabolism serves to decrease base loss (citrate metabolism generates 3 HCO_3^-/citrate). In addition, the products of citrate metabolism, oxaloacetate (OAA) and acetyl CoA, provide substrates for gluconeogenesis and fatty acid synthesis, respectively, and OAA is also a product of the ammoniagenic process.[226] Thus, the combined effect of stimulating these transport and metabolic processes are enhanced net acid excretion, gluconeogenesis, and possibly fat synthesis.

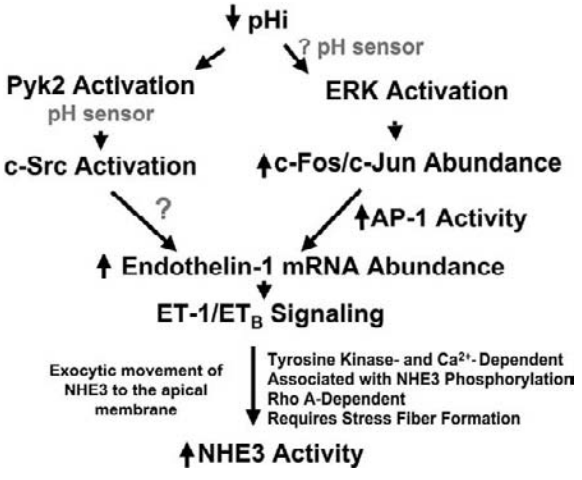

FIGURE 55. 8 Proposed acid-activated signaling pathways that mediates acid stimulation of NHE3 activity.

Preisig and Alpern used both *in vitro* (OKP cell line) and *in vivo* (C57Bl6 and various WT and KO transgenic mouse lines) models to identify the pathways that coordinately regulate the proximal tubule response to an acid load and determined that two apparently parallel pathways are involved. One pathway, involves Pyk2, the endothelin B receptor and calcineurin and the other Nocturnin, a deadenylase member of the circadian gene family (unpublished observations). As described above, Pyk2 serves as a pH sensor for activation of the proximal tubule response. Pyk2, the endothelin B receptor, and the Ca^{2+}/calmodulin/calcineurin pathway, but not the Nocturnin pathway is required for acid stimulation of both NHE3 and NaDC-1 activities. Pyk2 is required for acid stimulation of the three above mentioned mitochondrial enzymes (GA, GDH, and mAcon), while the endothelin B receptor is required for acid stimulation of only GA and GDH and Nocturnin is not required for stimulation of the mitochondrial enzymes, but is required for acid stimulation of the citrate metabolic enzymes (mAcon and ACL) (unpublished observations). Taken together, it appears that the Pyk2/endothelin B receptor/calcineurin pathway mediates acid regulation of apical membrane transport and ammoniagenesis, while citrate metabolism is regulated by the parallel pathway that requires nocturnin.

Perhaps consistent with the absence of an effect of apical membrane transport or ammoniagenic enzymes, Nocturnin knockout mice do not demonstrate a more severe metabolis acidosis when fed an acid diet (unpublished observation). In contrast, Pyk2 and endothelin B receptor knockout mice develop a more severe metabolic acidosis within the first week, but the difference progressively disappears, as has been shown by many investigators in chronic metabolic acidosis studies (unpublished observation).

Potassium Depletion

Using *in vivo* microperfusion Chan et al. compared rates of HCO_3 absorption in control and K depleted animals, demonstrating a 23% stimulation associated with K depletion, while acute changes in peritubular K concentration were without effect.[145] Soleimani and McKinney demonstrated parallel increases in Na/H antiporter and Na/3HCO_3 cotransporter activities in apical and basolateral membrane vesicles, respectively, prepared from K depleted animals and Amemiya et al. demonstrated increased NHE3 activity in OKP cells incubated in low K media.[229,230] The stimulation in transporter activities is an effect on the V_{max} with no effect on Na affinity. These increases in transporter activities, which mimic the adaptation to an acid load,

are likely mediated by an intracellular acidification as Adam and coworkers showed with ^{31}P NMR spectroscopy that the average renal intracellular pH is lower in K depleted animals and incubation of OKP cells in low K media leads to intracellular acidification.[229,231]

Extracellular Fluid Volume

Free flow micropuncture studies have found varying results regarding the effects of extracellular fluid volume on HCO_3 reabsorption. Cogan demonstrated that volume expansion has only a slight inhibitory effect on $NaHCO_3$ absorption, while Bichara et al. found a much larger effect on $NaHCO_3$ absorption.[232,233] Mercier et al. observed that prior parathyroidectomy prevents the large effect of volume expansion on $NaHCO_3$ absorption and proposed that the difference between the results of Cogan and Bichara et al. may be due to effects on PTH secretion.[234]

In vivo microperfusion studies identified two possible mechanisms by which expansion of extracellular fluid volume can inhibit proximal tubule $NaHCO_3$ absorption. First, Alpern et al. found that extracellular fluid volume expansion increases the paracellular HCO_3 permeability by 50%, which agrees with studies showing that transepithelial electrical resistance also decreases.[181,235,236] Second, Alpern demonstrated that changes in proximal tubule volume absorption modify the rate of $NaHCO_3$ absorption, an effect that is not due to changes in solvent drag, but, rather, represents a modification of transcellular H secretion, possibly mediated by changes in interstitial pH and HCO_3 concentration with secondary changes in transcellular H secretion as discussed above.[159] Consistent with this hypothesis, apical membrane NHE3 activity is regulated by hormones known to be involved in the regulation of extracellular volume (see below) and NHE3 knock out mice are hypotensive, hypovolemic, and have a mild metabolic acidosis.[44,237]

Moe et al. examined the effects of chronic changes in dietary Na intake on Na/H antiporter activity assayed in brush border membrane vesicles, comparing rats that had been placed on either a low or high NaCl intake for four days.[238] The 20% increase in Na/H antiporter activity observed in vesicles made from kidney cortex harvested from the rats on the low salt diet was associated with an effect on the Vmax and no effect on Na affinity. An increase in Na/H antiporter activity would increase both proximal tubular $NaHCO_3$ absorption and proximal tubular NaCl absorption.

A possible mechanism for dietary salt regulation of NHE3 was suggested by studies by Yang et al. that showed that following three weeks of a high salt diet, NHE3 phosphorylation on Ser^{552} doubled and was associated with the phosphorylated NHE3, dipeptidyl peptidase IV (DPPIV), myosin VI and the angiotensin II type 2 receptor being redistributed from the low-density plasma membrane-enriched fractions to higher-density intracellular membrane-enriched fractions and the phosphorylated NHE3, myosin VI and the angiotensin II type 2 receptor relocalized to the base of the microvilli (observed by confocal microscopy).[239] These observations are consistent with studies showing that DPPIV catalytic activity is required for NHE3-mediated $NaHCO_3$ reabsorption.[240]

Hormonal Regulation

Parathyroid Hormone: Free flow micropuncture studies demonstrated that parathyroid hormone (PTH) inhibits proximal tubular HCO_3 absorption in dogs and rats.[241,242] *In vitro* microperfusion studies in rabbit proximal tubules also demonstrated that addition of PTH to the peritubular fluid inhibits HCO_3 absorption.[243–245] This effect is mediated by inhibition of transcellular HCO_3 absorption, and is not associated with a change in HCO_3 permeability.[244,245] Using apical membrane vesicles prepared from proximal tubule suspensions or OK cells exposed to PTH, it was shown that PTH decreases Na/H antiporter activity, and that this effect is mediated by a PTH-induced modification of the internal pH sensitivity of NHE3.[64,246,247] Consistent with PTH having an inhibitory effect on NHE3 activity, Cohn et al. showed that *in vivo* thyroparathyroidectomy increases Na/H antiporter activity, assayed in apical membrane vesicles.[195]

The effects of PTH on Na/H antiporter activity are similar to those of dibutyryl or 8-bromo cyclic AMP.[244–246] In brush border membrane vesicles, OK cells, and Na/H antiporters reconstituted into liposomes, cyclic AMP-dependent protein kinase (protein kinase A) directly inhibits Na/H antiporter activity.[248–252] An important role for protein kinase A is confirmed by the observation that expression of a dominant negative protein kinase A catalytic subunit blocks inhibition of NHE3 by cAMP.[253] Moe et al. found that purified protein kinase A phosphorylates the cytoplasmic domain of NHE3 *in vitro*, and that 8-bromo cAMP phosphorylates NHE3 in cultured cells.[253,254] In *Xenopus* oocytes, 8-bromo cAMP inhibits wild type NHE3 activity, but not NHE3$_{\Delta cyto}$, in which the cytoplasmic domain is deleted.[254] It remains controversial as to which site in the cytoplasmic tail is phosphorylated by PKA/cAMP and mediates the inhibitory effect. Kurashima et al. found that both Ser^{605} and Ser^{634} (both in the cytoplasmic domain) are required for PKA regulation of NHE3, but only Ser^{605} is phosphorylated.[255] Zhao et al. found that cAMP phosphorylates multiple serines on the NHE3 cytoplasmic tail, and that phosphorylation of both Ser^{552} and Ser^{605} are required for PKA-mediated inhibition of

NHE3 activity.[253] The reason for this discrepancy is not clear. Kocinsky et al. generated Ser^{552}- and Ser^{605}-specific antibodies and demonstrated that in rat kidney cortex Ser^{552} is phosphorylated to a much greater extent than Ser^{605} in control animals, and that the Ser^{552}-phosphorylated NHE3 is localized to the coated pit region of the brush border membrane, where NHE3 is inactive. Consistent with this, Kocinsky et al. demonstrated that although phosphorylation of NHE3 at Ser^{552} and Ser^{605} is regulated by PKA both *in vivo* and *in vitro*, phosphorylation of these sites does not directly alter NHE3 activity.[78,79]

An alternative mechanism of PKA-mediated inhibition of NHE3 activity was proposed by Bezerra et al. who demonstrated that following exposure to PTH, decreased NHE3 activity was associated with diminished NHE3 surface expression and total cellular NHE3 protein and mRNA abundances, and a decrease in mRNA stability. Additional studies demonstrated that PTH exposure results in a PKA-dependent inhibitory effect on the NHE3 promoter that was responsible for the reduced mRNA half-life stablility.[256]

NHE3 regulation by protein kinase A also involves reorganization of the cytoskeleton and involvement of a second factor, NHERF-1 (Na/H exchange regulator factor, also known as ezrin binding protein 50).[257–262] NHERF-1 was identified by Weinman et al., when a brush border membrane protein fraction that did not contain Na/H antiporter activity was found to bestow regulation of the antiporter by protein kinase A.[263,264] *In vitro* studies demonstrated that NHERF-1 inhibits NHE3 activity, and that in NHERF-1 null cells or in the NHERF-1 knock-out mouse, PTH is without effect on NHE3 activity, a response that can be reinstated by expression of NHERF-1 in NHERF-1 null cells.[257,265,266]

NHERF-1 is one of four members of the NHERF family, the other three members being NHERF-2 [also called E3KARP (NHE3 kinase A regulatory protein)], NHERF-3 (also known as PDZK1), and NHERF-4 (also known as IKEPP). These proteins range in size from 337 to 519 amino acids. NHERF-1 and -2 contain ERM (ezrin, radixin, moesin) binding domains, while NHERF-3 and -4 do not.[267] NHERF-1 and -2 have two PDZ protein binding domains, while NHERF-3 and -4 have four PDZ domains. Weinman et al. have shown that the C-terminal PDZ domain (aa 150-241) in NHERF-1 is primarily responsible for NHE3 inhibition by cAMP.[266] Ezrin, an actin binding protein of the ERM family, links membrane proteins to the actin cytoskeleton.[259] Ezrin is also a protein kinase A binding protein, and studies have shown that interactions between NHE3, NHERF-1, and ezrin are required for protein kinase A-mediated phosphorylation and inhibition of NHE3 activity.[268] Thus, NHERF-1 appears to function as a scaffolding protein within the NHE3 regulatory signaling complex.

Rat proximal tubule and OK cells express only NHERF-1, while human, mouse, and possibly rabbit proximal tubules express both NHERF-1 and -2.[261] In mice, NHERF-1 distributes to the microvillus and co-localizes with NHE3, while NHERF-2 is localized predominantly in a submicrovillar region.[261,262] Although there is controversy regarding whether only NHERF-1 or both NHERF-1 and -2 play a role in cAMP-mediated inhibition of NHE3 activity, the studies mentioned above showing no cAMP regulation of NHE3 activity in the NHERF-1 knock-out mouse, which does express NHERF-2, suggests that only NHERF-1 mediates this effect.[258,265,269] Consistent with a link between NHE3, NHERF-1, ezrin, and the actin cytoskeleton, *in vivo* studies demonstrate that following PTH infusion, NHE3 retracts from the tips to the base of proximal tubule microvilli.[270]

Hruska et al. have found that PTH can also activate phospholipase C in proximal tubule cells leading to increased levels of inositol trisphosphate and diacylglycerol.[271] The increase in inositol trisphosphate leads to an increase in cell Ca^{2+} that may directly modify Na/H antiporter activity or activate other cell kinases. Increases in diacylglycerol activate protein kinase C, which may modify Na/H antiporter activity either directly or indirectly. Weinman et al. and Mellas et al. have found that protein kinase C directly increases Na/H antiporter activity in apical membrane vesicles and proximal tubule cell suspensions, respectively.[272,273] Inconsistent with these findings, Baum and Hays found that protein kinase C activation inhibits HCO_3 absorption in the *in vitro* perfused rabbit proximal tubule.[274] However, Wang and Chan showed in the *in vivo* perfused rat proximal tubule that this inhibition may be due to prolonged activation of protein kinase C, and that the acute effect is a stimulation of transcellular HCO_3 absorption.[275] Studies in cell culture have also yielded conflicting results with both stimulation and inhibition of NHE3 by protein kinase C reported.[49,276–279]

It has also been difficult to define the effect of increases in intracellular Ca^{2+} on Na/H antiporter activity. Both stimulation and inhibition of proximal tubular HCO_3 absorption have been observed with calcium ionophores.[280–282] Bertrand et al. found that NHE1 is stimulated by increases in cell Ca^{2+}, an effect mediated by Ca^{2+}-dependent binding of calmodulin to amino acids 636-656 in the cytoplasmic domain.[283] This cytoplasmic region was shown to inhibit the pH activation of NHE1, an effect blocked by binding of calmodulin.[284] NHE3, on-the-other-hand, is not regulated by cell Ca^{2+}, but a chimera containing the N-terminal half

of NHE3 and the Ca^{2+}-sensitive C-terminal half of NHE1 reinstated Ca^{2+}-induced regulation.[285]

Angiotensin II and Aldosterone: Liu and Cogan demonstrated that angiotensin II (Ang II) is a potent stimulator of proximal tubular HCO_3 absorption.[286,287] This effect occurs predominantly in the early proximal tubule but is also present in the late proximal tubule. The effect on HCO_3 absorption is independent of renal nerve activity. Geibel et al. reported that Ang II added to *in vitro* perfused proximal tubules increases both Na/H antiporter and $Na/3HCO_3$ cotransporter activities, consistent with other conditions that regulate transepithelial HCO_3 absorption.[288] Saccomani et al. showed that the effect of Ang II is on the V_{max} of Na/H antiporter activity, and is without effect on Na affinity.[289]

Cano et al. found that Ang II concentrations of 10^{-9}–10^{-12} M stimulate NHE3 activity, 10^{-8} M has no effect, and higher concentrations (10^{-6} M) inhibit the antiporter in cultured OKP cells.[62] This biphasic concentration response is similar to that previously reported for the effect of Ang II on transepithelial Na transport.[290,291] It is not presently clear whether the effects of high concentrations are physiologically relevant, however, Seikely et al. reported that luminal and peritubular capillary Ang II concentrations are in the range of 10^{-9}–10^{-8} M, suggesting that high concentrations may not be physiologically relevant.[292]

Liu and Cogan demonstrated that the Ang II effect on HCO_3 absorption is associated with a decrease in luminal cAMP concentration and that pertussis toxin pretreatment of the whole animal blocks the effects of Ang II on HCO_3 absorption and luminal cAMP concentration.[287] These results agree with other studies that show that Ang II inhibits adenylyl cyclase in renal cortical homogenates and in primary cultures of renal proximal tubules.[293,294] However, other pathways must also be important, as Cano et al. found in OKP cells that low concentrations of Ang II increase NHE3 activity without altering cAMP production.[62]

High concentrations of Ang II increase intracellular Ca^{2+} concentration.[295,296] However, these Ang II concentrations are associated with inhibition of solute flux in *in vivo* and *in vitro* studies.[290,291] Ang II also signals through protein kinase C, CaM kinase, phospholipase A_2, and the non-receptor tyrosine kinase c-Src.[297] The physiological effects of Ang II signaling through these pathways vary from preparation to preparation, and thus, the key physiological pathways are not yet clear.[297]

The effects of chronic exposure to Ang II (16 hrs to 7 days) has revealed conflicting results. In OKP cells 16 hr exposure to 10^{-7} M Ang II increases NHE3 activity and mRNA abundance, both effects inhibited by actinomycin D (inhibitor of transcription).[298] In tissues harvested from rodents infused with Ang II, 7 days exposure to a pressor dose increases NHE3 activity in brush border membrane vesicles and increases both mRNA and protein abundance in renal cortex and brush border membrane vesicles, respectively.[299] In contrast, another study found that 3 days exposure to a non-pressor dose of either Ang II or Ang II Type 1 (AT1) receptor blocker has no effect on NHE3 protein abundance in cortical or whole kidney homogenates, respectively, but Ang II increases and the AT1 receptor blocker decreases abundance of the basolateral membrane $NaHCO_3$ cotransporter in the same tissue preparation.[300] The cause of the difference between the two studies with respect to the Ang II effect on NHE3 is not known, but may be due to the use of an Ang II dose that raises blood pressure in the former study and one that has no effect on blood pressure in the latter study.

Angiotensin II at a concentration that stimulates NHE3 activity (10−7 M) also stimulates H-ATPase activity in a SV40-transformed rat proximal tubule cell line. This effect does not involve changes in mRNA or protein abundances of the B2 subunit, but is associated with increased cell surface expression of the V-ATPase. Tyrosine kinases, PI3K and p38 all were required for the effect of Angiotensin II on H-ATPase activity.[301]

In adrenalectomized rats, aldosterone stimulates NHE3-dependent proximal tubule volume absorption, an effect that is associated with an increase in brush border NHE3 protein abundance without a change in cortical NHE3 protein abundance.[302] Studies by Drumm et al. suggest that this effect is mediated through the EGF receptor, with aldosterone increasing EGF receptor expression in primary cultures of human renal proximal tubule epithelial cells.[303] More recently, tubule perfusion studies have suggested that luminal or peritubular aldosterone has a non-genomic stimulatory effect on HCO3 reabsorption in the proximal tubule, an effect that appears dependent on glucocorticoid receptors.[304]

Endothelin: The endothelins are important regulators of proximal tubule transport, mediating changes in volume absorption and regulation of the acidification process.[211,217,305–308] Endothelin-1 (ET-1) stimulates apical membrane Na/H antiporter activity in rat and rabbit proximal tubule.[309,310] In wild type OKP cells ET-1 does not regulate NHE3, however, ET-1 stimulation of NHE3 activity can be induced in OKP cells transfected with the endothelin B (ET_B), but not the endothelin A (ET_A), receptor.[63] This effect of ET-1 is mediated 50% by increases in cell Ca^{2+} and CaM (Ca^{2+}-calmodulin) kinase, and 50% by tyrosine kinase pathways.[63,311] In addition, stimulation of NHE3 activity is associated with phosphorylation and trafficking of NHE3 to the apical membrane.[312,313]

As a family, the endothelins are locally acting autocrine/paracrine factors. As mentioned above, in both cultured OKP cells and *in vivo*, media acidification or acid feeding, respectively, increases ET-1 expression, an effect that is mediated through an AP1 site in the ET-1 promoter.[209,219,221] Also as mentioned above, in mice in which the ET_B receptor has been knocked out in the kidney, acid feeding does not increase NHE3 activity in renal cortical brush border membrane vesicles, whereas NHE3 activity is significantly increased in vesicles prepared from wild-type mice, demonstrating that the effect of acid on proximal tubule NHE3 activity is indirect, and mediated by ET-1 signaling through the ET_B receptor.[211]

Given that the effect of acid on NHE3 activity is indirect and mediated by the ET-1/ET_B signaling pathway, recent studies have sought to determine which signaling intermediates in the acid-activated signaling pathway are "up-stream" and which ones are "down-stream" of ET-1/ET_B. Results have demonstrated that two non-receptor tyrosine kinases Pyk2 and c-Src and the MAP kinases ERK 1 and 2 are required for acid, but not ET-1 stimulation of NHE3 activity, placing them "up-stream" of ET-1/ET_B,.[213–215,217,314]

Catecholamines: Chan demonstrated that addition of catecholamines to the peritubular capillary fluid increases HCO_3 absorption in the microperfused proximal tubule and Nord et al. showed that catecholamines increase Na/H antiporter activity in proximal tubule cell suspensions.[315,316] These studies demonstrated that the catecholamine effect is mediated by α_2 agonists. Non-specific α agonists inhibit adenylyl cyclase in renal cortical tubules and α_2 agonists inhibit adenylyl cyclase in renal cortical homogenates.[317,318] Thus, the possibility exists that both α_2 agonists and Ang II stimulate NHE3 activity by inhibiting adenylyl cyclase through a $G\alpha_i$ protein. Recent studies have shown that α_1 adrenergic receptor stimulation also increases NHE3 activity, but this effect is mediated by MAPK.[319] Lastly, β_2 adrenergic agonists can activate NHE3 by inducing β_2 adrenergic receptor binding to NHERF through binding of a NHERF PDZ domain with the last few residues of the C-terminal cytoplasmic domain of the receptor.[320]

Glucocorticoids: Glucocorticoids administered *in vivo* increase Na/H antiporter activity in apical membrane vesicles from renal cortex.[321] Glucocorticoids added to the media of primary cultures of proximal tubule or OKP cells stimulate NHE3 activity, demonstrating a direct effect of glucocorticoids on the Na/H antiporter.[322,323] In both OKP cells and proximal tubules harvested from rabbits given glucocorticoids, the increase in NHE3 activity is mediated by stimulation of NHE3 transcription leading to increases in NHE3 mRNA abundance, effects that are blocked by preventing transcription or protein synthesis with actinomycin D or cycloheximide, respectively, or by blocking the glucocorticoid receptor with RU486.[58,59,324]

The above studies address the chronic mechanism by which glucocorticoids stimulate NHE3 activity. Studies have shown that glucocorticoid-induced stimulation of NHE3 activity preceeds the increase in NHE3 protein abundance, suggesting that the acute effects on NHE3 activity are mediated by another mechanism.[324] Consistent with this, the acute effects are blocked by the glucocorticoid receptor blocker RU486, but are insensitive to actinomycin D or cycloheximide.[324] Moe et al. demonstrated that acute regulation of NHE3 activity is mediated by dexamethasone-induced exocytic trafficking of NHE3 protein to the apical membrane.[325] Additional studies demonstrated that dexamthasone-induced phosphorylation of Ser[663] by serum- and glucocorticoid-inducible kinase (SGK1) preceeds this and is required for the dexamethasone-induced stimulation of NHE3 activity and the increase in apical membrane protein expression.[326]

As discussed above, in addition to directly stimulating NHE3 activity, glucocorticoids synergistically increase the effect of acidosis on NHE3 protein abundance.[208]

Insulin: In the proximal tubule insulin stimulates volume absorption, ammonia synthesis and excretion, and Na/H antiporter activity.[327–329] In OK cells the signaling mechanism mediating insulin stimulation of NHE3 activity is time-dependent.[330] Chronic exposure (24 hrs) stimulates NHE3 activity through the PI3K-SGK1 signaling pathway, while the pathway that mediates acute regulation (1-2 hrs) is not known, but has been shown not to involve the PI3K-SGK1 or cbl/CAP/TC10 (complex that assembles caveolae, which NHE3 may associate with) pathways, increases in apical membrane NHE3 expression, NHE3 phosphorylation, or association with megalin.[330]

LOOP OF HENLE AND THICK ASCENDING LIMB

The loop of Henle reabsorbs 10-20% of filtered HCO_3^-.[331] At least two important phenomena contribute to bicarbonate reabsorption in the loop of Henle. First, reabsorption of water in the descending limb concentrates the luminal fluid and elevates the HCO_3 concentration to ~10-25 mM, raising luminal pH.[332,333] The second phenomena is the reabsorption of HCO_3 by the thick ascending limb (TAL).[334,335] The initial elevation of luminal HCO_3 concentration facilitates reabsorption in the TAL, where reabsorption of bicarbonate is dependent on luminal HCO_3^- concentration and is

gradient limited as in the proximal tubule. In other words, the TAL cannot lower luminal HCO_3 concentration below ~5 mM,[334] if the fluid delivered to the TAL had a low HCO_3 concentration, as present at the end of the proximal tubule, HCO_3 could not be reabsorbed in the TAL. The alkalinization of luminal fluid is also important in raising luminal ammonia concentrations and hence the transport of ammonium from the loop to the collecting tubules.[336]

Earlier micropuncture studies demonstrated that ~50–70% of the HCO_3 remaining at the end of the accessible superficial proximal tubule is reabsorbed prior to the superficial distal tubule.[332,337] The site of this HCO_3 reabsorption was established when Good and colleagues found that rat cortical and medullary TAL perfused *in vitro* reabsorb HCO_3 at a rate of up to ~20 pmole/mm·min, comparable to that in collecting tubule segments.[334,335] (The late proximal tubule *in vivo* probably reabsorbs only a small amount of the filtered HCO_3.) Subsequent studies indicated that the general features of acid–base transport in the rat TAL are those depicted in Figure 55.9.[338] The apical H extrusion process is predominantly sodium-dependent and amiloride-sensitive, i.e., Na-H exchange.[334,339,340] The predominant apical membrane Na-H exchanger in the TAL is the NHE3 isoform.[341,342] However, NHE2 is also present on the apical membrane of the TAL.[343,344] A luminal vacuolar type of H-ATPase is also present

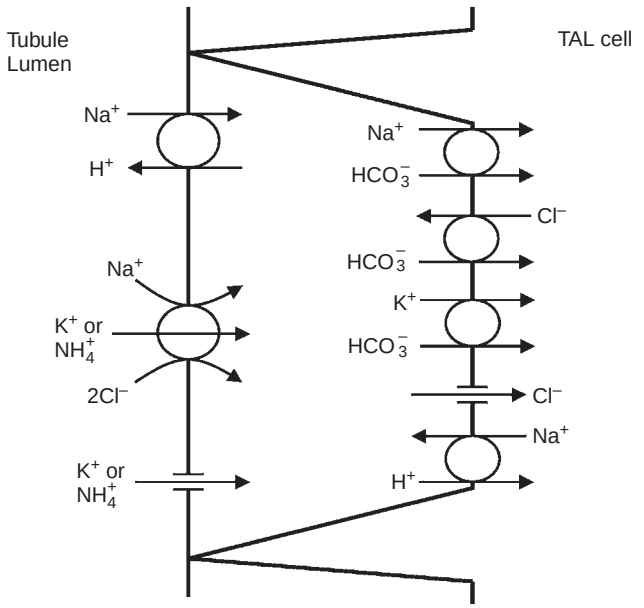

FIGURE 55.9 Model of acid–base transport in the thick ascending limb (TAL). Not shown is carbonic anhydrase, which is important in facilitating acid–base transport in this segment. Also not shown is apical H^+-ATPase, which may have a role in H^+ secretion. See text for additional details.

but its role in transepithelial HCO_3 transport in the TAL is not established.[17,338,340,345,346] Similarly, K-ATPase activity and a K^+-dependent HCO_3 transport pathway (possibly a K^+–HCO_3^- cotransporter) have been found in TAL but their roles are not clear either.[347,348]

The basolateral extrusion of HCO_3 probably occurs via a Na/HCO_3 cotransporter as in the proximal tubule. Krapf identified a sodium-dependent, chloride-independent, SITS-sensitive HCO_3 transport system on the basolateral membrane of the rat cortical TAL.[349] Similar findings were reported for the mouse medullary TAL.[340] Electroneutral NBC 2 (also known as NBCn1, *Na-Bi*carbonate *Co*-transporter) is thought to be the predominate mechanism, at least in the medullary portion of the TAL.[350,351] In addition, basolateral Cl/HCO_3 exchange (AE2, anion exchanger 2) and K-HCO_3 transport are present and may be involved in transepithelial HCO_3 transport.[352–358] AE2 may mediate some of the adaptive changes that occur in acid–base transport in the TAL.[359,360]

Other acid–base transporters are present in the TAL as well. Basolateral Na-H exchange (NHE-1 and NHE-4) probably functions in pH_i and cell volume regulation, in regulation of apical Na-H exchange, and in absorption of NH_4^+.[133,357,361–363] The apical and basolateral Na-H exchangers appear to be functionally linked, increasing in activity of the basolateral Na-H exchanger are accompanied by increases in the apical rates as well.[364,365] NHE1 is proposed to control activity of NHE3, and consequently HCO_3^- reabsorption, by a mechanism involving a change in cellular polymerized actin.[366]

Basolateral chloride channels are present in the TAL but the role in acid–base transport has not been well defined. ClC-Kb/barttin (ClC-K2/barttin in rodents, barttin—a small necessary accessory protein) is present in the TAL,[367] distal convoluted tubule, and intercalated cells of the collecting duct. Mutations in either ClC-Kb or barttin leads to Bartter's syndrome, discussed elsewhere.[368]

The TAL also reabsorbs ammonium, probably via NH_4^+ movement on the apical Na-K-2Cl cotransporter, and possibly via apical K channels.[335,369–373] The lumen positive voltage may also drive some paracellular movement of NH_4^+.[369,370] Of particular note, the apical membrane of the TAL has been recognized to have an extremely low permeability to NH_3, compared to most other biological membranes.[340,372,373] Transport of ammonium across the basolateral membrane is likely via NHE4 and possibly NH_3 diffusion.[371] NHE4 adapts to metabolic acidosis to increase TAL absorption and ultimate excretion of ammonium.[374] Ammonia transport is discussed further in another chapter.

As in most nephron segments involved in acid–base transport, bicarbonate reabsorption in the TAL is dependent on carbonic anhydrase.[334] The rat TAL has both cytosolic and apical and basolateral membrane carbonic anhydrase,[157] the rabbit TAL, which does not have carbonic anhydrase, does not reabsorb HCO_3.[375,376] Human and mouse TAL also have carbonic anhydrase and therefore may reabsorb HCO_3.[375,377]

Regulation of HCO_3 reabsorption in the TAL has been examined both *in vivo* and *in vitro*. Acute and chronic metabolic acidosis stimulate, and chronic chloride depletion metabolic alkalosis inhibits, HCO_3 reabsorption in the TAL.[378,379] Acidosis increases NHE-3 and basolateral Na-HCO_3^- co-transport.[350,341] NHE-3 decreases with metabolic alkalosis.[380] However the effects of metabolic alkalosis on HCO_3 reabsorption i*n vivo* appear to vary with some experimental models perhaps due to opposing influences of the acid–base status and sodium and HCO_3 delivery. HCO_3^- reabsorption increases as luminal HCO_3^- concentration increases.[334,381]

Sodium chloride or sodium bicarbonate loading *in vivo* increase HCO_3 reabsorption in the TAL via mechanisms involving both NHE3 and NHE1,[382] and sodium depletion reduces HCO_3 reabsorption.[379] These effects of sodium balance have been thought to result from changes in sodium delivery rather than from changes in mineralocorticoids.[379] However, recently aldosterone has been shown to inhibit TAL HCO_3^- reabsorption by a non-genomic inhibition of NHE3.[383,384] Glucocorticoids and aldosterone at high doses have been reported to stimulate HCO_3 reabsorption *in vivo*.[345,378,385] Angiotensin II inhibits TAL HCO_3^- reabsorption via a P-450 dependent mechanism.[386] A variety of other peptide hormones have also been found to alter HCO_3 reabsorption in the TAL both *in vivo* and *in vitro*. Arginine vasopressin (AVP) and glucagon acting via cAMP inhibit HCO_3 reabsorption.[387–389] Nerve growth factor can either inhibit or stimulate TAL HCO_3 reabsorption, depending upon the presence or absence of other regulatory factors,[390] inhibiting HCO_3 reabsorption via ERK.[391] The effect of PTH is complex. *In vitro*, PTH modestly inhibits HCO_3 reabsorption,[388] however, *in vivo* PTH infusion enhances loop HCO_3 reabsorption in thyroparathyroidectomized rats, perhaps in part from an increased load of bicarbonate.[392] Toll-like receptor 4 (TLR4) and TLR2 activation inhibit NHE3 and TAL bicarbonate reabsorption.[393–395]

Osmolality and furosemide also alter HCO_3 reabsorption in this segment. Increases in osmolality, signaling via tyrosine kinase pathways, decrease apical Na/H exchange and HCO_3 reabsorption,[363,396] *in vivo*, this may be an additive factor with AVP during states of antidiuresis. Hyposmolality stimulates HCO_3 reabsorption via a PI-3 kinase mechanism.[397,398] However, PGE_2 reverses inhibition of HCO_3 absorption by AVP (but not hyperosmolality), this reversal occurs via PKC and pertussis toxin sensitive G protein pathways.[399,400] Furosemide stimulates TAL HCO_3 reabsorption, possibly due to decreased cell Na (and hence increased Na-H exchange) or cell hyperpolarization.[334,388] This effect may contribute to the enhanced urine acidification observed with furosemide.

An interesting effect is that basolateral NHE1 appears to regulate activity of apical NHE3, and consequently HCO_3^- reabsorption, by a mechanism involving a change in cellular polymerized actin.[366]

DISTAL NEPHRON

Luminal fluid delivered to the distal nephron is normally low in [HCO_3] and pH, usually 5-7 mEq/L and 6.5–6.7, respectively.[332,337] The distal tubule reabsorbs this remaining HCO_3 via H secretion, as in the proximal tubule. In contrast to the proximal tubule, however, net H secretion continues after reabsorption of virtually all of luminal HCO_3, lowering luminal and urine pH to less than 5.5 under appropriate conditions. This process requires active H secretion and an epithelium able to maintain large concentration gradients for H and HCO_3. H secretion or HCO_3 reabsorption in the distal tubule is generally considered to result from primary H secretion. Supporting primary H secretion are studies demonstrating an acid luminal disequilibrium pH under certain circumstances in the superficial distal tubule, in the cortical and outer medullary collecting tubules, and in papillary collecting tubules.[6,401–406]

The distal nephron, beyond the thick ascending limb, is composed of several distinct segments and a diversity of cell types, several of which are involved in acid–base transport, primarily H secretion. Some segments of the distal tubule can secrete HCO_3, at least under some circumstances. Despite this diversity, the general mechanisms of luminal H secretion (HCO_3 reabsorption) are likely similar along the distal nephron. A general model of an H secreting cell is depicted in Figure 55.10. This model originated from studies of the turtle urinary bladder and has been best confirmed in studies of intercalated cells of the rabbit cortical collecting tubule and outer medullary collecting tubule.[407–409] (The turtle bladder, an ancestral and embryologic relative of the collecting tubule, had been extensively used in the past as an *in vitro* model of distal nephron acid–base transport but will not be reviewed here.) The general features of H secreting cells in the distal nephron are the apical H pump, a basolateral Cl/HCO_3 exchanger, and a basolateral Cl channel. In addition, an apical H,K-ATPase is present in many of these cells.[410–412] In most, if not all, H

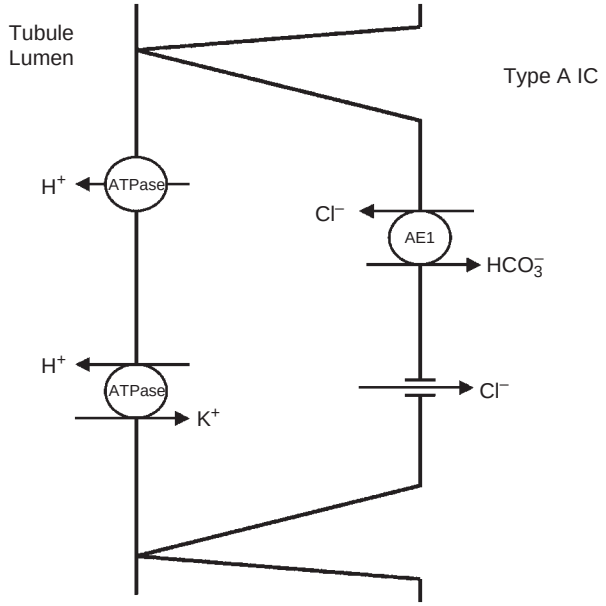

FIGURE 55.10 Model of H^+ secreting type A intercalated cell. Other transporters (such as Na^+-H^+ exchanger) may be present, but are probably not involved in transepithelial acid–base transport.

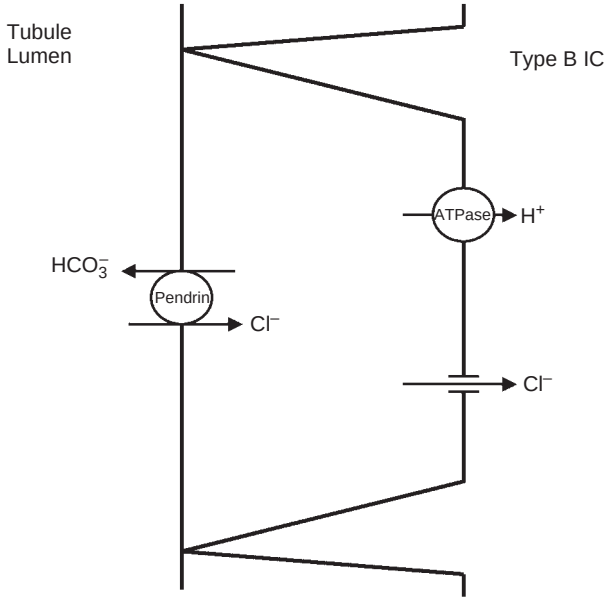

FIGURE 55.11 Model of HCO_3^- secreting type B intercalated cell of the cortical collecting duct. Other transporters (such as Na^+-H^+ exchanger) may be present, but are probably not involved in transepithelial acid–base transport.

secreting cells, the process is accelerated by cytosolic and/or membrane associated carbonic anhydrase. The primary apical H pump is a vacuolar type H-ATPase, at least in most of these cells.[413,414] The basolateral Cl/HCO_3 exchanger is related to the red cell Cl/HCO_3 exchanger, band 3 protein, which has been extensively studied.[415,416] Each of these features of the H secreting cell will be discussed in depth subsequently.

The opposite process, HCO_3 secretion, is modeled in Figure 55.11. The general features are apical Cl/HCO_3 exchange, basolateral H extrusion, and a basolateral Cl channel.[408,409] An apical H,K-ATPase may be present in some HCO_3 secreting cells but is not depicted in Figure 55.11 since the role in transepithelial transport is not clear.[417,418] HCO_3 secretion occurs in cells with carbonic anhydrase. HCO_3 secretion has been reported in the rat superficial distal tubule, the rat and rabbit cortical collecting tubule, and the turtle urinary bladder.[419–423] The models in Figures 55.10 and 55.11 will be used as starting points for the discussion of specifics segments and specific cellular mechanisms.

Some methodological considerations limit complete integration of the available studies of acid–base transport in the distal nephron. The evidence for the models depicted in Figures 55.10 and 55.11 derives mostly from studies of the turtle bladder and rabbit, rat, and mouse collecting tubules perfused *in vitro*. However, almost all of the *in vivo* physiology of distal acidification is derived from studies of rats. In addition, most of the biochemical and immunocytochemical studies (e.g., of H-ATPase) have been performed in the rat and mouse. Although most of the information on rats and rabbits is complementary, some differences are apparent, as discussed below, these differences limit direct extrapolation of data between species. In contrast to the rat and human, the rabbit usually excretes an alkaline urine with little ammonium present. Studies of cultured mammalian cells have complemented the studies of intact nephron segments.

Distal Tubule

Micropuncture studies of rats have usually defined the distal tubule as beginning just after the macula densa and extending to the first junction with another renal tubule. The distal tubule includes as many as four distinct morphologic segments or regions in sequence: a short portion of the thick ascending limb, the distal convoluted tubule, the connecting segment, and the initial collecting tubule.[424] In the rat and human, there is a gradual transition from the distal convoluted tubule to the collecting duct, so that the connecting segment has four cell types: distal convoluted tubule cells, connecting tubule cells, intercalated cells, and principal cells (the latter two described in detail for the collecting duct in the section below).[424] Also the intercalated cells are divided into at least two configurations, type A and type B, as described below.[425] The type A cells are presumed to secrete H,

based on the presence of apical H-ATPase and basolateral Cl/HCO_3 exchange, and morphologic changes with respiratory acidosis. By analogy with the cortical collecting tubule, the type B intercalated cells may be involved in HCO_3 secretion. As discussed below, there are other intercalated cells now classified as non-A, non-B cells.

Numerous micropuncture studies have demonstrated net H secretion (or HCO_3 reabsorption) in the superficial distal tubule of the rat.[426–432] The early distal tubule appears to reabsorb HCO_3 via both Na-H exchange and H-ATPase whereas the late distal tubule has H-ATPase and H,K-ATPase, the latter particularly during potassium depletion.[433–436] The Na-H exchanger is probably NHE2.[342,437,438] Colonic H,K-ATPase is clearly present in some cells of the connecting segment and early CCD.[433,434] Free flow micropuncture and *in vivo* and *in vitro* microperfusion studies have also demonstrated net HCO_3 secretion in this segment.[387,422,439,440] Net HCO_3 transport varies markedly with diet, acid-loading, and other conditioning of the animals and with tubule flow rate.[441] Studies using variations in luminal Cl concentration have suggested that separate processes of HCO_3 reabsorption and HCO_3 secretion are present in the late distal tubule just as in the cortical collecting tubule.[442,435] Since the cellular and molecular mechanisms of these processes have been elucidated better using *in vitro* microperfusion of rabbit cortical collecting tubules, the discussion of these mechanisms will be described in the next section.

Cortical Collecting Duct (CCD)

In a pivotal group of studies, McKinney et al. demonstrated that the rabbit CCD perfused *in vitro* can either reabsorb or secrete HCO_3, depending on the acid–base conditioning of the animals.[442–444] Subsequent studies extended these findings to rat and mouse CCD.[419,445–447] Considerable evidence suggests that bicarbonate reabsorption and bicarbonate secretion are separate processes mediated by distinct cell types as in Figures 55.10 and 55.11.[408]

The CCD consists of principal cells (PC) and more than two types of intercalated cells (IC). The principal cells represent ⅔ of CCD cells and mediate sodium, water, and probably most, if not all, of potassium transport under normal conditions.[448] Most evidence suggests that the principal cells are not involved in transepithelial acid–base transport. The PCs do possess several acid–base transporters on the basolateral membrane: Na-H exchanger, Na-independent Cl/HCO_3 exchanger, and Na/HCO_3 cotransporter.[449–451] These processes probably function to regulate pH_i. Direct studies of pH_i in PC have not identified any apical membrane acid–base transporters.[450,451] Also, immunocytochemical studies have failed to find immunoreactivity for H-ATPase, band 3 type protein (Cl/HCO_3 exchanger), and H,K-ATPase.[17,416,452] PCs do have a few intramembranous rod-shaped particles, which are associated with H-ATPase.[453] Hence, the weight of evidence for the PC suggests no involvement in transepithelial acid–base transport.

Two types of intercalated cells, A and B cells, are responsible for bicarbonate reabsorption and secretion, respectively, in the CCD. (Types A and B are sometimes used to only indicate rat cells, whereas α and β are used for rabbit cells, here A and B refer to any experimental species.) The model of separate intercalated cells (IC) is derived from several lines of evidence and is analogous to transport in the turtle urinary bladder.[454] Morphologically, the rat CCD has two distinct types of IC, both of which stain for carbonic anhydrase.[424,425,455,456] The type A cell has a mixture of apical microplicae and microvilli by scanning electron microscopy, immunoreactivity for H-ATPase on the apical membrane and for band 3 protein on the basolateral membrane, and apical intramembranous rod-shaped particles (which are associated with H-ATPase as described below).[17,415,425,457] The type B cell has a few apical microvilli and no immunoreactivity for band 3 protein, immunoreactivity for H-ATPase and rod-shaped particles are present on the basolateral membrane[415,425,457–459] (Figure 55.12). Pendrin is also located on the apical membranes of rat (and mouse) type B IC.[460,461] All of these characteristics agree with the models in Figures 55.10 and 55.11. These features are best resolved in rat CCD, in the rabbit CCD, IC do not clearly separate into types based on morphology.[453] In fact, rod-shaped particles are present in all rabbit CCD IC on both the apical and basolateral membranes, although to varying extent.[453] However, rabbit CCD IC do demonstrate heterogeneity with respect to other characteristics. Most rabbit CCD IC, especially in the outer cortex, have apical peanut lectin binding, and these cells exhibit characteristics of type B or HCO_3 secreting IC: predictable changes in cell pH with changes in luminal Cl or HCO_3, and cell acidification on removal of peritubular Cl.[416,451,462,463] In the rabbit, the type B IC (peanut lectin positive) usually exhibit diffuse staining for H-ATPase, rather than basolateral staining as in the rat type B IC.[464] Some rabbit CCD IC do have immunoreactivity for apical H-ATPase and basolateral band 3 protein (type A IC).[416,464] The type A IC in the rabbit CCD can also be identified by the endocytosis of fluorescent macromolecules, this presumably occurs in the recycling of apical membrane H-ATPase as discussed below.[462,192,465] These cells exhibit cell alkalinization on removal of basolateral Cl.[462,465]

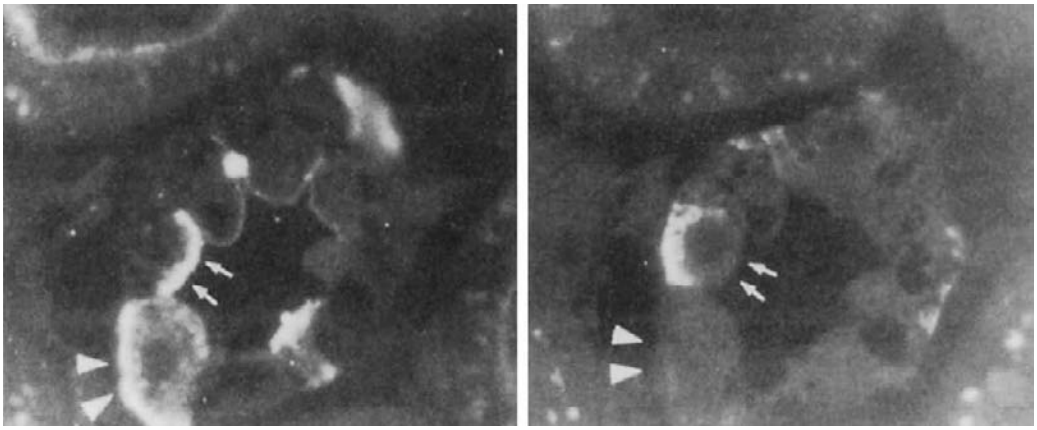

FIGURE 55.12 Left panel shows section of rat kidney cortex immunolabelled with antibodies against the H^+-ATPase (31-kD subunit). One cell (*arrows*) has apical staining (type A IC), while another has basolateral staining (*arrowheads*, type B IC). Right panel shows adjacent section stained with anti-band 3 antibody. The type A cell has basolateral staining. *(From Alper S, Natale S, Gluck S, Lodish HF, Brown D. Subtypes of intercalated cells in rat kidney collecting duct defined by antibodies against erythroid band 3 and renal vacuolar H^+-ATPase. Proc Natl Acad Sci USA 1989,86:5429–5433, with permission.)*

Type A IC become more abundant as the CCD approaches the junction with the medulla in the rabbit.[466,467] Although the morphologic differences between species are complex, both experimental species, rat and rabbit, exhibit IC cells resembling the models in Figures 55.10 and 55.11.

Importantly, IC have recently been found to be involved in regulation of NaCl reabsorption.[468,469] Cl can obviously be directly transported by pendrin on the apical membrane of type B IC but luminal pH/HCO_3 and voltage are also altered by H^+ secretion by type A IC, thereby modulating Na^+ transport.

Other types of IC exist based on a variety of experimental techniques and findings.[467,470,471] These are currently referred to as "non-A, non-B IC." These cells have both H-ATPase and pendrin on the apical membrane and neither H-ATPase or AE1 on the basolateral membrane. Some earlier investigators had called one group of such intercalated cells γ and G cells in rabbit and rat CCD respectively, defined functionally by both apical and basolateral Cl/HCO_3 in studies of intracellular pH.[470,471] These cells are only clearly identified so far by intracellular pH studies demonstrating both apical and basolateral Cl/HCO_3 exchange. The normal function and adaptive response of these non A, non B cells have not been clearly established. These cells may represent a versatile cell type able to respond to acid or base loads or other stimuli.There has been clear *in vitro* evidence that some CCD cells undergo significant functional changes with acid loads.[472,473] In contrast to the distinct classifications of subtypes, studies of cellular distribution of H-ATPase in rat CCD and OMCD demonstrate a spectrum of distribution ranging from predominantly apical location, to predominantly cytoplasmic, to predominantly basolateral, depending upon the acid–base status of the animal.[474] This regulation is discussed further below.

Both A and B IC probably have basolateral Cl channels as in Figures 55.10 and 55.11, and basolateral Na-H exchange to regulate intracellular pH.[451,475,476] (Actually, much of the data for type A IC in the CCD derives from studies on the IC of the outer medullary collecting duct, in which all of the IC are type A.) Rabbit IC also exhibit immunoreactivity for H, K-ATPase as discussed below.[452] Regulation of CCD HCO_3 transport, including the possibility of modulation of cell type, will be discussed in a subsequent section.

CCD from most untreated normal rabbits exhibit spontaneous HCO_3 secretion,[379,423,477–479] CCD from most untreated rats exhibit spontaneous HCO_3 absorption.[419,445] However, in both species, simultaneous secretion and reabsorption are probably occurring in separate cell types. Separate processes can be inferred from transepithelial flux studies which selectively abolish HCO_3 reabsorption (with removal of luminal HCO_3 or peritubular Cl) or alternatively abolish HCO_3 secretion (with removal of luminal Cl or basolateral HCO_3).[480,445,481] HCO_3 reabsorption can also be inhibited by basolateral disulfonic stilbenes.[404,478] Simultaneous HCO_3 secretion and H secretion can also be inferred from studies demonstrating an acid disequilibrium pH in rabbit CCD which have net HCO_3 secretion.[406]

The separate process of H secretion (or HCO_3 reabsorption) in the CCD appears to be analogous to the same process in the outer medullary collecting duct, where no HCO_3 secretion occurs.[406] The process is electrogenic (generating a lumen positive

transepithelial voltage in the absence of Na transport), sodium-independent, and sensitive to inhibition by acetazolamide.[404,444] Some data suggest that CCD H secretion is increased by mineralocorticoids independent of the increased lumen negative transepithelial voltage,[404] however, HCO_3 secretion in the CCD is also increased by mineralocorticoids administered *in vivo*.[480] As discussed below, *in vivo* and *in vitro* acid loads increase net HCO_3 reabsorption in the CCD. However, unidirectional HCO_3 reabsorption is stimulated less than unidirectional HCO_3 secretion is inhibited.[480–484]

Bicarbonate secretion in the CCD is electroneutral, sodium-independent, coupled to Cl absorption, and sensitive to acetazolamide.[443,478,479,485] The distinction between the apical Cl/HCO_3 exchanger in type B cells and the basolateral Cl/HCO_3 exchanger in type A cells will be discussed below. As discussed in detail below, the HCO_3 secretory process is decreased by *in vivo* or *in vitro* acid loads and is increased by *in vivo* mineralocorticoids (at least in alkalotic animals).[478,480,481,486]

In sum, the CCD has at least two different types of intercalated cells mediating separate processes of HCO_3 reabsorption and HCO_3 secretion. Net HCO_3 transport depends upon the sum of these processes which are determined by the conditioning of the animal. The transport proteins responsible for these processes will be discussed below.

Outer Medullary Collecting Duct (OMCD)

The OMCD is distinct from both the CCD and the inner medullary collecting duct. Both the rat and rabbit OMCD reabsorb HCO_3, no HCO_3 secretion has been reported.[419,477,487] In the rat, IC constitute 1/3 of the cells in the OMCD in both the outer and inner stripe ($OMCD_{os}$ and $OMCD_{is}$, respectively).[424,456] However, in the rabbit $OMCD_{is}$, only the outer portion has IC, the cells of the inner $OMCD_{is}$ differ from both PC and IC and have been termed "inner stripe cells".[407,453] The IC of the OMCD resemble type A IC of the CCD, these cells have apical or diffuse staining for H-ATPase, basolateral staining for band 3 protein, and cytoplasmic staining for H,K-ATPase.[416,464,452] The rabbit OMCD IC do not bind peanut lectin,[416] and in contrast to the type A IC of the CCD, only −2 of the OMCD IC endocytose macromolecules.[467] Studies of pH_i in OMCD IC demonstrate characteristics of the prototypical type A cell in Figure 55.10: Na-independent acid extrusion and basolateral Cl/HCO_3 exchange.[488] Electrophysiologic studies clearly distinguish PC and IC, the IC have a lower basolateral membrane voltage, a predominantly Cl selective basolateral membrane, and virtually no measurable ionic conductance across the apical membrane.[489,490] All of these findings are consistent with IC mediating the HCO_3 reabsorption observed in the $OMCD_{os}$ of the rabbit. As was the case for HCO_3 reabsorption in the CCD, HCO_3 reabsorption in the $OMCD_{os}$ is sodium-independent and coupled to basolateral Cl/HCO_3 exchange.[487] In contrast to the CCD, HCO_3 reabsorption is relatively insensitive to inhibition by carbonic anhydrase.[487]

As indicated by the morphologic differences with the $OMCD_{os}$, the $OMCD_{is}$ is functionally distinct. In contrast to the $OMCD_{os}$ and CCD which contain PC, the $OMCD_{is}$ has not been reported to reabsorb Na. All inner stripe cells ($OMCD_{is}$) in the rabbit have apical intramembranous rod shaped particles (associated with H-ATPase), although in varying density.[453] However, only some cells stain for H-ATPase (apical location) and basolateral band 3 protein.[17,416,464] The cells also exhibit heterogeneity for the uptake of the pH sensitive dyes 6-carboxyfluorescein and BCECF (from the lumen).[467,491] However, these differences among cells do appear to represent quantitative differences of functional activity, but may not indicate qualitative differences of cell type as in the CCD.[492] As expected for type A cells, the cells of the $OMCD_{is}$ do not bind peanut lectin and do not endocytose macromolecules.[416,467] Studies of pH_i demonstrate basolateral Cl/HCO_3 exchange and Na-independent H extrusion which is sensitive to NEM.[475,493,494] In addition, these cells demonstrate basolateral Na-H exchange in the recovery of pH_i from acid loads.[475] OMCDis IC also express an apical $Na\text{-}HCO_3^-$ cotransporter (NBC3) that functions predominantly in intracellular pH homeostasis.[495] Functionally, HCO_3 reabsorption in the $OMCD_{is}$ is electrogenic (lumen positive transepithelial voltage), sodium-independent, and coupled to basolateral Cl/HCO_3 exchange.[496,497] In contrast to the CCD, the rabbit $OMCD_{is}$ does not have a luminal disequilibrium pH, this finding indicates the functional presence of luminal carbonic anhydrase.[405] (An acid disequilibrium pH can be demonstrated with addition of carbonic anhydrase inhibitors to the luminal solution.) As discussed below, some functional evidence suggests that HCO_3 reabsorption in the $OMCD_{is}$, particularly from potassium depleted rabbits, is mediated at least in part by H,K-ATPase.[412,498]

In sum, both segments of the OMCD only reabsorb HCO_3, in contrast to the more complex situation in the CCD. However, the process of HCO_3 reabsorption is basically the same as in the type A cell of the CCD: apical vacuolar type H-ATPase and H,K-ATPase, and basolateral Cl/HCO_3 exchange by a band 3 protein.

Inner Medullary Collecting Duct (IMCD)

The IMCD is divided into the initial and terminal segments, $IMCD_i$ and $IMCD_t$ respectively, based on

distinct morphology and function, the transition between these segments occurs after the initial 1/3 to 1/2 of the IMCD.[424,499,500] The $IMCD_i$ corresponds to the $IMCD_1$ in other terminology, and the $IMCD_t$ corresponds to the $IMCD_2$ plus the $IMCD_3$. The rat $IMCD_i$ contains −10% IC, in the rabbit, the $IMCD_i$ resembles the inner stripe cells of the $OMCD_{is}$.[121,500] The cells of the $IMCD_i$ have apical rod shaped particles and membrane associated carbonic anhydrase, the $IMCD_t$ lacks these features.[453,500] The $IMCD_t$ cells are homogeneous without IC and are referred to as IMCD cells.[453,500] Immunoreactivity for H-ATPase, band 3 protein, and H,K-ATPase have not been found or reported in the IMCD, except in the IC of the $IMCD_i$. Although NEM-sensitive ATPase activity (ascribed to H-ATPase) has been reported in some studies of the $IMCD_i$, the cellular location of this activity is not known.[453,501,502] H,K-ATPase activity has been found in the IMCD, as discussed below.

The IMCD has been studied with micropuncture, microcatheterization, and microperfusion techniques in the rat.[503,504] These studies indicate luminal acidification, sodium-independent bicarbonate reabsorption, and an acid disequilibrium pH (at least during systemic bicarbonate infusion).[401,403,505–511] A few *in vitro* microperfusion studies of acid–base transport in the IMCD have been reported. Ishibashi et al. found no luminal acidification in the rabbit IMCD.[512] Wall et al. found some H secretion and HCO_3 reabsorption in the rat IMCD (both $IMCD_i$ and $IMCD_t$) perfused *in vitro*, but the rate appeared to be less than reported *in vivo*.[504,513]

Because of the limited studies of intact IMCD *in vitro*, cell culture and suspension studies of IMCD cells assume additional importance. Cell cultures and suspensions of rat and rabbit IMCD demonstrate both Na-dependent and Na-independent H extrusion.[514–523] The Na dependent process (Na-H exchange) has now been localized to the basolateral membrane, indicative of a role in pH_i regulation and not in urine acidification.[515,524] The exact nature and cellular origin of the Na-independent H extrusion have been problematic, particularly for the $IMCD_t$ where no IC and conflicting evidence for vacuolar-type H-ATPase are found. However, as discussed below, significant evidence for H,K-ATPase in the IMCD is now available.[410,504] Other studies find evidence for H-ATPase.[520,525] Basolateral acid–base transport processes in IMCD cells have been studied also. Studies of pH_i in perfused and cultured rat IMCD have demonstrated basolateral Cl/HCO_3 exchange that may represent AE1 and AE2 (discussed below).[526–528] Cultured IMCD cells have also been reported to possess basolateral Na-coupled HCO_3 transport.[529]

Cellular Mechanisms of H Secretion in the Distal Nephron

H-ATPase

Much evidence exists for a H-ATPase mediating H secretion in the mammalian distal nephron and in particular the cortical and outer medullary collecting ducts.[530,531] In addition, as previously discussed, H-ATPase mediates some component of H secretion/HCO_3 reabsorption in the proximal tubule. Although the initial evidence for H-ATPase mediating urine acidification derived from turtle bladder, most of the subsequent biochemical data has been from bovine and rat kidney.[413,409,532] The initial evidence supportive of a H-ATPase was a report by Dixon and Al-Awqati demonstrating a DCCD-sensitive increase in intracellular ATP in turtle bladders with an imposed electrical or H gradient, a result consistent with a reversible, H-ATPase.[532]

The H-ATPase involved in urine acidification is a member of a novel class of proton-translocating ATPases, the vacuolar H-ATPases.[19,530] These proton pumps acidify the interior of a variety of intracellular organelles: endosomes, Golgi-derived vesicles, lysosomes, endoplasmic reticulum, and chromaffin granules.[533] Plasma membrane localization, associated with cellular H extrusion, has been reported in kidney tubule cells, osteoclasts, macrophages, epididymis, vas deferens, and interdental cells in the inner ear. This class of H-ATPase has ancestral relationships to the F_1F_0 H-ATPases, the class containing the mitochondrial ATP synthetase, this relationship is indicated by some sequence homology and by structural similarities.[414,533,534] The vacuolar H-ATPases contain 8–10 protein subunits, ranging in molecular weight from 12,000 to 116,000. A distinguishing feature of this class of H-ATPase is the pattern of inhibitor sensitivity: sensitivity to N-ethylmaleimide (NEM), 7-chloro-4-nitrobenz-2-oxa-1,3-diazole (NBD-C1), dicyclohexylcarbodiimide (DCCD), omeprazole, and bafilomycin, resistance to vanadate, azide, and oligomycin.[414,533] H-ATPase is also inhibited by cadmium.[530] The holoenzyme has a molecular weight of 500-700 kDa. The H-ATPase from kidney has been purified, reconstitution restores both ATP hydrolysis and ATP-dependent H transport.[535–537] By analogy with the F_1F_0 H-ATPases, the vacuolar H-ATPases have been modeled to have: (1) several globular, cytoplasmic subunits involved in ATP hydrolysis, (2) multiple copies of small intramembranous subunits forming the H channel, and (3) other subunits possibly involved in membrane anchoring or in coupling between ATP hydrolysis and H transport.[413,414,533,534] These subunits are located in two distinct domains or sectors, a predominantly

transmembrane V_0 sector responsible for proton translocation and a cytosolic V_1 sector involved in ATP hydrolysis and regulation (Figure 55.13).[530] Several subunits have more than one isoform which are selectively expressed in various tissues. There are 4 isoforms of the α subunit suggesting distinct roles, but all 4 are expressed in IC.[538] Intercalated cells selectively express a unique isoform of the B or 56 KD subunit, B1.[539] However, the B2 subunit is also expressed in IC.[540] Mutations in the B1 subunit and the a4 subunit (genes Atp6v1b1 and Atp6v0a4 respectively) have been characterized as causing distal reanl tubular acidosis.[541,542]

The evidence that an H-ATPase of the vacuolar class mediates urine acidification derives from several lines of evidence. First, the physiology of distal tubule H secretion correlates well with the biochemical information: electrogenic, sodium-independent ATP-requiring process.[404,496,543] Second, antibodies directed against H-ATPase stain the apical plasma membranes of rat intercalated cells.[17,18,415,458] Third, rabbit outer medullary collecting ducts from the inner stripe have H secretion which is sensitive to luminal NEM.[493] Also, affinity purified H-ATPase form arrays of stud-like structures in liposomes which are identical to structures observed in apical membranes of H secreting cells.[544] And finally mutations in H-ATPases subunits cause distal renal tubular acidosis.[19]

Because of the unique inhibitor sensitivity of vacuolar H-ATPase (i.e., NEM sensitivity, and resistance to many other inhibitors), NEM-sensitive ATPase activity has been used to localize and quantitate activity in various nephron segments.[346,501,502,545,546] Although the segmental localization and chronic adaptation (e.g., to acid loads and mineralocorticoids) often correspond to expectations based on other data, the interpretation of NEM-sensitive ATPase activity must be cautious because of the non-specific nature of NEM and because of the presence of intracellular vacuolar H-ATPase associated with cellular organelles. In other words, NEM sensitive ATPase activity may not accurately reflect plasma membrane H pump.

Regulation of renal H-ATPase probably occurs via several mechanisms.[19,530] Since the pump is electrogenic, the rate of H secretion will vary depending on the transmembrane voltage which is influenced predominantly by the rate of Na transport in the distal nephron. Cl may directly activate the pump.[414,547] And Cl dissipates the transmembrane voltage in intracellular organelles allowing acidification,[414,533] however, in the apical membranes of the IC of the collecting ducts, such a Cl channel has not been found functionally[489,488,548] except in cultured cells.[549] The chloride channel ClC-5 colocalizes with H-ATPase in type A ICs, but the functional activity is unknown.[550] Also Slc26a11 has also been localized in IC and could serve this function.[551]

The best characterized and probably most important mode of regulation of H-ATPase is targeting and recycling of pumps into and out of the apical membrane discussed in the section on "regulation of distal nephron acidification" below. Regulated assembly and disassembly of the subunits is also a well characterized mechanism of regulation in some systems,[530,552,553] regulated assembly of the V_0 and V_1 domains leading to membrane insertion is coupled to glucose metabolizing enzymes and the phosphatidylinositol-3-kinase pathway.[530,554–556] The latter signaling mechanism

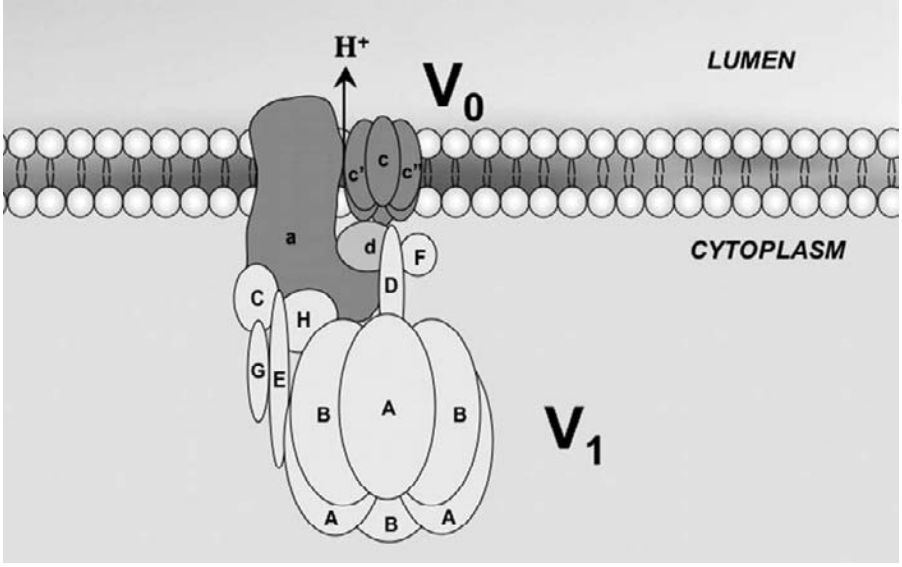

FIGURE 55.13 Model of H-ATPase. *(From Breton S, Brown D. New insights into the regulation of V-ATPase-dependent proton secretion. Am J Physiol Renal Physiol 2006,172:1107–1119, with permission.)*

may regulate H-ATPase via interaction with actin.[555] Other mechanisms of modulation of pump activity may include the lipid environment, cytosolic regulatory factors, and possibly activator and inhibitory proteins.[414,531,557–559] Transcriptional and translational regulation of H-ATPases do not appear to be important mechanisms, although the 31 kD subunit increases in IC with acidosis.[560]

H,K-ATPase

H,K-ATPases are also present in various distal nephron segments and contribute to acid secretion and HCO_3 reabsorption particularly in certain states such as potassium deficiency.[412,561–564] H,K-ATPases secrete H^+ and absorb K in an electroneutral manner. K-ATPase activity, insensitive to sodium and ouabain but sensitive to inhibitors of the gastric H,K-ATPase, was initially identified in distal nephron segments.[565,566] The impact of these findings was then amplified by a series of studies demonstrating the effect of these same inhibitors on HCO_3 transport.[410–412] Several approaches have demonstrated the presence and function of at least two isoforms of H,K-ATPase, HKα1 and HKα2, defined below.[410–412] Functionally, H secretion via H,K-ATPase has been identified by loss of function on K removal or by use of inhibitors such as omeprazole or SCH28080 (Schering-Plough).[412,567] K-ATPase activity, distinct from Na,K-ATPase, has also been used.[565,566]

H,K-ATPases are K- dependent ATPases of the E1,E2 class (P-type ATPase) and consist of two subunits, the α catalytic subunit and the β subunit. Four isoforms of the α subunit of H,K-ATPase have been isolated, cloned, and sequenced,[410] these are designated as HKα1, HKα2, HKα3, and HKα4 cloned from rat stomach,[568] rat distal colon,[569] toad bladder,[570] and human skin,[571] respectively. The HKα1, 2, and 4 isoforms have been referred to as gastric, colonic isoforms and ATPlAL1, respectively, ATP1AL1, also known as α4, is probably the human ortholog of the α2 gene.[572] The colonic α2 subunit has at least two molecular variants.[434,573,574] The four known α isoforms have different, but still incompletely defined, inhibitor sensitivity (reviewed in[410,412]). The HKα1 or gastric isoform is sensitive to omeprazole and SCH28080 but not to ouabain. The HKα2 or colonic isoform is sensitive to ouabain but not SCH28080. Both SCH28080 and ouabain inhibit HKα3 and HKα4, note, however, that no mammalian form of HKα3 has been identified yet. Other isoforms or variants have been suggested based on various discrepancies (between enzymatic activities and molecular events, and between model systems),[562,575–577] but recent work in knock-out mice suggest that gastric and colonic isoforms do account for K-ATPase enzymatic activities (an area of discrepancy and controversy particularly in rats).[578] Two β subunits have been shown to interact with H,K-ATPases, a gastric 2 isoform which is also expressed in kidney and the β1 subunit of Na,K-ATPase.[561,562,579–584]

The relative role of H,K-ATPase (versus H-ATPase), distribution of isoforms, and regulation have been examined. Both HKα1 and HKα2 mRNA have been found all along the collecting duct.[410] Mice with knockouts for either gastric or colonic H,K-ATPase have normal acid–base status,[585,586] but this may result from compensatory adaptations. In the CCD, H,K-ATPase functions in H^+ secretion at least after potassium depletion.[412,587] In the $OMCD_{is}$ under normal conditions, 35–70% of HCO_3 reabsorption appears to be mediated via H,K-ATPase.[588,589] Increased HCO_3 reabsorption in response to metabolic acidosis is secondary to increased H-ATPase[482,589,590] but the acute response to respiratory acidosis may be H,K-ATPase, at least in CCD.[591] But metabolic acidosis does stimulate H,K-ATPase activity.[417,592] Calcitonin and isoproterenol both stimulate H-K-ATPase activity, presumably in distinct IC populations, but the physiologic roles are not clear.[593,594]

Some data suggests a role for H,K-ATPase in HCO_3 secretion.[587,595] However, an apical H,K-ATPase (not basolateral as expected for HCO_3^- secretion) appears to be present in type β IC.[417,418,433,434,596] HKα2 is increased in CCD with metabolic alkalosis.[595]

With potassium depletion, increased HCO_3 reabsorption appears to be predominantly SCH28080 sensitive H,K-ATPase.[498,588,590] However, most information suggests that HKα2 (not usually SCH28080 sensitive) is the predominant isoform induced by potassium depletion particularly in medullary collecting ducts.[597–601] However, HKα1 may be also induced in CCD in potassium depletion.[598] Several studies of IMCD also demonstrate that SCH28080 inhibitable H secretion is present under basal conditions and stimulated by potassium depletion.[504,518] Other studies of cultured IMCD cells, however, have found predominantly H-ATPase.[520,525] As alluded to above, the isoforms of H,K-ATPase responsible for various functional findings are not entirely clarified. Some evidence suggests that an unidentified, H,K-ATPase isoform may be induced by hypokalemia or that the properties of known isoforms may be altered in potassium depletion.[562,577]

H,K-ATPase may play a role in sodium transport since sodium can substitute for potassium to accomplish sodium absorption and low Na diets up-regulate H,K-ATPase activity.[602–604] NH_4 may also substitute for H and thereby H,K-ATPase function in NH_4 secretion.[605–607] Isoproterenol and calcitonin stimulate collecting duct H,K-ATPase activity via a cAMP and ERK dependent manner.[593,594]

Basolateral Cl/HCO_3 Exchange

Early studies of H secretion in the turtle bladder and collecting tubule suggested basolateral Cl/HCO_3 exchange which was sensitive to disulfonic stilbenes (SITS and DIDS).[497,511,608] Inhibition of basolateral Cl/HCO_3 exchange inhibits luminal H secretion.[487,497,511] Studies of pH_i in IC of rabbit are also consistent with basolateral Na-independent Cl/HCO_3 exchange.[462,467,475,494] Studies using antibodies directed against the red cell Cl/HCO_3 exchanger (band 3 protein or anion exchanger AE1, SLC4A1) demonstrated immunoreactivity with mitochondria rich cells of the turtle bladder and with type A IC of rat, rabbit and human collecting ducts.[415,416,457,609,665,711] The molecular details of AE1 and the related kidney protein were subsequently elucidated.[612–616] A single gene encodes both the red cell and the kidney AE1 protein, however, an alternate start site leads to an mRNA in the kidney which has exons 1–3 deleted.[352,613,616] The major kidney AE1 protein therefore has a truncated N-terminus, this region of the protein is part of the cytoplasmic domain not directly involved in Cl/HCO_3 exchange.[611,617] SLC26A7 may also contribute to basolateral Cl^-/HCO_3^- exchange in the medullary CD and be regulated by distinct stimuli such as hypertonicity.[618–620]

The driving force for basolateral Cl/HCO_3 exchange would appear to be a concentration gradient of Cl from basolateral solution to cell, since most studies of pH_i in the collecting tubule suggest that the intracellular [HCO_3] in H secreting cells is close to or below extracellular [HCO_3].[475,462,467,488,494] Primary active H secretion across the apical membrane potentially produces cell alkalinization and elevation of intracellular [HCO_3], HCO_3 then is extruded across the basolateral membrane. Evidence does not support conductive pathways or significant sodium-coupled pathways for this HCO_3 exit in most distal nephron H secreting cells.[475,494,527] Cell Cl is undoubtedly lowered by a basolateral Cl channel as in Figure 55.10, the cell negative transmembrane voltage will drive Cl exit from the cell. Studies of IC in the CCD and $OMCD_{os}$ and of inner stripe cells have demonstrated that the basolateral membranes are predominantly Cl conductive.[548,489,621,622]

Few studies have directly addressed the regulation of either the basolateral Cl/HCO_3 exchanger or the basolateral Cl channels. However, two studies have examined the kinetics of the basolateral Cl/HCO_3 exchanger in intact $OMCD_{is}$. Breyer et al. reported a K_m for extracellular Cl of −10 mM, while Hays and Alpern reported a K_m of −114 mM.[475,494] The higher value of Hays and Alpern was measured in the presence of competing HCO_3 and thus represents an apparent K_m under physiologic conditions. This value would indicate that changes in extracellular [Cl] in the physiologic range could have important effects on $OMCD_{is}$ H secretion. In either case, the K_m for Cl is much higher than for H secretion in the turtle bladder (K_m <1 mM measured in the absence of HCO_3 which competes with Cl). Basolateral AE1 in the collecting duct does adapt to acid–base conditions.[623,624]

Although principal cells in the CCD also have basolateral Cl/HCO_3 exchange, the identity of the protein responsible is not clear.[450,451] Antibodies to AE1 protein do not label PC basolateral membrane, although this could be a result of low density of the transporter in these cells.[415,416] The PC Cl/HCO_3 exchanger is not active under normal conditions, but is activated by elevations in pH_i.[451,625] Similarly, all inner stripe cells and inner medullary collecting tubule cells apparently exhibit Cl/HCO_3 exchange,[475,494,514,527] but only some of the inner stripe cells and no $IMCD_t$ cells label with antibodies against AE1.[416,457] Basolateral Cl/HCO_3 in the collecting duct which is not accounted for by AE1 may be AE2. AE2 is on the basolateral membrane of some collecting duct cells, particularly in the inner medulla.[353,526,626,627] AE4 may also mediate some of basolateral HCO_3 transport.[628] SLC26A7 may also mediate basolateral Cl/HCO_3 exchange in the OMCD.[618,620] As noted above, cultured IMCD cells do exhibit basolateral Na-HCO_3 symport.[524]

In sum, cellular HCO_3 is extruded in most H secreting cells of the distal nephron by a truncated form of band 3 or AE1 protein. Cl/HCO_3 exchange also occurs in other cells, but the molecular identity of the other exchangers is not resolved. Basolateral chloride channels are discussed below.

Cellular Mechanisms of HCO_3 Secretion

Apical Cl/HCO_3 Exchange

The apical process in HCO_3 secreting IC is the Cl/HCO_3 exchanger pendrin, SLC26A4. The functional properties were established by transepithelial flux studies and directly demonstrated by studies of pH_i in rabbit IC.[443,451,462,478,479] Transepithelial flux studies of HCO_3 and Cl first demonstrated Cl/HCO_3 exchange in CCD.[476,478,479] Studies of cell pH have subsequently clearly shown apical Cl/HCO_3 exchange in CCD IC. For instance, changes in luminal Cl or HCO_3 alter cell pH in a predictable fashion.[451,467] These cells also show cellular acidification with removal of basolateral Cl, indicative of apical Cl/HCO_3 exchange, presumably as basolateral Cl is removed, cell Cl is depleted, and Cl will enter the cell across the apical membrane in exchange for extrusion of cellular HCO_3.[451,462] Prior

removal of luminal Cl, before removal of basolateral Cl, blocks the cell acidification.[451] Physiologic studies demonstrate that the apical exchanger differs from the basolateral exchanger present in type A IC.[478,629] Also, the apical membranes of type B IC (or most IC of the rabbit CCD) do not stain with antibodies to AE1 protein, in contrast to the basolateral membranes of type A IC.[415,416,457,610,611] The apical Cl/HCO_3 exchanger in B IC is likely not the same protein as the basolateral Cl/HCO_3 exchanger in type A IC. The exchanger appears to function in transepithelial anion transport but does not appear to be involved in acute regulation of intracellular pH.[625] The exchanger has little if any role in cell pH recovery from acid loads and also may not be activated by cell alkalinization.[625] The exchanger actually exchanges Cl for Cl (Cl self exchange) at a rate greater than Cl/HCO_3 exchange.[476,629,630] The exchanger appears to be activated by cAMP as discussed below.[478,631,632] The K_m for luminal Cl is 10 mM in the rabbit CCD,[632] with the apparent halide affinity $Cl^- \sim Br^- > I^- > F^-$.[633]

Pendrin has now been established as the apical Cl/HCO_3 exchanger in B IC. Pendrin (SLC26a4) is the gene product, originally identified as an iodine transporter defective in Pendred's Syndrome, an autosomal recessive deafness and goiter. It localizes to the apical membrane of HCO_3 secreting type B IC and non- A, non-B IC. CCD from pendrin knock-out mice does not secrete HCO_3.[460,447,634] Pendrin expression and apical localization increase with alkali loads and mineralocorticoids and decrease with acid loads.[460,635–638] Pendrin likely has both cytosolic and extracellular pH regulatory sites.[639] Pendrin expression also responds to chloride balance and appears to be involved in blood pressure regulation.[640,637,641,642]

In contrast to studies implicating pendrin, some earlier evidence suggested that the apical Cl/HCO_3 exchanger in Type B IC is a form of AE1.[643–646] These investigators suggest that the kidney form of AE1 is not detected by usual immunocytochemical methods because the antigen is Alatent@ or hidden in the apical domain of B cells.[643] Another anion exchanger AE4 has also been proposed to account for apical Cl/HCO_3 exchange, at least in the rabbit.[647] However, other studies find properties of AE4 (such as a lack of change with acid–base perturbations) that differ from CCD HCO_3 secretion.[628]

Basolateral H Extrusion

HCO_3 secretion in the turtle bladder and mammalian CCD is active and acetazolamide sensitive.[409,443] The basolateral H extrusion mechanism in bicarbonate secreting cells is the active driving force for HCO_3 secretion. The molecular mechanism of H extrusion in these cells is undoubtedly a vacuolar H-ATPase, at least in large part.[408] In the rat, antibodies against vacuolar ATPase stain the basolateral membrane of a portion of IC in the CCD,[17,415,458,474] H-ATPase may be be stabilized there by association wih NHERF1.[530] In the rabbit CCD, most lectin positive cells (B IC) have diffuse cytoplasmic, rather than basolateral, immunoreactivity for H-ATPase.[464] However, all the physiologic data in rabbit CCD are consistent with basolateral H-ATPase.[416,443,479] Although Na-H exchange is present on the basolateral membranes of type B IC (to regulate pH_i),[451] HCO_3 secretion in the rabbit CCD is insensitive to ouabain, peritubular amiloride, and removal of sodium.[416,443,479,648] [One study did show a decrease in HCO_3 secretion with removal of sodium.[443]] Na-H exchange appears to mediate all of the pHi recovery from intracellular acid loads in type B IC.[451] Rod shaped particles are present in both membranes of rabbit CCD IC and in the basolateral membrane of some rat IC, as discussed alone.[453,459] The possible role of H, K-ATPase in HCO_3 secretion has not been tested in the CCD. In sum, most evidence is consistent with basolateral H-ATPase mediating HCO_3 secretion.

BASOLATERAL CHLORIDE CHANNELS AND OTHER TRANSPORTERS

Basolateral Cl channels are present in both type A and type B IC. A predominant basolateral Cl conductance has been clearly demonstrated by electrophysiologic techniques in type A IC of CCD and $OMCD_{os}$ and in inner stripe cells of $OMCD_{is}$.[489,490,548,622] The possible role of these channels in regulation or modulation of HCO_3 reabsorption is unknown. Cl channels presumably recycle Cl across the basolateral membrane, extruding Cl which enters the cells on the basolateral Cl/HCO_3 exchanger. The exact nature of Cl channels in IC (e.g., selectivity, unit conductance, molecular identity, etc.) has not been clearly determined. Although chloride channels have been isolated from the kidney, the exact function of these is still unsettled.[649] In addition, two potential regulators of chloride channels, P-glycoprotein and CFTR, have been found in collecting ducts among other sites in the kidney.[649,650] In the rat $IMCD_i$, a basolateral HCO_3 conductance is found, without a basolateral Cl channel.[651]

The apical membranes of H secreting cells do *not* appear to possess functional Cl channels despite the usual association of vacuolar H-ATPase with Cl channels, this conclusion is based on electrophysiologic studies which show the fractional resistance of the apical membranes of these cells to be approximately 1.[489,490,548] Since Cl secretion is stoichiometrically equal to H secretion (or HCO_3 reabsorption) in the $OMCD_{is}$ which has no other active transport, Cl flux presumably occurs via the paracellular pathway, driven by the lumen positive voltage.[497] In cultured CCD cells which

resemble IC cells, an apical Cl channel has been observed in excised patches, however, these channels were not usually open in cell-attached patches.[549] The chloride channel ClC-5 has been found to colocalize with H-ATPase in Type A IC but its function there is unknown.[550] ClC-5 which also is located in the proximal tubule may function in endocytosis rather than in transepithelial transport,[550] ClC-5 is mutated in Dent's disease, which is characterized by hypercalciuria and kidney stones.

Cl channels in the basolateral membranes of type B IC have been studied little via electrophysiologic techniques.[622] However, tracer flux experiments in rabbit CCD have indirectly shown several important features of these channels.[476] In the CCD, Cl reabsorption occurs via two pathways.[476] First, Cl is reabsorbed via the paracellular pathway as sodium is absorbed, Cl moving down an electrochemical gradient, predominantly due to the lumen negative transepithelial voltage. Second, Cl is reabsorbed via the type B IC. With sodium reabsorption blocked, Cl moves predominantly via the latter pathway which involves the series of the apical Cl/HCO_3 exchanger (or Cl/Cl self exchanger) and the basolateral Cl channel.[476] Inhibition of transepithelial Cl self exchange by peritubular chloride channel blockers is evidence for the presence of basolateral Cl channels in type B IC. cAMP appears to activate these channels in conjunction with acceleration of apical Cl/HCO_3 exchange (or Cl/Cl self exchange).[629,632] Also low concentrations of intracellular HCO_3 activate these channels.[40,630,652] These channels are inhibited by typical Cl channel blockers such as DPC (diphenylamine-2-carboxylic acid) and anthracene-9-carboxylate.[629,652] The chloride channel ClC-3 has been localized to type B IC.[653]

Electroneutral NBC-3 (or NBCn1) is in the apical membrane of Type A IC and OMCD cells, and in the basolateral membranes of Type B IC and IMCD cells,[654–656] but the exact role and function in transepithelial acid–base transport is unknown.[495,657] The KCl co-transporter KCC4 is in the basolateral membrane of type A IC and may have a role in acid secretion.[658]

Role of Carbonic Anhydrase

Carbonic anhydrase (CA) facilitates acid–base transport in the distal nephron, just as in the proximal tubule and the thick ascending limb discussed previously.[157,158,659] Both histochemical methods (e.g. Hanson's technique) and immunocytochemical methods, and more recently molecular techniques, have been used to localize CA along the distal nephron. Principal cells either do not stain for CA or stain weakly. In contrast, intercalated cells along the distal nephron have intense cytoplasmic CA staining,[375,377,660,661] probably representing Type II CA.[377,662–665] CA II may be important in the development of the IC phenotype.[530] In addition to cytosolic CA, mouse and rabbit IC have membrane associated CA staining, particularly on the apical membrane.[375,453] In the rat, IC do not have membrane associated CA staining[660] or immunoreactivity for CA type IV, the predominant renal membrane associated with CA.[666] In the human kidney, in contrast to other species, all distal convoluted tubule cells are reportedly positive for CA,[377,664,667] in the rat, distal convoluted tubule cells have basolateral membrane staining.[661] In the rabbit $OMCD_{is}$, staining for CA is predominantly in the apical membrane but there is variability along the length of the segment, the number of positive cells increasing from outer to inner zone of $OMCD_{is}$,[453] rabbit $OMCD_{is}$ and $IMCD_i$ have CA type IV by RT-PCR.[668] Although the $IMCD_i$ has predominantly membrane staining as in the $OMCD_{is}$, the $IMCD_t$ does not have CA staining at least in the rabbit,[453] mouse,[375] and probably the rat.[661] Cells in the human kidney IMCD do stain for both CA II and IV.[664,669] Studies of rat IMCD also demonstrate CA activity.[514,670] Another isozyme of membrane associated CA, CA XII, has been shown in the basolateral membranes of the TAL, the distal tubule, and principal cells of the collecting duct.[671–673] Obviously, variations in species, cell types, and techniques prevent a cohesive understanding of the role of CA along the distal nephron. However, CA is present in most, if not all, distal nephron cells involved in acid–base transport. Despite the membrane staining in some cells, functional studies discussed below demonstrate no luminal CA in most distal nephron segments.

Acid–base transport, both HCO_3 reabsorption and secretion, in each segment of the distal nephron is sensitive to inhibition of CA.[443,444,477,481,487,510,511] Bicarbonate reabsorption in the papillary collecting duct (or $IMCD_t$) is also sensitive to CA inhibition,[510,511] despite the apparent lack of staining for CA by either histochemical or immunocytochemical methods,[661,662,666] this may indicate a lack of sensitivity of the localization methods. Both CA II and CA IV are induced by metabolic acidosis in those nephron segments expressing basal activity.[668,674]

Several segments of the distal nephron have been found to have a spontaneous acid disequilibrium pH, this not only indicates H secretion, as opposed to base absorption, but also implies the functional absence of luminal CA. A spontaneous acid disequilibrium pH has been found in the superficial distal tubule, the CCD, $OMCD_{os}$, and papillary collecting duct.[6,401,403,405,406] The acid disequilibrium pH, but not

H secretion or HCO_3 reabsorption, can be eliminated by perfusion of tubules with exogenous carbonic anhydrase.

The acid luminal disequilibrium pH in the distal nephron is important in at least two regards. First, a low luminal pH maintains luminal NH_3 concentrations low, favoring NH_3 diffusion into the collecting duct. Second, the lack of luminal CA is important in the elevation of urinary pCO_2 above plasma pCO_2, infusion of CA lowers urinary pCO_2 to blood levels.[401,675] In the presence of luminal HCO_3, H secretion in the distal nephron acidifies the luminal fluid, but in the absence of CA, the formation of CO_2 from HCO_3 and carbonic acid is slow. CO_2 formed in the inner medullary collecting duct does not diffuse into the adjacent vasa recta because of a high pCO_2 in these structures, a result of trapping of CO_2 in the medullary countercurrent system.[401] CO_2 formed in the renal pelvis or below does not rapidly diffuse out, presumably because of a low surface-to-volume ratio in these structures.

Functional evidence for luminal CA has been found in two distal nephron segments, the $OMCD_{is}$ of the rabbit and the $IMCD_i$ of the rat.[405,668,676] In the $OMCD_{is}$ this was initially shown by a disequilibrium pH which was apparent only during perfusion with a carbonic anhydrase inhibitor.[405] Later studies demonstrated inhibition of bicarbonate reabsorption by membrane impermanent CA inhibitors.[677] To demonstrate luminal CA in the rat $IMCD_i$ *in vitro*, H were generated in the lumen by creating a lumen-to-peritubular NH_3 gradient, pulling the reaction $NH_4^+ \rightarrow NH_3 + H$ to the right, with this protocol, no disequilibrium pH was present in $IMCD_i$ whereas an acid disequilibrium pH was produced in the $IMCD_t$.[676] Luminal CA in these segments of the distal nephron may facilitate reabsorption of any remaining HCO_3 presented to the distal nephron.[676]

Thus, cellular CA facilitates acid–base transport in the distal nephron. However, in most distal nephron segments, the functional absence of luminal CA results in an acid luminal disequilibrium pH, facilitating trapping of NH_3/NH_4^+.

Regulation of Distal Nephron Acidification

Peritubular and Luminal pH

Both *in vivo* and *in vitro* studies have demonstrated that systemic or peritubular pH modify distal nephron acid–base transport.[441,485,678] This regulation has both acute and chronic components. Acutely systemic pH alters U-B pCO_2 (urine pCO_2–blood pCO_2), an index of distal nephron H secretion.[401,679,680] Also acute metabolic acidosis has been found to stimulate inner medullary H secretion.[509] Although some studies have demonstrated systemic pH effects in the distal tubule,[436,483,484] some prior studies have not found changes in superficial distal tubule acid–base transport in acute metabolic acidosis.[430,431] Several studies have addressed acute changes in acid–base transport in isolated perfused rabbit collecting ducts. This decreases in peritubular [HCO_3] and pH increase net HCO_3 reabsorption in both cortical and outer medullary collecting ducts.[512,681,682] Also increasing peritubular pCO_2 increases HCO_3 reabsorption in the $OMCD_{os}$ and $OMCD_{is}$.[683] Results of studies examining the effect of pCO_2 on CCD have differed. Breyer and colleagues reported no change in net HCO_3 transport with elevation of pCO_2,[681] however, similar studies by McKinney and Davidson reported increased net HCO_3 reabsorption.[683] This discrepancy may result from different rates of bicarbonate secretion or bicarbonate reabsorption in the control condition, no studies have addressed the effects of elevations of pCO_2 on unidirectional HCO_3 secretion.

Acutely increased H secretion or HCO_3 reabsorption with decreased peritubular pH may result from several mechanisms. Decreased peritubular [HCO_3] will directly accelerate basolateral Cl/HCO_3 exchange in H secreting cells.[494] This will secondarily lower pH_i. Decreases in cell pH (independent of pCO_2 or [HCO_3]) have been shown to accelerate apical H secretion, at least in the turtle bladder.[684] The effect of cell pH on H secretion is likely to result, at least in part, by direct effects on the H pump, via both kinetic and thermodynamic effects.[409,684–687] However, the direct effects of pHi on the kinetics of H-ATPase may be small.[413] Increased pCO_2 will also lower cell pH since CO_2 is extremely permeable across cell membranes. Increased H secretion may then result from effects of lowered cell pH. The increased H secretion with increased CO_2 can not result from thermodynamic effects since luminal pH will be decreased just as cell pH. Recent studies of mechanisms of pH regulation of acid–base transport have focused on potential pH and/or HCO_3^- "sensors." GPR4, a G protein coupled receptor, appears to be such a pH sensitive receptor located in the collecting duct that may serve to regulate acid–base homeostasis.[688] H-ATPase itself and soluble adenylyl cyclase (discussed below) are potential pH/HCO_3 sensing mechanisms.[689]

The best characterized mechanism of acute (and perhaps chronic) regulation of H-ATPase is insertion and removal from tubulovesicular structures and the plasma membrane. The process of membrane recycling resembles the insertion and retrieval of clathrin coated vesicles but is not associated with clathrin or calveolin in the collecting tubule.[530,690,691] Exocytic insertion of H pumps is also microtubule/

microfilament dependent and similar to mechanisms of neurosecretory exocytosis, involving SNARE and SNAP proteins.[692,693] A variety of intracellular proteins may be involved in the trafficking machinery: syntaxin 1A, SNAP23, cellubrevin, ARNO, and Arf6.[530,693–695] H-ATPase subunits may also interact interact with the actin cytoskeleton for localization and trafficking.[530] Changes in cell calcium (discussed below) may be involved in the interaction of H-ATPases and the actin cytoskeleton.

The exocytic insertion of H pumps into the apical membrane from subapical endocytic vesicles was historically demonstrated early for increased pCO_2 but may be applicable for decreased cell pH in general and a variety of other stimulators of acidification.[465,690,696] The exocytic insertion of H pumps was first demonstrated in the turtle bladder, but has since been extended to both the proximal tubule and the collecting tubule.[192,697,698] Studies using fluorescent probes attached to macromolecules (dextran or albumin usually) demonstrate luminal endocytosis into acidic subapical vesicles with lowering pCO_2. On stimulation of H secretion with increased pCO_2 or with application of weak acids, these vesicles fuse with the apical membrane, releasing their contents and presumably inserting more H pumps into the plasma membrane.[192,462,465,697] In the turtle bladder, there is simultaneous increased apical H secretion, an increase in apical surface area of H secreting cells, and increased electrical capacitance,[696,698–700] in rabbit $OMCD_{is}$ there is no apparent acute change in surface area.[683] However, morphologic studies of rat type A intercalated cells after several hours of increased pCO_2 do demonstrate this fusion and apparent recycling of rod shaped intramembranous particles (associated with H-ATPase) between subapical tubulovesicular structures and plasma membrane, apical surface area is increased and subapical vesicles are decreased.[425,455,701] Similar changes occur with metabolic acidosis *in vivo*.[702,703]

One component of the relationship between decreased intracellular pH and exocytosis is an increase in cell calcium, buffering of cell calcium prevents the exocytosis and the increase in H secretion.[692,704] The exocytic process and increased H secretion are also sensitive to colchicine and other inhibitors of microtubule and microfilament function.[683,697,698,705] The increase in H secretion with increased pCO_2 may return cell pH back towards normal, yet transepithelial transport remains stimulated.[704] Other conditions, previously thought to alter H secretion directly by changes in pH_i, may also have other mechanisms of action. For instance, acetazolamide increases cell pH but additional mechanisms of inhibition of H secretion seem likely, acetazolamide appears to induce apical endocytosis which could be responsible in part for reduced H secretion.[699,706] In sum, acute changes in peritubular and cell pH alter H transport by at least two mechanisms: (1) direct effects on the H pump and on the basolateral Cl/HCO_3 exchange process, and (2) exocytic insertion of additional H pumps with stimulation. Recycling of H-ATPase between apical membrane and subapical tubulovesicular structures appears to be an important mechanism of the regulation of H secretion in the collecting duct.[465,690,696]

Chronic changes in systemic pH or peritubular pH induce additional changes in distal nephron acid–base transport. This is best illustrated by *in vitro* studies of collecting tubules which have been obtained from animals which have been loaded with acid or base. McKinney and colleagues first reported that rabbit CCD could either reabsorb or secrete HCO_3 *in vitro*, depending on the prior *in vivo* conditioning of the animals.[405,423,443] Similar results have since been obtained in rat cortical collecting ducts perfused *in vitro* and rat superficial distal tubules perfused *in vivo*.[419,422,439] Inner medullary collecting ducts also adapt to metabolic acidosis or alkalosis.[507,508,511,513] In contrast to these results, rabbit outer medullary collecting ducts (both $OMCD_{is}$ and $OMCD_{os}$) perfused *in vitro* have not consistently shown adaptation to either acid loads or respiratory acidosis *in vivo*.[477,487,589,707] The adaptations of the CCD occur rapidly after *in vivo* signals, one hour after an acid load in rabbits and one hour after chloride depletion alkalosis in rats, but the changes persist *in vitro* for relatively long times (greater than an hour) despite incubation in solutions of normal pH.[445,708] Speculatively, the signals for these changes in acid–base transport may not require changes in extracellular pH per se since feeding or high protein diets which cause little or no change in plasma pH alter transport,[429,422,709] the signals for any pH-independent changes associated with acid or protein loads are not known. However, at least for pendrin expression, changes in chloride excretion in addition to acid–base status are important.[710]

The cellular mechanisms of the changes in the cortical collecting duct have been examined by Schwartz, Al-Awqati, and colleagues. Early studies suggested that type A and type B cells could interconvert or reverse polarity.[462] In these studies, type A and B intercalated cells were defined by endocytosis of macromolecules and peanut lectin binding, respectively.[462] With acid loading of rabbits, an increased number of type A cells and a decreased number of type B cells were found. Since cellular proliferation was excluded and the total number of intercalated cells remained constant, reversal of cell polarity was proposed. Subsequent studies by Satlin et al. examined lectin

positive cells during continuous exposure to an acid peritubular media *in vitro*, after 3–5 hours, cells lost peanut lectin binding, developed endocytosis, and exhibited decreased apical Cl/HCO_3 exchange.[486] Subsequent studies of acidosis *in vitro* have shown both decreased HCO_3 secretion and increased HCO_3 reabsorption via H-ATPase.[482] Further studies demonstrated that with acid incubation, some type B IC not only lose apical Cl/HCO_3 exchange, but acquire basolateral Cl/HCO_3 exchange, an effect mediated in part by the extracellular protein hensin.[473,472,711] Purkerson et al. using immunofluorescence for AE1 and pendrin have confirmed this model of variation in these anion exchangers with acidosis and recovery.[712] Although these results do not confirm strictly defined reversal of polarity, they do demonstrate remarkable cellular remodeling. Even though reversal of polarity in the strictest sense has been controversial based on the differences in the apical and basolateral Cl/HCO_3 exchangers discussed previously, Al-Awqati and collaborators demonstrated reversal of polarity in an immortalized β IC cell line *in vitro*, in addition to the findings in perfused tubules sited above.[643,644,713] In this cell line reversal of polarity is dependent on seeding density, subsequent studies demonstrated that the mediator of this reversal of polarity was the extracellular matrix protein, hensin/DMBT1, interacting with integrins and two secreted proteins, galectin-3 and cypA (a cis-trans prolyl isomerase).[472,643,644,711,713,714] Blocking antibodies against hensin prevent the polarity reversal, and deletion of hensin blocks conversion of B to A IC.[473,715] Galectin-3 facilitates hensin's role in the adaptation to acidosis.[716] Other studies demonstrated that the response to acidosis involving hensin requires cyclophilins, evidenced by inhibition by cyclosporine A.[717]

Bastani et al.,[474] examining cellular H-ATPase distribution in rat CCD using immunocytochemistry, found a spectrum of patterns ranging between prototypical B cells to prototypical A cells, with H-ATPase on the basolateral and apical membranes, respectively. The distribution of H-ATPase polarity in this spectrum varies with acid or base loads.[474] Besides distribution in apical and/or basolateral membranes, H-ATPase in IC resides in submembrane vesicles in the cytoplasm. Other morphologic studies of the rat CCD have shown that respiratory acidosis induces distinct changes in type A cells but no clear evidence of interconversion of cell types.[425] Another study of rat CCD found a constant percentage of intercalated cells with apical H-ATPase, suggesting no reversal of polarity, the remaining IC cells had an inverse proportion of cells with basolateral staining and with diffuse cytoplasmic H-ATPase immunoreactivity, suggesting alterations between these two forms only.[458] The presence of significant numbers of intercalated cells with diffuse cytoplasmic staining for H-ATPase (rather than apical or basolateral membrane staining) has led to an alternative hypothesis that some cells are "hybrid cells" able to change function depending on conditions.[464,474,690] Two functional studies using rabbit CCD suggest that acid loading *in vivo* results in tubules with dramatically reduced unidirectional HCO_3 secretion, but with minimal increases in unidirectional HCO_3 reabsorption.[413,480] This would be consistent with altered function of type B intercalated cells in rabbits, but with little effect of acid loads on type A cells, the latter would correspond with the lack of effect of acid loads on outer medullary collecting duct HCO_3 reabsorption.[477,487] In contrast, studies of CCD from rats with chloride depletion metabolic alkalosis suggest that both HCO_3 reabsorption and HCO_3 secretion are altered.[445] Also, studies of both rabbit CCD and $OMCD_{is}$ demonstrate adaptation of HCO_3 reabsorption, in addition to changes in HCO_3 secretion in CCD.[482,589] Recent studies in rats suggest that type A IC in the cortical and outer medullary CD proliferate in response to systemic acidosis and that growth differentiation factor 15 is involved early in this process.[718,719] In sum, dramatic changes occur in the structure and function of intercalated cells of the CCD with acid loads, however, the exact nature and mediators of these changes remain under study. Clearly, intercalated cells exhibit considerable variation in phenotype and remarkable plasticity.

Besides these "remodeling" changes in CCD, additional mechanisms of adaptation of transport may also occur with chronic acid loading. The adaptations in the IMCD during acidosis are unlikely to result from any changes in intercalated cells since these are not present in the inner medulla. Metabolic acidosis has been reported to increase NEM-sensitive ATPase at least in the CCD.[346,502] However, there are varying results regarding whether mRNAs for H-ATPase subunits increase with acidosis.[474,560]

Luminal pH may also alter distal nephron acid–base transport based on findings in turtle bladder studies.[720] In these studies, H secretion decreased linearly with decreases in mucosal pH, a result of a decreased H pump rather than an H leak.[720] Assuming that a low luminal pH does inhibit collecting duct H secretion, increased delivery of luminal buffers will enhance H secretion by decreasing changes in luminal pH as H secretion occurs. Some *in vivo* microperfusion studies of the rat superficial distal tubule have demonstrated increased HCO_3 reabsorption with increased loads.[426,428]

Although the effect of luminal pH or buffer delivery has not been well studied in distal nephron segments, microperfusion studies have confirmed that the rabbit CCD and $OMCD_{is}$ and the rat superficial distal tubule

have low H and HCO_3 permeabilities.[428,681] Also studies of pH_i in $OMCD_{is}$ and IMCD have shown minimal changes with luminal pH.[494,527] Similar findings have been reported in the principal cells of the CCD.[625] Therefore, pH_i of distal nephron cells appears to be predominantly affected by peritubular pH rather than by luminal pH. However, luminal HCO_3 does influence pH_i of type B intercalated cells, as expected with an apical Cl/HCO_3 exchanger.[625]

In sum, systemic and luminal pH alter distal nephron H secretion and HCO_3 reabsorption. The mechanisms are multiple: acute kinetic and thermodynamic effects on membrane transporters, acute insertion of additional transporters into the plasma membrane, and chronic alterations in cellular structure and function. As discussed below, endogenous hormones such as prostacyclins and endothelin may mediate some of these changes.

Sodium and Chloride Delivery and Transepithelial Voltage

Clearance studies have clearly shown that the delivery of sodium and the nature of the accompanying anion have marked influences on distal nephron acidification.[721–723] Increasing sodium delivery, especially in the presence of nonreabsorbable anions, increases H secretion, this effect is most evident in animals with volume depletion or increased mineralocorticoids.[722] However, as reviewed above, luminal H secretion is independent of Na in all of the distal nephron segments past the TAL.[404,430,444,496,511] The effect of sodium delivery and the accompanying anion can be explained by the electrogenic nature of distal H secretion.[543,685,724] H secretion in the CCD and $OMCD_{is}$ has been shown to be both electrogenic and sensitive to the transepithelial voltage.[404,496,725] In the CCD, sodium reabsorption results in a lumen negative transepithelial voltage which will stimulate H secretion, with increased mineralocorticoids or a nonreabsorbable anion the magnitude of the lumen negative voltage will be increased, resulting in more H secretion. In the $OMCD_{is}$, sodium reabsorption does not occur, and H secretion results in a lumen positive transepithelial voltage.[477,496,725] H secretion in the IMCD also appears to be electrogenic, at least in part,[516] however, the influence of transepithelial voltage is unknown in this segment. In the rat superficial distal tubule, luminal flow rate and HCO_3 delivery are also important determinants of HCO_3 transport.[426,428,439]

Chloride concentrations are also an important determinant of distal nephron acid–base transport. Several studies have clearly shown that chloride concentrations in the luminal and peritubular solutions alter net HCO_3 transport in the CCD.[442,479,726] Based on the models in Figures 55.10 and 55.11, HCO_3 reabsorption depends on the presence of peritubular Cl, and HCO_3 secretion depends on the presence of luminal Cl, this has been experimentally verified.[442,479,480] Changes in Cl delivery *in vivo* may be important since the K_m for luminal Cl/HCO_3 exchange in HCO_3 secretion is 5–10 mM,[632] this range of concentrations is relevant for considerations of the maintenance and repair of chloride depletion metabolic alkalosis. The plasma concentrations of Cl may also be physiologically important since some studies have suggested that the K_m for $OMCD_{is}$ Cl/HCO_3 exchange is 115 mM, i.e., in the physiologic range.[494] Chloride concentration gradients may also alter H secretion by altering transepithelial voltage.[725,726]

Mineralocorticoids

Mineralocorticoids are an important determinant of net acid excretion by the kidneys[727,728] and may mediate the effects of extracellular fluid volume on distal nephron acidification.[729] Several mechanisms explain the stimulation of H secretion in the distal nephron. First, mineralocorticoids are well known to stimulate Na reabsorption and the lumen negative transepithelial voltage in the CCD, H secretion will increase secondary to the altered voltage. Second, mineralocorticoids directly stimulate H secretion in the CCD and $OMCD_{is}$, independent of Na transport.[404,496] Some of this response occurs after only a few hours and can be observed *in vitro*. Recently, a rapid nongenomic stimulation of H-ATPase activity by aldosterone was reported in OMCD,[730] a transient rise in intracellular calcium and a requirement for PKC were found in this response. Chronic mineralocorticoids also increase NEM sensitive ATPase.[501,546] Therefore mineralocorticoid stimulation of H secretion may have both early and late mechanisms of action, as has been shown for stimulation of Na transport. Mineralocorticoids also stimulate inner medullary collecting duct H secretion, probably independent of Na reabsorption.[731] Mineralocorticoids also have effects on H,K-ATPases and ammonia transporters. The effects on H,K-ATPase include increased mRNA of H,K-ATPase $\alpha 2$.[732] These effects interact with luminal V1a AVP receptors in IC.[733] Another potential mechanism of mineralocorticoid stimulation of H secretion is via potassium depletion, discussed below.

Mineralocorticoids also stimulate HCO_3 secretion in the CCD.[446,734] Acid-loading of mineralocorticoid-treated animals eliminates this HCO_3 secretion.[480] Therefore, the increased HCO_3 secretion may be secondary to the systemic alkalosis produced by mineralocorticoids. However, the effect of mineralocorticoids to

increase HCO_3 secretion could be direct, but still inhibitable by acid loading.

Potassium

Clinically potassium depletion is usually associated with metabolic alkalosis and inappropriate urine acidification. However, the direct effects of K depletion on distal nephron acidification are complicated by changes in aldosterone secretion.[735] Potassium depletion *per se* decreases aldosterone levels, clinically however, K depletion often occurs in conditions associated with increased mineralocorticoids. Potassium depletion appears to potentiate the effects of mineralocorticoids to increase H excretion.[736]

Hypokalemia significantly increases HCO_3 reabsorption in the superficial distal tubule.[426,427] The effect of *in vivo* potassium depletion on distal acidification has been addressed in several studies. Initially McKinney and Davidson studied K depleted rabbits and found increased HCO_3 reabsorption in the CCD and decreased HCO_3 reabsorption in OMCD, mineralocorticoids administered to the K depleted animals increased both CCD and $OMCD_{is}$ HCO_3 absorption.[737] The K depleted animals had decreased aldosterone levels and metabolic acidosis, which complicates the interpretation. Hays et al. also studied K depleted rabbits, but their animals were alkalotic, despite the alkalosis, no HCO_3 secretion was found in CCD and HCO_3 reabsorption in $OMCD_{is}$ was unchanged from control values.[737] These studies suggest that K depletion is associated with increased or inappropriate collecting duct H secretion or HCO_3 reabsorption, especially considering the suppression of aldosterone in the experimental models.

As discussed previously (see section on H,K-ATPase), Wingo found that HCO_3 reabsorption in $OMCD_{is}$ from K depleted animals is sensitive to luminal omeprazole, an inhibitor of gastric H,K-ATPase.[498] Other studies also suggest increased H,K-ATPase activity in collecting ducts from K depleted animals.[565] Since these early studies, a variety of studies (discussed previously) have found increased H,K-ATPase along the collecting duct in potassium depletion.[410,412] Increased membrane insertion of H-ATPase in K depletion is another probable mechanism of increased collecting duct H secretion since an increased number of rod-shaped particles is found in IC, as in acidosis.[738] Other studies demonstrate enhanced apical H^+ATPase, and basolateral AE1 and Slc26a7 during K depletion.[739]

Endothelin: Endothelin has been shown to mediate some of the effects of systemic acid loads on distal tubule acid−base transport.[210] Acid loading of rats increases renal cortical interstitial endothelin-1 (ET-1), and inhibition of Type B endothelin receptors blunts the HCO_3 secretory and reabsorptive changes induced by acid loading.[210] Infusion of ET-1 *in vivo* increases H^+ secretion via Na-H exchange and decreases HCO_3 secretion in rat superficial distal tubules.[436,740] Acidosis directly increases ET-1 secretion by renal microvascular endothelial cells.[741] Further *in vitro* studies indicate that the ET_B receptor and signaling via NO-guanylate cyclase is involved in the down-regulation of HCO_3^- secretion in the CCD in response to acidosis.[742] Thus, intra-renal endothelin may play an important role in regulating distal nephron acid−base transport.[743]

A variety of other hormones have also been implicated as having effects on acid−base transport in the distal nephron.[744,745] However, the exact role and physiology of all of these is not as well characterized as that of mineralocorticoids, and the physiologic role is expected to be less important.

Parathyroid hormone (PTH) and Calcium: PTH has been implicated in stimulating distal nephron acidification.[392,506,746,747] PTH is released in response to HCl induced acidosis.[746] PTH increases H secretion in the toad bladder.[748] However, the effect of PTH to increase distal acidification in the rat may be predominantly secondary to an increased distal delivery of phosphate,[747] phosphate could stimulate distal acidification both as a buffer and as a poorly reabsorbable anion as discussed previously. Of note in regard to the possibility of a direct effect of PTH on the distal nephron, PTH stimulates adenylate cyclase in the distal convoluted tubule and connecting segment, but not in the collecting tubule of either rat or rabbit.[749] Calcium may also stimulate distal acidification.[750]

Arginine vasopressin (AVP or antidiuretic hormone): ADH has been reported to increase rat distal nephron acidification.[387,744] Net bicarbonate secretion is converted to net bicarbonate reabsorption both in superficial distal tubules *in vivo* and in the rat CCD *in vitro*.[387,751] The mechanism and responsible cell type have not been established. Glucagon has been shown to stimulate net HCO_3 secretion in the rat superficial distal tubule *in vivo*.[389] The mechanism has not been delineated but glucagon is known to stimulate cAMP in both cortical and medullary collecting ducts of the rat.[749] Bicarbonate reabsorption is stimulated by cAMP in the rabbit $OMCD_{is}$ *in vitro*,[752] however, the primary hormones which stimulate this action are not known. Prostaglandin E_2 inhibits, and indomethacin stimulates, HCO_3 reabsorption in the $OMCD_{is}$ to a modest extent.[752]

Isoproterenol and cAMP: Isoproterenol increases HCO_3 secretion in the cortical collecting tubule via a cyclic AMP dependent action.[478] The mechanism probably involves activation of both the apical Cl/HCO_3

exchanger and the basolateral Cl channel in type B intercalated cells.[631,632,478,629] The evidence for these separate actions are a decreased intracellular pH and an increase in the apparent chloride conductance of the CCD.[631,632] Bicarbonate secretion in the turtle bladder is also sensitive to cAMP, but in this case the stimulated secretion may be via an electrogenic mechanism.[753,754,755,756] Of note, turtle bladder HCO_3 secretion also responds to activation of protein kinase C, whereas CCD HCO_3 transport is not altered by this mechanism.[757,758] In contrast, isoproterenol (or VIP) may increase HCO_3 reabsorption in the rat distal tubule.[744]

Recent studies have directly implicated cAMP and PKA in regulating the expression and distribution of H-ATPase.[759] The metabolic sensor AMPK (AMP-activated kinase) can override the effects of cAMP/PKA. The upstream activators and physiologic integration of these findings are not clear but the bicarbonate stimulated soluble adenylyl cyclase (sAC) has been suggested.[760]

Prostacyclin (PGI_2): PGI_2 increases rat distal tubule HCO_3 secretion, probably via a cAMP dependent process.[761] And importantly, alkali loads increase urinary metabolites of PGI_2.[761] Therefore, PGI_2 may mediate some of the transport changes induced by alkali loads *in vivo*.

Angiotensin II: Angiotensin II has a variety of effects on distal nephron acid−base transport.[762] Angiotensin II was found to stimulate HCO_3 secretion in rabbit CCD[763] but to increase HCO_3 reabsorption is rat distal tubule.[744,764] Recently AII has been found to increase H secretion via H-ATPase insertion into the apical membrane of type A IC in mice, this effect may be important not only in acid−base transport but also in facilitating NaCl reabsorption in the CCD.[765] Increased H-ATPase activity may also occur in type B IC.[766] In the OMCD, angiotensin II reduced HCO_3 reabsorption.[461]
