advancing rapidly. For example, there is increasing evidence that methylation of cytosine in the DNA, leading to hypermethylation of promoter regions, is frequent in most types of cancers, including lung cancer.[148] Promoter regions of many human genes have loci rich in CpG dinucleotides, regions referred as CpG islands.[148,149] Hypermethylation of the CpG islands can be detected by polymerase chain reaction methods. Cells with abnormal methylation of genes have been detected in sputum of subjects before their diagnosis of lung cancer, suggesting that hypermethylation could be a useful marker for early detection.[150,151]

In a general formulation of determinants of cancer risk, the risk depends on carcinogen exposure as well as the factors that determine host susceptibility, including genetic predisposition.[152] Central to the molecular epidemiology approach are biomarkers, measures of indicators of exposure and dose, susceptibility, and response in biologic materials, including tissue samples, blood, urine, and saliva.[153] As research evolves within this paradigm, a more complete biologic understanding of the specific events underlying the multistage model, originally proposed on a conceptual basis, can be anticipated.

This framework indicates multiple points where genetically determined host characteristics might be important: carcinogen metabolism and activation, DNA repair, and cell cycle control/apoptotic response. There is a rapidly expanding literature on the molecular and cellular basis of lung cancer.[130] The evidence has expanded and deepened our understanding of how smoking injures cells and causes cancer and indicates potential approaches to identifying high-risk individuals and molecular screening.

Studies to investigate genotypic variation in relation to lung cancer risk have evolved rapidly since the 1980s. Initially, the research paradigm relied on identifying and studying candidate genes with functional polymorphisms hypothesized to be directly related to lung carcinogenesis, such as carcinogen detoxification or DNA repair. The sequencing of the human genome and the development of high-throughput assays that enable increasingly larger number of single nucleotide polymorphisms (SNPs) to be measured in larger studies has led to the new paradigm of genome-wide association studies (GWAS). In contrast to the candidate gene approach, which is based on deduction, the GWAS approach is inherently inductive. GWAS studies entail measuring as many tagging SNPs as possible; currently hundreds of thousands to more than a million, to determine which regions of the genome are associated with lung cancer risk. Because of the exploratory nature of the GWAS approach, these studies are usually specifically designed to guard against false-positive findings.

Of primary interest in studies using the candidate gene approach have been genes that encode for enzymes in carcinogen metabolism and DNA repair pathways and that are polymorphic in humans. A few selected examples are described later. The metabolism of toxic agents, including carcinogens, generally proceeds through two phases.[154] In phase 1, unreactive nonpolar compounds

are converted, usually by oxidative reactions, to highly reactive intermediates. These intermediates are then able to form complexes with conjugating molecules in phase 2 conjugation reactions, which are usually less reactive and more easily excreted. However, the intermediate metabolite may react with other cellular components, such as DNA, before conjugation occurs. This binding to DNA may be the first step in the initiation of the carcinogenic process.[154]

Many carcinogenic compounds in tobacco smoke, for example, polycyclic aromatic hydrocarbons, undergo metabolic activation by phase I enzymes of the cytochrome p-450 system to form reactive intermediates that bind to DNA and cause genetic injury. For example, for *CYP1A1*, the current evidence suggests that two specific polymorphisms, in MspI[155] and in exon 7,[156] are associated with increased lung cancer risk.

Glutathione *S*-transferase is a phase II enzyme that detoxifies reactive metabolites of polycyclic aromatic hydrocarbons. The results of a meta-analysis indicated that those with the *GSTM1* null–versus–present genotype had slightly higher risk of lung cancer, but a pooled analysis of data from 21 case-control studies did not indicate that this susceptibility was stronger among cigarette smokers than among nonsmokers.[157] Another pathway where genetic variation has been of hypothesized importance in determining susceptibility to lung cancer is DNA repair.[158,159] One of the most extensively studied DNA repair genes to date is the nucleotide excision repair gene *XPD*.[160,161] The evidence has not yet revealed a consistent pattern of associations for any specific polymorphism. These are examples where the candidate gene approach has not yielded clear-cut associations with lung cancer risk.

GWAS are now being reported, with encouraging results. The results of four separate studies, all published in 2008, have been remarkably consistent in identifying a region on the long arm of chromosome 15 (15q24-25.1).[162–165] For example, those with at least one variant allele of a specific SNP in this region (rs8034191), present in approximately one third of the study population, were at 1.3 times greater risk of lung cancer than those with the wild-type allele.[163–165] Now that this genomic region is identified, identifying the specific genetic variants that are directly responsible for determining lung cancer risk within this region is a major priority.

Presence of Human Immunodeficiency Virus

As human immunodeficiency virus (HIV)–positive patients maintain their immune function with highly active antiretroviral therapy (HAART) and live longer, evidence has emerged to indicate that HIV-positive individuals have an increased risk of lung cancer, especially non–small cell lung cancer (NSCLC).[166,167] In the HAART era, a greater than twofold increase in lung cancer risk has been observed among HIV-positive men and women.[167,168] In addition, HIV-positive individuals are diagnosed with lung cancer at a median age of 45 years or younger,[167,168] younger than the norm.

Some aspects of the occurrence of lung cancer in HIV-positive patients are similar to patterns seen in the general population. This includes a predominance of NSCLC,[169,170] with adenocarcinoma and squamous cell carcinoma as the two most common cell types.[167,169,171] In addition, the increased risk of lung cancer in HIV-positive patients applies to both men and women, so the fact that the preponderance of HIV-positive patients with lung cancer are males[169] may reflect the higher prevalence of HIV infection in men than in women.

There are several hypotheses as to the basis for the excess lung cancer risk in HIV-positive individuals. The elevated lung cancer risk may simply be due to a higher prevalence of cigarette smoking in HIV-positive individuals.[169,172] Alternatively, HIV may itself contribute to lung carcinogenesis.[172a] If so, potential explanations for the increased lung cancer risk could include (1) HIV acting as a viral carcinogen, (2) defective immune surveillance, and (3) recurrent opportunistic infections and parenchymal lung inflammation leading to inflammatory foci and scar carcinomas.

Presence of Acquired Lung Disease

In addition to hereditary factors, increased susceptibility to lung cancer may result from underlying lung disease. Such acquired lung diseases assume two major forms: (1) those that obstruct airflow, such as chronic obstructive pulmonary disease (COPD) and (2) fibrotic disorders that restrict lung capacity, such as pneumoconiosis.[173]

A substantial body of evidence suggests that COPD or impaired lung function is associated with the occurrence of lung cancer.[174] However, because cigarette smoking is the principal cause of both COPD[175] and lung cancer, statistical adjustment procedures that "remove" the effect of cigarette smoking may not be well-founded. For example, the presence of COPD may indicate that the affected individual has received a greater dose of tobacco carcinogens than the typical unaffected individual. Alternatively, cigarette smoke may induce an inflammation that can contribute both to COPD and to lung cancer.[174a] Regardless of mechanism, the presence of COPD is a clinically useful risk indicator.

Clarifying the possible relationship between pneumoconioses and lung cancer poses particularly vexing challenges. Even for asbestos exposure, which is clearly established as a potent cause of lung cancer,[93] whether lung cancer results from asbestos per se or from asbestosis remains unresolved (see earlier). For other mineral fibers, the evidence is even more uncertain.[176] For example, determining whether silica exposure or silicosis mediates the increased lung cancer risk in silica-exposed persons has proved difficult.[177,178] The presence of silicosis is associated with an increased risk of lung cancer.[179] Understanding the basis of this association will entail isolating the independent effects of silica exposure and lung fibrosis while controlling for exposure to smoking and other lung carcinogens.[176]

Such differences in the pattern of associations between pneumoconioses and lung cancer emphasize that "fibrosis" is not a homogeneous exposure, but one dependent

upon the properties of the specific mineral fiber or other environmental agent. Properties of the agent, such as its size, shape, and durability, and the effects of other exposures such as cigarette smoking are important considerations in assessing its potential harmfulness.[180]

Gender

The hypothesis has been advanced that females may have a greater risk of lung cancer than males at the same level of smoking.[181,182] There are several methodologic issues that have clouded the interpretation of the data on this issue,[183] but the results of studies that have compared the relative risk estimates for men and women for a specific degree of smoking history demonstrate very similar risks.[41,184]

FUTURE DIRECTIONS

In developing lung cancer prevention strategies, certain groups warrant particular attention. Steps need to be taken toward the goal of reducing the very high lung cancer incidence rates in African American men.[185] Lung cancer is also a major women's health issue. Owing to historical cigarette smoking patterns, the epidemic of lung cancer started later in women than in men, but in contrast to the situation in men, lung cancer incidence rates in women are still increasing.[186] Though lung cancer remains a critical public health problem, the decrease in the overall lung cancer burden that is presently occurring in the United States, as in much of the developed world, reflects the successes of preventive strategies. A critical global priority is to prevent the uptake of cigarette smoking in developing countries where smoking prevalence is still low.

A consideration of the epidemiology of lung cancer consistently reinforces one major theme: the pandemic of lung cancer is a consequence of the tragic and widespread addiction to cigarettes throughout the world. Curtailing the pandemic of lung cancer will require preventing youths from starting to smoke cigarettes and effectively promoting smoking cessation among addicted smokers.

KEY POINTS

- In the United States, lung cancer remains the leading cause of cancer death in both men and women.
- The predominant cause of lung cancer is exposure to tobacco smoke, with active smoking causing most cases but passive smoking also contributing to the lung cancer burden.
- The reductions in smoking prevalence in men that occurred in the late 1960s through the 1980s will continue to drive lung cancer mortality rates downward in men during the first portion of this century, but rates in women have not yet begun to decrease.
- Fortunately, exposures to major occupational respiratory carcinogens have largely been controlled, but the population is still exposed to environmental causes of lung cancer, including radon, the second leading cause of lung cancer death.

Hematologic Effects
Hypercalcemia
Syndrome of Inappropriate Antidiuretic Hormone Secretion
Ectopic Corticotropin Syndrome
Neurologic Effects

INTRODUCTION

Lung cancer is the most common cause of cancer deaths worldwide. In the United States, lung cancer accounted for an estimated 215,000 cases of cancer and 161,840 cancer deaths in 2008. Although Chapter 46 is dedicated to the epidemiology of lung cancer, some of the information found therein is worth repeating. For example, added together, the number of cancer deaths from breast, colon, and prostate cancer each year would not equal the number of cancer deaths related or due to lung cancer. A common misconception among the general public is that breast cancer accounts for more cancer deaths in women. However, lung cancer will account for 25% of cancer-related deaths among women in the United States. A total of 71,000 women were expected to die from this disease in 2008. Particularly alarming is the fact that young women are the fastest-rising demographic of new cigarette smokers in the United States. Many have clearly made the association between weight control and cigarette smoking. This will have effects on the prevalence of lung cancer in the decades to come.

One of the more disturbing trends in lung cancer is the explosion in rates of lung cancer in countries of the developing world. In 1985, it was estimated that there were 921,000 lung cancer deaths worldwide—an increase of 17% from 1980.[1] The International Agency for Research on Cancer in France found that the rates of lung cancer in Africa in the early 1990s were similar to those in the United States in the 1930s, at about

5/100,000. By 1999, the rate of lung cancer in males of developing countries was 14/100,000 and on the rise, compared with a rate of 71/100,000 in developed countries, which continues to decline. These rates may actually be underestimates of the true rates of lung cancer, because many cases may go undiagnosed or underreported in areas where health care is not readily available.[1] An example of how serious this problem has become is found in China, where it is estimated that nearly 800,000 Chinese men died of lung cancer in 1998.[1] At present, Chinese men smoke an average of 11 cigarettes/day, which is equivalent to the highest average rates of smoking ever seen among males in the United States. In fact, the consumption of cigarettes in China alone may surpass that of all developed countries combined.[1,2] Overall, 66.9% of Chinese men smoke. In view of such statistics, it is imperative that the medical community devotes much of its educational efforts and resources toward the elimination of cigarette smoking worldwide, which would nearly eliminate the development of lung cancer.

This chapter reviews the current strategies for the diagnosis, introduces the new staging system, and describes the current treatment of lung cancer. As much as possible, evidence-based review of the best currently available literature has been included. An extended section on computed tomography (CT) screening for lung cancer is presented because the question of whether or not to screen for lung cancer on a routine basis will be one that pulmonologists will face for years to come. The role of the pulmonologist is described for every aspect of lung cancer care, from diagnosis to staging to caring for the complications of the disease itself and the complications of cancer treatment.

SCREENING FOR LUNG CANCER

The current position of the American Cancer Society and the U.S. Preventive Services Task Force is that there is no role for screening for lung cancer, even in high-risk individuals.[3] This position is based on the results of five randomized, controlled trials that suggest that neither chest radiography nor sputum cytology satisfies the primary criterion of a beneficial screening test: reduction in lung cancer mortality.[4–6] There continues to be ongoing debate about the interpretation of these studies. One deficiency is that most of these studies did not include a "no screening" arm. Others have argued that the sample size of the studies was inadequate. The Mayo Lung Project and the Czechoslovakian studies were powered to detect a 50% reduction in lung cancer mortality in the screened group and could have missed detecting a 20% to 30% reduction.[4,7] An ongoing trial sponsored by the National Cancer Institute (Prostate, Lung, Colorectal, and Ovarian Trial) is a randomized trial of chest radiography versus no screen in a low-risk population of both genders. It is powered to detect a 10% reduction in mortality due to lung cancer. Accrual to this study has been completed, but the final results will not be available for several years.

CT has been shown to be much more sensitive for detecting pulmonary nodules than the standard chest radiograph. As of 2003, there have been at least six reports of single-arm screening trials utilizing low-dose spiral computed tomography (LD-CT), defined as a single breath-hold scan that exposes the patient to five to six times less radiation dose than a standard CT scan, with or without sputum cytology.[4,8–13] These trials have consistently shown that spiral CT detects more lung cancers than chest radiography. The study by Sone and colleagues[11] from Japan detected 44 lung cancers with spiral CT, only 11 of which were visible by chest radiography. Similarly, the New York study detected 27 lung cancers with CT, only 7 of which were visible on chest radiograph.[9] The LD-CT studies have consistently shown a high prevalence of noncalcified nodules. In general, it appears that the thinner the CT slices, the more noncalcified nodules are detected. A study from Germany with 5-mm slices detected at least one noncalcified nodule in 43% of 817 participants screened,[8] and a report from Mayo Clinic investigators observed noncalcified nodules in 51% of individuals with 5-mm slices and 3.75-mm reconstruction intervals.[13] The number of noncalcified nodules detected is increasing as centers begin to use 8- and 16-multislice detector scanners and decreasing slice thickness. In the Mayo Clinic trial, only 1.7% of the noncalcified nodules were subsequently shown to be malignant. However, once found, all noncalcified nodules must be followed up with CT at some interval (at least yearly), which adds to the cost of screening. Studies are under way to try to determine the optimum follow-up and evaluation algorithm, although the best algorithm to date appears to be that set forth by the Fleischner Society.[14]

Recently, a large multicenter, multinational, nonrandomized trial named the International Early Lung Cancer Action Program (I-ELCAP) was reported.[15] The I-ELCAP screened 31,567 subjects using LD-CT. Lung cancer was identified in 484 patients, with 412 having stage I disease. The estimated 10-year survival was 80% for all patients regardless of stage and treatment, and 88% for stage I cancer. This study confirmed earlier observations that lung cancers detected by CT screening are very early stage and highly treatable.

Although this study provides a basis for optimism, it is insufficient to confirm the effectiveness of LD-CT screening for lung cancer. Welch and coworkers[16] nicely summarize the key elements missing from this trial. First is the lack of a control group, which would allow one to understand what would happen to a similar group of subjects in the absence of screening. Second is the absence of an unbiased outcome measure, which would control for the confounding features of *lead-time bias*, *length-time bias*, and *overdiagnosis* that can lead to an apparent increase in survival without actually changing the overall mortality of those with lung cancer. *Lead-time bias* is the detection of tumors earlier in their course; *length-time bias* is the greater detection of less aggressive, slower-growing tumors than more aggressive, faster-growing tumors; and *overdiagnosis* is the detection of tumors that would otherwise

never cause symptoms or death. Third, the study does not take into account what is already known about lung cancer screening, particularly the evidence for overdiagnosis bias arising in single-arm studies from Japan.[17] Finally, although the I-ELCAP accentuates the positives of screening, it does not account for potential harm; particularly the unnecessary workup or therapy for benign disease.[17a]

In contrast to the optimistic findings published by the I-ELCAP investigators, Bach and associates[18] examined three single-arm studies conducted in Milan, Rochester, and Florida that screened 3246 high-risk subjects with annual CT scans with a median follow-up of 3.9 years. The frequency of observed new lung cancer cases, lung cancer resections, advanced lung cancer cases, and deaths from lung cancer was compared with the expected number of cases based on two validated models. There were 144 individuals diagnosed with lung cancer compared with 44.5 expected cases (relative risk [RR], 3.2; 95% confidence interval [CI], 2.7–3.8; $P < .001$). The rate of lung cancer resection was 10-fold higher, 109 resected compared with 10.9 expected cases that were predicted for that cohort (RR, 10.0; 95% CI, 8.2–11.9; $P < .001$). The survivorship of those stage I patients resected was similar to that seen by the I-ELCAP investigators There were 42 cases of advanced lung cancer compared with 33.4 expected cases, and 38 deaths, which is what was predicted for that cohort (RR, 1.0; 95% CI, 0.7–1.3; $P = .90$). This study showed that screening with LD-CT may increase the rate of lung cancer detected and resected, but may not reduce the risk of advanced lung cancer or overall mortality from lung cancer. Screening for lung cancer can be shown to be of benefit only when it is found to decrease the overall mortality from the disease.

The LD-CT trials have consistently detected non–small cell lung cancer (NSCLC) as stage IA in 60% to 90% of cases, and early survival data from Japan suggest a major improvement in 5-year survival.[10] However, it is not possible to determine if this is due to lead-time bias, length-time bias, or overdiagnosis.[19] None of the trials reported to date has had a control arm for comparison and, without the comparison group, screening with LD-CT has not yet been shown to reduce lung cancer mortality. A reduction in lung cancer mortality is the primary end point of the National Lung Cancer Screening Trial (NLST). This trial has randomized 50,000 high-risk participants to screening with LD-CT or chest radiography. Subjects were screened yearly for 3 years and are currently in follow-up for 5 years. The trial is powered to detect a 20% reduction in lung cancer mortality. The NLST completed accrual in early 2004, but final results may not be available until 2010. Until the result of the NLST is known, the American College of Chest Physician guidelines recommend that individuals should be screened with LD-CT only in the context of well-designed clinical trials. The guideline recommends against the use of single LD-CT or serial LD-CT to screen for lung cancer in individuals without symptoms or a history of cancer.[20]

PRESENTATION

Unfortunately, the symptoms of lung cancer can be nonspecific, thereby delaying the diagnoses for patients who present with this disease and leading to an advanced stage at the time of diagnosis. Approximately 40% of patients in a screened population and 98% of patients in a hospitalized population will present with symptoms.[7,21] Table 47-1 displays some of the common symptoms associated with the presentation of lung cancer. Most are nonspecific; however, some clues can be gained from the history, thus raising the clinician's suspicion that lung cancer is present. Although many smokers cough, lung cancer patients usually admit to a change in the character of their cough. The cough can increase in frequency or strength or may not be relieved with local measures. Chest pain can be present in 25% to 50% of patients at the time of presentation for evaluation for lung cancer.[21,22] The pain is generally dull in nature, tends to be persistent, remains in the same location, and is not relieved with local measures. Chest pain is usually related to involvement of the pleura but can be related to extension into the mediastinum or chest wall. Chest pain in and of itself does not preclude the patient from consideration for surgery with curative intent. Dyspnea is frequently a complaint of patients who present with bronchogenic carcinoma, occurring in half of all new patients at presentation.[21] A partial list of the reasons for dyspnea related to lung cancer includes pulmonary embolism, superior vena cava syndrome, deconditioning, reactive airway disease, endobronchial obstruction with tumor, prior obstructive pneumonia, hemoptysis, hemorrhage, malignant pleural effusion, and extrinsic compression of the airway by tumor.

Hemoptysis in a smoker should always raise the suspicion of lung cancer. Hemoptysis can present as blood streaking of the sputum and can be noted over a lengthy period of time before presentation to the physician's office because it is attributed to smoking-related bronchitis. The clinician should not be led astray, even if the chest radiograph is normal, because up to 5% of those patients with a smoking history and a normal radiograph

TABLE 47-1. Presenting Symptoms with Bronchogenic Carcinoma

Symptoms	Patients (%)
Cough	45–75
Weight loss	8–68
Dyspnea	37–58
Hemoptysis	27–57
Chest pain	27–49
Hoarseness	2–18

can harbor lung cancer.[23] Because of the vascular nature of lung cancer, patients can also present with massive hemoptysis. Weight loss, a nonspecific symptom, in the right clinical setting should raise the suspicion of both lung cancer and metastatic disease. Weight loss alone has been correlated with an advanced presentation and poor outcome from lung cancer.

In summary, patients with lung cancer can present asymptomatically or with relatively nonspecific symptoms of underlying pulmonary disease. There are often clues in the history that should alert the clinician that lung cancer is a possibility and further investigation is warranted.

LUNG CANCER STAGING

Perhaps the most critical role of the pulmonologist in the management of lung cancer is in the diagnostic and staging evaluation of the patient. Accurately staging patients with newly diagnosed lung cancer is critical because staging dictates the patient's treatment options and predicts survival. It is intuitive that early-stage disease has a much better survival than late-stage disease. What may not be so obvious is that simple staging procedures are available to the diagnostician that can help stage patients accurately. The treatment options for lung cancer have now evolved so that treatment for patients in different stages is vastly different. In general, early-stage lung cancer (stage I) is treated with surgery alone. Stage II lung cancer is treated with surgery followed by adjuvant chemotherapy. Locally advanced lung cancer (stage IIIA and B) is treated with a combination of chemotherapy and radiotherapy, and stage IV (metastatic disease) is treated with chemotherapy alone. However, there are important exceptions to these general rules that are discussed later in this chapter.

The staging of NSCLC using the tumor-node-metastasis (TNM) classification underwent revision in 1997 and has recently undergone a major revision.[24,25] The new staging system is remarkable in that it is based on over 100,000 cases of lung cancer from 23 institutions, 12 countries, and 3 continents. The data are robust, internally validated, and externally validated against the Surveillance Epidemiology and End Results (SEER) cancer registry.[25] Tables 47-2 and 47-3 show the revised TNM descriptors and stage groupings.

There are several important changes adopted in the new staging system. The main modifications are in the T and M classification; the N status will remain the same. Within the T classification, tumor size was found to be an important prognosticator and the T factor was subdivided based upon five different size criteria. Because survivorship was better than previously thought, a primary tumor with satellite nodules in the same lobe was reclassified from T4 to T3 and a tumor with additional nodules in a different lobe of the ipsilateral lung was moved from an M1 designation to T4. This change in classification and stage will allow more patients to be considered for surgery. Malignant pleural effusion was reclassified from T4 (or stage IIIB) disease to M1 disease because the survival of patients in this group was found to resemble metastatic disease more than locally advanced disease. Another significant change is that the M status is now split into M1a (metastatic disease confined to the chest) and M1b (extrathoracic metastatic disease) because survival was found to be better in those patients with metastatic disease confined to the thorax compared with those with extrathoracic metastases.

Whereas the TNM staging system is applied to NSCLC, a more simplified version is employed for patients with small cell lung cancer. In this classification, patients are classified as having limited or extensive disease. Limited disease (LD) is disease limited to one hemithorax, although it can include supraclavicular and mediastinal lymphadenopathy; extensive disease (ED) is any disease outside of the hemithorax. The implication in this classification is that LD is treated with chemotherapy and radiotherapy and ED is treated with chemotherapy alone.[26] Malignant pleural effusion can technically be categorized as LD in the staging classification for small cell lung cancer if the patient otherwise meets criteria. However, for all intents and purposes, patients with malignant pleural effusions and small cell lung cancer have the same characteristics as those with ED, and the large cooperative group trials have treated them as such.

Some important nuances to staging are described in detail later in this chapter. However, there are certain tenets of staging that must be emphasized. Prior to classifying a patient within a certain stage, the clinician should make every effort to verify any noninvasive radiologic findings with tissue confirmation of malignancy. This is particularly important in cases in which surgical resection would be precluded based on noninvasive radiologic tests. Thus, a patient who would otherwise be resectable except for a single abnormality suspicious for metastasis should have tissue confirmation of that abnormality prior to being deemed unresectable. As is pointed out later in this chapter, no noninvasive radiologic study is infallible. In studies of the mediastinum, false-positive findings range from 12% in positron emission tomography (PET) scans to 20% in CT scans with lower false-positive findings using integrated PET-CT, at the cost of lower sensitivity.[27,28] Therefore, reliance on the scan alone to predict malignancy is simply not sufficient.

Staging can be accomplished by a number of noninvasive and invasive studies. The choice of the most appropriate study rests with the clinician and is based upon how the patient presents. Some patients—for example, those with isolated solitary pulmonary nodules—may be referred for immediate surgical resection as both a diagnostic and a therapeutic maneuver. Others, such as those with extremely poor performance status or those suspected of widely metastatic disease, may undergo no testing at all. The next sections present a discussion of the attributes of each of the staging options available. For ease of understanding, they are divided into noninvasive and invasive techniques.

TABLE 47-2. Tumor-Node-Metastasis (TNM) Descriptors in the Revised 7th Edition of the TNM Classification of Lung Cancer

T (PRIMARY TUMOR)	
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)[a]
T1a	Tumor ≤2 cm in greatest dimension
T1b	Tumor >2 cm but ≤3 cm in greatest dimension
T2	Tumor >3 cm but ≤7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if ≤5 cm)
	Involves main bronchus, ≥2 cm distal to the carina
	Invades visceral pleura
	Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor >3 cm but ≤5 cm in greatest dimension
T2b	Tumor >5 cm but ≤7 cm in greatest dimension
T3	Tumor >7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina[a] but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe
N (REGIONAL LYMPH NODES)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M (DISTANT METASTASIS)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion[b]
M1b	Distant metastasis

[a]The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified at T1.

[b]Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathologic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as T1, T2, T3, or T4.

NONINVASIVE STAGING TECHNIQUES

Chest Radiography

The majority of lung cancers are detected initially by plain chest radiograph. In certain situations, the plain film may be sufficient to detect spread to the mediastinum. For example, the presence of bulky lymphadenopathy in the superior or contralateral mediastinal areas may be considered adequate evidence of metastatic disease to preclude further imaging evaluation of the chest. This may be particularly true if the patient is too ill or unwilling to undergo treatment of any kind. Still, most patients should undergo CT scan of the chest unless they are so debilitated that no further evaluation or treatment is planned. The chest radiograph is simply too insensitive a measure of mediastinal lymph node involvement with lung cancer, and thus, further noninvasive or invasive assessment is usually necessary.

Computed Tomography of the Chest

The vast majority of patients who present with lung cancer will undergo CT scanning of the chest. CT is helpful in defining the size, location, and characteristics of the primary mass (e.g., smooth-bordered, spiculated, calcified), the presence or absence of lymphadenopathy and, if performed through the adrenal glands, the presence of abnormalities in the liver and adrenal glands. The bony structures of the thoracic cavity can also be evaluated by chest CT.

TABLE 47-3. Stage Groupings in the Revised 7th Edition of the TNM Classification of Lung Cancer

Sixth Edition T/M Descriptor	Proposed T/M	N0	N1	N2	N3
T1 (≤2 cm)	T1a	IA	IIA	IIIA	IIIB
T1 (>2–3 cm)	T1b	IA	IIA	IIIA	IIIB
T2 (>3–5 cm)	T2a	IB	**IIA**	IIIA	IIIB
T2 (>5–7 cm)	T2b	**IIA**	IIB	IIIA	IIIB
T2 (>7 cm)	T3	**IIB**	**IIIA**	IIIA	IIIB
T3 (invasion)		IIB	IIIA	IIIA	IIIB
T4 (same lobe nodules)		**IIB**	**IIIA**	**IIIA**	IIIB
T4 (extension)	T4	**IIIA**	**IIIA**	IIIB	IIIB
M1 (ipsilateral lung)		**IIIA**	**IIIA**	**IIIB**	**IIIB**
T4 (pleural effusion)	M1a	**IV**	**IV**	**IV**	**IV**
M1 (contralateral lung)		IV	IV	IV	IV
M1 (distant)	M1b	IV	IV	IV	IV

CT of the chest is the most widely available and commonly used noninvasive modality for evaluation of the mediastinum in lung cancer. Numerous studies of CT have been performed comparing clinical staging by CT with the "gold standards" of mediastinoscopy or surgery. The results demonstrated that regardless of the lymph node size used as a threshold for defining malignant adenopathy, CT findings in isolation could not be considered as conclusive evidence that lymph nodes were malignant. In other words, in all studies, there are meaningful numbers of false positives detected by CT scan. The vast majority of reports evaluating the accuracy of CT scanning for mediastinal lymph node staging have employed the administration of intravenous contrast material. Although contrast is not absolutely necessary in performing chest CT for this indication, it is useful in helping to distinguish vascular structures from lymph nodes as well as in delineating mediastinal invasion by centrally located tumors. The most widely accepted criterion for an abnormal lymph node is a short-axis lymph node diameter of 1 cm or greater on CT.

The American College of Chest Physicians (ACCP) compiled the studies assessing the performance characteristics of CT scan for staging the mediastinum in a meta-analytic format.[28] Thirty-five studies were identified, comprising 5111 evaluable patients. The pooled sensitivity of CT scanning for staging the mediastinum was 51% (95% CI, 47%–54%) and the pooled specificity was 86% (95% CI, 84%–88%). The corresponding positive and negative likelihood ratios were 3.4 and 0.6, respectively, confirming that CT scanning has a limited ability either to rule in or to exclude mediastinal metastasis.[28] However, because CT usually guides the selection of nodes for biopsy by mediastinoscopy or needle aspiration, it remains an important diagnostic tool in lung cancer. Accurate noninvasive node staging is essential because the choice of individual nodes for sampling by minimally invasive techniques, including transbronchial, transthoracic, or transesophageal needle aspiration, will be directed by the findings of the CT scan. The limitation of CT-based mediastinal lymph node evaluation is evident in the fact that 5% to 15% of patients with clinical T1N0 lesions will be found to have positive lymph node involvement by surgical lymph node sampling.[29] Perhaps the most important message in evaluating the accuracy of CT scanning is that approximately 40% of all nodes deemed malignant by CT criteria are actually benign, depending on the patient population.[30] Specificity can be affected by clinical factors such as the presence of obstructive pneumonitis.[30] There is no node size that can reliably determine stage and operability. In cases in which the CT criteria for identification of a metastatic node are met, the clinician must still prove beyond reasonable doubt by biopsy or resection that the node is indeed malignant. Given the limitations of the imperfect sensitivity and specificity of CT, it is usually inappropriate to rely solely on the CT scan to determine mediastinal lymph node status. Nonetheless, CT continues to play an important and necessary role in the evaluation of patients with lung cancer and is recommended as part of the evaluation of patients who present with newly diagnosed or suspected lung cancer.[28]

CT can also be helpful in the evaluation of pleural effusion in patients with lung cancer. The CT scan can indicate the presence or absence of fluid, the contour of the pleural space, and whether or not nodules or masses are present on the pleural surface. However, the clinician should interpret these findings with caution because pleural disease can predate cancer and the presence of pleural effusion does not guarantee that the cytology will be positive. This is an important staging issue because the finding of malignant pleural effusion in NSCLC is now considered as evidence of metastatic disease or stage IV. If the pleural fluid has benign cytology (e.g., fluid from obstructive pneumonia), then the patient may still be considered for surgical resection. To resolve this issue, recommendations have been made to perform thoracentesis with cytology on two separate occasions, followed by thoracoscopy to evaluate the pleural surface directly. If the patient remains cytology-negative, then the stage and treatment offered should reflect the lower stage. CT is often inaccurate in differentiating direct tumor invasion of the visceral pleura (T2) from that of the parietal pleura or chest wall (T3). Thoracoscopy can be helpful in differentiating the extent of the primary tumor involvement into or through the pleural but, at times, open thoracotomy is needed to sort out this issue. (For a further discussion of these issues, see Chapters 23 and 75.)

Positron Emission Tomography

Perhaps the single most notable addition to the staging armamentarium for the evaluation of lung cancer is PET. With the image created by the biologic activity of neoplastic cells, PET is a metabolic imaging technique based on the function of a tissue rather than on its anatomy. Lung cancer cells demonstrate increased cellular uptake

of glucose and a higher rate of glycolysis when compared with normal cells.[31] The radiolabeled glucose analogue [^{18}F]fluoro-2-deoxy-D-glucose (FDG) undergoes the same cellular uptake as glucose but, after phosphorylation, is not further metabolized and becomes trapped in cells.[32] Accumulation of the isotope can then be identified using a PET detector. Specific criteria for an abnormal PET scan are either a standard uptake value of greater than 2.5 or uptake in the lesion that is greater than the background activity of the mediastinum. It has proved useful in differentiating neoplastic from normal tissues. In two well-performed studies that evaluated the use of PET in the preoperative setting for lung cancer,[33,34] nearly 20% of patients were staged differently after evaluation by PET scan. However, the technique is not infallible because certain non-neoplastic processes, including granulomatous and other inflammatory diseases as well as infections, may also demonstrate positive PET imaging. Furthermore, size limitations are also an issue, with the lower limit of resolution of the study being approximately 7 to 8 mm depending on the intensity of uptake of the isotope in the abnormal cells.[33] One should not rely on a negative PET finding for lesions less than 1 cm on CT scan.

A burgeoning number of studies in the last several years have reported on the utility of FDG-PET scanning in the assessment of the mediastinum in patients with lung cancer. Increasing availability of the technology now allows PET to be used widely as a diagnostic tool. It should be remembered that PET is primarily a metabolic examination and has limited anatomic resolution. It is possible for PET to identify lymph node stations but not individual lymph nodes. CT scanning provides much more anatomic detail but lacks the functional information provided by PET. The second edition of the ACCP guidelines on lung cancer revealed that with more widespread use of this technology, the test characteristics of PET have become slightly less favorable.[28] In 2865 evaluable patients, the pooled estimates of sensitivity and specificity for identifying mediastinal metastasis were 74% (95% CI, 69%–79%) and 85% (95% CI, 82%–88%), respectively. Corresponding positive and negative likelihood ratios for mediastinal staging with PET scanning were 4.9 and 0.3, respectively. These findings demonstrate that PET scanning is more accurate than CT scanning for staging of the mediastinum in patients with lung cancer, though PET is far from perfect. This imaging technique will almost certainly assume an increasingly important role in the evaluation of patients with lung cancer. However, like CT scanning, PET can be wrong. Whereas a negative mediastinal PET may obviate the need for mediastinoscopy prior to thoracotomy in certain situations, a positive mediastinal PET should not negate further evaluation or the possibility of resection. In the latter case, lymph node sampling should still be pursued because the possibility of a false-positive PET scan cannot be ignored.

Where PET is available, a PET scan should be obtained during the staging evaluation for lung cancer.[20] Newer technology includes CT/PET fusion, a single machine that incorporates CT and PET during the same scan. This allows the clinician to obtain anatomic (CT) and functional (PET) images simultaneously. Early work suggests improvement in the number of patients correctly staged with this modality over CT or PET alone.[35,36] The future of PET in lung cancer may also include its use to evaluate response to treatment.

Magnetic Resonance Imaging

There are very few circumstances in which magnetic resonance imaging (MRI) is a useful tool in staging lung cancer. However, MRI can be useful in evaluating superior sulcus tumors, especially for possible invasion of the brachial plexus, and for evaluating vertebral invasion.

The Search for Metastatic Disease

The purpose of extrathoracic scanning in NSCLC is usually to detect metastatic disease at common metastatic sites, such as the adrenal glands, liver, brain, and skeletal system, thereby sparing the patient fruitless surgical intervention.[37] CT of the chest, CT or MRI with contrast of the brain, and ^{99m}Tc nuclear imaging of the skeletal system are the staging studies of choice when the clinician needs to evaluate for metastatic disease. More recently, the use of whole-body PET scans for extrathoracic staging has been introduced, and the initial studies suggest that PET can disclose non–central nervous system metastatic disease not detected by standard methods in 10% to 20% of cases.[33,34,38-40] PET appears to be at least as sensitive as isotope bone scans for detecting metastases and has fewer false-positive results.

The initial clinical evaluation may reveal abnormalities, such as abnormal symptoms, physical findings, and routine blood tests, that then lead to an expanded clinical evaluation (Table 47-4).[37] With abnormalities on these clinical evaluations, scans will be abnormal in

TABLE 47-4. Expanded Clinical Evaluation

SYMPTOMS ELICITED IN HISTORY
Constitutional—weight loss >10 lb
Musculoskeletal—focal skeletal pain
Neurologic—headaches, syncope, seizures, extremity weakness, recent change in mental status
SIGNS FOUND ON PHYSICAL EXAMINATION
Lymphadenopathy (>1 cm)
Hoarseness, superior vena cava syndrome
Bone tenderness
Hepatomegaly (>13-cm span)
Focal neurologic signs, papilledema
Soft tissue mass
ROUTINE LABORATORY TESTS
Hematocrit <40% in males
Hematocrit <35% in females
Elevated alkaline phosphatase, GGT, AST, calcium

AST, aspartate aminotransferase; GGT, gamma-glutamyl transpeptidase.

around 50% of cases. Conversely, in the absence of all clinical abnormalities, the scan yield is much lower, giving rise to the recommendation that scans be omitted in this setting.[28,37] Advanced thoracic lesions and mediastinal lymphadenopathy are important variables because more scan abnormalities are associated with advanced thoracic lesions.[37,41] This is particularly true for N2 disease, in which asymptomatic metastases have been documented at a higher rate than would have been expected.[41] Although several studies have documented a higher incidence of brain metastases in patients with adenocarcinomas than in those with squamous cell cancers,[42,43] the largest single series of patients with stage I and II lung cancer found no difference.[44]

Several important caveats must be considered in the search for metastatic disease. First and foremost, there is the problem of false-positive scans. Adrenal adenomas (present in 2%–9% of the general population), hepatic cysts, degenerative joint disease, old fractures, and a variety of nonmetastatic space-occupying brain lesions are present in the general population. When clinically indicated, additional imaging studies, biopsies, or both are performed to establish the diagnosis; however, complications and costs resulting from such subsequent investigations have received little attention.[45] There is also the problem of false-negative scans, scans that fail to detect actual metastases. For example, in a CT study of the adrenal glands, Pagani[46] found metastatic NSCLC by percutaneous biopsy in 12% of radiologically normal adrenal glands. An additional problem is that the studies in this area often fail to specify exactly which elements make up the prescan clinical evaluation or they use differing clinical indicators. For example, organ-specific findings such as headache and non–organ-specific complaints such as weight loss are both important.[47,48] In addition, in many studies, abnormal findings on scans have not been pursued with biopsies to prove metastatic disease. Finally, there are few prospective randomized trials and outcome studies to guide appropriate use and interpretation of extrathoracic scanning. One retrospective study showed that scanning asymptomatic patients with early NSCLC did not help predict recurrences postoperatively or improve survival.[49] The only prospective randomized trial showed no statistical difference in recurrence rates or survival in a group randomized to bone scintigraphy and CT of the head, liver, and adrenals, compared with the group assigned to CT of the chest and mediastinoscopy, followed by thoracotomy when appropriate.[50] It is hoped that careful studies in this area will improve the workup of patients with lung cancer.

Adrenal and Hepatic Imaging

It is relatively common to encounter adrenal masses on routine CT scan, but many of these lesions are probably unrelated to the malignant process. A unilateral adrenal mass in a patient with NSCLC is more likely to be a metastasis than a benign lesion according to some[51,52] but not other[53,54] studies. In the presence of clinical T1N0 NSCLC, adenomas predominate,[55,56] whereas adrenal metastases are frequently associated with large intrathoracic tumors or other extrathoracic metastases.[52,57] Many studies suggest that the size of a unilateral adrenal abnormality on CT is an important predictor of metastatic spread, but this is not a universal finding.[58] Lesions larger than 3 cm are more likely to signify metastases, but benign disease is still possible.

For adrenal masses, CT, MRI, percutaneous biopsy, and even adrenalectomy can be used to help delineate benign from malignant disease. Well-defined, low-attenuation (fatty) lesions with a smooth rim on unenhanced CT are more likely to be benign adenomas,[59–61] but the CT appearance of many lesions is insufficiently distinctive.[61] Follow-up scanning with repeat CT, serial ultrasonography, MRI (especially with chemical shift and dynamic gadolinium-enhanced techniques[62]), or 6-β-iodo-^{131}I-methyl-norcholesterol scanning[63] can sometimes help with the critical distinction between metastatic disease and adenoma. Percutaneous adrenal biopsy is a relatively safe and effective means of achieving a definitive diagnosis in doubtful cases and is especially important when the histology of the adrenal mass will dictate subsequent management.[64,65] However, this procedure may be nondiagnostic or infeasible due to anatomic constraints. When insufficient material results from a biopsy, repeat aspiration or even adrenalectomy should be considered.[58,61]

Most liver lesions are benign cysts and hemangiomas, but contrast CT (or ultrasound) is often required to establish a likely diagnosis.[29] Percutaneous biopsy can be performed when diagnostic certainty is required. One meta-analysis that specifically reviewed hepatic studies derived a pooled yield of 3% for liver metastases in asymptomatic patients with NSCLC.[45]

Brain Imaging

In most studies, the yield of CT/MRI scanning of the brain in NSCLC patients with negative clinical examinations is 0% to 10%,[37,66–71] possibly rendering the test cost-ineffective.[72] The negative predictive value of the clinical evaluation in this setting is 95% (range, 91%–96%).

An association of positive findings between brain metastases and N2 disease in the chest and adenocarcinoma has been described.[42,68,70] The false-negative rate, wherein patients return with brain metastases within 12 months of the original scan, is reported to be 3%.[70] False-positive scans can be a problem in up to 11% of cases due to brain abscesses, gliomas, and other lesions[73]; therefore, biopsy may be essential in cases in which management is critically dependent on the histology of the brain lesion.

MRI is more sensitive than CT of the brain and picks up more lesions and smaller lesions,[74] but in some studies, this has not translated into a clinically meaningful difference in terms of survival.[75] Although studies show that MRI can identify additional lesions in individual patients with metastases, there are no studies that show that MRI is better than CT in its ability to identify additional patients with metastases from lung cancer. Therefore, CT is an acceptable modality for evaluating

patients for metastatic disease. However, MRI remains the preferential modality at many centers.

Bone Imaging

False-positive scan abnormalities in radionuclide bone scintigraphy are common concerns because of the frequency of degenerative and traumatic skeletal damage and the difficulty in obtaining a definitive diagnosis via follow-up imaging or biopsy. The negative predictive value in this setting is 90% for radionuclide bone imaging with a negative clinical assessment. PET has a higher specificity for bony metastases.[28]

Summary

The noninvasive clinical staging of lung cancer relies on the clinical evaluation and a number of readily available staging studies. The clinician must be wary of abnormal scans that may falsely suggest metastatic disease to the mediastinum and distant sites. Tissue confirmation by whatever means necessary is the rule rather than the exception prior to deciding on correct stage and the most appropriate treatment. The search for metastatic disease is not necessary if the patient has a normal clinical evaluation. If the patient has clinical findings indicative of metastatic disease, further evaluation is necessary because nearly 50% of the time the patient will have metastases.[28]

INVASIVE DIAGNOSTIC AND STAGING TECHNIQUES

There are a myriad of methods that can be utilized to diagnose and stage patients with lung cancer. In certain circumstances, this is accomplished with a single test. For example, a positive percutaneous biopsy of the adrenal gland performed as a first test in a patient with a lung mass will provide both a diagnosis and a stage (stage IV) simultaneously. Every effort should be made to utilize the least invasive, most accurate procedure to expedite the patient's treatment, to minimize patient discomfort and inconvenience, and to ensure that the most appropriate treatment is rendered.

Sputum Cytology

Sputum cytology is the least invasive method for obtaining a diagnosis of lung cancer. Its accuracy depends on the expertise of the health care team in obtaining the sample (three samples are required), the preservation technique, and the size and location of the lesion. Central lesions are more likely to yield positive cytologic results than are peripheral lesions.[76] Sputum cytology should be obtained in all patients with central lesions who are at risk for more invasive biopsy techniques. In addition, patients with hemoptysis with or without a mass on chest radiographs should have sputum cytology obtained. The sensitivity and specificity of sputum cytology are 66% and 99%, respectively.[76]

Transthoracic Needle Aspiration

Transthoracic needle aspiration (TTNA), usually under CT or fluoroscopic guidance, is an expedient and relatively safe way to diagnose the primary tumor mass and establish a diagnosis of lung cancer. As a general rule, if a lesion is less than 3 cm in size and lateral to the midclavicular line, bronchoscopy would not be the diagnostic procedure of choice. TTNA should be considered under such circumstances if tissue diagnosis is necessary. One important point about TTNA or other nonsurgical biopsy techniques for peripheral pulmonary lesions is that they afford no preoperative benefit because they do not eliminate the need for surgery in most cases.[77] In the circumstance of a patient presenting with a solitary pulmonary nodule suspicious for malignancy (e.g., noncalcified, upper lobe, spiculated lesion in a long-term smoker), the diagnosis, stage, and therapy can be accomplished simultaneously with a thoracotomy and surgical resection. Thus, TTNA may be essential only in certain situations: patients who are poor surgical candidates but who require tissue diagnosis prior to treatment, patients in whom a noncancerous lesion is strongly suspected, patients who request that a diagnosis of cancer be confirmed prior to considering surgery, and patients with high likelihood of metastatic disease. The sensitivity and specificity of TTNA are 90% and 97%, respectively.[76]

One drawback of TTNA is the risk of pneumothorax. Several investigations have reported a 22% to 45% risk of pneumothorax for CT-guided TTNA.[78–80] Although pneumothorax may lead to hemodynamic compromise without therapeutic tube thoracostomy, in most cases of pneumothorax secondary to TTNA, treatment is not required.[81] The primary factors shown to increase the risk or incidence of pneumothorax are the presence of emphysema, a smaller lesion size, and a greater depth of needle penetration from the pleural surface to the edge of the lesion.

Fiberoptic Bronchoscopy

More than 50% of patients with advanced-stage lung cancer will have involvement of the central airways either by bulky endobronchial disease, extension into the airways, or extrinsic compression of the airways by the tumor or by lymphadenopathy.[82] Patients with known or suspected lung cancer may have symptoms due to endobronchial involvement that require airway inspection with bronchoscopy: shortness of breath, unilateral wheezing, hemoptysis, and cough. Endobronchial lesions can be visualized easily and biopsied through a flexible bronchoscope. The yield with three or more biopsies should approach 100% for centrally located lesions.[83,84] Data from 4507 patients revealed that central endobronchial biopsies provide the highest sensitivity (74%), followed by brushings brushing (61%) and washings (47%).[76] The combination provides a diagnosis in 88% of cases.[76] Studies on the sensitivity of needle aspiration of centrally located endobronchial lesions are difficult to interpret. These studies have varied dramatically in terms of sample size and technique used. Because

endobronchial biopsies or brushings provide a diagnosis in most cases, endobronchial needle aspiration is rarely performed. However, the diagnosis is likely to be made in a bit more than half the cases using needle aspiration.[76]

Submucosal and Peribronchial Lesions

When lung cancer presents with submucosal infiltration or extrinsic compression from peribronchial disease, endobronchial forceps biopsy has a lower yield (55%) than transbronchial needle aspiration (TBNA) (71%).[85] In these situations, normal mucosal markings are often obscured and the surface is replaced with bronchial collateral vessels and firmer surface tissue, which may have to be penetrated to reach malignant cells. In addition, peribronchial tumor may be inaccessible to biopsy forceps. TBNA can be more effective if the lesion is close enough to the tracheobronchial tree to be encountered with a 1.3- to 1.5-cm-long needle. Of note, in cases like this in which sampling error may be high, diagnostic yields may be improved by combining different methods.

Bronchoscopy for Staging Lung Cancer

Initially, the role of bronchoscopy in staging lung cancer was limited to the determination of T (tumor) status. Now, bronchoscopy has a crucial role in determining the presence of metastatic deposits of tumor in mediastinal lymph nodes, thus contributing to an accurate and a minimally invasive staging method for lung cancer.

The use of TBNA in staging lung cancer has been reported to be both sensitive and specific in diagnosing spread of cancer to lymph nodes.[86–88] The overall sensitivity of TBNA for NSCLC is 78%, and the specificity is 99%.[89] The standard method of performing TBNA starts with a CT scan of the chest to guide needle aspirations toward the most involved group of lymph nodes. Lesions localized by a CT scan can be accessed with bronchoscopy by measuring the number of CT slices above or below the carina (or other airway landmarks) and placing the needle the required distance above or below the landmark corresponding to that number of CT slices. When performing TBNA, the question invariably arises about the number of negative passes to perform before stopping. For various reasons, such as patient comfort and safety, need for sedation, and time spent by medical staff, it is imperative to manage the time for bronchoscopy. It has been shown that a plateau in yield for malignancy is achieved after seven passes with the needle through a lymph node.[90] The importance of having a qualified and experienced cytopathologist on site cannot be overemphasized. Thorough interpretation by such individuals who are available for rapid on-site evaluation has been shown to enhance yield from TBNA.[91] With the assistance of these individuals, the adequacy of sampling can be rigorously assessed. All samples should contain a preponderance of lymphocytes to define true nodal sampling. Specimens without lymphocytes should be deemed unsatisfactory, and the presence of respiratory epithelium should raise concerns about contamination.

TBNA allows for minimally invasive sampling of the mediastinum and hilar lymph nodes and potentially avoids more invasive procedures such as mediastinoscopy, mediastinotomy, and open thoracotomy. There is no doubt that the combined use of TBNA and CT scan can improve not only the diagnostic but also the staging evaluation of lung cancer. However, thus far, there has been wide variability in training and in usage of this helpful procedure. It is also operator-dependent, with certain techniques allowing for higher yields. For an in-depth discussion of bronchoscopy, see Chapter 22.

Endoscopic Ultrasound

Endoscopic ultrasound (EUS) is another modality that has significantly impacted lung cancer staging, primarily due to its superior ability to sample the posterior mediastinum through the esophageal wall. Currently, EUS with fine-needle aspiration is performed using real-time ultrasound. In pooled analysis of more than 1000 patients with lung cancer and mediastinal adenopathy, EUS has a sensitivity and specificity of 84% and 99.5%, respectively.[89] In patients with lung cancer who have no adenopathy seen on CT scan, EUS has been shown to sample nodes as small as 3 mm in diameter. This is useful given the high incidence of metastasis found in normal-sized lymph nodes in lung cancer.[92] Based on surgical studies, it may be possible to predict the location of mediastinal lymph node metastases at certain levels based on the location of the tumor. This relationship may influence the use of EUS in certain patients without adenopathy on chest CT scan. Lymphatic pathways favor spread to aortopulmonary window nodes from left upper lobe tumors and to subcarinal nodes from left and right lower lobe lesions.[93] EUS has been studied in patients with known lung cancer without enlarged mediastinal lymph nodes on CT, and it has detected mediastinal involvement (stage III or IV disease) in up to 42% of cases.[94]

In addition, EUS has the advantage of being able to stage lung cancer from locations outside the mediastinum. The left lobe of the liver, a substantial part of the right lobe of the liver, and the left (but not the right) adrenal gland can be identified and sampled in 97% of patients.[95] In addition, left pleural effusions can be visualized and sampled during an EUS procedure. EUS is increasingly being combined with endobronchial ultrasound (EBUS) for minimally invasive staging of lung cancer (see below).

Endobronchial Ultrasound

Perhaps the greatest addition in the armamentarium for staging lung cancer is endobronchial ultrasound with fine-needle aspiration (EBUS-TBNA). EBUS-TBNA is indicated for the assessment of mediastinal and hilar lymph nodes and diagnosis of lung and mediastinal tumors. It can be used to sample the highest mediastinal (station 1), the upper paratracheal (station 2R, 2L), the lower paratracheal (station 4R, 4L), the subcarinal (station 7), as well as the hilar (station 10), and the interlobar (station 11) lymph nodes (Fig. 47-1A). The para-aortic (station

6), aortopulmonary window or subaortic (station 5), paraesophageal (station 8), and pulmonary ligament (station 9) lymph node stations are usually not accessible by this technique (see Fig. 47-1B). Pooled analysis of nearly 1000 patients shows that EBUS-TBNA has a sensitivity and specificity of 90% and 100%, respectively.[89] Should a patient present with a lung mass and mediastinal lymphadenopathy in the lymph node stations described earlier, EBUS-TBNA should be considered as a test of first choice because this modality can provide a diagnosis and stage simultaneously. The combination of EUS and EBUS has shown better yield than either technique alone and may provide near-complete access to the mediastinum for staging,[95a] even in the radiologically normal mediastinum.[95b] For a further discussion of EBUS, see Chapter 20.

Mediastinoscopy

Mediastinoscopy remains the gold standard for invasively staging the mediastinum in patients with known or suspected lung cancer. If there is mediastinal adenopathy on CT, often a surgical mediastinal procedure is performed prior to thoracotomy. Mediastinoscopy is most often used to sample nodes of the paratracheal (station 4), and anterior subcarinal (station 7) region (see Fig. 47-1A). The subcarinal area is more difficult to sample and thus has a lower yield. An extended cervical mediastinoscopy can be carried out to reach aortopulmonary and para-aortic lymph nodes (stations 5 and 6) by using the same cervical incision as mediastinoscopy but dissecting into a different fascial plane. Alternatively, an anterior mediastinotomy (the so-called Chamberlain procedure) may be needed to sample lymph nodes in these aortopulmonary and para-aortic locations (stations 5 and 6) (see Fig. 47-1B). Overall, mediastinoscopy has a reported sensitivity of 78%, with a specificity of 100%.[89] Mediastinoscopy may also be able to differentiate between stage IIIA and IIIB mediastinal involvement. As more is learned about lung cancer treatment, this will be important for prognosis and for potential therapy. As with any surgical procedure, mediastinoscopy has risks and limitations. It requires general anesthesia, with a morbidity of 2% and a mortality of 0.08%.[89]

TREATMENT OF LUNG CANCER

The overall 5-year survival for patients diagnosed with lung cancer is a dismal 14%.[96] This figure has not changed

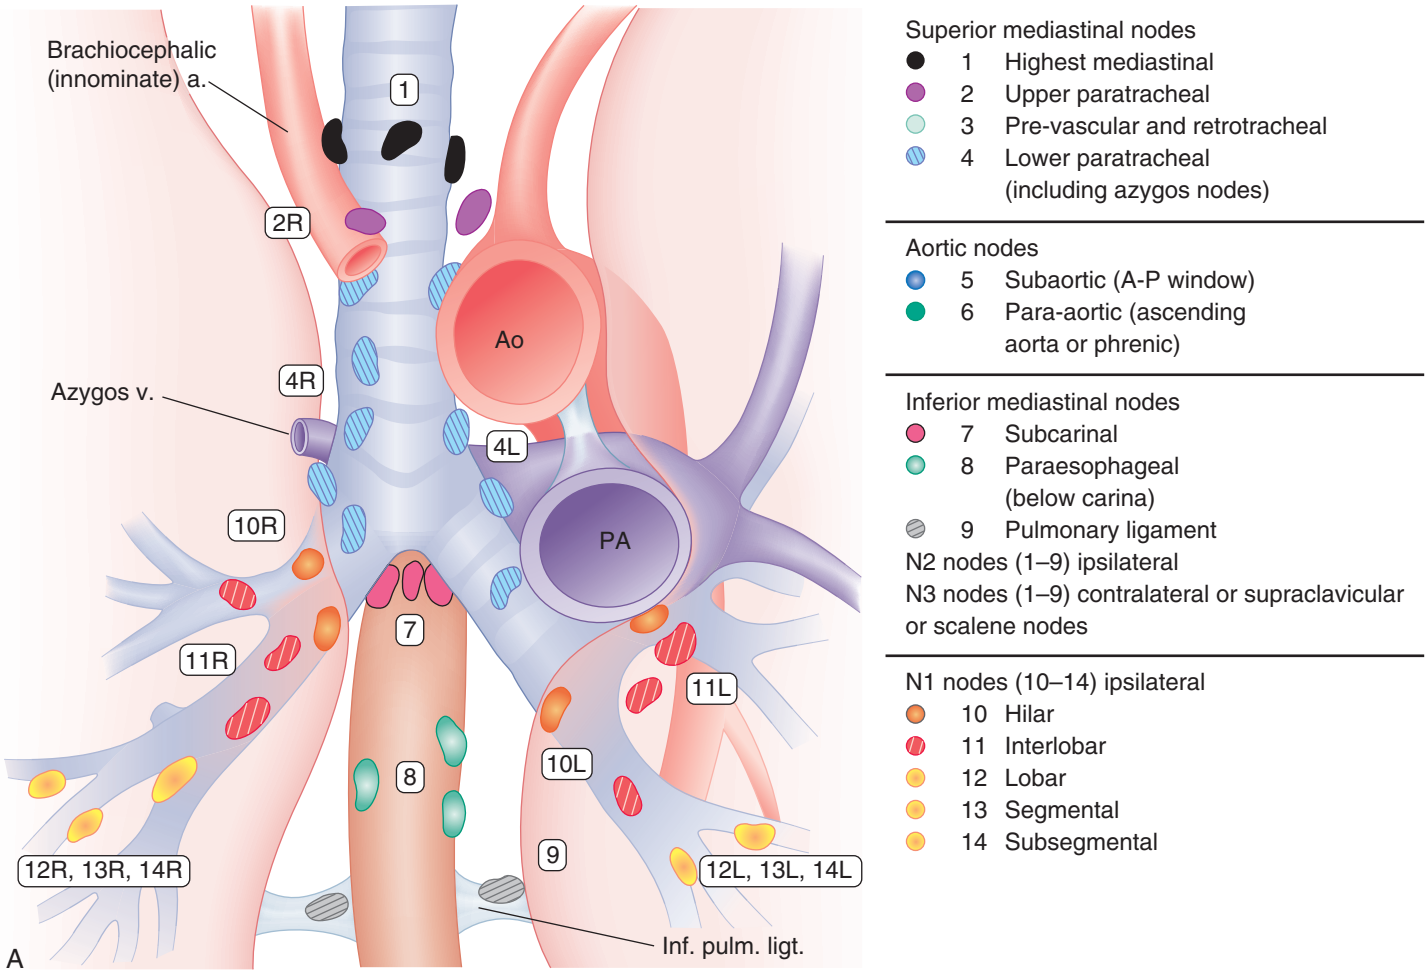

FIGURE 47-1 ■ (A and B) Mediastinal lymph node maps. a, artery; Ao, aorta; A-P, aortic-pulmonary; PA, pulmonary artery; v, vein. (Redrawn from Mountain CR, Dresler CM: Regional lymph node classification for lung cancer staging. Chest 111:1719, 1997.)

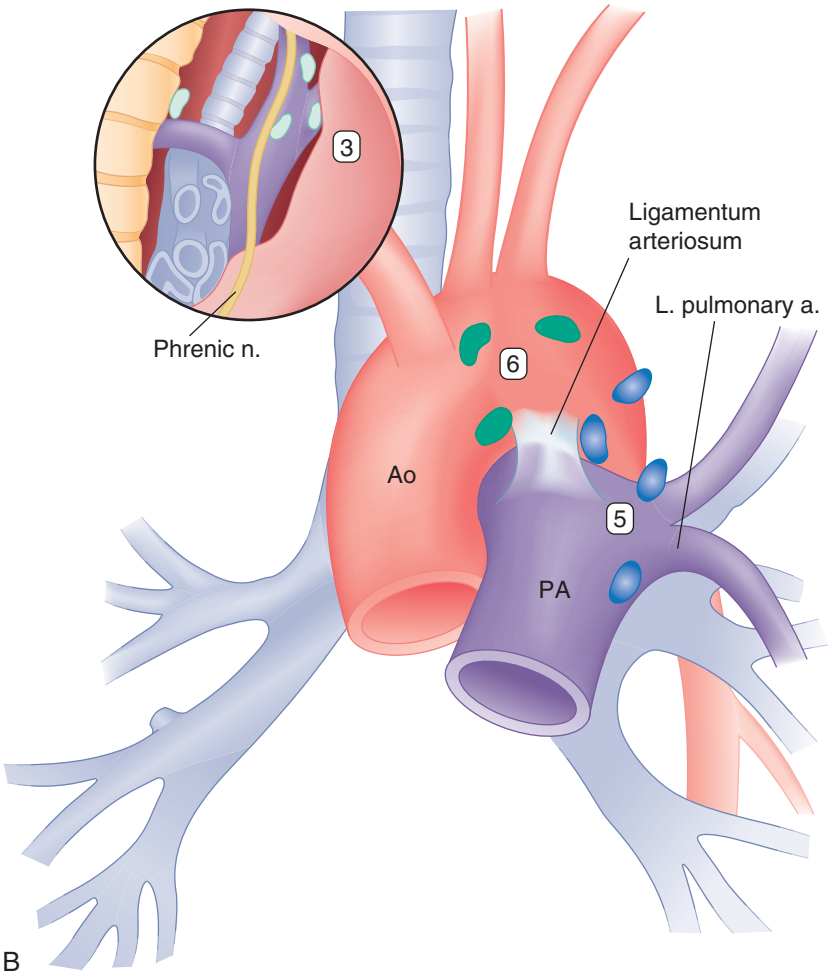

Superior mediastinal nodes
- 1 Highest mediastinal

substantially since the 1980s. The survival curves vary by stage, with earlier-stage lung cancer patients enjoying a much better survival than do patients with later-stage disease. Treatment is based on the stage of the disease and the patients' performance status at the time therapy is initiated. In general, early-stage disease is surgically managed, locally advanced disease is managed with chemotherapy and radiotherapy, and advanced disease is managed with chemotherapy with supportive care or supportive care alone. This paradigm has begun to shift toward multimodality therapy (surgery, chemotherapy, and radiotherapy).[97-100] This raises the issue of how best to manage patients with newly diagnosed lung cancer through their diagnosis, staging, and therapy. The ACCP guidelines on lung cancer recommend the use of a multidisciplinary lung cancer setting wherein patients can be evaluated by the major disciplines involved in the care of these patients, namely the pulmonologist, the thoracic surgeon, and the medical and radiation oncologists.[101] At the very least, a "tumor board" that includes the aforementioned specialties, with the addition of chest radiology, pathology, nursing, and social work, should review all new cases to ensure that patients receive optimal treatment and are considered for enrollment in clinical trials.

Prognostic Factors for Lung Cancer

Based on an analysis of large databases in inoperable lung cancer patients, the strongest predictors of survival are good performance score (Karnofsky scale), lower extent of disease (stage), age, and absence of weight loss.[102-104] Some reports have shown female gender to be a predictor of better survival, but this varies between studies. Performance score and the presence or absence of symptoms are predictors of outcome even with resectable early-stage disease.[105-107] For example, in stage I NSCLC patients undergoing curative resection, those who were symptomatic at presentation had a worse survival than those who were asymptomatic.[106] Although individual reports have noted superior survival for patients with one cell type of NSCLC versus another, the general consensus in the literature is that histologic subtypes of NSCLC are not a major predictor of survival.[105,106,108] Absence of smoking or smoking cessation has been associated with improved survival. The maximal standard uptake value of the primary tumor on PET scanning has been inversely correlated with survival.[109]

In more recent years, there have been numerous reports that various molecular markers are associated with outcome. Some of the best known markers include

K-Ras, epithelial growth factor receptor (EFGR), p53, p16, and Bcl-2. However, in many instances, the results are conflicting about the prognostic significance of these individual molecular markers,[110–112] perhaps due to the types of cases under review and to individual laboratory variations in techniques for measuring these molecular markers. In a meta-analysis, K-Ras mutations were associated with poorer survival, especially in adenocarcinoma where the hazard ratio was 1.59 (95% CI 1.26–2.02).[113] Whereas testing the genetic profile of resected tumors is not yet standard practice, this is likely to change rapidly; indeed, the testing of K-Ras and EGFR mutations is already standard in some centers (see Chapter 45).

Non–Small Cell Lung Cancer Treatment by Stage

This section presents a discussion of the treatment of NSCLC by stage and cell type, followed by a discussion of the treatment of small cell lung cancer (SCLC). Table 47-5 presents an overview of treatment strategies for NSCLC based on stage.

Stage I

In the new staging system for NSCLC, stage I NSCLC is broken down into stage IA (tumors ≤ 2 cm [T1a] and tumors between 2 and 3 cm [T1b]) and stage IB (tumors between 3 and 5 cm [T2a]). All stage I tumors are completely surrounded by lung parenchyma in the parenchyma, greater than 2 cm away from the carina and not invading the chest wall or parietal pleura (Fig. 47-2). Stage I lung cancer does not include patients who have malignant lymph node disease or patients with metastatic disease. Thus, the TNM classification is either T1aN0M0, T1bN0M0 (stage IA) or T2aN0M0 (stage IB). The differences between the two are the size of the primary tumor and the survival after surgical resection. Although stage I disease offers the best chance for long-term survival, the sad fact is that only 15% of all lung cancers present with stage I disease.[114,115]

The current treatment for stage I lung cancer is surgery alone. The surgical procedure of choice is a lobectomy or pneumonectomy with mediastinal lymph node sampling. It should be recognized that the patient must be a reasonable surgical candidate. The 5-year survival for surgically resected stage IA lung cancer is 73%, whereas the survival for stage IB lung cancer is 58%.[25] Local postoperative radiation for stage I and II lung cancer, after either complete or incomplete resection of the tumor, has not been found to be of any benefit.[114] Postoperative adjuvant chemotherapy has not been shown to improve survival for those with resected stage I disease.[116] A further discussion of postoperative adjuvant therapy is presented later (see "Stage IIIA").

Some patients are surgically resectable but medically inoperable, usually because the patient does not have the pulmonary reserve to tolerate a lobectomy. These patients, particularly those with T1 tumors, may be able to tolerate a wedge resection or segmentectomy of their tumor as opposed to a lobectomy or pneumonectomy. In such cases, the local recurrence rate is higher than that of a complete resection, but the overall 5-year mortality is no different.[117] Still, whenever possible, a complete anatomic resection is preferred over a minimal resection. For discussion of radiofrequency ablation and other non-surgical treatments, see Chapters 22 and 49.

Patients who are "close calls" for surgery should be thoroughly evaluated by both a pulmonologist and a

TABLE 47-5. Summary of Current Treatment Strategies for Non–Small Cell Lung Cancer

Stage	Surgery	Chemotherapy	Combined Radiotherapy	Chemoradiotherapy	Comments
I and II	1st line	Adjuvant—stage IIA, IIB	2nd line	No	Survival improvement with adjuvant therapy (= 5%) Radiotherapy for inoperable patients
IIB (T3N0M0) Pancoast	1st line	No	No	1st line—neoadjuvant	Neoadjuvant chemoradiotherapy improves survival in this subset of stage IIB
IIIA	1st line	Adjuvant treatment—in totally resected IIIA	Controversial	1st line	Combined chemoradiotherapy followed by surgery is feasible, but more data are needed to recommend routinely
IIIB (T4N0-1M0) Resectable	1st line	No	No	± Neoadjuvant—1st line	Neoadjuvant chemoradiotherapy followed by surgery may be considered in carefully selected patients
IIIB Unresectable	No	No	No	1st line	Treatment similar to unresectable stage IIIA
IV	No	1st line	No	No	Radiotherapy is used for palliation only

Bevacizumab is approved as an adjunct to chemotherapy in the first-line setting in patients with nonsquamous histology and no other contraindications.
The EGFR inhibitors are indicated as frontline treatment for those with advanced NSCLC and documented EGFR mutations but, as of this printing, are FDA-approved only as second and third line therapy.
EGFR, epidermal growth factor receptor; FDA, U.S. Food and Drug Administration; NSCLC, non-small cell lung cancer.

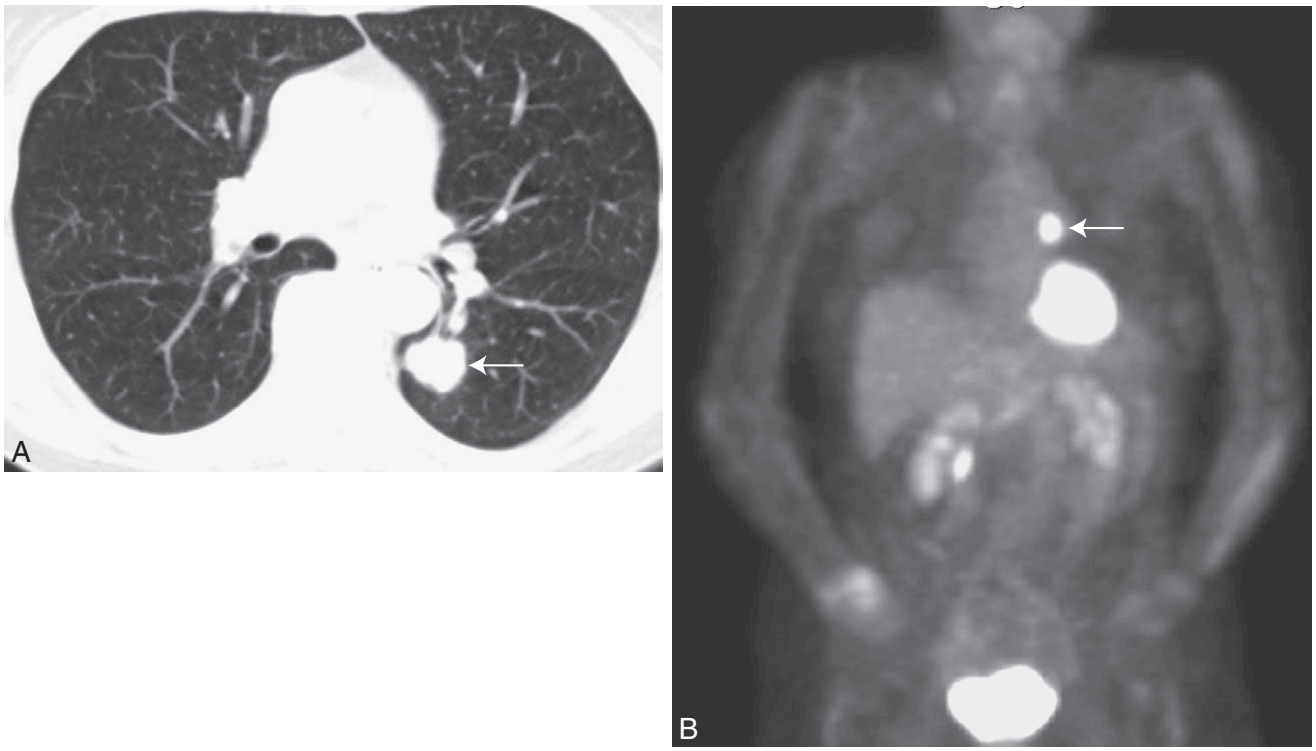

FIGURE 47-2 ■ Computed tomography (CT; **A**) and positron emission tomography (PET; **B**) scans of a patient with T1N0M0 tumor (*arrows*).

thoracic surgeon prior to making a decision on operability. As previously stated, there is a difference between a patient who is resectable and a patient who is operable. Chapter 26 is devoted to the preoperative evaluation of patients with lung disease, but a brief review is warranted here. Patients with a postoperative percent predicted forced expiratory volume in 1 second (FEV_1) or diffusion capacity less than 40% will have a higher morbidity and mortality following lung cancer surgery. Patients with borderline values preoperatively should be referred for a differential ventilation-perfusion scan for a better prediction of postoperative function. Where there is still a question, a cardiopulmonary exercise test can be obtained. Compared with those with an oxygen consumption of greater than 20 mL/kg/min, patients with an oxygen consumption between 11 and 19 mL/kg/min have a higher morbidity but no greater mortality and those with an oxygen consumption less than 10 mL/kg/min have both a higher predicted morbidity and mortality.[118]

For patients who either refuse surgery or are deemed medically unfit for surgery, primary radiotherapy for cure can be considered. This approach was evaluated in a meta-analysis of 1 randomized and 35 nonrandomized trials.[119] The studies were heterogeneous, and the 5-year cancer-specific survival ranged between 13% and 39%. The authors concluded that, even in patients with severe emphysema, radiation therapy can be tolerated if careful planning with three-dimensional conformal techniques is undertaken to minimize the radiation dose to the remaining noncancerous lung. We would recommend referral to a radiotherapist for patients who are medically inoperable for consideration of "curative" radiation therapy.

Stage II

In the new staging system, stage II NSCLC lung cancer remains divided into stage IIA and stage IIB. Stage IIA is defined as a T1aN1M0, T1bN1M0, or T2aN1M0 disease and stage IIB includes T2bN1M0 and T3N0M0. The 5-year survivals for stage IIA and IIB are 46% and 36%, respectively.

Stage IIA lung cancer is quite uncommon, representing between 1% and 5% of patients treated in several surgical series.[120–125] Stage IIB cancer may represent up to 15% of surgically resected cases.[116,120,122,125] For stage IIA and IIB cancer, surgical therapy is the treatment of choice. There is no benefit to postoperative radiotherapy. The value of adjuvant chemotherapy after surgery is discussed later (see "Stage IIIA") but, in short, adjuvant chemotherapy is recommended for all patients with resected stage II disease. With chest wall invasion (T3N0M0), an en bloc resection of the tumor and chest wall is the treatment of choice. A specific discussion of the evaluation and treatment of Pancoast's tumor is discussed later in the chapter.

The outcome of lung cancer surgery is improved when the surgery is performed at hospitals with a higher volume of procedures.[121] It is also important that the surgery be performed by a thoracic surgeon; when lobectomy is performed by a thoracic surgeon compared to a general surgeon, mortality is nearly halved.[126]

Stage IIIA

Stage IIIA NSCLC represents a heterogeneous group of patients with N2 disease and includes T3N1 patients (Fig. 47-3). In addition, within the new staging system, patients with T4N0-1 have been downstaged to IIIA from their previous classification.[25]

For carefully selected T4N0-1M0 patients, surgery may be indicated with or without neoadjuvant chemotherapy or neoadjuvant chemoradiotherapy (superior sulcus tumors). Individuals with T4N0-1 disease due to main carinal involvement have been treated with carinal resection with or without pulmonary resection. Carinal resection carries an operative mortality of 10% to 15% and 5-year survival of approximately 20% in carefully selected series. Patients who are T4N0 due solely to tumor nodules within the ipsilateral nonprimary lobe have a 5-year survival of around 20% with surgery alone.[127]

There is substantial debate over what constitutes resectable IIIA (N2) disease. All agree that T3N1 patients are best treated with surgical resection. At surgery, when a complete resection of the lymph nodes and the primary tumor is possible, some patients are found to have occult N2 metastasis. If so, these patients are best served by resecting all known disease. It is more unclear how best to treat patients when N2 (single or multiple station) metastases are documented prior to thoracotomy. Two small randomized prospective trials have compared surgery alone with preoperative (neoadjuvant) chemotherapy followed by surgery.[98,100] Both trials observed superior survival in those who received preoperative

chemotherapy. Investigators have reported the preliminary results of a prospective trial that randomized patients with IIIA (N2) disease to chemoradiotherapy alone versus chemoradiotherapy followed by surgery.[128] There was no difference in the median survival time (23.6 vs. 22.2 mo) or the 5-year survival (27% vs. 20%, respectively; $P = 0.24$). However, the final manuscript on this study has yet to be published. A compilation of several other randomized trials of neoadjuvant chemotherapy followed by surgery versus chemoradiotherapy have found similar results. In the second iteration of the ACCP evidence-based guidelines, a review of all relevant studies on neoadjuvant therapy in stage IIIA lung cancer concluded that there was no benefit to a neoadjuvant chemotherapy/surgical approach. Their final recommendation is that in patients with NSCLC with N2 disease identified preoperatively (IIIA), induction therapy followed by surgery is not recommended except as part of a clinical trial.[129] In summary, the evidence for treatment of stage IIIA disease does not currently support the use of neoadjuvant chemotherapy followed by surgery. The standard of care for patients with stage IIIA lung cancer is combined chemoradiotherapy.

Postoperative (adjuvant) treatment of resected stage IIIA NSCLC is now recommended. The International Adjuvant Lung Trial randomized patients with completely resected stage I, II, and IIIA NSCLC to observation or to three or four cycles of adjuvant cisplatin-based chemotherapy.[130] Approximately 39% of all patients in the trial had stage IIIA disease. Overall, there was an absolute 4% improvement in 5-year survival (44% vs. 40%) in participants receiving adjuvant chemotherapy. National Cancer Institute (NCI) Canada investigators demonstrated a 15% improvement in 5-year survival (69% vs. 54%) with four cycles of vinorelbine and cisplatin adjuvant chemotherapy in patients with resected stage IB and II NSCLC.[131] Similarly, French investigators in the Adjuvant Navelbine International Trialist Association (ANITA) study observed an 8.6% survival advantage with adjuvant therapy in resected stage IB-IIIA NSCLC.[132] A recent pooled analysis (Lung Adjuvant Cisplatin Evaluation [LACE]) of adjuvant chemotherapy trials concluded that adjuvant cisplatin-based chemotherapy resulted in a reduction in the hazard ratio of death of 0.89 and a corresponding 5-year survival benefit of 5.4%.[133] This survival benefit was observed in stage II and IIIA but not in patients with stage IB disease.[133] Adjuvant chemotherapy in completely resected stage II and IIIA NSCLC is now the standard of care. Although adjuvant radiotherapy in the fully resected stage IIIA NSCLC patient has not been shown to improve survival, radiotherapy has been shown to reduce local recurrences and should be considered in selected patients.[128] Several nonrandomized trials have suggested that adjuvant radiotherapy may benefit patients with resected N2 disease; currently, prospective studies are trying to answer this question.[134]

Those individuals with bulky (>2 cm in diameter) or multistation N2 nodal metastasis make up a less favorable subset of stage IIIA disease and are not generally considered to be operable. In the past, these patients were treated with thoracic radiotherapy alone, but their 5-year survival was only 3% to 5%. A multitude of trials have evaluated combination chemotherapy and thoracic radiotherapy versus thoracic radiotherapy alone. Three meta-analyses of these trials have all concluded that cisplatin-based chemotherapy combined with radiotherapy results in survival benefit over radiotherapy alone.[135–137] Anticipated 5-year survival with combined-modality therapy is 15% to 20%. Two multicenter trials have concluded that concurrent chemoradiotherapy is superior to sequential therapy with chemotherapy followed by thoracic radiotherapy.[138,139] Concurrent therapy is recommended for those individuals with good performance scores (0 or 1) and less than 10% weight loss. Concurrent therapy is associated with a higher rate of severe esophagitis than is sequential therapy.

Stage IIIB

Stage IIIB is also a heterogeneous group and includes T4N2M0 and any T N3M0 patients. There are no phase III randomized trials to date that demonstrate that neoadjuvant chemoradiotherapy followed by surgery for stage IIIB disease results in prolonged survival compared with chemoradiotherapy alone.[140]

Patients with unresectable stage IIIB NSCLC are treated the same as those with unresectable IIIA disease. The median survival time is generally 15 to 18 months, with a 5-year survival of 10% to 20%. The randomized trials of chemoradiotherapy versus radiotherapy alone included both stage IIIA and IIIB disease participants. Combination chemotherapy with a cisplatin-based regimen and thoracic radiotherapy results in better survival than radiotherapy alone.[135–137] Trials have evaluated multiple daily fractions of thoracic radiotherapy, but there are no convincing data that hyperfractionated thoracic radiotherapy (the same total dose of radiation therapy split into two treatments in the same day) is superior to standard once-daily treatment. For stage IIIA or IIIB patients with a performance score of 0 or 1 and minimal weight loss, concurrent chemoradiotherapy is recommended.[140] Concurrent therapy appears to be associated with improved survival versus sequential therapy.[138,139]

Stage IV

Malignant pleural or pericardial effusions are now classified as stage IV disease. There are virtually no 5-year survivors with stage IV NSCLC. The goal of therapy is to try to control the disease and palliate symptoms. Major response rates with current chemotherapy regimens are 10% to 30%. Patients who respond to chemotherapy may gain an additional 3 to 9 months of life on average but eventually relapse and die of their disease. In previous trials in the 1970s and 1980s, patients were randomized to best supportive care or systemic chemotherapy. A meta-analysis evaluated eight of these randomized trials, including over 700 patients.[135] Each of these trials used a cisplatin-based chemotherapy versus supportive care. With best supportive care, the median survival time was 4 months and the 1-year survival was 15%; with chemo-

therapy, there was an increase in the median survival of 1.5 months and an increase in 1-year survival of 10%. In the 1990s, a number of new chemotherapy agents were introduced, including paclitaxel, docetaxel, irinotecan, vinorelbine, and gemcitabine. Phase III trials have incorporated these newer agents in combination with cisplatin or carboplatin.[141]

Trials comparing single-agent chemotherapy to a chemotherapy doublet containing a platinum compound have shown that the chemotherapy doublet is superior. Treatment with three drugs has not been shown to be superior to that with two drugs. Large randomized trials have tried to identify the optimum chemotherapy doublet.[142–144] The results were uniformly similar, with response rates of 20% to 30% and median survival times of 7 to 9 months. No one platinum doublet has been shown to be superior. The chemotherapy combinations did have different toxicity profiles.

Since the 1990s, there has been increasing interest in novel targeted therapies for lung cancer. Two main targets of interest are the vascular endothelial growth factor (VEGF) receptor and the EGFR. Bevacizumab is a monoclonal antibody against VEGR. Sandler and coworkers[145] conducted a randomized trial with paclitaxel and carboplatin with or without bevacizumab. The novel agent resulted in superior survival with a median survival time of 12.3 versus 10.3 months and a hazard ratio for death of 0.79; $P = .003$. A large randomized trial in Europe was conducted with gemcitabine and cisplatin with or without bevacizumab.[146] This trial has also shown a small but significant improvement in progression-free survival (6.7 and 6.5 months with low- and high-dose bevacizumab vs 6.1 months with placebo).[146] A large number of antiangiogenesis drugs are currently under evaluation for their activity against lung cancer. This class of agents has been associated with an increased of bleeding, hypertension, and nephrotoxicity.

In 2004, investigators identified activating mutations in the tyrosine kinase domain of EGFR that predicted response to the novel tyrosine kinase inhibitors (TKIs) in selected patients with NSCLC.[147,148] Multiple studies have demonstrated that the phenotypes most associated with response to the EGFR TKIs, gefitinib and erlotinib, are adenocarcinoma, never-smokers, female, and East Asian descent. Subsequent reports have shown that these are the groups most likely to harbor the activating EGFR mutations. Emerging data have demonstrated that K-Ras and EGFR mutations are almost always mutually exclusive and that patients with K-Ras mutations do not respond to EGFR-TKIs.[149] Erlotinib has been shown in a phase III trial in previously treated patients with NSCLC to result in superior survival versus placebo (6.7 vs. 4.7 mo).[150] On this basis, erlotinib was approved by the U.S. Food and Drug Administration (FDA) for second-line treatment. A phase III trial of gefitinib in second-line therapy failed to show a significant improvement in survival and approval for second-line therapy was withdrawn by the FDA in North America.[151] Gefitinib is still used in East Asian countries because of its significantly higher activity in East Asians than in North Americans and Europeans. Phase II trials have documented the activity of both gefitinib and erlotinib in patients with untreated NSCLC and phase III trials with these agents versus standard cisplatin doublet chemotherapy as initial treatment are under way.[152,153] A phase III trial in East Asia randomized patients with untreated stage IV disease to gefitinib- or platinum-based chemotherapy. Gefitinib resulted in superior survival overall (24.9% 12-month progression-free survival with gefitinib vs. 6.7% with carboplatin-paclitaxel). Of the 609 patients, 261 (43%) had EGFR mutations. This subgroup responded significantly better to gefitinib than to chemotherapy. The subgroup negative for mutations responded better to the chemotherapy.[154] The current role for anti-EGF therapy is evolving rapidly and represents an exciting development for targeting treatment for subsets of patients with lung cancer.

The ACCP guidelines recommend that patients with good performance scores (0 or 1) should be considered for platinum-based chemotherapy based on the survival advantage over best supportive care.[155] The duration of first-line therapy should be brief, consisting of four cycles of treatment, or fewer if there are signs of progression. In addition, patients with good performance scores who develop progressive disease should be offered second-line chemotherapy. Single-agent docetaxel, pemetrexed, and erlotinib have all been shown to prolong survival when used in a second-line setting and have been approved by the FDA for this indication.

Small Cell Lung Cancer

SCLC accounts for 15% to 20% of all lung cancers. This cell type has the strongest association with cigarette smoking and is rarely observed in a never-smoker. It is the cell type most commonly associated with paraneoplastic syndromes such as the syndrome of inappropriate (excessive) antidiuretic hormone secretion (SIADH), ectopic corticotropin secretion, Lambert-Eaton myasthenic syndrome (LEMS), and sensory neuropathy.

SCLC usually presents as a centrally located mass in the hilum on chest radiograph and may be associated with obstructive pneumonia. In 5% or fewer cases, SCLC may present as a solitary pulmonary nodule/mass. SCLC is generally staged according to the old Veterans Administration Staging System, rather than the American Joint Committee on Cancer Staging System previously outlined, and classified as limited (LD) or extensive (ED) stage. LD-stage disease is confined to one hemithorax, the mediastinum, and the ipsilateral supraclavicular lymph nodes. It is a disease that can be safely encompassed within one radiation portal without irradiating too much normal lung. ED stage is any disease spread beyond these sites. Malignant pleural effusion or disease extending to the contralateral supraclavicular or hilar lymph nodes is generally considered to be ED. After establishing the histologic diagnosis of SCLC, patients are usually staged with MRI of the brain, CT of the chest (through the adrenal glands), and bone scan or PET scan. In the unusual case of SCLC that presents as a peripheral nodule, the treatment of choice is surgical resection followed by adjuvant chemotherapy and possibly sequential thoracic radiotherapy. Careful preoperative staging should be performed in these individuals to rule

out metastatic disease. Preresection mediastinoscopy should also be performed. If there are mediastinal node metastases, then surgery should be abandoned, and the patient treated with concurrent chemoradiotherapy as outlined later. Five-year survival for peripheral SCLC that is treated with surgery and adjuvant therapy is approximately 30% to 40%.

Approximately one third of patients have LD at diagnosis. LD-SCLC has a response rate of 70% to 80% with standard chemotherapy and thoracic radiotherapy, and a complete clinical response of 50% to 60%. In a meta-analysis of trials with chemotherapy alone versus combined chemotherapy and thoracic radiotherapy, survival was significantly better with combined-modality therapy. Chemotherapy usually consists of a platinum-based regimen. The two most commonly used regimens are etoposide and cisplatin or etoposide and carboplatin. Chemotherapy beyond four to six cycles has not been shown to prolong survival.

The best approach to radiotherapy for LD-SCLC is under evaluation. Two cooperative group trials randomized patients to once-daily versus twice-daily thoracic radiotherapy with concomitant chemotherapy.[156–158] The long-term follow-up of the patients enrolled in the Eastern Cooperative Oncology Group/Radiation Therapy Oncology Group (ECOG/RTOG) trial demonstrated a superior survival at 5 years with the twice-daily radiotherapy (26% vs. 16%).[158] All patients received four cycles of etoposide and cisplatin (two cycles concurrent with radiotherapy) and thoracic radiotherapy began on day 1 with chemotherapy. However, the North Central Cancer Treatment Group trial did not demonstrate any difference in survival with twice-daily radiotherapy versus once-daily therapy.[156,157] All patients received identical chemotherapy with six cycles of etoposide and cisplatin. Radiotherapy began with cycle 4 of chemotherapy. Both trials demonstrated that the median survival time for LD-SCLC is now 18 to 20 months when patients are treated with concurrent chemoradiotherapy, and 20% to 25% of patients will be alive at 5 years. It is unclear if twice-daily thoracic radiotherapy is superior to standard once-daily radiotherapy. Local recurrence is still a problem in over 50% of individuals with radiotherapy doses less than 50 Gy. Current trials are exploring higher doses of thoracic radiotherapy in SCLC. It is generally agreed that concurrent thoracic radiotherapy should begin early, with the first or second cycle of chemotherapy.

ED-SCLC is treated with the same platinum-based chemotherapy doublets and has a response rate of 60% to 80%, with only 20% achieving a clinical complete remission. The median survival time for ED-SCLC is 8 to 9 months, with 10% of patients or fewer alive at 2 years.[159,160] There are virtually no 5-year survivors with ED-SCLC. Many trials have evaluated alternating non–cross-resistant chemotherapy, maintenance chemotherapy (after the initial four to six cycles), and dose-intensity chemotherapy, but none of these approaches has been shown to increase survival. The standard approach to therapy of ED-SCLC is to treat with a platinum-based regimen for four to six cycles and then to observe until the patient's disease progresses, and then offer second-line chemotherapy.[156,158–160] A study from Japan compared irinotecan and cisplatin versus etoposide and cisplatin in ED-SCLC.[160a] The response rate (89% vs. 67%) and survival (median survival time, 12.8 vs. 9.4 mo) were superior with the irinotecan and cisplatin regimen (2-year survival, 19.5% vs. 5.2%). This study was small, with fewer than 100 patients in each arm, and the trial was closed early by the data safety monitoring committee. Subsequently, the Southwestern Oncology Group (SWOG) completed a much larger trial and was unable to observe any difference in survival with the irinotecan and cisplatin regimen (median survival time, 9.9 vs. 9.1 mo).[160b] This regimen was associated with more grade 3 diarrhea, but the etoposide and cisplatin regimen had significantly more hematologic toxicity. Several trials have evaluated a number of the novel agents but, to date, none have shown improved response or survival when added to standard treatment of small cell lung cancer.

Prophylactic cranial irradiation (PCI) is an area of controversy. If a patient with SCLC achieves a complete remission, then there is a 50% chance of development of cranial metastasis within the next 2 years. A meta-analysis of seven randomized trials of PCI versus no PCI for patients in complete remission reported an observed beneficial effect after PCI, with a 5.4% increase in absolute survival (20.7% vs. 15.3%) at 3 years.[161] The major questions raised by the meta-analysis concern the optimal dose of PCI and the neuropsychological sequelae of PCI. Most oncologists recommend PCI in patients who achieve a complete remission with initial therapy.

When patients relapse after initial therapy, the median survival is 3 to 4 months. There are no cures with second-line therapy. If a patient has been off treatment for 6 months or greater, then it is reasonable to use the same agents that he or she received initially. If initial therapy did not include a platinum agent, then second-line therapy should be with a platinum-containing doublet. Currently, the only drug approved for second-line treatment of SCLC by the FDA is single-agent topotecan.[162] Other single agents such as paclitaxel, irinotecan, and epirubicin are active but are not yet approved by the FDA for second-line treatment of SCLC. Epirubicin is commercially available and approved for second-line treatment in Japan. Finally, although there have been promising leads, no targeted therapy has yet been approved for SCLC.[163]

PALLIATIVE CARE

Although much of this chapter is devoted to efforts to cure lung cancer, most patients will eventually succumb to their disease. Although pulmonologists are adept at providing supportive care in the intensive care unit (see Chapter 93), caring for the ambulatory dying patient with lung cancer requires special consideration. There is a vast literature on ambulatory pain management, the use of interventional pulmonary techniques such as tumor ablation and stent placement to relieve malignant airway obstruction, and the use of hospice to provide end-of-life care in the home setting. With the tools now available to physicians, patients need not suffer

debilitating cough, nausea, dyspnea, or pain. Pulmonologists are encouraged to provide "aggressive palliation" with the same conviction that they provide treatments for critically ill patients in the intensive care unit.[164,165]

SPECIAL CONSIDERATIONS IN LUNG CANCER

Superior Sulcus Tumors and Pancoast's Syndrome

Pancoast's syndrome is a constellation of symptoms and signs that include shoulder and arm pain along the distribution of the eighth cranial nerve trunk and first and second thoracic nerve trunks, Horner's syndrome, and weakness and atrophy of the hand.[166–168] The underlying cause is usually local extension of an apical lung tumor located in the superior pulmonary sulcus (Pancoast's tumor). The most common cause of this symptom complex is NSCLC; however, SCLC and a number of other types of tumors and infections may rarely present in this manner.[166] The most common initial symptom is shoulder pain, which is produced by tumor involvement of the parietal pleura, brachial plexus, vertebral bodies, and first, second, and third ribs. The pain may radiate along the upper back or shoulder into the axilla and along the distribution of the ulnar nerve. Patients are commonly treated for arthritis or bursitis of the shoulder for months before the correct diagnosis is determined. Horner's syndrome consists of ptosis, myosis, and anhydrosis and is caused by the invasion of the paravertebral sympathetic chain and the inferior cervical (stellate) ganglion.[166] Pancoast's syndrome is present in approximately one third of patients with superior sulcus tumors reported in the literature. The intrinsic muscles of the hands may become weak and atrophied as the tumor progresses. With further extension through the intervertebral foramina, spinal compression and paraplegia may develop.

The chest radiograph may show an apical tumor, although, in some cases, a tumor can be identified only on a CT scan of the chest. If the diagnosis is suspected, but the chest radiograph is negative, then a CT chest scan should be obtained (Fig. 47-4). CT also provides additional information about the extent of the tumor and is especially helpful in identifying other pulmonary nodules and mediastinal adenopathy. MRI of the chest is considered to be superior for evaluating patients with superior sulcus tumors because of better assessment of invasion through the pleura and subpleural fat, better evaluation of plexus involvement, and better definition of subclavian vessel involvement.[169] Magnetic resonance angiography may give the best assessment of vascular invasion of the subclavian vessels. Flexible fiberoptic bronchoscopy is frequently the first diagnostic test for apical tumors and has a diagnostic yield of approximately 50%.[170] TTNA has a very high diagnostic yield (>90%) even if the bronchoscopy is nondiagnostic.[171] Superior sulcus tumors are usually staged as T3N0M0 (stage IIB) or higher depending on size of the tumor (T3 or T4) and extent of lymph node involvement. In a large series from M. D. Anderson, 25% of patients were stage IIB, 22% were IIIA, and 53% were stage IIIB (T4 or N3).[172] Obviously, some patients are stage IV at diagnosis, but they were excluded from that report. It is estimated that one third to one half of all superior sulcus tumors have identifiable distant metastasis at diagnosis. In addition to the stage of disease and performance score, other important poor prognostic factors include weight loss and vertebral body or supraclavicular involvement. The presence of N1 or N2 nodal involvement and incomplete resections have a worse prognosis.[172,173] In patients treated for localized disease (stage IIB or IIIB), the brain is the most common site of relapse.[174] In the past, the most common treatment for localized superior sulcus tumors due to NSCLC was preoperative radiotherapy of 30 to 50 Gy followed by resection. This resulted in a 5-year survival of 25% to 35%. The current standard of practice is to perform neoadjuvant chemoradiotherapy followed by resection. This is based on results of the North America Intergroup Trial in which patients with a negative mediastinoscopy were treated with two cycles of etoposide and cisplatin chemotherapy and concurrent thoracic radiotherapy (45 Gy in 5 wk). In the resected specimen, a pathologic complete response or minimal microscopic disease was identified in 66% of patients. The overall survival at 5 years was 44% and, for those with a complete resection, 54%.[174] In a phase II trial in Japan, chemotherapy with mitomycin, vindesine, and cisplatin with concurrent thoracic radiotherapy led to a 5-year survival of 56%.[175] Although the optimal regimen of treatment has not been proved, a reasonable choice is that utilized in the U.S. Intergroup Trial study described above.

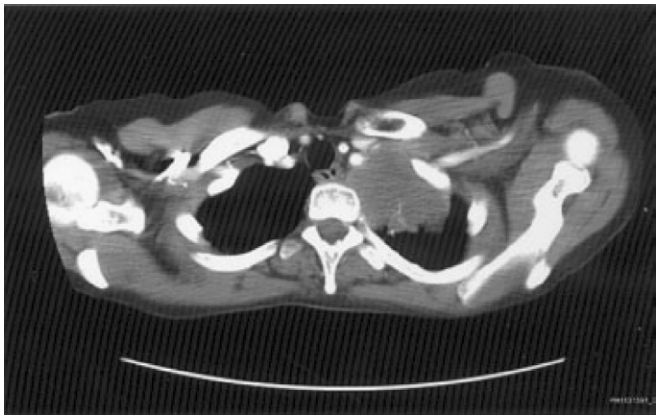

FIGURE 47-4 ■ CT scan of patient with a Pancoast tumor.

Superior Vena Cava Syndrome

The blockage of blood flow in the superior vena cava (SVC) results in SVC syndrome.[176] Bronchogenic carcinoma accounts for the vast majority of these cases in older adults.[177,178] In teenagers and young adults, SVC syndrome is usually due to non-Hodgkin's lymphoma. Patients complain of dyspnea and a sensation of fullness in the head and/or light-headedness when bending over.

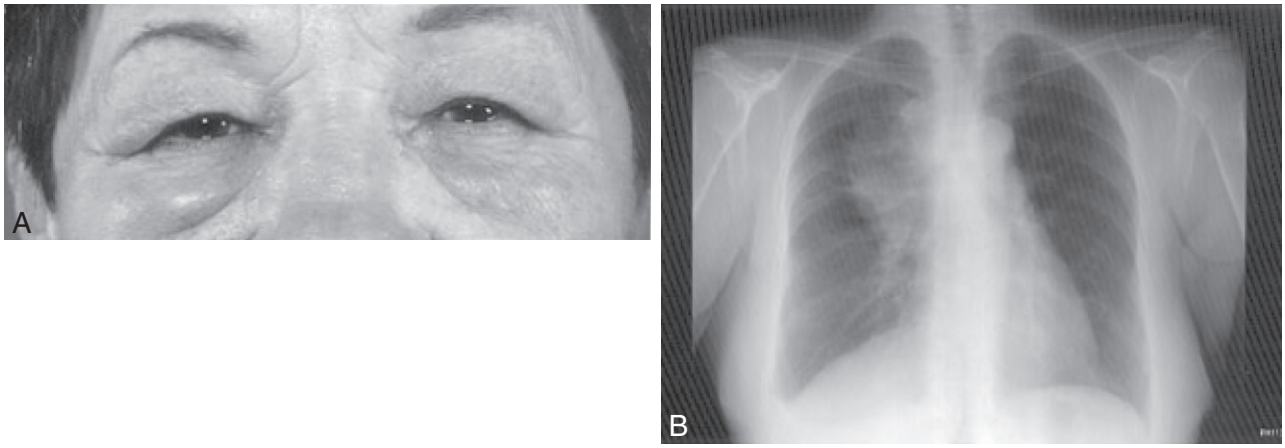

FIGURE 47-5 ■ **A,** Facial swelling in a patient with superior vena cava (SVC) syndrome. **B,** Chest radiograph depicts right hilar mass in patient with SVC syndrome.

They may also note facial swelling. Cough, pain, and dysphagia are less frequent symptoms. Physical examination findings included dilated neck veins, a prominent venous pattern on the chest, facial edema, and a plethoric appearance (Fig. 47-5A). The chest radiograph typically shows widening of the mediastinum or a right hilar mass (see Fig. 47-5B). Occasionally, it may be normal. Dilated veins on the anterior chest wall and compression of the SVC may be demonstrated with a contrast-enhanced CT scan. SVC syndrome is not generally a medical emergency, and patients should not be treated without a tissue diagnosis. Bronchoscopy or mediastinoscopy can be safely performed in the setting of SVC syndrome.[179] SVC syndrome due to SCLC is best treated with chemotherapy. Generally, after treatment, symptoms will start to resolve in 5 to 7 days because SCLC is chemosensitive.[180] NSCLC is best treated with concurrent chemoradiotherapy (see earlier discussion of treatment of stage IIIA/IIIB NSCLC). For immediate relief of SVC obstruction, vascular stenting should be strongly considered. A Cochrane meta-analysis reported that SVC stents relieved obstruction in 95% of cases.[180] Stenting has been associated with a complication rate of 3% to 7%.

PARANEOPLASTIC SYNDROMES

Hormonal, neurologic, hematologic, or other remote effects of cancer not related to the direct invasion, obstruction, or metastatic effects of tumor are generally termed *paraneoplastic syndromes*. Paraneoplastic syndromes related to bronchogenic carcinoma occur in 10% to 20% of patients (Table 47-6).

Musculoskeletal Effects

Clubbing of the digits may be a manifestation of lung cancer or other diseases. Clubbing may involve the fingers and toes and consists of selective enlargement of the connective tissue in the terminal phalanges. Physical findings include loss of the angle between the base of the nail bed and the cuticle, rounded nails, and enlarged fingertips. Clubbing is an isolated finding and is usually asymptomatic. Nonmalignant causes of clubbing include pulmonary fibrosis, congenital heart disease, and bronchiectasis. Hypertrophic pulmonary osteoarthropathy (HPO) is an uncommon process associated with lung cancer. HPO is characterized by painful arthropathy that usually involves the ankles, knees, wrists, and elbows and is most often symmetrical. The pain and arthropathy are caused by proliferative periostitis that involves the long bones but may also affect metacarpal, metatarsal, and phalangeal bones. Patients may have clubbing of fingers and toes in addition to the painful arthralgias. The pathogenesis of HPO is uncertain, but it may arise from a humoral agent. For patients who smoke and have a new onset of arthralgias, HPO must be considered. A radiograph of the long bones (i.e., tibia and fibula) usually shows characteristic periosteal new bone formation. An isotope bone scan typically demonstrates diffuse uptake by the long bones. Large cell and adenocarcinoma are the most common histologic types associated with HPO. The symptoms of HPO may resolve after thoracotomy, whether the primary cancer is resected or not. For inoperable patients, treatment is with nonsteroidal anti-inflammatory agents. Recently, case reports have observed resolution or marked improvement of symptoms with bisphosphonate treatment.[181]

Although still a topic of debate, population-based studies from Scandinavia suggest a frequency of malignancy of 15% to 25% in patients with dermatomyositis-polymyositis.[182] The highest risk of malignancy is in the first 2 years after the diagnosis of dermatomyositis-polymyositis. A reasonable approach to cancer surveillance in these patients is a careful history and physical examination, chest radiograph, basic laboratory tests, and age-appropriate cancer screening examinations. Other tests should be based on abnormalities detected during the basic evaluation.

Hematologic Effects

Anemia frequently occurs in patients who have lung cancer and may be caused by iron deficiency, chronic

TABLE 47-6. Paraneoplastic Syndromes Associated with Bronchogenic Carcinoma

System	Paraneoplastic Syndrome
Musculoskeletal	Clubbing
	Hypertrophic osteoarthropathy
	Polymyositis
	Osteomalacia
	Myopathy
Cutaneous	Dermatomyositis
	Acanthosis nigricans
	Pruritus
	Erythema multiforme
	Hyperpigmentation
	Urticaria
	Scleroderma
Endocrinologic	Cushing's syndrome
	Syndrome of inappropriate secretion of antidiuretic hormone
	Hypercalcemia
	Carcinoid syndrome
	Hyperglycemia/hypoglycemia
	Gynecomastia
	Galactorrhea
	Growth hormone excess
	Calcitonin secretion
	Thyroid-stimulating hormone
Neurologic	Lambert-Eaton myasthenic syndrome
	Peripheral neuropathy
	Encephalopathy
	Myelopathy
	Cerebellar degeneration
	Psychosis
	Dementia
Vascular/hematologic	Thrombophlebitis
	Arterial thrombosis
	Nonbacterial thrombotic endocarditis
	Thrombocytosis
	Polycythemia
	Hemolytic anemia
	Red cell aplasia
	Dysproteinemia
	Leukemoid reaction
	Eosinophilia
	Thrombocytopenic purpura
Miscellaneous	Cachexia
	Hyperuricemia
	Nephrotic syndrome

disease, or bone marrow infiltration. Eosinophilia is more commonly associated with Hodgkin's disease but may occur in patients who have lung cancer. Production of various cytokines by neoplastic cells may result in eosinophilia, leukocytosis, or thrombocytosis, of which thrombocytosis is by far the most common. The association of deep venous thrombosis and malignancy was described by Trousseau over a century ago, and lung cancer is the most common malignancy associated with Trousseau's syndrome. The causes of the hypercoagulable state remain poorly understood. One large study documented clinically significant association of idiopathic thrombosis and the subsequent development of overt cancer; however, other investigators concluded that the literature does not enable firm recommendations about whether to screen for a malignant neoplasm in patients who have unexplained venous thromboembolism.[183] Thromboembolism in the patient who has malignancy is often refractory to warfarin treatment. Treatment with low-molecular-weight heparin (LMWH) on a chronic basis may be effective. In a randomized trial, patients with cancer and deep vein thrombosis, pulmonary embolism, or both were randomized to receive LMWH (dalteparin) subcutaneously once daily or oral warfarin daily for 6 months.[184] At 6 months, the probability of recurrent thromboembolism was 9% with dalteparin treatment and 17% with warfarin, a difference that was highly significant. The risks of major bleeding or any bleeding were not different in the two groups. The other advantage of LMWH is that it is unnecessary to monitor the anticoagulant effect, except in some patients with renal insufficiency. A recent Cochrane analysis concluded that, for long-term treatment in patients with cancer, LMWH reduced venous thromboembolism events, but not death, as compared with vitamin K antagonists. There was no significant difference in the risk of bleeding.[185]

Hypercalcemia

Hypercalcemia in association with malignancy may arise from a bony metastasis or, less commonly, from secretion by the tumor of a parathyroid hormone–related protein (PTHrP) or other bone-resorbing cytokine. The most common cancers to cause hypercalcemia are those of the kidney, lung, breast, head, and neck and myeloma and lymphoma. In one study of 690 consecutive lung cancers, 2.5% of cases had tumor-induced hypercalcemia.[186] Squamous cell histology is the most common cell type associated with hypercalcemia, and generally patients have advanced disease (stage III or IV) and are unresectable. Symptoms of hypercalcemia include anorexia, nausea, vomiting, constipation, lethargy, polyuria, polydipsia, and dehydration. Confusion and coma are late manifestations, as are renal failure and nephrocalcinosis. Cardiovascular effects include shortened QT interval, broad T wave, heart block, ventricular arrhythmia, and asystole. Individual patients may manifest any combination of these signs and symptoms in various degrees.

Hypercalcemia of malignancy that is not caused by bony metastases results from accelerated bone resorption, decreased bone deposition, or increased renal tubular reabsorption of calcium. Accelerated bone resorption is caused by activation of osteoclasts by cytokines or PTHrP in most cases. Serum parathyroid hormone levels are usually normal or low, but an elevated level of PTHrP can be detected in the serum in approximately one half of these patients.[186] Cytokines or PTHrP are secreted autonomously by the tumor. Not only does PTHrP cause renal calcium reabsorption, but

also it interferes with renal mechanisms for reabsorption of sodium and water, with resultant polyuria. Polyuria and vomiting result in dehydration; decreases in glomerular filtration further aggravate the hypercalcemia.

Mild elevation of serum calcium may not require treatment, so the decision is based on the patient's symptoms. For patients who have widely metastatic and incurable malignancy, it may be most appropriate to give supportive care only and not treat the hypercalcemia. The average life expectancy in this situation is 30 to 45 days, even with aggressive treatment.[187] Most patients who have a serum calcium of 12 to 13 mg/dL or higher are treated.

The four basic goals of treatment are to (1) correct dehydration; (2) increase renal excretion of calcium; (3) inhibit bone resorption; and (4) treat the underlying malignancy. Because of the polyuria, patients with hypercalcemia are volume contracted. Initial treatment is with intravenous normal saline, using 3 to 6 L/24 hr as tolerated, with careful attention to volume status. Previously, a loop diuretic such as furosemide or ethacrynic acid was added to maximize calcium excretion but has become less common due to the efficacy of the bisphosphonates in inhibiting bone resorption. Thiazide diuretics are not used because they increase calcium reabsorption in the distal tubule. Fluids and diuretics generally result in only a mild decrease of the calcium; additional treatment is needed to inhibit the accelerated bone resorption. The bisphosphonates have a high affinity for bone and inhibit osteoclast activity. Zoledronate, a newer bisphosphonate, is the most effective; the usual dose is 4 mg given intravenously over 15 minutes.[188] Normal calcium levels are achieved within 4 to 10 days in 85% of patients and last a median of 30 to 40 days. Adverse effects are generally mild and transient and include fever, hypophosphatemia, asymptomatic hypocalcemia and, occasionally, renal failure. Calcitonin inhibits bone resorption, increases renal calcium excretion, and has a rapid onset of action, but the duration of action is short-lived. Calcitonin is a relatively weak agent and, when used alone, does not usually normalize the serum calcium of patients who have marked hypercalcemia. Use of calcitonin is appropriate when the calcium is greater than 14 mg/dL or needs to be lowered urgently (onset of action is 4–6 hr) while waiting for the more effective but slower-acting agents to take effect or when relief of bony pain is desired. The effects of calcitonin and bisphosphonates are additive. Tachyphylaxis may occur to calcitonin after 48 hours. Other agents such as gallium nitrate or plicamycin have been used to treat hypercalcemia but have not generally been adopted as first-line therapies because of inconvenience of administration schedules or associated toxicities.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Causes of hyponatremia include tumors, pulmonary infections, central nervous system disorders, and drugs. Although only 10% of patients with SCLC exhibit SIADH, SCLC accounts for approximately 75% of cases of SIADH. Antidiuretic hormone (vasopressin) is secreted in the anterior hypothalamus and exerts its action on the renal collecting ducts by enhancing the flow of water from the lumen into the medullary interstitium, thereby concentrating the urine. The criteria for the diagnosis of SIADH include (1) hyponatremia associated with serum hypoosmolality (<275 mOsm/kg), (2) inappropriately elevated urine osmolality (>200 mOsm/kg) relative to serum osmolality; (3) elevated urine sodium (>20 mEq/L); (4) clinical euvolemia without edema; and (5) normal renal, adrenal, and thyroid function. The serum uric acid is usually low, and the urine osmolality–to–serum osmolality ratio is frequently greater than 2. The severity of symptoms is related to the degree of hyponatremia and the rapidity of the fall in serum sodium. In one large series of SIADH patients, only 27% had signs or symptoms of hyponatremia despite a median sodium of 117 mEq/L (range, 101–129 mEq/L). Symptoms of hyponatremia include anorexia, nausea, and vomiting. With a rapid onset of hyponatremia, symptoms caused by cerebral edema may include irritability, restlessness, personality changes, confusion, coma, seizures, and respiratory arrest. In minimally symptomatic or asymptomatic patients, fluid restriction of 500 to 1000 mL/24 hr is the initial treatment of choice. Conivaptan is an intravenous vasopressin receptor antagonist that has been shown to be useful in correcting hyponatremia but its use is limited to the hospital. Oral vasopressin receptor antagonists are under evaluation but not yet available.[189,190]

If further treatment is needed, oral demeclocycline (900–1200 mg/day) can be considered. Demeclocycline induces a nephrogenic diabetes insipidus and blocks the action of antidiuretic hormone on the renal tubule, thereby increasing water excretion. The onset of action varies from a few hours to a few weeks, so this drug is not recommended for acute emergency treatment. Demeclocycline has potential kidney toxicity. In patients who have more severe or life-threatening symptoms (serum sodium <115 mEq/L), treatment consists of intravenous saline, supplemental potassium, and diuresis with loop diuretics such as furosemide or ethacrynic acid. With severe confusion, convulsions, or coma, it may be appropriate to treat with 300 mL of 3% saline given over 3 to 4 hours in combination with a loop diuretic (saline without a diuretic will not increase the sodium concentration). Rapid correction of the sodium may have life-threatening consequences, and caution is advised.[191] The rate of correction of the sodium is best limited to a maximum of 20 mEq/L/day, until a level of 120 to 130 mEq/L is reached. Faster correction has been associated with the development of central pontine myelinolysis, which may result in quadriplegia, cranial nerve abnormalities that manifest as pseudobulbar palsy, alteration in mental status, and subsequent death. Accordingly, in the course of treating hyponatremia, the serum sodium must be monitored frequently to ensure that correction is not too rapid. For patients with SIADH due to SCLC, treatment with chemotherapy should be initiated as soon as possible and is likely to result in

improvement in the hyponatremia within a few weeks. After an initial response to chemotherapy, SIADH may recur when the tumor relapses.

Ectopic Corticotropin Syndrome

Ectopic production of corticotropin or corticotropin-releasing hormone with associated Cushing's syndrome has been identified in patients who have SCLC, carcinoid tumor (lung, thymus, or pancreas), and neurocrest tumors such as pheochromocytoma, neuroblastoma, and medullary carcinoma of the thyroid.[192] Of those with ectopic corticotropin secretion, SCLC accounts for 75% of cases, although only 1% to 2% of patients with SCLC develop Cushing's syndrome. Cushing's syndrome is seldom caused by NSCLC.

Classic features of Cushing's syndrome include truncal obesity, striae, rounded (moon) facies, dorsocervical fat pad (buffalo hump), myopathy and weakness, osteoporosis, diabetes mellitus, hypertension, and personality changes. However, the rapid growth of SCLC means that patients are more likely to present with edema, hypertension, and muscular weakness than with the classic features of Cushing's syndrome. Hypokalemic alkalosis and hyperglycemia are usually present. Patients with SCLC and Cushing's syndrome appear to have shortened survival compared to those without the syndrome, perhaps because of more frequent opportunistic infections. The best screen for Cushing's syndrome is the 24-hour urine free cortisol measurement. Elevation of cortisol production, lack of suppression with high-dose dexamethasone, and plasma corticotropin levels greater than 200 pg/mL (40 pmol/L) are highly suggestive of ectopic corticotropin as the cause of Cushing's syndrome in the absence of a pituitary adenoma. The plasma level of corticotropin is elevated in many, but not all, patients. Treatment of Cushing's syndrome due to ectopic corticotropin has included adrenal enzyme inhibitors such as metyrapone, aminoglutethimide, and ketoconazole, given alone or in combination. Ketoconazole given orally at a dosage of 400 to 1200 mg/day or metyrapone 250 to 750 mg three times per day may control hypercortisolism within a few days to weeks, but the response is variable.[193] Dose adjustments are based on achieving normal urinary free cortisol levels or morning plasma cortisols of 7 to 11 μg/mL. Symptomatic hypoadrenalism may result from treatment, and some authorities recommend a replacement dose of glucocorticoid when an enzyme inhibitor is started. When Cushing's syndrome arises from SCLC, it is advisable to proceed with appropriate chemotherapy and carefully watch for superimposed infections, as is necessary for any patient who is receiving high-dose corticosteroids. Cushing's syndrome related to a bronchial carcinoid or thymic carcinoid is best treated by surgical resection of the tumor.

Neurologic Effects

The paraneoplastic neurologic syndromes associated with lung cancer, mostly small cell type, are quite variable. They include LEMS, subacute sensory neuropathy, encephalomyelopathy, cerebellar degeneration, autonomic neuropathy, retinal degeneration, and opsoclonus.[194] The frequency of any of these neurologic syndromes in SCLC is approximately 5%, and neurologic symptoms may precede the diagnosis by months to years.[195,196] Most patients who have SCLC and an associated paraneoplastic syndrome have LD-SCLC that may or may not be obvious on initial evaluation. Careful radiographic evaluation of the lungs and mediastinum is indicated in a smoker who has a suspected paraneoplastic neurologic syndrome. In this setting, even subtle abnormalities of the mediastinum require a biopsy. A PET scan may help identify an occult lesion and facilitate biopsy confirmation of the diagnosis.[197,198] Many reports have suggested that patients with paraneoplastic neurologic syndromes have a better prognosis than those without the paraneoplastic syndromes with similar stage and histology.

These paraneoplastic neurologic syndromes are thought to be immune-mediated, based on the identification of a number of antibodies in the serum that react with both the nervous system and the underlying cancer.[194] However, not all patients with paraneoplastic syndromes have identifiable antibodies in their serum. The literature is confusing because of different names employed by various investigators. The anti-Hu antibody is the same as antineuronal nuclear antibody type 1 (ANNA-1), and the anti-Ri antibody is identical to ANNA-2. Both of these antibodies, but predominantly ANNA-1, have been associated with SCLC. ANNA-1 binds to the nuclei of all neurons in the central and peripheral nervous system, including the sensory and autonomic ganglia, the myenteric plexus, and cells of the adrenal medulla. Such antibodies should not be confused with the anti–Purkinje cell antibody (anti-Yo), which is characteristically found in patients who have subacute cerebellar degeneration as a manifestation of gynecologic malignancy or breast cancer. The CRMP-5 antibody, also known as anti–CV-2, has been associated with SCLC and thymomas.[194]

In a review of 162 sequential patients who had elevated ANNA-1 (anti-Hu), 142 (88%) were proved to have cancer, 132 of whom had SCLC.[196] In 97% of these cases, the diagnosis of SCLC followed the onset of the associated neurologic syndrome, usually by less than 6 months but, in 20%, the period was greater than 6 months. Of special note is that 90% of cases had disease limited to the lung or to the lung and mediastinum (LD-SCLC). In a report from Europe, 144 patients out of 200 with anti-Hu antibodies had a tumor in the chest.[195] Of these, 111 were proved to be SCLC. In one large series, ANNA-1 antibodies were identified in 16% of all patients with SCLC. These antibodies were associated with limited-stage disease, complete response to therapy, and longer survival compared with patients who had SCLC and no ANNA-1 antibody. These neurologic syndromes seldom improve with treatment, so the goal is to prevent progression by starting treatment of the underlying tumor as soon as possible.

Less common manifestations of neurologic paraneoplastic syndromes are orthostatic hypotension and

intestinal dysmotility. The gastrointestinal symptoms may present as nausea, vomiting, abdominal discomfort, or altered bowel habits suggestive of intestinal pseudo-obstruction. Many of these patients present with gastrointestinal symptoms and significant weight loss prior to the diagnosis of SCLC.

Proximal muscle weakness, hyporeflexia, and autonomic dysfunction characterize LEMS.[199,200] Cranial nerve involvement may be present and does not differentiate LEMS from myasthenia gravis. LEMS has been strongly associated with antibodies directed against P/Q-type presynaptic voltage-gated calcium channels (anti-VGCC antibodies) of peripheral cholinergic nerve terminals. These anti-VGCC antibodies, identified in over 90% of patients with LEMS, block the normal release of acetylcholine at the neuromuscular junction. In contrast, myasthenia gravis is associated with anti–acetylcholine receptor antibodies, which are present in approximately 90% of myasthenic patients. Malignancy is present in approximately one half of patients who have LEMS, and SCLC is by far the most common malignancy. In a recent study of 63 patients with SCLC examined prospectively, only 3% had clinical and electrophysiologic signs of LEMS, 8% had elevated anti-VGCC antibodies and 26% had other neurologic symptoms unrelated to LEMS.[199a] The diagnosis of LEMS is based on characteristic electromyographic findings that show a small amplitude of the resting compound muscle action potential and facilitation with rapid, repetitive, supramaximal nerve stimulation or after brief exercise of the muscle. A single-fiber electromyogram is optimal for making the diagnosis. LEMS is the predominant paraneoplastic neurologic syndrome that may improve with successful treatment of the associated lung cancer. The use of acetylcholinesterase inhibitors is of limited benefit in LEMS.[201] Diaminopyridine enhances the release of acetylcholine and has been used with sustained improvement over months in the majority of patients with LEMS either with or without cancer.[202]

KEY POINTS

- Lung cancer currently claims more lives than breast, colon, and prostate cancer combined and is the number-one cancer killer of both men and women in the United States.
- A new staging system, based on survival data from a large, international population with lung cancer, has changed the tumor (T) and metastasis (M) but not the nodal (N) classifications. The revised classifications and stages should predict survival and guide therapy more closely than the former TMN system.
- Routine screening for lung cancer is not recommended at this time. In the near future, prospective, randomized, controlled studies that avoid lead-time bias, length-time bias, and overdiagnosis bias will help determine whether routine screening actually reduces the mortality from lung cancer.
- In general, for NSCLC, early lung cancer (stage I) is treated with surgery alone, stage II lung cancer is treated with surgery followed by adjuvant chemotherapy, locally advanced lung cancer (stage IIIA and B) is treated with a combination of chemotherapy and radiotherapy, and metastatic disease (stage IV) is treated with chemotherapy alone.
- For SCLC, localized disease (disease within one hemithorax that can be encompassed in a radiation port) is treated by chemoradiotherapy; extensive disease is treated with chemotherapy alone.
- A certain subgroup of lung cancer patients has been recognized to exhibit an activating mutation of the tyrosine kinase domain of the epidermal growth factor receptor. This subgroup, mostly female, never smokers of East Asian descent with adenocarcinoma, may respond to blockade of this receptor by the EGFR TKIs gefitinib and erlotinib. This exciting development is the first example of therapy targeted to a molecular abnormality in lung cancer and illustrates the hope for the future of targeted therapy in this disease.

Vascular Sarcomas

LESSONS LEARNED FOR THE MANAGEMENT OF RARE PRIMARY PULMONARY TUMORS
Specific Radioclinical Presentation
Specific Diagnostic Strategy
Distinguishing Primary Tumors from Metastases
General Therapeutic Management

INTRODUCTION

Rare lung tumors are defined as lung tumors with low prevalence and unusual histology. Overall, these tumors account for less than 1% of all primary lung tumors, whereas they correspond to more than 100 different histologic, clinical, radiologic, and prognostic entities. Some rare lung tumors are specific to the lung, whereas others represent tumors more frequently found in other organs that only rarely occur in the lungs. It is estimated that about 60% of rare primary pulmonary tumors correspond to benign and low-grade lesions and 40% are malignant.

The rare tumors are characterized by their low incidence, but also by poor clinical and imaging descriptions, by the low number of experienced specialists for each tumor subtype, and by the absence of specific therapeutic data. Recognition of rare lung tumors relies on characteristic clinical and radiologic signs, on a modified diagnostic and imaging strategy, and on the determination of their primary or secondary nature.

Because an exhaustive review is outside the scope of this chapter, we discuss selected lesions of special interest because of their relatively high incidence or because they illustrate specific issues regarding the overall diagnostic and therapeutic management of rare malignant primary pulmonary tumors.

CHARACTERIZATION OF RARE LUNG TUMORS

Although accounting for less than 1% of lung malignancies, rare lung tumors correspond to a large array of

histopathologic, clinical, radiologic entities.[1–4] Prevalence may also range from merely uncommon lesions, such as carcinoids, which account for 0.15% of primary lung tumors, to extremely unusual tumors, such as primary pulmonary melanoma, with fewer than 50 reported cases.[5,6] Overall, the most frequent rare malignant primary lung tumors are, in decreasing order of frequency: carcinoid, mucosa-associated lymphoid tissue (MALT) lymphoma, and pneumoblastoma.[1,7]

Most rare lung tumors develop from orthotopic tissues, constitutive of the normal lung parenchyma, and from hematopoietic tissues[1,2] whereas tumors derived from ectopic tissues, including melanoma and meningioma, are more uncommon.[8] Some rare tumor subtypes, such as lymphomatoid granulomatosis, arise specifically within the lung, whereas others, such as blastomas and perivascular epithelioid cell tumors, arise in many different tissues of the body including the lung and are infrequent wherever they are located. Furthermore, some primary tumors that are uncommon within the lung may be frequent in other locations, including lymph node lymphomas and soft tissue sarcomas, which present with specific histopathologic differentiation when originating in the lung, such as MALT lymphoma and angiosarcoma, respectively.[1]

Knowledge regarding these tumors is mainly based upon case reports or small retrospective series, most of which are out of date. Moreover, the interpretation of early series may be hampered by the evolution of concepts in histopathologic classifications; for example, some tumor subtypes such as large cell neuroendocrine, basaloid, and sarcomatoid carcinomas were added to the 1999 and 2004 World Health Organization (WHO) classifications.[7]

From a clinical point of view, the hallmarks of rare lung tumors may be, more than their actual low frequency, the absence of comprehensive clinical data, the low number of specialized groups for the care of each tumor subtype, and the lack of specific therapeutic recommendations. More than 90% of rare lung tumor observations are published as case reports or small series including fewer than five patients.[7] Currently, only carcinoids and large cell neuroendocrine carcinoma, as the most frequent of the rare tumor subtypes, have been characterized regarding their clinical, therapeutic, and prognostic features in large retrospective and prospective studies.[9–11]

Patients with rare lung tumors, as many patients with cancer, tend to go through several stages of grief, including depression, uncertainty, hope, disappointment and, in most cases, physical degradation and social isolation. The rarity of the tumor may also enhance these feelings, owing to the relative lack of information and the increased feeling of isolation, the geographic disparity in access to specific care, the longer duration of the pretherapeutic workup, the involvement of multiple specialists, a feeling of injustice especially in young and never-smoking patients, and the complex management undertaken in a state of uncertainty.[12] As a result, patients with rare lung tumors may not receive equal care and some may feel as "orphans," being incompletely integrated in the process of care of patients with the more frequent bronchogenic carcinoma.

PRIMARY PULMONARY LYMPHOMA AND OTHER LYMPHOPROLIFERATIVE DISEASES

Primary pulmonary lymphoma is defined as a lymphoma affecting one or both lungs, without evidence of extrapulmonary involvement or bone marrow disease at the time of diagnosis and during the subsequent 3 months.[13] For clinicians, pulmonary lymphomas associated with small-size satellite mediastinal and/or systemic nodes are also regarded as originating from the lung.[13–16] Even including these tumors, primary pulmonary lymphomas are rare, representing 0.4% of all lymphomas.[15,17] The most frequent subtypes are MALT-type lymphoma and lymphomatoid granulomatosis. Other subtypes are found only in immunocompromised patients.

Mucosa-Associated Lymphoid Tissue Lymphoma

Pulmonary MALT lymphoma is referred to as nodal marginal-zone B-cell lymphoma, with similar cytopathologic features to other MALT lymphomas, especially gastric lymphoma.[18] These low-grade lymphomas account for 70% to 90% of primary pulmonary lymphomas. At pathologic examination, MALT lymphoma appears as a diffuse infiltrate of small monomorphic lymphoid cells, with a typical lymphangitic growth pattern spreading along the bronchovascular bundles and interlobular septa, and forming solid nodules that fill the alveolar spaces and obliterate the normal lung architecture (Fig. 48-1C and D). Immunohistochemistry forms the basis of the subtype classification, with the expression of the pan-B-markers CD20 and CD79 and the absence of staining for CD5 and CD10.[19] The proliferation is monotypic, with surface and/or cytoplasmic expression of immunoglobulin M (IgM) and, less frequently, IgG and IgA (see Fig. 48-1E and F). Light chain restriction can be detected in the plasmacytic component using flow cytometry. MALT lymphomas are associated with unique chromosomal translocations, such as the t(11;18)(q21,q21) resulting in a fusion of the *API2* and *MALT1* genes, the t(1;14)(p22;q32) involving the *BCL10* and *IgH* genes—which is overall much less frequent, more specific to lung locations, and never found in high-grade lymphoma—and the t(14;18)(q32;q21) involving the *IgH* and *MALT1* genes.[20] The precise mechanisms leading to the development of these translocations remain unknown but they all appear to result in an inhibition of apoptosis and a survival advantage to the cells.[20] In cases with the t(1;14)(*BCL10/IgH*) translocation, immunohistochemistry on paraffin-embedded tissues can detect the strong nuclear overexpression of BCL10, thought to have prosurvival functions. The diagnosis often requires a surgical lung biopsy, as cytologic examination of bronchoalveolar lavage or fine-needle biopsy may show the CD20-positive B-cell infiltration but fail to exclude differential diag-

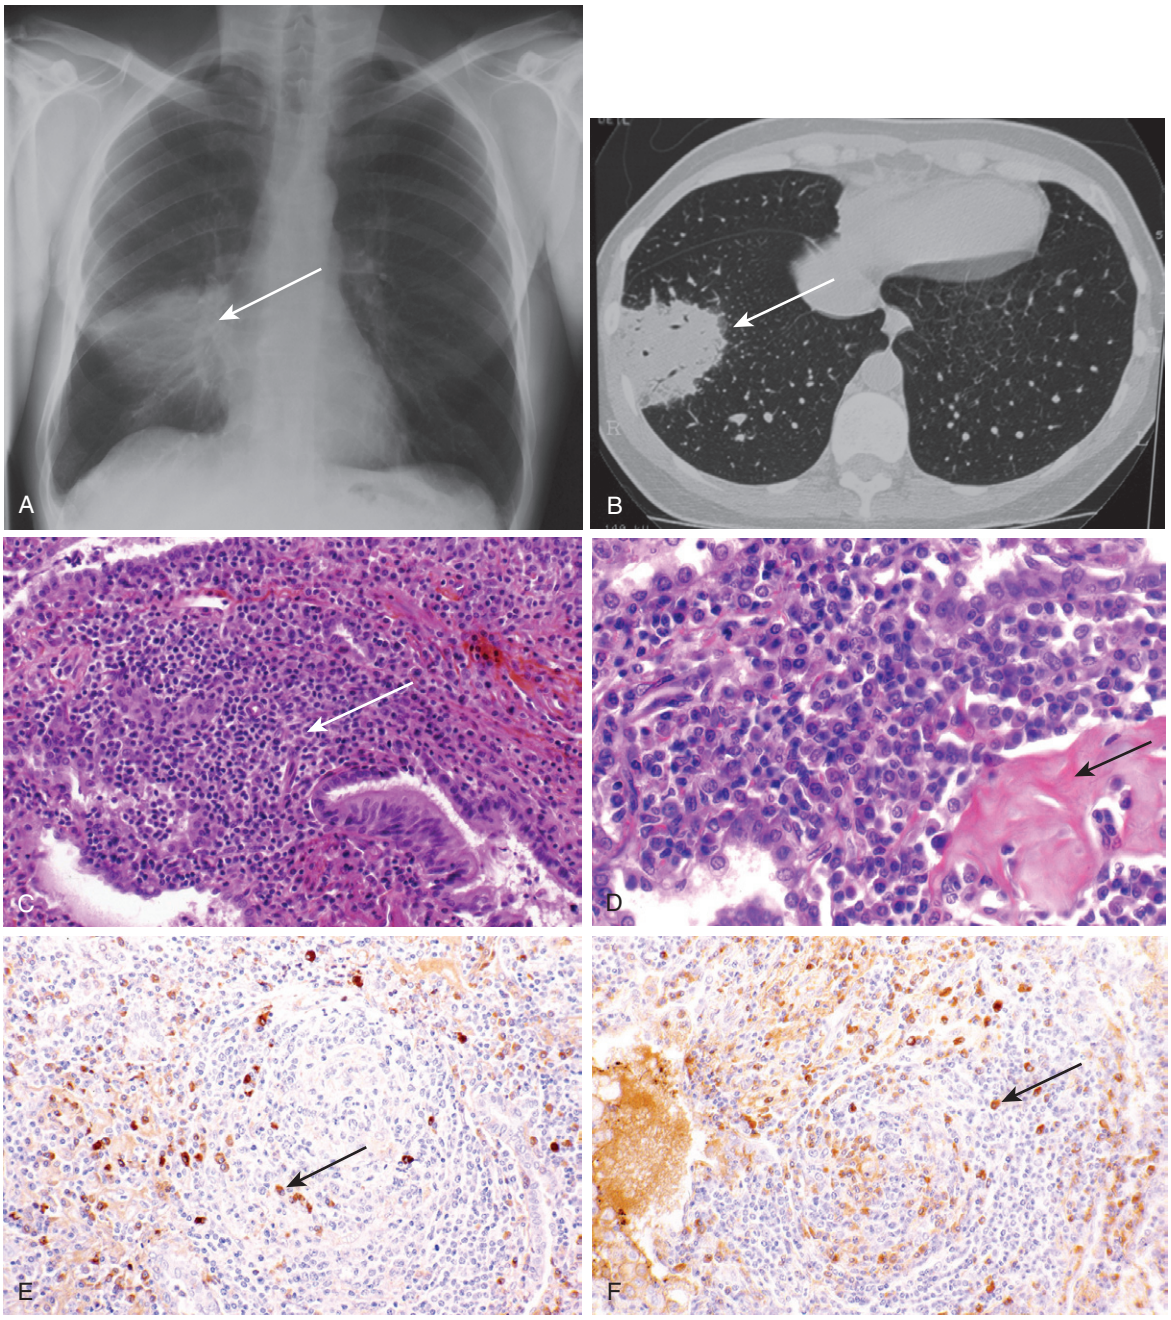

FIGURE 48-1 ■ Primary pulmonary mucosa-associated lymphoid tissue (MALT) lymphoma. Chest radiography (**A**) and computed tomography (CT) scan (**B**) show persistent alveolar opacities in the right lower lobe, despite prolonged antibiotic therapy. Pathologic examination of surgical biopsy showed: **C,** proliferation of small-size lymphoid cells infiltrating the bronchial wall. Note a bronchial epithelium encased in destructive lymphoid proliferation (*arrow*); **D,** at high magnification, lymphoplasmacytic-like cells of the marginal zone lymphoma associated with amyloid deposit (*arrow*); **E,** with immunoglobulin (Ig) lambda light chain immunostaining, a predominance of lambda chain plasma cells (lambda chain restriction) (*arrow*); and **F,** with Ig mu heavy chain immunostaining, a predominance of IgM type in plasmacytic and plasma cells (*arrow*).

noses, such as reactional lymphoid proliferation, follicular bronchiolitis, or lymphoid interstitial pneumonia.[14,18,19] Amplification of the *IgH* gene from paraffin-embedded or cytologic samples with polymerase chain reaction (PCR)–based assays, was demonstrated to be a reliable method to detect monoclonality in more than 60% of MALT lymphomas.[21]

Contrary to extrapulmonary MALT lymphomas, for which a strong relationship has been established with chronic bacterial inflammation related to *Helicobacter pylori* in the stomach and to *Chlamydia psittacci* in the ocular adnexae, no chronic infectious condition has been associated with pulmonary MALT lymphoma, although concurrent evolution with chronic hepatitis C

has been described. However, MALT is absent in the normal bronchial tree and is thought to develop only after long-term inflammation, secondary to smoking or to an autoimmune condition.

MALT lymphoma has mainly been observed in patients older than 45 years, with a slight male predominance, but may also arise in younger patients with underlying immunosuppression, especially related to human immunodeficiency virus (HIV) infection, or with inflammatory conditions such as Sjögren's disease or rheumatoid arthritis, or in association with Epstein-Barr virus (EBV) infection.[14–17,22–24] Less than 50% of patients are symptomatic, with nonspecific symptoms including cough, dyspnea, and chest pain.[14–17] Unlike the situation with other lymphomas, systemic signs such as fever, swelling, and weight loss are uncommon. Association with IgM or IgG blood monoclonal gammopathy is observed in 30% of cases. MALT lymphoma exhibits three imaging patterns at chest radiography and computed tomography (CT) scan: (1) the most frequent and suggestive is the "pneumonia-like" alveolar consolidation with an air bronchogram, typically localized in the middle lobe (see Fig. 48-1A and B); (2) the "tumor-like" aspect with a solitary well-circumscribed nodular opacity (30% of cases) and possible central air bronchogram; and (3) the "infiltrative" pattern with diffuse poorly defined ground-glass opacities, assumed to represent early-stage disease before tumor cells invade alveolar spaces.[14–17,25] The combination of a nodular opacity with peripheral peribronchovascular ground-glass attenuation halo is frequent. Pleural effusion is unusual.

About a third of MALT lymphomas are multifocal at the time of diagnosis, a presentation that may hamper the determination of the primary site.[26] Pulmonary MALT lymphomas are associated with tumor locations in the gastric mucosa in 10% to 20% of patients and in the bone marrow in 15% to 20% of patients. Gastroscopy and bone marrow biopsy are then frequently performed as a pretreatment workup. ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) scan may not be sensitive enough in MALT lymphoma to exclude extrathoracic disease. The Ann Arbor staging system, although not designed for extranodal lymphoma, may be applied in pulmonary MALT lymphoma, which would be staged as IE (one site, extranodal) in case of lung unilateral or bilateral involvement, and IIE (two sites, both above the diaphragm, extranodal) in case of hilar or mediastinal lymph nodes.

Therapeutic options are based on the degree of tumor extension. Surgical resection ensures both the diagnosis and the treatment of nodular lesions. In asymptomatic patients, a watch-and-wait attitude may be preferred to aggressive treatment. More advanced MALT lymphoma requires more aggressive management, and several options have been described, from resection to radiotherapy, or single-agent chemotherapy with chlorambucil, fludarabine, or rituximab. Rituximab, an anti-CD20 antibody, is particularly effective and well-tolerated and may represent an alternative to chemotherapy, especially in the case of t(11;18) translocation.[27] Current data favor systemic treatments in MALT lymphomas, considering that these tumors may represent the early-stage manifestation of a systemic disorder of mucosal immunity.[15,17] Furthermore, the fact that surgical resection has not been shown to improve prognosis in some series is an additional argument against local treatments.[15] Prognosis of MALT lymphomas is excellent, with an indolent and localized prolonged course. Historical series reported 5-year survival rates higher than 80%, and the more recent availability of rituximab may even improve these results.[14] Local and systemic recurrences develop in about 50%, but are usually controllable with chemotherapy. Evolution to high-grade B-cell lymphoma occurs in less than 5% of cases. Young age is the most significant favorable prognostic factor.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis, also called "angiocentric lymphoma," is a malignant B-cell angiocentric and angiodestructive lymphoproliferative disorder. Long considered an inflammatory granulomatous disease owing to its radioclinical presentation similar to other granulomatoses such as Wegener's disease, lymphomatoid granulomatosis is now recognized as a lymphoid malignancy. The lung is the most frequent location, but the disease may also involve the brain, the skin, and the liver.[28–30]

Lymphomatoid granulomatosis forms multiple and confluent nodules composed of an atypical, angiocentric, and polymorphous lymphoid infiltration involving the vascular walls, from the subendothelium to the adventitial zones, with focal lumen obliteration. By immunohistochemistry, these lymphoid cells are characterized mostly as $CD4^+$ T-lymphocytes, with scattered atypical cells of B-phenotype.[28] Large B-cells are infected by EBV in 65% of cases, a fact that correlates with the grade of the lesion. Pulmonary biopsy is required in most cases to exclude Wegener's granulomatosis, which is a polyclonal proliferation of inflammatory cells associated with necrotizing vasculitis.

Lymphomatoid granulomatosis occurs in middle-aged patients, from 40 to 50 years old, with a male predominance.[29,30] Nearly all patients present with respiratory and systemic symptoms, consisting of cough, dyspnea, hemoptysis, chest pain, fever, and weight loss. Peripheral and mediastinal lymphadenopathy is absent. Prolonged immunosuppression is a frequent underlying condition. The typical radiologic presentation consists of multiple smooth bilateral nodules, exhibiting a peribronchovascular pattern, ranging from 2 to 10 cm, and mainly localized in the lower lobes, mimicking multiple metastases.[1,13,29] As in Wegener's granulomatosis, convergent nodules may migrate and form cavitated pseudotumoral masses.

Chemotherapy based on high-dose steroids with cyclophosphamide is the most frequently reported treatment of lymphomatoid granulomatosis. The additional use of rituximab may increase the efficacy of these cytotoxic agents.[31] The overall prognosis is grim, with a 5-year survival of 30% to 40%, owing to progression to nodal diffuse aggressive lymphoma in 20% to 50% of patients. As in lymphoma, the main prognostic factors are age, extension of the lesions, and response to first-

line chemotherapy.[32] Lymphomatoid granulomatosis is increasingly considered a low-grade or early-stage lymphoma, and a histopathologic grading system has been developed, based on the degree of cellular atypia and necrosis, to predict the risk of evolution to high-grade lymphoma and to select patients for early aggressive treatment.[32]

Other Lymphomas and Lymphoproliferative Diseases

Other primary pulmonary malignant lymphoproliferative diseases are very rare and include high-grade diffuse large B-cell lymphoma, intravascular large cell lymphoma, Hodgkin's lymphoma, and plasmacytoma.

Primary pulmonary diffuse large B-cell lymphoma is likely underrecognized owing to its rapid spread to mediastinal nodes and other extrathoracic sites, which may hide its pulmonary origin.[22,33] Histologically, it shows characteristics similar to those of diffuse large B-cell lymphomas at other sites, with diffuse infiltration of large blastic lymphoid cells, expressing pan-B antigens (CD20 and CD79a). Primary pulmonary high-grade B-cell lymphomas typically develop in immunocompetent patients in their sixth to seventh decade. In younger patients, large B-cell lymphoma may be caused by latent EBV infection, which may develop following drug-induced immunosuppression, as from methotrexate or antilymphocyte antibodies in transplant recipients,[34] or following HIV-related immunosuppression. In patients with HIV infection, the availability of highly active antiretroviral therapy led to the near disappearance of primary pulmonary high-grade lymphomas, which are now less frequent than MALT lymphomas in these patients.[13,22] Patients often present with marked respiratory and systemic symptoms. Radiologic studies usually show multiple well-defined rounded solid masses of various sizes, more frequently in the subpleural areas of the lower lobes.[24] Chemotherapy is based on the same multiagent regimens as those used in high-grade nodal lymphomas, including adriamycin, prednisone, and rituximab.[13,22] The overall prognosis is much worse than for MALT lymphoma, with a 5-year survival lower than 20%.

Intravascular large cell lymphoma is a variant of non-Hodgkin's lymphoma, in which neoplastic lymphoid cells proliferate within the lumen of small and intermediate-sized blood vessels, resulting in thrombotic and ischemic complications.[35] Clinical manifestations are multiple, but lymphadenopathy is usually absent. Pulmonary imaging features include bilateral ground-glass opacities and/or sometimes migratory atelectatic shadows.[35] Treatment with conventional combination chemotherapy with or without rituximab leads to remission with prolonged survival.[13,35]

Primary pulmonary Hodgkin's lymphoma has been reported exclusively in old studies, and might actually correspond to nodal Hodgkin's disease with secondary pulmonary involvement.[36] At chest radiography, it is described as a solitary mass with cystic and heterogeneous features, typically involving the upper lobes, or as a multinodular disease. Diagnosis is based on the recognition of characteristic Reed-Sternberg cells at pathologic examination. The overall outcome is poorer than in nodal Hodgkin's lymphoma.

Primary pulmonary plasmacytoma is a solitary lesion exclusively composed of atypical monoclonal plasmocytes, possibly associated with amyloid deposition, without evidence of extrapulmonary myelomatous disease.[13,37,38] Again, the apparent decrease of the incidence of primary pulmonary plasmacytoma may be related to the increased sensitivity of biologic and imaging studies for the detection of primary extrapulmonary disease. Moreover, about one third of patients operated upon for pulmonary plasmacytoma were reported to present with multiple myeloma in following years.[37,38] Surgical resection is, however, recommended for solitary tumors, with a 5-year survival of 60%.[38]

Amyloidosis

Amyloidosis is characterized histopathologically by tissue infiltration with fibrillar protein with a β-sheet structural conformation, specifically stained by Congo red dye with a yellow-green birefringence under polarized light.[39] Amyloidosis has a highly variable presentation and may manifest in the lung as either parenchymal nodules or masses.[40] Pulmonary amyloidosis may be localized to the lung or be associated with systemic amyloidosis.

Pulmonary nodules usually consist of AL ("amyloid light chain") amyloid, which is the most common subtype of amyloidosis deposition.[40] AL amyloidosis is primary in more than 80% of cases and associated with inflammatory or lymphoproliferative disease in 20% of cases. AL amyloidosis develops as a result of the abnormal production of light immunoglobulin chains, often of lambda isotype. AL amyloidosis may be either systemic (e.g., in myeloma) or localized (as in primary pulmonary lymphoma), with mild pulmonary interstitial (especially vascular) involvement that is usually asymptomatic.[41] Serum and/or urinary monoclonal gammopathy is frequent.[42]

Pulmonary nodular amyloidosis has been observed in patients in their seventh decade, without gender predominance. Patients are usually asymptomatic. Association with Sjögren's syndrome has been reported.[43] Radiologically, pulmonary nodules are rounded and sharply delimited. Most nodules are peripheral. The nodules may range from 5 mm to more than 15 cm, may be solitary or multiple, and may be calcified. Nodules have shown increased activity on PET and may thus mimic bronchogenic carcinoma.[44] Fine-needle biopsy may provide a pathologic diagnosis.[45] Pulmonary amyloid nodules may remain stable for years,[46] and surgical resection is proposed only in case of threatening symptoms. Recurrence is frequent after surgery.[47]

Nonamyloidotic Monoclonal Immunoglobulin Deposition Disease

Nonamyloidotic monoclonal immunoglobulin deposition disease (NAMIDD) is rarer than amyloidosis and presents with deposits that are not stained by Congo red dye and do not demonstrate birefringence under

polarized light.[48] These deposits most usually consist of light chains, frequently kappa, or more rarely of single heavy chains or of mixed light and heavy chains.[48] The lung is a very rare location.[49–51] Pulmonary NAMIDD most frequently presents as multiple parenchymal nodules or less frequently, as multiple cysts; deposition is usually limited to the lung without systemic involvement. Approximately half of the cases are associated with hematologic malignancies. Treatment of any underlying hematologic disease usually leads to regression of the monoclonal peak but has little effect on existing deposits. Pulmonary NAMIDD may benefit from lung transplantation in cases of severe respiratory failure and in the absence of an underlying hematologic disorder.[50]

CARCINOIDS AND OTHER NEUROENDOCRINE TUMORS

Primary lung neuroendocrine tumors share common histopathologic features and correspond to four different clinical and prognostic entities: low-grade typical carcinoids, intermediate-grade atypical carcinoids, and high-grade large and small cell neuroendocrine carcinomas.[52] The small cell lung carcinomas are quite common, accounting for 15% to 20% of all primary lung malignancies. On the contrary, carcinoids and large cell neuroendocrine carcinomas account for 0.5% to 2% of lung tumors and are thus considered the most frequent lesions among the rare lung tumors.

Pathologic Classification

Neuroendocrine tumors share varying degrees of neuroendocrine morphologic features, including organoid nesting, the palisading and trabecular pattern, and "rosette-like" structures. Classification is mainly based on the mitotic index and the amount of necrosis.[52] Typical carcinoids exhibit neuroendocrine features, with a mitotic index less than 2 mitoses per 10 high-power fields (2 mm^2), and the absence of necrosis in a tumor that is more than 5 mm in diameter. Atypical carcinoids exhibit a mitotic index ranging from 2 to 10, or areas of focal necrosis (Fig. 48-2C). Peripheral carcinoids may also often be associated with small (≤5 mm) neuroendocrine "tumorlets" and/or with diffuse hyperplasia of pulmonary neuroendocrine cells.[53] These lesions may correspond to early-stage in situ carcinoid proliferation.

Large cell neuroendocrine carcinomas exhibit a mitotic index higher than 10 (actually ranging from 70–80 in most cases), and extensive necrosis. Unlike small cell carcinoma, large cell carcinomas have large tumor cells, with moderate to abundant cytoplasm and, frequently, prominent nucleoli. Immunohistochemically, the expression of at least one neuroendocrine marker, including chromogranin, synaptophysin, or N-CAM (CD56), confirms the diagnosis. The pathologic classification also distinguishes large cell neuroendocrine carcinoma from non–small cell lung cancer (NSCLC) "with neuroendocrine differentiation," a pattern without specific prognostic or therapeutic implications.[54]

Carcinoid Tumors

Excluding small cell lung cancer, more than 80% of lung neuroendocrine tumors are carcinoids.[11] Carcinoids arise mostly in never smokers (60%-80% of cases).[5,11] Carcinoids develop in the proximal airways in 60% to 70% of cases and may produce chronic cough, hemoptysis, and signs of bronchial obstruction. Peripheral carcinoids are asymptomatic, unless they are associated with diffuse hyperplasia of pulmonary neuroendocrine cells that produces bronchiolar obstruction in 50% of cases[55] and possible airflow obstruction. Unlike carcinoids in extrathoracic locations, lung carcinoids are small size lesions only rarely associated with liver metastases and do not generally produce the carcinoid syndrome (<2% of cases).[5,11] CT scan shows a peripheral or proximal well-circumscribed solitary nodular lesion in 90% of cases.[55] Carcinoid tumors may present as "iceberg-like" lesions, with a small amount of endobronchial growth and a prominent parenchymal mass (see Fig. 48-2A and B). In some cases, lobar or segmental atelectasis may constitute the sole manifestation of endobronchial small-size

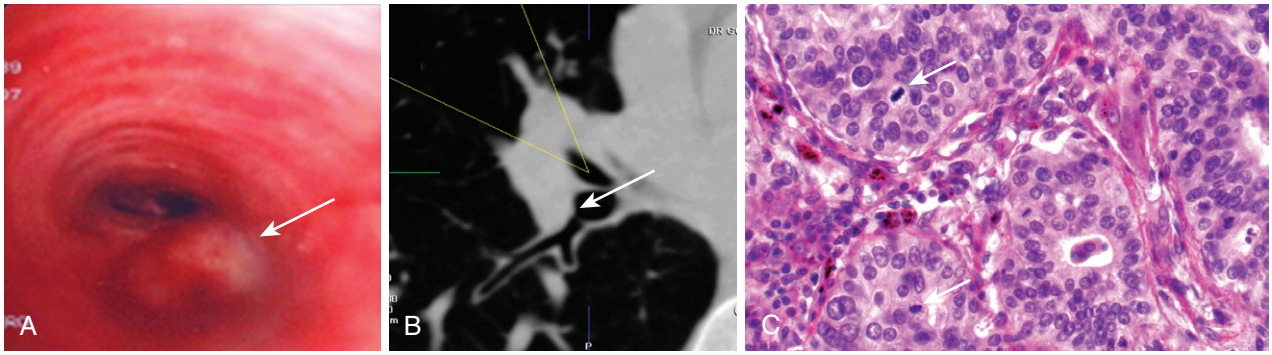

FIGURE 48-2 ■ Atypical carcinoid in a 17-year-old patient, presenting with recurrent infectious pneumonia. **A,** Endobronchial appearance of carcinoid (*arrow*), with a partial stenosis of the right main bronchus. **B,** At CT scan, an "iceberg-like" growth in the lung parenchyma (*arrow* showing small endobronchial aspect overlying larger parenchymal mass). **C,** Histopathologic aspect: endocrinoid growth pattern of uniform polygonal cells shows nestings, palisading, and rosettes. Two mitoses (*arrows*) are present in the field, characterizing this as an atypical carcinoid.

lesions. Peripheral calcifications may be observed in up to 30% of cases.[55] Their hypervascularity can distinguish carcinoids from mucous plugging. Regional lymph node invasion is more frequent in atypical carcinoids (40% to 50% of cases vs. 10% to 15% of typical carcinoids), and the tumor-node-metastasis (TNM) classification, although designed for carcinomas, has been used to stage carcinoids.[5,11,55] Although hypervascularized, carcinoids generally exhibit a low to moderate activity on PET scan.[56] Imaging for somatostatin receptors using ^{111}Indium-labeled octreotide has shown great promise and may increase the sensitivity for diagnosis, staging, and follow-up for recurrence.[57] The risk of hemorrhage following endobronchial biopsy is less than 1%.[11,55,57]

Surgery is the standard treatment for stage I-II and most stage III carcinoids, which account for 75% and 15% of cases, respectively. Typical carcinoids, with a low local recurrence rate, can be treated with limited resection with segmentectomy and regional lymph node dissection; this local approach is associated with local control and survival rates identical to that following extensive procedures.[10] Endobronchial techniques, such as cryotherapy, have also been reported as an alternative approach for typical carcinoid but fail to ensure accurate counting of the mitotic index and, therefore, the confirmation of the subtype.[58] Atypical carcinoids, which have a higher local recurrence rate, require lobectomy and mediastinal lymph node dissection.[10,59] Lung carcinoids metastasize in less than 10% of cases. In those cases, cisplatin-based chemotherapy is ineffective, whereas local treatment of metastases may lead to prolonged remission. In sum, the most significant prognostic factor is the histopathologic subtype, because 5-year survival rates of typical and atypical carcinoids are 87% to 98% and 56% to 73%, respectively.[5,11]

Large Cell Neuroendocrine Carcinoma

The incidence of large cell neuroendocrine carcinoma has long been underestimated, probably because these tumors are often misdiagnosed as large cell undifferentiated carcinoma either on cytology or on tissue sections in the absence of immunostaining for neuroendocrine markers.[5,60]

Large cell neuroendocrine carcinomas are strongly associated with tobacco smoking (90% of cases).[60,61] Clinical and radiologic features are similar to those of other bronchogenic carcinomas, and in most reported series, treatment follows recommendations for NSCLC, including resection in stage I-II tumors.[62,63] Efficacy of chemotherapy is, however, significantly better, with up to 75% of response to the cisplatin-etoposide combination in a neoadjuvant (presurgical) setting.[64,65] Several studies, including one prospective trial, showed a reduced metastatic recurrence rate and increased survival in patients receiving adjuvant chemotherapy even in early-stage tumors.[9,60,62,64] Overall survival is better than in small cell carcinoma, with stage the most significant prognostic factor, with 5-year survival of 52% to 88%, 20% to 45%, and 0% to 15% in stages I-II, III, and IV, respectively.[60–64]

RARE MALIGNANT PRIMARY PULMONARY EPITHELIAL TUMORS

Mucoepidermoid Carcinoma

Primary pulmonary salivary gland type tumors include mucoepidermoid carcinoma, adenoid cystic carcinoma, and epithelial-myoepithelial carcinoma. Mucoepidermoid carcinoma is the most frequent variant. It is a mixed malignant tumor characterized by the presence of squamous cells, goblet mucin-secreting cells, and cells of intermediate type (Fig. 48-3C and D).[65] Identification of these three cellular subtypes in cytologic examination is pathognomonic.[65,66] Tumors are classified as low-, intermediate-, and high-grade lesions, depending on the mitotic index, the degree of cellular atypia, and the degree of necrosis. High-grade tumors contain predominantly squamous and intermediate cells and tend to infiltrate the lung parenchyma.

Mucoepidermoid carcinoma in adults mostly develops between the third and the fourth decades, with an equal sex distribution.[66–69] High-grade tumors (30% of cases) are usually diagnosed in older patients. Mucoepidermoid carcinoma is often associated with tobacco smoking. Symptoms, including dyspnea, cough, and hemoptysis, are related to the level of bronchial obstruction. Metastases are found at time of diagnosis in 20% of cases, mainly in the liver, the bone, and the subcutaneous tissues (see Fig. 48-3B). In the lung, mucoepidermoid carcinoma often presents as a well-circumscribed homogeneous, lobulated homogenous mass, often with cystic and/or calcification features (see Fig. 48-3A).[70] The lesion is solitary in 40% to 70% of cases. Hilar involvement is found only for high-grade lesions. There is increased uptake on PET scanning.[70,71] Proximal mucoepidermoid tumors can be diagnosed using endobronchial biopsy.[67]

Treatment is the same as for NSCLC with, when feasible, extensive surgical resection including mediastinal lymph node dissection.[66–69] High-grade lesions have often been reported to receive postoperative radiotherapy and chemotherapy, without clear benefit. Chemotherapy of metastatic tumors in most cases is based on cisplatin and/or 5-fluorouracil. As in NSCLC, a small number of patients with mucoepidermoid carcinoma may benefit from specific epidermal growth factor inhibitors.[72] Prognosis is correlated to the grade of the lesion, the existence of nodal involvement, and the success of the initial surgical resection. Low-grade mucoepidermoid tumors mostly occur in children and young adults, usually do not present with hilar involvement, and have a 5-year survival ranging from 70% to 80%. High-grade tumors have a substantially worse prognosis, with a 5-year survival of only 30% to 45%.

Pneumoblastoma

Pulmonary blastoma is a biphasic tumor that is classified among the sarcomatoid carcinomas in the current WHO classification. This tumor contains both an epithelial well-differentiated component, showing tubular

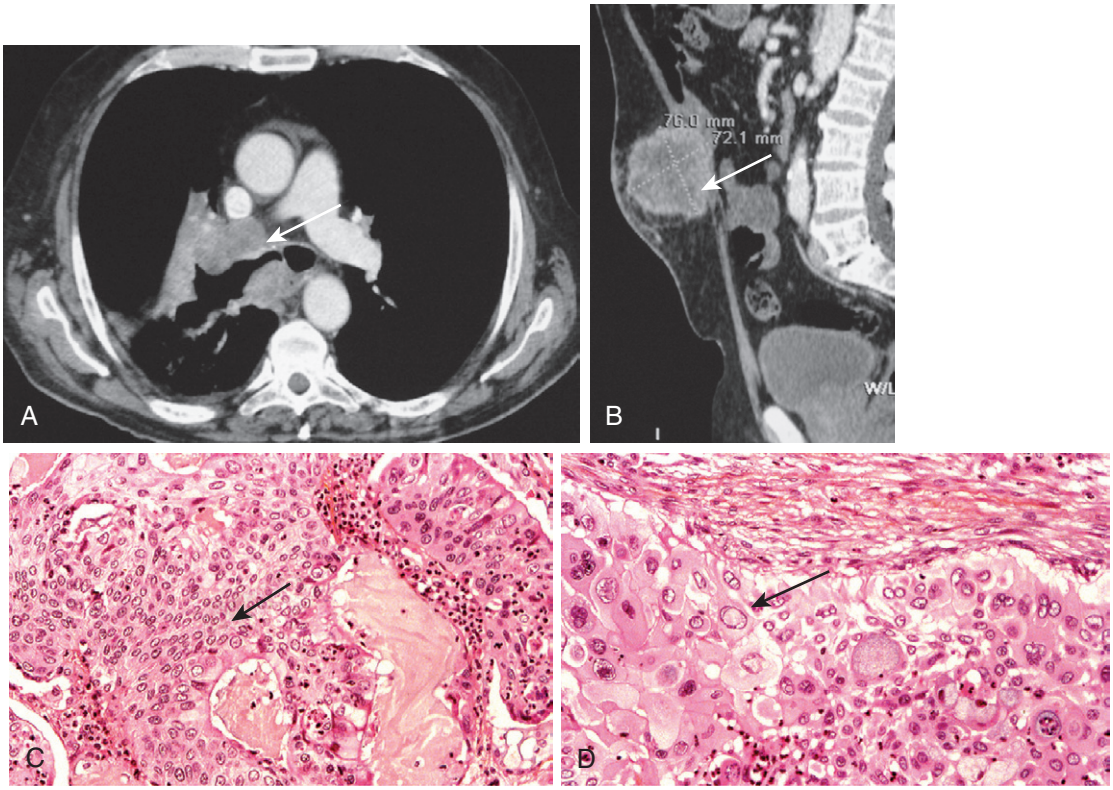

FIGURE 48-3 ■ Primary pulmonary mucoepidermoid carcinoma. **A,** The tumor is located in the right upper lobe and is invading the mediastinum (*arrow*). Radiologic features are identical to those of non–small cell lung cancer (NSCLC). **B,** A metastatic mass is discovered on clinical examination of the abdomen. Magnetic resonance imaging (MRI) confirms the location in the anterior abdominal wall (*arrow*). **C** and **D,** Histopathologic features: a mixture of squamoid (**C**) and mucin-secreting (**D**) cells (see *arrows*).

architecture resembling the normal fetal lung, and a mesenchymal undifferentiated stroma defining the "blastema-like" configuration.[73] Pulmonary pneumoblastoma arises in adults and has to be distinguished from "pleuropulmonary blastoma," a tumor of early childhood related to other embryonic neoplasms, such as nephroblastoma and neuroblastoma.

Pulmonary pneumoblastoma arises in patients from 30 to 45 years old, with a marked female predominance (70% of cases), and frequent association with tobacco smoking.[74–76] CT scan shows a solitary well-circumscribed homogeneous mass,[77] often with cystic and necrotic features. PET scans show increased uptake. In many cases, the tumor is initially thought to be a bronchogenic carcinoma, and complete surgical resection with mediastinal lymph node dissection ensures both the initial diagnosis and the therapy.[74,76,78,79] Adjuvant treatment, mostly consisting of radiotherapy, has been reported in a few cases following incomplete resection or in patients with N2 mediastinal involvement.[76,79–82] In unresectable tumors, chemotherapy is based on protocols used for sarcomas, including doxorubicin and ifosfamide. In most recent reports, survival is better than in NSCLC, especially in completely resected cases.[74]

Sarcomatoid Carcinomas (Other Than Pneumoblastoma)

Sarcomatoid carcinomas are a group of poorly differentiated non–small cell carcinomas that contain a sarcomatous component. In addition to pneumoblastoma, four subtypes are recognized: (1) pleomorphic carcinoma, which corresponds either to the combination of adenocarcinoma, squamous cell carcinoma, or large cell carcinoma with spindle or giant cells or to a carcinoma consisting only of spindle and giant cells[83,84]; (2) spindle cell carcinoma, which is exclusively made of fascicular cells; (3) giant cell carcinoma, composed of highly pleomorphic mono- or multinucleated cells[84]; and (4) carcinosarcoma, containing a mixture of carcinoma (frequently of epidermoid subtype) and poorly differentiated fibromatous sarcoma.[85]

Sarcomatoid carcinoma has been defined in the 1999 WHO classification. These tumors represent from 0.3% to 1.3% of lung tumors, and their specific clinical and radiologic features are rarely reported. Moreover, small biopsies usually do not disclose both the epithelial and the sarcomatous components of the tumor, which is then misdiagnosed as an NSCLC in more than 60% of

cases.[1] Clinical features are similar to other non–small cell carcinomas. Sarcomatoid carcinomas develop mostly in men, with a mean age of 65 years at diagnosis.[83–86] Tobacco smoking is described in more than 80% of cases. Radiologic studies usually show a solitary voluminous peripheral heterogenous mass, invading the chest wall in 60% of cases.[87,88] Vascular invasion is observed in 20% of cases. PET scans show increased uptake.

Sarcomatoid carcinomas are often treated as other non–small cell carcinomas. Alternatively, chemotherapy has been reported to follow soft tissue sarcoma regimens.[89] Response to epidermal growth factor receptor (EGFR)–targeted therapies is infrequent, which may be related to frequent *K-ras* mutations in the epithelial component.[90]

Contrary to pneumoblastomas, the other sarcomatoid carcinomas have been considered as highly aggressive tumors with early metastastic spread, especially in unusual sites such as the esophagus, the peritoneum, the kidney, and the subcutaneous tissues. Median overall survival ranges from 6 to 20 months.[83–86,88] The main favorable prognostic factors include tumor size, stage, and the absence of mediastinal involvement.[83–86,88–90]

PRIMARY PULMONARY SARCOMAS

Primary pulmonary sarcomas account for 20% of all primary rare lung malignancies and comprise parenchymal lung sarcomas, pulmonary artery sarcomas, and small vessel sarcomas.[1,2]

Parenchymal Sarcomas

Primary lung parenchymal sarcomas show identical pathologic subtypes to those of their soft tissue counterparts, with a wide spectrum of differentiation from low- to high-grade. Leiomyosarcoma is the most frequent primary lung sarcoma[91–93] and presents with fascicles of spindle cells at right angles and/or an epithelioid growth pattern with marked hypercellularity and polymorphism. Tumor cells have irregular nuclear chromatin and prominent nucleoli. Immunohistochemistry shows a high level of muscular actin, vimentin, and h-caldesmon, an actin-binding protein. Synovial sarcoma is the second most frequent subtype and presents with a prevalent monophasic growth pattern consisting of interweaving fascicles of densely packed spindle cells. As in their soft tissue location, the chromosomal translocation t(X;18)(p11.2;q11.2) is pathognomonic of the diagnosis[94] and results in the fusion of two genes, *SYT-SSX1* and *SYT-SSX2*. Other subtypes include pleomorphic sarcoma, made of atypical spindle cells showing a "cartwheel" or so-called storiform or radiating pattern, with elongated nuclei and giant cells with multiple and bizarre nuclei and prominent nucleoli, as well as osteosarcoma and chondrosarcoma. Because most mesenchymal malignant tumors have a benign counterpart, pathologic examination must, first, evaluate the grade of the lesion, according to the three-grade system of the French Federation of Cancer Centers Sarcoma Group (FFCCSG),[95] and second, rule out some epithelial tumors with sarcomatoid differentiation, such as pneumoblastoma, or myofibroblastic tumors.[1,7] Differential diagnosis also includes "benign" metastases from uterus (metastasizing leiomyoma) or bone (giant cell tumor).

Compared with their soft tissue counterparts, primary pulmonary sarcomas present in older patients, mainly from the sixth to eighth decade.[91–93,96–99] Clinical symptoms are nonspecific and usually consist of cough, dyspnea, and hemoptysis, depending on the size and the location of the lesions. The incidence of radiation-induced sarcomas has decreased because cobalt-based radiotherapy has been abandoned.[100] Contrary to metastatic sarcoma, primary pulmonary sarcoma presents as a solitary lesion, with heterogeneous cystic, necrotic, or hemorrhagic features but well-defined circumference. Size ranges from 4 to 25 cm (Fig. 48-4A). PET scanning shows increased uptake (see Fig. 48-4B).[101] Tumor progression is mainly local, and mediastinal lymph node invasion and systemic metastases are rare at the time of diagnosis (<2%).[92,93,96]

Surgery is then the most effective treatment, and complete resection is obtained in 80% of cases.[91–93,96–99] Adjuvant chemotherapy, which is recommended for soft tissue sarcoma, has never been evaluated specifically for primary pulmonary sarcoma.[102] Strategies developed in soft tissue sarcoma may not be applicable to primary lung sarcomas: for example, neoadjuvant chemotherapy is commonly used in soft tissue locations but has been disappointing in primary lung tumors.[93,96] In case of unresectable lesions, chemoradiation may be the best therapeutic strategy. As in soft tissue sarcoma, imatinib mesylate is not efficient, despite focal expression of its target CD117/Kit.[103] Prognosis mainly depends on the completeness of initial surgical resection, which, when combined with the grade of the lesion, is the best predictive factor of recurrence-free and overall survival. Overall 5-year survival varies from 40% to 50%[91–93,96–99] and may be better for leiomyosarcomas.[104]

Vascular Sarcomas

Primary pulmonary vascular sarcomas include pulmonary artery sarcomas and small vessel sarcoma, corresponding to epithelioid hemangioendothelioma (EHE), and its high-grade counterpart, angiosarcoma.[105]

Pulmonary artery sarcoma presents as an endoluminal polypoid or nodular mass, which spreads along the intima of the pulmonary artery. Histologic features consist of an undifferentiated spindle cell proliferation, with marked cellular pleomorphism and high mitotic index.[105] Leiomyosarcoma is the most frequent subtype (60% of cases).[105,106] Pulmonary artery sarcomas mainly develop in patients in their fifth to sixth decade.[107,108] Symptoms may mimic pulmonary embolism, with dyspnea, chest pain, cough, and hemoptysis.[107,108] Failure of anticoagulants in this setting, as well as the presence of symptoms of weight loss and fever (arising in 40% of cases), may also suggest the diagnosis. Radiographic findings also help to differentiate between pulmonary artery sarcoma and pulmonary embolism: CT scanning

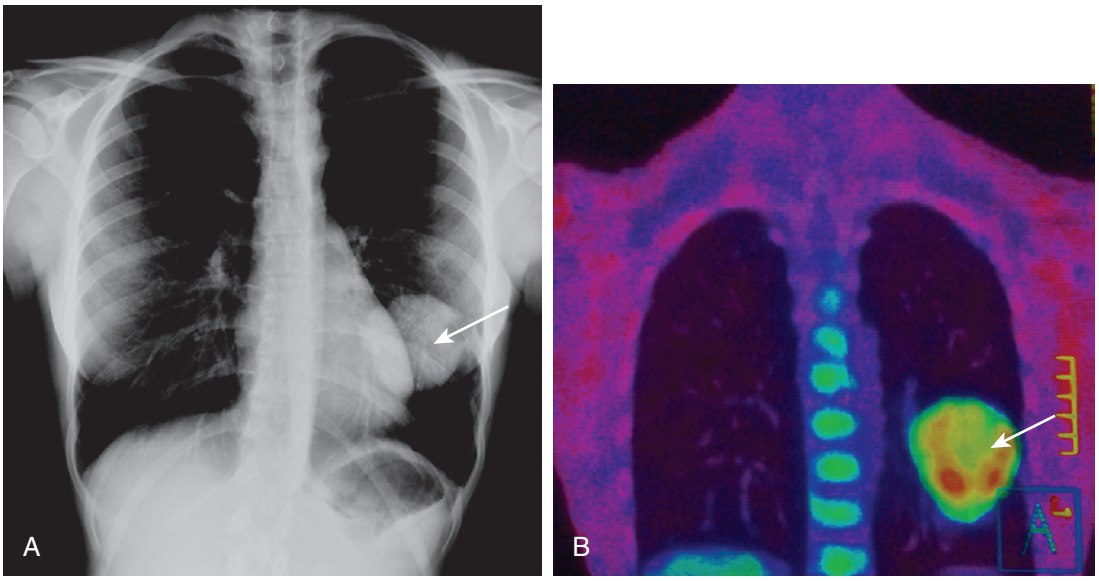

FIGURE 48-4 ■ Primary pulmonary leiomyosarcoma. Chest radiography shows a large well-circumscribed homogeneous mass in the left lung (**A,** *arrow*), which is hypermetabolic at ^{18}F-fluorodeoxyglucose positron emission tomography (PET) scan (**B,** *arrow*).

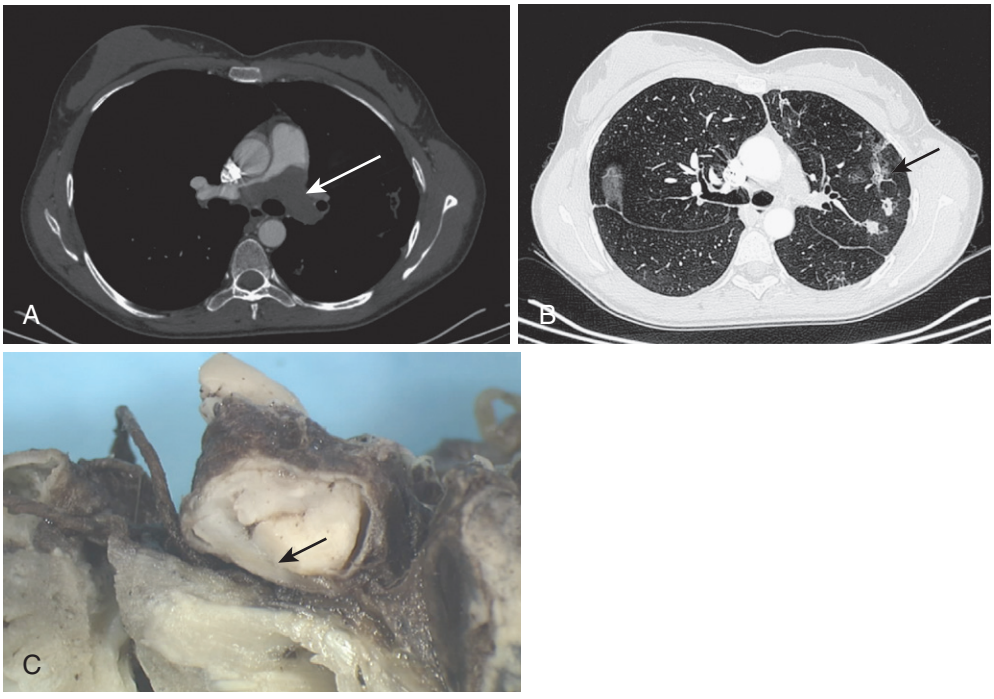

FIGURE 48-5 ■ Pulmonary artery sarcoma. CT scan discloses a mass filling the pulmonary artery lumen (*arrow*) (**A**), associated with peripheral irregular alveolar opacities (*arrow*) (**B**), without pleural contact. **C,** Specimen at pneumonectomy shows the infiltration of the pulmonary artery wall by the tumor (*arrow*).

may show a polypoid filling defect in the pulmonary artery but, contrary to thromboembolic disease, sarcoma forms a contiguously soft, smooth, tapering tissue, with possible extravascular nodular spread in the parenchyma (40% of cases), and localized ground-glass opacities (Fig. 48-5A and B).[108] Sarcoma also presents with a heterogeneous appearance including areas of necrosis and hemorrhage, and with intense hyperactivity on PET scanning.[109] Magnetic resonance imaging (MRI) shows T1-weighted heterogenous enhancement, T2-weighted peripheral enhancement, and increased uptake of gadolinium, signs which are not found in emboli.[109]

Surgery is the only potentially curative treatment and, even if performed in an emergency setting in case of acute right-sided heart failure, allows resectability in 60% to 75% of cases[88–90,92] (see Fig. 48-5C). Alternatively, heart and lung transplantation may be an alternative option for unresectable tumors. A slight improvement of overall

survival has also been reported following adjuvant chemotherapy and/or radiotherapy. Contrary to soft tissue sarcoma, prognosis is mainly related to tumor location, because half of the patients die as a result of the progressive obstruction of the pulmonary trunk.[110] Reoperation is feasible in 30% of cases. However, in recent series, overall median survival is as low as 6 to 12 months.[110]

EHE is a low- to intermediate-grade mixed epithelioid, endothelial, and vascular tumor.[111,112] Lung is the most frequent extrahepatic location (10% of cases), as EHE can also arise from the liver (63% of cases), the bone (8% of cases), and the skin (6% of cases).[113] EHE was initially considered an intravascular and intra-alveolar extension of bronchoalveolar carcinoma, and thus was called "intravascular bronchoalveolar tumor."[111,112] Now, however, it is clearly identified as a mesenchymal tumor, corresponding to low-grade angiosarcoma. EHE is characterized by polypoid nodules, with a central sclerotic paucicellular zone, growing into the alveolar spaces with an angiocentric distribution. Lymphangitic spread may mimic metastatic carcinoma. A recently identified translocation t(1;3)(p36.3;q25) involving the PAX7 gene may be helpful to make the diagnosis.[114]

Clinically, 80% of cases of EHE occur in white females.[113,115] Median age is higher than for other locations and ranges from 35 to 50 years.[115] The tumor is asymptomatic in 50% of cases; when present, symptoms are nonspecific and include pleuritic chest pain, nonproductive cough, dyspnea, and hemoptysis. Physical examination may reveal inspiratory crackles in 30% of cases. By CT imaging, EHE appears either with bilateral slow-growing perivascular multiple nodules, usually located adjacent to small vessels or bronchi, or with predominant infiltrative ground-glass opacities with a micronodular pattern, mimicking carcinomatous lymphangitis. EHE nodules usually range from 3 to 50 mm, and their number varies from 10 to 20 lesions.[113,115] Nodules show increased uptake with PET scanning.[116]

Although there are a few reports of spontaneous remission, the complete resection of all pulmonary nodules is the only curative treatment of EHE.[117,118] Incomplete lung resection, such as by segmentectomy and wedge resection, is associated with a short disease-free interval and poor outcome. Surgery remains effective even in cases of localized recurrence. In contrast, EHE is generally insensitive to chemotherapy or radiotherapy.[118] In most cases, EHE is a slow-growing tumor that rarely metastasizes and is associated with a median survival of 5 to 6 years. Endobronchial spread, pleural effusion, and extended endovascular disease have been identified as unfavorable prognostic factors.[117]

High-grade primary pulmonary vascular sarcomas include epithelioid angiosarcoma and Kaposi's sarcoma. No direct transformation from EHE to angiosarcoma has been so far reported. Clinical features of angiosarcoma are similar to EHE, but massive hemoptysis is more frequent. Radiologic features of angiosarcoma include multiple nodules with a typical surrounding halo of ground-glass attenuation, with a specific "cauliflower-like" appearance on T2-weighted MRI.[119] Management of angiosarcoma is not established: surgical resection is rarely possible owing to local and regional invasion; radiotherapy and chemotherapy are poorly effective, as seen in other localizations of angiosarcoma.

LESSONS LEARNED FOR THE MANAGEMENT OF RARE PRIMARY PULMONARY TUMORS

Specific Radioclinical Presentation

As discussed previously, some clinical and radiologic features, although infrequent, strongly suggest the diagnosis of rare lung tumors, such as the endobronchial "iceberg-like" aspect in carcinoids and mucoepidermoid carcinoma, air bronchograms in MALT lymphoma, or a peripheral "halo" in vascular sarcoma. The absence of tobacco-smoking history, especially in men, is more frequently seen for rare lung tumors than for bronchogenic carcinoma (60% vs. 15%, respectively),[1] as well as a young age at diagnosis, because more than 50% of rare lung tumors occur before the fourth decade. Finally, some rare malignant tumors such as pulmonary sarcoma and MALT lymphoma may also mimic benign lesions, such as pulmonary embolism and recurrent pneumonia, respectively.

Specific Diagnostic Strategy

In addition to the general oncologic workup, which is similar to NSCLC, some rare lung tumors also require specific diagnostic or staging investigations: MRI for vascular sarcomas, bone marrow biopsy for lymphoproliferative disorders, technetium-99m scintigraphy for osteosarcomas, and perhaps ^{111}Indium-octreotide scintigraphy for carcinoid. Preoperative biopsies and intraoperative frozen sections may not be sufficiently representative of the tumor to ensure accurate histopathologic diagnosis, especially in biphasic or composite tumors, for which small-size samples may identify only one cellular component. Rare primary lung tumors that are metastatic at time of diagnosis are usually not resected and may then be misdiagnosed as bronchogenic carcinoma. Sophisticated pathologic studies, including flow cytometry and molecular and cytogenetic analysis, may have a critical role both in diagnosis and in the evaluation of tumor grade.

In many cases, initial surgical resection provides the correct diagnosis and the first step of the therapy of rare lung tumors, even though they are originally considered to be bronchogenic carcinoma. However, preoperative diagnosis remains important for specific subtypes, such as lymphoma, for which extensive resection is ineffective, and for sarcoma, which does not spread to the mediastinal lymph nodes and thus does not require nodal resection.

Distinguishing Primary Tumors from Metastases

In making the diagnosis of a rare primary lung tumor, one must also consider the fact that most lung tumors with

unusual histology represent metastases from extrapulmonary tumors. The main criteria favoring metastases include a prior history of extrathoracic tumor and the finding of multiple pulmonary lesions. PET scanning may also be helpful, assuming that the metabolic features of each rare tumor subtype are sufficiently well-described.[101,120] The primary pulmonary nature of some rare tumors may actually be difficult to establish, either because of early systemic spread, as for EHE which presents with synchronous pulmonary and hepatic lesion in 20% of cases, or because of an ectopic origin, as for melanoma or Hodgkin's disease for which a primary pulmonary origin is highly controversial.

General Therapeutic Management

Finally, three main clinical scenarios may arise in the course of evaluation of patients with rare lung tumors:

1. Surgical resection of a tumor assumed to be NSCLC was complete, and pathologic examination disclosed an unusual histopathologic subtype, such as carcinoid. In this case, no adjuvant therapy is recommended.
2. Specific clinical and radiologic signs led to recognition of a rare tumor, such as lymphoma or pulmonary artery sarcoma, followed by specific diagnostic and therapeutic management.
3. Surgery of a pulmonary mass initially thought to be NSCLC led to recognition of a rare tumor subtype, and therapeutic and prognostic implications are unknown. In those cases, decision of adjuvant treatment is based either on a NSCLC standard of care (e.g., to use radiotherapy in case of incomplete surgical resection) or on therapeutic strategies established for similar tumor subtype in other locations (as it is done for lymphoma and sarcoma).

In the absence of evidence-based recommendations, expert consensus is mandatory for selection of a specific therapeutic strategy. Also, these issues emphasize the need for multicenter collaboration to generate cohorts and to launch observational studies and clinical trials of rare lung tumors.[121]

KEY POINTS

- Rare lung tumors are mainly defined as uncommon lung tumors with unusual histology.
- Diagnosis of rare lung tumors is based on the recognition of specific clinical and radiologic signs, when present, and on the determination of their primary as opposed to metastatic nature.
- The most frequent rare malignant primary lung tumors are carcinoids, mucosa-associated lymphoid tissue lymphoma, and pneumoblastoma.
- Understanding the molecular features of some rare tumors may lead to improved diagnostic techniques (e.g., detection of specific chromosomal translocations in MALT lymphoma or of somatostatin receptors in carcinoid). Moreover, the identification of genes and pathways involved in the carcinogenesis of rare tumors may guide the use of specific targeted therapies.
- Specific therapeutic recommendations are available for carcinoids and large cell neuroendocrine carcinoma. In other cases, expert consensus is mandatory to plan specific therapeutic strategies.

INTRODUCTION

The lung is a common site for metastasis of malignant tumors from other organs. Logic would suggest that the lung is a preferred site because it receives the entire right ventricular cardiac output, and therefore, is the natural destination for malignant cells that gain access to the venous circulation.[1] Indeed, this likely does play a role in the eventual seeding of the lungs when cancers metastasize via the hematogenous route. However, as the understanding of the metastatic process becomes more sophisticated, it is clear that specific properties of the primary tumor and the microenvironment of the tissue of origin and of the lung all play a significant role in directing the process of metastasis to the lung. This notion is not new; Paget[2] initially proposed what became known as the "seed and soil" hypothesis in 1889 based upon his observations of the nonrandom nature of breast cancer metastasis. As a result of advances in science, we can now understand this paradigm on a molecular level.[3] This chapter reviews the epidemiology of lung metastasis, advances in our knowledge of the pathophysiology of metastasis, approaches to help distinguish metastasis from primary lung cancer, advances in diagnostic methods, and a variety of treatment options that vary from palliation to curative surgery.

Epidemiology

Estimates of the incidence of lung metastasis among patients with cancer vary from 20% to 40%.[1,4] The precise incidence of metastasis to the lung from all tumors is difficult to determine from published reports because most series focus on a single tumor type as the origin of lung metastases. The reported incidence also varies depending on the duration and the means used for detection and for follow-up. Published reports on the incidence of lung metastasis in patients with cancer have employed different approaches: surveillance of those with respiratory symptoms, routine surveillance with chest radiographs or with computed tomography (CT) scans, or autopsy data. The reported incidence of lung metastasis increases with each of these means of ascertainment, respectively. Whereas the proportion of cancers reported to metastasize to the lung varies, the lung is always among the most commonly reported sites of metastasis of solid tumors.[4]

Clinical History

Lung nodules arising in the context of an extrapulmonary neoplasm can be either *synchronous* (discovered at the same time as the primary tumor) or *metachronous* (discovered at some period after the initial solid tumor, either incidentally in the course of follow up of a prior

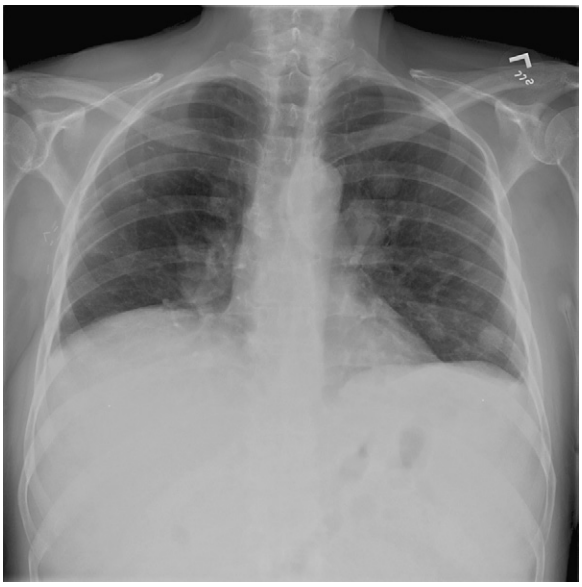

FIGURE 49-1 ■ Plain chest radiograph of a 76-year-old man with a prior history of melanoma who presented only with fatigue and dry cough. Multiple large bilateral lung nodules and masses were present that proved to be metastases.

malignancy or in the context of new pulmonary symptoms). Because of the large degree of reserve pulmonary function in most individuals, hematogenous metastases to the lungs rarely produce symptoms, and even patients with a large metastatic tumor burden can present with minimal or no pulmonary symptoms (Fig. 49-1). Nonspecific symptoms of cough, dyspnea, chest pain or chest discomfort can result from a very large tumor burden, extensive lymphatic infiltration, or the presence of a large pleural effusion. The first clue to the presence of lung metastasis comes most commonly from surveillance radiographs in patients with known prior cancer, in which the most common presentation is multiple nodules in the lower lobe. Occasionally, an incidental solitary pulmonary nodule is the first sign of metastatic cancer from a distant organ, making the distinction of metastasis from that of a primary lung tumor challenging. The physical examination is unlikely to disclose evidence of lung metastasis but, in the context of a solitary pulmonary nodule, the examination should include a search for malignancy elsewhere in the body (e.g., breast or abdominal masses or enlarged lymph nodes). Rarely, a metastasis can affect the airway producing localized wheezing, which an astute clinician discovers on auscultation. Malignant pleural fluid accumulation produces the physical findings of reduced breath sounds, a dull percussion note, and decreased tactile fremitus. These findings should prompt evaluation for a pleural effusion with decubitus chest radiographs and, if needed, thoracentesis with or without ultrasound guidance. Management of malignant pleural effusions is discussed in Chapters 73 and 75.

MECHANISM OF METASTASIS TO THE LUNG

When one considers that the lung receives the entire cardiac output, it is perhaps surprising that lung metastases are not even more common among patients with cancer. However, research has shown that the majority of cancer cells that gain access to the circulation never result in a clinically overt metastatic focus,[5,6] suggesting that mere access to the lung is not sufficient. Additional mechanisms must, therefore, account for the propensity of certain tumors to seed distant organs preferentially in a clinically detectable fashion. Following are examples of recent advances that help clarify our understanding of the molecular and cellular biology of organ-specific metastasis.

Chemokines are a group of small cytokines originally discovered as mediators of leukocyte trafficking. Research now shows that chemokines mediate several important pathologic aspects of tumor biology, including angiogenesis, cell proliferation, invasion, and metastasis.[7] The pattern of constitutive expression of chemokine receptors on cancer cells combined with expression of the corresponding chemokine ligands in various organs may be responsible for the organ-specific pattern of metastasis of a variety of solid tumor types, including breast, prostate, and lung cancer.[8-10] In an important study, the chemokine receptors CXCR4 and CCR7 were found to be highly expressed in human breast cancer cell lines, in primary breast tumor samples, and in their metastases whereas the corresponding ligands CXCL12 and CCL21 were constitutively expressed in organs to which these tumors commonly metastasize (lung, brain, bone, and lymph nodes).[10] In the breast cancer cell lines, signaling through the receptors CXCR4 or CCR7 was shown to promote in vitro migration and invasion. Most interestingly, antibodies or small molecule antagonists directed against CXCR4 significantly impaired metastasis of breast cancer cells to the regional lymph nodes and lung *in vivo*. In another study, malignant melanoma, which has a metastatic pattern similar to that of breast cancer but also has a high incidence of skin metastases, showed high expression of the chemokine receptor CCR10 in addition to CXCR4 and CCR7. The ligand for CCR10 (cutaneous T-cell attracting chemokine, or CTACK/CCL27) is highly expressed in normal dermis, which may explain the frequent metastatic spread of melanoma to the skin.[11] In a study of lung cancer metastasis, cells from metastases were found to be enriched for the expression of CXCR4 compared with cells from the primary tumors, suggesting that CXCR4-expressing cells enjoyed an advantage in the metastatic niche.[9] Chemokine receptors on cancer cells in concert with tissue-specific expression of their chemokine ligands appear to have a critical role in determining the metastatic destination of circulating tumor cells.

Recent insight into another mechanism by which cancer cells target the lung comes from elegant studies showing that transforming growth factor-β (TGF-β), a cytokine present in the local breast tumor microenviron-

ment, primes breast cancer cells for lung-specific metastasis by up-regulation of the gene angiopoietin-like 4 (*ANGPTL4*).[12] TGF-β induction of *ANGPTL4* in breast cancer cells enhanced their subsequent retention in the lungs but not in bone. The tumor cell–derived protein, Angptl4, disrupted the pulmonary microvascular cell-cell junctions, increasing the permeability of lung capillaries and facilitating the passage of tumor cells into the lung parenchyma. In contrast, in the bone marrow sinusoids that are normally more leaky microvascular beds, this mechanism did not confer an advantage.[12] Such advances in the knowledge of molecular mechanisms that promote or facilitate organ-specific metastasis should lead to new treatments to prevent, reduce, or treat established lung metastasis and could have a significant impact on cancer mortality.

DIAGNOSIS

Differential Diagnosis

Given the range of diagnostic and therapeutic options in cases of known or suspected lung metastasis, patient care is optimal when delivered within the context of a multidisciplinary team. A pulmonologist deciding whether to biopsy a lung nodule in a patient with a prior history of cancer should speak to the oncologist and/or the surgeon to know whether metastatic cancer would have therapeutic options or whether the results of a biopsy would alter those options. If a patient with suspected metastasis is otherwise a surgical candidate, a preoperative tissue diagnosis may not change the ultimate management, as is discussed later. Conversely, surgeons may prefer a preoperative tissue diagnosis to improve their discussion of risks, benefits, and alternatives with the patient. For these and other reasons, the management of these patients is best served when clinicians can communicate patient-specific concerns to one another. Multidisciplinary conferences and shared clinical space can facilitate these important discussions.

The patient with a prior history of cancer and suspicion of a lung metastasis should be managed with knowledge of several interacting factors: the type of prior cancer, its natural history, its propensity to cause lung metastasis, its sensitivity to chemotherapy or radiation therapy, and the number and location of lung nodules. A decision to biopsy should take into account the likelihood of an alternative diagnosis and whether the results of the biopsy will change the management options.

The diagnostic possibilities for a single lung nodule or multiple nodules in the patient with a history of cancer vary with the type of prior cancer. For example, the implications of finding a cavitary nodule in a patient with prior leukemia after a bone marrow transplant are quite different from those of finding a cavitary nodule in an individual with prior head and neck cancer. In general, the differential diagnosis of a lung nodule in a patient with prior cancer includes the same diagnoses found in the general population, with the noted exception that metastatic disease must be considered as well. Both primary malignant and benign causes, including infectious and noninfectious etiologies, should be considered (Table 49-1).

Distinguishing Metastases from Primary Lung Tumors

When a nodule or nodules are discovered in a patient with a prior history of cancer, it is important to distinguish lung metastasis from a primary lung cancer because the treatment can be very different. Clues such as the type of prior cancer, radiologic characteristics of the nodule, and the pathologic appearance of subsequent biopsy material can be used to guide treatment decisions. Multiple pulmonary nodules with smooth borders located in the lower (dependent) lobes are most likely to be metastatic, based on clinical grounds alone. When a single nodule is the only evidence of metastasis, recognizing it as metastatic can be more difficult. In some instances, the type of prior cancer can provide a clue to the likelihood of a metastasis versus a primary lung cancer. In a retrospective study of patients with single pulmonary nodules and a prior history of cancer, multiple factors were examined as possible predictors for metastasis including the histologic characteristics of the original extrapulmonary neoplasm, patient age, and smoking history.[13] Of 161 patients with solitary pulmonary nodules, 81 (50%) were determined to have a primary lung cancer; this outcome was more common in patients with a prior history of cancer of the head and neck, bladder, breast, cervix, bile ducts, esophagus, ovary, prostate, or stomach. Fifty patients (31%) were determined to have metastasis, a finding more common in patients with salivary, thyroid, and adrenal tumors, melanoma, and sarcoma. Primary lung cancer or metastases were equally likely in patients with prior cancer of the colon, kidney, or uterus. In those with prior

lymphoma or leukemia, there was a high proportion of patients with a benign diagnosis (6 of 14), perhaps reflecting the predilection of these patients for granulomatous infections.[13] In total, 30 of 161 patients (19%) had nodules of a benign nature. The large percentage of benign diagnoses in this study by Quint and coworkers[13] (1994–1999) contrasts with a larger but much earlier study by Cahan and colleagues[14] (1940–1975) in which only 11 of 800 patients (1.3%) proved to have a benign diagnosis. The higher incidence of benign disease in the later study may be explained by two factors: the greater use of CT scanning and thus the higher rate of detection of nodules in the later study and the fact that the earlier study was a surgical series in which patients with a high pretest probability of benign disease may have been excluded. A consistent finding in these two studies representing nearly 40 total years from two large centers was the high proportion of patients with head and neck squamous or esophageal cancers who subsequently developed a *primary* lung cancer. Of course, common risk factors exist for patients with these types of cancer, and the presence of a smoking history increases the likelihood that a solitary lung nodule in someone with a prior nonpulmonary neoplasm will prove to be a lung cancer. By understanding the data in these and other studies, clinicians can more accurately estimate the likelihood that a pulmonary nodule is metastatic, primary, or benign.

Pathology

When biopsy tissue from the prior cancer and the lung nodule are both available, the pathologist's evaluation of the metastatic nodule begins with a knowledge of the prior cancer, its stage and grade (if applicable), and the pretest likelihood of lung metastasis from a tumor with such characteristics. The gross and microscopic pattern of the possible metastasis may be sufficiently similar to the original primary tumor that the diagnosis is rendered easily. Owing to overlapping histologic features, however, it may be impossible for pathologists to distinguish primary from metastatic carcinoma.[15] In many situations, the appearance of an adenocarcinoma is not sufficiently distinctive to permit a differentiation between metastasis and primary lung cancer, and immunohistochemical stains are used to help guide the diagnosis (Table 49-2). Lung adenocarcinoma can be identified by specific immunohistochemical markers including cytokeratin-7, thyroid transcription factor-1 (TTF-1), and the surfactant proteins A and B (SP-A, SP-B).[15] For example, cytokeratin-7 can be useful for distinguishing adenocarcinoma of the lung from colon cancer metastasis, with cytokeratin-7 favoring lung, and cytokeratin-20 favoring a colon primary.[15] TTF-1, a nuclear transcription protein expressed in embryonic and adult epithelial cells of the lung and thyroid,[16] is detected in 75% of lung adenocarcinomas but rarely detected in other adenocarcinomas that commonly metastasize to the lungs, except for thyroid cancer.[16] Markers specific for other tumors can also be used to identify lesions as metastatic; for example, breast cancers that metastasize to the lung can maintain their original pattern of staining for estrogen receptor or Her-2/Neu and staining of the lung nodule can identify it as a metastasis. Thus, in instances in which the primary tumor stains for specific markers, these stains can be useful for identifying a lesion as a metastasis.

TABLE 49-2. Immunohistochemical Stains Useful for Distinguishing Lung Cancer from Metastatic Cancer from a Nonpulmonary Origin

Cancer	Positive Markers	Negative Markers
Lung	CK7, TTF-1, SP-A, SP-B	CK20
Colon	CK20	TTF-1
Breast	ER, PR, Her2/Neu	TTF-1
Prostate	PSA, prostatic acid phosphatase	TTF-1
Melanoma	HMB45, S100, tyrosine hydroxylase	Cytokeratin
Thyroid	TTF-1, thyroglobulin	
Germ cell	Alpha-fetoprotein	

CK, cytokeratin; ER, estrogen receptor; PR, progesterone receptor; PSA, prostate specific antigen; SP, surfactant protein; TTF, thyroid transcription factor.

Molecular Classification

With the advent of gene expression arrays and, in the future, proteomic classification of tumors, molecular classification is an emerging tool to assist in determining whether a lung nodule is primary or metastatic. Giordano and colleagues[17] attempted to develop a molecular classification scheme to discriminate adenocarcinomas of the lung, colon, and ovary. They identified three groups of 20 differentially expressed genes that correctly identified the origins of all but 2 of 154 tumors.[17] Other groups of investigators have proposed classifiers for a broader representation of tumors in an effort to identify the primary tissue of origin of carcinomas of unknown primary. Tothill and associates[18] developed and validated a gene array-based classifier on a training set of 229 samples of known origin. This gene classifier was then able to assign a "tissue of origin" in 9 of 11 cases of carcinoma of unknown primary.[18] The two tumors that the gene classifier failed to classify were actually not adenocarcinoma, but squamous carcinomas. Subsequent review of the clinical course of the patients supported the assessment of the gene classifier.[18] Another study attempted to generate a gene expression-based classifier to distinguish metastases of head and neck squamous carcinoma from primary lung squamous carcinoma, a clinically difficult task because of both the histologic similarity and the shared risks for these squamous cancers. This study identified 10 genes whose expression was able to discriminate between tumors of lung and upper aerodigestive origin with high accuracy in both training and validation samples.[19] Certainly, molecular techniques will provide new ways of classifying tumors and, in so doing, improve the ability to identify

the origin of a lung nodule. When the prior tissue is available for comparison, molecular testing may also assist identification of the new nodule as either a metastasis related to the prior cancer or a new and different cancer.

Options for Obtaining a Tissue Diagnosis

A biopsy may not be necessary when a patient with a history of prior cancer presents with nodules with highly typical characteristics: (1) history of a cancer likely to metastasize to the lungs with (2) multiple, (3) new (or growing), (4) lower lobe pulmonary nodules with (5) smooth borders. A less common situation in which biopsy *may* be unnecessary is the patient whose prior cancer is associated with measurable serum markers (CA19-9, CA125, carcinoembryonic antigen [CEA], alpha-fetoprotein, β-human chorionic gonadotropin, CYFRA21-1). In such a patient, the presence of a rising level of tumor-associated markers may confirm the diagnosis of metastatic disease and preclude the need for a biopsy. However, for most tumors other than those of germ cell origin, these epithelial markers are not sufficiently specific and a biopsy is warranted to guide therapy. In all cases, before performing a lung biopsy, it is important to search for evidence of metastasis to other sites where a less invasive biopsy may yield the diagnosis. This should begin with a thorough physical examination directed to finding any enlarged lymph nodes, skeletal tenderness, or hepatomegaly that would guide the next imaging study or tissue sampling.

Tissue sampling in older series is generally derived from surgical material, and indeed surgical resection remains the "gold standard" owing to the quantity of material available for gross and microscopic examination, as well as special immunochemical stains or molecular analyses.[14] In addition, surgery may be the appropriate definitive therapy for patients with lung metastases from solid tumors. However, there are now multiple options other than surgery, each with strengths and drawbacks that can be weighed to develop an approach that allows a clinician to determine the best balance between certainty, risk, and cost. The diagnostic options including fiberoptic bronchoscopy, percutaneous CT-guided biopsy, and surgical resection are discussed later, with each successive option associated with increased accuracy (sensitivity and negative predictive value) but also with increased risk and cost.

Bronchoscopy

Fiberoptic bronchoscopy is particularly useful for accessing centrally located lesions and mediastinal lymph nodes. Transbronchial needle aspiration of enlarged mediastinal lymph nodes is safe and has a reasonable diagnostic accuracy in cases of malignant mediastinal lymph node metastasis (see Chapter 22). The addition of real-time linear probe endobronchial ultrasound increases sensitivity and permits the biopsy of much smaller lymph nodes in both the mediastinum and the hilar lymph node stations (see Chapter 20). The accuracy of bronchoscopy for lung parenchymal lesions declines rapidly as the distance from the main-stem bronchi increases, so that traditional transbronchial sampling techniques have less than 20% sensitivity for peripheral lung nodules.[20] More recently, a newer technique employing three-dimensional CT reconstruction combined with electromagnetic navigation of an extended working channel has allowed biopsy of small peripheral lung nodules with significantly greater accuracy. Experienced users of this newer approach report a 69% to 80% sensitivity for the diagnosis of small peripheral lung nodules (as small as 7 mm, ranging up to 8 cm, with an average size < 2 cm).[21,22] Combining this technique with real-time imaging using a radial probe ultrasound catheter to confirm the location suggested by virtual images further increased the accuracy of transbronchial biopsy to 88% in one series[23] (Fig. 49-2). Using bronchoscopy, multiple samples can be taken from one area or from multiple different nodules in a single procedure without an appreciable increase in the risk for pneumothorax. Given the low risk of pneumothorax (1%-5%) and major bleeding, the chief risk of the bronchoscopic biopsy, even when combined with electromagnetic navigation and real-time radial-probe ultrasound, is that of a false-negative biopsy.

CT-Guided Biopsy

Clinicians' experience in CT-guided biopsy is becoming widespread and, as experience has increased, the accuracy of this biopsy technique has improved significantly.[24] This approach has greater sensitivity than bronchoscopy, particularly for peripheral lesions. The sensitivity of CT-guided biopsy of lung nodules varies with the size of the lesion, with a 65% to 75% accuracy for smaller lesions (<1 cm diameter), and a greater than 95% sensitivity for lesions larger than 1.5 cm in diameter.[24,25] Larger size of the nodule and a more peripheral location are factors associated with greater diagnostic accuracy.[26] Core biopsies, in addition to or instead of cytologic material, can be obtained with larger 19-gauge needles. The major risk of CT-guided transthoracic needle biopsy is pneumothorax, with up to 35% of patients developing pneumothorax, and 10% to 15% requiring tube thoracostomy or catheter drainage.[27] The risk of pneumothorax appears to increase with the length of the needle tract, as well as the presence of obstructive lung disease.[26] In one large retrospective series,[27] severe complications of CT-guided biopsy were quite rare; of 6881 cases, 74 patients were reported with severe complications including 6 patients with air embolism, 10 with tension pneumothorax, 6 with severe pulmonary hemorrhage, 9 with hemothorax, and 6 with seeding of the needle tract. Eight deaths were reported. In general, CT-guided biopsies are safe and accurate, especially for peripheral lesions.

Surgery

Resection of a nodule provides the greatest sensitivity in determining the nature of the lesion(s) and makes it possible to diagnose and occasionally to treat the lesions

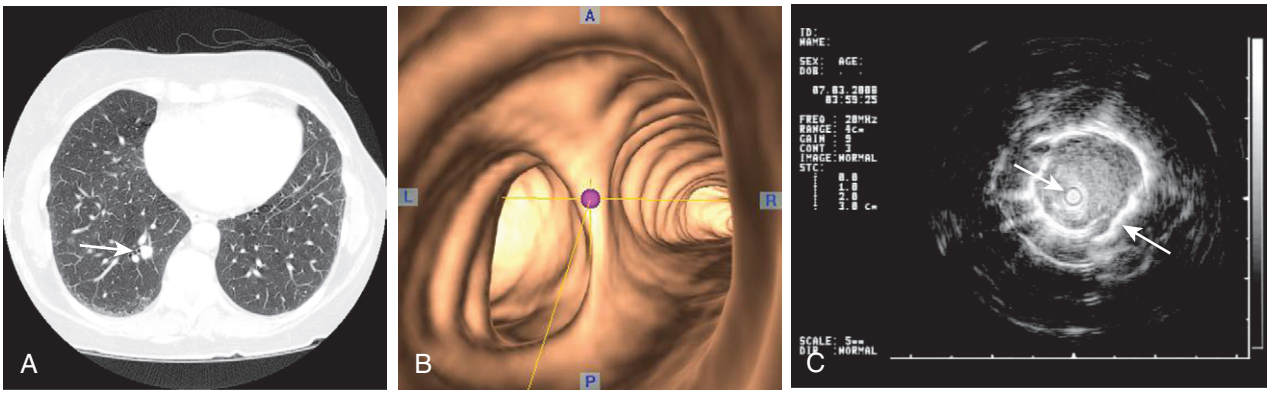

FIGURE 49-2 ■ **A,** Computed tomography (CT) scan of a 53-year-old woman with a newly discovered right lower lobe nodule (*arrow*) 12 years after lumpectomy and adjuvant chemotherapy and radiation for breast cancer. **B,** Virtual bronchoscopic image generated with software for electromagnetic navigation. Fiducial registration points using recognizable airway landmarks are created (*purple dot*) and the nodule is located with planning software. The fiducial points are then registered (touched) during the procedure using a steerable probe, the location of which is sensed within a field generated by the location processor under the patient's thorax, a process that matches the patient's anatomy with the virtual CT images. The navigation of an extended working channel is guided by the virtual CT image during the procedure using the steerable probe. **C,** Real-time radial probe ultrasound image of the nodule, obtained by passing the ultrasound probe through the extended working channel. The probe is seen at the center of the photograph (*upper left arrow*), and the edge of the nodule is indicated by the echogenic border between the solid nodule and the air-filled lung surrounding it (*lower right arrow*). This image is used to confirm the location of the extended working channel within the nodule. The probe is removed, and biopsy tools are then passed through the extended working channel to sample tissue. Transbronchial biopsy in this patient confirmed a diagnosis of metastatic breast cancer.

definitively in a single procedure. The selection of patients in whom nodule resection is appropriate is a matter of controversy. There are few, if any, randomized studies comparing surgical and nonsurgical treatment of lung metastasis and the data from reported series on surgical treatment of lung metastases suffer from a lack of uniformity in selection criteria. The sensitivity of surgery for diagnosis is likely close to 100% given that it is the accepted gold standard for tissue diagnosis of lung lesions. However, very small lung lesions can be difficult for the surgeon to palpate and may be missed. The risks of surgery for diagnosis include those for general anesthesia in addition to the risks associated with lung resection. Thoracoscopic surgery is also discussed later as a treatment and may be the preferred option when surgery is required for diagnosis.

TREATMENT OF LUNG METASTASES

Multimodality Therapy of Systemic Disease

Treatment for lung metastasis is largely dictated by the tissue of origin (Fig. 49-3). In cases of curable cancers, patients with lung metastases should be treated aggressively with multimodal therapy appropriate for the original tumor. Germ cell tumors, neuroblastoma, gestational trophoblastic tumors, lymphoma, and osteosarcoma are included in this category. In certain cases, residual nodules persist following chemotherapy and can then be resected. In patients with nonseminomatous germ cell tumors, resection of residual nodules or masses after systemic chemotherapy is an aggressive but appropriate approach. In cases of testicular cancer, such residual masses after chemotherapy remain in approximately 40% of patients who have advanced disease and negative serum tumor markers at the conclusion of treatment.[28,29] When resected, approximately half of these masses contain only necrotic tissue, a further 25% show a mature teratoma, and the rest contain residual carcinoma. Long-term follow-up studies after chemotherapy suggest that most patients (90%) with metastases from testicular cancer found to have mature teratoma on resection and even 50% of those with residual carcinoma are cured by "adjuvant" surgery.[28,29] In other tumors, treatment options are mainly nonsurgical. For patients with lymphoma, for example, in whom treatment alternatives are more numerous and systemic therapy is necessary, biopsy rather than excision is more appropriate. These varied treatment options highlight the importance of undertaking the care of these patients with multidisciplinary input.

Palliative Care

Unfortunately, most adult patients with pulmonary metastases from solid tumors have incurable disease, and palliative therapy is often necessary. For selected cancers, palliative treatment may include radiotherapy, chemotherapy, hormonal, or biologic/targeted therapies. Agents chosen for palliative therapy should balance acceptable levels of toxicity with the expected degree of tumor response and symptom control. Radiation therapy for patients with radiosensitive tumors can provide rapid and effective symptom relief. For patients

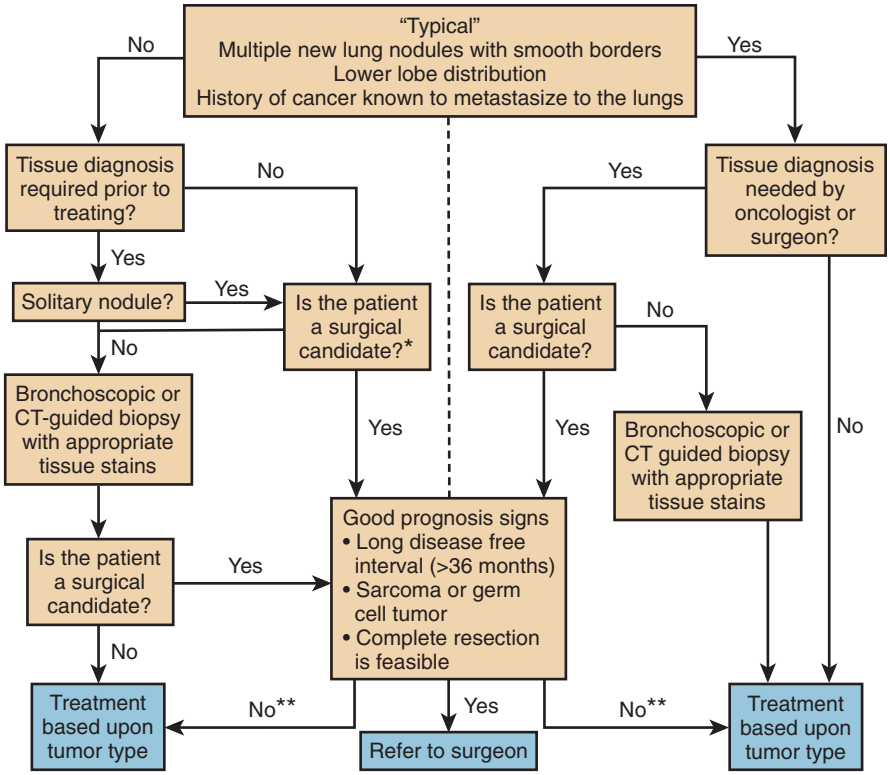

FIGURE 49-3 ■ Suggested management algorithm for patients with known prior cancer and new lung nodule(s). A suggested management algorithm taking into account the typical or atypical appearance of a lung nodule(s) in a patient with prior known cancer, the utility of a tissue diagnosis to the treating physicians, the physiologic fitness of the patient for surgery, and the known prognostic indicators for a favorable outcome after metastasectomy. Each patient should be managed individually, within the context of the skills and experience of local providers with the varied diagnostic and therapeutic options. *Patients at high risk for primary lung cancer should be managed with this possibility in mind, including diagnostic lobectomy when appropriate. **These are suggested criteria for surgical resection of lung metastases, and multidisciplinary teams should make this decision. Radiofrequency ablation (RFA) may be an excellent choice for these patients as well.

with endobronchial obstruction, endobronchial tumor ablation using brachytherapy, laser, or cryoprobes can be very effective for palliation (see Chapter 22). These approaches require specialized training, and referral to a center with experience in such techniques is advisable. Because most centers may specialize only in one, or at most two, of these interventional methods, direct comparisons of the efficacy and safety of palliative interventions for malignant airway obstruction have not been reported. Opiates and oxygen therapy may relieve symptoms of end-stage dyspnea. Social, emotional, and physical rehabilitation support as well as hospice services have important roles in the care of such patients.

Radiofrequency Ablation of Metastases

Thermal ablation is a minimally invasive therapy that can be used for local cure or control of either primary or metastatic lung tumors. Radiofrequency ablation (RFA) which uses radiofrequency energy to generate frictional heating and cell death, is the most commonly performed thermal ablation procedure used to treat lung tumors. Although the role of RFA is not as clearly defined as other options, studies supporting use of this procedure for lung metastases are mounting and the role for RFA in treating lung metastasis is emerging. Although RFA is more commonly performed to treat hepatic and renal tumors, it may be well suited to the lung owing to its ability to concentrate thermal energy focally within tumor tissue with little or no energy spreading to the adjacent aerated normal lung parenchyma.[30]

Smaller tumors, 3 cm or less in diameter, may be more effectively treated with RFA than larger tumors.[31,32] Peripheral tumors surrounded by lung parenchyma and away from hilar structures can be safely treated with RFA.[33,34] Even tumors contiguous with certain vital structures, such as the thoracic aorta and pulmonary vessels, may be safely treated, according to recent reports,[35] because the cooling effect of constant blood flow in large vessels may protect them from tissue damage. Multiple lesions in the same hemithorax can be treated at one sitting by experienced providers, but because of the risk of pneumothorax (as high as 50% in one series[36]), bilateral lesions should not be treated during the same procedure.

Surgical Resection of Metastases

Surgical resection of pulmonary metastases may be the appropriate choice in certain situations. As resection has become more common, factors associated with good outcome have been identified. In general, a complete resection of all metastases is vital to improved survival. Incomplete resection is associated with dismal survival rates that do not differ from those with no treatment at all. Another important good prognostic factor in numerous large series is a long disease-free interval (DFI) between the initial diagnosis of cancer and the discovery of lung metastasis.[37-39] For example, 5-year survival was 33% when the DFI was 0 to 11 months compared with 45% when the DFI was more than 36 months.[40,41] The number of pulmonary metastases was previously

believed to be a prognostic factor, but this has not been a consistent finding. More prognostic factors must be identified to improve selection of patients for metastasectomy. Suggested selection criteria for pulmonary metastasectomy, taken from various large series,[39,42] are shown in Table 49-3. Selection of patients for pulmonary metastasectomy according to these criteria provides the best survival.[39]

In 1991, the International Registry of Lung Metastases (IRLM; comprising over 5000 cases) was established to record and report upon the long-term results of pulmonary metastasectomy for various primary malignancies.[42] According to the registry, long-term success of pulmonary metastasectomy varies according to the primary malignancy. Cancers that metastasize exclusively to the lungs have more favorable outcomes from pulmonary metastasectomy than cancers that metastasize more widely. Malignancies with the greatest long-term survival after pulmonary metastasectomy include osteogenic and soft tissue sarcoma, colorectal cancer, uterine/cervical tumors, head and neck cancer, breast cancer, testicular tumors, renal cell tumors, and melanoma (Table 49-4). Patients undergoing lung metastasectomy for osteosarcoma have some of the best results, but success is not limited to this type of metastasis.[42]

Surgical resection of pulmonary metastases requires careful planning and preparation. As with any lung resection, the number, location, and size of the lesion(s), pulmonary function, and the general condition of the patient must be considered, as must any evidence for local invasion or the prospects for response to systemic therapy. CT has the greatest sensitivity and accuracy for localizing pulmonary nodules for resection. Small nodules can be localized using image-guided wires, dyes, and coils as well as ultrasound and radiation probes. An emerging strategy is the use of electromagnetic guidance navigation followed by dye marking to assist in localizing small peripheral lung nodules prior to thoracoscopic resection[43] (Fig. 49-4). In tumors that can be detected with fluorodeoxyglucose–positron emission

TABLE 49-3. Criteria for Pulmonary Metastasectomy[39]

ABSOLUTE CRITERIA

1. The patient is a good candidate for surgery.
2. The primary tumor is controlled.
3. No extrapulmonary metastases exist or, if present, they must be controllable by surgery or another treatment.
4. Pulmonary metastases are completely resectable.

RELATIVE CRITERIA

1. Pulmonary metastases are symptomatic (e.g., causing pneumothorax, hemoptysis).
2. Surgery is necessary to differentiate metastasis from primary lung cancer.

TABLE 49-4. Tumor-Specific 5-Year Survival Rates following Pulmonary Metastasectomy

Primary Malignancy	5-Year Survival (%)
Soft tissue sarcoma[51–53]	20–35
Osteosarcoma[54]	25–50
Melanoma[55,56]	5–33
Colorectal[57,58]	13–40
Testis (germ cell)[28,59]	50–80
Renal[60,61]	15–20
Breast[38,62,63]	25–50
Head and neck[64,65]	26–30

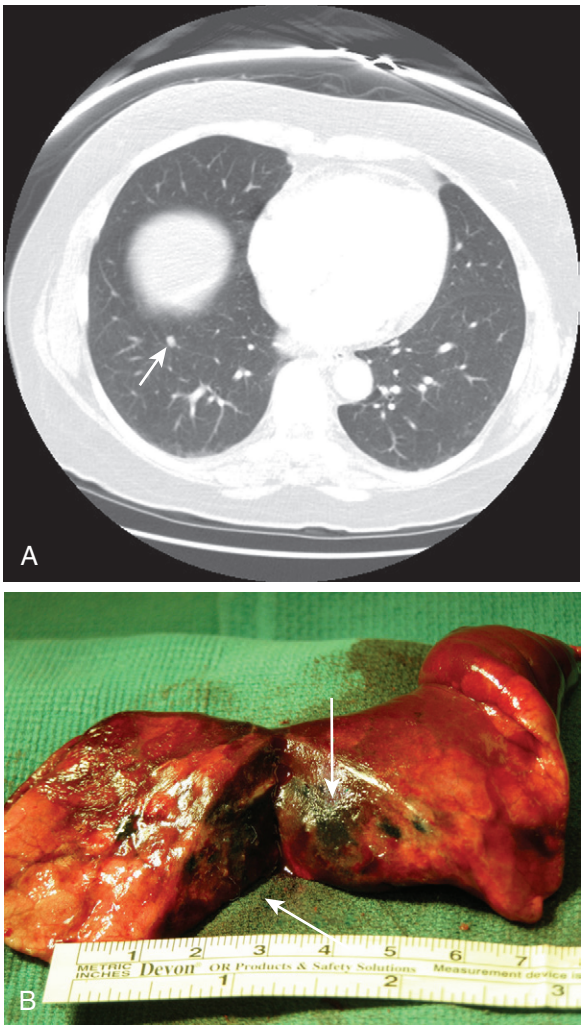

FIGURE 49-4 ■ **A,** Right lower lobe lung nodule (*arrow*) that appeared, then increased on follow-up serial CT scans in a 53-year-old woman with a history of rectal cancer. The nodule was localized using electromagnetic navigation, and the overlying pleura was tattooed with indigo carmine dye. She was then taken to the operating room where she underwent a thoracoscopic wedge resection of the tattooed pleura and underlying parenchyma. **B,** Gross specimen resected by the surgeon after thoracoscopic visualization of the ink on the diaphragmatic surface of the pleura (*lower arrow*) and the intraparenchymal nodule (*upper arrow*), found on pathologic examination to be a metastatic colorectal adenocarcinoma.

tomography (FDG-PET) scanning, it should be performed prior to pulmonary metastasectomy to exclude the presence of synchronous extrathoracic metastasis that would negate the benefit of lung resection. FDG-PET uptake or lymph node enlargement seen on CT can also suggest less invasive biopsy techniques such as mediastinoscopy, transthoracic needle biopsy, and transbronchial needle biopsy (with or without endobronchial ultrasound). With the exception of certain germ cell tumors and perhaps sarcomas,[43a] finding synchronous metastasis outside the lung would be a contraindication to pulmonary metastasectomy.

Thoracotomy has been the most frequently utilized approach for unilateral metastasectomy, primarily because it enables the surgeon to palpate the lung for lesions. Thoracoscopic pulmonary metastasectomy has been criticized based upon its limited ability to permit palpation of the lungs to identify unknown metastases. However, as the resolution of CT scanning improves, especially with multidetector scanners, the likelihood of pulmonary nodules that can be palpated but not visualized on CT scan decreases dramatically, thus improving the relative utility of a thoracoscopic approach for metastasectomy. In addition, instruments and techniques have evolved to allow enhanced visualization and even thoracoscopic palpation of lung parenchyma. Compared with thoracotomy, thoracoscopic metastasectomy has several advantages including smaller incisions, less pain, earlier recovery, and fewer postoperative adhesions. The latter is especially important because repeat pulmonary metastasectomy may be indicated based on the same criteria as the initial metastasectomy.[41,42] Indeed, more than 50% of patients who undergo complete pulmonary metastasectomy will develop recurrence. The probability of relapse is higher for sarcoma and melanoma than for epithelial or germ cell tumors. In the International Registry, repeat metastasectomy yielded 44% survival at 5 years and 29% at 10 years,[42] which is comparable with the results after initial metastasectomy. Thus, thoracotomy or thoracoscopy may be selected based on several criteria, including the surgeon's experience, and the possible need for repeat metastasectomy.[44]

Prior to any resection, all lung lesions should be identified in order to plan a resection that minimizes the loss of lung parenchyma. The extent of pulmonary resection is an important consideration. Registry data reveal that metastasectomy was achieved by wedge resections in 67%, segmentectomy in 9%, and lobectomy or bilobectomy in 21%.[42] Lymph node dissection is not encouraged owing to the low incidence of nodal involvement with pulmonary metastasis, associated morbidity, and the poor survival of patients with nodal metastasis regardless of resection. Pneumonectomy or extended resection was rarely used (3%) and should be reserved for special circumstances with acceptable surgical risk and reasonable likelihood of long-term survival.[42]

The morbidity and mortality for pulmonary metastasectomy should be very low. Most series report less than 2% mortality and 10% morbidity.[42] The most common complications are persistent air leak and infection. Preoperative chemotherapy or radiation may increase the risk of respiratory failure after metastasectomy when high fractional concentrations of oxygen are used perioperatively.[29] Anesthesiologists should be alerted to a history of chest irradiation or chemotherapy (particularly with bleomycin used for germ cell tumors) and use the lowest possible fractions of inspired oxygen possible for these patients. With appropriate patient selection, the survival following pulmonary metastasectomy can be quite good. The decision to operate should be influenced less by the type of prior cancer than on the eligibility criteria described in Table 49-3.

Most reports regarding the effectiveness of pulmonary metastasectomy have been retrospective. These nonrandomized and uncontrolled series introduce selection and lead-time bias that must be kept in mind when considering treatment options. Reported survival rates of 30% to 40% at 5 years are encouraging, but the selection criteria used for surgical resection, as well as the nonrandomized nature of these studies, must be taken into consideration. Additional studies are needed to define candidates that will receive maximum benefit from pulmonary metastasectomy.

SPECIAL CASES

Airway Metastasis

Although rare, large airway involvement with endobronchial metastasis can produce very distressing symptoms of dyspnea and/or hemoptysis. Awareness of the clinical scenario along with available diagnostic and management strategies can be very helpful in palliating these patients. Reported series of patients with endobronchial metastasis are generally small but uniformly emphasize the utility of fiberoptic bronchoscopy for diagnosis as well as for symptom control and palliation. Other than lung cancer, tumors that metastasize to the bronchi include colon, breast, renal cell carcinoma, melanoma, and many others.[45–47] Breast and colon cancers predominate in reported case series of endobronchial metastases, perhaps because they are more prevalent in the population of cancer patients in general. It should be noted that colon cancer can metastasize to the bronchi without involvement of the liver.[46] Radiation can be used for palliation in patients with malignant airway obstruction and radiosensitive tumors. Mechanical means including stents and endobronchial ablative methods (laser, cryoprobe, argon plasma coagulation, or physical débridement) can be used for tumors that are relatively radioresistant (see Chapter 22).

Vascular Embolic Metastasis

A rare but dramatic presentation of lung metastasis is tumor embolism. When clinically evident, the symptoms are those of "subacute cor pulmonale" with dyspnea, edema, elevated jugular venous pressure, and auscultatory evidence of pulmonary hypertension and right ventricular failure. Premortem diagnosis is difficult unless clinical suspicion is high. Tumor emboli have been

reported as the initial presentation of extrapulmonary cancer or as a postmortem finding in those with no premortem respiratory symptoms.[48] In a series of 214 autopsies, 89 had evidence of tumor emboli, and only 50 of these had clinical records indicating the presence of respiratory symptoms prior to death.[49] Tumors arising from the breast, liver, and pancreas accounted for more than 50% of the cases, but many tumor types were represented among this series.[48] When tumor embolism is suspected, cytologic examination of pulmonary capillary blood obtained via a wedged pulmonary arterial catheter is a possible diagnostic method.[50]

KEY POINTS

- Lung metastases are common and arise from most types of solid tumors.
- A pulmonary nodule in a patient with prior cancer can be a metastasis or a primary lung cancer; the likelihood of metastasis will vary with the original type of cancer and lung cancer risk factors.
- When clinical and/or histologic evaluation cannot distinguish primary lung cancer from metastasis, immunohistochemistry for tumor-specific markers can be useful. Future options will likely include molecular phenotyping.
- The choice of diagnostic method will be determined by the patient's clinical status, the natural history of the prior cancer, the availability of specialized diagnostic methods, and the need, or lack thereof, for a diagnosis prior to offering therapy.
- Radiofrequency ablation is a potential therapeutic option for local control when the patient is not a surgical candidate.
- Surgery for both diagnosis and treatment is appropriate for selected patients. The most important predictor of successful treatment is the ability to achieve complete metastasectomy of all visible and palpable lung nodules.

CHAPTER 50

BENIGN LUNG TUMORS

Jeffrey L. Myers, MD • Thomas J. Giordano, MD, PhD

INTRODUCTION
Clinical Manifestations
BENIGN EPITHELIAL TUMORS
Papillomas and Adenomas
Micronodular Pneumocyte Hyperplasia
Sclerosing Hemangioma
BENIGN NONEPITHELIAL TUMORS
Hamartoma and Related Lesions
Inflammatory Myofiboblastic Tumor
Solitary Fibrous Tumor
Meningothelial-like Nodules and Intrapulmonary Meningioma
Miscellaneous

INTRODUCTION

Benign lung tumors are uncommon, accounting for fewer than 5% of resected lung neoplasms. Whereas many are rare, other benign lung tumors occur with sufficient frequency to pose periodic diagnostic challenges for primary care providers, pulmonologists, radiologists, surgeons, and pathologists alike. In this chapter we briefly review the clinical and pathological features of benign lung neoplasms. We have included neither nonneoplastic conditions that may mimic tumors on imaging studies (e.g., organizing pneumonia) nor certain low-grade but fully malignant neoplasms, such as carcinoid tumors.

Clinical Manifestations

Most benign lung tumors present as asymptomatic solitary pulmonary nodules typically discovered on chest radiographs or computed tomography (CT) scans performed for other purposes. A minority cause symptoms due to airway obstruction, bleeding, or compression of other structures. A preoperative diagnosis may be possible based on a combination of imaging studies and either endoscopic or percutaneous needle biopsies, but most are recognized only after surgical resection of a lesion in which the possibility of malignancy could not be categorically excluded.[1,2]

A decision to proceed with surgical resection in a patient with an unexplained solitary pulmonary nodule is complex and predicated on analysis of various risk factors. Given the risk of malignancy in lung nodules, establishing a diagnosis and surgical removal should be emphasized. Watchful waiting may occasionally be appropriate but only in highly selected patients in whom the risk of malignancy is low, the risk of surgery is high, or patient preference is to not have surgery (Fig. 50-1).[3] Recent data suggest that nodules 4 to 5 mm or less in size may be safely managed by deferring repeat CT scans for 12 months.[4-6] Others have advocated for a surgical approach in the absence of contraindications or other mitigating clinical circumstances.[7]

BENIGN EPITHELIAL LESIONS

Papillomas and Adenomas

Solitary Papillomas

Papilloma refers to exophytic endobronchial lesions with a papillary architecture (Fig. 50-2). Most solitary papillomas occur in central large airways; rarely, they arise in smaller bronchioles and present as peripheral nodules.[8] Flieder and associates[9] divided lung papillomas into three categories based on the lining epithelium: squamous cell, glandular, and mixed types. Squamous lesions account for nearly 70% of reported cases, occur more frequently in men, and are more often associated with cigarette smoking and human papillomavirus (HPV) infection. Associated foci of squamous cell carcinoma in situ are rare, with only a single well-documented example of invasive carcinoma developing in a patient without respiratory papillomatosis (see later).[10] Most patients with papillomas do well regardless of histologic type. Local recurrences are rare and limited to patients who undergo only biopsy or subtotal bronchoscopic removal. Surgical resection is curative. The differential diagnosis includes rare endobronchial papillary variants

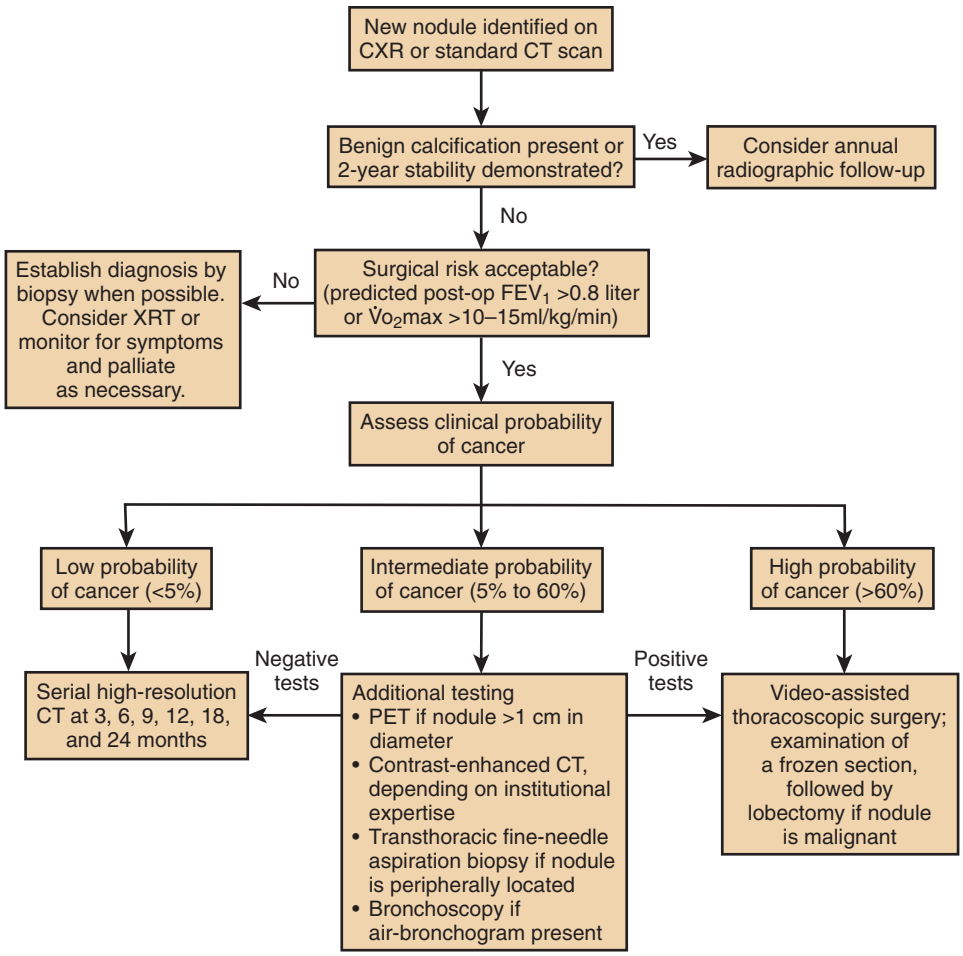

FIGURE 50-1 ■ Management algorithm for patients with solitary pulmonary nodules. CT, computed tomography; CXR, chest radiograph; PET, positron emission tomography; $\dot{V}o_2max$, maximal oxygen consumption; XRT, radiation therapy. (Adapted from Ost D, Fein AM, Feinsilver SH: Clinical practice: The solitary pulmonary nodule. N Engl J Med 348:2535–2542, 2003.)

of squamous cell or adenocarcinoma, a distinction that depends on recognition of cytologic atypia and stromal invasion.

Recurrent Respiratory Papillomatosis

Recurrent respiratory papillomatosis, also termed *juvenile laryngeal* or *laryngotracheal papillomatosis*, is a form of HPV-mediated papillomatosis that presents in early childhood.[11] Presenting symptoms include hoarseness, change or loss of voice, cough, respiratory distress, and stridor. HPV types 11 and 6 have been most commonly implicated and are perinatally acquired from mothers with genital infection.[11] Surgical excision or laser ablation are the mainstays of therapy for patients with symptomatic disease.[11] Recurrences are the rule and often necessitate multiple procedures. Squamous cell carcinoma is an infrequent complication but can affect either the upper or the lower respiratory tracts.[12,13]

Lung involvement occurs in about 3% of patients with juvenile-onset recurrent respiratory papillomatosis (RRP).[14,15] HPV-11 is especially prevalent in patients who develop peripheral lung disease, accounting for nearly 90% in whom testing was performed.[14] The latent period between diagnosis of RRP and recognition of lung involvement is variable but usually on the order of 8 to 10 years.[14] Lung disease presents as multiple asymptomatic nodules that may be cystic or solid (Figs. 50-3 and 50-4).[14–16] Symptomatic patients present with cough and various combinations of hemoptysis, dyspnea, fever, and chest pain. The histopathologic findings are unique, demonstrating tufts of benign squamous papillomas emanating from distal bronchioles with polypoid extensions into adjacent alveolar spaces (Fig. 50-5). The involved bronchioles are often ecstatic, thus mimicking the appearance of cavitation on imaging studies.

Lower respiratory tract disease in patients with RRP is often associated with an aggressive course. There is currently no effective medical therapy. Interferon and cidofovir, an antiviral agent, show inconsistent results and the latter has been implicated as potentially oncogenic.[14] Nearly two thirds of reported patients have died of disease, many from squamous cell carcinoma.[15] About 15% of patients with lower respiratory tract disease develop squamous cell carcinoma of the lung, with an average age at carcinoma diagnosis of 23 years.[14] No risk

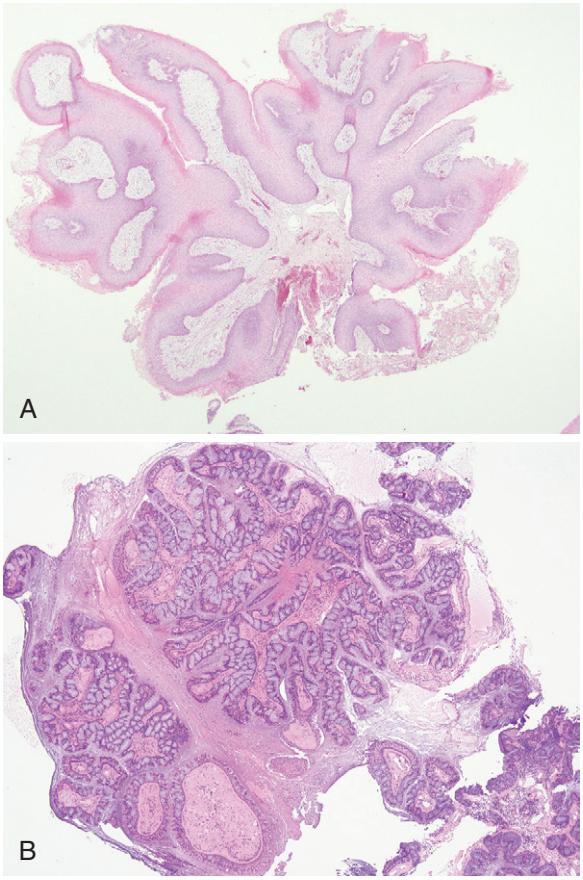

FIGURE 50-2 ■ Low-magnification photomicrographs illustrate two different solitary endobronchial papillomas from adults. **A,** Squamous papilloma showing papillary architecture with central connective tissue stalk covered by benign squamous epithelium with associated keratinous debris (original magnification ×20; hematoxylin and eosin stain). **B,** Glandular papilloma lined by benign mucinous columnar cells with abundant extracellular mucous (original magnification ×40; hematoxylin and eosin stain).

FIGURE 50-3 ■ Computed tomography (CT) scan from patient with recurrent respiratory papillomatosis involving her right lung. There are multiple nodules and opacities, the largest measuring 3 cm in greatest dimension. Some of the nodules appear cavitated. (CT image courtesy of Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

FIGURE 50-4 ■ Gross photograph of excised left lower lobe from a 19-year-old with multiple recurrences of respiratory papillomatosis as described by Kerley and coworkers.[16] He had extensive papillomatosis involving his central airways and a large cystic cavity containing innumerable papillomas replacing much of his left lower lobe.

factors clearly identify those patients likely to develop lung carcinoma.

Adenomas

Historically, the term *adenoma* was applied to a pathologically heterogeneous group of low-grade endobronchial malignancies that included carcinoid tumors and carcinomas homologous to those arising from salivary glands (i.e., adenoid cystic and mucoepidermoid carcinomas).[17-19] Today, the term is restricted to a group of benign neoplasms with variable clinical presentations and histologic appearances.

Endobronchial adenomas include two entities analogous to salivary gland counterparts. *Mucous gland adenomas* are rare, presenting as potentially obstructing, sessile, endobronchial masses occurring at the level of lobar or segmental bronchi.[20-22] Average age at diagnosis is 52 to 54 years but with a broad age range that extends to childhood. Most patients are symptomatic at the time of diagnosis. The most frequent complaints are cough, shortness of breath, and wheezing, a combination of findings that can be misconstrued as asthma.[22] Some patients are symptomatic for years before the diagnosis is made. Chest radiographs may be normal but more commonly show a solitary pulmonary nodule and/or postobstructive atelectasis or consolidation.[21] CT scans show discrete nodules that may be accompanied by an air-meniscus sign attesting to an endobronchial location.[21] Histologically, mucous gland adenomas are variably solid and cystic and composed of cytologically bland columnar mucinous cells (Fig. 50-6). Surgical resection is often required for diagnosis and is curative.

Pleomorphic adenomas, also termed *benign mixed tumors*, are biphasic neoplasms composed of stromal and epithelial elements. They usually arise in major salivary glands, with fewer than 20 well-documented

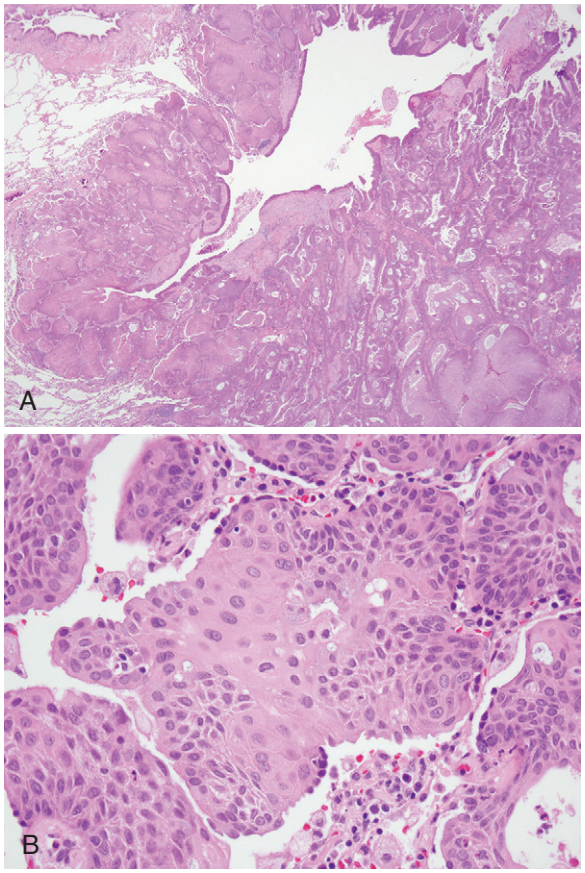

FIGURE 50-5 ■ Photomicrographs illustrate lung involvement in 40-year-old woman first diagnosed with recurrent respiratory papillomatosis at the age of 2 years. She underwent multiple resections of lung nodules starting in her second decade of life. **A,** Low-magnification photomicrograph illustrates multiple benign papillomas streaming from an ectatic bronchiole with a centrally dilated lumen (original magnification ×20; hematoxylin and eosin stain). **B,** High-magnification photomicrograph illustrates cytologically bland, benign appearance of the lung papillomas (original magnification ×400; hematoxylin and eosin stain).

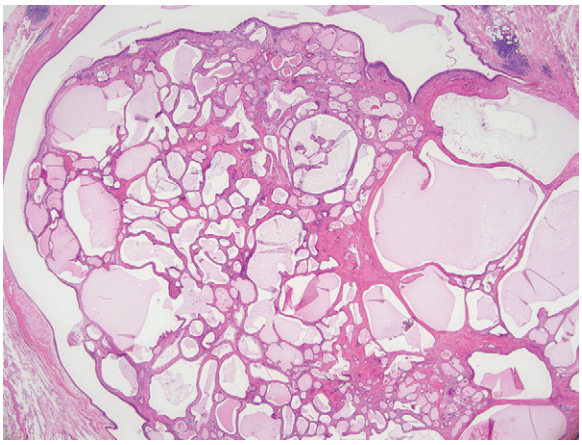

FIGURE 50-6 ■ Low-magnification photomicrograph shows an endobronchial mucous gland adenoma (original magnification ×20; hematoxylin and eosin stain). The smooth surface is covered by ciliated respiratory epithelium whereas the core comprises predominantly cystic spaces lined by variably attenuated columnar mucinous cells.

examples of primary lung tumors.[23-34] Primary pulmonary pleomorphic adenomas have been reported more commonly in women than men by a ratio of 2 : 1 with an average age at diagnosis of about 51 years. Cough is the most frequent presenting complaint and is sometimes associated with postobstructive pneumonia. A third of patients are asymptomatic at the time a solitary pulmonary nodule is discovered. Eighty percent occur within the larger central airways as polypoid exophytic tumors. Chest radiographs and CT scans show a solitary, well-circumscribed solid mass without distinctive features. Positron emission tomography (PET) in a single patient showed high ^{18}F-fluorodeoxyglucose (FDG) avidity.[27] Complete surgical resection with tumor-free margins is curative. As is true for their salivary gland counterparts, rare cases have been associated with malignant transformation usually taking the form of a carcinoma arising from a preexisting benign pleomorphic adenoma (carcinoma ex pleomorphic adenoma).[28] Primary pleomorphic adenoma must be distinguished from so-called *benign metastasizing pleomorphic adenoma*, a term that refers to rare patients in whom histologically benign salivary gland tumors inexplicably metastasize to various sites including lung.[35,36]

Adenomas involving peripheral lung parenchyma are rare. *Alveolar adenoma* is the most common variant with just under 30 reported examples.[37-41] Average age at diagnosis is between 50 and 55 years. Nearly all patients are asymptomatic at the time of diagnosis. Radiologically, alveolar adenomas present as well-circumscribed peripheral nodules averaging just over 2 cm in greatest dimension. Magnetic resonance imaging (MRI) may show a cystic space with central fluid and thin-rim enhancement.[38] Pathologically, alveolar adenomas are partially cystic nodules in which connective tissue septa are lined by cytologically bland epithelial cells (Fig. 50-7). The epithelial cells are derived from pneumocytes whereas the stromal cells are undifferentiated fibroblasts. Cytogenetic studies performed in a single case demonstrated a clonal translocation, supporting the conclusion that these are benign neoplasms.[42]

Papillary adenomas have been described in fewer than 10 patients.[43-46] Men and women are affected equally with an average age at diagnosis of 45 years (range 25–60 years). All patients in whom the lesion was discovered during life underwent surgical resection for an asymptomatic solitary peripheral nodule and remained free of disease at follow-up. Histologically, papillary adenomas are circumscribed lesions composed of connective tissue fronds lined by bland type 2 pneumocytes (Fig. 50-8).

Mucinous cystadenoma is a rare lung neoplasm that overlaps with unequivocally malignant mucinous adenocarcinomas.[47-52] Gao and Urbanski[48] proposed separating them into three histologically defined categories: mucinous cystadenoma, mucinous cystic tumor with atypia, and mucinous cystadenocarcinoma. Histologically

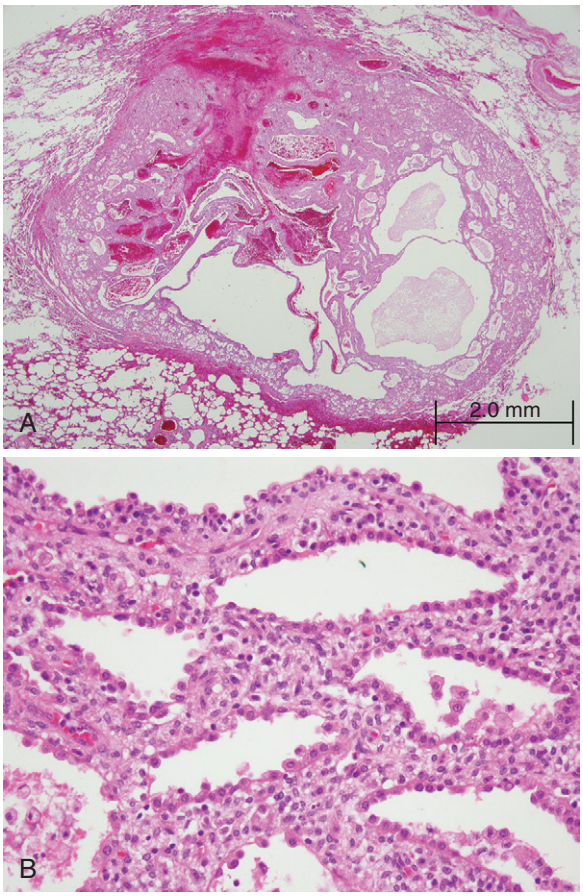

FIGURE 50-7 ■ Alveolar adenoma. **A,** Low-magnification photomicrograph shows a well-demarcated partially cystic mass in peripheral lung biopsy (original magnification ×20; hematoxylin and eosin stain). **B,** Higher-magnification photomicrograph illustrates connective tissue septa lined by bland pneumocytes (original magnification ×400; hematoxylin and eosin stain).

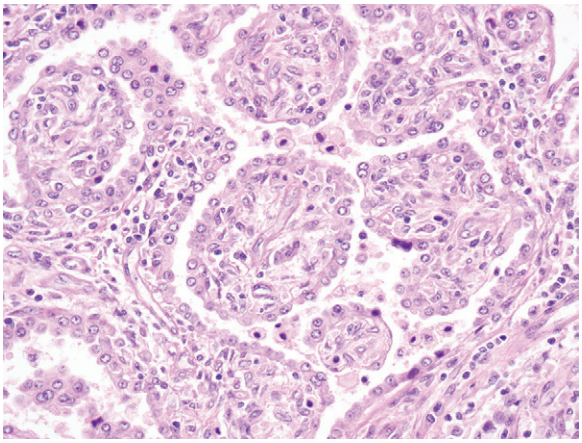

FIGURE 50-8 ■ Papillary adenoma. High-magnification photomicrograph of a solitary peripheral lung nodule shows papillary connective tissue cores lined by bland cuboidal pneumocytes (original magnification ×400; hematoxylin and eosin stain).

benign tumors without atypia accounted for only 13% of reported patients, further emphasizing that this is an extremely rare neoplasm. Patients typically present with slowly growing, well-demarcated, peripheral lung masses that may or may not appear cystic.[50–53] All patients with histologically benign cystadenomas have remained free of disease after surgical resection.

Micronodular Pneumocyte Hyperplasia

Micronodular pneumocyte hyperplasia is an unusual proliferation of alveolar epithelium seen almost exclusively in patients with underlying tuberous sclerosis complex and/or lymphangioleiomyomatosis.[54–58] Over 85% of reported patients were women. Radiologic findings are characterized by scattered nodules that are occasionally numerous and distributed in a miliary fashion, with or without the associated cystic changes typical of lymphangioleiomyomatosis.[55,57] The radiologic abnormalities correspond to ill-defined pale peripheral nodules occurring either in isolation or in the setting of lymphangioleiomyomatosis (Figs. 50-9 and 50-10). Histologically, micronodular pneumocyte hyperplasia demonstrates circumscribed proliferations of bland pneumocytes cytologically identical to those seen in

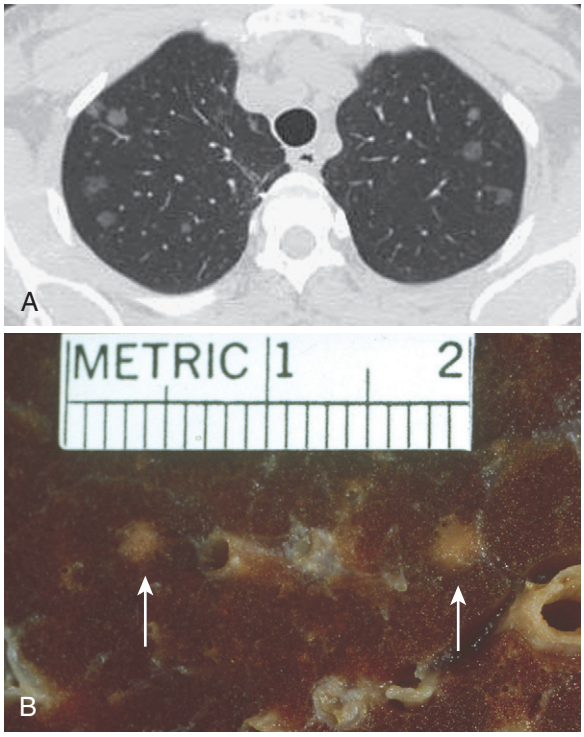

FIGURE 50-9 ■ Micronodular pneumocyte hyperplasia (MNPH) in tuberous sclerosis complex (TSC) without lymphangioleiomyomatosis (LAM). **A,** CT scan from 41-year-old woman with TSC and MNPH shows multiple bilateral nodules characterized by "ground-glass" attenuation. **B,** Photograph of autopsy lung specimen from another patient with TSC and MNPH (*arrows*). (**A,** CT image courtesy of Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

(**A,** CT image courtesy of Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

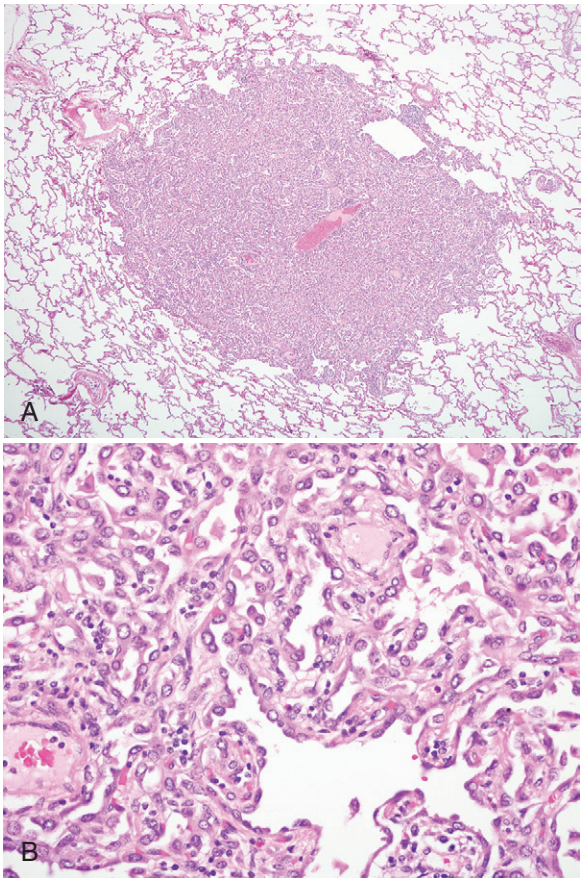

FIGURE 50-11 ■ Histologic features of MNPH in the TSC patient also illustrated in Figure 50-9B. **A,** Low-magnification photomicrograph shows a well-circumscribed nodule (original magnification ×20; hematoxylin and eosin stain). **B,** High-magnification photomicrograph shows cytologically bland pneumocytes distributed along alveolar septa (original magnification ×400; hematoxylin and eosin stain).

papillary adenomas, differing in that they are distributed along intact alveolar septa rather than papillae (Fig. 50-11).

Sclerosing Hemangioma

Sclerosing hemangiomas (SHs) are benign lung neoplasms derived from incompletely differentiated respiratory epithelium. SHs occur more frequently in women than men by a ratio of 7 : 1.[59-67] Mean age at diagnosis is the fifth decade of life, although they have been reported in a wide age range including children. Over three fourths of patients are asymptomatic at the time they are discovered to have a solitary pulmonary nodule. CT scans show well-circumscribed round or oval subpleural nodules with smooth margins and inhomogeneous enhancement.[68,69] Associated calcifications are present in about a third. Dynamic CT studies show strong, rapid enhancement that rivals the imaging characteristic of malignancies.[70] PET scanning has been reported in only one patient and was characterized by intermediate FDG avidity.[71] Multiple lesions occur in about 2% of patients. Deposits in regional lymph nodes are rare and have no impact on the fundamentally benign behavior of these lesions.[72-74]

SHs are usually well-circumscribed subpleural nodules averaging 2 to 3 cm in diameter (Fig. 50-12). The histologic hallmark is a heterogeneous appearance resulting from both a mixture of cell types and highly variable growth patterns. Two populations of epithelial cells are a characteristic feature: (1) surface cuboidal cells derived from pneumocytes or Clara cells and (2) pale interstitial round cells with an incompletely differentiated respiratory epithelial phenotype.[63,75-77] Molecular studies using a variety of techniques suggest that both populations of cells are neoplastic, an observation that fits with descriptions of both components in nodal deposits.[73,78,79] The cells are arranged in various growth patterns that include a focally conspicuous sclerotic stroma that is often calcified (Fig. 50-13). Pseudovascular blood-filled spaces

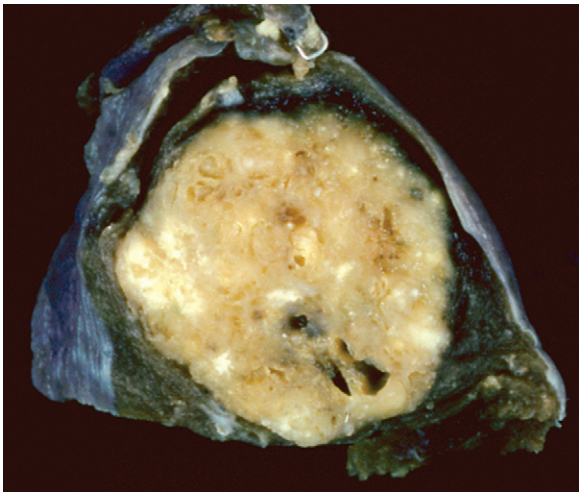

FIGURE 50-12 ■ Photograph of resected sclerosing hemangioma (SH). The lobulated nodule is well circumscribed and situated near the visceral pleura. The cut surface betrays the fundamentally heterogeneous nature of these neoplasms, showing a variegated pattern of pale brown and white with both solid and spongy areas.

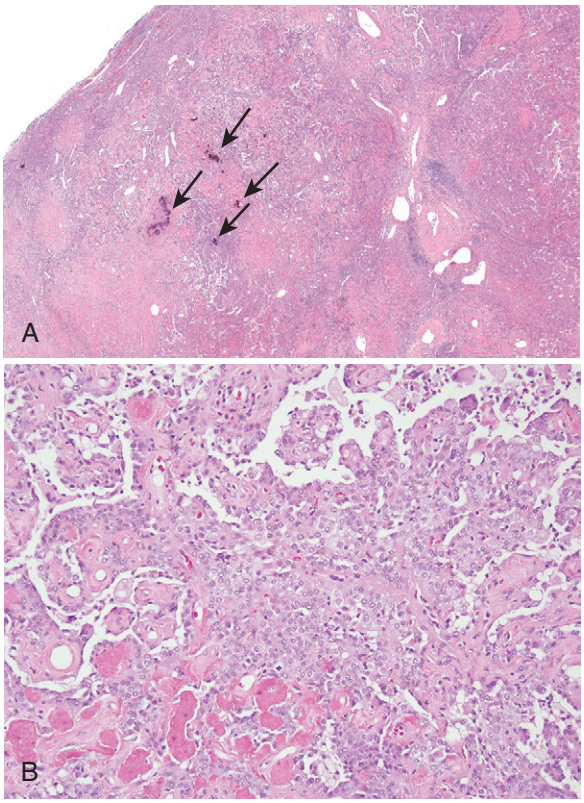

FIGURE 50-13 ■ SH. **A,** Low-magnification photomicrograph shows the classic features of SH in which sclerotic zones with dense collagen deposition and focal calcifications (*arrows*) alternate with variably cellular regions (original magnification ×2; hematoxylin and eosin stain). **B,** Higher-magnification photomicrograph shows solid and papillary growth patterns. The central area is solid and composed of the pale-staining round cells demonstrating a phenotype consistent with incompletely differentiated respiratory epithelium (original magnification ×400; hematoxylin and eosin stain).

occur in some cases and account for the term *hemangioma*, in this case a misnomer.

Molecular studies of these tumors have demonstrated acquired genetic alterations at the *p16* and *RB* genes that resemble those found in early-stage adenocarcinomas, supporting an origin from respiratory epithelial cells and suggesting similarities between the molecular pathogenesis of SHs and bronchoalvealor adenocarcinoma.[80] However, a more recent molecular analysis of SHs failed to identify alterations in some genes (*EGFR*, *HERS*, and *K-ras*) that are commonly mutated in bronchoalvealor adenocarcinoma, thereby raising doubts about a common link.[79] Genome-wide approaches will likely be necessary to resolve this controversy.

BENIGN NONEPITHELIAL LESIONS

Hamartoma and Related Lesions

Pulmonary hamartomas are the most common benign neoplasm in adults who undergo surgical resection but are present in less than 0.5% of consecutively autopsied patients.[2,81,82] The term *hamartoma* implies that these are tumor-like malformations rather than true neoplasms, but recent studies show consistent and characteristic genetic abnormalities indicating that hamartomas are clonal neoplasms.

Pulmonary hamartomas are discovered in men more often than in women by a ratio of 2:1 with an average age at diagnosis in the sixth or seventh decade of life.[83,84] Most patients present with asymptomatic solitary lung nodules with no lobar predilection. Multiple nodules are present in 2% or less of patients.[83,85] About 10% of hamartomas are endobronchial in location and are more likely to be associated with cough. CT scans show a characteristic combination of calcifications and/or fat in two thirds of patients (Fig. 50-14).[86] Resection is nearly always curative with rare reports of recurrence or malignant transformation.[87,88]

Pulmonary hamartomas usually occur as well-circumscribed nodules, averaging 1.5 to 2.0 cm in diameter. A variegated cut surface reflects an admixture of stromal elements (Fig. 50-15). Mature hyaline cartilage is an almost universal component and is typically intermingled with mature fat, fibromyxoid tissue, and rare smooth muscle cells (Fig. 50-16). Any of the stromal components can predominate, however, resulting in a histologic spectrum of neoplasms that includes *leiomyomas* and *lipomas*.[89–91] Entrapped non-neoplastic respiratory epithelium often results in a characteristically biphasic appearance, a phenomenon that contributes to relatively high rates of false-positive diagnoses in fine-needle aspiration biopsies.[92]

Pulmonary hamartomas, like other benign mesenchymal tumors such as lipoma and leiomyomas, frequently contain chromosomal rearrangements of genes encoding nonhistone chromosomal high-mobility group family of proteins (HMGA family) with AT-hook DNA-binding motifs.[93–96] These proteins play a broad role in growth, differentiation, proliferation, and death of mesenchymal

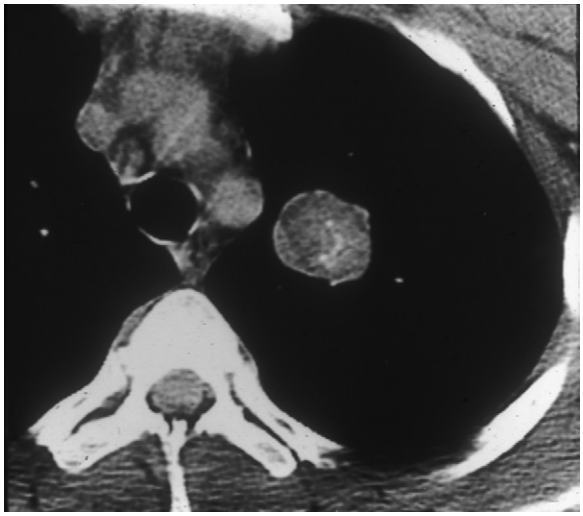

FIGURE 50-14 ■ CT scan of a proven hamartoma shows a well-marginated nodule in which there is evidence of intratumoral fat and calcification. This combination is characteristic but occurs in only about a fourth of cases.

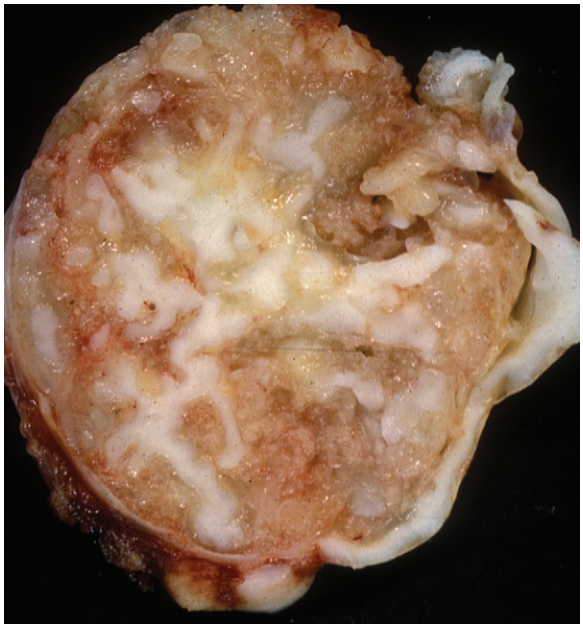

FIGURE 50-15 ■ Photograph of resected hamartoma. The cut surface of this well-circumscribed nodule shows glistening irregularly shaped cartilaginous islands alternating with pale yellow adipose tissue.

cells through a mechanism that involves regulation of transcription via modification of DNA conformation.[97] Two main cytogenetic regions containing abnormalities have been defined in pulmonary hamartoma: 6p21 and 12q14-15. The *HMGA1* (also known as *HMGIY*) gene maps to 6p21.3, whereas *HMGA2* (also known as *HMGIC)* maps to 12q14-15. Their dual role as regulators of adipogenesis and mesenchymal differentiation and gene expression is provocative, although additional

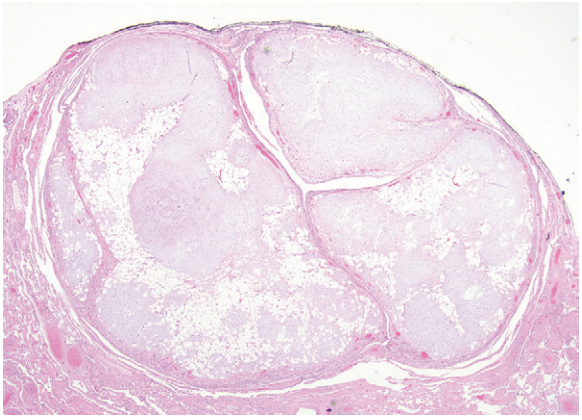

FIGURE 50-16 ■ Low-magnification photograph of a typical pulmonary hamartoma in which cartilaginous islands are interspersed with adipose tissue resulting in a lobulated appearance (original magnification ×20; hematoxylin and eosin stain).

work needs to be done to fully elucidate the role of *HMGA* fusion genes in pulmonary hamartoma.

Pulmonary chondroma, a related cartilaginous lung tumor, constitutes one component of the triad (i.e., pulmonary chondroma, paraganglioma, and gastric stromal tumors) described by Carney and colleagues in 1977.[98] Pulmonary chondromas occur in about three fourths of patients and are multiple in half.[85,99] Chondromas are distinct in being purely cartilaginous without the other stromal and epithelial elements characteristic of hamartoma.[85]

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumors (IMTs) of the lung comprise a spectrum of lesions ranging from benign spindle cell tumors to frankly malignant sarcomas. Pulmonary IMTs, also termed *plasma cell granulomas* by Liebow,[100] are defined in the World Health Organization (WHO) classification of lung tumors as "a subgroup of the broad category of 'inflammatory pseudotumours.'"[101] The staggering profusion of synonyms that have been applied to these unusual tumors, which also occur in multiple extrapulmonary sites, reflects the controversy and confusion regarding their pathogenesis and histogenesis.

IMTs of the lung can occur in any age group but tend to affect children and young adults; over half of patients are less than 40 years of age at the time of diagnosis.[100–107] Most patients present with asymptomatic peripheral lung nodules. Endobronchial tumors account for around 15% of patients and are more likely to be accompanied by symptoms of cough and/or hemoptysis. Chest radiographs typically show a well-circumscribed mass ranging in size from 0.8 cm to 36 cm (Fig. 50-17), the majority measuring between 1 and 6 cm in greatest dimension.[100,104,106,108–110] Most primary pulmonary IMTs are cured with complete surgical resection.[102,106,109] Incomplete resection is associated with substantial risk of recurrence and, rarely, locally aggressive behavior and death.[103,110] Cyclooxygenase-2 (COX-2) inhibitors may

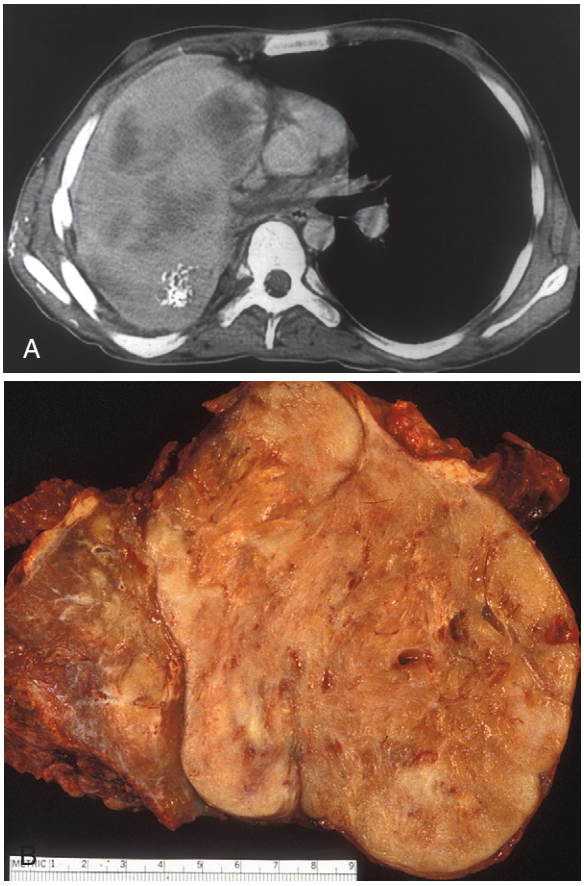

FIGURE 50-17 ■ Large inflammatory myofibroblastic tumor (IMT) occurring in 21-year-old man in whom an intrathoracic mass was first detected at the age of 10. **A,** CT scan shows a large mass filling the right hemithorax with heterogeneous attenuation and calcification. **B,** Photograph of right pneumonectomy specimen shows a large mass that despite its size, was well circumscribed without invasion beyond lung parenchyma.

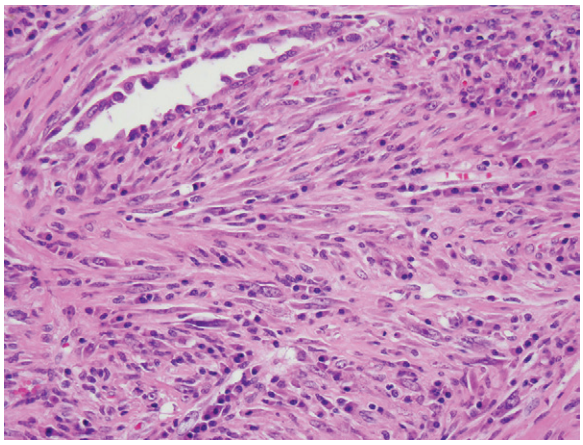

FIGURE 50-18 ■ High-magnification photomicrograph from the IMT illustrated in Figure 50-17. Neoplastic spindle cells are associated with a prominent infiltrate of plasma cells. Nonneoplastic respiratory epithelium (*upper left*) is surrounded by neoplastic spindle cells resulting in a biphasic appearance, a common phenomenon in benign or low-grade nonepithelial tumors (original magnification ×400; hematoxylin and eosin stain).

have therapeutic value in large unresectable tumors, a treatment strategy for which only limited anecdotal evidence is available.[111-113]

The long list of competing terms for IMTs attests to their histologic diversity. The most consistent histologic finding is a combination of neoplastic spindle cells and a variably dense infiltrate of polyclonal plasma cells (Fig. 50-18). Immunohistochemical and ultrastructural studies show that the spindle cells have features of myofibroblasts, including expression of smooth muscle–associated proteins. ALK1 protein expression occurs in somewhere between a third and a half of lung tumors, is more frequent in young patients,[103,114-116] and reflects the observation that the *ALK* gene is fused to a variety of constitutively activated genes via balanced translocations (see later).[117,118] Absence of ALK expression may be associated with a greater risk for aggressive behavior.[103]

IMTs are low-grade neoplasms rather than non-neoplastic inflammatory lesions. Various techniques have identified a range of genetic abnormalities consistent with their neoplastic nature.[115,117-121] The most consistent molecular alteration is a balanced translocation of the *ALK* gene locus (2p23), which encodes a tyrosine kinase receptor. Fusion of a silent gene (*ALK*) with one of several constitutively expressed genes (e.g., *TPM3, TPM4, CLTC*) results in aberrant expression of the silent gene that then typically functions as an oncogene, thus contributing to tumorigenesis. A similar role for *ALK* gene fusions is observed in anaplastic large cell lymphomas. The role of HPV-8 in the pathogenesis of IMTs is controversial and uncertain.[107]

Solitary Fibrous Tumor

Solitary fibrous tumors (SFTs), formerly referred to as *localized fibrous mesotheliomas*, are mesenchymal neoplasms that frequently arise from visceral or parietal pleura. SFTs are not unique to the pleura, however, and have been described as intraparenchymal lung tumors (intrapulmonary solitary fibrous tumors), in the mediastinum, and in numerous extrathoracic sites.[122-126]

Pleural and intrapulmonary solitary fibrous tumors affect men and women equally.[127-132] Mean age at diagnosis is the sixth decade of life. Just over half of patients are symptomatic with presenting complaints that include chest pain (25%), shortness of breath (15%), and/or cough (12%).[128,129,131-133] Clubbing is present in about 2% of patients. A paraneoplastic syndrome of hypoglycemia is rare and results from tumor production of insulin-like growth factor.[30,134-137] Imaging studies show large intrathoracic masses with an average maximum diameter of between 8.5 and 10.5 cm.[128,129,132,133,138] CT scans show a lobulated and sharply marginated mass with a broad base abutting the chest wall, frequently associated with compression of surrounding structures (Fig. 50-19).[138,139] Heterogeneous attenuation and heterogeneous enhancement are characteristic.[138] Calcifications are rare. Most pleural and intrapulmonary solitary fibrous tumors

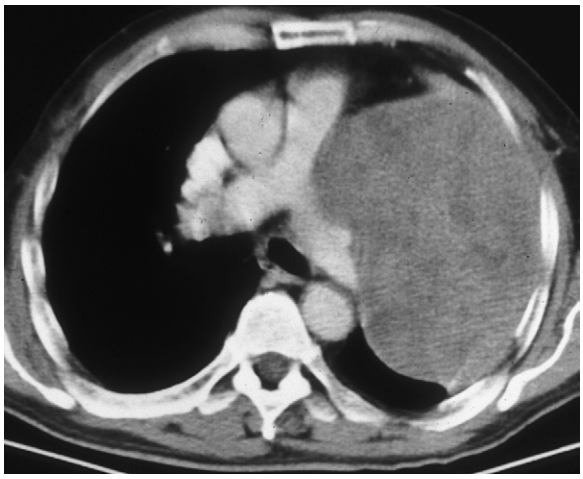

FIGURE 50-19 ■ CT scan shows a large benign solitary fibrous tumor (SFT) arising from the visceral pleura with nearly complete atelectasis of the left lung. Together, SFT and IMT are the most likely diagnoses in patients who present with large benign intrathoracic tumors.

behave as benign neoplasms. Patients with histologically benign tumors are cured with complete surgical excision. A more aggressive course is seen in just over 10% of patients and is limited to those who either undergo incomplete surgical excision or have histologically malignant tumors (malignant SFTs).[127-129,131-133,140]

SFTs are three times more likely to arise from visceral than parietal pleura. Those arising from visceral pleura are frequently pedunculated and attached to the lung surface by a connective tissue pedicle (Fig. 50-20). Occasional examples arise within the fissures, resulting in a radiologic appearance difficult to separate from an intrapulmonary tumor (see Fig. 50-20). Parietal pleural lesions are more commonly sessile with a broad base of attachment to chest wall, diaphragm, or mediastinum. Histologically, SFTs are variably cellular spindle cell neoplasms with a collagenous stroma. Malignant variants are larger, more likely to have an invasive growth pattern, and more cellular with associated cytologic atypia, increased mitotic rates, and necrosis.[128]

Meningothelial-like Nodules and Intrapulmonary Meningioma

Pulmonary *meningothelial-like nodules*, termed *chemodectomas* historically, have been described in as many as 4.9% of autopsies but are seen more commonly as incidental findings in surgical specimens, occurring in 13.8% and 48% of surgical lung biopsies and lobectomies from adults, respectively.[141-145] Meningothelial-like nodules are more common in women and occur with greater frequency in patients with chronic lung diseases, including chronic interstitial pneumonias and thromboembolic disease.[143] A rare syndrome of multiple, bilateral meningothelial-like nodules (diffuse pulmonary meningotheliomatosis) has been described in women who present in the sixth to eighth decade of life with

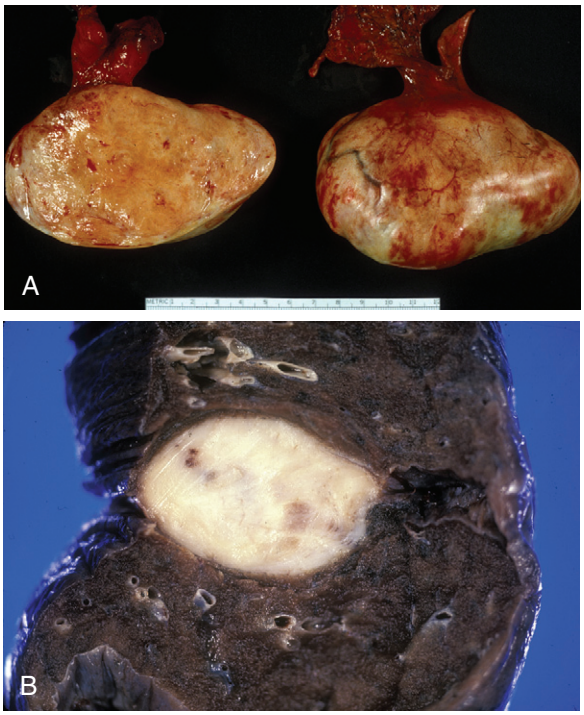

FIGURE 50-20 ■ Photograph of a resected SFT arising from the visceral pleura. **A,** As demonstrated in this example, most visceral pleural SFTs are attached to the lung by a pedicle and are characterized by a smooth glistening surface (*right*) and an encapsulated homogeneous cut surface without necrosis (*left*). **B,** Less commonly, SFT arises within the fissures as illustrated in this bilobectomy specimen.

multiple nodules on CT scan.[146,147] Half complain of dyspnea or cough at presentation. Microscopically, meningothelial-like nodules are composed of nests of epithelioid cells that are histologically and immunophenotypically indistinguishable from meningothelial cells of the central nervous system (Fig. 50-21). Despite this unexplained phenotypic overlap, molecular studies demonstrate significant differences between meningothelial-like nodules and conventional central nervous system meningiomas.[146]

Primary *intrapulmonary meningiomas* are rare solitary lesions that are unrelated to meningothelial-like nodules.[148-150] Men and women are affected equally and present at an average age of 56 years with asymptomatic solitary nodules averaging 3.0 cm (standard deviation ± 2.2 cm) in greatest dimension. Patients with multiple lesions should be presumed to have metastatic disease from a central nervous system primary until proved otherwise.[151] Complete surgical resection is curative in patients with histologically benign meningiomas.

Miscellaneous

Granular cell tumors, referred to in older literature as *granular cell myoblastomas*, are uncommon primary lung neoplasms that typically present as pedunculated or sessile endobronchial tumors (Fig. 50-22).[152,153] Lesions

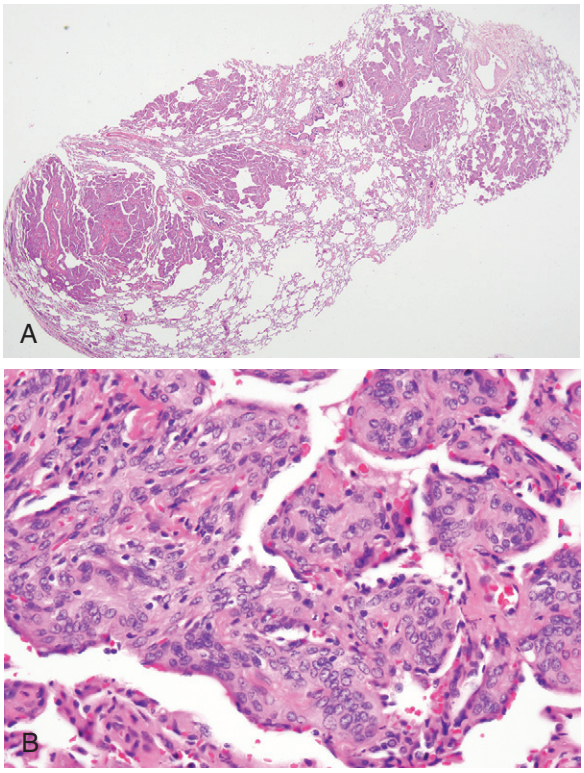

FIGURE 50-21 ■ Multiple meningothelial-like nodules (diffuse pulmonary meningotheliomatosis) in surgical lung biopsy from 56-year-old woman who presented with dyspnea. **A,** At low magnification, multiple nodules are randomly distributed throughout the biopsy (original magnification ×20; hematoxylin and eosin stain). **B,** At higher magnification, the nodules comprise bland meningothelial cells arranged in poorly formed nests and expanding the interstitium (original magnification ×400; hematoxylin and eosin stain).

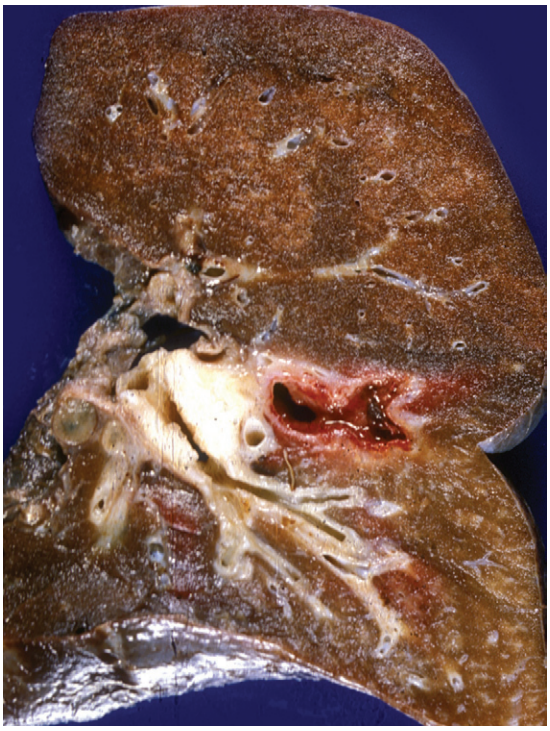

FIGURE 50-22 ■ Photograph demonstrates the cut surface of pneumonectomy specimen in which a granular cell tumor partially obstructs the lower lobe bronchus.

are multiple in a fourth of patients. Symptoms are reported in half and result from airway obstruction. Peripheral lung nodules are rare. Pulmonary granular cell tumors are benign and can usually be managed with conservative excision.

Clear cell ("sugar") tumors are rare primary lung tumors that invariably present as asymptomatic solitary lung nodules.[154] Histologic, ultrastructural, and immunophenotypic features are indistinguishable from PEComas and renal angiomyolipomas, a family of neoplasms derived from perivascular epithelioid cells (PECs) and related to mutations of the tuberous sclerosis complex genes that affect regulation of the mTOR pathway.[155,156]

KEY POINTS

- Benign lung tumors are uncommon but frequently pose challenges in diagnosis and management.
- Benign lung tumors are pathologically diverse, comprising a range of epithelial and nonepithelial neoplasms.
- Benign lung tumors present most commonly as asymptomatic solitary peripheral nodules and less commonly as symptomatic endobronchial lesions.
- Some benign lung tumors may become large enough to cause symptoms by compression or displacement of intrathoracic structures.
- Surgical resection is frequently required for diagnosis of benign lung tumors and is usually curative.

CHAPTER 51

PULMONARY THROMBOEMBOLISM

Timothy A. Morris, MD • Peter F. Fedullo, MD

INTRODUCTION

PATHOGENESIS AND RISK FACTORS

NATURAL HISTORY: DEEP VENOUS THROMBOSIS

NATURAL HISTORY: PULMONARY EMBOLISM

CLINICAL PRESENTATION

DIAGNOSIS OF VENOUS THROMBOSIS
Contrast Venography
Duplex Ultrasonography
Impedance Plethysmography
Magnetic Resonance Imaging
Computed Tomography
Hemostaseologic Assays
Clinical Prediction Rules

DIAGNOSIS OF PULMONARY EMBOLISM
Standard Laboratory Evaluation
Echocardiography
Ventilation-Perfusion Scanning
Spiral (Helical) Computed Tomography
Lower Extremity Venous Evaluation
D-Dimer Testing
Pulmonary Angiography
Clinical Prediction Rules

PREVENTION OF VENOUS THROMBOEMBOLISM
Low-Dose Unfractionated Heparin
Low-Molecular-Weight Heparin
Pneumatic Compression Devices
Sodium Warfarin
Miscellaneous Agents

MANAGEMENT OF VENOUS THROMBOEMBOLISM
Heparin
Inferior Vena Cava Filters

MASSIVE PULMONARY EMBOLISM
Thrombolytic Therapy
Pulmonary Embolectomy

POSTEMBOLIC PROPHYLAXIS

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION
Diagnosis
Treatment

OTHER FORMS OF EMBOLISM
Schistosomiasis
Air Embolism
Fat Embolism
Amniotic Fluid Embolism
Septic Embolism
Other Emboli

INTRODUCTION

The one generalization about venous thromboembolism (VTE) that is free from controversy is that many aspects of this disorder remain controversial. There are multiple reasons why VTE continues to engender lively debate. Perhaps the major reason, notwithstanding the substantial advances that have been made since the late 1990s, is that a number of fundamental questions continue to exist regarding the pathogenesis, clinical presentation, diagnosis, and therapy of the disease.

VTE represents a potentially fatal disease process with a clinical presentation that is often silent or nonspecific and for which a wide range of diagnostic techniques is

available, many with technical and interpretive limitations. Although estimates vary widely, the best available information suggests that at least 5 million episodes of venous thrombosis occur annually in the United States.[1] The overall average age- and sex-adjusted annual incidence of acute pulmonary embolism (PE) is approximately 70/100,000, based on discharge diagnosis (*International Classification of Diseases*, 9th Revision [ICD-9]) codes.[2] Extrapolating the rates on U.S. census data, the annual rate of diagnosed PE has been estimated to be 237,000 cases.[3] These data, of course, represent only those patients in whom the diagnosis of acute PE was correctly made. Autopsy series suggest that the true number of deaths from acute PE (including those patients that died without the diagnosis ever being made) is at least threefold higher.[4–7] For this reason, the most current evidence-based estimation is that the majority of PE–related deaths can be attributed to PE that was undiagnosed (and therefore untreated) during life.

As many as 10% of those patients who suffer embolism may die from their disease.[8] The overwhelming majority of these deaths do not appear to arise from therapeutic failure. With the exception of patients who initially present with hemodynamic impairment, in whom mortality rates approach 20% to 30%, embolic recurrence is rare and death is uncommon once the diagnosis of embolism is confirmed and appropriate therapy initiated.[9] The majority of deaths related to embolism appear to arise from a failure to prevent the disease in patients at risk of it and from a failure to make the diagnosis in those afflicted.[8] The incidence of fatal PE appears to have declined over the past several decades.[10,11] For example, the Centers for Disease Control and Prevention Compressed Mortality File (CMF) for 1978 to 1998 reported that an average of 9685 deaths/year were attributed by clinicians to acute PE.[12] A significant, but incomplete improvement was reported in the current (1999–2005) CMF, in which acute PE was deemed by clinicians to be responsible for an average of 8532 deaths/year.[13] However, these statistics do not account for fatal PE that had been undiagnosed clinically, as described previously. Mortality from acute PE remains a substantial public health care problem as a result of the demographics of an aging population and the ability of modern medicine to treat patients with chronic disease.[14]

Contributing to the debate surrounding VTE is the involvement of a wide range of medical disciplines in its prevention, diagnosis, and management. Thrombosis is not a discrete subspecialty. The problem of VTE involves pulmonologists, cardiologists, hematologists, internists, specialists in vascular disease, radiologists, a range of surgical subspecialists, obstetricians, and others. Because specific prophylactic, diagnostic, and therapeutic strategies within one discipline may not necessarily be applicable to another, a perception of coherence in the clinical approach to this disease process often appears to be lacking.

During the past decade, many of the long-standing controversies surrounding the natural history, diagnosis, and therapy of VTE have been partially or completely reconciled, resulting in substantial changes in the diagnostic and therapeutic approach to the disease. The persistence of a number of unresolved issues, and the emergence of still others, should not be a cause for clinical cynicism. In the approach to the patient with suspected VTE, an understanding of what is unknown can prove invaluable to the decision-making process.

PATHOGENESIS AND RISK FACTORS

The triad of venous stasis, alterations in coagulation, and vascular injury identified by Virchow in 1856 as primary factors in the pathogenesis of VTE has been supported by a considerable amount of clinical and experimental evidence. Over the past several decades, severe abnormalities of the coagulation and fibrinolytic system, including isolated deficiencies of antithrombin III, protein C, protein S, and plasminogen as well as the presence of a lupus anticoagulant, had been described and their high association with first-time and recurrent VTE confirmed (Table 51-1).[15,16] In addition, there has been increasing recognition of less severe, but more common inherited "thrombophilic" conditions that are capable of shifting the hemostatic balance toward thrombosis and mildly increasing the risk of venous thromboembolic events.

The most common of the inherited thrombophilic conditions, first described in 1993 by Dahlback and designated *factor V Leiden mutation*, is the consequence of a single point mutation on the factor V gene (adenine for guanine) resulting in activated factor V (factor Va) with diminished sensitivity to the natural anticoagulant effect of activated protein C.[17] Approximately 5% of whites in Europe and North America are heterozygous for this genetic defect; lower rates of carrier frequency have been reported among Native American, African, and Asian populations.[18,19] Although initially detected in as many as 60% of *selected* patients with VTE, subsequent studies have detected the mutation in 10% to 20% of unselected patients.[20] The heterozygous state carries a 5- to 10-fold increase in lifetime risk for VTE.[21,22] Whereas the relative risk among patients homozygous for this mutation has been estimated to be as high as 80-fold, the estimates are based on a very small number of patients and may be somewhat imprecise.[21,22] Factor V Leiden mutation appears to be an important risk factor for VTE during pregnancy, in the postpartum period, and during oral contraceptive use.[23,23a] Compared with women who do not use oral contraceptives and are not carriers of the factor V mutation, the risk of thrombosis among those with both risk factors is increased approximately 30-fold.[24] In view of the prevalence of thrombophilia and the low prevalence of VTE in nonusers of combined oral contraceptives, the absolute risk remains low. Because the absolute increase in VTE is modest, selective thrombophilia screening based on previous personal or family history of VTE is more cost-effective than universal screening.

A sequence variation in the prothrombin gene (G20210A) was described in 1996 and is estimated to

TABLE 51-1. Thromboembolic Risk Factors

HEREDITARY THROMBOPHILIAS
Protein C deficiency
Protein S deficiency
Antithrombin III deficiency
Factor V Leiden mutation
Prothrombin 20210 G → A variation
Hyperhomocysteinemia
Dysfibrinogenemia
Familial plasminogen deficiency
ACQUIRED SURGICAL PREDISPOSITIONS
Major thoracic, abdominal, or neurosurgical procedures requiring general anesthesia and lasting >30 min
Hip arthroplasty
Knee arthroplasty
Knee arthroscopy
Hip fracture
Major trauma
Open prostatectomy
Spinal cord injury
ACQUIRED MEDICAL PREDISPOSITIONS
Prior venous thromboembolism
Advanced age (>60 yr)
Malignancy
Congestive heart failure
Cerebrovascular accident
Nephrotic syndrome
Estrogen therapy
Pregnancy and the postpartum period
Obesity
Prolonged immobilization
Antiphospholipid antibody syndrome
Lupus anticoagulant
Inflammatory bowel disease
Paroxysmal nocturnal hemoglobinuria
Behçet's syndrome

occur in approximately 2% to 4% of the population.[25] This mutation results in an overproduction of prothrombin, which is otherwise normal. It is associated with a three- to fourfold increased risk of lower extremity venous thrombosis.[25,26]

Hyperhomocyst(e)inemia has also been identified as a potential independent predisposition to VTE. Elevation of plasma homocysteine levels may be the result of genetic abnormalities, nutritional deficiencies of vitamins (B_6, B_{12}, folate), clinical disorders (renal insufficiency, hypothyroidism, inflammatory bowel disease), or a combination of the three. Although retrospective, case-control studies demonstrate an association between hyperhomocyst(e)inemia and VTE, the results of prospective studies have not been uniform.[27,28]

The three "common genetic thrombophilias" (factor V Leiden, prothrombin G20210A, and hyperhomocyst(e)inemia) appear to act as independent risk factors for increasing both the initial and the recurrent thrombosis risk.[29,30] Thus, the relative risk for patients with multiple thrombophilic conditions is higher than for patients with only one of them.

The identification of these risk factors, and the likelihood that others exist, raises the possibility that screening to determine relative thromboembolic risk may be feasible in the future. However, a consensus for such an approach does not exist at the present time. Despite its prevalence in the general population, screening for factor V Leiden mutation is not advised because most patients with this abnormality will never suffer a thromboembolic event. Furthermore, the absence of this abnormality should not influence the decision to provide prophylaxis to patients at clinical risk. In addition, recurrence of VTE is no more common in VTE patients with factor V Leiden[31] or the prothrombin G20210A gene[32] than in VTE patients without these mutations, and there is no evidence that prolonged anticoagulation would be more beneficial for VTE patients with either mutation than it would be in patients without them.

Patients with spontaneous ("unprovoked") VTE who also have *both* factor V Leiden and the prothrombin G20210A gene[32] appear to be at somewhat higher risk for recurrence than similar patients without those mutations. This observation does not establish a risk-benefit relationship for prolonged anticoagulation in patients with the combination of thrombophilic mutations, which remains unknown.

For all the reasons stated previously, the benefits of screening for the common thrombophilias is controversial. Patient groups in which screening is likely to yield positive results include those with a history of recurrent VTE or with a confirmed family history of thromboembolism, a first episode of thromboembolism at an early age, spontaneous venous thrombosis, thromboses in unusual anatomic sites, arterial thrombosis, and thromboembolism associated with pregnancy or estrogen use. Whether screening should be performed prior to the initiation of oral contraceptive agents remains a matter of debate.[33,34] The relative risk of VTE is increased approximately fourfold in users of oral contraceptives, although the increase in absolute risk is modest.[24,35] A policy of routine screening would deny effective contraception to a substantial number of women while preventing only a small number of PEs.

In most patients, even those with an identified thrombophilic state, some clinical condition associated with venous stasis, intimal injury, or both serves as the basis for the thromboembolic event.[36] Several trials have also confirmed that the risk of VTE in hospitalized patients is not limited to patients undergoing surgical procedures. Thromboembolic risk in patients admitted with a wide range of acute medical problems is comparable with that seen in surgical patients.[37–39]

Major risk factors include pelvic or lower extremity fractures, hip and knee surgery, a past history of VTE, acute paralytic stroke or spinal injury, major traumatic injury, open prostatectomy, and abdominal or pelvic surgery for malignant disease. Other factors that enhance risk include prolonged general anesthesia, advancing age, cardiac disease, pregnancy, the postpartum period, the use of estrogen-containing compounds, malignancy,

the presence of a lupus anticoagulant or antiphospholipid antibody, and prolonged immobilization.[40] It is important to recognize that these risk factors may be multiplicative.[36] Thromboembolic risk in an otherwise healthy 45-year-old individual undergoing an elective cholecystectomy is considerably less than the risk experienced by an obese 75-year-old with a history of prior VTE undergoing the same procedure. Similarly, the patient with hip fracture or hip replacement has, by virtue of that condition alone, a 60% to 70% risk of deep venous thrombosis (DVT) and a 2% to 4% risk of experiencing a fatal thromboembolic event in the absence of preventive measures. Add other risk factors, and the incidence of DVT—and the likelihood of a fatal complication—will be even higher. These considerations allow the development of a reasonable "risk profile" in an individual patient, a profile that should influence the use and intensity of prophylactic intervention.[36]

NATURAL HISTORY: DEEP VENOUS THROMBOSIS

Venous thrombi appear to originate either in the vicinity of a venous valve cusp, where eddy currents arise, or at the site of intimal injury.[41] Platelet aggregation and release of mediators initiate the sequence. With local accumulation of such factors, the coagulation cascade is activated and thrombus develops, composed primarily of fibrin and erythrocytes. As thrombus extension occurs, local fibrinolytic activity is enhanced. Thus, thrombus behavior becomes a dynamic process that may result in complete dissolution, partial resolution resulting in a variable degree of intimal narrowing and valvular damage, progressive proximal extension, or embolization. In more than half of patients, some degree of permanent venous wall scarring occurs, which is visible on ultrasound.[42] If the venous wall scarring causes severe obstruction, collateral veins develop.

Extensive autopsy and clinical studies have established that some 90% of PEs that elicit clinical attention arise from venous thrombosis in the deep veins of the lower extremities.[43] Venous thrombi capable of embolization can arise from other sites. Primary iliac or proximal femoral thrombi may develop in patients undergoing surgery involving the hip, and pelvic vein thrombosis can occur in patients undergoing pelvic or prostatic surgery. Axillosubclavian vein thrombosis may be spontaneous, resulting from congenital abnormalities of the thoracic outlet, or may be related to indwelling central venous catheters, pulmonary artery catheters, or transvenous pacing wires.[44,44a] In patients with dilated right heart chambers or pulmonary arteries, thrombi can form at those sites and embolize distally into the branches of the pulmonary artery.

The likelihood of embolism is influenced by the location of thrombi in the veins of the lower extremity. Although the majority of thrombi originate in the veins of the calf, it has been clearly demonstrated that thrombi that remain limited to the calf veins rarely result in PE.[45] However, approximately 25% of symptomatic, isolated calf thrombi when left untreated will extend to involve the proximal veins (popliteal, superficial femoral, and common femoral veins, or even more proximally).[46] Proximal extension poses a risk of embolization that approaches 50%.[47,48]

This natural history of DVT has several important diagnostic and therapeutic implications. First, because the vast majority of emboli arise from thrombi in the veins in the lower extremity, diagnostic approaches to DVT can be focused upon techniques that detect lower extremity DVT. Second, techniques that detect above-knee thrombi are of particular value whether or not they can detect calf-limited thrombi. Finally, although it is true that calf-limited thrombi rarely embolize, many have incorrectly concluded from this information that *symptomatic*, calf-limited DVT represents a clinically irrelevant condition. It must be emphasized that proximal extension of calf-limited thrombi may occur. Furthermore, symptomatic calf vein thrombosis appears to be subject to recurrence, albeit at a lower risk than proximal vein thrombosis.[49]

Although most above-knee thrombi represent extensions from calf thrombi, some do arise in the larger, proximal veins de novo. This occurrence appears to be restricted principally to patients with hip fracture or replacement, pelvic surgery (including prostatic resection), and other high inguinal pelvic trauma.

At any time during this process, a portion or all of the thrombus can detach as an embolus. This risk is highest early in thrombus development before significant fibrinolysis or organization occurs. Beyond this acute phase, the long-term outlook is influenced principally by the extent of residual venous obstruction and valvular damage. If significant obstruction or valvular damage persists, downstream stasis will be present, leading to a risk of recurrent DVT and development of the postphlebitic syndrome.[50,51]

NATURAL HISTORY: PULMONARY EMBOLISM

PE is not an isolated disease; it is generally a complication of venous thrombosis. Nonetheless, once it occurs, embolism can induce a series of pulmonary and cardiac effects.[52]

PE causes a number of consequences to gas exchange and other pulmonary functions. Regional obstruction to pulmonary blood flow, and diversion of the flow to unobstructed portions of the lung, may alter the ventilation-perfusion balance in both the obstructed and the unobstructed regions, resulting in hypoxemia.[53,54] If regional pulmonary vascular obstruction is total, alveolar dead space is created.[55] If a region's blood flow is severely obstructed, bronchoconstriction may occur in the lung distal to the area of obstruction as the result of alveolar hypocapnia.[56] This is probably uncommon in patients because they are free to inhale carbon dioxide–rich dead-space air into the associated lung regions and because obstruction is rarely total. Hyperventilation almost always occurs, the mechanism for which remains

uncertain. Arterial hypoxemia may be worsened when acute increases in right ventricular afterload lower the cardiac output enough to widen the arteriovenous oxygen difference and decrease the saturation of mixed venous gas.[57] This lowering of the mixed venous oxygen content magnifies the effects of the normal venous admixture, thereby lowering the arterial oxygen pressure (P_{O_2}). Another potential mechanism for hypoxemia in patients with massive PE is right-to-left shunt, on either an intrapulmonary or an intracardiac basis.[58] With embolic occlusion sufficient to increase pulmonary artery pressure, hypoxic vasoconstrictive mechanisms can be overcome and perfusion to poorly ventilated or nonventilated lung regions may occur. On occasion, embolic events massive enough to increase right atrial pressure may result in intracardiac right-to-left shunting through a patent foramen ovale. The final mechanism for hypoxemia relates to the loss of pulmonary surfactant.[59] Loss of surfactant does not occur immediately. It requires approximately 24 hours of total occlusion and lack of blood flow to develop. At that time or later, surfactant becomes depleted in the obstructed alveolar zones, resulting in atelectasis and edema. If partial thrombus resolution and reperfusion to this atelectatic region develop, hypoxemia can result.

One uncommon local consequence of PE is pulmonary infarction. Infarction is uncommon because the pulmonary parenchyma has three potential sources of oxygen: the pulmonary arteries, the bronchial arteries, and the airways.[60] In patients with no coexisting cardiopulmonary disease, large infarctions (such as those visible by chest radiography) are rare.[61,62] However, autopsy series suggest that infarctions of smaller pulmonary arteries are more common.[63,64] Infarction occurs in approximately 20% to 33% of patients with significant cardiac or pulmonary disease that compromises either bronchial arterial flow or airway patency. In patients with left ventricular failure, increased pulmonary venous pressure may decrease bronchial flow and infarction may result.[65]

The cardiac and hemodynamic effects of embolism are related to three factors: the degree of reduction of the cross-sectional area of the pulmonary vascular bed, the preexisting status of the cardiopulmonary system, and the physiologic consequences of both hypoxic and neurohumorally mediated vasoconstriction.[66–71] Mechanical obstruction of the pulmonary vascular bed by embolism is accompanied by release of vasoconstrictive substances such as thromboxane A_2 and serotonin.[72] The combination acutely increases the workload on the right ventricle, a chamber ill equipped to deal with high-pressure load. In patients without preexisting cardiopulmonary disease, obstruction of less than 20% of the pulmonary vascular bed results in a number of compensatory events that minimize adverse hemodynamic consequences. Recruitment and distention of pulmonary vessels occur, resulting in a normal or near-normal pulmonary artery pressure and pulmonary vascular resistance; cardiac output is maintained by increases in the right ventricular stroke volume and increases in the heart rate. As the degree of pulmonary vascular obstruction exceeds 30% to 40%, increases in pulmonary artery pressure and modest increases in right atrial pressure occur. The Frank-Starling mechanism maintains right ventricular stroke work and cardiac output. When the degree of pulmonary artery obstruction exceeds 50% to 60%, compensatory mechanisms are overcome, cardiac output begins to fall, and right atrial pressure increases dramatically. With acute obstruction beyond this amount, the right heart dilates, right ventricular wall tension increases, right ventricular ischemia may develop, the cardiac output falls, and systemic hypotension develops. In patients without prior cardiopulmonary disease, the maximal mean pulmonary artery pressure capable of being generated by the right ventricle appears to be 40 mm Hg (representing a pulmonary artery systolic pressure of ~70 mm Hg). The correlation between the extent of pulmonary vascular obstruction and the pulmonary vascular resistance appears to be hyperbolic, reflecting at its lower end the expansible nature of the pulmonary vascular bed and at its upper the precipitous decline in cardiac output that may occur as the right ventricle fails.[73]

The hemodynamic response to acute PE in patients with preexisting cardiopulmonary disease may be considerably different.[71] Unlike patients without prior cardiopulmonary disease, in whom there is a general relationship between the degree of pulmonary vascular obstruction and the level of the pulmonary artery pressure, patients with prior cardiopulmonary disease demonstrate degrees of pulmonary hypertension that are disproportionate to the degree of pulmonary vascular obstruction. As a result, severe pulmonary hypertension may develop in response to a relatively small reduction in pulmonary artery cross-sectional area. Thus, evidence of right ventricular hypertrophy (rather than right ventricular dilation) associated with a mean pulmonary artery pressure in excess of 40 mm Hg (pulmonary artery systolic pressure in excess of ~70 mm Hg) in a patient suspected of embolism should suggest an element of chronic pulmonary hypertension resulting from a potentially diverse group of etiologic possibilities (e.g., chronic thromboembolic pulmonary hypertension, left ventricular failure, valvular disease, right-to-left cardiac shunts).

Beyond the acute embolic event, the behavior of emboli parallels that previously described for venous thrombi; that is, they undergo resolution by fibrinolysis, by organization and recanalization, or both. Although there is a great deal of interpatient variability, resolution of PEs typically is substantial during the first week, somewhat more gradual for the next 4 to 8 weeks, and then very slow thereafter.[55,74–79] (The most rapid resolution of a large embolus that has been documented is 51 hr.[80]) The term *resolution* is used here because it is uncertain, in humans, to what degree lysis (versus organization) participates in embolic resolution. Most sequential data regarding resolution in humans are based on perfusion scan, not angiographic data. However, these data suggest that residual anatomic defects are common following embolism and, contrary to prior opinion, that complete restoration of pulmonary blood flow represents the exception rather than the rule.[55,74–79] In terms of hemo-

dynamic resolution, it would appear that a stable pulmonary artery pressure is reached within 6 weeks.[81] How often anatomic and mild hemodynamic residuals persist is not known. What is known is that residual obstruction sufficient to cause pulmonary hypertension is rare. The clinical course and management of this small group of patients are dealt with later in this chapter.

CLINICAL PRESENTATION

The most common symptoms and physical findings of venous thrombosis include swelling, pain, erythema, and warmth. "Classic" findings such as *Homan's sign* (calf pain with flexion of the knee and dorsiflexion of the ankle), *Moses' sign* (pain with calf compression against the tibia), or a palpable cord occur infrequently and are nonspecific.

Multiple investigations have established that the clinical diagnosis of venous thrombosis is imprecise.[43,82–84a] In patients with clinical signs and symptoms suggestive of venous thrombosis, 60% to 80% will not have the diagnosis established by objective testing. Furthermore, and even more disquieting, the majority of high-risk patients who are monitored and who develop DVT will not have signs or symptoms suggesting that diagnosis.[85] Algorithmic clinical models incorporating risk factors, symptoms, and physical signs have been demonstrated to have the ability to stratify *symptomatic* patients into risk categories, although not to a level in which clinical diagnosis, in the absence of objective testing, can be relied on exclusively to either confirm or exclude the diagnosis.[84,86] The differential diagnosis of DVT is extensive and includes cellulitis, arthritis, muscular injury or tear, neuropathy, arterial insufficiency, lymphedema, ruptured Baker's cyst, superficial thrombophlebitis, and chronic venous insufficiency.

Similarly, the diagnosis of PE cannot be confirmed or excluded solely on clinical grounds.[87–89] However, recognition of the clinical signs and symptoms associated with embolism is valuable because clinical findings and clinical suspicion represent an essential first step in the diagnostic pathway. Although a somewhat arbitrary classification because presenting symptoms and signs of embolism frequently overlap, the presentation of PE can be categorized into one of three clinical syndromes: (1) isolated dyspnea; (2) pleuritic pain or hemoptysis; and (3) circulatory collapse.[90] Among patients without prior cardiopulmonary disease in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, the syndrome of pleuritic pain or hemoptysis was the most common mode of presentation, occurring in approximately 60% of patients; isolated dyspnea occurred in approximately 25%, and circulatory collapse occurred in 10%.

The most common presenting symptom of acute embolism is the sudden onset of dyspnea.[89–91] In various studies, this has occurred in the majority of patients. However, it must be emphasized that in the PIOPED study,[91] dyspnea was not present in 27% of patients ultimately proven to have embolism. Pleuritic chest pain was present in 66% of patients, whereas hemoptysis (15%) was uncommon. Other symptoms occurring in less than 50% of patients included cough (37%), leg swelling (28%), and leg pain (26%). A sense of impending doom also is reported, particularly with massive embolism. Angina also can occur with massive embolism, representing, in this circumstance, right ventricular ischemia. Syncope also may be a presenting complaint in major embolic occlusion.

The most common physical finding is unexplained tachypnea (respiratory rate > 20/min). In the PIOPED study,[91] however, tachypnea was not present in approximately 30% of patients with embolism. Clinical findings noted less frequently include crackles (55%), tachycardia (30%), and an increased pulmonic component of the second heart sound (S_2; 23%). Fever may develop some hours after the event and often reaches but rarely exceeds 38.3°C. As noted previously, hemoptysis may be observed; it usually is quite modest in extent, although it persists for some days. Brisk hemoptysis is rare and almost never the initial finding. With massive embolism, there may be evidence of right ventricular overload or failure, such as a right ventricular tap along the left sternal border and an accentuated pulmonary valve closure sound. If right ventricular failure occurs, there may be narrowed or fixed splitting of S_2, an S_3, and/or an S_4, distended neck veins, and cyanosis. Careful examination of the legs may elicit evidence suggesting venous thrombosis. In the PIOPED study,[91] clinically apparent venous thrombosis was found in only 15% of patients.

Obviously, these symptoms and signs are nonspecific. In the PIOPED study,[90,91] none of the presenting symptoms was capable of discriminating between those patients with positive angiograms and those in whom the angiographic findings were negative. Also, in terms of presenting signs, only the presence of crackles, an S_4, and an increased pulmonic component of S_2 could differentiate between those with positive and negative angiograms.[90,91] Furthermore, in patients with underlying cardiopulmonary disease, the presenting symptoms and signs frequently may be obscured by elements of the underlying illness.[88] It is also important to recognize that the clinical presentation of embolism has been characterized in trials composed of symptomatic patients. Prospective studies of high-risk patients have established that asymptomatic emboli occur in some 40% or more of patients with proximal DVT.[47,87,92] It is likely that the frequency and severity of symptoms are influenced by the extent of embolic occlusion and the prior cardiopulmonary status of the patient. Small- or moderate-sized emboli may induce few or no symptoms in an otherwise normal individual. In patients with preexisting cardiopulmonary disease, symptoms are more common and severe.[92a]

Owing to the nonspecific presentation of PE, the differential diagnosis is varied and extensive, especially in hospitalized patients with coexisting cardiac or pulmonary disease. Common considerations include congestive heart failure, exacerbation of chronic lung disease, postoperative atelectasis, and viral pleurisy. Emboli presenting with fever, dyspnea, and chest radiographic abnormalities easily can be confused with a bacterial

pneumonia. The presence of fever and leukocytosis (rarely >15,000/μL) are uncommon but well-described accompaniments of VTE.[93,94]

These precautionary statements regarding clinical diagnosis are not meant to suggest that the clinical presentation of venous thrombosis or PE cannot be used as a basis for clinical decision making. However, they are meant as a reminder that the clinical presentation of VTE may often be atypical or subtle and should serve only to generate a suspicion of that diagnosis. A reliance on signs and symptoms that are considered "classic" prior to making the decision to proceed to confirmatory testing may lead to underdiagnosis and unnecessary mortality.

DIAGNOSIS OF VENOUS THROMBOSIS

The proper diagnostic approach to VTE must take into account the central fact that venous thrombosis and PE are manifestations of the same disease process: venous thrombosis representing the source of PE, and PE representing a complication of venous thrombosis.

Contrast Venography

In validating any test, there must be a "gold standard." In the case of lower extremity venous thrombosis, that standard is contrast venography (Fig. 51-1). In investigative contexts, it is a good gold standard (as indicated later, however, that often is not the case in clinical contexts). The venogram is performed according to a specific protocol described by Rabinov and Paulin in 1972.[95]

FIGURE 51-1 ■ Contrast venogram discloses a large filling defect (*arrows*) due to thrombus in the popliteal and distal superficial femoral veins. Such thrombi pose substantial embolic risk.

The most reliable criterion for the diagnosis of venous thrombosis is a constant intraluminal filling defect evident in two or more views. Other criteria such as nonvisualization of deep veins, venous collaterals, or nonconstant filling defects are less reliable. Under circumstances in which the proper protocol and interpretative criteria are utilized, contrast venography has high sensitivity and specificity. However, the study is not without shortcomings. As those who have seen many venograms recognize, the study is not easy to interpret, especially in patients with a prior history of venous thrombosis. Venous cannulation may often be difficult, especially in the presence of edema; expert interpretation is essential for accurate diagnosis; injection of contrast material with its associated allergic and nephropathic risks is necessary; venous thrombosis may be induced by the procedure itself; and the cost, invasive nature, and discomfort of the study make sequential studies impractical.

Owing to these limitations, a number of noninvasive studies capable of being performed on a sequential basis were introduced into clinical practice. At the present time, the two most commonly validated noninvasive techniques are duplex ultrasonography and impedance plethysmography (IPG). Magnetic resonance imaging (MRI) and computed tomography (CT) have proved capable of detecting thrombi, but their widespread utilization has been limited by cost, limited access, and in the case of CT, the need for contrast administration.

Duplex Ultrasonography

Since the late 1990s, duplex ultrasonography, which refers to the combination of Doppler venous flow detection and real-time B-mode imaging, has assumed a central role in the noninvasive diagnosis of symptomatic lower extremity DVT.[96] A number of criteria are used to diagnose venous thrombosis, the most reliable of which is noncompressibility of a venous segment (Fig. 51-2). Secondary, less reliable criteria include the presence of echogenic material within the venous lumen, venous distention, and loss of phasicity, response to Valsalva's maneuver, and augmentation of spontaneous flow. The absence of an echogenic luminal mass cannot be considered useful in excluding the diagnosis of venous thrombosis because acute thrombus may not demonstrate echogenicity. Multiple studies since the late 1990s have demonstrated sensitivities and specificities exceeding 95% in *symptomatic* patients with proximal venous thrombosis. Although simplified compression examinations limited to the symptomatic leg or to the common femoral and popliteal veins (rather than the entire lower extremity venous system) have been suggested, the time saved with such approaches is limited, and a number of isolated superficial femoral vein or calf-limited thrombi may be overlooked.[97–99] Asymptomatic thrombi in the contralateral leg can be detected in approximately 5% to 10% of patients presenting with symptomatic acute venous thrombosis.[100] Although the detection of asymptomatic, contralateral thrombi has little impact on the immediate management of the patient, it may have long-

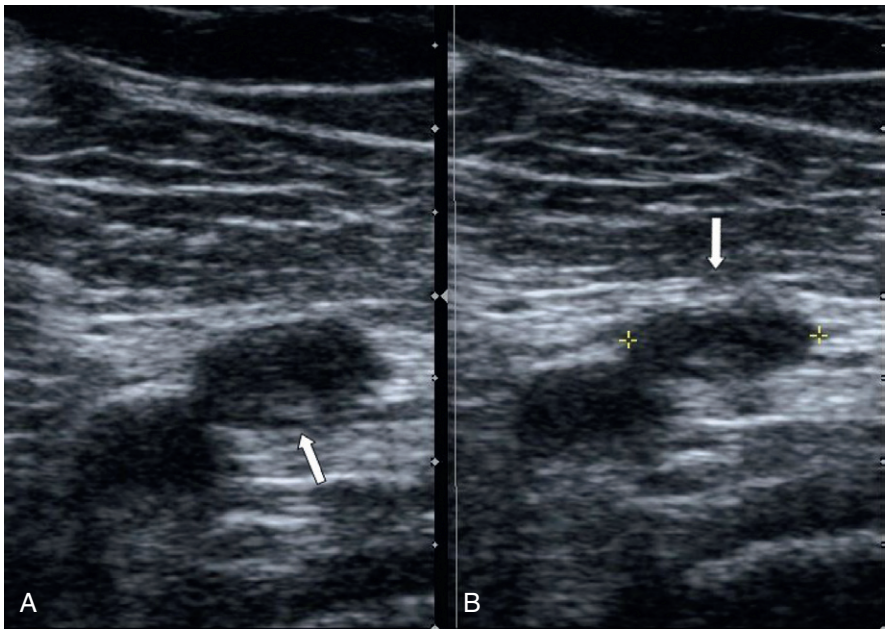

FIGURE 51-2 ■ Duplex ultrasonography demonstrates a noncompressible distal superficial femoral vein containing an echogenic mass (*arrow*), consistent with venous thrombosis.

term consequences when recurrence is suspected. A more prudent approach appears to be a complete examination extending from the inguinal ligament to the popliteal vein and examination of the contralateral extremity if thrombus is detected in the symptomatic leg.

Duplex ultrasonography is less accurate in the detection of symptomatic calf-limited thrombi (sensitivity ~70%) and in asymptomatic proximal vein thrombi (sensitivity ~50%), thereby limiting its utility as a screening study in high-risk populations.[101] When ultrasonography is negative in patients with suspected venous thrombosis, a strategy of serial testing has proved to be effective in detecting proximal extension.[102]

Impedance Plethysmography

IPG, an indirect technique that measures the rate of venous outflow, has been well standardized and carefully validated against contrast venography.[103] False-positive studies may result from conditions that diminish arterial inflow (congestive heart failure, shock, peripheral arterial disease) or that impede venous return (right ventricular failure, obstructive lung disease), thereby lowering the specificity of the technique. Early studies reported sensitivities of approximately 90% in symptomatic patients with proximal venous thrombosis.[103] Calf thrombi are detected in approximately 25%, a figure that reflects the lesser degree of venous obstruction in most (though not all) calf thrombi.

Clinical studies of IPG accuracy have raised questions regarding the ability of IPG to detect even symptomatic proximal vein thrombosis. Reported sensitivities in these studies have been in the range of 65% to 75%.[104,105] The low sensitivity of IPG in these studies may result from its use in patients with less severe symptoms because these patients are more likely to have small, nonocclusive, or distal thrombi that IPG cannot readily detect. Supporting this premise is the fact that IPG sensitivity returns to 85% to 90% when more extensive thrombi and those that have extended into the distal superficial femoral vein are evaluated. These data support the current recommendation that a single negative IPG study should not be used to exclude venous thrombosis in a symptomatic patient. However, a strategy of serial IPG testing has been demonstrated to be useful in detecting proximal extension.[102,106] Although this strategy has proved effective, confirmatory testing with duplex ultrasonography or venography may be necessary when IPG results conflict with clinical impression, especially in patients with limited cardiopulmonary reserve, in whom embolism would be tolerated poorly.[86]

The detection of possible recurrent venous thrombosis represents a diagnostic challenge for which IPG may play a role.[107] The resolution rate for IPG-documented venous thrombosis at 6 months has been found to be 85% and at 12 months to be 95%. Therefore, reversion of IPG results from normal to abnormal in a symptomatic patient with suspected recurrent venous thrombosis provides strong evidence that recurrence has occurred. However, the utility of such an approach mandates that follow-up IPG be performed and that IPG normalization has been documented in an individual patient.

Magnetic Resonance Imaging

MRI techniques for detecting venous thrombosis include spin-echo magnetic resonance, gradient-recalled-echo magnetic resonance, and magnetic resonance venography. Preliminary reports suggest that MRI is at least as sensitive and specific as duplex ultrasonography.[108,109] A potential advantage of MRI is that the entire length of the venous system, including the pelvic veins, can be evaluated. Disadvantages associated with MRI include cost and limited access as well as the expertise required to properly perform and interpret the studies.

Computed Tomography

The role of CT as a stand-alone test for venous thrombosis is limited. The sensitive and specificity of CT venography are comparable with those of ultrasonography but mandate contrast injection with its associated risks and radiation exposure. Potential advantages of CT venography include the ability to visualize the pelvic veins and vena cava. A diagnostic approach combining CT venography with computed tomography pulmonary angiography (CT-PA) may have a role in patients undergoing evaluation for PE (see later).[110,111]

Hemostaseologic Assays

The development of a rapid and accurate blood test capable of diagnosing VTE has held special appeal and has been the subject of considerable investigative interest. A number of different serologic markers have been investigated, including D-dimer, fibrin monomer, prothrombin fragment, thrombin–antithrombin III complex, fibrinopeptide B, and fibronectin. Of these, D-dimer, alone and in combination with other noninvasive studies, has been subject to the most rigorous clinical evaluation.[112,113] D-Dimer testing has proved to be highly sensitive but not specific; that is, elevated levels are present in nearly all patients with thromboembolism but also occur in a wide range of circumstances, including advancing age, pregnancy, trauma, infections, the postoperative period, inflammatory states, and malignancy. Therefore, the role of D-dimer testing is limited to one of thromboembolic exclusion. Multiple assays have been developed with sensitivities that range from 80% to almost 100%.[112,113,113a] Highly sensitive assays such as the enzyme-linked immunosorbent assay are capable of excluding thromboembolism but are associated with such a high frequency of false-positive results that their clinical utility is limited. Less sensitive assays (e.g., latex agglutination, red cell agglutination) lack the ability to exclude thromboembolism in isolation but have been used successfully in combination with either a clinical probability estimate or a noninvasive diagnostic study. Although potentially of substantial value in diagnostic pathways, the burgeoning selection of available assays, variations in sensitivity and specificity related to the type of assay, a range of discriminate values for positivity, and lack of standardization have limited generalized application of the technique due to uncertainty among clinicians regarding the predictive value of the test they are utilizing. D-Dimer testing has been utilized successfully as part of a number of different diagnostic strategies, and negative results of standardized, highly sensitive assays have proved capable of safely excluding venous thrombosis in outpatients presenting with a low or intermediate clinical likelihood of the disease.[114,115]

Clinical Prediction Rules

A major advance in the diagnostic approach to both venous thrombosis and PE has been a transition from a technique-oriented approach to one that utilizes bayesian analysis. In this strategy, the pretest probability of the disease, calculated independently of a particular test result either through empirical means or through a standardized prediction rule, is evaluated in combination with a test's likelihood ratio (derived from the sensitivity and specificity of that test) to create a posttest probability of the disease. This posttest probability can then be utilized as a basis for clinical judgment, either excluding the disease with a certain level of probability, confirming the disease with a certain level of probability, or supporting the need for additional diagnostic testing. This approach to diagnosis has proved especially useful in an era of noninvasive testing in which results are often presented as probabilities rather than as discrete answers.

Several clinical prediction rules for venous thrombosis have been developed and validated.[116] The Wells rule, initially described in 1995 and revised in 1997 to include nine clinical features, proved capable of stratifying patients with suspected venous thrombosis into three probability categories—low, moderate, and high—in which the incidence of venous thrombosis approximates 3%, 17%, and 75%, respectively.[117] By utilizing this prediction rule in combination with lower extremity ultrasonography, the diagnosis of venous thrombosis can be safely excluded in patients with a low clinical likelihood of venous thrombosis in combination with a negative lower extremity ultrasound and confirmed in patients with a high clinical probability and a positive lower extremity ultrasound. Such an approach dramatically reduces the need for contrast venography or serial lower extremity ultrasound studies.

The Wells prediction rule was subsequently revised in 2003 to include 10 clinical characteristics capable of stratifying outpatients into "clinically likely" and "clinically unlikely" categories (Table 51-2). For outpatients falling into the clinically unlikely category, DVT was reliably excluded when the result of a sensitive D-dimer assay was negative, thereby limiting the need for ultrasound evaluation.[115] The ability to exclude venous thrombosis in outpatients using a clinical prediction rule and negative results of a D-dimer assay has been confirmed in other studies.[118] It should be emphasized that clinical prediction rules constructed and validated in outpatients should be viewed critically before they are applied to an inpatient population.

DIAGNOSIS OF PULMONARY EMBOLISM

There are certain parallels between the approaches to the diagnosis of PE and DVT. Perhaps the most important parallels are that clinical evidence in isolation, although capable of raising the suspicion of the disease, cannot be relied upon to confirm or exclude the diagnosis and that the use of clinical prediction rules in combination with noninvasive testing can substantially decrease the need for invasive diagnostic testing.

Standard Laboratory Evaluation

Routine laboratory studies cannot make the diagnosis of PE. Although none has the discriminatory power to confirm the diagnosis of embolism, they do provide valuable adjunctive information and support for therapeutic interventions and may confirm the presence of an alternative diagnosis.

TABLE 51-2. Wells Clinical Model for Predicting the Pretest Probability of Deep Venous Thrombosis

Clinical Characteristic	Score
Active cancer (patient receiving treatment for cancer within the previous 6 mo or currently receiving palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for 3 days or more, or major surgery within the previous 12 wk requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below the tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Previously documented deep venous thrombosis	1
Alternate diagnosis at least as likely as deep venous thrombosis	−2

Score	Clinical Assessment Probability
<2 points	Unlikely
≥2 points	Likely

From Wells PS, Anderson DR, Rodger M, et al: Evaluation of D-dimer in the diagnosis of suspected deep vein thrombosis. N Engl J Med 349:1227–1235, 2003.

The majority of patients with PE have abnormal chest radiographs.[119] However, these abnormalities are usually subtle, nonspecific, and therefore nondiagnostic (Fig. 51-3). In the PIOPED study,[91] the most common radiographic abnormalities were atelectasis and pulmonary opacities. There is some confusion about the diagnostic configuration of radiographic abnormalities due to embolism. Although usually abutting a pleural surface, the opacities can be of any shape, not necessarily wedge-shaped. Although pleural effusions occur in almost half of the patients, the majority of effusions are small and involve only blunting of the costophrenic angle.[89] Findings once considered specific for embolism, such as the *Westermark sign* (focal areas of avascularity), the *Hampton hump* (pleural-based, wedge-shaped density), and the *Fleischner sign* (prominence of the central pulmonary artery), have not proved to have discriminatory value. In a patient with hypoxemia or pulmonary complaints, a normal chest radiograph may be quite useful in raising the index of suspicion of embolism and in excluding confounding diagnostic options. The major roles of chest radiography in suspected PE, therefore, are to exclude competing diagnoses and, if ventilation-perfusion (V/Q) scanning is anticipated, to evaluate the pulmonary parenchyma.

Likewise, electrocardiographic findings in PE, although occurring frequently, are diverse and nonspecific.[120] The most common abnormalities include nonspecific tachycardia, T wave inversion, and abnormalities of the ST segment. With more extensive occlusion, the electrocardiogram may reveal the more "classic" findings of right heart strain, including an "$S_1Q_3T_3$" pattern, a pseudoinfarction pattern (Qr in V_1), a complete or incomplete right bundle-branch block, or right axis deviation.[120,121] Rhythm disturbances other than sinus tachycardia are uncommon and usually confined to patients with underlying cardiac disease.[120]

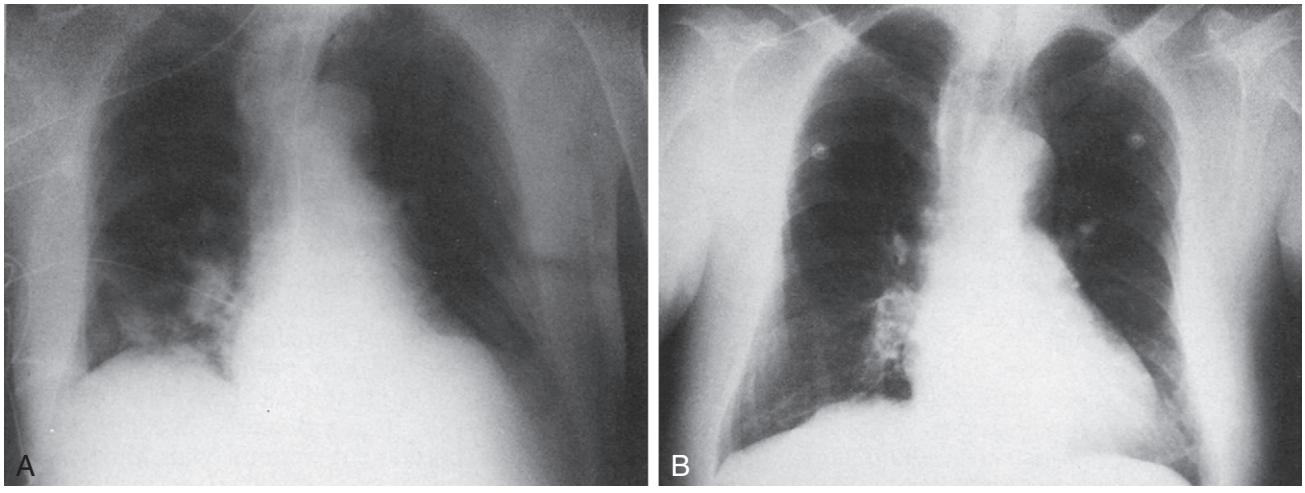

FIGURE 51-3 ■ Chest radiographs in a patient with pulmonary embolism. **A,** Opacities caused by atelectasis with edema in the right lower lobe and in the retrocardiac area in a patient with angiographically confirmed pulmonary embolus. **B,** Two weeks later, the opacities have cleared.

Arterial blood gas analysis is helpful, although not definitive.[122] Arterial hypoxemia may be present, and the more massive the obstruction, the more severe the hypoxemia is likely to be. However, many other conditions also cause hypoxemia, and embolism often does not cause hypoxemia or even a widening of the alveolar-arterial P_{O_2} difference. Hypocapnia usually is present with embolism; hypercapnia, conversely, is rare. Hypercapnia appears with embolism only in patients with marked antecedent ventilatory limitation or when such limitation has been imposed because the patient is on controlled mechanical ventilation when embolism occurs.

Echocardiography

Echocardiography may serve a valuable role in the diagnostic approach to PE. Under appropriate clinical circumstances, the detection of unexplained right ventricular volume or pressure overload might suggest the possibility of embolism and lead to confirmatory testing. A distinct echocardiographic pattern involving akinesia of the mid-free right ventricular wall with apical sparing has been described.[123,124] Properly performed *transesophageal* echocardiography has demonstrated excellent specificity for the detection of proximal emboli that involve the pulmonary trunk and the right and left main pulmonary arteries.[125] Transesophageal echocardiography also has proved valuable in the evaluation of competing diagnostic possibilities such as right ventricular infarction, endocarditis, pericardial tamponade, and aortic dissection in patients with unexplained shock and evidence of elevated central venous pressure. The overall sensitivity of *transthoracic* echocardiography in PE approximates 50%.[126] Therefore, it cannot be considered a primary diagnostic technique. Consideration can be given to its use in that subset of patients with suspected massive PE who are too ill for transportation or who have an absolute contraindication to the administration of a contrast agent.

More recently, echocardiography has been investigated along with other techniques as a means of stratifying risk in patients with embolism.[127] Short-term mortality risk in PE is strongly related to the presence of systemic hypotension at the time of diagnosis. However, systemic hypotension represents a late and potentially fatal manifestation of right ventricular dysfunction. For this reason, transthoracic echocardiography[127] and biochemical markers such as serum troponin[128] or serum brain natriuretic hormone[129] levels have been investigated as a means of evaluating right ventricular function in patients with embolism. Preliminary studies have suggested that these techniques are capable of identifying patients with a good prognosis and may identify a subset of patients who are at risk for adverse events, including death. However, it has not been conclusively established that the potential risks of a more aggressive therapeutic approach in all such patients in the latter group, the majority of whom have a satisfactory outcome when treated with conventional therapy alone, justifies the potential benefit.[130]

Ventilation-Perfusion Scanning

Despite limitations, V/Q lung scanning is a valuable step in the diagnosis of PE if it is interpreted appropriately.[91,131] First, a negative study rules out the diagnosis of PE with the same degree of certainty as a negative pulmonary angiogram (Fig. 51-4) and with a higher degree of certainty than is achieved by a negative CT scan.

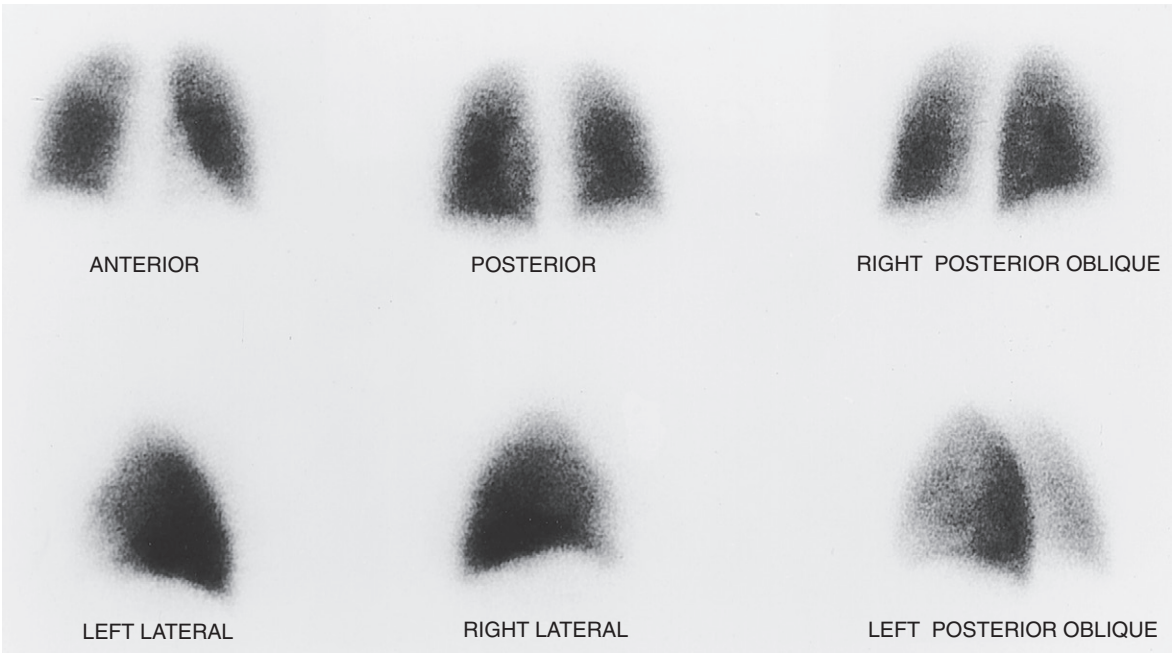

FIGURE 51-4 ■ Normal six-view lung perfusion scan. This finding is capable of excluding the diagnosis of embolism.

The results of clinical trials have been consistent in demonstrating that normal perfusion scans essentially rule out the presence of PE. This conclusion is illustrated by the results of two large prospective clinical trials comparing perfusion scanning to pulmonary angiography, the PIOPED trial[91] (performed in the United States) and the Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis (PISA-PED) trial[132] (performed in Europe). In both trials, normal pulmonary perfusion scanning was a highly sensitive method for ruling out the presence of PE. The value of a normal perfusion scan was not diminished even in a subset of patients who had a high pretest probability for PE[91] or were critically ill.[133]

The significance of a normal perfusion scan disclosed by the PIOPED and PISA-PED trials is consistent with all published longitudinal studies of patients suspected of having PE, but with normal perfusion scans.[134–136] A meta-analysis of diagnostic studies for PE calculated the incidence of PE following a normal perfusion scan to be 0.3%.[137] A subsequent case series of consecutive patients followed clinically after objective testing for PE disclosed no PEs in 188 patients who had normal perfusion scans.[138] These data support the clinical guidelines of the American Thoracic Society,[139] the British Thoracic Society,[140] the American Heart Association,[141] and the European Society of Cardiology,[142] all of which recommend that a normal perfusion scan be accepted as reliably ruling out PE, with the same validity as a pulmonary angiogram.

Second, the PIOPED study[91] demonstrated that a "high-probability" study (one characterized by multiple, segmental-sized, mismatched defects) is associated with embolism in approximately 87% of patients; when coupled with a high clinical probability of embolism, the positive predictive value increased to 96% (Fig. 51-5).

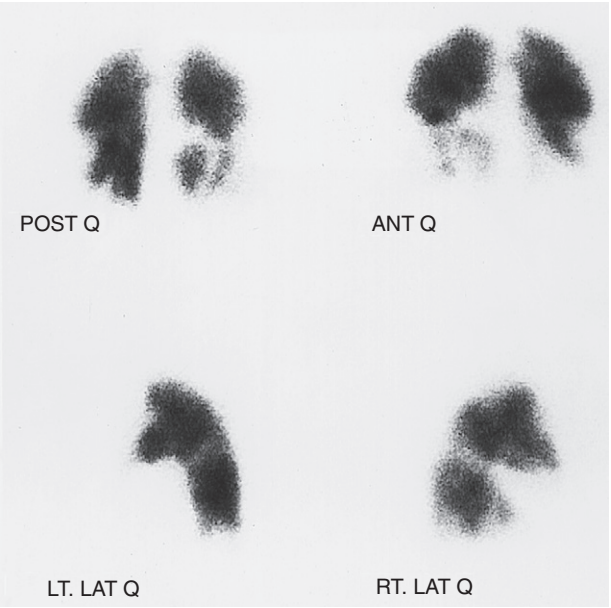

FIGURE 51-5 ■ Lung perfusion (Q) scan shows major segmental and lobar defects bilaterally. Ventilation scan and chest radiograph were normal. This pattern is strongly associated with the presence of embolism.

However, the PIOPED data also provided several pieces of disquieting information: (1) the overwhelming majority of patients with suspected embolism did not have scan findings that fell into a high-probability or normal category, the only categories that can be considered definitive; (2) the majority of patients with embolism did not have a high-probability scan finding; (3) the overwhelming majority of patients without embolism did not have a normal scan; and (4) a substantial and clinically significant percentage of patients with scan findings interpreted as intermediate probability (33%) and low probability (16%) were subsequently demonstrated to have angiographic evidence of embolism.[91] It is essential that clinicians recognize that the concept of a low-probability scan is misleading and potentially dangerous because of the frequency of PE in patients exhibiting this scan pattern.[143]

In order to improve perfusion scan specificity, traditional interpretive criteria, including the PIOPED criteria, rely on the number and size of the perfusion defects as well as on the results of a concurrent ventilation image. The intended basis for doing so is to differentiate pulmonary vascular obstruction ("mismatched" defects) from primary parenchymal disorders that result in compensatory pulmonary vasoconstriction ("matched" defects). The PISA-PED investigators[144] utilized a fundamentally different interpretive scheme that relied on the shape of the perfusion defects regardless of their number or size or their association with ventilation findings. The results of this study suggest that embolism can be diagnosed accurately and the need for angiography limited by perfusion results combined with an assessment of clinical likelihood in the absence of ventilation imaging. An analysis of a subset of patients from the PIOPED study came to a similar conclusion.[145]

The diagnostic approach to PE in patients with underlying chronic obstructive pulmonary disease (COPD) remains especially problematic because the presentation of PE in this population may closely mimic an exacerbation of their underlying disease. Unfortunately, the value of V/Q scanning in this population is even more limited than that in the general population in that an even higher proportion of scans fall into an indeterminate category.[146] However, among the more than half of COPD patients who had high-probability, normal or near-normal scans, both the positive predictive value and the negative predictive value were equivalent to that in the general population.

Spiral (Helical) Computed Tomography

CT has represented a major advance in PE diagnosis. Unlike V/Q scanning, it provides the ability to directly visualize emboli as well as to detect parenchymal abnormalities that may support the diagnosis of embolism or provide an alternative basis for the patient's complaints (Fig. 51-6). The reported sensitivity of helical CT scanning for embolism has ranged from 57% to 100%, with a specificity ranging from 78% to 100%.[147] Factors responsible for this wide divergence relate to the proximal extent of vascular obstruction that can be detected and,

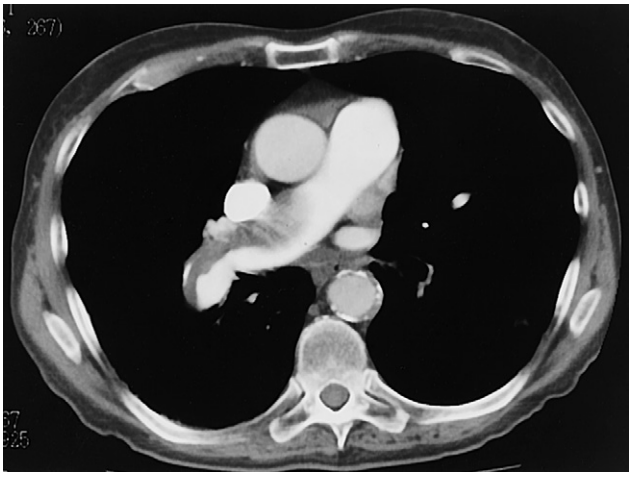

FIGURE 51-6 ■ Chest computed tomography scan demonstrates extensive embolization involving the right main, upper lobe, and lower lobe pulmonary arteries.

in part, to advances in CT technology that allow higher resolution, dramatically faster scanning times, more peripheral visualization, and less motion artifact than that provided by earlier generation scanners. Sensitivity and specificity of CT scanning for emboli involving the main and lobar pulmonary arteries exceeds 95%. Vascular involvement confined to segmental or subsegmental pulmonary vessels is associated with a decline in both sensitivity and specificity. In one series, the sensitivity of CT scanning for subsegmental arteries reported by two readers ranged between 71% and 84% even after nonevaluable scans were excluded.[148] Isolated involvement of the subsegmental pulmonary arteries is not unusual and in various series has been demonstrated to occur in up to 30% of patients.[149,150] These findings suggest that filling defects consistent with embolism involving the main or lobar pulmonary arteries can be considered diagnostic of embolism. Defects involving the segmental and subsegmental arteries can be considered suggestive of embolism but should be supported by additional objective data. The absence of detectable filling defects reduces the likelihood of embolism but appears incapable of excluding the possibility with the same degree of certainty as a negative V/Q scan.

Although CT-PA scanning has increased the number of cases of acute PE that are diagnosed,[151] it has inherent limitations. The technique requires infusion of intravascular iodinated contrast agents and the most common serious complications of testing arise from their use. During CT scanning, the peripherally infused dye fills the lumen of the pulmonary arteries, hopefully at the exact time that the chest is imaged. Emboli are detected as focal defects in pulmonary artery filling. When performed and interpreted expertly, CT-PA scans are capable of identifying emboli in the segmental or larger pulmonary arteries (as does V/Q scanning[152,153]). However, certain areas, such as the hila, are prone to false positives. Reading emboli in these areas should be done with special care. Perhaps more importantly, CT scans have a particular weakness in imaging emboli in subsegmental pulmonary arteries. The smaller clots account for about 20% to 30% of PEs[149,154] and represent the very cases in which V/Q scans are the most limited.[91]

The National Institutes of Health (NIH)–funded "Prospective Investigation of Pulmonary Embolism Diagnosis—2" (PIOPED-2) study highlighted the strengths and limitations of CT-PA.[111] Prior to enrolling the study population of 1090 patients, the investigators excluded 1350 patients because their abnormal creatinine levels reflected some degree of renal dysfunction, which would have increased the risk involved with the administration of contrast dye. An additional 272 patients were excluded because of a history of contrast dye allergy. During the performance of the trial, 6% of the scans were excluded because the images were of poor quality. Even after the inconclusive scans were disregarded, the sensitivity of the thoracic CT scans was only 83%.

The PIOPED-2 investigators also excluded another 976 patients from the study because they had history of long-term anticoagulation therapy. This highlights another weakness of CT-PA in that luminal filling defects remain long after an acute pulmonary embolic event, so the test cannot differentiate between chronic and acute VTE. This is clinically relevant because the rate of recurrence is about 7% during the half-year after an acute PE and about 3%/yr for the subsequent 5 years.[155]

Finally, CT-PA can expose patients to clinically significant doses of radiation.[156,157] Current clinical protocols deliver a radiation dose to the female breast ranging from 4 to 6 cGy per scan.[157] This dose is especially concerning because most CT-PA evaluations are negative, even when the criteria for scanning are rigorously followed.[111,131] In addition, because PE has a relatively high rate of recurrence, patients are commonly reimaged after their first occurrence. Younger women, who have a known elevated incidence of PE, are particularly at risk from radiation damage to breast and lungs.

From a clinical (outcomes-based) perspective, CT scanning and V/Q scanning have many similarities, and either can be used to exclude clinically significant PE in stable patients under many circumstances. Outcome studies have demonstrated that withholding anticoagulant therapy in patients with a negative CT scan coupled with a negative lower extremity ultrasound study appears to be a safe strategy except in those patients who present with a high clinical likelihood of embolism.[158,159] Similarly, withholding anticoagulation from patients with "non–high-probability" findings on V/Q scan coupled with negative lower extremity studies is safe, except in those with inadequate cardiopulmonary reserve.[160,161] A recent randomized, controlled trial comparing CT and V/Q for the management of suspected PE found the two studies to be comparable for excluding clinically significant PE.[131] Specifically, the study disclosed no difference in outcome among patients in whom anticoagulation was withheld based on the combination of a negative CT and negative leg studies compared with patients in whom anticoagulation was withheld based on the combination of a "non–high-probability" V/Q scan and negative leg studies or on a negative V/Q scan (without the need for leg studies). However, it should be emphasized

that the outcome studies were done on relatively stable patients. Those with instability or poor cardiopulmonary reserve may required a higher degree of diagnostic certainty in order to safely rule out PE.[161]

Lower Extremity Venous Evaluation

Because the majority of PEs arise from the deep veins of the lower extremities, the detection of lower extremity proximal vein thrombosis in a patient suspected of embolism, although not confirming that embolism has occurred, is strongly suggestive of that diagnosis and has an equivalent therapeutic implication. Positive ultrasound findings without symptoms or signs referable to the lower extremities should be interpreted judiciously, especially in patients with low pretest probability of PE, because even a highly specific test can yield false-positive results in some circumstances.[162] Lower extremity ultrasonography has a very low yield in patients without leg symptoms or risk factors strongly suggestive of thromboembolism.[163,164] Conversely, it is typically positive in only about 10% to 20% of patients with suspected embolism and in 50% of patients with proven embolism.[165] Therefore, a negative ultrasound finding cannot exclude the diagnosis. CT venography as an adjunct to helical CT scanning appears to be capable of detecting femoropopliteal thrombosis with the same accuracy as duplex ultrasonography while also detecting pelvic and abdominal thrombosis.[110,111] However, the combined CT technique is technically complicated[111] and significantly increases the amount of pelvic radiation exposure to the patient.[156,157,166]

D-Dimer Testing

The utility of D-dimer testing in PE diagnostic pathways is limited by the same shortfalls as those encountered in venous thrombosis pathways: that is, a low specificity that makes it most useful as an exclusionary technique in outpatients and a lack of standardization. However, studies have demonstrated that a normal D-dimer result can safely exclude embolism in patients with a low clinical probability of disease.[167–169] Although preliminary data suggest that a highly sensitive assay is capable of excluding embolism at all levels of clinical probability, these results require confirmation.[169]

Pulmonary Angiography

The studies reviewed to date are capable of excluding or confirming the diagnosis of embolism in the majority of patients with suspected embolism. Angiography should be considered in patients in whom the diagnosis has not been confirmed or excluded using noninvasive techniques and when it is considered unsafe to withhold anticoagulation; when cardiopulmonary instability is present; and when the results of diagnostic testing are at such odds with the clinical impression as to warrant the risk of the procedure. Like contrast venography, however, pulmonary angiography has a number of limitations as a gold standard. First, the procedure is invasive and not without risk, especially in patients with acute right ventricular failure. However, experience has demonstrated that the perception of risk associated with angiography outweighs the actual risk.[170,171] Pulmonary angiography can be performed quite safely if certain safeguards are observed and experienced personnel are involved.

Even though the risk of angiography should be nominal, the procedure has other limitations. One is accessibility: Angiography must be performed in a special facility to which the patient must be transported. In some institutions, the logistical problems involved are modest; in others, they are substantial. The other limitation is interpretation. The interpretation of pulmonary angiograms is heavily influenced by three factors: the location of the thromboembolic obstruction, the quality of the images, and the experience of the interpreters. Only two angiographic findings are diagnostic of acute embolism: the filling defect and abrupt cutoff of a vessel (Fig. 51-7). Technical adequacy of the angiogram is critical to accurate identification of both. Flow artifacts can falsely suggest a filling defect. It is essential that good vessel opacification be obtained and that the filling defects be identified as real on a sequence of images.

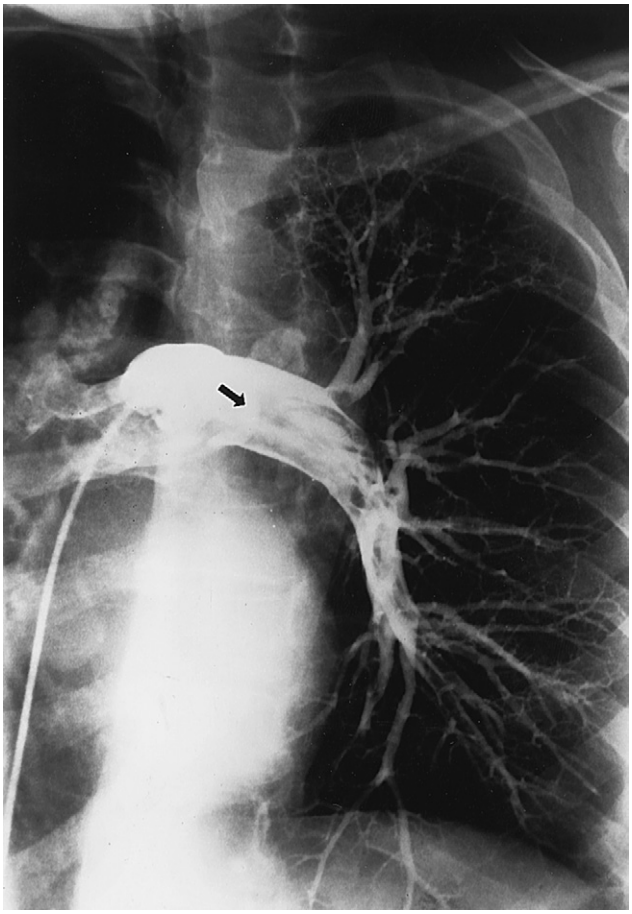

FIGURE 51-7 ■ Left-sided pulmonary angiogram shows extensive filling defects within the left pulmonary artery (*arrow*) and the upper lobe, lingula, and lower lobe arteries, consistent with the diagnosis of pulmonary embolism.

Although concern about risk should not deter pulmonary angiography, there are noteworthy limitations on its performance and value. Still, it is a rather odd commentary on medical thinking that few would advise against performance of a coronary angiogram in a patient with coronary thrombosis or ischemia because of risk, yet the question of risk often deters pulmonary angiography in a patient in whom embolism is suspected. Given that the case-fatality rate of undiagnosed and untreated embolism exceeds that of myocardial infarction, it is not clear why this disparity exists; and it should not exist, given equal competence in the performance and interpretation of these two procedures.

Clinical Prediction Rules

A major advance in the diagnostic approach to embolism, as it has been in the diagnostic approach to venous thrombosis, has been the development of clinical prediction rules. A number of standardized prediction rules have been evaluated and published that range widely in their complexity. Simple, standardized prediction rules (Table 51-3) involve information that can be easily acquired even in an outpatient setting or the emergency room.[167,172] Complicated prediction rules involve an increased number of clinical variables and require expert interpretation of radiographic and electrocardiographic data.[173,174] Although probability assessments, whether empirical or standardized, are incapable of confirming or excluding the presence of PE with a clinically acceptable degree of certainty, they have proved capable of stratifying patients into categories of likelihood. By combining this derived clinical probability with the results of a noninvasive diagnostic technique, diagnostic accuracy in terms of both the confirmation and the exclusion of embolism can be increased well beyond that achieved by the use of either clinical probability or the noninvasive diagnostic technique alone and can substantially limit the number of patients who require pulmonary angiography.

TABLE 51-3. Wells Clinical Model for Predicting the Pretest Probability of Pulmonary Embolism

Variable	Points Assigned
Clinical signs and symptoms of deep venous thrombosis	3.0
An alternative diagnosis is less likely than pulmonary embolism	3.0
Heart rate > 100 beats/min	1.5
Immobilization or surgery in the previous 4 wk	1.5
Previous deep venous thrombosis or pulmonary embolism	1.5
Hemoptysis	1.0
Malignancy (on treatment, treated in the last 6 mo, or palliative)	1.0

Score	Clinical Assessment Probability
<2 points	Low probability
2–6 points	Intermediate probability
>6 points	High probability

From Kearon C: Diagnosis of pulmonary embolism. CMAJ 168:183–194, 2003.

In summary, an almost bewildering array of diagnostic techniques is available for patients with suspected VTE. What the clinician at the bedside must understand and accept is that multiple approaches are possible and that a stepwise diagnostic strategy, rather than any single diagnostic technique, may be necessary to confirm or exclude the diagnosis (Fig. 51-8). Furthermore, the clinician must understand that these steps are essential and potentially lifesaving. Withholding anticoagulation in a patient who has suffered an embolic event places that patient at risk for recurrent, potentially lethal events; instituting empirical anticoagulant therapy in a patient who has not suffered an embolic event will involve unnecessary hospitalization and therapy, places the patient at risk for hemorrhagic complications, and establishes a "preexisting" condition that may adversely affect future health care costs. Finally, the clinician must understand that the use of a clinical prediction rule derived from an outpatient population might have a very different predictive value when applied to an inpatient, less healthy population.

Many strategies to confirm or exclude the diagnosis of PE have been investigated. Because the initiating point for the diagnostic pathway begins with clinical suspicion, the following discussion centers about that approach. Also, given substantial variations in practice that currently exist, strategies that incorporate V/Q scanning or helical CT as the initial objective diagnostic technique are considered.

In patients in whom the clinical suspicion of embolism is considered high (>70% likelihood), a positive helical CT scan or a high-probability V/Q scan result would be considered diagnostic of embolism with greater than 95% certainty, whereas a negative perfusion scan would exclude the diagnosis. In all other patients (non–high-probability V/Q scan or negative CT scan), lower extremity evaluation may be undertaken. A positive study would confirm the diagnosis. In the remaining patients, several strategies are possible. Serial lower extremity evaluations could be performed. Although not confirming the absence of embolism, negative results would suggest that the likelihood of recurrence is small. Alternatively, pulmonary angiography could be performed. This latter approach is especially applicable to unstable patients with preexisting cardiopulmonary disease, in whom the consequences of recurrence could be catastrophic.

The predictive value of CT varies substantially when clinical assessment is taken into account, with the major variance occurring when there is discordance between the clinical assessment and the CT finding. Both the positive predictive value in patients with a low clinical probability and the negative predictive value in those with a high clinical probability are in the range of 60%. For patients in whom the diagnosis remains uncertain,

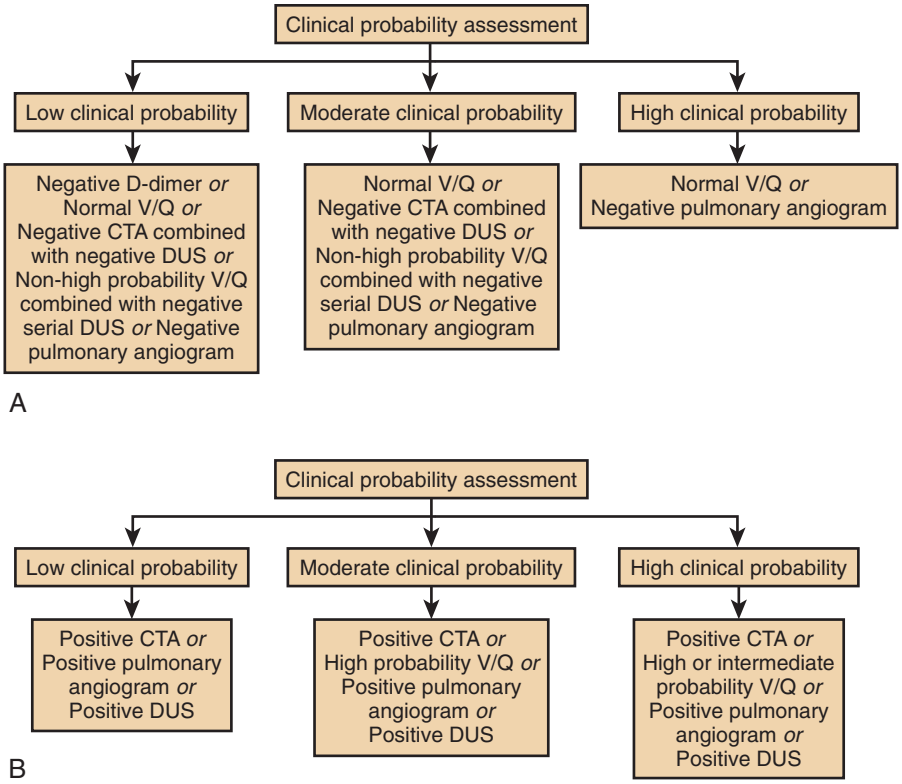

FIGURE 51-8 ■ Diagnostic strategies capable of excluding (**A**) and confirming (**B**) the diagnosis of pulmonary embolism. CTA, spiral computed tomographic angiography; DUS, Doppler ultrasound; V/Q, ventilation-perfusion scan.

lower extremity evaluation may be undertaken. A positive study would confirm the diagnosis. For those in whom CT scanning represented the initial diagnostic procedure, outcome data have demonstrated that withholding anticoagulant therapy is safe when the clinical probability of embolism is considered low and results of CT scanning and lower extremity ultrasonography are negative. For those in whom V/Q scanning represented the initial diagnostic procedure, a low- or intermediate-probability scan result in combination with a negative lower extremity ultrasound study is sufficient to withhold anticoagulation; a high-probability scan result should be followed by additional diagnostic testing (pulmonary angiography, CT, or sequential lower extremity testing). The utility of D-dimer determinations in hospitalized patients is limited by a lack of specificity. However, a negative D-dimer result has been proved capable of safely excluding embolism in outpatients with a low probability of embolism.

In patients in whom the clinical suspicion of embolism is considered moderate (~10%–70% likelihood), a high-probability V/Q scan or a positive helical CT scan would be considered diagnostic of embolism, whereas a negative perfusion scan would exclude the diagnosis. In the remaining patients, lower extremity evaluation should be undertaken. For those in whom CT scanning represented the initial diagnostic procedure, outcome data have demonstrated that withholding anticoagulant therapy is safe when the clinical probability of embolism is considered moderate and results of CT scanning and lower extremity ultrasonography are negative. In some cases in which V/Q scanning represented the initial diagnostic procedure, a non–high-probability scan should be followed by additional diagnostic testing.

Special circumstances do exist that may guide the diagnostic approach. In the setting of severe, preexisting pulmonary parenchymal or airway disease, V/Q scanning is of limited utility given the high likelihood that the scan result will be nondiagnostic. Although the positive predictive value of a high-probability scan and the negative predictive value of a normal or near-normal scan in patients with underlying lung disease are similar to that in the general population, the proportion of patients whose scans fall into a nondiagnostic category is increased substantially.[146] Under this circumstance, an approach utilizing helical CT scanning as the initial objective diagnostic study would be appropriate. The amount of contrast required for CT scanning (100–150 mL) poses a substantial risk of radiocontrast-induced nephropathy for patients with preexisting renal insufficiency, especially when it is associated with diabetes mellitus.[175] In such patients, a strategy utilizing duplex ultrasonography and V/Q scanning would appear prudent, followed by selective conventional pulmonary angiography should the noninvasive techniques not yield a definitive diagnosis. VTE is a leading cause of maternal mortality[176]; however, given the potential risk of radiation exposure to the fetus,[166] a diagnostic approach that limits that exposure is warranted. Therefore, duplex ultrasonography is an appropriate initial diagnostic approach. If ultrasonography is negative, the diagnostic evaluation should proceed as previously described based

on the clinical assessment probability and using V/Q scanning as the next diagnostic technique. Helical CT scanning has not been recommended as a diagnostic choice owing to the risk of fetal radiation exposure, although some data would suggest that fetal radiation exposure with CT scanning is comparable or even lower than with V/Q scanning.[157,177]

PREVENTION OF VENOUS THROMBOEMBOLISM

One of the most striking changes in the field of VTE since the late 1980s has been an emphasis on prevention. This emphasis is totally appropriate and, indeed, should be the cornerstone of modern management. It is clear that if the goal is to prevent PE, the only effective approach is to prevent DVT. The basic information and tools required for developing a prophylactic strategy are now available.

To develop such a strategy, three fundamentals must be in place: (1) the population at risk must be identified; (2) the duration of the increased thromboembolic risk must be ascertained; and (3) effective, low-risk prophylactic options must be available. Populations at risk of DVT, and therefore of PE, have been identified; and such risk can, to a considerable extent, be quantified as high, moderate, or low. Furthermore, a variety of effective and safe prophylactic approaches are available. It should be emphasized that the trend toward earlier hospital discharge has been accompanied by an increased incidence of postdischarge VTE. Thromboembolic risk does not necessarily end at the time of hospital discharge or transfer to a lower level of care.[178] In patients with an ongoing predisposition to thrombosis at the time of discharge from an acute inpatient setting, prophylaxis should be continued until the risk for VTE has resolved.

The objective of the prophylactic strategy is to identify the degree of thromboembolic risk in the individual patient and to match the intensity of prophylaxis to that degree of risk. Although a variety of prophylactic approaches have been investigated and utilized, four approaches have proved effective: low-dose unfractionated heparin, low-molecular-weight heparin (LMWH), intermittent pneumatic compression devices, and warfarin.

Low-Dose Unfractionated Heparin

Low-dose heparin has been widely studied as a prophylactic modality. Heparin, given subcutaneously in a dose of 5000 units every 8 or 12 hours, is begun as soon as the risk of DVT is evident and is continued until that risk has abated. This regimen has been shown to be effective in reducing the incidence of DVT, PE, and fatal PE in patients at low to moderate risk, such as those undergoing surgical procedures requiring general anesthesia for 30 minutes or longer and with medical conditions requiring bed rest for several days.[179] However, this form of prophylaxis has not been optimally effective in patients whose thromboembolic risk is higher, such as those with hip fracture or hip replacement, those undergoing prostate surgery, and patients suffering major traumatic injuries.[180] Furthermore, although the bleeding risk of low-dose heparin is nominal in most patients, there are groups of patients in whom heparin administration is contraindicated, for example, those with active bleeding, hemorrhagic diathesis, and hemorrhagic stroke and those undergoing neurologic surgery. Patients to be placed on prophylactic heparin should be screened with an initial platelet count, partial thromboplastin time, and prothrombin time. During therapy, however, monitoring of coagulation tests is not useful, because such tests do not reflect the safety or efficacy of the regimen. Monitoring of platelet counts on at least a weekly basis would appear to be a prudent option.

Low-Molecular-Weight Heparin

LMWH preparations represent another prophylactic option. In trials that have been performed comparing the prophylactic efficacy of LMWH with unfractionated heparin in general surgical and medical populations, LMWH has not proved superior to unfractionated heparin, although a trend toward increasing bleeding complications associated with unfractionated heparin may exist.[181] However, this may simply represent a dose effect. LMWH preparations appear more effective than unfractionated heparin as prophylactic agents in several high-risk groups: patients undergoing hip or knee replacement, patients with spinal cord injury, patients with ischemic strokes, and patients with multiple trauma.[180,181]

Pneumatic Compression Devices

Another extensively evaluated and effective prophylactic approach in low- to moderate-risk patients is the use of mechanical leg compressive devices.[180] These devices periodically (e.g., once or twice per minute) compress the leg by an air-inflatable bladder. A variety of devices are available: thigh-length systems that provide both thigh and calf compression, calf-compressive devices, single-pulse systems, and sequential compression systems. A variety of questions remain unanswered about pneumatic compression devices. For example, it is not known whether the various compressive devices differ in efficacy. It is also unknown whether efficacy depends on strict (24/7) compliance with this intervention during the period of increased thromboembolic risk.[182,183] In addition, it is unclear whether pneumatic compression devices are as effective as unfractionated heparin in general medical, surgical, gynecologic, and urologic patients, and their use is indicated in patients in whom pharmacologic methods of prophylaxis are contraindicated.

Sodium Warfarin

Warfarin and other "prothrombinopenic" drugs, started like heparin at the onset of high risk (e.g., preoperatively), also have been shown to be effective and safe.[180]

Unfortunately, use of "prothrombinopenic" agents has not gained wide favor as a prophylactic approach. The use of warfarin requires careful monitoring, and there is a perception among physicians that the bleeding risk associated with its use is greater than that reported in the literature. In patients undergoing hip replacement, warfarin has proved effective and has achieved general acceptance. Two regimens are widely used: small doses (1 to 2 mg) given daily for several days before surgery, with dose escalation to therapeutic range, or initiation after surgery.[184] LMWH preparations appear superior to warfarin, albeit at higher bleeding risk, in patients undergoing knee or hip replacement, with efficacy related, in part, to timing of administration.[185] It also has become evident that increased thromboembolic risk in patients undergoing hip or knee replacement can extend for 4 to 6 weeks after hospital discharge.[186] A strategy of extended prophylaxis may be appropriate.[187]

Miscellaneous Agents

Fondaparinux, a synthetic pentasaccharide that selectively inhibits activated factor X (factor Xa), has been demonstrated in several trials to be effective in the prevention of VTE in patients undergoing lower extremity orthopedic surgery.[180,188,189]

There is one option available to prevent PE in patients at high risk who cannot be provided pharmacologic or mechanical prophylaxis. Patients with extensive trauma often fall into this category, particularly those with pelvic or lower extremity fractures and internal or intracranial bleeding. In this group, prophylactic placement of an inferior vena cava filter in selected patients provides protection against otherwise nonpreventable emboli.[190]

In summary, given the effective options available, few patients at risk for venous thrombosis cannot be protected. However, despite this awareness, surveys have demonstrated that prophylaxis is underused in populations at risk.[191,192] A number of different rationales have been proposed to account for this lack of compliance. The overstated perception of bleeding complications associated with pharmacologic methods of prophylaxis appears to remain a deterrent. Furthermore, fatal PE is uncommon in any individual physician's experience, thereby diminishing the perception of risk. Finally, the issue of prophylaxis is often subordinated to the compelling demands of the patient's admitting diagnosis and therapy. Whatever the reason, increased use of prophylaxis must occur if a substantial impact is to be made on the considerable and often unnecessary morbidity and mortality associated with PE. Not only must prophylaxis be applied, it must be applied in a manner proportionate to the patient's risk of thromboembolism.

MANAGEMENT OF VENOUS THROMBOEMBOLISM

The basic approaches to management are defined chiefly by what is known, as already described, about the pathogenesis, pathophysiology, and natural history of venous thrombosis and PE.

Heparin

Heparin, both unfractionated and low molecular weight, remains the mainstay of therapy for venous thrombosis and for PE not associated with hemodynamic compromise.[193] With a strong suspicion of embolism based on clinical findings and laboratory tests, heparin therapy should be instituted immediately, without awaiting diagnostic confirmation, unless anticoagulation places the patient at significant risk.

Data suggest that physician practices in the administration of unfractionated heparin often result in levels of anticoagulation that fall below those currently recommended in the literature.[194] To overcome these problems, standardized protocols for heparin administration and monitoring have been recommended. A number of different intravenous heparin dosing schemes have been published, all of which have demonstrated the potential to reach a therapeutic threshold more rapidly than a nonstandardized approach.[195] The most widely utilized of these is a weight-based system that includes an 80 unit/kg intravenous bolus of heparin followed by an 18 unit/kg/hr infusion.[196] Whatever regimen is used, an activated partial thromboplastin time (aPTT) is generally obtained 6 hours after the bolus dose, 6 hours after each prescribed dose adjustment, and then on a daily basis for the duration of therapy. Because maintenance of the aPTT within a rigidly defined range does not appear to increase the efficacy or safety of the drug, frequent dosage adjustments are not necessary once the dose has been stabilized within a therapeutic range. This therapeutic range of aPTT, which corresponds to heparin levels of 0.2 to 0.4 unit/mL by protamine sulfate titration or 0.3 to 0.7 unit/mL by anti–factor Xa assay, may vary substantially depending on the sensitivity of the reagent utilized and among coagulometers.[197] Given the variance in aPTT values possible with different analyzers and reagents, individual institutional validation should be performed to define a therapeutic aPTT value. It also should be recognized that heparin requirements tend to decrease during the course of therapy, resulting in an increase in the level of the aPTT. For patients with heparin resistance (defined as the need for >40,000 units/day), monitoring heparin with an anti–factor Xa assay appears safe and effective and results in less escalation of the heparin dose than monitoring with the aPTT.[198]

Supporting the importance of using adequate heparin doses are data that suggest *supratherapeutic* aPTT values are not associated with an increased risk of clinically important bleeding complications.[199] There is no direct evidence that the absolute dose of heparin or the level of the aPTT can predict the likelihood of bleeding. Instead, bleeding during heparin therapy appears to be related to the presence of concurrent illness such as renal disease, a history of heavy alcohol consumption, aspirin use, and prior surgical procedures or peptic ulcer disease. Failure to treat patients early with sufficient doses appears to have long-term as well as short-term

implications for thromboembolic recurrence. It is somewhat controversial, however, whether the aPTT level itself, independent of the heparin dose, is associated with higher recurrence rates[200] or whether it is strictly a matter of insufficient dosing itself.[201]

Subcutaneous LMWHs are widely used for the treatment of VTE because of their high bioavailability and longer half-life, which allows the strategy of weight-adjusted dosing once or twice daily, without the need for adjustment by aPTT monitoring.[193,202] However, it has been recently established that the same strategy may also be applicable to subcutaneous (unfractionated) heparin as well, administered in high doses. An approach utilizing a fixed dose of subcutaneous unfractionated heparin, administered as an initial dose of 333 U/kg followed by a dose of 250 U/kg every 12 hours, has been demonstrated to be as safe and effective as LMWH in patients presenting with venous thrombosis and PE.[203] Clinicians must recognize that the administration of LMWH may not be preferable under certain clinical circumstances. Standardized dosing is problematic in patients at the extremes of body weight; owing to renal clearance of the drug, dose adjustments and monitoring with anti–factor Xa levels are necessary in patients with renal insufficiency; the anticoagulant effect of the drug cannot be monitored easily; populations exist (e.g., patients at high bleeding risk) in which a longer drug half-life is not a desirable effect; the ability of protamine sulfate to reverse the anticoagulant effect remains uncertain; and drug costs are substantially higher than with unfractionated heparin.

Clinical trials have demonstrated that the safety and efficacy of LMWH preparations are comparable with those of unfractionated heparin in patients with venous thrombosis.[204] Trials have also demonstrated that most patients with acute venous thrombosis can be treated safely on an outpatient basis with LMWH and that outpatient therapy can reduce total medical expenditure.[205] However, not all patients with venous thrombosis can or should be treated in an outpatient setting. Approximately 50% of patients are ineligible for outpatient therapy owing to such factors as major bleeding risk, compliance problems, renal failure, significant comorbid disease, inadequate cardiopulmonary reserve, and inaccessibility for follow-up. Furthermore, embolism can occur during the early aspects of therapy in patients treated with both unfractionated and LMWH preparations. Although this circumstance would not be diminished in an inpatient setting, the potential consequences of recurrence, especially in patients with preexisting cardiopulmonary disease, might be more promptly detected and managed in this setting. Outpatient therapy would be most feasible in patients with submassive embolism, preserved right ventricular function, and a low risk of bleeding. The definitive answer to this question will likely parallel investigations evaluating the role of risk stratification approaches in PE. Even in patients who require initial inpatient management, however, the duration of hospitalization can be decreased considerably by a quick transition to outpatient therapy.

In terms of duration of heparin therapy, studies have shown that utilizing a 5-day course of therapy in patients with proximal venous thrombosis is associated with a recurrence rate identical to that of a 10-day course.[206] This assumes, of course, that warfarin is started early and is in a therapeutic range for 2 consecutive days before heparin is discontinued, a target often difficult to achieve. It is likely that a short course of heparin therapy would be similarly effective in patients with uncomplicated PE. However, a longer course of therapy is advisable in patients with major PE or extensive iliofemoral venous thrombosis.

The major complications of unfractionated heparin and LMWH are bleeding and the development of thrombocytopenia.[207] There are no predisposing factors to heparin-associated thrombocytopenia other than a history of a previous exposure, and it appears to occur with the same frequency with either (unfractionated) heparin or LMWH.[208] Two types of thrombocytopenia are associated with heparin administration: an early-onset (1–5 days), non–immune-mediated reduction in platelet count (type I) believed to be secondary to a direct agglutinating effect of heparin on platelets; and a late-onset (≥4 days), immune-mediated thrombocytopenia (type II) that may be associated with venous and arterial thrombosis. Immune-mediated thrombocytopenia can occur within a day of initiating therapy in patients who have been exposed to the drug within the prior 100 days.[209] The incidence of thrombosis with heparin-associated thrombocytopenia appears to be low, but when it occurs, it is associated with considerable morbidity and mortality. Therefore, heparin should be immediately withdrawn if this diagnosis is suspected. If heparin-associated thrombocytopenia type II is confirmed by either a functional assay or an immunoassay, withdrawal of heparin alone may be associated with an adverse outcome.[210] A number of options exist, including the use of direct thrombin inhibitors (lepirudin or argatroban), which do not react with heparin antibodies, or danaparoid, which appears to have a low rate of in vivo cross reactivity with heparin.[211,212] Cross reactivity between unfractionated heparin and LMWH is relatively common, and these drugs should be avoided.[213]

Inferior Vena Cava Filters

Scientific evidence supporting the use of inferior vena cava filters (Fig. 51-9) is limited.[214,215] Established indications for filter placement in the therapy of VTE include (1) protection against PE in patients with acute VTE in whom conventional anticoagulation is contraindicated (recent surgery, hemorrhagic cerebrovascular accident, active bleeding, heparin-associated thrombocytopenia, etc.); (2) protection against PE in patients with acute VTE in whom conventional anticoagulation has proved ineffective; and, (3) protection of an already compromised pulmonary vascular bed from further thromboembolic risk (massive PE, chronic thromboembolic pulmonary hypertension).

Mortality from filter placement appears to be quite low regardless of what filter is used.[214] Nonfatal compli-

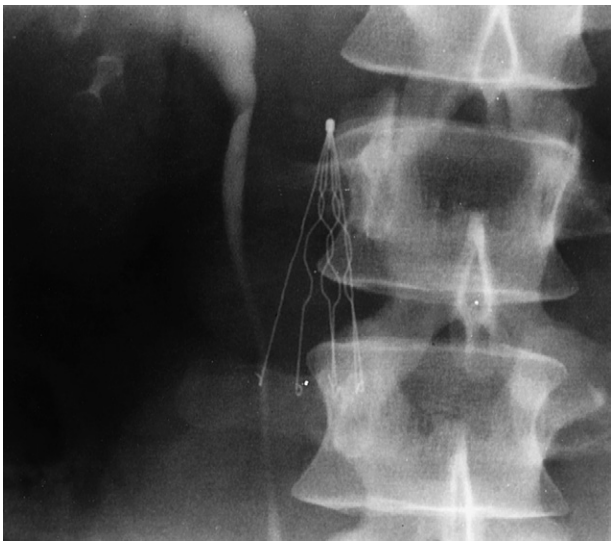

FIGURE 51-9 ■ Inferior vena cava filter in place below the renal veins.

cations of inferior vena cava filters that occur with increased frequency include (1) complications relating to the insertion process; (2) venous thrombosis at the site of insertion; (3) filter migration; (4) filter erosion through the inferior vena cava wall; and (5) inferior vena cava obstruction. The majority of clinically important complications appear to involve venous thrombosis at the insertion site and inferior vena cava obstruction.[215]

Filter placement should not be considered as primary therapy for VTE unless an absolute contraindication to anticoagulation exists. Although protecting the pulmonary vascular bed, filter placement does not inhibit the extension of existing venous thrombi or diminish the systemic prothrombotic state. Small thrombi can pass through patent filters or through collaterals around obstructed filters; furthermore, thrombus extension can occur through the filter itself. One study demonstrated that placement of a vena cava filter was capable of diminishing the incidence of early occurrence of PE.[215] The benefit was somewhat offset by an increased risk of recurrent DVT within 2 years, although an 8-year follow-up did not disclose an increased risk of recurrence or postphlebitic syndrome.[216] The development of retrievable filters suggests that the intervention will no longer be irreversible, although extensive randomized clinical trials have not yet been performed to establish the safety and efficacy of this strategy.[217] Given these considerations, long-term anticoagulation should be utilized following filter placement if no contraindications exist or as soon as any existing bleeding risk resolves.

MASSIVE PULMONARY EMBOLISM

The significant mortality associated with massive PE justifies a separate consideration of the diagnostic and therapeutic approach to this problem.[218] The definition of massive PE should be based on hemodynamic considerations rather than purely anatomic ones. This impression is supported by mortality statistics from the urokinase trials and others.[219–221] Although anatomically massive emboli have a greater likelihood of being associated with hemodynamic compromise, not all anatomically massive emboli lead to hemodynamic compromise. Irrespective of the degree of vascular obstruction, patients with PE who present with shock have a mortality rate, regardless of the type of intervention, that approaches 30%.

The therapeutic approach to the patient with hemodynamically massive PE should be designed to counteract the adverse physiologic consequence of pulmonary vascular obstruction whether or not that obstruction is anatomically massive. Basic care of a critically ill patient should not be overlooked while specific diagnostic and therapeutic considerations are being implemented. Oxygen should be administered to alleviate the hypoxic pulmonary vasoconstriction, which might be contributing to the pulmonary hypertension. Intubation and mechanical ventilatory support might be required to improve oxygenation and decrease metabolic demands. Although volume resuscitation has been advised, excessive preload may further distend the right ventricle and increase right ventricular wall tension, resulting in decreased coronary perfusion and right ventricular ischemia. The judicious use of inotropic support can also prove useful in increasing blood pressure, preserving right coronary artery perfusion, and supporting right ventricular function.[222] Although there is a tendency to utilize central hemodynamic monitoring in critically ill hypotensive patients, this intervention should be considered carefully in the patient with massive PE. A femoral approach poses the risk of dislodging residual ileofemoral thrombus, and balloon flotation poses the risk of dislodging embolic material that might be trapped within the right atrial or ventricular cavities.

Although the central goal of therapy in massive PE should be to relieve pulmonary vascular obstruction, the severely compromised nature of the pulmonary vascular bed makes prevention of recurrence an important secondary consideration. Therefore, assuming the requisite expertise in filter placement is available and that placement of a filter will not interfere with the primary management of the patient, placement of a filter should be considered in all patients with hemodynamically massive embolism.

Thrombolytic Therapy

The use of thrombolytic agents in acute PE remains controversial.[223,224] Although thrombolytic therapy does appear to accelerate the rate of thrombolysis, there is no convincing evidence to suggest that it decreases mortality, increases the ultimate extent of resolution when measured at 7 days, reduces thromboembolic recurrence rates, improves symptomatic outcome, or decreases the incidence of thromboembolic pulmonary hypertension.[225–227] The one issue about which there can be little controversy is that the use of thrombolytic agents is associated with a substantially increased risk of bleeding, including intracranial hemorrhage. Intracranial hemor-

rhage has occurred in 0.5% to 2% of patients treated with thrombolytic agents in trials evaluating the use of these agents in both PE and myocardial infarction.[226,228]

Based on these data, and assuming there is no contraindication to its use, the role of thrombolytic therapy in PE should be limited to those circumstances in which an accelerated rate of thrombolysis may be considered lifesaving, that is, in patients with PE who present with hemodynamic compromise or who develop hemodynamic compromise during conventional therapy with heparin. In patients with embolism associated with intracavitary right atrial or ventricular thrombi, thrombolytics may be a reasonable consideration, although direct, surgical removal should also be considered.[229,230] At the present time, the finding of right ventricular dysfunction on echocardiography in the absence of hemodynamic instability should not serve as a justification for thrombolytic therapy.[130,223] Approximately one third of patients with PE will have echocardiographic evidence of right ventricular dysfunction.[231] Until criteria have been established that identify a subset of patients with right ventricular dysfunction who are at risk for an adverse outcome and benefit from thrombolytic therapy, there is little basis for exposing all such patients to the considerable risk of hemorrhagic complications associated with this intervention. This is especially true given the recent advances that have occurred in heparin administration strategies.

Pulmonary Embolectomy

The role of pulmonary embolectomy in acute hemodynamically massive PE also remains controversial.[232–235] Patients with anatomically massive or submassive emboli who are hemodynamically compromised, who have not had a cardiac arrest, and who do not have an absolute contraindication to thrombolytic therapy should be managed initially with aggressive medical therapy, including thrombolytic therapy plus heparin. Patients in whom acute embolectomy might be considered are those with hemodynamically massive PE who have an absolute contraindication to anticoagulant or thrombolytic therapy, those who have suffered a cardiopulmonary arrest (although the mortality associated with embolectomy in those who have is far higher than those who have not), and those in whom aggressive medical therapy, including the use of thrombolytics, has proved ineffective.

The concept of relieving the pulmonary vascular obstruction and decreasing right ventricular afterload with a percutaneous device has been appealing. Several such devices designed to extract or fragment thrombi have been reported. Their role in massive PE remains investigative.[236]

POSTEMBOLIC PROPHYLAXIS

The duration of outpatient anticoagulation for patients with PE remains a subject of controversy.[49,237–240] Much of the difficulty in making definitive recommendations regarding the duration of outpatient anticoagulation results from the diverse population that is affected by the disease process. The decision to continue or withdraw therapy should be made on an individual basis and take into account factors such as the nature of the initial thromboembolic event (spontaneous or associated with a defined clinical circumstance), the type of initial event (venous thrombosis or PE), the presence of an ongoing predisposition (either clinical or hereditary), and possibly the persistence of residual venous thrombosis as determined by ultrasonography or persistently high D-dimer levels in the blood.[49,51,237–241]

Patients with a clearly defined initial predisposition, whose initial thromboembolic risk factors have resolved and whose V/Q scan and noninvasive lower extremity test results have normalized, can likely be managed with a 3-month course of anticoagulation.[240] Patients without a clearly defined initial predisposition to thromboembolism and those with persistent V/Q scan defects or abnormal lower extremity test results probably should be treated for 6 months or more.[193,237,238] Finally, certain patients should be treated with an indefinite period of anticoagulation even though such a strategy is associated with an increased risk of hemorrhagic complications. Clinical circumstances in which indefinite periods of anticoagulation should be considered include a history of more than one episode of idiopathic venous thrombosis or PE; the presence of certain irreversible acquired or hereditary risk factors for VTE (active cancer, immobilization, antiphospholipid antibody syndrome); the presence of extensive residual venous thrombosis or the postthrombotic syndrome; and the presence of extensive residual V/Q scan or CT scan defects or pulmonary hypertension. Although the presence of the heterozygous factor V Leiden mutation or the prothrombin gene mutation individually does not appear to increase recurrence risk, the presence of homozygous factor V Leiden mutation or the heterozygous factor V Leiden mutation in combination with the prothrombin gene mutation does appear to be associated with an increased recurrence risk.[30]

A standard for repeating noninvasive testing of either the lungs or the deep veins of the lower extremities at the anticipated time of anticoagulant discontinuation does not exist. Although the cost implications would be substantial, such an approach would be beneficial in establishing a new baseline study that could be used for comparison in the event thromboembolic recurrence was suspected and in identifying patients with pulmonary vascular obstruction of sufficient extent to place them at risk for the development of chronic thromboembolic pulmonary hypertension.

Regarding postembolic anticoagulant "intensity," the recommended therapeutic range for the International Normalized Ratio (INR) of prothrombin time in the majority of patients with VTE is 2.0 to 3.0. It is controversial whether patients with the antiphospholipid syndrome should be an exception to this rule, because a retrospective analysis suggested that an INR of 3.0 to 4.0 was considered more effective in reducing recurrence rates than an INR less than 3.0.[242] However, a subsequent randomized treatment trial of patients with the antiphospholipid syndrome showed the standard

INR target of 2.0 to 3.0 to be just as effective as the higher target range.[243] In patients with a lupus anticoagulant, in whom the baseline INR may be elevated, the INR may not reliably reflect the level of anticoagulation. In these patients, the use of tests that are insensitive to the lupus anticoagulant, such as the prothrombin-proconvertin time or chromogenic factor X assay, has been recommended.[244]

Trials evaluating the effectiveness of low-intensity anticoagulation (maintaining the INR in a range of 1.5–2.0) following a standard 3- to 6-month period of anticoagulation have demonstrated that such an approach is superior to placebo but is less effective than standard therapy, without an appreciable reduction in bleeding complications.[245,246]

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

After a PE, thrombotic material in the pulmonary arteries either resolves by fibrinolysis or is remodeled into organized scars. The extent to which remodeling occurs, and the severity of the resulting vascular obstruction, varies among patients. In some, lung perfusion is rapidly restored,[80] although the resolution in the first week is typically incomplete. Recovery continues at a slower pace for the next 1 to 2 months,[247,248] during which clot remodeling may be occurring. Residual defects persist commonly beyond this period, suggesting that the clots have been remodeled into permanent vascular scar.[55,74–79,249] In a very small percentage of patients, estimated to represent about 1% of the 450,000 patients who survive a pulmonary embolic event each year in the United States, such resolution does not occur and the residual obstruction is of sufficient extent to cause persistent pulmonary hypertension.[250]

Most patients who present with chronic thromboembolic pulmonary hypertension were previously diagnosed with acute pulmonary emboli or DVT, but their presentations (e.g., clot burden, clinical stability) appear indistinguishable from patients who resolve their acute clots.[250] A prospective study of patients presenting with PE disclosed that in addition to the size of the initial PE, factors such as recurrent PE, idiopathic PE, and PE at a young age were associated with a higher risk for chronic thromboembolic pulmonary hypertension.[251] Other clinical factors associated with chronic thromboembolic pulmonary hypertension are right heart strain (e.g., pulmonary artery pressures < 50 mm Hg) during the acute PE,[81,251] advanced age,[251] previous splenectomy,[252,253] the presence of a ventriculoatrial shunt for the treatment of hydrocephalus,[252,253] and a variety of chronic inflammatory disorders (e.g., osteomyelitis, inflammatory bowel disease).[252,253] A number of laboratory findings have been associated with chronic thromboembolic pulmonary hypertension, the most prominent of which is the lupus anticoagulant.[254] In addition, elevated plasma levels of factor VIII,[255] lipoprotein (a),[256] and even non-O blood groups[257] have had at least a statistical association with chronic thromboembolic pulmonary hypertension after an acute PE.

Despite the associations mentioned previously, the reasons thromboembolic pulmonary hypertension develops are not clear; that is, it is not evident why this minority of patients fail to resolve their emboli. It has been found that in approximately half of the patients, the initial diagnosis of pulmonary thromboembolism was not made and, therefore, no treatment was given.[258] Despite extensive investigation, the only identifiable thrombotic predisposition has been the presence of a lupus anticoagulant or antiphospholipid antibody syndrome in approximately 10% to 50% of patients.[254,259] The prevalence of other thrombophilic tendencies, such as antithrombin III, protein C, and protein S deficiency, does not appear to be higher than that encountered in the normal population. Preliminary evidence also suggests that the factor V Leiden mutation is no more common in patients with chronic thromboembolic pulmonary hypertension than in the general population; moreover, no consistent defect in fibrinolytic activity has been identified.

The diagnosis of thromboembolic pulmonary hypertension is usually not made until the degree of pulmonary hypertension is advanced. As a result, the exact hemodynamic evolution of the disease has not been fully established.[260] The extent of pulmonary vascular obstruction appears to be a major determinant of disease initiation, with involvement of greater than 40% of the pulmonary vascular bed present in the majority of patients. Hemodynamic progression in certain patients may involve thromboembolic recurrence or in situ pulmonary artery thrombosis. However, hemodynamic progression in many patients appears to involve the development of a hypertensive pulmonary arteriopathy, similar to that encountered in other causes of secondary pulmonary hypertension.[261] This supposition is supported by several lines of evidence: a poor correlation between the extent of central anatomic obstruction and the degree of pulmonary hypertension; documented hemodynamic progression in the absence of recurrent embolic events or evidence of in situ pulmonary artery thrombosis; and histopathology demonstrating arteriopathic changes in the resistance vessels of both the involved and the uninvolved pulmonary vascular system.

Survival without intervention is poor and proportional to the degree of pulmonary hypertension at the time of diagnosis. In one study, the 5-year survival rate was 30% when the mean pulmonary artery pressure exceeded 40 mm Hg and 10% when it exceeded 50 mm Hg.[262] In another study, a mean pulmonary artery pressure above 30 mm Hg appeared to serve as a threshold value portending a poor prognosis.[263]

Diagnosis

Perhaps the most important aspect of dealing with this patient group is the proper approach to its recognition. Progressive dyspnea is a complaint common to all patients with chronic thromboembolic pulmonary hypertension. Later in the course of the disease, exertional chest pain, near-syncope or syncope, or lower extremity edema may develop.

Although a history of documented thromboembolism may not be present, many patients can provide a history consistent with an acute embolic event. They may describe an episode of "pleurisy," lower extremity "muscle strain," or prolonged, atypical "pneumonia," or they may describe a hospitalization or surgical procedure from which they never fully recovered. That an episode of VTE was not diagnosed, or was misdiagnosed, is not surprising given recent data confirming the frequency with which venous thrombosis and PE are overlooked in the population at large.[264]

Diagnostic delay, particularly in the absence of an acute history of VTE, occurs commonly. Progressive dyspnea and exercise intolerance are often attributed to coronary artery disease, cardiomyopathy, interstitial lung disease, asthma, deconditioning, or psychogenic dyspnea. Therefore, an abnormality of the pulmonary vascular bed should be considered in any patient with dyspnea in whom a definitive etiology cannot be defined. Later in the course of the disease, exertional chest pain, presyncope, or syncope may occur due to the presence of severe pulmonary hypertension and the inability of a compromised right ventricle to meet cardiac output demands.

Physical examination findings may be subtle early in the course of the illness, thereby contributing to this diagnostic delay. Prior to the development of significant right ventricular hypertrophy or overt right ventricular failure, physical examination abnormalities may be limited to a narrowing of S_2 or to a subtle accentuation of its pulmonic component. Late in the course of the disease, obvious findings such as a right ventricular heave, jugular venous distention, prominent *a*- and *v*-wave venous pulsations, fixed splitting of S_2, a right ventricular S^3, murmurs of tricuspid regurgitation or pulmonic insufficiency, hepatomegaly, and ascites may develop. Peripheral edema, a result of chronic lower extremity venous outflow obstruction or right ventricular failure, may be present.

A unique physical finding in certain patients with chronic thromboembolic disease is the presence of flow murmurs over the lung fields.[265] These subtle bruits, which appear to originate from turbulent flow through partially obstructed or recanalized thrombi, are high pitched and blowing in quality, heard over the lung fields rather than the precordium, accentuated during inspiration, and frequently heard only during periods of breath-holding. Their importance arises in not having been described in primary pulmonary hypertension, which represents the most common competing diagnostic possibility.

The intent of the diagnostic evaluation is to establish the presence and degree of pulmonary hypertension, to define its etiology, and if major vessel thromboembolic disease is present, to determine whether it is accessible to surgical intervention. Findings on standard laboratory tests are nonspecific, depending on the point in the natural history of the disease at which they are obtained, and reflective of the hemodynamic and gas-exchange consequences of the thromboembolic obstruction and the accompanying cardiac dysfunction.

Chest radiography, although often normal, may demonstrate findings that suggest the diagnosis.[266] Enlargement of both main pulmonary arteries or asymmetry in the size of the central pulmonary arteries may be present (Fig. 51-10). Areas of hypoperfusion or hyperperfusion

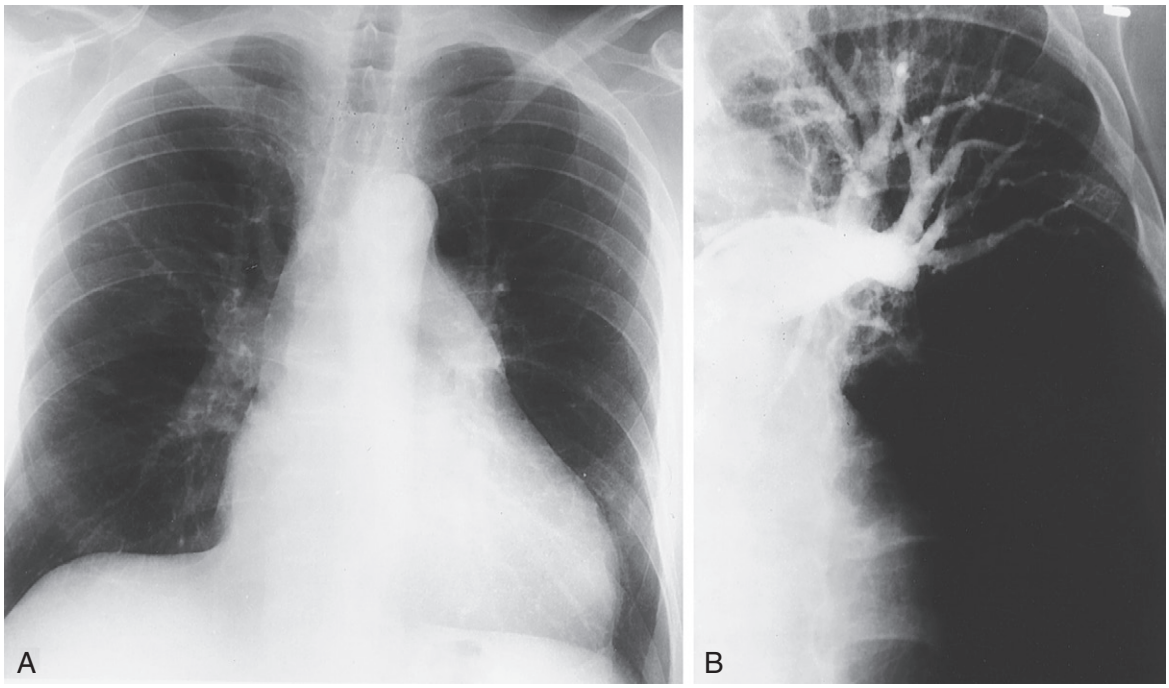

FIGURE 51-10 ■ Chest radiograph in a patient with chronic thromboembolic pulmonary hypertension. **A,** Note asymmetry of central pulmonary arteries, absence of descending left pulmonary artery, left lower lobe oligemia, and peripheral density representing prior infarct. **B,** Angiogram in the same patient demonstrates complete proximal occlusion of the descending left pulmonary artery.

may be present. There also may be evidence of old pleural disease, unilaterally or bilaterally. The cardiac silhouette may reflect obvious right atrial or right ventricular enlargement; more often, right ventricular hypertrophy and enlargement are suggested only on the lateral image by encroachment on the normally empty retrosternal space.

Early in the course of the disease, electrocardiographic findings may be normal. Later in the course, electrocardiography demonstrates evidence of right ventricular hypertrophy. Pulmonary function testing, performed to evaluate the patient's dyspnea, is often within normal limits. The majority of patients have a reduction in the single-breath diffusing capacity for carbon monoxide; however, a normal value does not exclude the diagnosis. Approximately 20% of patients demonstrate a mild to moderate restrictive defect due in part to the presence of infarct-related parenchymal scars.[267] However, the degree of spirometric defect is almost always disproportionate to the patient's gas-exchange abnormalities, symptomatic complaints, and degree of pulmonary hypertension.

In terms of gas-exchange findings, the arterial P_{O_2} may be within normal limits. However, the alveolar-arterial P_{O_2} difference is typically widened, and the majority of patients have a decline in the arterial P_{O_2} with exercise. Dead-space ventilation is often increased at rest and worsens with exercise. Minute ventilation is typically elevated as a result of this increased dead-space ventilation.[268]

Echocardiography commonly provides the initial objective evidence that pulmonary hypertension is present. Once the diagnosis of pulmonary hypertension has been established, determination of whether it originates from abnormalities of the small, resistance vessels or from central, chronic thromboembolic obstruction is essential. V/Q lung scanning appears to provide an excellent, noninvasive means of distinguishing between potentially operable major vessel thromboembolic pulmonary hypertension and small vessel pulmonary hypertension.[269] In chronic thromboembolic disease, at least one (and, more commonly, several) segmental or larger mismatched V/Q defects are present. In primary pulmonary hypertension, perfusion scans either are normal or exhibit a "mottled" appearance characterized by subsegmental defects. Other disorders leading to pulmonary hypertension may be associated with segmental defects on perfusion scan, including pulmonary veno-occlusive disease, pulmonary artery sarcoma, fibrosing mediastinitis, and large vessel vasculitides.[270]

It is important to recognize that the V/Q often understates the actual extent of central pulmonary vascular obstruction.[271] Channels through central obstructing lesions or partial flow around them, a result of the often complex patterns of recanalization and organization that occur following an embolic event, allow the radioisotopic agent to reach the periphery of the lung. Depending on the distribution of flow, these areas may appear normal or as relatively hypoperfused "gray zones." Therefore, V/Q scanning, although capable of suggesting the potential presence of chronic thromboembolic obstruction, is incapable of determining the magnitude, location, or proximal extent of the disease, information critical to the question of surgical accessibility.

The role of CT scanning in the evaluation of patients with chronic thromboembolic disease remains incompletely defined. A variety of CT abnormalities have been described: chronic thromboembolic material located in an eccentric position within the central pulmonary arteries, right ventricular enlargement, dilated central pulmonary arteries, bronchial artery collateral flow, parenchymal abnormalities consistent with prior infarcts, and mosaic attenuation of the pulmonary parenchyma.[272] However, the absence of these findings does not preclude the possibility of surgically accessible chronic thromboembolic disease. Furthermore, the presence of central thrombus has been described in primary pulmonary hypertension and other chronic pulmonary disorders.[273] CT scanning is also incapable of providing essential hemodynamic data. CT is particularly useful in the evaluation of the main pulmonary arteries and of unilateral or predominantly unilateral pulmonary vascular obstruction as determined by V/Q scanning.[272] Under these circumstances, the probability of other diagnostic possibilities such as pulmonary artery sarcoma, vasculitis, malignancy, and mediastinal fibrosis is increased. CT also has a role, along with physiologic testing, in helping to evaluate the status of the pulmonary parenchyma in patients with coexisting obstructive or restrictive lung disease.

Right-heart catheterization and pulmonary angiography are essential to designate the degree of pulmonary hypertension, to exclude competing diagnoses, and to define the surgical accessibility of the obstructing thrombotic lesions. If hemodynamic measurements at rest demonstrate only modest degrees of pulmonary hypertension, measurements should be obtained following a short period of exercise. In patients with chronic thromboembolic obstruction sufficient to abolish normal compensatory mechanisms, exercise-related increases in cardiac output will be accompanied by an almost linear elevation in pulmonary artery pressure.

The angiographic findings in chronic thromboembolic disease bear little resemblance to the sharply defined, intraluminal defects diagnostic of acute embolism.[274] Five distinct angiographic patterns have been described that correlate with the finding of organized thromboembolic material at the time of thromboendarterectomy (Fig. 51-11): (1) pouch defects; (2) pulmonary artery webs or bands; (3) intimal irregularities; (4) abrupt narrowing of the major pulmonary arteries; and (5) obstruction of lobar or segmental vessels at their point of origin, with complete absence of blood flow to pulmonary segments normally perfused by those vessels.

In certain patients, pulmonary angioscopy has proved valuable in confirming the presence of chronic thromboembolic obstruction and in determining whether it is accessible to surgical intervention.[275] The pulmonary angioscope is a fiberoptic device that allows visualization of the pulmonary arteries to the segmental level. The normal pulmonary artery has a round or oval contour with a smooth, pale, glistening appearance to the intima

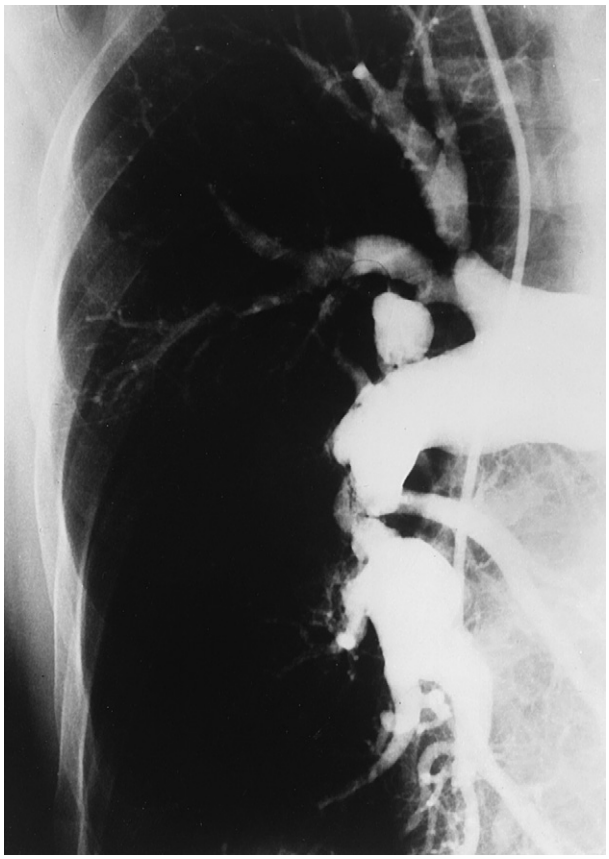

FIGURE 51-11 ■ Right-sided pulmonary angiogram in a patient with chronic thromboembolic pulmonary hypertension. Many of the classic angiographic findings associated with this disease are present, including pouch defects, intimal irregularity, pulmonary artery webs with poststenotic dilation, and complete obstruction to flow of the right middle lobe and several lower lobe segmental arteries.

and bright red blood filling the lumen (Fig. 51-12). The features of organized chronic emboli consist of roughening or pitting of the intimal surface, bands and webs across the lumen, pitted masses of chronic embolic material within the lumen, and partial recanalization.

Although pulmonary angiography/angioscopy usually completes the diagnostic sequence and confirms surgical accessibility, adjunctive studies may be necessary to exclude competing diagnoses. CT of the chest can be useful in determining whether a mediastinal process (e.g., fibrosing mediastinitis, malignancy) is responsible for the angiographic findings and, in selected cases, in defining the extent and accessibility of the obstructing thrombi. Arch aortography can be useful if an arteritis is being considered.[276]

The major conditions from which thromboembolic pulmonary hypertension must be distinguished include primary pulmonary hypertension and other forms of secondary pulmonary hypertension such as fibrosing mediastinitis with pulmonary arterial or venous obstruction, pulmonary hypertension associated with congenital atrial or ventricular septal defects, congenital pulmonary artery branch stenoses, pulmonary artery agenesis, tumors arising in or obstructing the central pulmonary arteries, and Takayasu's arteritis. The standard diagnostic approaches previously discussed, preferably performed at a center experienced in the management of pulmonary hypertension, are capable of excluding the majority of these competing diagnoses.

Treatment

For patients suffering from chronic thromboembolic pulmonary hypertension, the decision to proceed to pulmonary thromboendarterectomy is based on both objective and subjective factors, which are carefully defined during the preoperative evaluation.[277]

†Data in 23 patients at 3-mo follow-up.
‡34 patients by sternotomy, 16 patients by thoracotomy.
PVR, pulmonary vascular resistance in dyne-sec·cm^{-5}.

Pulmonary thromboendarterectomy is considered in symptomatic patients with hemodynamic or ventilatory impairment at rest or with exercise. The mean pulmonary vascular resistance in patients undergoing surgery (Table 51-4) is typically 800 to 1000 dyne-sec·cm^{-5}, with a range of 300 to 2000 dyne-sec·cm^{-5}.[260] Patients in the lower range of pulmonary hemodynamic impairment include those with involvement limited to one main pulmonary artery, those with vigorous lifestyle expectations in whom high dead-space and minute ventilatory demands are disabling, and those who live at altitude. Thromboendarterectomy is also considered in patients with normal or near-normal pulmonary hemodynamics at rest who develop significant levels of pulmonary hypertension with exercise. If surgery is deferred in patients with this hemodynamic profile, careful monitoring is recommended to detect whether progression of the pulmonary hypertension is occurring.

The location and extent of the proximal thromboembolic obstruction is the most critical determinant of operability. Occluding thrombi must involve the main, lobar, or proximal segmental arteries. Those that originate more distally are not amenable to thromboendarterectomy with current surgical techniques. In terms of extent, the anatomic and hemodynamic findings must be interpreted in concert. An acceptable postoperative hemodynamic outcome requires that the preoperative hemodynamic impairment be consistent with the magnitude of surgically accessible thromboembolic material determined by angiography or angioscopy. This determination is critical. If the major component of the preoperative hemodynamic impairment derives from surgically inaccessible disease or from the resistance conferred by a secondary, small vessel arteriopathy, residual pulmonary hypertension will be present postoperatively. Depending on the extent of the postoperative pulmonary hypertension, this outcome may be associated with adverse short-term and long-term consequences.

The only absolute contraindication to thromboendarterectomy is the presence of severe underlying lung disease, either obstructive or restrictive. Thromboendarterectomy in this population can improve the hemodynamic profile but may have little effect on the ventilatory impairment. Advanced age, severe right ventricular failure, and the presence of collateral disease influence risk assessment but do not represent absolute contraindications to the procedure if the anticipated relief of the pulmonary hypertension will improve both the quality and the duration of life. Patients as young as 16 and as old as 84 years, as well as those with complex comorbid conditions, have successfully undergone the procedure.

Prior to surgery, several other essential issues must be considered. It is important that the patient be protected against embolic recurrence, both over the long term and during the high-risk perioperative period. Therefore, an inferior vena cava filter should be placed prior to surgery unless an obvious nonleg or nonpelvic source of embolism is present. For those at risk of coronary artery disease, coronary angiography is routinely performed prior to surgery, usually at the time of the right heart catheterization and pulmonary angiography. Coronary artery bypass grafting, if necessary, can be performed safely at the time of the thromboendarterectomy.[277]

Sternotomy with cardiopulmonary bypass and periods of circulatory arrest represents the procedure of choice. This approach allows access to both pulmonary arteries and ensures more complete removal of the chronically obstructing material.[278] A sternotomy approach also provides adequate exposure for additional procedures that need to be performed. In a review of 1190 patients undergoing thromboendarterectomy, 90 patients (7.6%) required such a combined procedure exclusive of solitary closure of a patent foramen ovale, which is performed in approximately 30% of thromboendarterectomy procedures.[277] The use of cardiopulmonary bypass allows periods of complete circulatory arrest, which provides a bloodless operative field essential for meticulous lobar and segmental dissections.

Thromboendarterectomy bears little resemblance to acute pulmonary embolectomy. The neointima in chronic thromboembolic disease is deceptive and is often not easily recognizable as chronic thrombus. The procedure is a true endarterectomy that requires careful

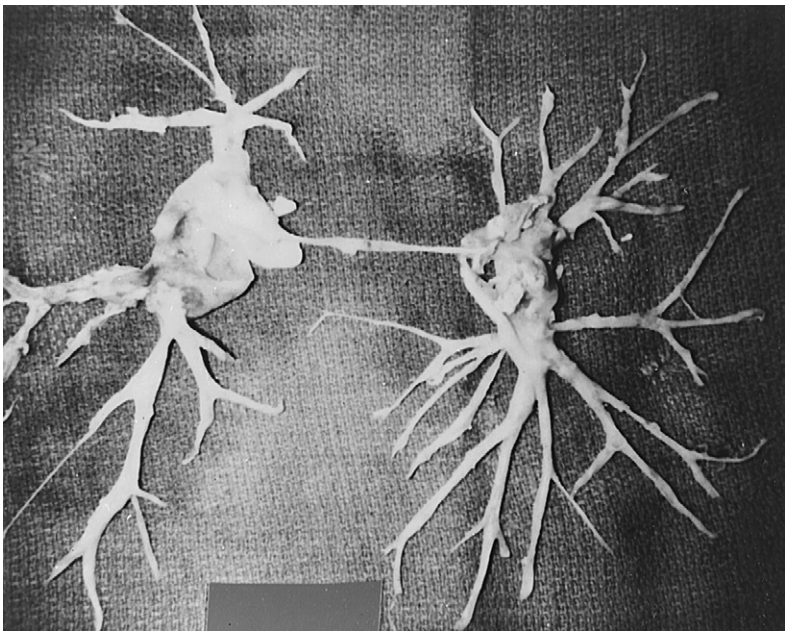

FIGURE 51-13 ■ Specimen obtained at the time of pulmonary thromboendarterectomy. In addition to central thromboembolic obstruction, note multiple segmental extensions. Failure to adequately remove these distal extensions will result in an inadequate hemodynamic outcome.

dissection of chronic endothelialized material from the native intima to restore pulmonary arterial patency. Considerable experience is required by the surgical team to identify the correct operative plane and to remove the segmental-level extensions of the more proximal obstruction (Fig. 51-13). Failure to do so results in an inadequate hemodynamic outcome.

During the development of and early experience with this procedure, mortality was related to many causes. At the present time, the major causes of death have been related to reperfusion pulmonary edema and to residual postoperative pulmonary hypertension and right ventricular failure in patients in whom pulmonary thromboendarterectomy failed to achieve substantial improvement in pulmonary hemodynamics.[278]

Although an immediate improvement in pulmonary hemodynamics occurs, the postoperative course can be complex. In addition to complications common to other forms of cardiac surgery (arrhythmias, atelectasis, wound infection, pericardial effusions, delirium), patients undergoing pulmonary thromboendarterectomy often experience two unique complications capable of significantly impairing gas exchange: reperfusion pulmonary edema and pulmonary artery "steal."[279,280]

Pulmonary artery steal (Fig. 51-14) represents a postoperative redistribution of pulmonary arterial blood flow away from previously well-perfused segments and into the newly endarterectomized segments. Long-term follow-up has demonstrated that pulmonary vascular steal resolves in the majority of patients.[281] Reperfusion pulmonary edema appears to represent a form of high-permeability lung injury that is limited to those areas of lung from which proximal thromboembolic obstructions have been removed (Fig. 51-15). It may appear up to 72 hours after surgery and is highly variable in severity, ranging from a mild form of edema resulting in postoperative hypoxemia to an acute, hemorrhagic, and fatal complication. When associated with pulmonary artery steal, reperfusion pulmonary edema can represent a significant challenge in terms of postoperative gas exchange. Pulmonary blood flow is directed toward edematous, noncompliant areas of lung that contribute poorly to gas exchange. Management of reperfusion edema, as with other forms of acute lung injury, is supportive until resolution occurs.

Although exact figures are not available, approximately 2500 thromboendarterectomy procedures have been performed worldwide. In reported series of patients undergoing thromboendarterectomy since 1999 (see Table 51-4), in-hospital mortality rates have ranged between 4.4% and 21.4%.[278,282–286] The specific factors affecting perioperative mortality have not been completely defined. Several studies have suggested that New York Heart Association functional class IV status, age older than 70 years, the severity of preoperative pulmonary vascular resistance, the presence of right ventricular failure as manifested by high right atrial pressures, details of the postoperative management, and perhaps the duration of pulmonary hypertension may adversely influence outcome. It is also reasonable to suggest that there may exist a strong relationship between volume of procedures performed and outcome, as has been demonstrated with other high-risk surgical procedures.[287] In the case of thromboendarterectomy, this may be related to consistency of patient evaluation, surgical experience, uniform delivery of postoperative care, and the presence of dedicated resources for dealing with postoperative complications. Should this prove to be the case, strong consideration could be given to performing the procedure at a limited number of referral centers.

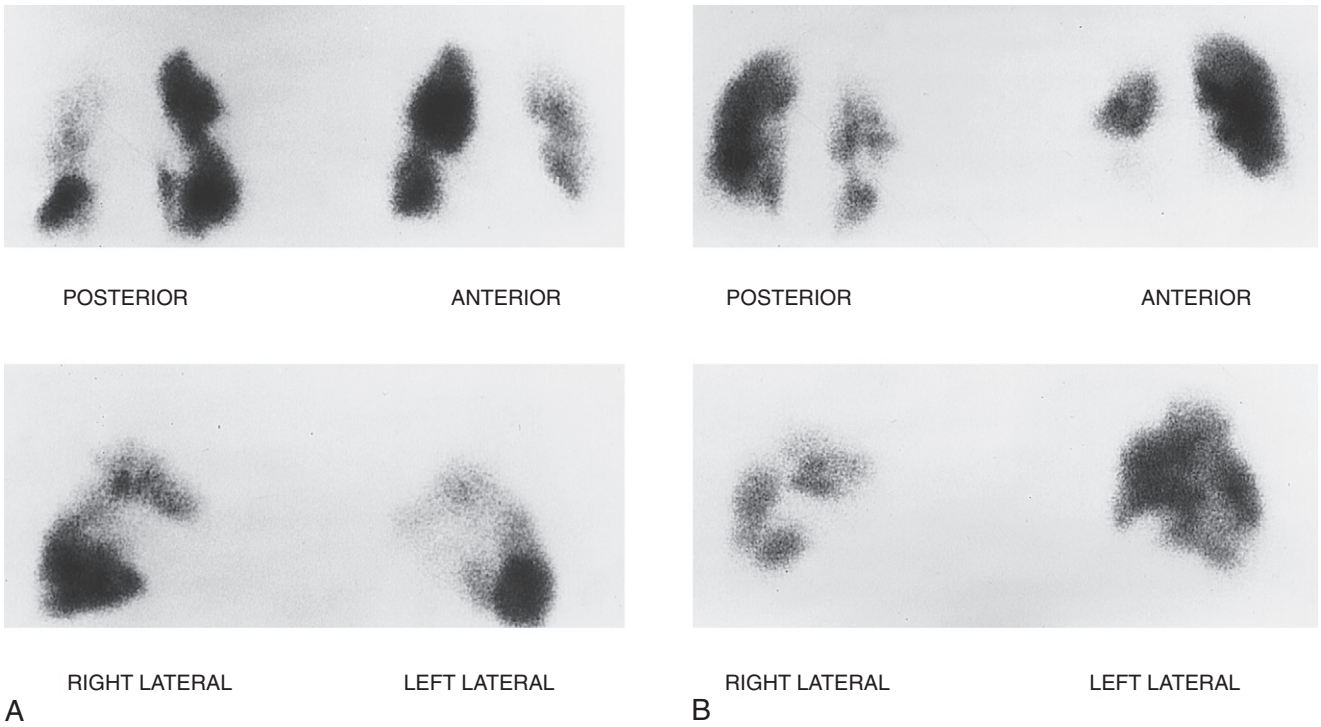

FIGURE 51-14 ■ Perfusion scans show pulmonary artery steal. **A,** Preoperative perfusion scan demonstrates minimal flow to the left lung. **B,** Perfusion scan obtained in the early postoperative period demonstrates dramatic reversal of flow with vascular "steal" from right lung. Equilibration and normalization of flow over time is the rule.

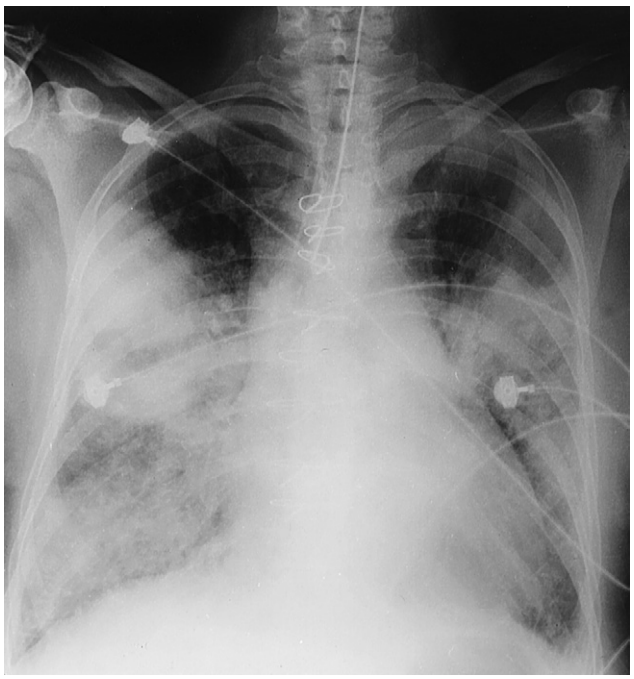

FIGURE 51-15 ■ Chest radiograph shows postoperative reperfusion pulmonary edema. Only the upper lobes, from which no thromboembolic material was dissected, are spared.

Given what is known about the natural history of the disease and the progressive nature of the pulmonary hypertension associated with it, these findings suggest that early referral is preferable to late unless the possibility of a recent embolic event exists. Under this circumstance, a period of 6 to 8 weeks of conventional therapy is recommended to allow optimum thrombus resolution. Beyond this period of time, further improvement in the level of pulmonary hypertension cannot be achieved with medical therapy alone.[81]

Among survivors of thromboendarterectomy, restoration of pulmonary artery patency results in an immediate and dramatic hemodynamic improvement (Fig. 51-16). In published series, the mean reduction in pulmonary vascular resistance has approximated 70%, and a pulmonary vascular resistance in the range of 200 to 350 dyne-sec·cm^{-5} can be achieved (see Table 51-4). The long-term hemodynamic and symptomatic outcomes have been equally dramatic. Many patients are restored to normal activity, the majority return to class I functional status, and essentially all have improved at least one grade in the classification of cardiac disability.[288–290] Approximately 10% to 15% of patients undergoing thromboendarterectomy will have residual levels of pulmonary hypertension following the procedure that have been associated with a negative long-term outcome. One therapeutic option for patients who have undergone thromboendarterectomy with an inadequate hemodynamic outcome and for those not deemed candidates for thromboendarterectomy is lung transplantation. Preliminary

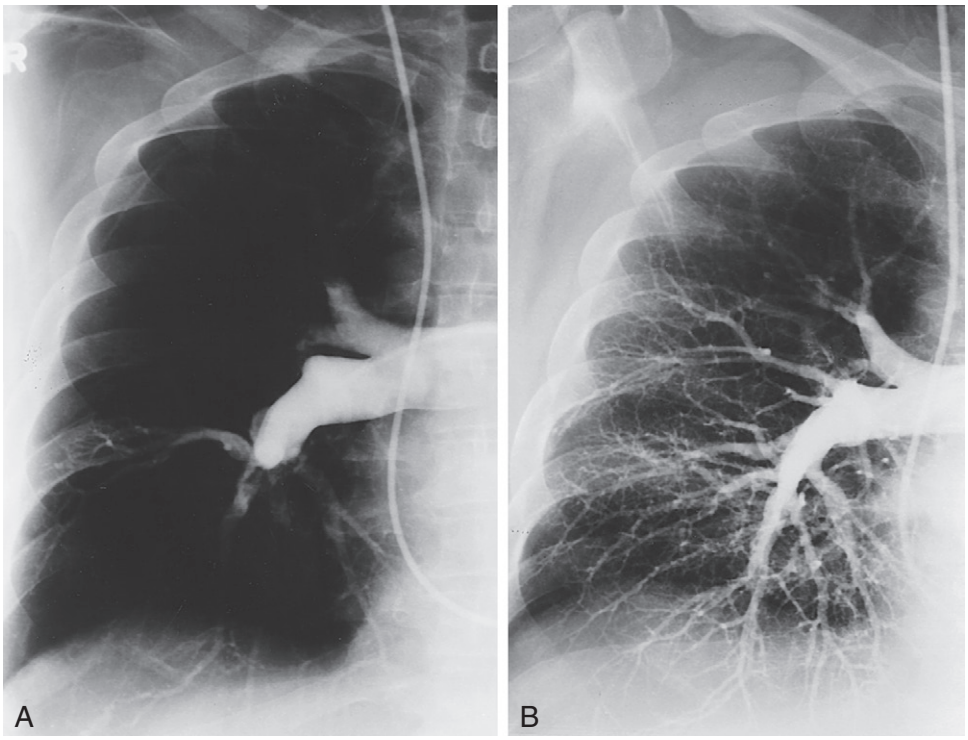

FIGURE 51-16 ■ **A,** Preoperative pulmonary angiogram shows thromboembolic obstruction involving the right upper, middle, and lower lobe arteries. **B,** Postoperative angiogram shows normalization of flow. This angiographic improvement was accompanied by a corresponding hemodynamic improvement.

results suggest that patients who are not considered candidates for thromboendarterectomy and those with residual pulmonary hypertension following the procedure may benefit from medical therapy including prostanoids, endothelin receptor antagonists, and phosphodiesterase inhibitors.[291-294] Epoprostenol has been used preoperatively in patients with chronic thromboembolic pulmonary hypertension associated with severe hemodynamic impairment and has been demonstrated to improve the hemodynamic profile.[295] Whether such an approach improves outcome or decreases the incidence and severity of postoperative complications has not been determined.

OTHER FORMS OF EMBOLISM

Because the lungs receive all of the blood flow returned from the venous system, the pulmonary vascular bed serves as a "sieve" for all particulates entering the venous blood and is the first vascular bed to be exposed to any toxic substance injected intravenously. As a result of its strategic position, the pulmonary vascular bed is therefore exposed to a wide variety of potentially obstructing and injurious agents.

Schistosomiasis

Among such agents, the most common on a worldwide basis, although not within the United States, is schistosomiasis.[296] This parasitic disorder may cause pulmonary hypertension by three mechanisms: anatomic obstruction by the organism itself, an intense inflammatory vasculitic response to the components of the organism, and the development of portopulmonary hypertension. In endemic areas, schistosomal disease is the most common cause of cor pulmonale. Limited data suggest that cardiopulmonary schistosomiasis is seen most often in *Schistosoma mansoni* infection. This form of cor pulmonale does not occur in the absence of concomitant schistosomal liver disease because the liver is always involved, usually quite extensively, before pulmonary involvement occurs. The premortem diagnosis of cardiopulmonary schistosomiasis depends on serology and the detection of schistosomal ova in stool or urine along with evidence of hepatic fibrosis and pulmonary hypertension. Treatment with praziquantel can effectively eradicate schistosomal infections with minimal toxicity. However, cardiopulmonary manifestations are not likely to be reversible given the chronic fibrotic changes that have already occurred (see Chapter 37).

Air Embolism

An increasingly common form of nonthrombotic embolism in the United States is air embolism.[297] The increasing frequency of the problem reflects the wide variety of invasive surgical and medical procedures now available, the broad use of indwelling central venous catheters, the use of positive-pressure ventilation with high levels of positive end-expiratory pressure, and the frequency of thoracic and other forms of trauma. The

simple inadvertent transection or disconnection of a large-bore intravenous catheter, particularly in the jugular or subclavian vein, can result in ingress of substantial quantities of air. Air bubbles enter the pulmonary vascular bed and, from there, are diffusely distributed throughout the body either by way of an intracardiac shunt or, more likely, through microvascular pulmonary shunts.

Physiologic consequences of pulmonary air embolism include an abrupt rise in pulmonary artery pressure. Noncardiogenic pulmonary edema may develop, lung compliance falls, and hypoxemia ensues. The symptoms of air embolism are variable and nonspecific and may include alterations in sensorium, chest pain, dyspnea, or a sense of impending doom. These and other consequences appear to be due to two phenomena: actual lodgment of the bubbles in capillary beds, which interferes with nutrient supply to the affected organs; and the formation of platelet-fibrin aggregates, creating diffuse microthrombi.[298] Thrombocytopenia may be seen as a consequence of this latter event. The most serious consequences result from cerebral or coronary artery air embolism, the severity of the consequences depending upon the volume of air that gains access to the venous circulation.[297]

The best approaches to air embolism are prevention and early detection. Treatment consists of measures designed to restore blood flow and to promote reabsorption of the intravascular air. Measures designed to restore flow include patient positioning (Trendelenburg position with the left side down), removal of air through central venous catheters or direct needle aspiration, and closed-chest cardiac massage. Measures designed to increase absorption include the use of 100% oxygen and the institution of hyperbaric oxygen therapy as early as possible.[299,300] Utilizing such aggressive measures, mortality from air embolism has been dramatically reduced.

Fat Embolism

Another reasonably frequent and dramatic form of nonthrombotic embolism is fat embolism.[301] A rather characteristic syndrome follows entry of neutral fat into the vascular system, consisting of the onset of dyspnea, petechiae, and mental confusion. There is a variable lag time of 24 to 48 hours in the onset of the syndrome following the inciting event.

By far the most common inciting event is traumatic fracture of marrow-containing long bones; the incidence of fat embolism rises with the number of fractures. However, orthopedic procedures and trauma to other fat-laden tissues (e.g., fatty liver) occasionally is followed by the same syndrome.

The reasons for the variability in incidence of the syndrome after apparently comparable injuries are not clear. Perhaps variations in incidence and severity relate to the amount of fat released. The pathophysiologic consequences appear to derive from two events: (1) actual vascular obstruction by neutral particles of fat and (2) the injurious effects of free fatty acids released by the action of lipases on the neutral fat.[302] The latter effect is probably the more important, causing a diffuse vasculitis with leakage from cerebral, pulmonary, and other vascular beds.[303]

The diagnosis of fat embolism syndrome is a clinical one suggested by the onset of dyspnea, neurologic abnormalities, petechiae, and fever in the proper clinical context.[304] Petechiae, typically distributed over the head, neck, anterior chest, and axillae, are present in only 20% to 50% of cases.[305] Therefore, their absence should not preclude consideration of the disease. No laboratory test is diagnostic of the syndrome.

Although a variety of treatments have been suggested (e.g., intravenous ethanol, albumin, dextran, heparin), none has proved effective. The role of corticosteroid therapy to prevent the onset of fat embolism syndrome after an inciting event remains controversial. Supportive treatment, including mechanical ventilatory support when necessary, is the primary approach, and survival is now the rule with meticulous supportive care.

Amniotic Fluid Embolism

Another special form of embolism is amniotic fluid embolism, a rare but unpredictable and catastrophic complication of pregnancy that represents the third leading cause of maternal mortality.[306,306a] This disorder occurs during or after delivery when amniotic fluid gains access to uterine venous channels and, thereby, to the pulmonary and general circulations. The delivery may be either spontaneous or by cesarean section; there are case reports of amniotic fluid emboli occurring during therapeutic abortion. Unexpectedly and suddenly, severe respiratory distress, cyanosis, hypotension, and often, cardiovascular collapse occur. Although obstruction of the pulmonary vascular bed may exist, the major hemodynamic impairment appears to be related to left ventricular dysfunction.[307] Most cases develop during labor, but delayed onset of symptoms up to 48 hours after delivery has been reported.[308] Advanced maternal age, multiparity, premature placental separation, fetal death, and meconium staining of amniotic fluid are associated with increased risk of amniotic fluid embolism.

Amniotic fluid contains particulate materials that can cause pulmonary vascular obstruction, but the major pathogenetic mechanism of the syndrome remains uncertain. Amniotic fluid does have thromboplastic activity that leads to extensive fibrin deposition in the lung vasculature and, occasionally, in other organs. As a consequence of fibrin deposition, a severe consumptive coagulopathy develops, including marked hypofibrinogenemia and thrombocytopenia. Following the acute event, an enhanced fibrinolytic state often occurs.[305,309]

The diagnosis of amniotic fluid embolism is based on a compatible clinical picture, often enhanced by finding amniotic fluid components in the pulmonary circulation. The presence of squamous cells in pulmonary arterial blood, once considered pathognomonic, has proved to be a nonspecific finding.[306]

Although various forms of therapy have been suggested (e.g., antifibrinolytic agents such as aminocaproic acid, cryoprecipitate), the best approach is supportive.

Even in the setting of aggressive supportive measures, however, maternal mortality is in the range of 60% to 80%, with many survivors suffering from long-term neurologic disability.

Septic Embolism

Septic embolism is another special disorder that, unfortunately, is also increasing in frequency owing to widespread injection drug abuse and the expanding use of indwelling intravenous catheters. Previously, septic embolism was almost exclusively a complication of septic pelvic thrombophlebitis secondary to both septic abortion and postpuerperal uterine infection. Those conditions still occur, but injection drug abuse is now by far the more common cause.[310] An increasingly common cause is iatrogenic: infections secondary to indwelling catheters inserted for a variety of diagnostic or therapeutic purposes.[311]

Microscopically, septic phlebitis consists of purulent material admixed with fibrin thrombus. Embolization from such material does occur and can result in obstruction of small pulmonary vessels, but the major consequence is pulmonary infection. Characteristically, the chest radiograph displays scattered pulmonary opacities that undergo cavitation. An increasing number of such opacities develop over periods of hours to a few days. Symptoms and signs include a septic temperature course, dyspnea, cough, pleuritic chest pain, and hemoptysis. Initial treatment consists of appropriate antimicrobial drugs. If an indwelling catheter is the source of the infection, it should be removed. If there is not a prompt response to this regimen, surgical isolation of the septic vein, if present, should be considered. The role of systemic anticoagulation remains uncertain. Endocarditis may complicate septic phlebitis, or mimic it, particularly in drug addicts.

Other Emboli

Because of its sieve function, the lung may also be embolized on occasion by a wide variety of other materials. Cancer cells, of course, often find their way into and adhere to the pulmonary vessels; on occasion, tumor emboli (admixtures of thrombus with cells) can occur and mimic bland embolization. Trophoblastic tissue can escape the uterus and lodge in the pulmonary circulation during evacuation of a molar pregnancy or during hysterectomy for an invasive mole. After head trauma, brain tissue has been found in the lungs; the same is true of liver cells following abdominal trauma and of bone marrow after cardiopulmonary resuscitation.

Finally, in this era of injection drug abuse, noninfectious vasculitic-thrombotic complications are being seen with increasing frequency. Particulate and irritant drug carriers (e.g., talc), and occasionally, the drugs themselves, may cause vascular inflammation and secondary thrombosis.[312] More commonly, uptake of the talc into the pulmonary interstitium results in fibrosis and advanced emphysema.[313,314]

KEY POINTS

- PE from DVT is an extremely important cause of morbidity and mortality.
- A major reduction of this morbidity and mortality will occur only through the widespread use of prophylactic measures in populations at risk and through a heightened clinical suspicion and awareness of the often subtle and nonspecific presentation of the disease.
- Appropriate use of anticoagulants decreases the risk of further thrombosis and recurrent embolism.
- Remaining uncertainties regarding the role of CT scanning in the diagnosis of PE, D-dimer testing in the exclusion of VTE, risk stratification in patients with confirmed embolism, and populations in whom outpatient management is feasible should be resolved.
- Physicians should be aware of these advances and begin to apply the new knowledge about the pathogenesis, natural history, diagnosis, and treatment of PE and, especially, of its antecedent, DVT.

INTRODUCTION

Idiopathic pulmonary arterial hypertension (IPAH; formerly primary pulmonary hypertension [PPH]) is a disease in which there is a persistent elevation of pulmonary artery pressure without demonstrable cause. There is expert agreement that the definition of pulmonary hypertension, as was required for entry into the PPH registry of the United States National Institutes of Health (NIH)[1] and for inclusion in all recent clinical trials, is a resting mean pulmonary artery pressure greater than or equal to 25 mm Hg. A pulmonary artery occlusion pressure, or left ventricular end-diastolic pressure less than 16 mm Hg, in the setting of pulmonary hypertension, is compatible with a diagnosis of pulmonary arterial hypertension (PAH).

CLASSIFICATION

The classification of PAH has undergone several revisions since the 1960s; the latest—and hence the current "gold standard"—is shown in Table 52-1.[2] This revised classification system includes additions to WHO group 1 (PAH) of chronic hemolytic anemias and schisosomiasis based on emerging evidence that these disorders produce an arteriopathy strikingly similar to other forms of PAH.

EPIDEMIOLOGY

What is now called IPAH first was described at autopsy by Romberg in 1891.[3] Patients with pulmonary hypertension of unknown cause were reported infrequently over the next 60 years, with two cases identified from 10,000 consecutive autopsies at Massachusetts General Hospital.[4] However, the condition was recognized more commonly after the advent of cardiac catheterization. Wood in 1950[5] detected 6 cases of what he called "idiopathic pulmonary hypertension" among 233 unselected British patients with presumed congenital heart disease, 152 of whom were catheterized. One year later, the term "primary pulmonary hypertension" was introduced by Dresdale and associates[6] in a detailed clinical and hemodynamic study of similar patients.

Since these original studies, IPAH has been reported with increased frequency. Shephard and colleagues[7] and Chapman and coworkers[8] described 14 patients with the condition in 1957; in 1958, Yu[9] reviewed the findings in 55 persons older than 12 years reported previously in the literature. Wolcott and colleagues[10] selected 23 cases from among Mayo Clinic patients seen from 1946 to 1965. A review of 17,901 autopsies performed on persons older than 1 year from 1944 to 1981 at the Johns Hopkins Hospital yielded 24 cases of IPAH; this amounted to a prevalence of 0.13% of all

TABLE 52-1. Fourth World Symposium Diagnostic Classification of Pulmonary Hypertension (2009)

GROUP 1: PULMONARY ARTERIAL HYPERTENSION (PAH)
Idiopathic PAH
Heritable PAH
- BMPR2
- ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
- Unknown genes

Drug- and toxin-induced
Associated with:
- Connective tissue diseases
- HIV infection
- Portal hypertension
- Congenital heart disease
- Schistosomiasis
- Chronic hemolytic anemia

Persistent pulmonary hypertension of the newborn

GROUP 1′: PULMONARY VENO-OCCLUSIVE DISEASE (PVOD) AND/OR PULMONARY CAPILLARY HEMANGIOMATOSIS (PCH)

GROUP 2: PULMONARY HYPERTENSION OWING TO LEFT HEART DISEASE
Systolic dysfunction
Diastolic dysfunction
Valvular disease

GROUP 3: PULMONARY HYPERTENSION OWING TO LUNG DISEASES AND/OR HYPOXEMIA
Chronic obstructive pulmonary disease
Interstitial lung disease
Other pulmonary diseases with mixed restrictive and obstructive pattern
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Developmental abnormalities

GROUP 4: CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION (CTEPH)

GROUP 5: PULMONARY HYPERTENSION WITH UNCLEAR MULTIFACTORIAL MECHANISMS
Hematologic disorders: myeloproliferative disorders, splenectomy
Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis: lymphangioleiomyomatosis, neurofibromatosis, vasculitis
Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK1, activin-like kinase type 1; BMPR2, bone morphogenetic protein receptor type 2; HIV, human immunodeficiency virus.

patients.[11] The IPAH registry included 187 cases collected from 32 centers between 1981 and 1985.[1] In 1984, Rich and Brundage[12] noted that IPAH was found at autopsy in approximately 1% of patients with cor pulmonale.

IPAH customarily has been considered a disease of young women. Indeed, all of Wood's[5] six patients were women between 20 and 45 years of age, as were the three patients described by Dresdale and associates.[6] An overall female-to-male ratio of 1.7:1 was found in the U.S. registry. However, IPAH has been reported in both sexes within a wide age range. For example, the mean age of patients in the registry series was 36 years, with a range of 1 to 81 years.[1] The disease appears to affect older men and women in equal numbers, although most younger patients continue to be female. It should be noted that, although in the NIH registry 7% of "IPAH" patients were over age 65, it is unclear how rigorously left-sided heart disease was excluded.[1] Given the high frequency of left ventricular diastolic dysfunction, for example, one wonders how many of these older "IPAH" patients actually were closer to diagnostic group 2.

PATHOLOGY

Wood in 1958[13] divided pulmonary hypertension into six types: *passive*, as seen with increased pulmonary venous pressure due to raised left atrial or ventricular pressure; *hyperkinetic*, caused by increased pulmonary blood flow; *obstructive*, resulting from pulmonary embolism or thrombosis; *obliterative*, manifested by a reduction of pulmonary vascular capacity; *vasoconstrictive*, brought about by functional and presumably reversible vasospasm; and *polygenic*, arising in two or more of the preceding ways. Vasoconstrictive pulmonary hypertension occurred most characteristically in response to alveolar hypoxia and usually responded to the inhalation of oxygen or the injection of acetylcholine into the pulmonary artery. Reversible vasoconstriction also was seen as an added component of the passive hypertension of mitral stenosis and the hyperkinetic hypertension caused by congenital left-to-right intracardiac shunts before the onset of Eisenmenger's syndrome. The histologic lesions observed in these reversible kinds of pulmonary hypertension consisted of medial hypertrophy of the pulmonary artery and scant intimal hyperplasia.

Also in 1958, Heath and Edwards[14] documented the pathology of hypertensive pulmonary vascular disease in a study of 67 patients with congenital heart disease and 2 patients with IPAH. These investigators argued that the progression of lesions in these patients was so stereotyped as to allow division of the structural effects of pulmonary hypertension into six grades as follows: grade 1, medial hypertrophy of the pulmonary arteries and arterioles without intimal changes; grade 2, medial hypertrophy with cellular intimal proliferation; grade 3, medial hypertrophy, intimal proliferation, and intimal fibrosis; grade 4, progressive generalized vascular dilation and occlusion by intimal fibrosis and fibroelastosis; grade 5, appearance of dilation lesions, including vein-like branches of occluded pulmonary arteries, plexiform lesions, angiomatoid lesions, and cavernous lesions; and grade 6, necrotizing arteritis.

Heath and Edwards' grading system[14] focused on the muscular pulmonary arteries 100 to 1000 μm in size. Grades 1 and 2, which were characterized by medial thickening, were comparable with the reversible vasoconstrictive phase of Wood's scheme.[13] In grades 3 and 4, intimal changes led to progressive obstruction of the vessels, which then dilated in the presence of high pressure. Some of the dilated areas evolved into microaneurysms in which there was endothelial proliferation and the formation of in situ thrombosis; these made up the characteristic plexiform lesions. In grade 5, the dilation became rigid, and hemosiderin was extruded from vessels that either burst or allowed the diapedesis of erythrocytes. Grade 6 was seen rarely and involved perivascular neutrophilic inflammation and fibrinoid necrosis.

Heath and Edwards[14] lumped the pathology of congenital heart disease and IPAH together, and a large series of patients with the latter disorder was not available until 1970. In that year, Wagenvoort and Wagenvoort[15] described the morphology of the pulmonary vessels of 150 persons in whom the diagnosis of IPAH had been made on clinical grounds. Despite their common diagnosis, the cases could be divided into several groups on histologic analysis: chronic pulmonary thromboembolism, chronic pulmonary venous hypertension, pulmonary veno-occlusive disease, sarcoidosis, chronic bronchitis and pulmonary emphysema, pulmonary schistosomiasis, and vasoconstrictive IPAH. The patients with the last disorder were the largest group, consisting of 36 men and 74 women with a mean age of 23 years and an age range of 4 days to 69 years.

The lesions that Wagenvoort and Wagenvoort[15] attributed to vasoconstrictive IPAH were strikingly similar to those described earlier by Heath and Edwards[14] and Wood.[13] The earliest abnormalities were medial hypertrophy of the muscular pulmonary arteries and muscularization of the arterioles. These findings were especially prominent in children and were the only irregularities found in young infants. Although the medial thickening might be interpreted as a persistence of the high-resistance fetal circulation, it was considerably greater than that observed in infants of the same age. Less marked in children but apparent in all adults studied were intimal proliferation and laminar intimal fibrosis that gave an onionskin appearance to the pulmonary arteries. This pattern was not seen in any patients with initially unsuspected chronic pulmonary thromboembolism and also was absent from an additional 20 patients with known thromboembolic disease.

Dilation lesions, including the plexiform variety, were observed in 77 patients with vasoconstrictive IPAH and 1 patient with schistosomiasis (who also had *Schistosoma mansoni* ova) but was not evident in persons with chronic pulmonary thromboembolism or other disorders.[15] Necrotizing arteritis occurred in 34 patients with chronic pulmonary thromboembolism; it never involved the veins as it does in pulmonary veno-occlusive disease. Wagenvoort and Wagenvoort[15] noted that vasculitis occurred only in persons with advanced disease and probably was a result rather than a cause of pulmonary hypertension, in contrast to the true pulmonary vasculitides. They believed that the progression of lesions in PPH was entirely consistent with a vasoconstrictive mechanism.

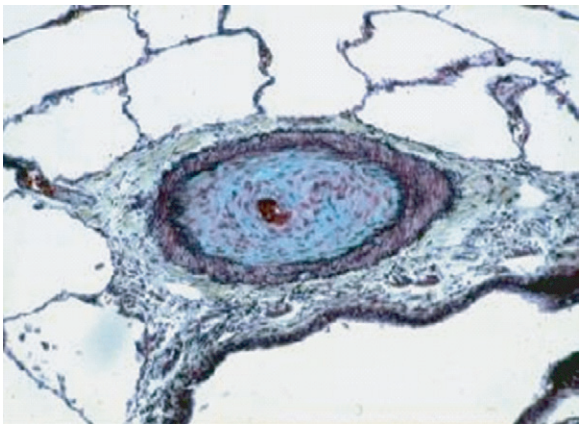

FIGURE 52-1 ■ Typical advanced pulmonary arteriopathy in idiopathic pulmonary arterial hypertension (IPAH). Note the proliferative changes in all three vessel layers, including intimal hyperplasia, medial hypertrophy, and adventitial fibrosis.

Subsequent investigators[16] confirmed the findings of Wagenvoort and Wagenvoort,[15] including the histologic distinctions between IPAH, chronic pulmonary thromboembolism, and pulmonary veno-occlusive disease. A typical arteriopathic muscular artery is shown in Figure 52-1.

Despite the distinct pathologic findings in IPAH, there is more recent evidence that the pathologic arteriopathic changes are, in fact, not unique to this disease and have been reported in congenital heart disease, connective tissue disease,[17] and chronic thromboembolic disease.[18] For this reason, in addition to the risk of lung biopsy in patients with pulmonary hypertension, one rarely obtains pathologic tissue prior to lung transplant or death.

PATHOGENESIS AND ETIOLOGY

A dramatic change has taken place over the last several years in our thinking regarding the pathogenesis of IPAH. The "paradigm" has shifted from one of vasoconstriction to one of growth and proliferation. There are several lines of evidence suggesting that IPAH develops as a result of abnormal proliferation of vascular smooth muscle cells affecting all three layers of the vessel wall and leading to intimal hyperplasia, medial hypertrophy, and adventitial proliferation. What initiates this abnormal growth is not entirely known, but there are several clues. The concept of genetic predisposition toward growth and proliferation has more recently emerged. Mutations in the bone morphogenic protein receptor 2 (*BMPR2*) gene have been reported in patients with the familial form of IPAH.[19] This gene contributes to the apoptotic process through a complex series of messenger proteins, as part of the transforming growth factor-β (TGF-β) family of genes. Thus emerges the possibility that

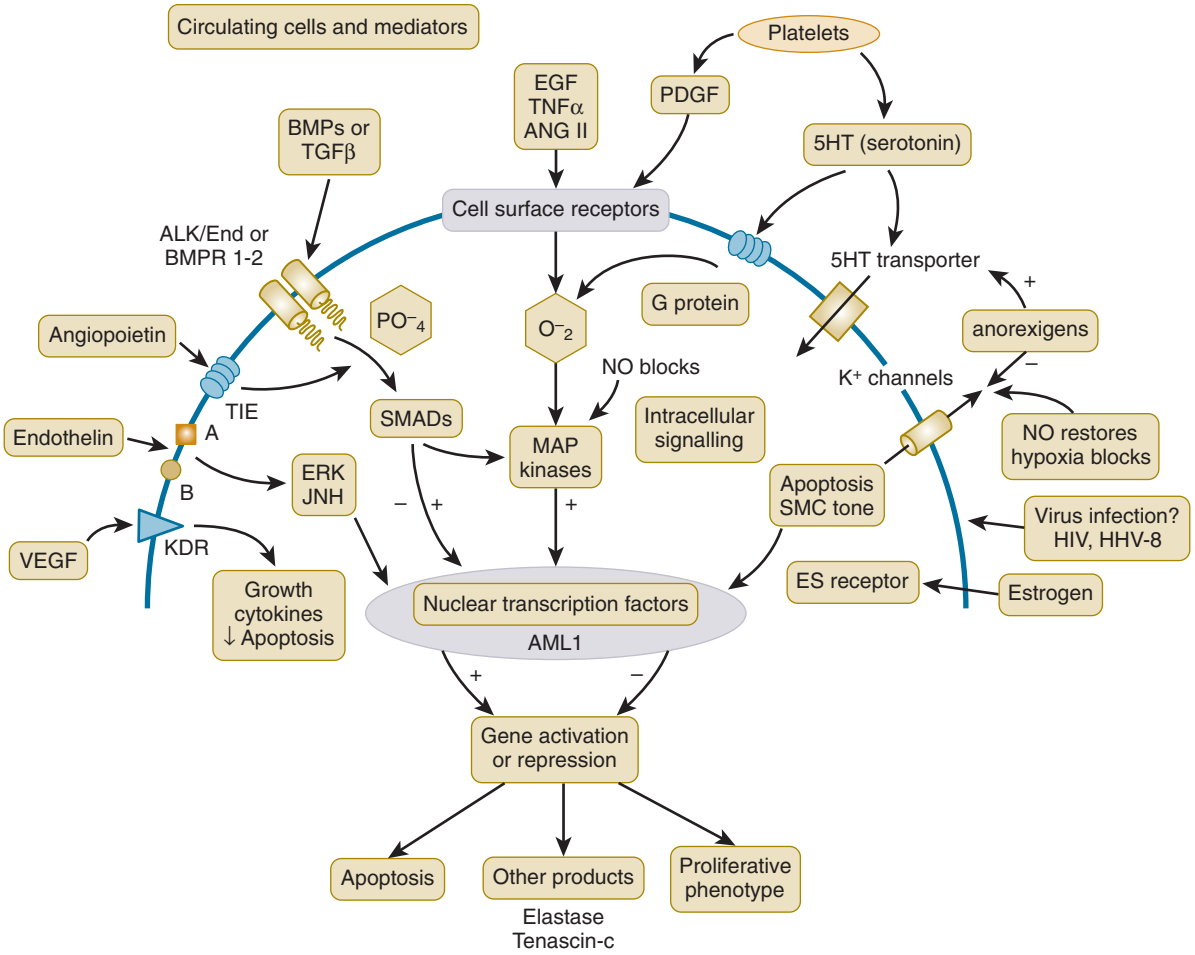

FIGURE 52-2 ■ Schematic of the possible pathogenetic factors in IPAH.

pulmonary arteriopathy is a failure of normal apoptosis. Some investigators have even referred to IPAH as "cancer of the pulmonary artery." Although this is an attractive hypothesis, the story is not that simple. For one, the presence of a *BMPR2* mutation is not always associated with the development of IPAH. It is likely that another genetic or acquired insult is required to initiate the arteriopathic process. Defects in a specific voltage-gated potassium ion channel, the Kv1.5 channel, have been found in the pulmonary artery smooth muscle cells from patients with IPAH.[19] A defect or deficiency of this channel allows excess calcium to enter the cell and thus promotes both cell contraction and growth. Overexpression of the serotonin transporter has been described in patients with IPAH.[20] This genetic defect might lead to increased internalization of serotonin and subsequent smooth muscle cell growth. Recent interest has focused on the role of impaired apoptosis on the development of proliferative arteriopathy in IPAH. It is clear that functional mutations seen in the *BMPR2* gene with resultant abnormal downstream signaling results in impaired apoptosis.[21–23]

In addition to potential genetic defects, several abnormalities in endothelial cell function have been found, many of which are likely a result of some vascular insult. The basis for currently approved therapeutics is the deficiency in prostacyclin and nitric oxide release and the excess in endothelin-1 and its receptor expression in patients with pulmonary hypertension.[24–27] The complex cellular and molecular processes contributing to IPAH are shown in Figure 52-2.

OTHER FORMS OF PULMONARY ARTERIAL HYPERTENSION

Etiologies other than IPAH leading to PAH are worth discussing because they may be considerably more common than IPAH and share many features. Patients with the scleroderma spectrum of diseases, most notably limited scleroderma (previously CREST [calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia]) have been reported to have pulmonary hypertension in up 40% of cases.[28–30] Pulmonary vascular involvement is associated with worse survival in scleroderma.[31] Other connective tissue diseases associated with PAH, albeit less commonly, include systemic lupus erythematosis,[32–34] mixed connective tissue disease,[35–37] and rheumatoid arthritis.[38–40]

Congenital heart disease is a well-recognized "risk factor" for development of PAH. In 1958, Wood[13] coined the term "Eisenmenger's complex" to describe pulmonary hypertension at the systemic level due to high pulmonary vascular resistance (PVR), with reversed shunting through a large ventricular septal defect. Subsequently, the term has been used to describe pulmonary hypertension with cyanosis with any systemic to pulmonary circulatory shunt. The likelihood of developing pulmonary hypertension depends on the size of the defect. However, patients with even small atrial septal defects can develop pulmonary hypertension. These patients may, in fact, have IPAH and the atrial septal defect merely serves as a "trigger" in a susceptible patient.

In patients with ventricular septal defects, it has been shown that 3% of patients with a defect of 1.5 cm or smaller will develop Eisenmenger's syndrome whereas half of patients with a large defect will develop significant pulmonary hypertension, which will also appear earlier than in atrial septal defect, often in infancy.[41] PAH due to true Eisenmenger's syndrome is associated with a longer natural history and apparent adequate right ventricular compensation. In addition, the defect may actually function as a protective mechanism, providing a route for blood to reach the underfilled left ventricle.

The effects of drugs and toxins on the human pulmonary circulation have been graphically demonstrated in the past. Between 1967 and 1970 in Switzerland, Austria, and Germany, a 20-fold increase in pulmonary hypertension was observed after the introduction of aminorex, an appetite suppressant resembling epinephrine and amphetamine.[42] The pulmonary lesions produced by this agent resembled plexogenic pulmonary arteriopathy in every respect. Although the case against aminorex was weakened by the facts that 20% of patients with idiopathic pulmonary hypertension in Central Europe did not take the drug, only 1 in 1000 persons taking the drug actually developed pulmonary hypertension, and an animal model could not be created.[43] The case was strengthened by the observation that the incidence of pulmonary hypertension decreased to its previous level after aminorex was withdrawn from the market. Pulmonary hypertension has been associated with another family of appetite suppressants with similar chemical structure, fenfluramine and dexfenfluramine.[44] In a case-controlled prospective study performed in Europe, the risk of developing pulmonary hypertension was increased by 20-fold in individuals who used these drugs for periods exceeding 3 months. Reversible pulmonary hypertension has been reported after discontinuation of a similar agent.[45] Interestingly, application of both aminorex and fenfluramine to pulmonary artery smooth muscle cells results in K channel function alterations that are similar to those observed in cells from patients with "spontaneous" IPAH.[46]

Illicit drug use has been observed with increasing frequency as a cause of severe pulmonary hypertension. An especially strong association between methamphetamine use and PAH was found in a single-center case-control study.[47] In that study, patients with PAH and no other identifiable risk factors were 10 times more likely to have used methamphetamine than a control group of patients with other forms of PAH.

Portal hypertension is another disease associated with PAH. Mantz and Craige[48] first described simultaneous occurrence of portal and pulmonary hypertension in a patient with portal vein thrombosis and speculated that multiple emboli emanating from portacaval anastomoses were responsible for the pulmonary hypertension. Naeye in 1960[49] reported six cases of coexisting portal and pulmonary hypertension and also implicated embolization from the portal vein. A subsequent large retrospective autopsy study found pulmonary hypertensive changes in 0.73% of patients with portal hypertension.[50] A subsequent study in patients undergoing liver transplantation found an incidence of pulmonary hypertension of 4%.[51] The mechanism of pulmonary hypertension development in portal hypertension is not known. One hypothesis is that portosystemic shunting allows vasoactive substances, normally cleared in the liver, to reach the pulmonary vasculature. Hemodynamically, patients with portapulmonary hypertension tend to have higher cardiac outputs and lower PVRs.[52] Despite more favorable hemodynamics, the mortality risk following liver transplantation has been shown to be approximately 50% in patients with even mild pulmonary hypertension (PVR > 250 dynes/sec/cm^{-5}).[53] Knowledge regarding the high mortality in patients with portapulmonary hypertension undergoing orthotopic liver transplantation has led to development of aggressive strategies for screening and treatment of these patients prior to surgery.[54,55] The association between HIV and PAH is well known.[56–59] In several studies, the incidence of pulmonary hypertension in HIV has been reported as high as 0.5%. The mechanism of HIV-associated pulmonary hypertension is not known, although theories include release of cytokines and growth factors and the presence of human herpesvirus 8 (HHV8), a promoter of angiogenesis such as occurs in Kaposi's sarcoma. One report noted the presence of HHV8 in the cells from plexiform lesions in 10 of 16 patients with PPH.[60] Subsequent reports, however, failed to reveal HHV8 in plexiform lesions.[61,62] Pulmonary hypertension can occur in all stages of HIV, including patients with no detectable viral load. There is the suggestion that many of these patients have a concomitant history of illicit intravenous drug use in as many as 42% of cases.[63] At the authors' Pulmonary Hypertension Center, the vast majority of patients with HIV-associated PAH have a methamphetamine use history, suggesting the possibility that stimulant drugs contribute substantially to the risk of PAH in HIV patients. Clinical and hemodynamic features of HIV-associated pulmonary hypertension are similar to those of IPAH, although, in one study of 112 patients,[64] the survival rate was lower.

SYMPTOMS

Dyspnea is the cardinal symptom of IPAH, occurring in more than 95% of patients in the major clinical series.[1] Breathlessness is the presenting symptom in 60% of patients and usually is noted first on exertion, but

eventually occurs at rest. Its mechanism is probably complex: the most likely cause for the dyspnea of pulmonary hypertension is the inadequacy of cardiac output relative to metabolic requirements.[65] Reeves and Groves[66] have postulated that stretch receptors on the main pulmonary arteries also may be involved. Regardless of its mechanism, Packer[67] stresses that the severity of dyspnea does not correlate with the elevation of pulmonary artery pressure in patients with IPAH.

Closely related to dyspnea are sensations of fatigue and weakness, reported by a majority of patients with IPAH.[1] These sensations usually are experienced before the general disability that is present with advanced disease. They presumably reflect impaired tissue oxygenation resulting from the depressed cardiac output in patients with IPAH. This impairment is usually evident during cardiac catheterization as both a low cardiac output and a decreased mixed venous oxygen pressure (P_{O_2}).

Substernal chest pain also commonly is reported in patients with IPAH.[68] It frequently occurs on exertion, radiates to the left shoulder or axilla, and is relieved by rest. The pain has been likened to angina pectoris and has been attributed to coronary insufficiency in the presence of increased right ventricular work and hypoxemia, a concept supported by the occasional relief produced by nitroglycerin. However, pain may be present in young patients without coronary artery disease, prompting Viar and Harrison[68] to argue that the pain is caused by distention of the pulmonary artery, whose afferents enter the nervous system along the same pathways as afferents from the heart. Another plausible but unproven explanation is that the chest pain of IPAH is variant angina in patients with generalized vasospastic disease.

Syncope occurs in some patients with IPAH and may be its initial manifestation. This symptom also is experienced first on exertion but may happen later at rest. The syncope probably is caused by a decrease in cerebral blood flow that follows an increase in pulmonary artery pressure and a decrease in cardiac output. Dresdale and associates[6] speculated that cardiac output would be especially depressed in patients with concurrent coronary insufficiency and right ventricular failure.

Another symptom associated with IPAH is hemoptysis that presumably stems from microvascular rupture under the high pulmonary artery pressure. In addition, hoarseness may result from pressure of the enlarged main pulmonary artery on the recurrent laryngeal nerve. Peripheral edema and ascites may develop after the onset of right ventricular failure.

PHYSICAL FINDINGS

Patients with early IPAH may manifest no physical abnormality. However, signs of pulmonary hypertension and a decreased cardiac output should be evident with advanced disease. As Wood[13] observed, the hands and feet of a patient with severe pulmonary hypertension are cold, the peripheral pulse is diminished, the blood pressure is likely to be low, and the pulse pressure is reduced. Signs of systemic venous hypertension should be present, including a prominent jugular venous *a* wave, which is exaggerated by abdominal compression (hepatojugular reflux) and transmitted to the liver in a presystolic hepatic pulse, and prominent *c-v* waves, which are indicative of tricuspid regurgitation. Palpation of the chest should reveal a right ventricular lift at the left sternal border that is sustained throughout the pressure-overloaded cardiac contraction, in contrast to the unsustained parasternal impulse felt in pure volume overload.

On auscultation of the chest, the second heart sound is closely split, and the second (pulmonic) component is accentuated. The valvular closure sound should increase in intensity on inspiration and may become palpable as pulmonary artery pressure rises. A systolic ejection click reflecting sudden distention of the right ventricular wall also may be heard. A murmur of tricuspid regurgitation heard best along the left sternal border and increasing in intensity with inspiration, is frequent. A pulmonic regurgitant murmur may become evident after dilation of the main pulmonary artery and its valve annulus. Diastolic vibration of the aortic valve leaflet (Graham Steell murmur) may be present along with third and fourth heart sounds. In addition to these findings, patients with right-sided heart failure usually have peripheral edema and abdominal distention due to ascites. If tricuspid regurgitation is present, the liver may become pulsatile.

Cyanosis occurs with variable frequency in patients with IPAH and is likely to be a late phenomenon. It is most marked during exercise but also may be present at rest. Peripheral vasoconstriction and impaired oxygenation of arterial blood due to mixed venous hypoxemia resulting from the decreased cardiac output appear to be the most common mechanisms. Patients in whom right atrial pressure equals or exceeds left atrial pressure may develop severe hypoxemia and cyanosis because of opening of the foramen ovale with subsequent right-to-left shunting of blood. In addition to cyanosis, vascular plethora may be observed in hypoxemic patients with secondary polycythemia. With the exception of patients with cirrhosis and pulmonary hypertension, clubbing is not a usual manifestation of IPAH. The presence of clubbing warrants a careful search for other causes of pulmonary vascular disease.

DIAGNOSIS

Although pulmonary hypertension may be appreciated on physical examination, IPAH cannot necessarily be distinguished from the other causes of pulmonary hypertension by examination alone. The major entities in the differential diagnosis are chronic pulmonary thromboembolism; cardiac disorders, such as congenital heart disease, mitral stenosis, and left atrial tumors; and pulmonary veno-occlusive disease (discussed subsequently). Although the severity of pulmonary hypertension may be assessed by physical examination, laboratory evaluation is required for precise quantification.

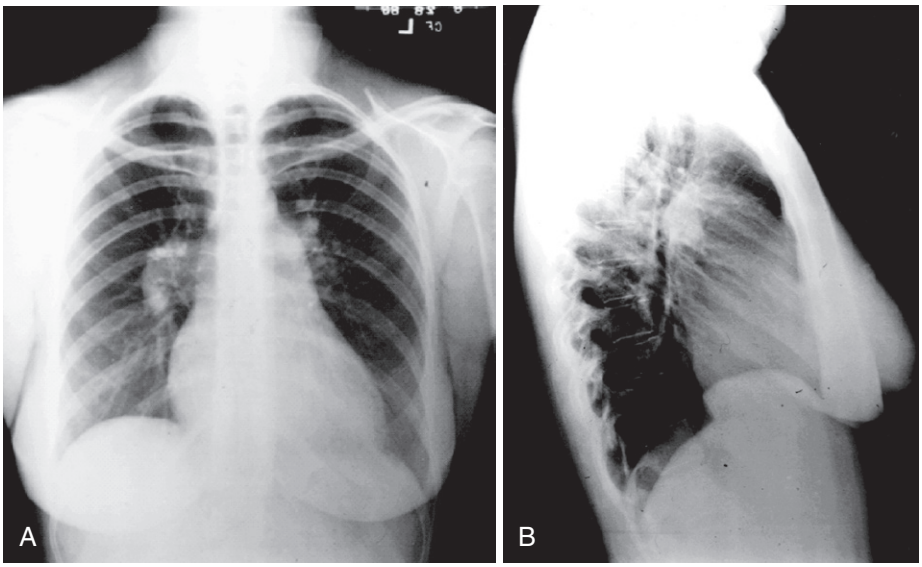

FIGURE 52-3 ■ Typical chest radiograph in IPAH. Note the clear lung fields, cardiomegaly, and the decrease in retrosternal airspace on the lateral film, indicating right ventricular enlargement.

Blood studies are an important part of the laboratory evaluation. The complete blood count is particularly helpful in documenting polycythemia, which is present in hypoxemic patients with PAH.

The plain chest radiograph is potentially useful in suggesting the presence of pulmonary hypertension and in providing clues of underlying conditions such as parenchymal lung disease (Fig. 52-3). In patients with IPAH, the radiograph characteristically reveals protrusion of the main pulmonary artery, increased width of the descending branch of the right pulmonary artery, peripheral oligemia, and an increase in the cardiothoracic ratio.

Systemic arterial blood gas analysis in patients with IPAH usually reveals a low arterial carbon dioxide pressure ($Paco_2$) and a normal pH, reflecting chronic respiratory alkalosis. The systemic arterial oxygen pressure (Pao_2) may be normal or abnormal, but the alveolar-to-arterial Po_2 difference usually is increased. Several mechanisms have been proposed for the hypoxemia of patients with IPAH, including diffusion impairment caused by a reduction in the number of pulmonary vessels coupled with the shortened time spent by erythrocytes in traversing the pulmonary circulation; ventilation-perfusion mismatching due to alterations in pulmonary blood flow and concomitant conditions such as bronchospasm; and right-to-left intracardiac shunting through a patent foramen ovale. Dantzker and Bower[69] demonstrated with the multiple inert gas elimination technique that the hypoxemia is caused by a combination of ventilation-perfusion mismatching, intrapulmonary shunt, and a low mixed venous Po_2 resulting from a reduced cardiac output.

Pulmonary function tests performed in patients with IPAH usually reveal normal expiratory flow rates with normal or mildly reduced lung volumes. The modest restrictive defect has been attributed to diminished distensibility of the pulmonary vessels.[70] The diffusing capacity for carbon monoxide often is reduced to a mild or moderate degree.

Exercise testing serves to bring out physiologic abnormalities in patients with IPAH if these abnormalities are not present at rest. Characteristically, patients with pulmonary hypertension achieve their target heart rate and anaerobic threshold at low levels of exercise, often accompanied by a reduction in the arterial Po_2 or an increase in the alveolar-to-arterial Po_2 difference. The dead space–to–tidal volume ratio either fails to decrease as it should in healthy persons or actually increases during graded exercise. Recent data suggest that cardiopulmonary exercise testing with hemodynamic measurements (level 4 test) can distinguish various forms of exercise-induced pulmonary hypertension.[71] Submaximal exercise testing by the 6-minute walk test is extremely useful as a prognostic marker and in following patients on therapy. Six-minute walk distance has served as the primary outcome end point in several pivotal pulmonary hypertension clinical trials.

The electrocardiogram usually discloses right ventricular hypertrophy in patients with advanced IPAH. Electrocardiographic criteria for right ventricular hypertrophy include a QRS axis in the frontal plane that is greater than or equal to 110 degrees, an R wave in lead V_1 that is greater than 5 mm, an R-to-S ratio in V_1 that is greater than 1, and an R-to-S ratio in lead V_6 that is less than 1. Patients also may manifest right atrial enlargement with a symmetrical and peaked P wave in lead II that is greater than 2.5 mm in amplitude. ST segment depression and T-wave inversion may be seen in the anterior chest leads. These abnormalities may not be present if pulmonary hypertension is not pronounced or if patients are young.

The echocardiogram may be helpful in documenting pulmonary hypertension and in ruling out conditions such as mitral valve disease and left ventricular systolic or diastolic dysfunction. IPAH has been associated in

one-dimensional echocardiography with midsystolic notching, diminution of the *a* dip, prolongation of the right ventricular preejection period, increased right ventricular systolic dimensions, and midsystolic fluttering of the pulmonary valve.[72–74] Two-dimensional echocardiography helps quantitate right atrial and right ventricular size and may identify systolic flattening or diastolic bulging of the interventricular septum due to increased pulmonary artery pressure.[74] Pulmonary artery pressure can be estimated by measuring the velocity of the tricuspid regurgitant jet using the equation:

$$\text{RV systolic pressure} = \text{TR velocity}^2 \times 4 + \text{estimated CVP}$$

where RV is right ventricular; TR is tricuspid regurgitation; and CVP is central venous pressure. The precision of the pulmonary artery systolic estimate compared with right heart catheterization measurement is controversial, with studies suggesting both good and poor concordance. Intracardiac shunting may be observed after the intravenous injection of microbubbles. More advanced echocardiographic techniques such as tissue Doppler[75] and calculation of the tricuspid annular shortening (TAPSE)[76] may provide more precise information.

Perfusion lung scanning has been used primarily to differentiate IPAH from chronic pulmonary thromboembolism. D'Alonzo and associates[77] studied 25 patients; in all 8 patients with chronic pulmonary thromboembolism, lung scans indicated a high probability of embolic disease due to multiple segmental defects, whereas 17 patients with IPAH had scans that were normal or indicated a low probability of embolism. This study suggests that lung scans are highly specific in differentiating the two conditions. If chronic thromboembolic pulmonary hypertension is suspected, pulmonary angiography is recommended to confirm the diagnosis and assess surgical accessibility.

In the evaluation of IPAH, right heart catheterization is mandatory to document the presence and severity of pulmonary hypertension, rule out cardiac causes, and determine if there is acute pulmonary vasoreactivity using pharmacologic agents. Hemodynamic values, especially right atrial pressure and cardiac index, correlate closely with survival.[78] Cardiac chamber and pulmonary arterial pressures are recorded, and the wedge pressure is measured to rule out disease at the level of the left ventricle, left atrium, or large pulmonary veins. Cardiac output is measured, and from it and vascular pressures, the pulmonary and systemic vascular resistances are calculated. Blood gas samples are taken to determine oxygen contents in the two circulations. These and other variables may be studied at rest or during exercise. Left-to-right intracardiac shunts may be excluded by the measurements of blood oxygen contents in the various cardiac chambers and by indicator techniques.

Cardiac catheterization in patients with IPAH may reveal elevated right atrial pressure, pulmonary arterial pressures that are increased often to systemic levels, and depression of cardiac output. PVR generally is increased, whereas systemic vascular resistance is in the normal range.

Virtually identical hemodynamic and clinical findings may be encountered in the rare form of PAH termed *pulmonary veno-occlusive* disease (PVOD). Like IPAH, PVOD appears to be a morphologic rather than an etiologic entity. In addition, PVOD tends to afflict infants, children, and young adults, although patients older than 60 years have been reported. However, in the adults with veno-occlusive disease who have been reported, there is a slight male preponderance. A familial occurrence of veno-occlusive disease also has been noted. Veno-occlusive disease has been associated with viral syndromes, toxin exposure, and chemotherapy. The characteristic histologic feature of PVOD is obstruction of pulmonary venules and veins by intimal fibrosis; intravascular fibrous septa, which usually are considered pathognomonic of recanalized thrombi, are nearly always present.[79] These findings have led to the speculation that thrombosis is an essential pathogenetic mechanism in most cases, but the factors causing or contributing to thrombus formation are completely unknown.

Of considerable interest is the observation that narrowing or obliteration of pulmonary arteries is found in approximately half the cases of PVOD.[79] The morphologic appearance of the arterial lesions indicates that they also were produced by organization of intravascular thrombi and that the abnormalities were not merely secondary to pulmonary venous obstruction with attendant medial hypertrophy and arterial hypertension. These observations raise the question whether there are two variations of the same basic disorder: the classic form of PVOD, in which the arteries are spared, and a generalized form, in which both arteries and veins are involved. PVOD cannot be distinguished with certainty from IPAH by right heart catheterization unless the pulmonary capillary wedge pressure is elevated. Apart from the difficulties of successfully wedging a catheter in patients with pulmonary hypertension, whether the wedge pressure is elevated depends on whether the venous obstruction is in the venules or the large veins. This is because the pressure actually measured at the tip of a catheter positioned in an obstructed pulmonary artery, by either wedging or inflating a balloon, is the pressure in the next freely communicating downstream vessel. Accordingly, if venules are occluded, as is often the case in PVOD, the next freely communicating vessel may be a vein in which the pressure is normal. In contrast, if (large) veins are the sites of occlusion, then the pulmonary venous pressure is likely to be elevated proximally and to be detectable at catheterization. Indeed, the wedge pressure may vary in different sites within the lung in patients with veno-occlusive disease. The chest radiograph may show signs of pulmonary hypertension with prominent Kerley B lines in the absence of other signs of left-sided heart failure, and this is often the most useful clue to the diagnosis in a patient with unexplained severe pulmonary hypertension. Computed tomography (CT) scanning may reveal interlobular septal thickening, pleural effusions, and enlarged pulmonary arteries. The perfusion lung scan may show defects suggestive of thromboembolism but with unremarkable pulmonary angiograms.[80] In addition, patients with veno-occlusive disease may

develop acute pulmonary edema in response to pharmacologic agents that reduce upstream PVR and increase cardiac output, such as prostacyclin. This phenomenon probably is caused by an increase in pulmonary blood volume in the face of downstream vascular obstruction. A recent analysis of PVOD cases suggested that bronchoalveolar lavage could be useful, as patients with PVOD almost always had increased hemosiderin-laden macrophages in bronchoalveolar lavage (BAL) fluid.[81]

Acute vasodilator testing is performed using a short-acting agent. Commonly used drugs include inhaled nitric oxide, adenosine, and prostacyclin. Oxygen and nitrates are not adequate testing agents in patients with IPAH. Criteria for defining vasoresponsiveness are discussed later, but fundamentally acute testing is performed to identify patients who will benefit from long-term calcium channel blocker therapy.

TREATMENT AND PROGNOSIS

IPAH is now a treatable disease. Clear-cut short- and long-term benefits are seen with currently available therapies. To optimize a patient's outcome, a comprehensive medical approach is essential. Once the diagnostic process in a patient with pulmonary hypertension is complete, and the patient is characterized as having IPAH (WHO group 1), therapy should be initiated. But many questions arise regarding IPAH therapy. What are the goals and expected outcomes of IPAH therapy? Which drug should be used first? When should another therapy be added? Should more than one therapy be used? In what order? When should transplantation be considered? Are there published guidelines in which experts have evaluated the quality of evidence and issued a "grade" for the therapy?

Therapy for IPAH may be subdivided into "supportive" or "conventional" therapies, defined as empirical treatments or recommendations for which there is no prospective, randomized, controlled data, and "specific" or "targeted" therapies, which have been tested and approved by regulatory authorities for the treatment of PAH.

Supportive Therapies

Exercise and Physical Activity

There is no evidence-based guidance regarding physical activity or exercise in PAH. Patients should avoid activities that lead to undue symptoms such as severe dyspnea, chest pain, light-headedness, or syncope. However, low- to moderate-levels of exercise to prevent deconditioning and improve mental outlook are appropriate. One recent study demonstrated that exercise and respiratory training is safe and results in measurable improvements in subjective and objective parameters.[82] Mereles and coworkers[82] randomized 30 patients (23 with PAH and 7 with chronic thromboembolic pulmonary hypertension) to exercise training versus no change in treatment. In addition to being safe, patients in the exercise-training group had improved their quality of life scores, functional class, maximal oxygen consumption, and 6-minute walk distance (of 111 m compared with the placebo group).

Avoidance of Altitude

Hypobaric hypoxia causes pulmonary vasoconstriction and, thus, can worsen the pulmonary hypertension in PAH patients. Patients with PAH not infrequently report symptomatic worsening when traveling to elevations above 1000 m. It is generally recommended that patients flying on commercial airliners (pressurized to 1500–2400 m) or traveling to elevation above 5000 feet use supplemental oxygen. Not surprising, patients with severe PAH residing at high elevations often improve if they move to sea level.

Avoidance of Pregnancy

Pregnancy and especially delivery are extremely risky in patients with PAH.[83] Although there are rare case reports of patients managed with epoprostenol and undergoing successful pregnancies and deliveries,[84,85] it is strongly recommended that women of childbearing potential use appropriate methods of birth control to avoid pregnancy. In terms of which birth control method is preferable, no consensus exists. Some experts recommend avoiding estrogen-containing hormonal contraceptives. Medroxyprogesterone acetate (Depo-Provera) is an effective, convenient agent commonly used in PAH patients. It should be noted that in patients on endothelin-receptor antagonists such as bosentan or ambrisentan, an additional barrier method of birth control should be used.

Warfarin

There is strong rationale for the use of anticoagulants in PAH. Many of the endothelial cell abnormalities that predispose patients to pulmonary arteriopathy also increase thrombosis. The presence of heart failure and an indwelling central venous catheter are independent risk factors for thromboembolic events, which are poorly tolerated by patients with an already marginal pulmonary vascular reserve. In addition, microscopic thrombotic lesions in the pulmonary vasculature are well appreciated in PAH patients.

Warfarin is the anticoagulant most frequently used in patients with PAH. In clinical trials with PAH drugs, about 50% to 85% of patients are on anticoagulants at study entry. However, anticoagulation has risks (i.e., bleeding) as well as the need for frequent monitoring. What data justify the use of warfarin in PAH? Three studies have examined the effects of warfarin in IPAH or anorexigen-induced PAH.[86–88] All three were retrospective analyses with some patients on warfarin. All three demonstrated better survival in patients on warfarin than those not anticoagulated. In an early study by Fuster and colleagues,[86] 120 patients with a clinical diagnosis of IPAH were studied; anticoagulation improved survival at 3 years (49% vs. 21%). However, of note, the overall

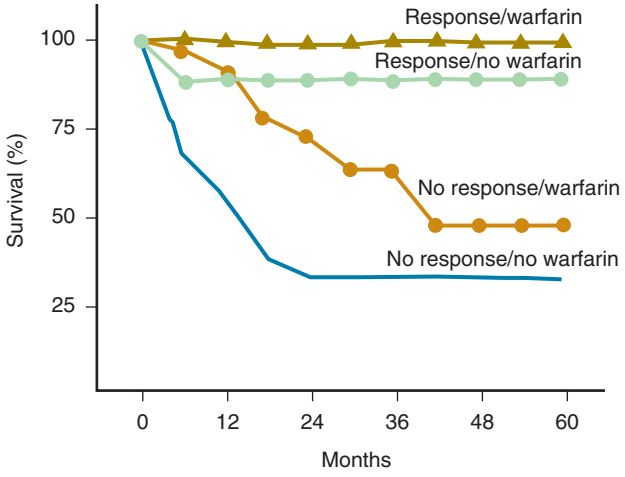

FIGURE 52-4 ■ Survival in patients with IPAH based on acute vasoreactivity and treatment with warfarin. In patients who were not vasoreactive, warfarin was associated with a modest survival advantage versus nonreactive patients who were not on warfarin. (Redrawn from Rich S, Kaufmann RN, Levy PS: The effect of high doses of calcium-channel blockers on survival in primary pulmonary hypertension. N Engl J Med 327:76–81, 1992.)

5-year survival for the entire cohort was only 21%. In addition, 57% of the patients in whom autopsy was performed had predominantly thrombotic lesions noted, raising the question of whether some of these "IPAH" patients may have been misdiagnosed and actually had chronic thromboembolic pulmonary hypertension. In the Rich and associates' study,[87] which primarily looked at the long-term benefit of calcium channel blockers in IPAH, a survival benefit with warfarin was noted predominantly in patients who were "nonresponders" to calcium channel blockers (Fig. 52-4). The third retrospective study, by Frank and coworkers,[88] compared survival in aminorex-induced PAH and IPAH with and without anticoagulation. In both groups, the use of oral anticoagulant therapy was associated with better survival, with the longest mean survival observed in anticoagulated aminorex-PAH patients (8.3 years vs. 6.1 years for nonanticoagulated aminorex-PAH patients).

Although these three retrospective studies all suggest a survival benefit with warfarin in PAH, it is important to note that none of the studies were conducted during the "modern" era of effective, targeted PAH therapies, which are already associated with better survival than that seen in these "historical" studies. Whether warfarin further improves outcome in patients on these therapies (e.g. endothelin receptor antagonists, phophodiesterase-5 inhibitors, prostanoids) remains unclear.

Despite the serious limitations in the existing data, published guidelines recommend, with a "B" grade, that patients with IPAH be treated with warfarin.[89] There is less guidance regarding the use of anticoagulation in other forms of PAH, such as that associated with congenital systemic-to-pulmonary shunts or associated with connective tissue diseases. There may be specific cases in which warfarin would be indicated, such as in patients with advanced heart failure, indwelling central venous catheters, or erythrocytosis. Conversely, if there are patients at increased risk for bleeding (thrombocytopenia, history of hemoptysis or gastrointestinal bleeding), withholding anticoagulation, given the limited data, may be prudent.

Supplemental Oxygen

The benefits of supplemental oxygen in PAH patients, unlike patients with pulmonary hypertension associated with lung diseases such as chronic obstructive pulmonary disease (COPD),[90,91] are not clear. In fact, most PAH patients are not hypoxemic, at least at rest. Mild hypoxemia, when present, is likely on the basis of reduced mixed venous oxygen saturation caused by low cardiac output with mild ventilation/perfusion inequality. The presence of more profound hypoxemia in a PAH patient should raise suspicion for underlying parenchymal lung disease, systemic to pulmonary shunting, PVOD, pulmonary capillary hemangiomatosis, or pulmonary arteriovenous malformations as seen in patients with Osler-Weber-Rendu–associated pulmonary hypertension.

Although oxygen is a pulmonary vasodilator, there are no long-term studies supporting its efficacy. However, the consensus is that if arterial P_{O_2} is less than 60 mm Hg or systemic arterial O_2 saturation is less than 90% at rest, supplemental oxygen is indicated. One exception to this approach is in patients with Eisenmenger's syndrome, with hypoxemia due to right-to-left shunting. In this group, the use of supplemental oxygen remains controversial.[92,93] There is no general agreement about whether exercise-only systemic arterial O_2 desaturation warrants oxygen supplementation. In addition, the "stigma" of nasal cannulae for a PAH patient often limits compliance outside the home.

Diuretics

Diuretics have long been a mainstay of therapy for heart failure, including right ventricular failure. Both total-body and intravascular volume overload are common in PAH patients. In pivotal trials of PAH drugs, the majority of patients entered the studies on chronic diuretic therapy.[94,95]

In addition to causing symptomatic peripheral edema, volume overload of the right ventricle can cause compression of the left ventricle and contribute to decreased cardiac output and prerenal azotemia. Thus, it is a common observation that in decompensated PAH patients, aggressive diuresis leads to clinical and physiologic improvements. Despite the benefits of diuretics in PAH patients, there are no controlled studies to guide the clinician in using these agents.

A loop diuretic is frequently employed first. Although furosemide is often the loop diuretic of choice, there is some evidence that torsemide might be more efficacious without increased side effects.[96] In addition, in patients with marked extravascular fluid accumulation and poor intestinal absorption, intravenous diuretic therapy is frequently needed. Anti-aldosterone drugs (e.g., spironol-

actone) are commonly combined with loop diuretics in PAH patients. Whether data suggesting a morbidity and mortality benefit of spironolactone in left-sided heart failure[97] can be extrapolated to right-sided heart failure is not known.

In some cases, addition of a thiazide diuretic to the regimen is appropriate. The combination of metolazone and furosemide has been found by the authors to be effective in causing a brisk diuresis. However, marked hypokalemia can occur with this regimen.

Although it is possible that in some PAH patients, the right ventricle is preload dependant and therefore overdiuresis can be detrimental, this has not been the authors' experience. More often, aggressive diuresis (1–3 L negative fluid balance per day) leads to improvement in renal function and blood pressure, consistent with improved cardiac output.

Calcium Channel Antagonists

In 1958, Paul Wood[5] first defined the clinical entity of pulmonary hypertension with reference to the "vasoconstrictive factor." It is not surprising, then, that a search for pulmonary vasodilators as effective therapies ensued. Agents including phentolamine,[98] tolazine,[99] captopril,[100] and hydralazine[101] were evaluated in uncontrolled reports. Results, although variable, were not overwhelmingly favorable. No systematic studies of these medications were carried out.

Out of the myriad of oral antihypertensive agents emerged calcium channel blockers. Ostensibly, this class of agents "made sense" for treating pulmonary hypertension. Calcium channel blockers have acceptable side effect profiles and are potent pulmonary as well as systemic vasodilator agents. The role of intracellular cytosolic calcium in the vasoconstriction of pulmonary artery smooth cells was well established. Thus, blocking influx of calcium into the cells seemed desirable.

In a highly quoted paper, Rich and associates[87] described favorable survival in a subgroup of IPAH patients treated with either diltiazem or nifedipine. In that study, patients manifesting acute pulmonary vasoreactivity with calcium channel blockers, defined as an acute decrease in mean pulmonary arterial pressure and PVR of at least 20%, had a 5-year survival of 94%. In contrast, patients who did not have an acute response had only a 55% 5-year survival. In addition, predicted survival for the "acute responders," using an equation based on hemodynamics at time of diagnosis, was significantly worse than the observed survival. Although not a placebo-controlled study, these data suggested a benefit with calcium channel blockers in some IPAH patients.

The Rich and associates' study,[87] although seminal, likely led to overuse of calcium channel blockers, not only for IPAH but for other forms of PAH as well. Calcium channel blockers are not selective pulmonary vasodilators. In addition, calcium channel blockers have potential negative inotropic effects. Thus, in patients with minimal or no acute pulmonary vasoreactivity, the negative effects of calcium channel blockers can become predominant, with potential for catastrophic consequences.

A subsequent, large retrospective study by Sitbon and colleagues[102] has further narrowed the role of calcium channel blockers in IPAH patients. In that study, 557 IPAH patients were tested for acute pulmonary vasoreactivity using either intravenous prostacyclin (e.g., epoprostenol) or inhaled nitric oxide. Seventy patients (about 13%) had an acute response (at least a 20% fall in mean pulmonary artery pressure and PVR) and were treated with calcium channel blockers. However, only half of those "acute responders" (about 7% of the total) did "well" long term on calcium channel blockers, defined as being alive and in functional class I or II at 5-year follow-up (see Fig. 52-2). The long-term survivors had less severe disease as assessed by hemodynamics at baseline and had reached a lower mean pulmonary artery pressure with acute vasodilator challenge than the long-term calcium channel blocker failures (33 mm Hg vs. 46 mm Hg). In other words, rather than the percent drop in mean pulmonary artery pressure during an acute test, the absolute mean pulmonary artery pressure reached appeared to be better in defining the patients that would benefit long term with calcium channel blockers. These data have been codified into evidence-based guidelines,[89] which define potential calcium channel blocker candidates as IPAH patients in whom, during an acute pulmonary vasoreactivity test, the mean pulmonary artery pressure decreases by at least 10 mm Hg to a level below 40 mm Hg, with no decrease in cardiac output.

The method for performing acute pulmonary vasoreactivity testing varies among pulmonary hypertension centers. Most frequently, one of three short-acting pulmonary vasodilators is used in the cardiac catheterization laboratory (i.e., inhaled nitric oxide, intravenous adenosine, or intravenous epoprostenol). Using a short-acting agent prevents refractory systemic hypotension that could result when a PAH patient with minimal pulmonary vasoreactivity is given a systemic vasodilator. A distinct advantage of inhaled nitric oxide is the absence of systemic hemodynamic effects, the very rapid "on-off" properties of the drug (i.e., half-life 20 seconds), and the absence of side effects. With inhaled nitric oxide, an acute pulmonary vasoreactivity test with repeat hemodynamic measurements can be accomplished in less than 20 minutes.

Targeted Therapies

PAH-specific therapies have been available since 1995, when intravenous epoprostenol was approved by the U.S. Food and Drug Administration (FDA), based on the first prospective randomized, controlled trial done in PAH. Since then, an additional five therapies have been approved for PAH: subcutaneous and intravenous treprostinil, inhaled iloprost, the oral endothelin receptor antagonists bosentan and ambrisentan, and the phosphodiesterase-5 inhibitor sildenafil. These therapies were developed to offset the imbalance in endothelial-derived mediators seen in PAH: excessive endothelin-1 production, deficient prostacyclin, and abnormal nitric oxide production (Fig. 52-5).

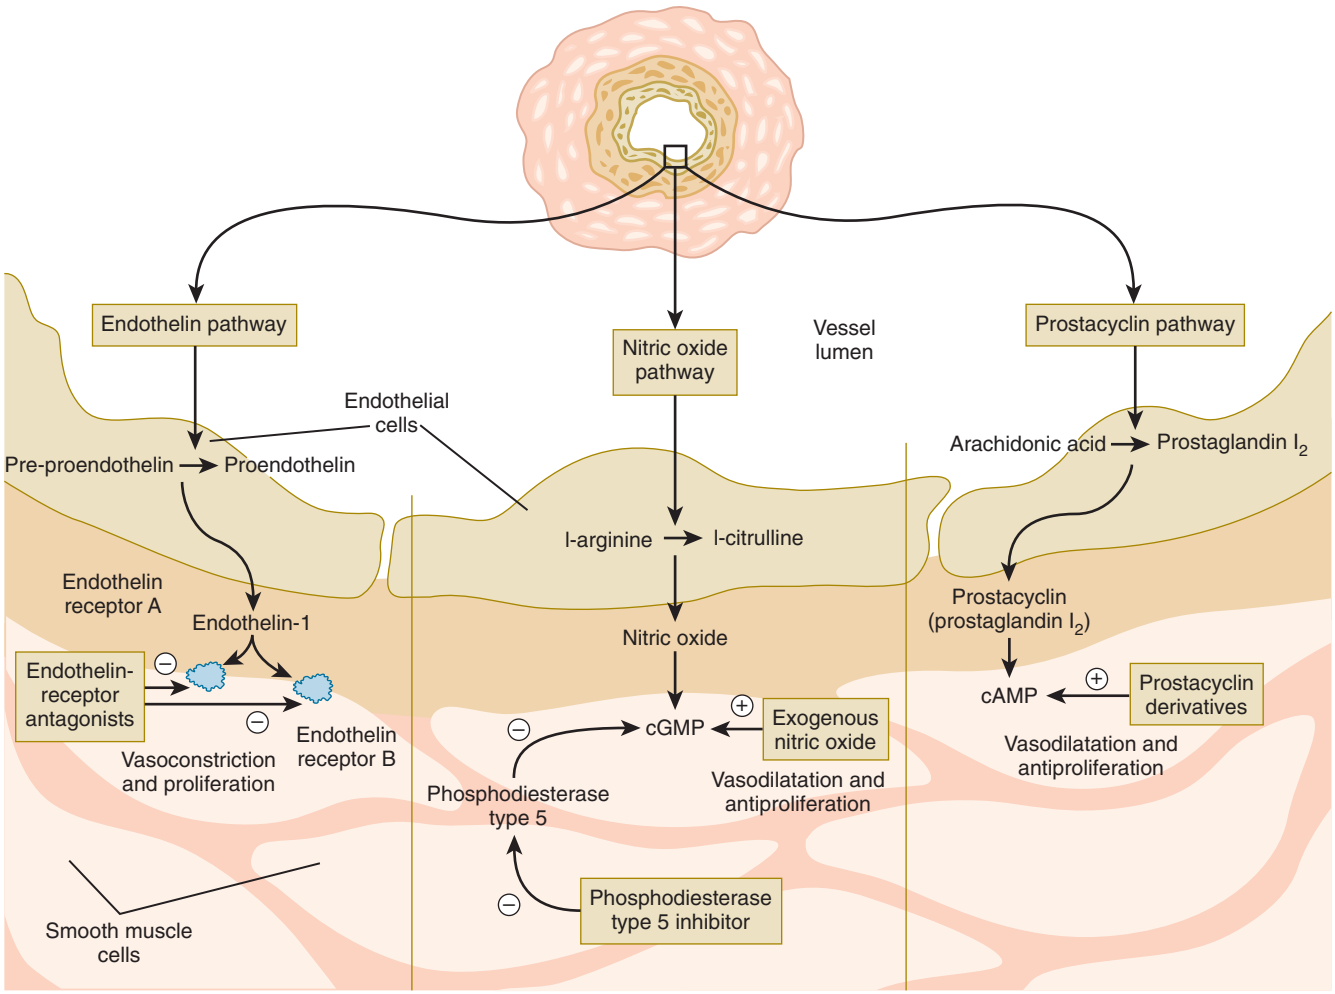

FIGURE 52-5 ■ Schematic of three abnormal endothelial mediator pathways that are targeted by current therapies.

Prostacyclin Analogues

Epoprostenol. Epoprostenol (Flolan) was first approved by the FDA on September 20, 1995, for the indication of "long-term intravenous treatment of primary pulmonary hypertension in New York Heart Association (NYHA) class III and class IV patients." Continuous intravenous infusions of prostacyclin (prostaglandin I_2, epoprostenol) have been used, either as a primary mode of treatment or as a bridge to transplantation, and produce sustained improvement in hemodynamics and exercise tolerance as well as prolonged survival. In this first randomized, prospective study,[94] 81 patients with NYHA class III or IV symptoms, despite treatment with conventional therapy, which included oral vasodilators, digoxin, diuretics, and supplemental oxygen, were randomized to either continuous intravenous epoprostenol plus conventional therapy or conventional therapy alone for 12 weeks. The primary outcome was the change in exercise capacity, as measured by the 6-minute walk test. Secondary outcomes included change in hemodynamics, quality of life, NYHA functional class and survival. At 12 weeks, the 6-minute walk distance improved in the continuous intravenous epoprostenol group by 32 m and decreased by 15 m in the conventional therapy group. Mean pulmonary artery pressure, cardiac index, and PVR significantly improved in the epoprostenol group. There were also significant improvements in the epoprostenol group when measuring quality of life and NYHA functional class. Eight patients died during the 12-week study and all were in the conventional treatment arm. Notably, this is the only PAH trial ever to show, compared with a control group, a beneficial effect on survival.

Follow-up studies have confirmed the long-term benefits of epoprostenol on survival compared with historical controls, with 5-year survival estimates of greater than 60% in treated patients,[103] a great improvement from the median survival of less than 3 years in the "pre-epoprostenol" era. Interestingly, the benefits of epoprostenol may be progressive. In one report of four patients,[104] chronic epoprostenol infusions resulted in normalization or near-normalization of pulmonary hemodynamics, allowing transitioning to oral medications. Despite its benefits, chronic use of epoprostenol is complex and requires an indwelling central venous catheter, continuous-infusion pump, and daily preparation of the medication. In addition numerous side effects including jaw claudication, leg and foot pain, diarrhea, rash, and

weight loss occasionally with ascites occur. The complexities of dosing prostacyclin and assessing response to the therapy obligate a dedicated team, typically present only at large pulmonary hypertension centers.

Treprostinil Sodium. Treprostinil sodium (Remodulin) is a tricyclic benzindene analogue of prostacyclin that is chemically stable at room temperature and has a half-life of approximately 4 hours. In a double-blind, randomized, controlled trail, 470 patients with IPAH (58%), PAH associated with connective tissue disease or associated with congenital systemic pulmonary shunts with WHO functional class II, III, or IV were randomized to continuous subcutaneous treprostinil or placebo for 12 weeks.[105] As with other PAH trials, the primary outcome measure was exercise capacity as defined as placebo-corrected improvement in 6-minute walk distance. In addition, "reinforcing" principal end points included a composite score assessing signs and symptoms of pulmonary hypertension, dyspnea fatigue rating, and clinical worsening (number of patients dying, undergoing lung transplantation, or discontinuation of the study drug). The placebo-corrected improvement in 6-minute walk distance was 16 m ($P = 0.006$). Thirteen patients in the treprostinil group and 16 patients in the placebo group died, required lung transplantation, or discontinued therapy secondary to clinical worsening. Borg dyspnea scores and quality of life measures were significantly improved in the treprostinil group compared with placebo. Patients treated with treprostinil had improved pulmonary hemodynamics, including significant improvement in mean right atrial pressure, mean pulmonary artery pressure, cardiac index, PVR, and mixed venous oxygen saturation. Review of the treprostinil subset analysis suggested that significantly higher doses than with epoprostenol were needed to get efficacy. Infusion site difficulties were the major adverse event, with 200 (85%) patients in the treprostinil group versus 62 (27%) in the placebo arm reporting site pain.

Subsequent to approval of subcutaneous treprostinil, the intravenous route was approved based on bioequivalence. There has not been a prospective, randomized, controlled trial of intravenous treprostinil, but two uncontrolled reports have been published.[106,107]

Iloprost. Iloprost is a stable prostacyclin analogue approved by the FDA in the inhaled formulation. Inhaled iloprost is delivered via ultrasonic nebulizer directly to the lungs. It received FDA approval in December 2004 based on the Aerosolized Iloprost Randomized study (AIR), a double-blind, placebo-controlled trial that randomized 203 patients with NYHA class III or IV IPAH (50%) or PAH associated with anorexigans, scleroderma, or chronic thromboembolic pulmonary hypertension to receive 2.5 μg or 5 μg inhaled iloprost versus placebo six or nine times per day for 12 weeks.[108] The primary outcome was a combined end point: At least 10% improvement in 6-minute walk distance in the treatment group and improvement in at least one NYHA functional class. Secondary outcome measures included change in 6-minute walk distance and NYHA class, dyspnea index scores, pulmonary hemodynamics and quality of life, and clinical worsening (defined as deterioration, death, or need for transplantation). Seventeen patients in the iloprost group versus 5 in the placebo arm met the combined primary end point, which was statistically significant with an estimated odds ratio of 3.97. Cardiac output, systemic arterial oxygen saturation, and mixed venous oxygen saturation as measured at "peak" following an inhalation increased significantly and the PVR and right atrial pressure decreased significantly in the iloprost group at 12 weeks as compared with the placebo group. Adverse events included syncope, flushing, and jaw pain in the iloprost group.

Endothelin Receptor Antagonists

In humans, two endothelin (ET)-1 receptor subtypes are found, ET-A and ET-B. Antagonism of one or both receptors has been shown to be an effective treatment strategy for IPAH, with two FDA-approved therapies, bosentan and ambrisentan. A third agent, sitaxsentan, was not approved in the United States but is available in Europe and other countries.

Bosentan. Bosentan is a potent, nonpeptide, oral ET-A and B receptor antagonist, with higher affinity for the ET-A subtype receptor. Bosentan received FDA approval in November 2001 for patients with WHO functional class III or IV PAH. The first double-blind, placebo-controlled trial randomized 32 patients with IPAH (84%) or pulmonary hypertension associated with scleroderma with NYHA class III to bosentan or placebo for 12 weeks.[109] The primary end point was the placebo-corrected change in 6-minute walk distance, with secondary end points including change in pulmonary hemodynamics, WHO functional class, Borg dyspnea index, and clinical worsening. The placebo-corrected improvement in 6-minute walk distance was 76 m in favor of the bosentan group, In addition, pulmonary hemodynamics, especially cardiac index and PVR, were favorably affected by bosentan (Fig. 52-6). There were asymptomatic increases in liver aminotransferases in 2 patients on bosentan, but these returned to baseline without discontinuing or changing the dose.

The larger BREATHE-1 (Bosentan Randomized Trial of Endothelin Antagonist Therapy) trial, which randomized 213 patients with IPAH (70%) and pulmonary hypertension associated with connective tissue disease with WHO functional class III and IV to placebo or bosentan at 125 mg or 250 mg twice daily, confirmed the efficacy and safety of bosentan over 16 weeks.[95] At 16 weeks, a placebo-corrected 6-minute walk distance improvement of 44 m was noted ($P < 0.001$) (Fig. 52-7A). There were also improvements in the Borg dyspnea score and time to clinical worsening in both bosentan groups. Increases in liver aminotransferases greater than eight times the upper limit of normal was again noted in the bosentan group and was dose-dependent with 2 patients in the 125-mg group and 5 patients in the 250-mg group.

In addition to the just-discussed "pivotal" trials of bosentan, a recently published randomized, controlled trail of bosentan in PAH patients less functionally impaired (WHO class II), the EARLY (Endothelin Antagonist Trial in Mildly Symptomatic Pulmonary Arterial Hypertension Patients) trial demonstrated a benefit in reducing PVR and preventing clinical worsening at 6

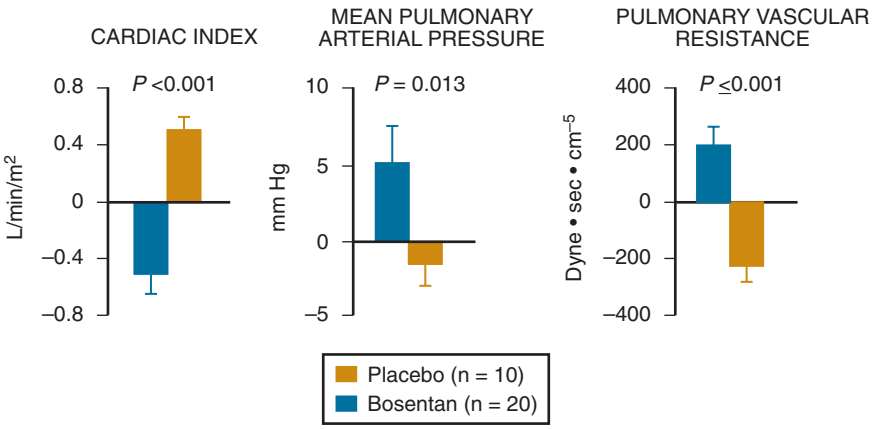

FIGURE 52-6 ■ Hemodynamic effects of bosentan in pulmonary arterial hypertension (PAH) patients. Bosentan-treated patients had significantly improved cardiac output, pulmonary vascular resistance, and pulmonary arterial pressure compared with those receiving placebo. (Adapted from Channick RN, Simonneau G, Sitbon O, et al: Effects of the dual endothelin-receptor antagonist bosentan in patients with pulmonary hypertension: A randomised placebo-controlled study. Lancet 358:1119–1123, 2001.)

months. No statistically significant effect on 6-minute walk distance was seen, although baseline walk distance was greater than 400 m, confirming that this cohort had better baseline exercise capacity.[110]

Ambrisentan. Ambrisentan is a specific ET-A receptor antagonist approved for PAH, functional classes II and III at doses of 5 mg or 10 mg once daily. Following a phase 2 dosing study showing favorable pulmonary hemodynamic effects,[111] two randomized, controlled trials of ambrisentan (Ambrisentan in Pulmonary Arterial Hypertension, Randomized, Double-Blind, Placebo-Controlled, Multicenter, Efficacy Studies [ARIES] 1: 5 mg, 10 mg, placebo; ARIES 2: 2.5 mg, 5 mg, placebo) enrolled a total of 394 patients.[112] Both trials achieved the primary end point of placebo-corrected improvement in 6-minute walk distance (see Fig. 52-7B). In ARIES-2, there was a significant improvement in time to clinical worsening in the treatment group as compared with placebo. There was a trend toward improvement in time to clinical worsening in the ARIES-1 study, but it was not statistically significant ($P = 0.3$). WHO functional class improvement was significant in ARIES-1 and there was a trend toward improvement in ARIES-2 but did not reach statistical significance ($P = 0.1$). Two hundred ninety-eight patients were enrolled and followed in the long-term extension study over 48 weeks. Eighteen patients required additional therapies (prostanoids [PD-5] inhibitors). Of the 280 patients continued on ambrisentan monotherapy, the improvement in 6-minute walk distance at 12 weeks was 40 m and maintained at 39 m. Although there was no patient with elevations in serum aminotransferases more than three times the upper limit of normal while on ambrisentan, in the trials, long-term follow-up has revealed cases of transaminase elevations that resolve upon discontinuation of ambrisentan.

Both approved endothelin receptor antagonists require monthly liver function test monitoring and have teratogenic properties, necessitating monthly pregnancy tests in women of childbearing age (see package inserts).

Phosphodiesterase Type 5 Inhibitors

Sildenafil. Sildenafil (Revatio) was approved by the FDA in June 2005 for the indication of symptomatic IPAH. The pivotal trial of sildenafil, SUPER-1 (Sildenafil Use in Pulmonary Arterial Hypertension) trial, was a 12-week randomized, double-blind, placebo-controlled trial comparing placebo, 20 mg, 40 mg, and 80 mg three times daily.[113] The study design was similar to other trials. In the sildenafil 20-mg group at 12 weeks, the placebo-corrected 6-minute walk distance was 45 m. In the 40-mg group, the improvement was 46 m, and in the 80-mg group, it was 50 m (see Fig. 52-7C). There was no significant effect of sildenafil on Borg dyspnea score or time to clinical worsening. There was an improvement in the percentage of patients with improved functional class, particularly with the higher doses of sildenafil (7% in placebo group, 28% in the 20-mg group, 36% in the 40-mg group, and 42% in the 80-mg group). However, despite the dose-related improvements in hemodynamics and WHO functional class in patients on higher dosages of sildenafil, the FDA approved only the 20-mg dose of sildenafil in the treatment of IPAH. This medication appeared well-tolerated and there were no laboratory abnormalities noted. Common adverse events included flushing, epistaxis, and gastritis. Use with nitrates is contraindicated.

Combination Therapy

There is strong rationale for combining drugs to treat IPAH. To date, however, there are very limited controlled data.

The PACES (Pulmonary Arterial Hypertension Combination Study of Epoprostenol and Sildenafil) trial randomized 267 patients with IPAH (79%) or PAH associated with connective tissue disease, anorexigen use, or corrected congenital-systemic shunts, on stable epoprostenol therapy to either additional sildenafil or placebo for 16 weeks.[114] Patients were on continuous epoprostenol as baseline therapy for an average of 2.91 and 2.75 years, in the treatment and placebo arms, respectively. They were randomized to either sildenafil 20 mg three times a day or placebo for 4 weeks and up-titrated to 80 mg three times a day or placebo up-titration. The primary outcome measurement was exercise capacity as measured by 6-minute walk test. The placebo-corrected 6-minute walk distance improvement in the sildenafil-epoprostenol group was 28.8 m. Hemodynamic improvements in the sildenafil-epoprostenol group compared

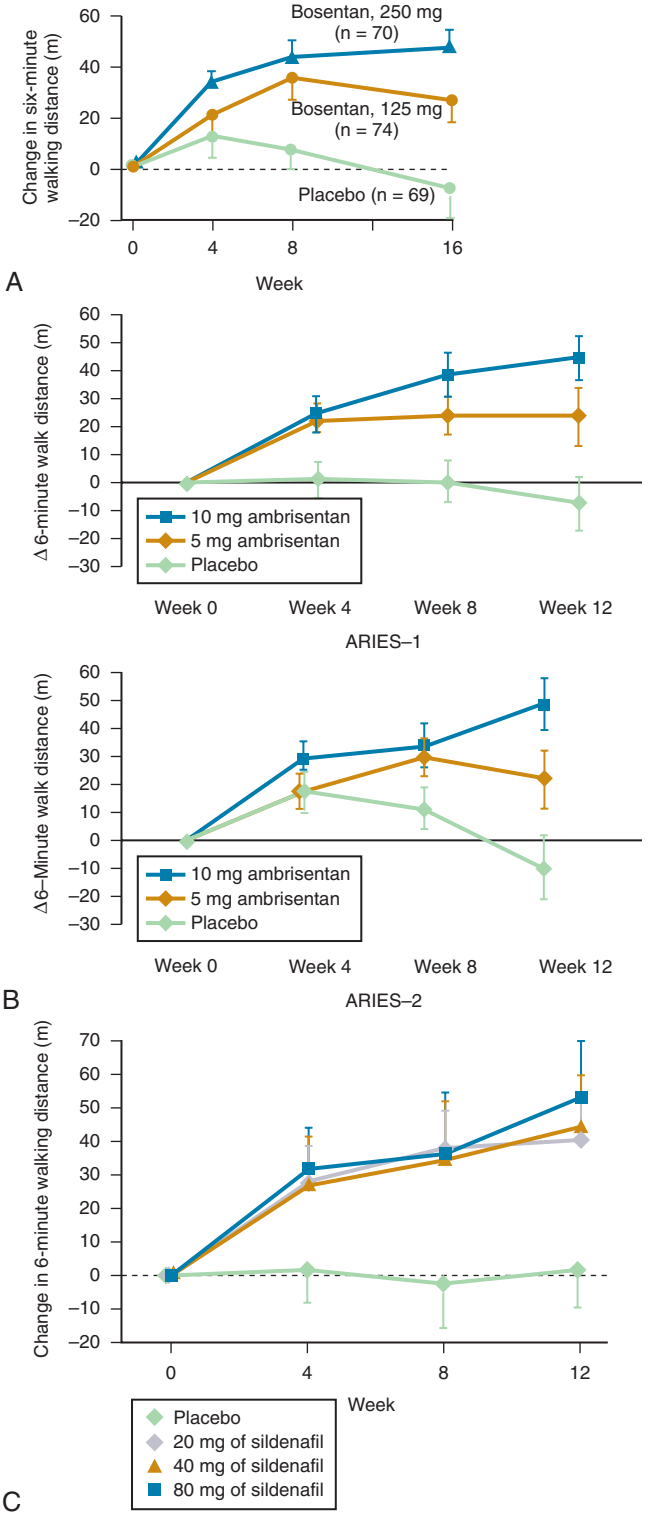

FIGURE 52-7 ■ Six-minute walk effects of the three currently approved oral therapies for PAH. All agents (**A,** bosentan; **B,** ambrisentan; **C,** sildenafil) demonstrated significant placebo-corrected improvements in 6-minute walk distance, which was the primary end point in each pivotal trial. (Data from references 95, 112, and 113.)

with placebo-epoprostenol were noted. Although mortality was not a prespecified end point, during the 16 week trial, there were 7 deaths, all of which occurred in the placebo-epoprostenol group.

The STEP (Iloprost Inhalation Solution, Safety and Pilot Efficacy) trial randomized 67 patients with IPAH (55%) and pulmonary hypertension associated with connective tissue disease, repaired congenital heart disease, HIV, or anorexigen use on stable therapy with bosentan for at least 4 months to inhaled iloprost or placebo for 12 weeks.[115] The study was designed primarily as a safety study, but efficacy end points were also evaluated, including 6-minute walk test, with secondary end points including functional class, Borg dyspnea score, pulmonary hemodynamics, and time to clinical worsening (defined as PAH-related death, hospitalization, study discontinuation from worsening pulmonary hypertension, initiation of new PAH-specific therapy, lung transplantation, or atrial septostomy). At 12 weeks, there was a borderline statistically significant placebo-corrected improvement in 6-minute walk test of 26 m in the bosentan-inhaled iloprost group ($P = 0.05$). In addition, there was a significant improvement in both the functional class and the time to clinical worsening in the iloprost-bosentan group compared with placebo-bosentan.

The addition of inhaled treprostinil (currently under FDA review) to oral PAH therapy has been evaluated and shown to be beneficial, first in a pilot study[116] and then in the pivotal TRIUMPH-1 (Treprostinil Sodium Inhalation Used in the Management of Pulmonary Arterial Hypertension) study,[117] a 12-week study that compared the addition of inhaled treprostinil versus placebo to either bosentan or sildenafil in 235 patients with NYHA functional class III and IV. The primary outcome was change in 6-minute walk test with secondary end points including change in functional class, Borg dyspnea score, signs and symptoms of pulmonary hypertension and clinical worsening. The 6-minute walk test improved significantly by 20 m in the treprostinil arm as compared with placebo. There were no significant changes in the secondary end points. Inhaled treprostinil appeared to be safe, with the most frequent adverse events reported as cough, headache, and nausea.

Clearly, further study is needed to elucidate the role of add-on or combination therapy. Importantly, the development of longer-term, event-driven trials will be necessary, because add-on therapy may provide less incremental improvement, as evidenced by the relatively modest effects on 6-minute walk distance seen in the STEP and TRIUMPH studies.

Lung Transplantation

Lung transplantation is a viable option when all therapies for IPAH have been tried without success. According to recent United Network of Organ Sharing (UNOS) data, a minority of lung transplants is done for IPAH and these are usually double-lung transplants. The primary goal of lung transplantation is to provide a survival benefit; however, in certain situations (e.g., COPD), a significant improvement in quality of life is also deemed as important as an end point.

In patients failing maximal medical therapy, lung transplantation is the "ultimate" option. According to the International Society of Heart and Lung Transplantations, current recommendations for consideration of transplantation include persistent NYHA class III or IV on maximal medical therapy, low or declining 6-minute walk test, failing therapy with intravenous epoprostenol, cardiac failure with cardiac index less than 2 L/min/m^2, and elevated right atrial pressure (>15 mm Hg).[118] Considerations for referral to a transplant center include any patient with rapidly progressive disease or NYHA functional class III or IV, regardless of therapeutic options. The lung allocation scoring system, although not perfect, has enabled more appropriate listing of IPAH patients. Patients who are declining will, hopefully, receive higher scores, allowing shorter waiting times and, presumably, better outcomes. In patients doing well on oral therapies alone, evaluation for transplantation is no longer necessary.

One-year survival after lung transplantation for pulmonary hypertension was estimated at 80% in one series.[119]

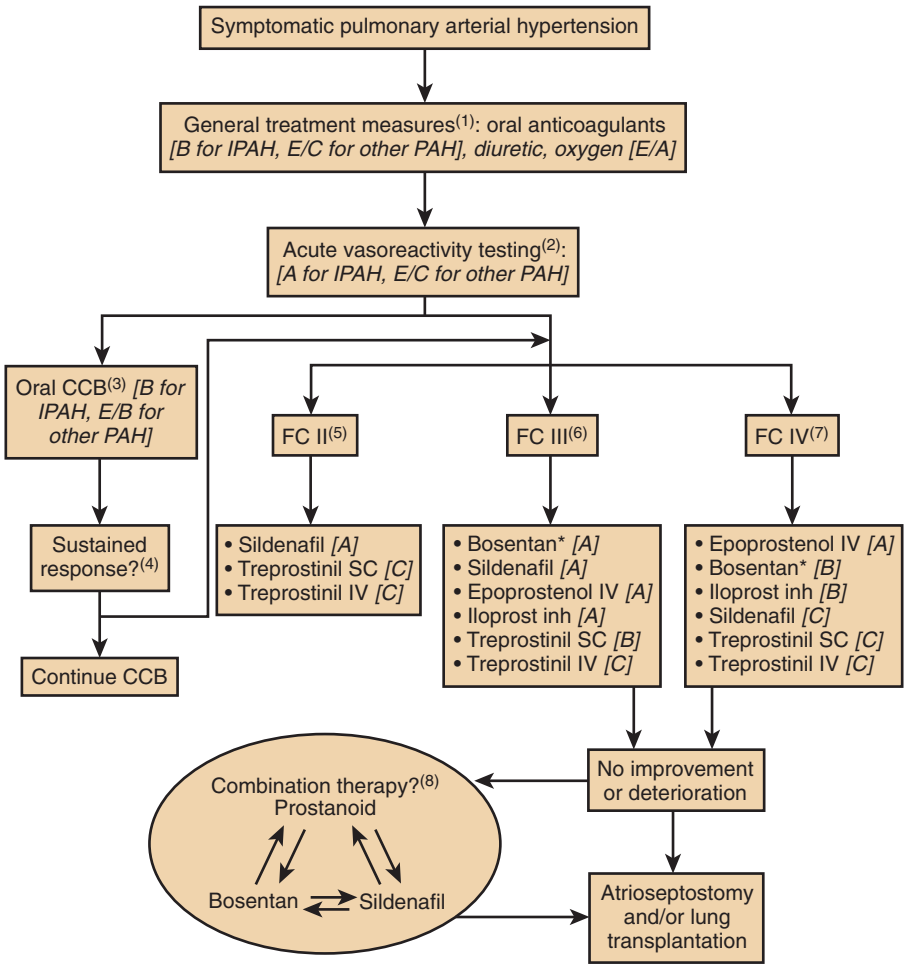

FIGURE 52-8 ■ Evidence-based treatment algorithm for PAH. The recommended therapies presented in this algorithm have been evaluated mainly in patients with IPAH, or PAH associated with connective tissue disease or anorexigen use. Extrapolation to other forms of PAH should be made with caution. Country-specific regulatory agency approval status and functional class indications for PAH medications vary. (1) Anticoagulation should be considered for patients with IPAH, and patients with an indwelling catheter for the administration of an IV prostanoid, in the absence of contraindications. Diuretics and oxygen should be added as necessary. (2) A positive acute vasodilator response is defined as a fall in mean PPA ≥ 10 mm Hg to ≤40 mm Hg, with an unchanged or increased cardiac output when challenged with inhaled nitric oxide, intravenous (IV) epoprostenol, or IV adenosine. (3) Consideration should be given to using a PAH-specific medication such as a phosphodiesterase 5 inhibitor, endothelin receptor antagonist, or prostanoid as first-line treatment instead of a calcium channel blocker (CCB) in patients with PAH that is not IPAH or PAH associated with anorexigen use, or in those in an advanced functional class (FC) given the exceedingly low long-term response rate to CCB monotherapy in the former and poor prognosis in the latter. (4) Sustained response to CCB therapy is defined as being in functional class I or II with normal or near-normal hemodynamics after several months of treatment. (5) First-line therapy for functional class III includes bosentan, sildenafil, epoprostenol, inhaled (inh) iloprost, and subcutaneous (SC) or IV treprostinil (see text for details). (7) Most experts recommend IV epoprostenol as first-line treatment for unstable patients in functional class IV. (8) Randomized controlled trials studying add-on combination treatment regimens are underway. *[A]*, strong recommendation; *[B]*, moderate recommendation; *[C]*, weak recommendation; *E/A*, strong recommendation based on expert opinion only; *E/B*, moderate recommendation based on expert opinion only; *E/C*, weak recommendation based on expert opinion only; *, not in order of preference. (Adapted from Badesch DB, Abman SH, Simonneau G, et al: Medical therapy for pulmonary arterial hypertension: Updated ACCP evidence-based clinical practice guidelines. Chest 131:1917–1928, 2007.)

In a recent article by the group from Pittsburgh,[120] the actuarial survival of all lung transplants for IPAH from 1994 to 2006 was 86% at 1 year, 75% at 5 years, and 66% at 10 years.

However, despite these recommendations, a minority of patients undergo lung transplantation for IPAH. This is likely related to the surge of treatments now available to treat IPAH.

Overall Therapeutic Strategy: Challenges

With several effective medical therapies and lung transplantation available for treatment of IPAH, how does one decide what therapy to use, when to reassess, when to add or change therapy, and what to add or change? Several consensus committees have attempted to evaluate the evidence for approved therapies and grade recommendations for these treatments. An algorithm recently published by an American College of Chest Physicians Consensus Group[89] is shown in Figure 52-8. Supportive therapies including diuretics, warfarin, and oxygen are considered. An acute vasoreactivity test is recommended for IPAH patients, and if a positive response is seen, calcium channel blocker treatment is recommended. For the patients without acute vasoreactivity, recommendations are given regarding specific therapies, based on the initial functional class. Oral therapies have been given "A" recommendations for less severely limited patients, intravenous epoprostenol for functional class IV patients.

Less specific guidance is given regarding combination therapy or timing of lung transplantation, given less data on these interventions. In practice, when a patient either fails to improve adequately or worsens on initial therapy, additional medications are often utilized. However, if such patients can be enrolled in a clinical trial evaluating "add-on" therapy, this route is probably preferable.

Survival

Long-term survival data are emerging in the era of IPAH treatment. In patients treated with epoprostenol, two papers demonstrated survival estimates of approximately 60% at 3 years.[103,121] In these retrospective studies, favorable survival was best predicted by response to therapy (improvement in 6-minute walk distance, functional class, and PVR). Survival data are also available for other therapies. For example, in 169 IPAH patients enrolled in the two pivotal trials of bosentan, estimated survival at 1 and 2 years was 96% and 89%, respectively, as compared with the predicted survival of 69% and 57%[95,122] (based on a validated equation calculating predicted survival from baseline hemodynamics). It should be acknowledged that there are no prospective, controlled survival data with the newer agents, given obvious ethical concerns about such trials in the era of existing therapy.

Experimental Therapies

The clinical therapeutics development landscape in PAH continues to evolve. Several new, novel agents are being evaluated, including a new-generation, tissue-targeted endothelin receptor antagonist, inhaled vasoactive intestinal peptide, a guanylate cyclase inhibitor, and a nitric oxide synthase coupler. In addition, antineoplastic agents such as imatinib and sorafinib that, through kinase inhibition, attack the excessive growth of cells, are being evaluated in IPAH.

KEY POINTS

- Pulmonary hypertension has been classified by WHO into 5 groups: (1) PAH, (2) pulmonary hypertension with heart disease, (3) pulmonary hypertension with lung disease, (4) pulmonary hypertension with pulmonary thromboembolism, and (5) miscellaneous.
- PAH has further been classified into (1) idiopathic IPAH, (2) heritable, (3) related to other conditions, (4) PPH of the newborn, and (5) PVOD.
- Heritable pulmonary hypertension has been associated with bone morphogenic protein receptor 2 (BMPR2), but mutations are not always associated with pulmonary hypertension, indicating other defects or insults are required. Evidence also supports involvement of a voltage-gated potassium ion channel and serotonin transporter.
- The basis for treatment of IPAH stems from deficiencies in prostacyclin and nitric oxide release and excess endothelin-1 found in patients with pulmonary hypertension.
- Pulmonary hypertension can be diagnosed to some extent by physical examination, chest radiology, electrocardiography, and echocardiography, but establishing the diagnosis with certainty requires a right-sided cardiac catheterization, which can check for left heart failure and response to a pulmonary vasodilator.
- Therapy includes moderate exercise, warfarin, oxygen, and calcium channel blockers.
- Targeted therapy with the prostacyclins, phosphodiesterase inhibitors, and endothelin receptor antagonists has made major improvements in the life of patients with PAH.

INTRODUCTION

Pulmonary vasculitis is a general term that encompasses a wide variety of specific diseases whose primary target is the vasculature of the lung. Pathologically it is characterized by the presence of cellular inflammation that infiltrates vessel walls, causes their destruction, and results in tissue necrosis. The clinical features of any particular disorder are determined by the site, size, and type of vessel involved as well as the relative amounts of vessel inflammation, destruction, and tissue necrosis present. While simple to define, the recognition, diagnosis, and management of the pulmonary vasculitides are among the most demanding challenges in medicine. Protean in their presentation and variable in their clinical evolution, their signs and symptoms fully overlap with infection, malignancy, connective tissue disease, and even medication reactions. Even in patients with a known vasculitis, separating active disease from complicating infection, drug toxicity, or some combination thereof will challenge the most resolute physician. Despite these hurdles, the astute clinician can make the diagnosis, initiate and manage therapy, as well as minimize complications by keeping some broad concepts in mind.

CLASSIFICATION

The major clinical benefit of classifying the vasculitides is to provide a framework that allows for an appreciation of the presenting features of disease. To this end, most current classification schemes are variations of the 1994 Chapel Hill nomenclature[1] and based on clinicopathologic presentations rather than etiology (Table 53-1). Unfortunately, most of the classification criteria currently used are relatively insensitive and nonspecific as diagnostic tools and cannot be used as such.[2] Thus, *the diagnosis of vasculitis relies upon the astute clinician recognizing patterns of disease made up of specific clinical, laboratory, imaging, and pathologic features* rather than strict adherence to a set of clinical diagnostic guidelines.

Using this approach, a scheme that classifies by vessel size (large, medium, and small) can be useful as it can suggest the clinical features associated with a particular disease. The large vessels are made up of the aorta and its largest branches (clinically affecting the extremities and head/neck), the medium-sized vessels are made up of the main visceral arteries (the renal, hepatic, coronary, and mesenteric vessels), while the small vessels are made up of the capillaries, venules, and arterioles. There can

TABLE 53-1. Classification of Vasculitis

PRIMARY IDIOPATHIC
Small Vessel
- Necrotizing granulomatous vasculitis (NGV)
- Churg-Strauss syndrome (CSS)
- Microscopic polyangiitis (MPA)
- Idiopathic pauci-immune glomerulonephritis
- Idiopathic capillaritis

Medium Vessel
- Polyarteritis nodosa (PAN)
- Kawasaki's disease

Large Vessel
- Takayasu's arteritis (TA)
- Giant cell arteritis (GCA)

PRIMARY IMMUNE COMPLEX MEDIATED
- Goodpasture's syndrome
- Henoch-Schönlein purpura
- Immunoglobulin A nephropathy
- Behçet's disease
- Essential cryoglobulinemia

SECONDARY VASCULITIS
Classic autoimmune disease
- Systemic lupus erythematosus (SLE)
- Rheumatoid arthritis (RA)
- Antiphospholipid antibody syndrome (APAS)

Infection
Paraneoplastic
Drug-induced (e.g., propylthiouracil)
Inflammatory bowel disease
Hypocomplementemic urticarial vasculitis

Data from references 1, 112.

be some overlap in the size of vessels affected as the small and large vessel vasculitides sometimes involve medium-sized arteries, but large and medium vessel vasculitides generally do not involve vessels smaller than arteries.

A second level of classification defines the vasculitides as antineutrophil cytoplasmic antibody (ANCA) positive or negative. The identification of these antibodies in the 1980s revolutionized the thinking regarding diagnosis and pathogenesis of vasculitis (see later). The vasculitides that are most commonly encountered in the practice of pulmonary medicine—the primary, idiopathic small vessel vasculitides—are also the ANCA-associated vasculitides and include necrotizing granulomatous vasculitis (NGV) (formerly Wegener's granulomatosis),[2a] Churg-Strauss syndrome (CSS), and microscopic polyangiitis (MPA).

A third approach to classification is sometimes used, defining the vasculitides by the presence or absence of granulomatous inflammation. Two of the ANCA-associated vasculitides (NGV and CSS), as well as the large vessel vasculitides (Takayasu's arteritis and giant cell arteritis), are characterized by the presence of granulomatous inflammation.

EPIDEMIOLOGY

The overall incidence and prevalence of vasculitis is unknown. All of the available epidemiologic studies contain significant flaws that limit their applicability. For example, the available data are neither geographically nor ethnically diverse, and the diagnostic criteria used vary from study to study. Furthermore, the availability of ANCA testing has significantly increased case finding. With these caveats in mind, giant cell arteritis is the most frequently recognized systemic vasculitis, with an annual incidence of 150 to 350 per million persons over age 50. Those of Nordic extraction appear at particularly high risk, especially in older age. The primary systemic vasculitides have an overall prevalence estimated at between 90 and 257 per million in European populations. Among the individual disorders, the annual incidence of NGV ranges from 4.9 to 10.5 per million, that of CSS from 0.5 to 4.2, and that of MPA from 2.7 to 11.6. Their prevalence ranges from 24 to 157 for NGV, 7 to 38 for CSS, and 0 to 66 for MPA. Among the secondary vasculitides, the best data are for rheumatoid arthritis–associated vasculitis (incidence of 12.5 per million, though with the advent of biologic therapy this appears to have fallen dramatically) and systemic lupus erythematosus (SLE)–associated vasculitis (3.6 per million).[3]

NORMAL VASCULAR ANATOMY AND HISTOLOGY

In a group of diseases pathologically defined by abnormalities of the vasculature, understanding the normal organization and location of the arterial and venous blood supplies in the lung is useful in appreciating their clinical features. The lung has a dual blood supply: the pulmonary and the bronchial circulations. The bronchial arteries arise from the systemic circulation (aorta and intercostal arteries) and form a plexus in the bronchial wall. The bronchial veins associate closely with the bronchial arteries, though neither is commonly affected in the pulmonary vasculitides.

During embryogenesis, the pulmonary arterial system forms in tandem with the branching bronchial buds and is recognized on histologic examination by its close proximity to the corresponding bronchi or bronchiole (Fig. 53-1A). In the normal lung, arteries and adjacent airways (either bronchi or bronchioles) are similarly sized, and size differences between the two can be an indication of pathology.[4] The arterial system consists of four components: elastic arteries, muscular arteries, arterioles, and capillaries. The elastic arteries are larger than 0.5 to 1.0 mm in diameter and can be macroscopically recognized. They are composed of an endothelial cell lining layer and a smooth muscle medial layer, and have well-developed, multiple elastic laminae. Muscular arteries are between 100 and 500 μm in diameter, and are composed of an endothelial cell lining, a smooth muscle medial layer bound by two elastic laminae (inner and

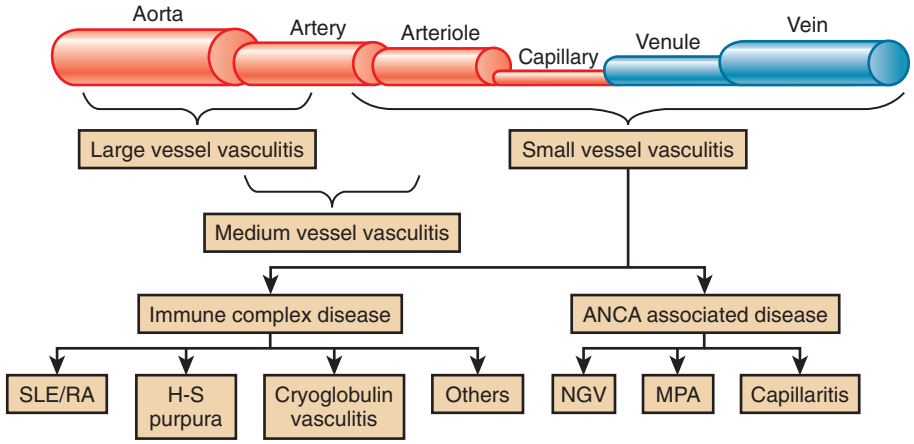

FIGURE 53-2 ■ Relationship between vessel size and mechanism. (See Table 53-1 for abbreviations.)

outer), and a collagenous adventitia. The smooth muscle layer progressively decreases in thickness until one reaches the arterioles, which are defined by a diameter of less than 100 µm and the absence of a muscular medial layer; however, they can become muscularized in a variety of disease states. The arterioles empty into the capillaries, which are characterized by the presence of a single layer of endothelial cells and an underlying basement membrane. They form part of the alveolar septa, and are the most common vessel affected in pulmonary vasculitis. On hematoxylin and eosin (H&E) stains of surgical lung biopsies, identifying the capillaries is difficult as a number of cells—endothelial cells, fibroblasts, and mononuclear inflammatory cells—are normal occupants of the alveolar septa.

The location of the pulmonary veins in the mature lung is typically within interlobular septa, as the embryonic pulmonary veins form branches that grow into the mesenchyme surrounding the lung buds. Pulmonary veins can be distinguished from pulmonary arteries by their single elastic lamina (see Fig. 53-1B and C). However, in the diseased lung, there can be reduplication of the elastic lamina, causing "arterialization" of the pulmonary veins, and anatomic location may be the only indicator as to the vessel type.

HISTOPATHOLOGY OF VASCULITIS

Although the diagnosis of vasculitis does not rely on pathology alone, both the diagnosis and a subclassification can be obtained from histopathology based on the size and location of the affected vessels (Fig. 53-2). The findings common to all the pulmonary vasculitides are inflammatory cell infiltration (inflammation) of the vessel wall with destruction of elastic laminae (in the case of arteries and veins) and, often, an accompanying fibrinoid necrosis. The lining endothelial cells may also show histologic abnormality, with subendothelial inflammation ("endothelialitis"), cellular disruption, and even loss of endothelial cells. The type of inflammation can vary widely; neutrophilic, eosinophilic, lymphoplasmacytic, or mixed infiltrates can all be seen. Granulomatous inflammation, consisting of poorly formed granulomas or multinucleated giant cells and/or epithelioid histiocytes, is of particular importance as one level of classification is based on its presence or absence (see earlier).

The term *capillaritis* is used to describe vasculitis of capillaries; however, it is often difficult to specifically identify the capillary on routine H&E stains, much less the endothelial disruption necessary to make the diagnosis. Therefore, identifying neutrophils and nuclear debris

(evidence of apoptosis) within alveolar septal walls is used as an indirect sign of capillaritis.

Not only do the size and type of vessel affected provide critical information, but changes to the associated lung parenchyma provide additional clues to the diagnosis. For example, a nodular parenchymal infiltrate is commonly seen in NGV, with microabscesses, necrosis, eosinophilic pneumonia, organizing pneumonia, and/or hemorrhage all adding important data. The specific pathologic findings associated with each entity are discussed in more detail later in the chapter.

PATHOGENESIS AND ETIOLOGY

Most of the vasculitic syndromes are hypothesized to be mediated by immunopathogenic mechanisms that occur in response to antigenic stimuli. Why some patients develop vasculitis in response to a particular stimulus, while others do not, is unknown. The etiology is likely multifactorial, including genetic predisposition, environmental exposures, and individual immune responses. Three broadly defined mechanisms have been proposed: directly pathogenic antibodies, immune complex deposition, and pathogenic T-cell responses. For each of these mechanisms, some combination of the direct immunologic attack and the endothelial and vascular wall response appears responsible for the histopathologic and subsequent clinical findings.[5]

A large variety of autoantibodies have been described in the vasculitic syndromes, including the anti–glomerular basement membrane (type IV collagen) antibodies seen in Goodpasture's syndrome, anti–endothelial cell antibodies, antilaminin antibodies, antiphospholipid (β2-glycoprotein 1) antibodies, and ANCAs among others. Of these, the best-studied mechanism is that hypothesized for the ANCA-associated vasculitides, especially WG.

The clinical syndrome was described in the 1930s[6–8]; however, it was not until 1982 that its closely associated autoantibodies, now known as ANCAs, were described.[9] While the role of ANCAs in the pathogenesis of disease is unknown, some clinical data suggest that, while not sufficient to cause disease alone, the presence of ANCAs appears to be required for the development or recurrence of systemic disease. These data include the link between the presence of these autoantibodies and the development of systemic vasculitic complications, ANCA-positive patients generally requiring systemic immunosuppressive therapy for disease control, and patients who become ANCA negative being at low risk of relapse. Mechanistically, the majority of the clinically significant ANCAs are directed against microbiocidal components used by neutrophils in host defense. These antibodies have been shown to have significant proinflammatory effects with activation of neutrophils, monocytes, and endothelial cells.[10] ANCAs stimulate the release of chemokines from neutrophils, monocytes, and endothelial cells; enhance the expression of cell adhesion molecules on endothelium; and activate primed neutrophils to release proteolytic enzymes and oxygen radicals.[11,12] Each of these steps would contribute to the vascular and tissue damage seen in vasculitis.

The trigger for ANCA production and persistence is also poorly understood. A role for active infection/inflammation in the disease pathophysiology has been proposed as there is evidence that chronic or concurrent infections can lead to disease exacerbation or relapse.[13–15] ANCA positivity has also been directed against a variety of antigens seen with viral, fungal, bacterial, and protozoal infection, as well as subacute bacterial endocarditis and cystic fibrosis.[16,17] It has been hypothesized that infections may give rise to ANCAs through molecular mimicry and contributes to their persistence through T- and B-cell stimulation by microbial superantigens.

Other potential mechanisms for the development of vasculitis include the direct invasion of the vessel wall by pathogenic organisms (e.g., bacterial, mycobacterial, spirochetal, rickettsial, fungal, viral) leading to an acute, direct vasculitic response as well as deposition of circulating immune complexes in the blood vessel wall. This deposition of immune complexes can lead to complement activation, anaphylatoxin production, and mast cell degranulation. Mast cell degranulation leads to release of vasoactive substances, and the anaphylatoxins can act as chemotactic agents for neutrophils, eosinophils, and mononuclear inflammatory cells. The prototypical disease for this mechanism is SLE, in which complexes of nuclear antigens such as DNA, immunoglobulins, and complement proteins lead to vascular injury.[18,19] Other immune complex–mediated vasculitides include rheumatoid vasculitis, Henoch-Schönlein purpura, and cryoglobulinemic vasculitis.

THE INITIAL DIAGNOSIS

Clinical Scenarios Suggestive of Vasculitis

The importance of the initial history in the evaluation of a patient with suspected vasculitis cannot be overemphasized. Symptoms that initially appear of only minor importance and unrelated must not be overlooked as both vasculitis and its mimics (connective tissue diseases, infection, malignancy, drug toxicity, etc.) present with and evolve through a variety of confusing clinical manifestations. Similarly, a careful physical examination may reveal otherwise asymptomatic disease that suggests the presence of a systemic disorder. To put some order to this, the identification of particular clinical scenarios can suggest the presence of a systemic vasculitis and the importance of its inclusion in the differential diagnosis.[20]

Destructive Upper Airway Lesions

Once primary infectious, allergic, and anatomic causes have been excluded, the presence of chronic refractory sinusitis and/or destructive soft tissue or bony lesions can prompt consideration of vasculitis.

Chest Imaging Findings of Cavitary or Nodular Disease

While a wide variety of nondiagnostic features may be seen on chest imaging when vasculitis involves the lung, the presence of nodular or cavitary disease should raise one's suspicion. While infection and malignancy are the most common explanations, in the correct clinical setting a vasculitis, particularly an ANCA-associated vasculitis, should be considered. For example, chest imaging findings of cavities are found in 35% to 50% and nodules in 55% to 70% of patients with NGV.[21,22]

Diffuse Alveolar Hemorrhage

Clinically defined by the presence of hemoptysis, diffuse alveolar opacities, and a drop in hematocrit, *diffuse alveolar hemorrhage* (DAH) refers to diffuse intra-alveolar bleeding generally from the alveolar capillaries and less frequently from the precapillary arterioles and postcapillary venules. However, the hemoptysis can be difficult to identify, often occurring only intermittently or not at all in up to one third of patients. The alveolar opacities do not have to be diffuse, and a drop in hematocrit can be difficult to document. Because of these caveats, DAH should be considered in patients with otherwise unexplained diffuse alveolar opacities, particularly when these opacities complicate symptoms of a connective tissue disease or new-onset renal insufficiency. An increase in the diffusion capacity of more than 30% over baseline can be suggestive of DAH. Bronchoalveolar lavage can be diagnostic when serially aspirated aliquots of fluid reveals persistently bloody return. On surgical lung biopsy, capillaritis, diffuse alveolar damage, or bland hemorrhage can be seen. When DAH is the complication of an ANCA-associated vasculitis, capillaritis can almost always be found; however, when partially treated, only bland hemorrhage may be seen. The finding of DAH with pulmonary capillaritis without an associated systemic vasculitis is termed *idiopathic pauci-immune pulmonary capillaritis,* and is classified within the family of primary idiopathic, small vessel vasculitis, despite generally being ANCA negative. The differential diagnosis of DAH includes diseases associated with the histopathologic finding of capillaritis (including both the primary idiopathic and secondary vasculitides) (Fig. 53-3) and in its absence (i.e., bland hemorrhage) (Table 53-2).

Acute Glomerulonephritis

Rapidly progressive glomerulonephritis is defined by an active urinary sediment, including hematuria (especially with dysmophic red cells), red cell casts, proteinuria (>500 mg/day), and a rising blood urea nitrogen and serum creatinine. The microscopic examination of the urine needs to be performed on a fresh urine sample as red cell casts and dysmophic red cells can quickly degenerate. Once rapidly progressive glomerulonephritis is identified, the differential diagnosis includes the ANCA-associated vasculitides, idiopathic pauci-immune glomerulonephritis (isolated small vessel renal vasculitis), SLE, Goodpasture's syndrome, postinfectious glomerulonephritis, immunoglobulin A (IgA) nephropathy, Henoch-Schönlein purpura, essential cryoglobulinemia, and membranoproliferative glomerulonephritis.[23–26]

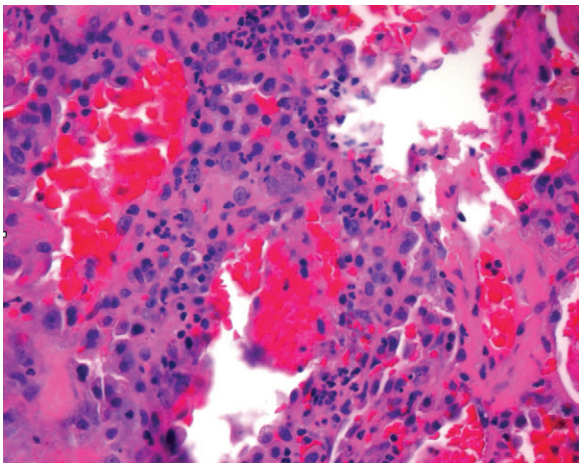

FIGURE 53-3 ■ Capillaritis showing disruption of the alveolar septa by infiltrates of neutrophils and nuclear debris. The septal borders are vague, indicating wall damage.

TABLE 53-2. Causes of Diffuse Alveolar Hemorrhage

WITH HISTOPATHOLOGIC CAPILLARITIS
Classic vasculitides
Primary idiopathic small vessel vasculitis
ANCA-associated—NGV, CSS, MPA
Isolated pulmonary capillaritis
Immune complex mediated
Goodpasture's syndrome
Essential cryoglobulinemia
Henoch-Schönlein purpura
Secondary vasculitis
Classic autoimmune disease—SLE, RA, PM/DM, SSc, MCTD
Primary antiphospholipid antibody syndrome
Lung or bone marrow transplantation
Drug-associated disease (chemotherapeutic agents, diphenylhydantoin)
Behçet's disease
WITHOUT CAPILLARITIS (BLAND HEMORRHAGE)
Idiopathic pulmonary hemosiderosis
Coagulopathy
Mitral stenosis
Inhalation injury (e.g., trimellitic anhydride)
Drug-associated disease (e.g., chemotherapeutic agents, penicillamine, amiodarone, nitrofurantoin)

ANCA, antineutrophil cytoplasmic antibody; CSS, Churg-Strauss syndrome; MCTD, mixed connective tissue disease; MPA, microscopic polyangiitis; NGV, necrotizing granulomatous vasculitis; PM/DM, polymyositis/dermatomyositis; RA, rheumatoid arthritis; SSc, systemic sclerosis; SLE, systemic lupus erythematosus.
Data from references 113, 114.

Pulmonary-Renal Syndrome

Pulmonary renal syndromes are classically defined as the presence of both DAH and rapidly progressive glomerulonephritis. However, whenever a destructive airway lesion or chest imaging findings of nodules or cavities occur with renal insufficiency, vasculitis should be considered. When this happens, the primary differential should includes the ANCA-associated vasculitides, Goodpasture's syndrome, and SLE.

Palpable Purpura

The presence of palpable purpura on physical examination implies a small vessel, cutaneous vasculitis.[27] The most common explanation is a cutaneous (hypersensitivity) vasculitis secondary to a drug reaction; however, the ANCA-associated vasculitides, cryoglobulinemia, connective tissue diseases, infections, and malignancy should all be considered.

Mononeuritis Multiplex

Defined by the occurrence of abnormalities in two or more peripheral nerve distributions, mononeuritis multiplex should raise particular suspicion.[28,29] A variety of other central or peripheral nervous system manifestations can also be seen, including pain, numbness, paresthesias, weakness, or loss of function (e.g., sudden onset of a footdrop or wristdrop).

Multisystem Disease

Unusual combinations of signs and symptoms that involve multiple organ systems either simultaneously or over time should raise the possibility of a vasculitis. This requires a high index of suspicion from the clinician as items such as constitutional symptoms (e.g., fever of unknown origin), unusual "rashes," migratory polyarthritis, or "chronic sinus disease" must be considered relevant when the primary clinical presentation is breathlessness, renal failure, or abnormal chest imaging.

Specific Testing

Antinuclear Cytoplasmic Antibodies

ANCAs were first described in the early 1980s in patients with vasculitis, glomerulonephritis, and NGV, and recognized by a pattern of diffuse immunofluorescent staining of ethanol-fixed neutrophils. Near the same time, a pattern of perinuclear immunofluorescent staining of ethanol-fixed neutrophils was described in patients with MPA and pauci-immune glomerulonephritis.[9] Currently, two specific indirect immunofluorescent staining patterns, cytoplasmic (c-ANCA) (Fig. 53-4A) and perinuclear (p-ANCA) (see Fig. 53-4B), are described. Each pattern is associated with specific antibodies against a variety of intracellular antigens in neutrophils and monocytes. c-ANCA are primarily, but not exclusively, directed against proteinase 3 (PR3, in azurophilic granules), while the p-ANCA are most commonly myeloperoxidase (MPO, also in azurophilic granules), but have a much wider group of potential intracellular targets. Specific enzyme-linked immunosorbent assay (ELISA) testing for PR3 and MPO is available and has clinical usefulness. These antibodies describe the group of small vessel vasculitides that commonly affect the lung: NGV, CSS, and MPA. These ANCA-associated small vessel vasculitides all involve the small vessels and share a number of clinical features. Renal involvement (when present) is similar (pauci-immune, crescentic, and focal necrotizing glomerulonephritis).

The diagnostic utility of ANCA testing is dependent upon the sensitivity, specificity, and positive predictive value of c-ANCA (or anti-PR3) for NGV and p-ANCA (or anti-MPO) for MPA and CSS. When these tests are applied indiscriminately, the positive predictive value of the testing declines dramatically. Mandl et al. demonstrated that, by using clinical guidelines to identify at-risk patients, the positive predictive value of the tests increased without reducing sensitivity.[30] While ANCA testing alone or PR3 and MPO ELISA testing alone are used by many centers as their initial screening test, the combination of ANCA immunofluorescent testing plus ELISA testing maximizes their sensitivity.[30-34]

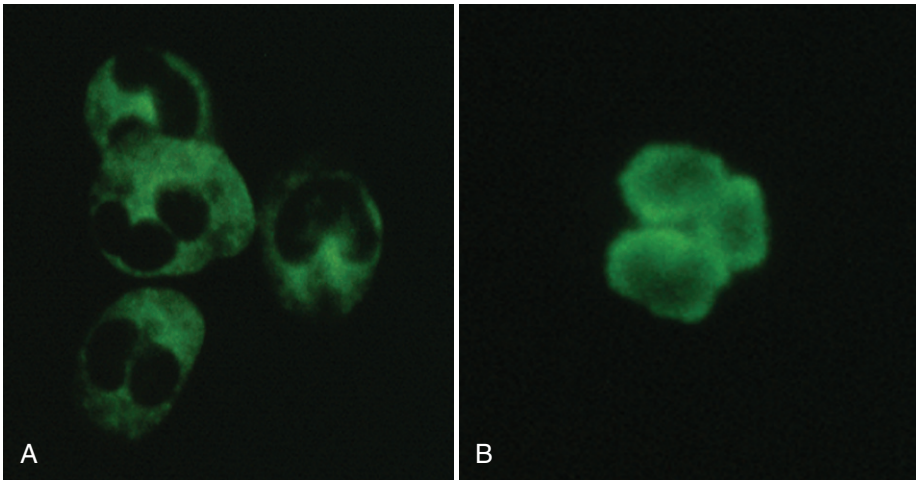

FIGURE 53-4 ■ Indirect immunofluorescent staining patterns of **(A)** c-ANCA and **(B)** p-ANCA.

With the caveats noted above, c-ANCA is highly sensitive (90% to 95%) in active, systemic NGV but slightly less so (65% to 85% sensitive) in organ-limited disease.[35] Specificity is approximately 90%. In the proper clinical setting, with a very high pretest probability of disease, a positive c-ANCA/anti-PR3 has sufficient positive predictive value that biopsy may be deferred.[36] Conversely, p-ANCA and anti-MPO generally lack sufficient sensitivity and may provide no more than suggestive evidence of CSS, MPA, or pauci-immune rapidly progressive glomerulonephritis, as they can be found in rheumatoid arthritis, Goodpasture's syndrome, and a wide variety of other clinical circumstances.[33]

Considerable attention has been focused on the utility of ANCA to assess disease activity, particularly the role of rising ANCA titers in predicting relapse.[37,38] Unfortunately, there appears to be no clear relationship between antibody titers and disease activity. In a recent prospective interventional study in which PR3-ANCA levels were routinely obtained, decreasing ANCA titers did not predict time to remission and increasing titers did not predict relapse. Increasing titers were associated with a relapse in only 40% of patients over a 12-month period. Therefore, the decision to modify therapy in patients with ANCA-associated vasculitis must be a clinical decision based on evidence of disease activity independent of ANCA titers.[35]

Based on high-quality evidence, recommendations have been offered that ANCA testing by immunofluorescence should be performed in the appropriate clinical context to detect the labeling pattern, and that all positive samples be tested for anti-PR3 and MPO specificity.[39] A positive test for c-ANCA targeted to PR3, or for p-ANCA targeted to MPO has a high sensitivity and specificity for the diagnosis of ANCA-associated vasculitis. It should also be recognized that the absence of a positive test does not rule out a diagnosis of vasculitis. ANCA testing should be performed in accredited laboratories that participate in external quality-control programs and undergo regular review of laboratory management and staff performing the assays.[40]

Other Laboratory Studies

Cultures of blood and other potentially affected organs (when tissue is obtained) should be performed to exclude infection. Routine laboratory studies (complete blood count with differential, chemistries, liver function tests, blood urea nitrogen and creatinine) should be obtained; however, the findings are generally nonspecific. An elevated erythrocyte sedimentation rate and elevated C-reactive protein lack specificity but are common. Urinalysis with microscopy should be performed on a fresh sample in all patients, as proteinuria and microscopic hematuria are common early findings in NGV and MPA. Anti–glomerular basement membrane antibodies should be obtained in all patients with pulmonary hemorrhage or a pulmonary-renal syndrome. Antinuclear antibodies and rheumatoid factor can be positive, although high titers—especially with the presence of disease-specific antibodies (e.g., anti-dsDNA, anti–SS-A/anti–SS-B, anti-RNP, anti–Scl-70, anticentromere, anti–JO-1)—favor a connective tissue disease. Immunoglobulin E should be obtained when CSS is being considered.

Chest Imaging

Plain chest radiographs and computed tomographic scanning will often be abnormal even in the absence of symptoms. Findings are best described in NGV and include nodular opacities and masses, particularly those that cavitate; diffuse ground-glass opacification when DAH is a possibility, airway stenoses, and ulcerations should raise the possibility of vasculitis. Adenopathy is not common and is more suggestive of infection or malignancy.[41]

Bronchoscopy

Bronchoscopy is primarily used to assess for the presence of malignancy, infection, stenotic or ulcerative upper airway or endobronchial lesions, pulmonary eosinophilia, and alveolar hemorrhage. Bronchoalveolar lavage should be grossly examined for evidence of alveolar hemorrhage, and then sent for culture (bacterial, fungal, and mycobacterial), cytology, and a differential count. Biopsies may provide important information that helps exclude infection or malignancy; however, they are rarely useful in making a positive diagnosis of vasculitis. When Hoffman et al.[42] performed 59 transbronchial biopsies in 48 patients with NGV, only 4 provided useful diagnostic features. Schnabel et al.[43] found that transbronchial biopsies provided support for a diagnosis of NGV in only 2 of 17 patients, while otolaryngologic examination and biopsy of the clinically involved areas of the upper respiratory tract yielded useful information in 13 of 19 NGV patients.

Diagnostic Biopsy

While a confident diagnosis may occasionally be made without tissue, diagnostic tissue biopsy remains necessary for a definitive diagnosis. While skin or upper airway tissue may be useful in some cases, when the lung is involved, definitive pathology generally requires a surgical lung biopsy. When Hoffman et al.[42] examined 82 open-lung biopsies in patients with small vessel vasculitis, diagnostic features were found in 90%. Renal biopsy is often performed to determine the cause of an acute glomerulonephritis. Specific features indicative of vasculitis, such as granulomatous inflammation or vascular necrosis, are rarely found; however, the presence of focal, segmental necrotizing glomerulonephritis without immune deposits (pauci-immune) is strongly suggestive of a systemic vasculitis.[42,44–46]

It is important to appreciate that the pathologic features of vasculitis often overlap with inflammatory lesions such as necrotizing infectious granulomas; all of the histopathologic features of vasculitis may not be present because of the timing of the biopsy and/or modification of the histology secondary to prior treatment, particularly corticosteroids. Because of this, it is critical

for the surgeon, pulmonologist, and pathologist to have a coordinated plan prior to the biopsy that includes the clinical differential diagnosis. This differential will dictate the appropriate specimens to collect and will include fresh tissue for culture and immunofluorescence (the presence of characteristic immunofluorescence patterns, such as IgA deposition in Henoch-Schönlein purpura, linear immunoglobulin G deposition in Goodpasture's syndrome, and irregular immunoglobulin and complement deposition in SLE, can be diagnostic) as well as for formalin fixation.

SPECIFIC CLINICAL DISORDERS

Being systemic disorders, apart from polyarteritis nodosa (PAN), virtually all of the vasculitides have been described to involve the lung. This involvement ranges from DAH to cavitary nodules, parenchymal inflammation, pleural disease, vascular aneurysms, and thrombotic and thromboembolic phenomena. A full accounting of each described disorder and their pulmonary manifestations is beyond the scope of this chapter. However, the primary idiopathic small vessel vasculitides deserve special attention.

Necrotizing Granulomatous Vasculitis (Formerly Wegener's Granulomatosis)

NGV is the most common of the ANCA-associated small vessel vasculitides, occurs at any age (generally 40 to 60), and equally affects the sexes. It is clinically recognized by its ability to involve the upper airway (e.g., chronic sinusitis and/or otitis, upper airway ulceration and/or structural deformity, subglottic or endobronchial stenosis); lower respiratory tract (e.g., chest symptoms of cough, chest pain, shortness of breath, hemoptysis, and/or chest imaging abnormalities); and kidney (e.g., glomerulonephritis) (Table 53-3). However, involvement of all three sites is neither necessary nor frequent at presentation. For example, even though 80% to 90% of patients will ultimately develop renal disease, as few as 40% will have renal involvement at time of first presentation.[42,47,48]

Constitutional symptoms (fever, asthenia, myalgias, arthralgias) and skin, eye, musculoskeletal, and peripheral and central nervous system disease are common.[26,42,47,48] Abnormal chest imaging occurs in the majority of patients, with alveolar, mixed, or interstitial opacities and nodular or cavitary disease.[21,22] A positive c-ANCA is seen in 90% to 95% of cases of active, systemic disease but in only 60% to 65% of cases of limited disease.[37,49-51]

The histopathology on surgical lung biopsy is dependent on the stage of the disease and whether there has been prior treatment. A small and medium vessel, necrotizing vasculitis with granulomatous inflammation and parenchymal necrosis, often with a geographic appearance, is characteristic (Fig. 53-5A).[52-56] The pathologic manifestations can be divided into major and minor histologic features. The three major features are (1) parenchymal necrosis, in the form of either geographic necrosis or neutrophilic microabscesses; (2) vasculitis (often small to medium-sized arteries, but can also involve veins and capillaries) (see Fig. 53-5B and C), and (3) granulomatous inflammation (see Fig. 53-5D). Although the inflammation in NGV is typically described as granulomatous, it is often mixed and includes granulomas, giant cells, neutrophils, lymphocytes, plasma cells, histiocytes, and eosinophils. The minor histologic criteria include organizing pneumonia (70% of cases), DAH (10% of cases), eosinophilia, and bronchocentric granulomatosis (1% of cases).[52,57] If the biopsy is performed early in the course of disease, some of the classic histologic findings may be absent. With prior treatment, there may be no significant inflammatory infiltrates and the only (nonspecific) clue may be scarring of arteries and/or airways.[58] A distinctive, but uncommon, histologic appearance in NGV is the presence of isolated capillaritis (see Fig. 53-3).

Prognostically, appropriately treated disease is associated with a 5-year survival rate of 75%. Death occurs from a variety of causes, including infection, cardiac disease, renal failure, and malignancy.[59] Poor outcomes correlate with advanced age, lack of otorhinolaryngology clinician involvement, more severe renal impairment, pulmonary involvement (particularly with alveolar hemorrhage), and low albumin and high-level anti-PR3 positivity.[60]

Churg-Strauss Syndrome

CSS is a specific ANCA-associated small vessel vasculitis that is clinically distinct from NGV and MPA (see Table 53-3), affects adults of all ages, and equally affects the sexes. Its presentation often overlaps with the eosinophilic lung diseases (chronic eosinophilic pneumonia, allergic bronchopulmonary mycosis, drug reactions, hypereosinophilic syndrome, parasitic infection, asthma/atopic disease) and difficult-to-control asthma/atopy. The syndrome is characterized by its own triad of (1) asthma, (2) hypereosinophilia, and (3) necrotizing vasculitis. The vasculitis classically has a three-phase presentation: the initial presence of atopy/rhinitis/sinusitis/asthma, followed by an eosinophilia, and a final vasculitic phase. However, the three phases do not need to occur sequentially, and the asthma may even postdate the vasculitis. Asthma is essentially universal, with common involvement of the upper airway.

In contrast to NGV and MPA, while pulmonary hemorrhage and glomerulonephritis may occur, they are much less common.[61-64] Significant cardiac disease (conduction abnormalities, systolic or diastolic dysfunction, intracavitary thrombus, pericarditis) and/or gastrointestinal disease (perforation, ischemia, bleeding) are dreaded and well-recognized complications.

ANCA is positive in a perinuclear immunofluorescent pattern (p-ANCA) in 40% to 70%, with peripheral eosinophilia (absolute eosinophil count >1500 cells/μL) almost universal at some point in the disease course.

Chest imaging is abnormal in two thirds of cases, with parenchymal opacities and less commonly nodules. Pleural effusions can be seen in 10%.

TABLE 53-3. Clinical Findings in the ANCA-Associated Vasculitides

	NGV	CSS	MPA
Constitutional	Commonly fatigue, malaise, fevers, and weight loss.	Common.	Very common. Generally precedes renal disease by months.
Pulmonary	70–95% of patients with respiratory symptoms or chest imaging abnormalities. Tracheobronchial and endobronchial disease in 10–50%.	Asthma essentially universal. Eosinophilic infiltrates in 30–50%. Diffuse alveolar hemorrhage in 0–20%.	25–55% of patients. 10–30% with diffuse alveolar hemorrhage. Fibrosis, focal infiltrates, and effusions rare.
Renal	50–90% of patients.	25–60% of patients.	Rapidly progressive glomerulonephritis is almost universal.
Upper Airway	70–95% of patients. Destructive or ulcerating lesions are suggestive.	Sinusitis in 20–70% of patients. Generally not destructive.	5–30% of patients, with sinus disease most common.
Musculoskeletal	Arthralgias, synovitis, and myalgias in up to 80% of patients.	Arthralgias and myalgias reported in up to 50% of patients.	Arthralgias and myalgias in at least 50% of patients.
Eyes	25–60% of patients. Vision-threatening disease including uveitis, ocular ulcers.	<5% of patients.	0–30% of patients. May be clinically silent.
Cardiac	5–30% of patients.	15–50% of patients and a major cause of mortality. Conduction delays or other ECG abnormality, systolic or diastolic dysfunction, pericarditis, or coronary artery vasculitis.	10–15% of patients. CHF and pericarditis have been described.
Gastrointestinal	<10% of patients.	15–60% of patients and a major cause of morbidity and mortality. Hemorrhage, abdominal pain, infarct, or perforated viscus.	35–55% of patients. Findings similar to PAN. Pain, bleeding, and ischemia. Rare visceral aneurysms.
Dermatologic	Up to 60% of patients. Palpable purpura, ulcers, nodules, or vesicles.	50–70% of patients. Nodules, papules, leukocytoclastic vasculitis with or without eosinophils.	35–60% of patients. Purpura common.
Neurologic	Both central and peripheral nervous system involvement.	Mononeuritis multiplex in 50–75% of patients. CNS in 5–40%.	Mononeuritis multiplex in 10–50% of patients.
Chest Imaging	Abnormal in >80% of patients. Alveolar, interstitial, or mixed opacities, often with nodular and/or cavitary disease.	Opacities in 40–75% of patients. Airways disease common (airway wall thickening, hyperinflation).	Opacities in 10–30% of patients. Pleural effusions in 5–20%.
ANCA	ANCA positive in >90% of patients and c-ANCA/anti-PR3 ELISA positive in >85% with generalized active disease.	ANCA positive in 40–70% of patients, with most of these being p-ANCA/anti-MPO positive.	ANCA positive in 50–75% of patients, with most of these being p-ANCA/anti-MPO positive.

ANCA, antineutrophil cytoplasmic antibody; c-ANCA, cytoplasmic ANCA; CHF, congestive heart failure; CNS, central nervous system; CSS, Churg-Strauss syndrome; ECG, electrocardiogram; ELISA, enzyme-linked immunosorbent assay; MPA, microscopic polyangiitis; MPO, myeloperoxidase; NGV, necrotizing granulomatous vasculitis; PAN, polyarteritis nodosa; p-ANCA, perinuclear ANCA; PR3, proteinase 3.
Data from references 21, 26, 42, 48, 61–64, 68, 75, 78, 109, 115–125.

Pathologically, both a necrotizing, small vessel vasculitis and an eosinophil-rich cellular infiltrate with necrotizing granulomas are seen.[65,66] The *diagnostic* findings on lung biopsy include eosinophilic pneumonia, necrotizing vasculitis, and granulomatous inflammation (Fig. 53-6A and B). The vasculitis consists of artery, vein, or capillary wall infiltration by lymphocytes and eosinophils. The granulomas often show central areas of necrosis with abundant necrotic eosinophils, surrounded by palisaded histiocytes and multinucleated giant cells. Findings *highly suggestive* of CSS include the combination of eosinophilic pneumonia and necrotizing vasculitis. Findings *suggestive* of CSS include the combination of eosinophilic pneumonia and parenchymal necrosis.[66]

Mortality is generally due to cardiac complications (up to half of CSS-related deaths), gastrointestinal complications, or status asthmaticus and respiratory failure.[61,62,67] While mortality rates of up to 40% were described in the 1970s, it is not clear from more recent data that adequately treated disease has an increased mortality.[68] Overall 5-year survival has been estimated at 68% to 100%.[60] A validated prognostic five-factor score has been defined. Made up of proteinuria (>1 g/24 hours), serum creatinine greater than 1.58 mg/dL, and clinically significant gastrointestinal, cardiac, or central nervous system involvement, each organ system involved counts as a score of 1. When two or more organs are involved, mortality is increased.[61]

Over the last several years, an association between the use of leukotriene inhibitors and CSS had been suggested in number of case reports and case series.[69,70] This led to the concern that leukotriene inhibitors may help promote

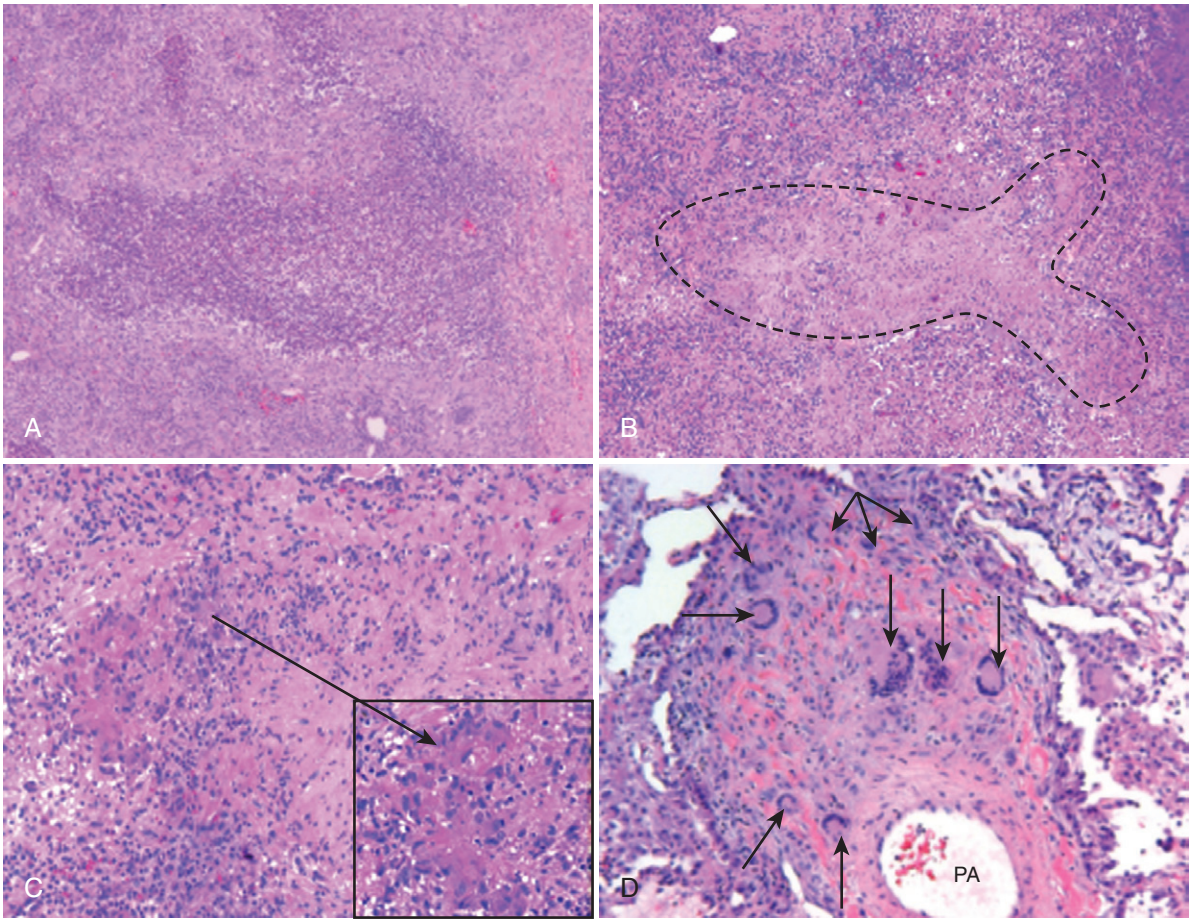

FIGURE 53-5 ■ **A,** Irregular outlines of geographic necrosis are typical of the parenchymal necrosis found in necrotizing granulomatous vasculitis. (Case courtesy of Dr. Christopher Bee.) **B,** Low-power view of a branching vessel demonstrating necrotizing vasculitis (Hematoxylin and eosin stain.) **C,** Higher power views of same vessel shown in **B.** Note the basophilic necrosis accompanied by chronic inflammation and vague granulomas (*inset*). **D,** Granulomatous inflammation (*arrows*) of the adventitia of a pulmonary artery (PA).

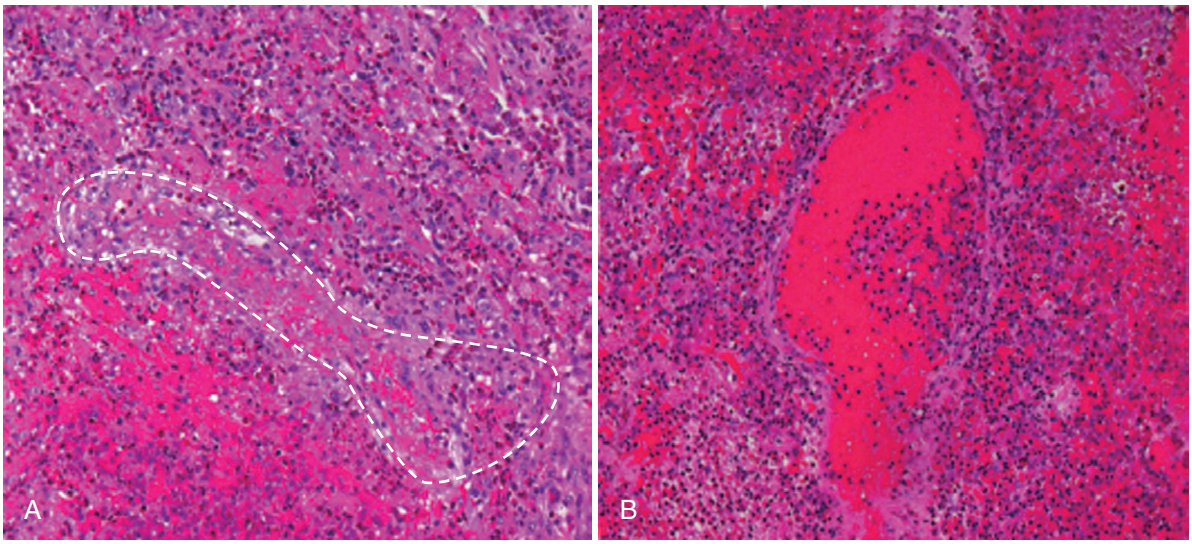

FIGURE 53-6 ■ **A,** Outline (*dotted line*) of a destroyed vessel in Churg-Strauss vasculitis. Note the marked eosinophilic infiltrates. **B,** A small vein showing destruction of its wall by eosinophils. There is an accompanying eosinophilic pneumonia characterized by numerous clusters of eosinophils within the air spaces. Hemorrhage is also present.

the biologic conversion of severe asthma/atopic disease to CSS.[71] However, recent analyses of postmarketing surveillance data and a number of patient cohorts have not offered supportive evidence of a pathogenic role for leukotriene receptor antagonists.[68,72–74] The appearance of CSS appears more likely to be related to the associated withdrawal of corticosteroids.

Microscopic Polyangiitis

Clinically, MPA is an ANCA-associated small vessel vasculitis generally heralded by weeks to months or longer of profound constitutional symptoms (fever, asthenia, myalgias, arthralgias) followed by the development of renal disease, generally rapidly progressive glomerulonephritis (see Table 53-3). It is more common in men, with an average age of onset in the sixth decade. Its clinical manifestations overlap considerably with those of PAN, explaining the decades of confusion over their relationship. The glomerulonephritis is essentially universal, whereas pulmonary involvement occurs in a minority of cases (10% to 30%).[75–77] In patients who develop lung disease, DAH/capillaritis is most common, while hemoptysis occurs in up to a third. Pulmonary fibrosis is uncommon, but associated with a high mortality rate. Skin disease occurs in over half of patients, most commonly with purpura. The peripheral nervous system (most commonly with mononeuritis multiplex) is involved more frequently than the central nervous system, and gastrointestinal involvement with bleeding and ischemia occurs with some frequency.[78] ANCA is positive in a perinuclear pattern in 50% to 75%.

Pathologically, a focal, segmental necrotizing vasculitis and a mixed inflammatory infiltrate without granulomata are seen. Vasculitis in MPA affects venules, capillaries, and arterioles. Neutrophilic capillaritis (see Fig. 53-3) is the classic histologic finding in the lung, with pulmonary alveolar hemorrhage and hemosiderin-laden macrophages (Fig. 53-7A–C). As the lesions heal, plugs of organizing pneumonia may fill air spaces, resulting in a pattern similar to brochiolitis obliterans with organizing pneumonia. Unlike the other small vessel vasculitides, MPA lacks granulomatous inflammation.

The overall 5-year survival rate has been estimated to range from 45% to 75%.[60] The prognostic five-factor score (see earlier) has been validated in MPA: the more organs that are involved, the worse the prognosis. The 5-year survival with a score of 0 is 88%, while a score of

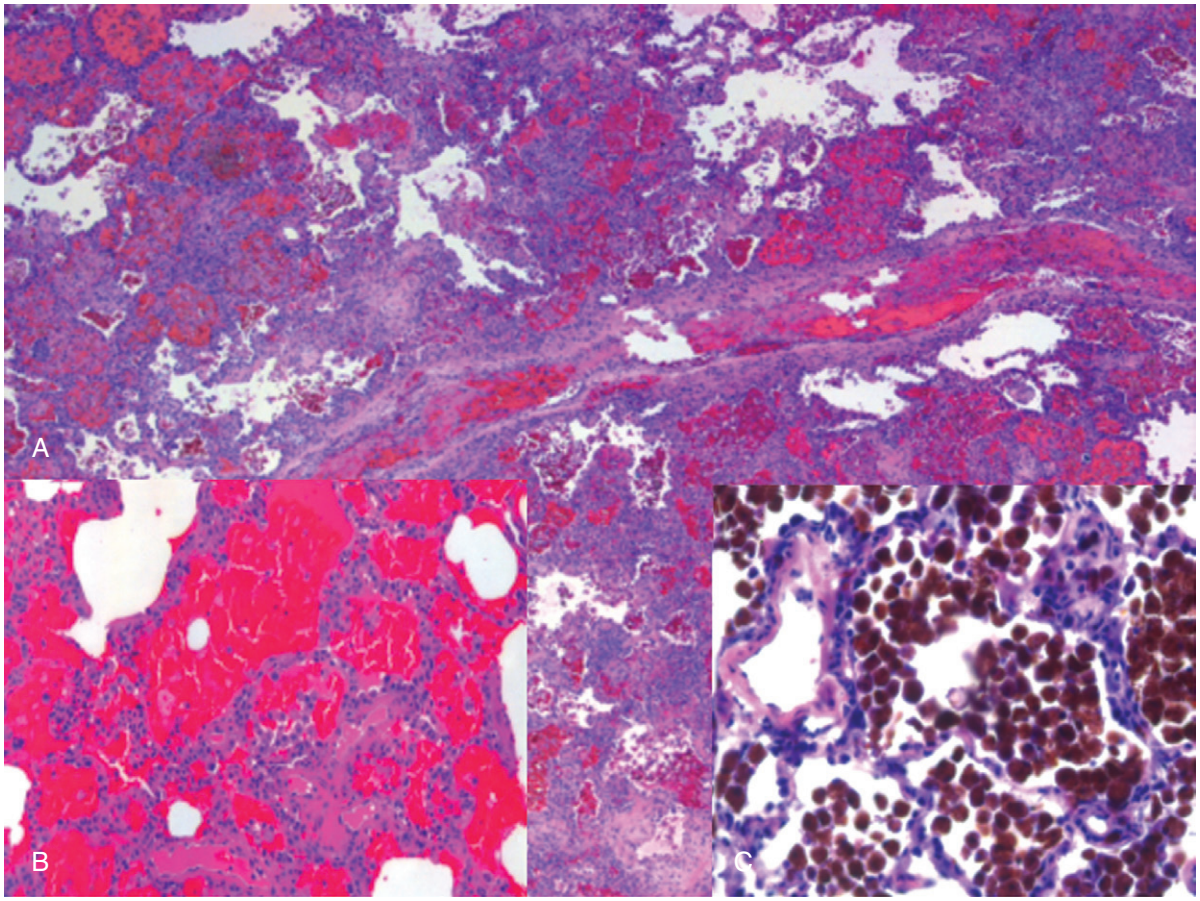

FIGURE 53-7 ■ **A,** Low-power view of diffuse alveolar hemorrhage. The air spaces are filled with red blood cells and the alveolar septa show concomitant inflammatory thickening. **B,** Alveolar hemorrhage demonstrating the smudged, homogeneous appearance of the disrupted red blood cells in the air spaces. Occasional hemosiderin-laden macrophages can be seen in the center. **C,** Hemosiderin-laden macrophages indicating chronic hemorrhage.

TABLE 53-4. European Vasculitis Study Group Disease Severity and First-Line Treatment Options for Induction Therapy

Disease Classification	Constitutional Symptoms	Renal Function	Threatened Organ Function	Treatment Options for Induction
Limited	No	Serum creatinine < 120 mmol/L (1.4 mg/dL)	No	Corticosteroids *or* methotrexate *or* azathioprine
Early generalized	Yes	Serum creatinine < 120 mmol/L (1.4 mg/dL)	No	Cyclophosphamide + corticosteroids *or* Methotrexate + corticosteroids
Active generalized	Yes	Serum creatinine < 500 mmol/L (5.7 mg/dL)	Yes	Cyclophosphamide + corticosteroids
Severe	Yes	Serum creatinine > 500 mmol/L (5.7 mg/dL)	Yes	Cyclophosphamide + corticosteroids + plasma exchange
Refractory	Yes	Any	Yes	Consider investigational or compassionate-use agents (see text).

Data from references 80, 98, 99, 101, 116, 126–132.

2 or greater is associated with 54% survival.[57] The intensity of therapy is therefore dictated by the number of organs involved. Relapses after successful induction therapy are common (25% to 33%)[75] but usually less severe and responsive to therapy.

TREATMENT

General Principles

As therapy for the vasculitides involves aggressive immunosuppression, treatment-related complications are common and can be severe. The risk of some complications is often directly associated with the intensity of immunosuppression. Therefore, rather than the diagnosis alone, often the disease severity dictates treatment intensity need to control the disease, while minimizing the risk of treatment-related adverse events. Similar to cancer therapy, treatment is divided into two parts, an initial "remission-induction" phase to control active disease and a "maintenance" phase to maintain disease remission while lowering treatment-related risk. Regardless of the phase of therapy, both disease-specific and drug-specific monitoring is required, focused on the early identification of disease activity, infection, or drug toxicity.

Clinicians should be familiar with the common toxicities associated with each drug and have a standard protocol for the monitoring of potential treatment-related side effects during both remission-induction and maintenance therapy. Not to be forgotten, oxygen therapy when needed, the treatment of comorbid disease, appropriate vaccinations, physical and occupational therapy, nutrition, and psychosocial support should be provided as they help to minimize the morbidity associated with these diseases.

As noted above, treatment recommendations depend upon an accurate assessment of disease severity. The European Vasculitis Study Group has devised a clinically useful grading system that categorizes the patient's disease as (1) limited, (2) early generalized, (3) active generalized, (4) severe, and (5) refractory. Clinical criteria and first-line treatment recommendations appear in Table 53-4.

Remission-Induction

Limited Disease

Limited disease refers to localized disease of the upper airway. There are no systemic symptoms, end-organ function is not threatened, and there is no renal involvement. Here, therapy can often be limited to a single agent such as corticosteroids, azathioprine, or methotrexate. Some authors have recommended trimethoprim-sulfamethoxazole alone for this group,[79] although it is not clear whether trimethoprim-sulfamethoxazole alone represents effective therapy (see later). For more aggressive, limited disease, therapy outlined for early generalized or active generalized disease may be necessary.

Early Generalized Disease

Early generalized disease differs from active generalized disease by the absence of a threat to specific organ function. While treatment recommendations have traditionally been similar for these (cyclophosphamide plus corticosteroids are the first-line therapy for both), the Methotrexate versus Cyclophosphamide for 'Early Systemic Disease' trial (NORAM) suggests that methotrexate is as efficacious as cyclophosphamide in the induction of disease remission in early generalized disease.[80–82] Thus, both agents represent acceptable first-line therapy in early disease.

Active Generalized Disease

Since Fauci's early studies,[48] cyclophosphamide plus corticosteroids have been the primary first-line therapy for

the treatment of active generalized disease. It has also recently been shown that pulsed intravenous cyclophosphamide is as effective as oral cyclophosphamide, with fewer side effects.[83–85]

Severe Disease

Severe disease is defined by impaired function of critical organs, such as severe renal disease (creatinine >5.7 mg/dL), DAH, or other organ-threatening disease. The addition of plasma exchange therapy to the standard cyclophosphamide plus corticosteroid regimen has been shown to be superior to high-dose, pulsed intravenous steroids at restoring renal function in patients with severe renal impairment.[86–92] Based upon several case reports and a case series, this strategy may also be effective for the treatment of DAH.[91] Additional therapies described at the case report level for patients with unresponsive DAH include activated human factor VII[93,94] and extracorporeal membrane oxygenation (used to "buy time" until other interventions have had a chance to work).[95]

Refractory Disease

Patients who have not responded to high-dose corticosteroids, cytotoxics, and plasma exchange are deemed to have refractory disease. There is no standard therapy that has been shown to work in this group of patients, and one must consider the use of novel or experimental agents. Treatments such as rituximab,[96–98] intravenous immune globulin, and antithymocyte globulin[99] have all been suggested.

Maintenance

Maintenance therapy to preserve disease control can hopefully be obtained with treatment associated with fewer and less severe adverse effects. During this phase of treatment, patients are generally converted to azathioprine or methotrexate, often combined with a low dosage of corticosteroids. As with all cytotoxic agents, these agents must be introduced with drug-specific monitoring to identify adverse effects as early as possible. Additional agents that have been used in selected patients include mycophenolate mofetil, leflunomide, and cyclosporine.[80,81,100–103]

The timing of transition from the induction agent to the maintenance therapy has been a subject of debate, with many physicians arguing that patients should have 12 months of induction therapy, while others have argued for using remission of clinical evidence of disease activity as the chief determinant of when to transition. The results of the Cyclophosphamide versus Azathioprine for Remission in Generalized Vasculitis (CYCAZAREM) trial demonstrated that patients with active generalized vasculitis may be transitioned from oral cyclophosphamide to azathioprine once a clinical remission (using defined criteria) has occurred (generally within 3 to 6 months) with no increase in the rate of relapse or disease activity scores or change in renal function.[98] The optimal duration of maintenance therapy is also a source of uncertainty. Absent convincing data, a number of experts have advocated for the use of at least 2 years of maintenance therapy before treatment cessation is considered.[104]

Another point of controversy has been the use of trimethoprim-sulfamethoxazole[15,105] or reduction of nasal *Staphylococcus aureus* carriage in the therapy of ANCA-associated small vessel vasculitis.[14,106] Studies have demonstrated a reduced frequency of disease relapse in patients who are maintained on trimethoprim-sulfamethoxazole compared to those without,[105] with additional work suggesting that this is related to *S. aureus* nasal carriage.[14,106] The European Vasculitis Study Group–sponsored Placebo-Controlled Trial of Nasal Mupirocin for the Prevention of Relapse (MUPIBAC) trial, in which patients are randomized to eradication of nasal *S. aureus* with topical mupirocin or placebo, hopefully will answer the question as to whether disease relapse is indeed related to *S. aureus* nasal carriage. Regardless of the results of this study, trimethoprim-sulfamethoxazole should be considered for *Pneumocystis jirovecii* prophylaxis in patients maintained on cyclophosphamide or other aggressive immunosuppression regimens, barring a sulfa allergy or other contraindication.

Monitoring for Complications

Monitoring for complications is mandatory in order to minimize the morbidity and mortality of both the disease and its treatment. When clinical deterioration occurs, infection, drug toxicity, disease relapse, or a new complication (such as deep venous thrombosis or thromboembolic disease[107]) should be considered. Infection is a major contributor to both morbidity and mortality and is frequently difficult to separate from disease activity. Up to 10% of patients treated with cyclophosphamide develop clinically important infections (i.e., pneumonia or sepsis) even in the absence of drug-induced leucopenia.[108] Combining high-dose glucocorticoids and cytotoxic therapy puts patients at especially high risk. Drug toxicity is also a common complication. In NGV patients treated with cyclophosphamide, cystitis is described in up to 12%, myelodysplastic syndrome in 8%, and solid malignancy in 5%.[109]

Historically, up to 50% of patients with an ANCA-associated vasculitis have suffered at least one relapse despite active treatment. Relapses are more common among patients with NGV (40% to 65%) and less common among patients with CSS (15% to 25%).[56,110] The features of clinical deterioration during a relapse may be similar to the patient's original presentation or may be novel, with symptoms and signs in previously unaffected organs. A relapse generally requires reinduction therapy. While disease relapse remains a clinical diagnosis at this time, a recent study applying a proteomic approach to identifying remission in NGV suggests that serum markers may one day permit accurate discrimination between quiescent and active disease.[111]

KEY POINTS

- Pulmonary vasculitis describes a variety of disorders characterized by their ability to cause vascular inflammation, destruction, and tissue necrosis in the lung.
- The presentation, clinical features, and evolution overlap fully with much more common diseases. The initial history is critical in the evaluation of a patient with suspected vasculitis.
- A confident diagnosis may occasionally be made without tissue; however, diagnostic tissue biopsy remains necessary for a definitive diagnosis.
- The ANCA-associated vasculitides—necrotizing granulomatous vasculitis, Churg-Strauss syndrome, and microscopic pulmonary angiitis—are the most commonly encountered vasculitides in the practice of pulmonary medicine.
- A number of high-quality randomized, controlled trials have allowed the development of evidence-based treatment recommendations with the expectation of a beneficial response.
- Therapy for the vasculitides involves aggressive immunosuppression; consequently, treatment-related complications are common and can be severe.

PULMONARY ARTERY ANEURYSMS
Etiology and Pathogenesis
Diagnosis and Treatment

INTRODUCTION

Pulmonary vascular abnormalities occur in a variety of acquired and congenital conditions. These structural defects include vascular communications that either are confined to the pulmonary circulation, as is the case with pulmonary arteriovenous malformations, or join the systemic and pulmonary circulations, as with bronchopulmonary sequestration. Aneurysmal dilations of the pulmonary artery and its branches also occur and are considered in this chapter. Although all these conditions are rare, their diagnosis and treatment are important, because many are associated with complications that cause severe morbidity or mortality.

PULMONARY ARTERIOVENOUS MALFORMATIONS

Pulmonary arteriovenous malformations (PAVMs) are abnormal vascular structures that provide a direct capillary-free communication between the pulmonary and systemic circulations. They range in size from large complex structures consisting of a bulbous aneurysmal sac between dilated feeding arteries and draining veins (Fig. 54-1), to dilated smaller vessels (Fig. 54-2), to communications within the microvasculature (telangiectases). The true anatomic shunts of PAVMs are usually distinguished from the diffusion-perfusion defects that arise in patients with intrapulmonary vascular dilations secondary to the hepatopulmonary syndrome, which is fully described in Chapter 83.

Pulmonary arterial blood passing through these right-to-left (R–L) shunts cannot be oxygenated, which leads to hypoxemia. In addition, the absence of a filtering capillary bed allows particulate matter to reach the systemic circulation, where it impacts in other capillary beds, including the cerebral circulation, resulting in embolic cerebrovascular accidents (CVAs) and brain abscesses. It is crucial for the pulmonologist to assimilate the recent data demonstrating that—irrespective of PAVM size—all patients are at risk of paradoxical emboli. Importantly, recent data also confirm that most patients with clinically significant PAVMs do not have respiratory symptoms or profound hypoxemia. The incidence of

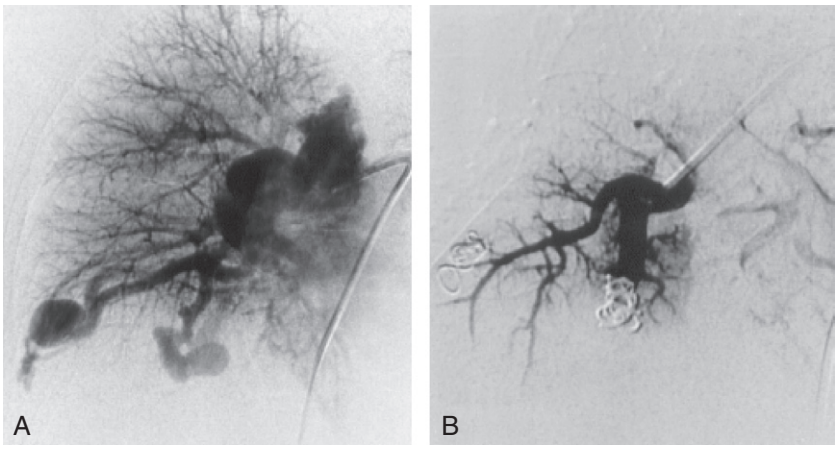

FIGURE 54-1 ■ Macroscopic right lower lobe pulmonary arteriovenous malformations (PAVMs) before **(A)** and after **(B)** embolization. Note embolization coils and restored perfusion of pulmonary arterial branches in **B.** Similar PAVMs were present in the left lung. Embolization over an 18-month period reduced the right-to-left shunt (and arterial oxygen saturation) from 32% (78% erect) to 3% (92% erect).

FIGURE 54-2 ■ Diffuse small pulmonary arteriovenous malformations in a patient left with a right-to-left shunt greater than 30% following maximal embolization. The patient declined transplantation; arterial oxygen saturation (erect) was unchanged at 78% to 79% over the next 12 years.

major, usually neurologic, complications approaches 50% (Table 54-1), with nearly 13% incidence of cerebral abscess and 27% of embolic stroke or transient ischemic attack recorded in all series. These complications can be limited if the underlying condition is recognized and treated with embolization using metal coils, balloons, or plug devices, the treatment of choice for almost all patients. Risk-benefit analyses are almost always in favor of treatment, though the possibility of contraindications needs to be considered.

TABLE 54-1. Features of Untreated Pulmonary Arteriovenous Malformations

	N	Mean (%)	Range (%)
RESPIRATORY			
Asymptomatic	260	49	25–58
Dyspnea	685	50	27–71
Chest pain	390	12	6–18
Hemoptysis	671	11	4–18
Hemothorax	1	1	0–2
Cyanosis	467	27	9–73
Clubbing	459	28	6–68
Bruit	455	31	3–58
CENTRAL NERVOUS SYSTEM			
Cerebral abscess	636	12.9	0–25
CVA/TIA	401	27	11–55
CVA	262	13.7	9.5–18
TIA	262	22.1	6.3–36
Migraine	266	44.7	38–57

CVA, cerebrovascular accident; TIA, transient ischemic attack.
Data from various sources referenced in text.

Etiology

New data highlight that the majority of PAVMs occur in individuals affected by the inherited vascular disorder hereditary hemorrhagic telangiectasia (HHT, or Osler-Weber-Rendu syndrome) (Table 54-2).[1,1a] In one series of 219 consecutive PAVM patients, a clinical diagnosis of HHT could be established in 93.6% of cases.[2] Additional cases may occur as a result of surgical treatments for several forms of complex cyanotic congenital heart disease, especially following surgical generation of cavopulmonary or atriopulmonary shunts, in which PAVMs may develop in the lung not receiving hepatic venous blood.[3,4] Traumatic PAVMs are rare.[5] Sporadic cases do occur, but many of these are, in fact, due to underlying, undiagnosed HHT; because the diagnosis of

TABLE 54-2. Clinical Features of Hereditary Hemorrhagic Telangiectasia

Curaçao Criteria*	Approximate Frequency (%)
Epistaxes (nose bleeds)	90
Mucocutaneous telangiectasia	80
GI bleeding	25
Pulmonary AVMs	50
Hepatic AVMs	20
Cerebral AVMs	10
Spinal AVMs	<1

*Rare noncriterion manifestations include juvenile polyposis,[19] pulmonary hypertension (see text), prothrombotic states,[127b] and immune dysfunction.[173]
AVMs, arteriovenous malformations; GI, gastrointestinal.

HHT is more difficult to make than many textbooks suggest, and because HHT features develop with age, many HHT patients go undiagnosed. In one recent series, 121 of 205 consecutive PAVM patients with HHT (59%; 95% confidence interval [CI], 52.2% to 65.5%) were unaware they had HHT when their PAVMs were diagnosed.[2] Sporadic PAVMs are usually single, and multiple PAVMs should raise particular suspicion that there is underlying HHT.[2,6,7] These considerations are particularly pertinent for children presenting with PAVMs.[8]

Hereditary Hemorrhagic Telangiectasia

HHT is a disorder of vascular development inherited as an autosomal dominant trait. It is usually underdiagnosed because clinical appreciation of mild phenotypes is poor. The lesions associated with HHT may remain silent and unnoticed for many years, and small lesions may never be detected unless specific screening is undertaken. Careful epidemiologic studies reveal a true incidence of 1 in 5000 to 8000 in France, Denmark, and Japan,[9–11] substantially higher than early figures based on analyses of medical records. Higher prevalences are described in isolated communities.[9,12] Because PAVMs affect approximately 50% of HHT patients,[13] the incidence of PAVMs may be estimated to be at least 1 in 10,000 to 16,000.

Clinical Features and Diagnosis. Many individuals with HHT are unaware they have the disease until the family history is unmasked by the question "Who in the family has nosebleeds?" Most patients will have nosebleeds at some stage of their life, often as children, and many meet the classical 19th century descriptions of having florid epistaxes, demonstrating mucocutaneous telangiectasia, and having needed iron supplementation (or required blood transfusions) due to nasal or gastrointestinal bleeding. The majority of patients are, however, minimally symptomatic and often unknown to the medical profession until a member of their family presents with a major complication. Even then, due to the late-onset penetrance, individuals of childbearing age may display no clinical evidence of HHT: Data suggest that, by the age of 16 years, 71% of individuals will have developed some sign of HHT, rising to over 90% by the age of 40 years.[14–16] However, these data mean that, during his or her childbearing years, an apparently unaffected child of an HHT patient still has a 5% to 20% chance of actually carrying the family's HHT disease gene.

To permit a high level of clinical suspicion without leading to overdiagnosis, international consensus diagnostic criteria were developed based on four findings: (1) spontaneous recurrent nosebleeds, (2) mucocutaneous telangiectasia, (3) visceral involvement, and (4) an affected first-degree relative.[1] When three criteria are present, "definite HHT" can be diagnosed; with two criteria, most commonly family history and nosebleeds, "suspected HHT" is diagnosed. With only one criterion, typically spontaneous nosebleeds, in a patient with neither a family history nor a first-degree relative of an HHT patient, and with no signs of the disease, the diagnosis of HHT is "unlikely" (see Table 54-2). A crucial issue for families (and medical practitioners) is that no child of a patient with HHT can be informed that he or she does not have HHT, unless the child has had a molecular diagnosis.

Genetics and Pathogenesis. HHT is a genetically heterogeneous condition. Three disease-associated genes have been identified. HHT type 1 (HHT1) is caused by mutations in *ENG,* encoding endoglin,[17] and HHT type 2 (HHT2) by mutations in *ACVRL1,* encoding activin receptor–like kinase (ALK1).[18] By April 2008, 311 different *ENG* mutations and 250 different *ACVRL1* mutations had been reported to the HHT Mutation Database (located at www.hhtmut.org/). Most families have a unique mutation; the individual number of reports corresponds to first-order decay kinetics, confirming the absence of common mutations. More rarely, mutations in *MADH4* cause HHT usually in association with juvenile polyposis (JPHT).[19] There are at least two further unidentified genes that can cause classical HHT, *HHT3* on chromosome 5q between *D5S2011* and *D5S2490,* and *HHT4* on chromosome 7p between *D7S2252* and *D7S510.*[20,21]

ENG and *ACVRL1* encode proteins expressed on vascular endothelial cells. Confirmation that the gene mutations cause HHT is available from experiments in transgenic mice, which demonstrate that some mice carrying one normal and one null copy of the respective gene (i.e., *endoglin*$^{+/-}$ or *ACVRL1*$^{+/-}$ heterozygote mice) display features of HHT.[22,23] Endothelial cells derived from HHT1 or HHT2 patients express approximately one half of the normal endoglin or ALK1 levels, respectively.[24,25] It is therefore believed that, in most if not all cases, HHT results from endoglin or ALK1 haploinsufficiency: in other words, a lack of sufficient protein for normal function. Dominant negative mutations in endoglin can be generated but appear to cause different phenotypes.[26] As endothelial cells derived directly from arteriovenous malformations (AVMs) in HHT1 patients also express half the normal levels of endoglin, these malformations do not appear to be due to an

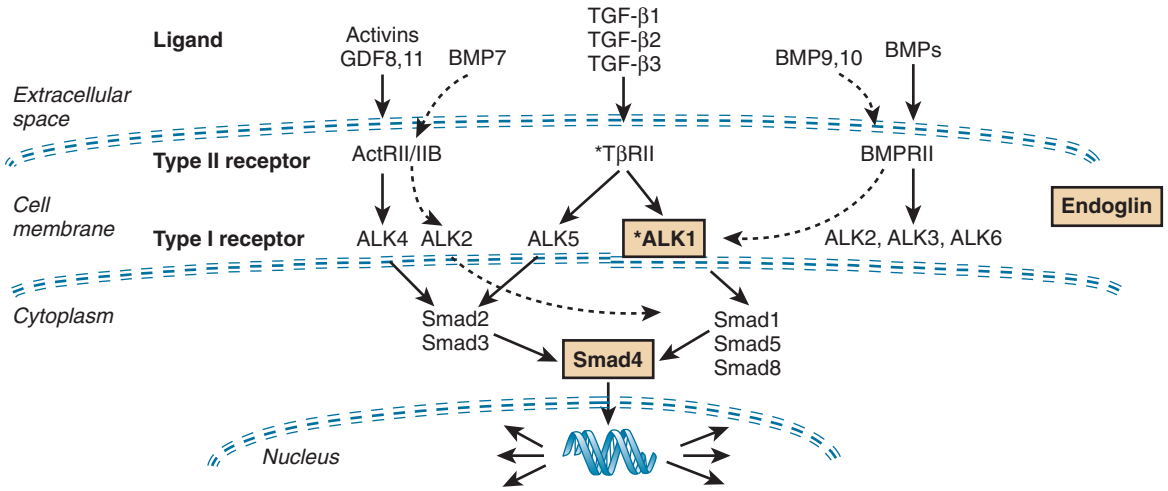

FIGURE 54-3 ■ TGF-β signaling pathway. Endoglin can interact with both type I and type II receptors. The genes mutated in HHT are highlighted in **bold.** (Adapted from Cole SG, Begbie ME, Wallace GMF, Shovlin CL: A new locus for hereditary haemorrhagic telangiactasia (HHT3) maps to chromosome 5. J Med Genet 42:577–582, 2005.)

additional local loss of endoglin expression due to a "second hit."[27] In 2009, interest in the role of angiogenesis in provoking or unmasking an HHT phenotype was renewed, owing to animal models, in particular, implicating a role for aberrant angiogenesis during wound healing.[28]

The genes mutated in HHT encode proteins that mediate signaling by the transforming growth factor-β (TGF-β) superfamily. Superfamily ligands such as TGF-βs, activins, and bone morphogenetic proteins (BMPs) affect cellular growth and differentiation through signal transduction cascades from transmembrane receptor complexes (Fig. 54-3). Generally, type II TGF-β receptors such as TGF-β receptor II and BMP receptor II (mutated in primary pulmonary arterial hypertension; see Chapter 52) bind the ligand directly, and recruit and activate type I receptors that activate downstream cytoplasmic signaling molecules via Smad-dependent and Smad-independent pathways.[29] Smad 4 mutations in JPHT implicate Smad-dependent pathways in HHT. Activated Smads translocate to the nucleus where, together with coactivators and corepressors, they influence transcriptional activation of target genes. As ALK1 is a type I receptor, and endoglin associates with different signaling receptors and can modify TGF-β1 signaling, the abnormal vessels in HHT were proposed to develop because of aberrant TGF-β signaling at some stage during vascular development and homeostasis. Current models include the "balance hypothesis" whereby the endothelial state depends on the predominant endothelial TGF-β type I receptor (ALK5/ALK1) and, hence, the Smad pathway utilized[30,31]; other models incorporate recent data that BMP-9 and BMP-10 are specific ALK1 ligands that can also bind endoglin.[32,33,33a] As additional HHT disease genes are identified, these will also likely play a part in this signaling pathway, possibly either as ligands, receptors, or downstream transducers of TGF-β family member signals.

Phenotype-Genotype Correlations. A characteristic finding is that different members of the same HHT family display different pattern of disease. This is also observed in the mouse models, suggesting that other genetic and environmental influences modify the HHT phenotype. The presence of specific *ENG* or *ACVRL1* mutations does not allow a strong prediction of the likely course of HHT because all features of HHT can be seen in both HHT1 and HHT2. Nevertheless, all recent large series support early observations that reported finding pulmonary and cerebral AVMs more commonly in patients with HHT1 (*ENG* mutations), and hepatic AVMs more commonly in those with HHT2 (*ACVRL1* mutations).[34–37] Although there was an initial suggestion that overall severity of disease is greater in HHT1 than HHT2,[38] this study predated the recognition of pulmonary hypertension (see later), and there was no difference in 90-month mortality in a later series.[34]

Cavopulmonary Shunts. In non-HHT patients, PAVMs commonly occur in those who have undergone surgical treatments of several forms of complex cyanotic congenital heart disease resulting in anastomoses between the superior vena cava and pulmonary arteries.[3] PAVMs associated with cavopulmonary or atriopulmonary shunts are macroscopically indistinguishable from sporadic and HHT-associated macroscopic PAVMs. Using angiography, PAVMs were detected in 31% of patients undergoing classic Glenn anastomoses after a mean follow-up of 6.8 years.[3] The only independent predictor of development of PAVMs was time after cavopulmonary shunting ($P < 0.05$), though there was a trend toward PAVMs developing more commonly in the presence of pulmonary hypertension in the contralateral lung.

The incidence of PAVMs rises substantially if microscopic AVMs detectable by contrast echocardiography are included[39]; moreover, microscopic arteriovenous shunting may develop within 2 hours of the procedure.[40]

Some have suggested that, following superior bidirectional cavopulmonary anastomosis (Kawashima procedure), the development of functional intrapulmonary shunts may be universal. In one study, technetium-99m–labeled albumin macroaggregates (^{99m}Tc-MAA) detected R–L shunts ranging from 11% to 64% of the cardiac output in the 17 patients studied, compared to 3% to 8% in controls.[41] Contrast-enhanced magnetic resonance (MR) angiography is emerging as a useful assessment modality for these patients.[42]

The key etiologic feature appears to be the route taken by hepatic venous effluent, because PAVMs develop in the lung that receives no or minimal hepatic venous return,[4,39] and can be treated either by rerouting the hepatic veins to the pulmonary arteries[43]; by reconnecting the pulmonary arteries[44]; or by incorporating the hepatic vein into the cavopulmonary system.[45] In the largest study, in 11 of the 15 survivors of 16 patients who underwent incorporation of the hepatic vein into the cavopulmonary system, hypoxemia improved from 76% (range, 56% to 85%) to greater than 93% at 2.8- to 10-year follow-up.[45] These observations, and data from patients with the hepatopulmonary syndrome (see Chapter 83), highlight the role of hepatic metabolism in influencing dilation and/or remodeling of the pulmonary vascular bed. Whether there will be common underlying mechanisms between the PAVMs that develop in the setting of cavopulmonary shunts and the vascular malformations found in HHT is unclear.

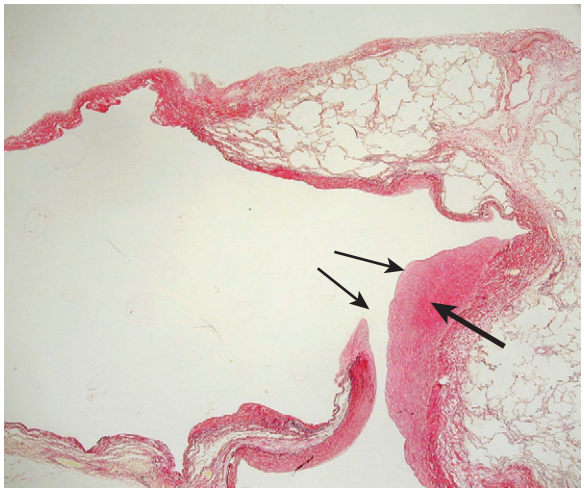

FIGURE 54-4 ■ Histopathology of a pulmonary arteriovenous malformation that ruptured in pregnancy. Note site of rupture (*narrow arrows*) at lower border, and region of endothelial intimal fibrous proliferation (*thick arrow*). (From Shovlin CL, Sodhi V, McCarthy A, et al: Estimates of maternal risks of pregnancy for women with hereditary haemorrhagic telangiectasia: Suggested approach for obstetrics services. BJOG 115:1108–1115, 2008.)

Pathophysiology

Anatomic Basis

Macroscopic (see Fig. 54-1) and microscopic or diffuse PAVMs are recognized. Dilated feeding arteries and dilated veins are characterized by walls of varying degrees of thickness even over relatively short segments, with disorganized adventitia. Medial thinning is observed, but also prominent are areas of focal thickening with abundant elastin tissue and a varying contribution of smooth muscle cells (Fig. 54-4).[27,46] Diffuse PAVMs have been defined as multiple small PAVMs affecting every segment of one or more lobes[47] or a single segment.[48]

PAVMs occasionally develop in the pre- or perinatal period.[49–52] Screening of vulnerable individuals over a period of years shows that PAVMs can develop in adult life in radiologically and/or physiologically normal vessels,[53,54] although it is likely that functional changes at a cellular or microscopic level predate the development of the macroscopic lesions. Once present, PAVMs tend to increase in size, particularly during puberty, in female patients during pregnancy,[53] or in the presence of pulmonary venous hypertension secondary to mitral stenosis or left ventricular dysfunction.[55] On rare occasions, spontaneous regression has been described.[56]

Physiologic Attributes at Rest

Right-to-Left Shunt. PAVMs provide an anatomic R–L shunt, with the proportion of the cardiac output using the shunt pathways (shunt fraction) varying widely, but reaching up to 60% in severe cases. In earlier series,[57–61] mean R–L shunt fractions were generally higher (23% to 38%) than found in later reports (8% to 13%),[2,62,63] in which earlier diagnosis had taken place owing to more energetic screening procedures.

Arterial P_{O_2} and oxygen saturation are inversely related to the size of the R–L shunt fraction.[64] The contribution of ventilation-perfusion mismatch to arterial hypoxemia in PAVMs is small, except in the occasional patient with significant coexisting lung disease. Calculations of the R–L shunt from arterial oxygen saturation measurements breathing air, often referred to as the venous admixture effect, are in good agreement with measurements of the anatomic R–L shunt,[59] confirming that the R–L shunt is the predominant cause of the arterial hypoxemia.

Pulmonary Hemodynamics. The absence of a microvascular network of capillary vessels means that the pulmonary vascular resistance (PVR) of PAVMs is less than that of the surrounding normal lung. The effect on the overall PVR depends on the proportion of the cardiac output flowing through the shunt channels. In one study of eight PAVM patients with large R–L shunt fractions (mean 31% ± 4% [standard error]), mean PVR and pulmonary artery pressure (P_{PA}) were 0.33 ± 0.08 (normal 0.5 to 1.3) mm Hg/L/min and 14 ± 0.6 (normal 12 to 16) mm Hg, respectively.[57] PVR was low, in spite of normal P_{PA}, because total pulmonary blood flow was high (8 ± 0.8 L/min [160% of predicted]). In later studies with smaller mean R–L shunt fractions (8.5% to 11.5%), mean pulmonary systolic and diastolic pressures have been in the normal range,[62–65] and recent studies have focused on the occasional presence of coexisting pulmonary

hypertension (see section on HHT-related pulmonary hypertension).

Pulmonary Function. Vital capacity is generally normal,[58–62] but was reduced to 51% to 81% of predicted values in 7 of 15 patients with large PAVMs and R–L shunts.[66] There is no airflow obstruction.[58,62,66] With large R–L shunts (>20%), the carbon monoxide diffusing capacity (D_{LCO}) is often moderately reduced (71% to 78%),[58,61,66] but in the majority of patients with less R–L shunting, D_{LCO} is equal to or greater than 90% of predicted (interquartile range, 76% to 100%).[62] The ratio of D_{LCO} to the measured alveolar volume (DL/VA, or KCO) is better preserved.[58,62] Values less than 70% are unusual[66]; in one study, only 16 of 63 patients had values less than 90% of predicted.[62] Those with the lowest D_{LCO} and DL/VA generally had widespread and small vascular malformations. In addition, data from patients following embolization (discussed later) indicate that, in some patients, a vascular steal through the low-resistance PAVMs also contributes to the low diffusion values.[62]

Physiologic Consequences of Posture and Exercise

Posture. PAVMs are more common in the lower than upper lobes,[7,58] hence for gravitational reasons, the shunt fraction tends to increase when patients stand up: R–L shunt increased from 28.7% to 39% in eight patients on standing.[59] Accordingly, arterial oxygen saturation falls considerably more in patients with PAVMs than in normal individuals, in whom the mean fall in arterial oxygen saturation on assuming the upright posture is only 0.3%.[67] The absolute decrease in arterial oxygen saturation (supine to erect) reflects the size of the R–L shunt, being generally larger for R–L shunts greater than 20%.[59,60,62,64]

Exercise. In the healthy lung, PVR falls on exercise to half its value at rest, because of dilation and recruitment of vessels predominantly in the pulmonary capillary bed. The effects of exercise on pulmonary hemodynamics in a PAVM-affected patient depend on the change in vascular resistance through the shunt channels in relation to the change in the resistance of the normal channels. It is not known what happens to the PVR of PAVMs as overall blood flow increases on exercise; in one group of eight PAVM patients with severe arterial hypoxemia on exercise (arterial oxygen saturation 74% ± 3%), there was an excessive increase in total pulmonary blood flow (142% of predicted) in relation to the observed oxygen consumption ($\dot{V}O_2$), resulting, in turn, in higher than predicted tissue oxygen delivery on exercise.[57] It is reasonable to suppose that, for PAVMs, which lack a capillary network and have dilated vessels, vascular resistance will fall somewhat less than that of normal lung, and the R–L shunt fraction will decrease on exercise. In one study comparing the R–L shunt at rest with that on maximal exercise, a fall in shunt fraction of 1% to 10% was demonstrated for four of six patients with larger and treatable PAVMs (postembolization residual shunts <10%), suggesting that these bigger sacs do not enlarge further as pulmonary flow increases.[60] In the same study, however, the R–L shunt fraction increased (38% to 47%) in the six patients with diffuse small PAVMs (feeding vessels ≤ 2 mm diameter), suggesting that the smaller PAVMs may be more compliant.[60]

The change in arterial oxygen saturation from rest to exercise depends both on the change in the shunt fraction and the fall in mixed venous oxygen saturation on exercise. For PAVM patients, overall, the fall in arterial oxygen saturation (rest to exercise) averaged 6% for mean shunts greater than 30%,[57,60] 3% for mean shunts of 20% to 25%,[58,60,62] and 1% to 2% for mean shunts less than 12%.[62] The importance of a fall in mixed venous oxygen saturation on exercise is demonstrated by a study involving 18 patients (R–L shunt at rest 42% ± 13%),[57] in whom R–L shunt fraction (which increased in 12 patients and decreased in 6) and arterial oxygen saturation were measured simultaneously. By interpolation, zero change in R–L shunt during submaximal exercise at 30 to 75 watts predicted a 3% fall in arterial oxygen saturation on exercise, reflecting the fall in mixed venous oxygen saturation on exercise.

Overall, gas-exchange efficiency in terms of the ventilatory equivalent ($\dot{V}E/\dot{V}O_2$) is abnormally high on exercise; observed values are directly related to the exercise R–L shunt, and inversely related to exercise arterial oxygen saturation.[57] Work capacity is well preserved in PAVM patients, even when arterial oxygen saturation on exercise is less than 80%. There is a relationship between exercise capacity in watts (as % of predicted) and the resting R–L shunt; for mean shunts greater than 20%, maximum power output was 65% to 75% of predicted, increasing to 75% to 85% of predicted for mean shunts of 10% to 15% and exceeding 90% for mean shunts less than 10%.[62,64]

Pulmonary Hypertension

Pulmonary hypertension has been recognized in a number of HHT patients.[55,61,68–70] As recently reviewed,[65] the causes of pulmonary hypertension in HHT are diverse, as in the normal population.[71] Two forms of pulmonary hypertension predominate in HHT, true pulmonary hypertension phenotypes,[61,69,72] and a postcapillary pulmonary hypertension occurring in the context of high-output cardiac failure secondary to hepatic AVMs, a potentially reversible form of pulmonary hypertension.[73] Mixed pictures are also observed.[65] The frequency of pulmonary hypertension and hepatic AVMs differs with HHT genotype: pulmonary hypertension phenotypes and hepatic AVMs are more common in HHT type 2—due to *ACVRL1* mutations—than in HHT type 1—due to *ENG* mutations.[69,71,74] Although pulmonary hypertension in HHT was initially considered attributable solely to *ACVRL1* mutations, there are now rare reports of pulmonary hypertension associated with *ENG* mutations, and both genes are to be included in the latest World Health Organization classification of pulmonary hypertension.

The overall prevalence of pulmonary hypertension in HHT is low. Catheter-based studies in a group of 143 PAVM/HHT patients, mean age 47 (range, 8 to 78) under-

going PAVM embolization, identified median (interquartile range) values for PPA as 23 (19 to 27) mm Hg systolic, 7 (5 to 9) mm Hg diastolic, and 13 (11 to 16) mm Hg mean, compared to normal values of 13 to 26, 6 to 16, and 7 to 19 mm Hg, respectively; there was a significant increase in PPA with age.[65] While PPA mean exceeded 20 mm Hg in 9 of 143 patients (6%), only 2 referred from services other than specialized pulmonary hypertension units had mean PPA values exceeding 35 mm Hg.[65] In an echocardiographic study of 68 HHT patients from a separate HHT population whose mean age was 51 years (range, 19 to 84), estimated systolic PPA values (40 to 58 mm Hg) were above the normal range in 9 (20.5%).[70]

Clinical Features

Respiratory Symptoms

Dyspnea. Dyspnea is the respiratory symptom most commonly reported by PAVM patients, but this is present in under 50% of all cases (see Table 54-1) and may not be appreciated until after the condition has been treated. One recent series of 219 consecutive PAVM patients stratified the proportion of dyspneic patients according to the degree of hypoxemia, and indicated that PAVMs generally result in symptomatic dyspnea only when resting arterial oxygen saturations are below 80%.[2,65]

Hemoptysis. The fragile vessels in HHT should be more prone to hemorrhage than normal pulmonary vessels but, surprisingly, hemoptysis and hemothorax are relatively rare features for PAVMs (see Table 54-1), with two important exceptions: (1) spontaneous and postembolization systemic arterial blood supply to PAVM sacs,[48,71] and (2) pregnancy-associated changes.[46] Both conditions place patients at higher risk of hemorrhage from PAVMs, which may be massive and life-threatening.

Chest Pain. Pleuritic chest pain of uncertain etiology occurs in up to 10% of PAVM patients (see Table 54-1). PAVM associations are likely to be overestimated, however, in series that do not correct for ascertainment bias of incidental PAVM detection following protocol-driven computed tomography (CT) scans for suspected pulmonary embolism.[2]

Strokes and Cerebral Abscess

PAVMs pose a substantial risk to patients because of paradoxical emboli leading to cerebral abscess or ischemic stroke, as repeatedly reported in high proportions of patients in historical series (see Table 54-1).[6,75,76] In a more recent series of 219 PAVM patients, in which correction was made for ascertainment bias (i.e., diagnosis of PAVMs because of the occurrence of stroke/abscess), the respective rates were 9% for cerebral abscess and 11.3% for ischemic stroke (Fig. 54-5).[2] Relative

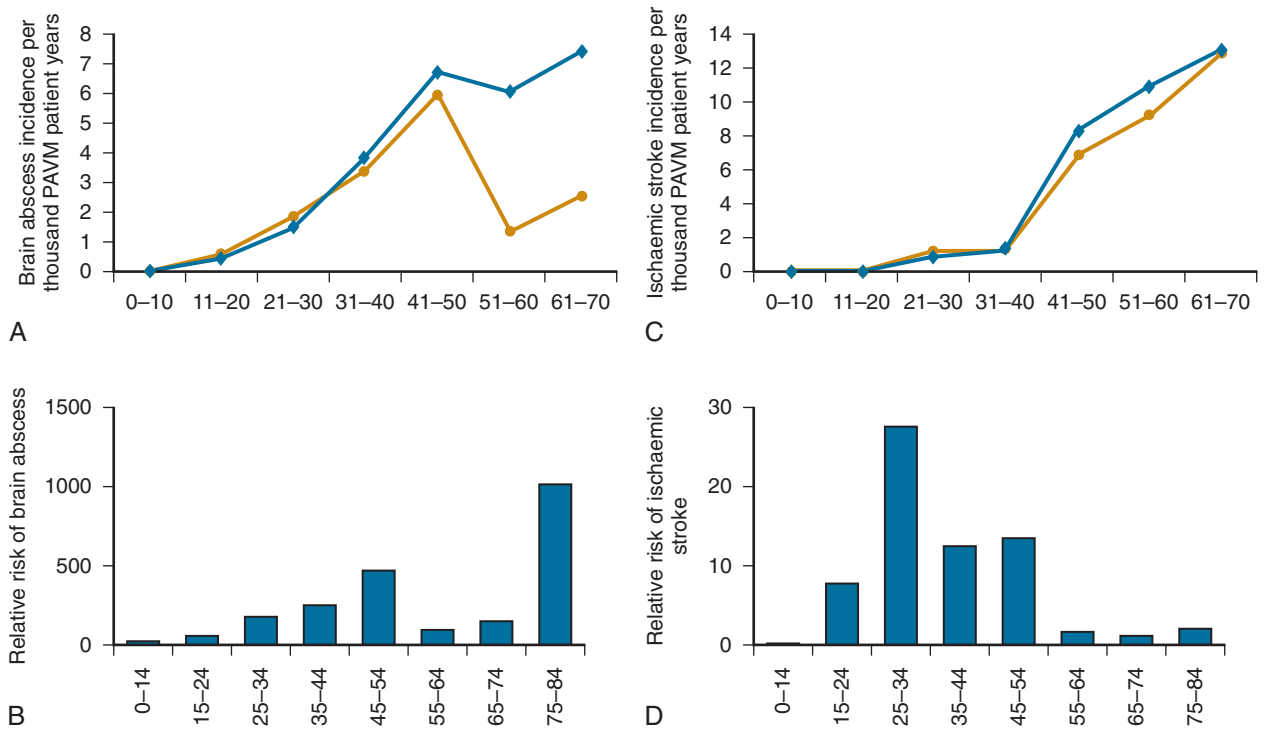

FIGURE 54-5 ■ Age-specific incidence rates and relative risks of brain abscess and ischemic stroke. Age-specific incidence rates of brain abscess **(A)** and ischemic stroke **(C)** for all patients (*diamonds/blue lines*), and patients excluding ascertainment bias (*solid circles/brown lines*). Relative risk (fold increase) for brain abscess **(B)** and ischemic stroke **(D)** for PAVM patients, excluding individuals who presented because of their stroke/abscess. Brain abscess rates are compared to the Olmsted County, Minnesota, series[77]; ischemic stroke to the U.K. Oxfordshire stroke study.[78] (Redrawn from Shovlin CL, Jackson JE, Bamford KB, et al: Primary determinants of ischaemic stroke and cerebral abscess are unrelated to severity of pulmonary arteriovenous malformations in HHT. Thorax 63:259–266, 2008.)

risks compared to control populations[77,78] were particularly high in young adults.[2] The risks of stroke/abscess for PAVM patients are poorly recognized and were not mentioned in a recent authoratitative set of guidelines for stroke prevention.[79] Evidence is now available that failure to recognize stroke/abscess risk leads to referral delays of 6.8 years (95% CI, 4.1 to 9.5 years) for patients with respiratory symptoms, and 7.5 years (95% CI, 4.3 to 10.8 years) for asymptomatic patients compared to 1.1 to 1.7 years for patients diagnosed either by post-stroke/abscess investigation or by screening programs.[2]

Small studies utilizing univariate analyses had suggested that neurologic complications were more common in patients with more severe PAVMs, defined by either PAVM size[80] or diffuse characteristics.[48] By contrast, a recent cohort study of 219 consecutive PAVM patients utilizing the Anderson Gill extension of the Cox proportional hazards models indicated that—contrary to expectations—there was no clear relationship between the risk of ischemic stroke or cerebral abscess and the presence of any of six markers of PAVM severity (symptoms, arterial oxygen saturation, R–L shunt, PAVM multiplicity, diameter of largest feeding vessel, or presence of small untreatable PAVMs); in addition, stroke risk was also unrelated to conventional neurovascular risk factors such as smoking, hypertension, diabetes mellitus, atrial fibrillation, and hypercholesterolemia.[2] There was a very strong association between ischemic stroke and low mean PPA (hazard ratio 0.89 [95% CI, 0.83 to 0.95] per mm Hg increase, $P < 0.0001$), as well as strong associations between cerebral abscess and male gender and dental microrganisms.[2]

Migraines

An excess of migraine first noted in HHT populations[81,82] was subsequently highlighted in observational PAVM series.[7,80] A clear association between migraine and the presence of PAVMs was established in a series of 538 HHT patients with a mean age of 39 years[83]: the overall migraine prevalence was 16%, compared to general population figures of 10% to 12%,[84] with a statistically significant excess of migraine in the patients with PAVMs compared to those without (21% vs. 13%, $P = 0.02$).[83] In a further study of 116 HHT patients, who were compared to an age- and sex-matched control group, there was a higher prevalence of migraine in both HHT patients with PAVMs (39.6% vs. 19.8%, $P < 0.001$) and HHT patients without detectable PAVMs (26.3% vs. 11.5%, $P = 0.003$).[85]

Pregnancy

Case reports and small series indicated that both PAVM hemorrhage,[46,86,87] and PAVM growth[53,86,87] could occur during pregnancy. A recent study of 484 pregnancies in women with HHT and PAVMs demonstrated that 1.0% (95% CI, 0.1% to 1.9%) of pregnancies resulted in a major PAVM bleed, and 1.0% (95% CI, 0.13% to 1.9%) resulted in maternal death.[46] In four women, the severity of PAVMs associated with life-threatening hemorrhage could be evaluated: two had small PAVMs associated with normal arterial oxygen saturations and near-normal R–L shunts; none had evidence of pulmonary hypertension.[46] Moreover, in women experiencing a life-threatening event, prior awareness of HHT or of a diagnosis of PAVM was associated with improved survival ($P = 0.041$).

Diagnosis

Classic PAVM cases with large R–L shunts are easy to diagnose because of cyanosis, clubbing, a vascular bruit, and characteristic chest radiographs displaying lobulated masses and dilated feeding arteries and draining veins. Detection of smaller PAVMs, however, often requires a high degree of clinical suspicion. Many patients are diagnosed as a result of a chest radiograph obtained either routinely or for nonspecific respiratory symptoms, often proven by subsequent thoracic CT scan. In other cases, PAVM screening in an at-risk population will be required in order to confirm or refute the diagnosis of PAVMs.

Radiology

Chest radiographs may demonstrate one or more well-circumscribed lobulated masses, connected by prominent blood vessels to the hilum (see Fig. 54-1). Careful scrutiny is required to detect lower lobe PAVMs, which may be partially obscured by one of the hemidiaphragms on posteroanterior chest radiographs, and which may present as subtle abnormalities, particularly for smaller PAVMs. Before 2007, there was a widespread opinion that the only PAVMs of clinical significance had feeding artery sizes larger than 3 mm, and the goals of many screening programs reflected this. Data presented in this era were that the chest radiograph was abnormal in 60% to 90% of instances.[58,62,88,89] It is anticipated that the frequency of positive standard frontal radiographs will fall further as smaller PAVMs are sought, in keeping with the recognition that these are an important cause of neurologic complications.[2,90]

Spiral (or helical) CT usually demonstrates the anatomy of PAVMs and their feeding vessels[91]; the radiation burden is greatly lessened and the resolution improved by the use of newer multislice (multidetector) CT protocols, which limit x-ray exposure to a single short breath-hold scan, and which allow elegant three-dimensional reconstructions of the images (see Fig. 19-21). Where there are difficulties with interpretation of dilated and apparently vascular structures, confirmation of R–L shunting may be helpful. Magnetic resonance imaging has been less effective than CT or pulmonary angiography because small PAVMs with rapid blood flow are not visualized.[92] Methodology, though, is improving,[93] and this modality provides no radiation exposure. But the frequency of its use may not increase as attention focuses on identification of smaller yet clinically significant PAVMs.

Measurement of Right-to-Left Shunt

Two techniques for measurement of R–L shunt are in common usage: (1) measurement of arterial P_{O_2} breathing 100% oxygen, and (2) ^{99m}Tc-MAA lung and kidney scans, both of which have proved useful in monitoring outcomes after coil or balloon embolization treatment for PAVMs.[58,62] R–L shunt measurements by either of these methods may confirm a diagnosis suspected on clinical grounds and provide useful follow-up data, but as shown in Table 54-3 (electronic version), they do not have sufficient sensitivity for use as a screen to exclude the presence of PAVMs.

100% Oxygen Breathing. In the classical technique, arterial P_{O_2} and hemoglobin concentration are measured after 100% oxygen has been breathed for 15 to 20 minutes, including periodic deep breaths, to wash nitrogen out of the lungs. In healthy subjects, the R–L physiologic shunt is usually less than 5% of the cardiac output and represents blood draining into the left atrium and ventricle from the bronchial and coronary circulations plus blood perfusing nonventilated alveoli. Rather than quoting the measured arterial P_{O_2} value, an estimated R–L shunt is usually calculated as a percent of the cardiac output using the shunt equation shown in the appendix; the resulting value depends on assuming an arteriovenous oxygen content difference, generally the standard amount of 5.0 mL/100 mL, even though the value is somewhat higher than that actually measured in the majority of PAVM patients: 4.4 mL/100 mL (attributed to the high resting cardiac output in PAVMs). Shunt size is therefore slightly underestimated: a 10% calculated shunt was measured as 11%.[63]

Radiolabeled Particles. This method measures a truly anatomic shunt, rather than a physiologic estimate of the anatomic shunt. After intravenous injection, ^{99m}Tc-radiolabeled human serum albumin particles (macroaggregates, 10 to 80 μm, or microspheres, 7 to 25 μm) normally impact in small branches of the pulmonary arterioles, generating the classical perfusion scan images (Fig. 54-6). In the presence of an anatomic shunt in the heart or lungs, a fraction of the particles, proportional to shunt flow, will escape into the systemic circulation and impact in systemic capillary beds. The R–L shunt can be measured following gamma camera measurements of activity over the lung fields and over the right kidney. Assuming 10% of the cardiac output goes to the right kidney, the R–L shunt is measured by the ratio of (right kidney counts × 10)/injected dose (*the kidney:dose method*), or (right kidney counts × 10)/[total lung counts + (right kidney counts × 10)] (*the kidney:lung method*).[60] Ideally, renal flow should be measured directly using a second tracer (*kidney2:lung method*), as the actual flow fraction to the right kidney deviated from the assumed 10% by ± 3% (standard deviation) absolute in one study.[63] The limits of agreement for a 100% O_2 shunt of 20% were 14% to 29% for the kidney:dose method,[64] 5% to 35% for the kidney:lung method, and 12% to 28% for the kidney2:lung method.[63] Owing to these differences, the methods cannot be used interchangeably in the follow-up of shunt size in a particular patient.

A B

FIGURE 54-6 ■ Right-to-left shunt quantification by radionuclide scans. **A,** In contrast to normal perfusion scans, the activity is not restricted to the lungs (included for reference). Renal images are used for quantification. **B,** Cerebral imaging illustrating risk of paradoxical microemboli.

Contrast Echocardiography. The method of contrast echocardiography (CE; synonym "echo-bubble") demonstrates intrapulmonary shunts by tracing the circulatory transit of microbubbles generated by intravenously injected echocontrast material. In contrast to intraventricular cardiac shunts—in which contrast passes immediately from the right to the left ventricle—R–L shunting through PAVMs results in a delayed appearance of microbubbles in the left side of the circulation, either the left ventricle or carotid artery. Bubbles arriving up to 10 cardiac cycles later have been associated with PAVMs[94]; most recent studies, however, utilize a delay of 3 to 4 cardiac cycles to distinguish PAVMs from a patent foramen ovale (Table 54-4, electronic version). Grading has been recommended based on the number of microbubbles appearing in the left ventricle on a single frame. Initial reports utilized a descriptive 5-point scale,[95] with individual groups interpreting this in varying ways (see Table 54-3). Specificity has been a concern (see Table 54-4): intrapulmonary shunting was demonstrated in 5 of 19 healthy subjects by injection of contrast directly into the pulmonary artery, bypassing any intracardiac shunt, in one early study,[96] and by CE in 7% of a more recent group of 100 control subjects, with a detection rate for patent foramen ovale of 6% in both controls and HHT patients.[97]

CE consistently detects more intrapulmonary R–L shunting in HHT patients than other PAVM screening modalities.[88,94–96,98] Initial reports in the adult HHT population suggested 100% sensitivity,[88] but false negatives have been reported.[99,100] Nevertheless, the negative predictive value of a negative CE assessed in several specialized units is of the order of 98%.[100] The positive predictive value of a positive result is more variable, with sensitivities in different studies ranging from 21% to 74% (see Table 54-3).

It was soon recognized that patients with lesser CE shunt severity were less likely to have a PAVM detected by subsequent studies. In a retrospective study of 104 patients[94] and a prospective study of 190 patients,[97] patients with grade 1 (minimal) opacification had a positive predictive value for PAVMs of 0 to 0.02 (see Table 54-4). In contrast, in another prospective study of 105 patients, grade 1 CE was associated with a positive predictive value of 0.22.[101] All three studies utilized CT scans as the "gold standard" and, where CT scan detection

rates were presented, positive detection rates were comparable (23% of full screened population, 74% of grades 2 and 3 shunt[97]; 36.5% of full screened population, 67% of grades 2 and 3 shunt[101]). Recent data suggest that shunt grade on CE may influence the likelihood that such lesions will be amenable to embolization therapy; in a prospective series of 105 patients with a positive R–L shunt, none of the patients with PAVMs on chest CT and a CE grade 1 or 2 shunt were candidates for embolotherapy.[101] However, in the other studies, grade 2 positive shunts were associated with PAVMs of a size amenable to embolization.[94,97]

Screening Patients

The overall incidence of PAVMs in the general population is so low (~0.01%) that targeted screening protocols are required. Dyspnea, hemoptysis, or other clinical symptoms are not appropriate to target screening because PAVM patients are often asymptomatic, and these symptoms occur commonly in the non-PAVM population. Suitable populations to screen would be patients with HHT (approximately 50% of whom have PAVMs), patients with cerebral abscesses, and any young patient with an embolic CVA, even if an apparent alternative cause is present.[102] The high proportions of HHT/PAVM patients undiagnosed at the time of their PAVM-induced ischemic stroke or cerebral abscess (in one series 66.7% and 64.3% respectively)[2] highlight the importance of robust PAVM screening programs for the HHT population. Screening HHT patients poses a particular difficulty as most individuals with HHT are unaware they have the disease, plus as demonstrated in Table 54-3, there are no cut-offs for available tests with sufficient sensitivity to rule out clinically significant PAVMs.

PAVM centers differ in the exact screening modalities employed, according to the particular expertise of the institution. Common to all programs are the policies of minimizing the radiation burden in an often young population, having a sensitive screen to detect all clinically significant PAVMs, and concern to avoid missing any treatable PAVMs: the choice usually lies between thoracic CT scans and CE. Many specialized PAVM units with extensive CE expertise utilize CE as a first-line screen for PAVMs, reserving the radiation exposure of CT scans for patients with a positive shunt and, potentially, a CE shunt of a particular severity.[101] At other institutions, CE is not used routinely due to time, training, and resource implications given the majority of scans will be positive, and the new generations of multislice CT scanners mean that a diagnosis of PAVMs can be made efficiently and quickly using a single-breath thoracic CT scan. Some centers will use pulmonary angiography as a tool to confirm the diagnosis, but in order to reduce the radiation burden, we prefer to restrict angiography to therapeutic embolization sessions.

Management

A "wait and see" policy is indicated only when physician and patient are fully informed of the risks of leaving PAVMs untreated, bearing in mind that PAVMs are not benign lesions that can be safely ignored.

Embolization

Percutaneous transcatheter embolization, which was introduced in 1978,[103,104] is now the treatment of choice for the vast majority of patients. More than 700 pulmonary AVM embolizations have been reported.

The technique of embolization at our institution has been described previously.[62] We start by administering prophylactic antibiotics 1 hour before the combined diagnostic and therapeutic procedure. First, a pigtail catheter is inserted to measure pulmonary artery pressure and to obtain angiograms of each lung. Then, the catheter is exchanged for one appropriate for emolization of the feeding vessels of the AVMs: usually with detachable metallic coils, plugs, or balloons, depending on the size and blood supply of the malformation. Occluding devices must be placed as close as possible to the neck of the malformation in an attempt to avoid the occlusion of normal pulmonary artery branches and to reduce the risk of the develoment of a bronchial arterial collateral supply to the sac (see later).

In individual patients, if the anatomy of the PAVMs precludes "conventional" embolization, other techniques are required such as packing the venous sac with coils. Treatment of particularly large and high-flow PAVMs may be achieved with coils inserted through the lumen of an occluding balloon catheter temporarily inflated to obliterate flow within the feeding vessel.[62] It is unclear how long occlusion is required in order to prevent flow: in one series of patients studied at a mean follow-up of 99 months (range, 63 to 123 months), 8 of 14 detachable silicone balloons were deflated at radiographic chest film follow-up, but at pulmonary angiographic follow-up all embolized malformations were without flow, irrespective of whether or not the balloons were visible.[105] Postembolization, residual shunting through untreatable (<2–3 mm diameter) arterial feeding vessels is common (Table 54-5). For example, in a series of 192 PAVM patients in whom feeding arteries less than 3 mm in diameter were embolized,[2] 70% had residual disease, a finding supported by other studies.[98,106,107]

Long-Term Outcome. Anatomic long-term results of transcatheter embolization have been evaluated by several centers. In the first study, a 2- to 21-year follow-up of after embolization of 64 PAVMs in 38 patients, the treatment success rate was 75%, with delayed recanalization requiring repeat embolization observed in 19%.[108] In a second study, a 1- to 7-year follow-up of 393 embolized PAVMs in 144 patients, recanalization was seen in 6.9% of patients.[105] In a further center, reperfusion was observed in 19 of 112 consecutive patients (17%), with recanalization the most common cause of reperfusion; factors associated with reperfusion included low number of and oversized coils, and proximal placement of coils, in one study,[109] and altered pulmonary hemodynamics (development of pulmonary hypertension or presence

of hepatic AVMs) but not technical embolization parameters in another.[108]

Physiologic Outcome. Physiologic outcomes have improved with time, as shown in Table 54-5. Although substantial improvement in oxygenation is the rule for patients with preembolization hypoxemia,[61,65,106,110] the effects on other pulmonary function measurements are small. Vital capacity and forced expiratory volume in 1 second do not change.[58,62,64] There is a trend for the DL_{CO} and DL/VA (KCO) to improve,[58,64,66] and in one series of 60 patients, the 16 who had a low DL/VA preembolization showed significant improvement postembolization from 78% to 87% of predicted.[66] Exercise capacity, often relatively unimpaired preembolization, may improve in some patients,[64] and not necessarily in those in whom the DL/VA improves.[62] Arterial oxygen saturation at maximum exercise improves significantly, by 6% to 10% in groups with mean preembolization saturation values less than 82%,[62,64] and by 3% to 4% if mean preembolization saturation is 92% or higher.[62]

Clinical Outcome. After embolization in the majority of patients, there will be little improvement in dyspnea or exercise tolerance unless their PAVMs were associated with substantial R–L shunts and hypoxemia. In the authors' experience, hemoptysis often improves; rare preexisting chest pains do not. Clinical improvement therefore usually focuses on the expected improvement in neurologic risk, but until recently, no direct evidence of risk reduction had been presented. Two studies have now demonstrated the clinical efficacy of embolization in improving stroke/abscess risk,[2] and reducing the prevalence of migraine.[111] In the first, a cohort study of 219 consecutive individuals with PAVMs, no ischemic strokes or abscesses occurred in 58 of the 192 treated patients (30.2%) in whom all angiographically visible PAVMs were obliterated at embolization, and there was no evidence of recurrence during follow-up.[2] This group included 13 individuals who had had an ischemic stroke or brain abscess prior to PAVM embolization. Strokes/abscesses did occur in some patients postembolization in this series—as in others—due to small untreatable PAVMs (feeding artery diameter ≤ 2 to 3 mm) in addition to the PAVMs that had been embolized. Overall, the strongest model available demonstrates that embolization at a median age of 45 years significantly reduces the rate of ischemic stroke (P = 0.028).[2] Improvement in migraines following PAVM embolization was demonstrated in a prospective study of 84 patients, with a reduction in prevalence from 45% to 35% after 6 months (P = 0.01).[111] Improvement in migraine was also suggested by a study in a separate population.[112]

Risks of Embolization

In expert hands, embolization is efficacious and complications are rare, though the procedure is not without risk. Successive series highlight a learning curve, and smaller series have higher complication rates. The most common complication is transient pleurisy in up to 10% of patients, particularly those with peripheral PAVMs. Higher rates are seen for patients with diffuse PAVMs.[48] The mechanism for the pleurisy is unknown, but it appears unrelated to pulmonary infarction.[58,62] Angina, due to transient air bubble emboli, has been reduced by the technical advances reported in later series. There are occasional reports of long-term neurologic complications following paradoxical emboli.[113]

Development of Systemic Arterial Supply. The risk of massive hemoptysis from PAVM sacs that persist postembolization and that acquire a systemic arterial collateral blood supply was first highlighted in a small series published in 1998.[114] In view of the known importance of pulmonary-bronchial communications (see "Systemic-to-Pulmonary Vascular Communications" section later), it would not be unexpected for systemic collaterals to develop to supply an area of the pulmonary capillary bed that had lost its pulmonary arterial supply as a result of embolization. In one postembolization series, 13 of 32 patients demonstrated abnormally large arteries of bronchial, inferior phrenic, musculophrenic, internal mammary, or intercostal origin, and this group were more likely to have demonstrated clinical or angiographic evidence of pulmonary infarction as a result of the procedure.[115] Systemic supply is of consequence only if the fragile PAVM sac persists. None of the cases in Brillet and coworkers' series[115] experienced hemoptysis, in contrast to the majority of those in a smaller series.[114] To reduce the risk of development of systemic arterial collateral supply to any persistent sac, standard practice is to place embolization devices as close as possible to the neck of the malformation.[62] This is particularly difficult for patients with diffuse PAVMs, in whom sac persistence is inevitable. Expert institutions differ in the degree to which such PAVMs will be embolized. At our institution, more limited embolization is undertaken and in the presence of ongoing neurologic symptoms or hemoptysis, surgical resection is considered. Other approaches include dense packing of the most severely involved segmental arteries.[48]

Development of Pulmonary Hypertension. PAVM embolization may be expected to elevate PPA, because PAVMs provide low-resistance pathways for pulmonary blood flow. Data on PPA measurements pre- and postembolization were scarce. In three of the first four reported cases, each selected from larger series, PPA increased postembolization, whereas in the fourth it was unchanged.[61,73,116,117] There was also a report of worsening pulmonary hypertension after surgical resection of a PAVM.[118]

PPA measurements before and after successful PAVM embolization, as demonstrated by improved arterial oxygen saturation, were recently reported for 35 patients with measurements from two or more consecutive embolization sessions, and for 8 patients in whom PPA measurements were repeated at the end of embolization in the same session due to higher baseline PPA; there was no evidence of a sustained or acute change in PPA in the majority of patients, and in half, embolization led to a fall in PPA.[65]

Should embolization of PAVMs be performed in patients with severe preexisting pulmonary hypertension? This question was specifically addressed in a recent article evaluating risks-benefits in the light of new data regarding stroke risk,[2,118a] and data indicating that test balloon occlusion did not predict subsequent rise in PPA following definitive embolization.[65] The main indications for PAVM embolization are to reduce the risk of paradoxical embolic stroke/brain abscess, and, for individuals with hypoxemia, to improve dyspnea and exercise tolerance. Because the risk of paradoxical embolic stroke is substantially lower in individuals with higher PPA,[2] and symptomatic relief from dyspnea should not be expected for patients with pulmonary hypertension and arterial oxygen saturations higher than 90%, as was the case in all four patients with severe pulmonary hypertension in their series, the authors concluded that, for patients with preexisting severe pulmonary hypertension, the risks of PAVM embolization generally outweigh potential benefits.[65] It was recognized that the most difficult judgments relate to individuals with severe pulmonary hypertension and major hemoptysis.[118a]

Nonembolization Options

There are circumstances when PAVMs cannot be treated by embolization, the most common reason being that the feeding artery is too small (<2 mm diameter). It is doubtful that advances in transcatheter embolization techniques will permit routine embolization of feeding vessels of less than this size; thus, the issue arises of what to do with patients with small PAVMs not amenable to embolization.

Surgery. Surgery remained the treatment of choice until the 1980s, but was never the ideal solution for the multiple PAVMs of HHT; more recently, however, surgery has been a useful adjunctive therapy for selected cases. There may be circumstances in which small PAVMs are single or sufficiently localized for thoracoscopic resection if embolization is not feasible. At our institution, we reserve this for patients whose condition declares them to be at risk as evidenced by ongoing ischemic strokes or transient ischemic attacks following maximal embolization, as recommended by others.[119] In emergency situations, particularly associated with massive hemoptysis, lobectomy or pneumonectomy may be appropriate.[46,52]

Lung transplantation has been undertaken in a few patients with severe hypoxemia secondary to diffuse disease.[120,121] The long-term complications of untreated PAVMs, however, are likely in most cases to be less than transplantation-associated morbidity and mortality. Three PAVM patients in our clinic (one male, two female) who elected not to proceed with transplantation—after discussion of the risks at two different U.K. transplantation centers—have since remained stable over 15, 16,

and 19 years, respectively, and one patient has had three successful pregnancies. In a retrospective series of 36 patients with diffuse PAVMs for whom follow-up data were available for a mean of 8.5 years (range, 0.12 to 26 years), 24 of the 27 survivors were working or studying full time; one of the deaths was transplantation associated.[48]

Medical Management

Dental Issues. For patients with PAVMs and HHT, owing to the strong link between oral bacteria and cerebral abscess, antibiotic prophylaxis before dental and surgical procedures was recommended based on the endocarditis paradigm.[122-124] Furthermore, the evidence for an association between oral microorganisms and brain abscess was strengthened recently.[2] In the interim, however, the American Heart Association (AHA)[125] and British NICE[126] guidelines were published indicating that antibiotic prophylaxis is no longer required for most patients with structural heart disease at risk of infective endocarditis. This has led to confusion among dentists and medical practitioners caring for PAVM patients. A recent article exploring why PAVM/HHT patients do not fall into the groups considered by the AHA/NICE guidelines provided recommendations to reduce the risk of dental bacteremias, including the use of antibiotic prophylaxis prior to dental procedures.[127]

Pregnancy. In view of the risks of PAVM growth and rupture during pregnancy, female patients should be advised to defer pregnancy pending formal PAVM assesment and treatment. Pregnancies should be managed with close liaison between obstetricians, pulmonologists, and interventional radiologists, using appropriate "high-risk" obstetric management strategies.[46] Patients and their medical practitioners should be alerted to the possibility of hemoptysis or sudden severe dyspnea that requires urgent admission and management: embolization in the second and third trimesters is feasible and safe.[46,127a] The question of whether PAVM embolization should be offered to asymptomatic pregnant women differs between countries; at our institution it is not performed.[46]

Thromboembolic Risks. There are no data on maneuvers to reduce thromboembolic risks, but based on the high frequency of cerebral thromboembolic complications in these patients, and evidence that many have a prothrombotic state,[127b] we suggest that options such as cessation of hormonal therapy, or antiplatelet therapy, should be considered on a case-by-case basis for patients experiencing transient ischemic attacks, even if there is underlying HHT.

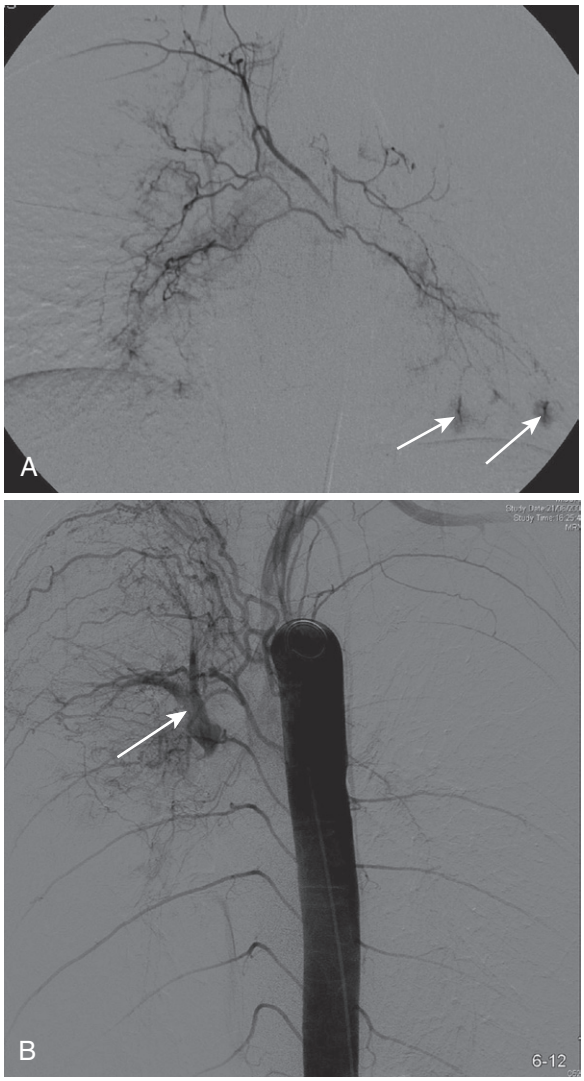

FIGURE 54-7 ■ Diagram showing normal and abnormal bronchial circulations. **A,** Selective digital subtraction angiogram showing normal bronchial arteries. Normal peripheral pulmonary artery branches are opacified (*arrows*) via normal bronchopulmonary anastomoses. **B,** Digital subtraction descending aortogram in a patient with hemoptysis due to previous right apical tuberculosis. There is bronchial and nonbronchial systemic artery hypertrophy supplying the right upper zone, with retrograde opacification of the entire right upper lobe pulmonary artery (*arrow*) via enlarged bronchopulmonary anastomoses.

SYSTEMIC-TO-PULMONARY VASCULAR COMMUNICATIONS

Anatomy

Communications between the systemic and pulmonary circulations are part of normal anatomy, since terminal branches of the bronchial microcirculation communicate with peripheral pulmonary artery branches (Fig. 54-7A). These vessels are functionally important in preventing lung infarction in the great majority of cases of pulmonary embolic disease. Their presence may be detected during specialized functional scans such as contrast-enhanced, time-resolved perfusion MR imaging of regions of the lung in which hypoxic pulmonary vasoconstriction reduces pulmonary arterial supply; late filling might reflect the systemic arterial component.[128]

Normally, there is a profound pressure drop between the systemic and pulmonary vessels, ascribed to *Sperrarterien,* or "blockading arteries," which were first described by von Hayek,[129] and visualized (by scanning electron microscopy of resin-injected sheep lungs) as deep focal constrictions within intrapulmonary bronchial arteries of 100 to 300-μm diameter.[130] In the presence of chronic intrapulmonary inflammatory disease, these normal bronchopulmonary anastomoses enlarge considerably (see Fig. 54-7B), increasing the perfusion pressure to the diseased lung, thereby increasing the likelihood of bleeding (see also Fig. 19-25).

In chronic inflammatory pulmonary disease, especially when located peripherally, additional systemic supply is recruited transpleurally through dense inflammatory adhesions between the lung and the chest wall. Direct communications between systemic arteries and the pulmonary circulation are also observed in several other settings (see later), such as when systemic arteries communicate with the pulmonary artery or its branch via the pulmonary ligament, which encloses the lung hilum. Intralobar sequestration (see "Bronchopulmonary Sequestration" section) is a developmental anomaly in which a systemic artery replaces a segmental pulmonary artery.

Adult (Acquired) Systemic-to-Pulmonary Communications

As noted, abnormally large systemic-to-pulmonary communications form part of the inflammatory response to the presence of chronically inflamed or necrotic lung tissue; the most frequent causes, according to Yoon and colleagues,[131] are pulmonary tuberculosis (usually chronic), aspergilloma (secondary to chronic sarcoidosis or tuberculosis), and bronchiectasis, including that caused by cystic fibrosis[132] (see Fig. 54-7B). Overlying pleural thickening provides transpleural access for systemic vessels from the intercostal, internal mammary, thyrocervical, axillary, and inferior phrenic arteries. For more proximal intrapulmonary disease, vascular hypertrophy and new vessel formation occurs within the bronchial circulation.

Fetal- and Perinatal Systemic-to-Pulmonary Artery Collaterals

During bronchial branching in the developing fetus, the dividing buds are supplied by a capillary plexus derived from the primitive aorta; this plexus later regresses as the growing lung advances and the developing pulmonary artery takes over. Between the 40th and 50th days of gestation, the lungs have a dual source of blood supply.[133,134] Systemic-to-pulmonary artery collaterals arising from the proximal or distal part of the aortic arch persist in later gestation and were detected and found to be functional in 88 of 133 (66%) premature, very-low-birth-weight (<1500 g) infants admitted to the neonatal intensive care unit at a mean gestational age of 28 ± 13 weeks; color Doppler scanning follow-up indicated that the systemic-to-pulmonary artery collaterals declined with maturity, until at 1 year of age only 2 of the original 88 infants still had collaterals.[135]

When present postnatally, these vessels, which provide additional extracardiac L–R shunts, effectively function as miniature patent ductus arterioses, placing the neonate at higher risk of heart failure, which developed in 11% of infants with systemic-to-pulmonary artery collaterals in one series.[135]

Aberrant Congenital Systemic-to-Pulmonary Communications

In addition to persistent fetal systemic-to-pulmonary artery collaterals, other congenital vascular anomalies are recognized, but rarely cause problems. The systemic artery is usually the internal mammary or a coronary artery. Iskandrian and colleagues[136] reported 12 patients with coronary-to-pulmonary artery communications, mostly discovered accidentally during routine coronary angiography for chest pain. Large-flow congenital systemic-to-pulmonary artery collaterals characteristically present in the second or third decade of life with a continuous murmur similar to that of a patent ductus arteriosus. Hearne and Burbank[137] reviewed 11 reported cases of communications between an internal mammary artery and the pulmonary arteries; 8 cases were considered to be congenital, 2 traumatic, and 1 neoplastic in origin.

Cavopulmonary Anastomoses

Systemic-to-pulmonary artery collaterals are a feature of Glenn/Fontan circulations constructed surgically as a palliative correction for tricuspid atresia or a functionally univentricular heart,[138] operations that are also associated with the development of PAVMs in the lung deprived of hepatic venous blood (see earlier section in this chapter). In a retrospective series by McElhinney and associates,[139] 59% of 76 patients had systemic-to-pulmonary artery collaterals on follow-up catheterization at approximately 2.5 years; their presence, however, was not associated with a poorer outcome.

Treatment

Treatment requirements depend upon the presence of symptoms. Even systemic-to-pulmonary artery collaterals derived from coronary arteries generally do not serve to "steal" blood flow from the coronary artery.[136] Whereas earlier cases from series spanning 1947 to 1979 were treated by ligation of the vessels and resection of the lobe, more recent cases were left untreated. Treatment is now offered in three settings: (1) for hemoptysis, the most common complication of acquired systemic-to-pulmonary artery collaterals; (2) for heart failure, predominantly affecting neonates with persistent fetal collaterals[135]; and (3) for patients with Fontan circulations in whom there is concern about induction of high-flow-induced pulmonary hypertension.[139]

Managements of Hemoptysis

Hemoptysis from systemic-to-pulmonary artery collaterals may be massive and require emergency management. Bronchoscopy may help to localize the source of bleeding,[140] but multidetector CT performed during the aortic phase of contrast enhancement is usually more helpful; CT angiograms document the underlying cause of bleeding in most instances and will also clearly demonstrate the presence or absence of hypertrophied bronchial or nonbronchial systemic arteries.[141] In an emergency, angiography takes precedence, with a view to embolization of the bleeding vessels. In 1977, Rémy and associates[142] reported their results of selective bronchial artery angiography and embolization on 105 patients with hemoptysis.

Bronchial artery or collateral vessel embolization is carried out at angiography with particulate polyvinyl alcohol; it is a highly specialized interventional radiology technique.[143,144] Complications are uncommon, but one of the most feared is that of a transverse myelitis, which may occur if inadvertent embolization is performed of a spinal artery arising from an intercostal or bronchial artery. The use of "superselective" coaxial catheters (3-French gauge), with peripheral placement of the tip in a stable position distal to normal arterial branches and without reflux after injection, has made the procedure much safer.[143-145] In 80% to 90% of cases, immediate control of hemoptysis will be achieved,[146] although 20% will rebleed in the first 6 months, and a further 50% will have significant hemoptyses on longer follow-up; repeat embolization is usually helpful in these individuals. While bronchial artery embolization is not curative and the risk of further hemoptysis is always present, embolization can be repeated several times.

Surgery is falling out of favor as first-line treatment for massive hemoptysis for three main reasons: (1) the patient's condition is often poor, (2) the disease is usually extensive and often bilateral, and (3) pleural thickening is present, and traversed by extensive collateral vessels and often adheres the lung to the chest wall. In 10 series, the average perioperative mortality for pleuropulmonary aspergilloma resection was 9% (range, 0 to 23%).[147] Increasingly, surgery is confined to low-risk cases in which recurrent hemoptysis is a problem.

BRONCHOPULMONARY SEQUESTRATION

Classification

Bronchopulmonary sequestration was first described by Pryce[148] in 1946 and defined by him as "an abnormal artery from the aorta supplying a bronchopulmonary mass or cyst which is dissociated from the normally connected bronchial tree." A distinction is usually made between intralobar sequestrations, which share a common visceral pleural investment with the adjacent normal lung tissue, and the much less frequent extralobar sequestrations, which have their own pleural lining that separates them from the remaining lung tissue. Both types have an abnormal systemic blood supply, most often from the thoracic aorta, but in roughly 20% of cases the artery originates from the abdominal aorta; atypical origins of the feeding vessels, even from coronary arteries, are well described. The venous drainage in intralobar sequestrations is generally via a pulmonary vein, whereas in the extralobar variety it is often via the azygous vein, but variations are common.[149]

Pathogenesis

During bronchial branching, which is completed in humans 16 weeks after conception, the dividing buds are supplied by a capillary plexus derived from the primitive aorta; this plexus later regresses. Growth arrest locally of the pulmonary artery during bronchial division may disrupt maturation and tracheobronchial integrity, as well as lead to persistence of the blood supply from the aorta. The developing lung bud lies in close proximity to the developing foregut, from which it is derived, which explains the high incidence of associated foregut anomalies and linkage with congenital cystic adenomatoid malformation. In 1987, Clements and Warner[150] developed an alternative nomenclature and anatomic classification that unifies these embryologically related anomalies, many of which are now being diagnosed in utero owing to the extensive use of prenatal imaging studies.[151]

Clinical Features

Most patients with sequestrations are symptomatic, and the diagnosis is made in 50% to 60% before the age of 20. Diagnosis in adults older than 50 is uncommon, but a series of 17 patients was recently reported.[152] According to a 1979 review of 540 cases by Savic and colleagues,[153] 15% of patients are asymptomatic.

Typically, symptoms develop during infancy or childhood and are characterized by chronic cough and recurrent pneumonias and episodes of acute bronchitis, which are related to underlying progressive bronchiectasis, scarring, and cyst formation in the poorly communicating sequestered lung. Hemoptysis is also common. Chest radiographs classically show a left basilar density, but involvement of the right basilar region also occurs; much less commonly, sequestrations may involve more superior intrapulmonary anatomic units.

The diagnosis depends on demonstrating the anomalous systemic arterial blood supply, which can reliably be shown by multislice (multidetector) CT techniques (Fig. 54-8), which as described in Chapter 19 allow three-dimensional reconstructions to be made that vividly display not only the arterial input but the venous drainage as well (see also Fig. 19-24). MR angiography is also a valuable means of diagnosing sequestration, and has the advantage of not involving ionizing radiation,[154] but this may be offset by longer imaging times when compared with CT, particularly in pediatric patients, in whom sedation is required.[149]

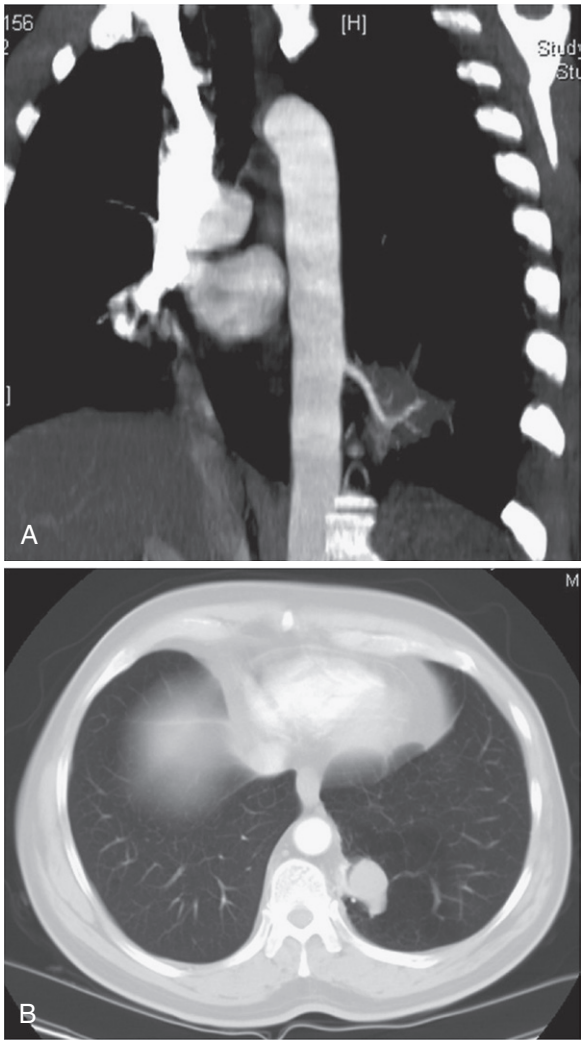

FIGURE 54-8 ■ Pulmonary sequestration presenting as a lung mass at the left lung base in an asymptomatic 55-year-old man (found on employment radiograph). **A,** Coronal reformation from contrast-enhanced multislice CT demonstrates the systemic arterial blood supply, which arises from the lower thoracic aorta and travels to a soft tissue mass in the left lower lobe. **B,** Axial image on a lung window demonstrates the soft tissue mass with hyperinflation of the surrounding lung due to disruption of the normal airway to this segment and resulting lung trapping.

Treatment

The recommended treatment of patients with symptomatic sequestrations is surgical removal of the affected lung, which often requires a lobectomy but which can sometimes be carried out by segmentectomy to conserve the normal portion of lung in patients with intralobar sequestrations. Recently, the feasibility of using video-assisted thoracic surgery has been demonstrated, but its final role in treatment is unknown.[155] A prerequisite of operative intervention is thorough definition of the origin and course of the aberrant arterial blood supply; Lee and coworkers[149] believe, also, that an additional surgical advantage lies in the demonstration of the venous drainage pathways by multislice CT examination. In patients in whom resection cannot be performed for technical reasons, ligation or embolization of the feeder artery is advised to prevent hemoptysis; embolization may also be performed preoperatively to help reduce blood loss.

PULMONARY ARTERY ANEURYSMS

Pulmonary artery aneuryms (PAAs) are rare vascular anomalies. Historically they were classified as peripheral (predominently tuberculous) or proximal (predominently syphilitic). It is now recognized that PAAs can develop in a wide range of clinical settings and that the distinction between large and medium to small vessels is by no means absolute.

Although tuberculosis and syphilis are no longer the main precipitating factors, there is still some merit and pathophysiologic basis to the proximal-versus-peripheral classification. Proximal PAAs develop primarily due to inherited defects in the vascular wall, or to trauma due to pulmonary hypertension or jets of blood impacting on specific sites, such as distal to pulmonary stenosis or opposite a patent ductus arteriosus. They can also result from focal endovascular infection or vasculitis, or disease of the vaso vasorum as in syphilis. Peripheral PAAs are more usually attributed to infection—either adjacent to an area of infected lung (as in Rasmussen's aneuryms), or due to endovascular seeding of infected foci—or to vasculitis. In many cases more than one etiologic factor is present, and it is not clear whether an intrinsic vascular defect, endovascular trauma, or infection is primarily responsible for the development of the aneurysm. Multiple aneurysms should raise the possibility of underlying Behçet's disease.

Pulmonary artery aneurysms are unstable structures: As the radius of the aneurysm increases, the wall tension (T) becomes higher at any given level of intravascular pressure, thus increasing the dilating force via the Laplace relationship:

$$T = \frac{pr}{2d}$$

where p is the intravascular pressure, r the radius of the aneurysm, and d the thickness of its wall. Although only some aneurysms continuously dilate via this vicious circle until they rupture, all have the potential to do so. The main risks of these unstable structures are pulmonary hemorrhage (which may be life-threatening from any site), and dissection for proximal lesions. In dissecting aneurysms, blood tracks within the arterial wall following an intimal tear. False or pseudoaneurysms occur when all layers of the wall are breached, but the blood is contained by the surrounding tissues or by clotting. If an aneurysm ruptures and is not contained in this way, blood may enter the bronchus sharing the common bronchovascular connective tissue sheath, causing hemoptysis and sometimes death from exsanguination.

Etiology and Pathogenesis

Infection

Small artery pseudoaneurysms are generally infective (mycotic) in origin, often mycobacterial or fungal. Pathologically, granulation tissue replaces a large part of the arterial wall. Tuberculosis and syphilis used to be the most common causes. Tuberculous Rasmussen's aneuryms, classically described as the tortuous abnormal vasculature of tuberculous cavity walls, were seen in 4% of autopsies (45 of 1114) in patients with chronic pulmonary tuberculosis, and caused death in the majority of those patients in whom they were present.[156] Rasmussen's aneuryms remain important; in 1984, they were reported in approximately 5% of cases of massive hemoptysis.[157] In contrast, in the era of untreated syphilis only 8 cases of proximal syphilitic PAA were found in 109,571 autopsies.[158]

Although the contribution of syphilis in particular has waned, infection remains a relatively common etiology, particularly secondary to tuberculosis or lung abscess. Other in situ pulmonary arterial wall infections occur from endovascular seeding from right-sided heart valve vegetations, typically in chronic drug abusers[159] or, in one case, from *Candida* endocarditis introduced by a Swan-Ganz catheter.[160]

Vascular Trauma

Large artery aneurysms have a variety of causes, the most common of which is congenital heart disease, especially patent ductus arteriosis; less common causes are pulmonary valve stenosis, atrial or ventricular septal defect, and Fallot's tetralogy. The mechanism is thought to be trauma to the artery wall from jets of blood ejected at high velocity by ventricular contraction. External sources of trauma include penetrating injuries such as stab wounds[161] and tube thoracostomy.[162] Disruption of the arterial wall during inflation of pulmonary artery balloon catheters has led to a significant number of false aneurysms, particularly in patients with preexisting pulmonary hypertension or on anticoagulants, though this remains a rare complication.[163] Catheterization can cause a pseudoaneurysm if the vessel wall is lacerated by the catheter tip and bleeding is contained, temporarily or permanently, by the surrounding tissues. Alternatively, a true aneurysm, with or without rupture, can develop if the catheter balloon is overinflated in a small branch of the pulmonary artery. Kearney and Shabot,[164] in a retrospective review of 32,442 in patients requiring catheterization from 1975 to 1991, found that catheter-induced pulmonary artery rupture associated with hemoptysis occurred in 10 patients (0.03% incidence). The risk factors were both technical, related to peripheral placement and overinflation of the balloon; and pathophysiologic, the most important of which was an age greater than 60 years, which reflects the greater fragility of pulmonary arteries in the elderly.

Weakness of the Arterial Wall

Vascular wall weakness may predispose to aneurysm formation. This most commonly occurs in the context of vasculitis, presumably from disease of the vasa vasorum, which originate from the bronchial circulation. Large artery aneurysms have been reported in patients with giant cell arteritis.[165] Multiple aneurysms may occur in Behçet's syndrome or in its variant, the Hughes-Stovin syndrome.[166] Pulmonary hypertension, when associated with atheromatous disease and cystic necrosis of the media, may lead to dissecting pulmonary artery aneurysms. Similarly, cystic necrosis and dissecting aneurysm are also caused by fibrillin deficiency in Marfan syndrome.[167] In many cases more than one etiologic factor is present, and it is not clear whether an intrinsic vascular defect, endovascular trauma, or infection is primarily responsible for the development of the aneurysm.

Diagnosis and Treatment

Pulmonary artery aneurysms usually come to light during the investigation of an unusual mass on a routine chest radiograph or during the workup for hemoptysis. Echocardiography (including transesophageal echocardiography), CT scanning, and MR imaging are replacing angiography as first-line diagnostic investigations.[168] In the absence of hemoptysis, treatment should first be directed to the underlying cause (such as infection, vasculitis, pulmonary hypertension, and congenital heart disease). Such measures may not be possible in patients with hemoptysis in whom emergency treatment of the aneurysm is required. When the aneurysm does not include the pulmonary trunk or main pulmonary arteries, embolization is the treatment of choice using metal coils or detachable silicone balloons. Embolization is also becoming the preferred choice for large artery aneurysms.[165] When a pulmonary artery pseudoaneurysm is demonstrated, usually during selective bronchial arteriography—because of pulmonary artery opacification via a systemic artery–to–pulmonary artery shunting—both bronchial and pulmonary artery embolization is likely to be necessary to control bleeding.[169]

Proximal aneurysms have been repaired by a variety of surgical techniques, including pulmonary artery banding or excision of the aneurysm and prosthetic patch replacement.[170] Stents and grafts inserted endovascularly are likely to replace open heart surgery in some instances.[171] Surgical resections in this group have been superceded as they result in excessive loss of parenchymal tissue, and carry a high morbidity and mortality. Lung tranplantation may be an option in patients with underlying primary pulmonary hypertension.[172]

Tables 54-3 and 54-4 can be found on Expert Consult

KEY POINTS

- Over 90% of PAVMs occur in individuals affected by the genetically determined vascular disorder hereditary hemorrhagic telangiectasia, which is inherited as an autosomal dominant trait with varying phenotypic patterns.
- Right-to-left shunting of blood through PAVMs leads to hypoxemia and paradoxical emboli presenting clinically as cerebral abscess or ischemic stroke.
- Diagnosis is facilitated by three-dimensional multislice CT techniques or contrast echocardiography. Two non-interchangeable techniques are available to quantify the magnitude of R–L shunting.
- Embolization of PAVMs with coils, plugs, or balloons generally decreases R–L shunting and the risk of paradoxical emboli. Small vessel malformations are difficult to close.
- Systemic to pulmonary communications are apt to be asymptomatic but may cause heart failure in neonates and hemoptysis in later life.
- Bronchopulmonary sequestrations are supplied by an abnormal systemic artery, usually from the aorta, and lack a normal communication with the tracheobronchial tree. Symptoms, if they develop, may start at a young age and are characterized by cough and recurrent infections. Treatment is surgical removal.
- Pulmonary artery aneurysms are rare vascular abnormalities of varying etiology, whose major complication is hemoptysis. Diagnosis is usually made by CT scanning or MR imaging. Treatment is directed at the underlying cause (infection, vasculitis, pulmonary hypertension, or congenital heart disease); hemoptysis is best treated by embolization.

Increased Pressure Edema

Increased Permeability Edema

OVERVIEW

INTRODUCTION

Excessive extravascular water in the lungs (pulmonary edema) is a common clinical problem. It is always a manifestation of a serious underlying disease or disorder. Pulmonary edema can be life-threatening, but effective therapy is available to rescue patients from the deleterious consequences of disturbed lung fluid balance. The cause of the disturbance often can be identified and, in many instances, corrected. Because rational and effective therapy depends on understanding basic principles of normal and abnormal liquid and solute transport in the lungs, this chapter begins with a brief overview of the major factors that govern fluid filtration in the lungs before turning to the pathophysiology of pulmonary edema and acute lung injury (ALI). For further information, the reader is referred to the detailed description of the regulation of fluid balance in the lungs, including its anatomic basis and pharmacologic influences, that is provided in Chapter 6. This chapter emphasizes the diagnosis, treatment, and outcome of pulmonary edema and ALI, with an update from recent randomized clinical trials.

PATHOPHYSIOLOGY OF PULMONARY EDEMA AND ACUTE LUNG INJURY

Pulmonary edema occurs when fluid is filtered into the lungs faster than it can be removed. Accumulation of fluid can have serious consequences on lung function because efficient gas exchange cannot occur in fluid-filled alveoli. Lung structure relevant to edema formation and to the forces governing fluid and protein movement in the lungs has been the subject of classic and more recent reviews.[1-7]

There is always a net outward flux of fluid and protein crossing from the vascular space into the interstitium in the lungs because the balance of driving forces normally causes filtration out of the bloodstream and the microvascular endothelium is a leaky barrier. *Leaky* is a relative term: Lung lymph flow normally is less than 0.01% of lung blood flow. Because fluid filtration in the lungs is not limited to capillaries, the term *microvascular* is used throughout this chapter to refer to the sites where fluid exchange occurs. Because of the vast surface area of the lungs, most fluid and protein exchange in the lungs occurs across the interconnecting network of capillaries

embedded in the alveolar walls. Exchange can also occur across capillaries located in the interstitium at alveolar wall junctions (*corner vessels*) and across small interstitial arteries and veins. Their thick walls and small surface area probably limit fluid exchange in larger vessels in the lungs.

The essential factors that govern fluid exchange in the lungs are expressed in the Starling equation for the microvascular barrier:

$$Jv = LpS[(Pc - Pi) - \sigma d\,(\pi c - \pi i)]$$

where Jv is the net fluid-filtration rate (volume flow) across the microvascular barrier; Lp is the hydraulic conductivity ("permeability") of the microvascular barrier to fluid filtration (a measure of how easy it is for water to cross the barrier); S is the surface area of the barrier; Pc is the pulmonary capillary (microvascular) hydrostatic pressure; Pi is the interstitial ("perimicrovascular") hydrostatic pressure; πc is the capillary (microvascular) plasma colloid osmotic (or oncotic) pressure; πi is the interstitial (perimicrovascular) fluid osmotic pressure; and σd is the average osmotic reflection coefficient of the barrier (a measure of how effective the barrier is in hindering the passage of solutes from one side of the barrier to the other).

The microvascular hydrostatic pressure is the principal force that causes fluid filtration in the lungs. If blood were not flowing through the lungs, the opposing hydrostatic and osmotic forces on either side of the microvascular barrier would be equal, their sum would be zero, and there would be no filtration. It is the pumping action of the heart that causes blood to flow through the lungs, and the microvascular hydrostatic pressure generated in the process establishes the steady-state values of the other driving pressures and causes fluid to filter.[6,8]

According to the Starling equation, the balance between the prevailing transmural hydrostatic pressures (Pc − Pi) and the colloid osmotic pressures ($\pi c - \pi i$) provides the "driving force" for fluid filtration. The actual amount of filtrate that forms at any given driving force is determined by the integrity of the barrier to filtration, which is reflected in the conductivity (Lp) and reflection (σd) coefficients. The equation predicts the development of two fundamentally different kinds of pulmonary edema: the first, *increased pressure pulmonary edema*, occurs when the balance of the driving forces increases, forcing fluid across the barrier at a rate that can no longer be accommodated by lymphatic drainage; and the second, *increased permeability pulmonary edema*, occurs in the presence of ALI that damages the normal barriers to fluid filtration and allows increased conductance of liquid and protein in the lungs. There also is a third type of pulmonary edema caused by impaired lymphatic drainage of filtered fluid, but this has less clinical relevance and is not discussed in detail. The lymphatic drainage of the lungs is an important means of removing filtered fluid and proteins from the perimicrovascular interstitial space.[6,8]

Because the normal microvascular barrier is leaky, the alveolar barrier must serve as the principal protection against the accumulation of alveolar edema. Fluid and protein do not normally move into alveoli because the alveolar barrier has a low permeability even to small molecules (similar to cell membrane permeability) and because the fluid that is filtered is continuously being pumped back into the interstitium by alveolar epithelial cells,[2] drained away from the alveolar walls through the interstitium, and removed by lymphatic vessels and the lung microcirculation.

TABLE 55-1. Safety Factors That Protect the Lungs against Interstitial and Alveolar Edema Accumulation

1. Lung lymphatic system
2. Resorption into blood vessels
3. Drainage into the mediastinum
4. Drainage into the pleural space
5. Extremely low alveolar epithelial barrier permeability
6. Low alveolar surface tension (surfactant)
7. Active transport by alveolar and distal airway epithelial cells

The several factors (Table 55-1) that normally protect the lungs against edema have been called *safety factors*. Under normal conditions, the lymphatic system pumps filtered fluid and protein out of the lungs as rapidly as they are formed, even when filtration of fluid and protein from the bloodstream into the interstitium is increased. Increases in fluid and protein filtration across the microvascular barrier also can be drained away from the alveolar walls down the prevailing pressure gradient into the loose peribronchovascular connective tissue or can be resorbed directly into blood vessels.[4] The lung lymphatics can increase their pumping capacity manyfold, particularly when the microvascular wall has been injured.[6] When the balance of driving forces is upset by higher hydrostatic pressure, the increase in filtration of water across the microvascular barrier is much larger than that in protein flux because the microvascular barrier has a low protein conductance. This results in dilution ("washdown") of interstitial protein concentration and thereby an increase in the balance of the osmotic pressure opposing the higher hydrostatic pressure (because plasma protein concentration remains high). The interstitial gel is also hydrated. Exclusion volume for protein decreases, either because of swelling or because of alteration of composition as hyaluronan is washed out from the interstitium, reducing the concentration of protein by expanding the available volume.

The osmotic safety factors work only when the microvascular barrier is normal (increased pressure edema). If the endothelial barrier is injured and its functional integrity is compromised (increased permeability edema), barrier conductance increases and the osmotic reflection coefficient decreases, making this safety factor much less effective or completely ineffective. The compliance of the interstitial space also protects the lungs against edema. Increases in interstitial volume result in only small elevations of interstitial pressure until the interstitial volume is large. This keeps the hydrostatic driving pressure across the alveolar barrier suitably low. When

interstitial pressure is elevated to greater than pleural pressure, fluid flows across the visceral pleura into the pleural space, where its effects on lung function are relatively minor. Pleural fluid is drained by lymphatics in the parietal pleural and, even when pleural liquid accumulates, does not flow back from the pleural space into the lungs. The extremely low alveolar barrier solute conductance provides an osmotic force that favors absorption of water out of the air space rather than filtration of water into the air space. Fluid that does accumulate in the alveoli is pumped out by active ion transport.[2] There are several mechanisms that can up-regulate the rate of alveolar fluid clearance (see Chapter 10).

In summary, pulmonary edema results from increases in either driving pressures (increased pressure edema) or barrier conductance (increased permeability edema) or both mechanisms. What distinguishes the two types is barrier permeability, which is normal in increased pressure edema but abnormal in increased permeability edema. Fluid flow into the lungs is driven across the barrier in both types of edema by the balance of pressures.

Increased Pressure Edema

Increased pressure pulmonary edema (Fig. 55-1) is caused by an increase in the balance of driving forces for fluid filtration into the lungs. The essential feature of this edema is that the barriers to fluid and protein flow into the lungs are functionally intact. Increased pressure edema is often called *cardiogenic*, *high-pressure*, *hydrostatic*, or *secondary pulmonary edema* but more appropriately would be called *normal barrier pulmonary edema* because it is the barrier resistance to fluid and solute movement into the lungs that distinguishes the types of pulmonary edema.

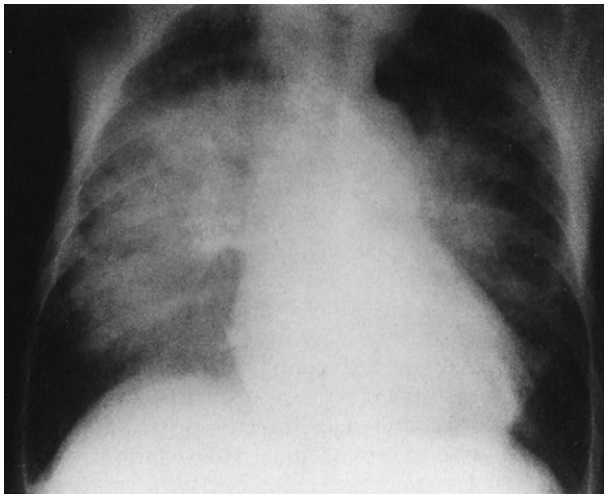

FIGURE 55-1 ■ Chest roentgenogram in a patient with increased pressure pulmonary edema. The heart is enlarged, and the vascular pedicle is widened. The "butterfly" pattern of edema (infiltrates centrally distributed, close to the heart and hila) is often seen with volume overload. The patient had chronic renal failure and volume overload.

Pathophysiology

The flow of fluid and protein into the lungs increases when the sum of driving pressures is elevated. If the rate of fluid accumulation exceeds the rate at which it can be removed, increased pressure edema occurs. Because the barriers limiting fluid and protein flow into the lungs are intact, the lungs are protected against edema by the normal safety factors. Especially important is the ability to protect against increases in the principal driving pressure, lung microvascular hydrostatic pressure. Because of the microvascular barrier's low protein conductance, fluid flow increases much more than protein flow with an elevation in microvascular hydrostatic pressure. Interstitial protein concentration is diluted both by this higher fluid flow relative to protein flow and by a diminished exclusion volume for proteins as the interstitial gel is hydrated and swells. Lower interstitial protein concentration (washdown or washout of interstitial proteins) results in lower perimicrovascular osmotic pressure and thereby a greater protein osmotic pressure difference across the barrier, opposing any rise in hydrostatic pressure. In experimental animals, slightly less than 50% of an increase in hydrostatic pressure is offset by the increase in osmotic pressure difference.[8] Increased pressure edema may be slow and gradual in onset and progression because any elevation in microvascular hydrostatic pressure is attenuated by a rise in osmotic pressure difference across the microvascular barrier, owing to a decline in interstitial protein osmotic pressure.

There are limits to the ability of widening osmotic pressure difference to oppose increases in hydrostatic pressure at the microvascular barrier. Because the barrier is leaky, some protein is always carried into the interstitial space with water by convection, and washdown is limited by the barrier osmotic reflection coefficient. These factors impose limits to the decrease in interstitial protein concentration such that the maximum osmotic pressure difference able to oppose an increase in hydrostatic pressure can at most about double, from close to 10 mm Hg to just over 20 mm Hg. This effect is also limited by the concentration of proteins in the vascular space. At low plasma protein concentrations, the capacity to oppose hydrostatic pressure increases is reduced[9] because the osmotic pressure difference across the barrier cannot be as large as normal. Lymphatic function is essential to this safety factor. Protein flow is greatly enhanced in increased pressure edema because proteins are swept into the lungs with water, and all the extravasated protein must be removed in lymph if washdown is to succeed. Lymphatic function may be compromised by an elevation in hydrostatic pressure at the outflow of the pulmonary lymphatic system into the large thoracic veins, which afford the back-pressure that must be pumped against,[10] and lymphatics in the lungs may be compressed by accumulating edema and rising pressure in the peribronchovascular connective tissue spaces. In long-standing or chronic high-pressure states (e.g., mitral stenosis), lymphatics have been said to proliferate and hypertrophy, improving the effectiveness of the lymphatic system for fluid and protein removal.[1]

TABLE 55-2. Effects of Vascular Congestion and Edema on Pulmonary Function and Lung Mechanics

VASCULAR CONGESTION
Increased diffusing capacity

Increased closing volume
Decreased maximal expiratory flow
Increased ventilation-perfusion mismatching
Decreased arterial P_{O_2}
ALVEOLAR FLOODING
Increased closing volume (air trapping)
Increased vascular resistance
Decreased lung volume (especially vital and inspiratory capacities)
Decreased compliance
Decreased diffusing capacity
Right-to-left shunting of blood (severely compromised gas exchange)

The consequences of increased pressure edema on lung mechanics and gas exchange (Table 55-2) depend on how much edema accumulates.[11] Dehydration of normal subjects increases lung volumes and improves tests of ventilatory function,[12] indicating that water in the lungs affects even the normal condition. Early in the progression of edema, increases in hydrostatic pressure result in greater intrapulmonary blood volume (as vessels are recruited or distended by rising pressure), and the diffusing capacity of the lung for carbon monoxide may actually be greater than normal because pulmonary capillary blood volume is increased. Similarly, arterial oxygen pressure (P_{O_2}) may also rise because ventilated units are better perfused when vascular pressures increase.[13] The small, reversible changes in airflow resistance and dynamic compliance, unaffected by vagotomy, that occur in congested lungs appear to be due to reflex bronchoconstrictor responses, but only when baseline bronchial tone is normal.[14]

When interstitial edema is present, closing volume may be increased[15] and maximum expiratory flows may be decreased. These changes were originally believed to be due to a decrease in caliber of small airways caused by compression by rising volume and pressure in the peribronchovascular connective tissue spaces. This effect would have to be in airways larger than bronchioles, because bronchioles and smaller airways do not have loose connective tissue sheaths[1] and their diameter is a function of lung volume, not transpulmonary pressure.[16] Lung compliance may be decreased in interstitial edema, but changes have been found not to be related closely to the amount of lung water[1,17]; decreased lung compliance may be due to decreased lung volume, a reflex phenomenon, or to large airway compression.[18] Arterial P_{O_2} may fall as a result of ventilation-perfusion mismatching, but gas exchange is not seriously compromised until the alveoli are flooded.

With alveolar flooding, lung volumes are diminished.[13] This is most marked in measurements of vital capacity, with inspiratory capacity affected more than expiratory capacity. Airways may close at higher than normal distending pressures, resulting in trapping of larger volumes of gas in the lungs.[19] Lung compliance is reduced when alveolar edema is present because lung volume is decreased.[20] Gas exchange is, of course, severely compromised when flooded alveoli are perfused (right-to-left shunt),[21] and there is an increase in wasted ventilation (ventilation of units where no gas exchange occurs).

Airflow resistance increases more with increased pressure edema than with increased permeability edema, perhaps due to effects on the bronchial circulation: Bronchial veins drain into the right atrium, so increased systemic venous pressure would result in increased bronchial venous and capillary pressures.[21] In addition to changes in airway resistance, pulmonary vascular resistance increases as edema progresses.[22] The cause of decreased pulmonary blood flow with edema is believed to be compression of alveolar wall vessels by the weight of the edema fluid. Increased resistance to blood flow in extra-alveolar vessels occurs at low lung volumes.[23] Blood flow may also be redistributed: Flow decreases at the bases as lung volume is diminished by edema.[24]

Intact red blood cells are often found in the edema fluid in increased hydrostatic pressure edema. Their presence may be due to rupture of a small number of tiny blood vessels with very high pressure, probably at the base of the lungs, where pressure is highest, and mixing of extravasated cells with edema fluid. Increased pressure edema fluid has low protein concentration, and there is no evidence that new pathways for leaking blood into the air spaces are opened up as the pressure climbs. If new pathways were created, the protein concentration of the edema fluid would increase along with the pressure. Protein concentrations in edema fluid decrease as pressure increases, indicating that proteins are effectively sieved by the barrier (passing in proportion to their size).

Light and electron microscopic examination of human and animal lung tissue in increased pressure edema shows alveolar edema and hemorrhage; thickened interstitial compartments (especially large peribronchovascular fluid cuffs) with separated, dispersed collagen fibrils; and increased capillary surface area and volume.[25–29] More intercellular vesicles can be seen, but otherwise no detectable changes in the ultrastructure of the vascular endothelium occur, and the gap widths at intracellular junctions are not different from those in normal lungs. Electron-lucent zones (laminae rarae) may be seen in the basement membranes, particularly where the alveolar-capillary barrier is thinnest. Long-standing edema (e.g., in patients with mitral stenosis) can be associated with basement membrane thickening and increased distance between the alveoli and the capillaries; increases in fibroblasts, histiocytes, and bulky strands of collagenous fibers can be seen in the interstitium. Permeability might

be lowered across these widened barriers.[30] Dogs with pacing-induced chronic congestive heart failure developed a significant increase in the threshold for high-vascular-pressure edema formation (about a 50% reduction in the amount of water and protein cleared across the lung microvascular endothelial barrier at high pulmonary vascular pressures as compared with controls).[31] Morphometric analysis of the alveolar-capillary barrier showed that endothelial, interstitial, and epithelial thickness were increased compared with controls, indicating that remodeling confers an increase in the resistance to development of high-pressure–induced alveolar edema. Alveolar type II cells may be more numerous than in normal lungs, and alveolar macrophages proliferate.[29] Chronic, severe increased pressure edema may also become organized and fibrotic, may calcify, and may even result in bone formation.[32]

Mechanisms

The most common cause of increased pressure edema is elevated lung microvascular hydrostatic pressure. The sum of driving pressures might also be greater if perimicrovascular hydrostatic pressure or the osmotic pressure difference across the microvascular barrier were decreased. At the alveolar barrier, an increase in interstitial hydrostatic pressure, a decrease in alveolar hydrostatic pressure, or a decrease in osmotic pressure difference across the barrier might result in a greater sum of driving pressures. The possibilities are listed in Table 55-3.

Increased Microvascular Hydrostatic Pressure. Congestive heart failure is the most common cause of increased pressure edema. That is why increased pressure edema is often called "cardiogenic" even though the heart is not always primarily involved. Elevated pressures in the pulmonary microvasculature are usually due to left-sided heart failure, with elevated left atrial pressures transmitted retrograde into the pulmonary circulation. Common causes are left ventricular dysfunction (e.g., caused by acute myocardial infarction, severe coronary insufficiency, tachyarrhythmias, bradyarrhythmias, cardiomyopathies, constrictive pericarditis, aortic stenosis or regurgitation, mitral regurgitation, coarctation of the aorta, rupture of chordae tendineae or intraventricular septum, systemic hypertension) or mechanical obstruction of the left atrial outflow tract (e.g., as in mitral stenosis, left atrial myxoma). Left atrial pressure and subsequent pulmonary microvascular pressure can also be elevated by severe volume overloading in a patient with a normal or diseased heart.

An unusual cause of increased microvascular hydrostatic pressure is pulmonary venous hypertension in the absence of left ventricular or atrial disease, which can occur if the pulmonary veins are contracted (e.g., by possible muscular sphincters[33]), compressed, or obstructed (e.g., because of veno-occlusive disease or mediastinal fibrosis[34]). Bronchial venous hypertension does not appear to significantly increase fluid filtration in the lungs.[35]

Increases in fluid filtration can also be associated with increases in vascular pressure proximal to the filtration sites in the lungs. For example, pulmonary hypertension, in combination with depressed left ventricular function, has been implicated in the pathogenesis of cocaine-induced pulmonary edema.[36] Whether such increases lead to pulmonary edema depends on what happens to microvascular pressure. If high right-sided pressures are caused by increased resistance before the main site of filtration in the lungs (e.g., hypoxic pulmonary vasoconstriction of small arterial vessels,[37,38] primary pulmonary hypertension, pulmonary artery or valvular stenosis), edema does not occur. Conversely, if the lung vascular bed is only partially constricted or obstructed, or if the vascular surface area is greatly decreased (e.g., by lung resection), higher flow in perfused vessels leads to increased pressure edema[38] because microvascular pressures at the fluid exchange site are elevated in the overperfused lung. Pulmonary edema occurred in about 15% of patients after pneumonectomy and seemed to be exacerbated by administration of fresh frozen plasma,[39] probably because intravascular volume is increased by such transfusions. Any increase in blood flow through the lungs increases the pulmonary microvascular pressure at the fluid exchange sites even if the pulmonary venous pressure remains constant, because pulmonary microvascular pressure is the sum of pulmonary venous pressure plus the product of pulmonary venous resistance and blood flow.[1] High systemic venous pressure might also promote edema formation by raising the outflow pressure and thereby reducing the flow of lymph.[10]

The mechanisms of two less common causes of pulmonary edema, those occurring at high altitude and during severe neurologic insults, may involve increased microvascular hydrostatic pressure. *High-altitude pulmonary edema*,[40,41] which is also discussed in Chapter 65, appears to be caused by severe pulmonary hypertension that develops in susceptible individuals as a consequence of hypoxic vasoconstriction when the inspired P_{O_2} falls at altitude. Nonhomogeneous obstruction of the pulmonary vascular bed by exaggerated hypoxic vasoconstriction results in high blood flow and transmission

TABLE 55-3. Mechanisms of Increased Pressure Pulmonary Edema

INCREASED LUNG MICROVASCULAR HYDROSTATIC PRESSURE

INCREASED ALVEOLAR SURFACE TENSION
Inspiratory airway obstruction

of pressure to portions of the pulmonary vascular bed that are not protected by vasoconstriction, and pulmonary edema results from high intravascular pressure. Patients who develop high-altitude pulmonary edema have been found to have very high pulmonary arterial pressure (sometimes at systemic levels). The excessive rise in pressure precedes the development of the edema, and agents that lower pulmonary arterial pressure (e.g., oxygen, nifedipine, hydralazine, phentolamine, inhaled nitric oxide, and inhaled β_2-agonists) are effective in prevention or treatment, or both.

Postmortem edema fluid has been described as proteinaceous in high-altitude pulmonary edema, and measurements of edema fluid protein concentration have been made in two patients.[42] In one, the edema fluid–to–plasma protein concentration ratio (0.6) was in the range predicted for increased pressure edema; in the other, the ratio (0.8 in one sample, 1.1 in another) was in the range typical of increased permeability pulmonary edema. Bronchoalveolar lavage (BAL) fluid of six climbers with high-altitude pulmonary edema showed a marked increase in high-molecular-weight proteins (as well as many red blood cells and alveolar macrophages).[43] Because water is resorbed from edema fluid in the alveoli much faster than protein,[44,45] the protein concentration of edema fluid increases progressively as edema resolves. The high protein concentration of postmortem high-altitude pulmonary edema and BAL fluids may be due to observations made during a time when fluid was being resorbed from, rather than added to, alveoli.

As noted earlier, overperfusion of a restricted pulmonary vascular bed, even in the absence of hypoxia, causes increased pressure edema, not increased permeability edema.[38] This can explain why some cases of high-altitude pulmonary edema are correctly classified as increased pressure pulmonary edema. Evidence from climbers studied at high altitude suggests that high intravascular pressures cause physical damage to vascular walls (so-called stress failure), which has been shown to occur at extreme, but sometimes transient, increases in pulmonary vascular pressures in experimental animals.[46–48] Such structural failures need not occur in large numbers to explain even severe increased permeability edema, because edema would form readily and in a quantity driven by the prevailing elevated vascular pressure.[49] The suggestion has been made that high-altitude pulmonary edema results from the stress failure of overdistended, relatively thin-walled pulmonary arteries rather than from microvascular rupture,[50] which might help explain why the prevailing vasoconstriction does not seem to offer much protection to downstream vessels, why there are no reports of gradual progression through an indolent prodrome of increased pressure edema before stress failure occurs, and why high-altitude pulmonary edema is first detected radiographically in the central lung fields surrounding large vessels rather than in the lung bases and periphery.

Plasma selectins have been measured in subjects at high altitude.[51] Levels of E-selectin were inversely related to arterial oxygen saturation in control subjects and in subjects with acute mountain sickness and with high-altitude pulmonary edema. Because endothelial cells are the only known source of E-selectin, increased plasma levels were considered to be a sign of activation or injury of endothelial cells. Plasma levels of P-selectin were not found to be elevated at high altitude.

Alternative mechanisms for the increased permeability in high-altitude pulmonary edema have been proposed. However, inflammatory responses in high-altitude pulmonary edema are probably a consequence rather than a cause of the edema.[40,52,53] The rapid reversibility of high-altitude pulmonary edema with descent to lower elevation, oxygen therapy, or pharmacologic reduction of pulmonary vascular pressure is not characteristic of ALI and increased permeability pulmonary edema suspected to be caused by or related to inflammation. Also, some work supports the conclusion that this disorder is primarily a hydrostatic type of pulmonary edema.[54]

Neurogenic pulmonary edema[55] also may be related to elevated pulmonary vascular pressures. Measurements of edema fluid protein concentration relative to plasma protein concentration in 12 patients with neurogenic pulmonary edema have been reported.[56] Seven of the patients had ratios typical of increased pressure pulmonary edema, and the other 5 had ratios consistent either with increased permeability pulmonary edema or with sampling during the resolution phase of increased pressure pulmonary edema (when edema fluid protein concentration rises as fluid is resorbed from the alveoli at a faster rate than protein). Measurements in 8 patients had previously been reported; 2 of the measurements indicated increased pressure edema, and 6 indicated increased permeability edema or sampling during the resolution phase. Thus, half the cases of neurogenic pulmonary edema in which edema fluid protein concentration has been measured appear to involve increased pressure edema, and the fraction is perhaps even higher, depending on the timing of edema sampling.

Measurements of the alveolar-to-plasma protein concentration ratios in dogs with neurogenic pulmonary edema induced by intracisternal veratrine showed a wide range of values, indicating that both increased pressure and increased permeability mechanisms may be involved to varying degrees in that type of neurogenic pulmonary edema.[57] In other animal experiments, filtration increases in neurogenic edema[58–61] and edema following transient pulmonary hypertension[62] were attributable to increased pressure or increased vascular surface area, or both, perhaps in combination with acute lymphatic insufficiency. Animal studies can be difficult to interpret. Some models have been complicated by primary lung injury that is separate from effects on the central nervous system[63] or by evidence that vascular permeability was abnormal in control experiments[62] performed in surgically traumatized, acutely prepared animals.[64]

Both human and experimental neurogenic pulmonary edema can be associated with massive discharge of the sympathetic nervous system, resulting in systemic vasoconstriction and translocation of blood from the systemic to the pulmonary circulation, producing marked increases in pulmonary blood flow and vascular pres-

sures. Peak pulmonary arterial pressure can reach systemic levels. Hydrostatic pressure at the fluid exchange sites in the lungs can also be elevated by catecholamine-induced left ventricular dysfunction, increased pulmonary venous resistance, and mitral valve insufficiency secondary to left ventricular dilation. Thus, as in high-altitude pulmonary edema, high pulmonary vascular pressures could result in either increased pressure edema (from elevated microvascular hydrostatic pressure) or increased permeability edema (if pulmonary vascular pressures were high enough to cause stress failure of pulmonary vessels). Whether neurogenic pulmonary edema can occur by pressure-independent mechanisms remains controversial and unproved.[55] Some episodes of neurogenic edema may involve increased pressure; others appear to involve increased permeability. More information is needed to sort out the precise causes.

Decreased Perimicrovascular Hydrostatic Pressure. The sum of driving pressures would be greater if perimicrovascular hydrostatic pressure was diminished, thereby resulting in an increase in fluid and protein filtration at the microvascular barrier in the lungs. Pulmonary edema has been described in circumstances in which this might occur. The best clinical example is *postobstructive pulmonary edema* as a consequence of upper airway obstruction or its release, which can be caused, for example, by laryngospasm, endotracheal tube obstruction, foreign body aspiration, epiglottitis, croup, severe acute asthma, airway compression by tumors, strangulation, or hanging. High negative intrathoracic pressures generated by inspiratory attempts against the occluded airway are transmitted to the interstitium, promoting fluid movement into the interstitium. Mechanical effects on the cardiovascular system likely contribute to this kind of edema: High negative intrathoracic pressure causes increases in cardiac preload and afterload and in pulmonary blood flow, all of which increase the microvascular pressure that drives fluid out into the interstitium. Three patients with upper airway obstruction and pulmonary edema were reported, all with low edema fluid protein concentration relative to plasma protein concentration (ratios of 0.44, 0.31, and 0.52), indicating increased pressure pulmonary edema.[65]

Aspiration of air or fluid from the pleural space with consequent reexpansion of a collapsed lung could result in a decrease in perimicrovascular hydrostatic pressure as the lung expands to fill the thorax. So-called *reexpansion pulmonary edema* has been reported in experimental animals[66,67] and in patients[68,69] after lung reexpansion, but the high edema fluid protein concentration measured in three patients[70,71] indicated that reexpansion may result in an increased permeability edema rather than an increased pressure edema. However, one study of protein concentration in pulmonary edema fluid from patients with reexpansion edema indicates that hydrostatic mechanisms are important.[72] The increased permeability hypothesis was supported in studies of rabbits with experimental reexpansion edema.[73,74]

Reexpansion pulmonary edema may be a form of ischemia-reperfusion injury,[75] with the increase in lung microvascular permeability being related to restoration of blood flow, formation of oxygen free radicals, release of proinflammatory mediators, and activation of neutrophils. On reperfusion, pulmonary vascular resistance shifts more toward postcapillary venules, which elevates pressure in the microvascular vessels at the fluid exchange sites in the lungs and would aggravate edema formation across the injured barrier.[76] A patient with apparent reperfusion pulmonary edema complicating thrombolytic therapy for pulmonary embolism has been reported,[77] and reperfusion injury is probably one of the causes of the pulmonary edema that occurs in transplanted lungs.[78] Hemorrhagic and traumatic shock have also been conceived of as types of a "whole-body ischemia-reperfusion syndrome."[79]

If high alveolar surface tension were transmitted to the interstitium, perimicrovascular hydrostatic pressure would also be lowered, thereby increasing filtration across the microvascular barrier. Such an effect has been suggested by experimental findings in dog lungs.[80,81] The effect of alveolar surface tension on lung fluid balance is discussed later.

Decreased Transmural Osmotic Pressure Difference. The sum of driving pressures would be increased if the osmotic pressure difference opposing the hydrostatic pressure difference across the microvascular barrier were decreased (by lowering plasma protein concentration or by raising interstitial protein concentration), resulting in an increase in the sum of driving pressures for fluid and protein flow into the lungs. This theoretical mechanism of increased pressure edema has been the subject of study in experimental animals, with contradictory results. In some studies, hypoproteinemia was not found to increase lung microvascular liquid conductance or protein permeability.[82,83] Because the microvascular-perimicrovascular osmotic pressure gradient is generated by the microvascular hydrostatic pressure and by the barrier descriptors (conductivity and reflection coefficient), it is not possible to decrease the osmotic pressure gradient by depleting plasma proteins except transiently while a new steady state is being established. Although fluid flow would be increased temporarily, it would return to normal when a new steady state is reached, unless hydrostatic pressure or barrier characteristics were also changed. This is not to imply that protein concentrations are not important forces in lung fluid balance. Although an isolated decreased osmotic pressure gradient across the microvascular barrier cannot be sustained or be an important mechanism for increased pressure edema, the absolute concentration of protein has a profound effect on lung fluid balance when hydrostatic driving pressure is increased. When plasma osmotic pressure is low, the ability of the osmotic pressure gradient to widen in response to increased hydrostatic pressure is diminished, and edema accumulates at hydrostatic driving pressures lower than those needed to cause edema when protein concentration is normal.

Alveolar Barrier Function. The driving pressure for fluid and protein flow across the alveolar barrier would be elevated, resulting in increased pressure edema, if the interstitial hydrostatic pressure were raised

or if the alveolar hydrostatic pressure or the osmotic pressure difference across the alveolar barrier were lowered. Because the osmotic pressure difference across the barrier is established by the relevant hydrostatic forces and barrier descriptors (as across the microvascular barrier), an isolated decrease in the osmotic difference could result in only a transiently increased pressure filtration until a new steady state is achieved. This transient phenomenon would not be an important mechanism for increased pressure edema in the alveolar spaces.

Interstitial hydrostatic pressure rises as interstitial edema accumulates in the lungs.[4,84] Increased interstitial hydrostatic pressure would raise the sum of driving pressures across the alveolar barrier and could drive edema formation across the alveolar or airway epithelium. The role of interstitial hydrostatic pressure in edema formation is not simple, however. Although increased interstitial hydrostatic pressure favors edema formation across the alveolar barrier, it opposes edema formation across the microvascular barrier. The relative contributions of these disparate effects have not been separated. The osmotic pressure difference across the intact alveolar barrier provides a powerful force that opposes filtration increases driven by hydrostatic pressure. Because the barrier is normally virtually impermeable even to small solutes, filtration of water would result in a decrease in alveolar osmotic pressure. A decrease of only 1 mOsm (<0.5% of the normal alveolar osmotic pressure) would balance a 19 mm Hg increase in interstitial hydrostatic pressure.

Greater pressure filtration across the alveolar barrier would also result from an increase in the sum of driving pressures if alveolar hydrostatic pressure were lowered. This is complicated by the interrelation between alveolar and interstitial hydrostatic pressures.[4,85] A drop in alveolar hydrostatic pressure, which increases the sum of driving pressures across the alveolar barrier, also results in a lowering of interstitial hydrostatic pressure, which decreases the sum of driving pressures across the alveolar barrier but increases the sum of driving pressures across the microvascular barrier. The influence of alveolar surface tension on lung fluid balance has been investigated in dogs. Administration of a detergent aerosol resulted in loss of surfactant activity, higher alveolar surface tension, lower static compliance, atelectasis, and pulmonary edema; low protein concentration in alveolar edema fluid and left-hilar afferent lymph relative to plasma protein concentration indicated that this was an increased pressure type of pulmonary edema.[86,87] Because increased pressure edema can impair surface activity of dog lung extracts[88] and isolated rabbit lungs,[89] it is possible that changes in alveolar surface tension may accelerate edema formation. However, the notion that changes in alveolar surface tension in edema lead to a self-perpetuating vicious circle of edema formation is not borne out clinically.

The only kind of clinical pulmonary edema caused by transmural osmotic pressure differences is near drowning.[90,91] Seawater is three times more hyperosmotic (1000 mOsm) than plasma, so the volume of fluid in the air spaces after salt water aspiration increases threefold to reach osmotic equilibrium, thus markedly increasing the alveolar edema already present because of the volume of seawater itself in the alveoli. Osmotic equilibrium is reached in minutes as water is drawn from the vasculature into the alveoli by osmotic pressure.[90-92] Alveolar barrier function is not significantly compromised (unless perhaps the patient aspirates gastric contents or the seawater is contaminated or rich in particulate matter), and the alveolar edema is cleared very rapidly (50%–60% of excess alveolar fluid is cleared in 4 hr). However, transient, minimal disturbances in endothelial barrier function may occur if cellular water loss causes cell shrinkage, thereby opening up paracellular pathways (junctions between cells) for fluid and solute movement. Freshwater near drowning proceeds in the opposite fashion: osmotic equilibrium is reached rapidly by flow of water out of the alveoli into the interstitium and bloodstream. Severe hemodilution, with hemolysis and fibrinolysis, also occurs, and the rapid water flux and hypotonicity cause severe distortion of pulmonary ultrastructure, including damage to type I and type II cells, endothelial cell swelling, basement membrane detachment, and cell disruption. Both alveolar epithelium and microvascular endothelium can thus be injured by the hypotonic fluid, leading to increased permeability pulmonary edema rather than a normal barrier type of pulmonary edema.

Increased Permeability Edema and Acute Lung Injury

Increased permeability pulmonary edema (Fig. 55-2) is caused by an increase in liquid and protein conductance across the barriers in the lungs. The essential feature of

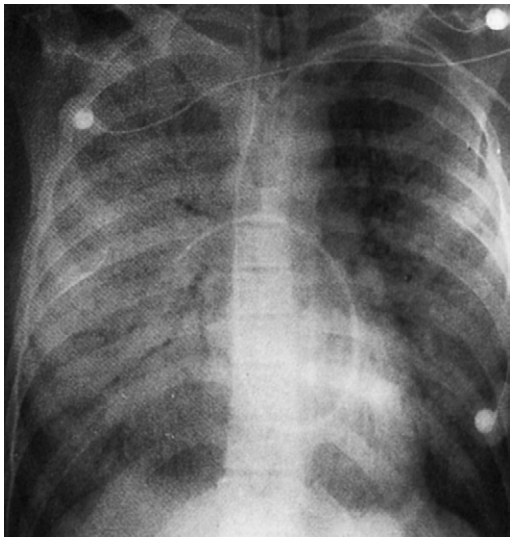

FIGURE 55-2 ■ Chest roentgenogram in a patient with increased permeability pulmonary edema. The heart is not enlarged, and the vascular pedicle is of normal size. Edema is peripheral and not gravitationally distributed. Air bronchograms are present, a finding more common in increased permeability edema than in increased pressure edema. The patient had drug overdose, coma, and hypotension.

this edema is that the integrity of the barrier to fluid and protein flow into the lung interstitium and the alveoli is altered. Increased permeability edema is sometimes called *noncardiogenic* or *primary pulmonary edema*, and the resulting clinical syndromes in humans are commonly lumped together as *ALI* or the *acute respiratory distress syndrome* (ARDS).[93,94]

Pathophysiology

Accumulation of fluid and protein increases when the lung endothelial and epithelial barriers are injured. If the rate of fluid accumulation exceeds the rate at which it can be removed, increased permeability edema occurs. Because the barriers limiting fluid and protein flow into the lungs do not function normally when the lungs are injured, the lungs are not protected against edema by the usual safety factors. Although increases in fluid and protein filtration across the barriers are removed by lymphatics and drained away from the alveolar walls as in increased pressure edema, much more fluid and protein are filtered at any given sum of driving pressures because the barriers to their flow are much less restrictive than normal. Edema formation in injured lungs is very sensitive to driving pressures.[49] Driving pressures are often increased when the lungs are injured because of the vasoconstrictive effects of inflammatory mediators such as thromboxanes, which may shift the main site of resistance to postcapillary venules, thus increasing hydrostatic pressure at the microvascular fluid exchange sites,[95] or because of effects on the heart as well as on the circulation. For example, elevated left atrial pressure, pulmonary venoconstriction, and an increase in cardiac output in sepsis can increase hydrostatic pressure at the microvascular fluid exchange sites.[96] Microvascular hydrostatic pressure in injured lungs is not related simply to pulmonary artery occlusion ("wedge") pressure, and such measurements can be misleading.

Because the barriers are leaky, protective osmotic pressure differences are lost across them; driving pressure is unopposed by osmotic pressure, and even normal hydrostatic pressure results in significant fluid and protein extravasation into interstitial and alveolar spaces. The ability of the lymphatics to pump the excess filtrate away is increased when the lungs are injured. Maximal lung lymph flow increases more when the microvascular wall has been injured than when hydrostatic pressure alone is increased (as a result of poorly understood "edema-dependent lymphatic factors"), but even this augmented lymphatic pumping capability is taxed at low driving pressures. If the epithelial barrier is injured, edema may accumulate readily in the alveoli, because most of the resistance to fluid and protein flow into the alveoli is in the epithelial barrier.[97,98] Increased permeability edema is often rapid in onset and progression because injured barriers offer much less resistance to flow and because hydrostatic driving pressure is unopposed by increases in osmotic pressure difference. Clinically, patients with increased permeability edema usually have a low intravascular hydrostatic pressure, commonly measured as a low or normal pulmonary capillary wedge pressure. In some cases, this reflects the low intravascular pressures associated with the underlying disease process (e.g., sepsis).

The consequences of increased permeability edema on lung mechanics and gas exchange depend on how much edema accumulates and how severe the causative lung injury is.[99] As with increased pressure edema, the major effects on pulmonary mechanics occur with alveolar flooding. In experimental lung injury, functional residual capacity was found to be decreased as a consequence of alveolar flooding, and this loss of ventilated units accounted for virtually all the observed decrease in static lung compliance.[100,101] Computed tomography has provided new insights into structure-function relationships in human ALI.[102,103] In the early stage of lung injury, when alveolar edema predominates, the lungs are characterized by a homogeneous alteration of vascular permeability, and edema accumulates evenly in all lung regions with a nongravitational distribution. Increased lung weight due to edema causes collapse of lung regions along the vertical axis through the transmission of hydrostatic forces (compression atelectasis, caused by the weight of edema). Thus, collapse occurs mainly in the dependent lung, where the superimposed weight from above is greatest.

Measurements of pulmonary mechanics in mechanically ventilated patients with ALIs[99] showed decreased static lung compliance as a consequence of this loss of ventilated lung. In addition, airflow resistance was increased as a result of decreased lung volume. Bronchospasm adds to the increase in airflow resistance and can be substantially reversed with bronchodilator inhalation.[104] Chest wall compliance was reduced, probably because of alterations of intrinsic mechanical properties of the chest wall by abdominal distention, chest wall edema, and pleural effusion.[99] Different respiratory mechanics and response to positive end-expiratory pressure (PEEP) during mechanical ventilation were reported in patients with ARDS originating from pulmonary disease (pneumonia, which caused consolidation) or from extrapulmonary disease (which caused edema and subsequent alveolar collapse).[105] Lung elastance was higher in pneumonia, whereas chest wall elastance and intra-abdominal pressure were higher in patients with extrapulmonary causes of their lung injuries. In pneumonia, PEEP appeared to distend normal alveoli, which are more compliant that involved alveoli, whereas in extrapulmonary causes of ALI, PEEP appeared to recruit previously collapsed alveoli.

Although the effects of surface forces on decreased lung compliance in ALI were believed to be small, results of experiments in isolated rabbit lungs indicated that increased permeability edema may result in more severe mechanical changes than equivalent degrees of increased pressure edema.[89] In contrast, experiments in awake sheep showed that similar degrees of pulmonary edema, regardless of the mechanism, caused similar changes in compliance and gas exchange.[21] Other experiments showed that dynamic and static lung compliance decreased early in evolving lung injury.[106] Surfactant is strongly thromboplastic, and coagulation may

compound surfactant depletion when plasma proteins enter the air spaces. The injured lung may release substances that can interfere with the normal low surface tension in the alveoli,[107] and activated polymorphonuclear leukocytes (PMNs) have been shown to impair surfactant function in vitro and to degrade the major surfactant apoprotein by a combination of proteolysis and oxidant-radical–mediated mechanisms.[108] Human lung surfactant obtained by BAL of patients at risk for ALI and patients with established ALIs has been reported to be abnormal in chemical composition and functional activity.[109] Abnormalities also could be caused by interactions between surfactant and edema proteins, because plasma proteins (especially fibrin monomers but also fibrinogen and albumin) interfere with surfactant function. Proteinaceous edema fluid has been associated with surfactant inhibition in various experimental models.[110–112] The role of surfactant in the development and treatment of ALI and the potential role for surfactant therapy are discussed in more detail later in this chapter.

As in increased pressure edema, gas exchange is severely compromised in increased permeability edema, owing both to intrapulmonary shunting of blood and to ventilation-perfusion inequalities.[113,114] The available evidence taken together does not support the concept that tissue oxygenation may be further compromised by an abnormality in the regulation of oxygen extraction, which has been hypothesized to occur in patients with ALI (so-called pathologic dependency).[115,116]

Patients with early ALI have a marked increase in their pulmonary dead-space fraction, indicating that many ventilated lung units are not well perfused, although intrapulmonary shunting may also contribute to the elevated dead space.[117] This finding explains why the minute ventilation is twice normal (~12 L/min) at the onset of the ARDS. An elevated pulmonary dead-space fraction also has been reported in pediatric patients with ALI.[118]

Mechanical and gas-exchange abnormalities change with time during the course of ALI. The early, exudative stage of injury, in which edema predominates, is characterized by small effective alveolar space (so-called baby lung) and true shunt; the later, proliferative stage of injury, in which fibrosis and remodeling predominate, is characterized by small and stiff lungs, with superimposed emphysema-like alterations (bullous disease), decreased alveolar ventilation, and ventilation-perfusion maldistribution rather than true shunt.

Other consequences of ALI (beyond those related to edema formation) probably depend on the cause and extent of injury. Bronchoconstriction, caused by injury and mediator release, may add to mechanical and gas-exchange abnormalities. Vascular reactivity to hypoxia and other stimuli may also be altered in the injured lung's vascular bed.[119–121] Perhaps because lung metabolic function is compromised, the injured lung may add or fail to extract vasoactive substances (e.g., biogenic amines, arachidonic acid metabolites, and drugs) from the blood, and angiotensin-converting enzyme (ACE) activity may be abnormal.[122] This could have effects on the heart and the systemic circulation as well as on the pulmonary circulation. Changes in the surface of microvascular endothelial cells may lead to activation of the clotting cascade.[123] Disseminated intravascular coagulation, often associated with endotoxemia and gram-negative infections, is an ominous complication associated with thromboses, hemorrhage, and endothelial cell injury in the lungs and other organs. Abnormalities of fibrin turnover[124] and lung fibrinogen uptake[125] have been reported in ALIs. There is also mounting evidence that there is a procoagulant and antifibrinolytic environment in the distal air spaces and the plasma of patients with early lung injury.[126,127] Pulmonary vascular resistance between arteries and veins also may increase as a result of morphologic alterations of the microvascular endothelium or disruption and loss of the pulmonary vascular bed.[128] If the lungs have severe structural damage, mechanical and gas-exchange abnormalities may be much greater than can be explained by edema accumulation alone.

The light and electron microscopic appearance of human[128–136] and animal[137–139] lung tissue in ALI is variable. Lung morphology depends on the severity and the duration of injury and the treatments administered in addition to the cause of injury. Exudative, proliferative, and fibrotic changes usually appear in sequence.

The earliest changes are marked by widespread alveolar and interstitial edema and hemorrhage. Injury to alveolar ducts may be particularly severe. Hyaline membranes, composed of precipitated plasma proteins, fibrin, and necrotic debris, can be seen. The alveolar epithelium may be more extensively damaged than the vascular endothelium, even if the underlying insult is bloodborne. Widespread, local areas of destruction of type I alveolar epithelial cells alternate with normal-appearing alveoli. The injured alveolar epithelium is swollen, disorganized, discontinuous, and often lifted off exposed, but usually intact, basement membranes, which are covered by hyaline membranes. Type I cells are more severely damaged than type II cells, and the thin cytoplasmic extensions of the cells far from the nucleus covering the thin side of the alveolar-capillary barrier may be most severely affected. The interstitium is widened by edema (especially in peribronchovascular cuffs) and may be choked with leukocytes, platelets, red blood cells, fibrin, and debris (especially near the alveolar walls). The thick portion of the alveolar interstitium is usually involved more than the thin portion. The microvascular endothelium is relatively preserved, usually showing little other than irregular, focal thickening as a result of cytoplasmic swelling or vacuoles and greater numbers of luminal leukocytes. Intracapillary thrombi are rare in this and subsequent phases. Large endothelial gaps are not seen, probably because they would be incompatible with even brief survival because massive edema pours across even small, focal gaps. The alveolar capillary is the usual site of injury, but some insults involve other vessels (e.g., focal gaps in arterioles less than 1 mm in diameter in air emboli–induced lung injury).

The exudative phase is followed by a proliferative phase, which begins within the first week after onset of injury.[133,140] The relative contributions of the original insult, repair processes, and effects of therapies to this

and subsequent phases are not well known, but some of the abnormalities that occur after the initial exudative phase seem to be related to the effects of traditional modes of mechanical ventilation that used tidal volumes between 12 and 15 mL/kg predicted body weight. In the proliferative phase, fluid has been reabsorbed from the air spaces. Fibrin may be prominent in alveoli and interstitium, and there is infiltration with inflammatory cells and fibroblasts (which may have been activated very early in the course of lung injury). The alveolar epithelium is often cuboidal, made up largely of proliferating type II cells. The air-blood barrier can be greatly thickened by interstitial and epithelial enlargement. The pulmonary vascular bed may be partially or completely disrupted, and structural alterations may greatly reduce its surface area. The proliferative phase can present clinically as an inflammatory syndrome with fever, leukocytosis, low systemic vascular resistance, diffuse alveolar infiltrates, diffuse and intense pulmonary uptake of gallium, and neutrophilia on BAL, all in the absence of any infection.[141]

A final stage may follow, often about 2 weeks after the initial insult, in which fibrotic changes of the alveolar ducts, alveoli, and interstitium predominate. Alveoli may be obliterated, alveolar walls coalesced, and functional lung units lost. The lungs may be emphysema-like, with extensive bullous changes.[133] Even severe changes at any stage may be reversible, with slow recovery toward normal lung function in patients who survive.[142,143]

Mechanisms

Most of the conditions that have been associated with ALI in humans are listed in Table 55-4. The most common causes are pneumonia, sepsis, gastric aspiration, and major trauma. The insult to the lungs occurs via either the airways or the bloodstream. The exact mechanisms by which the lungs are injured have been the subject of intense investigation in humans, animal models, and cellular systems.[94] Human studies have provided descriptive data about the events that occur in the air spaces before and after the onset of lung injury. Studies using BAL in patients before and after the onset of ALI have shown that there is a major acute inflammatory response that begins before ALI is clinically recognized, peaks during the first 1 to 3 days of clinically defined ALI, and resolves slowly over 7 to 14 days in patients who remain intubated.[141-143] These studies have shown the complexity of the evolving inflammatory responses, which are characterized by the accumulation of acute response cytokines and their naturally occurring inhibitors, oxidants, proteinases and antiproteinases, lipid mediators, growth factors, and collagen precursors involved in the repair process.[144-155] Extensive efforts have been made to find single biologic markers that predict the onset or the outcome of ALI, but these have met with only limited success.[156]

Hypotheses about mechanisms of lung injury have been tested in animal models and in vitro studies, and several reviews have summarized the findings.[157] The existing animal models do not completely reproduce all of the aspects of ALI in humans, in part because human ALI evolves over a longer period of time than can be studied in the laboratory. In addition, the lungs of humans are exposed not only to the initial injurious insult but also to the therapies that are used to treat ALI, such as mechanical ventilation. Experiments with isolated cells have been useful to test specific concepts, but the

TABLE 55-4. Clinical Disorders Associated with Acute Lung Injury

INFECTIOUS CAUSES
Gram-negative or gram-positive sepsis
Bacterial pneumonia
Viral pneumonia
Fungal pneumonia
Parasitic infections
Mycobacterial disease

ASPIRATION
Gastric acid
Food and other particulate matter
Fresh or sea water (near drowning)
Hydrocarbon fluids

TRAUMA
Lung contusion
Fat emboli
Nonthoracic trauma
Thermal injury (burns)
Blast injury (explosion, lightning)
Overdistention (mechanical ventilation)
Inhaled gases (phosgene, ammonia)

HEMODYNAMIC DISTURBANCES
Shock of any etiology
Anaphylaxis
High-altitude pulmonary edema
Reperfusion
Air embolism
Amniotic fluid embolism

DRUGS
Heroin
Methadone
Propoxyphene
Naloxone
Cocaine
Barbiturates
Colchicine
Salicylates
Ethchlorvynol
Interleukin-2
Protamine
Hydrochlorothiazide

HEMATOLOGIC DISORDERS
Disseminated intravascular coagulation
Incompatible blood transfusion
Rh incompatibility
Antileukocyte antibodies
Leukoagglutinin reactions
Post–cardiopulmonary bypass, pump oxygenator

METABOLIC DISORDERS
Pancreatitis
Diabetic ketoacidosis

NEUROLOGIC DISORDERS
Head trauma
Grand mal seizures
Increased intracranial pressure (any cause)
Subarachnoid or intracerebral hemorrhage

MISCELLANEOUS DISORDERS
Lung reexpansion
Upper airway obstruction

complexity and redundancy of intact biologic systems are not reproduced in simplified experimental systems. Most experimental work purposely limits a study to a single causative agent; however, this turns the reality of clinical complexity into the simplicity of a single experimental pathway. Increased permeability edema in humans is likely to be caused by interactions between a number of different pathways acting in parallel or in series.

Studies in isolated organs and small animals in which hemodynamic variables are not measured can be difficult to evaluate because indices of lung injury, usually measured by the appearance of markers in lungs, lavage fluid, or perfusate, are not determined solely by the barrier function of the microvasculature. For example, when the vascular endothelium is injured, fluid and protein movement from the vascular space into the lungs is extremely sensitive to hydrostatic driving pressures and surface area for filtration,[49] and the effects of experimental interventions may be caused by changes in these parameters and not solely by changes in microvascular barrier function. The effects of microvascular driving pressures and surface area can be difficult to evaluate even in large, instrumented animals. In sheep and goats, interpretation of lung lymph fluid and protein flow changes are further complicated by contributions from lymphatics outside the lungs,[158,159] physical forces acting on lymphatics,[160] and possible intranodal modification of lymph.[161] Data from experimental animal models suggest that there are at least two broad categories of mechanisms of ALI: those that are *indirect* (i.e., requiring the participation of intermediary mechanisms, such as host defenses) and those that are *direct* (i.e., not requiring intermediary mechanisms, with injury probably occurring as a result of contact between an offending substance and lung tissue). These categories overlap because, once the lungs are injured, inflammatory responses occur, which may compound the primary mechanism of injury. Three major hypotheses about the mechanism of ALI are discussed next. Each is discussed separately, but they are interrelated. A recent review provides specific information on animal models of ALI.[157]

Infection. ALI develops in 20% to 45% of patients with severe sepsis.[162–164] Increased microvascular permeability to albumin has been shown to accompany human sepsis,[165] and infection and the sepsis syndrome are major causes of ALI in humans.[166] Patients who develop shock in response to known or suspected infection have a particularly high incidence of ALI, and the mortality of patients with ALI associated with infection, the sepsis syndrome, or bacteremia is increased.[166–169] ALI also appears to predispose the lungs to infection, and delayed infection is an important cause of morbidity in patients who survive the initial lung insult.[170–173]

The mechanism by which infection and the sepsis syndrome injure the lungs is not certain.[174] It seems likely that lung injury may be related to factors other than direct damage by bacteria or other microorganisms because prognosis has not been found to be related to documented bacteremia or pneumonia.[175,176] In experimental animals, intravenous infusions of live *Pseudomonas aeruginosa*,[177] endotoxins from *Escherichia coli*,[178–180] and surgically induced peritonitis[181] all resulted in increased permeability pulmonary edema in sheep. Instillation of endotoxin into the airways of sheep also led to lung inflammation with variable degrees of lung injury.[182,183] *P. aeruginosa* has also been reported to cause lung injury in pigs, and *E. coli* endotoxin has been reported to injure the lungs of baboons[184] and dogs[185] and to result in neutrophilic alveolitis in rats.[186] ALI caused by endotoxin in sheep is believed to be an inflammatory response mediated at least in part by PMNs and by tumor necrosis factor (TNF). Endotoxin can also affect the clotting system and metabolic functions of the lungs,[187] and it may dispose the lung to the development of pulmonary infections by increasing adherence of bacteria to endothelium.[188] However, ALI in septic humans does not appear to be necessarily related to endotoxemia, because endotoxin may be undetectable or present only in low concentrations in septic patients. In one study, endotoxin was detected in plasma samples of 74% of patients believed to be at risk who subsequently developed ARDS, 64% of patients who already had ARDS, and 22% of patients believed to be at risk who did not develop ARDS.[189] Exoproducts of bacteria, such as elastase and *Pseudomonas* exoenzyme U, also have been shown to injure the lungs.[190,191]

In addition to a direct role in the pathogenesis of lung injury, bacterial products and mechanical stretch interact in a synergistic and bidirectional manner to enhance lung inflammation and injury.[192,192a] Gram-negative lipopolysaccharide (LPS) causes an acute inflammatory response in the lungs of humans.[193] Bacterial LPS enhanced the responses of human alveolar macrophages to positive-pressure ventilation,[194] and pretreatment of rats with intravenous LPS enhanced cytokine production in the lungs during mechanical ventilation ex vivo.[195] In turn, mechanical ventilation with moderate or large tidal volumes increases the sensitivity of lung macrophages to LPS in vitro and increases the expression of the LPS recognition molecule, CD14, on lung cells in vivo.[196] Mechanical ventilation also amplifies the effects of circulating LPS on lung inflammation.[197] Endotoxin recognition pathways are increased in the lungs of patients with ARDS, and the biologic effects of LPS are amplified in the lungs of patients with lung injury.[198,199] Bacterial LPS and mechanical ventilation interact to activate a series of key biologic transcription modules in the lungs.[200] The synergism between bacterial products and mechanical stretch suggests that interrupting these pathways could limit some forms of ALI in humans.[192]

Increased pressure edema and increased permeability edema are associated with impaired antibacterial defenses,[201,202] and bacterial infections worsen ALI in dogs,[203] baboons,[204] and hamsters.[205] The cause of impaired bacterial defenses in ALI is not known. Bactericidal properties of the alveolar lining material might be altered in injured or flooded lungs, and alterations in surfactant concentration and function may be important.[206] Although PMNs may be present in large numbers in the BAL fluid of patients with ALI, evidence indicates the function of these PMNs is compromised.[207,208]

Inflammation. Substantial evidence implicates host defenses and inflammatory responses in the underlying mechanism of many ALIs. Neutrophils, complement, and

other humoral mediators of inflammation, injury, and repair are discussed in detail in Chapter 17. The neutrophil has a dual role in inflammation and lung injury. PMNs are a vital component of host defenses, and patients with severe neutropenia are at increased risk of bacterial and fungal infections. Conversely, PMNs release toxic oxygen radicals, proteases, and other biologically active mediators that initiate inflammation. Other important cells include alveolar[209] and pulmonary intravascular macrophages[210] and eosinophils.[211] The major mediators of the acute inflammatory response (innate immunity) are listed in Table 55-5. Normally, the pulmonary circulation contains a very large pool of marginated PMNs,[212] which must change shape to squeeze through the lung capillaries. When PMNs are activated, they stiffen and become less distensible. Such PMNs are retained for longer periods of time in the pulmonary microcirculation. Endothelial activation leads to increased expression of leukocyte adhesion molecules, providing a second mechanism to slow the transit of PMNs through the lungs.[213,214] Trapped PMNs respond to chemotactic gradients generated by chemokines produced by alveolar macrophages and mesenchymal cells and migrate into the air spaces.[215] Activated PMNs generate and release toxic substances (e.g., oxygen metabolites[216] and granular constituents, such as proteases, and cationic lysosomal enzymes) that disrupt the function of the microvascular and epithelial barriers, which normally limit liquid and protein flow out of the vascular space and into the alveolar spaces, leading to increased permeability edema. New experimental data provides evidence that neutrophil-mediated acute lung injury may be potentiated by platelets, with additional evidence that aspirin can prevent lung injury in mice from either acid-induced lung injury and transfusion-induced lung injury.[216a]

Inflammatory responses also have the potential to induce injury to lung cells by activating cell death pathways, which lead to apoptosis.[217] Bacterial products, such as *Pseudomonas* exoenzyme U, and mechanical stretch may lead to direct cellular necrosis.[190,191] Apoptosis is mediated by a family of death receptors,[218] which include the TNF receptors and the Fas receptor. The Fas ligand (FasL) is a 45-kd peptide that is shed from the cell surface by the action of metalloproteinases such as matrilysin. Biologically active soluble FasL (sFasL) accumulates in the lungs of patients with ARDS and induces apoptotic death of human lung epithelial cells in vitro.[219] Human sFasL induces epithelial cell death in the lungs of rabbits,[220] and a monoclonal antibody that activates membrane Fas causes alveolar wall apoptosis and fibrosis in the lungs of mice.[220,221] Apoptosis and inflammation pathways intersect, as stimulation of membrane Fas induces cytokine production in human macrophages[222] and inflammation in the lungs of rabbits and mice.[220,223] In addition, lung injury may be able to trigger apoptosis pathways in distant organs, such as the kidney, perhaps by increasing the concentrations of circulating sFasL.[224] Thus, inflammatory responses may trigger cell death pathways, and cell death pathways triggered by sFasL can induce inflammation in the lung alveolar environment. Human studies implicate apoptosis in human lung injury.[225]

Direct Toxicity. Inflammation is not required for all forms of ALI. ARDS occurs in neutropenic patients,[226,227] and a clinical trial using granulocyte colony-stimulating factor to increase the number and activation state of circulating neutrophils in patients with severe pneumonia was not associated with an increased incidence of ARDS.[228] Lung injuries that do not require the participation of PMNs have been reported in animal models. Examples include injuries caused by ethchlorvynol in dogs[229]; by oleic acid in isolated dog lungs[230]; by oxygen in rats[231]; by thrombin infusions in dogs[232]; by *E. coli* endotoxin in rabbits,[233] and by *E. coli* septicemia in baboons.[234] Important species differences exist in the mechanisms involved. For example, in some species, PMN depletion lessens the injuries caused by oleic acid,[235] thrombin infusions,[236,237] and phorbol myristate acetate.[238]

Direct lung injuries are also thought to occur in humans. Putative agents that directly injure the lungs include mechanical forces during mechanical ventilation[239–241]; toxic and corrosive chemicals and gases (e.g., hydrochloric and other acids, ozone, ammonia, chlorine, phosgene, nitrogen dioxide, the vapors of cadmium and

mercury, combustion products, and oxygen, especially at high concentrations); ionizing radiation; aspiration of fresh water (near drowning) or hydrocarbon compounds (e.g., kerosine, gasoline, and dry-cleaning fluid); high temperatures (parenchymal lung burns from fires or explosions); and mechanical injuries (e.g., lung contusion from nonpenetrating chest trauma or blast injury from explosions or lightning).

Many of these injuries develop rapidly, supporting the idea that injury is caused directly by contact with the respiratory epithelium in the airways, the alveolar walls, or both. It is likely that inflammatory pathways are rapidly activated after many types of direct lung injury, as probably occurs after aspiration of gastric secretions (one of the most common causes of clinical ALI). Lung injury occurs rapidly, especially to the epithelium, and is related in part to the low pH of the aspirated stomach contents and also to proinflammatory cytokines in gastric juices.[242,243] Aspiration of gastric contents with pH greater than 2.5 is relatively benign, whereas aspiration of gastric contents with pH less than 2.5 causes severe pulmonary injury in rabbits, rats, and mice. Aspirated acid is quickly neutralized when it contacts lung tissue, but within hours, proinflammatory mediators are released and the injured lung becomes infiltrated with PMNs; then fibrin accumulates in the alveolar spaces and further structural damage is seen on histologic examination. The important role of mechanical stretch is suggested by the National Institutes of Health (NIH) ARDS Network study, which tested two different tidal volume settings in patients with established ARDS.[244] Patients ventilated with lower tidal volumes had a significantly lower mortality, and this was associated with a more rapid fall in circulating concentrations of interleukin-6 than in those receiving higher tidal volumes. In an earlier study, Ranieri and associates[245] found that a lung-protective strategy of mechanical ventilation was associated with a faster decline in inflammatory parameters in BAL fluid, suggesting that reducing stretch reduces inflammation.

Host Factors. Host factors have important effects on susceptibility to ALI. Poorly controlled diabetes is an important risk factor for infections that can lead to ALI, although some epidemiologic evidence suggests that diabetics are actually at a decreased risk for lung injury.[246] Chronic alcoholism increases susceptibility to sepsis and ALI, most likely by altering oxidant/antioxidant balance in the lungs by depleting glutathione in the alveolar microenvironment.[247,248] Genetic determinants also affect susceptibility to inflammation, sepsis, and ALI. The inflammatory response in the lungs of patients with ALI is triggered by innate immunity pathways, and normal people vary a great deal in the intensity of their innate immune responses to bacterial and viral products.[249] Modern rapid DNA sequencing methods have led to the identification of many different single nucleotide polymorphisms (SNPs) that change the base sequence of host DNA. Whether or not these SNPs alter gene function or change amino acid sequence of encoded proteins, SNPs serve as DNA markers that provide clues to genetic determinants of disease. An increasing number of SNPs have been associated with either the onset or the outcome of ALI (reviewed in Gao and coworkers[250]),[251,252] in some cases by altering key proinflammatory pathways in blood or lungs.[253–255]

DIAGNOSIS

The diagnosis of advanced pulmonary edema, particularly when caused by heart failure, is usually easy. Unraveling the cause of other kinds of pulmonary edema may not be so straightforward, particularly in patients with increased permeability edema.

Clinical Assessment

Symptoms and Signs

The clinical manifestations of pulmonary edema vary with its severity and depend on the underlying pathophysiology and the extent to which excess fluid has accumulated in the lungs. Basic initial symptoms are dyspnea, cough, and tachypnea. Wheezing may be heard and may present a problem in differential diagnosis, but patients with asthma generally do not have other symptoms and signs of congestive heart failure or pulmonary edema.[256] Patients who develop increased pressure edema may complain only of vague fatigue, mild pedal edema during the day, or exertional or paroxysmal nocturnal dyspnea. Once alveolar flooding has occurred, the diagnosis of pulmonary edema is not subtle. Patients with alveolar edema usually have severe dyspnea, tachypnea, and cough that is often productive of frothy and sometimes blood-tinged edema fluid. Crackles and rhonchi are heard over the chest, and wheezing may be present. The patient may be cyanotic if alveolar flooding has seriously compromised gas exchange. Cheyne-Stokes respiration is common in severe congestive heart failure and does not necessarily portend a poor immediate prognosis.[257]

Development of edema is often insidious in increased pressure pulmonary edema because the alveoli are protected by the normal safety factors (see Table 55-1). In contrast, in increased permeability edema, alveolar flooding usually occurs rapidly and the onset of symptoms may occur over a short period of time. Edema that occurs suddenly (or unexpectedly) sometimes is called "flash pulmonary edema."

Because pulmonary edema is always a sign of an underlying pathologic process, its cause must be identified so that effective therapy can be directed at the underlying problem producing abnormal transvascular fluid and solute flow into the lungs. Increased pressure edema is usually caused by cardiac failure and thus is usually accompanied by a history of heart disease. This can include signs and symptoms of any of the causes of chronic and acute congestive heart failure, such as coronary insufficiency, hypertension, valvular heart disease, and severe volume expansion. Elevated jugular venous pressure, cardiac enlargement, gallop rhythms, heart murmurs, arrhythmias, large tender liver, and peripheral edema suggest an underlying abnormality of cardiac

function. However, pulmonary edema may be the only manifestation of silent myocardial infarction or diastolic dysfunction of the left ventricle.[258]

History and physical examination may also be helpful in differentiating increased permeability edema from increased pressure edema and in identifying a possible cause of ALI. Patients with increased permeability edema usually do not have signs or symptoms of underlying cardiac disease. The cause of ALI may be suggested by a history of exposure (e.g., to toxic gases or chemicals, near drowning, drug ingestion, trauma), the clinical setting (e.g., sepsis, pneumonia, emesis, seizures, pancreatitis, burns, high altitude), or the physical findings (e.g., chest trauma, long bone fractures, coma, shock). Because infection and the sepsis syndrome are major causes of ALI in humans, a thorough search must be made for signs and symptoms of an infectious cause. Pulmonary and intra-abdominal sources are the most common sites of infection, and all patients should be examined carefully, with special attention being paid to abdominal, rectal, and pelvic examinations. Most patients with ALI are febrile, whether or not an infection is clinically apparent.

Diagnostic Studies and Definitions

Laboratory and other diagnostic studies are helpful, but by the time many of the results are abnormal, the diagnosis is usually obvious. In the special case of pulmonary edema suspected to be caused by saltwater near drowning, measurement of plasma magnesium level can help determine whether or not a patient has aspirated or swallowed seawater, or both: Severe hypermagnesemia (6.7 mg/dL; normal range, 1.6–2.7 mg/dL) has been reported because of the high concentration (around 125 mg/dL) of magnesium normally found in seawater.[90] Appropriate cultures for microorganisms and toxicology screens of blood and urine are useful in identifying underlying causes of ALIs. Sputum or trachea aspirate examination, bronchoscopy with protected-specimen brushing, or BAL with quantitative cultures are all useful in diagnosing pneumonia in ventilated patients, even those who are being treated with antimicrobial drugs.[173,175,176,259] Lung biopsy can provide a specific diagnosis in some patients with ALIs,[260,261] but the results often are not helpful because lung injuries caused by diverse underlying conditions have the same appearance and because specific therapies may not be available.

The criteria for the diagnosis of ALI have been somewhat controversial. Two definitions have gained some acceptance: the expanded definition of ALI[262] and the American-European Consensus Conference definition.[263]

TABLE 55-6. Expanded Definition of Acute Lung Injury

Phase (acute or chronic)
Lung injury score (see Table 55-7)
Etiology (underlying cause or association; see Table 55-4)
Nonpulmonary organ dysfunction

The expanded definition of ALI has four elements (Table 55-6). The first element establishes the time at which the diagnosis is made and separates the group of patients suffering from the immediate consequences of ALI from those who have progressed to more indolent, chronic disease. This is an important distinction because the causes of morbidity and mortality, appropriate supportive and specific therapy, and prognosis differ between the two phases. The second element is the actual Lung Injury Score (Table 55-7), which provides an assessment of the severity of lung injury, taking into account supportive therapy, such as mechanical ventilation with PEEP and oxygen supplementation. This score is important because not all lung injuries are of equal

TABLE 55-7. Components and Individual Values of the Lung Injury Score

	Value
1. CHEST ROENTGENOGRAM SCORE	
No alveolar consolidation	0
Alveolar consolidation confined to 1 quadrant	1
Alveolar consolidation confined to 2 quadrants	2
Alveolar consolidation confined to 3 quadrants	3
Alveolar consolidation in all 4 quadrants	4
2. HYPOXEMIA SCORE	
$PaO_2/FIO_2 \geq 300$	0
PaO_2/FIO_2 225–299	1
PaO_2/FIO_2 175–224	2
PaO_2/FIO_2 100–174	3
$PaO_2/FIO_2 < 100$	4
3. PEEP SCORE (WHEN VENTILATED)	
PEEP ≤ 5 cm H_2O	0
PEEP 6–8 cm H_2O	1
PEEP 9–11 cm H_2O	2
PEEP 12–14 cm H_2O	3
PEEP ≥ 15 cm H_2O	4
4. RESPIRATORY SYSTEM COMPLIANCE SCORE (WHEN AVAILABLE)	
Compliance ≥ 80 mL/cm H_2O	0
Compliance 60–79 mL/cm H_2O	1
Compliance 40–59 mL/cm H_2O	2
Compliance 20–39 mL/cm H_2O	3
Compliance ≤ 19 mL/cm H_2O	4
The final value is obtained by dividing the aggregate sum by the number of components that were used.	

	Score
No lung injury	0
Mild to moderate lung injury	0.1–2.5
Severe lung injury (ARDS)	>2.5

ARDS, acute respiratory distress syndrome; PaO_2/FIO_2, arterial oxygen tension to inspired oxygen concentration ratio; PEEP, positive end-expiratory pressure.

From Murray JF, Matthay MA, Luce JM, et al: An expanded definition of the adult respiratory distress syndrome. Am Rev Respir Dis 138:720–723, 1988.

severity and severity changes over time. The term *acute respiratory distress syndrome* is applied only to the most severe injuries (those that yield a score > 2.5); milder lung injuries, termed "mild to moderate," may have a better prognosis and may differ from ARDS in other important aspects. The third element, etiology, separates the many underlying disorders that can result in ALI (see Table 55-4, which is not meant to be an exhaustive or exclusive list). Multiple etiologies may be present. Finally, the fourth element, which was separated when the expanded definition of ALI was first proposed, recognizes the occurrence of injury to organs other than the lungs. This is important because injury is often not limited to the lungs. Dysfunction of other organs is common,[264] and prognosis varies between isolated pulmonary and generalized systemic disorders.

The Glasgow Coma Scale is widely used to assess neurologic status. Criteria have been proposed to evaluate abnormalities in renal, cardiovascular, hepatic, gastrointestinal, and hematologic function, all of which can complicate or coexist with ALI. The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system and the Simplified Acute Physiology Score have been used to define an individual patient's overall severity of injury.[265]

The American-European Consensus Conference Definition (Table 55-8) also has four elements: (1) timing (onset must be "acute"); (2) oxygenation (arterial P_{O_2}/F_{IO_2} [fractional concentration of oxygen in inspired gas] ≤ 300 mm Hg, regardless of the level of PEEP, for the diagnosis of ALI to be made, and arterial P_{O_2}/F_{IO_2} ≤ 200 mm Hg, regardless of PEEP level, for the diagnosis of ARDS to be made); (3) chest radiograph (bilateral infiltrates seen on frontal view); and (4) pulmonary artery wedge pressure (≤18 mm Hg when measured, or no clinical evidence of left atrial hypertension).

The two definitions differ in the exact criteria that must be met for a diagnosis to be established, but they identify similar patients[266] and are complementary. The power of the Consensus Conference definition is that it was reached by consensus and that it is also easy to remember. The advantages of the expanded definition are that it provides a grading system (the Lung Injury Score) whereby equally injured patients can be grouped and compared and the progress (or lack thereof) of any individual patient's course over time can be measured; that it recognizes the distinct phases of the progression of lung injuries (early vs. late disease); that it separates the different underlying conditions that are associated with ALI (conditions in which the exact etiology and mechanism of ALI may differ); and that it recognizes and requires identification of associated extrapulmonary disease (which has profound effects on mortality of patients with ALIs).

Despite these clinical criteria, defining ALI and ARDS is not without problems.[267] The most serious deficiency of both definitions is the failure to link the underlying pathophysiology of ALI to the functional abnormalities that are at the core of the definitions (i.e., data are lacking that link any particular arterial P_{O_2}/F_{IO_2} to any particular change in the structure or function of the relevant barriers in the lungs or to the degree of edema). What defines ALI in a meaningful way is the altered barrier permeability of the lungs. What defines ARDS in a meaningful way is structural damage to the lung microvascular endothelial barrier, the alveolar epithelial barrier, or both. Many respiratory disorders can reach the definitions' thresholds for "diagnosis," and many ALIs, especially mild ones, fail to reach them at all. For example, bacterial pneumonia may not be a different disease when it crosses some arbitrary threshold and meets criteria for ALI or ARDS; venous air emboli–induced and heroin-induced pulmonary edemas are ALIs, even if they fail to disturb oxygenation sufficiently to satisfy an arbitrary definition of ALI or ARDS. In small numbers of patients, the Lung Injury Score has correlated with bedside measurements of lung vascular permeability[268–270] and with the extent of abnormalities on computed tomography.[271] In the future as current research work evolves, the clinical definitions need to be supplemented with biologic criteria to help categorize ALI and ARDS into more specific disease entities.

The Consensus Conference definition also has limitations. First, it requires that timing be acute, but it neither specifies the degree of acuity required nor accounts for the considerable heterogeneity in the course of patients with ALIs, each progressing, or not progressing, at its own given pace, through exudative, proliferative, and recovery phases. Second, it requires an arbitrary pulmonary artery wedge pressure (or no clinical evidence of left atrial hypertension), but left atrial hypertension or the lack thereof is not part of the basic pathophysiology of ALI. It is the pulmonary microvascular pressure that matters when the lungs are injured, and that pressure can be low, normal, or (often) elevated. However, the Consensus Conference definition is simple to apply and has facilitated enrollment of patients in clinical trials.[94]

Both definitions have been faulted for failing to allow early diagnosis and for failing to accurately predict mortality.[272,273] Regarding mortality, the relevant question about any definition is not whether it can predict who

TABLE 55-8. American-European Consensus Conference Definition of Acute Lung Injury and Acute Respiratory Distress Syndrome

TIMING
Acute
OXYGENATION (REGARDLESS OF PEEP LEVEL)

P_{aO_2}/F_{IO_2} ≤ 200 = acute respiratory distress syndrome
CHEST RADIOGRAPH
Bilateral infiltrates on frontal view
PULMONARY ARTERY WEDGE PRESSURE
≤18 mm Hg when measured, *or*
No clinical evidence of left atrial hypertension

P_{aO_2}/F_{IO_2}, arterial oxygen tension to inspired oxygen concentration ratio; PEEP, positive end-expiratory pressure.

will live and who will die, but rather whether it can correctly identify and distinguish who has ALI and who does not. Death is often not directly related to ALI, but rather to nonpulmonary organ dysfunction, chronic liver disease, or sepsis.[273] The severity of the oxygenation defect, which is what the definitions measure, does not have major prognostic value early in the course of clinical lung injury. Finally, assessment of the accuracy of definitions[266] is difficult because there is no "gold standard" for ARDS against which the accuracy of any given definition can be measured.

Chest Radiographs

The plain chest radiograph is the most practical laboratory study available for the detection of pulmonary edema.[274–277] Disadvantages are that chest radiographs are insensitive to small changes in lung water and are only semiquantitative.[1,278] An additional limitation is that chest radiographs are not consistently helpful in distinguishing increased pressure edema from increased permeability edema.[279–281] These disadvantages are balanced by the advantages that chest radiographs are noninvasive, inexpensive, easily repeatable, readily available, and free of side effects.

Before alveolar flooding, the plain chest radiograph can show distended vascular shadows (particularly in the upper lung fields), enlargement and loss of definition of hilar structures, development of septal lines (Kerley's lines), loss of peribronchial and perivascular definition (cuffing), and perihilar haze indicating the presence of interstitial pulmonary edema. Acinar shadows, often confluent and creating irregular, patchy increases in lung density that obscure vascular markings, indicate the presence of alveolar edema. Air bronchograms may be observed in severe edema. Because the radiographic signs of interstitial and alveolar edema are determined by gas and blood volumes and their distribution in the lungs in addition to the presence of edema, the recognition and quantitation of edema are not precise, and the radiographic appearance of edema is strongly influenced by the lung volume at the time the film is made. The chest roentgenogram score is an integral part of the Lung Injury Score, but the interpretation of chest radiographs is not well standardized and significant interobserver variations have been reported.[282]

Arterial Blood Studies

Although not specific, the arterial P_{O_2}, carbon dioxide pressure (P_{CO_2}), and pH are the most informative laboratory indicators of overall pulmonary function in patients with pulmonary edema. Arterial blood studies are not sensitive to early edema. Arterial P_{O_2} may actually rise in the earliest stages of increased pressure edema because the increase in vascular pressures distributes blood flow more uniformly to well-ventilated units. Interstitial pulmonary edema does not usually affect oxygen uptake in the lungs beyond modest hypoxemia caused by ventilation-perfusion mismatching. In contrast, alveolar flooding seriously compromises gas exchange. Hypoxemia is due to right-to-left shunting of blood resulting from perfusion of alveoli that cannot be ventilated because they are fluid filled or collapsed. Ventilation-perfusion abnormalities also contribute to the hypoxemia of edema. In two studies of groups of patients with diverse lung injuries, oxygenation appeared to depend more on the vasoconstrictive ability of the pulmonary circulation (i.e., the ability to reduce perfusion of damaged and edematous areas of the lungs) than on the amount of edema present.[283,284]

Arterial P_{CO_2} is often low in edema, especially in the early stages, when tachypnea results in alveolar hyperventilation. An elevated P_{CO_2} (more common with severe edema) indicates alveolar hypoventilation, which can be caused by underlying lung disease, increased metabolic production of carbon dioxide (perhaps related to increased work of breathing), increased wasted ventilation (ventilation of poorly perfused alveoli or airways leading to flooded, nonventilated alveoli), or mechanical impairment caused by weak respiratory muscles.[285] Elevated P_{CO_2} does not necessarily indicate a poor prognosis[286] and often resolves with treatment of pulmonary edema.

Acid-base disturbances are common in increased pressure edema but often do not correlate with severity, morbidity, or mortality.[287] When edema is mild, tachypnea results in hyperventilation and consequent respiratory alkalosis (and subsequent compensating metabolic acidosis). When edema is severe or the lungs have been injured, many patients develop metabolic acidosis as a result of tissue hypoxia, increased work of breathing, intrinsic lung lactate production, or all of these.[286,288] Attempts to correct acidosis with parenteral bicarbonate administration usually are not necessary; rather, the underlying cause must be identified and treated appropriately. Respiratory acidosis caused by alveolar hypoventilation can be treated either by noninvasive ventilation or by invasive mechanical ventilation with endotracheal intubation. Metabolic acidosis can often be corrected by alleviating hypoxemia and improving cardiac function; the possibility of underlying disease amenable to surgery (e.g., intestinal ischemia or infarction, perforation of a viscus) or pancreatitis should not be overlooked.

Pulmonary Edema Fluid Protein Concentration Measurement

When florid pulmonary edema is present, measurement of protein concentration in simultaneously collected edema fluid (suctioned through an endotracheal tube) and plasma provides a rapid, noninvasive method for distinguishing increased pressure edema from increased permeability edema.[156] Because the microvascular barrier is functionally intact in increased pressure edema, plasma proteins remain largely confined to the intravascular space, and edema fluid protein concentration is low relative to plasma protein concentration (the ratio of edema fluid to plasma protein concentration generally <0.65). Because the microvascular barrier is injured and cannot effectively confine plasma proteins to the vascular space in increased permeability edema, edema fluid

protein concentration is high relative to plasma protein concentration (ratio of edema fluid to plasma protein concentration generally >0.75). Intermediate values (between 0.65 and 0.75) may indicate that both types of edema are present and suggest the relative contributions of each. Measurement of the ratio of edema fluid to plasma protein concentration has been shown to be a simple method for separating the types of pulmonary edema in numerous reported series of patients with pulmonary edema.[78,289–294] Three studies indicated that an increasing protein concentration in serial measurements of edema fluid in ALIs was a good sign, reflecting an intact epithelial barrier and net removal of edema fluid from the alveoli.[78,293,294] There is new evidence that the edema fluid to plasma protein ratio has prognostic value as well as diagnostic value.[294a] Such measurements need to be correlated with the patient's clinical condition, because an increasing protein concentration in edema fluid over time might also mean that increased permeability edema was complicating what had been increased pressure edema or that the lungs were injured more severely or more extensively as time passed.

Edema fluid can be collected by inserting a standard 14- to 18-gauge catheter through an endotracheal tube and advancing it into a wedged position in the distal air spaces (similar to the procedure for wedging a bronchoscope). Gentle suction is applied as the catheter is slowly withdrawn, and fluid is collected in a small trap. Several attempts may be needed; if no fluid can be suctioned, the clinician should try changing the patient's position. Samples grossly contaminated with airway secretions (which have a very low protein concentration, <1.0 g/dL), such as mucus, pus, and debris, should be discarded. Protein concentrations can be measured by the clinical laboratory or estimated quickly at the bedside from the protein scale of a handheld refractometer.

BAL has been used as a research and diagnostic tool that may also yield useful information about the cellular biochemical and microbial composition of the air space,[156,295] but lavage is not useful as a method to measure alveolar protein concentration, because the instilled saline dilutes alveolar fluid by approximately 50- to 100-fold, depending on the method that is used.[156]

Pulmonary Function Tests

With the exception of arterial blood gas analyses, by the time results of conventional tests of pulmonary function are abnormal in patients with pulmonary edema, the diagnosis is usually obvious or the patient is too sick to study. The general sequence of developing abnormalities as edema accumulates was discussed earlier in this chapter. The earliest abnormality detectable by conventional studies in increased pressure edema is a rise in diffusing capacity of the lung for carbon monoxide caused by an increase in pulmonary capillary blood volume as a result of pulmonary vascular congestion. Closing volume may be greater when interstitial edema is present, but consistent changes in routine pulmonary function tests are generally not found until the alveoli begin to flood and vital capacity begins to diminish. Because pulmonary function tests are neither sensitive nor specific in edema, provide no information for separating the two types of edema, and are difficult to perform in patients who are ill, such tests are not useful in the diagnosis of pulmonary edema.

Hemodynamic Measurements

Pulmonary vascular pressures are sometimes recommended as helpful for differentiating increased pressure edema from increased permeability edema. However, measurement of vascular pressures in the lungs is expensive and invasive and can be associated with significant morbidity and mortality,[296–298] although one study reported no excess morbidity or mortality in patients with ARDS who had a pulmonary arterial catheter inserted.[299] The problems with measuring and interpreting pulmonary artery occlusion pressures have been reviewed.[297,300–302]

Measurement of Lung Water and Barrier Function

Measurement of the amount of water in the lungs could be useful in detecting early pulmonary edema and in assessing its clinical course and response to treatment. However, no ideal technique is available. Methods in use or under investigation focus on either measurement of lung density or equilibration of tracers with water in the lungs.[1,303] Interest in such measurements assumes that accurate knowledge about lung water would be useful in diagnosis and would be beneficial in the treatment of patients with pulmonary edema. Recent work with a single thermal indicator for measuring extravascular lung water has shown promise based on several studies.[304–307]

Lung Density Methods

Because lung density is determined by air and blood as well as extravascular tissue and water contents, densitometric techniques are only semiquantitative, and baseline lung densities vary widely. These techniques are most useful when a series of studies can be compared in order to estimate changes in lung water content. They are of little use in early edema because lung fluid filtration can increase greatly before lung water content actually increases. The most widely used method is the plain chest roentgenogram, because it is readily available, is relatively inexpensive, is noninvasive, and can be repeated frequently at little risk to the patient. Unfortunately, it is insensitive (lung water must increase by >30% before being recognizable) and nonspecific (other interstitial or alveolar processes produce similar radiographic shadows). More precise density measurements may be made with techniques such as transmission computed tomography,[308,309] but the problem of separating changes in gas and blood volumes from changes in water content remains. Similar information may be gathered from transthoracic γ-ray attenuation[310] or Compton scattering.[311] It might be possible to relate changes in sound

speed across the lungs to lung water content,[312] but such measurements would also depend on lung volume. A theoretically related technique, transthoracic bioelectric impedance analysis, attempts to relate the resistance to an alternating electrical current passed through the thorax to the amount of water in the lungs.[313]

Nuclear magnetic resonance imaging[314] and positron emission tomography[315] techniques for measuring lung water are also under investigation. Their theoretical advantages are the noninvasive measurement of density without ionizing radiation (in the case of nuclear magnetic resonance imaging) and lack of effects of ventilation and perfusion abnormalities; their disadvantages are that the hardware for both techniques is expensive and not readily available and the slow scanning time and cumbersome equipment are not suitable for studying seriously ill patients.

Tracer Methods

Attempts have been made to assess lung water by measuring either the rates of equilibration of a diffusible indicator and an intravascular indicator (multiple-indicator dilution technique) or the uptake of inhaled gases (soluble-gas technique). Both methods have been the subject of considerable investigation, but neither method is in clinical use. These methods are limited by the inhomogeneous distribution of the tracers and the complexity of the equipment needed to make measurements.

Multiple-Indicator Dilution Techniques. These are invasive techniques based on measuring differences in transit-time volumes between two indicators, one nondiffusible (restricted to the intravascular space) and one diffusible (able to enter the extravascular space).[316] Suitable tracers are injected into a systemic vein or the right side of the heart, and time-concentration curves are recorded from a systemic artery. Because the diffusible tracer can in theory equilibrate with a much larger volume (extravascular and intravascular volumes) than the nondiffusible tracer (intravascular volume only), the differences in concentrations of the two tracers over time after traveling through the lungs can be used to calculate both blood flow and extravascular mass (mainly water) of the lungs.

Such techniques are limited by several factors: time, which may not allow the diffusible tracer to reach areas of the lungs remote from the microvascular bed; blood flow inhomogeneities, which restrict the tracers to perfused portions of the vascular bed; inhomogeneity of water distribution in the lungs; recirculation of the indicator; measurement of mass (e.g., dry lung, blood vessels, heart) in addition to water mass; and a host of technical details concerning the appropriateness of the indicators and the methods of their injection, withdrawal, and measurement, and calculation of concentration over time. The major problems are underestimation of lung water in pulmonary edemas in which uneven distribution of blood flow develops, which occurs in most lung injuries, and insensitivity (a 50% increase in measured lung water may be significant, but edema is obvious by that time).

Two methods have been the subject of considerable research, the thermal-dye method[317] and the multiple-isotope method.[318] The thermal-dye method has come closest to clinical use, and a refinement of the method (using a fluorescent indicator) allows measurements to be made with an indwelling catheter without blood withdrawal. The major problems are underestimation of lung water, particularly when vascular perfusion inequalities exist in the lungs or large volumes of edema are present, and accuracy of measurement of thermal changes.[319] Prospective evaluations of extravascular lung water measurements by the thermal-dye method versus pulmonary artery wedge pressures to guide the hemodynamic management of critically ill patients claimed superiority of the lung water technique[320,321]; benefit may have accrued as a result of restrained fluid therapy. The multiple-isotope method requires blood withdrawal for tracer measurement and, like the thermal-dye method, underestimates water content if there is perfusion inhomogeneity.[322] This latter method appears to provide a better estimation of lung permeability–surface area product than of lung water content.

Measurement of Barrier Function

Because transvascular fluid flow into the lungs can be abnormal long before lung water content increases, and because the two types of edema can be separated on the basis of differences in barrier function, detection of increased transvascular fluid flow into the lungs and measurement of barrier integrity might be more helpful than measurement of lung water content in edema. Clinical distinction between increased pressure edema and increased permeability edema is difficult.[323] A simple and practical method exists to evaluate barrier integrity (edema fluid protein concentration measurements, discussed earlier), and several methods have been studied to detect early edema and changes in barrier function. However, none is in routine clinical use.

Detection of Lung Injury

Because lung injury occurs before measurements of barrier integrity or transvascular fluid flow are abnormal, methods to detect lung injury before the appearance of abnormal liquid and solute transport might be of help. Early detection of lung injury would be especially valuable if therapies were developed on the basis of the mechanisms of lung injuries. Although tests to determine the causes of lung injuries are not available, methods such as studies of the metabolic functions of the lung and a variety of specific lung injury makers are being investigated to detect whether lungs have been injured.

Changes in Metabolic Functions of the Lung

The lungs are involved in the metabolism of a variety of biologically active substances. Because the removal and metabolism of such substances depend on endothelial cell function, alterations in metabolic function in the lungs might be sensitive early tests of endothelial cell

injury. Abnormal levels, activities, or uptakes of various substances (e.g., ACE, vasoactive amines, metabolites of arachidonic acid, endothelin-1, certain drugs) have been detected when the lungs are injured. Unfortunately, the finding of normal or abnormal uptake by the lungs is neither specific nor sensitive for all ALIs; metabolic functions can be influenced by drugs, cardiac output, vascular surface area, and hypoxia or hyperoxia, and serious lung injury can occur without changes in metabolic function. Although alterations in metabolic functions of the lungs are not clinically useful indicators of endothelial cell function at this time, their potential use for early detection of lung injury justifies continuing investigation.

Biologic Markers of Lung Injury

Potential markers of ALI have been the subject of several comprehensive reviews.[156,324,325] There is considerable interest in finding a simple blood, urine, or BAL test that could identify patients at risk who are destined to develop ALI, or who are in the earliest stages of ALI, or that could predict the outcome of patients with injured lungs. To be of clinical use, such a marker would have to be practical and inexpensive to measure as well as sensitive and specific for ALI; with the exception of measurements of edema fluid protein concentration relative to plasma protein concentration (discussed earlier), none has become clinically useful yet. There may be many reasons for the lack of progress in identifying suitable markers: many (if not most) patients cannot be enrolled into studies of early or predictive markers because they already have injured lungs when they present or injury occurs very soon after the causative insult; ARDS is not a disease, but rather a symptom complex that may result from diverse causes; injury to the lungs is often overwhelming, and subtle differences in potential markers may be missed; measurements of potential markers in biologic fluids may not reflect what is happening at the tissue and cellular levels; and there has been limited uniformity among studies in diagnostic criteria and design (e.g., suitable controls, such as patients with increased pressure pulmonary edema and severe lung disease other than ALI, are often not studied; measurements of putative markers are often made at a single time rather than regularly over the course of ALI). The result is that it might never be possible to find a suitable single marker, but new work shows the potential value of using more than one biologic marker.[326] Considerable progress has been made in studying biologic markers for their pathogenetic significance.[325,327]

Products of complement activation were proposed as markers but were later shown to be poorly correlated with lung injury.[328,329] Measurement of circulating endotoxin was not appropriately sensitive or specific for the presence or the risk of developing lung injury. Release or activity of ACE has not been found to be sensitive or specific for ALIs. von Willebrand factor antigen was useful as a plasma marker of impending ALI in septic patients, and one study confirms that von Willebrand factor antigen levels are elevated in the edema fluid and plasma of patients with ALI and correlate with poor clinical outcomes.[330] Other biochemical and inflammatory markers have been found to have some association with lung injury and mortality, including most recently surfactant protein D.[331] Elevated levels of interleukin-6 in the plasma are also associated with mortality.[244] So far at least, no simple biologic marker has been identified that can be used as elevations in cardiac enzymes are used to diagnose acute myocardial infarction.

Because PMNs are associated with the mechanism of many lung injuries, detection of their presence in the lungs, tests of their function, or measurement of their toxic metabolites might be useful. For example, increased hydrogen peroxide has been measured in the breath and urine of patients with ALIs,[332,333] presumably reflecting the presence of oxygen metabolites in their injured lungs. Evidence of oxidant activity was also reported in BAL fluid.[334] Other mediators of inflammation might be appropriately considered as well. For example, TNF-α has been detected in blood[335] and BAL fluid, but an association between TNF and the development of ARDS was not found,[336] and TNF was found to be elevated in patients with severe congestive heart failure[337]; various lipoxygenase products of arachidonic acid metabolism have been detected in pulmonary edema fluid,[149] BAL fluid,[338] plasma, and urine[339]; and elastase has been detected in BAL fluid.[340–343] In addition to these possible markers, sporadic reports of abnormal substances or abnormal levels of normally occurring substances detected in fluids obtained from small groups of patients with ALI are continually being reported. Often, there is overlap between levels in patients who have ALIs and those who do not. The results are often of interest to illustrate the wide variety of abnormalities that can be detected when the lungs are injured and to suggest the complexity of the underlying pathophysiology.

Several studies from multicenter clinical trials have reported the independent predictive value of some plasma markers for mortality and other clinical outcomes in patients with ALI. The biologic markers of greatest predictive value are surfactant protein D,[344] interleukin-6 and interleukin-8,[345] von Willebrand factor antigen,[346] soluble TNF-α receptors I and II,[347] intercellular adhesion molecule-1,[348] protein C and plasminogen activator-1,[349,350] and the receptor for glycation end products (RAGE).[351,352] Because ALIs follow a wide variety of insults and range in severity, and because many abnormalities detected in ALI are found in other severe illnesses of diverse etiology that do not involve the lungs, it seems unlikely that any single marker will be found that unequivocally identifies the risk or the presence of ALI. Focus on particular subgroups of patients with common causes of injury and study of much larger groups of better diagnosed patients might be helpful. An approach that has not received much attention is investigation of the sensitivity and specificity of combinations of markers. In support of this approach, one recent study found that combinations of three plasma biomarkers had a statistically significant better prognostic value for predicting death than the use of standard clinical predictors alone.[352a] The new field of targeted proteomics will

expand this kind of investigation and perhaps identify patterns of protein abnormalities that can be found in the plasma, edema fluid, and BAL fluid of the air spaces of the lung in ARDS.[353–356]

TREATMENT

Treatment of pulmonary edema requires adequate life support followed by specific therapy directed at the factors that led to accumulation of water in the extravascular spaces of the lungs. Rational therapy also requires a correct diagnosis and an understanding of the nature of the underlying disease state and of the strategies that might prove useful in limiting further edema accumulation and favor fluid removal from the lungs.[357]

Immediate Therapy

Patients with alveolar edema are often severely ill and require immediate treatment for acute respiratory failure. The basic principles of treatment of hypoxemic respiratory failure are discussed in Chapters 84 and 85. Essential requirements for patients with pulmonary edema include preservation of the airway, provision of adequate ventilation, and maintenance of satisfactory oxygenation. New methods for the noninvasive measurement of blood gases have made monitoring of their oxygen saturation possible, which can be useful in assessing the adequacy of oxygen support and the effects of therapy. Blood pressure and other forms of circulatory support may also be needed.

Hydrostatic Pulmonary Edema

If the patient is not hypotensive, morphine sulfate, 5 to 10 mg, or its equivalent, should be given intravenously slowly over several minutes (rapid injection can cause pulmonary vasoconstriction and increased permeability via histamine release from the lungs). Morphine is an extremely useful drug in the treatment of cardiogenic pulmonary edema because it is a potent vasodilator as well as a central nervous system sedative and because it does not depress myocardial contractility. Its vasodilating effects can substantially reduce pulmonary capillary pressure and may improve depressed cardiac output. The work of the heart is lessened by the vasodilating, bradycardic, and sedative effects of morphine. Cautiously administered morphine usually does not cause respiratory failure or aggravate existing carbon dioxide retention associated with acute pulmonary edema, but the patient must be closely watched if he or she is not intubated and receiving assisted ventilation. Hypotension following morphine administration indicates that too much drug was given or that the intravascular volume is lower than suspected.

If medical care is not immediately available, two historical treatments for increased pressure pulmonary edema can be lifesaving. First, rotating tourniquets can act to reduce blood volume (and thereby pulmonary perfusion pressure) by trapping blood in the extremities, away from the pulmonary circulation. Tourniquets, or blood pressure cuffs inflated to less than systolic pressure, are applied to three of the four extremities and rotated every 15 minutes. The purpose is to decrease venous return, not to stop all blood flow to the extremities. Care must be taken that the tourniquets are rotated and that venous return from any extremity is not obstructed for more than 45 minutes at a time. A study of patients with left ventricular dysfunction following myocardial infarction showed trapping of considerable blood volume in the periphery by tourniquets, but variable and sometimes unfavorable effects on left ventricular function.[358] Second, phlebotomy[359] (100–500 mL) can be used to reduce blood volume in acute pulmonary edema when the patient is not in shock and if drugs and supportive care are not available.

When supportive care is available, positive airway pressure, supplied by a tight-fitting face mask[360,361] or by mechanical ventilation after endotracheal intubation, performs the same function as rotating tourniquets without risking loss of limbs: High pressure in the thorax impedes venous return and traps blood volume peripherally, which has the same usually beneficial but sometimes unfavorable effects on left ventricular function as tourniquets. Positive airway pressure, mechanical ventilation, or both can also help reverse some of the physiologic disturbances that can contribute to the development of pulmonary edema: improved oxygenation can increase myocardial oxygen supply, mechanical ventilation can be of benefit to decrease the work of breathing and thus lower the work of the heart, and left ventricular afterload can be reduced when positive pleural pressure replaces the wide swings in negative pressure that occur with spontaneous ventilation. A recent clinical trial showed no improvement in mortality in patients with acute cardiogenic pulmonary edema who were treated with continuous positive airway pressure or bilevel positive airway pressure by mask as compared with supplemental oxygen alone.[362]

Major Options

After emergency treatment has been instituted, there are three major therapeutic options: vasodilators, diuretics, and inotropic agents. The goal of therapy with these agents is to lower the hydrostatic pressure at the filtration sites in the pulmonary vascular bed while maintaining adequate systemic delivery of oxygen. The choice of therapy is dictated by the patient's condition and the cause of the pulmonary edema.

Perhaps the most controversial topic in management is the role of bedside right-sided heart catheterization. One prospective cohort study of critically ill patients showed that flotation heart catheterization was associated with increased 30-, 60-, and 180-day mortality.[298] Subgroup analysis did not reveal any patient group for which right-sided heart catheterization was associated with improved outcome, and patients with acute respiratory failure and multiple organ system failure were at greatest hazard to do worse when a pulmonary artery catheter was placed. This was an observational study,

not a randomized clinical trial, and the reasons for lack of benefit from right-sided heart catheterization were not clear: the pulmonary artery catheter might directly worsen outcome, for example, if its risks and deleterious effects outweighed any benefits; benefits might not be realized if interpretations of hemodynamic measurements were incorrect (lack of skill and knowledge is a common problem in the interpretation of such measurements); the pulmonary artery catheter might be a marker for an aggressive style of care that increases mortality; or changes in therapy in response to hemodynamic information from pulmonary artery catheters might increase mortality. The study cohort appeared to exclude the possibility that right-sided heart catheterization was used in sicker patients, thus resulting in higher mortality (the patients with and without pulmonary artery catheters were matched for severity of illness). In addition to increased mortality, bedside flotation heart catheterization was associated with increased costs and use of resources. As a result of this observational study, the National Heart, Lung, and Blood Institute (NHLBI) sponsored clinical trials to assess the clinical usefulness of pulmonary artery catheterization in critically ill patients. The ARDS Network clinical trial of 1000 patients demonstrated that there was advantage to using a pulmonary arterial catheter versus a central venous catheter in patients with ALI.[363] There were no major complications with the use of pulmonary artery catheterization in this trial, but on balance, the results showed no benefit in most patients with ALI. Similarly, a different clinical trial reported no clinical benefit from the use of pulmonary artery catheters in surgical patients with preoperative cardiac dysfunction, and the patients who had pulmonary artery catheters had a increased incidence of pulmonary embolism, perhaps because they were sicker.[364,365] On balance, pulmonary artery catheters provide a great deal of clinically useful physiologic information, but the information gained does not alter clinical outcome, and their use has declined dramatically. Some patients with shock might still benefit from a pulmonary artery catheter.[366]

Vasodilators

Vasodilators are useful pharmacologic agents for treatment of acute increased pressure pulmonary edema. Their effects occur in minutes. Through dilation of veins, vascular capacitance is increased and blood is redistributed peripherally, thereby lowering the driving pressure for fluid filtration in the lungs; through dilation of arteries, systemic vascular resistance (cardiac afterload) falls, cardiac output and stroke volume increase, and the heart works more efficiently. In addition to morphine, three classes of vasodilators may be useful in pulmonary edema: venodilators (e.g., nitrates), arteriolar dilators (e.g., phentolamine, hydralazine), and mixed dilators (e.g., nitroprusside).

Sodium nitroprusside, a direct-acting venous and arteriolar dilator, is a commonly used agent in acute pulmonary edema. Its advantages are that the effects are immediate, its half-life is short, and cardiac output is maintained by arteriolar dilation and subsequent increased cardiac stroke volume even as central blood volume is lowered (thereby reducing pressure in the pulmonary vascular bed). Its main disadvantage is that invasive hemodynamic monitoring (i.e., an arterial cannula for continuous measurement of systemic blood pressure) is required because the dose must be carefully titrated to avoid profound hypotension. Prolonged infusions can result in cyanide or thiocyanate toxicity; the earliest sign is metabolic acidosis. Arterial oxygenation can deteriorate during therapy with any vasodilator if increased pulmonary blood flow and inhibition of hypoxia-mediated pulmonary vasoconstriction result in relatively increased perfusion of a nonventilated, fluid-filled, or collapsed lung. Therapy with both nitroprusside and nitroglycerin can be complicated by methemoglobinemia, and all nitrates can precipitate increased intracranial or intraocular pressure.

Nitroprusside is usually started at 10 μg/min by intravenous infusion and increased by 5 to 10 μg every 3 to 5 minutes until the desired effect is achieved. Arterial pressure should not be allowed to fall below 60 mm Hg diastolic, and peak systolic pressure should be kept higher than 90 mm Hg. Most patients require 50 to 100 μg/min to achieve the desired effects.

Nitroglycerin and other nitrates are also direct-acting vasodilators, but their predominant effect is on the venous capacitance bed. Intravenous nitroglycerin may be particularly useful in patients with increased pressure pulmonary edema associated with acute myocardial infarction or myocardial insufficiency. Nitroglycerin consistently dilates intercoronary collateral vessels, thereby improving blood flow to ischemic or marginally perfused regions of myocardium. Nitroprusside infusion does not consistently have this effect and may actually result in a decrease in collateral blood flow to ischemic regions of the heart. Nitroglycerin may also be useful in patients with borderline hypotension; because its effects (at least at lower infusion rates) are predominantly venodilating, systemic arterial pressure can be preserved while increased venous capacitance leads to lower driving pressures for fluid filtration in the lungs. At higher doses, nitroglycerin also exerts arteriolar dilator effects similar to those of nitroprusside. The major disadvantage of intravenous nitroglycerin is that invasive hemodynamic monitoring is generally required.

Intravenous nitroglycerin infusion is started at 10 to 15 μg/min and increased 5 to 10 μg/min every 3 to 5 minutes until mean arterial pressure falls (usually by >20 mm Hg), the pulmonary vascular pressure is brought to the desired level (if it is being measured), headache becomes intolerable, or angina (if present) is relieved. Development of tachycardia during nitroglycerin infusion can indicate that cardiac filling pressures and cardiac output have fallen to low levels. Nitroprusside, which preserves cardiac output, might be a more appropriate therapeutic option under this circumstance.

Isosorbide dinitrate can also be given intravenously. In patients with severe pulmonary edema, the combination of high-dose isosorbide dinitrate plus low-dose furosemide was found to be more effective (50% fewer acute

myocardial infarctions) than the combination of high-dose furosemide plus low-dose isosorbide dinitrate. The onset of action of intravenous isosorbide dinitrate is rapid (peak vasodilation at 5 min), but the short half-life (about half an hour) requires frequent repeat dosing when it is given by bolus injection. Usually, 3 mg is injected intravenously every 5 minutes until oxygen saturation increases, arterial blood pressure falls more than 30%, or systolic pressure is less than 90 mm Hg. The effective cumulative dose is generally around 12 mg.

Other nitrates can also be useful, especially in increased pressure pulmonary edema, if the patient is not so critically ill that urgent intravenous therapy is required. *Transdermal nitroglycerin* ointment, 0.5 to 2 inches, and oral isosorbide dinitrate, 20 to 100 mg, are effective venodilators with prolonged duration of action (3–5 hr). The advantage of ointment is that it can be wiped off if necessary, but both agents have the disadvantage that effects cannot be as precisely controlled as in intravenous therapy. Tolerance to the effects of transdermal nitroglycerin can develop rapidly but can be restored after a nitrate-free interval (usually overnight).

Other vasodilators may be useful in the treatment of selected cases of acute increased pressure pulmonary edema but have not been widely used. *ACE inhibitors*, such as captopril and enalapril, act both to reduce pulmonary vascular pressure and to increase cardiac output. The ACE inhibitors have proved to be useful agents in the treatment of more indolent pulmonary edema states. However, their use is not recommended in the setting of acute myocardial infarction. A placebo-controlled, randomized, double-blind clinical trial of intravenous enalaprilat (1 mg over 2 hr) in a small number of congestive heart failure patients with acute pulmonary edema showed reduced pulmonary capillary wedge pressure, increased renal blood flow, and slightly improved oxygenation with therapy.[367]

Diuretics

Patients with symptoms of pulmonary edema may also benefit from administration of diuretic agents.[368] These drugs may exert a modest immediate effect by increasing venous capacitance and decreasing the relative perfusion of flooded alveoli (acting as vasodilators), but their principal mechanism of action is to increase sodium and water excretion by the kidneys. The resultant diuresis causes a decrease in left ventricular volume and pressure and thereby a reduction in the pressure at the filtration sites in the lungs. The effects of therapy may be delayed for hours to days. The potent loop diuretic *furosemide*, 20 to 40 mg by slow intravenous injection, is the most useful agent in pulmonary edema. Furosemide is equally effective when administered by continuous infusion: a loading dose of 80 mg is followed by a continuous infusion at 10 to 20 mg/hr; if there is no response in an hour, the loading dose is given again and the infusion rate is doubled. Equivalent doses of other loop diuretics (bumetanide, torsemide, or ethacrynic acid) should have the same effects. Because these drugs cause excretion of substantial amounts of potassium and chloride in addition to sodium and water, their use can be associated with severe hypokalemic, hypochloremic metabolic alkalosis and an increased tendency for development of cardiac arrhythmias if potassium balance is not carefully corrected. Oral or parenteral administration of potassium chloride is usually necessary. Potassium-sparing diuretics, such as *spironolactone*, may also be of some benefit, but the delayed onset of their relatively mild diuretic action makes them less useful than the loop diuretics in the treatment of acutely ill patients.

If the patient is hypotensive or in frank shock, diuretics are usually not of much benefit, because poor renal perfusion limits any effects they might have on the nephron. In this circumstance, continuous venovenous ultrafiltration can reduce intravascular volume even in patients who require vasopressors for blood pressure support.

If the patient has severely diseased kidneys, diuresis may not be an option. In this circumstance, continuous arteriovenous hemofiltration with or without countercurrent dialysis[369,370] or venovenous ultrafiltration,[371] should be considered. These techniques represent considerable advances over traditional hemodialysis, which was often impossible in hemodynamically unstable patients (especially those with low cardiac output or hypotension), and peritoneal dialysis, which was both slow and poorly tolerated. Hemofiltration can be instituted, maintained, and managed successfully by well-trained intensive care unit nurses and physicians, and it is not complicated by hypotension because the circuits have small volumes, and pressures are low. Considerable fluid (≤200–300 mL/hr) can be removed gradually, with the amount being titrated to the patient's cardiovascular status.

Reduction of blood volume by diuresis (or other means) may not be possible or beneficial in all patients. If the patient is hypotensive, responds to intravascular volume reduction with dramatic decreases in cardiac output and delivery of oxygen to tissues, or develops significant tachycardia, another approach to therapy must be considered in addition to, or in combination with, blood volume reduction.

The value of diuretics in patients with ALI is discussed later.

Inotropic Agents

Patients with pulmonary edema who have poor cardiac output and hypotension may benefit from inotropic agents, which can be useful in managing patients with hypotension caused by cardiac pump failure, mechanical ventilation, or therapy directed at reducing thoracic blood volume. Inotropic agents increase cardiac output and therefore can lower the driving pressure for fluid filtration in the lungs by improving myocardial contractility.

Catecholamines are the most useful agents in the acute situation. Actions of these drugs are related to the magnitude of their effects on α- and β-adrenergic receptors: α stimulation results in peripheral vasoconstriction; β_1 stimulation results in cardiac stimulation; and β_2 stim-

ulation results in vasodilation (and bronchodilation). Relatively nonselective agonists, such as norepinephrine, increase cardiac contractility, but their usefulness is somewhat limited by their tendency to raise systemic vascular resistance (which in turn limits the improvement in cardiac output) and to increase myocardial oxygen consumption because of increased heart rate and afterload. The selective β-agonist isoproterenol causes large increases in cardiac output and decreases in pulmonary capillary pressure, but its vasodilatory effects often lead to reductions in arterial pressure and increases in heart rate. The myocardium may become increasingly irritable, and myocardial ischemia can be aggravated by reduction of arterial diastolic pressure. The drugs most commonly used to provide short-term, intravenous inotropic support in acute pulmonary edema are *dopamine* (the immediate precursor in the endogenous synthesis of norepinephrine) and the synthetic catecholamine *dobutamine*.

At low doses, dopamine increases cardiac contractility, improves cardiac output without causing significant changes in heart rate or myocardial oxygen consumption, reduces systemic vascular resistance, and can directly increase renal blood flow by stimulating dopaminergic receptors, thereby increasing urine output and salt and water excretion. It is particularly useful when hypotension complicates pulmonary edema; its vasopressor activity raises systemic blood pressure while cardiac output is maintained or increased. Ventricular filling pressures are often unchanged or even raised by dopamine infusion, however, and the pressure for fluid filtration in the lungs may actually increase. Venoconstriction may aggravate this stronger force for edema accumulation in the lungs by redistributing blood volume toward the thorax. For this reason, a vasodilator (e.g., nitroglycerin and nitroprusside) may also be given in order to reverse some of the undesired vasopressor effects of dopamine. When hypotension is a major concern, a predominant venodilator (e.g., intravenous nitroglycerin, nitroglycerin ointment) can be administered with dopamine to reduce thoracic blood volume while arterial pressure is supported. Dopamine can also be used to counteract hypotension caused by nitroprusside infusions. Measurement of pulmonary vascular pressure, in addition to systemic blood pressure, may be helpful when vasodilators are also being infused. As the dose of dopamine is increased, α stimulation begins to occur along with the release of endogenous norepinephrine from nerve endings. This produces a pressor effect but also increases heart rate, ventricular irritability, and arrhythmias. Increased filling pressures in the heart also aggravate the tendency for edema formation in the lungs. Intravenous dopamine therapy is started at 2 to 5 μg/kg/min, and the dose is titrated to produce the desired effects. Doses greater than 10 to 15 μg/kg/min are usually associated with prominent α effects, and such therapy may be complicated by arteriolar vasoconstriction so intense that digital necrosis may occur. Dopamine must be infused through a large-bore, secure catheter because tissue infiltration results in necrosis from local vasoconstriction.

Dobutamine differs from dopamine in that dobutamine does not cause systemic vasoconstriction. It is primarily a positive inotropic agent but also has a mild vasodilating effect. Dobutamine increases cardiac output because it has a direct inotropic effect and because systemic vascular resistance is decreased. Filling pressures in the heart tend to fall with dobutamine infusions (rather than rise, as with dopamine), which is beneficial relative to the forces governing fluid filtration in the lungs. Dobutamine might also increase the rate of alveolar fluid clearance,[372] but the clinical relevance of this effect is also unknown. Renal blood flow tends to increase with dobutamine infusions because cardiac output improves (rather than because renal dopaminergic receptors are stimulated, as with dopamine). Dobutamine is particularly useful for the treatment of pulmonary edema due to cardiac decompensation resulting from decreased ventricular contractility.

Dobutamine infusions are started at 2 to 3 μg/kg/min, and the dose is increased every 10 to 30 minutes until the desired effects are produced. Effects may be delayed several minutes, and the maximal effect of any dose occurs after 10 minutes or more. The usual dose is 5 to 15 μg/kg/min. Side effects are common when the dose exceeds 15 μg/kg/min. Arrhythmias may occur, and tachycardia indicates the dose is too high and stroke volume is not adequate. In this circumstance, myocardial oxygen demands are excessively increased by the rapid heart rate in the presence of positive inotropy. Myocardial oxygen supply is decreased because coronary perfusion pressures are reduced and diastolic perfusion time is shortened. Dobutamine therapy is most successful when left ventricular filling pressures are kept at 18 to 20 mm Hg or higher. Dobutamine should be administered cautiously to patients with atrial fibrillation because the drug facilitates atrioventricular nodal conduction and may cause an increase in ventricular rate. Digitalis may be a more appropriate inotropic agent in that circumstance.

The lives of a limited number of patients with severe pulmonary edema refractory to immediate drug therapies might be saved by temporary mechanical support of hemodynamics (i.e., intra-aortic balloon pumps or ventricular-assist devices). Extrapulmonary gas exchange,[373] or heart transplantation, lung transplantation, or both[374] (see Chapter 89) can be appropriately offered to limited number of patients, but the possibilities can be considered only if all other therapeutic options have been exhausted.

Therapeutic Strategy

The possible therapeutic options that have been discussed are directed at the immediate treatment of patients with life-threatening pulmonary edema. Therapy must be clearly goal oriented, responsive to the underlying pathophysiology, and frequently reassessed until the patient is stable. In hydrostatic pulmonary edema, the common goal of therapy is to reduce the transudation of fluid into the lungs. Because the rate of edema formation increases exponentially with increases in pulmonary vas-

cular pressures,[375] pressure control is crucial for successful therapy.

Increased Pressure Edema

The acute recognition and management of congestive heart failure has been the subject of comprehensive reviews.[376] With hydrostatic pulmonary edema, the goal of therapy is to reduce the hydrostatic pressure causing edema formation in the lungs. The major objective is to achieve a net negative fluid balance without adversely affecting myocardial performance. The work of the heart must be reduced as much as possible by restricting physical activity and preventing pain and anxiety, which act to increase the work of the heart by increasing sympathetic tone. As the heart fails, cardiac performance is reflexly preserved by progressive increases in vascular volumes that act to increase cardiac stroke volume and work (the Frank-Starling mechanism). This compensatory increase in preload of the left ventricle results in pulmonary venous hypertension and raises the driving pressure for fluid filtration out of the pulmonary microcirculation. As heart failure worsens, cardiac output falls, pulmonary and systemic venous pressures rise, systemic vascular resistance increases, and edema, in the lungs and in the periphery, becomes the major manifestation of compromised cardiac function. In patients with increased pressure pulmonary edema, a reduction of vascular volume and an increase in cardiac output cause the driving pressure for edema formation to decrease. Because the normal safety factors protecting the lungs from edema driven by high filtration pressures are intact, the pressure need be lowered only to near normal. At pulmonary capillary wedge pressures less than 20 mm Hg, fluid filtration in the lungs usually should not be sufficient to cause pulmonary edema. Patients with severe cardiac failure may tolerate higher pressures (because baseline barrier permeability is lowered in the lungs and lymphatic removal capability is increased) and may require such pressures to maintain cardiac output. Therapy is directed at reducing the work the heart must perform and at increasing the heart's efficiency for the work it must do. Some patients with severe hydrostatic pulmonary edema require mechanical ventilation with positive-pressure ventilation. The resolution of alveolar edema in these patients is not simply a function of lowering lung vascular pressures; other mechanisms that augment alveolar fluid clearance are important.[377]

Most patients with acute pulmonary edema caused by cardiac failure have systolic dysfunction, but a sizable minority (~30%) have diastolic dysfunction. Cardiac contraction is normal, but relaxation is impaired. Because the ventricle does not relax normally, end-diastolic pressure is increased, thereby increasing hydrostatic pressure in the lung microcirculation. Acute diastolic dysfunction producing pulmonary edema is now recognized as a common manifestation of acute myocardial ischemia or uncontrolled hypertension. Other causes include diabetes mellitus, aortic stenosis, infiltrative cardiomyopathies, endocardial fibroelastosis, hypothermia, septic shock, elevated thoracic pressures from mechanical ventilation, and pericardial effusion. Causal or aggravating conditions should be corrected (e.g., revascularization for coronary artery disease, control of systemic hypertension). The goal of therapy in acute diastolic dysfunction is to lower elevated filling pressures (by the cautious use of diuretics and nitrates) without significantly reducing cardiac output. These patients are prone to develop hypotension in response to diuretics and nitrates because adequate cardiac output depends on elevated filling pressures in the heart. Because systolic function is normal, positive inotropic agents do not help and can actually aggravate ischemia.

In the setting of acute increased pressure pulmonary edema, it is especially important to identify and treat correctable causes of heart failure. Acute myocardial infarction, ongoing myocardial ischemia, arrhythmias, valvular lesions, systemic hypertension, ventricular septal rupture, rheumatic or other inflammatory myocarditis, digitalis intoxication, pulmonary embolism, infection, thyrotoxicosis, or severe anemia may have caused the heart to fail and must be corrected. Cardiac patients presenting with pulmonary edema may not complain of chest pain, but most of them have significant coronary artery disease, and pulmonary edema may be the only manifestation of silent myocardial ischemia.

Increased Permeability Edema

The strategy for managing patients with ALI and increased permeability pulmonary edema differs from that for patients with increased pressure pulmonary edema because the endothelial and epithelial barriers are damaged in permeability edema, whereas they are normal in high-pressure edema. The problem is not that the driving pressure for edema formation is abnormally high, but that edema forms even at low driving pressures. The goals of therapy (Table 55-9) are to treat the cause of lung injury, to provide support while the repair phase begins, to use a lung-protective ventilator strategy that will not worsen the lung injury, and to reduce as

TABLE 55-9. Acute Lung Injury: Important Principles of Management

MINIMIZE EDEMA ACCUMULATION
Ensure lowest possible pulmonary microvascular pressure
Reduce vascular volume
FIND AND TREAT INFECTION
PROVIDE SUPPORTIVE THERAPY
Administer oxygen
Use lung-protective ventilation
Optimize blood pressure and cardiac output
DO MORE GOOD THAN HARM
Avoid hypotension
Avoid volume overload
Avoid oxygen toxicity
Avoid infection

much as possible the driving pressures for fluid movement across the injured barriers into the lungs.

The cause of lung injury may not always be apparent. If the cause is not obvious, it should be assumed to be infection, which is the most common treatable underlying cause of ALI. Although the patient is often seriously ill, diagnostic studies must be performed to identify a possible source of infection, so that appropriate drainage and antimicrobial therapy can be instituted. Plain chest roentgenograms usually are not helpful. Abdominal sonograms and computed tomography scans can be diagnostically useful. Sepsis from intra-abdominal infection is common and may be especially difficult to identify. Many of these infections require surgical drainage if antimicrobial drug therapy is to be effective. Because specific therapy for ALI is not usually available (unless the cause is a localized infection), supportive therapy is extremely important. The initial concerns are to support ventilation and circulation. Patients with ALI may be hemodynamically unstable, and ventilatory support can be complicated by hypotension or frank shock. PEEP, which may be required for adequate oxygenation, may compound the problem by impeding venous return to the heart and decreasing cardiac function.

Patients with low pulmonary capillary wedge pressures (<10 mm Hg) or central venous pressure (<4 mm Hg) and systemic hypotension require fluid resuscitation to support blood pressure and end-organ perfusion. If the patient has active, ongoing blood loss or the hemoglobin concentration is low (<7.0 g/dL), packed red blood cells are effective not only to expand intravascular volume and restore blood pressure but also to increase the oxygen-carrying capacity of the blood. Patients who are not bleeding and who have normal hemoglobin concentrations should be resuscitated with crystalloid solutions. Because the barriers restricting colloid movement from the vascular space into the lungs are not functioning normally when the lungs are injured, osmotic pressure differences favoring fluid movement into the vascular space cannot be established in the lungs; therefore, there is no advantage to fluid resuscitation with expensive colloid solutions.

Patients whose hypotension does not respond to fluid resuscitation or who have normal (>10 mm Hg) or elevated pulmonary capillary wedge pressure require vasopressors or positive inotropic agents. If systemic vascular resistance is elevated, dobutamine is appropriate. For patients with septic shock, generalized vasodilation resulting in low systemic vascular resistance is the major hemodynamic abnormality.[378] Dopamine and norepinephrine, with their vasopressor properties, are often useful to support blood pressure.

Aggressive hemodynamic and ventilatory support of critically ill patients can be detrimental if complications of therapies become more significant problems than the underlying disease itself. Strategies to increase systemic oxygen delivery (e.g., with inotropes, intravascular fluids, and blood transfusions) or to achieve supranormal values for the cardiac index or normal values for mixed venous oxygen saturation did not improve mortality when applied to all critically ill patients, but did improve outcome in patients with sepsis who were treated very early in their course.[379,380] A recent ARDS Network clinical trial showed that after the initial treatment of shock in the first 24 hours, a strategy to restrict fluids to reduce intravascular pressures (central venous pressure or the pulmonary arterial wedge pressure) improved clinical outcomes in patients with ALI.[381]

A multicenter, randomized, controlled clinical trial of transfusion requirements in critically ill patients with euvolemia after initial treatment showed that a restrictive strategy of red cell transfusions (in which red cells were transfused if the hemoglobin concentration dropped below 7.0 g/dL and hemoglobin concentrations were maintained at 7.0–9.0 g/dL) was at least as effective as and was possibly superior to a liberal transfusion strategy (in which transfusions were given when the hemoglobin concentration fell below 10.0 g/dL and hemoglobin concentrations were maintained at 10.0–12.0 g/dL), with the possible exception of patients with active coronary ischemic syndromes, such as acute myocardial infarction and unstable angina.[382]

Lung-Protective Ventilator Strategies. In experimental animals, ventilation with high tidal volumes can increase vascular filtration pressures; produce stress fractures of microvascular endothelium, alveolar epithelium, and basement membranes; and cause lung rupture (so-called ventilation-induced lung injury).[239,383,384] The injury appears to be due to increased lung excursions at high volumes (so-called volutrauma), not high airway pressure per se, because it can be prevented by limiting thoracic motion (e.g., by placing the chest in a cast). Because the evidence from animal experiments and small clinical trials seemed compelling,[385,386] clinical studies were done to test the potential benefit of lower tidal volumes and reduced airway pressures. In a large multicenter trial, mortality was reduced from 40% to 31% with a 6-mL/kg ideal body weight tidal volume strategy that also limited plateau airway pressure to less than 30 cm H_2O.[244] In this large clinical trial of 861 patients, the small tidal volume approach also was associated with a lower incidence of nonpulmonary organ failure. The protocol for carrying out the lung-protective ventilatory strategy is described in detail in Table 55-10. The results of this trial have transformed management of patients with ALI. In fact, a follow-up clinical study has indicated that ventilation with this level of tidal volume and plateau pressure limitation used in the original NIH ARDS Network trial is associated with an overall reduction of mortality to 26%.[387] In this study, elevated levels of PEEP did not decrease mortality, but the basic lung-protective strategy was validated as effective for reducing mortality.

Interestingly, results from an Italian study showed that a low tidal volume strategy in ARDS patients attenuated the inflammatory response in both the lungs and the bloodstream, as measured by a reduction in neutrophil and cytokine concentrations in BAL fluid and a reduction in cytokines in circulating blood.[245] Other studies have confirmed that low tidal volume lung-protective ventilation is associated with reduction in inflammatory markers in the lung.[244] There is also evidence that

TABLE 55-10. National Institutes of Health ARDS Network: Lower Tidal Volume Ventilation for Acute Lung Injury/Acute Respiratory Distress Syndrome Protocol Summary

Ventilator mode	Volume assist-control													
Tidal volume	≤6 mL/kg PBW*													
Plateau pressure	≤30 cm H_2O													
Ventilation set rate/pH goal	6–35, adjusted to achieve arterial pH ≥ 7.30 if possible													
Inspiratory flow (I:E)	Adjust flow to achieve I:E = 1:1–1:3													
Oxygenation goal	65 mm Hg ≤ Pa_{O_2} ≤ 80 mm Hg *or* 88% ≤ Sp_{O_2} ≤ 95%													
F_{IO_2}/PEEP COMBINATIONS:														
F_{IO_2}	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7	0.7	0.8	0.9	0.9	0.9	1.0
PEEP (cm H_2O)	5	5	8	8	10	10	10	12	14	14	14	16	18	18, 22, 24
(Further increases in PEEP to 34 cm H_2O allowed but not required.)														
Weaning	Attempts to wean by pressure support required when F_{IO_2}/PEEP ≤ 0.40/8													

*PBW:
Male PBW = 50 + 2.3 [height (inches) − 60] *or*
50 + 0.91 [height (cm) − 152.4]
Female PBW = 45.5 + 2.3 [height (inches) − 60] *or*
45.5 + 0.91 [height (cm) − 152.4]

ARDS, acute respiratory distress syndrome; F_{IO_2}, fraction of inspired oxygen; I:E, ratio of the duration of inspiration to the duration expiration; Pa_{O_2}, partial pressure of oxygen in arterial blood; PBW, predicted body weight; PEEP, positive end-expiratory pressure; Sp_{O_2}, oxyhemoglobin saturation by pulse oximetry.
From Brower RG, Ware LB, Berthiaume Y, et al: Treatment of ARDS. Chest 120:1347–1367, 2001.

there probably is reduction in alveolar epithelial injury based on a decline in surfactant protein D levels in the plasma of patients treated with the lung-protective ventilatory strategy.[331] More clinical and experimental work is being done to determine the mechanisms responsible for the lung-protective effect. It is clear that use of the lung-protective ventilatory strategy is not associated with an adverse effect on hemodynamics or an increased need for supportive therapies, including intravenous fluids, diuretics, vasopressors, sedation, or neuromuscular blockade.[388]

A number of adjuncts to conventional mechanical ventilation have been proposed and studied in small numbers of patients, including prone positioning extrapulmonary gas exchange (oxygenation, carbon dioxide removal, or both),[389] liquid ventilation, tracheal gas insufflation, permissive hypercapnia, and high-frequency ventilation.[390] All of these adjuncts are investigational, and their use should probably be restricted to controlled clinical trials. Repositioning the patient is the simplest and least invasive of these techniques.[391] Turning patients with severe respiratory failure to the prone position can result in improved pulmonary gas exchange,[392] probably as a result of increased ventilation of dorsal lung units and more favorable matching of ventilation and perfusion. Turning critically ill, mechanically ventilated patients from the supine to the prone position is not an easy task, however, and there are risks involved (e.g., extubation, kinked ventilator tubing, disconnection of catheters, hemodynamic instability, pressure sores on the face). Not all patients respond by improving their oxygenation. A randomized trial showed no benefit of prone positioning for patients with acute respiratory failure, including ALI.[393,394]

Prevention of ventilator-associated pneumonia has been the subject of a comprehensive review and a meta-analysis.[370] Although a relation between gastric colonization with gram-negative bacilli and nosocomial pneumonia in intensive care unit patients has been shown,[395] selective decontamination of the digestive tract does not appear to significantly improve mortality even though respiratory tract infections are prevented.[396] The simple approach of increasing the angle of the head of the bed to 45 degrees is beneficial in reducing nosocomial infection.[397] Simple precautions, such as meticulous handwashing and removal of unnecessary catheters, should be followed.

The literature from the patients' point of view is sparse: Only a few group studies and scattered personal observations about patient experiences in intensive care units have been reported.[398] No reports of what it is like to have pulmonary edema could be found. A critical care text has sections dealing with nursing perspectives but no section on patient perspective, and both nurses and patients are slighted in this textbook. The limited information available indicates that many patients had significant amnesia for most of their intensive care unit stay and poor insight into their condition. Many survivors experience depression, which tends to diminish over a prolonged recovery time. Some experience posttraumatic stress disorder. Patient experience and longer-term outcomes are important areas that have only recently been better studied.[143,399]

Specific Pharmacologic Therapies. Therapeutic agents that have a rational place in our incomplete understanding of the pathogenesis of ALIs and that have been studied in patients with ALIs and sepsis disorders include corticosteroids, ibuprofen, nitric oxide, prostaglandin E_1 (PGE_1), liposomal prostaglandins E_1 and E_2, surfactant, antiendotoxin and anti–TNF-α antibodies, platelet-activating factor receptor antagonist, interleukin-1 receptor antagonist, ketoconazole, *N*-acetyl-

cysteine, oxothiazolidine carboxylate, and pentoxifylline. None of these agents has shown any benefit on mortality in large-scale, prospective, randomized, controlled clinical trials. There have been sporadic reports indicating that other agents might be useful. The state of clinical trials in ARDS was the subject of conference reports in 1992,[400] and in 2000,[94] which summarized the status of possible therapies and the opportunities and challenges faced in evaluating them. Another recent review summarizes the data.[401] The establishment of the ARDS clinical trials network by the NHLBI has already fostered the conduct of large, well-designed studies to define the efficacy and appropriate use of therapy for ALI; additional trials on the value of glucocorticoids late in the evolution of ARDS have just been completed, and a study on the efficacy of reducing lung vascular pressures is under way.

Whether or not newer anti-inflammatory therapies will be useful in patients with ALI remains an important question. Although inflammatory reactions can damage tissue, it is important to remember that inflammation plays an important beneficial role in the elimination of invading microorganisms. Because inflammatory pathways are redundant, blocking any one inflammatory mediator (or even multiple mediators) may have little or no effect on the overall inflammatory response. If the mechanisms of lung injury differ after various clinical events, the application of therapy directed at particular mechanisms would not be appropriate until all the underlying mechanisms are recognized. The moderate incidence of severe ALI among patients admitted with high-risk diagnoses[402] complicates the problem. Finally, the timing of therapy is likely to be an important factor.

Corticosteroids. Of the possible pharmacologic agents for treatment of ALIs, corticosteroids have the longest history. Despite a seemingly compelling rationale for their use in the setting of ALI from sepsis, four separate, prospective, randomized, double-blind, placebo-controlled trials of high-dose methylprednisolone therapy failed to show any benefit.[403] Corticosteroid therapy did not prevent the development of ALI or decrease its incidence in patients with the sepsis syndrome. Neither did it hasten the reversal of ARDS, lower mortality, or improve respiratory function. Moreover, corticosteroids were associated with both a greater 14-day mortality rate in patients who developed ALI and an increased frequency of associated infections. Corticosteroids also were ineffective in the sepsis syndrome[404] and may have caused harm. Thus, corticosteroids should not be given to patients at risk for or with developing ALIs unless there is some other indication, such as a history of recent steroid therapy or another reason to suspect adrenal insufficiency. One exception may be the fat embolism syndrome. A prospective, randomized, double-blind, placebo-controlled trial of corticosteroid treatment in 64 patients with long bone fractures showed that high-dose methylprednisolone effectively prevented the development of the fat embolism syndrome,[405] and short-course corticosteroid therapy appears to be appropriate in such patients, particularly in those who developed the characteristic petechial rash.

The generally disappointing results of corticosteroid trials in ALI have not discouraged investigators. Because of the diversity of underlying causes and the changing character of ALIs as they progress, some investigators believe that corticosteroids might be beneficial in subsets of patients or when given at a particular time (e.g., during the proliferative phase) or for a more sustained period.[406] Results of studies of corticosteroid therapy late in the course of ARDS (so-called rescue therapy) were encouraging, and a small (24-patient), randomized, double-blind, placebo-controlled clinical trial in patients with severe ARDS whose Lung Injury Score had failed to improve by the seventh day of respiratory failure showed improvement in lung injury and other organ dysfunction scores, and reduced mortality in the treated patients.[407] However, an NHLBI-sponsored trial of corticosteroid therapy (methylprednisolone 2 mg/kg) beginning on day 7 to 21 of ARDS showed no reduction in 60- or 180-day hospital mortality in patients treated with corticosteroids compared with placebo.[408] In addition, there were important neuromuscular complications in patients treated with methlprednisolone.

One major lesson learned from the experience with corticosteroids as early or late treatment for ALI is that no matter how compelling the rationale for their use might be based on preclinical studies, well-designed and executed large-scale clinical trials must be conducted before a promising therapy is accepted for clinical use.

Surfactant. The possibility of administering exogenous surfactant in the treatment of ALI has attracted considerable attention.[409] The rationale for such therapy is based on abnormalities of surfactant composition and function that have been found in ALIs and on the approval of an artificial surfactant (colfosceril [Exosurf]) for clinical use. Surfactant therapy has revolutionized the treatment of neonatal respiratory distress syndrome. Among the many possible benefits of surfactant therapy are stabilized alveoli, improved respiratory compliance, decreased work of breathing, improved gas exchange and consequently decreased need to administer toxic concentrations of oxygen, and enhanced phagocytosis and bronchial transport; these advantages plus surfactant's antibacterial and antiviral activity should reduce the possibility of lung infection. Surfactant might also inhibit the respiratory burst of PMNs and might modulate lung fibroblast and macrophage activity to decrease release of inflammatory mediators.

Results in experimental models have been mixed, but taken as a whole, they appear to indicate that animals are not harmed by surfactant therapy and that improved gas exchange and lung compliance are reasonable possibilities. A preliminary communication indicated that colfosceril could be administered safely to ventilated patients with sepsis-induced ARDS, but no differences were found in any physiologic parameters when compared with control subjects, and a dose-dependent trend in reduction of mortality did not reach statistical significance.[410] The pilot trial was followed by a large-scale, prospective, double-blind, randomized, placebo-controlled clinical trial of aerosolized surfactant in patients with sepsis-induced ARDS.[411] This study showed no significant

effect on 30-day survival, length of stay in the intensive care unit, duration of mechanical ventilation, or physiologic function. A more recent large clinical trial of recombinant surfactant protein C demonstrated no reduction in mortality or in the duration of mechanical ventilation in patients with the ARDS.[412]

Antioxidants. Clinically, *N*-acetylcysteine has advanced farther than any other therapeutic strategy because of the hypothetical role of oxidants in the pathogenesis of ALI. *N*-Acetylcysteine is unique among the free radical scavengers because it is already in widespread clinical use for acetaminophen and paracetamol overdose, conditions for which it has been found to be safe and effective. It is also novel among anti-inflammatory agents being tested for human therapy because it acts selectively to quench oxygen radicals rather than globally to suppress leukocyte function. *N*-Acetylcysteine appears to act both directly, by scavenging oxygen free radicals, and indirectly, by metabolism into glutathione, which is an important endogenous antioxidant.

Experimental animal studies were encouraging. Results from a randomized, double-blind pilot trial in 30 patients with ALI showed that plasma and red blood cell glutathione levels were decreased in the presence of ALI and could be increased by *N*-acetylcysteine administration. Improvements were shown in chest radiograph edema scores, pulmonary vascular resistance, shunt fraction, static compliance, cardiac output, oxygen delivery, and oxygen consumption.[413] Four subsequent small clinical trials in ALI patients examining the effects of *N*-acetylcysteine or oxothiazolidine carboxylate (Procysteine), which also acts to augment glutathione stores, have been conducted.[414] Enthusiasm for this type of therapy has been tempered by the possibility that antioxidants could compromise defenses against infection.

Pentoxifylline. Pentoxifylline is a phosphodiesterase inhibitor that increases cyclic adenosine monophosphate in PMNs and inhibits their inflammatory function.[415] Pentoxifylline has been in clinical use for many years in the treatment of intermittent claudication, based on its purported ability to increase the flexibility of red blood cells and thereby reduce blood viscosity and increase capillary blood flow. The hypothesized role of leukocytes in ALI led to studies in experimental models that have demonstrated prevention or attenuation of various ALIs in several species, apparently by inhibiting PMN function.[416] However, a related compound, lisofylline, failed to show efficacy in a large phase III NHLBI trial.[417]

Treatments for Sepsis. Two different monoclonal antibodies against endotoxin have been investigated as therapy for sepsis, the most common antecedent to ALI and ARDS: HA-1A human (also known as Centoxin or nebacumab) and E5 murine (also known as Xomen).[418] The underlying rationale for therapy with these agents and the two original clinical trials that were reported have been critiqued, an economic assessment of HA-1A monoclonal antibody for gram-negative sepsis has been made, and a detailed analysis of the original trials and the questions raised about them and regarding the cost and resulting ethical dilemmas[419] was published.

In patients with sepsis and a documented gram-negative infection who were not in shock, ARDS (as defined previously in a trial of corticosteroids in patients with ALI) occurred in 14% of the patients in the E5 murine trial; 60% (6 of 10) of those treated with the E5 antibody died, compared with 78% (7 of 9) of those treated with placebo. In the second E5 trial, the antibody appeared to offer some protection against development of ARDS in sepsis patients, but there was no effect on survival.[418] In the HA-1A trial, ALI (ARDS as defined by the expanded definition of ALI) occurred in 11% of the patients with documented gram-negative bacteremia; data on the resolution of lung injury were not published, but major complications of sepsis, which included the patients with ARDS, resolved in 62% of the treated patients compared with 42% of those given placebo. A subsequent publication discussed the results of HA-1A therapy in the 63 septic patients with ARDS from the larger trial: The antibody did not reverse acute respiratory failure or improve long-term survival.[420]

In addition to these antiendotoxin antibodies, large-scale clinical trials in patients with sepsis syndrome treated with inhibition of TNF-α[421] and of interleukin-1[422] have been reported. Neither showed a significant difference in mortality in patients who received the inhibitors as compared with those who received placebo. No differences in the frequency of continuing or new organ system failures, such as occurs in ARDS, were found in the anti–TNF-α trial. In the interleukin-1 receptor antagonist trial, a secondary analysis of the results indicated that survival time might have been increased for patients with ARDS (28-day mortality of 44% for placebo and 34% for antibody, with the improvement occurring in the sickest patients).

Conversely, one large clinical trial has reported efficacy of activated protein C for reducing mortality in severe sepsis. In this randomized, placebo-controlled clinical trial, mortality was reduced by 6%.[423] The most common source of severe sepsis was pneumonia, and 75% of the patients were mechanically ventilated and 75% were in shock. Because of the potential for inducing serious bleeding, patients were excluded from the trial who had a history of recent surgery, recent bleeding, severe trauma, or other factors that would increase the risk of bleeding. The mechanisms by which activated protein C works to reduce mortality are probably multifactorial. There is evidence that activated protein C reverses the procoagulant environment induced by severe sepsis and also that it has anti-inflammatory effects that may reduce cytokine-induced organ injury. Because of the relationship of organ injury in severe sepsis to the pathogenesis of ALI, there is interest in the possibility that treatment such as activated protein C might be efficacious for patients with ALI.[424,425] Other therapies that might inhibit coagulation and inflammation are also potentially worth testing in clinical trials. There has been some controversy regarding the results of the activated protein C trial, and some experts recommended further trials to evaluate the efficacy of this agent, particularly because two other clinical trials using anticoagulants did not show efficacy in patients with severe sepsis.

Consequently, a new placebo-controlled, double-blind clinical trial of activated protein C has been initiated to test its efficacy in severe sepsis. One recent clinical trial of 75 patients showed no benefit of activated protein C therapy for patients with ALI primarily on nonseptic etiologies.[426]

Prostaglandin E_1 and Inhaled Nitric Oxide. Another potential pharmacologic treatment of ALI was PGE_1, a vasodilator with anti-inflammatory properties. However, a 13-center, randomized, double-blind, placebo-controlled clinical trial showed no improvement in survival (mortality rate at 30 days was 60% in the treated group, 48% in the placebo group).[427] Reduction in systemic and pulmonary vascular resistance and evidence of increased oxygen availability and consumption were counterbalanced by such adverse effects as diarrhea, hypotension, fever, and cardiac arrhythmias. The trial was not designed to resolve the role of PGE_1 in patients at risk for developing ALI, so the question of any prophylactic benefit was left unanswered. A smaller, independent study from one institution found PGE_1 to be an effective vasodilator, but it did not influence the development of multiple organ failure or affect mortality of patients with ALI. A secondary report from the larger trial emphasized a purported benefit of PGE_1 on oxygenation in a subset of patients, even though survival was not improved; other studies have indicated that the drug causes deterioration of pulmonary gas exchange and aggravation of arterial hypoxemia by increasing perfusion of underventilated or unventilated lung areas. Another secondary report from the trial emphasized purported beneficial effects with PGE_1 therapy on hemodynamic performance, hepatic function, and leukocyte availability, but such effects were rather subtle, and their clinical significance was not obvious.

Inhaled nitric oxide can also improve oxygenation and lower pulmonary vascular pressure in patients with ARDS, but it does not lead to a sustained improvement in oxygenation as compared with conventional therapy,[428] and it has no beneficial effects on mortality.[429,430] Use of these drugs in patients with ALI is not recommended, although inhaled nitric oxide may have some value as a form of rescue therapy for ARDS patients with profound hypoxemia.

There is now preclinical data that the use of bone marrow-derived mesenchymal stem cells has potential value for the treatment of severe acute lung injury. In several of the studies, there is evidence that paracrine factors released by the cells can elaborate anti-inflammatory cytokines that decrease lung injury as well as growth factors such as keratinocyte growth factors that can enhance recovery from acute lung injury.[430a]

OUTCOME

Resolution of Edema

Until recently, much less was known about recovery from pulmonary edema than about its formation. Water (and extravasated proteins and cellular debris) must be removed from the alveoli and the interstitial spaces to restore the lungs to their normal condition. Edema could be cleared from the lungs by five routes: lymphatics, airways, blood vessels, the pleural space, and the mediastinum. Cellular debris and particulate matter must be removed from the alveoli by macrophages or must be expectorated from the airways.

The considerable advances in our understanding of the clearance of fluid and solute from the alveoli have been the subject of several reviews.[2,431–433] Active sodium chloride transport across the alveolar epithelial barrier into the interstitium drives edema fluid removal from the air spaces (see Chapter 10). The uninjured alveolar epithelium has a remarkable ability to clear fluid from the air spaces rapidly: for example, serial edema fluid protein concentration measurements relative to simultaneous plasma protein concentrations in a saltwater near drowning patient showed that 50% to 60% of excess alveolar fluid in the lungs was removed over the course of just 4 hours.[90] In experimental studies in rabbits, instillation of 4 mg/kg of seawater into the lungs resulted in a 300% increase in alveolar fluid volume in less than 5 minutes from mostly pure water drawn in osmotically from the plasma by the hyperosmolar (881 ± 29 mOsm) instillate, 80% of which was cleared from the alveoli in 6 hours.[434] Equivalent volumes of iso-osmotic (292 ± 6 mOsm) saline instilled into rabbit lungs were cleared at a similar rate. In neither circumstance was there evidence of injury to the alveolar epithelial barrier, which has been found to be more resistant than the endothelial barrier to a wide range of injuries, including ischemia, alveolar and intravenous endotoxin and bacteria, intravenous oleic acid, acid aspiration, saltwater aspiration, hyperoxia, intratracheal bleomycin, septic and hypovolemic shock, and rewarming after severe hypothermia. Even when mild to moderate alveolar injury occurs, the capacity to transport salt and water is often preserved; in severe injury, when the barrier is physically disrupted, the capacity to clear edema is lost, of course, and the vascular endothelium becomes the limiting barrier between the vascular system and the air spaces. Clinically, the capacity to remove some alveolar edema fluid (as indicated by increase in the edema fluid–to–plasma protein concentration ratio) in the first 12 hours after the development of ALI is a favorable prognostic finding, associated with a mortality of only 20%; in contrast, the inability to resorb alveolar edema fluid early in the course of ALI was associated with a mortality of nearly 80%.[293] The results of this earlier study were confirmed in a larger, more recent study.[294] Thus, the function of the alveolar epithelial barrier early in the course of ALI may be a useful prognostic index, perhaps because it serves as a marker of the severity and extent of lung injury.

Lung Na^+,K^+-ATPase activity was increased in rats recovering from experimental thiourea-induced increased permeability pulmonary edema.[435] Alveolar fluid clearance can be increased by salmeterol in uninjured, ex vivo human lungs.[436] Experimental studies have shown that alveolar fluid clearance can be increased pharmacologically (e.g., by catecholamines), even in the presence

of ALI and alveolar edema,[2] raising the potential of therapy to hasten the resolution of alveolar edema.

Because clearance of protein from flooded alveoli is much slower (1%–2%/hr) than clearance of fluid (10%–20%/hr),[431,437] the protein left behind becomes concentrated. The rising protein concentration in the alveoli as fluid is resorbed does not affect fluid clearance, because precipitated protein exerts no osmotic pressure and the concentration of soluble macromolecules is too small to counteract the differences in ion concentration resulting from transepithelial transport. Removal of fluid from flooded alveoli may be slowed, especially when lung vascular permeability is increased, if the fluid clots. Clotting can occur because extravasation of plasma into the air spaces may lead to activation of the clotting system by surfactant or macrophage-derived procoagulants.

Fluid cleared from alveolar spaces into the alveolar interstitium can leave the lungs by flowing into the lymphatic capillaries or by moving down the prevailing pressure gradient into the loose peribronchovascular connective tissue spaces or directly into the pleural space as well. Large amounts of fluid in the air spaces may be partially cleared into peribronchovascular cuffs through the hypothesized leaky terminal-airway epithelium,[438,439] leaving alveolar fluid and solute behind to be cleared more slowly through the more impermeable alveolar epithelium.

Most of the interstitial water in pulmonary edema is in the peribronchovascular loose connective tissue spaces rather than in the alveolar walls. Because the lymphatic capillaries are arranged to drain only the alveolar wall interstitium, this route for edema removal is not significant for most interstitial water. A study in goats showed that lung lymph originated mainly from alveolar wall interstitial fluid, and the contribution of the lung lymphatic system to the clearance of interstitial edema in bronchoalveolar cuffs and interlobular septa was small. The maximum possible contribution by lung lymphatics to the clearance of interstitial edema liquid was below 10%, and airway loss of liquid by evaporation was about twice the rate of lymphatic clearance.[440] In a study of in situ perfused sheep lungs with experimental low- and high-protein pulmonary edema, during recovery from pulmonary edema, interstitial liquid was resorbed into the circulation in inverse proportion to its protein concentration, and only a very small fraction of interstitial edema was cleared by the lung lymphatics during recovery from either type of edema.[441] Some fluid from the loose peribronchovascular interstitium may drain directly into the bloodstream by crossing the walls of blood vessels in the lungs. A study of isolated sheep lungs made edematous by raising vascular pressures showed that the primary route of edema clearance was by vascular resorption; 60% of filtered water was cleared over 3 hours, 42% by reabsorption into the bloodstream, and 18% by lymphatic, pleural, and mediastinal drainage.[442] Edema may also drain into the pleural space. Pleural effusions are more common in increased pressure pulmonary edema (occurring in about 25%–50% of patients, usually on the right side if the edema is unilateral), but are present in ALIs as well (occurring in about 35% of patients).[443–445] Formation and removal of pleural effusions are discussed in detail in Chapter 68. As much as 25% to 30% of pulmonary edema fluid may leave the lungs through the pleural space.[445,446] A significant portion of the interstitial edema probably follows the prevailing pressure gradient in the lungs to drain into the mediastinum, where it could be picked up by initial lymphatics.

Short-term alveolar protein clearance appears to proceed primarily by paracellular diffusion and is size dependent.[7] Most proteins are cleared intact rather than being degraded into smaller fragments (although a few specific proteins, such as vasoactive intestinal peptide and gastrin, are degraded before being cleared). An albumin-binding protein (albondin) is expressed on lung microvascular endothelial cells, and an antibody to this protein reacts with cellular proteins of alveolar epithelial cells, which also appear to have albondin-like binding sites for albumin. A polymeric immunoglobulin receptor has also been described. The significance of these receptors is unclear. The general consensus is that transcytosis (transport via vesicles) is not a major mechanism for clearing bulk quantities of albumin or other proteins from the alveolar space. Over the long term, cellular mechanisms, principally phagocytosis and catabolism by macrophages, account for most protein clearance from the alveolar space. All insoluble, precipitated proteins are removed in this way. Macrophages are also ultimately responsible for removing senescent and dead PMNs and other debris. The small ciliated surface area of the distal air spaces seems to indicate that the mucociliary route could account for only a minor fraction of alveolar protein clearance, although proteins might reach the mucociliary escalator along currents in the alveolar fluid layer. Even were this to occur, removal would be very slow (the half-time for mucociliary clearance of particles from the alveolar space is more than 4 wk). Complete clearance of alveolar protein from pulmonary edema by any route is slow.[7]

Little is known about the mechanisms and signals that regulate endothelial barrier function or how increased endothelial permeability is returned to normal.[447] The mechanisms of resolution of lung inflammation are also poorly understood.

Increased Pressure Edema

The outcome of increased pressure pulmonary edema is determined by the underlying cause and the treatment that is used. Because most increased pressure pulmonary edema is caused by heart disease, outcome is largely determined by the patient's cardiac function. Patients with pulmonary edema that is uncomplicated by acute myocardial infarction can be expected to do well (mortality rate, <10%).[448] In the presence of acute myocardial infarction, the prognosis is worse. However, thrombolytic therapy and coronary angioplasty and stent placement have improved the survival of patients with pulmonary edema complicating acute myocardial infarction. Patients who recover from increased pressure pulmonary edema caused by cardiac disease require

long-term outpatient management aimed at preventing recurrent episodes.

Some patients develop increased pressure pulmonary edema from noncardiac causes. Most cases are iatrogenic, being caused by massive volume overload or therapy with drugs that can affect cardiac function. This is a common cause of pulmonary edema in pregnant women, as discussed in Chapter 81. These patients can be expected to do well if the cause of the edema is removed.[449]

Increased Permeability Edema

The incidence of ALI is unknown. Many authors recite the 1972 NIH speculation that there are about 150,000 new cases each year (an incidence of about 75 cases/100,000 population/yr). Some estimates indicated that the NIH figure might have been too high,[450] but the large numbers of patients enrolled in the NHLBI ARDS clinical trials since 1996 suggest that the original NIH estimate may have been reasonably accurate. A careful prospective study in King County, Washington, with demographics similar to those for the United States also indicates that the original estimate of 75 to 85 cases/100,000 is correct.[451] The outcome of ALI and resultant increased permeability pulmonary edema is determined by the underlying cause, the extent of injury, and the treatment strategy. The reported mortality rates range from 20% to 90%, but yearly ARDS mortality rates reported from a single institution in the decade between 1983 and 1993 showed a significant decrease over time that occurred in patients younger than 60 years and in those with sepsis syndrome as their risk factor for ARDS.[452] In addition, the reported mortality in major epidemiologic and therapeutic trials of ARDS in the 20 years between 1975 and 1995 decreased. The explanation may be related to use of less injurious ventilator modes, more effective treatment of infection, and better nutritional supplementation.

ALI and increased permeability pulmonary edema are complications that occur late in the natural history of other diseases. The prognosis worsens as the number and the severity of underlying diseases increase.[94] Patients with sepsis have significantly higher mortality than patients with other clinical disorders associated with the development of ALI.[94] Medical patients have a higher mortality than surgical patients. Mortality is much higher in patients with chronic liver disease[273] or histories of chronic alcohol abuse.[453] Besides damaging the liver, chronic ethanol ingestion may reduce alveolar type II cell glutathione content and impair surfactant synthesis and secretion.[454] Mortality has been reported to increase with age, but the increased mortality of older ARDS patients might be due in part to decisions to withdraw supportive care, not to the medical futility of life-sustaining therapies for older patients.[455,456] Respiratory deaths are less common than deaths from the underlying disease, from nonpulmonary organ dysfunction, or from infection. Nosocomial pneumonia is an important clinical problem in patients who have sustained ALI. Patients with self-limited causes of injury (e.g., venous air emboli, fat emboli, isolated lung contusion and other trauma, massive blood transfusions, postictal pulmonary edema, heroin pulmonary edema) and those with milder degrees of edema have a greater chance of survival and often clear their edema rapidly (Fig. 55-3).

The long-term outlook for patients who survive diffuse lung injury, even if it is severe, has improved.[457–460] Most recover to have normal chest roentgenograms, no complaints of dyspnea on exertion, normal lung volumes and airflow, and normal resting and exercise arterial blood gas findings and shunt fraction. Some patients have residual airway hyperreactivity. The most common abnormality is a reduced diffusing capacity, which tends to improve gradually. Not surprisingly, patients with the most days on positive-pressure ventilation and those with the lowest static lung compliance during the course of their ALIs are most likely to experience residual pulmonary impairment. Laryngotracheal stenosis, a consequence of prolonged endotracheal intubation, should be considered in patients with persistent exertional dyspnea.[461] Histologic abnormalities usually also gradually regress. Some longer-term patient follow-up studies demonstrate that a significant fraction of ARDS survivors have persistent disabilities 6 to 12 months after discharge from the

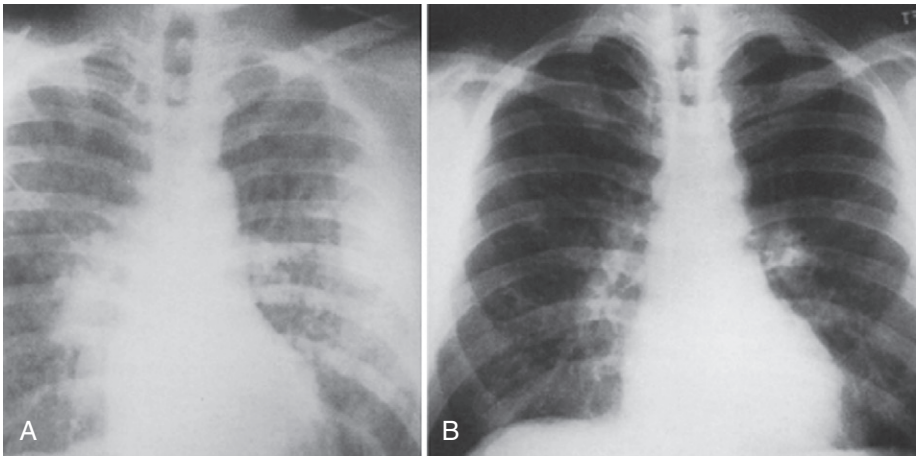

FIGURE 55-3 ■ Chest roentgenograms in a patient with heroin-induced increased permeability pulmonary edema. **A,** At the time of the initial film, the heart was not enlarged, the vascular pedicle was normal, and edema was patchy, peripheral, and not gravitationally distributed. **B,** Forty-eight hours later, the chest film was normal and the patient had fully recovered. Increased permeability pulmonary edema may resolve rapidly if the initiating agent of lung injury is transient and mild and the chronic phase of parenchymal lung injury (type II cell hyperplasia, fibrosis, connective tissue deposition, vascular remodeling) does not develop.

hospital, although this may not be specific for ARDS but rather may be a consequence of critical illness.[399]

Healing often involves some degree of fibrosis.[462,463] The fibroproliferative reaction to ALI seems to begin very early in the course of ALI.[153,464,465] Patients who develop fibrosis are less likely to survive than those who do not.[466] How much of this problem is due to disease and how much to treatment is not known. It may be possible to modify vigorous fibrotic reactions to lung injury, but the consequences of such therapy are unknown. It might also be possible to accelerate reconstitution of alveolar structure in injured lungs; for example, keratinocyte growth factor (fibroblast growth factor-7), which promotes alveolar epithelial hyperplasia in rodents, reduced mortality when given as pretreatment to rats exposed to hyperoxia,[467] and soluble and insoluble fibronectin increased alveolar wound healing in vitro.[468] More information about repair and healing might open new possibilities for therapy.[463,469]

Although several pharmacologic therapies for ARDS have not been effective in decreasing mortality,[94,390] the 30% reduction in mortality achieved with a lung-protective ventilatory strategy represents a major advance in understanding how to prevent ventilator-induced worsening of lung injury in these patients.[244,387]

OVERVIEW

Among the significant advances since the late 1960s has been the acquisition of important new knowledge concerning the physiology of fluid, solute, and protein transport in healthy and diseased lungs. Pulmonary edema—the abnormal accumulation of extravascular fluid in the lung—is a pathologic state that occurs when fluid is filtered into the lungs faster than it can be removed. The many causes of pulmonary edema have been grouped into two main pathophysiologic categories: increased pressure edema that results from an increase in the hydrostatic or osmotic forces (or both) that act across the barriers that normally restrict movement of fluid and solutes in the lungs and increased permeability edema from ALI that results from a breakdown of the normal barrier properties of the endothelium or the epithelium of the lung, or both. Although these two different types of pulmonary edema share many features, they can usually be distinguished clinically and they have different treatment requirements and prognoses. This distinction is possible by careful clinical, radiologic, and physiologic evaluation. However, increased permeability and elevated lung vascular pressure often coexist, as illustrated by the results of a large clinical trial in which pulmonary arterial wedge pressure and cardiac output was measured in 500 patients with ALI.[363] Although cardiac output was normal in the vast majority of patients, the initial pulmonary arterial wedge pressure was greater than 18 mm Hg in 29% of the patients, even though they also had good evidence for increased lung permeability from an infectious or noninfectious cause.[363]

Major advances in the treatment of ALI have occurred because of the successful application of lung-protective ventilatory strategies early to patients with clinical lung injury (see Table 55-10). A low tidal volume (6 mL/kg ideal body weight) coupled with a plateau pressure limit (<30 cm H_2O) is still the only therapy proven to reduce mortality in patients with ALI.[244,387] New insights into the pathogenesis of ALI suggest that other therapies may also prove to lower mortality in this common syndrome of severe acute respiratory failure.

A major development has been the ability to conduct large, prospective, randomized clinical trials sponsored by the NHLBI to test a variety of therapies that provide supportive care for patients, including mechanical ventilation, fluid therapy, and pharmacologic agents. For example, the recent 1000-patient fluid and catheter treatment trial demonstrated that the use of the pulmonary arterial catheter for most cases of ALI does not improve clinical outcomes,[363] although there are some patients with shock who may still benefit from the hemodynamic information provided by a pulmonary artery catheter.[366] Also, this trial demonstrated that a fluid conservative management strategy can reduce the duration of mechanical ventilation in patients with ALI.[381]

KEY POINTS

- Diagnosis of the cause of pulmonary edema should include detailed history, thorough physical examination, and selected laboratory data including the chest radiograph, the electrocardiogram, cardiac enzymes, and in some patients, microbiologic cultures, an echocardiogram, and occasionally, a pulmonary artery catheterization.
- ALI pulmonary edema may be complicated by the presence of elevated pulmonary intravascular pressures, especially from coexistent cardiac failure or volume overload.
- Treatment for cardiogenic pulmonary edema should include the immediate administration of supplemental oxygen and pharmacologic measures to reduce preload.
- The diagnosis of ALI should always initiate a thorough search for a treatable infection.
- If the patient with ALI requires intubation and positive-pressure ventilation, then the ventilation should be done with 6 mL/kg tidal volume with a plateau pressure less than 30 cm H_2O.

Surgery

NATURAL HISTORY

INTRODUCTION

The term *cor pulmonale,* or pulmonary heart disease, has been used rather loosely for many years to describe three broad groups of patients, all of whom have pulmonary hypertension resulting in progressive right ventricular hypertrophy, right ventricular dilation, and eventual cardiac decompensation from (1) disorders that primarily affect ventilatory drive or musculoskeletal respiratory mechanics; (2) pulmonary airway, infiltrative, fibrotic, or vascular diseases; and (3) disease in which the clinical picture as it affects the lungs and pulmonary circulation is the consequence of a primary cardiovascular disorder. To clarify matters, in 1963, an expert committee appointed by the Director General of the World Health Organization (WHO) recommended a definition based on morbid anatomy. Specifically, the committee defined chronic cor pulmonale as "hypertrophy of the right ventricle resulting from diseases affecting the function and/or the structure of the lung, except when these pulmonary alterations are the result of diseases that primarily affect the left side of the heart or congenital heart disease."[1] Subsequently, the WHO organized a major symposium on pulmonary hypertension that was held in Evian, France, in September 1998; from that meeting, which was attended by experts from around the world, a revised classification of pulmonary hypertension emerged,[2] which included replacing the terms "primary" and "secondary" pulmonary hypertension with a clinically meaningful classification. Eleven years later, the classification was again modified at the Fourth World Symposium on Pulmonary Hypertension in Dana Point, California (Table 56-1).[3] The resulting classification of pulmonary hypertension is generally accepted as the "gold standard" today. This chapter on cor pulmonale primarily deals with the group of disorders classified by this expert committee as "Pulmonary Hypertension Associated with Lung Diseases and/or Hypoxemia." We limit our discussion mainly to diseases that affect the airways and lung parenchyma, the pulmonary vasculature, or alveolar ventilation. Pulmonary thromboembolism (Chapter 51), pulmonary hypertension and related disorders (Chapter 52), and pulmonary vasculitis (Chapter 53) are discussed elsewhere.

PULMONARY CIRCULATION

The major pulmonary arteries normally have less medial thickening than the systemic arteries, reflecting the

TABLE 56-1. Fourth World Symposium Diagnostic Classification of Pulmonary Hypertension (2009)

GROUP 1: PULMONARY ARTERIAL HYPERTENSION (PAH)
Idiopathic PAH
Heritable PAH
- BMPR2
- ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
- Unknown genes

Drug- and toxin-induced
Associated with:
- Connective tissue diseases
- HIV infection
- Portal hypertension
- Congenital heart disease
- Schistosomiasis
- Chronic hemolytic anemia

Persistent pulmonary hypertension of the newborn

GROUP 1′: PULMONARY VENO-OCCLUSIVE DISEASE (PVOD) AND/OR PULMONARY CAPILLARY HEMANGIOMATOSIS (PCH)

GROUP 2: PULMONARY HYPERTENSION OWING TO LEFT HEART DISEASE
Systolic dysfunction
Diastolic dysfunction
Valvular disease

GROUP 3: PULMONARY HYPERTENSION OWING TO LUNG DISEASES AND/OR HYPOXEMIA
Chronic obstructive pulmonary disease
Interstitial lung disease
Other pulmonary diseases with mixed restrictive and obstructive pattern
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Developmental abnormalities

GROUP 4: CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION (CTEPH)

GROUP 5: PULMONARY HYPERTENSION WITH UNCLEAR MULTIFACTORIAL MECHANISMS
Hematologic disorders: myeloproliferative disorders, splenectomy
Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis: lymphangioleiomyomatosis, neurofibromatosis, vasculitis
Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK1, activin-like kinase type 1; BMPR2, bone morphogenetic protein receptor type 2; HIV, human immunodeficiency virus.

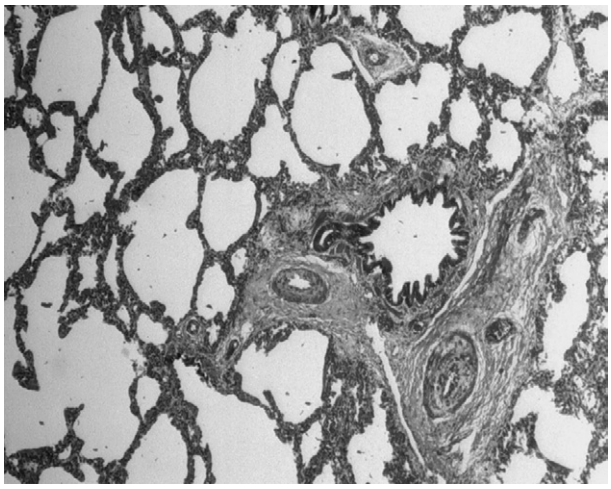

FIGURE 56-1 ■ A microscopic section from the lung of a patient who had chronic pulmonary hypertension. The small branches of the pulmonary artery are seen in juxtaposition to a terminal bronchiole. There is intimal thickening and marked medial hypertrophy.

fact that the pressures in the pulmonary arteries are approximately one fifth to one sixth of those normally found in the systemic arteries. In the systemic arteries, the ratio of medial thickness to external arterial diameter is 20% to 25%, but in the pulmonary arteries it is closer to 5%.[4] Postmortem casts of the human pulmonary arterial tree show there to be 17 branching orders, from the main pulmonary artery to the alveoli, that follow closely the branching pattern of the bronchial tree.[5,6] The number of vessels increases by a factor of approximately three with each branching order. As these vessels branch, their overall diameter ratio remains relatively constant, ensuring that the resistance to blood flow is minimal.

Muscular branches of the pulmonary artery, vessels with a luminal diameter between 100 and 1000 μm, have circular muscle fibers capable of causing vasoconstriction. These branches also demonstrate muscle hypertrophy in patients with chronic pulmonary hypertension (Fig. 56-1). True pulmonary arterioles, comparable to systemic arterioles, are not seen normally in the pulmonary circulation. Vessels smaller than 100 μm in diameter at the terminal end of the pulmonary arteries are usually referred to as pulmonary arterioles, but they normally have little or no medial smooth muscle. However, with chronic pulmonary hypertension, a single smooth muscle cell layer may extend longitudinally down these vessels. Therefore, normal pulmonary arterioles lack a true muscular media capable of reacting with vigorous vasoconstriction, but they still are capable of distending. Resistance to blood flow through the normal lung lies primarily in the capillary bed, but regulation resides chiefly in the very small branches of the pulmonary arterial system, and these branches are the major sites of the muscularization that is seen in patients who develop pulmonary hypertension. These vessels are less distensible in response to passive increases in pressure, and they can actively vasoconstrict in the presence of hypoxia. The pulmonary capillaries do not have smooth muscle cells within their walls and therefore do not contribute to pulmonary vasoconstriction. However, they can dilate to some extent during vascular engorgement, and numerous vessels are available for recruitment, both of which occur when pulmonary vein pressure rises. Although the pulmonary capillaries, which are literally suspended in

air, cannot vasoconstrict, their diameter can decrease in response to increases in intra-alveolar or intrapleural pressure. Their caliber may also decrease if there is perivascular inflammation or interstitial transudation of fluid.

Pulmonary Artery Pressure

Pulmonary artery pressure (PPA) in the normal resting recumbent adult averages 22/9 mm Hg, with a mean of 15 mm Hg. Pulmonary hypertension in the adult is said to be present when the resting pressure is higher than 30/15 mm Hg or the mean pressure is more than 25 mm Hg or 30 mm Hg with exercise. Commonly, pulmonary hypertension observed in cor pulmonale represents the net effect of a variety of different mechanisms. For example, in chronic obstructive pulmonary disease (COPD), a mixture of bronchitis and emphysema, the following effects on the pulmonary circulation may be seen: (1) reduction in the cross-sectional area of the pulmonary vasculature, reflecting anatomic loss of pulmonary capillaries from alveolar wall destruction; (2) increased pulmonary vascular resistance from hypoxic pulmonary vasoconstriction, with or without additional vasoconstriction resulting from hypercapnia and/or inflammation-induced vasoconstrictive stimuli and vascular remodeling; (3) medial hypertrophy of muscular pulmonary arteries and muscularization of the arterioles; (4) increased resistance to pulmonary blood flow resulting from polycythemia; (5) increased cardiac output and pulmonary blood flow from hypoxemia-induced systemic arteriolar vasodilation, which, in turn, raises PPA; and (6) an increase in intra-alveolar pressure with increasing lung inflation, which compresses pulmonary capillaries. Pulmonary hypertension may be variable—from mild elevations with exercise that return to normal with rest; to marked elevations in PPA associated with acute respiratory failure, but with restoration to the high-normal or mildly elevated range once ventilatory insufficiency is improved; to fixed severe pulmonary hypertension.

Disturbances in respiratory function ultimately affect the pulmonary circulation predominantly by production of alveolar hypoxia, regardless of whether obstructive or restrictive ventilatory insufficiency (or a combination of the two) is present, and regardless of the mechanism of abnormal gas exchange and whether it is caused by an anatomic or functional disturbance. In hypoxemia, with or without hypercapnia, PPA rises out of proportion to pulmonary capillary pressure owing to precapillary vasoconstriction, resulting in an increase in the work of the right ventricle and its subsequent remodeling.

Pulmonary Artery Wedge Pressure

The pulmonary artery wedge pressure is normally obtained during cardiac catheterization in the laboratory or at the bedside by occluding a small branch of the pulmonary artery in which the catheter is positioned, either by inflating a balloon at the end of the catheter or by wedging an end-hole catheter into the distal vessels. This extends the manometric system encompassed by the wall of the catheter, and the static column of fluid within it, to incorporate the walls of the vessel distal to the end of the catheter and the static column of blood within it (see Fig. 6-1 in Chapter 6). The extended manometric system then measures the pressure in the distal capillary-sinusoidal bed of the lung, where blood is still freely flowing (i.e., near the origin of the pulmonary venous system). Because the flow between the pulmonary capillaries and the left atrium normally is a low-resistance network, the pulmonary artery wedge pressure is usually within 1 or 2 mm Hg of left atrial pressure. Therefore, it is possible to estimate pulmonary vascular resistance by dividing the transpulmonary pressure gradient (mean PPA minus the pulmonary artery wedge pressure) by the cardiac output.

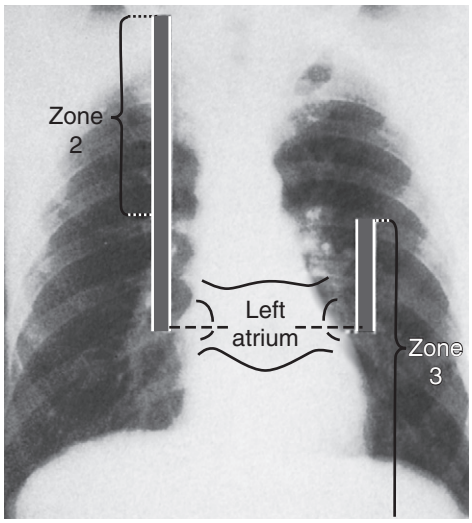

FIGURE 56-2 ■ Chest radiograph showing the distribution of zones in normal human lungs in the upright position. The *solid bar* on the left shows the height "reached" by pulmonary artery pressure, and the *bar* on the right shows the height "reached" by pulmonary vein pressure; both pressures are referenced to the mid-left atrium. More of the lungs are in zone 3 than zone 2, and there is no zone 1.

Although the apices of the lungs in a person who is sitting or standing are normally in West's zone 2 (Fig. 56-2), if PPA decreases, zone 1 relationships may develop (for further discussion, see Chapter 6). Under these conditions, estimates of left atrial pressure from pulmonary artery wedge pressures from zone 1 regions are difficult to obtain and may be inaccurate. However, because most measurements of pulmonary artery wedge pressures are made with the patient supine and the lungs mainly in zone 3, this is ordinarily not a significant practical problem. Should it be desirable to have measurements of pulmonary vascular resistance or estimations of accurate pulmonary artery wedge pressure while the patient is sitting or standing, the pulmonary artery catheter should be wedged in the dependent (posterobasal) portions of the lung: that is, in areas in which the vessel is below the level of the left atrium. Alternately, one may reasonably use total pulmonary resistance or the ratio of the mean PPA to the pulmonary blood flow when studying patients with pulmonary hypertension unrelated to left-sided heart events, in whom pulmonary vein pressures are presumably normal and, therefore, low. It should also be noted that the pulmonary artery wedge

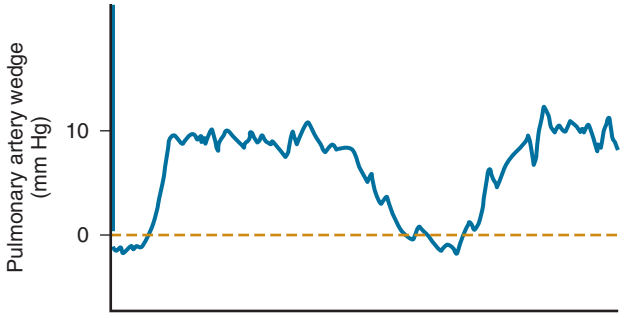

FIGURE 56-3 ■ Pulmonary artery wedge pressure in a patient with chronic obstructive lung disease. Note that the wedge pressure is normal. A prominent fall in wedge pressure is observed with the onset of inspiration as intrapleural pressure falls.

pressure may not reflect left atrial pressure if a patient is receiving positive-pressure ventilation. If there are wide swings in intrapleural pressure, the wedge pressure should be estimated at end-expiration and not as mean pressure (Fig. 56-3).

PATHOPHYSIOLOGY OF THE PULMONARY CIRCULATION

The normal pulmonary circulation, which is composed of highly compliant pulmonary arteries and a rich capillary network with a large recruitment capability, can accommodate large increases in blood flow (e.g., during exercise or with left-to-right congenital intracardiac shunts) without a significant rise in PPA. For example, this capillary reserve can be demonstrated in a healthy person at the time of cardiac catheterization by transient balloon occlusion of the left or right main pulmonary artery. No rise or only a small rise in the resting PPA results, despite the fact that the entire cardiac output must now go through the pulmonary circulation of only one lung.[7] Similarly, after recovering from pneumonectomy, patients often have only slightly raised resting PPA values.

Oxygen is the major mediator of pulmonary autoregulation, with pulmonary vasodilation occurring in regions where the partial pressure of oxygen is high and vasoconstriction occurring in lung regions that are poorly oxygenated so that blood flow is preferentially directed to areas that are better oxygenated. Hypoxic pulmonary vasoconstriction is the major mechanism implicated for the development of pulmonary hypertension in patients with lung disease; however, significant structural changes within the pulmonary vascular tree may also occur, which lead to destruction of the pulmonary capillary bed and contribute to the development of pulmonary hypertension. Early in the natural history of lung diseases, the resting pressure in the pulmonary artery is usually normal, and because of the large capillary reserve within the lung, it may not be readily apparent that significant capillary destruction is taking place until almost half of the capillary bed is destroyed.

The pathophysiology of pulmonary hypertension associated with advanced respiratory diseases is generally distinct from that of the pulmonary arterial hypertensive disorders, although they do share some similar mechanistic pathways. The vascular remodeling process in interstitial lung diseases and pulmonary arterial hypertension involve changes in all three levels of the vessel wall: the adventitia, media, and intima (luminal side). However, unlike the pulmonary arterial hypertensive disorders, which are characterized by marked intimal proliferation, adventitial collagen and extracellular matrix deposition, and plexigenic lesions, such severe findings are not generally present in patients with pulmonary hypertension associated with chronic obstructive or restrictive lung disorders.

Hypoxic Pulmonary Vasoconstriction

Several stimuli may result in precapillary pulmonary vasoconstriction with resultant pulmonary hypertension. Of these, the most potent and most important, alveolar hypoxia, may be present under a variety of circumstances.[8] Pulmonary vasoconstriction can occur in perfectly healthy lungs. For example, the pulmonary hypertension observed in persons living at high altitudes is caused by chronic hypoxemia despite the presence of hyperventilation with resultant hypocapnia. Similarly, hypoventilation sufficient to produce alveolar hypoxia and hypercapnia, which may occur in morbidly obese patients, results in pulmonary hypertension secondary to pulmonary vasoconstriction. Other causes of primary hypoventilation, whether it arises centrally or from weakness of the muscles of respiration, may also cause pulmonary hypertension secondary to inadequate alveolar ventilation. Hypercapnia, which is primarily mediated by an increase in hydrogen ion concentration, worsens pulmonary vasoconstriction, augmenting the pressure increase expected from a comparable degree of hypoxia alone.

It is of interest to contrast the consequences of hypoxic pulmonary vasoconstriction in healthy residents residing at high altitude and in patients with COPD with cor pulmonale residing at sea level. In the former case, a combination of alveolar hypoxia, hyperventilation, and hypocapnia is present; in the latter case, hypoxia is often associated with hypoventilation and hypercapnia. Subjects residing at high altitudes have an increased hematocrit and a decreased plasma volume. Their stroke volume and cardiac output tend to be low. In contrast, patients with COPD tend to have normal or increased blood volume, and their cardiac output is generally normal or even increased. Healthy subjects, even those residing at very high altitudes, normally do not develop right ventricular failure despite the presence of hypoxia and pulmonary artery hypertension, which suggests that acidemia and hypercapnia are important contributing elements to impaired right ventricular function in patients with COPD.

Low alveolar P_{O_2} increases PPA in a somewhat hyperbolic dose-response curve, with the pressure rising much more rapidly when arterial P_{O_2} values fall below 75 mm Hg. Nevertheless, there is still marked individual variability in the level of PPA at a given high altitude. In part this may be explained by differences in individual sensitivity to ventilatory drive produced by hypoxia, with some persons hyperventilating more than others.

However, some of the variability lies in the difference in pulmonary vasoconstrictive response, which probably reflects an inherited difference in pulmonary vascular reactivity. This latter viewpoint is supported by observations of the high-altitude pulmonary hypertensive disease among cattle known as *brisket disease.*[9] When cattle native to low altitudes are exposed to high altitudes for grazing, P_{PA} climbs only moderately in some, but in others the pressure climbs steeply. Cattle with either hyporesponsive or hyperresponsive pulmonary vascular reactivity transmit these phenotypes as a genetic trait from parents to offspring.[10]

Just as it has been suggested that genetic traits may play a role in the pulmonary pressor response to the hypoxia of high altitude, one explanation for the observation that some patients with COPD develop pulmonary hypertension, whereas others do not, attributes this variability to inherited differences in the ventilatory sensitivity to hypoxia and carbon dioxide or in pulmonary vascular reactivity, or both.[11]

Most patients who develop resting pulmonary hypertension with COPD are both hypoxemic and hypercarbic; presumably, the hypercarbic patients have a low ventilatory sensitivity to carbon dioxide, because, as noted, hypoxemic residents at high altitudes hyperventilate and are hypocarbic. It is therefore reasoned that some patients who are born with a normal ventilatory sensitivity to carbon dioxide and hypoxia have an increased ventilatory effort in response to obstructive lung disease and therefore maintain relatively normal blood gases. In contrast, a patient who responds with a low ventilatory sensitivity fails to compensate and consequently develops an insufficient ventilatory drive to overcome airway resistance, ultimately causing hypercapnia, hypoxemia, and pulmonary vasoconstriction.

Virtually all patients with COPD, whether characterized by the now obsolete terms "pink puffers" and "blue bloaters," have increased drive to breathe when evaluated by the mouth occlusion pressure ($P_{0.1}$) test.[12] The clinical differences between the groups are now believed to result from differences in the pattern of breathing and, probably, in intrapulmonary gas exchange.[13] It remains true, however, that in general the more abnormal the P_{O_2} and P_{CO_2} values in patients with COPD, the more severe the pulmonary hypertension and polycythemia and the greater the likelihood of cor pulmonale.

Pulmonary Vascular Remodeling

The presence of chronic hypoxemia and ventilatory insufficiency in patients with chronic respiratory diseases is well known to lead to pulmonary vascular remodeling, characterized by prominent medial smooth muscle hypertrophy, distal smooth muscle proliferation with neomuscularization of normally unmuscularized small pulmonary vessels, and mild intimal changes.[14] Hypoxic vasoconstriction increases pulmonary vascular resistance and pressure, wall stress, and shear force, and these mechanical forces in turn lead to a cascade of mediators and cellular changes that contribute to the remodeling process.

COPD is the most common and most studied lung disease associated with pulmonary hypertension and cor pulmonale. Significant structural changes occur in the pulmonary circulation in patients with COPD. The presence of hypoxemia and chronic ventilatory insufficiency is associated with hypoxic pulmonary vasoconstriction and early evidence of intimal thickening with medial hypertrophy in the smaller branches of the pulmonary arteries.[15] Vascular smooth muscle cells are laid down longitudinally within the intima, and hypertrophy of these cells and smooth muscle cells within the media becomes prominent. Localized thrombosis in situ can occur, obliterating parts of the pulmonary vascular tree. Progressive destruction of capillaries that course along alveoli that are being destroyed or coalescing into bullae further diminishes the cross-sectional area of the pulmonary vascular tree. The structural changes together with the effects of vasoconstriction result in a significant increase in pulmonary vascular resistance. The consequence is pulmonary arterial hypertension, which in itself may cause further structural damage to the smaller branches of the pulmonary circulation and serve as a stimulus for the development of medial hypertrophy and dilation of the larger branches of the pulmonary artery. If these developments are long-standing, prominent atherosclerotic changes may be seen in the main pulmonary artery and its major branches.[16]

The association of pulmonary hypertension with interstitial lung disease (ILD) is less well characterized than that with COPD; recent studies, however, have led to a greater understanding of the pathophysiologic mechanisms involved in the development of pulmonary hypertension in these patients. The ILDs most commonly associated with pulmonary hypertension include connective tissue disease–related ILD, sarcoidosis, idiopathic pulmonary fibrosis, and histiocytosis X. Pulmonary hypertension has been reported to develop in these patients through multiple, often diverse mechanisms, but chiefly from hypoxic pulmonary vasoconstriction and associated remodeling. In addition, vascular narrowing is worsened both by a reduction in pulmonary vascular distensibility from surrounding fibrosis and by hypoxia from mismatching between the distributions of ventilation and perfusion. Ultimately, large portions of the pulmonary vascular bed may be destroyed or obliterated from progressive parenchymal fibrosis, inflammation, perivascular fibrosis, and/or thrombotic angiopathy.[17–19]

The degree of pulmonary hypertension seen in patients with COPD and cystic fibrosis is usually, but with some exceptions, reported to be mild or moderate, often paralleling the degree of hypoxemia.[20,21] In a cohort of 500 patients with COPD and cor pulmonale, Stevens and colleagues[22] found that only 6 patients had severe elevations of P_{PA}, defined as mean P_{PA} greater than 50 mm Hg, and that the severity of P_{PA} increases did not appear to be related to the severity of underlying lung disease. Moreover, the direct correlation between arterial P_{O_2} and P_{PA} is not great. In a study of 120 patients with severe emphysema evaluated for entry into the National Emphysema Treatment Trial, multiple stepwise regression analysis revealed that arterial P_{O_2} was not an

independent predictor of mean PPA, and that indices of emphysema severity and PPA did not correlate either.[23] Studies in patients with ILD showed that the presence of pulmonary hypertension does not tend to correlate well with lung volumes, whereas diffusion impairment (reduced transfer factor for carbon monoxide) and the need for oxygen supplementation were predictors of pulmonary hypertension.[24,25]

Several studies suggest that vascular remodeling in patients with mild COPD without concomitant hypoxemia is a component of early-stage disease as evidenced by increased inflammatory cell density in the adventitia and increased thickness of the intima of pulmonary arteries.[26,27] Furthermore, endothelial lesions have been shown to be present in cigarette smokers without chronic airflow obstruction.[28] A study investigated the development of pulmonary arterial hypertension in patients with moderate to severe airflow obstruction who neither met criteria for long-term oxygen therapy nor had resting pulmonary arterial hypertension; 76 of 131 (58%) had exercise-induced pulmonary arterial hypertension. Five years later, 25% of the subjects had developed resting pulmonary arterial hypertension, including 32% who had exercise-induced pulmonary arterial hypertension at baseline.[29] These studies suggest that factors other than hypoxemia alone play a role in the development of pulmonary vasoconstriction and remodeling leading to pulmonary arterial hypertension.

As is the case with COPD, most patients with pulmonary hypertension associated with interstitial pulmonary fibrosis have mild to moderate elevations in PPA; however, occasional patients may present with severe pulmonary hypertension at or near systemic levels. A study of gene expression patterns in patients with interstitial pulmonary fibrosis who develop pulmonary hypertension reported abnormal vascular phenotypes, suggesting they may have an intrinsic vasculopathy.[30] Different mechanisms may contribute to the development of pulmonary hypertension among the various lung disorders. In patients with connective tissue diseases, for example, antibody-mediated vascular inflammation (vasculitis), in situ thrombosis and/or thromboembolism (related to a hypercoagulable state), and left ventricular diastolic dysfunction may be involved in the development of pulmonary hypertension. In addition, these patients may have coexistent pulmonary artery hypertension that is unrelated to the parenchymal lung disease. The pulmonary hypertension in patients with pulmonary histiocytosis X may be severe owing to the presence of an intrinsic proliferative pulmonary vasculopathy in the absence of advanced parenchymal destruction. In rare cases of histiocytosis X, pulmonary veno-occlusive disease has also been reported.[31] In patients with sarcoidosis and pulmonary hypertension, advanced fibrosis is usually the cause; however, granulomatous vasculopathy involving the pulmonary veins and arteries, as well as extrinsic compression of the large pulmonary arteries by lymphadenopathy, may also play a role. In addition, cardiac sarcoidosis can lead to pulmonary venous hypertension.[32] Studies by Shorr et al.[33,34] indicated that the need for supplemental oxygen in patients with pulmonary sarcoidosis was an independent predictor of pulmonary hypertension on multivariate analysis, whereas neither spirometric measures nor the need for corticosteroids was predictive of pulmonary hypertension.

The fact that the presence and degree of pulmonary hypertension in patients with interstitial pulmonary fibrosis cannot fully be explained by the degree of pulmonary fibrosis or hypoxemia alone has led to the theory that the development of fibrosis and vascular narrowing may be pathogenetically linked. Vasoactive and/or profibrotic mediators that have been implicated in the pathogenesis of both interstitial pulmonary fibrosis and idiopathic pulmonary fibrosis in patients or experimental models include increased endothelin-1 expression and reduced levels of nitric oxide (NO) synthase and prostaglandin E_2.[35,36] Endothelin-1 is a potent vasoconstrictor and mitogen, and NO is a pulmonary vasodilator and inhibitor of fibrosis. Other potential mediators associated with pulmonary hypertension in patients with ILD include thromboxane A_2, tumor necrosis factor-α, platelet-derived growth factor, transforming growth factor-β, and fibroblast growth factor.[37–39]

RIGHT VENTRICLE

The normal right ventricle is crescent shaped and has a wall thickness less than 0.6 cm (Fig. 56-4). Its weight is usually less than 65 g in men, and less than 50 g in women.[16] Embryologically, the right ventricle develops from two separate components: the bulbus cordis, which becomes the outflow tract, and the sinus venosus, which becomes the inflow tract. These are separated by a muscular ridge, the crista supraventricularis. Normally, the right ventricle contracts almost sequentially from inflow to outflow, thus effectively emptying its volume into the low-impedance pulmonary circulation. In the absence of cardiac disease, the right ventricle plays an almost passive role in maintaining cardiac output in accordance with the venous return and Starling's law of the heart. In fact, in congenital tricuspid atresia, early surgical approaches involved bypass of the right ventricle through anastomosis of the right atrium directly to the pulmonary artery (the so-called Fontan procedure), which resulted in perfusion of the pulmonary circulation from an elevated central venous pressure. However, it should also be noted that a damaged right ventricle with residual high central venous pressures resulting from an inferior myocardial infarction is associated with a distinctly reduced survival rate.

Because of the shape of the right ventricle, it is difficult to measure the right ventricular volume accurately by radiographic or echocardiographic techniques. In a series of 15 subjects without heart disease, right ventricular end-diastolic volume in the supine position measured by a thermodilution technique, which probably overestimates volumes, averaged 103 ± 24.4 mL/m^2.[40] With passive assumption of an upright posture by tilting, right ventricular end-diastolic volume falls due to gravitational pooling of blood within the distensible venous tree. In a separate series of eight subjects without heart

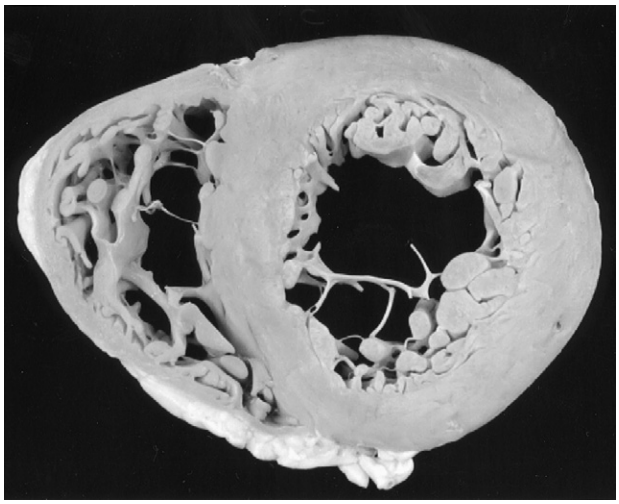

FIGURE 56-4 ■ A transverse section through a normal heart illustrates a somewhat crescent-shaped right ventricular cavity, together with the presence of prominent trabeculae carneae. Note that the myocardial thickness of the normal left ventricle is considerably greater than that of the right ventricle.

FIGURE 56-5 ■ Transverse section of a heart from a patient who had severe pulmonary hypertension showing dilation of the right ventricular cavity, which has a more spherical shape than the heart shown in Figure 56-4. Marked wall thickness of the right ventricle caused by massive hypertrophy is seen. The trabeculae carneae are also hypertrophied, and endocardial sclerosis is visible on several of them. The left ventricle is relatively normal, with protrusion of the posteromedial and anterolateral papillary muscles into the cavity. The bright white patches on the lateral free wall and posterolateral septum are highlight artifacts caused by reflection of the flash during photography.

disease, end-diastolic volume fell a mean of 16.3 mL/m^2 from a mean baseline of 98.1 ± 23.3 mL/m^2. This fall in right ventricular end-diastolic volume causes less of an end-diastolic fiber stretch and results in a fall in stroke volume with the assumption of an upright position. At the same time, aortic baroreceptor stimulation reflexively increases heart rate by about 12 beats/min, thus compensating for an average stroke volume fall of approximately 13.3 mL/m^2; therefore, cardiac output is maintained in essentially the same range as in a recumbent patient at rest.[41]

Acute increases in right ventricular afterload result in a significant fall in stroke volume[42]; in contrast, the left ventricle can accommodate an acute increase in afterload with little change in stroke output. Chronic pulmonary hypertension with a corresponding increase in right ventricular work results in uniform hypertrophy of the right ventricle. As a result, right ventricular weight increases as right ventricular wall myocytes thicken and exhibit enlarged nuclei. Varying degrees of interstitial fibrosis occur. As the ventricle further hypertrophies, it becomes increasingly able to expel the stroke output against high pulmonary vascular resistance and maintain cardiac output. Patients with idiopathic pulmonary arterial hypertension or with severe mitral stenosis and pulmonary vascular disease have been observed in whom the right ventricle maintained a pulmonary artery systolic pressure significantly higher than the systemic pressure.

In patients with COPD, hypoxic vasoconstriction is associated not only with right ventricular hypertrophy but also with right ventricular dilation. The normal crescent shape of the right ventricle is progressively transformed into a more spherical structure that is better able to generate an increased stroke work (Fig. 56-5).

The increase in right ventricular work associated with pulmonary hypertension, which results in both hypertrophy and dilation of the right ventricle, produces a significant increase in right ventricular myocardial oxygen consumption. At the same time, an increase in wall thickness tends to decrease right ventricular endocardial coronary perfusion. Furthermore, an increase in end-diastolic pressure occurs as right ventricular stiffness increases during diastole, adding to the compromise of endocardial coronary perfusion. Taken together, these factors result in an imbalance between right ventricular myocardial oxygen demand and supply. Nevertheless, in several studies the end-diastolic pressure-volume relationship, even in the presence of resting pulmonary hypertension, suggested well-preserved right ventricular contractility in patients with COPD. Only the additional presence of acidemia or infection precipitates right ventricular failure. When chronic hypercapnia with acidosis is present in patients with alveolar hypoventilation, the ability of the right ventricle to increase its work appears to be significantly impaired, and right ventricular end-diastolic pressure increases (i.e., there is a shift to the right in the family of Starling curves).

This impairment of myocardial contractility in the presence of hypercapnia probably plays a significant role in producing decompensated pulmonary heart disease in response to acute increases in arterial P_{CO_2} associated with exacerbations of COPD and accompanying decreases in alveolar ventilation. Recordings of right ventricular and pulmonary artery systolic pressures may show pulsus alternans similar to that often seen in left ventricular failure (Fig. 56-6). The development of right ventricular volume overload with ventricular dilation results in a decreased ejection fraction, because stroke volume tends to be maintained close to the normal range

in decompensated cor pulmonale.[43] With exercise, patients with COPD significantly raise their right ventricular afterload, which causes further increases in right ventricular end-diastolic volume and decreases in ejection fraction. It is likely that this deterioration in hemodynamics with exercise is a major factor limiting the ability of such patients to exercise normally.

Figure 56-7 describes the pathophysiology of right ventricular failure in patients with pulmonary hypertension. Right ventricular dilation and wall thinning result in increased right ventricular wall stress that, along with increased heart rate, leads to further increases in myocardial oxygen consumption. Increased myocardial oxygen consumption compounded by decreased myocardial perfusion as previously described results in right ventricular ischemia and worsening right ventricular function. In addition, as pulmonary pressures rise and the right ventricle dilates, severe tricuspid regurgitation ensues, which further compromises right ventricular forward cardiac output, thereby limiting left ventricular filling. Furthermore, right ventricular dilation in the setting of an intact pericardium compromises left ventricular filling through several mechanisms. A shift of the interventricular septum toward the left ventricle and an increase in intrapericardial pressure reduce left ventricular distensibility and transmural left ventricular filling pressure, which represents the true preload of the left ventricle. As a consequence of decreased left ventricular preload, the systemic cardiac output is significantly compromised, initially with exercise and eventually even at rest. With rising right atrial pressures in patients with a patent foramen ovale, significant right-to-left atrial shunting can occur, resulting in systemic oxygen desaturation and further worsening systemic oxygen delivery.[44]

In the presence of right ventricular failure and elevated central venous pressure when the patient stands up, neither right ventricular end-diastolic volume nor stroke volume decreases. Consequently, heart rate does not change. This lack of postural reflex compensation is attributable to failure of any incremental gravitational pooling of blood in the venous tree, because of increased plasma volume, increased tissue pressure from edema with decreasing venous distensibility, and increased venomotor tone.[41]

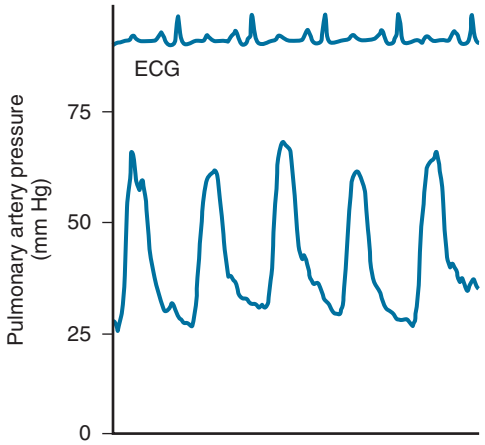

FIGURE 56-6 ■ A recording of the pulmonary artery pressure at the time of cardiac catheterization in a patient with cor pulmonale and heart failure, illustrating pulsus alternans in the pulmonary artery.

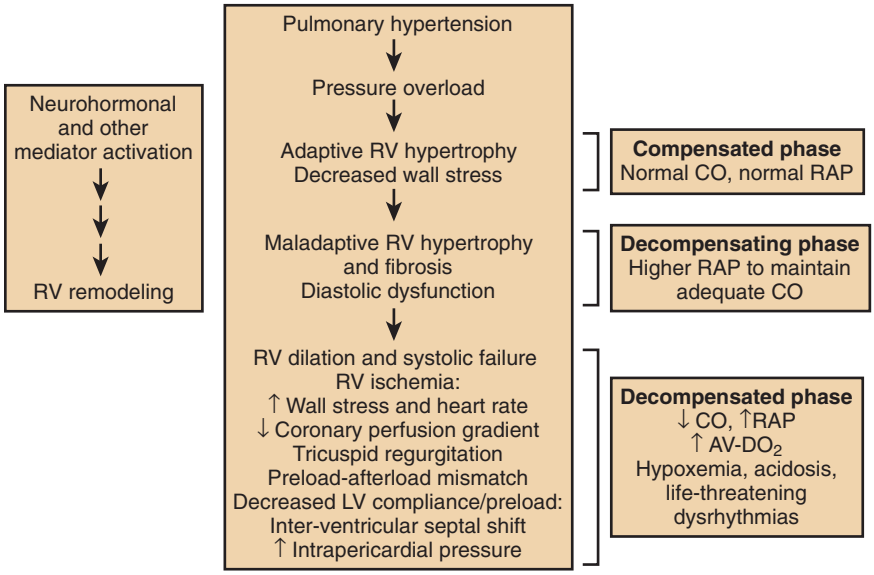
LEFT VENTRICLE

Controversy has existed over the years as to whether the left ventricle eventually fails when right ventricular failure results from chronic cor pulmonale. Part of the uncertainty has stemmed from the fact that the early studies of patients with cor pulmonale secondary to



AV-DO_2 = arteriovenous oxygen difference; CO = cardiac output; RAP = right atrial pressure; LV = left ventricular; RV = right ventricular

FIGURE 56-7 ■ Pathophysiology of right ventricular dysfunction in pulmonary hypertension.

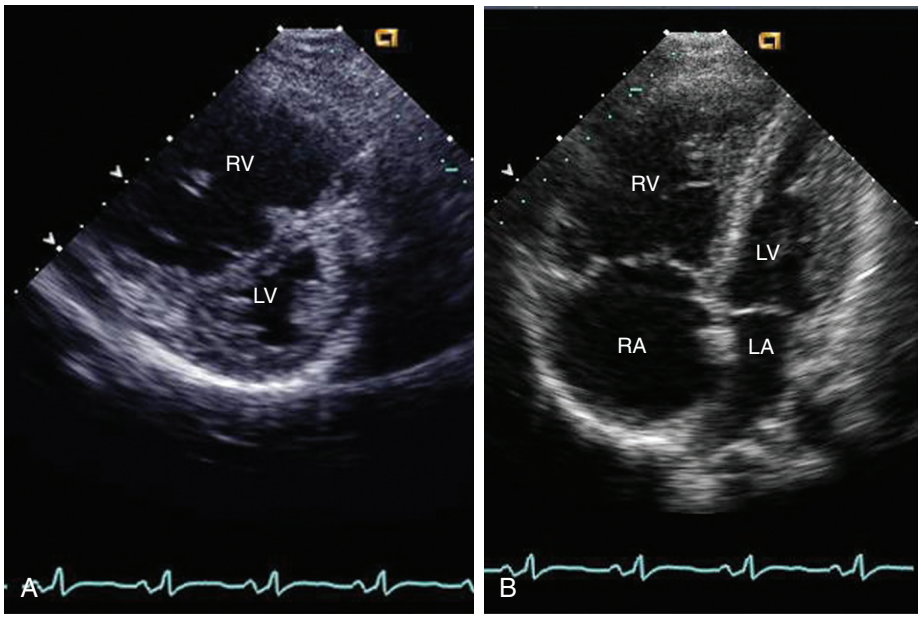


FIGURE 56-8 ■ **A,** Short-axis two-dimensional echocardiographic image of the right ventricle (RV) and left ventricle (LV) in diastole. Notice the enlarged RV with flattening of the interventricular septum (IVS), which causes the LV to assume a "D" shape. These findings, occurring in diastole, are indicative of RV volume overload. **B,** Apical four-chamber, two-dimensional echocardiographic view of all four cardiac chambers showing an enlarged right atrium (RA) and right ventricle (RV) with small, compressed left cardiac chambers. LA, left atrium; LV, left ventricle.

COPD included chiefly middle-aged or older men with a history of heavy cigarette smoking, who were likely to have coexisting coronary artery disease. Failure of the left ventricle in some of these patients may have reflected coexisting coronary artery disease rather than the natural history of decompensated pulmonary heart disease. Nevertheless, although left ventricular ejection performance is unimpaired, cardiac catheterization studies have revealed abnormal left ventricular end-diastolic pressure-volume relationships.[45] Echocardiographic studies also showed progressive impairment of left ventricular diastolic function that correlated with the severity of pulmonary hypertension.[46] It is likely that this results, in large part, from bulging of the interventricular septum from the hypertrophied and dilated right ventricle into the cavity of the left ventricle, and ventricular interdependence exerted by pericardial constraint.[44,47] As a result, left ventricular diastolic geometry becomes distorted (Fig. 56-8),[48] and filling characteristics may be altered such that a higher filling pressure is required to accomplish the same end-diastolic fiber stretch needed for a given stroke work, in accordance with Starling's law of the heart.

Furthermore, measurements of pulmonary artery wedge pressure as a reflection of left heart filling pressure can be distorted because of the increase in intra-alveolar pressures, as well as the large swings in intrathoracic pressure with resultant large swings in wedge pressure tracings seen in patients with COPD (see Fig. 56-3), and increases in intrapericardial pressure. This is particularly troublesome when the patient is receiving positive end-expiratory pressure from a mechanical ventilator. As mentioned, pulmonary artery wedge pressures should always be estimated at end-expiration rather than attempting to measure the mean wedge pressure. Furthermore, with severe right-sided heart failure and marked elevation in right atrial pressure, coronary sinus pressure increases significantly. This can result in an increase in left ventricular wall dimension limiting left ventricular distensibility. This mechanism leading to reduced left ventricular preload appears to act independently of diastolic ventricular interaction caused by right ventricular enlargement as previously described.[49]

NEUROHORMONES

Significant neurohormonal abnormalities occur in patients with cor pulmonale. Plasma catecholamine levels generally rise in patients with decompensated pulmonary heart disease in a manner comparable to that seen in patients with heart failure secondary to primary myocardial disorders. It is clear that increased sympathetic activity is present with decompensation from cor pulmonale, resulting in high plasma levels of circulating catecholamines and stimulation of the renin-angiotensin-aldosterone systems. In the measurements by Anand and associates,[50] vasopressin actually rose to a higher level than was seen in comparable patients with failure not associated with COPD. Because cardiac output is often normal or may even be increased in decompensated pulmonary heart disease, it is likely that the decrease in systemic vascular resistance resulting from both hypercapnia and hypoxia leads to a reflex increase in circulating catecholamines and other neural hormones. Central sympathetic stimulation may also be encouraged by the

direct effect of the increased P_{CO_2} on the central nervous system.

Recently, the neuropeptide vasoactive intestinal polypeptide (VIP) has been of significant interest in pulmonary hypertension. VIP primarily functions as a neurotransmitter and acts as a potent systemic and pulmonary vasodilator; it has been shown to inhibit platelet activation and vascular smooth muscle cell proliferation. These effects are mediated by stimulation of specific VIP receptors resulting in activation of the cyclic adenosine monophosphate and cyclic guanosine monophosphate (GMP) systems.[51–56] A deficiency of this neuropeptide has been found in the serum and lung tissue of patients with idiopathic pulmonary arterial hypertension. Chronic treatment with inhaled VIP in eight patients with idiopathic pulmonary arterial hypertension resulted in improved cardiopulmonary hemodynamics, exercise performance, and dyspnea.[57] The role of VIP in pulmonary hypertension associated with lung diseases or hypoxemia or both has yet to be investigated. However, given the findings described previously in idiopathic pulmonary arterial hypertension, VIP and its receptors represent rational and promising targets for the development of therapeutic strategies in other forms of pulmonary hypertension.

Angiotensin II

Angiotensin II is a potent vasoconstrictor of the pulmonary vascular bed. The pulmonary vasculature appears to be even more sensitive to the vasoconstrictor effects of angiotensin II than is the systemic vascular bed. This is noteworthy because increased circulating levels of angiotensin II and aldosterone are found in patients with cor pulmonale secondary to COPD who have hypoxia and hypercapnia.[58] Activation of the renin-angiotensin-aldosterone systems, together with hypoxemia, is probably an underlying pathophysiologic mechanism responsible for the elevation in pulmonary vascular resistance that is observed in patients with decompensated pulmonary heart disease.

A dose-response relationship of pulmonary vascular resistance to the infusion of angiotensin II has been observed in normal subjects.[59] In patients with pulmonary heart disease, lowering pulmonary vascular resistance and dropping P_{PA} is the ideal therapeutic goal. Angiotensin II inhibitors might be expected to produce this effect. They have been demonstrated to improve survival in patients with systolic heart failure caused by either coronary disease or idiopathic dilated cardiomyopathy. Could such a benefit be expected in patients whose right-sided heart failure results from COPD despite the earlier disappointing experience with vasodilators? Although such vasodilators are capable of reducing pulmonary vascular resistance, they may actually aggravate hypoxemia. Increased hypoxemia can result from administration of pulmonary vasodilators because perfusion may improve in areas of impaired ventilation, thereby worsening arterial hypoxemia. It is encouraging to note that the angiotensin-converting enzyme (ACE) inhibitor lisinopril has been demonstrated experimentally to attenuate significantly the pulmonary pressor response to hypoxic pulmonary vasoconstriction in healthy human volunteers.[60] In addition, angiotensin II receptor blockade has been shown to produce a similar effect in hypoxic pulmonary vasoconstriction in humans.[44] However, studies performed to date have not elucidated a role for ACE inhibitors or angiotensin II receptor antagonists in the treatment of cor pulmonale.

NATRIURETIC PEPTIDES

The family of natriuretic peptides includes atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). Circulating ANP and BNP levels are elevated severalfold in patients with cor pulmonale, even in the absence of impaired left ventricular function.[61] Presumably, right atrial distention or overactivity in response to increased right ventricular afterload is the stimulus for their release. CNP, which appears to be normal in the usual patient with congestive heart failure of left-sided origin, is elevated in patients with cor pulmonale, although not as extensively as ANP and BNP.[62] The elevation of CNP appears to be endothelial in origin, suggesting that its stimulus for release may be either arterial hypoxemia or endothelial damage occurring in cor pulmonale. ANP, BNP, and CNP have approximately equivalent pulmonary vasorelaxant activities. Although ANPs appear to have little effect on resting vasopulmonary artery tone, they do appear to interact with the vasoactive response of hypoxic pulmonary vasoconstriction. Experimentally, they can attenuate the increased pulmonary hypertension produced by hypoxia.[63] It has also been shown that BNP levels increase in proportion to the extent of right ventricular dysfunction in pulmonary hypertension.[64]

A recent study enrolled 44 patients with right ventricular overload, 18 of whom had atrial septal defect and 26 of whom had idiopathic pulmonary arterial hypertension or thromboembolic pulmonary hypertension. Plasma BNP and ANP levels were measured and right heart catheterization was performed. Right and left ventricular ejection fraction, myocardial mass, and chamber volumes were determined using electron beam computed tomography (CT). Plasma BNP and ANP levels were elevated in these patients compared to control subjects. Furthermore, the BNP-to-ANP ratios were significantly higher in patients with right ventricular pressure overload compared to volume overload. Levels of BNP correlated positively with pulmonary vascular resistance and right atrial pressure, but negatively with cardiac output and right ventricular ejection fraction. Long-term vasodilator therapy was also associated with reduced plasma BNP concentration. Another study of 60 patients with idiopathic pulmonary arterial hypertension established by right heart catheterization evaluated the long-term prognostic significance of BNP and other neurohormones.[65] On multivariate analysis, baseline plasma BNP was an independent predictor of mortality; patients with a supramedian level of baseline BNP (>150 pg/mL) had a significantly lower survival rate than those with an inframedian level ($P < 0.05$). Hence, BNP may serve as a

prognostic indicator in patients with idiopathic pulmonary arterial hypertension. In a study of 176 patients with various lung diseases, elevated serum BNP level predicted the presence of pulmonary hypertension and was a risk factor for death, independent of lung functional impairment or hypoxemia in both uni- and multivariate analysis.[24]

Patients with cor pulmonale, who demonstrate alveolar hypoxia and elevated circulating angiotensin II levels, have a dose-related decrease in PPA during an infusion of ANP.[66,67] The pulmonary pressor response to infused angiotensin II in humans appears to be significantly attenuated by BNP, but not by ANP. A similar effect is noted in response to hypoxic pulmonary pressor changes. Therefore, it is likely that BNP is the predominant natriuretic peptide modulating the response of the pulmonary vasculature to hypoxia and angiotensin II. BNP may play an important role in attenuating the pressor response that is likely to occur in humans through the actions of alveolar hypoxia and elevated angiotensin II levels. In patients with left-sided heart failure, the human recombinant BNP nesiritide has been shown to suppress endothelin and aldosterone levels, suggesting other mechanisms for the attenuating effect of this peptide on pulmonary vasoconstriction.[68] These findings suggest the possible clinical use of neutral endopeptidase inhibitors that increase circulating levels of endogenous natriuretic peptides by inhibiting their degradation.[69] Such agents might prove useful if added to ACE inhibitors and angiotensin II receptor antagonists in the management of chronic cor pulmonale characterized by alveolar hypoxia and pulmonary hypertension. However, this hypothesis has yet to be tested.

ENDOTHELIN-1

Endothelin-1 (ET-1) is a 21–amino acid peptide secreted by vascular endothelial cells in response to various stimuli, including pulsatile stretch, sheer stress, neurohormones, cytokines, growth factors, and thrombin. The secretion of ET-1 has been shown to be increased by hypoxemia in humans. The effects of ET-1 are mediated by the endothelin A (ET_A) and endothelin B (ET_B) receptors. ET_A is localized on vascular smooth muscle cells and ET_B is expressed on vascular smooth muscle cells, endothelial cells, and fibroblasts. The effects of ET-1 include vasoconstriction, hyperplasia, hypertrophy, fibrosis, and increased vascular permeability. Activation of ET_B receptors on endothelial cells mediates release of prostacyclin (prostaglandin I_2) and NO, which exert vasodilatory and antiproliferative effects while also inhibiting ET-1 production by endothelial cells. Furthermore, the pulmonary endothelial ET_B receptors are responsible for the pulmonary clearance of up to 50% of circulating ET-1.[70]

Increased ET-1 production has been described in patients with pulmonary hypertension. Increased ET-1 levels and increased expression of receptors have been shown to be present in plexiform lesions of the lung in patients with pulmonary hypertension.[70,71] High plasma levels of ET-1 have been observed in patients with pulmonary hypertension, and this elevation correlated with disease severity and adverse prognosis.[71–75] It has been demonstrated that ET-1 concentration is elevated in the sputum and urine of patients with COPD compared to normal subjects; moreover, urinary levels increase further during COPD exacerbations.[76,77] In addition, plasma ET-1 levels have been shown to be increased in subjects who exhibit oxyhemoglobin desaturation with exercise or at night.[78,79] In another study, patients with COPD and pulmonary hypertension were shown to have elevated transpulmonary ET-1 levels.[80] Increased plasma levels and lung tissue expression of ET-1 have also been identified with or without pulmonary hypertension.[71,81] These observations suggest that ET-1 plays an important role in mediating the development or perpetuation of pulmonary hypertension in various disease states, and hence is a rational therapeutic target.

SYMPTOMS AND SIGNS

Mild pulmonary hypertension reflected in small chronic elevations in right ventricular pressure generally causes minimal, if any, clinical, radiologic, or electrocardiographic findings. When moderate or severe pulmonary hypertension develops (mean PPA > 40 mm Hg), symptoms are often those associated with the underlying pulmonary disease. Most commonly, these are dyspnea on exertion, chronic cough productive of mucoid sputum (particularly in the morning hours), variable degrees of wheezing, and noticeable occasional cyanosis; clubbing of the fingers may be present. Moderate or severe pulmonary hypertension by itself (e.g., in patients with idiopathic pulmonary arterial hypertension) may result in only minimal or nonspecific symptoms. In addition to exertional dyspnea and fatigue, some patients experience dizziness or even exertional syncope, attributable to the inability to increase cardiac output during exercise in the face of a marked increase in pulmonary vascular resistance. Furthermore, these patients may have chest pain owing to right ventricular ischemia or stretching of the main pulmonary artery.

When resting PPA is sufficiently elevated, patients may eventually reach a point at which the right ventricle cannot meet the need for increased stroke work without a significant increase in right heart filling pressures. The resultant increase in central venous pressure is associated with developing symptoms of right-sided heart failure, such as peripheral edema, right upper quadrant discomfort nocturia, and easy fatigability. On examination, the patient is often cyanotic and sitting upright with tachypnea, prominent use of the accessory muscles of respiration, and arms extended holding on to the edges of the mattress. In COPD, pulsus paradoxus may be present. The chest may be hyperinflated. There may also be audible wheezing, particularly if the process of decompensation has been relatively acute and associated with a superimposed respiratory infection. Sinus tachycardia is often present; however, atrial and ventricular arrhythmias are also common.[82] Evidence of fluid reten-

tion may include dependent edema and some degree of ascites. The liver is enlarged and tender to palpation, and may be pulsatile, reflecting the presence of severe tricuspid insufficiency. Similarly, the neck veins are distended and, when tricuspid insufficiency is present, show a large *c-v* wave with rapid *y* descent; in addition, there may be a prominent *a* wave reflecting the increased force of right atrial contraction.

On examination of the chest, there may be a left parasternal systolic lift, owing to the overactivity of the enlarged right ventricle, and a thud felt over the pulmonary area as the pulmonary valve closes. The heart sounds are often difficult to hear if the patient has underlying COPD. The pulmonic component of the second heart sound (S_2) is accentuated and occurs earlier than usual, so the normal splitting may be abolished and a single loud S_2 heard. Normally not heard at the apex, the pulmonic component of S_2 may now be clearly heard. A high-pitched systolic ejection click may be heard in the second and third left intercostal spaces next to the sternum. It is often followed by a soft, localized systolic ejection murmur produced by ejection of the stroke volume into a dilated pulmonary artery. An S_3 gallop arising from the right side of the heart may be heard in the fourth and fifth interspaces immediately to the left of the sternum or even next to the xiphoid process. A presystolic S_4 gallop may also be heard, reflecting the increased forcible contraction of the right atrium with expulsion of blood into the hypertrophied and dilated right ventricle. Often tricuspid regurgitation is present, and this results in a prominent blowing pansystolic murmur in the same location, which may increase somewhat with inspiration. When prominent pulmonary hypertension is present, a diastolic murmur of pulmonary incompetence may be heard; this murmur, known as Graham Steell's murmur, is a soft, blowing decrescendo diastolic murmur, usually well localized to the second and third left intercostal spaces next to the sternum.

Acute respiratory failure is characterized by hypoxemia and hypercapnia, or by their worsening if they are chronically present when the patient is stable, and often requires hospitalization. Dyspnea becomes intense, and the patient is usually bedridden and visibly tachypneic. Coughing is likely to be exacerbated and sputum production increased. Congestive heart failure, if not present earlier, is now clearly evident in most cases. If it was chronically present before the exacerbation of respiratory failure, it will markedly worsen. The patient may exhibit confusion, insomnia, lethargy, and marked fatigue. Fever may be present if the episode has been precipitated or aggravated by an infectious process such as community-acquired pneumonia.

Chest Radiograph

The appearance of the chest radiograph depends in large part on the underlying cause for the presence of pulmonary hypertension. Generally, however, the main pulmonary artery segment is enlarged, together with large right and left descending pulmonary arteries. In contrast, there is abrupt tapering of the peripheral vessels, resulting in disproportionately large central pulmonary arteries and attenuated distal vessels. A right descending pulmonary artery with a diameter greater than 16 mm suggests pulmonary hypertension.[83] Enlargement of the right ventricle, which may be observed on echocardiography, is often not appreciated on the chest radiograph. If hyperinflation of the lungs is present, the overall diameter of the cardiac silhouette may not be increased, although the heart may have a globular appearance. Often some encroachment on or filling in of the retrosternal space by an enlarged right ventricle may be seen in a lateral view.

Pleural effusions (see Chapter 73) are seldom seen in patients presenting with pure cor pulmonale unless coexisting left ventricular dysfunction and failure are also present. The reason is evident in the mechanisms that govern fluid formation and clearance across the pleural membranes, which were largely set forth by Staub and coworkers[84] and are illustrated in Figure 73-4. The small amount of fluid that is normally present is filtered across the parietal pleura; removal of fluid occurs through lymphatic stomas that are also located in the parietal pleura. The visceral pleura plays little or no role in pleural fluid turnover in the normal lungs, but does serve as an important escape route for excess interstitial fluid that accumulates in the lungs during the evolution of cardiogenic pulmonary edema (see Chapter 55).

Given this analysis of the dynamics of pleural fluid exchange, pleural effusions might be expected in patients with chronic cor pulmonale and elevated right heart filling pressures, because they have increased systemic venous pressures, which must raise capillary pressures within the parietal pleura. Increased fluid transudation into the parietal pleural interstitium and then into the pleural space would be expected. Failure to find pleural effusions under these circumstances undoubtedly reflects the capacity of the parietal lymphatics to markedly increase their fluid removal capacity, by almost 20-fold. These mechanisms would appear to be substantiated by the findings of a prospective study of 37 patients admitted for congestive heart failure in whom the presence of pleural effusions correlated with the values of pulmonary artery wedge pressure but not with the right atrial pressure.[85] In a subsequent retrospective study of 18 patients with long-term right atrial or pulmonary hypertension or both, but with normal pulmonary artery wedge pressures, no pleural effusions were seen.[86] However, patients have been observed with chronic cor pulmonale and acute exacerbation of cardiac decompensation resulting from a superimposed respiratory infection who demonstrate transient small pleural effusions during the acute episode. It is of interest that cattle with brisket disease accumulate transudates in the thoracic cavity as well as in the abdominal cavity and pericardial sac.[87]

Electrocardiogram

The electrocardiogram can be quite helpful in establishing the presence of chronic cor pulmonale.[88] Characteristically, the P wave has a "p pulmonale" pattern with

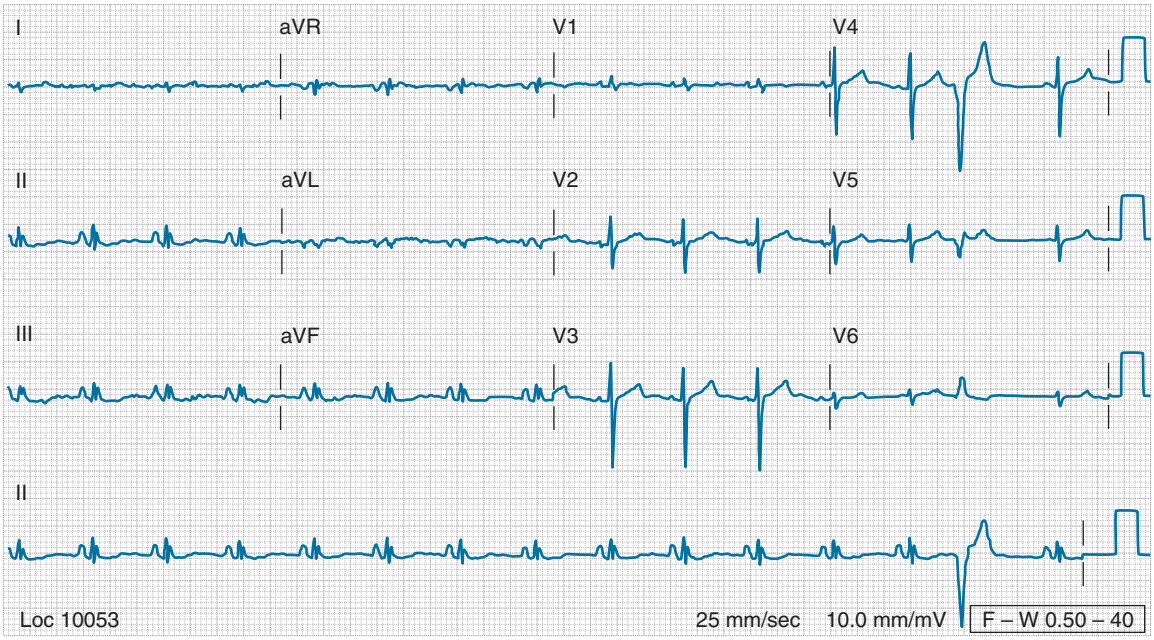

FIGURE 56-9 ■ An electrocardiogram in a patient with chronic cor pulmonale reveals prominent "p pulmonale" and other characteristic features (see text).

right-axis deviation resulting in an increase in its amplitude in leads II, III, and aVF to more than 2.5 mm (Fig. 56-9). The P wave may also be tall in the right precordial leads. The QRS vector in the frontal plane often shifts to the right in cor pulmonale, and a low-voltage QRS complex is common if lung hyperinflation is present. Prominent S waves are seen in leads I, II, and III, probably reflecting hypertrophy of the crista supraventricularis; an incomplete right bundle-branch block pattern is also frequently observed. When pulmonary arterial hypertension is moderate or severe, the more classic findings of right ventricular hypertrophy may dominate the electrocardiogram, which exhibits tall R waves in V_1 with an R/S ratio of more than 1, and a prominent S wave in V_5 and V_6 with an R/S ratio of less than 1. The presence of electrocardiographic evidence of cor pulmonale in patients with COPD is a poor prognostic sign.[89]

Echocardiography

Echocardiography is the most widely used and accepted screening tool for the presence of pulmonary hypertension and the evaluation of right ventricular structure and function. An echocardiographic examination can assist the clinician in eliminating various nonpulmonary causes of secondary pulmonary hypertension, such as left ventricular failure from coronary disease or dilated congestive cardiomyopathy, aortic or mitral valve disease, and congenital heart disease with left-to-right shunt. An estimation of the pulmonary artery systolic pressure can be determined in 36% to 86% of patients with pulmonary hypertension by taking advantage of the presence of tricuspid regurgitation and using continuous-wave Doppler to obtain the tricuspid regurgitant jet velocity.[90] The pressure gradient across the tricuspid valve between the right atrium and ventricle is calculated using the modified Bernoulli equation ($4v^2$), where v is the tricuspid regurgitant jet velocity, and this figure is then added to the right atrial pressure (estimated by the size and collapsibility of the inferior vena cava) to obtain an estimate of the right ventricular systolic pressure, which is equal to the pulmonary artery systolic pressure in the absence of pulmonary valve stenosis.

Additionally, there is usually pulmonary valve insufficiency detectable by Doppler echocardiography in the presence of pulmonary hypertension, which permits an estimation of pulmonary artery diastolic pressure. The size of the right atrium and the right ventricle can be determined and the contractile state of the right ventricle assessed. Flattening or leftward shift of the interventricular septum during systole suggests right ventricular pressure overload, whereas interventricular septal flattening during diastole is indicative of right ventricular volume overload. If right heart filling pressure (equal to right atrial pressure) is increased, it is usually associated with dilation of the inferior vena cava, which fails to collapse with respiratory maneuvers such as sniffing. The pulmonary velocity time integral can be used as a surrogate measure to estimate stroke volume and it can be monitored longitudinally in conjunction with the estimated pulmonary artery systolic pressure to assess response to therapy. Supine cycle ergometry with Doppler echocardiography can assess changes in PPA and provide insight into exertional symptoms.

Figure 56-10 illustrates a Doppler echocardiographic examination in a patient with COPD who presented with severe respiratory distress. The possibility of coexisting coronary disease, which arises frequently in the older male patient, led to the question of whether the patient was in respiratory distress from pulmonary congestion secondary to left ventricular failure or whether the problem reflected pulmonary hypertension and

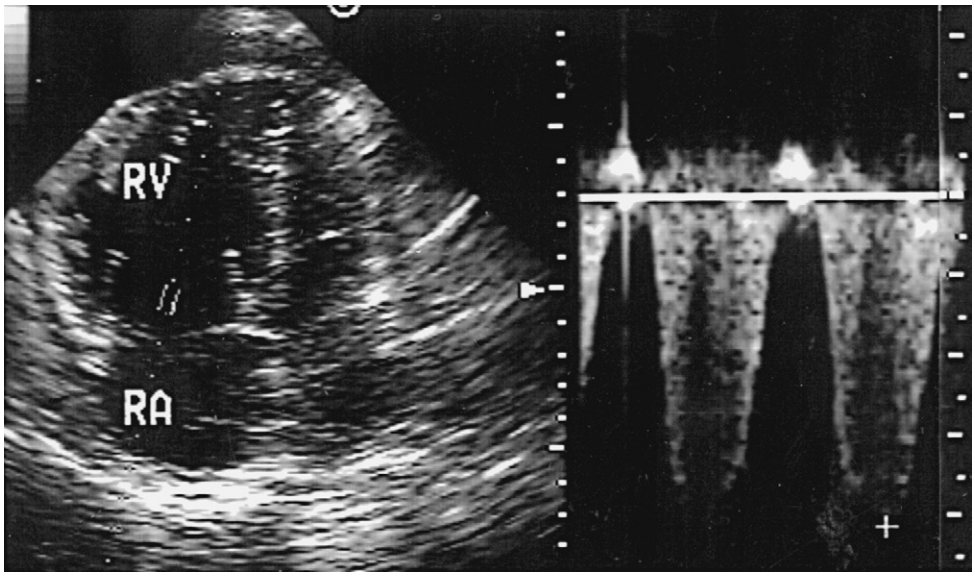

FIGURE 56-10 ■ *Left,* Normal left ventricular volume is seen on this echocardiogram of a patient with chronic obstructive pulmonary disease who presented with acute severe respiratory distress; normal contractility also was observed during recording. The right ventricle (RV) is markedly dilated (see text). *Right,* Estimation of the degree of pulmonary hypertension using continuous-wave Doppler measurement of the velocity jet from the tricuspid insufficiency that was present. A 55 mm Hg peak systolic pressure gradient between the RV and right atrium (RA) was calculated, indicating moderate to severe pulmonary arterial hypertension.

ventilatory insufficiency arising from decompensated pulmonary heart disease. The figure clearly illustrates that the left ventricle is small, and it was seen to have normal contractility during analog recording. In contrast, the right ventricle was severely dilated and was observed to have a significantly decreased right ventricular systolic contractile function. Right atrial enlargement was present as well. Although tricuspid insufficiency was not a major clinical problem in this particular patient, there was sufficient tricuspid insufficiency to permit Doppler estimation of the degree of pulmonary hypertension, which is often the case when pulmonary hypertension is present. The right section of Figure 56-10 illustrates a continuous-wave Doppler jet demonstrating that a peak systolic gradient of at least 55 mm Hg was present between the right ventricle and right atrium, indicating moderate to severe pulmonary hypertension.

Athough right ventricular ejection fraction was the most commonly used index of right ventricular function in the past, it is highly dependent on loading conditions and may not accurately reflect contractility. Moreover, echocardiography is less accurate than magentic resonance imaging (MRI)– and radionuclide angiography–derived right ventricular ejection fraction methods. In a study of 32 patients with advanced lung disease, Schenk and colleagues[91] found that, among various echocardiographic parameters, right ventricular end-diastolic area and fractional area change from the apical four-chamber view correlated best with MRI-derived right ventricular volume and ejection fraction, respectively. Newer Doppler-derived indices of right ventricular function, the tricuspid annular plane excursion (TAPSE)[91a] and right ventricular myocardial performance index (RVMPI),[91b] have both been shown to have prognostic value in patients with idiopathic pulmonary arterial hypertension and they are being studied in other classes of pulmonary hypertension. Three-dimensional echocardiography is a promising technique that could lead to a more accurate assessment of right ventricular volume and ejection fraction; however, difficulties in delineation of the anterior wall and infundibular plane still need to be overcome.

The presence of hyperinflation of the lungs impairs the transmission of ultrasound and can result in suboptimal transthoracic echocardiographic imaging. The sensitivity and specificity of Doppler echocardiography to predict the presence of pulmonary hypertension range from 0.79 to 1.0 and from 0.6 to 0.98, respectively,[90] and the actual echo-Doppler–derived estimate of pulomary artery systolic pressure may be imprecise compared with right heart catheterization.[92,93] If sufficient lung hyperinflation prevents adequate transthoracic examination, one may resort to transesophageal echocardiography (TEE) to clarify the problem. Often patients in this situation are intubated, and a transesophageal study probe can be slipped into the esophagus with relative ease. A much better delineation of cardiac function and any cardiac pathology can be obtained with TEE than is possible with a transthoracic probe. It is important to note that the estimation of pulmonary artery systolic pressure via echo-Doppler alone cannot fully address pulmonary hypertension, and in doubtful cases or when therapies directed at the pulmonary vasculature are being contemplated, a diagnostic right heart catheterization must be considered.

Computed Tomography

Chest CT is often used to visualize the pulmonary parenchyma in patients with respiratory disease. With this imaging modality, the size of the pulmonary artery can

be measured, and in patients with moderate to severe pulmonary hypertension, enlargement of the main pulmonary artery or an increased diameter of the pulmonary artery (>29 mm) may be documented. However, in a study of 65 patients with advanced idiopathic pulmonary fibrosis, main pulmonary artery diameter on high-resolution chest CT failed to differentiate between those who did or did not have pulmonary hypertension diagnosed with right heart catheterization.[94] Therefore, CT does not appear to be a reliable modality to screen for pulmonary hypertension. However, dilated right heart chambers on contrast-enhanced CT imaging would be suggestive but not diagnostic of cor pulmonale in patients with severe parenchymal lung changes.

Magnetic Resonance Imaging

MRI is the most accurate method for assessing right ventricular volume and ejection fraction. Compared with the normal left ventricular volume, the right ventricular volume is larger (66 ± 12 mL/m^2, range 44 to 89 mL/m^2 vs. 75 ± 13 mL/m^2, range 49 to 101 mL/m^2, respectively) and the ejection fraction is lower (67 ± 5%, range 57% to 78% vs. 61 ± 7%, range 47% to 76%, respectively).[95] Phase-contrast MRI has the capability to accurately calculate flow characteristics, including cardiac output, valvular regurgitant fraction, and shunt fraction. Because of its ability to penetrate diseased lungs and its high temporal resolution, the image quality of MRI to assess cardiac structures is superior to that of echocardiography, especially in patients with advanced lung disease. Although high cost, relatively long image acquisition time, and lack of widespread availability limit its use compared with echocardiography, cardiac MRI is increasingly being used as a standard tool for the evaluation of right ventricular structure and function in patients with pulmonary arterial hypertension. Its application in patients with respiratory diseases and cor pulmonale has yet to be evaluated.

Hemodynamics

Hemodynamic measurements in patients with decompensated pulmonary heart disease secondary to COPD are subject to error. Use of the direct Fick method to estimate cardiac output at the time of cardiac catheterization is complicated when hypoxemia is present. Hypoxemia may be caused both by shunting across the lungs, from perfusion of unventilated or poorly ventilated alveoli, and by a decrease in oxygen diffusion reflecting alveolar-capillary block from associated fibrosis, parenchymal infiltrative disease, inflammation, and/or edema. Consequently, true pulmonary blood flow, in terms of pulmonary capillary blood flow, is only approximated when systemic arterial oxygen content difference is used to calculate the arteriovenous oxygen content across the lungs. Further problems are provided by the fact that there may be difficulty in estimating oxygen consumption if the patient is receiving therapeutic oxygen.

Measurements of pulmonary blood flow by the use of indicator dilution curves such as thermodilution may also be spurious in patients with pulmonary shunting of blood and in those with very low cardiac outputs. In fact, the clinician should measure the oxygen saturation of pulmonary artery blood from the indwelling pulmonary artery catheter and verify that it is substantially lower than normal before accepting a thermodilution readout that cardiac output is markedly depressed. However, within these limitations, it would appear that cardiac output in patients with decompensated pulmonary heart disease from hypoxic pulmonary vasoconstriction is generally in the normal range or even increased due to the systemic vasodilation produced by hypoxemia; this finding contrasts with that in idiopathic pulmonary arterial hypertension, chronic obstructive embolic disease, mitral stenosis with pulmonary vascular disease, or decompensated heart failure caused by primary myocardial disease, in which low-output states are usually present. Hemodynamic studies in COPD patients with and without heart failure consistently show a normal cardiac output.[96,97] Measurements performed by Anand and associates[50] in nine patients with peripheral edema due to COPD and in six patients after recovery demonstrated that patients with edema had severe salt and water retention, reduction in renal blood flow and glomerular filtration rate, and a neurohormonal activation comparable to that seen in patients with congestive heart failure due to primary myocardial disease; these occurred despite the fact that mean cardiac output was normal, as was mean pulmonary artery wedge pressure. Therefore, after treatment that resulted in an increase in arterial P_{O_2} and a fall in P_{CO_2}, the patients became free from edema, with a corresponding increase in renal blood plasma flow and normalization of glomerular filtration rate.

In patients with pulmonary arterial hypertension as classified in Table 56-1, right heart catheterization is required to assess the hemodynamic severity and hence prognosis of pulmonary hypertension, to establish the pre- versus postcapillary etiology, to perform an oxygen saturation assessment across the right heart structures, to search for the presence of a congenital systemic-to-pulmonary shunt, to measure pulmonary vascular resistance, and to perform acute vasoreactivity testing to guide therapy as well as to monitor safety of treatment with calcium channel blockers.[2] It is not known if acute vasodilator therapy testing is of any utility in patients with pulmonary hypertension and cor pulmonale associated with diseases of the respiratory system or hypoxemia.

DIFFERENTIAL DIAGNOSIS

There are many causes of pulmonary artery hypertension, as noted in Table 56-1. At times, the underlying cause may be difficult to establish. Specific symptoms and signs of the basic disorder often help to establish the cause of pulmonary hypertension. For example, mitral stenosis noted on physical examination or by echocardiographic examination may represent the underlying cause of pulmonary hypertension. Early in the natural history of mitral stenosis, only passive pulmonary hypertension occurs; however, after prolonged elevation of left atrial and pulmonary vein pressure, P_{PA} rises out of proportion to the raised left atrial pressure from reflex

pulmonary vasoconstriction. Radiographic evidence of increased interstitial markings reflecting increased lung vascular volume from high pulmonary blood flow suggests the presence of congenital heart disease with a congenital systemic-to-pulmonary shunt. The diagnosis of idiopathic pulmonary arterial hypertension can be made only after other causes of increased obstruction to pulmonary blood flow have been eliminated. Obstructive pulmonary vascular disease caused by appetite suppressants or other toxic substances; pulmonary hypertension associated with occasional cases of portal hypertension; silent deep venous thrombotic disease that has resulted in multiple, relatively silent pulmonary emboli with subsequent pulmonary hypertension; and pulmonary vasculitis from systemic lupus erythematosus, scleroderma, or other collagen vascular diseases are but a few examples in which the underlying cause must be sought, beginning with a careful medical history and physical examination, to explain the basis of the pulmonary hypertension.

The diagnosis of chronic cor pulmonale due to obstructive or restrictive ventilatory insufficiency is usually rapidly established because these patients either have evidence of pulmonary parenchymal disease (e.g., radiographic evidence of pulmonary infiltrative or fibrotic disease, lung hyperinflation, radiologic findings suggesting bronchiectasis), present with symptoms or physical findings that suggest underlying pulmonary disease (e.g., bronchial wheezing, history of chronic bronchitis with a chronic productive cough), or have abnormalities of pulmonary function testing. Other patients present with evidence of chest wall deformities that may interfere with respiration (e.g., kyphoscoliosis). Morbid obesity may suggest the presence of the pickwickian syndrome or primary alveolar hypoventilation. Pulmonary edema on chest radiography, with dilation of the left side of the heart, indicates that COPD is not the cause, and suggests the presence of comorbid conditions affecting the left ventricle. Pulmonary edema may also occur without overt left ventricular failure in patients with acute respiratory distress syndrome (see Chapter 55).

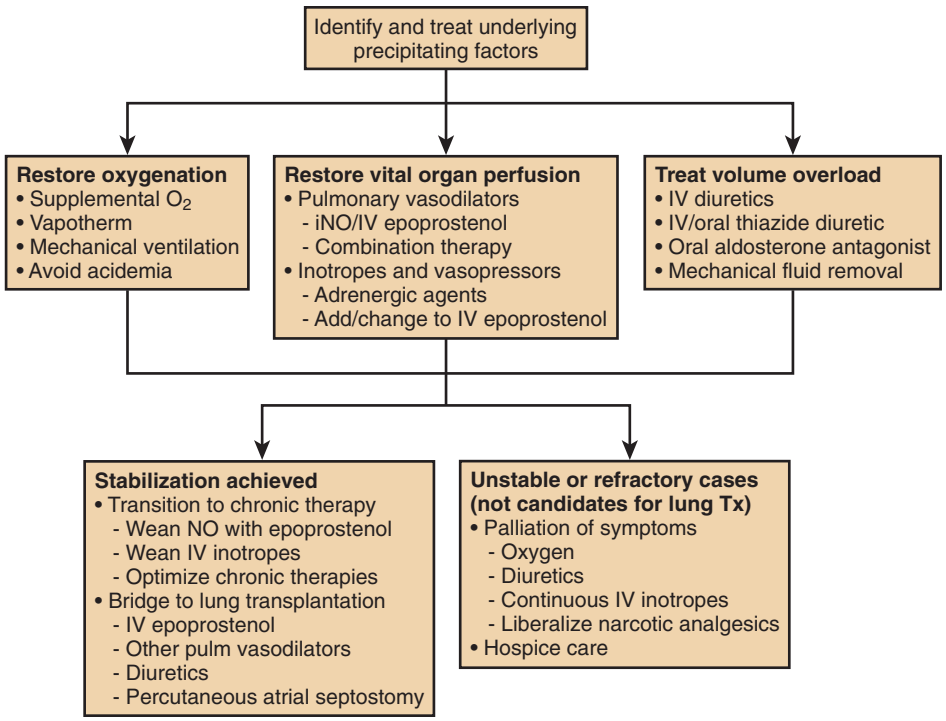
TREATMENT

The goals of treatment for cor pulmonale are similar to those for treating left-sided heart failure and include relief of symptoms, improvement of functional capacity, slowing of disease progression, and reducing morbidity and mortality. These goals can be attained, in part, by addressing the major operative pathophysiologic mechanisms: hypoxemia, acidemia, pulmonary hypertension, and neurohormonal activation.[44] Useful guidelines for the diagnosis and treatment of pulmonary hypertension have recently been published.[97a] Hemodynamic goals are very important in right-sided heart failure associated with pulmonary hypertension: (1) reduce right ventricular internal and external afterload (right ventricular wall stress and pulmonary vascular resistance, respectively) utilizing oxygen therapy and pulmonary vasomodulating agents; (2) decrease right ventricular preload, effecting a reduction in right ventricular wall stress and improving left ventricular filling (diuretics); and (3) augment right ventricular contractility. The therapeutic strategies for cor pulmonale are delineated in Table 56-2, and Figure 56-11 proposes an algorithmic approach to the management of acute decompensated right ventricular failure.[98,99] Certainly, treatment must be directed to the specific underlying pulmonary disorder leading to cor pulmonale (see Table 56-2). In the management of chronic cor pulmonale, diet and lifestyle modifications are important. These include smoking cessation, sodium restriction, weight loss, and exercise training to improve functional performance. Structured rehabilitation programs and breathing training have been shown to be useful.[44,100] Patients with severe pulmonary arterial hypertension, especially those with a history of syncope, should avoid overexertion. In addition, pregnancy and high altitudes (>4000 feet) should also be avoided in this setting. Oral anticoagulation is considered the standard of care in patients with moderate to severe pulmonary arterial hypertension. One retrospective and one prospective trial have suggested a mortality benefit.[101,102] In the

TABLE 56-2. Therapeutic Strategies for Cor Pulmonale

DIET AND LIFESTYLE
Smoking cessation
Weight loss
Sodium restriction
Judicious exercise training
Structured rehabilitation and breathing training programs
Avoidance of overexertion
Avoidance of pregnancy
Avoidance of high altitudes
INTERVENTIONS
Treatment of underlying condition
COPD (bronchodilators, corticosteroids, antibiotics, oxygen)
Interstitial lung disease (immunosuppression, oxygen, interferon gamma [investigational])
Sleep-disordered breathing and alveolar hypoventilation disorders (CPAP, BiPAP, surgery)
Chronic exposure to high altitudes (return to sea level)
Chronic thromboembolic disease (anticoagulation, inferior vena cava filters, thromboendarterectomy)
Supplemental oxygen
Pulmonary vasodilators
Anticoagulation
Diuretics
Digitalis glycosides (chronic therapy)
Nonglycoside inotropes (low-dose dobutamine or dopamine in acute severe right heart decompensation with hypoperfusion)
Lung volume-reduction surgery
Lung transplantation
Heart-lung transplantation (PAH secondary to complex congenital heart disease)
Percutaneous blade-balloon atrial septostomy (investigational)
Severe right-sided heart failure
Recurrent syncope

BiPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; PAH, pulmonary arterial hypertension.



IV = intravenous; NO = nitric oxide; Tx = transplantation.

FIGURE 56-11 ■ Management of acute decompensated right ventricular failure in pulmonary arterial hypertension.

management of chronic cor pulmonale with excessive right ventricular preload, diuretic therapy is the mainstay of therapy to alleviate dyspnea, hepatic congestion, and peripheral edema. Decompression of the right ventricle with diuretics may also improve right ventricular performance by reducing its preload and wall stress. With resultant reductions in intrapericardial pressure and potential attenuation of interventricular septal shift toward the left ventricle, left ventricular filling may increase, resulting in improved systemic cardiac output.

Management of patients with decompensated pulmonary heart disease must focus on improvement of the underlying pulmonary disorder if compensation is to be restored. The precipitating event for decompensation in patients with stabilized chronic cor pulmonale from either COPD or infiltrative lung disease is often an associated upper respiratory infection. Increased secretions and infection are likely to tip the balance toward further alveolar hypoxemia, hypercapnia, and acidemia, which aggravate pulmonary hypertension and worsen ventricular contractility, resulting in cardiac decompensation.

Improvement in right ventricular performance is best accomplished not only by correcting acidemia, but also by reducing the afterload facing the right ventricle (i.e., reducing P_{PA}). Correction of arterial hypoxemia through the administration of an increased concentration of oxygen in inspired air lowers P_{PA} in patients with hypoxic pulmonary vasoconstriction. Improvement in alveolar ventilation with intubation and mechanical ventilation helps eliminate the acute hypercapnia and acidemia that depress myocardial contractility. Therapy with digoxin is controversial, and its effects on right ventricular function are unclear; it produces a modest increase in cardiac output in patients with pulmonary hypertension and right ventricular failure,[102] thereby increasing pulmonary blood flow and reducing right-sided heart filling pressure. However, it does not lower P_{PA}.[103] Short-term treatment with digoxin in patients with right ventricular dysfunction from pulmonary hypertension is associated with a significant reduction in circulating levels of catecholamines, and this may be a mechanism for its reported favorable hemodynamic effects in some studies.[102] It is unknown at this time if digoxin exerts beneficial effects on progression of right ventricular failure, morbidity, or survival, and therefore its use remains controversial. It must be emphasized that patients with COPD are particularly sensitive to digoxin, and close attention to dosage and electrolyte balance to prevent digitalis toxicity is necessary.

Often, an episode of acute cardiac decompensation in a patient who has chronic pulmonary hypertension due to COPD is caused by an underlying pneumonitis or superimposed bronchitis. Patchy areas of atelectasis may also play a role. Empirical antimicrobials (see Chapter 39) should be administered until cultures identify the causative organism and allow more specific treatment to be used. β_2-Agonists such as albuterol are widely accepted as standard management. Not only are they bronchodilators, but they acutely produce a fall in pulmonary artery pressure and a rise in right ventricular ejection fraction with no significant fall in arterial P_{O_2}.[44,104] Anticholinergic drugs such as ipratropium bromide are also useful bronchodilators. Theophylline seems to lessen dyspnea and may be helpful in improving ventilation, but it has

considerable toxicity and is now seldom used. Finally, short-term corticosteroids appear useful in accelerating recovery from exacerbations of acute respiratory failure in patients with COPD and should be given as early as possible.

Sleep disorders are common in patients with COPD and can contribute to nocturnal hypoxemia and hypercapnia, leading to increased pulmonary vasoconstriction. As described in Chapter 79, continuous positive airway pressure can exert beneficial effects by keeping both upper and lower airways open and improving gas exchange. In patients with obstructive sleep apnea, continuous positive airway pressure is associated with improved ventricular function and survival and reduced hematocrit.[105-107]

If severe polycythemia is present, phlebotomy may be helpful, although clinicians are frequently reluctant to undertake this type of therapy today. In cattle with brisket disease, cardiac output and coronary blood flow increased without a rise in PPA when phlebotomy was performed.[108] Hypoxic patients also show improvement in right ventricular ejection fraction, exercise tolerance, and neuropsychological function after phlebotomy.[44]

The role of ACE inhibitors,[109] angiotensin II receptor blockers, or aldosterone receptor blockers in chronic cor pulmonale has not been independently studied in large randomized, double-blind, clinical trials, and their potential long-term benefits are unknown.

Oxygen

Young adults living at high altitudes have distinctly raised PPA values that fall to normal if they leave to live at sea level for several years. Such observations, combined with the clinical, pathologic, and physiologic data observed in patients with COPD, emphasize the importance of hypoxia in the genesis of pulmonary hypertension. They also suggest that continuous domiciliary oxygen therapy might reduce pulmonary arterial hypertension in patients with COPD and thereby improve outcome. Controlled trials evaluating long-term oxygen administration showed improvement in survival, although they failed to demonstrate a clear and consistent reduction in pulmonary hypertension.

Two major randomized trials have been carried out. In the British Medical Research Council evaluation of long-term domiciliary oxygen in chronic hypoxic cor pulmonale, long-term oxygen administration for at least 15 hr/day appeared to prevent further rises in PPA, compared with no oxygen administration in control patients[110]; it also lessened mortality. In a National Institutes of Health study in the United States, 12 hours of nocturnal oxygen therapy was compared with continuous therapy; continuous oxygen proved distinctly more favorable, with a lessened mortality rate at 2 years.[111] Additionally, a decrease was seen in pulmonary vascular resistance, contrasted to a small rise in the group receiving only nocturnal therapy. Furthermore, oxygen therapy has been shown to relieve renal vasoconstriction and improve oxygen delivery to critical organs such as the heart and brain.[112]

Based on the results of these studies, it is clear that severely hypoxemic patients with COPD should be provided home oxygen therapy, with a goal of continuous therapy but with at least 15 hr/day of oxygen. However, it must be remembered that the acute administration of *high* concentrations of oxygen to a patient with hypoxic cor pulmonale can have adverse effects on breathing and carbon dioxide removal, particularly if the patient is already displaying alveolar hypoventilation as evidenced by hypercapnia. This is important to keep in mind when evaluating a patient's pulmonary artery hypertensive response to oxygen administration in the catheterization laboratory, and when determining the dose for use at home. Patients given domiciliary oxygen need to be observed closely when they are initially being instructed on the use of this therapy to ensure that arterial oxygen saturation actually rises: flow rates of 1 to 3 L/min generally suffice. Further information about the long-term use of oxygen in pulmonary rehabilitation is provided in Chapter 94.

Vasodilators

The recommendations for the treatment of pulmonary arterial hypertension with pulmonary vasodilators are based on studies of patients with idiopathic pulmonary arterial hypertension or pulmonary arterial hypertension associated with connective tissue diseases, most commonly the scleroderma spectrum of disorders. To date, no large-scale studies or guidelines have been developed with respect to vasodilator therapy for patients with pulmonary hypertension secondary to lung diseases with or without hypoxemia. Management algorithms for patients with pulmonary arterial hypertension include right heart catheterization for diagnostic as well as therapeutic indications. Protocols for vasoreactivity testing with short-acting acute vasodilators may include testing high-flow oxygen, inhaled NO up to 20 ppm, parenteral epoprostenol, or parenteral adenosine. A reduction in the pulmonary vascular resistance by more than 20% from baseline identifies a group of "responders," which comprises less than 15% of the pulmonary arterial hypertension population, but which includes those who may respond to a hemodynamically monitored trial of calcium channel blockers, such as nifedipine, diltiazem, or amlodipine. Verapamil should be avoided as it can exert substantial negative inotropic effects and worsen right ventricular function. In the treatment of idiopathic pulmonary arterial hypertension, high-dose calcium channel blockers have been shown to improve New York Heart Association (NYHA) functional classification and to induce echocardiographically demonstrated regression of right ventricular hypertrophy. Patients who responded to calcium channel blockade had a reported 5-year survival of 94% compared to 30% in the nonresponders.[101]

It has been far less common to evaluate and subsequently use pulmonary vasodilators as chronic therapy in patients with cor pulmonale due to COPD or diffuse parenchymal disease. Attempts to date have not significantly affected long-term function or survival. One

reason is that initial acute pulmonary vasodilating responses to an agent may not persist when the agent is used chronically. For example, in a study of 53 patients with COPD and pulmonary hypertension, the decrease in pulmonary vascular resistance after initial use of the calcium antagonist nifedipine was 23% at rest and 35% during exercise. However, after an average of 13 months of treatment, the decrease in pulmonary vascular resistance was no longer significant.[113] Side effects from calcium channel blockers include worsening hypoxemia secondary to increased ventilation-perfusion mismatch and right-to-left shunting through a patent foramen ovale in the setting of greater reduction in systemic vascular resistance relative to pulmonary vascular resistance. Peripheral edema is also a frequent consequence of calcium channel blockade and may limit its long-term tolerance. Those patients who fail to respond to acute vasodilator testing or who have severe right ventricular failure, adverse effects with calcium channel blockers, or hypotension should be considered for treatment with oral bosentan (Tracleer), a dual endothelin receptor antagonist; subcutaneously infused treprostinil (Remodulin); or intravenously infused epoprostenol (Flolan).

Of major concern in patients with pulmonary hypertension due to lung diseases is that the pharmacologic reversal of hypoxic pulmonary vasoconstriction with vasodilators may increase pulmonary blood flow to poorly ventilated or nonventilated alveoli, with the net effect that arterial P_{O_2} may fall despite a drop in PPA. What is frequently unappreciated is that ventilation-perfusion matching also affects carbon dioxide elimination. Minute ventilation may increase to compensate for the retention of carbon dioxide; therefore, although arterial P_{O_2} may fall, hypercapnia may not worsen.[114] In patients with advanced COPD, one small study reported a decrease[115] and another no change[116] in P_{O_2} after inhaled NO. In patients with respiratory failure from COPD, P_{O_2} did decrease with epoprostenol treatment.[117] However, in stable COPD patients treated with amlodipine and felodipine, there was no significant fall in P_{O_2}.[118,119] Another practical problem limiting the use of pulmonary vasodilators is that often they also are systemic vasodilators and may result in significant hypotension. Physicians should be on the lookout for the occasional patient with pulmonary hypertension from recurrent pulmonary embolism, because of the considerable benefit from thromboendarterectomy.[120]

Endothelin Receptor Antagonists

Bosentan (Tracleer) is an orally administered competitive receptor antagonist that blocks both the ET_A and ET_B receptors. It was approved for the treatment of pulmonary arterial hypertension to improve exercise tolerance and functional capacity, and delay the time to clinical worsening in patients with WHO functional class III or IV symptoms. In a 12-week randomized, prospective, double-blind, placebo-controlled trial of 32 subjects with either primary pulmonary hypertension or pulmonary arterial hypertension associated with connective tissue disease, patients treated with bosentan (125 mg twice daily) improved their performance on the 6-minute walk test by a placebo-corrected treatment effect of 76 m ($P = 0.02$) and showed improvement in cardiopulmonary hemodynamics.[121] A similarly designed 16-week trial, the BREATHE-1 study, was carried out on 213 subjects with WHO classification III or IV symptoms. At 16 weeks the placebo-corrected mean improvement in 6-minute walk distance was 44 m ($P = 0.0002$) for the patients randomized to the bosentan arm. Bosentan therapy was associated with a significant improvement in WHO functional classification ($P = 0.042$) and an insignificant improvement in Borg dyspnea index score ($P = 0.059$). At 16 weeks, bosentan delayed the time to clinical deterioration. Ninety-five percent of patients on bosentan were free of adverse clinical events compared to 75% of the control patients. In a subgroup of 48 subjects who continued in the double-blind extension up to 28 weeks, 89% of those in the bosentan group compared to 63% in the placebo arm were event free ($P = 0.0015$).[122]

Therapy with bosentan has been associated with potential liver injury, teratogenic effects, and modest reductions in hemoglobin concentration. Close monitoring of liver transaminases and hemoglobin is recommended. Pregnancy must be prevented with reliable barrier contraception as hormonal contraceptive therapy is unreliable in the presence of concomitant bosentan treatment. Monthly pregnancy tests are recommended. Side effects from bosentan include nasal congestion, pharyngitis, dyspepsia, and peripheral edema. Although bosentan has been shown to be beneficial in patients with pulmonary arterial hypertension, its role in the treatment of patients with hypertension associated with disorders of the respiratory system has yet to be determined in large-scale trials. Studies are underway to investigate its utility in pulmonary arterial hypertension due both to COPD and to ILD.

The selective ET_A receptor antagonist ambrisentan was approved by the Food and Drug Administration for the treatment of WHO functional class II and III pulmonary arterial hypertension based on the results of the ARIES-1 and ARIES-2 studies.[123] Studies 1 and 2 were concurrent, double-blind, placebo-controlled trials carried out in the United States and Europe that randomized 202 and 192 patients with pulmonary hypertension to placebo or ambrisentan, 5 or 10 mg and 2.5 or 5 mg, respectively, once daily for 12 weeks. The primary end point, 6-minute walk distance, increased in all ambrisentan groups. In ARIES-1, the mean placebo-corrected treatment effects in 6-minute walk distance were 31 m ($p = 0.008$) and 51 m ($p = 0.001$) for the 5- and 10-mg ambrisentan doses, respectively. In ARIES-2, the mean placebo-corrected treatment effects were 32 m ($p = 0.022$) and 59 m ($p < 0.001$) for the 2.5- and 5-mg ambrisentan doses, respectively. In ARIES-2, improvements in time to clinical worsening and quality of life (Short Form-36 score) were observed. In the ARIES-1 trial, improvements in WHO functional class were shown. Improvements in Borg dyspnea score and BNP were observed in both studies. Ambrisentan was also well tolerated and associated with a low risk of aminotransferase abnormalities. No patient treated with

ambrisentan developed aminotransferase elevation greater than three times the upper limit of normal. Ambrisentan has not been studied in pulmonary hypertension associated with pulmonary diseases.

Prostacyclin and Its Analogues

Prostaglandins are synthesized by the pulmonary vascular endothelium. Neonatal calves that develop severe pulmonary hypertension when exposed to chronic hypobaric hypoxia have been shown to have a relative deficit in prostaglandin production in their pulmonary arteries; this suggests that prostaglandins may play a role in the development of pulmonary hypertension by the lack of vasodilatory stimuli.[124] Normal subjects exposed acutely to high-altitude hypoxia release both vasoconstrictive and vasoactive eicosanoids, with vasoconstrictors being released initially and vasodilators being released several days later.[125] Furthermore, the medium to small pulmonary arteries of patients with idiopathic pulmonary arterial hypertension exhibit reduced expression of prostacyclin synthase compared with arteries from control subjects.[126]

Epoprostenol (Flolan) is a systemic and pulmonary vasodilator that also inhibits platelet aggregation, affects vascular remodeling, and opposes the effects of thromboxane A_2.[127] These effects are mediated by enhanced adenyl cyclase activity resulting in increased cyclic adenosine monophosphate in vascular smooth muscle cells and platelets. As a result of its ultrashort half-life and instability, epoprostenol use is limited to continuous intravenous infusion through a permanent indwelling central venous catheter and portable infusion pump. Side effects of the drug include flushing, headache, nausea, vomiting, diarrhea, myalgias, arthralgias, paresthesias, and jaw pain. Other adverse effects of epoprostenol therapy are consequences of the complex delivery system, including pump malfunction, catheter-related infections, and thrombosis. Based on studies in patients with documented pulmonary arterial hypertension, epoprostenol has been approved for the long-term treatment of patients with NYHA functional class III or IV symptoms due to idiopathic pulmonary arterial hypertension, pulmonary arterial hypertension associated with connective tissue disorders, or chronic thromboembolic disease. An early randomized trial in 24 patients with idiopathic pulmonary arterial hypertension revealed that continuous intravenous administration of epoprostenol by portable infusion pump resulted in substantial hemodynamic and symptomatic improvement over 8 weeks.[128] Barst and associates,[129] in a nonblinded study, randomly assigned 81 patients with idiopathic or familial pulmonary arterial hypertension to receive either a continuous intravenous epoprostenol infusion added to conventional therapy or conventional therapy alone. The intravenous dosage, which was given continuously by infusion pump through an implanted catheter, was determined by the dosage tolerated in an earlier, short-term, dose-ranging phase of the study. By the end of 12 weeks, epoprostenol resulted in symptomatic and hemodynamic improvement, and improved survival.

A group of 69 patients with idiopathic pulmonary arterial hypertension were similarly given a continuous intravenous infusion of epoprostenol through an implanted catheter using a portable, battery-operated infusion pump, with an initial maximum dose titrated to symptoms or to a drop in systemic blood pressure greater than 10 mm Hg.[130] Patients were monitored up to 3 years, during which time 13 of the patients died, including 3 among 9 patients who underwent single-lung transplantation. However, 18 of the patients were monitored for 330 to 700 days and demonstrated an echocardiographically determined estimated mean fall in the right ventricular minus right atrial systolic pressure gradient from 84.1 ± 24.1 to 62.7 ± 18.2 mm Hg ($P < 0.01$). McLaughlin and colleagues[131] evaluated 27 patients with idiopathic pulmonary arterial hypertension who were given epoprostenol over a mean of 16.7 ± 5.2 months. By increasing the rate of infusion by an average 2.5 ng/kg/min each month, a 53% decline in pulmonary vascular resistance was achieved at the time of restudy.

Another study enrolled 111 subjects with pulmonary arterial hypertension associated with the scleroderma spectrum of connective tissue disorders. The patients were randomized to epoprostenol plus background conventional therapy versus conventional therapy alone for 12 weeks. Epoprostenol patients demonstrated an improvement in placebo-corrected median 6-minute walk distance by 99.5 m ($P < 0.003$) as well as improvements in cardiopulmonary hemodynamics and a reduction in dyspnea.[132]

All of these studies suggest the desirability of using chronic infusions of epoprostenol in patients with severe pulmonary arterial hypertension to improve exercise capacity, functional class, and survival. However, therapy with this agent is limited by its side-effect profile and complex delivery system. Hence, alternatives to epoprostenol are being sought and studies with stable prostacyclin analogues have been pursued. Large studies of epoprostenol in pulmonary arterial hypertension associated with lung diseases have not been undertaken. Because in one small study, patients with respiratory failure secondary to COPD treated with epoprostenol experienced reductions in P_{O_2}, further studies of epoprostenol in this patient population must be performed before deciding on its clinical value.[125]

Treprostinil (Remodulin) is a stable prostacyclin analogue with pharmacodynamic actions similar to epoprostenol but with a longer half-life. It can be administered either via continuous subcutaneous or intravenous infusion with a small pump or by inhalation. This agent was approved for treatment of patients with WHO classification II, III, or IV symptoms due to pulmonary arterial hypertension based on favorable results of a pivotal 12-week prospective, randomized, double-blind, placebo-controlled trial.[133] This study enrolled 470 subjects with idiopathic pulmonary arterial hypertension, pulmonary arterial hypertension associated with connective tissue disease, or congenital systemic-to-pulmonary shunts. Treprostinil improved exercise capacity with a between-treatment-group difference in median 6-minute walk distance of 16 m ($P < 0.006$). Treprostinil improved

dyspnea, quality of life, and cardiopulmonary hemodynamics. Patients who appear to tolerate higher doses of treprostinil and who have more severe disease appear to derive the most benefit from the agent. However, 85% of patients did experience infusion site pain, which required premature discontinuation of the infusion in 8% of the subjects; it is this side effect that may limit increased dosing with the agent and also its long-term usage.[133]

In an open-labeled study in 16 patients with pulmonary hypertension who had not been treated with other specific antihypertensive therapy, intravenous treprostinil was associated with significant improvements in exercise capacity.[134] At 6 weeks of treatment the mean 6-minute walk distance was 378 m ($p = 0.008$), and at 12 weeks of treatment mean 6-minute walk distance was 400 m ($p = 0.001$), compared to the baseline of 319 m. Adverse events were similar to those seen with other prostanoids. Although no head-to-head trial has been performed to date of intravenous treprostinil versus intravenous epoprostenol, this study supports the use of intravenous treprostinil, which is already premixed and more stable with a longer half-life in patients for whom intravenous epoprostenol may not be the best alternative.

Recently, the FDA approved a new form of treprostonil (Tyvaso), a solution for inhalation, based upon the results of the TRIUMPH-1 Trial, which are not yet published, but which showed a 20-meter improvement in the 6-minute walk distance in patients who received inhaled treprostinil compared to those who received inhaled placebo ($p = 0.0005$ at peak effect).

Inhalational iloprost is a stable prostacyclin analogue that has been shown to selectively dilate the pulmonary arterial bed while exerting preferential vasodilation in well-ventilated lung regions. After inhalation, its vasodilatory effects last from 30 to 90 minutes. A prospective, double-blind, placebo-controlled, randomized 12-week trial enrolled 203 patients with NYHA functional class III or IV symptoms due to idiopathic pulmonary arterial hypertension and pulmonary arterial hypertension associated with appetite suppressant use, scleroderma, and inoperable chronic thromboembolic disease.[135] Iloprost-treated patients had improvement in the combined primary end point of 6-minute walk distance and NYHA functional class in the absence of clinical deterioration or death compared to the placebo group ($P = 0.007$); dyspnea was also improved.[135] Inhaled iloprost has been studied as an add-on therapy to stable oral bosentan monotherapy in the STEP Trial, a safety study with secondary efficacy end points.[136] In this randomized trial of 67 patients with pulmonary hypertension, iloprost was well tolerated and safe. In addition, compared to placebo, significantly more patients assigned to the inhaled iloprost arm demonstrated at least a one-class improvement in the NYHA functional classification. Treatment with add-on iloprost was also associated with delayed time to clinical worsening.

The effects of various delivery methods of the prostanoids and other vasodilators were evaluated in eight patients with severe pulmonary hypertension associated with pulmonary fibrosis: intravenous prostacyclin, inhaled NO, aerosolized epoprostenol, and calcium channel blockers were compared in randomized order.[137] Aerosolized epoprostenol resulted in preferential pulmonary vasodilation and significant reduction in mean PPA and pulmonary vascular resistance. There was no change in systemic arterial pressure, arterial oxygen saturation and pulmonary right-to-left-shunt. Inhaled NO also produced selective pulmonary vasodilation and decreased the pulmonary right-to-left shunt. However, intravenous epoprostenol and calcium channel blockers were not pulmonary selective. Both agents resulted in a significant drop in systemic arterial pressure. Furthermore, epoprostenol infusion resulted in a marked increase in right-to-left shunt flow. In a patient with severe dyspnea and decompensated right-sided heart failure, aerosolized iloprost exerted acute effects on hemodynamics and gas exchange similar to inhaled epoprostenol, but the effects lasted longer. Long-term therapy with inhaled iloprost resulted in improved clinical status. Certainly more studies on the role of these agents alone or in combination with existing agents are required in patients with pulmonary hypertension secondary to lung disease.

Oral Phosphodiesterase V Inhibitors

Sildenafil (Viagra) is a selective inhibitor of cyclic GMP–specific phosphodiesterase type V, which is found in abundance in the smooth muscle cells of the pulmonary vascular bed. Attenuated degradation of cyclic GMP by sildenafil increases intracellular levels of this mediator, resulting in smooth muscle cell relaxation and vasodilation. When administered acutely to patients with pulmonary arterial hypertension or pulmonary hypertension in the context of lung fibrosis, sildenafil exerts potent effects on cardiopulmonary hemodynamics with significant reductions in pulmonary vascular resistance without increasing left-sided filling pressures or worsening hypoxemia.[138–142] It has also been shown to potentiate the effect of other agents such as inhaled iloprost and NO.[142–144] Chronic administration in adults and children with pulmonary hypertension appears to improve exercise distance and symptoms.[142–146] Sildenafil is well tolerated, but some subjects have experienced headache, flushing, dyspepsia, myalgias, impaired blue-green color discrimination, dizziness, hypotension, and nasal congestion. Use of sildenafil with concomitant nitrates is contraindicated due to potential life-threatening hypotension.

A large prospective, randomized, double-blind, placebo-controlled trial of 278 subjects with pulmonary arterial hypertension compared the effects of three oral doses of sildenafil (20 mg, 40 mg, and 80 mg three times daily) to placebo on exercise capacity, symptoms, and cardiopulmonary hemodynamics. Six-minute walk distance improved by 50 m for the 80-mg group, 46 m for the 40-mg group, and 45 m for the 20-mg group compared to placebo. When the sildenafil data were pooled, 35% of sildenafil-treated patients had improvement of one functional class compared to 7% of patients in the placebo arm. There was no significant difference in cardiopulmonary hemodynamics. Sildenafil was well toler-

ated. The most common adverse event was headache. A long-term trial with patients on the 80-mg dose is ongoing.[147]

Sildenafil was studied as add-on therapy to stable intravenous epoprostenol in a 16-week multinational, double-blind, placebo-controlled study.[148] Two hundred sixty-seven patients with pulmonary hypertension on stable epoprostenol were randomized to receive sildenafil 20 mg three times daily, titrated up to 80 mg three times daily at 4-week interval as tolerated, or placebo. At the end of the 16-week study period, more than 80% of patients were able to reach the 80-mg three times daily dose. There were seven deaths in the placebo group and none in the sildenafil group. Significantly fewer patients in the sildenafil arm sustained clinical worsening events (death, transplantation, hospitalization, and increase in epoprostenol dose). Furthermore, the placebo-adjusted increase in mean 6-minute walk distance was 26 m ($p < 0.0009$) in favor of the sildenafil-treated group.

The effects of sildenafil have been evaluated in patients with interstitial lung disease in small, open-label studies. Sixteen hospitalized patients with pulmonary fibrosis and precapillary pulmonary hypertension were administered inhaled NO and then randomized to receive open-label intravenous epoprostenol (mean dose 8 ng/kg/min) or oral sildenafil (mean dose 50 mg three times daily).[149] All three agents reduced the pulmonary vascular resistance index to a similar extent. However, only inhaled NO and sildenafil reduced the pulmonary vascular resistance–to–systemic vascular resistance ratio. Intravenous epoprostenol also decreased mean systemic arterial pressure and pulmonary artery P_{O_2}, owing to worsening ventilation-perfusion matching. By contrast, inhaled NO and sildenafil maintained ventilation-perfusion matching. Therefore, in patients with pulmonary fibrosis, sildenfil exerted a selective pulmonary arterial vasodilatory effect without worsening hypoxemia. Another open-label chronic study evaluated the effect of sildenafil on exercise capacity in patient with idiopathic pulmonary fibrosis and precapillary pulmonary hypertension.[150] Fourteen patients received open-label sildenafil 20 to 50 mg three times daily for 12 weeks. At study period, of the 11 patients who completed the 6-minute walk test, 9 demonstrated an improvement in the mean 6-minute walk distance of 49 m (90% confidence interval [CI], 17.5 to 84 m). Sildenafil was discontinued in two patients for adverse events (diarrhea, hypotension). Of the 11 patients who completed the study, 1 patient had mild diarrhea and headache, another patient had headache, and a third experienced blurry vision. Based on these small but encouraging studies, a National Institutes of Health double-blind, placebo-controlled, randomized study is now underway to evaluate the effect of sildenafil in a large cohort of patients with pulmonary fibrosis and pulmonary hypertension.

Recently, a second oral phosphodiesterase V inhibitor, tadalafil, was approved for the treatment of patients with pulmonary arterial hypertension. Tadalafil, 40 mg daily, significantly improved the distance walked in 6 minutes and the time to clinical worsening compared to patients taking placebo.[150a]

Nitric Oxide

NO is produced within endothelial cells by activity of the enzyme NO synthase in response to various stimuli. NO activates guanylate cyclase, which leads to increased smooth muscle cell cyclic GMP, resulting in vasodilation. In the pulmonary capillaries, inhaled NO is inactivated by binding to hemoglobin and forming nitrosylmethemoglobin. Therefore, inhaled NO specifically dilates the pulmonary vasculature and is inactivated before it reaches the systemic circulation.[151] In subjects with severe pulmonary arterial hypertension, inhaled NO at 40 ppm was shown to decrease pulmonary vascular resistance 5% to 68% from baseline with no change in systemic vascular resistance, whereas intravenous epoprostenol reduced both the pulmonary and systemic vascular resistances. Other effects of NO include suppression of smooth muscle cell proliferation and platelet aggregation.[152,153]

Inhaled NO may affect airway tone through a variety of different mechanisms. It also significantly affects pulmonary vascular tone.[154] Both pulmonary arterial and venous endothelial cells are capable of producing NO. Using an NO synthase inhibitor in 11 healthy volunteers, Stamler and colleagues[155] demonstrated that NO regulates normoxic pulmonary vascular tone. Furthermore, when volunteers were made hypoxic, inhalation of 40 ppm NO reversed pulmonary vasoconstriction without causing systemic vasodilation.[156]

Endothelial damage with impaired NO production has been proposed as contributing to both acute and chronic pulmonary hypertension.[157] In a study of pulmonary artery rings obtained from 22 patients with COPD undergoing heart-lung transplantation, impaired endothelium-dependent pulmonary artery relaxation was observed and was related to the preoperative levels of hypoxemia and hypercapnia. Additionally, reduced relaxation was significantly correlated to the degree of intimal fibromuscular thickening.[158] The inhalation of NO at 40 ppm by awake lambs reversed pulmonary hypertension caused by breathing a hypoxic gas mixture within 3 minutes.[159]

There is a reduction in the expression of NO synthase in the pulmonary arteries of patients with idiopathic pulmonary arterial hypertension, and the degree of expression is inversely correlated with total pulmonary resistance. Hypoxia markedly lessens NO synthase activity, decreasing NO release, and this deficiency in patients with chronic pulmonary hypertension may contribute to their increase in pulmonary vascular resistance.[160,161]

In persistent newborn pulmonary hypertension, inhaled NO has proved to be of clinical value.[162,163] Furthermore, in patients with idiopathic pulmonary arterial hypertension, inhaled NO has been used to predict those patients who might safely and effectively respond to calcium channel blockers. However, in patients with COPD, intermittent NO inhalations are not commonly used therapeutically, in part because of costs and practical difficulties, including toxicity associated with chronic use, but also because of concern that systemic oxygenation might worsen due to increased local ventilation-perfusion mismatches, as often occurs with other vasodilators. However, NO theoretically should vasodi-

late only those areas it reaches as it is being inhaled, thereby increasing blood flow only to areas being ventilated and improving ventilation-perfusion matching. It would seem reasonable, therefore, to test patients with severe COPD associated with acute respiratory failure (as well as patients with obliterative or idiopathic pulmonary arterial hypertension) for their responsiveness to this potential therapeutic agent as an acute intervention. However, at present there does not appear to be a clinically meaningful role for its chronic use.

Angiotensin-Converting Enzyme Inhibitors

Studies in rats exposed to chronic hypoxia in a barochamber and then transferred to an environment of normoxia revealed that enalapril reduced the content and concentration of collagen significantly, suggesting that partial regression of cardiac fibrosis may occur with enalapril, independent of the reduction in pressure load.[164] In another study of chronically hypoxic rats, the ACE inhibitor quinapril reduced the development of pulmonary hypertension. This was seen both early and after pulmonary hypertension was established. The degree of medial thickness in alveolar duct blood vessels was significantly reduced by quinapril treatment, and stains of vascular smooth muscle cells showed that quinapril appeared to inhibit either vascular smooth muscle cell proliferation or growth, or sometimes both.[165]

Experimental observations in normal volunteers demonstrated that the infusion of saralasin (an angiotensin II receptor blocker) not only produces pulmonary vasodilation when the renin-angiotensin system has been stimulated but also attenuates pulmonary vasoconstriction in response to acute hypoxia.[166] The results of studies in patients with chronic cor pulmonale have been inconsistent. When enalapril was added to conventional treatment in 30 patients with chronic cor pulmonale, not only was pulmonary hypertension decreased but renal vascular resistance fell, resulting in increased renal blood flow and improved glomerular filtration rate.[167] In contrast, the acute effects of captopril were studied in 15 patients with severe COPD who were recovering from right-sided heart failure. Although captopril reduced systemic arterial pressure, it failed to decrease pulmonary vascular resistance in these patients with hypoxic pulmonary hypertension, nor were there any changes in breathing frequency, minute ventilation, or pulmonary gas exchange compared with controls.[168]

Angiotensin II, type I, receptor blockade attenuates the pulmonary vasoconstrictive response of acute hypoxia in normal subjects.[169] This has led to studies of the efficacy of these drugs in patients with COPD and pulmonary hypertension, but with normal left ventricular systolic function. In an acute study evaluating the response to losartan, an angiotensin II receptor blocker, after at least 1 week of therapy, nine patients with COPD had a significant reduction in both mean P_{PA} and total pulmonary vascular resistance; this was associated with a significantly lower plasma aldosterone level compared with patients receiving placebo. Although losartan produced its maximal effects 4 hours after administration, it did not alter oxygen saturation in patients with hypoxemic cor pulmonale.

The inconsistency in results with ACE inhibition may reflect the small size and short duration of the studies, as well as variations in inclusion criteria. In the study by Kiely and associates,[169] all patients had documented pulmonary vascular reactivity as assessed by a significant fall in P_{PA} in response to acute oxygen administration. It is possible that there are other patients in whom failure to demonstrate such vascular reactivity to 100% oxygen would result in a failure to demonstrate benefit from the use of an angiotensin II receptor blocker or ACE inhibitor. At present, there would appear to be no routine role for these agents in COPD. Whether ultimately there may be therapeutic value for their use in patients with cor pulmonale and pulmonary hypertension awaits the results of larger, randomized, double-blind clinical trials.

Natriuretic Peptides

In patients with COPD, infusion of ANP has been shown to reduce P_{PA} and increase the cardiac index.[170] Both ANP and BNP infusions have been shown to produce dose-related pulmonary vasodilation in patients with cor pulmonale without worsening arterial oxygen saturation or affecting systemic hemodynamics. Both agents suppress aldosterone production, and BNP has been demonstrated to suppress ET-1 levels.[68,171] There is no information to date on the long-term safety or efficacy of natriuretic peptides or neutral endopeptidase inhibitors that prevent natriuretic peptide degradation in cor pulmonale.

Nonglycoside Inotropes

Figure 56-11 delineates a suggested approach to the management of acute decompensated right ventricular failure in pulmonary arterial hypertension.[98] In the setting of severe acute right ventricular decompensation with hypoperfusion, low-dose intravenous infusion of dopamine and dobutamine (1 to 2 mg/kg/min) may improve cardiac output, blood pressure, and renal perfusion. Oxygen and dopamine have been shown to be equipotent renal vasodilators in hypoxic COPD. Low-dose dopamine infusion (2 to 5 mg/kg/min) can increase cardiac output, reduce pulmonary vascular resistance, and improve oxygen delivery.[172] Higher infusions of dopamine (10 mg/kg/min) have been shown to increase diaphragmatic blood flow and contraction.[173] Although they are effective in acute decompensated right ventricular failure, the value of these agents or of chronic oral phosphodiesterase isoform III inhibitors in chronic cor pulmonale is yet to be determined.

Surgery

The role of lung volume-reduction surgery in severe emphysema[174] is covered in Chapter 39, and that of lung and heart transplantation in cor pulmonale is covered in detail in Chapter 95. Lung transplantation is generally

reserved for suitable candidates who continue to be highly symptomatic despite optimal medical therapy and will derive a significant improvement in quality of life from the procedure. The first-year survival following lung transplantation is approximately 65% to 70% and the 5-year survival is approximately 50%, being largely limited by the development of bronchiolitis obliterans.[175]

Atrial Septostomy

Patients with idiopathic pulmonary arterial hypertension and a patent foramen ovale demonstrate a better survival compared to similar patients without a patent foramen ovale.[176] As a result, atrial septostomy, which involves the creation of a perforation in the atrial septum by use of a catheter-based blade, followed by graded balloon inflation across the atrial perforation, has been utilized in carefully selected patients with severe right-sided heart failure and recurrent syncope.[177,178] This technique increases the right-to-left shunt through the atrial communication, decreases right atrial pressure, and increases left ventricular filling, thereby decompressing the right ventricle and improving cardiac output. Atrial septostomy can reduce syncope and improve exercise performance. However, this procedure is limited by resultant arterial oxygen desaturation, frequent closure of the atrial septal communication, and the potential for paradoxical emboli. It is also associated with a high procedure-related mortality rate. Therefore, this investigational technique should be performed only by experienced operators when other options are not available or are inappropriate, or to serve as a bridge to lung transplantation.[179]

Percutaneous blade-balloon septostomy has not been studied in patients with cor pulmonale in association with other disorders of the respiratory system. The arterial hypoxemia resulting from this procedure can be life-threatening, especially in this population, mitigating any potential beneficial effects on cardiopulmonary hemodynamics.

NATURAL HISTORY

Any advanced lung disease can be associated with pulmonary hypertension and eventual potential progression to right heart failure. In a study of 374 patients with advanced lung disease referred for lung transplantaion 25% had pulmonary hypertension by right heart catheterization.[92] A study of 176 consecutive patients evaluated circulating BNP concentrations and severity of pulmonary hypertension in patients with various chronic lung diseases with a mean follow-up of 1 year.[24] Right heart catheterization, pulmonary function testing, and a 6-minute walk test were performed. Significant pulmonary arterial hypertension (mean PPA >35 mm Hg) was identified in approximately one fourth of all patients (31.8% of patients with ILD) and resulted in reduced exercise capacity and survival. Elevated BNP levels identified significant pulmonary hypertension and predicted mortality, serving as a risk factor of death independent of pulmonary functional impairment or hypoxemia.[24] COPD is the cause of chronic cor pulmonale in more than 80% of all cases.[180] Therefore, the natural history of cor pulmonale reflects the natural history of COPD. The American Thoracic Society reported that the death rate in 1991 from COPD was 18.6 per 100,000 persons, resulting in its ranking as the fourth leading cause of death. This represented a rise of 32.9% from 1979. In the United States, cor pulmonale accounts for approximately 80,000 deaths per year.[181]

Patients with COPD may or may not have pulmonary hypertension at rest. Furthermore, the progression of pulmonary hypertension in COPD is slow.[5] Among patients who are found to have normal pressures at rest, changes in pulmonary hemodynamics are frequently minimal over time. For example, in a group of 61 patients without initial pulmonary arterial hypertension, all of whom had arterial hypoxemia, a second cardiac catheterization on average 93.4 months later revealed an average change in mean PPA from 15.5 ± 2.4 to 19.6 ± 7.0 mm Hg.[182] In a second group of 32 patients who had pulmonary hypertension on their first catheterization, there was a nonsignificant rise in mean PPA, from 27.7 ± 6.0 to 31.0 ± 9.3 mm Hg, after an average delay of 60 months.[183] Hemodynamic worsening, defined as an increase of 5 mm Hg or more, occurred in approximately one third of patients and was clearly related to worsening of hypoxemia. Mortality in the group with hemodynamic worsening was significantly higher than in those with stable hemodynamics. Now, there is no doubt that the development of cor pulmonale worsens overall prognosis and increases long-term mortality.[184]

A long-term survival experience for COPD in a group who initially required hospitalization and who were in the age range of 50 to 54 years was reported from Finland.[185] Among 2727 new COPD patients, the estimated cumulative survival rate for men with COPD after 10 years was 60.1%, and for women it was 78.0%. However, the primary cause of death among patients initially hospitalized with COPD was ultimately COPD in only 22.1% of cases, with other causes such as coronary artery disease playing a prominent role. Nevertheless, it is clear that the prognosis for COPD patients in their 50s who require hospital treatment is poor.

Prognostic factors in COPD patients receiving long-term oxygen therapy have been analyzed by Oswald-Mammosser and colleagues.[186] Eighty-four patients underwent right-sided heart catheterization before institution of long-term oxygen therapy. These patients had a mean age of 63 years; they had a persistent arterial P_{O_2} of less than 55 mm Hg or an arterial P_{O_2} between 55 and 60 mm Hg and either signs of cor pulmonale or a mean PPA of 25 mm Hg or greater. When actuarial survival curves were plotted with consideration of a number of variables, it was found that the 5-year survival rate for patients with an initial mean PPA of 25 mm Hg or less was 62.2%, whereas it was only 36.3% in the 40 remaining patients who had an initial mean PPA higher than 25 mm Hg. Therefore, it would appear that the level of the PPA at the time a patient undergoes long-term oxygen therapy is a better prognostic indicator than are such

factors as forced expiratory volume in 1 second, the degree of hypoxemia, or the level of hypercapnia. It is also clear that pulmonary hypertension in patients with COPD is associated with increased hospitalization[187] and higher mortality rate[188] compared to COPD patients without pulmonary hypertension. Only 33% of patients with COPD and pulmonary hypertension survive 4 years after diagnosis, compared with 64% of patients without pulmonary hypertension.[189] A mean PPA of 20 to 25 mm Hg or more is associated with a poor prognosis. In one study, the 5-year survival of patients with COPD receiving long-term oxygen therapy was found to be 48%.[186]

The development of pulmonary hypertension in patients with ILD and, specifically, idiopathic pulmonary fibrosis is associated with worsening symptoms, functional impairment, and increased morbidity and mortality.[32,190–192] In a retrospective study of 136 patients with idiopathic pulmonary fibrosis, the median survival of those with estimated systolic PPA of greater than 50 mm Hg by echocardiography was less than 1 year ($p = 0.009$) compared to 4.8 years for patients without pulmonary hypertension (systolic PPA < 35 mm Hg), and 4.1 years for patients with mild pulmonary hypertension (systolic PPA 36 to 50 mm Hg).[190] In a study of 79 patients with idiopathic pulmonary fibrosis referred for lung transplantation who had a right heart catheterization, 32% (24 of 79) had pulmonary hypertension documented by a mean PPA greater than 25 mm Hg.[191] The 1-year survival rates were lower (72%) in those patients with pulmonary hypertension compared to idiopathic pulmonary fibrosis patients without pulmonary hypertension (94.5%; $p = 0.002$).[191] Furthermore, patients with pulmonary hypertension who had lower DL_{CO} values were more likely to require supplemental oxygen, and to exhibit shorter 6-minute walk test distances as well as a lower arterial oxygen saturation nadir. Five-year survival of idiopathic pulmonary fibrosis patients with pulmonary hypertension is also significantly curtailed. In one study of 78 patients with pulmonary hypertension, using a cutoff based on a receiver operating curve, the 5-year survival rate was 62% for the group ($n = 37$) with mean PPA less than 17 mm Hg compared to 16.7% for the group ($n = 24$) with mean PPA greater than 17 mm Hg ($p < 0.001$). The relative risk of death was higher at 2.20 (95% CI, 1.40 to 3.45) for the high mean PPA group.[193] According to an analysis of 2972 patients with advanced idiopathic pulmonary fibrosis listed for lung transplantation between 1995 and 2004, those with pulmonary hypertension were 1.62 times more likely to die after being listed for transplantation compared to those without pulmonary hypertension.[192]

Management of patients with pulmonary hypertension associated with ILD includes treating the underlying ILD, providing supplemental oxygen, and treating the right heart failure. There are no studies evaluating the efficacy of anticoagulation in this condition. Vasomodulating therapy for pulmonary hypertension in ILD is currently under investigation in larger studies, but at this time remains an off-label use. In pulmonary hypertension with ILD, one must weigh the potential benefit of reducing right ventricular afterload to alleviate symptoms and improve exercise capacity, quality of life, and morbidity and mortality versus the potential risks of worsening hypoxemia from increased ventilation-perfusion mismatch and acute pulmonary edema in cases of ILD associated with pulmonary veno-occlusive disease. Lung transplantation remains a life-saving procedure for this diagnosis.[32]

KEY POINTS

- The term *cor pulmonale* is defined by the WHO as "hypertrophy of the right ventricle resulting from diseases affecting the function and/or the structure of the lung, except when these pulmonary alterations are the result of diseases that primarily affect the left side of the heart or congenital heart disease."
- The pathogenesis of pulmonary hypertension in patients with chronic pulmonary disease involves combinations of hypoxic pulmonary vasoconstriction and pulmonary vascular remodeling related to anatomic restriction and/or obliteration of the pulmonary vascular bed from alveolar destruction, fibrosis, inflammation, thrombosis, and the effects of mitogenic mediators that are related to the specific underlying lung disease.
- Management of patients with pulmonary hypertension associated with cor pulmonale includes treating the underlying lung disease, administering supplemental oxygen, and treating right heart failure with diuretics, vasomodulating agents, and contractility agents as needed.
- Vasomodulating agents approved for the treatment of the pulmonary arterial hypertensive disorders include endothelin receptor antagonists, phosphodiesterase V inhibitors, and prostacyclin analogues; however, these agents have yet to be proven efficacious for the treatment of pulmonary hypertension associated with chronic pulmonary disease.
- Pulmonary hypertension is present in approximately 25% of patients with advanced lung disease and is associated with significantly worse symptoms and functional impairment, and with increased morbidity and mortality.

INTRODUCTION

CLINICAL AND HISTOLOGIC CLASSIFICATION OF INTERSTITIAL LUNG DISEASE

CLINICAL, RADIOLOGIC, AND PHYSIOLOGIC FEATURES OF INTERSTITIAL LUNG DISEASES
Past History
Symptoms
Physical Findings
Radiographic Features
Functional Assessment
Laboratory Findings
Bronchoalveolar Lavage
Histologic Diagnosis

DIAGNOSIS AND MANAGEMENT OF THE IDIOPATHIC INTERSTITIAL PNEUMONIAS
Idiopathic Pulmonary Fibrosis
Acute Exacerbations of Interstitial Pulmonary Fibrosis
Familial Pulmonary Fibrosis
Nonspecific Interstitial Pneumonia
Respiratory Bronchiolitis–Associated Interstitial Lung Disease/Desquamative Interstitial Pneumonia
Acute Interstitial Pneumonia
Cryptogenic Organizing Pneumonia
Lymphocytic Interstitial Pneumonia
Conclusion

INTRODUCTION

The term *interstitial lung disease (ILD)*, in general, implies inflammatory-fibrotic infiltration of the alveolar walls (septa) resulting in profound effects on the capillary endothelium and the alveolar epithelial lining cells (Fig. 57-1). Under normal conditions, small numbers of interstitial macrophages, fibroblasts, and myofibroblasts reside within the interstitium. Other components of the interstitium include the matrix proteins of the lung, consisting of collagen-related macromolecules and the noncollagenous proteins such as fibronectin and laminin.

In many of the ILDs, interstitial fibrosis follows injury to the gas-exchanging units. This injury increases alveolar permeability, enabling the serum contents to enter the alveolar spaces. Fibroblastic proliferation and excessive collagen deposition, the histologic hallmarks of ILD, occur either as a direct result of the injury, as a result of an inflammatory cell response that releases proinflammatory and profibrotic cytokines, or as a consequence of the regenerative and reparative processes taking place at the epithelial and endothelial surfaces. Moreover, fibroblastic proliferation and collagen accumulation also occur within airway lumina and walls of small airways (alveolar ducts, respiratory bronchioles, and terminal bronchioles).

ILDs include many entities that injure the lung parenchyma, producing diseases with similar clinical, radiographic, and physiologic features. Some occur in the setting of other conditions, such as connective tissue disease; others are idiopathic. The primary goal of the clinician is to determine if the patient does or does not have idiopathic pulmonary fibrosis (IPF)/usual interstitial pneumonia (UIP) (see later).

CLINICAL AND HISTOLOGIC CLASSIFICATION OF INTERSTITIAL LUNG DISEASE

The exact prevalence and incidence of the ILDs are unknown. Studies suggest a prevalence of 80.9/100,000 for men compared with 67.2/100,000 for women. Similarly, the overall incidence of ILD is slightly more

common in men (31.5/100,000/yr) than in women (26.1/100,000/yr) and increases with age. For example, among men and women 75 years of age or older, the prevalence of IPF was 250/100,000 and the incidence was 160/100,000/yr.[1]

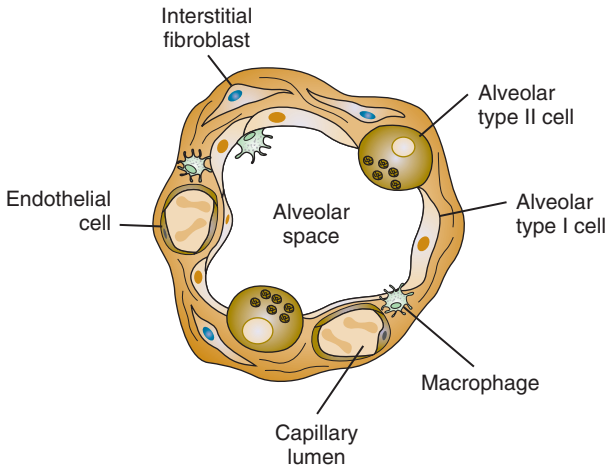

FIGURE 57-1 ■ Schematic depiction of the lung parenchyma surrounding an alveolar space shows the major cells that line and lie within the interstitial space.

A clinical classification of the ILDs is shown in Table 57-1.[2] Although the diagnosis of ILD due to occupational exposure, a medication, or a connective tissue disease may be obvious, the primary and idiopathic ILDs are difficult to diagnose on clinical grounds alone. This chapter presents an approach for the evaluation of these patients with emphasis on the idiopathic interstitial pneumonias (IIPs). An alternative method of histopathologic classification depends on the resultant pattern of injury found on lung biopsy. As seen in Table 57-2, dissimilar clinical entities may result in similar histologic appearances.

The causes of ILDs are daunting, but they are linked by many common features: clinical presentation, radiographic appearance, physiologic abnormalities, and in some instances, histologic findings. Nevertheless, a specific diagnosis can be made in many patients from the results of a careful history and certain laboratory tests. Bronchoscopy with bronchoalveolar lavage (BAL) and, often, transbronchial biopsy are useful in the diagnosis of some causes of interstitial infiltration. Thoracoscopic or open-lung biopsy is required for a definitive diagnosis of the remaining cases. Further information about many of the specific members of the interstitial disease family in this section is found in Chapters 57 through 63. Additional discussion of other causes of ILD is found

TABLE 57-1. Clinical Classification of the Interstitial Lung Diseases

CONNECTIVE TISSUE DISEASES
Scleroderma
Polymyositis-dermatomyositis
Systemic lupus erythematosus
Rheumatoid arthritis
Mixed connective tissue disease
Ankylosing spondylitis

TREATMENT-RELATED OR DRUG-INDUCED DISEASES
Antibiotics (nitrofurantoin, sulfasalazine)
Antiarrhythmics (amiodarone, tocainide, propranolol)
Anti-inflammatories (gold, penicillamine)
Anticonvulsants (dilantin)
Chemotherapeutic agents (mitomycin C, bleomycin, busulfan, cyclophosphamide, chlorambucil, methotrexate, azathioprine, BCNU [carmustine], procarbazine)
Therapeutic radiation
Oxygen toxicity
Narcotics

PRIMARY (UNCLASSIFIED) DISEASES
Sarcoidosis
Primary pulmonary Langerhans cell histiocytosis (eosinophilic granuloma)
Amyloidosis
Pulmonary vasculitis
Lipoid pneumonia
Lymphangitic carcinomatosis
Bronchoalveolar carcinoma
Pulmonary lymphoma
Gaucher's disease
Niemann-Pick disease
Hermansky-Pudlak syndrome
Neurofibromatosis
Lymphangioleiomyomatosis
Tuberous sclerosis
Acute respiratory distress syndrome
AIDS
Bone marrow transplantation
Postinfectious
Eosinophilic pneumonia
Alveolar proteinosis
Diffuse alveolar hemorrhage syndromes
Alveolar microlithiasis
Metastatic calcification

OCCUPATIONAL AND ENVIRONMENTAL DISEASES

Inorganic
Silicosis
Asbestosis
Hard-metal pneumoconiosis
Coal worker's pneumoconiosis
Berylliosis
Talc pneumoconiosis
Siderosis (arc welder)
Stannosis (tin)
Organic (hypersensitivity pneumonitis)
Bird breeder's lung
Farmer's lung
(For complete listing, see Chapter 66)

IDIOPATHIC FIBROTIC DISORDERS
Acute interstitial pneumonitis (Hamman-Rich syndrome)
Idiopathic pulmonary fibrosis/usual interstitial pneumonia
Familial pulmonary fibrosis
Respiratory bronchiolitis/desquamative interstitial pneumonitis
Cryptogenic organizing pneumonia
Nonspecific interstitial pneumonia
Lymphocytic interstitial pneumonia (Sjögren's syndrome, connective tissue disease, AIDS, Hashimoto's thyroiditis)
Autoimmune pulmonary fibrosis (inflammatory bowel disease, primary biliary cirrhosis, idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia)

AIDS, acquired immunodeficiency syndrome.

TABLE 57-2. Histologic Patterns in the Interstitial Lung Diseases and Their Disease Associations

Histologic Patterns	Clinical Associations
Usual interstitial pneumonia	Idiopathic pulmonary fibrosis; connective tissue diseases (uncommon); asbestosis; hypersensitivity pneumonitis; chronic aspiration pneumonia; chronic radiation pneumonitis; Hermansky-Pudlak syndrome; neurofibromatosis
Nonspecific interstitial pneumonia	Idiopathic; connective tissue diseases; drugs; hypersensitivity pneumonitis; diffuse alveolar damage; infections; lymphocytic interstitial pneumonia; AIDS; chronic eosinophilic pneumonia; infections; hemosiderosis; alveolar proteinosis
Diffuse alveolar damage	Acute interstitial pneumonia (Hamman-Rich syndrome); acute respiratory distress syndrome; drugs (cytotoxic agents, heroin, cocaine, paraquat, ethchlorvynol, aspirin); toxic gas inhalation; radiation therapy; oxygen toxicity; connective tissue disease; infections (*Legionella*, *Mycoplasma*, viral)
Organizing pneumonia	Cryptogenic organizing pneumonia; organizing stage of diffuse alveolar damage; diffuse alveolar hemorrhage; drugs (amiodarone, cocaine); infections; connective tissue diseases; hypersensitivity pneumonitis; eosinophilic pneumonia; Wegener's granulomatosis
Desquamative interstitial pneumonia/respiratory bronchiolitis	Cigarette smoking; idiopathic; connective tissue diseases; primary pulmonary Langerhans cell histiocytosis; asbestosis; hard-metal pneumoconiosis (cobalt); Gaucher's disease; Niemann-Pick disease; Hermansky-Pudlak syndrome; drugs (nitrofurantoin, amiodarone)
Lymphocytic interstitial pneumonia	Idiopathic; hypogammaglobulinemia; autoimmune diseases, including Hashimoto's thyroiditis, lupus erythematosus, primary biliary cirrhosis, Sjögren's syndrome, myasthenia gravis, chronic active hepatitis; AIDS; allogeneic bone marrow transplantation
Eosinophilic pneumonia	Idiopathic acute and chronic; tropical filarial eosinophilia; parasitic infections; allergic bronchopulmonary aspergillosis; allergic granulomatosis of Churg and Strauss; hypereosinophilic syndrome; AIDS
Alveolar proteinosis	Pulmonary alveolar proteinosis; acute silicosis; aluminum dust; AIDS; myeloproliferative disorder
Diffuse alveolar hemorrhage	
With capillaritis	Wegener's granulomatosis; microscopic polyangiitis; systemic lupus erythematosus; polymyositis; scleroderma; rheumatoid arthritis; mixed connective tissue disease; lung transplantation; drugs (retinoic acid, propylthiouracil, dilantin); Behçet's disease; cryoglobulinemia; Henoch-Schönlein purpura; pauci-immune glomerulonephritis; immune complex glomerulonephritis
Without capillaritis	Idiopathic pulmonary hemosiderosis; systemic lupus erythematosus; Goodpasture's syndrome; diffuse alveolar damage; pulmonary veno-occlusive disease; mitral stenosis; lymphangioleiomyomatosis
Amyloid deposition	Primary amyloidosis; multiple myeloma; lymphocytic interstitial pneumonia
Granuloma	Sarcoidosis; hypersensitivity pneumonitis; pulmonary Langerhans cell histiocytosis; silicosis; intravenous talcosis; berylliosis; lymphocytic interstitial pneumonia; infections

AIDS, acquired immunodeficiency syndrome.

elsewhere in the book: the pneumoconioses in Chapter 65, hypersensitivity pneumonitis in Chapter 66, and drug-induced pulmonary disease in Chapter 72.

CLINICAL, RADIOLOGIC, AND PHYSIOLOGIC FEATURES OF INTERSTITIAL LUNG DISEASES

The hallmarks of an ILD are progressive dyspnea and cough, an abnormal chest radiograph, and impaired pulmonary function tests.[2] However, 5% to 10% of symptomatic patients eventually diagnosed as having ILD have normal chest radiographs at the time of presentation. There are also dyspneic patients with or without abnormal chest radiographs in whom routine pulmonary function tests (flows, volumes, and diffusing capacity) are normal. Exercise testing, which stresses the cardiopulmonary system and measures gas exchange, may unmask abnormalities in these situations. Furthermore, high-resolution computed tomography (HRCT) scans and BAL can detect abnormalities in the presence of normal radiographs and physiologic tests in patients at high risk for development of ILD, such as those with connective tissue disease, asbestos exposure, or hypersensitivity pneumonitis, and those taking drugs known to injure the lung.

Past History

ILD occurring in a patient with an established connective tissue disease is obvious; however, there are patients in whom the lung disease precedes the more typical manifestations by months to several years (see Chapter 58).

Occupational History

The occupational history is of obvious importance. It should be thorough and detailed, because a long latency period may occasionally exist between exposure and the appearance of clinical impairment and disability. The exposure may have been of short duration but high intensity. Hypersensitivity pneumonitis, which can manifest either as recurrent acute or subacute pneumonitis or as an insidious form with slowly progressive dyspnea, must be excluded (see Chapter 66). A growing list of

occupational and environmental antigens can cause granulomatous pneumonitis.

Drug History

A review of the medications used in the recent and distant past is important. Uncommonly, the lung disease may appear weeks to years after the drug has been discontinued (see Chapter 72). Aspiration (often silent) of gastric contents because of gastroesophageal reflux (GER) can lead to the insidious development of ILD,[3] as can the nocturnal use of oily nose drops or use of mineral oil as a laxative.[4]

Smoking History

Determining any history of tobacco use is important. More than 90% of patients with pulmonary Langerhans cell histiocytosis (PLCH) of the lung are smokers at the time of diagnosis; this is also true for respiratory bronchiolitis. Of patients with Goodpasture's syndrome who smoked, 100% had diffuse alveolar hemorrhage, whereas only 20% of a nonsmoking group had pulmonary disease in addition to the renal involvement.[5] Tobacco use also appears to enhance the development of interstitial fibrosis in an asbestos-exposed population. The risk of asbestosis in exposed smokers was 13 times that in a nonsmoking asbestos-exposed cohort. Most patients with IPF have a history of tobacco abuse. Hypersensitivity pneumonitis, conversely, infrequently appears in the active smoker. Also, the incidence of sarcoidosis is higher in nonsmokers.

Family History

Familial associations (with an autosomal dominant pattern) have been identified in cases of IPF, sarcoidosis, tuberous sclerosis, and neurofibromatosis, Niemann-Pick disease, Gaucher's disease, and Hermansky-Pudlak syndrome are inherited in an autosomal recessive fashion[6–8] (see "Familial Pulmonary Fibrosis," later).

Gender

There are ILDs with a sex predilection. Lymphangioleiomyomatosis occurs exclusively in women. In addition, many connective tissue diseases more commonly affect women. Occupational causes are more likely in men. However, transmission of inorganic dust, either from clothes or by living in the vicinity of a manufacturing or mining facility, has resulted in asbestosis and berylliosis in women, children, and men not employed in the industry.

Symptoms

Progressive *dyspnea* is usually the most common symptom, but cough can be prominent, particularly in those patients with lymphangitic carcinomatosis in which the bronchial lymphatic channels are infiltrated.

Cough is a prominent symptom in ILDs that affect small airways or are bronchocentric in location, such as sarcoidosis, respiratory bronchiolitis, organizing pneumonia, pulmonary Langerhans cell granulomatosis, and hypersensitivity pneumonitis.

Wheezing, an unusual symptom in ILD, has been reported with lymphangitic carcinomatosis, chronic eosinophilic pneumonia, respiratory bronchiolitis, and hypersensitivity pneumonitis.

Substernal chest pain, an unusual complaint for most ILDs, is frequent in sarcoidosis. *Pleuritic-type chest pain* may accompany connective tissue and drug-related ILDs. The sudden appearance of *chest pain* due to a pneumothorax can be the presenting manifestation or complicate preexisting PLCH, lymphangioleiomyomatosis, tuberous sclerosis, or neurofibromatosis.

Hemoptysis is typical for the diffuse alveolar hemorrhage syndromes, lymphangioleiomyomatosis, pulmonary veno-occlusive disease, and long-standing mitral valve disease. However, alveolar hemorrhage may be present without hemoptysis. Hemoptysis occurring in a patient with an established ILD raises the possibility of a complicating malignancy.

Symptoms in patients with ILD are present for months to years and progress at varying rates. Several interstitial reactions are acute (days to several weeks). These are often confused with atypical pneumonias because they cause diffuse radiographic opacities and may be associated with fever. Included are acute interstitial pneumona (AIP; Hamman-Rich syndrome), acute eosinophilic pneumonia, some cases of hypersensitivity pneumonitis, occasionally drug-related ILDs, some cases of organizing pneumonia, the diffuse alveolar hemorrhage syndromes, and the acute immunologic pneumonias that occur with connective tissue diseases.

Physical Findings

The most typical physical finding is bibasilar inspiratory crackles. Crackles are less likely in the granulomatous diseases. Bilateral inspiratory crackles may also be present in a symptomatic patient with a negative chest radiograph. Clubbing of the digits, which in most cases indicates advanced fibrotic disease, is a common finding in patients with the idiopathic or familial forms of pulmonary fibrosis. However, the appearance of digital clubbing in a patient with an established case of ILD could indicate an underlying bronchogenic carcinoma. With advanced fibrosis, causing chronic hypoxemia, clinical signs of pulmonary hypertension and cor pulmonale appear. Attention to potential extrapulmonary physical findings or other manifestations may reveal a specific diagnosis (Table 57-3).

Radiographic Features

Although standard chest radiography is not as sensitive for detection of ILD as the HRCT scan, it is the logical starting point and the most practical way of identifying and defining disease.

TABLE 57-3. Extrapulmonary Physical Findings and Clinical Manifestations in the Interstitial Lung Diseases

Finding	Examples
Systemic hypertension	Connective tissue disease; neurofibromatosis; some diffuse alveolar hemorrhage syndromes
Erythema nodosum	Sarcoidosis; connective tissue disease; Behçet's syndrome
Maculopapular rash	Drug-induced; amyloidosis; lipoidosis; connective tissue diseases; Gaucher's disease
Heliotrope rash	Dermatomyositis
Albinism	Hermansky-Pudlak syndrome
Discoid lupus	Systemic lupus erythematosus
Neurofibroma	von Recklinghausen's disease
Telangiectasia	Scleroderma
Raynaud's phenomenon	Connective tissue disease
Cutaneous vasculitis	Systemic vasculitides; connective tissue disease
Subcutaneous nodules	von Recklinghausen's disease; rheumatoid arthritis
Calcinosis	Dermatomyositis; scleroderma
Uveitis	Sarcoidosis; Behçet's syndrome; ankylosing spondylitis
Scleritis	Systemic vasculitis; systemic lupus erythematosus; scleroderma; sarcoidosis
Keratoconjunctivitis sicca	Lymphocytic interstitial pneumonia
Salivary gland enlargement	Sarcoidosis, lymphocytic interstitial pneumonia
Peripheral lymphadenopathy	Sarcoidosis; lymphangitic carcinomatosis; lymphocytic interstitial pneumonia; lymphoma
Hepatosplenomegaly	Sarcoidosis; pulmonary Langerhans cell histiocytosis; connective tissue disease; amyloidosis; lymphocytic interstitial pneumonia
Pericarditis	Radiation pneumonitis; connective tissue disease
Myositis	Connective tissue disease; drugs (L-tryptophan)
Bone involvement	Pulmonary Langerhans cell histiocytosis; sarcoidosis; Gaucher's disease; lymphangitic carcinomatosis
Arthritis	Connective tissue disease; systemic vasculitis; sarcoidosis
Diabetes insipidus	Pulmonary Langerhans cell histiocytosis; sarcoidosis
Glomerulonephritis	Systemic vasculitis; connective tissue disease; Goodpasture's syndrome; sarcoidosis
Nephrotic syndrome	Amyloidosis; drug-induced (gold, penicillamine); systemic lupus erythematosus
Renal mass	Lymphangioleiomyomatosis; tuberous sclerosis

Plain Roentgenography

Ziskind and coworkers[9] classified the diffuse lung diseases according to the pattern on chest radiographs—alveolar filling and primarily interstitial patterns (reticular or nodular). Although computed tomography (CT) scanning has supplanted the chest radiograph in the assessment of diffuse parenchymal lung diseases, it is still very useful to recognize these patterns.

Alveolar Filling Pattern (Table 57-4). Alveolar filling is recognized by a homogeneous opacity that can be diffuse or patchy and is characterized by confluent nodules with ill-defined outer borders, air bronchograms, and obliteration or silhouetting of normal structures such as the diaphragm, heart, and intrapulmonary blood vessels (Fig. 57-2). Another feature is the acinar rosette or air alveologram, which indicates consolidation of the alveolus and small airways distal to an unobstructed terminal bronchiole (Fig. 57-3). Several have associated hilar adenopathy (e.g., sarcoidosis, pulmonary lymphoma). In patients with alveolar proteinosis, sparing of the lung parenchyma immediately adjacent to the diaphragm is seen. In chronic eosinophilic pneumonia, the pattern has been referred to as the radiographic negative of pulmonary edema, because the alveolar opacities are most prominent in the periphery. A similar alveolar

TABLE 57-4. Interstitial Lung Diseases Producing an Alveolar Filling Pattern on Chest Radiograph

Alveolar proteinosis (proteinaceous fluid)
Alveolar cell carcinoma (malignant cells)
Bronchioloalveolar metastases (malignant cells from pancreas, breast)
Pulmonary lymphoma (malignant lymphocytes)
Lymphocytic interstitial pneumonia (lymphoplasmacytic cells)
Alveolar sarcoid (lymphocyte-macrophage alveolitis or confluent granuloma)
Desquamative interstitial pneumonia (macrophages)
Diffuse alveolar hemorrhage (red blood cells; hemosiderin-filled macrophages)
Eosinophilic pneumonia (eosinophils, macrophages; lymphocytes)
Alveolar microlithiasis (calcium-phosphate microliths)
Bronchiolitis obliterans with organizing pneumonia (Masson bodies)
Mineral oil aspiration (lipid-filled macrophages)
Acute hypersensitivity pneumonia (lymphoplasmacytic cells)

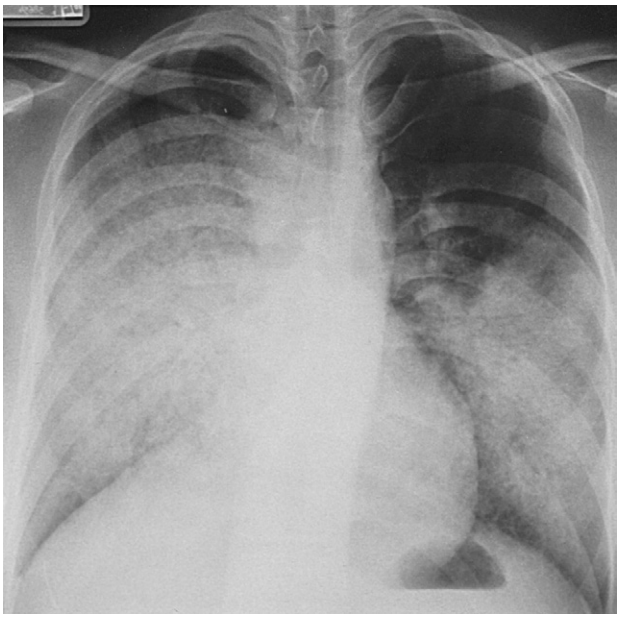

FIGURE 57-2 ■ Chest radiograph shows a characteristic pattern of alveolar filling disease in a patient with diffuse alveolar hemorrhage. Note the homogeneous consolidation with obliteration of the right heart border and the pulmonary vasculature in addition to air bronchograms.

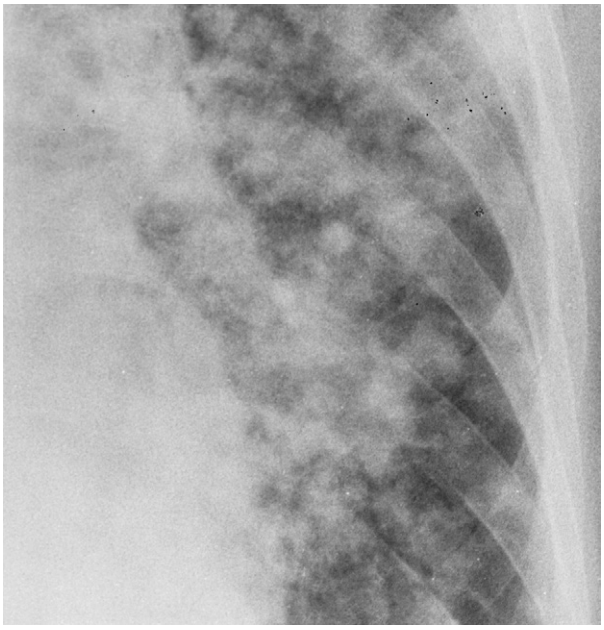

FIGURE 57-3 ■ Detailed view of chest radiograph shows alveolar nodules in a patient with alveolar cell carcinoma. Note the ill-defined nodules and distal air alveolograms.

pattern has also been reported to occur in some patients with organizing pneumonia (Fig. 57-4).

Interstitial Pattern. Radiographic interstitial opacities become apparent when the interstitial compartment becomes infiltrated and widened by inflammatory cells, excessive collagen, granulomatous inflammation, or smooth muscle proliferation. In other instances,

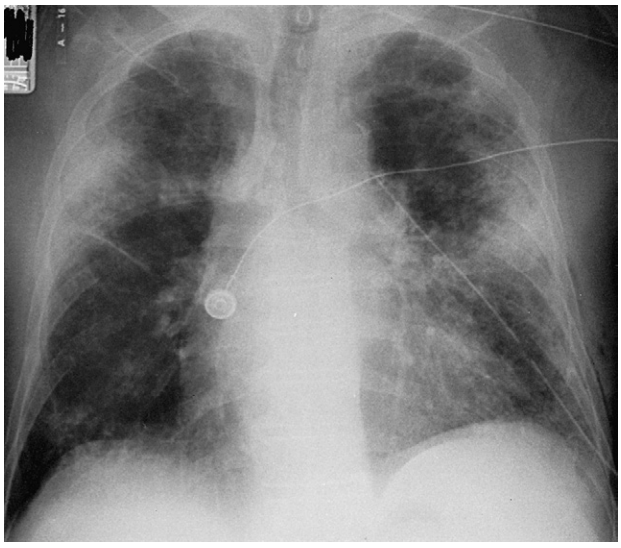

FIGURE 57-4 ■ Chest radiograph of a patient with organizing pneumonia shows bilateral peripheral alveolar opacities. A similar appearance is seen in chronic eosinophilic pneumonia.

malignant cells or amyloid deposits expand this compartment. These opacities appear as nodules, linear reticular opacities, or a combination of linear shadows and nodules ("reticulonodular" opacities).

Nodular Pattern. Nodules of varying size characterize the granulomatous lung diseases. Miliary nodules accompany infectious granulomas and noninfectious granulomas (e.g., sarcoidosis, PLCH, silicosis, and hypersensitivity pneumonitis) and some malignant diseases (e.g., melanoma, hypernephroma, and lymphoma) (Fig. 57-5). However, linear opacities possibly representing an underlying cellular interstitial infiltrate are also visible.

Linear or Reticular. Linear or reticular interstitial changes are seen in most ILDs (Fig. 57-6). It is typical for many ILDs (e.g., IPF, the connective tissue diseases, asbestosis, cytotoxic drug–induced disorders) to have the greatest concentration of the reticular opacities in the lower lung zones. The term *radiographic honeycomb lung* refers to a reticular and cystic pattern that correlates with the histologic "honeycombing." These small cystic structures, which are best seen in the lower and peripheral lung zones, indicate an underlying advanced fibrotic change (Fig. 57-7).

A criticism of the alveolar-interstitial classification is that a mixed pattern is often found. For example, interstitial fibrosis may eventually be superimposed on a disease that was primarily alveolar, such as alveolar proteinosis, diffuse alveolar hemorrhage, eosinophilic pneumonia, or organizing pneumonia. Sarcoidosis, a disease characterized by interstitial granuloma, can be alveolar in appearance due to either coalescence of granulomas with compression of adjacent lung or a lymphocyte-macrophage alveolitis. Dense fibrosis from any fibrotic lung disease can compress adjacent lung, producing homogeneous shadows. The appearance of alveolar

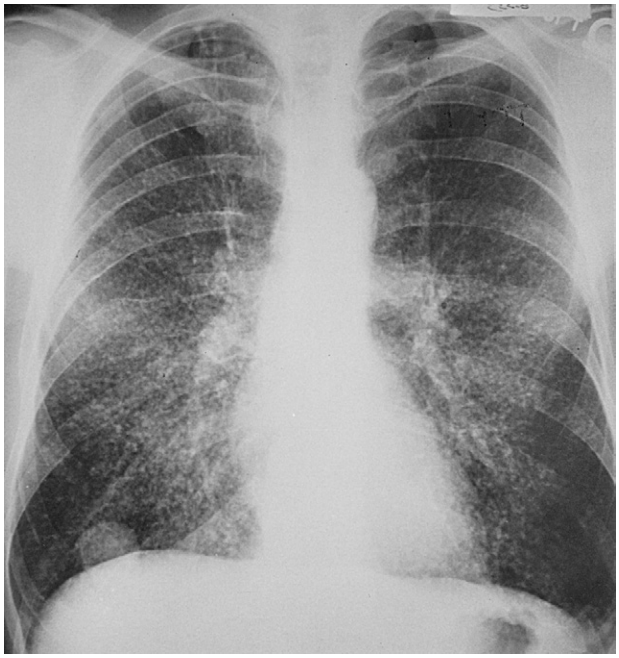

FIGURE 57-5 ■ Chest radiograph shows miliary interstitial nodulation in a patient with metastatic malignant melanoma. A large mass is also present in the right lower lobe.

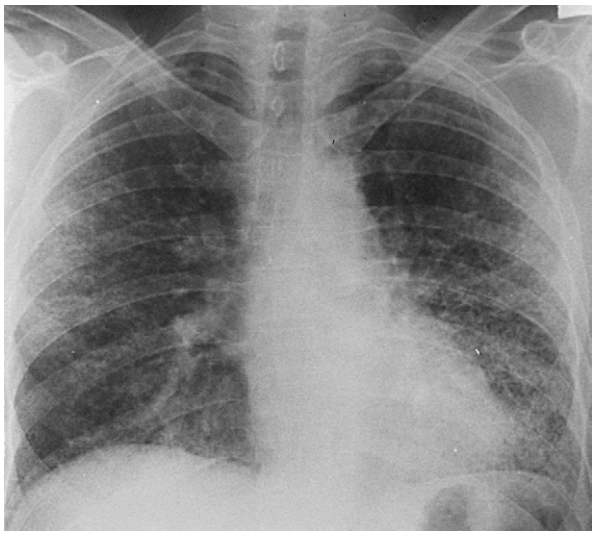

FIGURE 57-6 ■ Chest radiograph shows diffuse bilateral lower lung predominant reticular opacities in a patient with idiopathic pulmonary fibrosis (IPF).

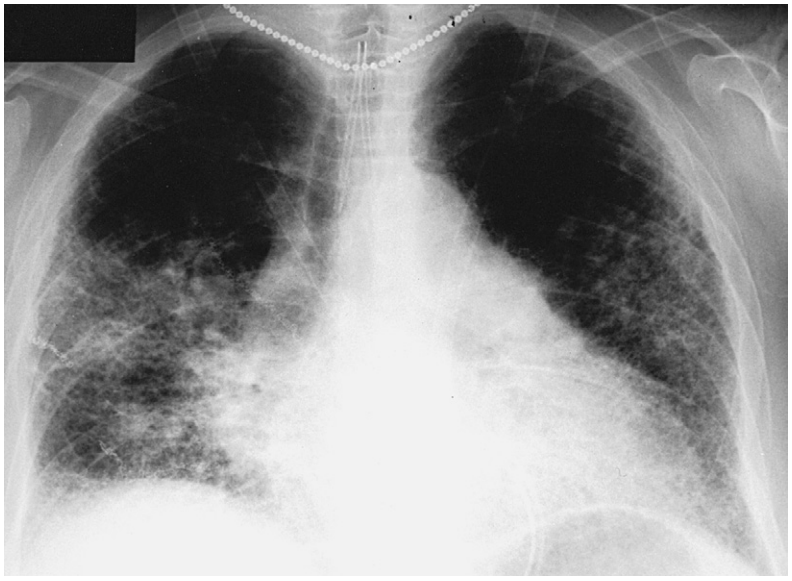

FIGURE 57-7 ■ Chest radiograph shows characteristic features of honeycomb lung. A network of 2- to 3-mm cystic spaces is distributed throughout the lung fields. This patient with end-stage IPF also had pulmonary hypertension and was receiving oxygen through a transtracheal catheter.

opacities during the course of an ILD may represent renewed activity of the primary disease, superimposed infection, or development of alveolar cell carcinoma or adenocarcinoma.[10,11]

Other Radiographic Features. Several distinctive patterns may accompany the interstitial changes and may point to a diagnosis (Table 57-5). There are a group of interstitial diseases, often granulomatous, in which the radiographic changes are more prominent in the upper lung zones (Fig. 57-8). There are interstitial diseases that are bronchiolocentric, resulting in either maintenance or expansion of the lung volume. If an ILD is superimposed on emphysema, the lung volumes often are preserved. The majority of ILDs result in a gradual reduction of the lung volumes. In fact, lower lobe volume loss and traction bronchiectasis are typical for the advanced stages of these diseases.[10–12] Short horizontal lines at the lung periphery (Kerley's B lines), representing thickened interlobular septa, are seen after obstruction of the pulmonary lymphatics (Fig. 57-9). Pneumothorax is often the presenting manifestation of PLCH or lymphangioleiomyomatosis. Diaphragmatic pleural calcification in a patient with interstitial opacities is indicative of asbestos exposure. Pleural thickening and pleural effusion

TABLE 57-5. Radiographic Features of the Interstitial Lung Diseases

Feature	Diseases
Upper zone–predominant disease	Radiation pneumonitis; neurofibromatosis; chronic sarcoidosis; pulmonary Langerhans cell histiocytosis; silicosis; chronic hypersensitivity pneumonitis; chronic eosinophilic pneumonia; ankylosing spondylitis; nodular rheumatoid arthritis; berylliosis; drug-induced (amiodarone, gold, BCNU [carmustine]); radiation
Increased lung volumes	Lymphangioleiomyomatosis; chronic sarcoidosis; chronic pulmonary Langerhans cell histiocytosis; tuberous sclerosis; neurofibromatosis
Radiographic honeycomb lung	Idiopathic pulmonary fibrosis; connective tissue disease; asbestosis; drug-induced; lymphocytic interstitial pneumonia; chronic aspiration pneumonia; hemosiderosis; Hermansky-Pudlak syndrome; alveolar proteinosis
Pneumothorax	Pulmonary Langerhans cell histiocytosis; lymphangioleiomyomatosis; tuberous sclerosis; neurofibromatosis
Kerley's B lines	Lymphangitic carcinomatosis; lymphangioleiomyomatosis; left atrial hypertension (mitral valve disease, veno-occlusive disease); lymphoma; amyloidosis
Lymphadenopathy	Sarcoidosis; lymphoma; lymphangitic carcinomatosis; lymphoid interstitial pneumonia; berylliosis; amyloidosis; Gaucher's disease
Pleural disease	Lymphangitic carcinomatosis; connective tissue disease; asbestosis (pleural calcification); lymphangioleiomyomatosis (chylous effusion); drug-induced (nitrofurantoin, radiation); sarcoidosis
Eggshell calcification of lymph nodes	Silicosis; sarcoidosis; radiation

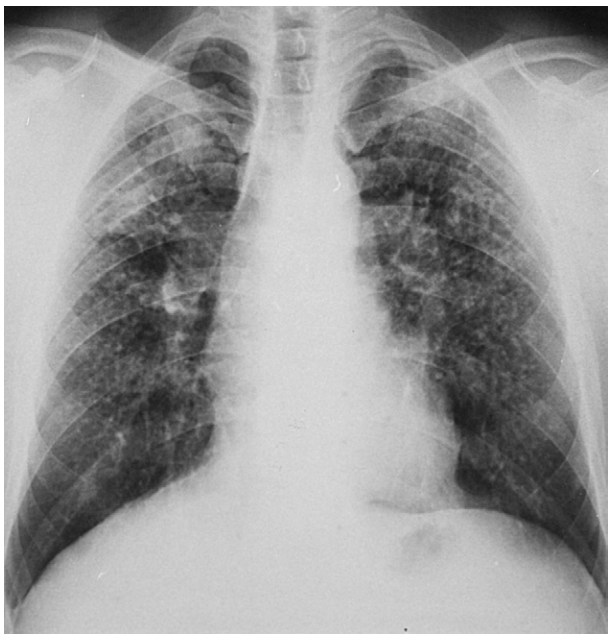

FIGURE 57-8 ■ Chest radiograph shows uncomplicated silicosis. Note the nodular interstitial disease with predilection for the middle and upper lung zones.

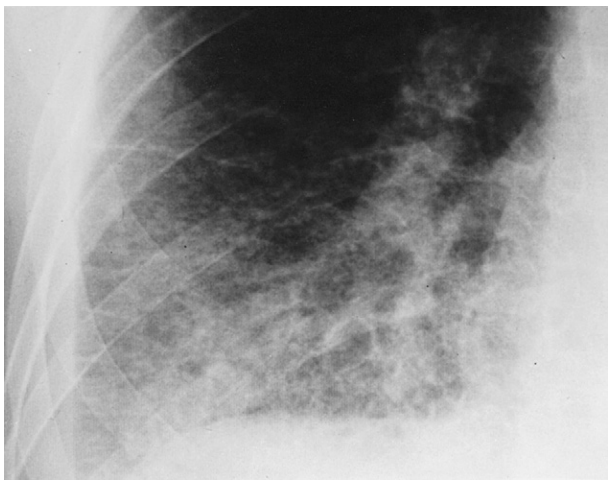

FIGURE 57-9 ■ Detailed view of right lung shows Kerley's B lines and pleural effusion in a patient with lymphangitic carcinomatosis.

may complicate the course of the connective tissue–associated ILDs (with the exception of polymyositis-dermatomyositis). Chronic hypoxemia results in radiographic evidence of pulmonary hypertension.

Computed Tomography

Conventional chest radiographic assessment for ILD may miss up to 10% of cases.[13] Conventional CT, obtained using 8- to 10-mm slices, offers little more for the detection of radiographic-negative ILD. HRCT, obtained with less than 3-mm slices, enables better visualization of fine parenchymal detail and therefore the detection of early air space filling or interstitial change (Fig. 57-10). In cases of suspected ILD with negative conventional radiography, it is important to perform HRCT with prone and supine views. Dependent lung density can mask interstitial change, and vascular engorgement of the dependent portion of lung mimics septal thickening on the supine view. Abnormalities that persist on the prone view are indicative of disease.

In patients with abnormal chest radiographs, the diagnostic accuracy increases with HRCT evaluation. In cases of IPF, peripheral reticular opacities, lower zone subpleural honeycombing, and traction bronchiectasis are seen (Fig. 57-11).[14] In the connective tissue diseases, asbestosis, and some drug-induced ILD, the results on

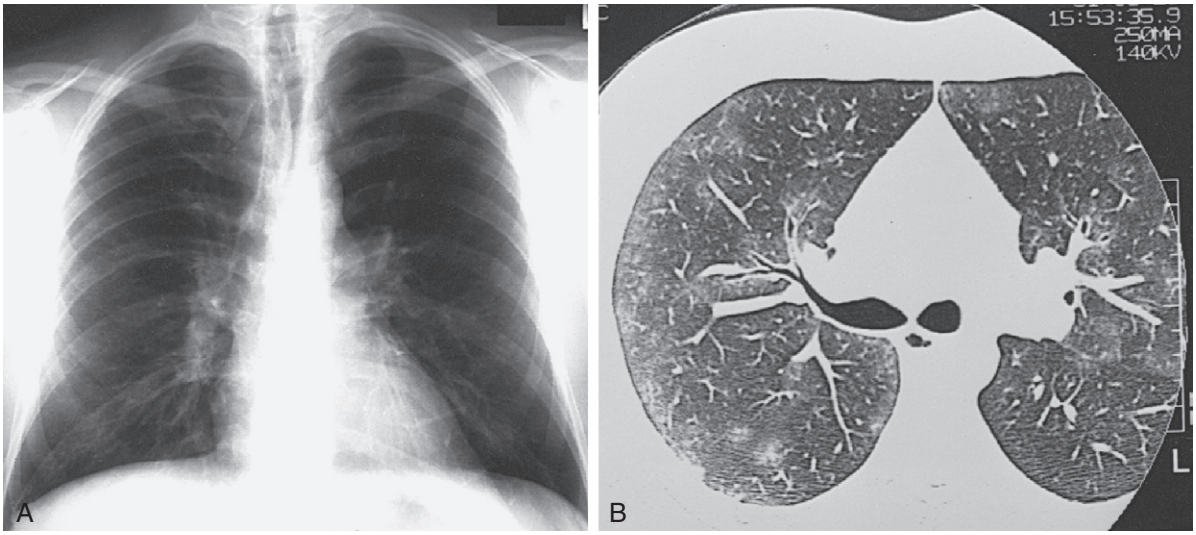

FIGURE 57-10 ■ **A,** A normal chest radiograph from a 45-year-old man with established hypersensitivity pneumonitis. At the time, his arterial oxygen pressure (Po_2) while breathing room air was 48 mm Hg. **B,** A high-resolution computed tomography (CT) image of the same patient demonstrates patchy ground-glass areas of air space–filling opacities.

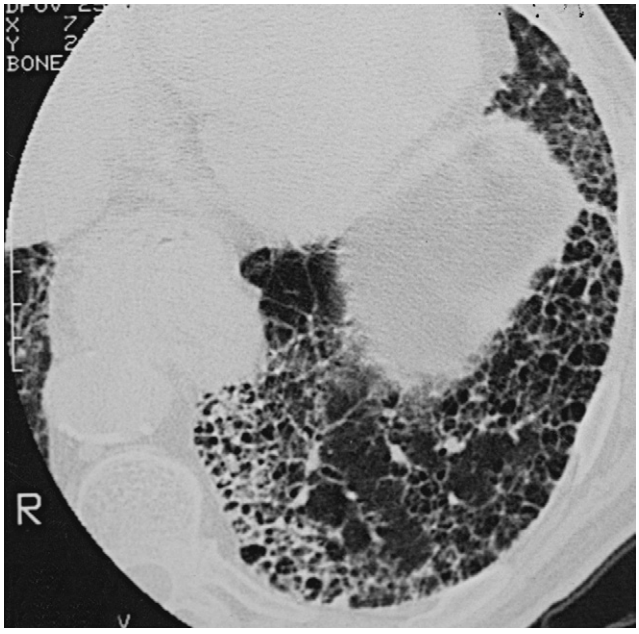

FIGURE 57-11 ■ High-resolution CT image of advanced IPF shows extensive honeycomb changes.

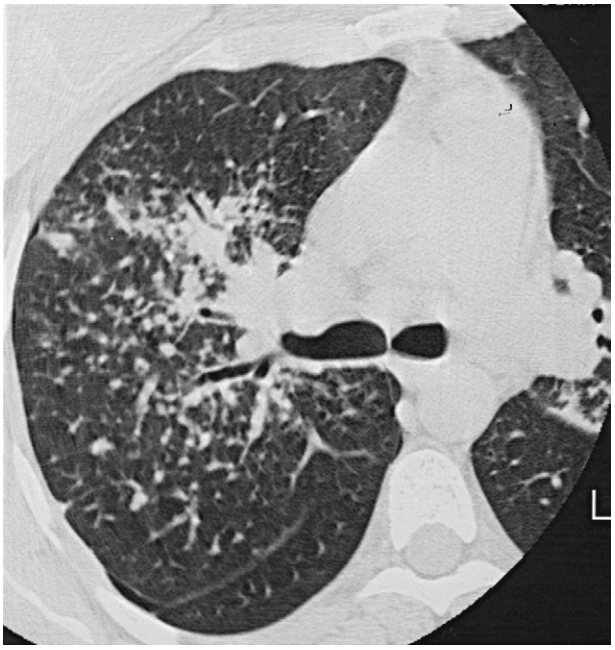

FIGURE 57-12 ■ High-resolution CT image from a patient with sarcoidosis shows hilar lymphadenopathy and nodular disease as well as dense air space filling.

HRCT, as on chest radiography, are indistinguishable from those of IPF or nonspecific interstitial pneumonia (NSIP). In scleroderma, a disease in which the prevalence rate of ILD approaches 100% in autopsy series, HRCT detects disease in 45% to 75% of patients when conventional radiography is negative.[15,16]

In sarcoidosis, in addition to the hilar and mediastinal adenopathy, nodules deposited along bronchovascular bundles and interlobular septa, air space filling due to the lymphocyte-macrophage alveolitis, and linear densities secondary to fibrotic scarring can be seen (Fig. 57-12). In patients with hypersensitivity pneumonitis, air space–filling centrilobular nodules and linear opacities without adenopathy are present. The HRCT can be normal in symptomatic patients with biopsy-proved hypersensitivity pneumonitis.[17] In patients with PLCH, the combination of centrilobular nodules and cysts, most prominent in the upper lobes and occasionally accompanied by a pneumothorax, is characteristic (Fig. 57-13). In earlier PLCH, coalescence of the nodules produces an air space–filling pattern.

In lymphangioleiomyomatosis, the HRCT is typical, revealing rounded, thin-walled cysts throughout (Fig.

FIGURE 57-13 ■ High-resolution CT image from a patient with pulmonary Langerhans cell histiocytosis shows diffuse centrilobular nodulation and cyst formation.

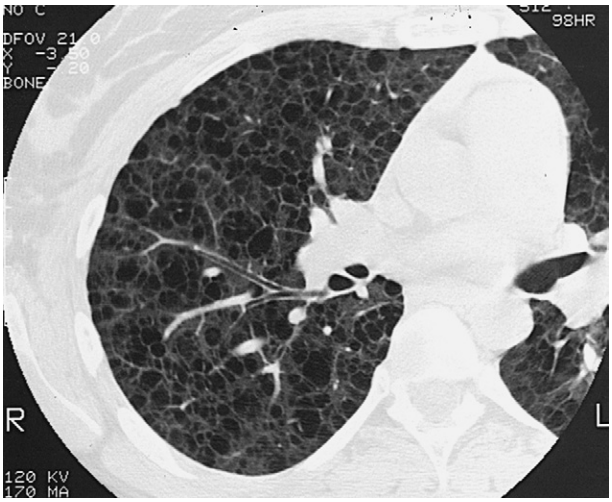

FIGURE 57-14 ■ High-resolution CT image from a patient with lymphangioleiomyomatosis shows characteristic thin-walled cysts throughout the parenchyma.

57-14). A pneumothorax or pleural effusion (chylous) may accompany this change. Except for the pleural effusion, identical findings are present in tuberous sclerosis. Lymphangitic carcinomatosis produces a beaded-chain appearance of the interlobular septa that correlates with Kerley's B lines seen with conventional radiography. In asbestos-related disease, noncalcified pleural plaques and early ILD are often difficult to detect, and the HRCT is more sensitive than conventional chest radiography.

Functional Assessment

In ILD, there are characteristic alterations of the lungs' mechanical properties and impairment of gas exchange at the alveolar-capillary interface. Assessment of ventilatory function and the mechanical properties of the lungs, as well as gas exchange, particularly during exercise, are vital components of the initial evaluation of patients with suspected ILD. In addition, serial measurements of function enable the physician to determine progression of the disease and the effects of therapeutic intervention.

Ventilatory Function

Ventilatory function tests provide an indirect index of alterations to the impedance to respiration offered by the elastic resistance to distention of the lungs and the frictional resistance to airflow in the tracheobronchial tree. Clinically, alterations of the mechanical properties of the respiratory system are also reflected in the pattern of breathing that is adopted by the patient. These patients tend to breathe rapidly and shallowly, because a larger tidal volume would require an inordinate increase in work of breathing to overcome the greatly increased elastic resistance.

Elastic Resistance

ILD is associated with an increase in elastic resistance (or decreased compliance), and this can be seen in a plot of the static transpulmonary pressure (i.e., at points of no flow) at differing decrements of lung volume from total lung capacity (TLC) to residual volume. In most patients with ILD, the plot of the volume-pressure relationship of the lungs is characteristically shifted downward and to the right, with a reduced slope (i.e., compliance is low) and a markedly increased coefficient of elastic recoil (maximum elastic recoil pressure, TLC). Conversely, as is demonstrated in Figure 57-15, there is significant variation in the position of the volume-pressure curve in patients with IPF and sarcoidosis,[18] and the correlation between alterations of the elastic properties (and lung volume compartments) and the degree of fibrosis present is poor. This is, at least in part, a consequence of the impact of smoking, which appears to differ in the two disorders. In patients with IPF who smoke, the volume-pressure curve is shifted upward and to the left, whereas in smokers with sarcoidosis, it is shifted downward and to the right.[18]

Measurements of lung volume reflect changes in position of the volume-pressure curve of the lungs. This is because alterations of the elastic recoil of the lung or chest wall disturb the balance between the elastic forces of the lungs, which act in an expiratory direction, and those of the chest wall, which act in an inspiratory direction. In patients with ILD, the TLC, functional residual capacity, and residual volume are generally lower than expected (Fig. 57-16). A lower than expected TLC (and vital capacity) in association with a normal functional residual capacity and a greater than expected residual volume generally reflects a mixed restrictive and obstructive disorder. However, because maximum effort is necessary to determine the inspiratory capacity and the expiratory reserve volume, a less than maximal inspiration or expiration, because of either weak respiratory

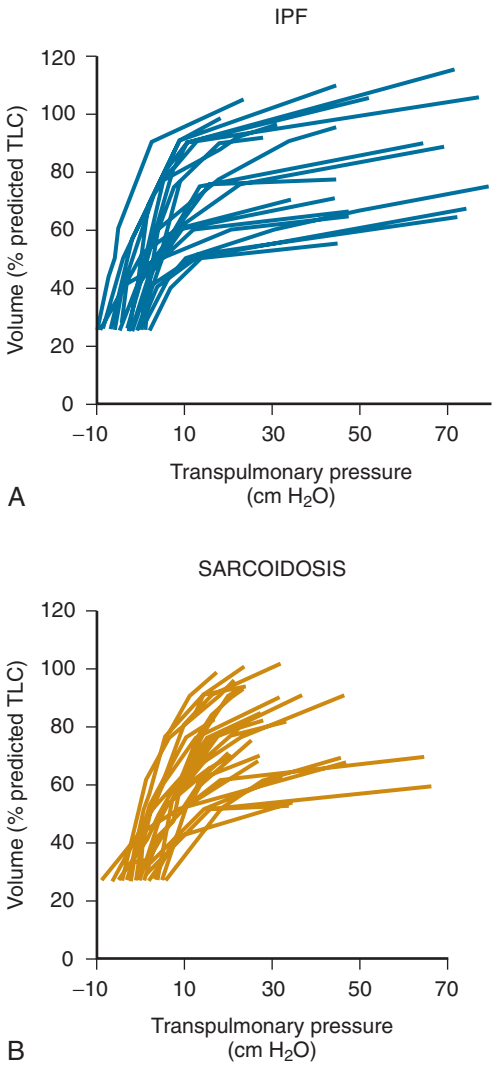

FIGURE 57-15 ■ Multiple recordings show volume-pressure characteristics in patients with IPF (**A**) and sarcoidosis (**B**). Note the marked variation of position and shape in both disorders. TLC, total lung capacity. (Redrawn from Hanley ME, King TE Jr, Schwarz MI, et al: The impact of smoking on mechanical properties of the lungs in idiopathic pulmonary fibrosis and sarcoidosis. Am Rev Respir Dis 144:1102, 1991.)

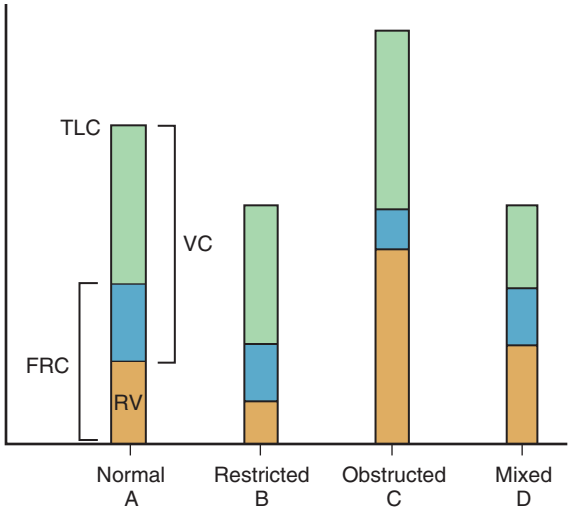

FIGURE 57-16 ■ Bar graphs show total lung capacity (TLC) and its subdivisions in healthy persons (**A**) compared with the typical abnormalities found in patients with restrictive disorders (**B**), obstructive disorders (**C**), and mixed disorders (**D**). FRC, functional residual capacity; RV, residual volume; VC, vital capacity. (Redrawn from Cherniack RM: Pulmonary Function Testing. Philadelphia: WB Saunders, 1992, p 212.)

muscles or poor effort, leads to the same findings. Similar qualifications apply to the vital capacity, which is often used as an index of alterations of elastic resistance. In addition, as can be seen in Figure 57-16, a low vital capacity is not specific for restrictive disorders, because it is also lower than expected in patients with airflow limitation (because of an increased residual volume).

Flow Resistance

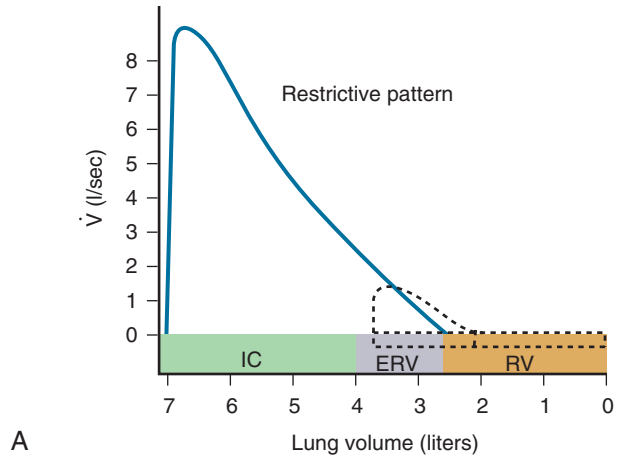
Measurement of lung volume is important when evaluating airflow resistance. This can be assessed directly from the relationship between the rate of airflow and the resistive component of the transpulmonary pressure.

In clinical practice, various indirect measures of flow resistance can be used: the forced expiratory volume in 1 second (FEV_1); the mean expiratory flow rate between 25% and 75% of the forced vital capacity (FVC), that is, $FEF_{25\%-75\%}$; the maximal expiratory flow rate ($\dot{V}max$) at a particular proportion (such as 75%, 50%, or 25%) of the FVC (from a flow-volume curve); the FEV_1/FVC ratio; or the FEV_1–to–vital capacity ratio. Low flow rates or a low FEV_1/FVC ratio (i.e., <70% of predicted) is believed to indicate expiratory airflow limitation. However, like airway resistance, $\dot{V}max$ values depend on the state of expansion of the airways (i.e., lung volume). The FEV_1/FVC ratio will be overestimated, and the degree of flow limitation underestimated, in the patient who does not exhale fully because of severe dyspnea or muscular weakness, pain, or poor effort.

Airflow resistance is not generally thought to be increased in ILD. As is seen in Figure 57-17, $\dot{V}max$ is low in ILD, not because of an increase in flow resistance but rather because the flow rates are being achieved at low lung volumes. In fact, in uncomplicated ILD, $\dot{V}max$ values are greater than expected at any particular lung volume (isovolume) because the lung elastic recoil pressure, which is the driving pressure for flow in the peripheral airways, is increased.[19] As a corollary, a $\dot{V}max$ lower than expected at a particular lung volume in a patient who is suffering from a restrictive disorder indicates an increase of flow resistance in the more peripheral (upstream) airways. An increase in upstream resistance has been reported in patients with IPF, hypersensitivity pneumonitis, and asbestos exposure.

Gas Exchange

Alterations of gas exchange are readily assessed by analysis of the arterial oxygen pressure (P_{O_2}) and carbon dioxide pressure (P_{CO_2}) and calculation of the



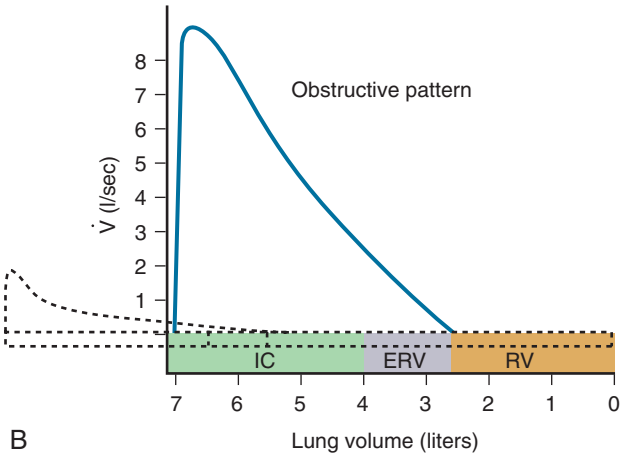


FIGURE 57-17 ■ Schematic volume-flow ($\dot{V}$) curves in a healthy person (*solid line*) are compared with those in patients (*dotted lines*) with a restrictive disorder (**A**) and with an obstructive disorder (**B**). Lung volume is reduced in the restrictive disorder, and maximum expiratory flow rates are low because they are achieved at low lung volumes. Flow rates are higher than expected at low lung volumes because the driving pressure (lung elastic recoil) is increased. ERV, expiratory residual volume; RV, residual volume. (Redrawn from Cherniack RM: Pulmonary Function Testing. Philadelphia: WB Saunders, 1992, p 218.)

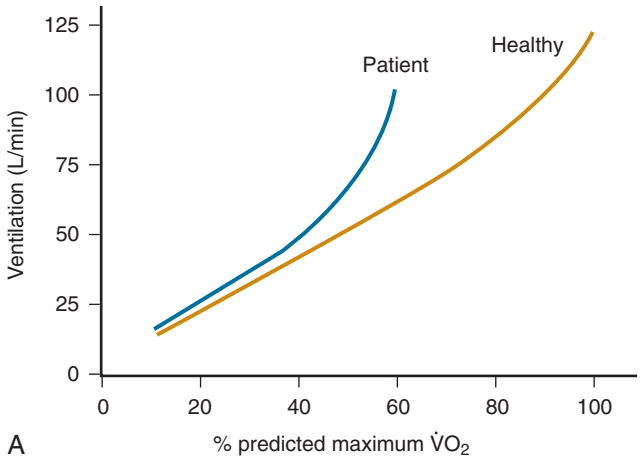

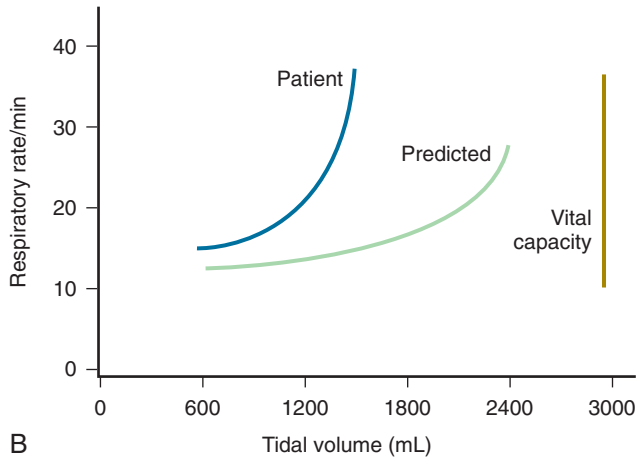

FIGURE 57-18 ■ Schematic curves show the ventilatory response (**A**) and respiratory pattern (**B**) during increasing exercise workloads expressed as a percentage of the predicted maximum oxygen uptake ($\dot{V}o_2$) in a healthy person and in a patient with IPF. (Redrawn from Cherniack RM: Pulmonary Function Testing. Philadelphia: WB Saunders, 1992, p 248.)

alveolar-arterial P_{O_2} difference ((A – a)P_{O_2}), both at rest and during exercise.

In patients with ILD, arterial blood analysis while at rest usually reveals hypoxemia and an increased (A – a)P_{O_2}, along with hypocapnia. In addition, the diffusing capacity for carbon monoxide ($D_{L_{CO}}$) is reduced, primarily because of a reduction in the alveolar-capillary surface available for gas exchange. The disturbance of gas exchange generally accompanies abnormalities in ventilatory function,[20] but gas exchange may be normal at rest in a significant number of patients. Similarly, the resting $D_{L_{CO}}$ may be only slightly reduced in patients who demonstrate a mild restrictive disorder or normal gas exchange while at rest, or both.

The $D_{L_{CO}}$ is generally greater than expected in those cases associated with recent pulmonary hemorrhage because the red blood cells in the pulmonary alveoli take up carbon monoxide readily. Sequential measurements of the $D_{L_{CO}}$ within minutes may aid in the establishment of the diagnosis of alveolar hemorrhage.[21] When there is fresh blood in the alveolar spaces, each successive $D_{L_{CO}}$ value will be lower as the hemoglobin in the alveoli becomes saturated with carbon monoxide.

Exercise

In most patients, gas exchange is disturbed during exertion, even in those with normal gas exchange at rest. Assessment of gas exchange during exercise provides the best correlation with the severity of disease[22] and is probably the most important physiologic determination in patients with ILD.

In general, patients with the most severe restrictive disease have the poorest exercise tolerance. As is shown in Figure 57-18, ventilation generally rises excessively

during exercise and may approach the ventilatory ceiling. Characteristically, the respiratory frequency rises inordinately with increasing exercise loads because of the increased work that would be required to overcome the elastic resistance of the lungs if the tidal volume were to increase.

The excessive ventilation is frequently preferentially distributed to areas of lung that have normal compliance but diminished perfusion (i.e., high ventilation-perfusion ratio); as a result, unlike the normal response, the calculated dead space (V_D) and the ratio of dead space to tidal volume (V_D/V_T) rise in association with rapid, shallow breathing. The increase in cardiac output with exercise and the rapid transit of blood through the pulmonary capillaries along with its redistribution in the lungs lead to a greater maldistribution of ventilation-perfusion ratios. This results in a rise in $(A - a)P_{O_2}$ and a fall in arterial P_{O_2} (Fig. 57-19). Except for heavy exercise, when the transit through the circulation is exceptionally rapid, it is unlikely that a reduced ability of oxygen to diffuse across a thickened alveolar-capillary membrane plays a significant role in the hypoxemia.

Laboratory Findings

Table 57-6 summarizes the results of laboratory tests that suggest or support the diagnosis of a specific ILD.

Bronchoalveolar Lavage

BAL is a technique employed to sample the distal airways via the instillation of sterile saline through a wedged fiberoptic bronchoscope. After aspiration, the contents, which are thought to represent the cellular, immunologic, and biochemical milieu of the alveolar structures, can be analyzed. The results of BAL for the evaluation of ILD have been difficult to interpret because of the lack of standardized techniques for both the performance of the procedure and the subsequent analysis of the data.[23,24] Furthermore, in some of the earlier studies, correlative data between lung biopsies and BAL were not obtained. Often, the treatment or smoking status of the patient was not considered. A multicenter publication has set forth the methods of performing and analyzing the results of BAL.[25] This study involved a large cohort of normal subjects of varying age and race who were compared with patients with documented ILD. Smoking affects the BAL

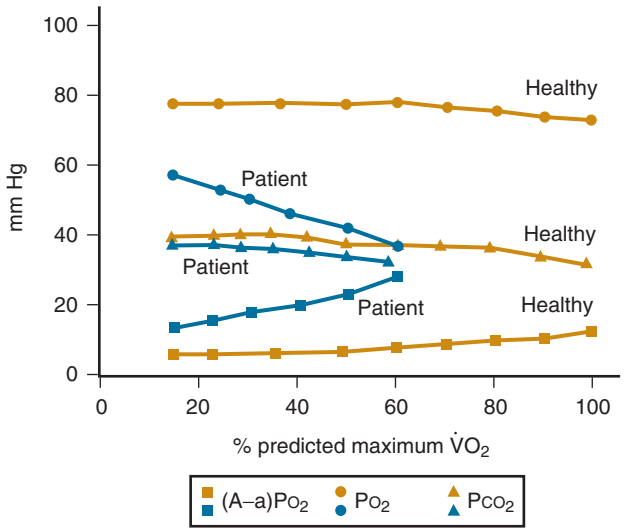

FIGURE 57-19 ■ The changes in arterial P_{O_2}, alveolar-arterial P_{O_2} difference ($(A - a)P_{O_2}$), and arterial carbon dioxide pressure (P_{CO_2}) during increasing exercise workloads expressed as the percentage of predicted maximum oxygen uptake ($\dot{V}_{O_2}$) in a healthy person and a patient with IPF. TABLE 57-6. Laboratory Findings in the Interstitial Lung Diseases

Finding	Diseases
Leukopenia	Sarcoidosis; connective tissue disease; lymphoma; drug-induced
Leukocytosis	Systemic vasculitis; hypersensitivity pneumonitis; lymphoma
Eosinophilia	Eosinophilic pneumonia; sarcoidosis; systemic vasculitis; drug-induced (sulfa, methotrexate)
Thrombocytopenia	Sarcoidosis; connective tissue disease; drug-induced; Gaucher's disease; idiopathic pulmonary fibrosis
Hemolytic anemia	Connective tissue disease; sarcoidosis; lymphoma; drug-induced; idiopathic pulmonary fibrosis
Normocytic anemia	Diffuse alveolar hemorrhage syndromes; connective tissue disease; lymphangitic carcinomatosis
Urinary sediment abnormalities	Connective tissue disease; systemic vasculitis; drug-induced
Hypogammaglobulinemia	Lymphocytic interstitial pneumonia
Hypergammaglobulinemia	Connective tissue disease; sarcoidosis; systemic vasculitis; idiopathic pulmonary fibrosis; asbestosis; silicosis; lymphocytic interstitial pneumonia; lymphoma
Serum autoantibodies	Connective tissue disease; systemic vasculitis; sarcoidosis; idiopathic pulmonary fibrosis; silicosis; asbestosis; lymphocytic interstitial pneumonia
Serum immune complexes	Idiopathic pulmonary fibrosis; lymphocytic interstitial pneumonia; systemic vasculitis; connective tissue disease; pulmonary Langerhans cell histiocytosis
Serum angiotensin-converting enzyme	Sarcoidosis; hypersensitivity pneumonitis; silicosis; acute respiratory distress syndrome; Gaucher's disease
Antibasement membrane antibody	Goodpasture's syndrome
Antineutrophil cytoplasmic antibody	Systemic vasculitis

results of both normal subjects and patients by amplifying the macrophage and eosinophil populations.[25]

BAL is a useful investigative tool in many ILDs. Cytologic analysis of BAL specimens can be diagnostic for lymphangitic carcinomatosis, alveolar cell carcinoma, and pulmonary lymphoma. If the eosinophil level exceeds 40% (normal, <2%), eosinophilic pneumonia is usually the cause of the diffuse pulmonary infiltration. BAL eosinophilia of a lesser degree may occur with some connective tissue diseases, IPF, or organizing pneumonia.

The finding of periodic acid–Schiff–positive lipoproteinaceous bodies in the lavage liquid was originally thought to be diagnostic for pulmonary alveolar proteinosis but has proved to be nonspecific. In cases of diffuse alveolar hemorrhage, red blood cells and hemosiderin-laden macrophages dominate the lavage specimen.

Lavage lymphocytosis (>35% lymphocytes) predominates in some diseases. Sarcoidosis and hypersensitivity pneumonitis are most common. Others include lymphocytic interstitial pneumonia (LIP), pulmonary lymphoma, berylliosis, and some drug-induced ILDs. Smaller but increased percentages of lymphocytes (normal range, 15%) can be seen with these entities in addition to a number of other ILDs, including IPF, organizing pneumonia, connective tissue diseases, and some pneumoconioses.[26] In patients with suspected asbestos-related disease, one or more asbestos bodies per high-powered field in the BAL specimen indicate significant exposure, but this does not establish the diagnosis of asbestosis. Because of the vertical gradient of asbestos bodies recovered in the lungs of patients with asbestosis, if lavage is used to document previous asbestos exposure, samples should be obtained from a basal segment of one of the lower lobes. A diagnosis of berylliosis is confirmed when lavaged lymphocytes undergo proliferation after exposure to the mineral in vitro.

In the BAL recovered from patients with PLCH, all inflammatory cells are increased even though their percentages remain unchanged. Electron microscopy demonstrates increased numbers of Langerhans cells. This monocyte, which is thought to be central in the pathogenesis, has a typical pentilaminar body (Birbeck granule) in the cytoplasm, as revealed by electron microscopy. Langerhans cells have been described in other fibrotic lung diseases, but not in numbers equivalent to those of PLCH.[27]

Other applications of BAL include disease staging (i.e., cellular infiltrates versus fibrosis on lung biopsies) and the prediction of therapeutic responsiveness. For example, in both the connective tissue diseases and IPF, BAL lymphocytosis is associated with a cellular histology (as opposed to fibrosis) and an improved response to treatment. Furthermore, the overall survival rate in these patients is increased. Conversely, the combination of lavage neutrophilia and eosinophilia without lymphocytosis often portends progressive unresponsive disease. In sarcoidosis, a disease characterized by increases in the number of T-helper ($CD4^+$) lymphocytes in the lung, it has been suggested that clinical deterioration may be expected if the BAL lymphocyte level exceeds 28%. More recent data indicate that the level of BAL lymphocytes has no value in predicting the clinical outcome in sarcoidosis.

The assessment of potential ILD in populations at risk is another role for BAL. For example, in patients with scleroderma and rheumatoid arthritis in whom clinical, radiologic, and physiologic evidence of ILD is lacking, BAL studies have revealed increases in inflammatory cell populations.

Histologic Diagnosis

The final step in the evaluation of a patient with ILD is to decide whether tissue is needed for diagnosis. As previously noted, the diagnosis of connective tissue, occupational, or drug-related ILD is often obvious after a careful history has been taken. In cases of idiopathic and primary ILD (see Table 57-1), the diagnosis may not be as obvious, although clinical, laboratory, and radiologic findings are often suggestive. Furthermore, the diagnosis of IPF, a commonly encountered disorder, in most situations can be established only by lung biopsy.

Transbronchial Biopsy

As a matter of practicality, transbronchial biopsy can be performed during the bronchoscopy for BAL. Transbronchial biopsy is relatively safe and is often diagnostic of sarcoidosis, diffuse malignancy, alveolar proteinosis, or eosinophilic pneumonia. Other entities are less frequently confirmed by this procedure. A transbronchial biopsy interpretation, which describes only inflammation, fibrosis, or both, is not evidence for IPF or any other entity listed in Table 57-1. Furthermore, even in clinically confirmed cases of connective tissue or drug-induced ILD, several different histologic patterns may evolve (see Table 57-2), and lung biopsy is often undertaken to predict prognosis and therapeutic responsiveness, particularly if BAL and HRCT are inconclusive.

Surgical Lung Biopsy

If the transbronchial biopsy, clinical, and lavage data are inconclusive and the patient is not at high risk, a video thoracoscopic or open-lung biopsy should be performed. Moreover, there is a poor correlation between the results of transbronchial and open-lung biopsies unless the transbronchial biopsy yields a specific diagnosis. Therefore, when the transbronchial biopsy is inconclusive and a definitive diagnosis is required, open- or thoracoscopic lung biopsy is indicated.[28]

DIAGNOSIS AND MANAGEMENT OF THE IDIOPATHIC INTERSTITIAL PNEUMONIAS

The IIPs comprise seven clinical-radiologic-pathologic entities that are sufficiently different from one another to be designated as separate diseases. The classification, diagnosis, our understanding of the pathogenic mecha-

nisms and management of the IIPs continue to evolve.[2,29,30] As a group, they can be distinguished from other forms of ILD by clinical methods including history, physical examination, chest radiology laboratory studies, and pathology.[29] Importantly, however, several of them are frequently secondary to a known cause which must be carefully investigated (e.g., cryptogenic organizing pneumonia [COP], NSIP, LIP). Furthermore, the histologic patterns are distinctive but not specific, and they can be seen not only in the idiopathic setting but also in a variety of other conditions.[31] Tables 57-7 and 57-8 provide an overview of the key clinical and pathologic features of the IIPs.

Idiopathic Pulmonary Fibrosis

IPF is a common ILD of unknown etiology. IPF is a well-defined clinical entity with characteristic clinical, radiographic, physiologic, and pathologic manifestations.[29–31] The exact prevalence of this condition is unknown. In a recent study using narrow case-finding criteria, the prevalence ranged from 0.8 to 64.7/100,000 individuals; comparable figures for incidence were 0.4 to 27.1/100,000 persons. Extrapolating these rates to the overall U.S. population, prevalence was estimated to be 14.0/100,000 (incidence, 6.8/100,000).[32] Both the prevalence and the incidence of IPF increase markedly with age.

Clinical Features

IPF occurs in middle age, usually between 50 and 70 years of age. In fact, it is quite uncommon for a patient to present before the age of 40. The typical patient presents with the insidious onset of exertional breathlessness and a nonproductive cough. Constitutional symptoms are uncommon, but weight loss, fever, fatigue,

TABLE 57-7. Contrasting Pathologic Features of the Idiopathic Interstitial Pneumonias

Features	UIP	DIP	RB-ILD	AIP	NSIP	COP
Temporal appearance	Variegated	Uniform	Uniform	Uniform	Uniform	Uniform
Interstitial inflammation	Scant	Scant	Scant	Scant	Usually prominent	Usually moderate
Fibrosis	Patchy	Variable, diffuse, moderate	Variable, focal, mild	Typically no, but may evolve to fibrosis	Variable, diffuse	No
Fibroblast proliferation	Fibroblast foci prominent	No	No	Diffuse	Occasional, diffuse or rare fibroblast foci	Intra-alveolar (Masson bodies)
Honeycomb change	Yes	No	No	No	Rare	No
Intra-alveolar macrophage accumulation	Occasional, focal (smokers)	Yes, diffuse	Peribronchiolar	No	Occasional, patchy	Foamy macrophages common
Hyaline membranes	No	No	No	Occasional, focal	No	No

myalgias, or arthralgia is occasionally present. Although patients may present with only a nonproductive cough, all patients experience dyspnea with exertion as the disease progresses. Most patients have these symptoms for months to years prior to definitive evaluation, usually around 12 to 18 months. Recently, an accelerated variant of IPF was described.[33] These patients, usually male smokers, present for evaluation a few months after the onset of symptoms with severe functional derangement and display rapid progression and shorter survival than typical IPF patients.

The physical examination is rarely normal. Most patients have bibasilar late inspiratory fine crackles (Velcro crackles) on chest examination. Clubbing of the fingers is seen in 40% to 75% of patients and is a late finding in the disease course. Cardiac examination is usually normal except in the middle or late stages of the disease, when findings of pulmonary hypertension (e.g., augmented P_2, right-sided lift, and S_3 gallop) and cor pulmonale may become evident. Similarly, cyanosis is a late manifestation indicating advanced disease. Spontaneous pneumothorax rarely occurs.

Blood and Serologic Studies

An elevated erythrocyte sedimentation rate, low-titer antinuclear antibodies, and rheumatoid factor have been identified in some of these patients.

Chest Imaging Studies

Chest Roentgenography. The typical finding in patients with IPF is peripheral reticular opacities with a netlike appearance of linear or curvilinear densities, with predominance at the lung bases (Fig. 57-20). A coarse reticular pattern or multiple cystic or honeycombed areas (i.e., coarse reticular pattern with translucencies measuring 0.5–1.0 cm in diameter) are roentgenographic findings that correlate with advanced disease and poor prognosis (see Figs. 57-6 and 57-7). Chest roentgenographic evidence of reduced lung volumes is usually present unless there is associated obstructive airway disease.

Pleural abnormalities are uncommon in IPF; their presence should suggest another diagnosis, such as collagen vascular disease (especially rheumatoid arthritis or systemic lupus erythematosus), mitral valve disease, congestive heart failure, asbestosis, infection, drug-induced lung disease, or lymphangitic carcinomatosis (see Table 57-5).

Computed Tomography Scan. CT plays a major role in the evaluation of pulmonary parenchymal diseases, especially IPF.[14,34] HRCT is useful in the differentiation of IPF from other ILDs, the determination of the extent and severity of disease activity, and most importantly, the detection of disease, especially in patients with normal or minimal change on plain chest roentgenograms. HRCT findings in IPF include a marked peripheral (subpleural) distribution of the interstitial densities. The involvement is patchy, with areas of reticulation intermingled with areas of normal tissue, often associated with cystic spaces 2 to 4 mm in diameter (see Fig. 57-11). Early disease appears as patchy, predominantly peripheral, subpleural reticular opacities and minor degrees of honeycomb change. In more advanced disease, a more diffuse reticular pattern in the lower lung zones with thickened interlobular septa and intralobular lines progresses to traction bronchiectasis and subpleural fibrosis.[12]

One of the key findings indicating the diagnosis of IPF is the presence of honeycomb cysts in a basilar subpleural distribution. Honeycomb changes appear on the HRCT scan as variably sized cystic spaces that share walls and frequently stack upon one another in several layers.[35] Ground-glass opacities are common but of mild severity and characteristically much less extensive than the reticular pattern. Architectural distortion, which reflects lung fibrosis, is often prominent.

Combined lower lobe pulmonary fibrosis and upper lobe emphysema has been recently described as a new computer tomography–defined syndrome (Fig. 57-21).[36,37] Smoking appears to be the predominant risk factor for this disorder. Patients with this entity are primarily males with a mean age of 65 years who have relatively preserved lung volumes but marked reductions in D_{LCO} on pulmonary function testing. Limited data suggest that these patients with IPF and coexisting emphysema are more likely to require long-term oxygen therapy, develop pulmonary hypertension, and may have worse outcome than those without emphysema.[38]

Identification of a relationship between pulmonary function testing and HRCT findings remains incomplete. FVC, D_{LCO}, arterial PO_2 measured at peak exercise, and oxygen desaturation during exercise are the physiologic parameters that best correlate with the global extent of disease on HRCT.[39,40] In one study, D_{LCO} was the physiologic characteristic most highly correlated with HRCT findings.[41] Serial HRCT scanning showed that the changes over time in the total extent of the disease were similar to those changes observed in D_{LCO} and FVC.[40] HRCT plays an important role but has not replaced lung biopsy in the diagnosis and assessment of most ILDs. In the case of IPF, connective tissue diseases (particularly scleroderma) and asbestosis may cause a similar HRCT appearance (except for the presence of parenchymal bands of fibrosis and pleural plaques in patients with asbestosis). Patients with chronic hypersensitivity pneumonitis can have similar reticular opacity or honeycombing, but often lack the bibasilar predominance seen in IPF.[42]

Studies evaluating the ability of HRCT scanning to diagnose IPF accurately have found that HRCT significantly increases the level of diagnostic confidence. In general, the sensitivity for a confident diagnosis is low (~48%) but the specificity is high (~95%).[43–47] The accuracy of a confident diagnosis of IPF made on HRCT by a trained observer appears to be about 90%.[42,48–50] Less experienced observers are substantially less accurate than experienced observers.[48] An HRCT pattern highly suggestive of the diagnosis of IPF is associated with a very poor prognosis.[51] Patients with basilar honeycombing have a worse survival than those without honeycombing on the HRCT scan but with a histopathologic

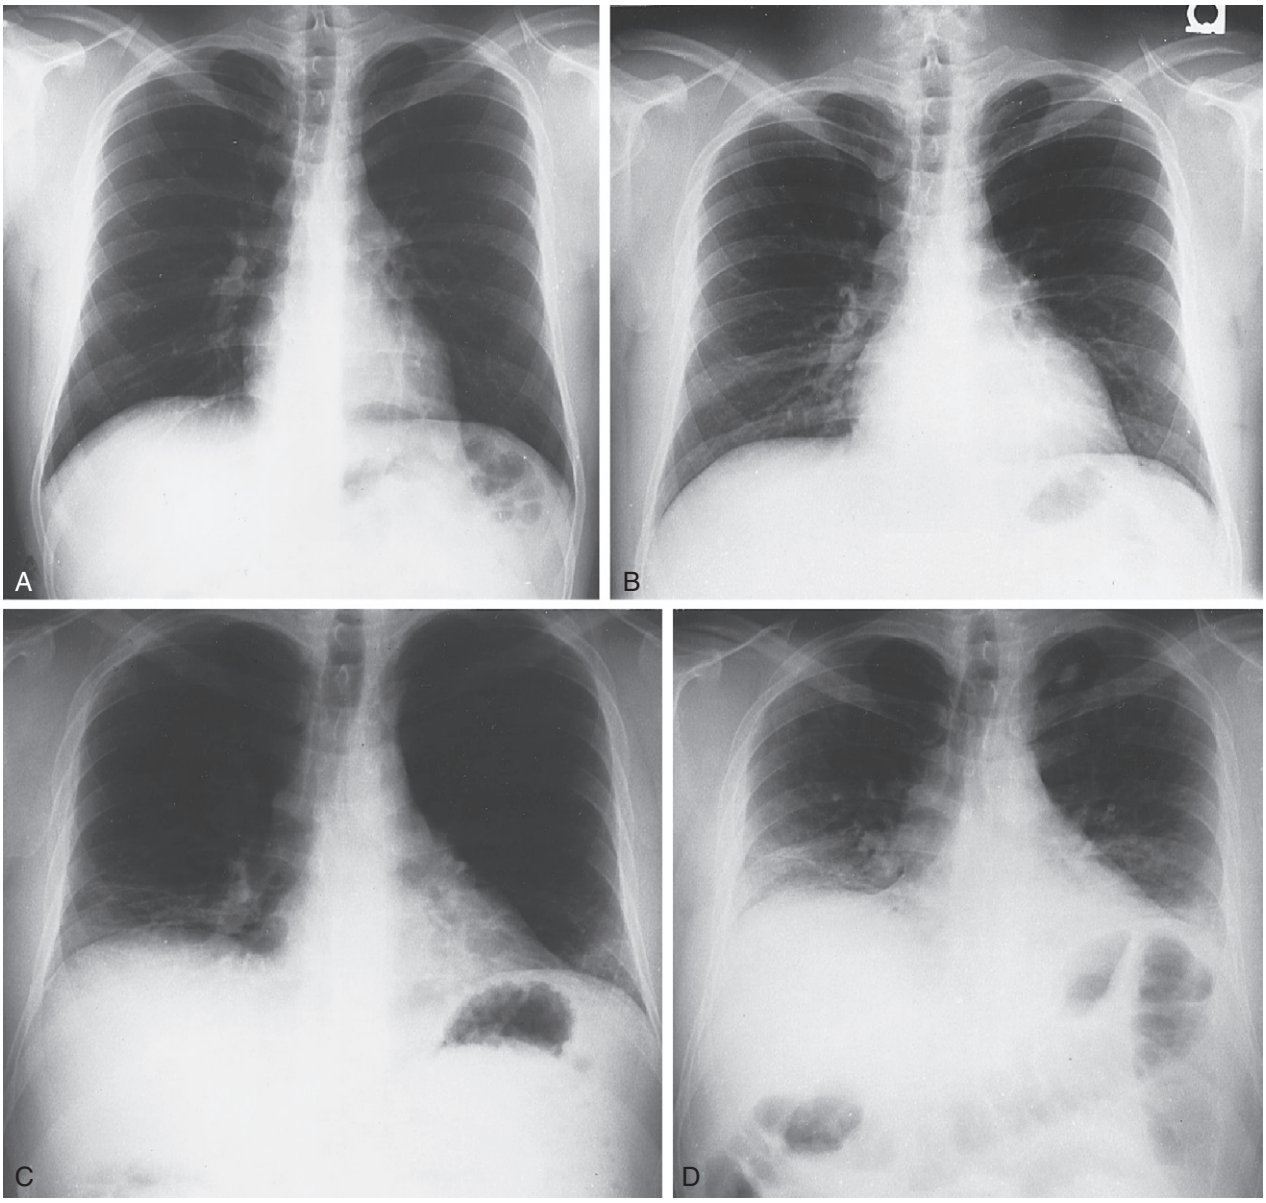

FIGURE 57-20 ■ Serial chest radiographs from a patient with IPF. **A,** The posteroanterior radiograph of the chest was obtained at the time of onset of breathlessness with exercise and mild cough. The chest appears normal. **B,** The follow-up film reveals progressive loss of lung volume and bibasilar, predominantly reticular opacities. The patient had stopped regular exercise because of breathlessness with exertion. **C,** Progressive changes are evident, with severe loss of lung volume. Predominantly in the lower lung zone are seen diffuse, bilateral, coarse reticular opacities typical of the radiographic appearance of the middle to late stage of pulmonary fibrosis. **D,** Continued disease progression is evident, with honeycombing and pulmonary hypertension. Open-lung biopsy revealed usual interstitial pneumonia with extensive fibrosis and histologic honeycombing. Treatment with corticosteroids and cyclophosphamide (Cytoxan) was started, but the patient experienced a progressive decline in functional status and died 6 months after lung transplantation.

diagnosis of UIP.[35] In a multivariate analysis of a large multicenter trial, it was found that extent of reticulation and honeycombing on HRCT is an important independent predictor of mortality in patients with IPF.[41]

Other Imaging Techniques

Gallium Scanning. Lung scanning with radioactive gallium (^{67}Ga) is a noninvasive test for staging the "alveolitis" found in ILDs, particularly sarcoidosis. Unfortunately, ^{67}Ga lung scanning is not recommended in the routine evaluation of IPF because inflammation is not a prominent feature, it is difficult to interpret, it is not specific, and a negative scan does not exclude disease.

Ventilation-Perfusion Lung Scanning. Ventilation-perfusion lung scanning is not recommended as a routine part of the evaluation. In most parenchymal diseases, ventilation-perfusion scanning reveals an inhomogeneous reduction of blood flow, ventilation, or both. Two types of perfusion abnormalities occur in IPF:

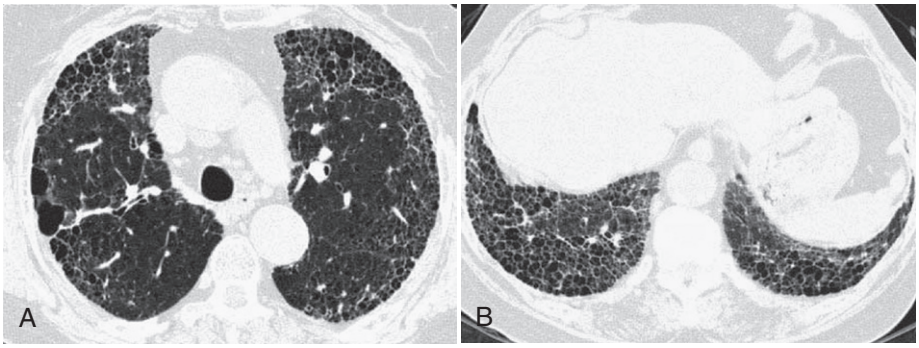

FIGURE 57-21 ■ Combined pulmonary fibrosis and emphysema. CT images from a 69-year-old woman with a 12-month history of worsening cough and dyspnea. She is a current heavy smoker. **A,** Upper zones of the lungs show emphysema and mild patchy peripheral reticular opacities. **B,** Lower zones of the lungs show emphysema and architectural distortion with patchy peripheral reticular opacities and extensive honeycombing lesions.

nonsegmental inhomogeneities, probably due to a localized loss of the capillary bed, most often in the lower lobes; and increased perfusion of the upper lung zones, resulting from pulmonary hypertension, which induces an upward shift in the gradient of capillary perfusion. Ventilation scans often reveal patchy, nonsegmental areas of decreased ventilation, reflecting regions of airway obstruction or alveolar destruction. Patchy areas of high and low ventilation-perfusion matching usually occur, with a few areas of well-maintained ventilation-perfusion matching. These findings of mismatching of ventilation and blood flow help explain the hypoxemia and high Vd/Vt ratio found in many of these patients at rest.

Magnetic Resonance Imaging for Differentiating Inflammation and Fibrosis

Although the traditional approach to lung imaging using HRCT consisting of 1-mm slices is increasingly being augmented by novel methods, the role of these techniques in IPF and other ILDs remains uncertain. MRI has several advantages over CT, including speed of imaging, lack of ionizing radiation, and ability to identify tissue characteristics at a nuclear level that may allow for novel assessments of lung function and microstructure.[52] In a recent study, 10 patients with IPF and 16 with NSIP were examined by comparing 3-T MRI of the lung to the morphologic findings on surgical biopsy.[53] Inflammation-predominant biopsy sites showed an early enhancement pattern on dynamic studies and high-signal intensity on T2-weighted triple-inversion black-blood turbo spin-echo (TSE) images compared with fibrotic areas. These results indicate that qualitative analysis of dynamic T1-weighted three-dimensional turbo field-echo magnetic resonance images obtained at 3-T may be helpful for differentiating inflammation- and fibrosis-predominant lesions.

Imaging of Fibrogenesis by Positron Emission Tomography. The putative role of physiologic imaging using ^{18}F-2-fluoro-2-deoxy-D-glucose (FDG) positron emission tomography (PET) scans in IPF has been recently explored in few patients without clear results.[54] In general, the lungs of patients with IPF appear to show increased uptake of FDG on PET. Some studies have suggested that cis-4-^{18}F-fluoro-L:-proline [^{18}F-proline] may be a reliable marker for fibrosis formation. Recently, this radioligand was tested for in patients with IPF.[55] PET acquisition was performed 1, 2, and 3 hours after injection of 400 MBq ^{18}F-proline. Surprisingly, low uptake of ^{18}F-proline was found in the lungs of all patients with IPF. The highest uptake was seen at 2 hours postinjection, with a decline at 3 hours past injection. The authors speculate that this low uptake may be due to the slow nature of fibrogenesis or to the relatively low dose of proline that can be used. Further research is needed to know if imaging through PET has a role in the diagnosis or prognosis of ILDs.

Pulmonary Function Tests

The lung volumes (TLC, functional residual capacity, and residual volume) are reduced in IPF. Early on, the lung volumes may be normal, especially in patients with superimposed chronic obstructive pulmonary disease (COPD). Lung volumes are higher in smokers with IPF compared with those who have never smoked.[18] As mentioned previously, a group of smokers develop a combined IPF and emphysema and show almost normal lung volumes, even in advanced disease.[36,37] Expiratory flow rates (FEV_1 and FVC) may be decreased because of the reduction in lung volume, but the FEV_1/FVC ratio is maintained. Because of the increased static elastic recoil found in these patients, flow rates (at any given lung volume) are often increased (see Figs. 57-15A and 57-17).

Patients with IPF are tachypneic, with rapid shallow breaths, probably because of increased work of breathing. This rapid respiratory rate presumably results from altered mechanical reflexes, caused by the increased elastic load, vagal mechanisms, or both, because no defined chemical basis for the hyperventilation has been identified (see Fig. 57-18).

The D_{LCO} is reduced, often prior to the loss of lung volume. The decrease in the D_{LCO} results from both a contraction of the pulmonary capillary volume and the presence of ventilation-perfusion abnormalities. Resting arterial blood gases are usually abnormal, revealing

hypoxemia and respiratory alkalosis. The major cause of resting hypoxemia is ventilation-perfusion mismatching, and it is not due to either impaired oxygen diffusion, as was originally suspected, or to anatomic shunts. With exercise, the (A – a) P_{O_2} widens, and the arterial P_{O_2} and oxygen saturation fall. During maximal exercise, 20% to 30% of the exercise-induced widening of the (A – a) P_{O_2} may be caused by some impairment of oxygen diffusion. Importantly, the abnormalities identified at rest do not accurately predict the magnitude of the abnormalities seen with exercise (see Fig. 57-19). In addition, gas exchange during exercise has been demonstrated to be a sensitive parameter for following the clinical course.

In patients with IPF, a highly significant correlation has been reported between the 6-minute walk distance test (6MWD) and $D_{L_{CO}}$ as well as $\dot{V}_{O_2}$max and is a strong predictor of mortality.[56] The 6MWD is difficult to perform in patients with advanced lung disease, however, and variability is common.

The 15-steps Climbing Test Oximetry has been found useful for estimating ventilatory reserve in patients with COPD and for predicting postoperative complications of lung resection.[57] In a recent study, it was shown that the desaturation measured by the 15-steps Oximetry Test in IPF patients is comparable with the desaturation measured by the cardiopulmonary exercise test and the 6MWD test, suggesting it may be a reliable tool for monitoring IPF progression and for evaluating the need for oxygen supplementation. This test may serve as a surrogate marker of $\dot{V}_{O_2}$max and an alternative to the 6MWD in this setting.[57]

During exercise, patients with IPF increase their minute ventilation primarily by increasing their respiratory frequency (see Fig. 57-18). This method of increase differs from that in normal subjects, in whom increased ventilation during mild exercise occurs by an increase in the tidal volume (V_T) rather than respiratory rate. Thus, patients with IPF have elevated minute ventilation during exercise that is in part related to the increase in V_D. In addition, the V_D/V_T ratio is increased at rest and is maintained or decreases only slightly with exercise. Occasionally, the V_D/V_T ratio increases in ILDs that have a prominent pulmonary vascular component, such as scleroderma or Langerhans cell histiocytosis.

Pulmonary Hemodynamics

New evidence suggests pulmonary arterial hypertension (PAH) is relatively common in IPF and may contribute substantially to functional status, quality of life, morbidity, and mortality.[58] The prevalence of PAH complicating the course of patients with IPF has been reported to occur in 32% to 85% of patients, being more frequent in advanced disease.[58] The most appropriate method to detect PAH noninvasively is transthoracic (Doppler) echocardiography. Unfortunately, echocardiography may be inaccurate in estimating pulmonary arterial systolic pressure in patients with ILD.[59] Right heart catheterization (RHC) is the "gold standard" for the hemodynamic evaluation of the pulmonary circulation and diagnosis of PAH but is an invasive technique. RHC may be necessary, however, to document the severity of PAH and potential right ventricular dysfunction. Abnormalities in gas exchange and exercise capacity seem to have a significant association with PAH in IPF. Thus, exaggerated exercise oxygen desaturation, out-of-proportion reduction of $D_{L_{CO}}$, and supplemental oxygen requirement should raise suspicion of (and may be a useful surrogate for) the presence of underlying PAH.[59,60] Brain natriuretic peptide (BNP) concentrations predicted moderate to severe PAH with 100% sensitivity and high specificity (89%) in a small cohort of patients with pulmonary fibrosis.[61] This study requires further validation.

Pathologic vascular findings in IPF consist of changes in the arteries, arterioles, and venules as well as destruction of the capillary bed.[62] Advential thickening around the pulmonary vessels reflects an increase of connective tissue. Smooth muscle cell hypertrophy and proliferation and collagen and elastin accumulation occur in the media of the small muscular pulmonary arteries, and distal pulmonary arterioles become muscularized. In addition, there may be extensive intimal hyperplasia, fibrosis, and reduplication of the inner elastic lamina in the small muscular pulmonary arteries in IPF.

Supplemental oxygen is the most obvious choice for prevention or treatment of PAH; however, there are no data supporting favorable effects of oxygen on survival in PAH associated with IPF. Vasodilators agents are currently being studied, but one must recognize that decreased physiologic vasoconstriction in low ventilation-perfusion lung units may worsen shunt and hypoxemia in IPF.

Endothelin-1 (ET-1) receptor antagonists have been useful in patients with PAH (mostly in primary PAH or associated with connective tissue disease). Clinical trials in PAH associated to IPF are ongoing (Table 57-9). Prostacyclin (prostaglandin I_2 [PGI_2]) analogues used via inhalation could maintain (or even improve) ventilation-perfusion matching and could have a beneficial effect targeting PAH. In one study, inhaled iloprost decreased mean pulmonary artery pressure without changes in shunt flow,[63] suggesting the utility of selective pulmonary vasodilation in patients with PAH/IPF. A randomized clinical trial of inhaled iloprost for this patient group has been recently completed, although the results have not yet been published.[64] Sildenafil, a phosphodiesterase-5 inhibitor, promotes vasodilation and decreases smooth muscle proliferation and vascular remodeling. In an open-label study of treatment with sildenafil for 3 months in a small cohort of patients with PAH and IPF, a modest but significant improvement in 6MWD was noticed.[65] Several randomized clinical trials are currently ongoing (see Table 57-9).

Abnormalities during Sleep

Many patients with IPF, especially those with low daytime arterial oxygen saturation or a history of snoring during sleep, develop sleep disturbances characterized by reduced rapid eye movement sleep, lighter and more fragmented sleep, and hypoxemia during rapid eye movement sleep. Severe hypoxemia occurs in the

absence of obstructive sleep apnea or changes in breathing pattern. Tachypnea persists during sleep. Identification and correction of the sleep disturbance may reduce morbidity and improve quality of life and patient survival. In a recent study, obstructive sleep apnea was confirmed in two thirds of IPF patients with complaints suggestive of sleep apnea. An increased body mass index and a significant impairment in pulmonary function testing may be predictors of obstructive sleep apnea in this population.[66]

Histopathology

The gross appearance of the lungs in IPF reveals a distinctive nodular pleural surface, sometimes with a marked cirrhotic appearance. The histopathologic pattern in IPF is UIP. UIP is characterized by a pattern quite distinguishable even on low-power magnification because of its characteristic heterogeneous, predominantly subpleural distribution (Fig. 57-22). This striking heterogeneous appearance is characterized by the presence of small areas of residual normal or nearly normal lung interspersed among extensively scarred parenchyma and microscopic honeycombing (areas characterized by enlarged air spaces lined by bronchiolar epithelium, often filled with mucin and variable numbers of inflammatory cells) abutting areas of active proliferation of fibroblasts and myofibroblasts (Figs. 57-23 through 57-25).[67] These discrete areas of fibroblastic proliferation have been termed *fibroblastic foci* and are essential to

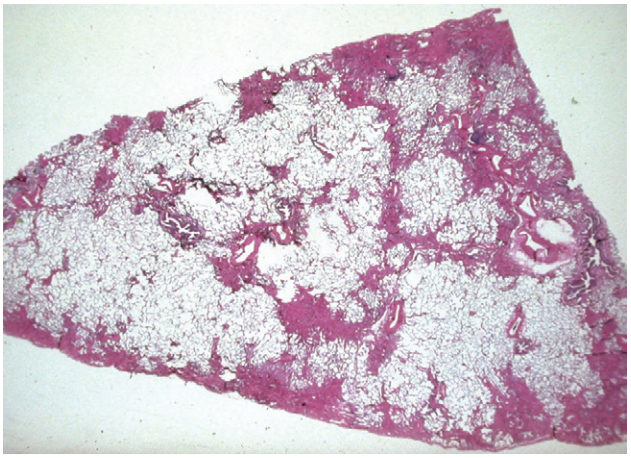

FIGURE 57-22 ■ Usual interstitial pneumonia pattern often shows a striking subpleural distribution. This low-power photomicrograph is from an area without the usual remodeling of the lung architecture with cystic (honeycomb) changes. (Courtesy of Thomas V. Colby, MD, Mayo Clinic, Scottsdale, AZ.)

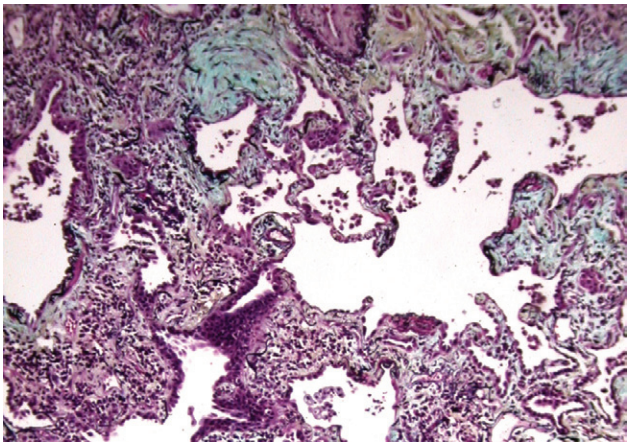

FIGURE 57-24 ■ Usual interstitial pneumonia pattern. Two fibroblastic foci of loose organizing connective tissue are seen in the top center and top right of the photomicrograph adjacent to an area of dense fibrosis. (Courtesy of Thomas V. Colby, MD, Mayo Clinic, Scottsdale, AZ.)

the histopathologic diagnosis of UIP[68] (see Fig. 57-24). Fibroblastic foci are composed of small dome-shaped collections of spindle-shaped fibroblasts and myofibroblasts within myxoid stroma, covered by hyperplastic alveolar lining cells. Generally, minimal interstitial inflammation is present in UIP; if present in significant amounts, the histopathologic diagnosis should be reconsidered. However, chronic inflammation, lymphoid aggregates with germinal centers, and even acute inflammation may be prominent around honeycomb areas, likely related to poor clearance from the areas of scarred lung.[67]

Bronchogenic carcinoma (all histologic types) has been identified with increased frequency in advanced IPF.[69] It has been postulated that carcinoma arises from the metaplastic bronchiolar epithelium that develops in these patients, but the pathogenic mechanisms are unclear. Interestingly, a number of the reported cases occurred in patients with familial IPF.

Etiologic Factors and Pathogenic Mechanisms

The inciting factors in the development of IPF are unknown. A widely held hypothesis is that this disorder occurs in susceptible individuals following some unknown stimuli. Inciting agents initiate an uncontrolled cascade of events that evolve to the fibrotic process. Smoking presents the most significant association with IPF, particularly for individuals who were ever smokers, with odds ratios (ORs) varying from 1.6 to 9.4.[70] The same association has been found in familial IPF. In a family-based case-control study of familial interstitial pneumonia, Steele and colleagues[71] identified 111 families, with 309 affected and 360 unaffected individuals. Adjusting for age and gender, ever smoking was strongly associated with familial interstitial pneumonia (OR, 3.6; 95% confidence interval [CI], 1.3–9.8). Some occupational and environmental exposures—primarily to wood

and metal dusts—have shown increased association with IPF.[70] The presence of Epstein-Barr virus found in some patients has led to speculation that chronic viral infection might play a role in the etiology of IPF,[72] but this virus has been found in other fibrotic lung diseases, as well as in many controls. Higher incidence of gastroesophageal reflux (GER) has been found in patients with IPF.[73] GER is frequent, however, in the normal population, as well as in patients with other advanced lung diseases, including cystic fibrosis, COPD, and fibrosis associated with scleroderma.[74]

The role of host genetic factors and their interactions with environmental factors leading to IPF is unknown. Numerous gene polymorphisms have been examined, and only a few of them have demonstrated confirmed (usually weak) association. Moreover, putative associations have not been corroborated in independent cohorts.

An important advance in our understanding of ILD has been the recognition that UIP appears to be a distinct pathophysiologic entity characterized by minimal inflammation and chronic fibroproliferation due to abnormal parenchymal wound healing.[75,76] This paradigm suggests the pathologic process of UIP is the result of persistent remodeling (abnormal wound healing) of the lung parenchyma. Multiple "microinjuries" damage and activate alveolar epithelial cells, which in turn provoke a profibrotic microenvironment.[77] Alveolar epithelial cells secrete growth factors and induce migration and proliferation of fibroblasts and differentiation into myofibroblasts. Aggregates of subepithelial fibroblasts-myofibroblasts (fibroblastic foci) and alveolar epithelial cells produce matrix-metalloproteinases 2 and 9 that may increase basement membrane disruption and allow fibroblast-myofibroblast migration into the alveolar spaces. In addition, alveolar epithelial cells induce an antifibrinolytic environment in the alveolar spaces, enhancing wound clot formation. Current evidence suggests that the tissue-factor–dependent extrinsic pathway is the predominant mechanism by which the coagulation cascade is locally activated in the lungs of patients with pulmonary fibrosis.[78] Both intra-alveolar and interstitial myofibroblasts secrete extracellular matrix proteins, mainly collagens. An imbalance between interstitial collagenases and tissue inhibitors of metalloproteinases provokes the progressive deposition of extracellular matrix.[79] Signals responsible for myofibroblast apoptosis seem to be absent or delayed in UIP, increasing cell survival.[80] These myofibroblasts produce angiotensinogen and hydrogen peroxide that have been implied in alveolar epithelial cell death, further impairing reepithelialization.[81,82] Although the molecular mechanisms that lead to end-stage pulmonary fibrosis in the IIPs are poorly understood, data support this "abnormal wound healing" hypothesis in UIP.[83–87] At least in part, the abnormal communication between alveolar epithelial cells and myofibroblasts may be provoked by an aberrant recapitulation of embryologic programs.[88,89]

One of the intriguing observations regarding IPF is that the disease is clearly associated with aging; it usually occurs in individuals older than 50 years, reaching a peak in subjects of 60 to 65 years old. In this context, two recent studies have shown that mutations in the genes encoding telomerase components are implicated in familial pulmonary fibrosis.[90,91] The same investigators demonstrated that patients with sporadic IPF have shorter leukocyte telomeres than age-matched controls and that some of them (10%–25%) had telomere lengths below the first percentile for their age.[92,93] Importantly, it was also determined that IPF patients had short telomeres in alveolar epithelial cells, suggesting that these cells may be the main lung culprit of this pathologic process.[92] Telomeres play a central role in cell fate and aging by adjusting the cellular response to stress and growth stimulation on the basis of previous cell divisions and DNA damage; their shortening has been associated with aging and several diseases.[94,95]

Diagnosis

The most definitive method of establishing a diagnosis is by surgical lung biopsy.[96] Open- or thoracoscopic lung biopsy is indicated because it provides an accurate diagnosis; it excludes neoplastic and infectious processes that occasionally mimic chronic, progressive interstitial disease; it may also identify a more treatable process than originally suspected (e.g., chronic hypersensitivity pneumonitis); and it provides a better assessment of disease activity.[28] Some studies have addressed the accuracy of the combined clinical and radiographic diagnosis of IPF.[43,45] In both studies, clinicians were blinded to the results of the surgical lung biopsies, which were used as the gold standard for diagnosis. The clinical diagnosis of IPF had a sensitivity of 48% and a specificity of 89% compared with the histopathologic diagnosis, which had a sensitivity of 62% and a specificity of 97%.[43,45] These studies argue that when the clinical and radiographic diagnoses are consistent, IPF can be confidently diagnosed. They also demonstrate, however, that this consistency is present in only about half of patients with biopsy-confirmed UIP. Furthermore, experts in the field performed these studies, and it is unclear how the outcome would vary with community physicians less familiar with these processes. In this context, significant disagreement has been reported regarding the diagnosis of IIPs between physicians based in communities compared with those in academic centers.[97] Importantly, community physicians were more likely to make a diagnosis of IPF, which has important implications, as individual patients with other ILDs (e.g., hypersensitivity pneumonitis, NSIP, or collagen vascular disease–associated ILD) are more likely to respond to immunosuppressive treatment, whereas patients with IPF should be referred, whenever possible, for participation in therapeutic trials or evaluated for lung transplant. In addition, this study also confirms that a multidisciplinary team approach between clinicians, radiologists, and pathologists improves interobserver agreement and enhances diagnosis specificity.[97]

Staging of Disease Activity and Predicting Outcome

The long-term survival in IPF is distinctly poor, with only a 20% to 30% survival 5 years after the time of diagnosis.[98] However, the rate of progression is variable. Attempts to predict who will respond to treatment have been largely disappointing primarily because the disease is relentlessly progressive with all the therapies used until now.

Clinical Features. Younger patients tend to have less fibrosis than do older patients, and younger patients and women survive longer than older patients and men. In a recent study, it was found that the percentage of monthly worsening in oxygen saturation is high in males, suggesting differences in disease progression according to gender and may explain the better survival of females with IPF.[99] Current smoking (i.e., at the time of presentation) was associated with improved survival in patients with IPF whereas heavy smoking (i.e., higher number of pack-years) was associated with a worse prognosis.[22] In addition, pulmonary fibrosis combined with emphysema and the accelerated variant of IPF that display the worst survival seems to be more frequent in smokers.[33,36,37]

In a recent study, it was shown that the Medical Research Council (MRC) Chronic Dyspnea Score estimated at the time of diagnosis is predictive of survival and may aid clinicians in assessing the prognosis of new cases of IPF.[100]

Serum Studies. The presence of immunologic markers, including autoantibodies, elevated sedimentation rates, circulating immune complexes, and increased serum immunoglobulins, has not been shown to influence the overall natural history of IPF.

Serum surfactant protein (SP) A and SP-D have prognostic value for mortality in patients with IPF.[101] A recent study showed that after controlling for known clinical predictors of mortality, an increased serum SP-A level is a strong and independent predictor of early mortality among patients with IPF. A prediction model containing SP-A and SP-D was substantially superior to a model with clinical predictors alone.[102]

Chest Roentgenography and High-Resolution Computed Tomography Scanning. A general pattern of evolution is seen in serial chest roentgenograms. The early changes include hazy opacities with reduction in lung volumes that progress to a reticular pattern and finally end in coarser, cystic areas of honeycombed lung. Unfortunately, the chest roentgenogram is not a useful monitor of the degree and extent of lesions. In fact, the only roentgenographic abnormality that correlates with the histologic pattern is honeycombing. Furthermore, the roentgenogram may demonstrate no changes even while clinically apparent physiologic deterioration is occurring. Another major problem with using the chest roentgenogram to follow the disease course or to estimate the stage of disease is that there is considerable interobserver variability in the interpretation of these studies.

HRCT scanning in IPF may be useful in staging disease activity. The finding of a higher extent of ground-glass opacities and a lower extent of reticular opacities on the initial HRCT identifies those patients with early disease who are the most likely to survive longer and respond (transiently) to corticosteroids.[103] Patients with a typical HRCT appearance of UIP experience the highest mortality.[51]

In a recent study, it was shown that by univariate logistic regression analysis, greater extent of fibrosis and lower skewness and kurtosis values by HRCT predicted short-term mortality during follow-up. The multivariate logistic regression analysis showed that the single best predictor of mortality during follow-up was the visual extent of fibrosis on CT images, and there was little additional predictive power to be gained from the more quantitative measures.[104]

Pulmonary Physiologic Tests. Reductions in the vital capacity correlate with the degree of fibrosis present and show a relationship with the overall histologic derangements. A marked reduction in the vital capacity (<50% of predicted) is associated with pulmonary hypertension and a reduced 2-year survival. Patients with normal Dl_{CO} values usually do not have significant gas-exchange abnormalities, whereas patients with values below 70% of predicted frequently have such changes at rest or with exercise. Survival is longer in patients with a more normal Dl_{CO} (>45% of predicted value). A marked reduction of the Dl_{CO} and resting hypoxemia are associated with pulmonary hypertension and decreased survival.

Patients with advanced disease and severe fibrotic process have greater abnormalities of the (A – a) Po_2 when compared with those with early disease and core preserved lung architecture. Alterations in gas exchange during exercise when compared with other indices of lung function correlate best with histopathologic findings. Serial measurements of gas exchange during exercise appear to be the best predictors of survival. In a recent study, it was demonstrated that the predictive ability of serial changes in physiology varied when patients are stratified by the presence/absence of desaturation 88% during a baseline 6MWT. For patients with baseline saturation less than 88%, the strongest observed predictor of mortality was serial change in DL_{CO}. For patients with saturation greater than 88% during their baseline walk test, serial decreases in FVC and increases in desaturation area significantly predicted subsequent mortality.[105] In summary, pulmonary function testing is useful in establishing the presence of impairment in IPF and following its course and response to therapy. The severity of the initial abnormalities in FVC, DL_{CO}, arterial Po_2, and (A – a)Po_2, as well as oxygen desaturation on a 6MWD,[56] correlate with poorer survival. Likewise, changes in DL_{CO}, TLC, FVC, arterial Po_2, oxygen saturation, and (A – a)Po_2 during follow-up are predictive of survival time after adjustment for baseline values.[106,107]

Bronchoalveolar Lavage. It has been suggested that the BAL cellular constituents reflect the state of the pulmonary inflammatory response. Unfortunately, many studies have failed to demonstrate a clear distinction between diseases based on the predominant cell type present in the lavage specimens. IPF is characterized by a severalfold increase in the total number of

inflammatory cells recovered from the respiratory tract with an increase in the percentage of neutrophils and eosinophils. Studies evaluating the association of BAL fluid cellular constituents and mortality have yielded conflicting results about the prognostic value of BAL and were limited by the size of the study cohort and the duration of follow-up.[108]

Turner-Warwick and Haslam[109] found that patients who failed to improve had elevated neutrophil and eosinophil counts throughout their course. Recent findings tend to confirm these findings, suggesting that increased BAL fluid neutrophil percentage may be an independent predictor of early mortality among persons with IPF.[110] The impact was most important in the first year of follow-up and attenuated with time.

In one study, it was found that SP-A is reduced in IPF, and decreases in its concentration referenced to total phospholipid (a marker of surfactant to normalize to the surface sampled by lavage and recovery) predict an adverse clinical outcome and poorer survival.[101]

Histopathology. Until recently, no specific histologic feature, other than end-stage fibrosis and honeycombing, has been shown to correlate with survival in UIP.[75,111] It has been proposed that the earliest and most characteristic manifestation of ongoing lung injury in UIP is the development of multiple fibroblastic foci.[67,68] The prognostic significance of these aggregates of fibroblasts and myofibroblasts in surgical lung biopsies from patients with IPF is unclear, and several studies have given contradictory results.[111-115] The effect of sample size, tissue sampling bias, and the different techniques for assessing the number of foci may account for these results. In general, detailed quantification of fibroblast foci on surgical lung biopsies may not be a consistent predictor of patient survival in this disease.

Prediction Models. Several investigators have attempted to identify parameters that best predict the clinical course and prognosis of IPF.[56,106,116-118] Individual changes in dyspnea score, TLC, FVC, arterial Po_2, oxygen saturation, or (A – a)Po_2 over 6 and 12 months may be useful as surrogate end points in monitoring therapeutic efficacy in individual patients. Prediction models based on combining multiple baseline clinical, radiologic, or physiologic measurements have been derived from large groups of carefully selected patients with IPF and appear to perform well as predictors of outcome.[22,117] Using hierarchical multivariable analysis of clinical, radiologic, and extensive physiologic variables (CRP), King and associates[22] developed a model that allows clinicians to make more precise prognostic estimations about patients with IPF. This model included the parameters of age, smoking history, clubbing, extent of profusion of interstitial opacities, presence or absence of pulmonary hypertension on the chest radiograph, percent predicted TLC, and arterial Po_2 at the end of maximal exercise. Although the CRP score is an accurate predictor of survival in IPF, it requires both detailed radiographic analysis and exercise physiologic measurements, neither of which is readily available to many physicians. This may limit its utility as a predictor of survival for those in general practice.

Wells and coworkers[117] identified a composite physiologic index (CPI) closely reflecting the morphologic extent of pulmonary fibrosis while accounting for the extent of emphysema (a finding commonly present in smokers with IPF). The CPI correlated strongly with disease extent on CT and mortality and was more accurate than any individual pulmonary function test.[117] However, its value in clinical practice appears limited.

Outcome and Causes of Death. Clinical deterioration in patients with IPF is expected. Most patients experience episodes of worsening shortness of breath, decreased exercise tolerance, or other decline in functional status during the course of their illness. Disease progression may be difficult to distinguish from disease-associated complications and adverse effects of therapy[119] (Table 57-10).

In a study of 42 consecutive patients with IPF who underwent a postmortem over a 9-year period, it was found that IPF by itself was the immediate cause of death in half of the patients either by acute exacerbation or from the gradual progression of the disease.[120] Other respiratory causes of death included pneumonia and aspiration. Cardiovascular disease including arrhythmia, myocardial infarction, and severe cor pulmonale was found to be the cause of death in 20% of subjects. Evidence of pulmonary hypertension was present in the

TABLE 57-10. Mortality from Disease or Therapy: Percent of All Deaths

PROGRESSIVE RESPIRATORY FAILURE
Gradual progression or acute exacerbation
Mortality: 39%
BRONCHOGENIC CARCINOMA
Mortality: 10%
Excess risk of 14:1 compared with general population; same histologic distribution as seen in population
CARDIOVASCULAR DISEASE
Mortality: 24%
Right ventricular hypertrophy, cor pulmonale due to progressive, long-standing pulmonary hypertension and right-sided heart failure
Left ventricular heart failure usually due to concurrent ischemic heart disease
PULMONARY INFECTION
Mortality: 2%–4%
Increased incidence: corticosteroids and cytotoxic therapy may further increase risk
PULMONARY EMBOLISM
Mortality: 3%–7%
Pulmonary angiography frequently required to make diagnosis
PNEUMOTHORAX
Occurs less often than in other interstitial lung diseases
May be difficult to manage

Adapted from Panos RJ, Mortenson RL, Niccoli SA, et al: Clinical deterioration in patients with idiopathic pulmonary fibrosis: Causes and assessment. Am J Med 88:396–404, 1990.

postmortem of 45% patients and was the immediate cause of death in 2 of them. Pulmonary embolism appears to be relatively common in IPF lung transplant recipients, although its prevalence is unknown.[121] Importantly, it has been shown that patients with IPF have a higher prevalence of coronary artery disease.[122] Also, patients with clinically stable IPF exhibit not only right ventricle diastolic and systolic dysfunction but also impaired left ventricle diastolic filling, while the systolic function is preserved.[123]

Therapeutic Approach

IPF is a progressive and fatal disorder without spontaneous remission, and no therapy to date has been shown to be effective. Although the natural history of IPF has not been appropriately defined, data thus far suggest the median survival after diagnosis, with or without treatment, is 2 to 3 years. Any therapy of IPF, regardless of the agent used, requires at least 1 year before its effectiveness can be assessed. For many years, IPF was treated with high dose of corticosteroids and/or immunosuppressive drugs. The basis for the use of anti-inflammatory therapies in this disease was the concept that a chronic inflammatory infiltrate led to progressive extracellular matrix deposition.

In recent years, several adequate randomized, controlled clinical trials of sufficient numbers of patients with IPF have been performed using putative "antifibrotic" drugs, but none thus far has shown significant improvements in outcome. Combination therapy with prednisone, azathioprine, and *N*-acetylcysteine (NAC) has been suggested as a reasonable choice for patients with mild to moderate disease.

Corticosteroids. Corticosteroids alone were the mainstay for the treatment of IPF, but there was never any randomized, placebo-controlled study.[124,125] However, the response to corticosteroid treatment in IPF has been almost uniformly poor.[126] In addition, significant complications can result from corticosteroid therapy, affecting the quality of life. Currently, there is no indication for the use of corticosteroids alone in the treatment of IPF.

Immunomodulatory and Antifibrotic Agents. Because of the poor responsiveness of IPF to corticosteroids, immunomodulatory agents (azathioprine or cyclophosphamide alone or in combination with corticosteroids) have been tried.[127–130]

Azathioprine. Azathioprine is a purine analogue that appears to act by the substitution of purines in DNA synthesis and by inhibiting adenine deaminase, which affects lymphocyte functions. Azathioprine has been reported to suppress natural killer cell activity, antibody production, and antibody-dependent cellular cytotoxicity. Older studies suggested azathioprine and low-dose prednisone might be useful in the treatment of patients with IPF.[128] The recommended dose for azathioprine in IPF was approximately 2 mg/kg, although the optimal dose for treating the disorder is as yet undetermined. Generally, the dose is 75 to 100 mg/day and does not exceed 150 mg/day.

Hematologic adverse effects include leukopenia, anemia, thrombocytopenia, pure red cell aplasia, and pancytopenia. Gastrointestinal complaints are the most frequent side effects, including nausea and vomiting and, less commonly, peptic ulcer disease and diarrhea. Mild elevation of hepatic enzymes has been described in approximately 5% of patients treated with azathioprine. Pulmonary complications of interstitial pneumonitis and diffuse alveolar damage (DAD) have been reported in some renal transplant recipients. The carcinogenic potential of azathioprine remains to be fully defined.

N-Acetylcysteine. In a recent double-blind, randomized, placebo-controlled multicenter study, it was found that NAC, a molecular precursor to the naturally occurring antioxidant glutathione, added to prednisone and azathioprine at a dose of 600 mg three times daily, decreases the drop or preserves vital capacity and Dl_{CO} better than does prednisone and azathioprine alone after approximately 1 year of follow-up.[131] No mortality benefit was identified in this study. The efficacy of NAC monotherapy has not been examined.

Cyclophosphamide. Cyclophosphamide was formerly used as a second-line drug in patients who either failed or could not tolerate corticosteroid treatment. Cyclophosphamide is an alkylating agent of the nitrogen mustard group that is absorbed orally and activated in the liver to several cytotoxic compounds. Its mode of action is the depletion of lymphocytes, thereby suppressing lymphocyte function. The recommended dose is 2 mg/kg/day given orally as a single dose, usually with oral prednisone at 0.25 mg/kg/day. Few data are available on the length of therapy. However, a large retrospective study of well-defined, matched patients with IPF suggested that treatment with combined corticosteroid and cyclophosphamide therapy does not improve survival compared with untreated patients.[127]

In addition, cyclophosphamide therapy also has severe side effects including leukopenia, thrombocytopenia, hematuria secondary to hemorrhagic cystitis (forced fluids and frequent bladder emptying are recommended to prevent this problem), gastrointestinal symptoms (including anorexia, nausea, and vomiting), bone marrow suppression, azoospermia and amenorrhea, infection, and the development of a hematologic malignant disease.

Other Agents. A number of other immunosuppressive or putative antifibrotic agents have been reported in individual cases or in small groups of patients with IPF without success. In vitro studies suggest several mechanisms by which *Colchicine* may interrupt the processes of collagen synthesis and deposition; it may have anti-inflammatory effects as well. On the basis of these mechanisms of action, colchicine has been used as a potential therapeutic agent in IPF, but there are no data affirming the efficacy of colchicine in IPF.[132–134] *Penicillamine* inhibits collagen synthesis by interfering with collagen cross-linking and is a suppressor of T-cell function. Limited studies have not shown efficacy in idiopathic pulmonary fibrosis.[134] *Interferon beta-1a* has been shown to reduce fibroblast migration/proliferation and inhibits collagen production by fibroblasts. Unpublished

randomized clinical trials in the United States and Canada failed to show any benefit.[135,136] *Captopril* inhibits the angiotensin-converting enzyme and completely abrogates Fas-induced apoptosis in human alveolar epithelial cells. It also has been shown to inhibit fibroblast proliferation in vitro, and reduce the fibrotic lung response in vivo. A small trial showed no effect.[137] *Chlorambucil* and *vincristine sulfate*, given alone or with corticosteroids, showed no beneficial effect.[138]

New Therapeutic Approaches. Based on the new knowledge about the pathogenic mechanisms involved in IPF, and the poor results obtained with immunosuppressive drugs, newer immunomodulatory or antifibrotic agents have been tried in patients with IPF.

Interferon-γ A large, controlled trial with interferon gamma-1b noted no difference in primary end point (progression-free survival) or most secondary end points.[139] In patients defined as having milder disease (FVC ≥ 55%; defined post hoc) or treatment-adherent, a potential survival benefit was suggested.[140] However, a much larger controlled trial (826 patients) with survival as the primary end point was recently discontinued based upon lack of efficacy. The overall mortality was of 14.5% in the IFN gamma-1b and of 12.7% in the placebo group.[141] A trial using interferon-γ as a nebulized mist is now ongoing (see Table 57-9).

Pirfenidone. Pirfenidone (5-methyl-1-phenyl-2-(1H)-pyridone) is a novel antifibrotic and anti-inflammatory agent that inhibits the progression of fibrosis in animal models. Raghu and colleagues[142] reported the results of a phase II, open-label study evaluating pirfenidone. They found that pirfenidone was well tolerated with minimal side effects. In addition, treatment with pirfenidone appeared to allow discontinuation or tapering of prednisone and immunosuppressive therapy without further loss of lung function. A multicenter, randomized, double-blind, placebo-controlled study of pirfenidone versus placebo was carried out in Japanese patients with IPF, although it was stopped at 9 months.[143] Pirfenidone was effective in stabilizing the lung function and reducing the number of patients who experienced acute exacerbation of their disease (5/35 placebo-treated patients compared with 0/72 pirfenidone-treated patients).[143] A large randomized, double-blind, placebo-controlled trial has recently been completed. Unpublished data suggest a treatment benefit may exist.

Endothelin-Receptor Antagonists. ET-1 contributes to the fibrotic phenotype of fibroblasts and is a downstream mediator of profibrotic responses to transforming growth factor-β (TGF-β).[144] In a rat model, it was found that ET-1 is involved in the pathogenesis of lung fibrosis and that blockage of its receptors reduces the fibrosis.[145] *Bosentan* is a dual ET-1 receptor antagonist (ET_A and ET_B) that has been shown to be effective in the treatment of PAH. Recently, a large, randomized, multinational, double-blind, placebo-controlled trial in patients with IPF was reported.[146] A total of 154 were included in the all-treated set (bosentan, $n = 71$; placebo, $n = 83$). Bosentan did not show an improvement over placebo with respect to 6MWD (primary end point), but patients treated with this drug showed a tendency to delayed time to death or disease progression, a predefined secondary end point. A surprising and unexplained finding was that this treatment effect was significant in the subset of patients who underwent surgical lung biopsy for confirmation of diagnosis. A new clinical trial with bosentan is currently ongoing. *Ambrisentan*, a selective ET_A antagonist, is also being studied in a large clinical trial.

Etanercept. The introduction of targeted biologic agents directed against tumor necrosis factor-α (TNF-α) has represented a novel and exciting avenue for the treatment of a variety of diseases. Elevated levels of this cytokine have been detected in experimental lung fibrosis and in patients with IPF as well. In a recent study, the effect of etanercept, a recombinant soluble human TNF receptor which binds to TNF and neutralizes its activity in vitro, was explored in IPF patients.[147] Sixty-five patients (etanercept, $n = 34$; placebo, $n = 31$) completed the 48 weeks of treatment. No statistically significant differences were observed between treatment groups in the three primary end points: changes in FVC%, DI_{CO}%, and the $(A - a)Po_2$ difference (at rest) at 48 weeks. However, this can be due in part to the modest number of subjects included in the trial. In post-hoc analysis, using rate of disease progression by death or absolute reduction in FVC (L), a tendency favoring etanercept was observed.

Ongoing clinical trials are summarized in Table 57-9.

Lung Transplantation

Since the late 1980s, lung transplantation has been used for the management of a wide range of severe lung disorders, with progressive disease unresponsive to pharmacologic treatment with evidence supporting quality of life and survival benefit for lung transplant recipients. The American Thoracic Society has published guidelines for the selection of IPF patients who should be considered potential transplant candidates.[148]

Unfortunately, given the scarcity of donors and the aging and disease complications of IPF patients, transplantation is indicated only in carefully selected patients. Early referral for consideration of transplant is highly desirable. It allows an orderly process for assessment, management of areas of concern, and patient education before active listing.[148]

Transplantation should be considered for patients who have signs or symptoms of progressive disease (including rest or exercise oxygen desaturation) with failure to improve or maintain lung function while being pharmacologically treated. Guidelines for referral and transplantation according to the international guidelines for the selection of lung transplant candidates updated in 2006 are as shown in Table 57-11.[148]

The 1-year and 5-year survival rates following lung transplantation for IPF according to the 2004 International Society for Heart and Lung Transplantation/United Network of Organ Sharing (ISHLT/UNOS) International Registry reporting experience over the previous 12 years was 68% and 40%, respectively.[149] Recently, survival of patients receiving transplantation for IPF ($n = 82$) was compared with survival of patients receiving transplanta-

TABLE 57-11. Guidelines for Referral and Transplantation of Patients with Idiopathic Interstitial Pneumonia

GUIDELINES FOR REFERRAL

1. Histologic or radiographic evidence of UIP irrespective of vital capacity.
2. Histologic evidence of fibrotic NSIP.

GUIDELINES FOR TRANSPLANTATION

1. Histologic or radiographic evidence of UIP and any of the following:
   a. A DL_{CO} < 39% predicted.
   b. A ≥ 10% decrement in FVC during 6 months of follow-up.
   c. A decrease in pulse oximetry below 88% during a 6-MWT.
   d. Honeycombing on HRCT (fibrosis score > 2).
2. Histologic evidence of NSIP and any of the following:
   a. A DL_{CO} < 35% predicted.
   b. A ≥ 10% decrement in FVC or 15% decrease in DL_{CO} during 6 months of follow-up.

DL_{CO}, diffusing capacity for carbon dioxide; FVC, forced vital capacity; HRCT, high-resolution computed tomography; 6-MWT, 6-minute walking test; NSIP, nonspecific interstitial pneumonia; UIP, usual interstitial pneumonia.

tion for non-IPF diagnoses (n = 387). Survival estimates after transplantation for IPF were 95%, 73%, 56%, and 44% at 30 days and 1, 3, and 5 years, somewhat worse than for matched non-IPF patients (P = .03). Survival for double- versus single-lung transplantation was 81% versus 67% at 1 year and 55% versus 34% at 5 years; however, among matched non-IPF patients, corresponding survivals were 88% versus 71% at 1 year and 72% versus 48% at 5 years (P = .3). These findings suggest survival after lung transplantation for IPF is worse than for other indications and that survival may be improved by double-lung transplant.[150]

Regular review of patients on the waiting list is required to detect complications that may impact on suitability for transplantation. Unfortunately, many IPF patients die while waiting. In this context, the lung allocation score was restructured in 2005 to an algorithm based on survival probability on the waiting list and after transplantation. The aim was to decrease the number of patients who die on the waiting list. A recent study shows that recipient diagnoses changed with an increase in IPF and a decrease in emphysema and cystic fibrosis.[151]

Rehabilitation

Twelve weeks of combined inpatient and home-based rehabilitation program (respiratory muscle training and bicycle riding to the limits of the patient's tolerance) has been shown to improve the quality of life and sensation of dyspnea in patients with ILD, despite changes in pulmonary function tests.[152] Currently, the effects of pulmonary rehabilitation on shortness of breath, exercise capacity, symptom control, mental health, cognitive function, and quality of life are being studied by the National Jewish Medical and Research Center and Mordecai Palliative Care Research Fund.

Acute Exacerbations of Interstitial Pulmonary Fibrosis

Some patients with IPF may experience a rapid deterioration in respiratory status after a period of relative stability.[153] This acute worsening may be related to viral or bacterial infection, aspiration by GER, or thromboembolic event. A growing body of evidence, however, indicates many of these acute, clinically significant episodes are of unknown etiology; these have been termed *acute exacerbations of IPF*.[153] The overall incidence of acute exacerbations in the IPF population remains unknown but has been suggested to range from 5% to 10%.[153,154] An analysis of the cause of death in the placebo arm of a large randomized clinical trial, however, showed that almost half of the deaths were acute in their onset after a period of decompensation that lasted 4 weeks or less, suggesting that acute exacerbations may be more frequent than usually believed.[155]

There is no established consensus on the diagnosis of acute exacerbation of IPF. Most definitions include a combination of the following data (occurring over < 4 wk): (1) severe worsening of dyspnea; (2) worsening hypoxemia (i.e., a fall in arterial P_{O_2} > 10 mm Hg); (3) new radiographic opacities, usually bilateral ground-glass opacities and consolidation superimposed on the reticular/honeycomb IPF pattern; (4) absence of an alternative explanation, such as infection, left heart failure, or pulmonary embolism.[153,156–158] It has been suggested that the pattern of the new ground-glass opacities may differ in the patients with acute exacerbation and that these differences might have prognostic implications.[158,159] Although radiographs of most patients typically show ground-glass attenuation at the periphery, near areas of underlying honeycombing, some demonstrate a multifocal or diffuse pattern in previously uninvolved areas. Such cases seem to have a worse prognosis than patients with only peripheral involvement.[160] Biopsies of most of these patients have a histopathologic pattern of DAD superimposed on underlying UIP. Occasionally, lungs may show features of prominent acute organizing pneumonia and extensive fibroblastic foci.[156,161] Cell profiles on BAL usually show an increase of neutrophils or both neutrophils and lymphocytes.

The etiology and pathogenesis of the acute exacerbations remain unknown. Disordered epithelial cell integrity, acute inflammation, excessive cytokines and matrix metalloproteinases release, and an antifibrinolytic alveolar milieu are all likely involved. Increased levels of interleukin-8 (IL-8) and α-defensin have been reported in some patients, suggesting the importance of neutrophils.[153] Exaggerated levels of serum ST2 protein, an orphan receptor with unknown natural ligand, have also been reported.[162] Importantly, ST2 is preferentially expressed on type 2 T helper (Th2) polarized cells expressing predominantly IL-4, IL-5, or IL-10 in vitro and ex vivo, indicating a role for activated (predominantly

Th2) lymphocytes.[163] More recently, antibodies to annexin-1 were detected in the sera and BAL fluids from half of patients with acute exacerbation of IPF, supporting the hypothesis that pulmonary epithelial apoptosis may be important in this pathologic event.[164]

Once infections and other causes of worsening have been excluded, treatment has generally consisted of enhanced immunosuppression with pulse doses of methylprednisolone (0.5–1 g/day). Some studies have also reported the use of additional immunosuppression with cyclophosphamide or cyclosporine, but no convincing evidence of benefit has been demonstrated. Unfortunately, no data from controlled trials have proved the efficacy of any treatment for this condition.

Familial Pulmonary Fibrosis

The clinical, radiographic, physiologic, and morphologic manifestations of familial IPF are indistinguishable from the sporadic form of the disease.[2,165] There may be a slight male predominance, and women tend to have a more favorable prognosis.[6,166] It is estimated that familial cases account for 0.5% to 2.2% of all patients with IIPs, with a prevalence of 1.34 cases/106 population in the United Kingdom.[166] In Finland, it was estimated that the prevalence for familial IPF was 5.9/million population.[167] The familial form explained 3.3% to 3.7% of all Finnish cases of IPF diagnosed according to the revised American Thoracic Society/European Respiratory Society international guidelines. Geographic clustering has been noted, suggesting a recent founder effect in patients with familial IPF.[166,167] Importantly, familial pulmonary fibrosis has been associated with multiple pathologic subsets of the IIPs: desquamative interstitial pneumonitis (DIP),[168] LIP,[169] and UIP.[6]

The genetic basis of familial pulmonary fibrosis is unclear and probably involves several genes. Thomas and associates[6] showed that mutations in the SP-C gene (*SFTPC*) are associated with familial DIP and NSIP and may cause type II cellular injury. The authors hypothesized that the presence of two different pathologic diagnoses in affected relatives sharing this mutation indicates that in this kindred, these diseases may represent pleiotropic manifestations of the same central pathogenesis.[6] Multiple heterozygous mutations in *SFTPC* have been reported in association with children suffering from ILD (DIP or NSIP), including familial and sporadic occurrences.[170,171] In addition, a deficiency of SP-C has been described in a small kindred suffering from a poorly defined form of interstitial pneumonitis, despite no sequence variation in *SFTPC*.[172] Taken together, these findings support a model in which misfolded pro–SP-C or SP-C can cause type II alveolar cell injury that results in ILD.[173] In the Finland families, *ELMOD2*, a functionally uncharacterized gene, was identified as a novel candidate gene for susceptibility in familial IPF.[174]

In a recent study, 111 families with two or more cases of IIP among first-degree family members having 309 affected and 360 unaffected individuals were evaluated. Older age, male sex, and having ever smoked cigarettes were associated with the development of IIP. Evidence of aggregation of disease was highly significant among sibling pairs, and 20 pedigrees demonstrated vertical transmission, consistent with autosomal dominant inheritance.[71] As reported previously, a substantial proportion of families displayed phenotypically heterogeneous IIP.

Nonspecific Interstitial Pneumonia

NSIP originated as a histopathologic categorization reserved for surgical lung biopsies not demonstrating a clearly identifiable pattern.[175] The histopathologic pattern of NSIP is found in a wide variety of diseases of known cause (e.g., hypersensitivity pneumonitis, drug-related, acquired immunodeficiency syndrome [AIDS]–related, and collagen-vascular diseases).[176] Moreover, many patients diagnosed with idiopathic NSIP meet the case definition of undifferentiated connective tissue disease, suggesting that idiopathic NSIP might actually be an autoimmune disease.[177] In addition, it is estimated that up to 15% to 20% of patients who present with a chronic ILD either have an occult connective tissue disease or subsequently develop a clinically overt connective tissue disease. In this particular group of patients, the initial clinical presentation may be essentially indistinguishable from that of several IIPs (especially NSIP and UIP).[178] Consequently, NSIP as a clinical form of IIP remains uncertain.[29]

Clinical Features

The presentation is quite similar to other forms of idiopathic pneumonias (see Tables 57-7 and 57-8). Most patients are middle-aged adults with a subacute onset of symptoms approximately 8 months prior to diagnosis.[175,176,179] Two thirds of the patients are women, and unlike patients with IPF, 70% are never smokers.[176] Cough and dyspnea are the main clinical manifestations. Serologic abnormalities (antinuclear antibodies and rheumatoid factor) are common. BAL findings do not discriminate between UIP and NSIP and have no prognostic value once the distinction between the two has been made histologically.[180]

Chest Imaging Studies

Chest Roentgenography. In patients with early NSIP, the chest radiograph may be normal. In advanced disease, bilateral reticular or hazy opacities are the most prominent abnormality. The lower lung lobes are more frequently involved, but an obvious apical-basal gradient, as seen in UIP, is usually absent.[175,176]

Computed Tomography Scan. In a recent review of 61 cases of confirmed idiopathic NSIP, the parenchymal abnormalities predominantly involved the lower lungs in the craniocaudal dimension. The most common HRCT features were a reticular pattern, traction bronchiectasis, and lobar volume loss (77%).[176] Ground-glass attenuation was present in nearly half of the cases, although it is a common manifestation in other series (Fig. 57-26). Other findings in advanced NSIP include

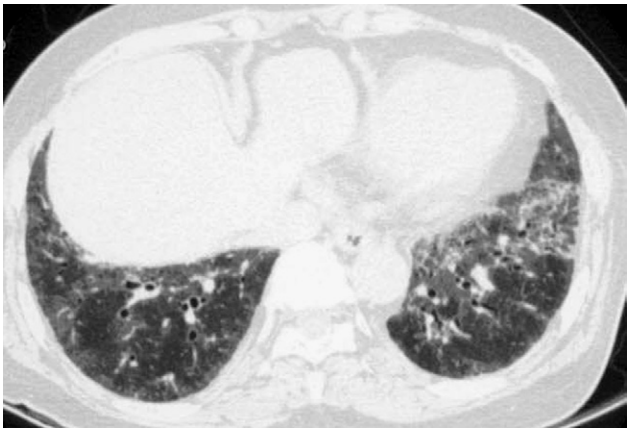

FIGURE 57-26 ■ High-resolution chest CT image from a patient with nonspecific interstitial pneumonia shows bilateral, patchy, ground-glass opacities without evidence of subpleural honeycombing.

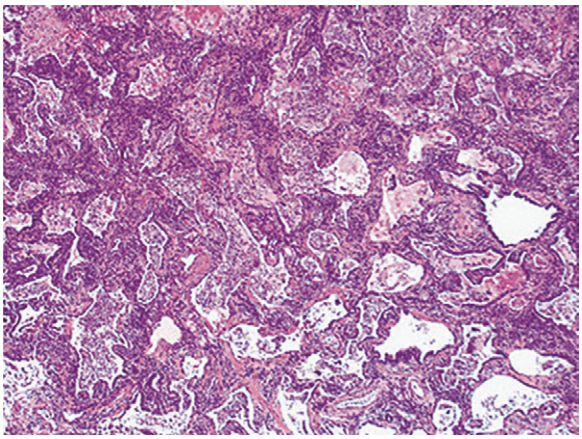

FIGURE 57-27 ■ Photomicrograph of nonspecific interstitial pneumonia. Note the lymphoplasmacytic cells expanding the interstitial compartment. Alveolar macrophages are present also. (Original magnification ×10.)

subpleural cysts. Compared with those of UIP, these cysts are smaller and limited in extent.[181] The major CT differential diagnosis for NSIP is UIP. Favoring the diagnosis of NSIP are homogeneous lung involvement without an obvious apical-basal gradient, extensive ground-glass abnormalities, a finer reticular pattern, and micronodules. Importantly, during follow-up, ground-glass opacities in NSIP patients usually do not evolve to areas of honeycombing. By contrast, progression of ground-glass attenuation to honeycombing is common in UIP and indicates irreversible fibrosis.[182]

Pulmonary Function Tests

Pulmonary function testing shows a typical restrictive ventilatory defect with gas-exchange abnormalities commonly found.

Pathologic Features

The histopathologic pattern of NSIP is characterized by temporally and spatially homogeneous lung involvement. This homogeneity is a key feature in differentiating the NSIP pattern from the UIP pattern. It is characterized by varying degrees of inflammation and fibrosis, with some cases having a primarily chronic inflammatory/cellular pattern (cellular NSIP) and most cases revealing a mixed cellular-fibrotic pattern (fibrotic NSIP)[175,176] (Figs. 57-27 and 57-28). Cellular NSIP is less common than fibrosing NSIP; it exhibits uniform alveolar septal infiltrates of lymphocytes and plasma cells. Neutrophils, eosinophils, and histiocytes are inconspicuous. Although NSIP may have significant fibrosis, it usually appears temporally uniform, and fibroblastic foci and honeycombing, if present, are rare. Fibrotic NSIP can be difficult to reliably distinguish from UIP, and significant interobserver variability among expert histopathologists exists.[183]

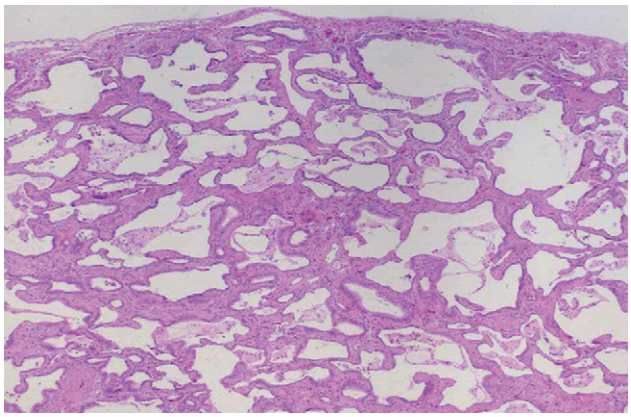

FIGURE 57-28 ■ Photomicrograph of nonspecific interstitial pneumonia with a mixed cellular-fibrotic pattern. The alveolar walls are thickened by dense collagen and a few lymphocytes and plasma cells. The fibroblastic foci that are commonly found in the usual interstitial pneumonia pattern are not present in this lesion.

Differential Diagnosis

Clinically, the most common diagnosis confused with fibrotic NSIP is IPF.[175,176,179] Patients who are known to be immunocompromised are not included in this group of patients. It is essential that the pathologist not use "UIP" or "NSIP" to refer to any nonclassifiable interstitial pneumonia because some of these cases represent a sampling error due to an inadequate lung biopsy. Importantly, most of the NSIP patients may have an ill-defined or inadequately evaluated connective tissue disease, drug-induced ILD, chronic hypersensitivity pneumonitis, recent acute lung injury (pneumonia or acute respiratory distress syndrome), or organizing pneumonia.[29,68,184–188] The NSIP pattern on surgical lung biopsy should prompt the clinician to revisit the clinical data, carefully looking for these conditions.

Although it has been suggested NSIP may represent early UIP, this possibility is unlikely for several reasons.

NSIP seems to occur predominantly in nonsmoker women whereas UIP occurs in smoker men.[176] Early UIP (as well as advanced UIP) does not have significant inflammation but rather has scattered fibroblast foci. Finally, the patchwork pattern that is so characteristic of UIP is not seen in NSIP, and therefore, one would have to postulate that during progression, some areas of NSIP reverted to normal whereas others evolved into fibrosis to become UIP.[67]

Clinical Course and Outcome

Several retrospective studies indicate the survival rate of patients with idiopathic NSIP is significantly higher than those with UIP.[176,179,189] This difference persists even after adjusting for age, gender, smoking history, and physiologic variables. The longest survival is observed in patients with a purely cellular pattern, indicating that prognosis depends primarily on the extent of fibrosis.[68,176] In the surgical lung biopsy, some patients may exhibit an NSIP pattern in one lobe and a UIP pattern in another.[190] Survival rate of these patients is similar to those with UIP. Corticosteroids combined with azathioprine may be more effective than corticosteroids alone.

Respiratory Bronchiolitis–Associated Interstitial Lung Disease/Desquamative Interstitial Pneumonia

Respiratory bronchiolitis–associated interstitial lung disease (RB-ILD) and DIP are related and, in some cases, inseparable conditions that probably represent different stages of the same process.[191,192] These diseases represent a distinct clinical syndrome found in current heavy smokers. The term respiratory *bronchiolitis-associated interstitial lung disease* is more anatomically accurate, as it conveys important pathogenic implications compared with the older term "desquamative interstitial pneumonia." Both (primarily RB-ILD) account for 15% to 20% of biopsied patients with IIPs (see Tables 57-7 and 57-8).[191,192] Importantly, respiratory bronchiolitis is an accurate histologic marker of cigarette smoking, and it may be found many years after smoking ceases.[193] The level of cytoplasmic pigmentation of macrophages and the presence of peribronchial fibrosis correlate with the pack-year smoking history.[193] Moreover, it was recently reported that those with significant lifetime secondhand smoke exposure, especially in the previous 12 months, have significant increases in ground-glass opacities on HRCT, suggesting an early or subclinical respiratory bronchiolitis/DIP.[194] Furthermore, RB/DIP-like histologic changes (1) are exceedingly common in PLCH, (2) may be sufficiently severe to cause the appearance of ground-glass attenuation on HRCT, and (3) correlate with the cumulative exposure to cigarettes smoked.[195] Although cigarette smoking is considered the main cause of RB-ILD/DIP, genetic abnormalities of surfactant function, specifically mutations in the SP-B, SP-C, and ABCA3 genes account for an increasing number of ILDs, including DIP.[196,197] In addition, DIP can be observed in various occupational or drug exposures.

Clinical Features

RB-ILD and DIP primarily afflict cigarette smokers between the third and the sixth decades of life. There is a male preponderance, with men affected nearly twice as often as women. Patients with either RB-ILD or DIP commonly present with insidious exertional dyspnea and persistent nonproductive cough. Less frequently, patients with DIP experience fatigue and weight loss. Coarse, bibasilar end-inspiratory crepitations are frequent findings on physical examination, whereas finger clubbing is uncommon.

Chest Imaging Studies

Chest Roentgenography. The chest radiograph is insensitive for detection of RB-ILD and is often normal. Sometimes, bronchial wall thickening or reticular opacities can be seen. Chest radiographs of DIP are nonspecific and usually reveal bilateral ground-glass opacities. Middle and lower lung field involvement with normal-appearing lung volumes predominates.[198] Air bronchograms can be found when this process surrounds the airways. The honeycomb pattern is rare.

Computed Tomography Scan. The key HRCT features of RB-ILD include central bronchial wall thickening proximal to segmental bronchi, peripheral bronchial wall thickening distal to segmental bronchi, centrilobular nodules, and areas of ground-glass opacity[198–202] (Fig. 57-29). Ground-glass opacifications may be diffuse or patchy, without basal or peripheral predominance.[202] The predominant abnormality in DIP is the bilateral, moderately symmetrical, peripheral and predominantly basal ground-glass attenuation. Tiny thin-walled cysts are noted in the ground-glass areas in 60% of cases. Honeycombing pattern is rarely found.[201,203,204]

There is occasional overlap in appearances between RB-ILD and DIP, although the ground-glass attenuation of DIP is usually more extensive, and nodules are infrequent or absent.[200]

Bronchoalveolar Lavage

BAL fluid in patients with RB-ILD/DIP is characterized by mild to moderate increases in total cell numbers, moderate to marked eosinophilia (a feature that in the absence of biopsy might raise the consideration of chronic eosinophilic pneumonia), and moderate neutrophilia.[180,198]

Pulmonary Function Tests

Pulmonary function testing may be normal but usually shows mild to moderate restriction, normal or slightly reduced diffusing capacity, and mild hypoxemia. A mixed obstructive-restrictive pattern is common, although an isolated increase in residual volume may be seen.

Pathologic Features

The cardinal feature of RB-ILD is the accumulation of alveolar macrophages within the membranous and respiratory bronchioles, variably extending into neighboring alveolar ducts and alveoli. Macrophages are characterized by glassy eosinophilic cytoplasm, usually with brown and finely granular pigmentation (representing constituents of cigarette smoke).[192,200,205] There is often a chronic inflammatory cell infiltrate in bronchiolar and surrounding alveolar walls. The changes are patchy at low magnification and have a distinctly bronchiolocentric distribution without the associated interstitial pneumonia necessary for a diagnosis of DIP (Fig. 57-30).[192] Bedrossian and coworkers[206] coined the term *DIP-like reaction* to identify prominent intra-alveolar macrophage accumulation around space-occupying pulmonary lesions. This DIP-like pattern can be seen in a number of other processes, including Langerhans cell histiocytosis, drug reactions (e.g., amiodarone), chronic alveolar hemorrhage, eosinophilic pneumonia, pneumoconioses (e.g., talcosis, hard-metal disease, asbestosis), obstructive pneumonias, and exogenous lipoid pneumonia. In these cases, however, the DIP-like reaction is usually minimal, without the uniform involvement of lung parenchyma seen in true cases of RB-ILD/DIP.

The histologic hallmark of DIP is the uniform filling of the alveolar spaces by cohesive clusters of numerous pigmented alveolar macrophages, including occasional multinucleated cells, eosinophils, and lymphocytes.[192] Alveolar septa are thickened by a sparse inflammatory infiltrate and lined by uniform hyperplastic type II pneumocytes. Peribronchiolar lymphoid hyperplasia is seen in the majority of cases (Fig. 57-31).[192,207]

The majority of DIP cases show a difference in the degree of pathologic change from one lobule to the next in a given biopsy specimen. Architectural destruction is usually observed. Akira and colleagues[204] have pointed out the presence of dilated alveolar ducts and bronchioles and/or pulmonary cysts, which corresponded to cystic spaces on HRCT.

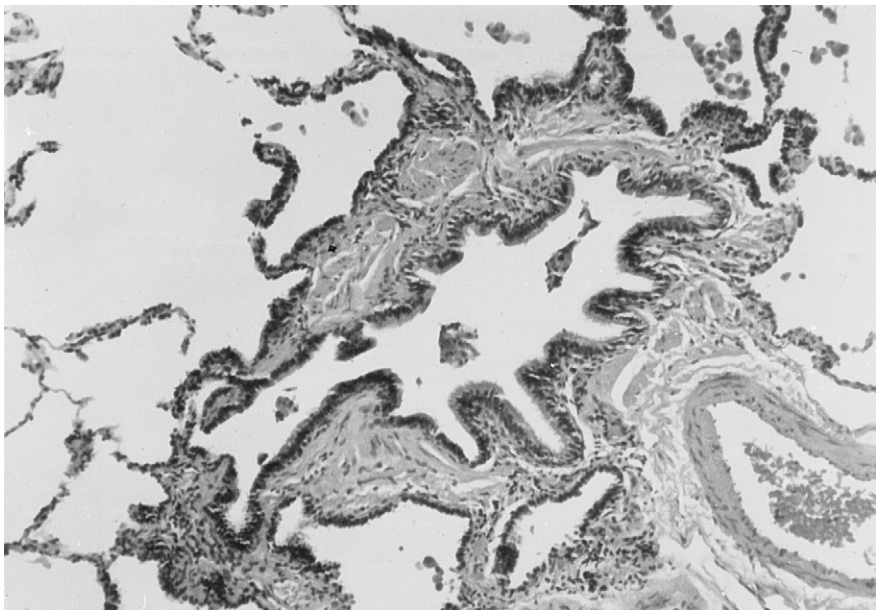

FIGURE 57-30 ■ Photomicrograph of respiratory bronchiolitis shows an ectatic small airway, with thickened walls and evidence of extension of the bronchiolar metaplastic epithelium into the immediately surrounding alveoli. Intraluminal macrophages are also present within the peribronchiolar alveolar spaces.

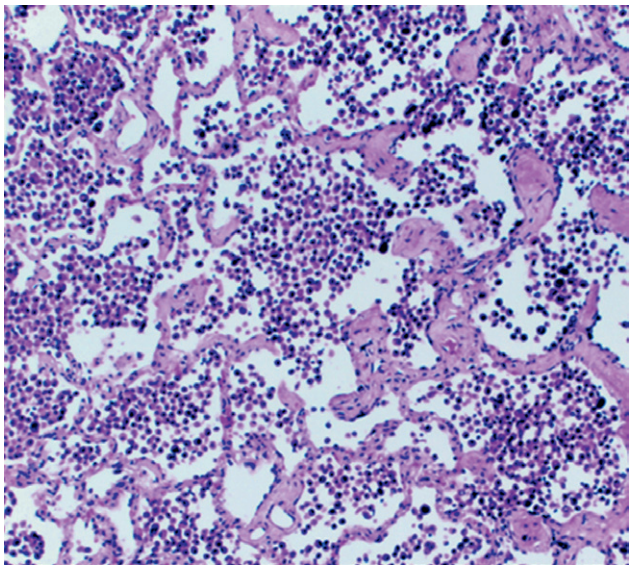

FIGURE 57-31 ■ Photomicrograph of desquamative interstitial pneumonia showing the characteristic dense collections of macrophages filling alveolar lumens. (Original magnification ×100.)

Clinical Course and Outcome

Because there has not been a longitudinal study of a large group of subjects, the clinical course and prognosis of RB-ILD are unknown. Most studies suggest a favorable response to quitting smoking and use of corticosteroids, with documented improvement in lung function and chest radiographs[205]; few deaths secondary to progressive lung disease have been reported.

Patients with the DIP stage of this process also have a good prognosis. Carrington and associates[208] reported a 28% mortality after an average survival of 12 years. Other studies have shown similar results, but additional study of a larger number of subjects is needed.[203–205] In a more recent study, symptomatic improvement (i.e., improved cough, dyspnea, or both) with prednisone treatment was noted in 24% of patients with DIP and 55% of patients with RB-ILD. Objective improvement with prednisone treatment, as evidenced by improvement in pulmonary function measurements or parenchymal infiltrates seen on chest radiography or CT scans, was noted in 33% of patients with DIP and 64% of patients with RB-ILD.[209] Unfortunately, these positive responses tended to be transient in half of the patients with tapering and discontinuation of prednisone treatment. This regression back to the baseline status occurred even in the absence of smoking.[209]

Nevertheless, because smoking plays a major role in the pathogenesis, smoking cessation is always indicated in these patients. In a recent study, both clinical symptoms and DL_{CO} improved significantly following smoking cessation, as did ground-glass opacities and centrilobular nodules seen on the initial HRCT examination.[210] Corticosteroids may be required in refractory or recurrent cases but should not be instituted in the absence of smoking cessation.

Acute Interstitial Pneumonia

AIP is a rare, fulminant form of lung injury that presents acutely (days to weeks from onset of symptoms), usually in a previously healthy individual.[211] AIP likely represents a subset of cases of idiopathic acute respiratory distress syndrome and is what Hamman and Rich[212] described and termed "acute diffuse interstitial fibrosis" (see Tables 57-7 and 57-8).

Clinical Features

Most patients are over the age of 40 years (mean age, 50 yr; range, 7–83 yr). Men and women are equally affected, and cigarette smoking does not seem to increase the risk for development of AIP. A prodromal illness, lasting usually 7 to 14 days before presentation, is common. The clinical signs and symptoms include fever, cough, and shortness of breath. Routine laboratory studies are nonspecific and generally not helpful.

Chest Imaging Studies

Chest Roentgenography. Diffuse, bilateral, air space opacification is seen on chest radiograph.[213,214]

Computed Tomography Scan. The typical HRCT features of AIP are bilateral, multifocal or diffuse areas of ground-glass opacity and consolidation, usually without pleural effusion.[35] A predominantly subpleural distribution may be seen. These radiographic findings are similar to those seen in acute respiratory distress syndrome; however, patients with AIP are more likely to have a symmetrical, bilateral distribution with a lower lobe predominance.[215] In the early phase of AIP, ground-glass opacities and less extensive areas of consolidation are the dominant CT pattern, reflecting the presence of alveolar septal edema and hyaline membranes.[35] During the organizing phase of the disease, HRCT findings consistent with evolving fibrosis are often present, including traction bronchiectasis, reticular opacities, and architectural distortion.[216] In this phase, consolidations resulting from intra-alveolar fibrosis may also be present. Mild honeycombing, usually involving less than 10% of the lung, may be seen on CT examination.

Pulmonary Function Tests

Most patients have moderate to severe hypoxemia and develop respiratory failure.

Pathologic Features

A surgical lung biopsy is required to confirm the diagnosis of AIP.[192,217] The histopathologic pattern of AIP includes DAD, which can be categorized into an early exudative phase and a chronic organizing phase, depending on the timing of the biopsy in relation to the lung insult. DAD develops after an acute injury to the alveolar capillary basement membranes.[211] It is most commonly seen in the acute respiratory distress syndrome or in immunosuppressed patients who have received cyto-

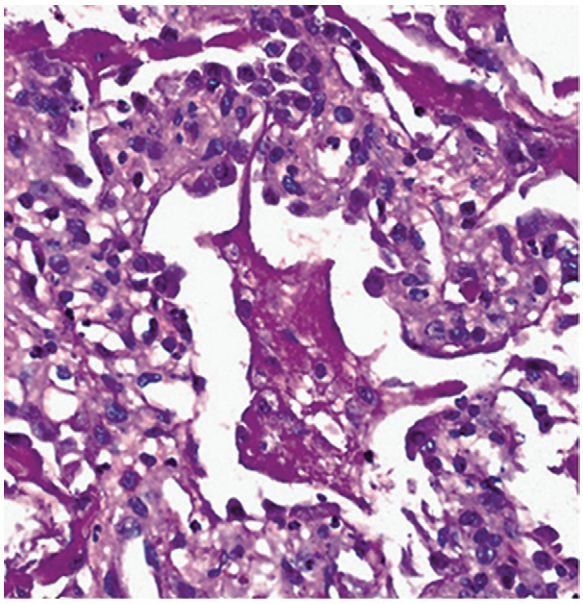

FIGURE 57-32 ■ Photomicrograph of acute interstitial pneumonia shows diffuse alveolar damage. Note the hyaline membranes within alveolar spaces and edema and inflammatory cell infiltration of the alveolar wall. (Original magnification ×10.)

toxic drugs or who have developed diffuse infectious pneumonias.[218]

After the endothelial-epithelial injury, there is leakage of serum proteins and red blood cells into the alveolar spaces. The alveolar epithelium becomes necrotic and is sloughed, and the interstitium becomes edematous. Hyaline membranes, recognized as eosinophilic debris and consisting of necrotic epithelial cells, protein, and fibrin, form within alveolar spaces (Fig. 57-32). In the reparative or organizing stage of DAD, there is proliferation and hyperplasia of the alveolar type II epithelial cells, often showing nuclear enlargement and prominent nucleoli. Extensive fibroblast proliferation is a dominant finding. Alveolar septa are uniformly thickened and distorted by proliferating fibroblasts and myofibroblasts within a myxoid basophilic matrix.[192] Fibrin thrombi are often present. With protracted or repeated parenchymal injury, irreversible fibrosis and honeycomb lung result.

Clinical Course and Outcome

Treatment is largely supportive and consists of mechanical ventilation and oxygen supplementation. Corticosteroids seem to be effective in the early phase of disease. Recently, chest ultrasound has become an attractive new tool for assessing lung status in ventilated critically ill patients. It is noninvasive, easily repeatable at the bedside, and provides an accurate evaluation of the respiratory status of patients with acute lung injury. It appears to be useful to diagnose lung consolidation, alveolar-interstitial syndrome, and pleural effusion.[219] According to most studies, the mortality from AIP appears to be high (>50%), with the majority of patients dying within 3 months of presentation. Most survivors of AIP experienced recurrences and chronic, progressive ILD.[214] However, significant lower hospital mortality (12.5%) with no evidence of either recurrent or progressive disease has been also described.[220]

Cryptogenic Organizing Pneumonia

COP is a specific clinicopathologic syndrome characterized by a "pneumonia-like" illness, with excessive proliferation of granulation tissue inside the alveolar spaces associated with chronic inflammation in the surrounding alveoli. The pathologic process may also involve the small airways (bronchiolitis obliterans with organizing pneumonia [BOOP]) (see Tables 57-7 and 57-8). Organizing pneumonia can be cryptogenic (COP) or associated with a number of lung injuries (e.g., postinfectious, drug-related, connective tissue disease–related, posttransplant, hypersensitivity pneumonitis, radiation [breast cancer], aspiration of particulate matter). There are no major differences in clinical features of COP and secondary organizing pneumonia.[221,222] BOOP may also be seen accompanying other histopathologic patterns (e.g., UIP). The diagnosis of COP is reserved for isolated organizing pneumonia in patients without an identifiable associated disease. The term *idiopathic BOOP* historically encompassed COP but is no longer recommended for this idiopathic condition.

Clinical Features[223]

The incidence of COP is similar in both men and women. The mean age at presentation is about 50 to 55 years (range, 21–80 yr). Patients with COP are frequently very specific about the timing of their disease onset. This is because the disease onset is recent (usually < 2 mo) and is often dramatic, with the development of a flulike illness characterized by cough, mild dyspnea, fever, malaise, fatigue, and weight loss. Physical examination usually discloses focal sparse crackles but may be almost normal. Finger clubbing is rare in patients with COP.

Routine laboratory studies are nonspecific. A leukocytosis without increase in eosinophils is seen in approximately half the patients. The initial erythrocyte sedimentation rate is frequently elevated in patients with COP.

Chest Imaging Studies

Chest Roentgenography. The roentgenographic manifestations are distinctive, usually including unilateral or bilateral patchy consolidations that resemble pneumonic infiltrates in the presence of normal lung volumes.[224,225] A peripheral distribution of the infiltrates, very similar to that thought to be "virtually pathognomonic" for chronic eosinophilic pneumonia, is commonly seen in COP.[224,226,227] Irregular linear or nodular interstitial opacities are rarely present as the only radiographic manifestation.[228] Honeycombing is rare and is seen only as a late manifestation in the few patients with progressive disease. Other radiographic abnormalities, such as pleural effusion, pleural thickening, hyperinflation, and cavities, are uncommon.

Computed Tomography Scan. CT scans of the lung reveal patchy air space consolidation, small nodular

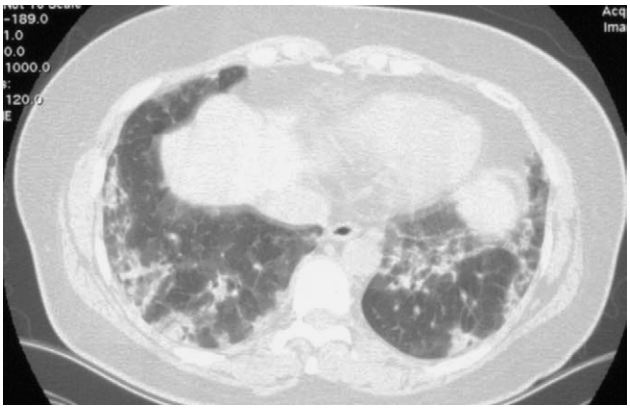

FIGURE 57-33 ■ High-resolution CT image from a patient with cryptogenic organizing pneumonia shows patchy areas of consolidation and diffuse ground-glass opacities (gray-appearing areas).

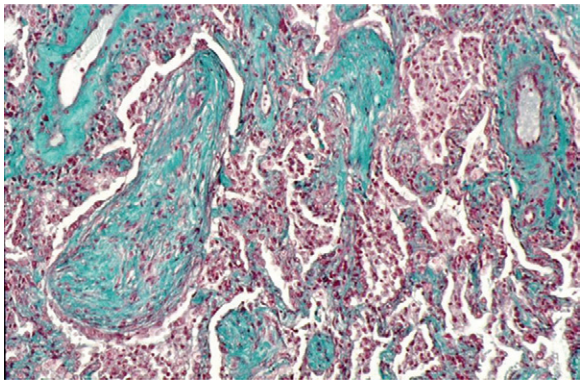

FIGURE 57-34 ■ Photomicrograph indicates organizing pneumonia. Immature connective tissue and proliferating fibroblasts appearing light blue (pentachrome stain) are present in alveolar ducts and alveolar spaces, and there is an interstitial infiltrate consisting of mononuclear cells. (Original magnification ×40.)

opacities, and bronchial wall thickening and dilation, most frequently in the periphery of the lung and often in the lower lung zones[224,228–231] (Fig. 57-33). Frequently, the CT findings are far more extensive than are expected by review of the plain chest film. These opacities have a tendency to migrate, changing in location and size, even without treatment. The CT finding of consolidation is associated with partial or complete resolution, whereas reticular opacities are associated with persistent or progressive disease.[232] Sometimes, COP shows unique findings such as the reversed halo sign, which is defined as central ground-glass opacity surrounded by more dense air space consolidation of crescentic and ring shapes. This sign is seen in around 20% of patients who have COP.[233] The presence of enlarged nodes is less common in COP than in the other IIPs.[234]

Focal organizing pneumonia has been described as a discrete form of COP and presents as an isolated focal lesion on chest imaging.[235] Many of these patients are asymptomatic and the lesion is discovered by chest x-ray or CT. It may be suspected to be a putative lung cancer, because most patients have a smoking history and are middle-aged or older.[236]

Pulmonary Function Tests

Pulmonary function is usually impaired, with a restrictive defect being most common, although obstructive defect (FEV_1/FVC ratio < 70%) is found in almost one fifth of subjects with COP, mostly in current or former smokers. Gas-exchange abnormalities are extremely common, with resting and exercise arterial hypoxemia. The DL_{CO} is reduced (<80% of predicted) in three fourths of patients.

Bronchoalveolar Lavage

An increase in lymphocytes (20%–40%), neutrophils (10%), and eosinophils (5%), with the level of lymphocytes higher than that of eosinophils, is the most common pattern at differential cell count.[237] BAL lymphocytes are activated and the CD4/CD8 ratio is usually decreased. An increase of plasma cells and/or mast cells may also be seen.

Pathologic Features

The diagnosis of COP depends on both the clinical setting and the finding of the characteristic pathologic features. Intraluminal fibrotic buds (Masson bodies) seen in respiratory bronchioles, alveolar ducts, and alveoli are the prominent feature.[237–240] Other pathologic features include foamy cells in the alveolar spaces, prominent type II cell hyperplasia, interstitial infiltrates, and fibrinous exudates.

Organizing pneumonia is recognized by the appearance in the small airways of intraluminal collections of proliferating fibroblasts and myofibroblasts that produce mucopolysaccharides and collagen. It is most prominent in the alveolar ducts but extends distally to the alveolar lumina and proximally to membranous bronchioles (Fig. 57-34). Masson bodies may also extend from one alveolus to the next through the interalveolar pores, giving a characteristic "butterfly pattern."[237] Organizing penumonias also show an interstitial lymphoplasmacytic infiltrate and hyperplasia of the type II epithelial cells. The organizing process, which may extend into the membranous bronchioles, produces an intraluminal polypoid bronchiolitis obliterans (Fig. 57-35). Organizing pneumonia represents a common reparative response to injury occurring in a variety of ILDs. If the injury is unresponsive to treatment, progression to irreversible fibrosis and honeycomb lung can result.

Clinical Course and Outcome

Corticosteroid therapy results in complete clinical, radiologic, and physiologic recovery in two thirds of patients. One third demonstrates recurrent or persistent disease. If reticular opacities are present on the chest radiograph or CT image, COP is less likely to respond to corticosteroids. In general, clinical improvement is rapid, within several days or a few weeks. Occasionally, recovery is quite dramatic. Relapses can occur when the corticosteroids are withdrawn, usually within 1 to 3 months.

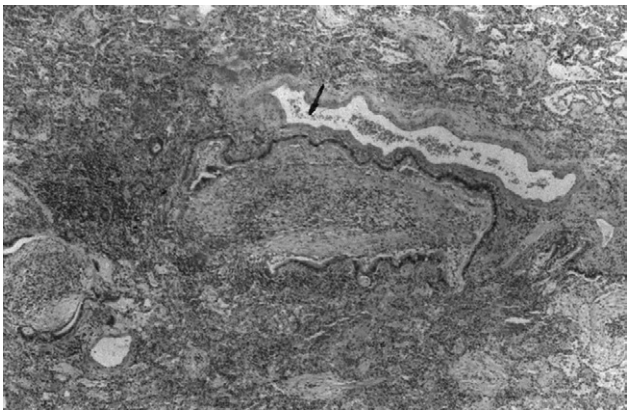

FIGURE 57-35 ■ Photomicrograph of organizing pneumonia shows a typical inflammatory polyp extending into the lumen of a terminal bronchiole. (Original magnification ×40.)

Most relapsed patients will improve when retreated with corticosteroids. It has been suggested that COP may also respond to macrolide therapy, but studies are scanty.[241] Spontaneous improvement may occur over 3 to 6 months in a few patients.[241-243] A seasonal (early spring) occurrence of COP with relapse every year at the same period has been reported.[244] Few of the patients with COP die as a result of this illness, but those prone to develop a rapidly progressive fatal form of organizing pneumonia have a clinical course similar to the "Hamman-Rich syndrome" (AIP).[245] In such patients, the diagnosis is usually delayed or missed.

The majority of cases of focal organizing pneumonia are cryptogenic, do not recur after surgical resection, and do not require corticosteroid therapy.[236,246]

Lymphocytic Interstitial Pneumonia

LIP is an uncommon pathologic process characterized by the presence of widespread, monotonous sheets of lymphocytic infiltration in the interstitium of the lung.[247] In addition to being differentiated from other IIPs, it must be distinguished from lymphocytic infiltrations associated with pseudolymphoma, primary lymphomas, lymphomatoid granulomatosis, benign lymphocytic angiitis and granulomatosis, plasma cell interstitial pneumonia, and angioimmunoblastic lymphadenopathy.

LIP has been associated with a variety of clinical conditions, including autoimmune diseases (especially Sjögren's syndrome), dysproteinemia, human immunodeficiency virus infection, variable immunodeficiency syndromes, and bone marrow transplantation. Once underlying systemic diseases have been excluded, LIP is called idiopathic. As an idiopathic disease, LIP is infrequent. It is far more common as a secondary disease in association with systemic disorders, most notably Sjögren's syndrome (Table 57-12).

Clinical Features

The clinical manifestations of LIP are dominated by those related to the underlying disease, such as Sjögren's syndrome. LIP occurs more commonly in women, usually in the fourth to sixth decade of life. It is also seen in children, particularly those with hypogammaglobulinemia or AIDS. Progressive dyspnea and cough are the most common presenting symptoms, although weight loss, pleuritic pain, arthralgias, and fever also occur. Bibasilar crackles on chest examination, cyanosis, and finger clubbing are common physical findings.

Chest Imaging Studies

Chest Roentgenography. The chest roentgenogram is nonspecific, with reticular opacities being the most frequent abnormality. A mixed alveolar-interstitial pattern appears as the disease progresses because of the coalescence of the opacities. Cysts, honeycombing, and pulmonary hypertension are also late manifestations.[248] Pleural effusions are infrequent and suggest a complicating lymphoma.

Computed Tomography Scan. The main parenchymal abnormalities on the initial CT scan consisted of ground-glass attenuation, thickening of interlobular septa, centrilobular nodules, thin-walled perivascular cysts, and air space consolidation[249] (Fig. 57-36). In contrast to the subpleural, lower lung cystic changes in UIP, the cysts of LIP are usually within the lung parenchyma throughout the mid lung zones and presumably result

FIGURE 57-36 ■ High-resolution CT image from a patient with lymphocytic interstitial pneumonia shows diffuse cysts.

from air trapping due to peribronchiolar cellular infiltration.[248] The cysts may be seen in up to 80% of the patients and are typically few in number and measure less than 3 cm in diameter. On follow-up CT, most patients improved, although several showed increased extent of disease. With the exception of cysts, the parenchymal opacities were reversible. New cysts developed in a few patients; these developed mainly in areas with centrilobular nodules on initial CT. Honeycombing was seen on follow-up CT in several patients in areas of previous air space consolidation on the initial CT.[249]

Pulmonary Function Tests

A restrictive defect including reduced FVC, elevated FEV_1/FVC, and reduced TLC is commonly seen and is often associated with a reduction in the D_{LCO} and arterial hypoxemia.

Bronchoalveolar Lavage

A striking T-cell lymphocytosis is seen on BAL.

Pathologic Features

Surgical lung biopsy is required for the diagnosis in almost all cases. The lymphocytic infiltration is usually extensive and severe, involving the alveolar septa and peribronchiolar and perivascular interstitium (Fig. 57-37). Reactive lymphoid follicles are often present and distributed along the peribronchiolar regions. The lymphocytes are polytypic (both B and T cells may be found), distinguishing them from the monotypic lymphocytic infiltrates characteristic of pulmonary lymphoma. The number of plasma cells and macrophages is also increased in these infiltrates.

LIP is distinguished from DIP and NSIP by the presence of monotonous sheets of lymphocytes infiltrating the interstitium and alveolar lumina.[250] Other features include the interstitial accumulation of macrophages, noncaseating granulomas, perivascular amyloid deposits, and germinal lymphoid centers. Conversion to a low-grade pulmonary lymphoma or progression to end-stage honeycomb lung may follow.[247,251]

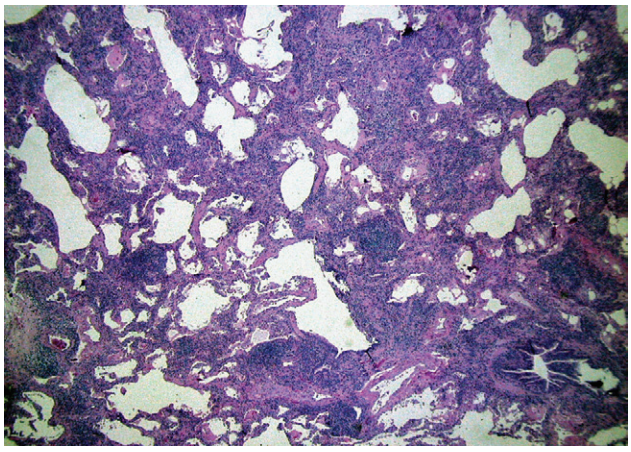

FIGURE 57-37 ■ Photomicrograph of lymphocytic interstitial pneumonia shows diffuse lymphoid infiltrate that extends through the pulmonary interstitium. (Original magnification ×10.)

Clinical Course and Outcome

The clinical course of idiopathic LIP is unknown. In cases in which LIP is associated with another disease, the underlying disease largely determines the outcome. Marked improvement or complete resolution follows corticosteroid therapy in many case reports. Progressive pulmonary fibrosis, cor pulmonale, and death can occur despite therapy. Infection is a common complication in these patients, especially those with an associated dysproteinemia. Progression to pulmonary or systemic lymphoma occurs but appears to be quite rare, and it is likely that this group of patients had malignant lymphoma from the outset.

Conclusion

Careful histopathologic evaluation has shown the traditionally clinical diagnosis of IIP to be more difficult and the findings to be more heterogeneous than was once thought. The subclassification of the IIPs, based on clinicopathologic criteria, has important therapeutic and prognostic implications. All patients with suspected IIP should be carefully evaluated with an in-depth history and physical examination, pulmonary function testing, bronchoscopy, and HRCT scanning by physicians experienced in the care of such patients. The most important diagnosis for clinicians to establish is whether or not IPF is present. Although the clinical and radiographic diagnosis of IPF can be made confidently in some cases, patients whose diagnosis is unclear after a thorough clinical and radiographic evaluation should undergo surgical lung biopsy to establish the underlying histopathology. New insight into the pathophysiology of IPF suggests a distinctly fibroproliferative process, and antifibrotic therapies are under evaluation. Referral for lung transplantation should be pursued early in those patients with progressive disease unresponsive to therapy. As our understanding of the pathogenic mechanisms of the IIPs grows, we will surely develop promising new agents that may significantly affect the morbidity and mortality of patients with these often devastating diseases.

KEY POINTS

Approach to the Patient with Interstitial Lung Disease

- ILDs include inflammatory and fibrotic diseases that ultimately disrupt the alveolar-capillary interface, leading to hypoxemia. ILDs usually lead to restrictive physiology, but airway involvement can cause obstruction or mixed physiology.
- ILDs arise in many clinical settings, including connective tissue disease; occupational, environmental and drug exposures; and primary pulmonary disorders.
- In many cases, the fundamental question to be answered is whether a patient has IPF or not.
- A careful detailed history and physical examination can be critical to uncovering clues that lead the thoughtful clinician to an accurate diagnosis.
- Characteristic radiographic features as well as certain laboratory tests can be helpful in delineating among possible causes of ILD. Pulmonary function testing is usually abnormal in patients with ILD. When it is normal, exercise challenge will often elicit underlying derangements in gas exchange.
- Ultimately, histopathologic examination of lung tissue obtained by surgical lung biopsy may be necessary to confirm a specific diagnosis in ILD.

Idiopathic Interstitial Pneumonias

- The IIPs are a subgroup of ILDs of unknown etiology and variable clinical course.
- IPF is the most common and is progressive, irreversible, and lethal. It has no effective treatment, although several clinical trials are ongoing.
- It is suggested that when possible, patients should be enrolled in a clinical trial and evaluated for lung transplant.
- Recent evidence indicates that 10% to 15% of IPF patients die from a rapid deterioration (acute exacerbation) that may be related to viral or bacterial infection, aspiration by gastroesophageal reflux, or thromboembolic event, or—most commonly—of unidentified cause.
- NSIP is characterized by diffuse, temporally and geographically homogenous cellular infiltrates (cellular NSIP) or fibrosis (fibrotic NSIP). NSIP is often associated to collagen vascular diseases, drug-induced disease, and hypersensitivity pneumonitis among others. In general, patients with NSIP (especially cellular NSIP) fare better than those with IPF.

INTRODUCTION

The lung may be involved in all connective tissue diseases (CTDs). The involvement is often subclinical, but its true extent may be masked by exercise limitation due to musculoskeletal features of the CTD. Patterns of lung involvement vary considerably within each CTD. The differential diagnosis is made even wider by inclusion of the drug-induced pulmonary reactions (Table 58-1) and the opportunistic infections secondary to therapy for the lung disease (Table 58-2), which may present with features indistinguishable from diffuse lung disease.

It is not surprising that the lung is involved frequently in CTDs because these are systemic syndromes, but it is disappointing that little is known about the true incidence and prevalence of lung disease because of the dearth of well-controlled prospective, unselected series. Imprecision of nomenclature has also confused the issue. With this background, the aims of this chapter are to highlight the ways in which the lung may be involved in the most common CTDs and to indicate, when appropriate, the most usual pattern of lung disease for each CTD, with an emphasis on approaches to diagnosis and efficient management.

SYSTEMIC SCLEROSIS (SCLERODERMA)

The preliminary criteria for classification of systemic sclerosis (SSc) require that one major or two or more of three minor criteria be present (Table 58-3).[1] The skin changes may affect the entire extremity or the face, neck, and trunk (thorax and abdomen). Scleroderma is traditionally classified on the basis of skin disease extent. Limited disease can involve the face, but the trunk and limbs proximal to the elbows and knees are spared. Diffuse disease can involve any part of the body.

Epidemiology and Risk Factors

The incidence of SSc is approximately 2 to 20/100,000/yr, with a peak incidence in the fourth to sixth decades. The prevalence is 30 to 120/100,000, with a 3:1 to 8:1 female preponderance.[2] Mortality rates have been

TABLE 58-2. Immunosuppressive Therapy: Common Drugs Used in the Treatment of the Major Pulmonary Complications of Connective Tissue Diseases

Drug	Dose	Duration	Comments	Monitoring
Azathioprine	2.5 mg/kg/day Maximum 200 mg/day	Continuous	• Maximal effect may not be evident for 6–9 mo but has better adverse effect profile than cyclophosphamide • May be used long term. • Starting dose 50 mg daily with monitoring full blood count in case of thiopurine methyltransferase deficiency; maintenance dose from 1 mo.	Full blood count Liver function tests
Cyclophosphamide Oral	2 mg/kg/day	Variable	Oral cyclophosphamide may be used continuously or substituted at 3 mo for azathioprine because of more favorable adverse effect profile in DLD.	Full blood count Liver function tests Urinalysis for blood
IV	15 mg/kg monthly for 1–6 mo	Variable	• IV therapy for rapid induction of remission at 2–4 mg/kg/day for 3–4 days, especially for vasculitis. • Pulsed IV cyclophosphamide may be given at 1- to 3-mo intervals with better adverse effect profile and lower long-term cumulative dose, particularly in nonvasculitic disease.	
Cyclosporin A	5 mg/kg/day	Continuous	• Bioavailability variable, thus blood monitoring necessary. • May be used in combination with prednisolone	Blood pressure Urea and creatinine Cyclosporin A level
Methotrexate	7.5–25 mg/wk	Continuous	• Little information to support use except as second-line therapy after first-line treatment. • Pulmonary toxicity may be limiting	Full blood count Liver function tests
Prednisolone	1 mg/kg/day or 20 mg alternate days	Continuous	Prednisolone used alone in high dose for cellular DLD and then titrated to control. In conjunction with immunosuppressants, the low-dose regimen is used.	Blood pressure Blood glucose Weight Bone densitometry
Methylprednisolone	500–1000 mg	3–5 days	Used for aggressive induction of remission, particularly for vasculitis or acute pneumonitis, then followed by maintenance therapy of prednisolone or prednisolone plus immunosuppressive agent.	

DLD, diffuse lung disease; IV, intravenous(ly).

remarkably consistent over the years, varying from 0.9 to 1.5/million for men and 2.1 to 3.8/million for women in the United States. The disease occurs worldwide. Although scleroderma clusters in families with other autoimmune disease, there are very few reports of first-degree relatives having SSc. Genetic involvement in the disease has been determined by the identification of chromosomal abnormalities and by studies of the major histocompatibility complex genes. Although many of the early studies were serologic, more recently, polymerase chain reaction technology has been employed. With this latter approach, an association between diffuse lung disease and human leukocyte antigens (HLA)–DR3, HLA-DR52a, HLA-DRB1*11, and HLA-DPB1*1301 has been recognized.[3,4]

Chemically Induced Scleroderma-like Disorders

A variety of agents are known to induce SSc-like disease, often with lung involvement, including D-penicillamine, tryptophan, bleomycin, pentazocine, and (particularly in

TABLE 58-3. Systemic Sclerosis (Scleroderma)

CRITERIA FOR DIAGNOSIS*
Major
Thickening of the skin of the hands
Minor
Sclerodactyly (i.e., the changes of the major criterion but limited to the fingers)
Digital pitting scars or loss of substance from the finger pad: depressed areas at tips of fingers or loss of digital pad tissue as a result of ischemia
Bibasilar pulmonary fibrosis
LUNG MANIFESTATIONS
Interstitial pulmonary fibrosis
Organizing pneumonia
Isolated pulmonary vascular disease
Aspiration pneumonia (secondary to esophageal dysmotility)
Chest wall restriction

men) the industrial agents vinyl chloride, benzene, toluene, and trichloroethylene.[5] Silica exposure increases the odds ratio of SSc, and silicosis increases the rate even further.[6] The toxic oil syndrome, first recognized in Madrid in 1981, results from ingestion of an adulterated cooking oil containing rapeseed oil denatured with aniline.[7] This provokes a scleroderma-like syndrome with pulmonary involvement. The association with silicone breast implants is unproved.

Pulmonary Manifestations

More is known about the pulmonary complications of SSc than any other CTD. Pulmonary involvement has emerged as the major cause of excess morbidity and mortality in SSc.[8] The patterns of lung disease with which SSc may present are variable and are shown in Table 58-3.

Interstitial Pulmonary Fibrosis

Pathogenesis. Of all of the lung problems in the CTDs, most is known about the pathophysiology of interstitial pulmonary fibrosis SSc. There are several distinct, but related, aspects of pathogenesis.

Predisposition. There is good evidence that individuals are predisposed genetically to develop SSc, and there are emerging markers that define risks for diffuse lung disease. The importance of genetics to SSc is illustrated by a study of Choctaw Indians residing in southeastern Oklahoma. The prevalence of SSc in full-blooded Choctaws is roughly 1:200, which is significantly higher than that found in non–full-blooded Choctaws (1:3000) and strikingly higher than the global prevalence of SSc in other Native Americans in Oklahoma (1:10,000).[9]

Class II major histocompatibility complex associations increase the risk of interstitial pulmonary fibrosis in SSc. The relative risk is increased if the anti-DNA topoisomerase (Scl-70) antibody is present. Recent studies have shown that there is an association between Scl-70 and an allele of the major histocompatibility complex *DPB1* gene.

The genetic susceptibility probably results in injury and an immune response. It has been shown that there are highly restricted T-cell responses to epitopes of DNA topoisomerase 1, both in healthy individuals and in those with SSc. Thus, in individuals with Scl-70–responsive T-cell clones, the autoantibody may be responsible for driving the immune response. In the lung, there is an accumulation of "memory-type" CD45 Ro lymphocytes and secondary lymphoid follicles with true germinal centers within lung biopsy samples.[10] Furthermore, the T cells present within the lung express cytokines of both the T helper 1 (Th1) and the T helper 2 (Th2) subsets.[11]

Inflammation Amplification. A wide variety of cytokines identified in bronchoalveolar lavage (BAL) fluid clearly contribute to the cascade of inflammation in the lungs.[12] The most striking of these are interleukin-8 (neutrophil chemoattractant and activator), tumor necrosis factor-α (TNF-α; an early cytokine involved in many pathologic processes), macrophage inflammatory protein-1α (important in neutrophil chemotaxis), and RANTES (regulated on activation normal T cell expressed and secreted; important in T-cell and eosinophil recruitment and activation). It is clear, therefore, that the downstream events of the initiation result in the release of a number of proinflammatory cytokines that are responsible for further recruitment and activation of inflammatory cells at disease sites.

Fibrogenetic Factors. The hallmark of SSc in both lung and skin is the accumulation of connective tissue matrix cells and proteins.[13,14] Many factors have been studied in this regard, and a wide variety of growth factors have been identified. Perhaps the most striking of these is connective tissue growth factor, which appears to depend on transforming growth factor-β (TGF-β) for up-regulation and has a potent effect on collagen production, as evidenced by collagen gel retraction studies.[15,16] TGF-β is found in high amounts in the lungs of patients with SSc,[17] and when TGF-β signaling is inhibited, minor epithelial injury leads to extensive fibrosis.[18] Endothelin (ET)-1 and coagulation cascade proteins are also present in high amounts in BAL fluid.[13,19] Fibroblasts from patients with lung disease exhibit dysregulated type I collagen biosynthesis and impaired messenger RNA down-regulation. The balance of ET receptors (A and B) is modified in the lungs of patients with scleroderma, with a consistent decrease in ET_A and an increase in ET_B receptors.[14,20] ET-1 may contribute to epithelial-mesenchymal transition of airway epithelial cells, resulting in fibrosis.[21]

A number of parallel events result in the development of lung injury and subsequent fibrosis. It is simplistic to target any one of these as being the important factor, but there seems little doubt that the key cytokines in the cascade include TNF-α (because it occurs very early in

disease and has been shown in animal models to be a pivotal factor in lung fibrosis)[22] and TGFr-β (which colocalizes with collagen gene up-regulation and is important in connective tissue growth factor release). Other important cytokines may include hepatocyte growth factor and insulin-like growth factor-II.[23,24] The balance of Th1 to Th2 cytokines is also key because, when the shift is in favor of Th2 cytokines, such as in idiopathic pulmonary fibrosis, the prognosis is worse and there is a much higher eosinophil influx into the lung, in comparison with patients with SSc, in whom the Th1/Th2 ratio is balanced and there is less eosinophil influx per unit lung involvement.[11]

Clinical Features. The prevalence of lung disease in SSc depends on the method used for detection. Symptoms or signs of lung disease are common. Dyspnea occurs in roughly 55% of patients (range, 21%–80%).[25] Cough, a less frequently reported symptom, tends to be dry and nonproductive. Hemoptysis is rare but may complicate carcinoma or bronchial telangiectasia.[26] Fine crackles are heard at the lung bases and are of a "Velcro" character. Pleural rub is almost never heard. Pleuritic chest pain is uncommon. Pneumothorax is even less common. Digital clubbing is extremely rare. Secondary pulmonary hypertension with appropriate clinical features of right ventricular strain, raised jugular venous pressure, and ankle edema may be seen during the terminal stages of the disease.

Chest radiographic abnormalities are present in 25% to 67% of patients, and lung function is impaired in up to 90%, although a large subset of patients has only a minor reduction in gas transfer. The lung is involved more commonly in patients with diffuse than with limited cutaneous SSc (i.e., involving skin proximal to the elbow), but the extent of skin involvement does not correlate with lung function changes. Patients are often symptom free, even with moderate pulmonary function impairment. Rarely, scleroderma of the chest wall may cause extrathoracic restriction.

Lung disease may be the first manifestation of SSc. In this setting, a history of Raynaud's phenomenon is often helpful. In addition, careful examination of the capillaries in the nail beds reveals the typical feature associated with scleroderma: abnormal loops associated with capillary "dropout." The presence of autoantibodies, particularly antinuclear antibodies, is helpful in suggesting a CTD etiology (Table 58-4).

Imaging. Chest radiography typically shows a reticular pattern in the lung bases and periphery in early disease. There is obvious loss of volume with more extensive reticular shadowing in more advanced disease. In this situation, honeycombing may be present (Fig. 58-1A).

Computed tomography (CT) has revolutionized the interpretation of the pattern and extent of disease. Disease is again localized to the peripheral rim, occurring earliest at the bases and posteriorly. As disease becomes more advanced, it progresses superiorly, centrally, and anteriorly. Esophageal dilation is common, which can be helpful in the diagnosis if the lung disease is the first manifestation of the systemic disease (see Fig. 58-1B and C).[27] The pattern may be "ground-glass" (reflecting either fine intralobular fibrosis or a more cellular histopathology) or an overtly fibrotic "reticular" pattern, consisting of intersecting linear abnormalities, often associated with traction bronchiectasis.[28] Honeycomb change is present in up to one third of cases but is usually limited in extent.[29]

CT extent correlates extremely well with lung function, particularly gas transfer. Strikingly, individuals with idiopathic pulmonary fibrosis have much more hypoxia than those with SSc once the extent of disease on CT has been taken into account.[30] The extent of individual patterns (ground-glass vs. reticular) is associated with the type of inflammatory cell found in BAL. More extensive reticular (consistent with more fibrosis) disease is associated with high neutrophil numbers, and this influx therefore appears to depend on disease extent regardless of disease type.[31]

Gallium scans provide no added value. Technetium-99m–labeled diethylenetriaminepentaacetic (DTPA) acid clearance has been used in some medical centers to identify early disease and to predict prognosis.[32] A more rapid clearance of this isotope is indicative of a loss of epithelial cell integrity, and rapid clearance indicates uptake from the air space into the circulation. A persistently rapid clearance rate confers an increased risk of subsequent lung function deterioration, and a persistently normal clearance rate predicts lung function stability.

Lung Function Tests. The interstitial pulmonary fibrosis of SSc is characterized by a restrictive ventilatory defect of mechanical function, which results in reduced pulmonary compliance, vital capacity, and total lung capacity. Residual volume is decreased. Diffusing capacity for carbon monoxide (DL_{CO}) is reduced and may be the only abnormality in early disease. Blood gas analysis usually reveals a reduced arterial oxygen pressure (Po_2) with a normal or low arterial carbon dioxide pressure (Pco_2). Hypoxia is usually not marked until very late in the disease process.

There have been a number of studies of rate of change of lung function in SSc.[33,34] In one study, 27 of 38 patients lost more than 30 mL of vital capacity per year (the normal rate of decline).[34] A second study showed that vital capacity loss was greater in patients who had evidence of an active alveolitis on BAL.[33] Rates of decline are often higher within 2 years of onset of SSc, emphasizing the importance of identifying lung disease early. Lower forced vital capacity (FVC) within 3 years of disease onset predicts decline in pulmonary function.[35]

Exercise lung function testing increases ventilation-perfusion mismatching and also increases diffusion abnormalities so that hypoxia results with widening of the alveolar-arterial gradient. Minute ventilation increases generally as a consequence of increased ventilation rate rather than tidal volume. Dead space ventilation may increase on exercise, with a rise in the dead space–to–tidal volume ratio. For a given degree of lung involvement defined by CT, abnormalities on exercise gas exchange are worse in patients with idiopathic pulmonary fibrosis than in those with interstitial pulmonary fibrosis in association with SSc.

TABLE 58-4. Autoantibodies in Connective Tissue Disease

CTD	Autoantibody	Target	Comments
SSc	Anticentromere	Centromere proteins (CENP A-F)	20%–40% total SSc, wide racial variation 70%–80% limited cutaneous variant with pulmonary hypertension
	Scl-70	DNA topoisomerase 1	28%–70% total SSc, wide racial variation; >30% diffuse cutaneous disease with ILD
	PM-Scl	—	Scleroderma-myositis overlap syndromes
	Antinucleolar	RNA polymerase-1	8%–20% SSc suggests poorest 10-yr survival, renal crisis
	Ku	DNA binding proteins	Scleroderma-myositis overlap syndromes
Rheumatoid arthritis	Rheumatoid factor	IgG	Seropositive disease more frequent with pulmonary nodules
	Antinuclear antibody	—	—
	Histone	Histone proteins	5% rheumatoid vasculitis
SLE	dsDNA	dsDNA	50%–75%, strong association with nephritis
	ANA	—	90%–95%
	Ro/La	RNA transcription factors	60%/20%
	Histone	Histone proteins	>90% drug-induced lupus, 20%–30% primary SLE
	Sm	—	10% whites and 30% African Americans and Chinese
	Lupus anticoagulant	Phospholipid	20%–30%
MCTD	U1-RNP	Small nuclear proteins	Myositis overlap syndromes (10% SSc)
	U2-RNP	—	Myositis, SLE, SSc
DM/PM	Jo-1	Histidyl tRNA synthetase	20%–30% inflammatory myopathy but 50%–100% when associated with diffuse fibrosing lung disease
	PL-7	Threonyl tRNA synthetase	<3% antisynthetase syndrome
	PL-12	Alanyl tRNA synthetase	<3% antisynthetase syndrome
	EJ	Glycyl tRNA synthetase	<2% antisynthetase syndrome
	OJ	Isoleucyl tRNA synthetase	<2% antisynthetase syndrome
	Mi-2	Nuclear proteins	<8% DM, associated with acute onset of classic DM
	Ku	Nuclear proteins	Associated with myositis-CTD overlap syndromes
Antiphospholipid syndrome	Anticardiolipin Lupus anticoagulant	Membrane phospholipids	Disease diagnosis depends on presence of clinical features
Relapsing polychondritis	Anticartilage	Cartilage	Unknown sensitivity
	Anticollagen	Collagen	
Sjögren's syndrome	Ro (SS-A)	RNA transcription factors	40%–50% primary Sjögren's syndrome (25%–30% SLE)
	La (SS-B)		50% Sjögren's (10% SLE)

ANA, antinuclear antibody; CTD, connective tissue disease; DM/PM, dermatomyositis/polymyositis; dsDNA, double-stranded DNA; IgG, immunoglobulin G; ILD, interstitial lung disease; MCTD, mixed connective tissue disease; SSc, systemic sclerosis; SLE, systemic lupus erythematosus; tRNA, transfer RNA.

Bronchoalveolar Lavage. BAL may identify alveolitis in SSc before the onset of pulmonary symptoms.[36] A neutrophil alveolitis has been described by some authors to predict more progressive disease.[33,37,38] However, it has been shown that an increase in neutrophils reflects an increase in the extent of disease on CT, particularly the reticular pattern, and this increase is, therefore, likely a marker of more extensive disease rather than an independent index of progressive disease.[31,39,40] BAL should not be used alone to determine whether treatment should be started. Many patients with apparently normal BAL findings may exhibit progressive disease. BAL is, therefore, not recommended routinely for the diagnosis or monitoring of SSc-related interstitial disease.

Biopsy. Surgical lung biopsy is largely not required in the diagnosis of SSc-related interstitial disease. If the pattern of disease is at all atypical after review of the less invasive indices, lung biopsy is recommended. No extra information is obtained by a transbronchial biopsy; therefore, surgical biopsy is required in this situation. Examples of circumstances in which biopsy is indicated include an unusual pattern of disease on CT, marked pleural disease, or clinical features of an overlap syndrome.

Pathologically, the most common pattern is nonspecific interstitial pneumonia, with thickening of the alveolar walls with inflammatory cells (mononuclear cells, granulocytes, and plasma cells), connective tissue matrix cells, and proteins combined with intra-alveolar inflammation (predominantly by macrophages), type II pneumocyte proliferation, and vascular obliteration. The distribution is subpleural and basal and is maximal in posterior segments, with the macroscopic findings of the lung surface taking on a fine nodular, "cirrhotic" appearance in the early stages and honeycombing with more advanced disease.[38] This pattern differs from usual

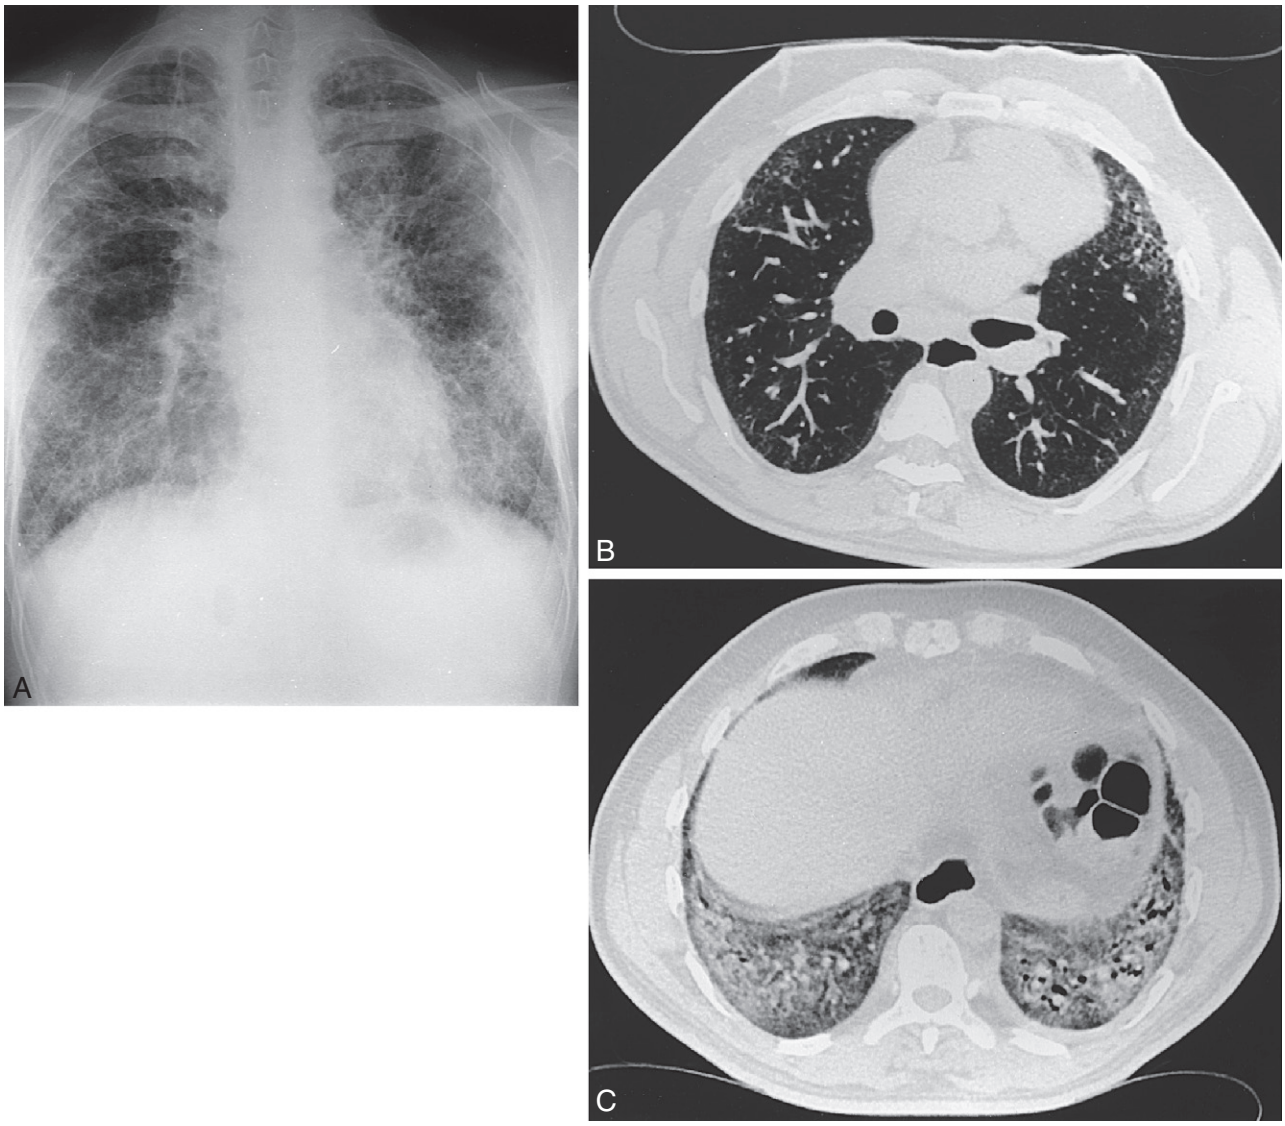

FIGURE 58-1 ■ Radiographic appearances in patients with systemic sclerosis. **A,** Chest radiograph from a patient with systemic sclerosis. Note the widespread, predominantly peripheral pattern of reticular opacities. The heart borders and the diaphragm are obscured. **B,** Computed tomography (CT) scan taken at a level just below the carina in a patient with systemic sclerosis. Note the peripheral reticular pattern that in this case is more prominent anteriorly. In this patient with subtle disease, the dilated esophagus is a clue as to the true cause of the fibrosing lung disease. **C,** CT scan taken at the level of the diaphragm in a patient with more extensive interstitial pulmonary fibrosis in the context of systemic sclerosis. Note in particular the very dilated airways, indicating that the apparent "ground-glass"/consolidation pattern is dense fibrosis. Again, the dilated esophagus indicates that this disease is likely to be part of systemic sclerosis.

interstitial pneumonia in exhibiting a homogeneous pattern of pathology. Much less commonly, the usual interstitial pneumonia pattern of histopathology is seen. One of the hallmarks of usual interstitial pneumonia is a heterogeneous appearance, with normal alveoli seen in the same section as areas of extensive alveolar remodeling.[41] These pathologic differences may denote disease subsets with differences in outcome. Electron microscopy shows early endothelial and epithelial cell injury, even without abnormalities on light microscopy. Autopsy studies show diffuse lung disease in up to 80% of cases and pulmonary vascular disease in up to 30%. In some patients with a more accelerated course of disease, histopathologic examination has shown a diffuse alveolar damage pattern.[42]

Serologic Investigations. Although SSc is traditionally defined on the basis of the extent of the skin disease, as outlined previously, the pattern of autoantibodies appears to be a much stronger determinant of the associated internal organ involvement.[43,44] Antinuclear antibodies are found in 90% to 100% of patients with SSc (roughly 30% of normal individuals have antinuclear antibodies at a titer of 1:40). Three major autoantibodies include anticentromere, occurring in 57% of patients with limited cutaneous disease; anti-topoisomerase (Scl-70), occurring in 40% of patients with diffuse disease; and PM-Scl,

occurring in a small fraction of cases in association with the polymyositis overlap syndrome. It is rare to have both Scl-70 and anti-centromere antibodies. Diffuse lung disease is rare in the presence of anti-centromere antibodies, and a protective role for this autoantibody has been argued but not substantiated. Interstitial pulmonary fibrosis is strongly associated with the Scl-70 antibody and with diffuse scleroderma. Limited cutaneous disease associates with vascular disease and the anti-centromere antibody. Both forms of lung disease may progress to pulmonary hypertension. Other autoantibody studies that have shown associations with organ involvement include a nucleolar pattern with diffuse lung disease and pulmonary hypertension[45]; the antibody B23 that recognizes this nucleolar phosphoprotein, with pulmonary hypertension and is associated with the presence of the anti-fibrillarin antibody; and anti-Th/To antibodies with "intrinsic" pulmonary hypertension and diffuse lung disease.

Prognosis. The prognosis of interstitial pulmonary fibrosis in SSc depends on the extent of disease at presentation. Worse lung function, particularly vital capacity and DL_{CO}, indicates a poorer outcome, and similar observations have been made based on extent of disease on CT as the criterion.[45a] A simple staging system using CT extent (above and below 20%), and FVC at presentation (above and below 70%), is highly discriminatory for both progression and death (Fig. 58-2).[46] Although crude mortality rates are 3.9%/yr for men and 2.6%/yr for women, lung disease remains the most common cause of death in patients with SSc.[47] In one series of causes of death, lung disease was the most common, accounting for 21% of all deaths.[47a] There is also an increased risk of lung cancer in SSc.[47b]

Treatment. A wide variety of treatments for interstitial pulmonary fibrosis in SSc have been explored.[48,49] Most of these include immunosuppression. A number of uncontrolled reports suggested an advantage of

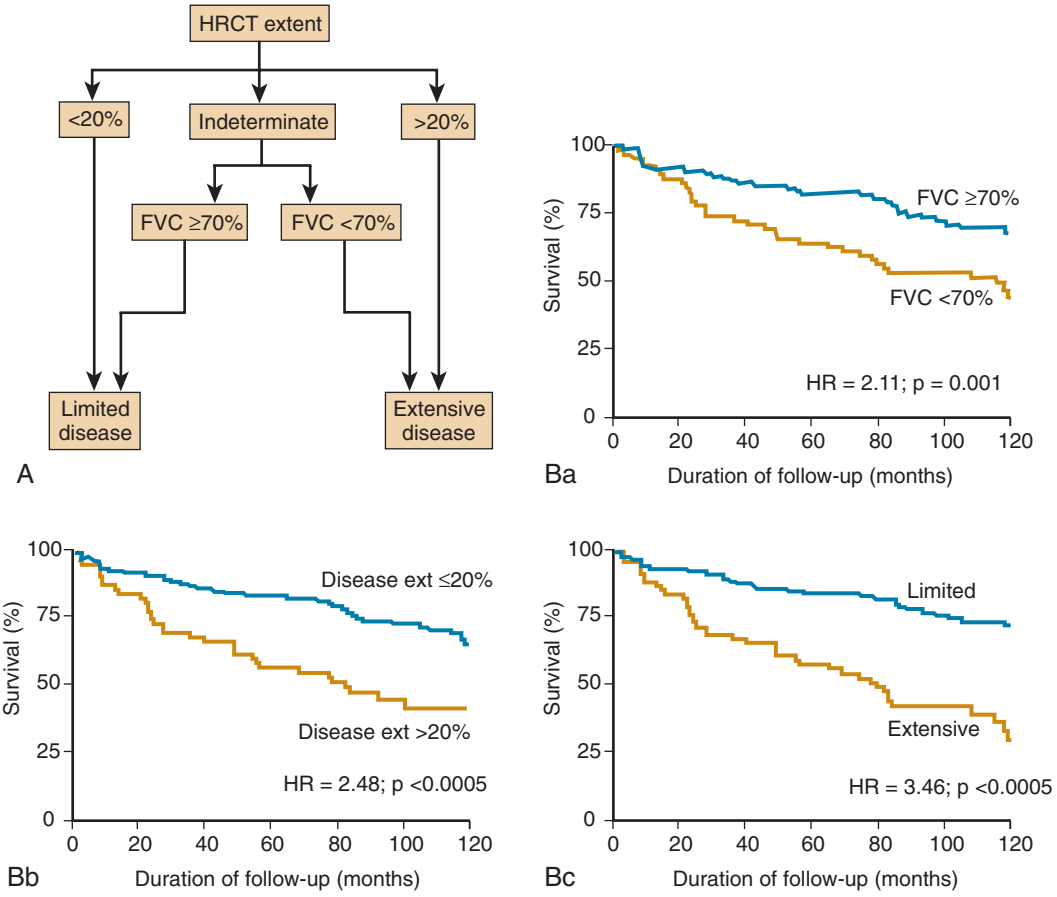

FIGURE 58-2 ■ Staging algorithm for interstitial lung disease due to systemic sclerosis. **A,** Flow diagram of limited/extensive staging system with use of high-resolution computed tomography (HRCT) scores and pulmonary function test data. Identification of overtly minimal/limited disease is based on disease extent threshold of 20% on HRCT versus severe/extensive disease that is identified by HRCT disease extent greater than 20%. In cases with an indeterminate extent of disease on HRCT, a forced vital capacity (FVC) threshold of 70% is used to separate the cases into limited or extensive disease. The HRCT scans are scored at five levels for total disease extent, extent of reticulation, proportion of ground glass, and coarseness of reticulation. **B,** Survival compared between patient subgroups with (*a*) FVC levels above and below a threshold value of 70%; (*b*) HRCT disease extent above and below a threshold value of 20%; and (*c*) limited disease (HRCT extent ≤ 10%, or when HRCT extent was 10%–30%, FVC ≥ 70%) versus extensive disease (HRCT > 30%, or when HRCT extent was 10%–30%, FVC < 70%). ext, extent. (Data from Goh NS, Desai SR, Veeraraghavan S, et al: Interstitial lung disease in systemic sclerosis: A simple staging system. Am J Respir Crit Care Med 177:1248–1254, 2008.)

treatment with cyclophosphamide, together with prednisolone, to improve lung function and prognosis.[50,51] The Scleroderma Lung Study demonstrated a small but significant benefit of oral cyclophosphamide over placebo for FVC, skin scores, as well as quality of life and dyspnea scores at 12 months.[52] The oral cyclophosphamide treatment regimen used most commonly is 2 mg/kg/day orally up to a maximum of 150 mg with moderately low dosages of prednisolone at 10 mg/day or 20 mg every other day. Close scrutiny with full blood counts, liver function tests, and urine testing for evidence of hemorrhagic cystitis is needed.

However, intravenous cyclophosphamide may have a better side effect profile.[53] Studies of intravenous cyclophosphamide (750–1000 mg/m^2) given at 2- to 4-week intervals for 6 to 12 months tended toward significance, as judged by CT and pulmonary function data.[54,55]

The question of *Pneumocystis* prophylaxis is not resolved. Some medical centers use cotrimoxazole three times a week if immunosuppressive agents are being given. A study of interferon-γ showed a greater deterioration in lung function at 1 year than with placebo.[56]

It has been observed that steroid therapy is associated with scleroderma renal crisis, both with high-dose therapy[57] and, more recently, with prednisolone doses of less than 10 mg daily.[58] However, confounding by severity cannot be excluded, as patients with more aggressive systemic disease are more likely to receive corticosteroids, although occasional cases of renal crisis are undoubtedly linked to high-dose corticosteroid therapy. Thus, low-dose steroid therapy remains justified as an invaluable adjunct to the treatment of lung disease, although renal function should be monitored from time to time. A number of retrospective studies support the use of mycophenolate mofetil[59–61]; however, a definitive controlled study has not been performed.

End-stage lung disease has been treated with single-lung transplantation provided there is no evidence of disease activity in other organs. There appears to be no greater mortality in this group than in individuals with primary diffuse lung disease. In terminal disease that is not amenable for transplantation, consideration must be given to regular oxygen therapy, treatment of supervening heart failure, and infection.

Pulmonary Vascular Disease in Systemic Sclerosis

Unlike the other CTDs, vascular involvement in SSc is caused by concentric fibrosis of small arterioles replacing the normal intima and media, but the plexiform lesions and fibrinoid necrosis of primary pulmonary hypertension are not seen. Isolated vascular disease occurs mainly in the limited form of SSc. Associated features are those of the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias) with prominent telangiectasia, esophageal disease, abnormal nail fold capillaries (dilated capillaries and dropout of capillary loops), and a positive anti-centromere antibody. Chest radiography, CT scanning, and BAL are all normal. Lung function studies show an isolated fall in D_{LCO}. When damage to the pulmonary vascular bed is extensive (gas transfer <50% of predicted), the risk of pulmonary hypertension increases.[62] Mortality rates are increased with increasing pulmonary hypertension.[63,63a]

DTPA clearance measurements are usually normal in patients with pure pulmonary vascular disease in scleroderma and help to differentiate vascular disease from early diffuse disease in patients with an isolated fall in D_{LCO}. Doppler echocardiography has been shown to correlate with measurements of pulmonary artery pressures made at right heart catheterization. Qualitative features found on echocardiography may also suggest pulmonary hypertension in the absence of a tricuspid regurgitant jet, precluding measurement of the gradient across the tricuspid valve and, thus, an estimate of pulmonary artery pressure. These include right ventricular dilation and right ventricular hypertrophy. Overall, echocardiography is moderately sensitive for the diagnosis of pulmonary arterial hypertension (PAH; 47%–88%).[64,65] However, echocardiography is less accurate at borderline and mild levels of pulmonary hypertension. Stress (exercise) echocardiography may be able to identify preclinical PAH.[66,67] NT-proBNP, released from cardiac ventricles in response to stretch, is elevated in SSc and is inversely related to gas transfer. Elevated NT-proBNP levels may predict the development of pulmonary hypertension in SSc.[68,69]

Although there are a number of emerging therapeutic options, optimal treatment of pulmonary vascular disease in SSc has not yet been defined. Calcium channel antagonists may be helpful, but often the dosage required to improve the pulmonary vasculature causes unacceptable drops in left-sided pressures and peripheral edema. Angiotensin-converting enzyme inhibitors can be helpful. Prostacyclin analogues cause potent pulmonary and systemic vasodilation and inhibit platelet aggregation. Intravenous and subcutaneous prostacyclin analogues have been shown to lead to improved pulmonary vascular resistance, pulmonary pressure, and 6-minute walk distances in the acute and longer term.[70–72] Exact dosage regimens need to be validated, however. Inhaled iloprost may also improve exercise capacity and cardiopulmonary hemodynamics.[73] Oral ET-1 receptor antagonists have been shown to improve exercise capacity and hemodynamics in patients with PAH and CTD (including SSc).[74–76] Sildenafil, a phosphodiesterase-5 inhibitor, leads to an improvement in exercise capacity and hemodynamics in patients with PAH (including patients with SSc).[77,78] The correct balance of these therapies, including combination therapy, is yet to be determined in controlled studies. Emerging therapies, such as the platelet-derived growth factor antagonist imatinib, show promise in animal studies.[79]

Other Pulmonary Complications

Aspiration pneumonia is extremely uncommon, particularly considering the prevalence of esophageal dysfunction in SSc. Pleural disease is uncommon. Rarely, the extent of skin tightness over the chest wall produces an

extrinsic restriction of ventilation. Occasionally, the first manifestation of pulmonary parenchymal disease is organizing pneumonia. This responds well to corticosteroid therapy, as does organizing pneumonia in other contexts.

RHEUMATOID ARTHRITIS

The American Rheumatism Association revised criteria for the classification of rheumatoid arthritis (RA) require that at least four of the criteria listed in Table 58-5 be satisfied for a minimum of 6 weeks.[80]

Epidemiology and Risk Factors

The reported incidence of RA ranges from 0.2 to 3.0/1000 person-years (<0.5/1000 person-years in most surveys), with a rising incidence with increasing age into the seventh decade. In adult whites, the prevalence of RA ranges from 0.5% to 2%, with a male-to-female ratio between 1:2 and 1:4. Depending on disease severity (as judged by disability scales and the need for long-term corticosteroid therapy), the age-matched mortality rate of RA is up to twofold higher than in the general population, with this increased mortality being attributed to cardiorespiratory complications.[81,82] The prevalence of RA is similar throughout the world. Evidence in support of a genetic predisposition includes familial and twin clustering and associations between RA and HLA-DRB1 alleles.[83] Hormonal factors may play a role, judging from the female preponderance of RA and a reduced incidence during pregnancy. Infectious agents and socioeconomic factors have not been shown to be etiologically important.

TABLE 58-5. Rheumatoid Arthritis

CRITERIA FOR DIAGNOSIS*
Morning stiffness (lasting at least 1 hr)
Arthritis (soft tissue swelling or fluid) of three or more joints (PIP, MCP, wrist, elbow, knee, ankle, MTP joints)
Arthritis of hand joints (swelling of at least one wrist, MCP, or PIP joint)
Symmetrical arthritis (i.e., simultaneous arthritis of the same joints on both sides of the body)
Rheumatoid nodules
Serum rheumatoid factor positivity (at a level such that <5% of normal controls are positive)
Radiographic hand or wrist changes typical of rheumatoid arthritis
LUNG MANIFESTATIONS
Interstitial pulmonary fibrosis
Organizing pneumonia
Obliterative bronchiolitis
Follicular bronchiolitis
Bronchiectasis
Vasculitis
Nodules
Pleural disease
Lymphocytic interstitial pneumonia
Drug induced

*At least four criteria for a minimum of 6 wk.
MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

Pulmonary Manifestations

Pleuropulmonary manifestations are multiple and are listed in Table 58-5.

Interstitial Pulmonary Fibrosis

The interstitial pulmonary fibrosis of RA has a male predominance (male-to-female ratio, 3:1).[84] High titers of rheumatoid factor[85] and the presence of rheumatoid nodules[86,87] are associated with an increased prevalence of pulmonary fibrosis in RA. Smoking is a risk factor for the development of overt pulmonary fibrosis in RA[85,88] and has also been associated with subclinical disease.[89,90] In the presence of HLA-DR susceptibility genes, smoking is strongly associated with development of anti-citrulline–positive RA.[88]

In early disease, a lymphocytic interstitial infiltrate is often the predominant abnormality,[91] and prominent peribronchiolar follicles, containing aggregates of lymphocytes with germinal centers, are often seen.[92] In long-standing disease, fibrosis predominates, often resulting in cystic changes or honeycombing. It is difficult to estimate the exact prevalence of subcategories of interstitial pulmonary fibrosis because, in historical series, histologic descriptions of "interstitial fibrosis" have not been detailed. Both nonspecific interstitial pneumonia and usual interstitial pneumonia are present in significant and likely similar proportions of patients with interstitial fibrosis.[93,94] However, it seems that usual interstitial pneumonia is associated with a better outcome in CTD than in an idiopathic setting.[41,95,96] Minor pulmonary fibrosis is common in RA; in one open-lung biopsy series performed in volunteers with RA (some without clinical evidence of interstitial lung disease), pulmonary fibrosis was seen in 60% of patients.[97]

Reductions in D_{LCO} are found in 40% of unselected RA patients.[98] However, radiologically overt pulmonary fibrosis is found in only 1% to 5% of RA patients (based on three large chest radiographic series).[86,89,99] In the largest prospective series reported to date, 150 consecutive patients were screened for pulmonary disease.[100] Of these, 19% had CT evidence of interstitial fibrosis, which was often subtle; 43% of those with interstitial abnormalities also had emphysematous bullae (previous or current smoking history). Chest radiography identified abnormalities in only 14% of the whole cohort, but physiologic abnormalities were seen in 82% (gas transfer) and 14% (restrictive pattern of ventilatory defect).[100] Disease severity as judged by CT reflects functional impairment.[101–103]

Severe progressive disease requiring hospitalization may be associated with cor pulmonale and respiratory failure and has a poor prognosis, with a 5-year survival

rate of less than 50%[45]; however, a large subgroup of patients have more indolent disease that progresses little during prolonged follow-up. A strong predictor of decline is a gas transfer less than 55% of predicted at presentation.[104] The most frequent symptom is exertional dyspnea, although this may be masked by a general loss of mobility due to systemic disease. The clinical picture is usually identical to that of idiopathic pulmonary fibrosis, with bilateral, predominantly basal crackles and tachypnea, cyanosis, and right heart failure in advanced disease. Finger clubbing, which is occasionally striking, is more prevalent than in other CTDs.

Organizing Pneumonia

Organizing pneumonia (bronchiolitis obliterans with organizing pneumonia) is characterized by plugs of granulation tissue in the air spaces distal to and including the terminal bronchioles, associated with lymphocytic infiltration within well-preserved bronchiolar walls and the surrounding lung interstitium. The term *bronchiolitis obliterans with organizing pneumonia* has caused confusion among clinicians, stimulating the recent use of the term *proliferative bronchiolitis*. Organizing pneumonia has a very different profile from the entity of bronchiolitis obliterans (also found in RA), with a clinical presentation of pneumonia (as opposed to airflow obstruction), multifocal consolidation on chest radiograph and CT, a restrictive functional defect, and a much higher chance of responsiveness to corticosteroids than bronchiolitis obliterans (with a good outcome in 15 of the first 17 reported cases) (Fig. 58-3).[105] Organizing pneumonia is more common in RA than in other CTDs (with the possible exception of polymyositis). In a series of 40 patients with RA undergoing open-lung biopsy, organizing pneumonia (6 cases) had a prevalence similar to that of interstitial fibrosis (5 cases),[106] although organizing pneumonia might have been overrepresented owing to an acute presentation (and thus a perceived need to reach a definitive histologic diagnosis). The good prognosis generally seen in organizing pneumonia has been emphasized in the medical literature, but a minority of RA

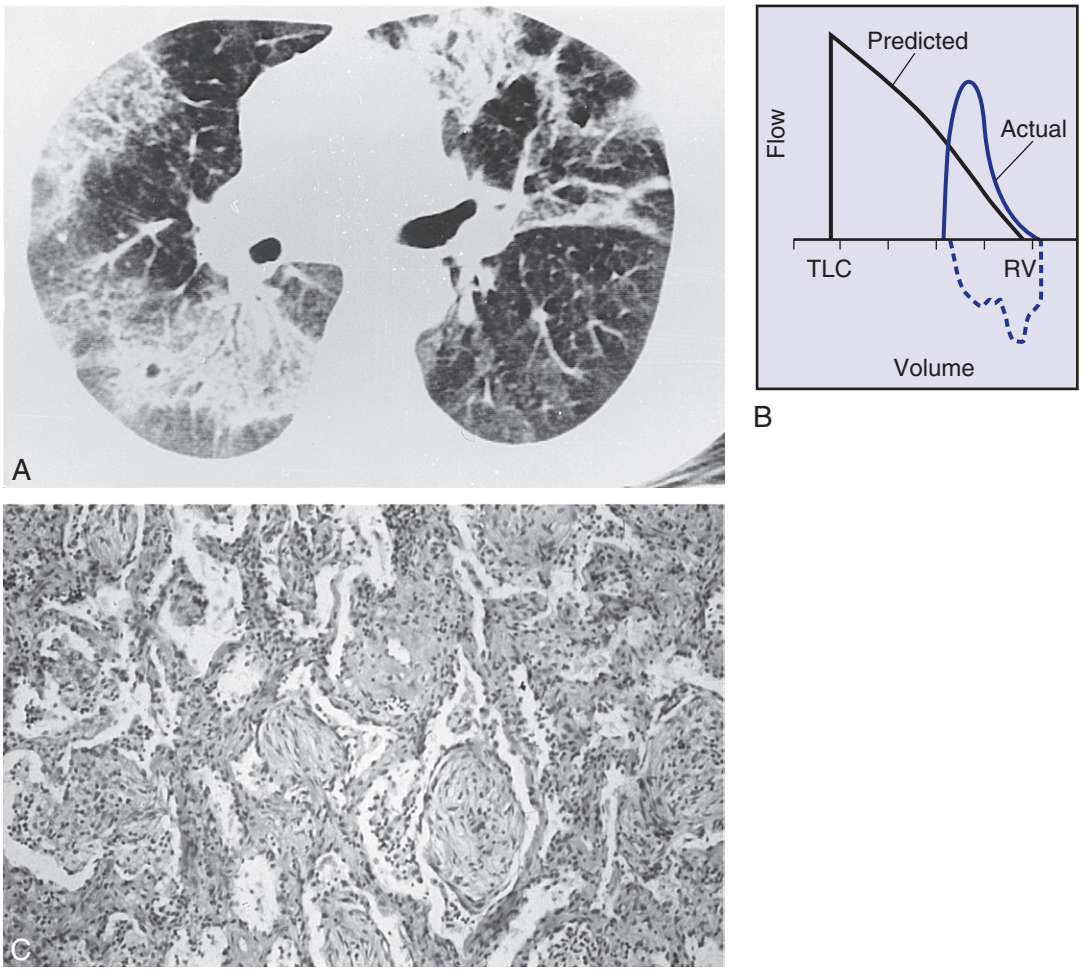

FIGURE 58-3 ■ **A,** CT scan from a patient with rheumatoid arthritis and organizing pneumonia. Note the bilateral pattern of air space consolidation. **B,** A flow-volume loop from the same patient as in **A.** The flow-volume loop is shifted to the right by comparison with the ideal predicted loop, but the flow rates are relatively well preserved. RV, residual volume; TLC, total lung capacity. **C,** Surgical lung biopsy specimen from another patient with organizing pneumonia in the context of rheumatoid arthritis. The alveoli and respiratory bronchioles are filled with loosely packed connective tissue.

patients progress to respiratory failure and death despite treatment.

Obliterative Bronchiolitis

Obliterative bronchiolitis (OB) in RA has now been described in numerous case reports and small series. OB (synonymous with bronchiolitis obliterans and constrictive bronchiolitis) (Fig. 58-4) is characterized histologically by destruction of the bronchiolar wall by granulation tissue, effacement of the lumen, and eventual replacement of the bronchiole by fibrous tissue. There is circumstantial evidence to suggest that OB may be preceded by an inflammatory exudate; prominent bronchiolar inflammation may be found in patients with the shortest symptomatic course.[107] The expression of HLA antigens B40 and DR1 is increased in OB associated with RA (but not in isolated OB).[108]

In early descriptions, the hallmark of OB was a rapidly progressive, often fatal, course; however, because clinician awareness of the disease was then low, patients with advanced and progressive disease were undoubtedly overrepresented. There is great heterogeneity in the speed of progression, with some patients having indolent disease[109]; the use of CT in RA patients with suspected pulmonary complications has now identified a subgroup with occult bronchiolitis, often admixed with interstitial lung disease. The prevalence of unsuspected OB in unselected RA patients remains uncertain, with unexplained airflow obstruction identified in a significant minority (including many nonsmokers) in one study[110] but no increase in the prevalence of pulmonary function abnormalities suggestive of isolated small airway disease in two subsequent controlled series.[111,112]

Two major associations with the development of OB in RA have been reported. It is likely that secondary

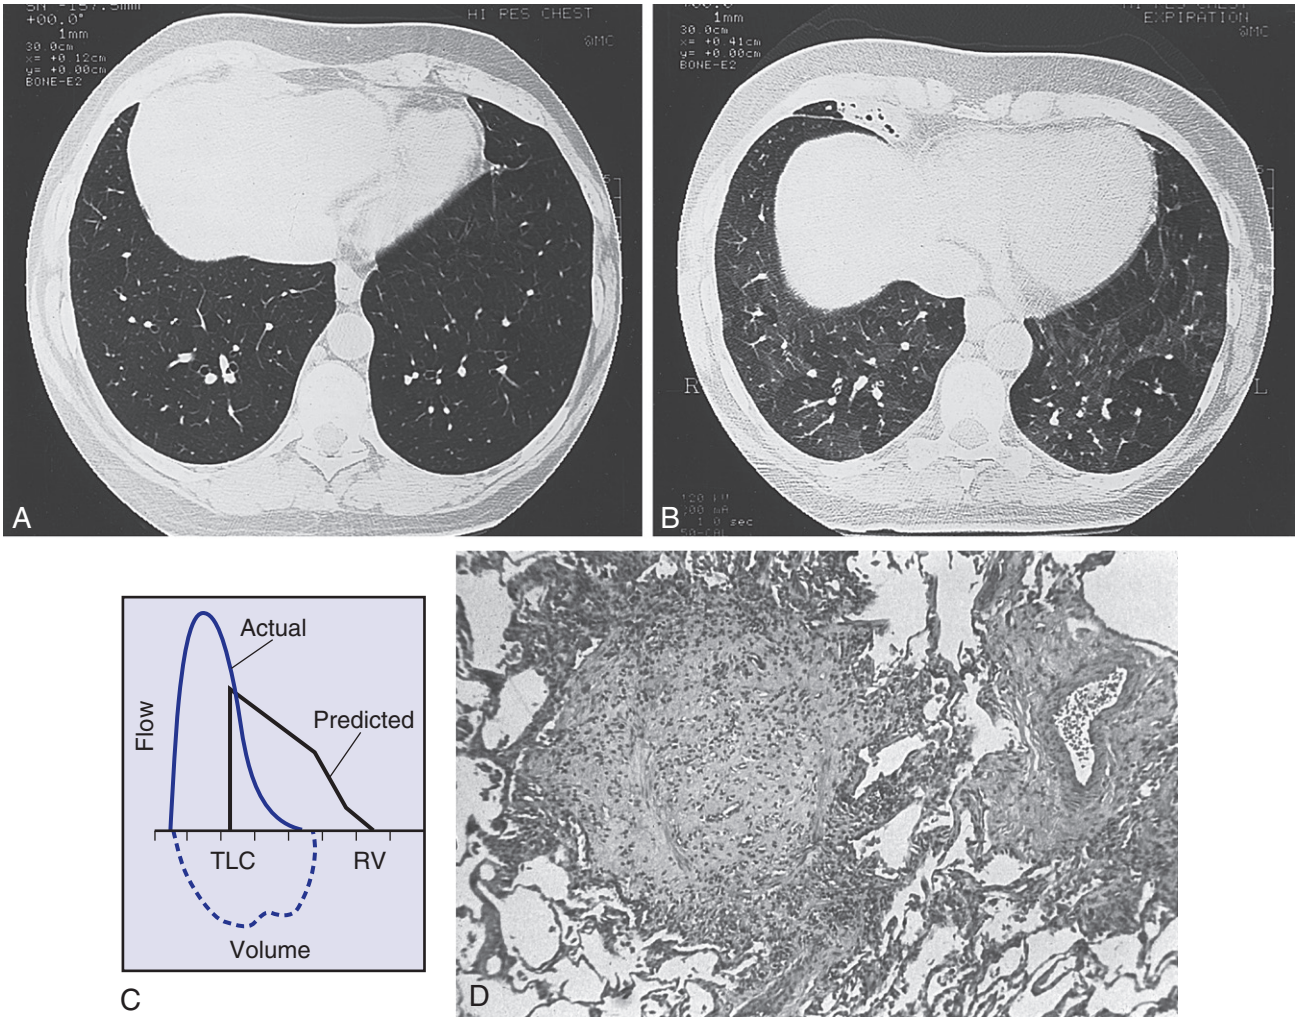

FIGURE 58-4 ■ Inspiratory and expiratory CT sections were obtained from a patient with rheumatoid arthritis with obliterative bronchiolitis. **A,** The inspiratory image is essentially normal. **B,** On the expiratory CT scan, there is extensive regional inhomogeneity, the reduced density resulting from regional vasoconstriction or regional gas trapping. **C,** A flow-volume curve from the same patient as in **A** and **B** shows marked elevation of total lung capacity (TLC) and residual volume (RV) associated with characteristic concavity of the expiratory limb, indicating airflow obstruction. **D,** Surgical lung biopsy specimen from a patient with obliterative bronchiolitis. A slitlike residual orifice is visible, but otherwise, the whole of this terminal bronchiole is effaced by dense fibrous tissue. Note that the surrounding alveoli are normal.

Sjögren's syndrome is an important predisposing factor, being associated with OB in five of six RA patients in one series[109]; the spectrum of histologic abnormalities in these cases, ranging from peribronchiolar lymphocytic infiltration to small airway destruction, was analogous to changes seen in the parotid gland in Sjögren's syndrome. As the presence or absence of Sjögren's syndrome is not documented in many case reports of OB in RA, the etiologic importance of Sjögren's syndrome remains uncertain.

More contentious is the reported association between OB and the use of penicillamine, first reported in the late 1970s.[113] After a number of case reports and small series, a significantly higher prevalence of OB was identified in RA patients who took penicillamine (3 of 133) than in other RA patients (0 of 469) in a large cohort.[107] It is possible that the development of OB and the use of penicillamine are both markers of more aggressive RA and are linked for this reason; however, OB developed less than 1 year after penicillamine was begun in 19 of the first 20 cases,[107] and thus the association is unlikely to be entirely spurious. Because OB has been reported in many RA patients not taking penicillamine, it is likely that an underlying predisposition to OB in RA is unmasked by penicillamine (which disrupts collagen linkage and thus interferes with tissue repair). A relationship between OB and gold therapy has been suggested but is not endorsed by recent clinical experience.

Follicular Bronchiolitis

Follicular bronchiolitis (FB) is characterized by external compression of bronchioles by hyperplastic lymphoid follicles, with variable lymphocytic infiltration of the bronchiolar wall. FB is associated more commonly with RA than with other CTDs[114] and is often found incidentally at lung biopsy in RA patients with interstitial pulmonary fibrosis. No causative mechanism has been identified, and it is unclear whether FB predisposes to the subsequent development of OB. When found in isolation, FB simulates interstitial lung disease, with reticular or nodular opacities on chest radiography and a pattern of functional impairment that may be restrictive or obstructive. Clinically significant isolated FB is rare in RA, but its recognition is important because a response to corticosteroid therapy, although not the rule, is much more likely than in OB; in six of the first nine reported cases, disease stabilized or regressed with treatment.[105] In a CT study of patients with histopathologically proven FB, the most prominent features were centrilobular and peribronchial nodules together with patchy ground-glass increases in attenuation in a bronchocentric distribution.[115]

Bronchiectasis

The prevalence of bronchiectasis is higher in RA than in other CTDs (Fig. 58-5). One literature review identified 289 patients with bronchiectasis associated with RA reported since 1928; however, because respiratory symptoms preceded the systemic manifestations of RA in 90%, it is likely that chance association accounts for a high proportion of early reported cases.[116] Although associated with long-standing RA in one study,[117] on prospective evaluation of 50 RA patients, bronchiectasis was present on 30% of CT scans.[118] Bronchiectasis in RA is not associated with more aggressive systemic disease and is often clinically silent, with little or no sputum production and a less progressive and disabling course than in patients with idiopathic bronchiectasis.

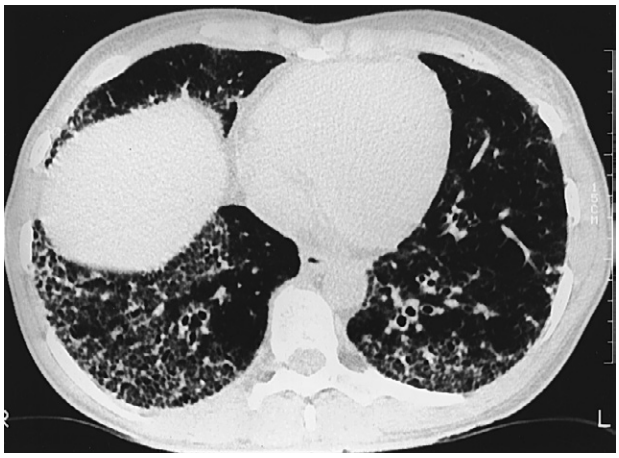

FIGURE 58-5 ■ Bronchiectasis in rheumatoid arthritis (RA). CT scan taken at the level of the diaphragm in a patient with RA. The typical reticular pattern of fibrosing alveolitis in the context of RA can be seen in the right lung. In the left lung, there are similar but less advanced changes. In addition, and notably remote from the fibrotic areas, there are airways that are clearly bronchiectatic.

Pulmonary Vasculitis

It is surprising that pulmonary vasculitis is reported only rarely in RA, given the relatively high prevalence of systemic vasculitis in the disease. Pulmonary hypertension resulting from pulmonary vascular disease (as opposed to extensive pulmonary fibrosis) is uncommon, although occasional cases of pulmonary vasculitis have been found at autopsy.[114] Similarly, diffuse alveolar hemorrhage is a rare complication of RA.

Pulmonary Rheumatoid Nodules

Pulmonary rheumatoid nodules may be single or multiple, are found on chest radiography in less than 1% of RA patients,[87] and are usually associated with rheumatoid nodules elsewhere in the body,[119] although they occasionally precede the development of systemic disease. Nodules are well circumscribed, with central necrotic material contained by palisading epithelioid cells and surrounded by fibrosis and lymphocytic infiltration. Nodule cavitation occasionally causes hemoptysis, and pneumothorax may result from the rupture of subpleural nodules. Diffuse infiltration by small nodules leading to respiratory failure has been reported.[120] However, nodules generally present as asymptomatic abnormalities on chest radiography and may vary in size according to underlying rheumatoid activity; thus, when solitary, their growth as judged by chest radiography may simulate

malignancy. Caplan's syndrome consists of the association of single or multiple nodules with coal worker's pneumoconiosis, which is often trivial, in keeping with the suggestion that nodule formation results from a hypersensitivity reaction to inhaled coal dust perhaps amplified by immunologic overactivity.

Pleural Disease

Pleural disease is seen at autopsy in approximately 50% of patients,[87] and 20% give a history of pleuritic chest pain.[121] However, pleural effusions are found in less than 5%,[85,86] usually in men,[119] and are frequently asymptomatic, often being identified on routine chest radiography. In a minority, pleuritic pain and fever are prominent, and the exclusion of empyema (which may be more prevalent in RA) is required. Occasionally, effusions may develop acutely in association with pericarditis or exacerbations of arthritis; more typically, radiographic abnormalities are chronic, often remaining unchanged for years. The fluid is an exudate, with a low glucose level (correlating poorly with serum glucose),[122] a low pH, and usually, a predominant lymphocytosis (although a neutrophilia is occasionally found). Pleural fluid rheumatoid factor levels tend to mirror serum levels and have little independent diagnostic value.

Other Pulmonary Complications

Other pulmonary complications of RA are rare. Lymphocytic interstitial pneumonia is an occasional finding at lung biopsy[106] and responds variably to corticosteroid therapy. Apical fibrosis mimicking the lung disease of ankylosing spondylitis has been reported.[123] Extensive apical cavitation in the absence of nodules or other causes of fibrocavitary disease (including tuberculosis) has been described in a handful of cases and may follow a fulminant course.[124] Amyloid has been reported occasionally. The incidence of pulmonary hypertension increases with time from diagnosis.[125] Lower respiratory tract infection is increased in frequency in RA; bronchopneumonia is a common terminal event, accounting for 15% to 20% of deaths in RA patients.[126,127] An increase in lung cancer has been reported in RA patients.[128]

Drug-Induced Pulmonary Disease

Drug-induced pulmonary disease is a particular problem in RA because of the widespread use of methotrexate in routine clinical practice, and it has been reported in 3% to 18% of RA patients treated with methotrexate.[129,130] Methotrexate pneumonitis is potentially life threatening. It presents with cough, dyspnea, fever, widespread crackles, and pulmonary infiltrates on chest radiography and CT, which may be focal or diffuse.[131] Although the presentation is sometimes explosive, more often, the onset is subacute (with symptoms evolving for up to 2 months before diagnosis)[131]; 50% of cases are diagnosed within 4 months of initiation of methotrexate therapy. As the clinical and radiographic features are nonspecific, methotrexate-induced lung disease should always be suspected in the treated patient presenting with progressive lung disease. Unfortunately, histologic findings are nonspecific, although prominent lymphocytic infiltration increases the probability of a methotrexate-injured lung.[132] There is conflicting evidence on whether preexisting lung disease predisposes to lung injury caused by methotrexate, but the published evidence does not suggest that functional impairment is an absolute contraindication to its use (although particular caution is warranted when pulmonary reserve is grossly compromised, and patients with previous methotrexate toxicity should not be retreated).[131,133] Pulmonary methotrexate toxicity is associated with a mortality rate of 15% to 20%[131]; because the lymphocytic component of disease is wholly or partially reversible, immediate withdrawal of methotrexate and the early institution of steroid therapy are warranted.

Pulmonary toxicity in RA has also been documented with sulfasalazine, gold therapy, and penicillamine (discussed earlier). Pulmonary infiltrates (due to organizing pneumonia) associated with sulfasalazine occur most commonly in the upper lobes; this side effect is rare in RA, with only a handful of cases reported (most cases occurred in ulcerative colitis).[134] Pulmonary disease induced by gold takes the form of alveolar opacities adjacent to bronchovascular bundles, best demonstrated by high-resolution CT, and often associated with fever or skin rash, relatively low rheumatoid factor titers, and a BAL lymphocytosis.[135] In most patients with sulfasalazine or gold toxicity, lung disease largely regresses with withdrawal of the agent and corticosteroid therapy.

There have been a number of reports of pulmonary toxicity relating to anti-TNF-α therapies including etanercept and infliximab. Toxicity ranges from infection (with particular focus on reactivation of tuberculosis) to interstitial disease and vasculitis.[136,137] Leflunomide has also been associated with pulmonary rheumatoid nodules and interstitial disease.[138,139]

Pulmonary Function Tests

Patterns of functional impairment in RA have been variable in unselected populations, with predominant airflow obstruction a frequent finding in one cohort[110] but reductions in D_{LCO} ascribed to occult interstitial fibrosis in at least 40%.[98] Inconsistencies in published data can be ascribed to the confounding effects of smoking and variations in the type and severity of associated pulmonary disease. Airflow obstruction may result from bronchiectasis or OB. Interstitial pulmonary fibrosis, organizing pneumonia, and lymphocytic interstitial pneumonia give rise to restrictive defects. Pleural disease may also be restrictive but is usually distinguished by elevation of the gas transfer index (KCO).

Radiologic Features

In chest radiographic series of unselected patients with RA, appearances indicative of interstitial lung disease are found in 1% to 5% of cases.[85,86,99,102] In interstitial pulmonary fibrosis, appearances are indistinguishable from

idiopathic pulmonary fibrosis, with symmetrical basal interstitial opacification in limited disease and diffuse coarse reticular abnormalities in extensive disease. Rheumatoid nodules are usually radiologically discrete and small but are often multiple and may reach up to 7 cm in diameter; in Caplan's syndrome, nodules appear in crops, often grow rapidly, and may cavitate. Other chest radiographic findings in RA include focal consolidation (in organizing pneumonia, infectious pneumonia, and lung disease induced by methotrexate), hyperinflation (in OB), and pleural thickening or effusion.

The CT appearances of interstitial pulmonary fibrosis in RA are similar to those in idiopathic pulmonary fibrosis,[139a] with the most common abnormality being a reticular pattern (irregular linear opacities with cyst formation or honeycombing, typically subpleural and most extensive posteriorly and at the lung bases, except in extensive disease). Ground-glass attenuation, consisting of a patchy or diffuse increase in lung density, is likely to denote inflammatory histologic appearances or fine intralobular fibrosis, as in other fibrosing lung diseases.

The cardinal CT feature of organizing pneumonia is patchy bilateral air space consolidation (often with associated ground-glass attenuation), which is often predominantly subpleural,[140] but may have a bronchovascular distribution.[141] Small nodules (≤1 cm in diameter) are common in organizing pneumonia; small pleural effusions and limited fibrosis (probably resulting from prolonged untreated inflammation) are occasional findings.

In bronchiolitis, bronchiolar structures are occasionally visualized directly on CT as centrilobular micronodular opacities and peripheral branching structures, denoting marked thickening of the bronchiolar wall; this appearance may be most frequent in FB.[142] In OB, areas of reduced lung density in a patchy distribution ("mosaic perfusion") are associated with a reduction in the caliber of pulmonary vessels in areas of decreased attenuation, indicative of regional hypoxic vasoconstriction in areas of severe bronchiolitis. Bronchiectasis and bronchial wall thickening on CT are common in constrictive bronchiolitis.

Treatment of Pulmonary Complications

The treatment of pulmonary disease has usually consisted of corticosteroid therapy, with or without immunosuppressive agents. Owing to small numbers, regimens have remained anecdotal. Organizing pneumonia and methotrexate pneumonitis often respond well to treatment. Regression of disease is highly variable in FB and lymphocytic interstitial pneumonia and is virtually never seen in OB. Lung function may improve in response to treatment in interstitial pulmonary fibrosis, but more often, the goal is to prevent further progression of disease, especially when extensive.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an inflammatory multisystem disorder of unknown etiology with protean clinical and laboratory manifestations and a variable course and prognosis. The 1982 revised American College of Rheumatology criteria for the diagnosis of SLE require that a minimum of four of the criteria listed in Table 58-6 be satisfied (although SLE is sometimes diagnosed with fewer than four criteria).[143]

TABLE 58-6. Systemic Lupus Erythematosus

CRITERIA FOR DIAGNOSIS*
Malar rash
Discoid rash
Photosensitivity skin rash
Oral or nasopharyngeal ulceration
Nonerosive arthritis involving two or more peripheral joints
Serositis (pleuritis or pericarditis)
Renal disorder (persistent proteinuria or cellular casts)
Neurologic disorder (unexplained seizures or psychosis)
Hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
Immunologic disorder (positive LE cell, anti-DNA antibody, anti-Sm antibody, false-positive syphilis serology)
Elevated antinuclear antibodies
LUNG MANIFESTATIONS
Acute lupus pneumonitis
Interstitial pulmonary fibrosis
Pulmonary vasculitis
Diffuse alveolar hemorrhage
Pulmonary hypertension
Shrinking lung syndrome
Antiphospholipid antibody syndrome
Organizing pneumonia
Pleural disease

*Minimum of four criteria required.
LE, lupus erythematosus.

Epidemiology and Risk Factors

SLE occurs throughout the world; the reported prevalence ranges from 12 to 50/100,000 population, and the incidence ranges from 1.8 to 7.6/100,000 population/yr.[144] There is a 6- to 10-fold female excess, and the disease is three times more common in African Americans than in whites. The 5-year survival rate exceeds 90%, but the mortality rate is three times higher than in the general population. Support for a genetic contribution to disease includes a high prevalence in monozygotic twins, familial clustering, and associations between SLE and HLA-DR2, HLA-DR3, and the C4A null allele.[145] No infectious or other environmental factor has been shown to play a major etiologic role.

Pulmonary Manifestations

Pleuropulmonary manifestations of SLE are listed in Table 58-6.

Diffuse Lung Disease

Diffuse lung disease on lung biopsy or at autopsy has been reported in 4%, 33%, and 70% of SLE patients.[146-148] These striking inconsistencies undoubtedly reflect major variations in the histologic diagnostic criteria: In the series with the highest prevalence, trivial interstitial thickening was categorized as "pulmonary fibrosis" but likely represented the minor residuum of infection or inflammatory complications of SLE. Only 3% of SLE patients have clinical evidence of diffuse lung disease at the onset of systemic disease, and a disease resembling interstitial pulmonary fibrosis develops during follow-up in less than 5%.[149] Risk factors for pulmonary fibrosis in SLE include increasing age, pneumonitis, and anti-RNP antibodies.[150]

Interstitial Pneumonia. The clinical presentation (dyspnea, cough, predominantly basal crackles, a restrictive lung function defect or isolated reduction in D_{LCO}, basal opacities on chest radiography) is similar to idiopathic pulmonary fibrosis. Features not typical of idiopathic pulmonary fibrosis include variably associated pleuritic pain, a paucity of patients with morphologically extensive or functionally severe lung fibrosis, and the frequent presence of enlarged peribronchiolar lymphoid follicles at lung biopsy (although other histologic findings are indistinguishable from usual interstitial pneumonia). Partial regression of disease with corticosteroids in 9 of 14 cases in one series[151] suggests that an empirical trial of therapy is usually warranted.

Acute Lupus Pneumonitis. Although seen in less than 2% of SLE patients, acute lupus pneumonitis is often life threatening, with a mortality rate of more than 50% (once respiratory failure has supervened) despite treatment.[152] The predominant histologic feature of diffuse alveolar damage is nonspecific, and it has been argued that acute lupus pneumonitis is merely a manifestation of aspiration or bacterial infection.[146] However, well-documented striking responses to corticosteroids and immunosuppressive agents after antibiotic failure suggest strongly that the disorder is a true, albeit rare, entity. Acute lupus pneumonitis is not to be confused with organizing pneumonia ("bronchiolitis obliterans with organizing pneumonia"), discussed elsewhere in this chapter and reported in only a handful of adult patients with SLE, or with lymphocytic interstitial pneumonia, described in a small number of patients with SLE.

Extrapulmonary Restriction

Extrapulmonary restriction, resulting in exertional dyspnea, a restrictive functional defect, and marked decrease of D_{LCO}, is a well-recognized complication of SLE. The "shrinking lung syndrome" was first described in patients with severe restriction and a marked reduction in lung volume on chest radiography, and it is generally ascribed to diaphragmatic weakness (Fig. 58-6).[153] However, the use of sniff pressures to evaluate diaphragmatic strength may be confounded by concurrent lung restriction or airflow obstruction; in one study, with the use of alternative methods to evaluate diaphragmatic function, the characteristic restrictive defect was attributed to an "unspecified restriction in chest wall expansion."[154] No treatment of proven efficacy currently exists, although a handful of patients have improved in association with corticosteroid or immunosuppressive therapy.[155] The disorder is almost always self-limited, although sometimes it is severe.

Diffuse Alveolar Hemorrhage

Although seen more frequently in SLE than in other CTDs, diffuse alveolar hemorrhage is rare in SLE. The typical presentation of acute dyspnea and extensive pulmonary opacities on chest radiography may mimic acute lupus pneumonitis, especially in the absence of hemoptysis.[156] Diffuse alveolar hemorrhage is often life threatening, with a mortality rate similar to that of acute lupus pneumonitis; however, because the two diseases are both treated empirically with corticosteroid and immunosuppressive therapy, the important differential diagnosis is opportunistic infection. Patients with SLE have

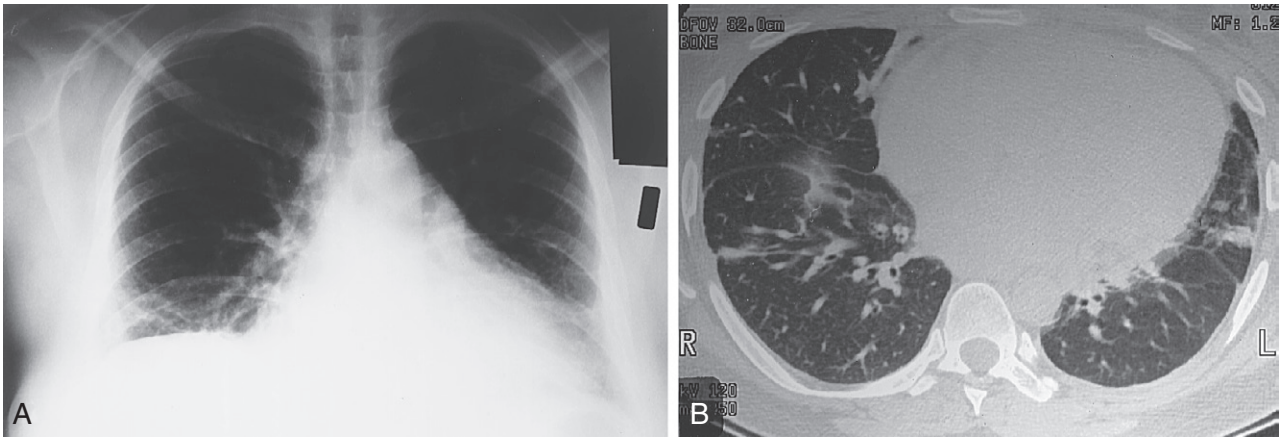

FIGURE 58-6 ■ **A,** Chest radiograph from a patient with systemic lupus erythematosus shows marked elevation of both hemidiaphragms, in keeping with "the shrinking lung syndrome." **B,** On a CT scan from the same patient as in **A,** linear abnormalities are seen that denote subsegmental atelectasis resulting from regional hypoventilation (due to diaphragmatic weakness). The heart is enlarged.

underlying defects in most arms of the immune system and are at added risk of fulminant infection with the use of corticosteroids or immunosuppressive agents.[157] In this context, a misdiagnosis of acute lupus pneumonitis or diffuse alveolar hemorrhage may lead to a potentially disastrous increase in immunosuppression. Thus, the performance of BAL to exclude opportunistic infection may be crucial in SLE patients with unexplained extensive pulmonary opacities.

Pulmonary Hypertension

Pulmonary hypertension was once considered rare in SLE, but it is now reported with increasing frequency[158] and has a 2-year survival rate of less than 50% in severe disease. Abnormalities indicative of subclinical pulmonary hypertension are found on echocardiography in 10% of SLE patients, usually in association with Raynaud's phenomenon,[159] and thus, it is likely that pulmonary hypertension results from vasoconstriction rather than pulmonary vasculitis (which is seldom identified in SLE); in autopsied patients with pulmonary hypertension, overt vasculitis is rare.

Important alternative mechanisms for pulmonary hypertension include vasculitis and thromboembolism.[160] Thromoboembolism has a high prevalence in SLE, especially in patients with antiphospholipid antibodies (which cross-react with coagulation factors).[161,162] In a 1993 study of 842 SLE patients, immunoglobulin G anticardiolipin antibodies were present more frequently than immunoglobulin M antibodies (24% vs. 13%), but both were associated with a 30% prevalence of thrombosis (as opposed to 10% in other SLE patients).[163] Patients with antiphospholipid antibody syndrome also have a higher incidence of impaired lung function than normal controls.[164] In view of the multiplicity of mechanisms potentially responsible for pulmonary hypertension, vasodilators and anticoagulation have all been advocated empirically for patients with the pulmonary vascular disease of SLE. Corticosteroid or immunosuppressive agents may be effective therapy for SLE-associated pulmonary hypertension.[160] In a small series of patients given chronic epoprostenol, measures of pulmonary hypertension, pulmonary vascular resistance, and exercise capacity all improved.[165]

Pleural Disease

Pleural disease is the most common pulmonary manifestation of SLE. Clinical or radiographic evidence of pleural involvement is seen in 20% of patients at the onset of systemic disease and occurs in at least 50% at some time[166] (with pleural abnormalities at autopsy in 50%–100%). Pleural disease is often asymptomatic, but pleuritic pain may be recurrent or intractable. The fluid is usually serosanguineous (but occasionally hemorrhagic) and exudative, with a neutrophilia in patients with pleurisy but a predominant lymphocytosis in chronic effusions.[166] The nonspecific histologic appearance of fibrinous pleuritis is not diagnostically useful. The identification of lupus erythematosus cells has largely fallen out of favor because technical difficulties greatly reduce the sensitivity of the test in confirming that a pleural effusion is due to SLE.[167] The measurement of pleural fluid antinuclear antibody titers may be more diagnostically useful when the etiology of pleural disease is in doubt.[168]

SJÖGREN'S SYNDROME

Sjögren's syndrome is an autoimmune disorder characterized by lymphocytic infiltration of the lachrymal, salivary, conjunctival, and pharyngeal mucosal glands, with variable involvement of extraglandular tissue. The cardinal clinical features of keratoconjunctivitis sicca (dry eyes) and xerostomia (dry mouth) may occur in isolation (primary Sjögren's syndrome, typically seen in women older than age 40) but are more often associated with CTDs such as RA, SSc, or SLE (secondary Sjögren's syndrome). Sicca symptoms are common in lung disease, however, and need to be carefully evaluated.[169] Variable diagnostic criteria are used internationally; in one proposed diagnostic algorithm, sicca symptoms are mandatory, with supportive evidence including ocular signs (positive Schirmer test, rose bengal score > 3), typical histologic appearances on salivary gland biopsy, antibodies to Ro (SS-A) or La (SS-B), or reduced salivary flow.[170]

Epidemiology and Risk Factors

The reported prevalence of primary Sjögren's syndrome ranges from 0.5% to 3.0%. The etiology of the disease is unknown. There is some evidence to suggest a genetic predisposition, including familial clustering and an association with HLA-Dw2 and HLA-Dw3, but no environmental triggers have been identified.

Pulmonary Manifestations

Pulmonary involvement is common in Sjögren's syndrome. In early series, primary and secondary Sjögren's syndromes were combined; it is likely that many of the pulmonary abnormalities seen in secondary Sjögren's syndrome were ascribed to the underlying CTD. Careful evaluation of patients with primary Sjögren's syndrome has shown that cough and dyspnea are common,[171] with objective evidence of pulmonary abnormalities in approximately one fourth of cases.[172] Lung involvement usually consists of lymphocytic infiltration similar to that seen in salivary glands and resulting in tracheobronchial disease or interstitial lung disease, depending on whether involvement is limited to secretory glandular tissue or is more widespread. However, population studies of respiratory involvement in Sjögren's syndrome have been hampered by variations in diagnostic criteria, failure to discriminate between primary and secondary Sjögren's syndrome, and failure to control for confounding features such as drug treatment and smoking. Lung manifestations include diffuse lung disease and tracheobronchial disease.

In a CT study of 35 patients, the most prevalent findings were large and/or small airway disease (n = 19) and diffuse lung disease (n = 12, including 7 in whom the features were suggestive of lymphocytic interstitial pneumonia). The patterns of physiologic abnormalities were consistent with the predominant CT pattern.[173]

Diffuse Lung Disease

Although often asymptomatic, diffuse lung disease in Sjögren's syndrome may present with cough, dyspnea, crackles on auscultation, reticular or nodular opacities on chest radiography, and a restrictive pattern of functional impairment. Interstitial involvement can be classified as pulmonary fibrosis, lymphocytic interstitial pneumonia, or lymphoma. Pulmonary fibrosis has been reported in up to 10% of patients with primary Sjögren's syndrome[174] and most frequently takes the form of fibrotic nonspecific interstitial pneumonia.[175] Although a presentation typical of extensive or progressive interstitial pulmonary fibrosis is rare and interstitial disease in Sjögren's syndrome is often regarded as clinically insignificant, Gardiner and coworkers[174] found that patients with primary Sjögren's syndrome complaining of dyspnea (~10%) have a high prevalence of histologic abnormalities (fibrosis or lymphocytic infiltration) on transbronchial biopsy.[174] A 10-year follow-up study of 30 patients showed that most patients do not develop progressive lung disease, although the total gas transfer level fell significantly in 7 cases.[176]

Lymphocytic interstitial infiltration may take the form of lymphocytic interstitial pneumonia, pseudolymphoma (extensive pulmonary lymphocytic infiltration with the formation of lymphoid follicles), or pulmonary lymphoma. Lymphocytic interstitial pneumonia, historically believed to be the most common diffuse lung disease in Sjögren's syndrome (Fig. 58-7),[177] is characterized by a diffuse lymphocytic infiltrate, with or without histiocytes and multinucleated giant cells, most prominent around bronchioles. Pseudolymphoma, characterized by pulmonary infiltration, may regress spontaneously and often responds well to corticosteroid therapy; however, some patients progress to pulmonary lymphoma. The prevalence of lymphoma is increased 40- to 50-fold in Sjögren's syndrome[178]; pulmonary lymphoma has a highly variable clinical and radiographic presentation, with the spectrum of disease ranging from diffuse interstitial involvement to discrete (often perihilar) masses. It is now believed that all lymphocytic interstitial pneumonia may represent malignant disease of varying nature.

Organizing pneumonia (bronchiolitis obliterans with organizing pneumonia) has been reported in Sjögren's syndrome but occurs less frequently than in RA or polymyositis. A response to corticosteroid therapy is usual but not invariable.

Tracheobronchial Disease

Tracheobronchial disease may take the form of loss of mucous secretion in the trachea (xerotrachea), chronic bronchitis, or small airway disease. Xerotrachea occurs in up to 25% of patients with primary Sjögren's syndrome and consists of atrophy of tracheobronchial mucous glands in association with a lymphoplasmocytic infiltrate, manifesting clinically as a relentless dry cough and endobronchial inflammation at bronchoscopy.[179] It is likely that similar histologic abnormalities in bronchi and bronchioles account for an increased prevalence of bronchial hyperresponsiveness, reported in 40% to 60% of patients with primary and secondary Sjögren's syndrome.[180]

Subclinical bronchiolitis may be common in Sjögren's syndrome. In the interstitial lung disease of Sjögren's syndrome, lymphocytic infiltration is more prominent around small bronchioles, resulting in a BAL lymphocytosis[181]; thus, it is likely that the occasional cases of isolated lymphocytic bronchiolitis, presenting with a clinical picture of chronic obstructive pulmonary disease, represent a more limited form of lymphocytic infiltration. The evaluation of airflow at low lung volumes in unselected patients with primary and secondary Sjögren's syndrome has demonstrated a high prevalence of small airway dysfunction[171]; aerosol penetration from central airways to the lung periphery is reduced,

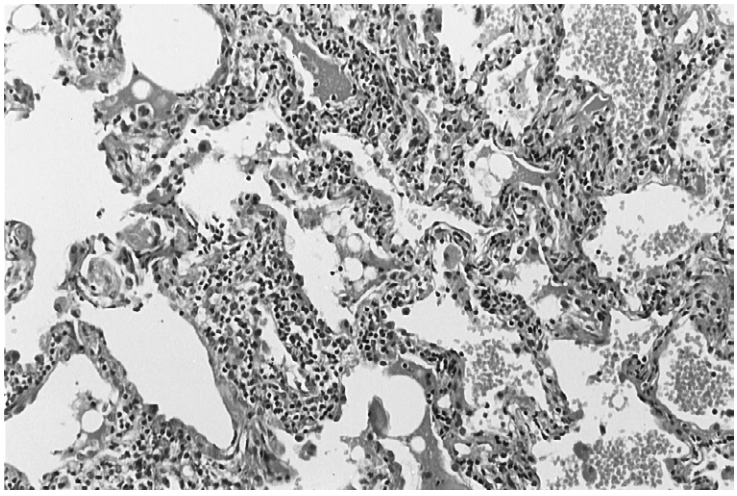

FIGURE 58-7 ■ Surgical lung biopsy specimen taken from a patient with diffuse lung disease in the context of Sjögren's syndrome. Note the dense lymphocytic infiltrate within the interstitium. (Courtesy of Dr. Andrew Nicholson, Royal Brompton Hospital, London, UK.)

indicating small airway obstruction.[182] These abnormalities, indicating either OB or mucous plugging, may contribute to an increased prevalence of bronchopneumonia but do not evolve into severe OB (which is not generally a feature of Sjögren's syndrome, except in occasional cases with associated RA). FB has been reported in a handful of patients with primary Sjögren's syndrome but may occur more frequently in secondary Sjögren's syndrome; in a number of reported cases of FB associated with RA, the presence of Sjögren's syndrome is not explicitly excluded. FB and diffuse bronchiolar lymphocytic infiltration may be part of the same spectrum of disease, but the relationship between the two disorders is uncertain.

POLYMYOSITIS AND DERMATOMYOSITIS

The defining criteria for polymyositis (PM) and dermatomyositis (DM) are listed in Table 58-7. For PM, a definite diagnosis is made if the first four features are present, a probable diagnosis is made if any three of the first four features are present, and a possible diagnosis is made if any two of the first four features are present. For DM, the typical rash must be present, plus any three of the first four for a definite diagnosis, two of the first four for a probable diagnosis, and one of the first four for a possible diagnosis (Bohan and Peter's criteria).[183]

The skin problems of DM include the presence of scaly cutaneous eruptions affecting extensor surfaces of the finger joints (Gottron's tubercles) and the characteristic edema and violaceous or purplish, heliotrope rash that surrounds the eyelids. Proximal muscle weakness tends to be insidious, progressive, and painless, affecting head, neck, and limb girdles and eventually involving the muscles of the tongue and pharynx and the respiratory muscles. Pulmonary complications occur in approximately 45% of patients and are the most frequent cause of death.

TABLE 58-7. Polymyositis with Dermatomyositis

CRITERIA FOR DIAGNOSIS
Symmetrical proximal muscle weakness
Muscle biopsy specimen showing myositis
Elevation of serum skeletal muscle enzymes
Characteristic electromyographic pattern of myositis
Typical rash of dermatomyositis
LUNG MANIFESTATIONS
Interstitial pulmonary fibrosis
Acute pneumonitis (with diffuse alveolar damage)
Organizing pneumonia
Aspiration pneumonia
Pulmonary vasculitis and alveolar hemorrhage
Respiratory muscle weakness

Epidemiology and Risk Factors

The inflammatory myopathies are relatively rare, affecting 2 to 10/100,000 population, with a female-to-male predominance of 2.5:1 and with a bimodal age distribution peaking in childhood and in the fourth to fifth decades. DM appears to have a higher expression of HLA-B8/DR3, HLA-B14, and HLA-B40, whereas PM associates with HLA-B8/DR3 and in African Americans with HLA-B7 and HLA-DRw6.[184] There are multiple manifestations of lung disease, as listed in Table 58-7. The presence of diffuse lung disease has been associated with two HLA haplotypes: HLA-DRB1*1302-DQA1*0102-DQB1*0604 and HLA-DRB1*0405-DQA1*03-DQB1*0401.[185] The prevalence of lung disease varies from series to series, and often the respiratory symptoms are masked by muscle fatigue. Nonetheless, pulmonary complications of the disease can be a frequent cause of death. In combined series, the prevalence of diffuse lung disease can be up to 64%. The disease may present with pulmonary symptoms, and in one series this was the case in 21 of 70 patients.[186]

Pulmonary Manifestations

Diffuse Lung Disease

Diffuse lung disease is the most common problem encountered in the context of DM with PM and may occur in up to 32% of patients.[187] The prevalence of diffuse lung disease may be less common in patients with amyotrophic DM, and is three to five times more common in women than men, most commonly presenting in the fifth decade. The pattern of diffuse lung disease often mimics that of chronic idiopathic pulmonary fibrosis, but an acute, rapidly progressive form of acute pneumonitis can occur.[188] Organizing pneumonia may also be the presenting feature (Fig. 58-8). The histopathologic features associated with these forms of presentation include usual interstitial pneumonia in patients with an interstitial pulmonary fibrosis pattern, diffuse alveolar damage in the acute pneumonitis and organizing pneumonia.[189–191] In a large series of 70 patients, Douglas and colleagues[186] reported that 82% of patients who were biopsied had the nonspecific interstitial pneumonia pattern of histopathology. It has been shown that one of the characteristic features of chronic diffuse lung disease in PM with DM is a combination of the features of organizing pneumonia and interstitial pulmonary fibrosis on high-resolution CT.[192] One report described an acute presentation of pulmonary capillaritis with alveolar hemorrhage in association with PM.[193]

Clinical Features. The clinical features of diffuse lung disease in PM with DM depend on the nature of the lung process. Dyspnea and nonproductive cough are the most common presenting symptoms. Breathlessness on exertion without wheeze is common, and if the myopathy is severe, orthopnea may be striking. Hemoptysis may occur if there is capillaritis. Pleural disease is uncommon. Pulmonary involvement can develop prior to the systemic disease and occur at any time in the disease

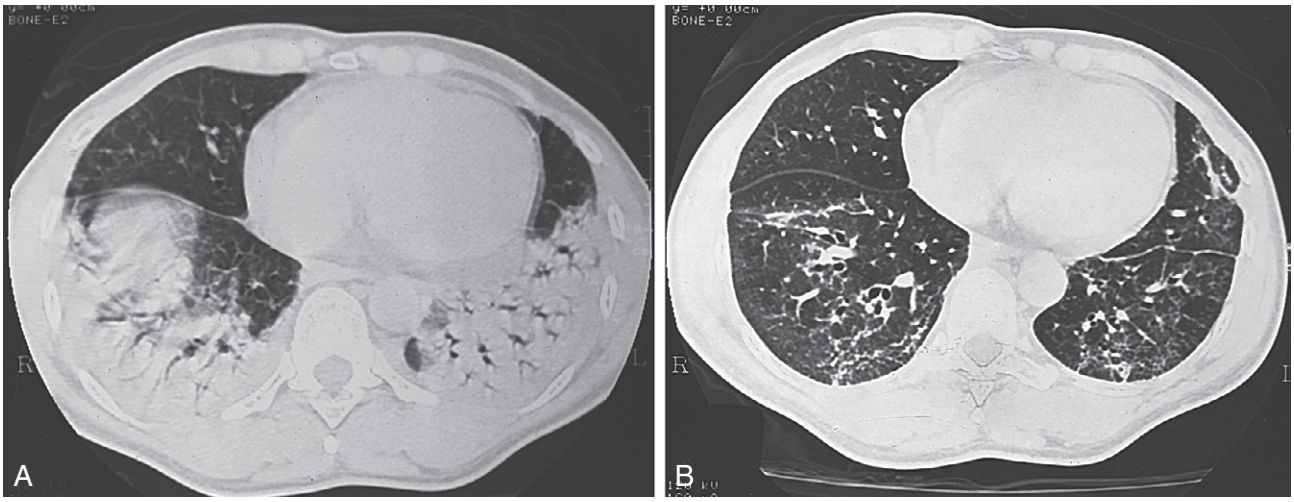

FIGURE 58-8 ■ **A,** CT scan shows dense consolidation that denotes organizing pneumonia in a patient with polymyositis. As shown in this example, the disease tends to be most prominent posteriorly in the lower lobes. **B,** After treatment, the dense consolidation has regressed, but there is extensive residual linear opacification, representing residual fibrosis and resulting in traction bronchiectasis on the right and a restrictive functional defect.

course. There is no correlation between the severity of pulmonary parenchymal involvement and the systemic musculoskeletal manifestations. Rarely, patients present acutely with or progress rapidly to acute respiratory failure.

Imaging. Chest radiography findings depend on lung disease. Chronic diffuse lung disease is associated with peripheral reticular opacities, particularly in the lung bases as for interstitial pulmonary fibrosis. Acute pneumonitis can result in ground-glass opacification on chest radiography and alveolar hemorrhage with areas of consolidation.

High-resolution CT is more sensitive and specific than chest radiography, highlighting the distributions of the different processes. CT findings include thickened interlobular septa, linear opacities, ground-glass opacification, and patchy consolidation. A combination of consolidation with a peripheral reticular pattern is highly characteristic.[194] Traction bronchiectasis and honeycombing are less common. The consolidation may evolve into a reticular pattern.[195] DM and PM are well-recognized paraneoplastic phenomena, so it is sometimes difficult to determine which condition presented first.[196] Screening for occult carcinoma is recommended with mammography, abdominal CT, pelvic ultrasonography, and tumor markers.

Pulmonary Function. Lung function tests show a restrictive ventilatory defect with reduced gas transfer. In recent hemorrhage or marked myopathy, there may be a disproportionate preservation of the D_{LCO}. However, it must be remembered that acute hemorrhage can occur in the context of previous chronic disease, and so the D_{LCO} may be normal or subnormal but elevated from a level that was previously lower. Severe reduction in D_{LCO} is associated with increased mortality.

Bronchoalveolar Lavage. BAL lymphocytosis and neutrophilia have been described in diffuse lung disease associated with DM/PM. The significance of BAL is debated, but it appears that neutrophilia on BAL is associated with clinical deterioration.[197]

Laboratory Tests. Several studies have reported no association between creatine kinase levels and respiratory disease. In fact, the presence of a low creatine kinase has been associated with more rapidly progressive diffuse lung disease.[198,199] Studies of autoantibodies have highlighted the association between the presence of antibodies to aminoacyl transfer RNA (tRNA) synthetases, inflammatory myopathies, and diffuse lung disease.[198] These antibodies help define the clinical antisynthetase syndrome: the coexistence of myositis, diffuse lung disease, and arthritis. The most common autoantibody is Jo-1 (a cytoplasmic antihistidyl tRNA synthetase), occurring in 20% to 30% of patients with inflammatory myopathy and correlating strongly with the presence of diffuse lung disease. Jo-1 antibodies are present in 50% to 100% of cases of inflammatory myopathy and diffuse lung disease, in contrast to less than 5% of patients without diffuse lung disease. A variety of novel autoantibodies have been described with affinity for other tRNA synthetase molecules: PL-12, PL-7, EJ, OJ, and Ku.[200]

Other Pulmonary Manifestations

Muscular weakness may lead to aspiration pneumonia in up to 20% of patients and is usually associated with dysphagia. Respiratory muscle weakness and hypercapneic respiratory failure occurs in up to 25% of patients, although severe respiratory failure requiring ventilatory support is less common. Bilateral diaphragmatic paralysis has been reported.

Treatment of Pulmonary Complications

Diffuse lung disease is a serious complication of DM/PM and is associated with increased mortality.[201] The clinical course and prognosis of DM/PM-associated diffuse lung disease is heterogeneous and depends on the histologic pattern of disease. The decision to treat, and the choice of therapy, therefore, needs to be individualized. Corticosteroids are the preferred initial therapy. Oral prednisolone (0.75–1.0 mg/kg/day) is usual, but intravenous corticosteroids are required in more severe or rapidly progressive disease. Immunosuppressive therapy may be used in patients who are steroid resistant or experiencing adverse effects from corticosteroids. There are some reports of efficacy of cyclophosphamide,[202,203] cyclosporine A,[204] and azathioprine.[204a,204b] In refractory cases, methotrexate and intravenous immunoglobulin should be considered. Mycophenolate has been shown to be safe and effective in treatment of the systemic disease, but no controlled studies have been performed in DM/PM-related lung disease.

Organizing pneumonia responds well to corticosteroids alone. Vasculitis may require a combination of high-dose prednisolone and immunosuppression. Occasionally, the myositis may resolve on treatment but the lung disease progresses; these cases may be very difficult to control.

MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease (MCTD) is defined by the presence of features of SLE, SSc, and PM (Sjögren's syndrome may also be seen) in association with high titers (>1:1600) of autoantibody directed against the extractable nuclear antigen U1-RNP.[205,206] Criteria that have been suggested for the diagnosis of MCTD include the presence of antibody to the U1 ribonuclear protein together with the clinical features of hand edema, synovitis, Raynaud's phenomenon, acrosclerosis, and myositis. At least three of these clinical features are needed in addition to the autoantibody finding. A fourth clinical feature is required if the initial three are Raynaud's phenomenon, edema, and acrosclerosis. The difference between MCTD and overlap syndrome may be semantic, but the former often presents more acutely and with greater specificity for U1-RNP. MCTD may differentiate into specific rheumatologic diseases. This differentiation may be genetically determined.[207]

Other overlap syndromes are reported in which clinical features of more than one CTD are present in the same patient. Although MCTD tissue disease remains the most clearly definable, other overlap syndromes occur both with and without typical autoantibody association. Of the former, overlapping clinical features found in association with U2-RNP and U3-RNP and the tRNA synthetase–associated diseases (see earlier) can be considered to be part of an overlap syndrome. Antibodies to PM-Scl, KU, and U2-RNP are associated with overlaps of SSc and PM.[206]

The prevalence of MCTD is unclear, but it is estimated at 1 in 10,000, with a 9:1 female preponderance, most frequently presenting in the fourth decade. Pleuropulmonary complications occur in 20% to 85% of patients, but diffuse lung disease (most commonly a nonspecific interstitial pneumonia CT pattern) is the most common lung complication.[208] In a CT study of 41 patients, the major abnormalities were ground-glass appearances in all, subpleural micronodules in 40 of 41, and nonseptal linear opacities in 32 of 41.[209] Pleural effusions occur in patients with other clinical features of SLE, and are usually small, exudative, and often resolve spontaneously. Pulmonary hypertension may also occur.[210] Respiratory muscle weakness, diffuse alveolar hemorrhage, and small airway disease are less common complications.

Survival is difficult to quantify owing to the heterogeneity of disease. Individual disease course tends to be similar to that of the CTD most closely resembled in that patient. Survival is better if the diffuse lung disease is associated with U1-RNP positivity than with no U1-RNP. Treatment depends on the nature of the lung disease and is identical to the approaches used for the other CTDs. Pleural effusions are often responsive to corticosteroids. A combination of low-dose prednisolone and an immunosuppressant (such as cyclophosphamide or azathioprine) is generally used to treat interstitial fibrosis, with an approach similar to that for SSc.

UNDIFFERENTIATED CONNECTIVE TISSUE DISEASE

Up to 25% of patients with autoimmune features do not fulfill American College of Rheumatology criteria for a specific CTD, and a large proportion never progress to a "differentiated" CTD. Interstitial lung disease may complicate undifferentaited connective tissue diseases,[211] but little is known about the prognosis or treatment of interstitial lung disease in this context.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is a rare disease characterized by recurrent progressive cartilaginous inflammation. Episodic, painful, cartilaginous inflammation occurs, resulting eventually in the widespread degeneration of cartilaginous structures. The diagnosis of relapsing polychondritis requires the presence of three or more of the following clinical features[212]: bilateral auricular chondritis; nonerosive, seronegative inflammatory polyarthritis; nasal chondritis; ocular inflammation; respiratory tract involvement (either upper or lower respiratory tract); cochlear with or without vestibular abnormality; and positive biopsy specimen. The presence of anticartilage antibodies may be helpful in the diagnosis.

The condition affects men and women equally and has a peak incidence between 40 and 60 years of age. It is considered an autoimmune process, and autoanti-

FIGURE 58-9 ■ Relapsing polychondritis. **A,** Loss of cartilage in this individual's nose results in a "saddle" deformity. **B,** Chest radiograph of the same individual as in **A** demonstrates tracheal narrowing. **C,** Tracheal narrowing and thickening shown more graphically in the CT scan. **D,** Thickening of the segmental bronchi is seen together with patchy attenuation ("mosaicism"), which indicates small airway involvement.

bodies have been found directed against cartilage and type II collagen. A weak association with HLA-DR4 has been reported.[213] Diagnosis is chiefly clinical but can be confirmed at biopsy of affected cartilage, including tracheal rings.

Relapsing polychondritis is usually multifocal, affecting cartilage of the ear (85%–94%), nose (54%–57%) (Fig. 58-9A), upper respiratory tract (31%–48%), and ribs. In addition, patients frequently suffer ocular inflammation, nonerosive arthropathy (52%), and vestibulocochlear dysfunction.[212,214] It may occur in association with a wide range of other conditions, especially CTD and vasculitis. Approximately 30% of patients have a preexisting CTD.

Respiratory involvement probably accounts for around 10% of deaths in this condition. Up to 25% of cases present with focal or generalized respiratory tract involvement. The larynx and upper trachea are the most common focal areas involved, but large or small airways may also be affected. Laryngotracheal involvement is a poor prognostic determinant. Destruction and obstruction of the glottis, trachea, and bronchi may lead to airway stricture, collapse, and distal infection (see Fig.

58-9B and C).[215] Pulmonary parenchymal disease is rare, with the exception of pulmonary vasculitis.

Clinical presentation is determined by the site of cartilaginous involvement. Upper airway involvement typically presents with wheezing and hoarseness. Lung function testing shows diminution in maximal inspiratory (large, extrathoracic airways) and expiratory (smaller, intrathoracic airways) flow rates, suggesting airway collapse while static recoil pressures are preserved. Radiography may show ectopic airway cartilage calcification or large airway narrowing, but is often insensitive. However, high-resolution CT scanning shows tracheal ring thickening, airway wall attenuation, and calcification. Dynamic CT scanning may show airway collapse on expiratory maneuvers and can help to localize the large airway disease.[216] Bronchoscopy may show endobronchial inflammation or stenosis and is useful in the exclusion of mechanical obstruction. Endobronchial biopsy may be diagnostic but is insensitive. Laryngoscopy and bronchoscopy are associated with risk of acute airway compromise, however.[215]

Treatment depends on disease severity. Mild cases may be controlled with nonsteroidal anti-inflammatory drugs, but troublesome relapses may require short-term high-dose corticosteroid therapy. In acute airway involvement, high-dose intravenous corticosteroid is used. In one large review of 159 reported cases, three fourths of the patients required chronic corticosteroid therapy, which in that series, decreased the frequency, duration, and severity of flare-ups but did not prevent disease progression.[217] Steroid-resistant lesions have been treated with immunosuppressive agents such as cyclophosphamide. Despite short-term improvement with steroid and immunosuppressive therapy, relapse and disease progression are common. Tracheostomy and stenting are occasionally indicated, but other surgical treatment is difficult owing to the diffuse nature of involvement and risk of relapse.[218] In one study, the use of multiple, self-expandable stents via fiberoptic bronchoscopy in five patients requiring mechanical ventilation resulted in improvement in four patients who were all able to live without mechanical ventilation for up to 20 months.[219] Newer self-expanding silicone stents have been used with variable effect in palliative cases.[220] Intraluminal stents may be complicated by hemorrhage, tracheal erosion, ulceration, or airway obstruction, however. Survival has been reported at 94% at 8 years[221] and is variable.

BEHÇET'S SYNDROME

Behçet's syndrome occurs predominantly in the countries bordering the Mediterranean Sea. Prevalence estimates approach 80 to 370/100,000 population in Turkey. Men and women are affected equally, and age of onset is usually in the second or third decade. There is an association between the HLA-B51 allele and, more controversially, more severely affected patients; relative risk of HLA-B51 carriers is roughly 13:1 in Turkey. Herpes simplex type 1 and streptococci have been suggested as causative agents.[222] Diagnosis requires the presence of recurrent oral ulceration occurring at least three times in a 12-month period and two of the four minor features listed in Table 58-8.[223] Mucocutaneous ulceration is the clinical hallmark, with aphthous oral and genital ulceration seen in almost all patients. Other cutaneous features include erythema nodosum, an acneiform rash, and papular lesions of cutaneous vasculitis. Uveitis is the major cause of morbidity, but systemic vasculitis may affect all systems.

TABLE 58-8. Behçet's Syndrome

CRITERIA FOR DIAGNOSIS
Major (required)
Recurrent aphthous ulceration occurring at least three times in a 12-mo period
Minor (two of four)
Recurrent genital ulceration
Ocular disease
Skin lesions (erythema nodosum, skin ulcers)
Positive pathergy test (a 2-mm erythematous papule or pustule at the prick site 48 hr after the application of a sterile hypodermic 20- to 22-gauge needle that obliquely penetrated avascular antecubital skin to a depth of 5 mm)

Pulmonary involvement is seen in 1% to 7% and tends to affect HLA-B51–positive younger males (<25 yr) more severely. The major pulmonary manifestations are pulmonary vasculitis,[224] pulmonary artery aneurysms, arterial and venous thromboses, pulmonary infarction, organizing pneumonia, and pleurisy.[225] Symptoms include dyspnea, chest pain, and recurrent hemoptysis that can be massive and fatal.[226]

The cardinal histologic feature is vasculitis affecting arterial and venous vessels of all sizes. Pulmonary arterial aneurysms are surrounded by inflammatory infiltrates and have thickened intima and degeneration of the elastic lamina with thrombosis. Arterial and venous thromboses, pulmonary infarcts, and occasionally, pleural effusion also occur.[227] The radiographic abnormalities are nonspecific but may include the features of small airway disease, pulmonary hemorrhage, vascular occlusion, or mass lesions representing arterial aneurysm(s).[228,229] Prognosis is variable. The disease course is relapsing-remitting. Pulmonary artery aneurysm carries the worst prognosis, with a 2-year survival of 70%.

Treatment is complex and depends on presentation. Steroids and immunosuppressive agents are used to control vasculitis, particularly in cases of pulmonary artery aneurysm, in which eventual regression is sometimes observed. Cyclosporin A and FK506 have been successful in some patients.[225] Anticoagulants may be required for control of thrombosis but should be used only if immunosuppression is insufficient, because there is a significant risk of hemorrhage. Pulmonary embolization and surgical resection have been reported to be

successful, but surgical treatment of aneurysms can result in aneurysms at the anastomosis site.[230]

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a seronegative spondyloarthritis developing in 0.05% to 1.5% of the general population and is associated with the major histocompatibility antigen HLA-B27.[231] The prevalence of AS is higher in white males, with a male-to-female ratio of 10:1. The cardinal site of disease is the vertebral column. As the disease progresses, inflammation leads to fibrosis and ossification, with ankylosis of the vertebral joints. Peripheral joint arthritis is seen in approximately one third of patients, and extra-articular features include aortic regurgitation, uveitis, pulmonary disease, and extrapulmonary restriction.

Lung disease, mainly upper zone fibrosis, can occur in up to 30% of case series but fibrobullous disease is less common. In a series of 2080 patients with AS, this pattern was seen in only 1% to 2% of patients.[232] Limited interstitial lung disease, small airway disease, bronchiectasis, and paraseptal emphysema are frequently present even when chest radiographic appearances are normal.[233–235] In another study, abnormalities were seen in 15 of 21 patients, comprising thickened interlobular septa (33%), bronchial wall thickening (29%), pleuropulmonary abnormalities (29%), and linear septal thickening (29%).[236] Pulmonary involvement, often subclinical, is an early manifestation of AS.[237] A subclinical lymphocytic alveolitis may be evident with BAL.[238] Histologically, lung abnormalities consist of a variable mixture of lymphocytic infiltration, fibrosis, and bullous change. On chest radiography, diffuse reticular opacities in the upper zones are usually symmetrical and are seldom extensive except in patients with severe spinal disease[239] or a long history of AS.[232] However, apical fibrosis occasionally may precede the development of extrapulmonary disease. No proven treatment exists to prevent the development of apical fibrosis; resistance to corticosteroid therapy is the rule.

Cavities may develop within distorted fibrotic apical tissue and are sometimes colonized by mycobacteria or fungi, especially *Aspergillus fumigatus,* which are isolated in up to 60% of AS patients with apical cavitation.[240] Life-threatening hemoptysis is an occasional complication of mycetoma formation within cavities and may be controllable by bronchial artery embolization; the resection of a mycetoma is a treatment of last resort owing to the high prevalence of postoperative bronchopleural fistula or empyema. Advanced apical fibrosis is often associated with apical pleural thickening, but pleural disease is seldom seen adjacent to normal lung parenchyma elsewhere in the thorax. There is an increased (≤10%) prevalence of pneumothorax in AS patients with apical fibrosis,[232] probably due to subpleural bullous degeneration in advancing disease.

Extrapulmonary restriction due to immobilization of the chest wall (costovertebral ankylosis) is an occasional complication of AS. Extrapulmonary restriction is often asymptomatic and associated with surprisingly little impairment in pulmonary function, perhaps because the diaphragm is able to make a major contribution in the presence of a high resting volume. Lung volumes may be mildly reduced, but gas transfer is almost always preserved in the absence of parenchymal disease.[241]

MARFAN SYNDROME

Marfan syndrome (MS) is an autosomal dominant condition of variable penetrance affecting approximately 5/100,000 population. MS is characterized by abnormalities of fibrous connective tissue with abundant type I collagen (in some cases due to mutations on chromosome 15), especially in the skeleton (long limbs, arachnodactyly, pectus excavatum, kyphoscoliosis), eyes (subluxation of the lens), and cardiovascular system (aortic or mitral regurgitation, aortic aneurysm). The reduced life expectancy of MS is largely attributable to cardiac complications; there is no effective treatment to reverse disease or to slow progression.

Respiratory complications can be subdivided into pulmonary and extrapulmonary abnormalities. Ten percent to 15% of patients with MS, have pulmonary involvement. The most common pulmonary complication is pneumothorax (often recurrent and bilateral). The high prevalence of pneumothorax in MS of 5% to 10%[242] (over 100-fold higher than in the general population) can be ascribed to the rupture of subpleural bullae. Localized bulla formation with a predilection for the lung apex[243] is an occasional striking finding in young patients. Emphysema is present on chest radiography in the majority of MS patients with pneumothoraces.[242,244] Generalized emphysema in nonsmoking patients with MS may become evident at any age and is sometimes fatal in childhood.[245] Underlying apical fibrosis has been reported in a handful of cases. Other less frequent parenchymal manifestations include congenital malformations of the middle lobes (which may be absent or rudimentary) and an increased prevalence of bronchopneumonia.[242]

Thoracic cage involvement is present in greater than 50% of MS patients. Isolated pectus excavatum in MS is seldom associated with significant impairment in lung function. However, occasionally kyphoscoliosis is associated with fatal cor pulmonale.[246] It is likely that nocturnal desaturation amplifies hypoxia due to kyphoscoliosis. Increased upper airway collapsibility during sleep is common in MS, accounting for an association between MS and obstructive sleep apnea.[247]

KEY POINTS

- In CTD the lung can be involved by a wide variety of patterns of pathology affecting the trachea through the parenchyma to the pleura.
- Sometimes, pulmonary manifestations may precede systemic features of the CTD.
- Often, combinations of patterns exist that flag the likelihood of CTD being the underlying problem. Some patterns of lung disease are more common in one CTD than the others. Specific pathologic entities that occur in these diseases do not generally follow the same course as their idiopathic counterparts.
- Common drugs used in the treatment of CTDs may result in major pulmonary complications.
- Increasing recognition of the pulmonary manifestations of these protean disorders is resulting in better outcomes and remains a growing field.

Management of Treatment Complications: Aspergilloma
Lung Transplantation

INTRODUCTION

Sarcoidosis is a multisystem, inflammatory disorder characterized by noncaseating granulomas that can infiltrate almost any organ but, most commonly, involves the lungs. Most often occurring in adulthood, sarcoidosis often presents with hilar lymphadenopathy, pulmonary infiltration, and eye and skin lesions. Because of its many and varied clinical manifestations and its worldwide prevalence, this disorder can mimic other inflammatory and infectious disorders. Major targets include the lungs, lymphatics, eyes, skin, liver, bone, heart, and neurologic system.[1] The American Thoracic Society criteria for the diagnosis of pulmonary sarcoidosis includes (1) the presence of a consistent clinical and radiographic picture; (2) the demonstration of noncaseating granulomas on biopsy; and (3) exclusion of other conditions that can produce granulomatous inflammation, including infections, autoimmune disorders, and inhalational diseases, as discussed later in the "Differential Diagnosis" section.[2]

BACKGROUND

Jonathan Hutchinson published the first description of sarcoidosis in 1877, reporting a patient who had developed multiple raised purple skin lesions over 2 years. He subsequently described several similar cases and suggested that they represented a distinct clinical entity. In 1899, Caesar Boeck reported a case of skin lesions similar to Hutchinson's and provided a name for this condition when he used the term "multiple benign sarkoid of the skin," referring to the histologic appearance that he thought resembled sarcoma. He subsequently published descriptions of similar pathology in multiple other organs, including lung and lymph nodes. The name *sarcoidosis* was derived from these descriptions.[1,2]

EPIDEMIOLOGY

Sarcoidosis occurs worldwide, with the highest incidence occurring in United States (among African Americans) and Sweden. The incidence of sarcoidosis in the Asian population appears to be lower than in white and black populations.[3] In most populations, there is a consistent predilection for adults aged 40 years or younger, peaking in 20- to 29-year old subjects. Another consistent observation across ethnic groups is a preponderance for affecting females more than males. However, there is some variation in the age-specific incidence of sarcoidosis across ethnic groups. For African Americans, the peak incidence occurs in the fourth decade of life; for Japanese, the male incidence rates peaked in the 20- to 34-year-old group. However, among women, the incidence appears biphasic, for example, among Japanese

and Scandinavian women, there is a second higher peak for those older than 50 years.[3] Disease can occur in children and the elderly as well. A recent study of childhood sarcoidosis among Danish children revealed that it carries a favorable prognosis, with complete resolution in approximately 75%, the majority recovering within 6 years of diagnosis.[4] The published rates likely underestimate the frequency of this disorder because many cases may go undiagnosed or be misdiagnosed.

Ethnic variation in clinical presentation is also observed among sarcoidosis subjects. The Japanese frequently present with ocular and cardiac involvement. An acute form of sarcoidosis, comprised of bilateral hilar lymphadenopathy, arthritis, and erythema nodosum (Löfgren's syndrome), is more common among Southern Europeans. African American sarcoidosis subjects are more likely to present with more frequent involvement of the eye, liver, bone marrow, extrathoracic lymph nodes, and skin other than erythema nodosum.[5]

ETIOLOGY AND PATHOGENESIS

The cause of sarcoidosis remains unknown. However, there is much evidence to support the hypothesis that the disease develops when a genetically susceptible individual is exposed to a specific environmental antigen.

Environment

Spatial and Temporal Clustering

A shared environmental exposure, or possibly person-to-person transmission, is suggested by spatial and temporal clustering of cases, reports of community outbreaks, and reports of work-related risk for health care workers and firefighters. Careful environmental investigation of new cases sometimes uncovers clusters of disease and may suggest sources of antigen exposures or exposures to known causes of granulomatous disease. For example, clusters of disease have been found among nurses and groups of firefighters.[6,7] A case-control study of a sarcoidosis cluster on the Isle of Man demonstrated that a significantly greater percentage of cases than controls reported previous contact with a sarcoidosis patient.[8] A multicenter case-control study of the etiology of sarcoidosis (A Case Control Etiologic Study of Sarcoidosis [ACCESS]) examined 706 case-control pairs.[9] The study recruited newly diagnosed, pathology-confirmed cases, excluded cases of possible tuberculosis or chronic beryllium disease, and used random-digit telephone dialing to recruit controls matched for age, gender, race, and ethnicity from 10 centers. Questionnaires were used to obtain information about previous occupational and environmental exposures, as well as family history of sarcoidosis. The study found weak but statistically significant associations for several occupational and environmental exposures, including those potentially related to microbial bioaerosols and pesticides. A previous case-control study had more specifically evaluated rural exposures as potential risk factors for sarcoidosis; the authors found, even in multivariable models, a significant and dose-dependent association existed between exposure to wood stoves or fireplaces and the development of sarcoidosis.[10] Still another case-control investigation enrolled African American individuals with sarcoidosis and collected detailed job histories from them and from sibling controls.[11] Several job titles and job exposures were found to be associated, both positively and negatively, with disease risk. The authors concluded that work involving exposure to metals or high humidity may place individuals at increased risk of developing sarcoidosis but that identification of specific relevant exposures was quite difficult in the face of complex occupational exposures.[11]

Infectious Agents

The observation of transmissibility infers that infectious agents may have a role in sarcoidosis pathogenesis. Among the putative microorganisms, mycobacteria and proprionibacteria remain leading candidates. More recent studies from independent laboratories have demonstrated the presence of mycobacterial nucleic acids and proteins in sarcoidosis granulomas. One study used a limited proteomics approach to detect tissue antigens that were poorly soluble in neutral detergent and resistant to protease digestion. Using matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF), they identified 16 of 75 peptide sequences that corresponded to *Mycobacterium tuberculosis* katG and one potential match for *M. tuberculosis* topoisomerase. They also found antimkatG immunoglobulin G (IgG) in the sera of 12 of 25 (48%) sarcoidosis subjects compared with 0 of 11 purified protein derivative (PPD)–healthy controls and four of 10 (40%) PPD+ controls.[12] In addition, polymerase chain reaction (PCR) analysis for mycobacterial nucleic acids have revealed the presence of conserved genes such as 16S rRNA, rpoB, and superoxide dismutase A.[13,14] A meta-analysis of studies from 1980 to 2000 that evaluated the presence of mycobacteria using molecular techniques in biologic samples found an overall positive association for the presence of mycobacterial nucleic acids within sarcoidosis granulomas.[15] The detection of T helper 1 (Th1) cellular immune responses to mycobacterial virulence factors in peripheral blood mononuclear cells and bronchoalveolar lavage (BAL) has been reported.[16,17] It has been shown that molecular analysis of sarcoidosis granulomas can identify microbial proteins that induce systemic Th1 immune responses in the same sarcoidosis subjects.[14]

Likewise, interesting data involving Japanese sarcoidosis subjects have suggested an association with *Proprionibacterium* species. It has been observed that *P. acnes* can be frequently isolated from patients with sarcoidosis.[18] Ishige and coworkers[19] reported that 15 of 15 sarcoidosis tissue samples were positive for propionibacterial (*P. acnes* or *P. granulosum*) rRNA by PCR analysis, compared with only 3 patients positive for mycobacterial DNA; conversely, 2 of 15 tissue samples from patients with tuberculosis were positive for propionibacteria and 15 of 15 were positive for mycobacteria. These results

were extended in a study involving 259 patients from five centers from Japan, Italy, Germany, and England.[20] Propionibacterial DNA was detected in all but 2 of 108 sarcoidosis lymph node samples compared with *M. tuberculosis* DNA that was found in 0% to 9% of these samples.[20] Of note, propionibacterial DNA was detected in 0% to 60% of *M. tuberculosis* or control samples. A study from an independent laboratory in Greece reported the presence of *Mycobacterium* and *Propionibacterium* nucleic acids in sarcoidosis specimens from Greece.[21] A study of successful culture and PCR analysis for *Proprionibacterium* species from lung tissues and lymph nodes from subjects with and without sarcoidosis suggested that *P. acnes* is a common commensal in peripheral lung tissues and mediastinal lymph nodes.[22]

Immunology

Autoantigens

In addition to infectious agents, autoantigens have been proposed to have a role in sarcoidosis pathogenesis. A recent report described isolation of common autoantigens from sarcoidosis BAL T cells of DRB1*0301-positive patients. From the BAL cells, human leukocyte antigen (HLA)-DR molecules were affinity purified and bound peptides acid eluted. Subsequently, peptides were separated by reversed-phase high-power liquid chromatography and analyzed by liquid chromatography mass spectrometry. Antigen, previously associated with autoimmune disease, such as vimentin and adenosine triphosphatase (ATP) synthase were identified.[23] The presence of antiendothelial cell antibodies has been reported among sarcoidosis subjects. The quantity of antibody appeared to correlate with disease severity and the need for immunosuppressive therapy.[24]

Immune Response

Although the etiology of sarcoidosis is not known, significant insight into sarcoidosis pathogenesis has been achieved through investigation of the sarcoidosis immune response. The core of sarcoidosis immunopathogenesis is the presentation of antigen(s) by host macrophages in the context of major histocompatibility complex (MHC) class II alleles, which are then recognized by antigen-specific $CD4^+$ T cells.

Sarcoidosis is mediated primarily through $CD4^+$ Th cells and cells derived from the mononuclear phagocytes.[25] $CD4^+$ T lymphocytes spontaneously proliferate, releasing interleukin-2 (IL-2) and interferon-γ (IFN-γ) in vitro. The IL-2 stimulates further T-lymphocyte proliferation and chemotaxis, recruiting more T lymphocytes to the affected site. IFN-γ amplifies the immune response through its effects on multiple target cells. The release of inflammatory cytokines serves to recruit additional peripheral blood monocytes to the affected organ, where they differentiate into exudate macrophages that show enhanced antigen-presenting capacity and release tumor necrosis factor-α (TNF-α) and IL-1β, both of which promote granuloma formation. These cells accumulate within the affected tissue, where they become increasingly organized, and form noncaseating granulomas. This infiltrative process is thought to be mediated primarily by $CD4^+$ T lymphocytes and mononuclear phagocytes, although other inflammatory cells (e.g., mast cells, fibroblasts) as well as epithelial and endothelial cells contribute to the nonspecific inflammatory response, leading to increased tissue permeability and cell migration. Because of chemoattractant signals, an elevated lymphocyte count and a marked increase in the $CD4^+$/$CD8^+$ T-lymphocyte ratio is observed in the affected organs of patients with active sarcoidosis. Several reviews describe in detail the current state of knowledge on the immune and inflammatory events.[26–28]

The recruitment of mononuclear cells in sarcoidosis is enhanced by the production of chemokines, including RANTES (regulated on activation, normal T cell expressed and secreted), monocyte chemoattractant protein-1, macrophage inflammatory protein-1α, and IL-8, all released by alveolar macrophages.[29] In addition, there is increased expression of adhesion molecules, such as intercellular adhesion molecule-1, vascular cell adhesion molecule-1, and the selectins, which promote cell binding.[30–34] Effector cells such as dendritic cells and macrophages function by presenting antigen to T cells and by producing proinflammatory cytokines, such as IL-12 and IL-15. IL-12 induces the differentiation of naive $CD4^+$ T lymphocytes into Th1 cells and promotes the release of IFN-γ. Th1 cells in sarcoidosis are antigen-activated $CD4^+$ T lymphocytes and produce IFN-γ and IL-2, resulting in a delayed-type hypersensitivity immune response. IL-15 acts synergistically with IL-2 and TNF-α to stimulate T-lymphocyte proliferation.

Sarcoidosis antigen–specific T lymphocytes generated during the initial host response play a central role in mediating the subsequent inflammatory events within the lung. Once naive T lymphocytes are activated, they undergo clonal expansion and differentiation into effector and memory T lymphocytes. In sarcoidosis, most of the T lymphocytes appear to have been previously stimulated, likely in regional lymph nodes, and to have migrated back to the affected organ.[35] Studies of the T-lymphocyte antigen receptor (TCR) repertoire in sarcoidosis demonstrate that the disorder is initiated by an antigen-specific immune response, based on observed oligoclonal expansion of T-lymphocyte subsets bearing particular, restricted α/β TCRs. Lymphocytes bearing γ/δ TCRs are likely to play some supporting role in the pathogenesis of this disorder, although the body of evidence most strongly supports the importance of T cells that bear particular α/β TCRs on their surface.[35,36]

In light of potential immunotherapeutic advances, it is noteworthy that TNF-α up-regulates endothelial cell adhesion molecules involved in leukocyte binding, stimulates T-lymphocyte release of IFN-γ, and enhances T-lymphocyte proliferation, among many other potential roles in inflammation. IL-1β may be needed in granuloma formation because it stimulates exudate macrophage production of IL-8 and granulocyte-macrophage colony-

stimulating factor, which, in turn, promotes monocyte differentiation and resultant macrophage proliferation. The net result is an amplification loop involving antigen recognition, proinflammatory cytokine release, cell activation, recruitment, and granuloma formation. Pathogenic aspects of granuloma formation and maintenance in sarcoidosis, as compared with other granulomatous disorders, have been the subject of recent reviews.[37,38]

Fibrosis

The progression from granulomatous inflammation to increasing amounts of fibrosis portends a poor prognosis. Factors leading from granuloma to fibrosis are poorly understood, but probably involve changes in local cytokine production toward a Th2 cell pattern (IL-4, IL-5) and increases in growth factor expression, including transforming growth factor-β (TGF-β), basic fibroblast growth factor, and insulin-like growth factor-1.[39]

Anergy

Many investigators have noted the presence of an immune paradox within sarcoidosis subjects: intense immune responses in affected organs, yet a state of peripheral anergy indicated by suppression of immune responses to common antigens such as tetanus, *Candida*, and PPD.[40] Some investigations have linked this observation of T cell anergy to T regulatory cell activity. Naturally occurring regulatory T cells are capable of suppressing proliferation and cytokine production of activated T cells via cell-cell contact. One study was able to demonstrate an accumulation of T regulatory cells in sarcoidosis BAL fluid, granulomas, and the peripheral blood of subjects with active disease. The sarcoid T regulatory cells were unable to completely down-regulate the production of inflammatory cytokines associated with granuloma formation, such as TNF-α, but did exhibit strong antiproliferative activity in the systemic circulation, which was felt to induce the observed anergic state seen in some sarcoidosis patients.[41] Another recent study identified the diminished systemic myeloid dendritic cell function as a contributor to anergy among sarcoidosis subjects. This diminished function also correlated the clinical pulmonary severity as determined by chest radiographs.[42]

Genetics

Familial Clustering

The observation of familial clustering of sarcoidosis cases, an increased incidence among monozygotic twins compared with non-twin siblings, as well as variations in disease susceptibility by race led to investigations of the role of genetics in sarcoidosis immunopathogenesis. Although the variation in incidence, severity, and manifestations of disease among different racial and ethnic groups may be consistent with either an environmental or a genetic contribution, observations of familial clustering of disease and the presence of disease two to four times more commonly in monozygotic than in dizygotic twins clearly demonstrate the importance of genetic factors. Previous studies have shown that up to 19% of affected African American families and 5% of white families have more than one member affected.[43,44] Results of ACCESS further support these observations. An analysis of nearly 11,000 first-degree and over 17,000 second-degree relatives of the 706 cases and controls revealed an overall adjusted familial relative risk of developing sarcoidosis of 4.7 (95% confidence interval, 2.3–9.7). Investigations of German families with more than one affected member similarly support a genetic contribution to disease development. Specifically, evaluations of the distribution of HLA and angiotensin-converting enzyme (ACE) polymorphic alleles in these families suggest an excess of specific alleles among affected first-degree relatives.[45–47] Given these observations, it is likely that multiple genes, rather than a single gene, account for the genetic predisposition to disease.

HLA Class II Associations

A number of chronic inflammatory diseases are associated with genes along the MHC class II region. Sarcoidosis is no exception. ACCESS enrolled biopsy-confirmed cases (736 total) from 10 centers in the United States, and performed high-resolution typing to define HLA class II associations with sarcoidosis. Of 474 matched cases and controls (948 total samples), the *HLA-DRB1* alleles were differentially distributed ($P < .0001$). The *HLA-DRB1*1101* allele was associated with sarcoidosis in blacks and whites ($P < .01$). In addition, there was a population-attributable risk of 16% in blacks and 9% in whites.[48] In contrast, *HLA-DQB1*0201* is associated with a good prognosis in African Americans as well as among British and Dutch patients.[49,50] Another analysis found that possession of the allele *DQB1*0602* has been associated with a poor outcome among African American and Dutch sarcoidosis patients.[51,52] This fact, along with HLA associations that are limited to clinical subsets of sarcoidosis, suggests that HLA phenotype is, at best, a modifier of disease susceptibility in a larger genetic, environmental, and immunologic context. Nonetheless, analysis of HLA associations may eventually deliver insights into the etiologic factors driving sarcoidosis or provide tools for prognostication.[53]

Of note, a body of work from Sweden in patients with Löfgren's syndrome and with acute, remitting sarcoidosis demonstrated a strong association between a lung-restricted expansion of Vα2.3 $CD4^+$ T cells and the expression of one of two specific antigen-presenting molecules (HLA-DRB3*0101, HLA-DRB3*0301) discussed earlier.[54] These data suggest that the combination of a specific T-cell antigen receptor and a particular HLA antigen presentation molecule interacts with the putative sarcoidosis antigen to trigger this acute form of disease. Genes such as Toll-like receptor 4, BTNL2, TGF-β, and annexin A11 have been shown to have associated with the clinical course of sarcoidosis patients.[55–59]

Investigation of other candidate genes in the MHC region has also yielded significant associations. Trans-

porter of antigenic peptide (TAP)-1 and TAP-2 are transporters critical in the processing of antigen prior to presentation through MHC class I, although some data suggest that they may play a role in delivery of antigen to the MHC class II complex as well. Evaluation of TAP-1 and TAP-2 polymorphisms in British and Polish sarcoidosis patients and controls revealed associations in each ethnic group of specific but distinct TAP-2 alleles with disease.[60] Similarly, specific polymorphic alleles in the TNF promoter have been associated with specific disease phenotypes in some studies.

A study has demonstrated a significantly increased frequency of the less common allele of the TNF-308 promoter polymorphism in patients with Löfgren's syndrome.[61] This allele has also been found in unexpectedly high frequencies in patients with cardiac sarcoidosis.[62] However, in two other studies, including one using a subpopulation from the ACCESS study, no difference was found in the TNF promoter-308 allele frequencies between cases and controls.[63,64] Investigation of the TNF-857 polymorphism in a British and Dutch population demonstrated an association between the less common -857T allele and sarcoidosis.[65] Taken together, these results support the existence of specific genetic variants, or more likely combinations of variants, within the MHC locus on chromosome 6 that contribute significantly to sarcoidosis disease risk.

Other Candidate Genes

There has also been evaluation of numerous genes outside of the MHC region with regard to their potential role in sarcoidosis susceptibility. Studies of many of these candidate genes have yielded negative or conflicting results. Of note among these is the ACE gene, selected because of the observed elevations in ACE levels in some sarcoidosis patients. This gene contains a polymorphism characterized by either the presence or the absence of a particular (287-base pair) fragment within the gene. Most studies have found no association of this polymorphism with sarcoidosis. However, one case-control study in African American subjects determined that homozygosity (the absence of this fragment in both copies of the gene) was associated with sarcoidosis susceptibility, particularly in cases with a family history of sarcoidosis.[66]

Several studies have found associations between sarcoidosis and specific alleles of polymorphisms in the IL-1α, the complement receptor 1, and various C-C chemokine receptor genes. The latter are of particular interest, as studies in three distinct populations (Japanese, Czech, and Dutch) have identified both strong positive and negative associations between specific polymorphic alleles and sarcoidosis.[67–69] Spagnolo and colleagues[69] evaluated haplotypes of four polymorphisms in the C-C chemokine receptor 2 gene in a Dutch population. They determined that haplotype 2 (A at nucleotide position 6752, A at 3000, T at 3547, and T at 4385) was strongly associated with Löfgren's syndrome, even after adjusting for other known risk factors for this sarcoidosis variant, such as HLA haplotype and female sex.

CLINICAL PRESENTATION

The clinical presentation of sarcoidosis ranges from an incidental chest radiographic finding in an asymptomatic patient to chronic progressive organ dysfunction. Usually, the disease appears between the ages of 20 and 50; however, both childhood and geriatric cases occur with some regularity. The vast majority of patients (~90%) have pulmonary involvement. However, sarcoidosis may affect any organ and, therefore, may present with symptoms referable to any organ. Patients may also present with nonspecific constitutional symptoms, including fatigue, fever, anorexia, and weight loss.

Acute Sarcoidosis

A distinct subgroup of sarcoidosis patients is characterized by an acute presentation, classically with Löfgren's syndrome. This syndrome, initially described by Sven Löfgren in 1946, is defined by acute erythema nodosum with bilateral hilar lymphadenopathy, fever, and polyarthritis. Symptoms are typically abrupt in onset and have a transient course. A vesicular or maculopapular rash, acute iritis, conjunctivitis, and Bell's palsy may also be features of acute disease. Chest radiographs typically are normal or show significant hilar and mediastinal lymphadenopathy, without pulmonary infiltrates. Arrhythmias may occur due to acute granulomatous cardiac involvement. In general, acute disease has a higher probability of spontaneous resolution. Although relapse may occur, it is thought to be less common than in those patients with a more chronic presentation. Prognosis of patients with an acute onset of sarcoidosis is generally good.

Chronic Sarcoidosis

Another subgroup of patients, often characterized by a more gradual, insidious onset, is more likely to develop chronic disease. Other risk factors for chronic disease include the presence of lupus pernio, which is a persistent, disfiguring, violaceous rash over the nose, cheeks, and ears, and the presence of multiorgan involvement at the time of diagnosis. Chronic eye involvement includes chronic uveitis, cataracts, glaucoma, or keratoconjunctivitis sicca, which can be confused with Sjögren's syndrome. Bone involvement is also much more common in chronic than acute cases, as are pulmonary infiltrates, nephrocalcinosis, and cor pulmonale. Persistence of disease and recurrence after treatment are common in the chronic form.

CLINICAL FEATURES AND DIAGNOSIS

Pulmonary Sarcoidosis

The lung is the most commonly involved organ in sarcoidosis, with physiologic or radiographic abnormalities, or both, demonstrable in more than 90% of patients.[1]

Symptoms and physical examination findings are nonspecific. Patients may present with cough, shortness of breath, and/or chest pain with crackles, wheezing, or a normal lung examination. Lung physiology is similarly nonspecific. Patients may have normal lung function, even with radiographic abnormalities, or may demonstrate restriction, obstruction, abnormal gas exchange, or a combination of these. Some studies report that the most frequent abnormalities are in the vital capacity and diffusing capacity, suggesting restrictive physiology; however, at least one study of newly diagnosed patients found airflow limitation to be the most common defect.[70] Airflow limitation may be due to endobronchial involvement, which can result in significant local stenosis. In general, measures of gas exchange provide greater sensitivity for sarcoidosis lung impairment and response to treatment than do measures of lung volume and airflow.

The radiologic patterns in sarcoidosis are classically described by the Scadding staging system, which is based on the chest radiograph. However, this staging system is increasingly being supplanted by use of imaging tools that have greater sensitivity, such as spiral/thin-section computed tomography (CT). The chest radiographic stages (0-IV) do not correspond to the chronologic progression of disease, but do correlate with likelihood of future radiographic and symptomatic disease resolution. A normal chest radiograph, or stage 0 disease, is seen in 5% to 10% of patients at presentation. Of note, in literature comparing chest radiographic to CT findings in sarcoidosis, up to one half of patients with stage 0 disease have pulmonary parenchymal abnormalities on CT scan.[71,72] In addition, 20% to 30% of these patients have physiologic abnormalities.[73] This group has a low likelihood of disease progression. Stage I disease (Fig. 59-1) is characterized by bilateral hilar and mediastinal lymphadenopathy, classically in the hila, right paratracheal region, and aortopulmonary window. Although the lungs appear normal radiographically in stage I disease, the majority of these patients will have diagnostic findings on transbronchial biopsies. Stage I disease is the most common radiographic presentation, and the majority (55%–90%) of these patients will demonstrate spontaneous resolution.[2] On CT scanning, stage I patients may also demonstrate adenopathy at less typical sites, such as the anterior and posterior mediastinum or axilla, as well as lymph node calcification.[72] A stage II radiograph reveals bilateral hilar or mediastinal adenopathy, or both, as well as pulmonary opacities (Fig. 59-2). Only 40% to 70% of these patients will experience spontaneous remission.[2] The parenchymal abnormalities may be nodular, reticular, or ground-glass and tend to occur in the middle and upper lung zones. In these patients, a classic CT appearance includes 2- to 10-mm nodules in a perilymphatic distribution around the hila, along bronchovascular bundles, and in the subpleural region. Nodular coalescence may occur. A stage III radiograph (Fig. 59-3) also shows parenchymal abnormalities and an absence of hilar or mediastinal lymphadenopathy.[72] Presentation with stage III is associated with only a 10% to 20% likelihood of spontaneous resolution. Finally, a stage IV radiograph demonstrates fibrosis, seen predominantly in the middle and upper lung zones, and is often associated with conglomerate mass formation, upper lobe volume loss, hilar retraction, peripheral bullae, and cystic lesions (Figs. 59-4 and 59-5). Once fibrosis is evident, spontaneous resolution does not occur.

A feared complication in patients with stage IV disease who develop cystic lesions is *Aspergilloma*. Symptoms may include a change in cough and sputum production, accelerated dyspnea, and especially hemoptysis. Imaging studies usually show cavitation, masses, or classic mycetomas with a mass within an increasing-sized cavity.

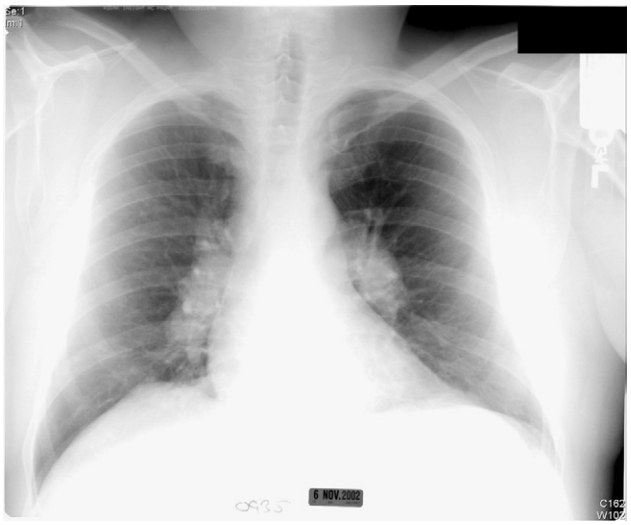

FIGURE 59-1 ■ Posteroanterior chest radiograph of stage I sarcoidosis. Important features include prominent hilar lymphadenopathy and normal appearing lungs.

FIGURE 59-2 ■ Posteroanterior chest radiograph of stage II sarcoidosis. Relevant findings include bilateral hilar lymphadenopathy and bilateral reticular and nodular interstitial infiltrates.

FIGURE 59-3 ■ Posteroanterior chest radiograph of stage III sarcoidosis. Characteristic findings include reticular and nodular interstitial infiltrates with an upper lung predominance and the absence of lymphadenopathy.

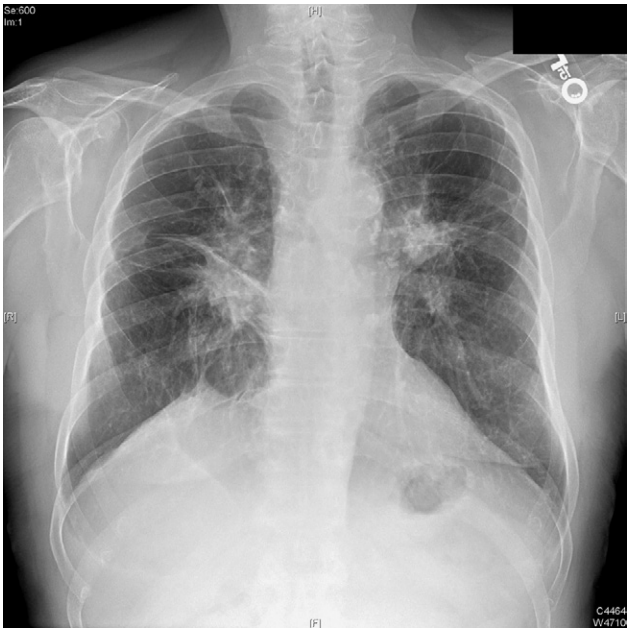

FIGURE 59-4 ■ Posteroanterior chest radiograph of stage IV sarcoidosis. This image demonstrates conglomerate mass formation, upper lobe volume loss, and hilar retraction.

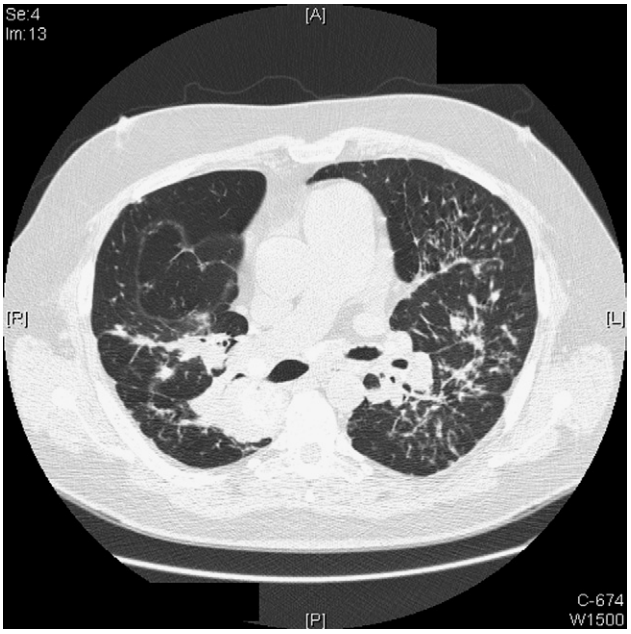

FIGURE 59-5 ■ High-resolution computed tomography scan of a patient with stage IV sarcoidosis demonstrates bilateral central fibrotic (conglomerate) masses with extensive central calcification, as well as parenchymal nodular abnormalities and septal thickening.

Diagnosis may be suggested by sputum cultures positive for fungi; skin tests for *Aspergillus* may be falsely negative due to the anergy.

Endobronchial involvement is another common presentation of pulmonary sarcoidosis. In one study, nearly half of all endobronchial biopsies demonstrated granulomatous inflammation.[74] In this group of 62 patients, positive endobronchial biopsies were associated with more progressive disease. In another study of patients with documented endobronchial disease, up to 10% had stenoses significant enough to result in an asthma-like syndrome, with airflow limitation, localized wheezing, and abnormal gas exchange.[75] Patients with endobronchial involvement have intractable cough. Airway obstruction may also result from bronchial distortion due to scarring in stage IV disease.[72]

Other pulmonary manifestations include various forms of pleural disease, including pleural effusion, pleural thickening, pleural nodules, pneumothorax, and chylothorax. Prevalence estimates for pleural involvement vary widely, depending on definition and method of assessment, from less than 1% to 96%. A review of the literature identified 145 biopsy-proven cases of pleural involvement.[76] Pleural disease was observed in all stages of disease (although radiographic stage was not always reported). The age range for all forms of pleural disease was 30 to 50 years, with an even distribution between men and women. In the majority of cases (>80%), the pleural involvement was unilateral, with the right side affected more often than the left (53% vs. 29%).[76] Pleural effusions should be diagnosed as being due to sarcoidosis only after careful exclusion of other etiologies, because one series reported that up to 40% of effusions in sarcoidosis patients may be due to other diagnoses, including reported cases of tuberculous effusion and mesothelioma.[77,78] Most of the effusions are small with lymphocytic exudates, although several eosinophilic effusions have been reported. Effusions have been reported to resolve spontaneously as well as with steroid therapy. Pleural thickening may be the most common sarcoid-related pleural abnormality, with CT studies reporting a prevalence of 11% to 71%.[76] High-resolution

CT has enhanced the detection of pleural disease, especially for pleural nodules, which have been reported in 22% to 76% of patients.[76]

Pneumothorax is a rare complication, and the relationship of the pneumothoraces to disease remains unclear. Some authors postulate that subpleural blebs (e.g., in advanced fibrocystic disease) or necrosis of subpleural granulomas cause the pneumothorax, whereas others have suggested that the occurrence is coincidental. The role of corticosteroids in treating this complication is similarly unclear.[76]

Chylothorax has also been reported in nine cases, with three of these confirming the presence of lymphadenopathy or adhesions obstructing the thoracic duct.[76]

Another rare form of pulmonary involvement with sarcoidosis that deserves special mention is *necrotizing sarcoid granulomatosis*. Liebow[79] first described this entity in 1973 in a publication that defined five idiopathic forms of pulmonary angiitis and granulomatosis. These were Wegener's granulomatosis, limited Wegener's disease, lymphomatoid granulomatosis, bronchocentric granulomatosis, and necrotizing sarcoid granulomatosis. Numerous case reports and case series have since documented the existence of this distinct entity. Patients may be asymptomatic at presentation or may have systemic symptoms, such as fever, malaise, fatigue, and weight loss; chest symptoms such as cough, chest pain, and dyspnea; or symptoms related to sites of extrathoracic involvement such as the eye or central nervous system. The typical radiographic appearance consists of solitary or multiple pulmonary nodules that often necrose and cavitate. Associated parenchymal opacification has also been described. These abnormalities are found in a distribution similar to that of sarcoidosis, subpleurally and along bronchovascular bundles, and may also be associated with lymphadenopathy. Necrotizing sarcoid granulomatosis is distinguished from sarcoidosis by the presence of cavitation on radiographic studies and the presence of necrosis and granulomatous vasculitis on histopathology, as described later. Typically the clinical course is benign and steroid-responsive; however, individual cases with severe extrathoracic involvement and initial critical illness have also been reported.[37,80]

The presence of bilateral hilar or mediastinal adenopathy (or both) in the absence of other symptoms or in the context of other features of Löfgren's syndrome is often adequate for a presumptive diagnosis of sarcoidosis. However, definitive diagnosis of intrathoracic involvement requires biopsy. It is generally recommended that patients with sarcoidosis have tissue confirmation of their diagnosis, especially if their disease is persistent or fails to fit conventional clinical patterns of multiorgan involvement, or if immunosuppressive treatment is being considered. The procedure of choice in most cases is transbronchial biopsy, which yields a diagnosis in 40% to 90% of procedures, depending on operator experience, the number of biopsies taken, and the Scadding stage.[2] Based on our clinical experience, a minimum of six good transbronchial biopsies are needed to maximize the yield from this procedure.[81]

Real-time endobronchial ultrasound (EBUS)–guided transbronchial needle aspiration (TBNA) has reported a sensitivity of approximately 90% in the diagnosis of sarcoidosis.[82] Other findings on bronchoscopy that support a diagnosis of sarcoidosis but are not diagnostic include BAL lymphocytosis (>10% lymphocytes) and an elevated CD4/CD8 ratio in the BAL fluid (>2:1).[83,84] These BAL criteria are rarely used in clinical practice. They are influenced by whether or not the patient has recently smoked (proportionately increasing the percentage of macrophages), and by the immunosuppressive treatment the patient has received (which can reduce the percentage of lymphocytes). Other supportive data may include an elevated serum ACE level, a positive gallium scan, or the presence of anergy.

If bronchoscopic biopsies are nondiagnostic, other options include mediastinoscopy, video-assisted thoracoscopic lung biopsy, and open-lung biopsy. If mediastinal adenopathy is present on CT scan, then many clinicians consider mediastinoscopy to be the procedure of choice because of the need to rule out malignancies such as lymphoma. It should be noted that in some cases, the tissue diagnosis can be made without a chest procedure. For example, some patients who have typical clinical and radiographic features and who have other organ involvement, such as skin nodules, sinus symptoms, or salivary gland symptoms, can have biopsies of those organs to demonstrate the presence of granulomas. In such cases, it is usually not necessary to do bronchoscopy or thoracoscopy.

The characteristic feature on lung biopsy is the noncaseating granuloma. As demonstrated in Figure 59-6, this is classically described as a well-formed, noncaseating epithelioid cell granuloma surrounded by a rim of lymphocytes and fibroblasts, with varying degrees of peripheral collagen deposition. The granulomas are found in a perilymphatic distribution, classically subpleurally and along bronchovascular bundles (Fig. 59-7). The

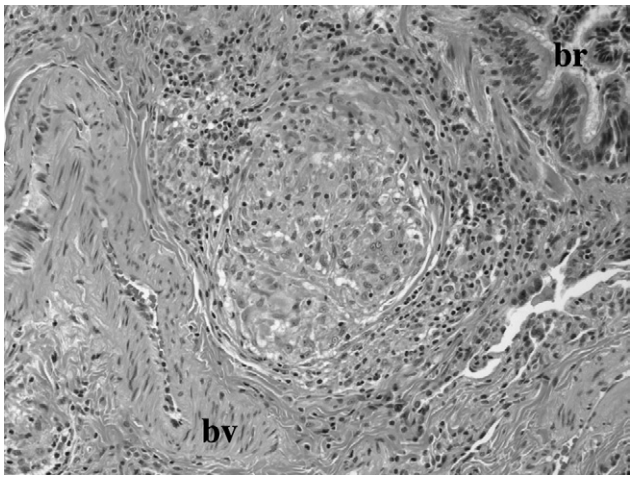

FIGURE 59-7 ■ View of a well-formed noncaseating granuloma located between a blood vessel (bv) and a bronchiole (br). (Original magnification ×200.) (Courtesy of Carlyne Cool, MD, National Jewish Medical and Research Center.)

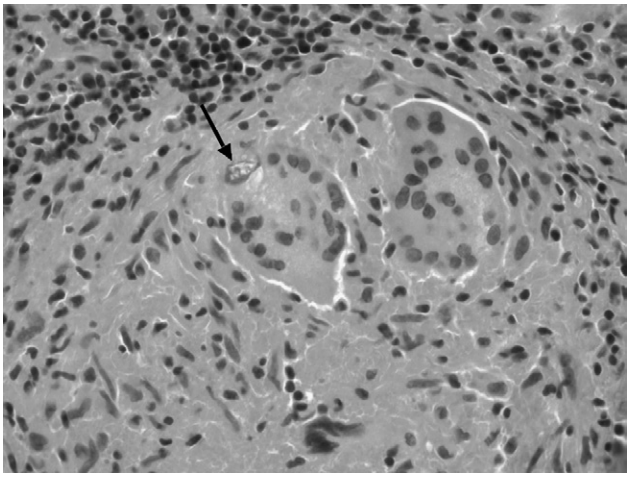

FIGURE 59-8 ■ A Schaumann body (*arrow*) within a multinucleated giant cell within a sarcoidosis granuloma of a pulmonary lymph node. (Original magnification ×400.) (Courtesy of Carlyne Cool, MD, National Jewish Medical and Research Center.)

granulomas may contain cytoplasmic inclusions within giant cells, such as asteroid bodies (star-shaped crystals consisting of microfilaments, microtubules, and other components embedded in a matrix) or Schaumann's bodies (small concentric laminated calcifications composed of calcium salts, iron, and a mucopolysaccharide matrix) (Fig. 59-8).[85]

This appearance is typical of sarcoidosis in the lung as well as in other organs. As noted previously, the diagnosis of sarcoidosis also requires exclusion of other possible etiologies of both the clinical and the pathologic presentation (see later discussion). The distinguishing histopathologic feature of necrotizing sarcoid granulomatosis is the presence of central necrosis within granulomas and a necrotizing granulomatous vasculitis. The appearance is similar to that of Wegener's granulomatosis, although the latter has a less extensive granulomatous reaction, a more severe clinical course, and positive cytoplasmic antineutrophil cytoplasmic antibodies in most cases.

Extrapulmonary Sarcoidosis

A characteristic of sarcoidosis is the potential for the development of granulomatous inflammation in virtually any organ. Confidence in the diagnosis of sarcoidosis rises if there is involvement elsewhere, in addition to lung and thoracic lymphatics. Key characteristics of some of the more commonly affected organs are described in this section.

Ears, Nose, and Throat

There is a range of otorhinolaryngologic presentations, including salivary gland involvement sometimes resulting in severe xerostomia, otitis media, vestibular symptoms, and hearing loss. However, nasal and paranasal sinus involvement can be the most difficult to diagnose and treat properly. Presenting symptoms are usually nonspecific, including nasal congestion, postnasal drip and sinus pressure, headaches, and infections. Sometimes, these will be associated with clinical features suggestive of sarcoidosis, such as lupus pernio (violaceous rash described later), nasal deformities such as saddle nose deformity, and nasal mucosal abnormalities such as friability with crusting, bleeding, and submucosal nodules. Rarely, these nodules may erode through the hard or soft palate, resulting in oral ulcerations or fistulous tracts. Other rare complications of nasal and sinus disease include epiphora (chronic tearing due to intranasal lacrimal tract outlet obstruction); anosmia (loss of the sense of smell due to direct involvement of the olfactory epithelium or obstruction of the olfactory cleft); and mass lesions with intraorbital or intracranial invasion. Even in cases with features suggestive of sarcoidosis, definitive diagnosis relies on biopsy evidence of granulomatous inflammation and exclusion of other infections and inflammatory etiologies (e.g., fungal or mycobacterial infection, Wegener's granulomatosis, rhinoscleroma).

There are a number of management strategies for sinonasal sarcoidosis, depending on disease severity. Krespi and associates[86] have proposed a staging system for nasal involvement that provides some general guidelines for therapy. Stage I nasal involvement is defined as mild nasal disease without paranasal sinus disease. These patients can typically be managed successfully with saline nasal spray, nasal irrigation, and topical nasal steroids. Stage II nasal involvement is moderate disease, with involvement of both nasal and paranasal sinuses; it is typically treated with both stage I therapy and intralesional steroids. Stage III nasal disease is characterized by severe, often irreversible, nasal and sinus disease that usually requires the therapeutic interventions of stages I and II, as well as systemic therapy. Courses of systemic antibiotics are also required for many patients who develop secondary infection related to mucus stasis or sinus ostium obstruction. Surgical interventions have traditionally been avoided owing to concerns

about worsening tissue destruction and inflammation; however, some reports suggest surgery can be performed safely and successfully in selected cases. Examples of surgical indications include severe nasal obstruction that has failed to respond to medical therapy, sinus obstruction with chronic infection, and need for biopsy for diagnosis.[87]

Peripheral Lymph Nodes

Lymphadenopathy is observed most commonly in the hilar and mediastinal lymph nodes (≤90% of patients); however, a minority of patients (5%–30%) have peripheral lymphadenopathy.[2] The nodes are typically nontender, mobile, and located in the cervical, axillary, epitrochlear, and inguinal regions.

Heart

Autopsy studies reveal that sarcoidosis involvement of the myocardium occurs in approximately 40% of patients, although clinical symptoms are present in approximately 10%.[88,89] Clinical manifestations most commonly include arrhythmias, conduction abnormalities, and congestive heart failure. Treatment includes immunosuppressant therapy, permanent pacemakers in the setting of conduction abnormalities, and implantable cardioverter-defibrillators in patients at risk for sudden cardiac death.[90] The "gold standard" for the diagnosis of cardiac sarcoidosis is endomyocardial biopsy. Although it carries high specificity, there is low sensitivity. Biopsy is typically performed from the right side of the heart, whereas sarcoidosis involvement tends to involve the basal and lateral regions of the left ventricle.

New cardiac-imaging techniques have emerged with permit noninvasive identification of cardiac sarcoidosis with high sensitivity. Gadolinium enhancement patterns and signal intensity on T2-weighted images on cardiac magnetic resonance imaging (MRI) can distinguish sarcoid involvement from ischemic scars. Fluorodeoxyglucose positron emission tomography (FDG-PET) imaging can also identify cardiac sarcoidosis lesions.[91,92] A recent study indicates that a history of cardiac symptoms, especially palpitations, as well as abnormalities on electrocardiography, Holter monitoring, or transthoracic echo, is sensitive and specific for cardiac sarcoidosis. Sarcoidosis lesions seen on cardiac MRI or PET scanning do not predict arrhythmias in patients with preserved cardiac function.[93]

Skin

Skin involvement is found in approximately 25% of sarcoidosis patients.[2] The two most classic skin lesions are erythema nodosum and lupus pernio. Erythema nodosum typically presents as raised, tender, red nodules, 1 to 2 cm in diameter, on the anterior surface of the lower legs. As described earlier, lupus pernio is a rare lesion consisting of purplish plaques typically found over the nose, cheeks, lips, and ears. It is observed more commonly in African American women and is associated with chronic, severe disease. More common skin abnormalities include red-brown to orange macules and papules, keloids, and hyper- or hypopigmentation. With the exception of the two classic lesions, definitive evidence of skin involvement relies on biopsy demonstrating noncaseating granulomas.

Eyes

Ocular involvement occurs in 11% to 83% of sarcoidosis patients.[2] The most common presentation is uveitis, with a higher prevalence of anterior uveitis in African Americans and of posterior uveitis in whites.[94] Anterior uveitis typically presents acutely, with pain, photophobia, lacrimation, and redness, but may have a more chronic course. Posterior uveitis is typically gradual in onset and is more likely to result in visual morbidity. Conjunctival nodules are another common, although usually asymptomatic, presentation. In fact, the diagnosis of sarcoidosis can sometimes be made with conjunctival biopsy, even in patients without any ocular symptoms. Although the yield varies depending on the presence of conjunctival follicles, other ocular abnormalities, and extraocular disease, small series of conjunctival biopsies have found yields of 33% to 70%, even without evident conjunctival disease.[95] Although less common, lacrimal gland enlargement is a characteristic finding (Fig. 59-9). In addition to posterior uveitis, the posterior segment of the eye may be affected with vitreous hemorrhage, cataracts, glaucoma, and retinal ischemia with neovascularization. Patients with disease of the posterior segment of the eye have a higher prevalence of central nervous system involvement.[96] Annual ophthalmologic evaluation with slit-lamp examination is recommended to evaluate for ocular involvement. Microvascular involvement can be detected using fluorescein angiography. Vigilance for ocular involvement is extremely important, as about 10% of patients with sarcoid-associated uveitis develop blindness in at least one eye.[97]

Nervous System

Neurosarcoidosis has been described in both the central and the peripheral nervous systems but is clinically evident in less than 10% of patients.[2] The most common form of central nervous system involvement is meningeal infiltration and inflammation. This may manifest clinically with cranial neuropathies, hydrocephalus, head-

FIGURE 59-9 ■ Enlargement of lacrimal glands in a sarcoidosis patient.

aches, and encephalopathy. Granulomatous inflammation of the cranial nerves most commonly presents as a unilateral seventh nerve palsy, but has been reported in every cranial nerve. Central lesions occur much less commonly and often present clinically when there is pituitary involvement. Clinical syndromes include diabetes insipidus and hyperprolactinemia. Peripheral neuropathy has also been described. Diagnostic tests that may be helpful include MRI for brain lesions and leptomeningeal involvement; cerebrospinal fluid examination, which typically reveals a lymphocytic pleocytosis and elevated protein in central nervous system disease; and electrodiagnostic studies and nerve biopsy for peripheral neuropathy. Although the sensitivity and specificity of many of these studies in neurosarcoidosis is not well defined, MRI with gadolinium is the preferred imaging study for sarcoidosis patients with central nervous system symptoms, with a sensitivity in this patient population of 82%.[98,99]

Endocrine Glands

Abnormal calcium metabolism is the most common endocrine disorder in sarcoidosis. Both hypercalcemia and hypercalciuria occur because of increased 1,25-dihydroxyvitamin D production by activated macrophages in sarcoidal granulomas.[100] Left untreated, these abnormalities can result in the formation of renal calculi, precipitation of calcium salts in the kidney itself (nephrocalcinosis), and sometimes, renal failure. Other unusual renal sequelae of sarcoidosis include interstitial nephritis and granulomatous masses.[2]

Parotid Gland

Parotid enlargement is a classic but rare disease feature. Heerfordt's syndrome, or uveoparotid fever, is characterized by parotid enlargement with fever, facial palsy, and anterior uveitis.

Liver and Spleen

Clinically apparent liver disease, such as palpable hepatomegaly or symptomatic cholestasis, is a rare complication of sarcoidosis. However, liver function test abnormalities are commonly observed.[2] Male gender, hepatomegaly, splenomegaly, and normal chest radiograph were associated with hepatic sarcoidosis. On multivariate analysis, male gender (odds ratio [OR] 2.8, $P = .012$), and splenomegaly (OR 9.2, $P < .0001$) were more prevalent in the group with liver disease. Liver involvement can also be detected radiographically, with hepatomegaly or nodular lesions detected on abdominal CT or MRI.[101] The demonstration of hepatic sarcoidosis after interferon therapy for hepatitis C has been reported.[102] These new lesions typically respond to steroid therapy. Splenic involvement is also rarely symptomatic, but is common, as determined by studies of fine-needle aspiration biopsies. Rarely, massive splenomegaly may occur and may cause thrombocytopenia or other cytopenias.[103]

FIGURE 59-10 ■ Joint and bone involvement in the hands of a sarcoidosis patient.

Joints

Although arthralgias are common in patients with Löfgren's syndrome, other forms of sarcoidosis less commonly demonstrate joint involvement. Arthralgias occur in 25% to 39% of patients, but deforming arthritis is rare.[2] Between 3% and 13% of patients display bony involvement,[104] although the increasing use of MRI may increase future estimates of the frequency of osseous sarcoidosis. Classically, if the bones are involved, plain radiographs or MRI will demonstrate bone cysts in the phalanges, although virtually any bone can be affected. Figure 59-10 illustrates the effects of bony involvement and arthritis in the hands of a sarcoidosis patient. Symptomatic muscle involvement, characterized by nodules, acute myositis, or chronic myopathy, is also rare; however, in systemic sarcoidosis without clinical manifestations of muscle disease, 20% to 75% of cases are found to have granulomas on muscle biopsy.[105]

Blood

Hematologic abnormalities are also seen, with as many as 40% of patients demonstrating anemia, leukopenia, lymphopenia, or a combination of these.[2] Thrombocytopenia is rare but can be the consequence of bone marrow involvement or splenic enlargement with platelet destruction.

Other Sites

Other unusual sites of biopsy-confirmed disease have been the subject of extensive reviews, including one by Judson and colleagues[106] that defines definite, probable, and possible criteria for organ involvement. These criteria were used to describe the case population in the ACCESS study.[106]

DIFFERENTIAL DIAGNOSIS

The diagnosis of sarcoidosis is made by exclusion of other conditions. Table 59-1 summarizes the major categories of both infectious and noninfectious disorders that must be considered prior to accepting the idiopathic diagnosis. Diagnostic considerations for pulmonary granulomatous inflammation include infections with mycobacteria, bacteria, fungi, spirochetes, and protozoa.

TABLE 59-1. Differential Diagnosis of Granulomatous Disease and Relevant Testing with Clinical Suspicion

Cause	Granulomatous Disease	Confirmatory Data
Infectious agents		
Mycobacteria	Tuberculosis, atypical mycobacterial infection	PPD; sputum or BAL culture
Fungi	Histoplasmosis, coccidioidomycosis	Serologic testing (histo); sputum or biopsy stains, serologies, skin tests (cocci)
Bacteria	Brucellosis	Culture (low yield); serologies
Spirochetes	Syphilis	RPR
Parasites	Leishmaniasis, toxoplasmosis	Tissue biopsy, culture, leishmanin test (leishmaniasis); serologies; BAL, lung biopsy cultures (toxoplasmosis)
Neoplasms	Carcinoma, sarcomas, malignant nasal granuloma	Full sectioning and histopathologic examination of lymph nodes
HP	Farmers' lung, bird breeder's lung, suberosis (HP secondary to moldy cork), bagassosis (HP secondary to moldy sugar cane)	Detailed history for likely exposures; examination of biopsies for other features characteristic of HP; precipitins
Metals	Chronic beryllium disease, zirconium or aluminum granulomas	Detailed history for likelihood of exposure; blood and/or BAL beryllium lymphocyte proliferation test
Silicates	Silicosis with granulomatous inflammation	Detailed history for likelihood of exposure; review of radiographic findings for features of silicosis; biopsy microanalysis for dust
Vasculitic granulomatoses and autoimmune disorders	Wegener's granulomatosis, Churg-Strauss syndrome, lymphomatoid granulomatosis, polyarteritis nodosa, bronchocentric granulomatosis, systemic lupus erythematosus, primary biliary cirrhosis, juvenile rheumatoid arthritis	Pathologic review for features of vasculitis; autoantibody studies, including c-ANCA, p-ANCA, ANA, anti-dsDNA, rheumatoid factor
Other conditions	Chronic granulomatous disease (children), Whipple's disease, lymphocytic infiltration after cancer chemotherapy, Blau syndrome, local sarcoidal reactions	

ANA, antineutrophil antibody; BAL, bronchoalveolar lavage; c-ANCA, cytoplasma antineutrophil cytoplasmic antibody; dsDNA, double-stranded deoxyribonucleic acid; HP, hypersensitivity pneumonitis; p-ANCA, perinuclear antineutrophil cytoplasmic antibody; PPD, purified protein derivative (of tuberculin); RPR, rapid plasma reagin test.

Diseases caused by occupational and environmental inhaled agents must also be considered, including hypersensitivity pneumonitis due to inhaled organic and inorganic antigens, metal-induced disorders such as chronic beryllium disease,[107] and silicosis.[108] In addition to the infectious and exposure-related diagnoses noted previously, other diagnostic considerations include Wegener's granulomatosis and idiopathic interstitial pneumonias such as lymphocytic interstitial pneumonia.

Chronic beryllium disease is of particular interest because it is clinically, radiographically, and histopathologically indistinguishable from sarcoidosis. Chronic beryllium disease is distinguished from sarcoidosis by a history of beryllium exposure and by laboratory evidence of immunologic sensitization to beryllium using blood or lavage cells in a beryllium lymphocyte proliferation test. A study from Israel illustrates the need to exclude chronic beryllium disease prior to accepting a diagnosis of sarcoidosis.[109] In this study, Fireman and coworkers[109] performed the blood beryllium lymphocyte proliferation test in 14 patients in their sarcoidosis clinic who, on repeat questioning, reported employment in industries with the potential for beryllium exposure (e.g., metal extraction, ceramics, electronics, space and atomic engineering, dental laboratories). Three of the 14 patients were found to be beryllium-sensitized and were therefore diagnosed as having chronic beryllium disease. Similar findings of chronic beryllium disease cases masquerading as sarcoidosis have been reported in a German cohort.[110] These studies highlight the importance of a thorough occupational history in patients with granulomatous lung disease.

The finding of noncaseating granulomas in lymph nodes is associated with a similarly broad differential diagnosis. Mycobacterial infection, brucellosis, toxoplasmosis, and cat-scratch disease can all cause a granulomatous lymphadenitis. Neoplasms, including Hodgkin's and non-Hodgkin's lymphoma and metastatic carcinoma, can cause lymph node enlargement and stimulate a sarcoid-like reaction. Therefore, when granulomas are identified on lymph node biopsy, the entire node must be examined histopathologically to exclude these diagnoses. Of note, nonthoracic lymph node granulomas without an identified etiology or evidence of other organ involvement are referred to as "granulomatous lesions of unknown significance," and are not sufficient to make a diagnosis of sarcoidosis. The differential diagnosis of noncaseating granulomas in other organs is similar. Other specific entities that can produce noncaseating granulomas include foreign body reactions in the skin, schistosomiasis, primary biliary cirrhosis, and Crohn's disease.[1,2]

The distinction between sarcoidosis and autoimmune disorders deserves specific mention. Sarcoidosis has been associated with elevation of various autoantibodies in serum, including nonspecific elevations of rheumatoid factor and antinuclear antibodies.[111] Several researchers have suggested an association between sarcoidosis and autoimmune endocrinopathies, as well as antiphospholipid antibodies.[112] The putative link between sarcoidosis and autoimmunity is supported by cases of concurrent diagnoses, as well as by some of the obvious similarities in clinical presentations between sarcoidosis and the autoimmune diseases.

Although sarcoidosis is rare in children, when it does occur in preschool children, it may mimic the manifestations of juvenile rheumatoid arthritis with skin, eye, and joint involvement without lung disease. Distinction between the two entities usually requires biopsy of skin, synovium, lymph node, or liver.[113] In contrast, in adults, the clinical presentations of rheumatoid arthritis and sarcoidosis are quite distinct. Interestingly, the coexistence of the two diseases with biopsy verification of both has been demonstrated in numerous case reports, suggesting a possible etiologic similarity.[114] Sjögren's syndrome and sarcoidosis may also coexist and be difficult to distinguish, particularly when there is lung involvement.[115] Both diseases can present with keratoconjunctivitis sicca, parotid swelling, lung involvement, and cutaneous anergy. Some authors suggest that labial minor salivary gland biopsy or lung biopsy can distinguish between the two diseases, but even biopsy findings are sometimes inconclusive.

EVALUATION AND MANAGEMENT

The recommended baseline evaluation and follow-up testing of sarcoidosis patients are shown in Table 59-2.[1] These recommendations are based on the major organs that are usually targeted by sarcoidosis. Other tests may be appropriate for evaluation and management, depending on the particular organs affected.

As a general principle, because there is no single sensitive or specific diagnostic test for sarcoidosis, the diagnosis depends on establishing the compatible clinicopathologic picture and excluding other granulomatous diseases. Ideally, the evaluation should provide histologic confirmation of disease and negative cultures and special stains for organisms.

The clinical impact of sarcoidosis depends on the extent of granulomatous inflammation and the particular organs affected. In determining the extent and severity of disease, clinicians should use available noninvasive tools as much as possible to assess which organs are clinically involved and to assess the extent and severity of organ injury. Asymptomatic organ involvement may be missed but is usually of mild or no clinical significance with three significant exceptions. A slit-lamp examination is recommended for all patients with suspected sarcoidosis to look for clinically undetected uveitis. Subclinical hypercalciuria, even in the absence of hypercalcemia, is associated with nephrolithiasis, and thus a baseline 24-hour urine calcium measurement is advisable. Periodic electrocardiograms should also be obtained to screen for rare, but potentially life-threatening, cardiac arrhythmias and conduction abnormalities.

A baseline complete blood count is recommended to evaluate for anemia, leukopenia, and thrombocytopenia. Serum calcium and liver enzymes may reflect organ involvement meriting treatment. Serum ACE activity is frequently elevated in sarcoidosis. This elevation is not specific but can be of use in monitoring the progression of disease and the response to therapy unless patients are being treated with an ACE inhibitor, which will lower ACE levels.

Tests demonstrating cutaneous anergy may help suggest a diagnosis of sarcoidosis, but the anergy panel is neither sensitive nor specific. Kveim-Siltzbach skin testing—using a preparation of sarcoidosis spleen that is intradermally injected—has been used in the past to help establish a diagnosis of sarcoidosis in patients with unexplained erythema nodosum, uveitis, liver granulomas, or hypercalciuria. This is not approved for general use in the United States and is not recommended.

TABLE 59-2. Recommended Baseline and Follow-up Clinical Evaluation for Sarcoidosis

BASELINE

- Detailed history, including occupational, environmental, and travel history to evaluate for exposure to known causes of granulomatous diseases (see Table 59-1).
- Physical examination with a focus on lungs, lymphatics, skin, eyes, liver, heart, nervous system, joints.
- Biopsy of an affected organ, with special stains, cultures for acid-fast bacillus and fungus to rule out infectious etiologies of granulomas.
- Chest radiography (posteroanterior and lateral).
- Full pulmonary function tests, including spirometry, lung volumes, and an assessment of gas exchange (e.g., diffusing capacity of carbon monoxide, arterial blood gases at rest and with exercise).
- Electrocardiogram.
- Ophthalmologic examination, including slit-lamp examination.
- Laboratory evaluation, including liver function tests, renal function tests, serum calcium, and a complete blood count with differential.
- Urinalysis and 24-hr urine collection for calcium and creatinine excretion.

OTHER TESTS

- To rule out other diagnostic possibilities (e.g., tuberculin skin test [with anergy panel], blood beryllium lymphocyte proliferation test).
- For clinical staging of organ system involvement and severity (e.g., computed tomography scan, magnetic resonance imaging, Holter monitoring, electromyogram, gallium scan).

FOLLOW-UP

Monitoring for resolution or progression:

- Track organs previously involved, using least invasive methods.
- Monitor for new involvement of common target organs annually or sooner if symptoms dictate.

Given the high likelihood of pulmonary involvement at some point in the course of sarcoidosis, we recommend that the extent of lung disease be thoroughly evaluated. Typically, this would include pre- and post-bronchodilator spirometry, lung volumes by body plethysmography, diffusing capacity, and in many cases, one or more direct measures of gas exchange. These include room air arterial blood gas measurements at rest and with exercise; a fall in arterial oxygen saturation during exercise is among the most sensitive indicators of lung impairment in sarcoidosis and other forms of diffuse lung disease. Baseline imaging studies, consisting at minimum of posteroanterior and lateral chest radiographs, should also be obtained. CT of the thorax using spiral and thin-section algorithms provides much greater detail of parenchymal abnormalities, including nodules, ground-glass, septal lines, and adenopathy, but is not required as a baseline study.[2] Generally, patients found to have pulmonary involvement can be followed with the simplest and least invasive testing. For example, in a patient found to have a low diffusing capacity, it is often possible to follow that test, along with spirometry and chest radiographs, rather than routinely performing more invasive studies such as exercise testing with arterial blood gases or serial chest CT scanning (which carries a greater cancer risk in this young population, especially among women).

Gallium-67 citrate scanning adds no specificity to the diagnosis of sarcoidosis, except in the case of patients with lacrimal and salivary gland involvement, in which case the so-called panda sign is observed due to increased uptake in those sites.[116] The "lambda" sign indicating hilar lymphadenopathy is also suggestive but not diagnostic.

Monitoring for disease progression, regression, or response to therapy should be customized, relying on the least invasive markers of disease activity and vital organ involvement, taking into consideration the relative sensitivity of the clinical tools available for monitoring. The clinician must remain vigilant given the tendency of this disorder to relapse and to erupt in new or previously subclinical organs.

TREATMENT

It is not known why some sarcoidosis patients recover and others progress. Even after an apparent recovery, a small proportion of patients may relapse months to years later. Factors associated with worse prognosis include older age at time of diagnosis, African American race, duration of illness greater than 6 months, pulmonary opacities, splenomegaly, lupus pernio, and number of organs involved. A more favorable prognosis has been found in patients with Lofgren's syndrome who expressed *HLA-DRB1*0301*.[117] It is important to recognize that the disease can spontaneously resolve without treatment and that some patients with sarcoidosis are disabled by their illness. The current paradigm for institution of therapy is based upon the presence of organ dysfunction. Thus, most treatment protocols incorporate a period of observation without treatment whenever possible.

Corticosteroids

A detailed summary of current pharmacotherapy in sarcoidosis has been the subject of several recent reviews.[118,119] This section addresses general treatment of sarcoidosis. Oral corticosteroids remain the first-line therapy in most cases. Corticosteroids inhibit proinflammatory cytokine production, including that of IL-1, IL-2, the IL-2 receptor, IFN-α, TNF, and perhaps, various colony-stimulating factors (CSFs) such as IL-3. In addition, corticosteroids, even in very low concentrations, inhibit the synthesis of a variety of proinflammatory enzymes, including the macrophage products collagenase, elastase, and plasminogen activator. Lymphocyte proliferation in vitro and delayed-type hypersensitivity in vitro are also inhibited by corticosteroids.

The use of oral corticosteroids in sarcoidosis is aimed at the relief of symptoms with intended improvement in quality of life and modulation of disease activity to prevent serious morbidity and mortality related to vital organ damage. It is debatable whether all of these goals can be achieved, especially in light of the side effects of corticosteroids.

In a systematic review, Paramothayan and Lasserson[120] identified all of the randomized trials of oral or inhaled corticosteroids in pulmonary sarcoidosis that included a control group. Their goal was to assess the beneficial and adverse effects of corticosteroid therapy. In synthesizing the data from eight studies that met their requirements for inclusion, the authors concluded that oral corticosteroids improved chest radiographs after 6 to 24 months of treatment and produced a small improvement in lung function and gas exchange. They found no data to suggest that systemic corticosteroid therapy alters long-term disease progression. Only two of these studies examined the efficacy of inhaled corticosteroid therapy. These demonstrated no effect on chest radiographic appearance and no consistent effects on lung function. In another review, Reich[121] suggested that corticosteroid-treated patients with a recent diagnosis of stage II or III sarcoidosis might derive more long-term harm than benefit, that the effect on those with disease of more intermediate duration is neutral, and that patients with chronic progressive pulmonary disease respond favorably, at least in the intermediate term. Obviously, the paucity of randomized, controlled clinical trials—especially for all of the various forms of sarcoidosis organ involvement—limits the conclusions that can be drawn. A review of the American Thoracic Society consensus statement[2] would suggest that patients with acute pulmonary sarcoidosis (stage I disease with isolated bilateral hilar adenopathy) *not* be treated because of the generally excellent outcome in the absence of therapy and the potential that corticosteroids may be detrimental if used in these acute cases.

Studies examining outcome at greater than 2 years suggest no significant benefit from corticosteroid therapy in asymptomatic sarcoidosis patients with more advanced

forms of pulmonary involvement.[122,123] In a British Thoracic Society study,[124] patients not meeting the indications for immediate therapy were observed for 6 months. At that point, using a strategy of alternate assignment, they were designated either to receive long-term corticosteroid therapy or to receive corticosteroids only as indicated symptomatically. Analysis of data at 2 years suggested that the long-term therapy group experienced only mild improvements in pulmonary function and reported numerous steroid side effects.

Based on the available literature and a survey of clinical practice in the United States and abroad, it is our general recommendation that whenever possible, corticosteroids should not be initiated until after a period of clinical observation of 3 to 6 months, unless there is a life- or sight-threatening indication to treat immediately. Urgent indications for treatment include eye disease that has failed to improve with topical therapy, cardiac involvement (e.g., cardiomyopathy, heart block, or serious arrhythmias), neurologic involvement (e.g., hypothalamic or pituitary dysfunction or other central nervous system involvement), hypercalcemia, hypercalciuria with associated renal insufficiency or recurrent nephrolithiasis, severe disfiguring skin lesions, severe thrombocytopenia with bleeding diathesis, progressive hepatic failure, severe incapacitating osseous or muscle involvement, and severe pulmonary involvement that is significantly impairing gas exchange. If no such urgent indications have intervened during the 3 to 6 months of observation, patients would be observed closely for pulmonary and other organ function. After these observation months, the persistence or progression of organ dysfunction would then be an indication for a trial period of treatment. Figure 59-11 offers a reasonable strategy for the use of corticosteroids and, as discussed later, methotrexate, in the treatment of acute-onset sarcoidosis.

There is no consensus regarding the optimal initial dosage of corticosteroids. The American Thoracic Society consensus statement[2] reports a usual starting dose of 20 to 40 mg of prednisone, or its equivalent, daily or on alternate days. The British Thoracic Society study[124] similarly used 30 mg of prednisolone (potency equivalent to prednisone) daily as a starting dose in both their long-term and their selective therapy groups. We typically start therapy at a dosage of 20 to 40 mg of prednisone daily or on alternate days, although we use higher doses (to a maximum of 60 mg daily) for severe disease, such as symptomatic cardiac involvement. Patients are seen back in the clinic 8 to 12 weeks later, at which time clinical, radiologic, physiologic, and laboratory assessments are repeated and patients are examined for side effects. Those who objectively improve on corticosteroids initiate a taper of corticosteroids to as low a dose as is tolerated without return of symptoms of organ dysfunction—usually 5 to 10 mg daily or on alternate days. The American Thoracic Society statement[2] recommends that for those who response to steroids, treatment should be continued for at least 1 year. Patients who become stable on high-dose corticosteroids but who have yet to improve are maintained at the same dosage, unless they have developed significant side effects. If intolerable side effects occur, or if the disease worsens, patients are considered candidates for the addition of a second-line immunosuppressive agent. If patients suffer relapse on maintenance therapy, we reinitiate higher dose prednisone and consider second-line, steroid-sparing options.[1,2,118] Patients who have evidence of a clinical response to corticosteroids over the time course described earlier are reevaluated using objective measures prior to attempts to withdraw immunosuppressive medication completely. In some patients, the disease remains quiescent off all

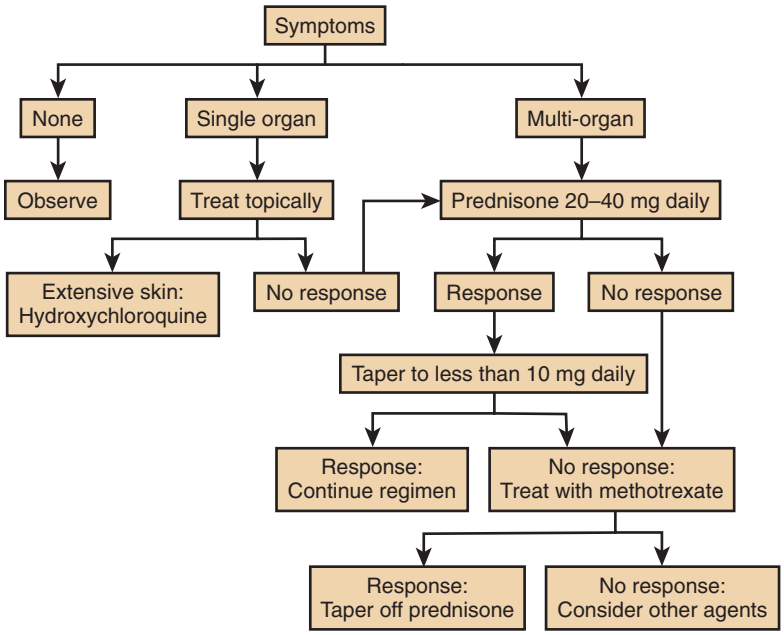

FIGURE 59-11 ■ A suggested treatment strategy for acute sarcoidosis (within 5 yr of diagnosis). Severe single organ sarcoidosis, including neurologic or cardiac, should be treated the same as multiorgan sarcoidosis. (Redrawn from Baughman RP, Costabel U, du Bois RM. Treatment of sarcoidosis. Clin Chest Med 29:535, 2008. © Elsevier Inc.)

corticosteroids. Unfortunately, in others, the disease relapses, requiring that therapy be restarted for purposes of symptomatic relief and clinical control of failing organs. Even patients who are believed to have entered remission should be followed periodically, given the propensity for sarcoidosis to relapse and given the lack of available information about predictors of long-term prognosis.

Other Immunosuppressive Agents

The use of other immunosuppressive agents in sarcoidosis should be reserved for those patients who experience symptomatic disease progression despite the use of systemic corticosteroids or who require systemic therapy but cannot tolerate the side effects of steroids. In general, there has been less clinical experience and fewer published studies testing the efficacy of other immunosuppressive agents, either as single agents or as steroid-sparing agents.

Methotrexate

Methotrexate has emerged as the preferred second-line immunosuppressive drug, especially when used as a steroid-sparing agent (see Fig. 59-11). Methotrexate's mechanisms of action is thought to be generated by the anti-inflammatory effects of adenosine accumulation; also Genestier and associates[125] have reported that methotrexate diminishes antigen-stimulated T-cell proliferation both in vitro and in T cells taken from patients taking methotrexate. There has only been one published randomized, controlled trial of methotrexate in sarcoidosis.[126] The primary end point of this small study was steroid dose after 6 to 12 months; although interpretation of the results was limited by a high dropout rate, there was a suggestion of a steroid-sparing effect in this population. The largest published experience comes from Baughman and Lower,[128] who reported improvement in 33 of 50 patients treated with methotrexate for a minimum of 2 years. Those with cutaneous and musculoskeletal involvement showed the greatest response. Twenty-five of 30 patients who were also receiving corticosteroids were able to decrease corticosteroid dosage; 13 discontinued corticosteroids entirely. A follow-up report of 209 patients showed that 52% on methotrexate entered remission and 16% remained stable, with or without low-dose prednisone.[128] Other reports confirm the beneficial effects of methotrexate in cutaneous and musculoskeletal sarcoidosis.[129,130] In a study by Kaye and colleagues,[130] low-dose methotrexate (average 10 mg/wk, range 7.5–15 mg), when used for an average of 30 months, controlled clinical symptoms in patients with musculoskeletal involvement and helped reduce corticosteroid dose. In most studies, treatment doses of methotrexate range from 5 to 15 mg/wk, usually taken as a single or divided oral dose taken 1 day/wk. Methotrexate may take up to 6 months to become effective in sarcoidosis. During this period, patients are usually maintained on corticosteroids. Leflunomide is a cytotoxic agent that has been used to treat pulmonary sarcoidosis patients, with fewer associated cases of interstitial pneumonitis than methotrexate.[131,132]

Cyclosporin A

Case reports on the benefits of cyclosporin A in sarcoidosis have not been supported by later larger cohort studies.[133,134] The first study to examine cyclosporine A in a more rigorous fashion found that cyclosporine A, administered at doses that achieved a blood level between 150 and 250 ng/mL, failed to produce clinical improvement in 20 patients who had pulmonary involvement, despite 6 months of therapy.[133] Cyclosporin A was undetectable in BAL fluid, suggesting poor penetration of cyclosporin A into the lung as a reason for its failure. A more recent randomized, controlled trial found the combination of prednisone and cyclosporin A to be no better and possibly worse than prednisone alone in treating pulmonary sarcoidosis.[134]

Azathioprine

Despite anecdotal reports and frequent use of azathioprine, there are few published studies examining the drug's efficacy in sarcoidosis. One group reported objective improvement in 7 of 10 patients with pulmonary sarcoidosis after receiving 150 mg/day of azathioprine for 6 months.[135] Some data suggest that it may be efficacious for extrapulmonary disease,[136] although side effects often limit the acceptance of this option. More recent case series evaluated combined therapy with azathioprine and corticosteroids in patients with chronic pulmonary sarcoidosis. A retrospective review of 10 patients demonstrated sustained improvement in lung function in only 2 patients, but a prospective evaluation of 11 patients demonstrated symptomatic relief and improvement in lung physiology and radiographic abnormalities in 9 after an average of 20 months of therapy. Thus, azathioprine may be an effective second-line agent in some sarcoidosis patients.[137,138]

Antimalarials

Chloroquine has proved effective in treating cutaneous manifestations of sarcoidosis,[139] hypercalcemia and hypercalciuria associated with sarcoidosis, and steroid-refractory neurosarcoidosis.[140,141] Generally, chloroquine therapy is initiated at a dosage of 500 mg/day and may be titrated up to a maximum of 1000 mg/day and decreased to a low of 250 mg/day. Because of the potential for significant ophthalmologic toxicity, hydroxychloroquine is often used instead, at a dosage of 200 to 400 mg daily. In 1967, the British Tuberculosis Association[142] reported the first controlled trial on the use of antimalarials in sarcoidosis. They observed some benefit early in attenuating symptoms of pulmonary sarcoidosis but showed little effect on disease outcome when comparing treatment and control groups at 6 months. A more recent trial examined the efficacy of

chloroquine therapy in chronic pulmonary sarcoidosis.[143] During an initial run-in phase, all subjects received chloroquine therapy for 6 months and demonstrated a significant improvement in several lung physiologic parameters. During the subsequent randomization phase, subjects were assigned to receive maintenance therapy with low-dose (250 mg/day) chloroquine or to be observed off therapy. With a mean of 19.7 months of follow-up, the maintenance group demonstrated significantly slower decline in lung function and a trend toward fewer relapses. Thus, although chloroquine and hydroxychloroquine are more commonly employed for extrathoracic disease, they may have a role in pulmonary disease as well.

Cyclophosphamide

Cyclophosphamide is employed in selected cases of corticosteroid-refractory sarcoidosis.[144,145] It appears beneficial for both cardiac sarcoidosis and neurosarcoidosis—in the latter case, even following failure of both corticosteroid and methotrexate therapy. If used, oral cyclophosphamide is given at a dose of 1 to 2 mg/kg/day to a maximum dose of 150 mg/day. Therapy is maintained for several months before tapering. In one open-label study, the investigators used intravenous pulse cyclophosphamide therapy for the treatment of neurosarcoidosis at a dosage of 0.75 to 1.5 g monthly.[145]

Anti–Tumor Necrosis Factor-α Therapy

Based on our present understanding of cytokine expression in sarcoidosis, it is logical to expect that anti–TNF-α therapies, either via inhibition of TNF production with thalidomide or pentoxifylline or via direct inhibition of TNF activity with etanercept or infliximab, should prove effective.[116]

There are individual published cases and small case series data supporting the use of thalidomide in treatment of patients with several forms of cutaneous sarcoidosis, including lupus pernio.[146–150] Pentoxifylline, at high doses, improved lung function in a group of patients with mild pulmonary sarcoidosis.[151]

A prospective, open-label study examined the treatment of sarcoidosis with etanercept, a dimeric fusion protein consisting of the extracellular binding domain of two human TNF receptors bound to the F_c portion of human IgG1.[152] This complex specifically binds TNF and inactivates it. Seventeen patients with progressive pulmonary sarcoidosis and on no other immunosuppressive agents were enrolled and followed for 3 to 12 months. The study was terminated prior to the full planned enrollment owing to excessive treatment failures, defined as a deterioration in two or three of the following: lung function (<10% decline in forced expiratory volume in 1 second, forced vital capacity, total lung capacity, or diffusing capacity for carbon monoxide), dyspnea score, and chest radiograph appearance. The authors concluded that etanercept should not be further studied as a therapeutic option for patients with stage II or III pulmonary sarcoidosis. Several shortcomings of this study are worth noting. First, at baseline, all of the mean lung function values were within the normal range. Therefore, this may have been a negative study because the subjects were too healthy to experience a significant benefit from etanercept. Second, patients were not permitted to be on any other immunosuppressive therapy. Because studies in other inflammatory disorders have demonstrated efficacy of TNF blockers in conjunction with other agents, this stipulation may have doomed the study to fail from the outset. Finally, the authors concluded that the drug deserves no further investigation despite the successful responses of nearly one third of the patients studied. It is, therefore, still certainly possible that for a subset of sarcoidosis patients with more significant pulmonary dysfunction and possibly on concomitant immunosuppressive therapy, this therapy will be effective.

In various case reports, infliximab, a chimeric humanized monoclonal antibody that binds TNF, has been used successfully in the treatment of lupus pernio, neurosarcoidosis, and progressive cutaneous sarcoidosis.[153–158] In one case, investigators reported clinical response in a sarcoidosis patient who presented with severe protein-losing enteropathy, hypoalbuminemia, and proximal myopathy.[159] A recent double-blind, randomized study demonstrated that infliximab therapy improved extrapulmonary sarcoidosis compared with placebo, as assessed by extrapulmonary physician organ severity tool. All patients in the study were required to be receiving a stable dose of corticosteroid or another immunosuppressant to control their pulmonary sarcoidosis. Therefore, the results of the present trial suggest that infliximab provides additional benefit for extrapulmonary sarcoidosis beyond that achieved with standard sarcoidosis treatment.[160]

It is worth noting that use of anti-TNF therapies has been associated with a significantly increased risk of active tuberculosis; therefore, any patient being considered for such therapy must be screened for previously untreated or active tuberculosis.[161] If screened using PPD, other positive controls should be included because of the potential for anergy. Special stains and cultures of lung tissue and BAL can also be used to help exclude tuberculosis.

Combination Treatment Regimens

Combined regimens are coming into increasing favor as treatments for sarcoidosis, although there have been few trials. Most combination treatment regimens for sarcoidosis are corticosteroids plus a second-line agent. The corticosteroid is then slowly tapered over a 3- to 6-month period as allowed by the patient's clinical status, leaving the second drug as the main therapeutic agent. In one study, the combination of cyclosporin A plus oral fluocortolone and oral methotrexate was studied in an open-label, uncontrolled trial in steroid-refractory patients.[162] All 11 patients entered remission. These preliminary results need to be confirmed with a larger, prospective, controlled trial.

Management of Treatment Complications: Aspergilloma

In the face of immunosuppression, sarcoidosis patients are at risk of aspergilloma. The underlying goal of any therapeutic intervention for aspergilloma is the prevention of massive, life-threatening hemoptysis, which may occur in up to 26% of patients with mycetomas.[163] Unfortunately, even with identified risk factors for a poor prognosis, including the severity of underlying lung disease, immunosuppression (including corticosteroids), and underlying sarcoidosis, the likelihood of significant hemoptysis is difficult to predict. Current practice guidelines and a review of the literature suggest that observation, without any therapeutic intervention, is appropriate in asymptomatic patients.[163,164] However, the optimal management of those patients with mild hemoptysis or systemic symptoms, or both, and the overall utility of medical interventions are unclear. There have been no prospective, randomized, double-blind, placebo-controlled trials. However, the available evidence suggests possible utility of endobronchial or intracavitary amphotericin B and of oral itraconazole in selected patients.[163] For those who do develop massive hemoptysis, bronchial artery embolization can sometimes be used as a bridge to surgery.[163,164] Unfortunately, although surgical resection is the definitive treatment, it carries a very high morbidity and mortality, the latter ranging from 1.5% to 23%.[165] In summary, this is a challenging clinical problem with little in the way of strong evidence to guide therapeutic decisions.

Lung Transplantation

Patients with severe and progressive pulmonary disease despite exhaustive medical therapy may be candidates for lung transplantation. The decision regarding timing of proceeding to transplantation is a difficult one; generally, patients with severe and irreversible disease with a life expectancy of less than 3 years are considered. This assessment can be quite challenging in sarcoidosis, as a retrospective study of sarcoidosis patients awaiting transplantation demonstrates. In this study, 23 of 43 patients died while awaiting transplantation; further analysis demonstrated that elevated right atrial pressure consistent with pulmonary hypertension was the only independent predictor of mortality.[165] A similar retrospective cohort study examined mortality of sarcoidosis patients listed for lung transplantation throughout the United States between 1995 and 2000. Among the 405 patients for whom adequate follow-up data were available, 111, or 27.4%, died while awaiting transplantation. The mortality prediction model found an association of higher mortality with African American race, amount of supplemental oxygen needed, and mean pulmonary artery pressure.[166] These data suggest that the development of a predictive model of life expectancy to assist in deciding the time of transplantation referral, as exists for such diseases as cystic fibrosis and primary pulmonary hypertension,[167] may improve survival to transplantation in this population.

There are several other issues unique to sarcoidosis patients that must be evaluated prior to proceeding to transplantation.[167] One is the search for and treatment of other etiologies of pulmonary dysfunction, such as bronchiectasis, often found in patients with stage IV disease, and congestive heart failure. Treatment of these disorders may yield enough clinical improvement to delay the need for transplantation. The presence of severe nonpulmonary disease, especially neurologic and cardiac disease, excludes patients from consideration for lung transplantation. Heart-lung transplantation can be considered for patients with severe cardiac and pulmonary involvement.

Another potential contraindication to transplantation, particularly in patients with end-stage fibrocystic disease, is the presence of one or more mycetomas (most commonly aspergillomas). Resection of mycetomas carries a high mortality and high incidence of postoperative complications. In addition, even with the successful removal of mycetomas, concern remains regarding the presence of residual subclinical invasive or noninvasive *Aspergillus* infection or colonization that may place the patient at high risk of severe and invasive infection on posttransplantation immunosuppressive therapy.[167] One case of an end-stage sarcoidosis patient with mycetomas who died from invasive *Aspergillus* infection after heart-lung transplantation has been reported.[168] In addition, a review of the lung transplantation experience at one center revealed that mycetomas were present in the explanted lungs of 3% of recipients. Most of those with mycetomas had sarcoidosis (six of nine). Posttransplantation mortality was significantly increased in this population, with better survival associated with aggressive pre- and posttransplantation antifungal therapy.[169]

The decision to proceed with single- versus double-lung transplantation depends largely on the infectious issues raised previously. If individuals with bilateral bronchiectasis or bilateral mycetomas are considered for transplantation, they should undergo double-lung transplantation. However, in most end-stage sarcoidosis patients, single-lung transplantation is considered adequate.[167] Another interesting feature of transplantation in this patient population is the recurrence of sarcoidosis in lung allografts, documented in numerous reports.[170–173] This has typically been observed on surveillance transbronchial biopsies and is rarely clinically significant. Lung transplant outcomes in this population have not been well studied. Several reviews of small series of patients demonstrate survival and obliterative bronchiolitis rates comparable with those reported in transplantation for other diseases.[174–177]

KEY POINTS

- Sarcoidosis is a multisystem, inflammatory disorder characterized by noncaseating granulomas that can infiltrate virtually any organ, but most commonly involves the lungs.
- Sarcoidosis should be considered in any patient presenting with systemic and multiorgan symptoms or whenever granulomatous inflammation is discovered on histology in any organ.
- Immunologic evidence suggest that sarcoidosis granulomas form as a result of (1) antigen exposure, (2) an antigen-specific cell-mediated immune response, and (3) inflammatory, or innate immune, responses that amplify and perpetuate the antigen-specific immunologic reaction.
- It is not known why some sarcoidosis patients recover and others progress. Persistence or progression of organ dysfunction is an indication for initiation of a trial period of treatment, usually with corticosteroids.
- Therapeutic advances based on an understanding of immune mechanisms will likely improve our approaches to medical management of this enigmatic condition.
- Further understanding derived from large, careful epidemiologic and genetic studies will also hopefully provide important clues about disease pathogenesis and potential pathways to prevention of this potentially devastating illness.

Niemann-Pick Disease
Pulmonary Alveolar Microlithiasis

INTRODUCTION

This chapter discusses diffuse alveolar hemorrhage (DAH) and other rare infiltrative disorders of the lung. DAH is a life-threatening medical condition characterized by widespread hemorrhage from the pulmonary microcirculation (arterioles, capillaries, and venules). It can be seen in many different diseases, often as the primary manifestation. In the second section of the chapter, we discuss several rare infiltrative disorders of the lung, including neurofibromatosis, Hermansky-Pudlak syndrome, dyskeratosis congenita, Gaucher's disease, Niemann-Pick disease, and pulmonary alveolar microlithiasis.

DIFFUSE ALVEOLAR HEMORRHAGE

Unlike the more common forms of pulmonary hemorrhage that result from focal lesions (e.g., necrotizing pneumonia, bronchitis, bronchiectasis, malignancy, pulmonary infarction, arteriovenous malformation), DAH affects the majority of the alveolar capillary surface. DAH is a medical emergency that often results in acute respiratory failure and death. Pulmonologists must be prepared to promptly identify DAH, diagnose the underlying disease that is causing it, and institute appropriate medical therapy.

DEFINITION

DAH is defined by its pathology, which is characterized by intra-alveolar accumulation of erythrocytes (Fig. 60-1). There is often evidence of chronicity to the hemorrhage, with intra-alveolar hemosiderin-containing macrophages, erythrophagocytosis, and collections of free interstitial hemosiderin.[1] These findings can help distinguish true DAH from biopsy-related bleeding. Other features of

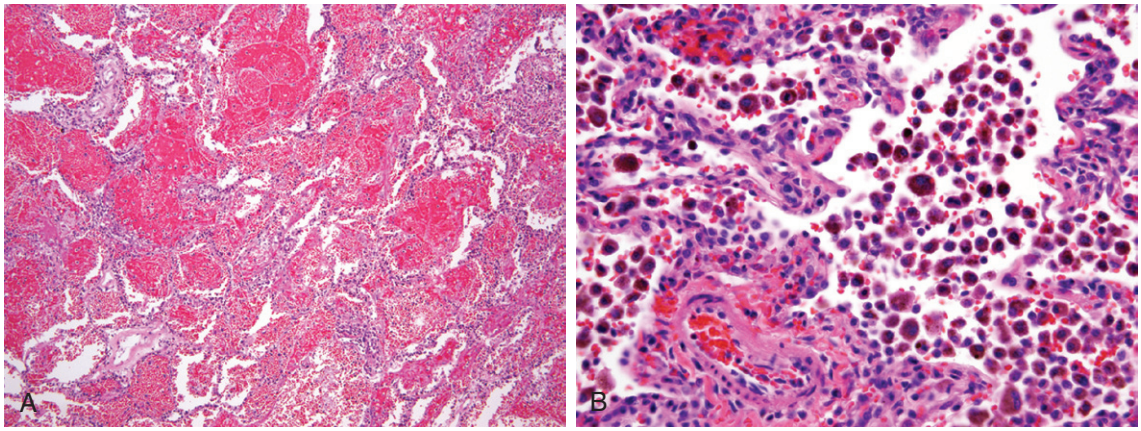

FIGURE 60-1 ■ Histopathology of diffuse alveolar hemorrhage. **A,** In acute diffuse alveolar hemorrhage, the alveoli show filling and distention by red blood cells admixed with fibrin. **B,** Chronic alveolar hemorrhage shows numerous hemosiderin-filled macrophages within air spaces. The alveolar septa may show mild fibrosis. (Images courtesy of Kirk Jones, MD, University of California, San Francisco.)

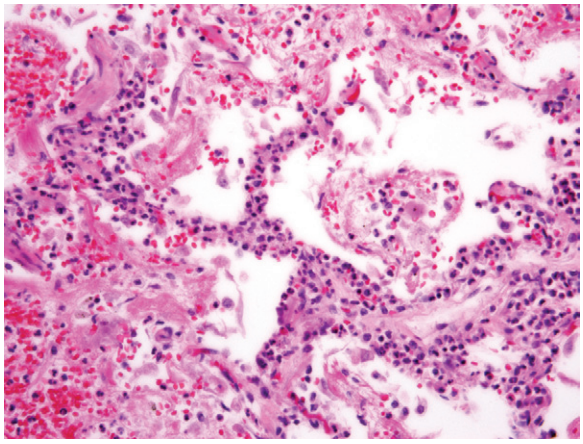

FIGURE 60-2 ■ Histopathology of diffuse alveolar hemorrhage accompanied by pulmonary capillaritis. Capillaritis is identified by accumulation of neutrophils within alveolar septa with accompanying fibrinoid necrosis and adherent alveolar fibrin within air spaces. (Images courtesy of Kirk Jones, MD, University of California, San Francisco.)

DAH include hyperplasia of the type II alveolar epithelial lining cells, intra-alveolar organization (organizing pneumonia), mononuclear cell infiltration of the alveolar interstitium, and small thrombi in the alveolar capillaries and venules.[1-3]

Many cases of DAH demonstrate neutrophilic inflammation of the alveolar interstitium known as *capillaritis* (Fig. 60-2).[4] Capillaritis is commonly associated with endothelial edema, injury, and localized fibrinoid necrosis.[2] Many of the neutrophils are undergoing leukocytoclasis and appear fragmented and pyknotic. Fragmentation of these cells leads to accumulation of nuclear dust in the lung parenchyma. Capillaritis may be central to the pathogenesis of many cases of DAH, with vascular injury and necrosis leading to loss of integrity of the epithelial-endothelial basement membranes and extravasation of red blood cells into the alveolar spaces.

CLINICAL PRESENTATION

History and Physical Examination

The classic clinical presentation of DAH includes hemoptysis, alveolar opacities on chest radiograph, and anemia.[5] However, many cases will demonstrate only one or two of these features; the absence of classic features does not rule out DAH. Other symptoms commonly reported are nonspecific (e.g., dyspnea, cough, chest pain, fever), although in some cases, disease-specific symptoms (e.g., sinusitis, rash, arthritis) may be present. In general, symptoms are usually of short duration, present from days to several weeks, and may be recurrent. The physical examination is likewise nonspecific, with inspiratory crackles common but not universal.

Radiology and Laboratory Evaluation

Laboratory evaluation often reveals anemia and leukocytosis. Serum creatinine levels may be elevated. Bronchoalveolar lavage (BAL) reveals a predominance of red blood cells and hemosiderin-containing macrophages.

The chest radiograph in DAH is generally abnormal, with bilateral alveolar opacities most commonly present (Fig. 60-3).[6] High-resolution computed tomography (HRCT) imaging is more sensitive for radiographic abnormalities showing bilateral "ground-glas" opacities or patchy consolidation (Fig. 60-4). With recurrent and chronic disease, reticulation may appear providing evidence of interstitial fibrosis. Kerley's B lines may occasionally be present.

Physiology

When measured, physiology may demonstrate restriction and gas exchange abnormalities, particularly in chronic cases. In acute DAH, an increase in the diffusing capacity for carbon monoxide (D_{LCO}) is often present, attributed to the increased binding of carbon monoxide

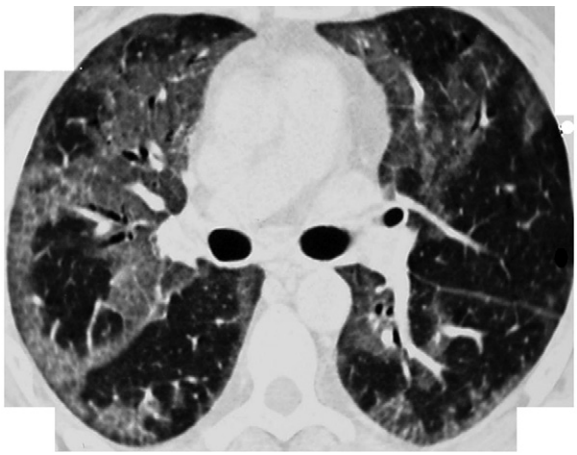

FIGURE 60-4 ■ High-resolution computed tomography scan of diffuse alveolar hemorrhage: confluent and patchy greyish areas.

to intra-alveolar hemoglobin.[7] This will generally resolve in 48 to 72 hours, as hemoglobin is degraded into hemosiderin.[8] Varying degrees of hypoxemia result from the ventilation-perfusion abnormalities produced by the alveolar hemorrhage, and patients often require ventilatory support.

CLASSIFICATION SCHEMA

There is no consensus classification schema for DAH, with clinical, histopathologic, and etiologic approaches all suggested.[5,9] One approach to classification is presented here (Table 60-1). The various causes of DAH are diverse; any source of injury to the alveolar microcirculation may contribute. The pathogenesis of DAH is thought to be primarily due to direct effects of autoantibodies on the alveolar capillary endothelium (Wegener's granulomatosis and microscopic polyangiitis), due to an

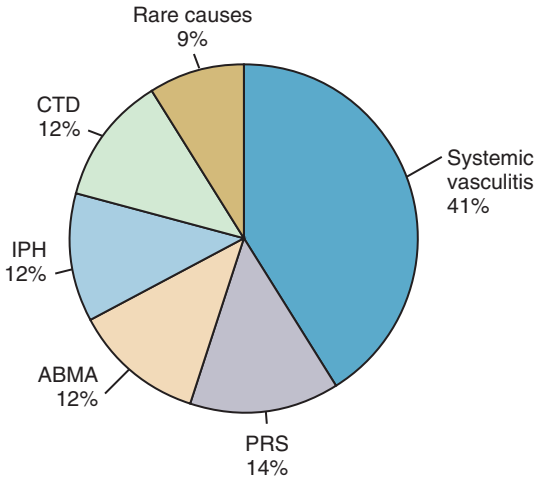

FIGURE 60-5 ■ Causes of diffuse alveolar hemorrhage. A retrospective review of 34 cases of diffuse alveolar hemorrhage found systemic vasculitis to be the most common cause (14 cases: 5 definite Wegener's, 6 probable Wegener's, and 3 unclassifiable), followed by unclassifiable pulmonary renal syndromes (PRS) (5 cases), Goodpasture's (4 cases), idiopathic pulmonary hemorrhage (4 cases), connective tissue disease (4 cases: 2 systemic lupus erythematosus, 1 rheumatoid arthritis, 1 juvenile rheumatoid arthritis), and other rare causes (3 cases: 2 idiopathic glomerulonephropathy, 1 immunoglobulin A [IgA] nephropathy); ABMA, anti–basement membrane antibody–mediated disease; CTD, connective tissue disease; IPH, idiopathic pulmonary hemorrhage. (Data from Travis WD, Colby TV, Lombard C, Carpenter H: A clinicopathologic study of 34 cases of diffuse pulmonary hemorrhage with lung biopsy confirmation. Am J Surg Pathol 14:1112–1125, 1990.)

antibody directed against the alveolar basement membrane (e.g., Goodpasture's syndrome), immune complex–mediated (e.g., systemic lupus erythematosus [SLE], Henoch-Schönlein purpura), or direct alveolar injury.[10]

Data on the relative frequency of the common causes of DAH are limited, but the most common cause of DAH appears to be systemic vasculitis, in particular Wegener's granulomatosis (Fig. 60-5). Other vasculitides are also implicated, including microscopic polyangiitis and isolated pulmonary capillaritis. A review of 34 cases of DAH found that vasculitis accounted for approximately half of the cases, followed by Goodpasture's syndrome (13%), idiopathic pulmonary hemosiderosis (IPH; 13%), connective tissue disease (13%).[1]

DIAGNOSTIC APPROACH

There are two steps to the diagnosis of DAH: identification of DAH and identification of its underlying cause. Both are essential to the timely evaluation of this life-threatening condition.

Diagnosis of Diffuse Alveolar Hemorrhage

The differential diagnosis for patients presenting with DAH is often broad because the classic findings of hemoptysis, alveolar opacities, and anemia are commonly absent. A thorough history and physical examination looking for evidence of potential associated conditions (e.g., connective tissue diagnosis, symptoms/signs of systemic vasculitis, anticoagulant medications) is essential, and initial studies should include a regular and an HRCT scan of the chest and complete blood count. If DAH remains in the differential diagnosis, the test of choice is fiberoptic bronchoscopy and this should be performed urgently.

Bronchoscopy with BAL is essential to the accurate identification of DAH. Serial BAL specimens should be obtained and sent for cell count and differential, with an increasing red blood cell count among sequential samples considered consistent with the diagnosis. Quantitative scoring of the hemosiderin concentration in alveolar macrophages obtained by BAL cytology has a good sensitivity for the diagnosis of DAH as well.[11] Importantly, BAL serves to rule out other conditions in the differential diagnosis such as infection, acute lung injury, and rare interstitial diseases such as acute eosinophilic pneumonia and pulmonary alveolar proteinosis.

Diagnosis of Underlying Cause

Once DAH has been identified, the underlying cause must be determined. Table 60-2 summarizes the differential clinical and laboratory features of some of the most common causes of DAH. In some cases, the etiology will be quite clear (e.g., history of SLE, drug exposure). In others, a careful laboratory evaluation is required. The presence of proteinuria and an abnormal urinary sediment (red blood cells and red blood cell casts) suggests an underlying glomerulonephritis consistent with the diagnosis of systemic vasculitis or Goodpasture's syndrome. Vasculitis is associated with the presence of antineutrophil cytoplasmic antibodies (ANCAs) directed against either proteinase 3 (c-ANCA) and myeloperoxidase (p-ANCA).[12] The c-ANCA level is more likely to be elevated in Wegener's granulomatosis, whereas P-ANCA is more likely to appear in microscopic polyangiitis, pauci-immune glomerulonephritis, and isolated pulmonary capillaritis. However, there can be crossover.[13] The diagnosis of Goodpasture's syndrome is supported by the presence of anti–glomerular basement membrane antibody (ABMA) in the serum. DAH in SLE is accompanied by reduced serum complement levels as well as the presence of antinuclear and native anti-DNA antibodies in the serum. Henoch-Schönlein purpura is characterized by the formation of immunoglobulin A (IgA) immune complexes present in the circulation and also bound to tissue.[14]

Role of Surgical Lung Biopsy

Surgical lung biopsy is rarely required for the diagnosis of DAH; BAL is generally sufficient. Whereas surgical lung biopsy can be useful in identifying the underlying cause of DAH, it is often nonspecific and most causes can be identified through clinical and serologic means.[1] Biopsy is most commonly considered in cases of

TABLE 60-2. Clinical Differentiation of Common Diffuse Alveolar Hemorrhage Syndromes

ABMA, anti-basement membrane antibody; ANA, antinuclear antibody; c-ANCA (PR3), c-antineutrophil cytoplasmic antibody (antiproteinase-3); C_L, complement; dsDNA, anti-double stranded DNA antibody; IgG, immunoglobulin G; p-ANCA (MPO), p-antineutrophil cytoplasmic antibody (antimyeloperoxidase); RF, rheumatoid factor.

presumed vasculitis or Goodpasture's syndrome with equivocal serologies. Generally, these conditions are more easily confirmed by kidney biopsy, even in the absence of clinically evident renal involvement.[15]

SPECIFIC CAUSES OF DIFFUSE ALVEOLAR HEMORRHAGE

Vasculitis

Wegener's Granulomatosis

Wegener's granulomatosis is a systemic vasculitis that commonly involves the upper and lower respiratory tracts and kidneys. Other organs (e.g., eyes, skin) may be involved. DAH secondary to pulmonary capillaritis can either complicate an established case of Wegener's granulomatosis or represent the initial manifestation of the disease. Pulmonary capillaritis can be the sole histologic finding, or it can occur in combination with the more typical pathologic features of Wegener's granulomatosis. Examination of open-lung biopsy specimens from 87 patients with Wegener's granulomatosis revealed a 31% incidence of capillaritis, but in only 3 patients was this an isolated finding.[3] In another series, capillaritis was present in 17% of 35 patients, but never as an isolated finding.[16] In a postmortem study of 22 patients, capillaritis was the sole histologic feature in 3 cases and occurred in conjunction with the more typical granulomatous vasculitis in 7 cases.[17] In cases in which the typical histologic features (granulomatous inflammation, small and medium vessel vasculitis, and parenchymal necrosis) and clinical presentation (sinusitis, cavitary lung lesions) are absent and only DAH with or without a cutaneous leukocytoclastic vasculitis or a focal segmental necrotizing glomerulitis is present, the differentiation from microscopic polyangiitis is difficult. The specific diagnosis then depends on the ANCA pattern, with c-ANCA suggesting the diagnosis of Wegener's granulomatosis. In this disease, the characteristic histologic and clinical features may appear months to years after an initial presentation of DAH and capillaritis.[18] Circulating endothelial cells have been found in patients with Wegener's granulomatosis and in microscopic polyangiitis The presence of circulating endothelial cells may serve as a novel marker of active ANCA-positive vasculitis.[19]

Alveolar hemorrhage is often subclinical and recurrent in Wegener's granulomatosis (as well as microscopic polyangiitis), suggested by the presence of hemosiderin-laden macrophages on BAL. This pattern of frequently recurring DAH appears unique to the ANCA-associated vasculitides, because patients with collagen vascular disease–related DAH rarely manifest iron-positive macrophages.[20]

More than 40 cases of Wegener's granulomatosis with DAH and pulmonary capillaritis have been described. The rate of early mortality is 37%, and this mortality is most often due to acute respiratory or renal failure.[3,16–18,21,22] Renal disease in the form of a focal segmental necrotizing glomerulonephritis (Fig. 60-6), a cutaneous leukocytoclastic vasculitis, and arthritis often accompany the DAH. Treatment with high-dose corticosteroids and cyclophosphamide is the recommended therapy and, depending on the severity of the disease, can be initially administered intravenously. Azathioprine may be substituted for cyclophosphamide after remission.[23] Recurrences with tapering of the medications are to be expected. Disease activity is monitored by measurements of erythrocyte sedimentation rates, ANCA levels, serial diffusing capacities, and microscopic urine examinations. Recurrent or persistent disease after standard therapy may respond to intravenous immunoglobulin, although the response appears transient and side effects, including renal insufficiency, are frequent.[24]

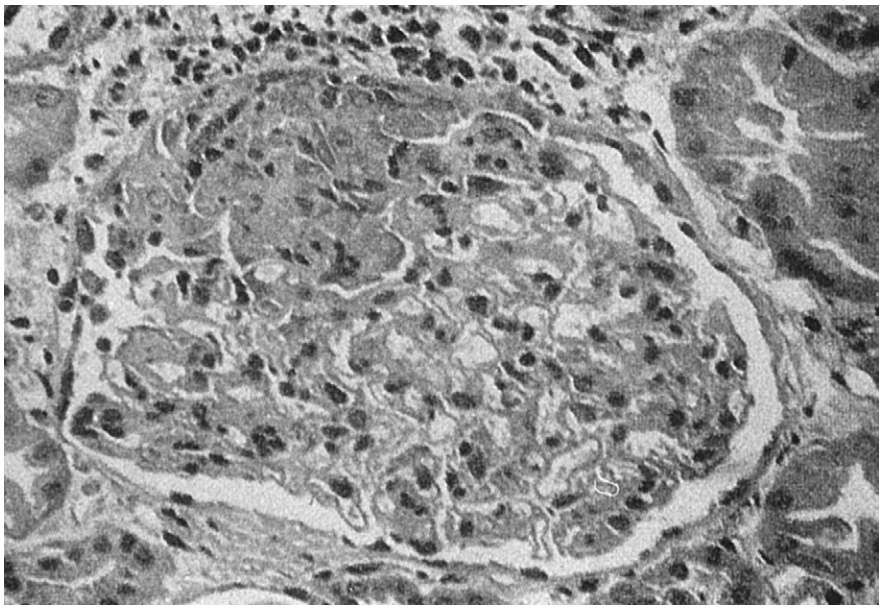

FIGURE 60-6 ■ Histopathology of a renal biopsy specimen demonstrates focal segmental necrotizing glomerulonephritis. (Original magnification ×40.)

Other novel therapies, including trimethoprim-sulfamethoxazole, antilymphocyte monoclonal antibodies, and tumor necrosis factor (TNF) inhibitors, have been tried with some success.[25]

As previously stated, the differentiation of Wegener's granulomatosis with DAH from microscopic polyangiitis is at times difficult because the clinical presentation, histopathologic findings, and serologic findings can be identical.[26] In fact, the response to treatment and the tendency for recurrences are similar. The differentiation can be established only after the development of the more typical upper airway disease and pathologic features of Wegener's granulomatosis.

Microscopic Polyangiitis

Microscopic polyangiitis is considered to be the small vessel variant of polyarteritis nodosa. It is a frequent cause of pulmonary capillaritis and DAH.[2,4,18,27–31] Microscopic polyangiitis is distinguishable from polyarteritis nodosa by the absence of medium-sized blood vessel involvement, the absence of asthma and systemic hypertension, and the relative sparing of the abdominal viscera. DAH has only rarely been documented as occurring with polyarteritis nodosa.[32]

The most consistent pathologic feature in microscopic polyangiitis is a focal segmental necrotizing glomerulonephritis, the renal lesion common to all systemic vasculitides. The lungs are involved by capillaritis in 20% to 30% of cases.[27,31] The alveolar hemorrhage tends to be severe and is often life-threatening. Other manifestations include fever, weight loss, cutaneous vasculitis, myalgias, arthralgias, diarrhea, and gastrointestinal bleeding from mucosal vasculitis that is often visible by direct examination, peripheral neuropathy, and in a few cases, sinusitis.[31,33,34] As with other vasculitides, the erythrocyte sedimentation rate is elevated, and nonspecific increases of serum rheumatoid factor and antinuclear antibody are found. Although circulating immune complexes are present in 45% of cases, tissue localization of these complexes is difficult to detect. Anti-DNA antibodies and hypocomplementemia, findings suggestive of SLE, are absent. A positive serum p-ANCA strongly supports the diagnosis. Antibodies to hepatitis B and C antigens are present in 33% of cases.[35]

Treatment consists of either oral or intravenous corticosteroids combined with cyclophosphamide or azathioprine.[23] Adjuvant treatment with plasmapheresis is recommended by some authors, but its additional efficacy is difficult to determine.[27,31] Outcome with early initiation of therapy for microscopic polyangiitis is generally good, with a 65% rate of 5-year survival. However, the presence of DAH contributes to an early mortality rate of 25%.[2,4,18,27–31] There is a tendency for recurrence with tapering of the medications. Intravenous immunoglobulin may be of use for resistant cases.[24] Factor VIIa has been used successfully with dramatic effects in one case of massive alveolar hemorrhage.[36]

The transition to pulmonary fibrosis and restrictive ventilatory impairment after recurrent DAH has been described,[8] and fibrotic lung disease has been reported as the presenting manifestation of microscopic polyangiitis.[37] There have been three cases of persistent, severe, irreversible airway dysfunction after recurrent episodes of DAH that complicated microscopic polyangiitis.[38] It is postulated that the combination of recurrent vascular obliteration from capillaritis and the release of neutral proteases and oxygen radicals from the overwhelming and recurrent burden of neutrophils causes permanent damage to the alveolar septa and results in emphysema.

Isolated Pulmonary Capillaritis

Isolated pulmonary capillaritis is a small vessel vasculitis confined to the lungs and without concomitant systemic involvement.[39] There are two forms: one with serum p-ANCA positivity and the other without this positive serology.[39,40] In one series, the latter type was the most frequent cause of pulmonary capillaritis and DAH.[39] Direct immunofluorescent studies of the lung in these patients have been negative. Although respiratory failure necessitating ventilatory support was frequent, response to corticosteroids and cyclophosphamide was good, and only one of eight patients died. Recurrences appeared in two subjects. During a 4-year follow-up period, clinical or serologic evidence for a systemic vasculitis or connective tissue disease did not appear.

Isolated forms of pulmonary capillaritis causing DAH must be distinguished from IPH, which is not associated with pulmonary capillaritis, as well as lung-limited forms of Goodpasture's syndrome, the initial presentation of collagen vascular disease, antiphospholipid antibody syndrome, and mitral stenosis. All patients who present with unexplained DAH should have an echocardiogram and undergo thoracoscopic or open-lung biopsy.

Mixed Cryoglobulinemia

Mixed cryoglobulinemia is a systemic vasculitis that is recognized by the presence of purpura, arthritis, hepatitis, and glomerulonephritis. It is thought to be an immune complex–induced disease, with most cases linked to hepatitis C (and less commonly hepatitis B) viral infection. Cutaneous vasculitis appearing as raised purpura is the clinical hallmark of this disease. Histologically, there is a perivascular polymorphonuclear infiltration with tissue extravasation and fragmentation in the dermis (leukocytoclastic vasculitis). The renal disease is a proliferative glomerulonephritis with positive granular immunofluorescence. Interstitial lung disease consisting of inflammation and fibrosis of the alveolar walls is the most common pulmonary manifestation.[41] There are two published cases of DAH with pulmonary capillaritis that complicated mixed cryoglobulinemia.[42,43]

Behçet's Syndrome

Behçet's syndrome is a chronic relapsing illness characterized by oral and genital ulceration, iridocyclitis, thrombophlebitis, and a multisystem disease consisting of a cutaneous vasculitis, arthritis, and meningoencephalitis.[44] Immune complexes have been identified in the

serum of active cases as well as in the lung and other organs.[44,45]

The lung is involved in 5% to 10% of cases of Behçet's syndrome. The pulmonary disease is typically a small vessel vasculitis affecting capillaries, venules, and arterioles. The renal disease is a focal segmental necrotizing vasculitis, as occurs in other systemic vasculitides. Immune complexes composed of IgG and complement have been identified in small pulmonary vessels in several cases.[44,45] In addition to alveolar hemorrhage, involvement of larger vessels can lead to aneurysms of the bronchial arteries, which can erode into bronchi, causing massive pulmonary hemorrhage and death.[46,47] Another potential cause for pulmonary hemorrhage in Behçet's syndrome is pulmonary arterial occlusion with infarction.[45] A review of 28 cases of pulmonary involvement in Behçet's syndrome emphasized several points: pulmonary complaints consisting of cough, hemoptysis, chest pain, and fever were more common in men than in women; pulmonary hemorrhage was the cause of death in 39%; and death usually occurred within 6 years of the first episode of hemoptysis. Other studies have confirmed the seriousness of this complication regardless of its cause.[46,47] Treatment consists of corticosteroids and immunosuppressive therapy.[48] Treatment with anti-TNF therapy has shown dramatic results in some case reports.[49]

Henoch-Schönlein Purpura

Henoch-Schönlein purpura, primarily a disease of children, also occurs in adults.[50] Adults typically present with palpable purpura (leukocytoclastic vasculitis) and glomerulonephritis.[14] The joints and gastrointestinal tract are commonly involved. Pulmonary involvement appears rare. In several large series, pulmonary disease, except for transient chest radiographic opacities, was not mentioned.[14] There have been proven cases of DAH with pulmonary capillaritis in patients with Henoch-Schönlein purpura.[51,52] In one, IgA immune complexes were present in the alveolar septa.[51] It is postulated that IgA immune complexes, which are present in the serum and kidneys of these patients, are responsible for the tissue damage that results in the clinical syndrome.[53] Corticosteroids were used in both cases and are generally recommended.

Pauci-immune Glomerulonephritis

Pauci-immune glomerulonephritis is one of three types of isolated renal vasculitides (the other two being immune complex–mediated glomerulonephritis and Goodpasture's syndrome). Pauci-immune glomerulonephritis lacks any immunoreaction product except for minimal accumulation of fibrin. It is histologically and immunologically similar to the glomerulonephritis of microscopic polyangiitis and Wegener's granulomatosis and is considered to represent a form of renal-limited vasculitis.[18] Up to 50% of affected patients develop pulmonary capillaritis and DAH, and a smaller number develop a full-blown systemic vasculitis indistinguishable from microscopic polyangiitis. Another indication that pauci-immune glomerulonephritis represents a limited form of vasculitis is the presence of serum p-ANCA in these patients. Because clinical manifestations are often limited to the lung and kidney, it can be confused with Goodpasture's syndrome.[18,53] Pauci-immune glomerulonephritis is distinguished by the absence of circulating basement membrane antibodies in the serum and by the negative findings of renal immunofluorescence studies. Treatment with high-dose corticosteroids plus immunosuppressive therapy with either cyclophosphamide or azathioprine is recommended.

Immunologic

Goodpasture's Syndrome

Whether the case reported by Goodpasture in 1919[54] describes the syndrome that bears his name is questionable. He described an 18-year-old man who died 6 weeks after an influenza infection and was found to have DAH, pleuritis, glomerulonephritis, splenic infarctions, and vasculitis of the small intestines. In 1965, an antibody to glomerular basement membrane (ABMA)—now identified as antibody against the NC1 domain of the α3 chain of type IV collagen—was identified in the kidneys and lungs of some patients with DAH and glomerulonephritis.[55,56] The diagnosis of Goodpasture's syndrome, also known as *ABMA disease*, is reserved for cases of DAH and glomerulonephritis in which this antibody appears in the serum, is bound to kidney and/or lung basement membranes in a linear manner by immunohistochemistry, or both.[18]

At least 90% of patients with Goodpasture's syndrome have a circulating ABMA.[57] The level of ABMA is not generally considered an accurate index of disease activity, although higher levels have been associated with more severe renal disease. In 60% to 80% of cases, the lung and renal disease appear simultaneously; in 5% to 10%, only the lung is affected; and in the remainder, renal disease exists by itself.[58,59] It is clear that ABMA is pathogenetic; however, the stimulus for its production remains unknown. The clinical onset of Goodpasture's syndrome has been temporarily related to infection with influenza A2 as well as to other respiratory infections, hydrocarbon exposure, and tobacco use.[60-62] The presence of histocompatibility human leukocyte antigens (HLA)-DRw2 and HLA-B7 (90% and 60%, respectively) in patients with Goodpasture's syndrome indicates that susceptible individuals are predisposed to disease that is often severe and progressive.[63,64] It is interesting to note that in some experimental models, the introduction of ABMA produces renal but not pulmonary disease. For deposition of this antibody to occur in the lung in those models, an additional injury that increases alveolar-capillary permeability is required.[65,66]

Men are more commonly affected (60%–80% of patients), and the concentration of cases is greatest between the ages of 20 and 30 years.[67,68] In older cases, the sex distribution is equal and the disease tends to be limited to the kidney.[61] Interestingly, DAH is more likely

to occur in patients who smoke.[61] The alveolar permeability is increased in most smokers and this is thought to be an important factor leading to DAH.[60] In one study, 100% of smokers with Goodpasture's syndrome developed both DAH and glomerulonephritis, whereas only 20% of nonsmokers developed DAH.[61] Resumption of cigarette smoking by patients who are in remission can result in recurrent episodes of DAH. Exposure to volatile hydrocarbons (e.g., petroleum products, turpentine, toluene, and pesticides) is associated with initiation, as well as exacerbations, of DAH.[58,59,69,70]

Symptoms most often refer to the lungs and consist of hemoptysis, cough, and dyspnea. Fatigue caused by iron-deficiency anemia and renal failure may predominate. Microscopic hematuria, proteinuria, and increases in the serum creatinine are often present, but gross hematuria with hypertension is unusual. The diffusing capacity may be increased during periods of active bleeding and is considered to be a useful monitor of new or recurrent DAH.[71] An increase of 30% above baseline is highly suggestive of an intra-alveolar hemorrhage, and this increase may precede pulmonary symptoms or radiographic changes. Chest radiography often reveals patchy air space abnormalities. HRCT scanning typically shows ground-glass opacities and consolidation and is more sensitive for DAH than plain chest radiography is.[72]

Pulmonary capillaritis is present in some cases of Goodpasture's syndrome, but the usual histologic appearance is bland pulmonary hemorrhage.[70] Alveolar wall necrosis, which is seen with systemic vasculitis, does not occur in Goodpasture's syndrome. The renal histologic findings are a focal segmental necrotizing glomerulonephritis with crescent formation. The major distinction between Goodpasture's syndrome and the other rapidly progressive glomerulonephritides is the presence of an uninterrupted linear deposition of immunoglobulin and complement along the glomerular basement membrane (Fig. 60-7). Identical findings are present on alveolar basement membranes.[73] Even when DAH dominates the clinical picture (i.e., there is no evidence of renal disease), renal biopsy will still reveal the typical linear staining.[74]

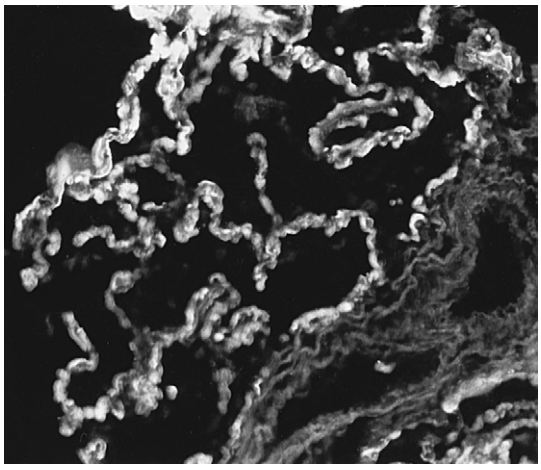

FIGURE 60-7 ■ Immunofluorescence study demonstrates linear staining (IgG) of alveolar walls in a patient with Goodpasture's syndrome. (Original magnification ×10.)

In the minority of patients without clinically evident renal involvement, DAH responds to oral or intravenous corticosteroids. Glomerulonephritis, if present, appears resistant to corticosteroid monotherapy. The combination of plasmapheresis (3–6 L daily for 2 weeks), corticosteroids, and cytotoxic drugs is effective, particularly in patients who do not have oligoanuria and do not require dialysis.[75–79] The combination of cyclophosphamide or azathioprine with corticosteroids leads to a dramatic fall in circulating ABMA, and oliguric dialysis-dependent subjects have responded to the point at which dialysis could be discontinued.[78,80] Anuric patients do not respond well to this combination therapy, and dialysis and renal transplantation are often necessary.[80] Case reports of successful treatment of refractory, life-threatening Goodpasture's syndrome with mycophenolate mofetil and anti-CD20 monoclonal antibody have been reported.[81,82] Bilateral nephrectomy, despite initial encouraging results for the control of DAH, no longer has a role in the management of Goodpasture's syndrome.

Over time, the survival rate in Goodpasture's syndrome has improved from 80% mortality at 6 months (half dying from DAH and the rest from renal insufficiency) to approximately 50% at 2 years.[68] With the aggressive treatment approach described previously, it is estimated that the 5-year survival rate exceeds 80% and fewer than 30% of patients require long-term dialysis. DAH is the usual cause of death, often being precipitated by a concomitant infection.[59] Spontaneous remission has occurred in cases without clinical evidence of renal disease, although this is not usual.[83] The most useful prognostic information comes from the kidney. Clinically, oliguric or anuric renal failure reduces the survival rate to 50% at 6 months. Histopathologically, less than 30% involvement of the glomeruli on biopsy predicts significant therapeutic response and improved survival. When 70% or more of glomeruli have formed crescents in conjunction with renal insufficiency, renal failure is progressive and often unresponsive to therapy, eventually necessitating dialysis.[80]

Connective Tissue Disease

Among the connective tissue diseases, DAH occurs most frequently in SLE.[18,84–86] It is unusual for DAH to be the initial manifestation of SLE, in contrast to acute lupus pneumonitis, which is often the initial manifestation.[87,88] Most patients with DAH have active lupus nephritis.[85] The onset of alveolar hemorrhage can be dramatic, producing severe gas-exchange abnormalities and necessitating mechanical ventilation. Reduced complement levels and increased serum titers of serum antinuclear antibodies confirm the diagnosis.

DAH must be distinguished from other causes of hemoptysis in SLE, specifically acute lupus pneumonitis. Acute lupus pneumonitis presents with fever, cough, and dyspnea. In 50% of cases, this is the initial manifestation of SLE.[88] It is an inflammatory condition, characterized histologically by organizing pneumonia, diffuse alveolar damage (DAD), cellular nonspecific interstitial

pneumonia, and occasionally, intra-alveolar hemorrhage. Although hemoptysis may accompany acute lupus pneumonitis, significant reductions of the hemoglobin are not to be expected. Unlike DAH, pleural and pericardial effusions are common in acute lupus pneumonitis. Other diagnostic considerations in the patient with suspected DAH include infectious pneumonias and pulmonary infarction associated with deep venous thrombosis with or without a circulating lupus anticoagulant.[89,90]

Histopathologic examination of DAH in patient with SLE generally reveals capillaritis, but bland pulmonary hemorrhage and DAD have been described.[88,91] Granular deposits of IgG and complement (C3) are commonly found in the alveolar interstitium and within the walls of intra-alveolar blood vessels (Fig. 60-8).[84,91–93] Capillaritis and immune complex deposition do not necessarily overlap. In one series of four patients with SLE and massive DAH associated with pulmonary capillaritis, only two demonstrated immune complexes by light and electron microscopic techniques.[94]

Treatment of DAH caused by SLE includes high-dose intravenous corticosteroids as well as azathioprine or cyclophosphamide. Plasmapheresis has been combined with chemotherapy in some cases, but it probably has little utility.[85] Broad-spectrum antibiotic coverage is recommended because of some evidence that infection may trigger the hemorrhage.[85] DAH is associated with a 50% mortality rate in SLE and can be recurrent in survivors.[87,91–95] Death is caused by massive hemorrhage, concurrent infection, or renal or central nervous system disease.

Rarely, DAH and glomerulonephritis occur in patients with rheumatoid arthritis,[96] scleroderma,[97] or mixed connective tissue disease. Isolated DAH with capillaritis has also been described in polymyositis, rheumatoid arthritis, and mixed connective tissue disease.[98,99] In polymyositis, DAH was the presenting manifestation, and in rheumatoid arthritis and mixed connective tissue disease, DAH and capillaritis followed the primary diagnosis (2–20 yr).[98,99] The absence of a systemic vasculitis in these cases, including glomerulonephritis, was unexpected.

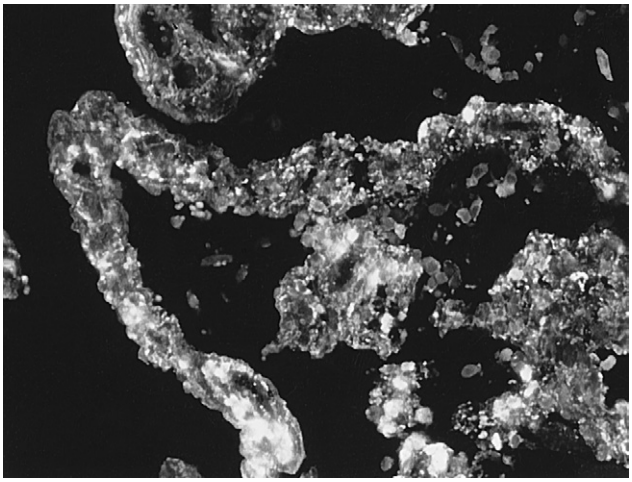

FIGURE 60-8 ■ Immunofluorescence study demonstrates granular deposition of IgG in the alveolar walls of a patient with systemic lupus erythematosus and diffuse alveolar hemorrhage. (Original magnification ×40.)

Immune Complex–Related Crescentic Glomerulonephritis

Immune complex–related crescentic glomerulonephritis is rarely accompanied by capillaritis and DAH.[1,100] Although the kidneys demonstrate granular immune deposits, immune complexes are not found in lung tissue.

Acute Pulmonary Allograft Rejection

Pulmonary capillaritis and DAH have been reported after lung transplantation for a variety of underlying diseases.[101] The suspected acute vascular rejection can occur weeks to months after the transplantation and may be the only histopathologic manifestation of allograft rejection. This represents a serious immunologic complication that threatens survival. In addition to standard anti-inflammatory therapy with corticosteroids and cytotoxic agents, plasmapheresis may be effective.

Coagulation Disorders

Coagulation disorders associated with DAH include disseminated intravascular coagulation,[102] idiopathic thrombocytopenic purpura,[103] thrombotic thrombocytopenic purpura,[104] acquired vitamin K deficiency,[105] and antiphospholipid antibody syndrome.[106] Uniquely among coagulation disorders, antiphospholipid antibody syndrome–associated DAH is sometimes associated with capillaritis.[107]

All anticoagulant medications have been associated with DAH, including coumadin and its derivatives,[108–110] thrombolytics,[111,112] and more recently, agents targeting the platelet glycoprotein IIb/IIIa.[113–115] In most iatrogenically anticoagulated patients, correction of the coagulation defect resolves the DAH.

DAH is common in patients with acute leukemia who have undergone induction chemotherapy and are thrombocytopenic.[116–118] Although thrombocytopenia surely contributes to the DAH, these patients also have evidence of DAD due to chemotherapy, oxygen toxicity, and infection that likely plays a central role.

Idiopathic Pulmonary Hemosiderosis

IPH is predominantly a disease of children, but adults represent approximately 20% of cases.[119,120] It is a diagnosis of exclusion,[119,120] and efforts to rule out other causes of DAH are essential. Among adults, men are more often affected, and there are reports of familial cases.[121] Some cases have occurred in the setting of celiac disease, and serum IgA levels are increased in 50% of cases.[122,123] The pathogenesis of IPH is not understood. Some cases may be secondary to environmental exposures, such as *Stachybotrys atra*, a toxigenic fungus that has been potentially linked to several cases of otherwise idiopathic alveolar hemorrhage.[124]

Recurrent hemoptysis due to DAH is the rule, ranging from intermittent blood-streaked sputum to life-threatening hemorrhage. Fever, cough, substernal chest pain, and fatigue secondary to iron-deficiency anemia are also reported. In selected pediatric cases, lymphadenopathy and hepatosplenomegaly are found. Renal disease is absent. In chronic recurrent disease, progressive dyspnea, finger clubbing, inspiratory crackles, and pulmonary fibrosis appear. Pulmonary function testing reveals a restrictive ventilatory defect with an increase in the D_{LCO} during periods of active bleeding. Chest imaging reveals diffuse ground-glass and ill-defined centrilobular nodules.[125] Measurements of serum antibodies reveal the absence of alternative etiology.

In adult cases, lung tissue is required to exclude the entity of isolated pulmonary capillaritis. The histologic examination of the lung in IPH reveals bland alveolar hemorrhage with hemosiderin accumulation.[120,126] There is hyperplasia of type II alveolar epithelial cells with capillary dilation and tortuosity. The iron content of the lung is increased, and it is the hemosiderin deposition in the interstitium that is thought to be the basis for collagen proliferation and parenchymal fibrosis. Pulmonary immune complexes are absent, differentiating IPH from isolated pulmonary Goodpasture's syndrome. Electron microscopic studies indicate degeneration of type I alveolar epithelial cells with exposure of and breaks in the basement membrane and discontinuity of the alveolar capillary structure.[126,127] Although nonspecific, these findings indicate a form of DAD.

Clinical benefit and recovery from the acute hemorrhage after corticosteroid therapy have been reported, but long-term benefit is unlikely.[120,128] Azathioprine has been successful in several cases.[126,129,130] Approximately 25% of patients are free of disease after the initial episode. Another 25% are free of active disease but have persistent dyspnea and anemia, and another quarter have persistent active disease that leads to fibrosis and severe restrictive lung disease. The rest have unresponsive disease with continued hemorrhage and death from respiratory failure. In those with persistent disease, the average survival is 3 to 5 years.[120,128] Adults have a better prognosis than children. Lung transplantation is controversial in this disease because IPH has been reported to recur after bilateral lung transplantation.[131]

Other Causes of Diffuse Alveolar Hemorrhage

Drugs/Toxins

There are many drugs that have been reported to cause DAH. Anticoagulants have been discussed previously. Most DAH due to drugs or toxins is associated with bland alveolar hemorrhage. This has been reported with abciximab, amiodarone, azathioprine, carbamazepine, cyclosporine, ara-C, dextran, docetaxel, fludarabine, hydralazine, methotrexate, radiographic contrast media, retinoic acid, sirolimus, TNF-α, and valproate.[132]

A few drugs have been associated with DAH and capillaritis, including tretinoin, propylthiouracil, phenytoin, and mitomycin.[133–137] DAH due to these drugs may also be associated with crescentic glomerulonephritis and elevated ANCA levels.

Penicillamine can result in DAH and an immune complex–mediated glomerulonephritis. Glomerular capillaries display a granular (as opposed to a linear) immunofluorescent pattern for IgG and C3.[138–141] Cases have appeared after as much as 20 years of treatment. Some authors have called this a drug-induced Goodpasture's syndrome, but the pattern of immunoglobulin deposition in the kidney differentiates this entity. Treatment with immunosuppressive therapy and even plasmapheresis may be required.[141]

Trimellitic anhydride is used for the manufacture of paints, epoxy resins, and plastics. DAH has been reported after the inhalation of fumes or dry powder, generally during spraying of this product on heated surfaces.[142–144] Antibodies to trimellitic anhydride in the serum and a latent period of 1 to 3 months both support an immunologic basis for this syndrome. Long-term physiologic impairment is unusual if further exposure is avoided.

Diffuse Alveolar Damage

DAD is the underlying histopathology of acute lung injury, and it has a variety of etiologies (Table 60-3). In DAD, the interstitium of the lung becomes edematous and the type I alveolar epithelial lining cells are sloughed. Neutrophilic inflammation and fibroblastic proliferation occurs, and hyaline membranes (eosinophilic strands of necrotic cells, protein, and fibrin) develop adjacent to the injured alveolar walls. In severe cases, red blood cells may enter the alveolar space as a result of injury to the alveolar-capillary interface, resulting in DAH. The neutrophilic inflammation in DAD-associated DAH is not as intense as it is in pulmonary capillaritis.

TABLE 60-3. Causes of Diffuse Alveolar Damage

ACUTE RESPIRATORY DISTRESS SYNDROME
Sepsis
Pneumonia (e.g., bacterial, viral, *Pneumocystis jirovecii* [*carinii*])
Trauma
Aspiration
Massive transfusion
Drugs (e.g., cytotoxic/chemotherapeutic agents, antibiotics)
CONNECTIVE TISSUE DISEASE
DIFFUSE LUNG DISEASE
Acute interstitial pneumonia
Acute exacerbation of idiopathic pulmonary fibrosis
RADIATION THERAPY
TOXIC INHALATION
Smoke
Ozone
Heavy metal fumes

Mitral Stenosis

Mitral stenosis can be clinically silent and, over time, can result in substantial pulmonary venous hypertension. In some cases, this can lead to the development of DAH.[145] The presentation can be dramatic, with massive hemoptysis occurring due to the rupture of engorged bronchial varicosities that develop as a result of long-standing left atrial hypertension. Less severe DAH may be recurrent and is often misdiagnosed, leading to chronic interstitial fibrosis. Radiographic findings consist of central ground-glass abnormalities and, in chronic cases, reticular abnormalities.[146] Repair or replacement of the stenotic mitral valve prevents recurrence.

Pulmonary Veno-occlusive Disease

Pulmonary veno-occlusive disease (PVOD) is a rare cause of pulmonary hypertension due to fibrous obliteration of small pulmonary veins and venules. PVOD affects men and women equally and involves all age groups, most commonly children and young adults.[147-149] Patients with PVOD present with dyspnea, syncope, and when severe, physical findings suggestive of cor pulmonale. Because PVOD is a postcapillary cause of pulmonary hypertension, paroxysmal nocturnal dyspnea, orthopnea, and DAH can also occur.

Right heart catheterization cannot easily distinguish PVOD from precapillary pulmonary hypertension because the pulmonary capillary wedge pressure is generally normal. Chest radiography shows signs of pulmonary hypertension; in some cases, interstitial opacities with septal thickening suggesting congestion as well as ground-glass abnormality from alveolar hemorrhage may be seen. Pleural effusions are common.

Pulmonary function studies reveal a reduced D_{LCO} with preservation of lung volumes, a physiologic picture similar to that found in other causes of pulmonary hypertension. Definitive diagnosis is achieved by lung biopsy, which demonstrates fibrous intimal obliteration of small pulmonary veins and venules, acute or recanalized thrombi, and hemosiderosis (Fig. 60-9).

Most cases of PVOD are idiopathic, but it has been reported after chemotherapy (e.g., carmustine, mitomycin, bleomycin) for malignant disease, bone marrow transplantation, and associated with connective tissue disease.[150-157] A mutation in the bone morphogenic protein receptor II gene (a gene associated with many cases of primary pulmonary hypertension) has been identified in a patient with idiopathic PVOD, suggesting an potential etiologic role.[158]

The use of pulmonary vasodilators in the treatment of PVOD is complicated and potentially harmful. Modest improvements with nifedipine and epoprostinol have been reported, but there have also been cases of these agents precipitating massive pulmonary edema and death.[159,160] Any trial of vasodilator therapy should be performed during right heart catheterization in an appropriate hospital setting. A few patients have had clinical responses to prednisone and azathioprine.[161,162] Anticoagulation for PVOD has been recommended based the potential role of thrombosis in the pathogenesis of PVOD and on limited data suggesting efficacy in patients with primary pulmonary hypertension. Anticoagulants should generally be avoided in patients who have had DAH.

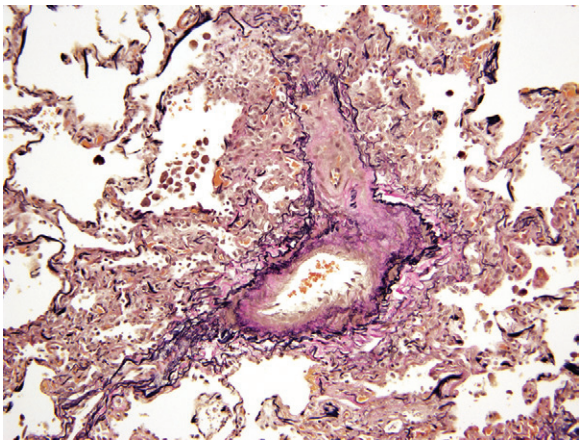

FIGURE 60-9 ■ Histopathology of pulmonary veno-occlusive disease. An elastic tissue stain (elastic van Gieson) shows marked intimal sclerosis with venous narrowing. These cases may show mild interstitial chronic inflammation and air space accumulation of hemosiderin-filled macrophages (hemosiderosis). (Images courtesy of Kirk Jones, MD, University of California, San Francisco.)

Pulmonary Capillary Hemangiomatosis

Pulmonary capillary hemangiomatosis (PCH) is a rare cause of pulmonary hypertension that can be associated with severe and recurrent DAH.[163-165] It is seen across age and gender. Patients universally present with dyspnea, often with evidence of right heart failure. Hemoptysis occurs in approximately one third of cases during the course of the disease.[163] Radiographic findings are nonspecific and commonly show alveolar opacities and evidence of pulmonary arterial hypertension. Pulmonary function test results are mixed, with both obstructive and restrictive changes described.[163] As with PVOD, right heart catheterization generally reveals a normal pulmonary capillary wedge pressure.

PCH is characterized by a proliferation of pulmonary capillaries, which infiltrate the interstitial, bronchial, and vascular structures of the lung (Fig. 60-10).[164] The exact mechanism of pulmonary hypertension and DAH is unclear, but mechanical rupture of hemangiomatous vessels in the setting of pulmonary arterial and venous occlusion and or thrombosis is likely responsible. Treatment of PCH with pulmonary vasodilators is generally contraindicated because worsening pulmonary edema and death have been reported as a result.[166,167] A few reports of treatment with recombinant interferon-alfa-2a suggest stabilization or improvement may occur.[163,168] Mean survival after diagnosis is usually 3 years, although successful treatment with lung transplantation has been reported.[163]

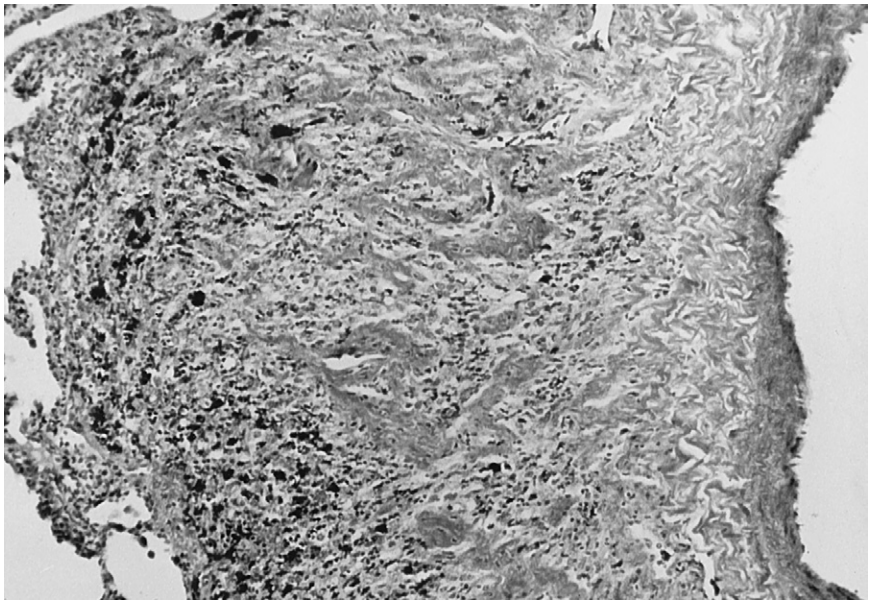

FIGURE 60-10 ■ Histopathology of pulmonary capillary hemangiomatosis. There is capillary proliferation in the wall of this large pulmonary vein. (Original magnification ×100.)

Lymphangioleiomyomatosis and Tuberous Sclerosis

Lymphangioleiomyomatosis (LAM) and tuberous sclerosis share a common pathobiology involving proliferation of smooth muscle in pulmonary interstitial, lymphatic, bronchial, and vascular structures (see Chapter 62 for a full discussion of these diseases).[169-171] Involvement of the pulmonary vasculature commonly results in episodes of alveolar hemorrhage. This alveolar bleeding is often focal; DAH is unusual. Pathologic specimens of the lung in LAM and tuberous sclerosis typically demonstrate focal areas of hemorrhage and hemosiderin deposition.

Subcutaneous neurofibromas
Rib notching (inferior) from intercostal neurofibroma
Kyphoscoliosis
Apical neurofibroma (Pancoast's syndrome)

RARE INFILTRATIVE DISORDERS OF THE LUNG

Neurofibromatosis

There are two clinically and genetically distinct forms of neurofibromatosis termed neurofibromatosis 1 and neurofibromatosis 2. Lung disease is generally associated with neurofibromatosis 1, also known as von Recklinghausen's disease.[172] Neurofibromatosis 1 is an autosomal dominant disease caused by mutations in the NF1 gene at 17q11 and is characterized clinically by the appearance of cutaneous café au lait spots, subcutaneous neurofibromas, and Lisch nodule in the iris. The thoracic manifestations of neurofibromatosis are listed in Table 60-4. Interstitial lung disease occurs in 10% to 20% of affected patients, with dyspnea appearing between the third and the sixth decades.[173-177] Lower zone interstitial disease is the rule, with bullous disease eventually appearing in the upper zones. Physiologic testing early in the course of the disease reveals restrictive ventilatory impairment, but with time, an obstructive lung disease supervenes, because the fibrotic process in the lung involves not only the interstitium but also the small airways. Histopathology reveals cellular and fibrotic interstitial pneumonia.[173] Scar carcinoma has been reported as a complication of neurofibromatosis.[176]

Hermansky-Pudlak Syndrome

Hermansky-Pudlak syndrome is an autosomal recessive disorder characterized by occulocutaneous albinism and bleeding, found predominantly in inhabitants of Puerto Rico and southern Holland.[178-180] The biochemical defect is unknown, although putatively responsible genes have been identified and several mutations have been reported.[181] In patients with this disease, there is an accumulation of a chromolipid ceroid (related to lipofuscin) in the reticuloendothelial system. This result in partial tyrosine-negative albinism and a qualitative platelet defect. In addition, granulomatous colitis and progressive pulmonary fibrosis occur.

The interstitial lung disease is more likely to occur in women and develops during the second through fourth decades.[179] It progresses slowly and is unresponsive to treatment. Spirometry and measurement of lung volumes reveal restrictive lung disease. Chest radiography shows reticular opacities that progress to radiographic honeycomb lung over time. The histologic appearance is one of extensive interstitial fibrosis with filling of the alveolar spaces by ceroid-containing macrophages. These macrophages are identified in BAL and by subsequent staining with the Fontana-Masson silver reduction technique.

Dyskeratosis Congenita

Dyskeratosis congenita (DKC) is a rare inherited condition consisting most generally of mucocutaneous features including nail dystrophy, skin pigmentation, and oral leukoplakia.[182,183] Mutations in the genes encoding telomerase and telomere maintenance have been identified in nearly 50% of patients with this disease. Most patients with DKC are male, suggesting an X-linked pattern of inheritance.[184] Telomere length is important to control of cell division, and shortening of telomeres (either due to aging or inherited abnormalities) eventually leads to cellular senescence. In DKC, this most commonly manifests as bone marrow failure (isolated cytopenias to aplastic anemia).

Pulmonary fibrosis has been described in patients with DKC. These were initially described in patients following bone marrow transplant and may have been the result of increased susceptibility to chemotherapy-related pulmonary toxicity.[185] Since that time, additional cases of pulmonary fibrosis in patients with DKC have been reported.[186] There is little information on the histopathologic appearance of these cases. Approximately 11% of deaths in one cohort were due to pulmonary complications, with another 11% of deaths due to pulmonary complications of bone marrow transplantation.[186]

Gaucher's Disease

Gaucher's disease results from a deficiency in the enzyme glucocerebrosidase, a central component of ganglioside catabolism. The infantile form of Gaucher's disease, a hereditary disorder that is most common in Ashkenazi Jewish people, is uniformly fatal because of central nervous system involvement. However, the adult form (type 1 disease) is relatively benign and is associated with good long-term survival. This condition presents with hepatosplenomegaly, anemia, thrombocytopenia, long-bone erosions, and an increase in serum acid phosphatase. It is an autosomal recessive disease, the pathologic hallmark being the Gaucher cell. The Gaucher cell is a reticuloendothelial cell with a foamy cytoplasm due to the accumulation of glucocerebrosides. This leads to an excessive deposition of glucocerebrosides in the reticuloendothelial system, bone marrow, central nervous system, and occasionally, the lung.

Pulmonary disease occurs in only a small minority of adult cases.[187-189] Parenchymal disease, which consists of radiographically visible small nodules, appears during the first 3 decades of life. Pathologic examination reveals conglomerate masses of glucocerebroside-filled macrophages in the alveolar spaces and infiltrating the interstitium. Remarkably, there are limited to no acute or chronic inflammation or fibrosis. In addition to interstitial lung disease, affected patients are susceptible to lung infection. A single case of pulmonary hypertension from diffuse small vessel obstruction by these cells has been reported.[190] Although enzyme replacement (glucocerebrosidase) has therapeutic promise for many of the manifestations of Gaucher's disease, the interstitial lung disease appears unresponsive.[191]

Niemann-Pick Disease

Niemann-Pick disease results from a deficiency of sphingomyelinase that causes accumulation of sphingomyelin in the cells of the reticuloendothelial and central nervous systems.[192] As in Gaucher's disease, there is an infantile form of Niemann-Pick disease that is rapidly fatal. The adult form (type B disease), which appears during the second and third decades, is relatively benign, presenting with hepatosplenomegaly, hemostatic defects, platelet dysfunction, and occasionally, cerebellar ataxia. Interstitial lung disease, which appears as diffuse nodular infiltrates on the chest radiograph, is usually asymptomatic, although a mild restrictive ventilatory defect and reduced diffusing capacity have been reported.[193,194] As in Gaucher's disease, collections of foamy alveolar macrophages are found on lung biopsy.

Pulmonary Alveolar Microlithiasis

Pulmonary alveolar microlithiasis is an idiopathic rare disease in which concretions composed of calcium and phosphorus collect in alveolar spaces (Fig. 60-11).[195,196] In more than 50% of cases, a familial association is found.[197] A systemic disorder of calcium metabolism has not been identified, and the serum calcium and phosphate levels are normal. Most authors believe that

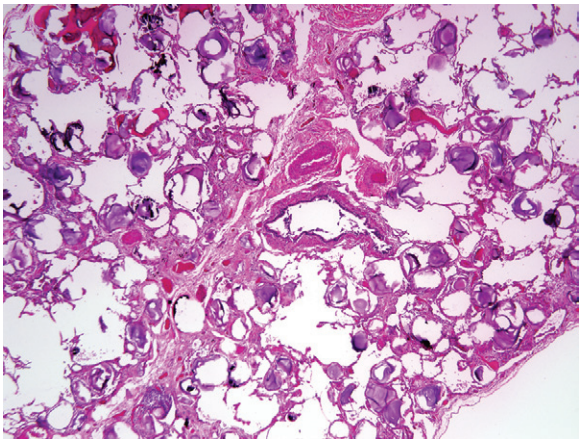

FIGURE 60-11 ■ Histopathology of pulmonary alveolar microlithiasis. Alveolar spaces are filled by lamellated, rounded microliths. (Images courtesy of Kirk Jones, MD, University of California, San Francisco.)

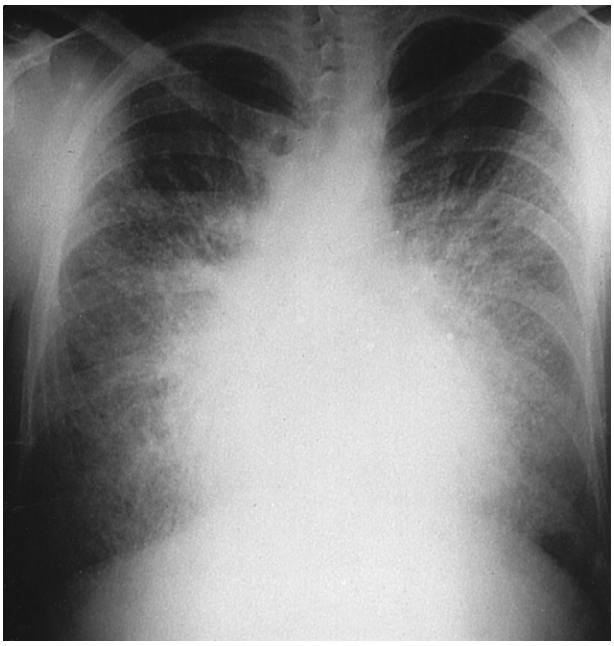

FIGURE 60-12 ■ Radiography of pulmonary alveolar microlithiasis.

the responsible mechanism is an inborn error of calcium metabolism that is confined to the lung and leads to precipitation of the salts.

Most cases of pulmonary alveolar microlithiasis are diagnosed during the third through fifth decades. Among familial cases, women are affected more often than men, but there is an equal distribution among the sporadic cases.[197,198] Cough and dyspnea are the most common presenting symptoms. Expectorated microliths have been reported.[195] Inspiratory crackles, finger clubbing, and signs of cor pulmonale may be present in more advanced disease.

The chest radiograph is characteristic and shows diffuse bilateral calcific opacities with predilection for the lower lung zones. This opacity is alveolar, producing air bronchograms and radiographic obliteration of the heart borders, pulmonary vessels, and diaphragmatic surfaces.[199] Chest computed tomography often demonstrates widespread intra-alveolar calcified nodules with a lower lobe and subpleural predominance, although early disease can be less conspicuous (Fig. 60-12).[200,201] Pulmonary function remains normal or only slightly impaired for a prolonged period after disease detection.[196] With time, the alveolar walls become fibrotic and a restrictive ventilatory defect with a reduced D_{LCO} develops. Technetium-99m bone scintigraphy or transbronchial lung biopsy can provide confirmation of the diagnosis.[202,203] Treatment is supportive. Whole-lung lavage has been tried without benefit.[204]

KEY POINTS

- DAH is an uncommon but striking condition that is associated with many different underlying disorders.
- DAH is a medical emergency that often results in acute respiratory failure and death.
- All of these diseases are rare, and many have a genetic basis.
- The classic clinical presentation of DAH includes hemoptysis, alveolar opacities on chest radiograph, and anemia.
- Most are diagnosable, and treatment is available for a few.
- Many of the disorders causing DAH appear to be immunologically mediated, either through injury to the capillary basement membrane by specific autoantibody or through deposition of immune complexes.
- Most conditions can be diagnosed by the presence of accompanying clinical features, laboratory abnormalities, and histologic findings, although overlap occurs.
- Bronchoscopy with serial BAL is essential to the accurate identification of DAH.
- Surgical lung biopsy is rarely required for the diagnosis of DAH.
- Many cases of DAH demonstrate neutrophilic inflammation of the alveolar interstitium known as capillaritis.
- The presence of proteinuria and an abnormal urinary sediment (red blood cells and red blood cell casts) suggests an underlying glomerulonephritis consistent with the diagnosis of systemic vasculitis or Goodpasture's syndrome.
- Accurate diagnosis is essential because aggressive treatment with corticosteroids, cytotoxic agents, and plasmapheresis (alone or in combination) is often helpful.

CHAPTER 61

EOSINOPHILIC LUNG DISEASES

Vincent Cottin, MD, PhD • Jean-François Cordier, MD

INTRODUCTION

EOSINOPHIL BIOLOGY

GENERAL FEATURES OF EOSINOPHILIC PNEUMONIAS
Historical Perspective
Clinical Presentation
Pathology
Diagnosis

EOSINOPHILIC LUNG DISEASE OF UNDETERMINED CAUSE
Idiopathic Chronic Eosinophilic Pneumonia
Idiopathic Acute Eosinophilic Pneumonia
Churg-Strauss Syndrome
Hypereosinophilic Syndrome

EOSINOPHILIC LUNG DISEASE OF DETERMINED CAUSE
Eosinophilic Pneumonias of Parasitic Origin
Eosinophilic Pneumonias of Other Infectious Causes
Allergic Bronchopulmonary Aspergillosis and Related Syndromes
Drug, Toxic Agents, and Radiation-Induced Eosinophilic Pneumonias

MISCELLANEOUS LUNG DISEASES WITH ASSOCIATED EOSINOPHILIA
Organizing Pneumonia
Asthma and Eosinophilic Bronchitis
Idiopathic Interstitial Pneumonias
Langerhans Cell Granulomatosis
Lung Transplantation
Other Lung Diseases with Occasional Eosinophilia

INTRODUCTION

The eosinophilic lung diseases are a group of disorders (Table 61-1) characterized by the presence and presumed pathogenetic role of eosinophils in the lesional processes. They are mainly represented by the eosinophilic pneumonias, which are defined by a prominent infiltration of the lung parenchyma by eosinophils. The other eosinophilic lung diseases mainly involve the airways, as in the allergic bronchopulmonary mycoses. Asthma, in which the eosinophil is considered to play an important role, is not discussed in this chapter.

EOSINOPHIL BIOLOGY

The role of the eosinophil in homeostasis function, physiology, and pathophysiology has become better appreciated in recent years.[1-3] Eosinophils are multifunctional leukocytes implicated in innate and adaptative immunity, including numerous inflammatory reactions to parasitic helminth, bacterial, and viral infections.[3] They have been especially credited with a beneficial role in parasitic infestation; however, results from in vivo infection studies gave conflicting results.[3a]

The eosinophil[1-3] matures in the bone marrow under the action of cytokines and especially of interleukin (IL)-5 (involved in the differentiation of eosinophil precursors), IL-3, and granulocyte-macrophage colony-stimulating factor (GM-CSF). It then circulates in the blood for about 1 day before being attracted into tissues by complex processes including adhesion and attraction, diapedesis and chemotaxis, where they undergo apoptosis unless survival factors are present.

Major advances have been made in the understanding of molecular and intracellular pathways regulating eosinophil differentiation, priming, activation, and mediator secretion (with especially the role of vesicle-associated membrane protein [VAMP]–2 and VAMP-7, members of the SNARE complex [sensory nerve action potential

TABLE 61-1. Classification of the Eosinophilic Lung Diseases

EOSINOPHILIC LUNG DISEASE OF UNDETERMINED CAUSE

Idiopathic eosinophilic pneumonias
- Idiopathic chronic eosinophilic pneumonia
- Idiopathic acute eosinophilic pneumonia

Churg-Strauss syndrome

Hypereosinophilic syndrome

EOSINOPHILIC LUNG DISEASE OF DETERMINED CAUSE

Eosinophilic pneumonias of parasitic origin
- Tropical eosinophilia
- *Ascaris* pneumonia
- Eosinophilic pneumonia in larva migrans syndrome
- *Strongyloides stercoralis* infection
- Eosinophilic pneumonias in other parasitic infections

Eosinophilic pneumonias of other infectious causes

Allergic bronchopulmonary aspergillosis and related syndromes
- Allergic bronchopulmonary aspergillosis
- Other allergic bronchopulmonary syndromes associated with fungi or yeasts
- Bronchocentric granulomatosis

Drug, toxic agents, and radiation-induced eosinophilic pneumonias
- Drugs (typical, occasional, or exceptional eosinophilic pneumonia)
- Toxic agents (toxic oil syndrome)
- Eosinophilic pneumonia induced by radiation therapy to the breast

MISCELLANEOUS LUNG DISEASES WITH POSSIBLE ASSOCIATED EOSINOPHILIA

Organizing pneumonia

Asthma and eosinophilic bronchitis

Idiopathic interstitial pneumonias

Langerhans cell granulomatosis

Lung transplantation

Other lung diseases with occasional eosinophilia
- Sarcoidosis
- Paraneoplastic eosinophilic pneumonia

{*SNAP*} *Re*ceptors] in the regulation of granule fusion in eosinophils). The eosinophil contains two types of intracytoplasmic granules. The larger granules, characterized by an electron-dense crystalloid matrix, contain the characteristic cationic proteins. The smaller amorphous granules contain arylsulfatase and acid phosphatase. Activation of the eosinophil results in degranulation with the extracellular release of the eosinophil-specific proteins including major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN) (or eosinophil-protein X), and the enzymatic protein eosinophil peroxidase (EPO) and MBP homologue. The finding of vacuoles in the cytoplasm of the eosinophil and ultrastructural evidence of loss of electron density from the central core of the granules (inversion or disappearance of core density) characterizes morphologically the process of degranulation. Eosinophils also release proinflammatory cytokines, arachidonic acid–derived mediators, enzymes, reactive oxygen species, and matrix metalloproteases. They express a variety of surface proteins, including adhesion molecules, apoptotic signaling molecules, chemokines, complement receptors, chemotactic factor receptors, cytokine receptors, and immunoglobulin receptors. Thus, eosinophil accumulation and the release of toxic substances may in itself contribute to the pathophysiology of eosinophilic disorders.

Many biologic properties of the eosinophil are directed by T helper (Th) lymphocytes, but the eosinophil interacts in many allergic or inflammatory processes with other cells including mast cells and basophils, endothelial cells, macrophages, platelets, and fibroblasts. Eosinophils are capable of regulating mast cell function and histamine release. Activated eosinophils express the major histocompatibility complex II protein human leukocyte antigen (HLA)–DR, and possess the ability to participate to numerous immune functions, including antigen presentation and secretion of an array of cytokines capable of promoting effector T-cell proliferation. In addition, eosinophils are implicated in the regulation of Th1/Th2 balance, through synthesis of IL-4, promotion of IL-4, IL-5, and IL-13 secretion by $CD4^+$ T cells, and the synthesis of indoleamine 2,3-dioxygenase (indirectly promoting Th1 apoptosis).

Recruitment of the eosinophil to the lung mostly implicates IL-5 and the eotaxin subfamily of chemokines (itself regulated by the Th2 cell–derived IL-13 cytokine). Release of toxic granule proteins and lipid mediators by eosinophils may contribute to tissue damage and dysfunction; however, histopathologic lesions in eosinophilic pneumonias are largely reversible with treatment. One possible exception is represented by tissue damage associated with eosinophil infiltration in bronchial mucosa in asthma, especially in allergic bronchopulmonary aspergillosis (ABPA), and persistent airflow obstruction in Churg-Strauss syndrome (CSS). Corticosteroids are the most effective agents for reducing eosinophilia in the blood and tissues, by shortening the half-life of cytokines such as eotaxins, and inhibiting the cytokine-dependent survival of eosinophils.

A major impediment in eosinophil research is the inability of murine eosinophils to degranulate either in vivo or in vitro, in contrast with human eosinophils that differentially release their granule proteins after contact with different stimuli, and the difficulties of animal models in mimicking human eosinophilic lung disease. The recent availability of humanized anti-IL-5 antibody, which lowers eosinophil levels in the blood and in the lung in humans, and of genetically engineered mice such as those deficient in IL5 or in eosinophils, may hopefully contribute to a better understanding of the pathogenic role of eosinophils.[3b] There is, in any case, no doubt that the eosinophil plays a role in many inflammatory processes occurring in a variety of organs, and especially the respiratory tract. Because it has very characteristic morphology and staining properties, it is easy to detect in the tissues or biological fluids.

GENERAL FEATURES OF EOSINOPHILIC PNEUMONIAS

Historical Perspective

Reeder and Goodrich[4] published in 1952 a series of cases of pulmonary "infiltration with eosinophilia," including probable idiopathic chronic eosinophilic pneumonia (ICEP) and CSS. Crofton and coworkers[5] published a series of 16 cases of "pulmonary eosinophilia" with a review of 450 cases from the literature and proposed the following classification:

1. Simple pulmonary eosinophilia (Löffler's syndrome), defined by mild symptoms and transient infiltrates.
2. Prolonged pulmonary eosinophilia characterized by radiographic shadows persisting for over 1 month.
3. Tropical eosinophilia.
4. Pulmonary eosinophilia with asthma, a rather heterogeneous category.
5. Polyarteritis nodosa.

The authors mentioned "a continuum from the simple and transient abnormalities of Löffler's syndrome to the severe and often fatal manifestations of polyarteritis nodosa." Churg and Strauss reported in 1951[6] the eponym syndrome of "allergic granulomatosis, allergic angitiis, and periarteritis nodosa," and Carrington and colleagues [7] described the syndrome of ICEP. McCarthy and Pepys[8] later reported 27 cases of "cryptogenic pulmonary eosinophilias," 2 of whom developed systemic vasculitis.

Clinical Presentation

Eosinophilic pneumonia is a pneumonia in which the eosinophils are the most prominent inflammatory cells on histopathologic examination. Other inflammatory cells, especially lymphocytes and neutrophils, are often associated, but eosinophils clearly predominate. In clinical practice, the eosinophilic pneumonias may be separated into two main etiologic categories: (1) those in which a definite cause is found or (2) those of undetermined origin, that is, idiopathic (with the eosinophilic pneumonia being either solitary or included in a systemic disorder such as CSS).

A definite cause must be carefully investigated in any patient with eosinophilic pneumonia because it has practical consequences (e.g., stopping a drug responsible for iatrogenic eosinophilic pneumonia or treating a parasitic infection). When no cause is identified, the eosinophilic pneumonias may usually be included within well-characterized and individualized syndromes.

The eosinophilic pneumonias may manifest by different clinicoradiologic syndromes, namely Löffler's syndrome, chronic eosinophilic pneumonia, or acute eosinophilic pneumonia, mostly differing from one another by the pattern of disease onset. Extrapulmonary manifestations accompanying eosinophilic pneumonia are the hallmark of CSS and, to a lesser extent, hypereosinophilic syndrome (HES). The vast majority of cases respond dramatically to corticosteroid treatment and heal without significant sequelae.

Pathology

Histopathologic studies of eosinophilic pneumonia have mainly been done in patients with ICEP,[7,9,10] which was initially diagnosed by open-lung biopsy. The pathologic features described in ICEP may be considered as a common denominator of all categories of eosinophilic pneumonias, whatever their origin. Occasional pathologic studies in eosinophilic pneumonias of known cause have further shown some specific features such as a possible distinctive distribution of lesions (e.g., bronchocentric distribution in ABPA) or the presence of causal agents such as parasites or fungal hyphae.

In ICEP, the alveolar spaces are filled with eosinophils (Fig. 61-1). Macrophages are also present with some multinucleated giant cells scattered in the infiltrate; these may contain eosinophilic granules or Charcot-Leyden crystals.[7] An associated interstitial inflammatory cellular infiltrate is invariably present, consisting of eosinophils, lymphocytes, plasma cells, and histiocytes. A proteinaceous and fibrinous exudate accompanies the cellular eosinophilic infiltrate. Some eosinophilic microabscesses may be observed (foci of necrotic intra-alveolar eosinophils surrounded by macrophages or epithelioid cells with palisading arrangement). Morphologic (especially electron microscopic) as well as immunohistochemical studies have shown eosinophil degranulation within the site of eosinophilic pneumonia.[11] The global architecture of the lung remains intact, without necrosis or fibrosis.

Organization of the alveolar inflammatory exudate is a rather common finding,[7] suggesting some possible overlap between ICEP and organizing pneumonia. However, intraluminal organization in the distal air spaces is only sparse and never prominent in ICEP.

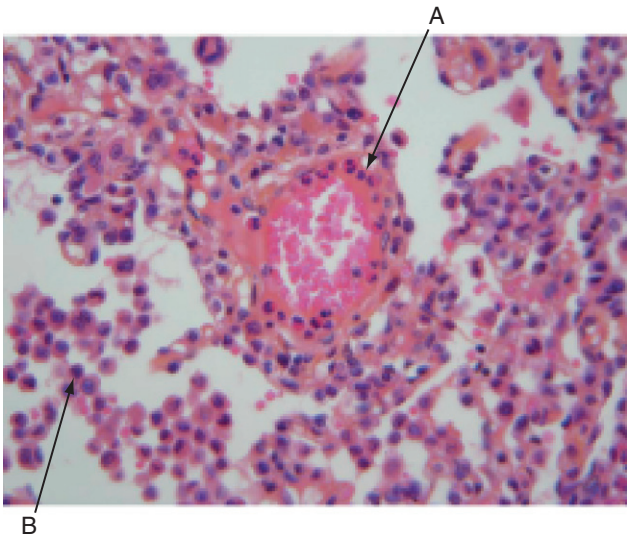

FIGURE 61-2 ■ Eosinophilic pneumonia. Eosinophils infiltrate the arteriolar wall (non-necrotizing vasculitis) (**A**) and are present within the alveolar lumen (**B**). (Courtesy of Françoise Thivolet-Béjui, MD, Department of Pathology, Louis-Pradel Hospital and Claude Bernard University, Lyon, France.)

Mucus plugs obstructing the small airways may be present in ICEP.[7]

A mild vasculitis involving both small arteries and venules is common, with perivascular cuffing and a few cells infiltrating the arterial media. In simple eosinophilic pneumonia, this vasculitis is *non-necrotizing* (Fig. 61-2).

The distribution of eosinophilic pneumonia is generally diffuse. However, it may be more focal in some cases, and the lesions may have an angiocentric or bronchiolocentric distribution in some etiologic groups of eosinophilic pneumonia.

The hilar lymph nodes associated with ICEP contain many eosinophils, and lymphoid hyperplasia is present.[7]

In idiopathic acute eosinophilic pneumonia (IAEP), the pathologic pattern includes intra-alveolar and interstitial eosinophilic infiltrates, diffuse alveolar damage, intra-alveolar fibrinous exudates, organizing pneumonia, and non-necrotizing vasculitis.[12]

Diagnosis

In clinical practice, the diagnosis of eosinophilic pneumonia is suspected in patients presenting with respiratory symptoms (dyspnea, cough, or wheezing), pulmonary opacities at chest imaging, and the demonstration of eosinophilia in the peripheral blood or, preferably, in the lung.

Although pathologic examination of the lung has been the "gold standard" to define eosinophilic pneumonia, lung biopsy is seldom necessary, and video-assisted thoracoscopic lung biopsy (which is a safe procedure) is necessary only in complex cases. Transbronchial lung biopsy may show characteristic features of eosinophilic pneumonia, but the small size of the specimen usually does not allow morphologic evidence of a possible etiologic process.

Bronchoalveolar lavage (BAL) has become a widely accepted noninvasive surrogate of lung biopsy for the diagnosis of eosinophilic pneumonia, although no study has definitely established a correlation between increased eosinophils at differential cell count and the finding of eosinophilic pneumonia at pathologic examination of the lung. In normal controls, BAL eosinophilia is lower than 1% of cells at differential count.[13] In contrast, BAL eosinophilia greater than 40% is found mainly in patients with chronic eosinophilic pneumonia, whereas BAL eosinophilia between 3% and 40% (and especially between 3% and 9%) may be found in various conditions, such as idiopathic pulmonary fibrosis, interstitial lung disease associated with connective tissue disorders, hypersensitivity pneumonitis, sarcoidosis, radiation pneumonitis, asthma, pneumoconioses, and infection.[14]

A conservative cutoff of 40% of eosinophils at BAL differential cell count has been adopted for the diagnosis of ICEP in clinical studies,[15,16] and a cutoff of 25% has been proposed for the diagnosis of IAEP.[17] For clinical practice, our recommendation is that a diagnosis of eosinophilic pneumonia is supported by alveolar eosinophilia when the eosinophils (1) are the predominant cell population (macrophages excepted) and (2) represent more than 25% and preferably more than 40% of differential cell count.

Although BAL is usually a safe procedure, it may not always be mandatory in typical cases. The diagnosis of eosinophilic pneumonia is usually accepted when both radiographic pulmonary opacities and peripheral blood eosinophilia are present, although alternative diagnoses such as bacterial or parasitic pneumonia, or pulmonary infiltrates related to Hodgkin disease, may also cause pulmonary opacities and peripheral eosinophilia. However, diagnosing eosinophilic pneumonia on the sole finding of blood eosinophilia and pulmonary opacities requires markedly elevated eosinophilia ($>1 \times 10^9$/L and preferably 1.5×10^9/L) together with typical clinicoradiologic features, because the finding of peripheral blood eosinophilia does not prove that the observed pulmonary opacities correspond to eosinophilic pneumonia. For example, BAL may occasionally be omitted for the diagnosis of Löffler's syndrome (as it occurs in ascariasis), with rather mild and nonspecific cough and wheezes, transient pulmonary opacities at chest radiograph, and frank blood eosinophilia. Conversely, peripheral blood eosinophilia may be missing in patients who have already received systemic corticosteroids, and it is often absent at presentation in IAEP. Nevertheless, BAL is recommended to confirm the diagnosis of eosinophilic pneumonia in most cases.

Once the diagnosis of eosinophilic pneumonia has been made, a thorough evaluation is necessary to investigate possible causes such as parasitic infection or drug or toxic exposure and to classify the case into one of the possible clinical entities (see Table 61-1).

EOSINOPHILIC LUNG DISEASE OF UNDETERMINED CAUSE

Either chronic or acute, the idiopathic eosinophilic pneumonias represent an eosinophilic pulmonary disorder without associated manifestations specific for any etiologic agent. ICEP is characterized by a progressive onset of symptoms over a few weeks with cough, increasing dyspnea, malaise, and weight loss. IAEP presents as an acute pneumonia (similar to acute lung injury or acute respiratory distress syndrome [ARDS]) with frequent respiratory failure necessitating mechanical ventilation.

Idiopathic Chronic Eosinophilic Pneumonia

Chronic eosinophilic pneumonia was defined as a distinct entity by Carrington and colleagues,[7] who described a series of 9 patients, with detailed clinical, radiologic, physiologic, and pathologic data. This syndrome was further confirmed and detailed by several series[10,16,18–20] and numerous case reports.

Clinical Features

ICEP occurs predominantly in women (with a 2:1 female-to-male ratio).[10,16] Although ICEP may occur in young people,[21,22] only 6% of patients are younger than 20 years old.[10] The incidence of ICEP peaks in the fourth decade,[10] with a mean age of 45 years at diagnosis.[16] A vast majority of patients with ICEP are nonsmokers,[10,16,19] suggesting that smoking might be protective.

A prior history of atopy is found in about half of the patients, with allergic rhinitis in 12%[10] to 24%,[16] drug allergy in about 10%,[10,16] nasal polyps in 5%[10] to 13%,[16] urticaria in 10%,[16] and eczema in 5%.[16]

Prior asthma is present in up to two thirds of the patients.[9,10,15,16,19,20] Asthma may also develop concomitantly with the diagnosis of ICEP in 15% of patients or develop after ICEP in 13%.[15] The presentation of ICEP is similar in asthmatics and nonasthmatics with the exception of higher total immunoglobulin (Ig) E in the former group.[15] ICEP may occur while asthmatic patients are on a desensitization program, but there is no proof that this may contribute to the development of ICEP. Asthma often gets worse after the occurrence of ICEP and requires long-term oral corticosteroid treatment even in the absence of recurrence of the eosinophilic pneumonia.[15]

The onset of ICEP is progressive, with a mean interval between the onset of symptoms and the diagnosis of 4 months in one series.[16] The most common respiratory symptoms are cough, dyspnea, and chest pain.[10,16] Dyspnea is usually not severe, although the necessity for mechanical ventilation after several months of progression of disease has been occasionally reported.[23] Hemoptysis occurs in about 10% of cases.[10,16] Wheezes at physical examination are found in one third of patients[10] and crackles in 38%.[16] Upper respiratory tract symptoms of chronic rhinitis or sinusitis are present in about 20% of patients.[16]

Systemic symptoms and signs are often prominent, with fever, weight loss (≥10 kg in about 10%). Asthenia, malaise, fatigue, anorexia, weakness, and night sweats are also common.

Imaging

The imaging features of ICEP are characteristic, although many of the features overlap with those found in cryptogenic organizing pneumonia (see Chapter 57). Peripheral opacities at chest x-ray are present in almost all cases[7,10,16,24–27] and are migratory in a quarter of the cases.[16] They usually consist of alveolar opacities with ill-defined margins, with a density varying from ground-glass to consolidation (Fig. 61-3). The classic pattern of "photographic negative or reversal of the shadows usually seen in pulmonary edema,"[26] highly evocative of ICEP,[26] is seen in only one fourth of patients.[10]

High-resolution computed tomography (HRCT) has further allowed description of the characteristic imaging features of ICEP. Whereas the opacities are bilateral in at least 50% of cases at chest x-ray,[10,19] the proportion of bilateral opacities may increase up to 97.5% at HRCT (Fig. 61-4).[16] Characteristic opacities predominate in the upper lobes[10,16,24] and are peripheral, with generally coexisting ground-glass and consolidation opacities at HRCT.[16,25,28] Consolidation with segmental or lobar atelectasis may be seen.[25] Septal line thickening is common.[28] Streaky or bandlike opacities parallel to the

FIGURE 61-3 ■ Chest radiograph of a patient with idiopathic chronic eosinophilic pneumonia shows bilateral alveolar opacities predominating in the upper lobes.

FIGURE 61-4 ■ Computed tomography (CT) scan of a patient with idiopathic chronic eosinophilic pneumonia shows bilateral symmetrical peripheral alveolar opacities.

chest wall may also be present.[25] Upon corticosteroid treatment, consolidation and ground-glass opacities rapidly show a decrease in size and extent, with possible change from consolidation to ground-glass opacities or inhomogeneous opacities, and later to streaky or band-like opacities.[25] Cavitary lesions are extremely rare and should lead to reconsideration of the diagnosis. Small pleural effusions are present in only 10% of cases at HRCT and mediastinal lymph node enlargement in 17%.[16]

Laboratory Studies

Peripheral blood eosinophilia over 6% was present in 88% of 111 cases in one literature review,[10] with a mean percentage of blood eosinophils at differential count of 26%. The mean blood eosinophilia was 5.5×10^9/L in our series, with eosinophils representing a mean of 32% of the total blood leukocyte count.[16] Because peripheral blood eosinophilia is often a diagnostic criterion of ICEP, the proportion of patients with ICEP and possible normal peripheral blood count is unknown.

Erythrocyte sedimentation rate is increased, and C-reactive protein level is elevated.[10,16,19] Total blood IgE level is increased in about half of cases and greater than 1000 kU/L in 15%.[16] Circulating immune complexes have been reported in ICEP in about one third of patients.[16] Antinuclear antibodies may occasionally be present.[16] Markedly increased urinary EDN level indicating active eosinophil degranulation is found in patients with ICEP.[29]

Bronchoalveolar Lavage

BAL has progressively replaced lung biopsy for the diagnosis of ICEP. Alveolar eosinophilia is a characteristic and constant feature in ICEP,[16,30] with a mean of 58% at differential cell count.[16] Alveolar eosinophilia may be associated with an increased percentage of neutrophils, mast cells, and lymphocytes.[16] BAL eosinophil cell count drops within a few days under corticosteroid treatment.[31] Sputum eosinophilia may also be present.[5,20]

BAL eosinophils of patients with ICEP show activation features such as the release of eosinophil proteins, which are taken up by macrophages.[32] ECP[33] and EDN[33] are increased in BAL fluid of patients with ICEP. Expression of HLA-DR in a patient with ICEP was present on 86% of alveolar eosinophils in contrast to 7% of blood eosinophils, suggesting compartmentalization of eosinophilic activation within the lung.[34] BAL lymphocytes are characterized by an accumulation of $CD4^+$ T cells that express activation surface antigens of memory T-cells ($CD45RO^+$, $CD45RA^-$, $CD62L^-$).[35] Recruitment of eosinophils to the lung involves various chemokines, which contribute to suppress Fas-induced apoptosis of eosinophils.[36]

Differential Diagnosis

Although ICEP is not a systemic disease, isolated and usually moderately severe extrapulmonary manifestations have been occasionally reported, including arthralgias, repolarization (ST-T) abnormalities on the electrocardiogram, pericarditis, altered liver biologic tests, eosinophilic lesions at liver biopsy, mononeuritis multiplex, diarrhea, skin nodule, immune complex vasculitis in the skin, and eosinophilic enteritis.[7,16,37] Such manifestations suggest an overlap between ICEP and CSS. Eosinophilic pneumonia similar to ICEP may be a presenting feature of CSS,[38,39] with patients often receiving corticosteroid treatment, which may prevent the development of overt systemic vasculitis. In a series of ICEP with especially high frequency of extrapulmonary signs (30%), some of which were quite evocative of the CSS, none of the patients treated with corticosteroids developed characteristic CSS or the idiopathic hypereosinophilic syndrome on follow-up.[37]

Lung Function Tests

Lung function tests in ICEP show an obstructive ventilatory defect in about half the patients[10,16] and a restrictive ventilatory defect in half the cases.[16] Hypoxemia defined by an arterial oxygen pressure (Pa_{O_2}) of 75 mm Hg or less was present in 64% of patients in a series[16]; CO transfer factor was less than 80% of predicted in 52%, and transfer coefficient was less than 80% of predicted in only 27%. An increased alveolar-arterial oxygen gradient has been reported in 90% of cases.[10] The impaired lung function tests normalize under treatment in most patients.[10] However, a ventilatory obstructive defect may develop over time in some patients, especially those with a markedly increased BAL eosinophilia at initial evaluation.[40]

Treatment and Prognosis

The natural course of untreated ICEP is not well known, because the dramatic response of ICEP to corticosteroids was observed shortly after these drugs became available.[10] Spontaneous resolution of ICEP may occur,[10,16] and death directly resulting from ICEP seems extremely rare. Symptoms improve within 1 or 2 weeks of corticosteroid treatment and even within 48 hours in about 80%[16] of

cases. Pulmonary opacities at chest x-ray clear rapidly. They disappeared within 1 week in 69% of patients in our series of patients treated with a mean initial dose of 1 mg/kg/day.[16] Almost all of our patients with ICEP treated with corticosteroids had a normal chest x-ray at their last follow-up visit.[16]

The optimal dose of corticosteroids is not established, but the usual doses vary between 20 and 60 mg/day. Our current recommendation is to start with 0.5 mg/kg/day of prednisone. Most patients require prolonged treatment (i.e., >6 mo) because of relapse while decreasing or after stopping the corticosteroid treatment. In one series, 58% of cases relapsed after corticosteroids had been discontinued and 21% while the corticosteroids were being tapered.[10] In our series, half of the patients relapsed after the corticosteroids had been weaned (with a mean delay of 72 wk) or were being tapered (the mean dose of corticosteroids at the time of relapse was 11 mg/day).[16] Relapses that may occur in the same areas of the lungs or in different areas[16] respond very well to resumed corticosteroid treatment; a dose of 20 mg/day of prednisone is usually sufficient to treat the relapses.

The clinical series in which follow-up is available clearly show that most patients need prolonged corticosteroid treatment: in our series with a mean 6.2 years of follow-up, only 31% were weaned at the last control visit.[16]

Relapses of ICEP are less frequent in patients with asthma, possibly because they often receive inhaled corticosteroids after stopping oral corticosteroids.[15,16] Inhaled corticosteroids might thus help in reducing the maintenance dose of oral corticosteroids, although they are not effective enough when given as monotherapy.[41]

Idiopathic Acute Eosinophilic Pneumonia

IAEP[12,17,20,42–45] differs from ICEP mainly by its acute onset, the severity of hypoxemia, the usual lack of increased blood eosinophils at presentation contrasting with frank eosinophilic alveolitis at BAL (BAL differential count with ≥25% eosinophils or predominance of eosinophils in open lung biopsy), and the absence of relapse after clinical recovery. Fever and bilateral opacities on chest x-ray are present in all patients. The absence of hypersensitivity to drugs, historical or laboratory evidence of infection, or other known cause of acute eosinophilic lung disease, are additional diagnostic criteria.[17] Our current diagnostic criteria of IAEP are listed in Table 61-2.[46]

TABLE 61-2. Diagnostic Criteria for Idiopathic Acute Eosinophilic Pneumonia

1. Acute onset of febrile respiratory manifestations (≤1 mo duration before consultation)
2. Bilateral diffuse opacities on chest radiography
3. Hypoxemia, with Pa_{O_2} on room air < 60 mm Hg, and/or Pa_{O_2}/Fi_{O_2} ≤ 300 mm Hg, and/or oxygen saturation on room air < 90%
4. Lung eosinophilia, with >25% eosinophils on BAL differential cell count (or eosinophilic pneumonia at lung biopsy)
5. Absence of infection, or of other known causes of eosinophilic lung disease (especially exposure to a drug susceptible to induce pulmonary eosinophilia)

Adapted from Allen JN, Pacht ER, Gadek JE, Davis WB: Acute eosinophilic pneumonia as a reversible cause of noninfectious respiratory failure. N Engl J Med 321:569–574, 1989; and Cottin V, Cordier JF: Eosinophilic pneumonias. Allergy 60:841–857, 2005.

Clinical Features

The average age at presentation is about 30 years[17,45]; but IAEP may occur in patients 20 years old or younger[21] and in older patients.[45] In contrast with ICEP, there is male predominance and no prior asthma history, although some patients may have a history of atopy.[20] Some patients had peculiar outdoor activities within the days before onset of disease, such as cave exploration, plant repotting, wood pile moving, smokehouse cleaning or motocross racing in dusty conditions.[17] Four patients from our series[45] had been exposed, respectively, to dust from indoor renovation work (two patients), gasoline tank cleaning, and explosion of a tear gas bomb. One case was reported in a New York City firefighter exposed to World Trade Center dust.[47]

A causative role of cigarette smoke seems established, because IAEP has developed soon after the initiation of smoking (especially when starting with large quantities) in numerous patients,[48–53] and challenge with cigarette smoking was positive in some of them,[48–51,53] but tolerance may develop in patients who resume smoking.[49–51] Flavoring components of smoked cigars have been suspected.[54] It is likely that inhalation of tobacco smoke or of any nonspecific injurious agent may initiate or contribute to the development of IAEP in individuals intrinsically prone to develop eosinophilic reactions to inhaled nonspecific causative agents. Recent alterations in smoking habits (e.g., beginning to smoke, restarting to smoke, or increasing the number of cigarettes smoked daily) especially within 1 month seem to play a major role in the onset of "idiopathic" AEP.[53] Increased levels of (1 → 3)-beta-D-glucan (a major component of the cell wall of most fungi and also one of the components of cigarette smoke) have been reported in BAL fluid of patients with IAEP.[52]

IAEP may develop acutely in previously healthy individuals, with symptoms at presentation consisting of cough, dyspnea, fever, and chest pain. It may also develop subacutely over a few weeks,[12] with no clinical difference between patients seen in a time interval of less than 7 days or 7 to 31 days from the first symptoms to the diagnosis of IAEP.[45] Abdominal complaints and also myalgias have been mentioned.[17] At physical examination, tachypnea and tachycardia are present, with crackles or, less often, wheezes on auscultation.

Imaging

Chest x-ray shows bilateral opacities, with mixed alveolar or interstitial opacities.[17,43–45] Bilateral pleural effusion

and Kerley B lines are common.[17] The chest x-ray returns to normal within 3 weeks,[17,43] with pleural effusions being the last abnormality to disappear.[17]

At computed tomography (CT) imaging, ground-glass opacities and air space consolidation are the most common patterns of parenchymal lesions, with poorly defined nodules and interlobular septal thickening seen in a majority of patients; pleural effusion present in at least two thirds of patients is usually bilateral.[17,27,43,45,55] We consider that bilateral pleural effusion and interlobular septal thickening are highly characteristic of IAEP in a patient with eosinophilic pneumonia.

Laboratory Studies

In contrast with ICEP, white blood cell count at presentation usually shows increased leukocytosis with a predominance of neutrophils, with eosinophils only rarely higher than 0.3×10^9/L, but the eosinophil count may rise to high values during the course of disease,[17,20,45] a finding very suggestive of IAEP. Eosinophilia is also present at pleural fluid differential cell count[17,49,56] and in the sputum.[20]

The IgE level may be raised in some patients,[56,57] and serum IgG and especially IgG2 and IgG4 levels may be reduced during the active phase of disease as compared with controls.[57] Serum levels of thymus and activation-regulated chemokine (TARC/CCL17) and KL6 are often increased in IAEP as opposed to other causes of acute lung injury (ALI).[58]

Bronchoalveolar Lavage

Given the usual lack of initial blood eosinophilia, BAL is the key to the diagnosis of IAEP, showing an average percentage of 37%[17] to 54%[45] eosinophils at differential cell count, with sterile bacterial cultures. After recovery, eosinophilia at BAL may persist for several weeks.[59] We consider that the finding of eosinophilia greater than 25% at BAL may obviate lung biopsy previously used for diagnosis, at least in immunocompetent patients.

Lung Function Tests

Hypoxemia may be severe and refractory to breathing 100% oxygen in some patients.[42,45] A majority of patients fit the definition of ALI (a pulmonary disorder characterized by an acute onset, bilateral opacities on chest x-ray, pulmonary artery wedge pressure ≤18 mm Hg when measured, or no evidence of left atrial hypertension, and a Pa_{O_2}/F_{IO_2} [fractional inspired oxygen concentration] ≤ 300 mm Hg) or the definition of ARDS (patients with ALI and with $Pa_{O_2}/F_{IO_2} \leq 200$ mm Hg). Mechanical ventilation, either noninvasive or with intratracheal intubation, is necessary in a majority of patients.[17,45] In contrast with ALI or ARDS, shock is exceptional[60,61] and extrapulmonary organ failure does not occur. F_{IO_2} may be decreased within a few hours of steroid treatment in many patients initially requiring oxygen.[17]

When performed in less severe cases, lung function tests have shown a mild restrictive ventilatory defect with normal forced expiratory volume in 1 second–to–forced vital capacity (FEV_1/FVC) ratio and reduced transfer factor.[57] Alveolar-arterial oxygen gradient is increased.[17] Lung function tests performed after recovery are normal in most patients, with possible ventilatory restriction in some of them.[17,62,63]

Lung Biopsy

Lung biopsy is seldom necessary. When done, it shows acute and organizing diffuse alveolar damage together with interstitial alveolar and bronchiolar infiltration by eosinophils, intra-alveolar eosinophils, and interstitial edema.[12,17,60,64]

Treatment and Prognosis

Recovery without corticosteroid treatment may occur,[45,58] demonstrating that improvement concomitant with corticosteroid treatment cannot be considered a diagnostic criterion of IAEP. However, when a diagnosis of IAEP is made, corticosteroid treatment is usually started with initially intravenous methyl prednisolone later changed to oral therapy that can be tapered over 2 to 4 weeks.[17] The response to corticosteroids occurs within 48 hours, allowing rapid weaning from the ventilator. Recovery is rapid with no significant clinical or imaging sequelae, and with no relapse after stopping corticosteroid treatment, in contrast with ICEP.

Although IAEP often presents clinically like ALI or ARDS, its prognosis is far better. The key to the diagnosis is eosinophilia at BAL, because blood eosinophilia is usually absent initially. A careful search for a cause of IAEP is mandatory, and especially infectious agents must be sought for in BAL fluid by cultures and appropriate staining.[65] Drug-induced IAEP must also be carefully excluded.

Churg-Strauss Syndrome

Although a subgroup of patients with periarteritis (polyarteritis) nodosa and associated asthma and eosinophilia had been previously characterized, Churg and Strauss described in 1951[6] the eponymous syndrome, mainly from autopsied cases. They described characteristic pathologic features consisting of granulomatous extravascular lesions as well as necrotizing, inflammatory, and granulomatous vascular changes, with an inflammatory exudate rich in eosinophils. The most frequent site of inflammation was the heart. In approximately half of the cases, a pneumonic process was found, with an eosinophil-rich exudate mixed with giant cells in the acute stage.

In the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis,[66] CSS was included in the group of small vessel vasculitides and defined as an eosinophil-rich and granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels, and associated with asthma and eosinophilia. CSS is one of the pulmonary antineutrophil cytoplasmic antibodies

(ANCA)–associated vasculitides, together with Wegener's granulomatosis and microscopic polyangiitis, with ANCA present in approximately 40% of cases of CSS.

Because the diagnosis is now made earlier in the course of disease, lung biopsy is seldom necessary, and patients may receive corticosteroids before overt vasculitis has developed, the pathologic lesions of CSS currently observed[67,68] only rarely comprise all the characteristic features on a single biopsy from one organ. When typical features are present, both vasculitis (necrotizing or not, involving mainly the medium-sized pulmonary arteries) and granulomatous eosinophilic infiltration are seen. The extravascular granuloma consists of palisading histiocytes and giant cells. When present, the eosinophilic pneumonia in CSS is similar to ICEP. The early (prevasculitic) phase of CSS is characterized by eosinophilic infiltration of the tissues without vasculitis (perivascular eosinophilis are commonly found).

Clinical Features

The clinical features of CSS have been well defined.[69–74] It is a very rare systemic disease, which occurs especially in adults younger than 65[73,75]; it has been occasionally reported in children and adolescents. There is no sex predominance. The mean age of onset of vasculitis ranges from 38 to 49 years.[73,76]

Asthma, generally severe and becoming rapidly corticosteroid dependent, occurs at a mean age of about 35.[73] It usually precedes the onset of vasculitis by 3 years and up to 9 years.[69,73,76,77] The interval between asthma and the onset of vasculitis may be much longer in rare cases,[77] or they may be contemporaneous.[76] The severity of asthma typically increases progressively until the vasculitis develops, but it may attenuate when the vasculitis flourishes and further increase once the vasculitis recedes.[73,77]

Chronic rhinitis present in about three quarters of cases of CSS[73,82,83] is often accompanied by relapsing sinusitis and/or polyposis, with eosinophilic infiltration at histopathology.[84] Paranasal sinusitis has been reported in 61% of patients.[69] Crusty rhinitis may be present, but the rhinitis in CSS is distinctly much less severe than in Wegener's granulomatosis, with septal nasal perforation or saddle nose deformation being exceptional.

Asthenia, weight loss, fever, arthralgias, and myalgias (all of which are unusual in simple asthma) often herald the development of the extrapulmonary manifestations of vasculitis.

Heart damage that may be severe and lead to cardiac failure or sudden death[69,73,74,76,77] results especially from eosinophilic myocarditis and much less commonly from coronary arteritis.[90] Cardiac involvement is often insidious and asymptomatic and, thus, may be recognized only when left ventricular failure and dilated cardiomyopathy have developed. Heart failure may require heart transplantation, but recurrence of eosinophilic vasculitis is possible in the transplanted heart. However, myocardial impairment as well as coronary arteritis may markedly improve with corticosteroid treatment, thus necessitating a strict cardiac evaluation in any patient with suspected CSS, including electrocardiogram, echocardiography, serum level of troponin, and magnetic resonance imaging of the heart.[91] Pericarditis with limited effusion at echocardiography is common in CSS; occasionally, pericardial effusion may be more important and give rise to tamponade. In contrast with the idiopathic HES, endomyocardial involvement is not a common feature. Patients with CSS are at greater risk of venous thromboembolic events.[92]

Peripheral neurologic involvement mainly consists of mononeuritis multiplex, present in 77% of patients,[69] or asymmetrical polyneuropathy, with sudden onset of painful, focal or multifocal weakness or sensory loss, generally in the lower extremities. Cranial nerve palsies and central nervous system involvement are rare. Digestive tract involvement present in 31% of cases[69] usually manifests as isolated abdominal pain, but intestinal or biliary tract vasculitis may be present. Other digestive manifestations include diarrhea, ulcerative colitis, gastroduodenal ulcerations, perforations (esophageal, gastric, intestinal), digestive hemorrhage, and cholecystitis. Cutaneous lesions present in about half of patients[69] mainly consist of palpable purpura of the extremities, subcutaneous nodules (especially of the scalp and extremities), erythematous rashes, and urticaria. Renal involvement present in 26% of cases is usually mild,[69] in contrast with the other ANCA-associated vasculitides, namely, microscopic polyangiitis and Wegener's granulomatosis.

Imaging

Pulmonary opacities corresponding to eosinophilic pneumonia represent the most typical abnormalities on chest x-ray and have been reported in large series with a frequency of 37%[69] to 72%.[73] The pulmonary opacities are usually noted at presentation, but the chest x-ray remains normal throughout the course of the disease in some patients. The pulmonary opacities usually consist of ill-defined opacities, sometimes migratory, transient, and of varying density.[73,77–80] In contrast to Wegener's granulomatosis, pulmonary cavitary lesions are exceptional. Pleural effusion (usually mild) and phrenic nerve palsy may be observed.

The pulmonary opacities on thin-section CT mainly consist of areas of ground-glass attenuation or air space consolidation, with peripheral predominance or random distribution (Fig. 61-5); less common findings include centrilobular nodules, bronchial wall thickening or dilation, interlobular septal thickening, hilar or mediastinal lymphadenopathy, pleural effusion, or pericardial effusion[27,79–81] (Fig. 61-6). When present, pleural effusion should lead one to consider cardiomyopathy as a possible cause. Because these abnormalities are nonspecific, a correct diagnosis of CSS was made on CT in only 44% of 111 patients with eosinophilic lung diseases.[27]

Laboratory Studies

Peripheral blood eosinophilia is a major feature of CSS that usually parallels the vasculitis activity. Blood eosinophils are generally between 5 and 20×10^9/L, but they

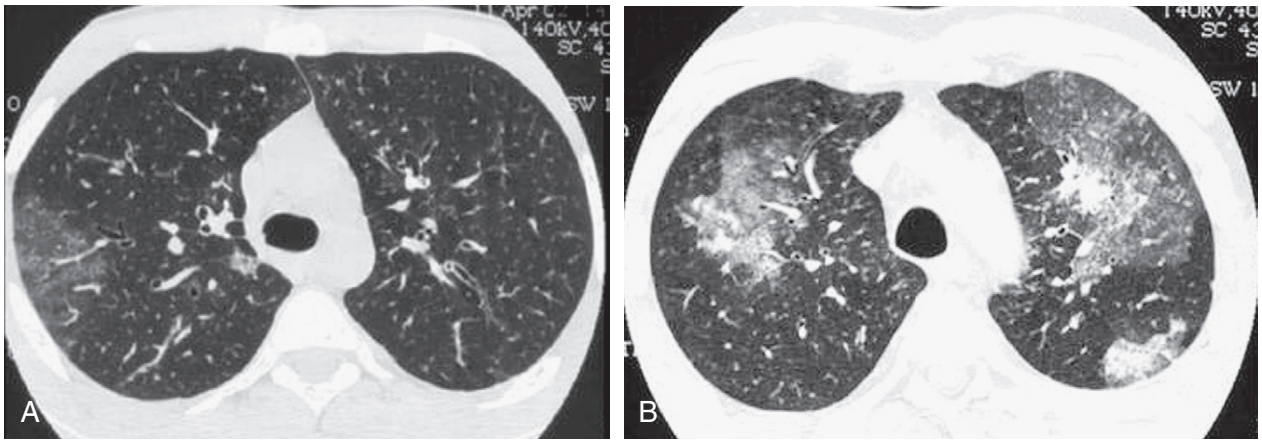

FIGURE 61-5 ■ CT scan of patients with Churg-Strauss syndrome shows ground-glass opacity of the right upper lobe (**A**) and bilateral central and peripheral opacities with varying density (**B**).

FIGURE 61-6 ■ Axial CT scan of a patient with Churg-Strauss syndrome, with lung consolidation and ground-glass opacities corresponding to eosinophilic pneumonia. In addition, pericardial effusion and bilateral pleural effusions are present due to cardiomyopathy.

may reach higher values.[69,73,77] Blood eosinophilia often disappears dramatically after the initiation of corticosteroid treatment (which may thus cause the absence of eosinophilia if blood tests are not done before starting corticosteroid treatment). Eosinophilia, sometimes greater than 60%, is found on BAL differential cell count[85] and in the pleural fluid when present.[86]

ANCA reported in 38% to 73% of patients are mainly perinuclear antineutrophil cytoplasmic antibody (p-ANCA) with myeloperoxidase specificity (much less often cytoplasmic antineutrophil cytoplasmic antibody [c-ANCA] with proteinase 3 specificity).[69,76,87,88] Serum IgE levels are markedly increased. The erythrocyte sedimentation rate and C-reactive protein level are increased, and anemia is common. High levels of urinary EDN have been reported, and these might represent an activity index of disease.[89]

Pathogenesis

The pathophysiology of CSS is not established. CSS may be considered as an autoimmune process involving T cells, endothelial cells, and eosinophils. Recent studies have identified possible defects in regulatory $CD4^+$ $CD25^+$ or $CD4^+$ $CD25^-$ T-cell lymphocytes (producing IL-10 and IL-2) in CSS (as compared with ICEP), possibly influencing progression and prognosis of disease.[93] Clonal $CD8^+/V\beta^+$ T cell expansions with effector memory phenotype and consistent with a hypothesis of persistent antigenic stimulation were found in peripheral blood lymphocytes by flow cytometry combined to analysis of T-cell antigen receptor (TCR)-γ gene rearrangement.[94] Some triggering or adjuvant factors (such as vaccines or desensitization) have been suspected to play a role in CSS.[95,96]

Although a family history of atopy and allergic rhinitis are often present, evidence of allergy (demonstration of specific IgE with corresponding clinical history) is present in less than one third of patients; when present, allergy in CSS mainly consists of perennial allergies especially to *Dermatophagoides*, with seasonal allergies less frequent than in asthmatic patients without CSS.[97] Genetic predisposition to develop CSS has been demonstrated in patients carrying the major histopathology complex DRB4 allele,[98] as well as the possibility of familial CSS.[99]

Other possible triggering factors include *Aspergillus*, allergic bronchopulmonary candidiasis, *Ascaris*, bird exposure, or smoked cocaine. Drug-induced eosinophilic vasculitis with pulmonary involvement has been reported in the past with sulfonamides used together with antiserum, and later with diflunisal,[100] macrolides,[101] and diphenylhydantoin.[102] CSS has also been reported in asthmatic patients treated with omalizumab, an anti-IgE antibody.[103–106]

The possible responsibility of leukotriene-receptor antagonists (montelukast, zafirlukast, pranlukast) in the development of CSS has generated much debate.[76,107–111] Although the association between leukotriene receptor antagonists and CSS is now established, there is

conflicting evidence whether it is the result of confounding by indication or a genuine causal association.[110] Whether the association is coincidental, whether some cases of smoldering CSS flare because of reducing oral or inhaled corticosteroids and/or adding leukotriene receptor antagonists, or whether these drugs really exert a role on the pathogenesis of the vasculitis is not established. However, CSS may occur following montelukast treatment in the absence of preexisting disease, may recur on rechallenge with leukotriene receptor antagonists, and may remit on withdrawal of this treatment without modifying the corticosteroid and/or immunosuppressive therapy.[108,110] We therefore consider that leukotriene receptor antagonists should be avoided in any asthma patient with eosinophilia and/or extrapulmonary manifestations compatible with smoldering CSS.

Diagnosis

The diagnosis of CSS may be difficult, because the clinician nowadays is more often faced with patients presenting with early and mild signs corresponding to the so-called formes frustes of CSS more or less suppressed by corticosteroid treatment for asthma, and which may later unmask especially when treatment is reduced or stopped.

The evolution of CSS usually follows three stages: asthma and rhinitis; tissue eosinophilia (such as a pulmonary disease resembling ICEP); and extrapulmonary eosinophilic disease with vasculitis. Diagnostic difficulties thus largely depend on the stage of disease at which the patient is seen. Although systemic disease is necessary to consider a diagnosis of CSS, it is extremely important that the diagnosis be established before severe organ involvement (especially cardiac) is present.

There are currently no established diagnostic criteria for CSS. Lanham and associates[73] have proposed three diagnostic criteria including (1) asthma, (2) eosinophilia exceeding 1.5×10^9/L, and (3) systemic vasculitis of two or more extrapulmonary organs. According to the classification criteria (which are not *diagnostic* criteria, however) of the American College of Rheumatology,[112] a sensitivity of 85% and a specificity of 99.7% are obtained if four or more of the six following criteria are present in a patient with proven systemic vasculitis: asthma; eosinophilia greater than 10% at differential blood cell count; mononeuritis (including multiplex) or polyneuropathy; fluctuating opacities on chest x-ray; bilateral maxillary sinusal abnormalities; or presence of extravascular eosinophils on a biopsy including a vessel. However, these diagnostic and classification criteria were proposed before ANCA were available. In the future, the presence of ANCA may probably be considered a major diagnostic criterion when present. A pathologic diagnosis of CSS is desirable, but not mandatory, in patients with characteristic clinical features and marked eosinophilia. The skin, nerve, and muscle are the most common sites where a pathologic diagnosis of vasculitis may be obtained.[69] Biopsy of the cutaneous lesions is the most common and simple procedure to obtain pathologic evidence of vasculitis. Lung biopsy is seldom done. Transbronchial biopsies usually do not show vasculitis or granulomata.

Differential Diagnosis

The borders separating CSS from the other ANCA-associated vasculitides and the other eosinophilic syndromes are sometimes difficult to establish. An eosinophilic variant of Wegener's granulomatosis has been described.[113] Concurrent CSS and pulmonary opacities and temporal arteritis (either with or without giant cells, either eosinophilic or not) has been described.[114] Distinguishing between mild CSS and ICEP with minor extrathoracic symptoms may also be difficult. Some mild vasculitis (non-necrotizing) is common on pathologic examination of the lung in patients with ICEP.[7] ICEP may further progress to CSS.[38] In addition, some cases of "limited" CSS have been reported[115] including those solely involving the lung or the heart. Formes frustes of CSS often consist of cases in which the disease has been controlled to a greater or lesser extent by corticosteroids given for asthma. Other cases are difficult to classify as either CSS or idiopathic HES. Careful clinical analysis, the presence of ANCA, the finding of a vasculitis and granulomas on biopsy, and molecular biologic analysis (in the cases of idiopathic HES) help in determining the final diagnosis.
