INTRODUCTION

The laboratory diagnosis of lower respiratory infection poses a number of major challenges. First, the diversity of etiologic agents (Table 18-1) imposes diverse specimen requirements and laboratory approaches. Second, lower respiratory secretions are usually obtained through the oropharynx, which is normally heavily colonized with 10^{10} to 10^{12} colony-forming units (CFU) of aerobic and anaerobic bacteria and yeasts per milliliter of volume (Table 18-2). Some of these organisms can be pathogens in the lower respiratory tract, but the vast majority of them often contaminate lower respiratory secretions collected for microbiologic examination.[1]

A third problem is that the oropharyngeal secretions, which normally contain only a few gram-negative bacilli (such as Enterobacteriaceae, *Pseudomonas, Acinetobacter*), often become colonized with as many as 10^7 CFU of gram-negative bacilli per milliliter in seriously ill patients requiring intensive care (Fig. 18-1),[2] patients treated with antibiotics after hospitalization for acute pulmonary inflammatory disease,[3] chronic alcoholics and diabetics,[4] the institutionalized elderly and chronically ill,[5] and hospitalized patients with acute leukemia.[6] Thus, aspiration of even minute amounts (0.1 to 1 μL) of oropharyngeal secretions by such patients can deliver a bolus of 10^4 CFU of gram-negative bacilli per milliliter to the tracheobronchial tree.[7] The distinction in such cases between gram-negative bacillary colonization of the upper respiratory tract and gram-negative pneumonia cannot be easily made by sputum examination and culture. However, the former predisposes to the latter, and prevention of gram-negative bacillary colonization of the oropharynx reduces the risk of gram-negative pneumonia.[7–9] Despite this association, it is important to note that upper respiratory colonization with potentially pathogenic microorganisms, such as gram-negative bacilli, may not be related to the actual etiologic agents of lower respiratory infection. Thus, a fourth problem with the laboratory diagnosis of lower respiratory infections is that sputum specimens contaminated with Enterobacteriaceae or *Staphylococcus aureus* from oropharyngeal secretions may obscure the diagnosis of pneumococcal pneumonia, anaerobic pleuropulmonary infection, or even tuberculosis.[10–12]

The effects of prior antimicrobial therapy on bacteriologic test results in patients with primary pneumonia constitute a fifth problem. Spencer and Philp[13] found that not a single sputum specimen from 52 patients who had received antimicrobial therapy before hospitalization for primary pneumonia grew either *Streptococcus pneumoniae* or *Haemophilus influenzae,* whereas sputum specimens from 22 of 24 patients (92%) who had not received antimicrobial therapy before hospitalization for primary pneumonia did grow either *S. pneumoniae* (15 patients) or *H. influenzae* (7 patients). Presumably, sputum specimens from many of the patients who had been treated with antimicrobials would have grown either of these two organisms, given that they are primary pathogens in community-acquired pneumonia (CAP).

The last problem is that of proper sputum collection. Active participation of patients, when they are able to cooperate, is seldom requested but essential to produce

TABLE 18-1. Well-Known Microbial Pathogens That Cause Lower Respiratory Tract Infections

BACTERIA

sputum specimens of good quality for microbiologic testing. The importance of proper sputum collection was documented by Laird 100 years ago in studies on the yield of *Mycobacterium tuberculosis* according to the appearance and cellular composition of the sputum examined (Table 18-3).[14] Once collected, the specimen should be delivered promptly to the laboratory for processing to prevent overgrowth of contaminating organisms.

SPECIMEN SELECTION AND COLLECTION

General guidelines for the types of specimen required and available tests according to etiologic agent are listed in Table 18-4. Expectorated sputum is the specimen most frequently obtained for the laboratory diagnosis of lower respiratory tract infection.[15,16] The first requirement for collection of a sputum specimen is an alert and cooperative patient who can rinse out his or her mouth with water or even brush his or her teeth before being instructed to produce a specimen resulting from a deep cough. The patient then must be encouraged to cough deeply to expectorate a specimen of lower respiratory secretions. Specimens are to be collected in sterile, leakproof, screw-capped containers. Containers with specimens from patients with suspected tuberculosis should be transported in a water-tight plastic biohazard bag to prevent contact with outside surfaces of the container.

Although a single sputum specimen may be sufficient for establishing the diagnosis of an acute bacterial inflammatory process, collection of a series of two or three single early morning sputum specimens obtained on successive days is recommended for patients suspected of having mycobacterial or fungal infections. Pooled specimens collected cumulatively over 12 to 24 hours are not satisfactory for this purpose because of excessive contamination with other bacteria. In patients with nonproductive cough or suspected mycobacterial, fungal, or *Pneumocystis jirovecii* infections, it may be helpful to induce sputum production with an inhaled aerosol of

hypertonic salt solution (3% to 10%). Specimens to be cultured for mycobacteria, if sent to a reference laboratory for processing, should be shipped refrigerated or treated first with cetylpyridinium chloride and sodium chloride in a screw-capped container,[17] which must be placed in a metal can with absorbent material and then packaged in an approved mailing container according to local specimen transport regulations. Although the recovery of fungi is optimal from cultures of fresh specimens, most clinically significant fungi appear to survive storage of 16 days or longer.[18] Specimens for viral cultures should be shipped refrigerated but not frozen, whereas specimens for chlamydial culture should be placed into sucrose-phosphate (2SP) medium and shipped frozen.

Sputum should be transported to the laboratory promptly after its collection to avoid overgrowth of contaminating flora and to improve isolation rates of pathogenic bacteria. Jefferson and associates[19] compared the results of respiratory specimens cultured immediately after specimen collection and after 2 to 5 hours of transportation, and found that fewer cultures yielded staphylococci, pneumococci, and gram-negative bacilli in the delayed group. Similarly, Penn and Silberman[20] found that organisms observed microscopically on Gram-stained smears of sputum specimens and their relative numbers in cultures changed dramatically between processing within an hour of collection and processing

BAL, bronchoalveolar lavage; CF, complement fixation; DFA, direct fluorescent antibody; EIA, enzyme immunoassay; GMS, Gomori methenamine silver; H & E, hematoxylin and eosin; ID, immunodiffusion; IFA, indirect fluorescent antibody; KOH, potassium hydroxide; LA, latex agglutination; MI, micro-immunofluorescence; PCR, polymerase chain reaction; RIA, radioimmunoassay; TMA, transcription-mediated amplification; TTA, transtracheal aspirate.

Data from Miller JM: A Guide to Specimen Management in Clinical Microbiology, 2nd ed. Washington, DC: ASM Press, 1998; and Waites KB, Saubolle MA, Talkington DF, et al: Cumitech 10A: Laboratory Diagnosis of Upper Respiratory Tract Infections (Sharp SE, coord ed). Washington, DC: ASM Press, 2006.

after overnight refrigeration. While there were no significant differences in the culture results between the immediate and delayed cultures in this study, the loss of reliable microscopic features had significant impact on the interpretation of culture results.

Since sputum is usually not obtainable from children under 5 years of age, one or more invasive approaches may be necessary to obtain specimens in such cases. Specimens may include blood, pleural fluid, tracheal aspirate through a catheter inserted by direct laryngoscopy, and, in critically ill children, percutaneous lung aspirate.[16] Unfortunately, cultures of nasopharyngeal secretions or tracheal aspirates obtained via a catheter passed through the nose or mouth may be misleading because of frequent isolation of potentially pathogenic bacteria from the throats of healthy children. For example, *H. influenzae* has been recovered from selective cultures of the throat in 80% of healthy children.[21]

As shown in Table 18-4, there are several other instances in which examination of specimens other than sputum is indicated. For example, sputum is not a suitable specimen for the diagnosis of anaerobic pleuropulmonary disease because of the predominantly anaerobic composition of the bacterial flora in the oropharynx that may contaminate the specimen. In such instances, consideration may be given to obtaining transtracheal aspirates for culture. If saline or Ringer's lactate solution is instilled during transtracheal aspiration to facilitate specimen collection, one must be certain that the solution does not contain a preservative or bacteriostatic agent. Aerobic and anaerobic cultures of protected catheter brushes have also been recommended for identification of organisms causing anaerobic pleuropulmonary disease.[22] However, Bordelon and coworkers[23] found a poor correlation between the bacteriology of paired specimens obtained by protected catheter brush and by transtracheal aspirate in this setting. For detection of respiratory viruses, throat swabs or nasopharyngeal aspirates or washings are preferred over sputum samples.[24] Throat swabs may also be used for detecting *Chlamydophila pneumoniae,*[25–28] *Mycoplasma pneumoniae,*[28–31] *Legionella* species,[28] and respiratory viruses[32–37] by nucleic acid amplification assays. Blood cultures may be obtained in cases of suspected acute bacterial pneumonia but are positive only in 3% to 37% of cases.[38] If pleural fluid is present, thoracentesis should be performed to obtain fluid for aerobic and anaerobic cultures. A positive culture from blood or pleural fluid has a high predictive value in establishing the microbial cause of the infection. Urine may also be a useful specimen in certain situations. Pneumococci, for example, may be recovered from urine cultures in as many as 38% of patients with pneumococcal pneumonia.[39] Urine may also be tested for the presence of pneumococcal[40] and *Legionella pneumophila*[41,42] antigens. However, because antigenuria may persist for weeks or months following an acute bacterial infection, its presence may be indicative of past rather than current infection. Fungal antigen tests of urine are also available for diagnosis of histoplasmosis and blastomycosis.[43,44] Serologic tests of acute and/or convalescent serum samples are useful for the diagnosis of pulmonary infections caused by *Legionella* species, *M. pneumoniae, Chlamydia trachomatis, Chlamydophila psittaci, C. pneumoniae,* viruses, and fungi. These diagnostic approaches are discussed further in the Serologic Tests section of this chapter.

When easily obtained samples such as sputum, blood, and urine do not yield a diagnosis, more invasive techniques may be necessary. Bronchoscopy offers a safe approach to the collection of a specimen, although the inevitable contamination of the lower respiratory tract by oropharyngeal flora during insertion of the bronchoscope has generally invalidated the results of bacterial cultures obtained by suction through the inner channel or by an unprotected brush. An alternative fiberoptic bronchoscopic technique to obtain uncontaminated lower respiratory secretions is to use a distally occluded, telescoping, protected catheter brush.[45] Several studies have demonstrated the high sensitivity and specificity of quantitative cultures of secretions obtained by a protected brush in establishing the diagnosis of nosocomial pneumonia when the criterion of greater than 10^3 CFU/mL is used to define a positive or clinically significant culture result.[46,47]

Bronchoalveolar lavage (BAL) is widely used for the diagnosis of nonbacterial pulmonary infections in immunocompromised patients, but in more recent years its use has been expanded to include diagnosis of bacterial pneumonia, especially for nosocomial cases.[46–48] In most instances, paired specimens are obtained by both protected catheter brush and BAL, with numerous studies in the literature comparing the results of culture of these two types of specimens. In patients with CAP requiring admission to the hospital, use of these procedures has been shown to provide microbiologic diagnoses that are not obtainable otherwise by noninvasive means.[49] In some patients, these procedures have yielded additional pathogens not obtainable by noninvasive approaches. Much work has been done also with the use of BAL for the diagnosis of ventilator-associated pneumonia.[47,49] One of the problems in assessing the literature on the value of BAL culture results is the varied criteria used by different investigators to define a positive result. These criteria have included (1) intracellular organisms present in more than 7% of the cells and greater than 10^5 CFU/mL of unconcentrated lavage fluid, and (2) 10^5 CFU/mL of concentrated lavage fluid.[46,47] Consequently, valid comparison of published studies must be made cautiously. Additional variables include the different criteria in selecting study patients eligible for evaluation, and inclusion or exclusion of patients receiving prior antimicrobial therapy. Although the results of cultures from protected catheter brushes and BAL specimens are quantitatively similar, Meduri and Baselski[49] concluded that BAL specimens provided a larger and more representative volume of lower respiratory tract secretions than the protected catheter brushes, allowing microscopic analysis of the cytocentrifuged BAL fluid to identify the type of bacteria present and to demonstrate the presence of an active inflammatory response (neutrophils with intracellular organisms). The study also showed that the

diagnostic value of breakpoints of bacterial growth (i.e., 10^3 to 10^5 CFU/mL) depended not only on the type of microbiologic processing used but also on the relationship of two variables: the concentration of pathogens present in the BAL fluid, and the degree of contamination of the bronchoscopic channel through which lavage fluid was injected and aspirated. Other variables affecting the sensitivity of BAL specimens include the volume of lavage fluid injected and the volume of fluid retrieved. In contrast, diagnostic specificity depends greatly on techniques used to minimize contamination of the specimen by upper respiratory flora, such as discarding the first aliquot of aspirated fluid.

Topical anesthetics used for bronchoscopy can exhibit in vitro antimicrobial properties. However, this antimicrobial effect may be negligible in vivo because of the relatively short period between exposure of bronchial aspirates to lidocaine and inoculation of BAL specimens onto culture media.[50]

Finally, more aggressive techniques, such as transbronchial lung biopsy, video-assisted and open-lung biopsy, may be necessary for definitive diagnosis of pulmonary infections in certain populations, such as immunocompromised hosts. Fortunately, the use of such approaches has become less frequent since the advent of BAL and protected catheter brushes using fiberoptic bronchoscopic techniques. BAL often provides an alternative to biopsy procedures in the diagnosis of opportunistic lung infections[51] or when treatment fails.[48]

When deemed necessary, open-lung biopsy or video-assisted thoracoscopy provides the most direct approach for obtaining adequate amounts of tissue for histopathologic examinations and microbiologic testing. Such specimens provide a significant amount of information because they may contain evidence of the entire pathologic process. Material from an abscess should include not only pus but also tissue from the wall of the abscess. Pus should be withdrawn into a sterile syringe, which can be transported directly to the laboratory, or the contents may be injected into an anaerobic vial for transport to the laboratory. The use of a swab to obtain pus from an abscess is inadequate, and this practice is strongly discouraged. Ideally, a surgical specimen should be bisected aseptically in the operating room, with one half of the specimen submitted to surgical pathology and the other half placed in a sterile, leak-proof, screw-capped container for transport to the laboratory for processing.

Regardless of the particular invasive approach selected for obtaining specimens from immunocompromised hosts, such specimens are obtained usually at some risk and considerable expense to the patient. Therefore, laboratory test protocols such as that shown in Figure 18-2 should be established for processing specimens obtained by these invasive procedures to maximize the diagnostic yield and avoid the need to repeat such procedures. The surgical pathologist should work closely with the clinical microbiologist to ensure that specimen requirements for each laboratory are met and unnecessary duplication of specific examinations is avoided, especially when the amount of specimen material obtained is limited and must undergo multiple tests.

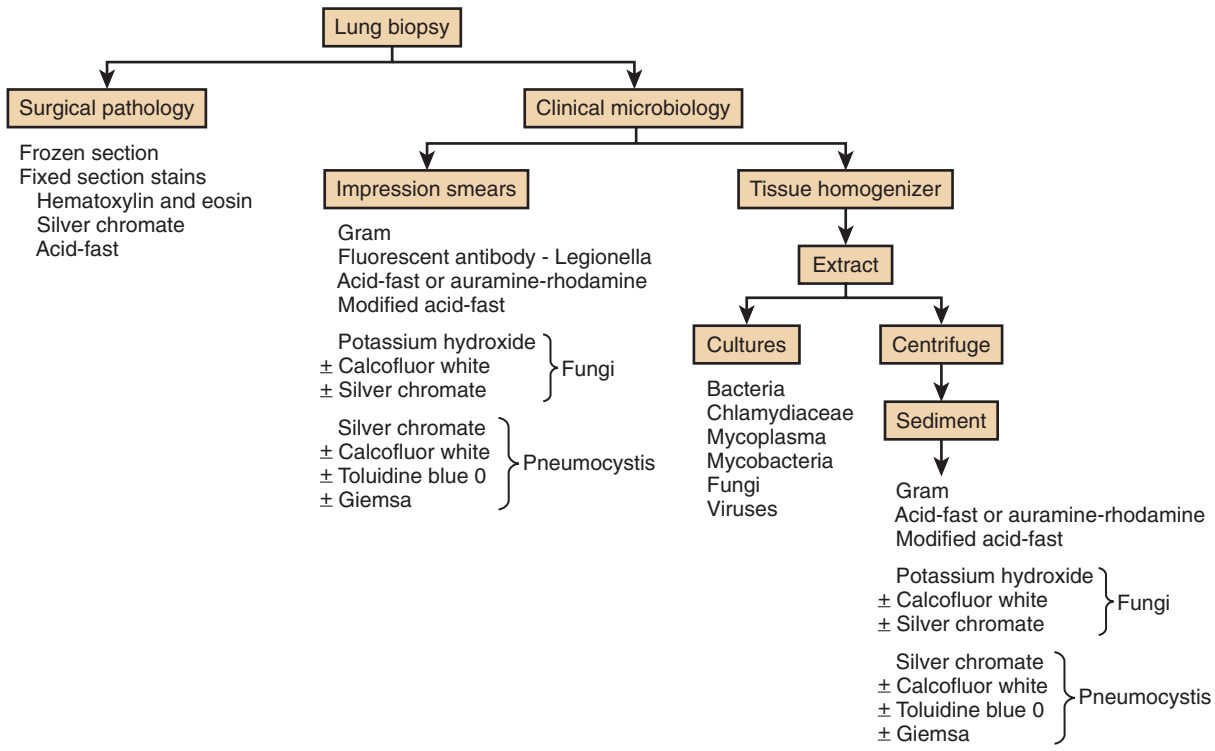

FIGURE 18-2 ■ Suggested protocol for processing video-assisted or open-lung biopsy specimens obtained from immunosuppressed patients. Variations on this protocol may be applicable in certain settings.

DIRECT EXAMINATION OF SPECIMENS

Microscopic or immunologic examination of specimens may offer a rapid approach to the diagnosis of lower respiratory infection and is an essential component of any laboratory protocol for processing BAL fluids and lung biopsy specimens from immunocompromised patients. The value of microscopic examination of the sputum to identify the nature of the inflammatory process was demonstrated in a beautiful series of illustrations in *Das Sputum,* by von Hoesslin, in 1921.[52] Similarly, Chodosh[53] and Baigelman and Chodosh[54] have urged examination of wet preparations of sputum stained with crystal violet to identify eosinophils and differentiate allergic from nonallergic inflammation. Microscopic examination of sputum cells has also been widely adopted as a screening procedure to determine the acceptability of a specimen for bacterial culture.[14]

The first step in the screening process is to select a purulent or opalescent area of the specimen and to transfer this portion of the sample to a sterile Petri dish. This sample is then used to prepare a wet mount or a Gram-stained smear for microscopic examination. The Gram stain is a rapid staining technique that differentiates bacteria based on the ability of their cell wall to retain a primary dye (typically crystal violet) following treatment with an iodine mordant and solvent. Bacteria that retain the dye are termed *gram positive,* while those that become decolorized and stain only with the subsequent counterstain (basic fuchsin or safranin) are termed *gram negative.* This staining method also stains squamous epithelial cells (Fig. 18-3A), ciliated columnar epithelial cells (see Fig. 18-3B), and alveolar macrophages or histiocytes (see Fig. 18-3C), which can be readily differentiated under high-power magnification (oil immersion, ≥ 630×) by an experienced microscopist. The presence of numerous squamous epithelial cells (>25 per low-power field, ≤ 100× magnification; Fig. 18-4AB) is indicative of oropharyngeal contamination. Such specimens should not be cultured for bacteria, and another specimen should be requested.

In contrast, specimens demonstrating a preponderance of polymorphonuclear leukocytes, ciliated columnar epithelial cells, or alveolar macrophages with few, if any, squamous epithelial cells (<10 per low-power field; see Fig. 18-4C) represent lower respiratory secretions that warrant further examination under high-power field and bacterial culture. The maximum recommended number of squamous epithelial cells per low-power field determining specimen acceptability for bacterial culture has been disputed in the literature.[55] However, Geckler et al.[56] found good overall agreement between the results of bacterial culture of paired sputa and transtracheal aspirates when the sputum contained fewer than 25 squamous epithelial cells per low-power field. The number of polymorphonuclear leukocytes had little effect on this correlation and should not be used alone to determine specimen adequacy for culture. The presence of alveolar macrophages is a more specific indicator of lower respiratory secretions than leukocytes and is more likely to be associated with a significantly lower incidence of oropharyngeal contamination.[57] These criteria have been established primarily to assess the quality of expectorated sputum samples suitable for bacterial culture. Similarly, endotracheal aspirates from adults and children should not be cultured for bacteria if the screening Gram-stained smears show no organisms or

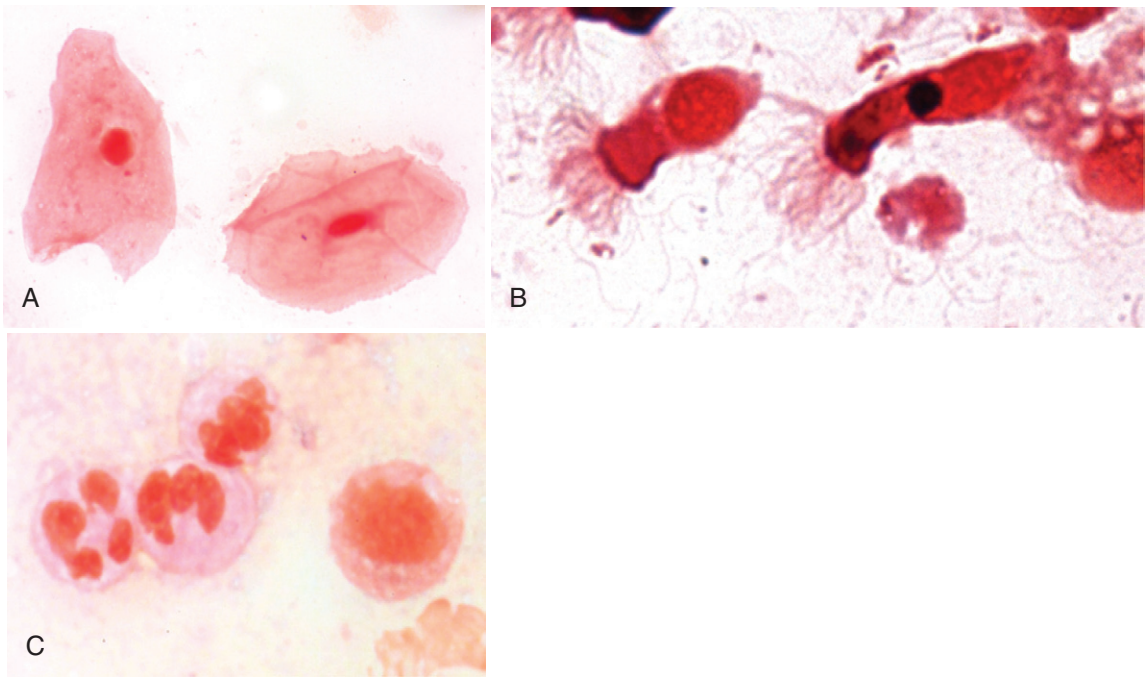

FIGURE 18-3 ■ Gram-stained appearance of typical cells in sputum smears (original magnification, ×630). **A,** Squamous epithelial cells. **B,** Ciliated columnar epithelial cells. **C,** Alveolar macrophage and three polymorphonuclear leukocytes.

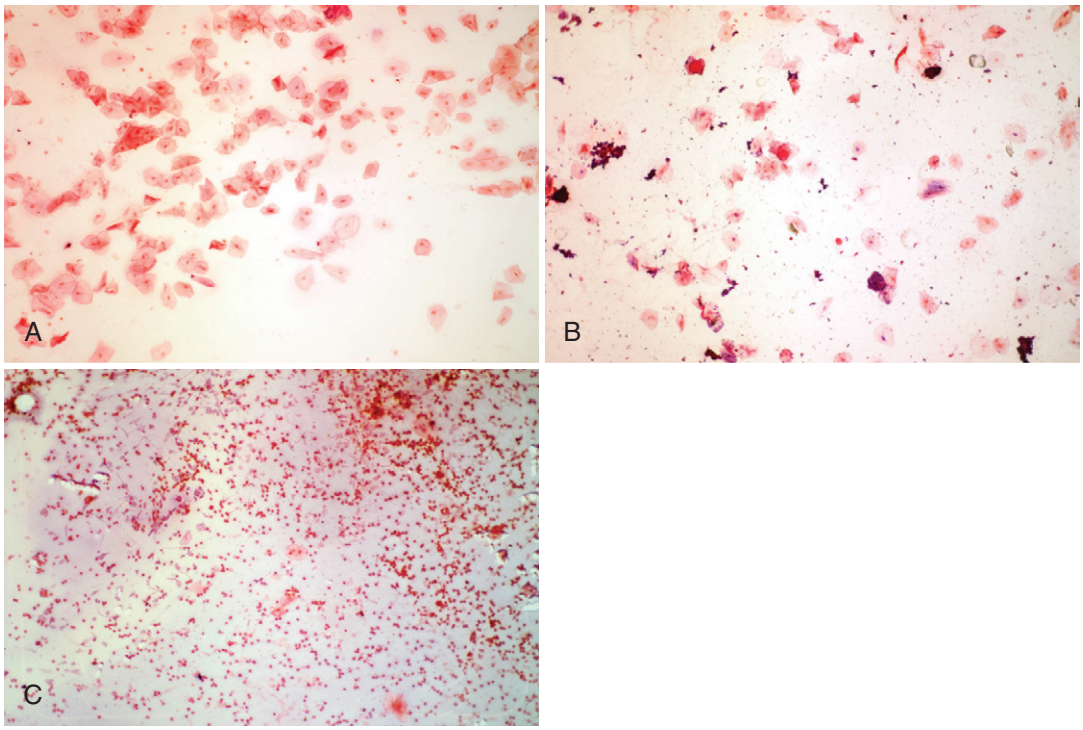

FIGURE 18-4 ■ Gram-stained smears of representative sputum specimens (original magnification, ×100; low-power field). **A,** <10 leukocytes, >25 epithelial cells. **B,** 10 to 25 leukocytes, >25 epithelial cells. **C,** >25 leukocytes, <10 epithelial cells.

leukocytes present.[58,59] Morris et al.[58] further showed that cultures for bacteria should not be performed if more than 10 squamous epithelial cells are present per low-power field in endotracheal aspirates from adults. However, cytologic screening to determine specimen acceptability is not indicated in respiratory specimens submitted for mycobacterial, fungal, and viral cultures because of the following reasons: (1) decontamination of these specimens is needed prior to these cultures, (2) selective culture media are used, and (3) little doubt exists regarding the clinical importance of mycobacterial, deep fungal, and viral isolates when they are present. Regardless of the type of cultures requested, direct correlation exists between quality of a given specimen and the yield of cultures (see Table 18-3).

Provided a specimen is acceptable for bacterial culture on the basis of cytologic screening, the smear should then be examined under high-power field to determine any predominance of a specific morphologic type of bacteria present. In general, high-power fields without any squamous epithelial cells and with at least three nonsquamous cells (e.g., polymorphonuclear leukocytes, macrophages, ciliated epithelial cells) should be examined for each stained smear.

In Gram-stained smears, *S. pneumoniae* (i.e., pneumococci) appear as lancet-shaped gram-positive diplococci. In assessing patients with acute CAP, Rein et al.[60] found that a preponderant flora of 10 or more gram-positive lancet-shaped diplococci per oil immersion field on a Gram-stained smear of sputum correctly predicted the presence of pneumococci in corresponding cultures in 90% of cases, with a sensitivity and specificity of 62% and 85%, respectively. As the criteria for defining the presence of pneumococci in the sputum Gram-stained smears were lowered, sensitivity increased but specificity decreased. Similar levels of sensitivity of Gram-stained smear have been reported by others in identifying pneumococci as well as *H. influenzae* in sputum specimens from patients with acute CAP.[61,62] For the diagnosis of pneumococcal pneumonia, a combination of Gram-stained smear and culture of sputum can yield the correct diagnosis in more than 80% of patients who received less than a 24-hour duration of effective antibiotic therapy.[63]

Diagnostic sensitivity and specificity also vary according to how strictly the criteria are set for defining a positive Gram-stained smear. If the presence of any lancet-shaped gram-positive diplococci is used as the criterion for positivity with *S. pneumoniae,* then the sensitivity of Gram-stained smear is excellent, but specificity is nil. Problems with such nonspecific criteria used by inexperienced microscopists such as house staff and medical students in examining Gram-stained smears of sputum were illustrated by several studies.[64,65] The use of the quellung reaction, in which *S. pneumoniae* capsule-specific antibodies enhance microscopic identification, has significantly improved the accuracy in detecting the presence of pneumococci in sputum.[66] However, the quellung reaction is subject to observer bias and has not been used widely in clinical laboratories.

Direct examination of sputum for identifying other pathogens causing acute bacterial pneumonia in adults, such as *H. influenzae, Moraxella catarrhalis,* and *Neisseria meningitidis,* may also be problematic. The presence of many pleomorphic, slender gram-negative

coccobacilli, especially within leukocytes, suggests the diagnosis of *H. influenzae.*[67–69] However, *H. influenzae* can often be found in the upper respiratory tract of asymptomatic patients,[21] and available data showed that Gram-stained smears of sputum are of variable diagnostic value.[67,68] Gram-stained smears of transtracheal aspirates have a higher diagnostic value in the diagnosis of *H. influenzae* pneumonia,[67,69] and should be considered when clinically indicated.

Similarly, *M. catarrhalis* and *N. meningitidis* may often be found in the upper respiratory tract. *Moraxella catarrhalis* is a normal commensal in this location, and nasopharyngeal carriage of *N. meningitidis* may range from 10% in healthy adults to 70% among healthy military recruits.[70] Their role as etiologic agents of pneumonia is strongly suggested by the finding of large numbers of gram-negative diplococci located within and outside of polymorphonuclear leukocytes in sputum specimens.[71–73] Furthermore, the correlation between sputum smear with these findings and transtracheal aspirate cultures is excellent.[73] However, *M. catarrhalis* cannot be distinguished from *N. meningitidis* on the basis of their microscopic morphology in Gram-stained smears of sputum specimens and should only be described morphologically (e.g., gram-negative diplococci) while awaiting culture results.

Because sputum microscopy (and subsequent culture) can give misleading results, the diagnosis of *Haemophilus, Moraxella,* or meningococcal pneumonia can only be confirmed by invasive techniques. And because invasive techniques are infrequently performed to identify the etiologic agents of acute CAP, the sensitivity and specificity of sputum Gram-stained smears cannot be determined reliably in such cases. Nevertheless, the presence of large numbers of organisms, intracellularly and extracellularly, resembling *Haemophilus, Moraxella,* or *Neisseria* in sputum Gram-stained smears should lead the clinical laboratory to identify these organisms in cultures and to test them for susceptibility to various commonly used antimicrobial agents.

A similar problem occurs in trying to distinguish between colonization and superinfection by gram-negative bacilli. Tillotson and Finland[3] found that the organisms considered responsible for bacterial secondary infection were present in moderate to large numbers in Gram-stained smears of sputum. Similarly, in a study of hospitalized patients with pneumonia, Noone and Rogers[74] found neutrophils and large numbers of gram-negative bacilli present in lower respiratory secretions that were collected by tracheobronchial suction and yielded 10^7 to 10^{10} CFU of gram-negative bacilli per milliliter. However, up to 10^8 CFU of gram-negative bacilli per milliliter may be found in respiratory secretions of patients on mechanical ventilation in intensive care unit without evidence of pneumonia,[2] and about 10^7 CFU of gram-negative bacilli per milliliter have been found in saline gargles from aspiration-prone patients.[4]

In summary, the Gram-stained smear is an essential and necessary part of the examination of sputum, for determining the quality and acceptability of sputum specimens for bacterial culture and for providing a rapid assessment of the most likely etiologic agent of the pneumonia. However, improper preparation and interpretation of Gram-stained smears by untrained health care providers do pose a serious limitation on the value of this diagnostic procedure.[60,75]

The Gram-stained smear may be used to assess the adequacy of specimens other than sputum, such as endotracheal aspirates from adults or children.[58,59] The Gram-stained smear of transtracheal aspirates is both sensitive and specific for the diagnosis of bacterial pneumonia and is especially useful in indicating the presence of anaerobic infections. Gram-stained smears of cytocentrifuged BAL fluids can also be helpful in identifying the type of bacteria causing the infection as well as the type of inflammatory reaction present, particularly with the finding of neutrophils with intracellular organisms.[49]

Many organisms, including the mycobacteria and *Legionella,* do not stain well or at all with Gram stain, and visualization requires the use of alternative methods. In particular, mycobacteria are visualized classically using fluorochrome and carbolfuchsin stains. Carbolfuchsin or "acid-fast" stains take advantage of the fact that most *Mycobacteria* species retain the primary carbolfuchsin stain following decolorization with acid-alcohol due to the high lipid content of their cell walls (i.e., they are acid-fast). Other bacteria will decolorize with this method and do not obscure the identity of the acid-fast organisms. Alternatively, fluorochrome stains selectively highlight mycobacteria with a fluorescent dye such as auramine-rhodamine. Microscopic examination of respiratory secretions stained with both fluorochrome and carbolfuchsin stains is about 50% sensitive and 99% specific in detecting *M. tuberculosis* in most clinical laboratories.[76,77] However, the percentage of smear-negative but culture-positive cases varies according to the severity of disease, ranging from 65% in patients with minimal disease to less than 10% in those with advanced disease, with overall incidence of 26% among hospitalized patients with pulmonary tuberculosis.[78] Among those initially smear-negative but culture-positive cases, 20% became smear-positive and culture-negative between 4 and 20 weeks after initiation of therapy. Thus, diagnostic value of the acid-fast stained smear is highly dependent on the types of populations studied and the prevalence of tuberculosis in those populations. Another variable influencing the sensitivity of the acid-fast stained smear is the relative centrifugal force used for concentration of the specimen.

Screening a slide for mycobacteria must be done in a careful and consistent manner. Approximately 10,000 acid-fast bacilli per milliliter of sputum must be present to be visualized under light microscopy using an acid-fast stain,[77] and detection can be time consuming and laborious. Fluorescence microscopic examination of sputum smears stained with the auramine-rhodamine fluorochrome rather than an acid-fast stain is more efficient in routine screening for mycobacteria in the diagnostic laboratory. Within the same amount of time, a much larger smear surface area can be examined with a 25× lens objective under fluorescence microscopy compared with the 100× lens objective required for screening

carbolfuchsin-stained smears under light microscopy. Because of the improved speed and ease of this laboratory technique, fluorescence microscopic examination is the method of choice for screening mycobacteria in sputum smears in high-volume clinical laboratories.

Immunofluorescence examination by direct fluorescent antibody (DFA) staining is an alternative method for direct visualization of organisms. The diagnosis of legionellosis is usually made by a combination of direct immunofluorescence examination and culture of respiratory specimens, and serologic testing of serum and urine. DFA staining can be done on sputum, transtracheal aspirate, bronchial washing, and lung tissue specimens, with sensitivities ranging from 25% to 66% for the diagnosis of *L. pneumophila* pneumonia, and specificities of more than 94%.[79] Both clinical and technical variables account for the broad range of sensitivity of this test, and accuracy of this method for detection of pneumonia due to other *Legionella* species is less precisely known. In the absence of other supporting evidence, a positive DFA result is generally not accepted as sufficient for the diagnosis of *Legionella* infection, and other confirmatory measures should be considered.

DFA has also been found to be sensitive and specific in detecting *C. trachomatis* in conjunctival and nasopharyngeal specimens from infants with conjunctivitis and pneumonia,[80,81] and has also been applied to respiratory secretions for diagnosis of respiratory infections due to respiratory syncytial virus (RSV), influenza A and B viruses, parainfluenza viruses, adenoviruses, and measles virus.[24] Although somewhat less sensitive than tissue culture techniques (as described later), these immunofluorescence microscopic methods offer rapid detection and a diagnostic approach for viral pathogens for which conventional viral culture techniques are tedious or not available.

Another method for direct examination makes use of phase-contrast microscopy of respiratory secretions mixed with 10% potassium hydroxide solution containing 10% glycerin. This important technique may provide immediate identification of *Blastomyces dermatitidis, Coccidioides immitis, Cryptococcus neoformans,* and *Aspergillus* species directly from clinical samples.[82] Calcofluor white, a fluorochrome that binds to chitin and cellulose present in fungal cell wall, can be added to potassium hydroxide or used alone to provide better delineation of fungal elements, including *P. jirovecii.*[83–85] Although calcofluor white stain may be used to detect *P. jirovecii,* other stains such as Giemsa, silver-based, or direct immunofluorescence are typically used for this purpose. Wolfson et al.[86] found the direct immunofluorescent monoclonal antibody staining method to be more sensitive and to require less screening time than the Giemsa staining method for detecting *P. jirovecii* in induced sputum and BAL specimens obtained from patients with human immunodeficiency virus. Cregan et al.[87] observed sensitivities of 95% with rapid silver stain, 97% with direct immunofluorescence, 97% with indirect immunofluorescence, and 92% with Diff-Quik (a modified Giemsa stain) for detecting *P. jirovecii* in sputum. All detection methods were slightly less sensitive for BAL fluid than sputum specimens. Kim et al.[83] found the rapid calcofluor white stain to be more sensitive than a modified methenamine silver stain in detecting *P. jirovecii* in various respiratory specimens, including BAL fluid, lung biopsy, induced sputum, expectorated sputum, tracheal secretions, and bronchial secretion.

As illustrated in Figure 18-2, direct microscopic examination is an essential component of the laboratory protocol for examining lung biopsy tissue specimens obtained from immunosuppressed patients. A variety of stains may be utilized depending on the organism(s) suspected, amount of tissue available, and capability of the processing laboratory. Like other respiratory specimens, the auramine-rhodamine fluorochrome stain is preferred over carbolfuchsin stains for screening mycobacteria in smears of lung tissue homogenate. Similarly, silver-based methods and calcofluor white may be used for staining fungi in tissue, although some prefer the toluidine blue O, Giemsa, or a fluorescent monoclonal antibody stain to detect *P. jirovecii.* Concentration of lung tissue homogenate by centrifugation has been shown to enhance the detection of *P. jirovecii* cysts (Table 18-5).[88] A laboratory protocol similar to that proposed for lung tissue samples should be followed when examining BAL fluids from immunosuppressed patients.

CULTURES, MICROBIAL ANTIGEN DETECTION, AND SUSCEPTIBILITY TESTING

Microbial culture of respiratory specimens should be performed to provide definitive identification of the pathogens and to permit determination of their susceptibility to antimicrobial agents. Numerous approaches to culture are available, with many culture media suitable for cultivation of particular groups of microorganisms. Such media may be "nonselective" to support the growth of a wide variety of organism or be "selective" to contain substances that favor growth of certain organisms to the exclusion of others. Media can also allow the differentiation of two different organisms growing on the same media (i.e., differential or indicator media). Selection of media optimal for isolation of suspected pathogens is a complex process and is beyond the scope of this chapter.

Bacteria

Over the years much laboratory effort has been directed to improving the sensitivity and specificity of bacterial cultures of sputum. In 1971, Barrett-Connor[11] suggested that routine sputum culture for the diagnosis of bacterial pneumonia had become a "sacred cow" (i.e., a laboratory test that is so highly regarded that it is not open to criticism). She challenged this notion by showing that only 45% of patients with bacteremic pneumococcal pneumonia had pneumococci isolated from their sputum cultures, whereas 27% of patients had moderate to heavy growth of another potential pathogen in these cultures. We now better understand how careful specimen collection, cytologic screening of specimens to obviate culture of those contaminated with oropharyngeal secretions, and use of the results of the Gram-stained smear to guide identification of isolates in culture all contribute to the diagnostic value of sputum culture in acute pneumococcal pneumonia. Anaerobic or microaerobic culture has also been shown to enhance the detection of pneumococci.[89,90] Usually, pneumococci can be isolated in culture when the organism is present at greater than 10^7 CFU/mL of sputum in acute pneumococcal pneumonia proven by cultures of transtracheal and bronchial aspirates.[91] However, such prediction of culture positivity of transtracheal aspirates based on number of organism present in expectorated sputum may not be reliable, due to differences in the laboratory methods used to process sputum.[10] Study of quantitative cultures of washed sputum specimens in which oropharyngeal contaminants were found in mean numbers of 10^4 CFU/mL and bacterial pathogens were present in mean numbers of 10^6 CFU/mL showed that few pathogens, such as *S. aureus, Klebsiella* spp., and *Pseudomonas aeruginosa,* were isolated from expectorated washed sputum but not from the corresponding transtracheal aspirate when they are present at 10^6 CFU or greater per milliliter of sputum.[92]

Due to the impracticality of the washed sputum–quantitative culture technique, equivocal results obtained from sputum cultures of hospitalized patients with serious CAP, or risks of opportunistic infections, diagnosis of bacterial pneumonia may occasionally require culture of clinical specimens obtained by invasive methods. Such samples include pleural or empyema fluids, transtracheal aspirates, and BAL. These should be cultured for aerobic, facultatively anaerobic, and anaerobic bacteria. Similar cultures should be performed on protected catheter brushes, although there is no universal agreement on the value of anaerobic culture.[23] In general, bacteria present in quantities of greater than 10^3 CFU/mL in cultures of protected catheter brushes[46] and in quantities of greater than 10^4 CFU/mL in cultures of BAL fluids[49] should be identified and tested for their susceptibility to appropriate antimicrobial agents.[93] Blood may also be cultured, although the yield in CAP is only up to 37% and less than 25% in nosocomial pneumonia.[38,94,95]

Specific pathogens require special culture media and incubation conditions. For example, respiratory specimens demonstrating a predominance of intra- and extracellular gram-negative diplococci in Gram-stained smears should be cultured on modified Thayer-Martin medium for the presence of *Neisseria* species. However, such culture medium is inhibitory to other potential pathogens such as *M. catarrhalis,* emphasizing the continued need for using nonselective culture media to detect other possible pathogens.

Legionella species also require special culture conditions. They can be recovered from lung tissue and other specimens of normally sterile anatomic sites when cultured on buffered charcoal yeast extract (BCYE) medium supplemented with α-ketoglutarate (BCYE-α). However, selective BCYE media containing polymyxin B, rifabutin, and either cefamandole (BMPA medium) or vancomycin (BVPA-α medium) are needed to recover *Legionella* from respiratory tract specimens (such as sputum) contaminated by oropharyngeal flora that will quickly outgrow and obscure *Legionella* isolates in culture.[79] Acid pretreatment of sputum as previously described may be of additional selective benefit.[96] Culture for *L. pneumophila* is about four times more sensitive than direct immunofluorescence examination by DFA staining of respiratory secretions, since the lower limit of detection by DFA staining is about 10^4 bacterial CFU/mL.[79] Urine is also useful for the detection of *L. pneumophila* antigens (see Serologic Tests section later).

Bacterial cultures of sputum should be performed only on specimens deemed acceptable by direct light microscopic screening of Gram-stained smears. If acceptable, sputum should be cultured on general purpose nonselective media (e.g., blood agar) that are suitable for the isolation of staphylococci, streptococci, pneumococci, and other nonfastidious bacteria. In addition, enriched media (e.g., chocolate agar) for culture of *Haemophilus* species and differential media (e.g., eosin–methylene blue or MacConkey's agar) for isolation of Enterobacteriaceae and *Pseudomonas* should be used. Any organism present in predominance with typical morphology in the Gram-stained smear should be specifically sought and identified in cultures and reported semiquantitatively (Table 18-6), whereas isolates from cultures of protected catheter brush specimens and BAL fluid should be reported quantitatively.[93] Sputum should never be

cultured in broth medium or under anaerobic conditions given the predominance of anaerobic upper respiratory flora, but microaerobic condition (5% CO_2) can be used to enhance growth and detection of pneumococci. Enriched selective media, such as the modified Thayer-Martin and BCYE, should be inoculated when sputa demonstrate a predominance of intra- and extracellular gram-negative diplococci and when legionellosis is suspected. Transtracheal aspirates, pleural or empyema fluids, and lung abscess fluid should be processed for both aerobic and anaerobic cultures. *Neisseria* and *Haemophilus* species isolated from sputum cultures are often reported as usual oropharyneal flora. However, they may be clinically significant respiratory pathogens, especially when they are present predominantly both within and outside polymorphonuclear leukocytes on Gram-stained smears, emphasizing the importance of correlating the culture results with the Gram stain findings.

Antimicrobial susceptibility tests are performed usually on most bacterial pathogens of the lower respiratory tract, such as *S. pneumoniae, S. aureus, H. influenzae,* Enterobacteriaceae, and *Pseudomonas* species. Testing methods and interpretation of results should be done according to national laboratory standards for the various categories of organisms. Based on available personnel resources, commercial testing systems, and expertise in the clinical laboratory, antimicrobial susceptibility may be determined by disk diffusion, agar dilution, microbroth dilution, concentration gradient, or a combination of the four methods. Various automated and semi-automated antimicrobial susceptibility testing systems are commercially available (e.g., BD Phoenix Automated Microbiology System, Etest, MicroScan WalkAway *plus* System, Sensititre, VITEK 2), but detailed description of these methods is beyond the scope of this chapter. Susceptibility test results are reported typically as qualitative categories: "susceptible," "intermediate," and "resistant," based on comparisons of the minimum inhibitory concentration or zone size of bacterial growth inhibition with the criteria values set by national standards for the specific antimicrobial agents and testing method used. However, not all pathogens isolated in the laboratory can be tested reliably by these standard methods, and there are currently no national standards of susceptibility criteria set for these pathogens, such as Chlamydiaceae, *Mycoplasma, Bacillus,* and corynebacteria. In these instances, clinical judgment and careful assessment of patient improvement on antimicrobial therapy is essential for optimal patient management.

Chlamydiaceae

As shown in Table 18-1, the members of the Chlamydiaceae family that cause lower respiratory infection are *Chlamydia trachomatis, Chlamydophila pneumoniae,* and *Chlamydophila psittaci. Chlamydia trachomatis* pneumonia is most commonly seen in infants and young children, and the diagnosis may be made by direct immunofluorescence, culture, and serology. Unlike the other two pathogens in the same family, it is rarely a source of CAP in immunocompetent adults.[97] Clinical specimens for *C. trachomatis* culture are usually inoculated into cycloheximide-treated McCoy heteroploid mouse cells that are incubated for 40 to 72 hours before being examined for the presence of intracytoplasmic chlamydial inclusions.[98] These inclusion bodies are visualized under light microscopy after iodine staining of the glycogen produced by *C. trachomatis* in the infected cells. However, use of monoclonal DFA stain provides a more rapid and sensitive direct examination method than the iodine stain.

Chlamydophila psittaci does not synthesize glycogen, and its intracytoplasmic inclusions must be detected by another stain (e.g., Giemsa) usually after 5 to 10 days of incubation. Since *C. psittaci* is highly infectious and poses potential occupational hazards to laboratory personnel, cell cultures are rarely done for this organism, and the diagnosis of psittacosis is usually made by serologic tests.

As a known cause of CAP, *C. pneumoniae* can be detected by inoculating respiratory specimens into HeLa 229 monolayer cell culture. After 3 to 5 days of incubation, the cells are stained by a monoclonal DFA antibody specific for the organism.

Diagnosis of infections by all three organisms is made frequently by serologic testing (see later). However, cell culture and/or microbial DNA amplification tests on respiratory secretions or lung tissue may be needed to detect and confirm the presence of these pathogens in immunosuppressed patients who may not be able to mount antibody responses.[99–101] Antimicrobial susceptibility testing of Chlamydiaceae has little clinical utility presently because strain-to-strain variation in drug susceptibility and newly acquired drug resistance are both very rare. Methods for such testing have not been standardized and are used only for research purposes.

Mycoplasma

Like the Chlamydiaceae, *Mycoplasma* species are bacteria that do not grow on standard bacterial culture media. Culture media for isolation of *M. pneumoniae* generally contain fresh yeast extract, peptone, and animal serum, and are usually formulated as a biphasic preparation with an agar base overlaid with broth containing a pH indicator (for glucose fermentation) as well as penicillin and thallium acetate to inhibit bacterial overgrowth. Other additives may include amphotericin B to inhibit fungal overgrowth and a polymyxin to inhibit growth of *Pseudomonas* and other enteric bacilli. Optimal detection of *Mycoplasma* by culture can be achieved by inoculating clinical specimens into both selective and nonselective (biphasic) agar media. Upon incubation, the biphasic culture media are examined for the development of faint turbidity or a decrease in pH, while they are subcultured onto a selective agar media after 4 to 6 days and again after 8 to 12 days. The selective agar culture media are observed for the appearance of colonies typical of *M. pneumoniae.* Growth is usually visible by the end of 2 weeks of incubation, but biphasic culture media are incubated for 30 days before being discarded and

reported as negative for growth. Visible colonies of *M. pneumoniae* present in culture media are identified on the basis of hemadsorption, tetrazolium reduction, or growth inhibition by specific antiserum.[102,103]

Compared to the approximately 10^5 CFU/mL limit of detection by the culture method, direct antigen detection of *M. pneumoniae* in respiratory secretions by enzyme immunoassay (EIA) has a sensitivity of approximately 10^4 CFU/mL.[104] Due to the slow growth rate of this organism and insensitivity of the culture method (~60%), diagnosis of *M. pneumoniae* infection is more often made by the presence of specific antibodies in serum or by nucleic acid amplification of microbial gene targets in clinical specimens (see details in later sections).[103]

For the same reasons as those stated for Chlamydiaceae, drug susceptibility testing of mycoplasmas is not clinically indicated at present and is reserved only for research purposes, including in vitro evaluation of new antimicrobial agents. In general, both Chlamydiaceae and mycoplasmas are predictably susceptible to tetracyclines, macrolides, ketolides, and fluoroquinolone antibiotics.

Aerobic Actinomycetes

The pathogenic aerobic actinomycetes include the genera *Nocardia, Streptomyces, Actinomadura,* and *Rhodococcus.* Within this group, *Nocardia* species are the main respiratory pathogens. Although they grow well on mycobacterial culture media as well as on ordinary bacterial and fungal culture media, optimal recovery from clinical specimens is obtained by using the same culture medium (BCYE) as that for the isolation of *Legionella.*[105] Growth of nocardial colonies is usually visible within 3 to 7 days but may take up to 3 weeks of incubation to yield visible growth. The clinical significance of isolating *Nocardia asteroides* from sputum specimens remains controversial, since some studies comparing results between sputum culture and invasive methods (transtracheal aspirate and percutaneous lung aspiration) found colonization in as many as 51% of patients, while others reported absence of colonization.[106] Isolation of newly recognized *Nocardia* species and differences in the culture and identification methods used probably accounted for some of the differences in the findings of these studies. Distribution of *N. asteroides, N. farcinica,* and *N. nova* differs in various geographic areas, and differences exist in antimicrobial susceptibility among the species.[106]

Growth of *Nocardia* is suspected by the appearance of heaped folded colonies that may be covered by chalky aerial mycelia, but these characteristics and the organism's partial acid-fastness seen in acid-fast stained smears are not sufficient to identify the organism or to speciate it definitively. Definitive identification at the genus and species levels is based on results of biochemical tests, and speciation of *Nocardia* remains complex.[106] Among the various drug susceptibility testing methods available, the BACTEC radiometric method has been shown to be the most accurate method for testing *Nocardia* isolates.[107]

Rhodococcus equi is widely distributed in nature and is a rare cause of pulmonary infections in immunocompromised patients.[108] Rhodococci grow well on ordinary bacterial and fungal culture media. *Streptomyces* species are usually regarded as saprophytes and, therefore, as contaminants in cultures of respiratory tract specimens. However, since *Streptomyces* species closely resemble *Nocardia* in morphology of culture colonies, the two genera must be differentiated from one another on the basis of biochemical reactions in the laboratory.

Mycobacteria

Following the previously described digestion and concentration process in the laboratory, specimens are inoculated onto either egg-based (e.g., Löwenstein-Jensen) or agar-based (e.g., Middlebrook 7H10) culture media. Selective media containing antimicrobial agents, such as Gruft's modified Löwenstein-Jensen medium and Mitchison's selective 7H11 medium, are often used to suppress the growth of bacterial and fungal contaminants. Incubation in ambient atmospheric condition supplemented with 8% to 12% CO_2 increases the number and size of colonies of mycobacteria detected in these solid media. Specimens may also be inoculated into liquid medium of one of several commercially available semi-automated or automated culture systems, such as a radiometric method using ^{14}C-palmitic acid substrate (BACTEC 480TB System) or nonradiometric systems using a fluorescent indicator of O_2 consumption (BACTEC MGIT 960 System), colorimetric detection of CO_2 produced (BacT/ALERT 3D), or detection of pressure changes (due to O_2 consumption and/or CO_2 production from microbial growth) within the headspace above the liquid medium in a sealed bottle (VersaTREK Myco, formerly ESP Culture System II). The liquid culture media may be used with or without antimicrobial agents to detect mycobacterial growth and to determine susceptibility of *M. tuberculosis* isolates to antituberculous drugs. Because of their increased sensitivity and rapid detection of mycobacteria, these enriched selective broth culture systems are used widely, usually in combination with an agar-based medium, making them an important component of laboratory testing for *M. tuberculosis.*[77,109]

In contrast to the limit of detection of mycobacteria at approximately 10^4 organisms/mL by acid-fast stained smears, solid and liquid cultures are capable of detecting mycobacteria present at 10 CFU/mL of sputum.[110] Therefore, mycobacterial cultures should be performed on all respiratory secretions and other specimens from patients suspected of having tuberculosis or other mycobacterial diseases (see also Chapter 34). Cultures for mycobacteria are incubated typically for 8 weeks to detect the presence of slowly growing mycobacteria.

Mycobacterium tuberculosis usually requires 3 to 5 weeks of incubation for detectable growth in primary culture media, and another 1 to 2 weeks for niacin test to confirm its identification and for susceptibility testing. Studies of acid-fast smear-positive specimens found the mean durations from inoculation to culture positivity in

conventional solid media and by radiometric liquid culture method to be 19.4 and 8.3 days, respectively, for *M. tuberculosis* and 17.8 and 5.2 days, respectively, for nontuberculous mycobacteria (NTM).[111] On average, detection and drug susceptibility testing required 18 days by the radiometric method and 38 days by conventional methods. Time to culture positivity in acid-fast smear-negative specimens is usually longer, but the radiometric method remained faster than conventional methods. Once isolated in pure culture, identification of mycobacterial isolates can be done by the slower conventional biochemical methods or more rapidly either by gas-liquid chromatography or genetic methods.[77,109]

The NTM (also referred to as mycobacteria other than tuberculosis, or MOTT) have been classified as photochromogens, scotochromogens, nonphotochromogens, and rapid growers, according to their growth rates and pigmentation types. However, speciation by new and more precise diagnostic techniques, including molecular testing, has rendered this classification less meaningful (see also Chapter 35). From a clinical standpoint, these NTM are classified more usefully as rapidly growing or slowly growing mycobacteria, depending on the duration to culture positivity (Table 18-7), which aids the selection of additional testing and identification.

Fungi

The laboratory diagnosis of pulmonary fungal infections, especially the opportunistic invasive fungal infections, must often be based both on isolation of the organism from cultures and on histologic and serologic evidence of fungal infection (see also Chapter 36). Since pathogenic fungi are generally intolerant of decontamination and concentration procedures used to process specimens before culture for mycobacteria in the laboratory, specimens such as those submitted for mycobacterial cultures cannot be relied on for recovery of pathogenic fungi.[112] Clinical specimens should be sent specifically to the laboratory for the isolation of fungal pathogens. These specimens are typically inoculated onto nonselective media, such as potato dextrose agar, Sabouraud dextrose agar, or brain-heart infusion agar (BHIA), as well as selective media, such as BHIA-containing chloramphenicol and gentamicin with and without cycloheximide, and inhibitory mold agar. Fungal culture media that contain cycloheximide, which inhibits rapidly growing molds that commonly contaminate cultures, may be inhibitory to some pathogenic fungi, such as *C. neoformans* and *Aspergillus fumigatus*, thus emphasizing the importance of using a combination of selective and nonselective media in the isolation of fungal pathogens in culture. In contrast to bacterial cultures (usually incubated at 35°C), fungal cultures are incubated at 30°C.

In some instances, fungal pneumonia may be associated with fungemia. A variety of approaches have been used for detection of fungemia, including conventional blood culture bottles with or without radiometric or infrared spectrophotometric detection, biphasic medium bottles, lysis-filtration, and lysis-centrifugation. Because yeasts and many filamentous fungi are strictly aerobic in their growth requirements, aerobic culture bottles must be included in blood cultures obtained to detect fungemia. Failure to do so will result in significantly lower isolation rates of fungi from blood. Routine subculture of the aerobic blood culture bottles to fungal agar media has been advocated by some clinical microbiologists to improve sensitivity of fungal blood cultures. The commerically available but labor-intensive lysis-concentration method (Isolator) of blood culture has been shown also to be highly sensitive for detection of candidemia.[113,114] Although fungal blood culture is a relatively insensitive marker of disseminated fungal disease, the quantitative information provided by the lysis-concentration method may be useful in the management of patients with fungemia.[113,114] In general, the automated fluorometric (BACTEC) and colorimetric (BacT/ALERT 3D) detection methods of blood culture provide rates of recovering yeasts equivalent to those of aerobic cultures of the manual lysis-centrifugation method.[114-116] However, isolation of systemic fungal pathogens, such as *Histoplasma capsulatum,* from blood usually requires the lysis-centrifugation method or the use of special enriched fungal medium bottles for the BACTEC and BacT/ALERT 3D culture systems.[117,118]

Most yeasts, including *Candida* and *Cryptococcus* species, grow readily on most common fungal culture media, including Sabouraud or potato dextrose agar, inhibitory mold agar, BHIA, and Sabhi agar. Culture media containing antibiotics, such as chloramphenicol and gentamicin, are helpful when culturing respiratory

secretions containing contaminating bacteria, but cycloheximide may be inhibitory to *C. neoformans* and to some *Candida* species. Further complicating the isolation of fungal pathogens from respiratory specimens is that yeasts are frequently isolated from respiratory secretions. They have been reported in as many as 75% of sputum specimens and 25% of bronchial washings submitted for fungal culture.[1] Therefore, yeasts present in these specimens are considered to be of upper respiratory origin and need not be routinely identified unless when they are urease-positive. Urease-positive colonies require identification to rule out the possibility of *C. neoformans.* Urease-negative yeasts (e.g., *Candida* species) from sputa and bronchial washings may be reported as "yeasts present, not *C. neoformans*" in culture results. When isolated from other respiratory sources such as BAL fluid and normally sterile sites such as blood, such urease-negative yeasts should undergo further identification, which can be accomplished on the basis of colonial and microscopic morphology and biochemical reactions in commercially available tests.

Invasive pulmonary aspergillosis (IPA) also requires demonstration of parenchymal invasion for definitive diagnosis, due to colonization of the lower respiratory tract by *Aspergillus* in up to 90% of patients when defined as having at least one positive result from cultures of sputum, bronchial washing, or lung tissue.[119] Conversely, less than 10% of patients with proven IPA had *Aspergillus* recovered from cultures of sputum specimens. For optimal interpretation of culture results, both transbronchial lung biopsy and protected catheter brush should be used to obtain specimens for fungal cultures in order to decrease the frequency of false-negative and false-positive culture results.[120] Detection of fungal antigen in serum and various body fluids to aid in the diagnosis of infections due to *Aspergillus* species, *B. dermatitidis, C. neoformans,* and *H. capsulatum* are discussed later in the Serologic Tests section.

The unreliability of both positive and negative cultures in establishing or excluding a diagnosis of opportunistic fungal pulmonary disease, including aspergillosis, candidiasis, and zygomycosis, can be very problematic when evaluating the immunocompromised patient with pulmonary infiltrates. The two most reliable criteria for the definitive antemortem diagnosis of these opportunistic infections are (1) the presence of the fungus in otherwise viable lung tissue (by culture and/or histopathologic examination); and (2) a positive culture from cerebrospinal fluid, intraocular fluid, or other sterile body fluids (excluding blood and urine) in which the fungus is never normally present and when contamination in any manner is absolutely excluded.

In contrast to the fungi causing opportunistic pulmonary infections, isolation of pathogenic dimorphic fungi, such as *B. dermatitidis, C. immitis, H. capsulatum, Paracoccidioides brasiliensis,* and *Sporothrix schenckii* from respiratory secretions, antemortem or postmortem lung tissue, or any other site is invariably of clinical importance. Whereas zygomycetes may appear in cultures within 1 to 3 days and *Aspergillus* within 3 to 7 days, growth of the dimorphic fungi usually requires approximately 14 days of culture incubation. However, the time required for such fungal growth to be visible in culture is inoculum dependent, so that cultures of specimens with many organisms may become visible within 2 to 3 days while those with few organisms may not become positive even after 30 days. For this reason, fungal cultures are routinely incubated for 4 weeks or longer when the cultures are of specimens from patients who have serologic evidence of infection or who are being treated for an established fungal infection.[121] With adequate duration of incubation and proper laboratory techniques, fungal cultures of respiratory specimens were positive in approximately 85% of cases with disseminated or chronic pulmonary histoplasmosis.[122,123]

Since the presence of contaminating oropharyngeal flora does not interfere with the interpretation of culture results for dimorphic fungi, respiratory secretions are usually the best source for cultures of these organisms. Definitive diagnosis can often be made rapidly by direct microscopic examination of potassium hydroxide–stained or calcofluor white–stained smears of respiratory secretions, looking for cellular structures that are typical of members of this group of pathogenic fungi. Specimens that are negative by direct examination should still be submitted for fungal culture, since the latter is a more sensitive method for detection of fungi. Structures that are typical of the dimorphic fungi may be identified also in histopathologic tissue sections stained with Gomori methenamine silver. The presence of histiocytosis or a granulomatous reaction within lung tissue or a lymph node should prompt the performance of special stains and cultures for fungi as well as for mycobacteria, although chronic granulomatous lesions, especially those due to *H. capsulatum,* may be negative for fungal growth in culture. Close communication between the surgical pathologist and clinical microbiologist is of the utmost importance to ensure that an adequate amount of material is available for both direct microscopic and histologic examination and that appropriate cultures are performed to confirm the abnormal histopathologic findings.

Definitive identification of the pathogenic dimorphic fungi is based on one or more of the following methods: (1) recognition of characteristic microscopic features of the mold forms present in cultures; (2) conversion of the mold form to the yeast or spherule form that can be recognized microscopically; and (3) detection of cell-free exoantigens by a micro-immunodiffusion method. Conversion to the yeast form on culture is easily accomplished with *B. dermatitidis* and *S. schenckii,* whereas the immunodiffusion (ID) test for exoantigens is usually reserved for testing colonies suspected to be *C. immitis* or *H. capsulatum.* As an alternative to detection of exoantigens, molecular tests using oligonucleotide probes are available for rapid identification of these dimorphic fungi directly from cultures[124–126] or in histologic tissue sections.[127,128]

With the availability of new antifungal drugs and increasing recognition of drug resistance among certain pathogenic fungi, antifungal susceptibility testing has become important in the management of patients with

invasive fungal infections. Standard laboratory testing methods and interpretive criteria are available for clinical laboratories to examine clinically significant fungal isolates for resistance to the antifungal drugs currently used for treating such infections.[129–131] However, the need for such susceptibility testing is usually reserved for testing pathogenic fungi, such as *Candida* spp., *Aspergillus terrae, Fusarium, Scedosporium, Trichosporum,* and zygomycetes, that are known to be resistant to some of the commonly used antifungal drugs (e.g., amphotericin B, the azoles).

Viruses

As discussed previously in the section on direct specimen examination, nonculture techniques for detection of pathogenic viruses in respiratory specimens may include direct examination of specimens (e.g., nasopharyneal aspirates, sputum, BAL fluid) containing virus-infected epithelial cells using DFA staining and EIA. These methods provide a rapid means of viral antigen detection for influenza viruses, parainfluenza viruses, adenoviruses, and RSV (see also Chapter 31). The sensitivity of these direct detection methods depends on the type of specimen and the timing of specimen collection. Generally, the earlier in the course of disease the specimen is collected, the more likely that the virus will be detected. However, with the exception of RSV, conventional cell culture is usually the more sensitive method for detecting viruses in respiratory specimens, but it is usually slow, requiring an average of 3 to 4 days to detect cytopathic effects from influenza A virus and 8 to 9 days from CMV. The time required for detection of HSV, CMV, and respiratory viruses can be reduced to 16 to 48 hours after inoculation by using the rapid shell vial culture technique, which combines low-speed centrifugation (700× *g*) after inoculation of cell culture monolayers and immunofluorescent staining with virus-specific monoclonal antibody.[132,133]

The detection of viruses in respiratory secretions must be based on knowledge of their source of isolation, potential presence as colonizers in certain sites, and epidemiologic characteristics. Thus, isolation of influenza viruses, parainfluenza viruses, and RSV, as well as rhinoviruses and coronaviruses, from either respiratory secretions or lung tissue is clinically significant. In contrast, because of known asymptomatic secretion for periods ranging from weeks to months, isolation of adenoviruses, HSV, and CMV from respiratory secretions is of questionable significance, while positive cultures of lung tissue for these viruses are very important diagnostically. In addition, simultaneous isolation of adenovirus from both the throat and feces has a greater probability of association with febrile and respiratory illnesses in infants and children than when the virus is isolated only from the throat or feces. Although the isolation of CMV from lung tissue is important clinically, infection with CMV is often concurrent in immunocompromised hosts with infections caused by bacteria or fungi, including *P. jirovecii,* and in infants with *C. trachomatis* pneumonia.

Parasites

Identification of pulmonary parasites is typically made by microscopic examination of specimens (e.g., sputum, blood, feces) in conjunction with a detailed clinical history, radiologic imaging, and serologic testing.[134,135] Culture and direct antigen detection of the parasites are uncommonly used in this setting but are appropriate in certain circumstances and may be invaluable for confirming diagnosis (see also Chapter 37).

Fecal culture may be useful in cases of suspected pulmonary involvement with *Strongyloides stercoralis* when sputum cytology fails to identify larvae. The agar plate method is a useful adjunct to standard microscopic fecal examination and may be up to six times more sensitive.[136–139] Fecal culture may also enhance the sensitivity of *Entamoeba histolytica* identification from feces or aspirated lung abscess material, but is not routinely available in the diagnostic laboratory.[140] Serology is more commonly used for diagnosis of disseminated amebic disease and is discussed later.[140]

The identification of microfilariae causing tropical pulmonary eosinophilia poses a diagnostic challenge since these parasites typically circulate only at night. As an attractive alternative to nightly blood draws, antigen detection for bancroftian filariasis in peripheral blood has proven to be both sensitive and specific for the detection of microfilaria.[141,142] Antigen testing may also be used for identification of *Toxoplasma gondii* in peripheral blood, but is not yet widely available.[143–145]

SEROLOGIC TESTS

Serologic diagnosis of infection can be made by detecting (1) humoral immune responses (e.g., antibodies) of the infected individuals, and/or (2) microbial antigens present in sera or various body fluids. Immunologic assay methods frequently used to identify and quantify a specific antibody or a pathogen-specific antigen are based, respectively, on binding interactions between a known amount of pathogen-specific antigen and the specific antibody of interest or between a known amount of pathogen-specific antibody and the specific antigen of interest. The resultant antigen-antibody complexes can be detected directly by precipitation methods or by labeling of the antigen or the anti-antibody with a radioactive, fluorescent, or enzyme probe. The complexes can also be detected indirectly by measurement of an antibody-directed reaction, such as complement fixation (CF). The serologic methods commonly used in diagnostic laboratories include precipitation, ID, agglutination, hemagglutination inhibition, EIA, indirect immunofluorescence assay (IFA), CF, and immunoblotting (including Western blot).

Immunocompetent individuals produce both immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies specific against pathogens during infection. In general, IgM is produced during the first exposure to a given pathogen and is no longer detectable after this relatively short period of time. Over time, production of

IgG replaces that of IgM in the immunologic response of exposed patients. Serologic testing is used commonly to identify infections due to pathogens that are difficult to detect by other conventional methods, to evaluate the course of an infection, and to determine the nature of the infection (primary infection versus reinfection, acute versus chronic infection). Serologic results are usually expressed as a titer, which is the inverse of the greatest dilution, or lowest concentration (e.g., dilution of 1 : 16 = titer of 16), of a patient's serum that retains the specific antibody-antigen reactivity. Patient's specific IgM or IgG titers can be determined separately through the use of labeled anti-human antibody specific for the antibody isotype in the particular serologic assay.

Diagnosis of infection based on serologic responses of the infected host is confirmed usually by occurrence of seroconversion during a primary infection. Seroconversion is defined as a minimum fourfold increase in antibody titer between serum during the acute phase of infection and that during the convalescent phase (≥2 weeks later). Reinfection or recurrent infection later in life causes an anamnestic (secondary or booster) immune response that can be detected as increase in antibody titer. Although a fourfold or greater rise in antibody titer between acute and convalescent sera is usually required for diagnosis, an elevated pathogen-specific IgM antibody titer in a single serum sample suggests recent infection by the specific pathogen. A falling titer of the specific IgM antibody provides further support for the etiologic significance of this organism. However, serologic testing of pathogen-specific IgG antibody in acute and convalescent sera remains the approach to establish a specific microbial cause of the infection.

Various commercial assays—EIA and IFA—are available for detection of (1) specific IgM and/or IgG antibodies to respiratory tract pathogens, and/or (2) pathogen-specific antigens in serum or various body fluids. These assays are useful for supporting or confirming the diagnosis of bacterial infections caused by *Legionella* species, *Francisella tularensis, Yersinia pestis, M. pneumoniae, C. trachomatis, C. pneumoniae, C. psittaci,* and *Coxiella burnetii.* With these assays, infection is confirmed typically by observing a fourfold or greater rise in pathogen-specific IgG antibody titer between the acute and convalescent sera in a given patient.

For the diagnosis of *L. pneumophila* infection, urine can also be tested for *L. pneumophila* serogroup 1 antigens by EIA, with diagnostic specificity of 100% and sensitivity varying from 70% to 100%.[79] Antigen is detectable in more than 80% of patients at onset and after 14 days of symptoms before receiving treatment, as well as at 42 days or longer after onset of treatment.[41] However, these urinary antigen assays are specific only for diagnosis of infections due to *L. pneumophila* serogroup 1 and not other *Legionella* species. Detection of *H. influenzae* type B antigens in urine is of potential diagnostic value in pediatric patients with pneumonia, but such antigenuria may also follow routine immunization with *H. influenzae* type B conjugate vaccine.[146]

With the relative ease of serum collection and low sensitivity of culture methods, serologic tests are important adjunct tools for the diagnosis of *M. pneumoniae* infection. Cold agglutinins, detected by agglutination of type 0 Rh-negative red blood cells at 4°C, are present in the sera of approximately 50% of patients with *M. pneumoniae* infection, and levels decline to baseline within 6 weeks after acute infection. However, the formation of this nonspecific serologic marker may be induced by a wide variety of viral infections, lymphoid malignancies, and autoimmune disorders. Antibodies are detected by CF test in more than 85% of culture-positive patients, and a single elevated titer of greater than 1 : 80 or a greater than fourfold rise in titer between acute and convalescent sera is required to establish a diagnosis. EIAs to detect *M. pneumoniae*–specific IgM and immunoglobulin A (IgA) antibodies have been developed with improved sensitivity and specificity over the CF assay.[103] Specific IgM antibodies appear during the first week of illness and reach peak titers during the third week. However, the IgM antibodies are not constantly produced in adults, so that a negative IgM result does not rule out acute *M. pneumoniae* infection, particularly in the elderly. Detection of specific IgA antibodies in the serum has been shown to be a reliable approach for diagnosis, since these antibodies are also produced early in the course of disease and more reliably present in the infected individuals regardless of age.

Serologic testing also plays an important role in the diagnosis of fungal respiratory tract infections due to *Aspergillus* species, *C. immitis, C. neoformans,* and *H. capsulatum.* Detection of serum *Aspergillus* galactomannan (a major cell wall component of the fungus) antigen in serum by EIA can aid in the early diagnosis of IPA, with diagnostic sensitivity ranging from 60% to 100% in various patient groups.[119,147–149] Platelia *Aspergillus* EIA (Bio-Rad Laboratories, Redmond, WA), a commercially available assay that uses the rat monoclonal antibody EB-A2 directed against galactomannan in *A. fumigatus, A. flavus, A. niger, A. versicolor,* and *A. terres,* has been shown to yield positive results at an early stage of infection, with positive and negative predictive values of more than 90% in high-risk patients who were tested biweekly.[147] However, cross reactivity of this assay may occur in patients with histoplasmosis, paracoccidioidomycosis, and cryptococcosis,[149,150] and false-positive galactomannan antigen assay results can be observed in patients receiving certain foods or intravenous pipercillin-tazaobactam.[151–153] BAL fluid specimens from lung transplant recipients have been evaluated also for testing by *Aspergillus* galactomannan detection assay, with sensitivity of 82% and specificity of 96%.[154] Of note, the Plasma-Lyte (Baxter International Inc., Deerfield, IL) solution commonly used to perform BAL has been found to yield false-positive results with the Platelia *Aspergillus* EIA.[155]

Another fungal antigenic marker that is used increasingly for the diagnosis of invasive fungal infection is (1→3)-β-D-glucan, which is a component of the outer cell wall of saprophytic and pathogenic fungi except zygomycetes (*Mucor* and *Rhizopus* species) and *Cryptococcus* species.[147,156] This antigen has been detected in serum or other body fluids of patients with invasive aspergillosis, invasive candidiasis, and infections caused

by *Fusarium, Acremonium, Trichosporum, Scedosporium, Saccharomyces,* and *P. jirovecii.*[157,158] A multicenter trial of one assay method yielded diagnostic sensitivity of 70% and specificity of 87% in neutropenic patients with acute leukemia.[159] Use of different assay cutoff values may result in differences in sensitivity and specificity among the various commercially available assays for detecting this antigen.[156] Nonspecific cross reactivity of (1→3)-β-D-glucan detection assays has been reported with the use of cotton gauzes, swabs, packs, pads, or sponges for wound care or surgery; cellulose filters in hemodialysis patients; and various antimicrobial agents.[156,160]

Infection due to *C. immitis* can be based on detection of antibodies to antigens derived from the coccidioidal mycelia or spherules, although cross reactivity may occur with antibodies to other yeasts and dimorphic fungi. Precipitin-specific IgM antibodies develop in up to 75% of individuals within 2 to 3 weeks after primary *C. immitis* infection, and subsequently disappear except in patients with disseminated infection. Complement-fixing IgG antibodies appear later and persist in relation to the severity of disease, but decline with disease remission. Titers of 1 : 32 or higher should suggest the possibility of disseminated infection.[161,162] However, a single elevated titer obtained by CF, no matter how high, should not be used to make the diagnosis of disseminated disease.

Serologic assays to detect polysaccharides of *C. neoformans* cell wall in serum or cerebrospinal fluid are helpful to confirm the diagnosis of cryptococcosis. Commercially available assays show more than 95% diagnostic sensitivity and specificity for detection of cryptococcal antigen in serum, provided that proteolytic enzymes (pronases) are used to limit the false-positive and false-negative results due to the prozone effect, localized infection, infection with a poorly encapsulated strain, or low organism burden.[163] Cryptococcal antigen may also be detectable in pleural effusions and BAL fluid of patients with cryptococcal pneumonia,[164,165] but some patients with disseminated cryptococcosis may be negative by the serum cryptococcal antigen test. Serial measurement of serum antigen titers over time is not useful for the management of patients with pulmonary cryptococcosis.[166]

Serum antibodies to *H. capsulatum* are detected by CF test using both yeast and mycelial antigens and ID assay, showing positive titers in more than 90% of patients with pulmonary histoplasmosis and approximately 80% with disseminated disease.[123] The CF test is more sensitive but less specific than the ID test for the diagnosis of subclinical and acute pulmonary histoplasmosis, with CF titers of 1 : 8 or higher in 90% of patients versus ID test indicating M bands in 75% and H bands in only 25% of cases.[43] Cross-reactive antibodies are observed more commonly in CF than ID for patients with blastomycosis, coccidioidomycosis, and paracoccidioidomycosis. Antibodies become detectable first by CF test at 2 to 6 weeks after *Histoplasma* infection and then by ID test 2 to 4 weeks later. However, the ID test remains positive longer than the CF test after resolution of infection, becoming negative 2 to 5 years later. Presence of an M band by ID test with a negative CF test result suggests remote or past histoplasmosis. The M band remains positive much longer (several years) than does the H band, while the presence of the H band is indicative of active or acute infection, usually disappearing within 6 months. These serologic tests are less sensitive in immunosuppressed patients, and antibody titers are low, whereas antibody levels remain high in those with chronic pulmonary infection, progressive disseminated disease, or fibrosing mediastinitis. The polysaccharide antigen of *H. capsulatum* can be detected in urine by EIA in approximately 90% of patients with disseminated disease and 75% with diffuse acute pulmonary histoplasmosis.[122,123] Urinary *Histoplasma* antigen levels persist during ongoing active infection, and become undetectable with successful therapy and rise with relapse of infection. However, the urinary *Histoplasma* antigen assay is known to yield positive results in patients with disseminated infections caused by *B. dermatitidis, P. brasiliensis,* and *Penicillium marneffei.*[167] Cross reactivity of the assay has not been observed in patients with invasive candidiasis, cryptococcosis, coccidioidomycosis, aspergillosis, or other opportunistic systemic mycoses.

Serologic testing plays an important role as an aid to the diagnosis of parasitic and viral infections such as *T. gondii, Trichinella spiralis, S. stercoralis,* influenza viruses, parainfluenza viruses, RSV, adenoviruses, severe acute respiratory syndrome (SARS)–associated coronavirus, HSV, varicella-zoster virus, CMV, and Epstein-Barr virus (EBV). Serologic detection of fourfold rise in virus-specific antibody titers is also helpful when influenza, parainfluenza, RSV, or adenovirus infection is suspected but the virus is undetectable by cell cultures or by direct viral antigen testing of respiratory specimens.

In summary, serologic testing makes an important contribution to the diagnosis of infection with numerous respiratory pathogens, and is the test of choice for some organisms. It offers a relatively noninvasive alternative to direct examination and culture methods of tissues, and may play an essential role in the identification of microorganisms that grow poorly, or not at all, in culture.

MOLECULAR TESTS

In recent years, diagnostic approaches for the detection and identification of microbial pathogens in the clinical laboratory have moved rapidly toward use of molecular techniques, including in-house and commercially available tests.[168–170] Most of these methods are based on amplification, detection, and confirmation of certain nucleic acid targets (genes) specific to the pathogens of interest. Such molecular testing methods offer several advantages over conventional direct examination, microbiologic cultures, and serologic assays. First, molecular methods have the ability to detect and identify pathogens more rapidly (usually in ≤1 day) than traditional laboratory tests, and may be able to determine antimicrobial susceptibility directly from respiratory tract specimens. For example, detection of *M. tuberculosis* and its susceptibility to isoniazid and rifampin can be accomplished directly

from sputum (in ~2 hours) using polymerase chain reaction (PCR)–based technology.[171,172] Second, some microorganisms are difficult or impossible to grow in cultures, and molecular techniques provide the best, if not the only, means of directly detecting these organisms. Certain NTM, for example, are very difficult to cultivate by conventional culture-based methods, and nucleic acid amplification techniques would enable the detection of these organisms in clinical specimens.[173] Third, molecular tests lessen or eliminate the biohazard risk of exposure of laboratory personnel to highly contagious laboratory cultures of certain microorganisms, such as *M. tuberculosis* and *C. immitis,* if proper handling of specimens and cultures is not observed.

Among the available molecular assays are microbial detection and/or identification by oligonucleotide hybridization probes for use on pure culture isolates. For example, nucleic acid probes, such as AccuProbe (Gen-Probe, Inc., San Diego, CA), are commercially available for the identification of colonies of *H. capsulatum, B. dermatitidis,* and *C. immitis* grown in fungal cultures. Species-specific labeled probes are designed to hybridize to specific gene targets of the organisms in question after microbial nucleic acids were extracted from pure culture colonies. These tests are rapid (completed in <2 hours) and can be done on younger cultures, providing results sooner than exoantigen testing. Compared to conventional microscopic and biochemical techniques of identification, these nucleic acid probe methods are accurate, with diagnostic sensitivities and specificities of 98% to 100%.[124–126] Genetic probes are also available for identifying *M. tuberculosis, M. avium* complex, and *M. kansasii* isolated from mycobacterial culture media.[174,175]

Molecular tests may also be performed directly on respiratory specimens. Nucleic acid amplification–based tests are available currently for molecular detection of *M. tuberculosis,* and include a transcription-mediated amplification and hybridization protection assay to detect ribosomal RNA (rRNA) (Amplified MTD Test; Gen-Probe, Inc., San Diego, CA) and DNA hybridization of a conserved region of the 16S rRNA gene amplified by PCR (AMPLICOR MTB Test; Roche Molecular Diagnostics, Branchburg, NJ).[176,177] Both of these assays can yield results in 3 to 4 hours. In comparison to results of conventional culture methods, these nucleic acid testing methods showed the following sensitivities, specificities, and positive and negative predictive values: Amplified MTD Test, 86%, 100%, 100%, and 98%, respectively; AMPLICOR MTB test, 83%, 100%, 100%, and 98%, respectively.[178]

The CDC has recently published updated guidelines for the use of nucleic acid amplification (NAA) tests in the diagnosis of tuberculosis.[179] Compared with direct microscopic examination for acid-fast bacilli, NAA testing provides (1) a greater positive predictive value (>95%) with smear-positive specimens in settings where nontuberculous mycobacteria are common, and (2) the ability to rapidly confirm the presence of *M. tuberculosis* in 50% to 80% of smear-negative, culture-positive specimens, weeks earlier than culture.[180] The updated recommendation states "NAA testing should be performed on at least one respiratory specimen from each patient with signs and symptoms of pulmonary TB for whom a diagnosis of TB is being considered but has not yet been established, and for whom the test result would alter case management or TB control activities." In addition, the World Health Organization has recommended the use of NAA tests to screen for multidrug-resistant tuberculosis; two such kits are commercially available in Europe and elsewhere, but none have been approved by the FDA.

Diagnostic methods have also been described for detecting the nucleic acids of *S. pneumoniae,*[181] *C. pneumoniae,*[25–27] *M. pneumoniae,*[28–31] *L. pneumophila,*[28] dimorphic fungi,[182,183] *Aspergillus* species,[183,184] *P. jirovecii,*[185,186] *T. gondii,*[187] respiratory viruses, HSV,[188] and CMV[189,190] directly in respiratory specimens of normal and immuncompromised hosts. These tests may be done by conventional, labor-intensive amplification techniques (requiring 2 to 3 days of test turnaround time) or by rapid, real-time amplification methods yielding results in less than 3 hours. The latter approach is based on immediate, simultaneous fluorescence detection of amplified gene targets as they are generated by the in vitro assays. However, caution is needed to interpret the results of such test methods in differentiating between colonization (or latent forms) and infection by these organisms in the hosts. For example, *S. pneumoniae, C. pneumoniae, M. pneumoniae, Candida* species, and *P. jirovecii* may be carried by (colonize) some individuals without causing disease. Similarly, herpesviruses (HSV, CMV, EBV), *T. gondii,* and *P. jirovecii* may exist in a latent state (as cysts in the cases of *T. gondii* and *P. jirovecii*) in human tissues and may not cause disease. The detection of nucleic acid sequences of dimorphic fungi (e.g., *H. capsulatum*) or *M. tuberculosis* in lung or lymphatic tissue usually indicates disease, although such nucleic acids could be preserved in nonviable organisms contained in fibrotic granulomas from past/resolved infection. In addition, a notable concern with these direct rapid molecular tests is the lack of ability to do antimicrobial susceptibility testing.

Published studies of clinical validation of these molecular detection tests have indicated that most of these assays are at least comparable, if not better, in sensitivity and specificity to combination of conventional culture, direct antigen, and/or serologic detection methods, especially when examining respiratory specimens that contain low numbers of pathogens. For example, rapid PCR assay has been applied for the diagnosis of an outbreak of *C. psittaci* which occurred as a result of transmission of this infectious agent from birds purchased in stores to humans, showing a 50% increase in the rate of *C. psittaci* detection compared with culture.[191] Compared to culture and serologic tests, PCR was also shown to be the most sensitive method for detection of *C. pneumoniae* during an outbreak of CAP.[192]

Conventional and real-time nucleic acid–based tests are available for *P. jirovecii* and may be more sensitive than conventional microscopic methods.[193] However, they are usually more time-consuming and expensive, and may be less specific (especially nested PCR assays), than direct microscopic examination using various stain-

ing methods (methenamine silver, Giemsa, or toluidine blue O stains).[185] The lowered diagnostic specificity is likely due to the detection of *P. jirovecii* nucleic acid from cysts that are present in low numbers and in a latent state in pulmonary tissues of asymptomatic patients.[194] This could potentially be overcome through use of quantitative assays.[193] *Pneumocystis jirovecii* pneumonia may also be diagnosed by PCR analysis of serum and gastric wash fluid, although the clinical utility of these approaches is uncertain.[195,196]

Cytomegalovirus is frequently present in respiratory secretions of immunosuppressed patients in the absence of CMV pneumonitis. Quantitative PCR and expression of CMV proteins have been used in an attempt to differentiate between shedding of CMV and CMV disease. Higher copy numbers of CMV DNA can be found in cases of CMV pneumonia than in CMV shedding, and expression of CMV glycoprotein H messenger RNA was detected only in patients with disease.[189] However, these specialized PCR techniques must be used to maintain specificity of these sensitive assays.

Due to the various technical difficulties encountered by clinical laboratories in the isolation of respiratory viruses, molecular detection methods have become increasingly popular and important for the management of patients with these viral infections.[170,197] Different respiratory specimens, including throat swabs and nasopharyngeal swabs or aspirates, have been studied by various microbial gene amplification assays for the detection of influenza A and B viruses (including the H5N1 strain),[33,34,198,199] parainfluenza viruses,[32,33,198] RSV,[32,33,35,36,198] adenoviruses,[32,33,37,198,200] human metapneumovirus,[201] and SARS-associated coronavirus,[202,203] with diagnostic sensitivity and specificity that are greater than those of culture and direct antigen detection methods. These molecular tests also offer the advantage of detecting viral nucleic acid targets in patients who are already receiving antiviral therapy.[204]

Molecular assays have also allowed for the identification of previously unknown respiratory viruses, such as human metapneumovirus, novel coronaviruses, and human bocavirus. Some of these have been definitively linked with respiratory disease. For instance, human metapneumovirus is now recognized as an important agent of acute lower respiratory tract disease in infants and young children.[205] The roles of other viruses in respiratory disease, such as the human bocavirus, have yet to be elucidated.

Recently, several large-panel multiplex molecular assays for rapid, simultaneous detection of respiratory tract pathogens, including bacteria and viruses, have been developed and studied.[206–208] Use of such assays has led to the recognition that coinfections with two or more respiratory pathogens are more common than previously thought.[206,209] However, further studies are needed to determine the clinical significance of multiply detectable respiratory tract pathogens in clinical specimens from various patient populations and the cost-effective application of such molecular tests in clinical practice.

With the useful capabilities of molecular diagnostic tests and the need for rapid, sensitive detection of respiratory tract pathogens, molecular assays will gain an increasing role in the diagnosis and management of patients with opportunistic and community-acquired pneumonia. In many large clinical laboratories, these tests have replaced conventional, less sensitive diagnostic methods for routine use by health care providers.

KEY POINTS

- The clinical microbiology laboratory plays a vital role in the microbiologic diagnosis of the specific cause of lower respiratory tract infections.
- Reliable results depend on obtaining suitable and adequate specimens, transporting them promptly to the laboratory in appropriate media or containers, and then processing the material according to the organisms of interest.
- Information from the health care provider is equally crucial in guiding the laboratory to detect and identify the actual pathogens from among the many possible microorganisms that may cause infection in a given patient.
- The laboratory diagnosis of pulmonary infections is frequently based on a combination of histopathologic, microbiologic, and serologic examinations, which must always be interpreted in conjunction with the patient's clinical, radiographic, and other laboratory test findings.
- Newly available rapid molecular assays are playing an increasingly important role in the diagnosis of the cause of lower respiratory tract infections.

INTRODUCTION

Chest radiographic techniques play a major role in the detection, diagnosis, and serial evaluation of thoracic disease. The appropriate use of radiographic methods requires some basic understanding of the technical aspects of imaging, of the abnormal findings visible with different techniques, and of the diagnostic accuracy of these techniques. It is not the intent of this chapter to provide a complete description of the techniques involved or an encyclopedic catalogue of radiographic abnormalities of chest diseases. Rather, this chapter is intended to provide a general survey of the imaging methods available, their most common indications, and certain principles concerning their use.

Since the late 1990s, remarkable advancements in the effectiveness of cross-sectional imaging techniques for the diagnosis of thoracic diseases has occurred, particularly the development of multislice computed tomography (MSCT) as well as improvements in magnetic resonance imaging (MRI) and ultrasonography. In many instances, cross-sectional methods have supplanted conventional radiography for the diagnosis of chest diseases. As with any radiographic method, the decision to utilize cross-sectional imaging should be based on consideration of the patient's clinical problem and the results of other imaging and laboratory testing.

Chest radiography still plays a fundamental role in the diagnosis of thoracic disease. Chest radiography is usually the initial imaging procedure performed when chest

disease is suspected, and despite the development of other imaging methods, chest radiography remains one of the most frequently performed radiographic examinations in the United States.

The thorax is difficult to image with conventional radiographic techniques because of large regional differences in tissue density and thickness. For example, with standard radiography, the number of x-ray photons passing through the lungs is more than 100 times greater than the number of x-ray photons penetrating the mediastinum.[1] The dynamic contrast range of conventional film-screen radiography is insufficient to properly demonstrate this range of x-ray photon transmission; with standard radiographic techniques, the use of exposure high enough to properly display the mediastinum and the subdiaphragmatic regions usually results in overexposure of the lungs.[1] Conversely, an exposure designed to provide the best visualization of the pulmonary parenchyma is normally too light for visualizing mediastinal anatomy. One of the advantages of digital imaging is that displayed contrast and brightness are largely independent of the kilovoltage and milliamperage values used to obtain the examination; both contrast and brightness can be manually adjusted by the user after the image has been obtained.[2] Furthermore, the dynamic contrast range (latitude) of digital radiographic techniques exceeds that of film-screen methods by a factor of 10 or more.[2]

Chest radiography has been in use since the discovery of x-rays, and evolutionary developments in radiographic technology have addressed some of the fundamental limitations of radiographic techniques.[1] Whereas film-screen projection radiography was the primary method by which chest radiography was performed for many years, digital radiography has largely supplanted film-screen techniques in many facilities, providing advantages such as image postprocessing and electronic storage of the radiographic data. The latter is particularly important because it allows for simultaneous access to imaging studies by multiple providers as well as transmission of the data over long distances in very short times.

Meticulous attention to technique is essential. Regardless of the method of recording the image, whether through standard film-screen radiography, image intensification, or digital recording, poor quality control leads to degradation of diagnostic information. Unfortunately, many technically inadequate radiographs are produced, leading either to repeat studies with additional patient exposure to ionizing radiation or to interpretation of the poor images, increasing the chance of diagnostic errors.

Indications for the use of chest radiography are protean and include the assessment of both acute (e.g., pneumonia) and chronic (e.g., chronic obstructive pulmonary disease [COPD]) lung diseases, assessment of dyspnea or other respiratory symptoms, evaluation of treatment success in patients with acute lung disease, follow-up of patients with a known chronic lung disease, monitoring of patients in intensive care units (ICUs), diagnosis of pleural effusion, screening for asymptomatic diseases in patients at risk, monitoring patients with industrial exposure, preoperative evaluation of surgical patients, and as the initial imaging study in patients with lung cancer and other tumors, vascular abnormalities, and hemoptysis. Abnormal radiographic findings can be quite subtle, however, and in many circumstances, the sensitivity and specificity of chest radiography is limited. In such situations, other imaging studies, especially thoracic computed tomography (CT), are performed to further investigate abnormalities visible on conventional radiographs or to evaluate patients considered high-risk for a particular condition, but with normal chest radiographic results.

The utility of chest radiographs has been studied in a number of clinical settings, and the appropriate criteria for their use have been determined by the American College of Radiology.[3] Although a detailed analysis of the diagnostic accuracy of chest radiographs in all instances is beyond the scope of this chapter, for illustrative purposes, their utility and limitations in several specific clinical settings are reviewed.

CHEST RADIOGRAPHY: TECHNIQUES

Standard Film-Screen Radiography

The goal of chest radiography is to optimize film quality and diagnostic information while limiting radiation exposure to the patient. Although there are minor disagreements among experts, virtually all definitions of image quality include three general factors: radiographic contrast, resolution, and image noise.[1,4] These are interrelated, and the ultimate quality of the radiograph is determined by the worst of the factors involved in its production.

Radiographic Contrast

With a standard film-screen system, radiographic contrast is principally determined by components of the system, chiefly the energy of the x-rays, and the degree to which secondary radiation (scatter) is eliminated. A film-screen combination possessing an intermediate or wide gray scale (latitude) is preferable to one producing extreme contrast.[1,4] Although very "white and black" radiographs appear to demonstrate excellent detail, differentiation of structures differing slightly in density, such as the pulmonary vessels and the background lung, is better achieved with a wide-latitude film-screen combination or digital radiography. Wide-latitude film-screen combinations or digital radiography also better displays the wide range of densities present in the thorax.[1] The use of a high-peak-kilovoltage (kVp) (120–150 kVp) technique reduces contrast between tissues of different densities and makes calcification more difficult to detect but provides considerably more information largely by allowing structures to be seen through the heart, mediastinum, and bones (Fig. 19-1).

When an object is radiographed, some photons are absorbed or scattered, whereas others pass unaffected through the object (Fig. 19-2A). If the object is close to the x-ray film or detector, exposure from scattered

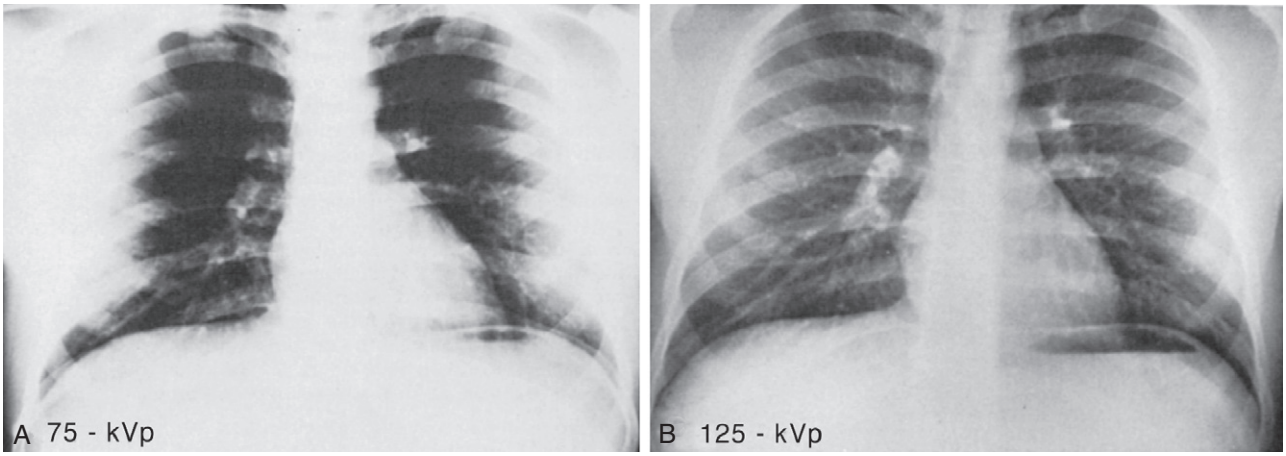

FIGURE 19-1 ■ **A,** This radiograph was made at 75 kVp. Note the lack of visibility of the peripheral lung and the area of the mediastinum. **B,** This radiograph was made at 125 kVp on the same patient. Note the improved definition of peripheral and mediastinal structures.

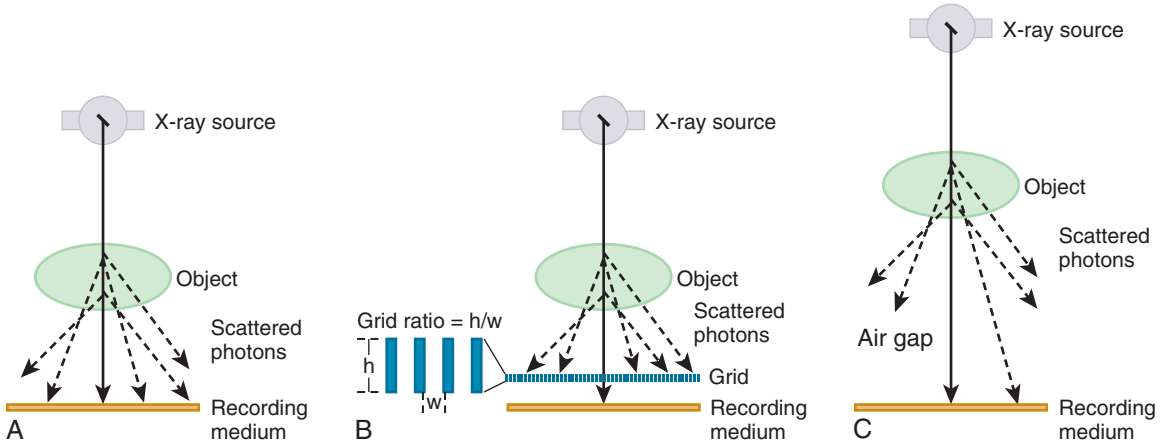

FIGURE 19-2 ■ Scattered radiation and scatter reduction. **A,** When an object is radiographed, some photons (the primary x-ray beam) (*solid line*) pass unaffected through the patient. Scattered or secondary radiation (*dashed lines*) arises at various angles to the primary beam and may expose the film or other recording medium, reducing image contrast and detail. **B,** Scatter can be reduced with a grid. An antiscatter grid placed between the object and the recording medium reduces exposure due to scattered radiation. A grid is made of thin layers of radiation absorber (e.g., lead). Scattered radiation traveling at an angle to the grid layers is absorbed, although some scattered radiation at shallow angles may pass through. The grid ratio is equal to the height of the radiation absorber strips divided by the distance between them. **C,** Scatter can be reduced with an air gap. When the distance between the object and the recording medium is increased, an air gap is created. With an air gap, scattered photons at sufficiently great angles miss the recording device or film.

radiation degrades image contrast and detail.[1,4] Because production of scatter radiation varies with the volume of tissue being imaged, the use of devices, referred to as "collimators," to restrict the beam size to the area being studied reduces scatter radiation. The further addition of filtration to the x-ray tube in the area of the collimator prevents low-kilovoltage radiation from reaching the patient, thus reducing the radiation absorbed by the patient without compromising diagnostic information.

Scattered radiation can also be removed by placing an antiscatter grid between the patient and the x-ray cassette (see Fig. 19-2B).[1,4-6] Such grids permit the passage of the parallel primary x-ray photons to expose the screen or detector while absorbing radiation scattered at an angle to the primary beam; the grid also absorbs some primary photons, making it necessary to increase the amount of radiation to which a patient is exposed. Care must be taken to ensure that the grid is of the proper type and is properly aligned to the x-ray beam. Placement off center, angulation, or the use of a grid focused at the wrong distance may affect the symmetry of radiograph exposure or even render it uninterpretable. Scatter radiation may also be reduced by increasing the distance between the x-ray cassette or detector and the patient, a process referred to as "creating an air gap" (Figs. 19-2C and 19-3).

Resolution

Spatial resolution of film-screen combinations in common use is 10 to 12 line pairs/mm. Many factors, however,

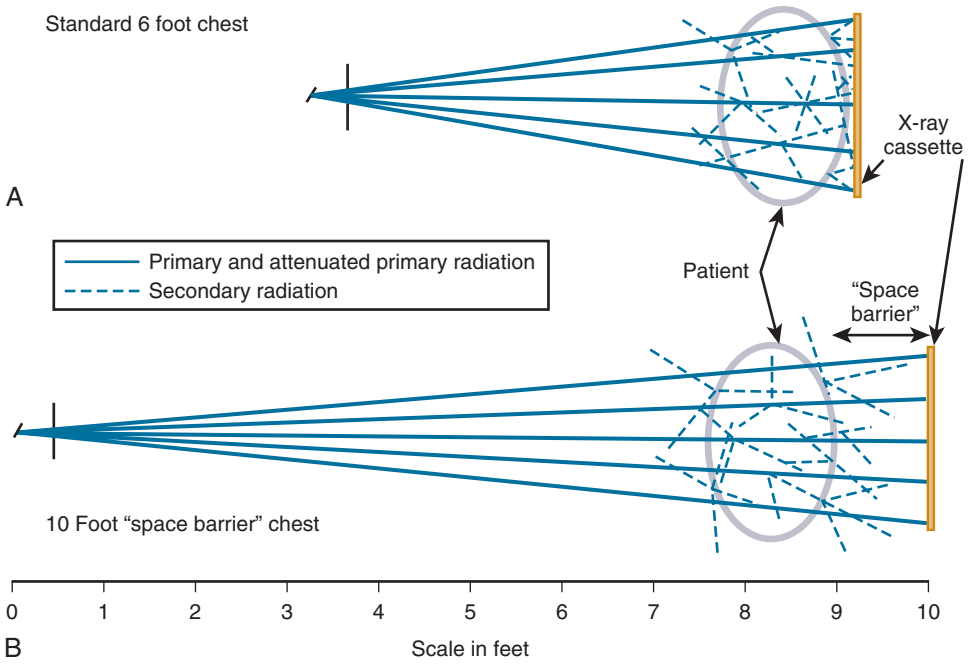

FIGURE 19-3 ■ **A,** The geometry of a standard 6-foot chest radiograph. For beam energies in the recommended range (≥120 kVp), a grid is necessary between the patient and the x-ray cassette or detector to diminish secondary radiation. **B,** A 10-foot air gap or "space barrier" can also be used. The air gap obviates the need for a grid. The 10-foot tube-to-film distance helps to minimize geometric enlargement. The avoidance of the grid diminishes patient radiation exposure.

can reduce the final resolution achieved on a chest radiograph. The use of large focal spots, particularly in thick body parts such as the thorax, degrades resolution by producing "edge unsharpness" or blur due to penumbra effects. Conversely, the limited capacity of a very small focal spot dictates a long x-ray exposure, and body motion can degrade spatial resolution, also causing edge unsharpness. A compromise choice in x-ray focal spot size of 1 mm or less is recommended. Lengthening of exposure duration causes degradation of spatial resolution because of insufficient power of the x-ray generator or deficiency of the heat capacity of the tube. Ideally, exposure duration should not exceed 25 msec and, for frontal projections, should be considerably less. A tube-film distance of at least 6 feet (1.8 m) is usually used to reduce magnification and image blurring (see Fig. 19-3).

Noise

All imaging systems are limited by noise. In radiography, noise is frequently referred to as "quantum mottle."[4] Image mottle is primarily determined by the number of x-ray photons used to produce the image. The fewer the number of photons, the noisier the image will be. With a given film-screen or digital system, attempts to increase speed generally result in decreased resolution because of mottle.

X-ray screens have been developed that employ rare earth phosphors and have the property of converting x-ray photons to light more efficiently. When used with properly matched films, these rare earth screens double or triple the speed at which a properly exposed radiograph can be made. They do not increase the noise of the system significantly, and they permit reduction of radiation exposure to the patient by one half or more.

American College of Radiology Standards

The American College of Radiology standards for performing adult chest radiography[7] specify the use of at least a 72-inch tube-film distance, a tube focal spot not to exceed 2.0 mm (0.6–1.2 mm recommended), rectangular collimation and beam filtration, a high-kilovoltage technique (120–150 kVp) appropriate to the characteristics of the film-screen combination, a film-screen speed of at least 200, an antiscatter technique (grid or air gap) equivalent to a 10:1 grid (preferably 12:1), and a maximum exposure time of 40 msec. The American College of Radiology also specifies a maximum mean skin entrance radiation dose (0.3 mGy/exposure).

Portable Radiography

The proliferation of ICUs and the increased use of patient monitoring for life-support devices have significantly increased the number of portable radiographs obtained.[1,8,9] As indicated earlier, these examinations are

necessary to determine whether catheters, endotracheal tubes, intra-aortic balloons, and various other devices have been correctly placed (Figs. 19-4 to 19-8).[10,11] Portable radiographs are also essential for assessing responses to therapy and for surveying for the presence of new thoracic disease.

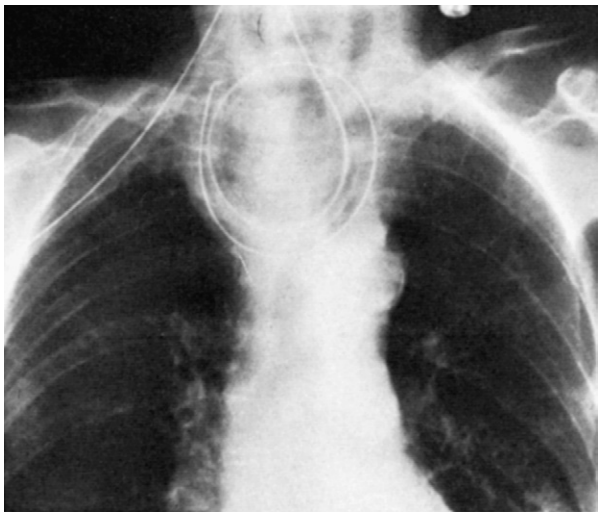

FIGURE 19-4 ■ An intensive care unit portable radiograph shows the nasogastric tube coiled in a Zenker's diverticulum, the existence of which was previously unknown.

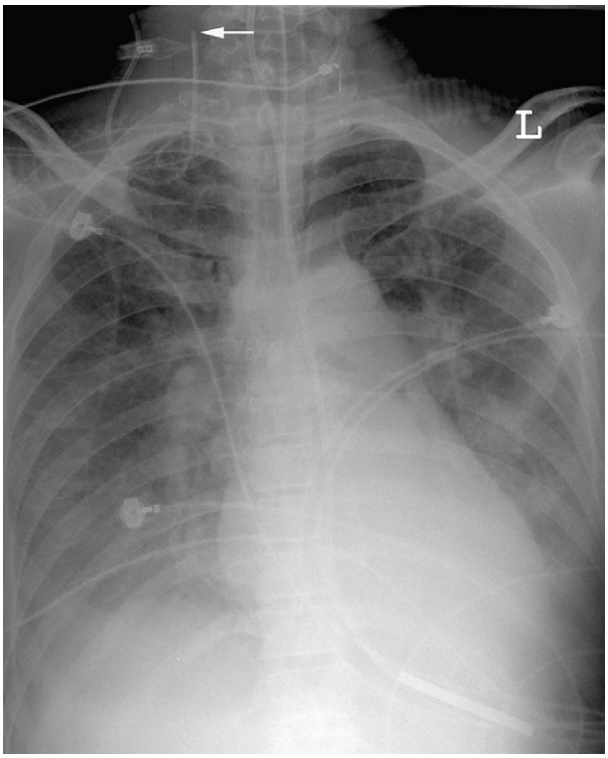

FIGURE 19-5 ■ A portable radiograph shows a misplaced central venous line. Note that the right external jugular venous catheter tip (*arrow*) is within the right internal jugular vein, rather than the superior vena cava. Extensive densities (pulmonary edema) are present in both lungs.

Even under ideal circumstances, the quality of the radiographs obtained with portable techniques does not approach the standard of those made in the radiology department (Fig. 19-9). Portable examinations are generally made at a focal spot–film distance of less than 72 inches, resulting in penumbral blurring, edge unsharpness, and degradation of fine detail.[4] The routine use of the anteroposterior (AP) projection, with the cassette adjacent to the patient's back, magnifies the cardiac silhouette and other anterior structures. When possible, the radiograph should be obtained with the patient in the sitting position, but this is frequently not feasible. Images obtained with the patient recumbent compromise the detection of pleural effusions and pneumothorax as well as the assessment of the gravitational distribution of pulmonary blood flow based on vessel size and lung zone opacity.

None of the several different types of mobile generators available is ideal. Exposure duration is difficult to control and is relatively long, and motion blurring degrades the image. Because of these limitations and the frequent need for immediate viewing of chest radiographs, storage phosphor-computed digital units are widely used for ICU radiography (see later discussion).[11] The storage plate phosphor's ability to provide relatively even density in overexposed and underexposed films and its ability to adjust the images digitally to better visualize mediastinal or pulmonary parenchymal areas are well suited for ICU portable radiography.

The American College of Radiology standards for performance of portable chest radiographs are relatively forgiving.[7] A tube-film distance of 40 to 72 inches is preferred. From 70 to 100 kVp is recommended if a grid is not used, whereas more than 100 kVp may be used in conjunction with a grid. Exposure times should be as short as feasible to reduce motion artifacts.

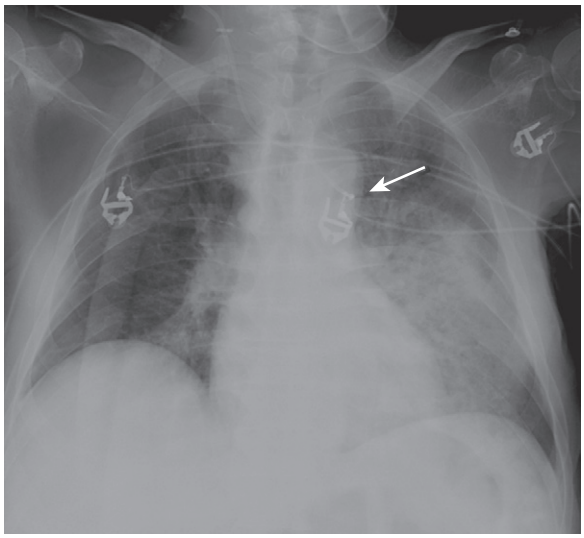

FIGURE 19-6 ■ An intensive care unit portable radiograph demonstrates malposition of a right central venous catheter. The catheter has been inadvertently inserted into the right carotid artery; the tip (*arrow*) resides in the aortic arch. A large area of consolidation is seen in the left lung.

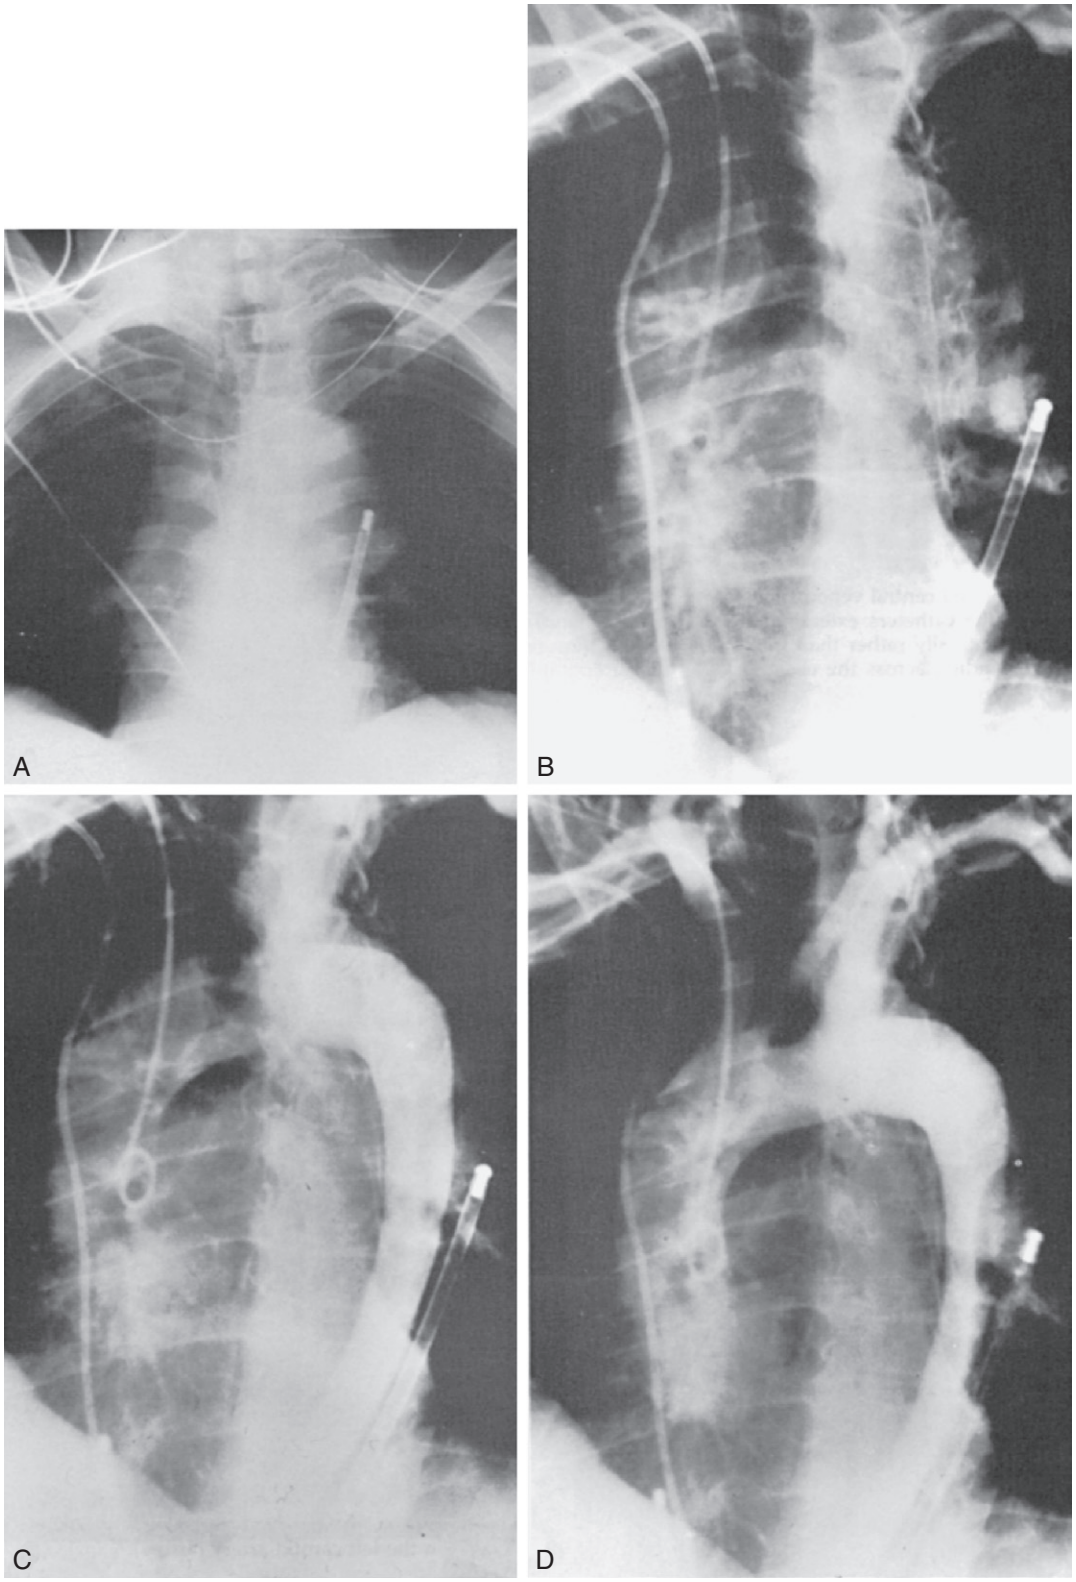

FIGURE 19-7 ■ Portable intensive care unit radiography is useful in several situations. **A,** A "routine" radiograph made after insertion of an intra-aortic balloon shows the catheter to be more lateral than usual. **B,** A portable oblique radiograph confirms the unusual position. The balloon-assist device appeared to be functioning adequately. **C,** An aortogram performed with a pigtail catheter in the ascending aorta reveals the balloon catheter to be outside of the lumen of the descending aorta. **D,** The diastolic cardiac phase is shown. The inflated balloon, which is in an aortic dissection, does partially occlude the aortic lumen, explaining why the balloon appeared to be functioning satisfactorily. The balloon had been inserted into the false lumen of an aortic dissection.

Digital (Computed) Radiography

The development of reusable radiation detectors along with advances in electronics and computer technology enabled the development of a new type of radiographic imaging: digital or computed radiography.[1,12] These systems are fundamentally different from film-screen radiography in that image detection can be completely separated from the method of image display, and because the images are digital in format, they can be subjected to significant postprocessing to improve diagnostic information. Also, digital image receptors have a much wider range of sensitivity or latitude compared with standard film-screen combinations (10,000:1 rather than 100:1), and their response to radiation is linear over this entire range.[1,2] Within these large limits, image contrast is independent of exposure. Furthermore, digital images can be displayed, transmitted, and stored electronically.[2,4]

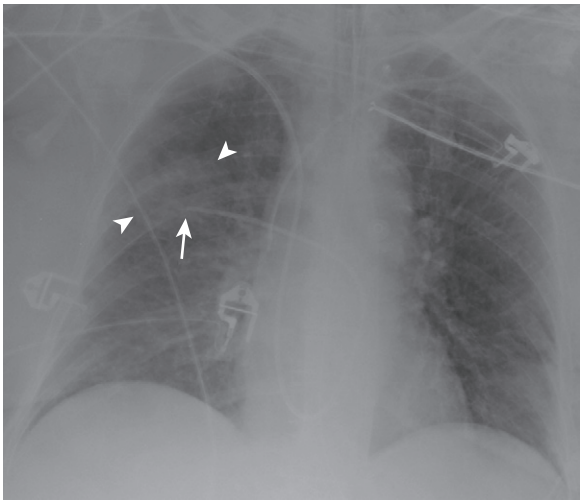

FIGURE 19-8 ■ Sequelae of a malpositioned Swan-Ganz catheter. The catheter (*arrow* = tip) extends too far peripherally into the segmental vessels of the right upper lobe artery. The catheter had been in this location for a number of hours. Note the opacity in the right upper lobe (*arrowheads*), representing pulmonary hemorrhage or infarction secondary to vessel obstruction by the Swan-Ganz catheter.

Storage Phosphor Systems

The most commonly employed system of digital radiography uses imaging plates that are exposed by conventional radiographic equipment and can be used like any x-ray cassette.[1,4] The reusable plates are coated with a photostimulatable phosphor that absorbs energy and retains a latent image when exposed to x-rays. The stored energy of the latent image is released as light when the plate is scanned by a laser in an image plate reader. The light produced is measured and digitized, yielding an image that can be subjected to contrast and spatial frequency enhancement and can be stored on magnetic or optical disks, viewed on monitors, or printed on film with a laser printer (Fig. 19-10). The imaging plates are erased by exposure to light and may be reused almost immediately.

The resolution of digital images depends on the matrix size used. Spatial resolution is less than that of film-screen combinations (2.5–5 line pairs/mm), depending on the size and type of plate used to capture the image.[1] The unit can be set to perform automatic processing by preprogramming parameters for certain examinations or may be postprocessed manually by the radiologist to enhance various specific image features.[13] The contrast

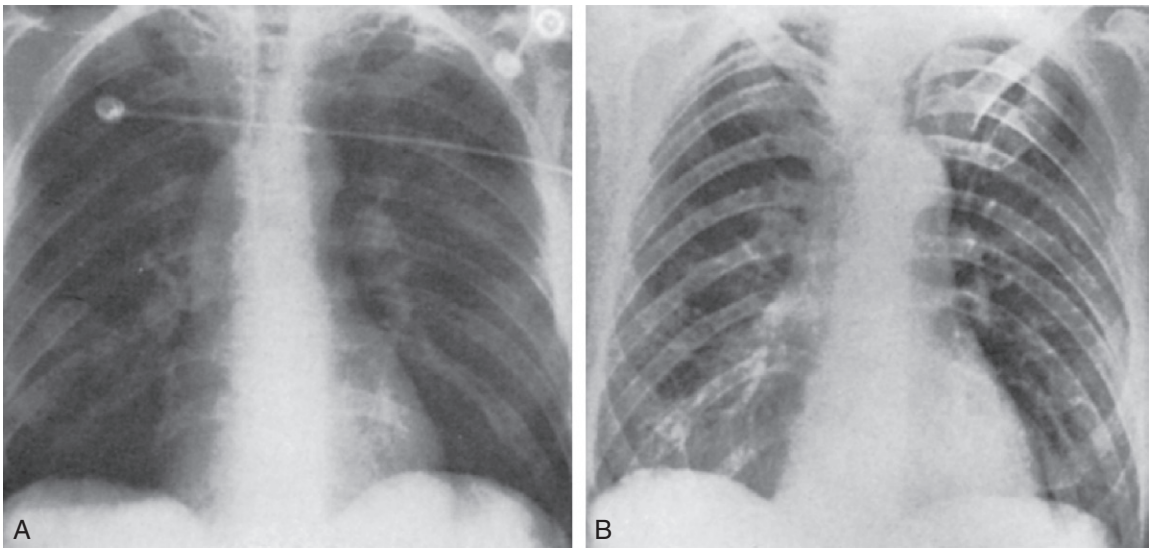

FIGURE 19-9 ■ Portable radiography has limitations. **A,** This anteroposterior (AP) supine portable radiograph was made in the intensive care unit. The energy of the beam was 100 kVp, and the focal spot–film distance was 40 inches. The pulmonary markings are poorly visualized because of a long exposure with motion blurring and a short focal spot–film distance with magnification and detail degradation. **B,** This radiograph was obtained from the same patient shortly after that shown in **A,** but in the main radiology department. The patient was sitting in a chair. The energy of the beam was 130 kVp, with a focal spot–film distance of 60 inches. Much better detail can be seen in the radiograph in **B.** It also has less magnification.

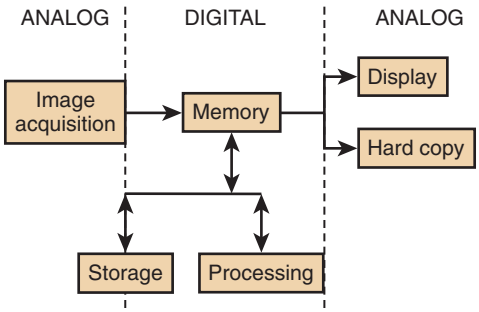

FIGURE 19-10 ■ This block diagram shows components of a digital radiographic system. Image manipulation, subtraction, and other such functions are performed during the digital phase. (From Nudelman S: *In* Digital Radiology—Physical and Clinical Aspects: Proceedings of Meeting Held at Middlesex Hospital and Medical School, London, England, March 9, 1983. London: Institute of Physical Sciences in Medicine, 1984, pp 1–43.)

scale can be altered, and the optical density of the entire image or of various areas can be changed. Edge enhancement can be obtained by amplifying high frequencies to visualize minute pulmonary detail. For the thorax, the automatic processing can be preset to produce a pair of images: one resembling a conventional film-screen radiograph and the other exhibiting varying amounts of edge enhancement (Fig. 19-11).

An obvious advantage is that the images can be immediately transmitted electronically and viewed at a workstation in the emergency room, ICU, operating room, or other area where online viewing is required.[1,4] Because the images are stored electronically, they may be recalled for comparison with subsequent studies, and they may be printed for conventional display at any time. High-resolution display units (2000-line) allow displayed images with excellent spatial resolution.

Clinical Efficacy

A large number of studies have compared digital imaging systems with conventional film-screen radiographs in both measured physical performance and interpretive accuracy. It is generally agreed that the denser portions of the thorax and the lung in front or behind these dense areas are seen significantly better with digital systems. There is disagreement concerning visualization of fine lung detail, line shadows, pneumothoraces, and interstitial lung disease.[14–18] An important consideration is that digital recording systems have a very wide exposure latitude, and adequate films can be obtained with a wide range of exposures, which reduces the need for repeated films.

Factors other than image quality are playing a preeminent role in the dissemination of digital techniques. Among these are immediate availability of the images, ease of storage and retrieval, interaction with hospital electronic information systems, and cost of film and file room operation. CT, MRI, ultrasonography, and nuclear medicine studies already are digital. The completely digital imaging department is increasingly common. In certain situations, digital images enables the use of computer-aided detection, particularly in the setting of mammography, chest radiography, and thoracic CT.[1]

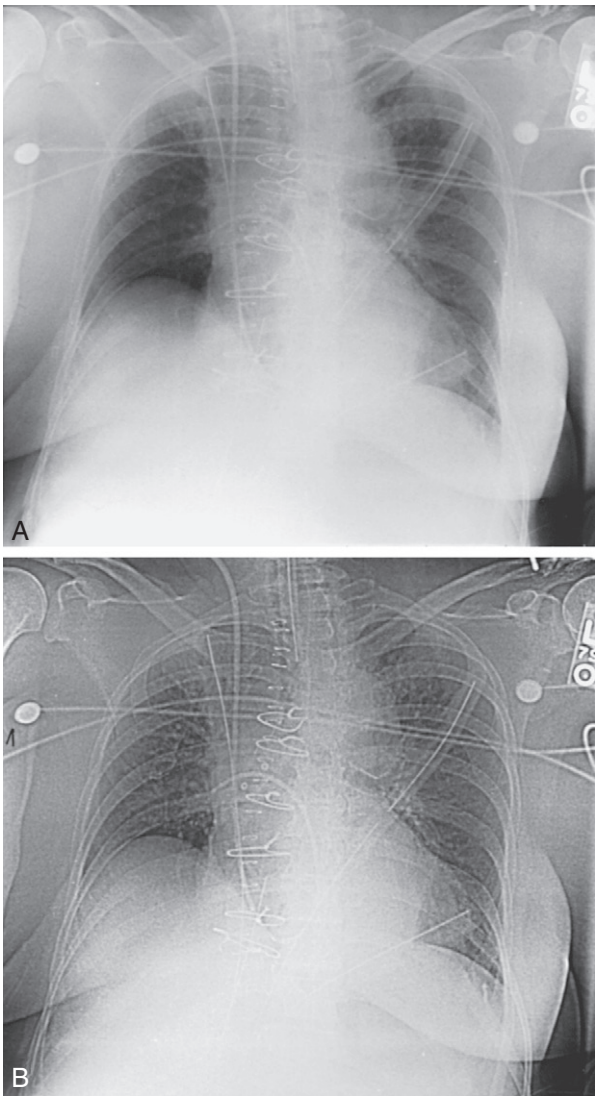

FIGURE 19-11 ■ This digital (computed radiography) study of the chest was made in an intensive care unit. **A,** This view resembles a "conventional" film-screen radiograph. **B,** This view was processed for edge enhancement.

Radiographic Views and Techniques

Routine Examination

A routine chest radiographic examination in an ambulatory patient usually consists of posteroanterior (PA) and left lateral projections. The utility of routine lateral radiographs, however, has been questioned. After analyzing over 10,000 radiographic chest examinations obtained routinely in a hospital-based population, Sagel and associates[19] concluded that the lateral radiograph could be safely eliminated in the routine examination of patients 20 to 39 years of age. Conversely, they and others[20] have concluded that the lateral radiograph should be obtained

in patients with suspected chest disease and in screening examinations of patients 40 years of age or older (Fig. 19-12).

Expiratory Views

Conventional radiographs are made at total lung capacity (i.e., full inspiration), thereby permitting the greatest volume of lung to be evaluated for possible pathology and providing the most contrast between intrapulmonary air and normal and abnormal intrathoracic structures (Fig. 19-13). However, localized or generalized air trapping in the lung or pleural space is more easily detected (and sometimes only detected) on a radiograph made during expiration. The normal lung diminishes in volume and increases in density with expiration. Areas of trapping usually retain their lucency and volume regardless of the phase of respiration. With unilateral or localized air trapping, mediastinal shift and failure of normal elevation of the hemidiaphragm on the affected side are frequently apparent only on expiration (Fig. 19-14). Small pneumothoraces, difficult to visualize and frequently overlooked on inspiratory radiographs, appear larger and more apparent on the expiratory study. As the thorax and underlying lung diminish in volume, the lung becomes denser, whereas the pneumothorax remains

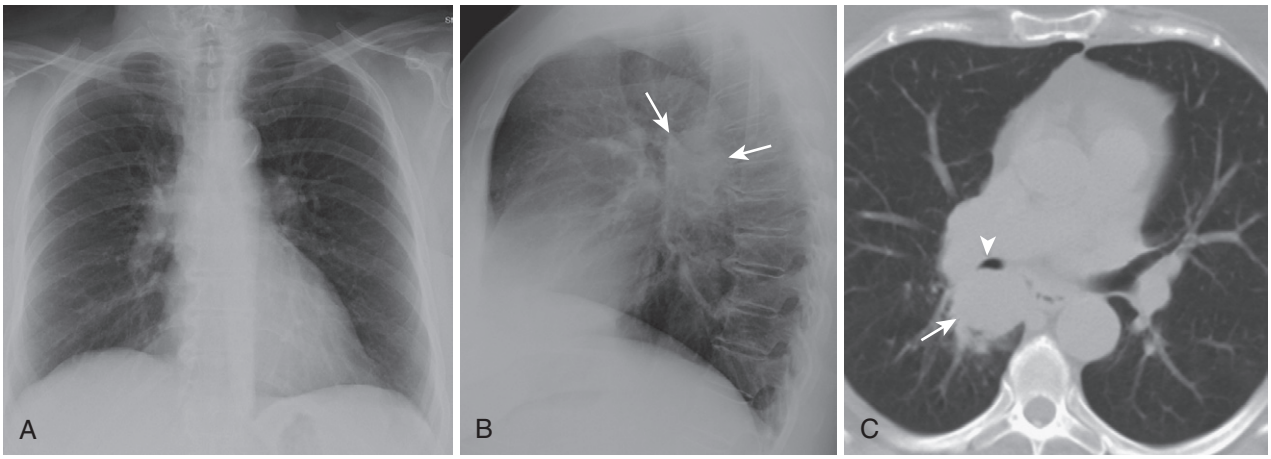

FIGURE 19-12 ■ The utility of the lateral radiograph. **A,** The posteroanterior (PA) radiograph shows no specific abnormalities. **B,** The lateral radiograph identifies a mass (*arrows*) projected over the hilum. **C,** Axial thoracic computed tomography (CT) confirms the presence of a mass (*arrow*) in the right lower lobe posterior to the bronchus intermedius (*arrowhead*). The lesion was shown to represent bronchogenic carcinoma.

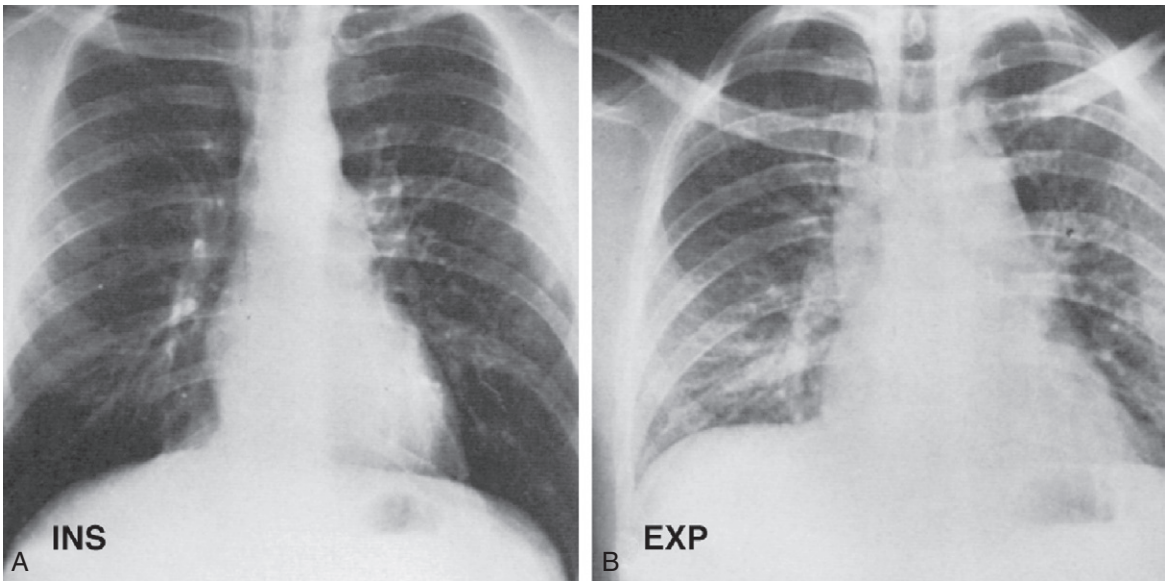

FIGURE 19-13 ■ These inspiration (INS) and expiration (EXP) radiographs are from a healthy man. **A,** With inspiration, the low level of the diaphragm permits visualization of the basal portions of the lung. There is normal radiolucency of the lung. The mediastinum is narrow, and the edges of the hilar structures are sharp. **B,** With expiration, the lung bases are obscured. The lung is dense. The mediastinum is wide and could be interpreted as abnormal if the fact that the film was made at residual volume was not appreciated.

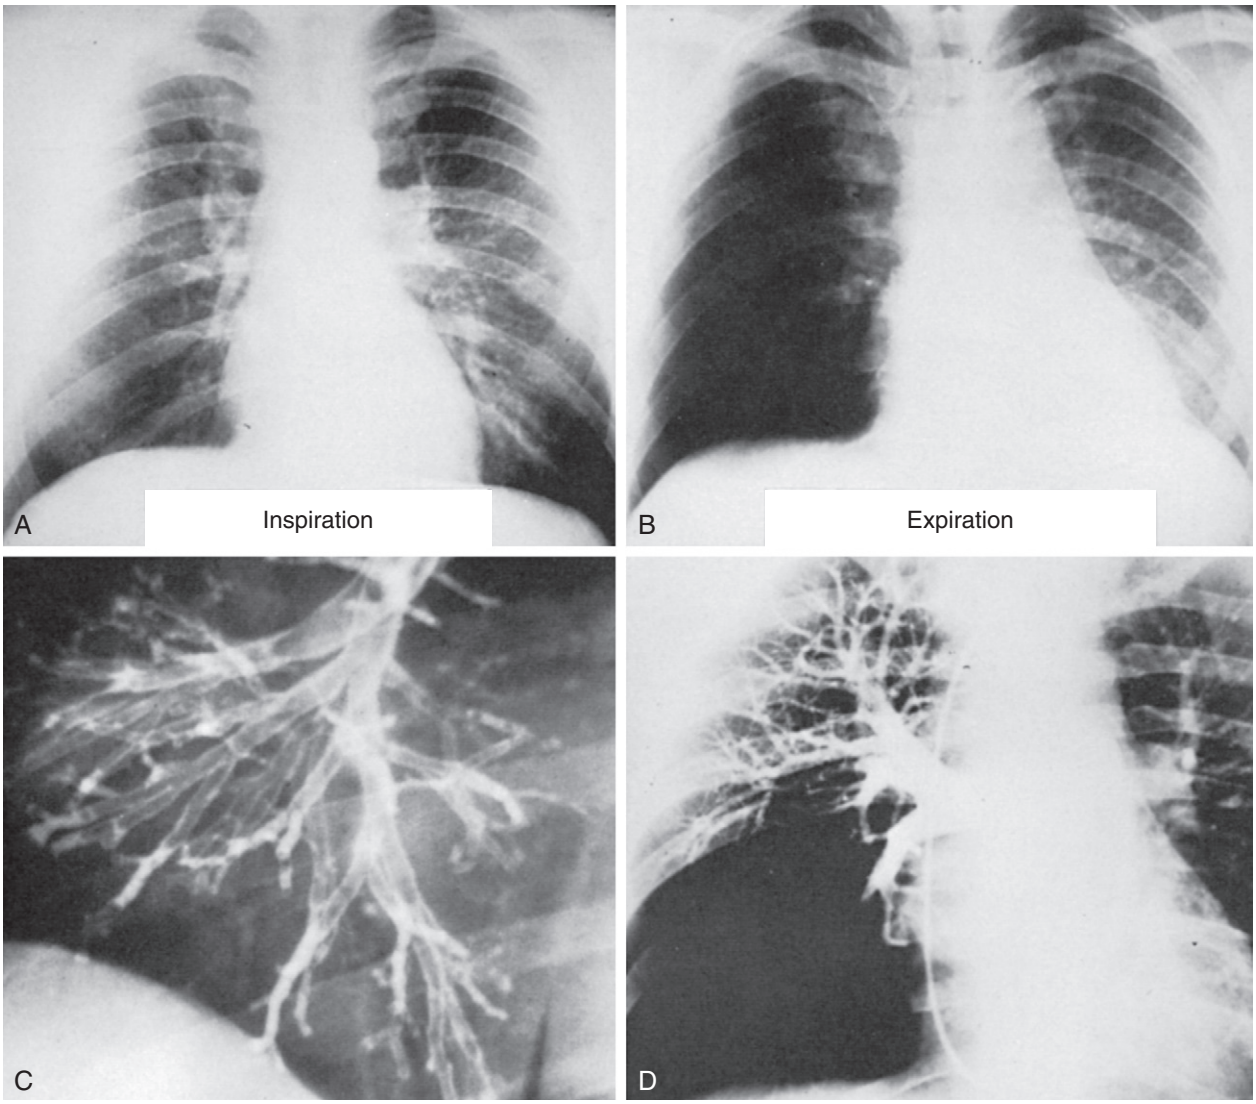

FIGURE 19-14 ■ The unilateral hyperlucent lung of an asymptomatic 32-year-old man. **A,** With inspiration, the vessels to the right lower lobe are smaller than those on the left, and the left hilus is prominent compared with the right. No radiographic evidence of air trapping is seen. **B,** With expiration, there is air trapping on the right. The left hemidiaphragm ascends normally, whereas the right remains low and fixed. The mediastinum shifts to the left. Lucency persists on the right. **C,** Bronchography with propyliodone fails to fill the small bronchi and bronchioles in the right lower lobe. Air movement is necessary to fill these small bronchi. The obliterative bronchiolitis causing the trapping (through collateral air drift) involves airways much smaller than those bronchi visualized on the study. Bronchiectasis, which may accompany this condition, is not present. **D,** Pulmonary angiography reveals a large perfusion defect in the involved area due to hypoxic vasospasm. This should not be mistaken for pulmonary embolism, because neither the trailing edge nor the wormlike defect of thrombi is seen. Neither bronchography nor angiography is indicated for asymptomatic patients with this condition.

essentially unchanged in size and occupies a greater proportion of the deflated hemithorax and is thereby outlined more clearly by denser pulmonary parenchyma (Fig. 19-15).

Other causes of localized or unilateral lucency on the radiograph are differentiated from air trapping by the expiratory study (Fig. 19-16). Among these are technical causes such as patient rotation, miscentered x-ray beam or grid, and "the anode-heel effect," an artifact of asymmetrical generation by the anode of the x-ray tube. Chest wall abnormalities, either congenital or postsurgical, can produce unilateral lucency. Undetected areas of atelectasis with compensatory overexpansion of portions of the lung and primary vascular disease, such as pulmonary embolus, may also produce lucency. None of these causes of pulmonary lucency will show trapped air on the expiratory radiograph.

Decubitus Views

Decubitus radiography is performed by placing the patient in the recumbent position, usually lying on one side and then the other. The x-ray exposure is made with a horizontal beam in either the AP or the PA projection.

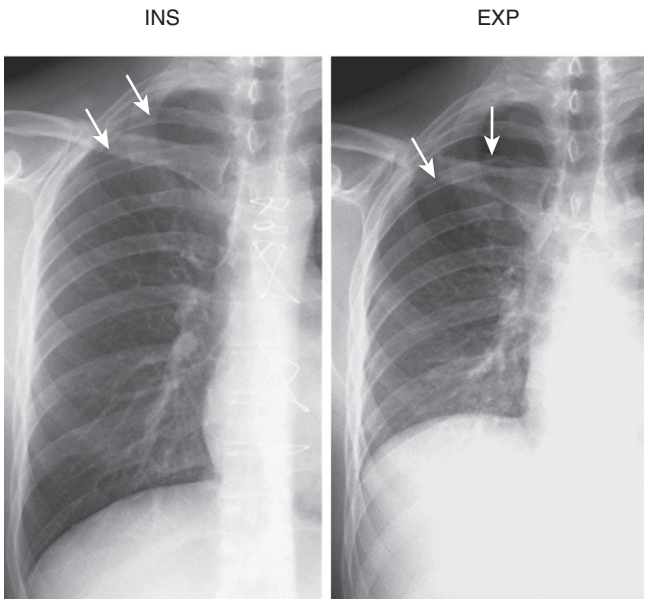

FIGURE 19-15 ■ Inspiration (INS) and expiration (EXP) films of a pneumothorax. **A,** With inspiration, the right pneumothorax is difficult to visualize but is faintly seen in the upper thorax (*arrows*). **B,** With expiration, the pneumothorax is outlined against denser lung. It appears to be considerably larger than in the inspiration study (*arrows*) (see text).

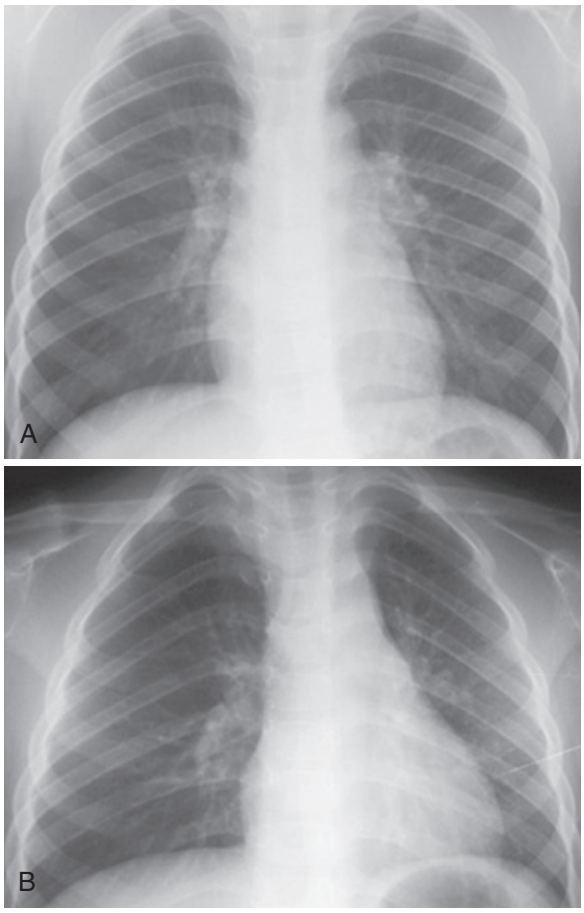

FIGURE 19-16 ■ Unilateral hyperlucent lung in an 8-year-old boy with a foreign body in the right main-stem bronchus. **A,** The inspiration radiograph shows mild hyperlucency of the right lung. **B,** The expiration film shows the right hemidiaphragm remains fixed in a low position, the right lung remains lucent, and the mediastinum is shifted to the left (air trapping). A foreign body was removed.

The technique is useful for determining the presence or absence of free fluid in the pleural space or parenchymal cavities, in estimating the size of effusions, and in diagnosing pneumothorax in patients who are unable to sit or stand. Free fluid gravitates to the dependent portion of the thorax, which in the decubitus patient lies against the lateral rib cage of the dependent hemithorax (Fig. 19-17) or the mediastinum of the contralateral side; pneumothorax does the opposite. In the typical AP supine chest radiograph, free fluid will layer posteriorly and manifest as an increase in density involving the entire hemithorax. Air within the pleural space will collect anteriorly and is often difficult to detect. The proper use of decubitus radiography will demonstrate the presence of free fluid, pneumothorax, or both (Figs. 19-18 and 19-19). When a portable study must be performed with the patient in bed, it may be technically difficult to obtain high-quality radiographs of the dependent portion of the hemithorax due to the underlying bed, clothes, or other inconveniences. For this reason, bilateral decubitus studies are advisable. Even in patients in whom PA and lateral erect radiographs can be performed, subpulmonic effusions may be difficult to detect, and no fluid meniscus may be visualized. Unless the fluid is completely loculated, a decubitus study will demonstrate its presence and size (see Fig. 19-19). As little as 20 mL of fluid can be seen in the decubitus position.

Lordotic Views

Radiographs made in the lordotic position can be of value in demonstrating lesions in the immediate subclavicular region or partially hidden by the clavicle. This is particularly true if these lesions are located posteriorly. In the lordotic view, which is most frequently obtained in the AP projection, the clavicle, being an anterior structure, is projected above the lung apex, and the subclavicular lung regions are well visualized. The lordotic view may also be used to confirm middle lobe or lingular atelectasis. A lordotic view centered over the lower portion of the chest will project the atelectatic lobe or segment so that it directly faces the x-ray beam, and it will be easily visualized as a dense triangular shadow.

Oblique Views

Occasionally, shallow oblique views are valuable in sorting out superimposed shadows and in visualizing pulmonary parenchymal opacities obscured by superimposition from the heart, mediastinum, or portions of the bony thorax. In general, it is more rewarding to study these opacities with CT.

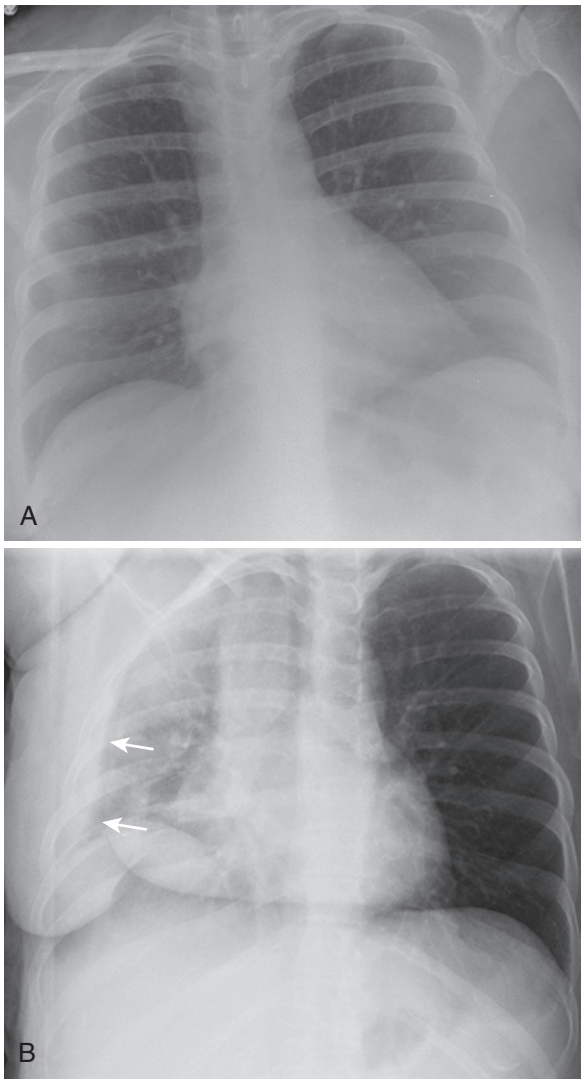

FIGURE 19-17 ■ The value of decubitus radiography. This patient had right pleuritic chest pain. **A,** A frontal chest radiograph shows no specific abnormalities; the right costophrenic angle is sharp. **B,** A right lateral decubitus radiograph shows a small right pleural effusion (*arrows*). Note that decubitus imaging causes collapse of the ipsilateral lung.

Fluoroscopy

Fluoroscopy at one time was commonly employed either as the primary method of radiologic examination of the chest or as an adjunct study to standard radiographs. Its use over the past several decades has diminished considerably. However, there remain a few situations in which fluoroscopy can provide information that is difficult to obtain by other means, such as for the detection of abnormalities of diaphragmatic motion that result from conditions affecting the phrenic nerve. The major use of chest fluoroscopy in current medical practice is as a guide for interventional procedures such as catheter angiography and needle or transbronchial biopsies.

Bronchography

Contrast bronchography, formerly a fairly common thoracic examination (see Fig. 19-14C), has been replaced by fiberoptic bronchoscopy and either CT or high-resolution computed tomography (HRCT) of the lung. In patients with suspected bronchiectasis, HRCT and spiral CT are as sensitive and are safer, more easily obtained, and much more pleasant to undergo than bronchography.[21]

Pulmonary Angiography

Pulmonary angiography has traditionally been employed primarily for the detection or exclusion of pulmonary embolism (Fig. 19-20; see also Fig. 19-14D). Although it has been traditionally regarded as the "gold standard" for making the diagnosis of pulmonary embolism, it has limitations and tends to be underutilized.[22] Other situations in which pulmonary angiography has been employed include the diagnosis and embolization of pulmonary arteriovenous malformations (Fig. 19-21), pulmonary arterial foreign body retrieval, pulmonary vasculitis (Fig. 19-22), and occasionally, the delineation of the anatomy of pulmonary vessels before lung surgery. The study is performed by rapidly injecting intravenous contrast material through a catheter and imaging the lung while the contrast material traverses the arteries and veins. Most frequently, the catheter is inserted into the femoral vein percutaneously and then guided into the pulmonary artery under fluoroscopic control.

Angiograms may be done with the catheter in a main branch of the pulmonary artery or more selectively in distal vessels. The radiographic contrast material is injected at the rate of approximately 10 to 25 mL/sec, depending on the vessel size. The volume of contrast depends on the location of the catheter. Between 40 and 60 mL of contrast material is usually injected into the right or left main pulmonary artery; half this amount of contrast is needed with digital subtraction techniques. Selective injections made within the more distal pulmonary arteries require smaller volumes. If the angiogram is performed for the detection or exclusion of pulmonary embolism after an abnormal but nondiagnostic perfusion scan, the location of the perfusion defect on the scan may act as a "road map" for the angiographer, and selective or superselective injections proximal to the area of perfusion deficit may be performed.

Unless the angiogram is done with a balloon occlusion technique, serial recording is necessary. In the past, rapid film changers were used with an exposure rate of 3 or 4/sec, but such "cut-film" techniques have been replaced by digital subtraction angiography. Filming is usually carried out for several seconds after injection to permit visualization of the pulmonary veins, the left side of the heart, and the thoracic aorta.

It is frequently necessary to image in several different projections to confirm or exclude pulmonary embolism. Oblique or lateral projections may be desirable. If the angiographic suite contains biplane equipment, the number of necessary contrast material injections can be

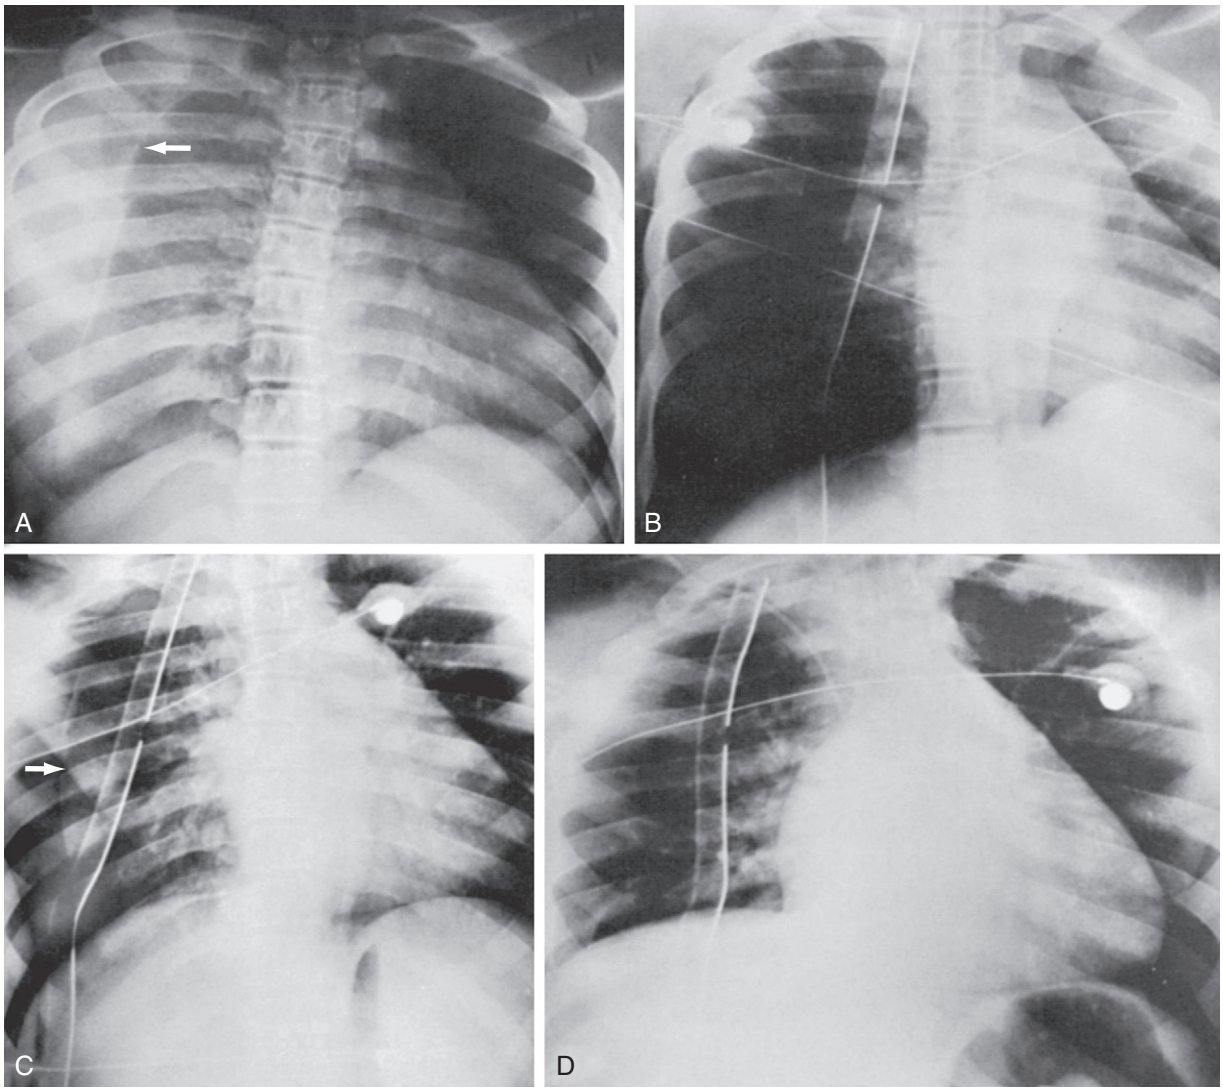

FIGURE 19-18 ■ The value of a decubitus film in portable radiography. A 20-year-old man was admitted to the hospital in shock after a knife wound to the right side of the chest. **A,** A supine AP portable radiograph shows a tension hemopneumothorax on the right. The mediastinum is deviated to the left. The right hemidiaphragm is depressed. The rib interspaces on the right are widened. The right lung is partially collapsed. No air-fluid levels are seen, but both sides of the pleural stripe are visualized, indicating that air is present along with fluid in the right hemithorax (*arrow*). **B,** A postoperative radiograph (AP supine) reveals air in the soft tissues. There is persistence of tension on the right despite the presence of a chest tube. It is not possible to determine whether the tension is due to air trapping within the lung or to a pneumothorax. **C,** A left lateral decubitus radiograph clearly shows the presence of a pneumothorax (*arrow*), even though the chest tube was draining small amounts of air out of the right hemithorax. The low position of the right hemidiaphragm is indicative of tension. **D,** An AP supine radiograph after reexploration shows no evidence of tension or of pneumothorax. The chest wound had been inadequately repaired at the first operation, permitting air to enter the right hemithorax on each inspiration. The tube, although draining small amounts of air, was partially obstructed with blood clot.

diminished by imaging in two orthogonal planes after a single injection of contrast medium. Magnification angiography may show emboli in vessels that are too small to be clearly seen on standard studies.

For a definite diagnosis of pulmonary embolism, it is necessary to visualize the embolus as either a filling defect (see Fig. 19-20) within a vessel or the trailing edge of a thrombus. Other abnormalities should not be regarded as diagnostic of embolism (see Fig. 19-14D).

Complications and death do occur, but fortunately are rare. Significant complications occur in less than 5% of patients, and death occurs in 0.1% to 0.5% of patients undergoing angiographic studies to evaluate suspected pulmonary embolism.[23] Minor arrhythmias are not infrequent when the catheter tip traverses the right ventricle. Ventricular fibrillation has been reported, as has refractory shock. Electrocardiographic monitoring and immediate availability of defibrillating equipment are necessary. Reactions to contrast material are most frequently minor and primarily consist of urticaria and vasovagal responses. However, major reactions with bronchospasm and cardiopulmonary collapse occasionally occur. Renal failure

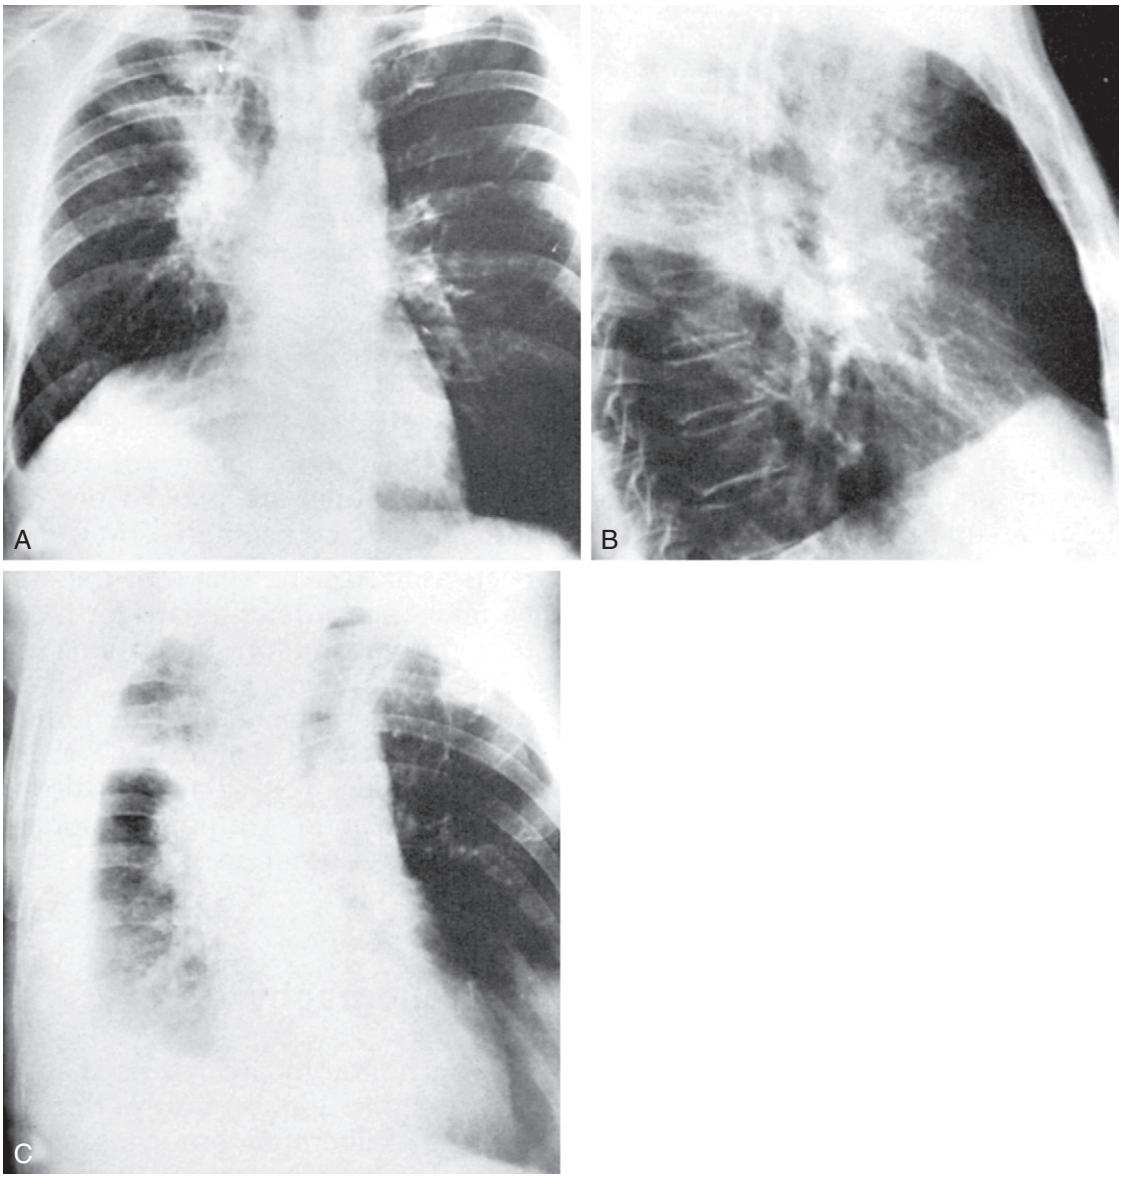

FIGURE 19-19 ■ The value of decubitus radiographs in a 55-year-old man with carcinoma of the right upper lobe. **A,** A PA radiograph shows an unusual configuration at the right base. Minimal blunting of the right costophrenic angle is present. The location of the hemidiaphragm cannot be determined. **B,** A lateral radiograph shows no definite evidence of fluid. The right hemidiaphragmatic shadow is elevated, particularly in its anterior portion. **C,** A right lateral decubitus projection reveals the presence of a large, free pleural effusion. The apparent elevation of the hemidiaphragm on the conventional PA and lateral films is due to subpulmonic effusion.

after administration of iodinated contrast material is a well-recognized complication, and preexisting renal disease manifested by elevated serum creatinine levels represents a relative contraindication to angiography. In all circumstances, the amount of contrast material injected should be the minimum required to produce diagnostic opacification of the pulmonary vessels. The use of nonionic or low-osmolar contrast material diminishes the number of minor reactions and increases patient comfort during the procedure and is now routine in most practices.

Aortography and Bronchial Angiography

Aortography is generally accomplished by the retrograde passage of a catheter from the femoral artery to the aorta or its branches after percutaneous insertion (Fig. 19-23). The study of the aorta and its branches plays a limited role in diseases of the lung. The imaging modalities of choice for diagnosing suspected aortic abnormalities, including aortic dissection, are MSCT, MRI, and in acute cases, transesophageal ultrasonography; aortography is seldom required. The diagnosis of pulmonary sequestra-

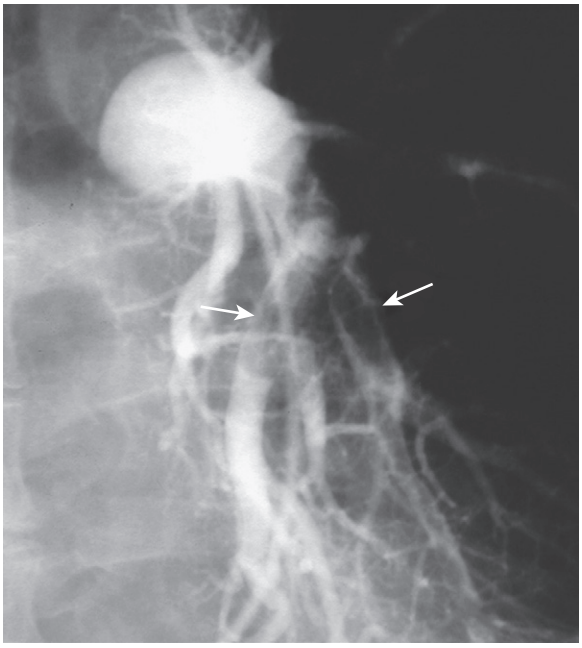

FIGURE 19-20 ■ Pulmonary angiography shows multiple emboli. Intraluminal filling defects (*arrows*) are present within the left pulmonary arterial vasculature, consistent with pulmonary emboli.

tion once depended on the demonstration of anomalous systemic blood supply by aortography, but in modern practice MSCT and MRI are often diagnostic and easily demonstrate the abnormal vascular supply (Fig. 19-24). Patients with severe hemoptysis may require bronchial arteriography and embolization of the bronchial artery or arteries supplying the bleeding site (Fig. 19-25). These studies require selective catheterization of the bronchial arteries. Angiographic technique is, for the most part, individualized to fit the particular clinical condition being studied.

Angiography can be performed with a technique termed "digital subtraction angiography." With digital subtraction angiography, an early image from the angiogram is recorded with an image intensifier and a high-resolution television camera and is digitized and stored. A later image in which vessels are opacified is handled in a similar manner. The first image is then subtracted from the second, and the resulting image is displayed. The background body structures are subtracted, leaving an image of the contrast-filled vessel (see Figs. 19-23 and 19-25). Because the body background does not obscure the final image, angiography can be accomplished with smaller amounts of contrast than otherwise necessary. Motion of structures in the area being studied may make subtraction of images difficult.

ULTRASONOGRAPHY

Ultrasonography, which is also discussed in Chapter 20, has limited usefulness in thoracic imaging, because the ultrasound beam is reflected at the air–soft-tissue interface around the lungs, but some specific uses have been recognized.[24-26] It is useful for studying vascular, cardiac, and some mediastinal abnormalities and for the localization of pleural fluid and air collections. Transesophageal sonography can allow imaging of some mediastinal structures and is often performed to assess the thoracic aorta and heart. The use of ultrasonography in lung imaging is largely limited to the pleura and immediate subpleural areas or to areas of consolidated lung or masses contacting or invading the chest wall. It is most commonly utilized for the detection, localization, and characterization of pleural effusions and to guide thoracentesis (Fig. 19-26).

Ultrasonography is also valuable in differentiating effusion from pleural thickening. Effusion is usually anechoic or hypoechoic, whereas pleural thickening results in an echogenic stripe within the enclosing rib margin.

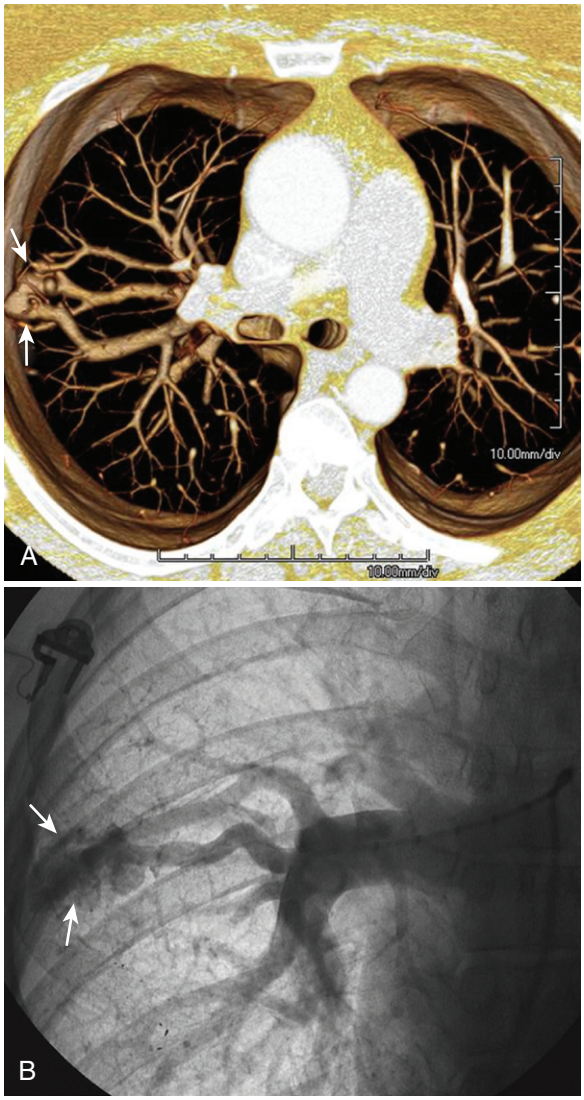

FIGURE 19-21 ■ Arteriovenous malformation. **A,** Axial thoracic volume rendered CT shows an arteriovenous malformation (*arrows*) in the peripheral right lung. **B,** Coronal pulmonary angiogram prior to embolization shows the arteriovenous malformation.

FIGURE 19-22 ■ Pulmonary arteriography in a patient with Takayasu arteritis shows a high-grade stenosis (*arrow*) of the right upper lobe pulmonary artery vasculature.

FIGURE 19-23 ■ Catheter aortography. Oblique coronal image from an aortogram shows the typical appearance of the aorta and great vessels.

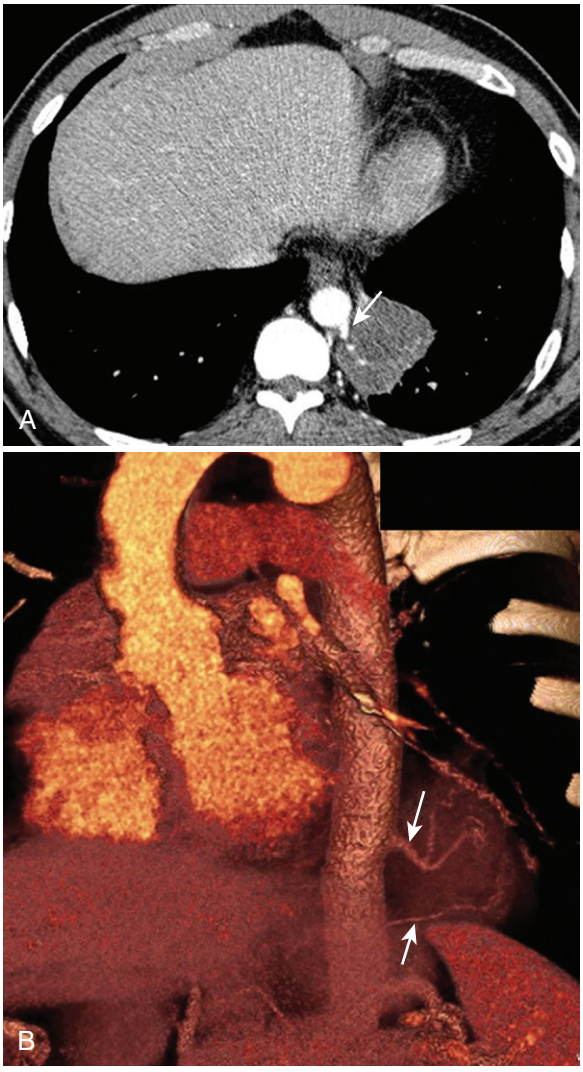

FIGURE 19-24 ■ Intralobar bronchopulmonary sequestration. **A,** Axial thoracic CT in a 24-year-old man with recurrent pneumonia shows a masslike opacity in the posterior basilar left lower lobe. Note the prominent aberrant vessel originating from the descending thoracic aorta (*arrow*) supplying the mass. **B,** Oblique coronal volume-rendered image shows the posterior basilar left lower lobe mass as well as two aberrant vessels (*arrows*) supplying the lesion.

When free-flowing or layering fluid is not demonstrated on decubitus radiographs in the presence of a thickened pleural stripe, ultrasound study may show collections of loculated fluid surrounded by pleural adhesions. Septations may be visualized within pleural collections, and their shape may change during the breathing cycle, confirming the presence of low-viscosity fluid. A complex echogenic fluid collection indicates the presence of exudate, empyema, or hemothorax, but an echo-free collection does not exclude these diagnoses. Ultrasound is also effective in differentiating subphrenic fluid from pleural effusion because the two hemidiaphragms are excellent reflectors of the ultrasound beam and therefore provide a visible boundary distinguishing intrathoracic from subdiaphragmatic spaces. The presence of a hypoechoic area caudal to the echogenic diaphragmatic stripe but cranial to the liver or spleen indicates ascites (Fig. 19-27).

FIGURE 19-25 ■ Bronchial arteriography in a patient with right lower lobe bronchiectasis and hemoptysis. **A,** Initial contrast injection into a hypertrophied bronchial artery. **B,** Injection into the same artery as in **A** shows significantly decreased blood flow following coil embolization.

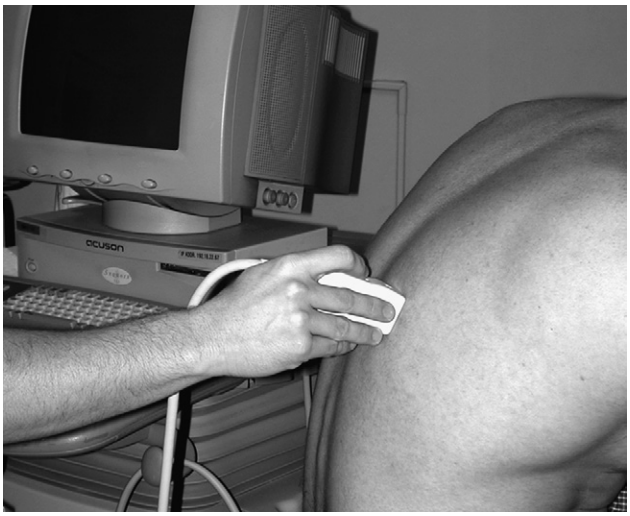

FIGURE 19-26 ■ The position of a patient for ultrasonically guided thoracentesis.

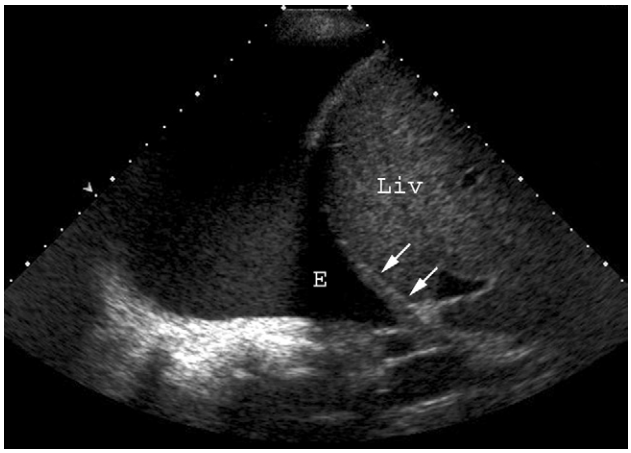

FIGURE 19-27 ■ Ultrasound examination of the lower left chest shows effusion (E) above the right hemidiaphragm (*arrows*). Liv, liver.

Ultrasound-guided thoracentesis is frequently performed when loculated fluid is suspected or after attempts at thoracentesis have failed.[27] The use of real-time equipment permits the performance of this procedure at the bedside (see Fig. 19-26). After locating the apparent fluid collection, the appropriate depth to which the needle should be inserted is displayed on the screen, and the aspiration is performed in the usual manner. Placement of catheters for drainage can be accomplished in a similar fashion.

Pleural neoplasms, mediastinal masses, or parenchymal masses that abut the pleural surface may be biopsied under ultrasonic guidance, provided that no aerated lung intervenes between the lesion and the pleura. The tip of the needle can be guided and identified within the mass, thus confirming appropriate placement before aspiration or biopsy.[28] However, CT or fluoroscopic guidance is more frequently employed for this purpose.

COMPUTED TOMOGRAPHY

Physical Principles

CT is based on the precise measurement of attenuation of a thinly collimated x-ray beam. Differential x-ray beam attenuation by different tissues forms the basis of image contrast on CT images. The advantages of CT are its axial

tomographic ("slicelike") format and its high sensitivity to differences in density between different tissues.

To obtain CT images, x-rays—produced by a modified standard x-ray tube—are passed through the patient, and the transmitted photons are measured by a series of x-ray detectors. The detectors produce an electric current that is proportional to the intensity of the beam of x-rays. The strength of this current is measured and digitized by an analog-to-digital converter and thus is available for computer manipulation. The reduction in the intensity of the beam as it passes through the patient's body is termed "attenuation" and is due to scattering and absorption of the x-ray photons by tissue. The attenuation (more precisely, the linear attenuation coefficient) of each point within the body can be calculated by the scanner's computer, provided that multiple measurements of x-ray attenuation can be made from different angles. The details of the x-ray beam and detector motion by which these multiple measurements are obtained vary considerably between scanners. Spiral or helical scanners, and more recently, MSCT scanners, use a continuously rotating gantry (containing the tube and detector array) and are capable of imaging the entire thorax in a single breath-hold. Because the x-ray attenuation measurements are stored in the computer, the image can be enhanced or manipulated mathematically with specific reconstruction algorithms. For example, the technique of HRCT combines thin collimation and image reconstruction with a high-spatial-frequency algorithm to produce increased sharpness in the final stage.

Image Display

The reconstructed CT image is made up of a matrix of picture elements or "pixels." The x-ray attenuation of each pixel is normalized to that of a test object containing pure water. The CT number is the ratio of tissue attenuation minus water attenuation relative to water attenuation multiplied by 1000, and is expressed in Hounsfield units (H). The CT number for lung is about –700 to –900H, whereas soft tissues have CT numbers ranging from approximately –100 (fat) to +100H (blood clot), with water measuring 0 H and most soft tissues in the 20- to 60-H range. The range of CT numbers encountered in patients is approximately 2000, ranging from –1000 (air) to +1000 (bone). However, although the computed image contains 2000 number levels, which could correspond to 2000 shades of gray, the human eye can perceive only about 16 to 20 distinct shades of gray. It is thus necessary when displaying CT images to restrict the image display to a small fraction of the actual range of attenuation values.

This restriction is done first by combining similar CT numbers into a single gray shade and second by setting the "window width" and "window level" display settings. The window width is the range of densities that will be displayed as shades of gray; all higher pixel values are shown as white, and all lower ones are shown as black. The window level is simply the median pixel value about which the display range is centered. Thus, to view the lungs, an appropriate window level is –700H, with a window width of 1000 to 1500 H. For viewing soft tissues, pleural space, mediastinum, or hila, a window level of 20 to 40 H with a width of 350 to 500 H is preferred. These are usually referred to, respectively, as "lung window" and "mediastinal or soft-tissue window" settings, and both should be displayed for a chest CT study.

Spiral and Multislice Computed Tomography

Spiral CT employs continuous scanning as the patient moves through the scanner gantry. In many patients, the entire thorax can be scanned during a single breath-hold. Spiral CT has the advantages of (1) volumetric imaging, which ensures contiguous image reconstruction and allows multiplanar or three-dimensional reconstructions to be performed; (2) more rapid scanning; and (3) more rapid contrast infusion with denser opacification of vessels.

MSCT markedly improves upon the advantages offered by single-slice spiral CT. MSCT scanners acquire scan information using multiple channels during a single tube rotation, thereby dramatically increasing the data acquisition rate. Current MSCT scanners may acquire up to 64 images per tube rotation for a given collimation, whereas routine single-slice spiral CT scanners may only acquire 1 image per tube rotation for a similar collimation. Scanners with even more detectors (as high as 320) are currently being introduced into the market. The speed advantage of MSCT scanning is obvious, and this tremendous speed allows for rapid imaging of large volumes of tissue in practically any phase of intravenous contrast enhancement. The image data sets provided by MSCT scanners also allow for improved-quality reformatted images.

Computed Tomography Scan Protocols

CT scans are obtained with different parameters, depending on the indication for the examination. Variables include scanning range, patient position, scan section thickness, table transport speed/pitch, and intravenous contrast injection rate, timing, and volume. These parameters are briefly reviewed later. The influence of table transport speed/pitch on CT protocols has evolved with the proliferation of MSCT scanners, and consideration of these variables is more relevant to cardiovascular imaging, and is not discussed here. The interested reader is referred to excellent reviews on the topic of MSCT scan parameters and the technical aspects of MSCT scanning.[29,30]

Scanning Range

In most instances, a chest CT study should encompass the entire thorax, from the lung apices to the posterior costophrenic angles. This is easily accomplished in a matter of a few seconds with MSCT. In patients with lung cancer, chest CT done for staging purposes may include the

adrenal glands and liver, although the liver acquisition should be timed properly to obtain images in the correct phase of liver enhancement. In practice, lung cancer staging studies are typically performed as dedicated examinations of the entire chest, abdomen, and pelvis.

Patient Position

Normally, patients are scanned in the supine position. However, decubitus positioning or prone positioning may be used to elucidate whether pleural fluid collections are free or loculated, to distinguish dependent atelectasis from parenchymal fibrosis, or to position lung lesions optimally for biopsy. Images are normally obtained at total lung capacity to obtain maximum air-tissue contrast and to spread anatomic structures and lesions over a larger area, thus minimizing volume averaging. Prone images are usually obtained with HRCT studies. Technical advances now permit the acquisition of CT images during, rather than after, forced expiratory vital capacity maneuvers.

Scan Section Thickness

In the era of single-slice spiral CT, the thickness of an individual CT section was set to a predetermined value before scanning by setting the x-ray beam to a certain thickness: a process referred to as "collimation." Typical slice thicknesses for single-slice spiral CT ranged from 1 to 10 mm, with 5- to 7-mm collimation employed for most "routine" thoracic CT applications. With the development of MSCT systems, although various collimation choices are still possible, most MSCT protocols employ certain detector configurations that either favor narrow detector width (to promote optimal spatial resolution) or wider detector widths (to facilitate rapid volume of coverage). As systems with greater numbers of detectors are developed, the choice of high spatial resolution at the expense of volume of coverage and total length of exposure—an age-old compromise in the era of single-slice spiral CT—is becoming less of a quandary. Modern MSCT systems now allow the entire thorax to be scanned with a narrow detector configuration (1-mm) in a matter of a few seconds. Once such images are acquired, they may be combined in various ways for optimal viewing. For example, a thoracic CT study obtained on an MSCT system with detector elements arranged in a manner resulting in 1-mm detector configuration would produce several hundred 1-mm images for the thorax of an averaged-sized patient. However, these 1-mm images can be "combined" to generate 5-mm images, and these images can be displayed for routine review; this results in about 50 to 70 images for a typical thoracic CT. Should the radiologist desire to view the high-resolution, 1-mm images, these images can be reconstructed from the original dataset as long as the original scan data are saved. For example, with single-slice spiral CT scanners, frequently the patient would need to return for additional thin-section (narrow-collimation) imaging to characterize any nodules encountered at the examination. The only way to avoid bringing patients back in this setting was to keep the patient on the scanner while the study was reviewed, but this approach seriously decreases scanner throughput. Even if the patient were held during the scan review, additional nodule characterization with single-slice CT would require repeat scanning with narrow collimation to optimally detect fat or calcium within the nodule, with requires additional radiation exposure. With MSCT, when a nodule is recognized on a study, images may be reconstructed according to the narrowest detector configuration to accomplish this goal long after the patient has left the scanner, without the need for additional scanning.

An additional benefit realized by the development of MSCT is the ability to image using isotropic voxels. The term *isotropic voxel* indicates that the resolution of the scan in the x-, y-, and z-planes is equal. In other words, MSCT scanning using isotropic voxels allows the CT data to be reconstructed in any plane with resolution equal to that of the axial scans. Most single-slice CT examinations did not possess this capability, and therefore non-axial reformatted images suffered from degraded quality compared with that of the axial scans. MSCT's ability to scan using isotropic voxels allows creation of images in any desired plane that are equal in resolution to the axial scans—this multiplanar capability was previously an advantage enjoyed by MRI and ultrasound over CT.

Contrast Enhancement

The injection of intravenous iodinated contrast material during chest CT is important in many situations. Administration of contrast material is not routine except for the diagnosis of vascular abnormalities such as aortic dissection, aneurysm, pulmonary embolism, when using a specific protocol in selected patients with pulmonary nodules, or for examinations performed for lung cancer staging (Fig. 19-28) or assessment of pleural of chest wall diseases. If possible, iodinated contrast materials are

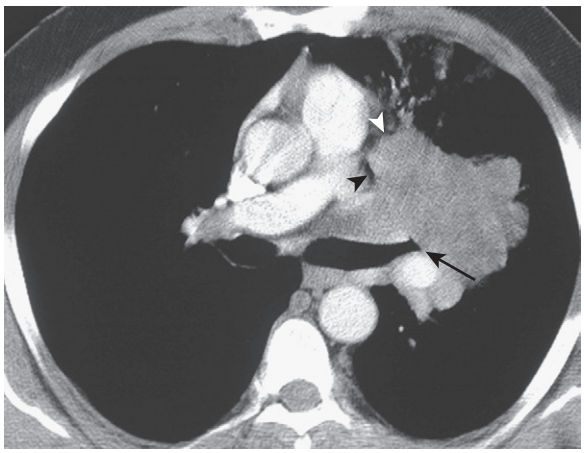

FIGURE 19-28 ■ CT was performed after contrast administration in a patient with left hilar bronchogenic carcinoma with mediastinal invasion. The primary hilar tumor obstructs the left upper lobe bronchus (*arrow*) and can be seen extending into the mediastinum anterior to the left main bronchus (*arrowheads*).

avoided, for they are expensive and are associated with a small but definite risk of serious reactions and toxicity. Although contrast infusion can be helpful in distinguishing vessels and soft-tissue masses in the mediastinum and hila, it is not considered necessary for diagnosis by all radiologists. For routine CT of the lungs (e.g., to rule out metastases), contrast material is rarely required.

Nonionic and low-osmolar contrast materials have proved to have a lower incidence of adverse reactions than high osmolar agents.[31] Patients with a prior history of contrast reaction should be treated with extreme care, as they are at higher risk for subsequent serious reactions, particularly those rare patients that have experienced contrast reactions despite proper premedication with corticosteroids and antihistamines.[31a] If vascular pathology is of interest in such patients, MRI is the preferred modality. If CT with contrast enhancement is necessary, pretreatment with corticosteroids is essential, and the referring physician should personally alert the radiologist to the patient's history.

The technique of intravenous contrast material administration is important. Peak opacification of vascular structures is desirable. To achieve this, a bolus of contrast material must be administered, preferably via a calibrated mechanical injector, and the area of interest must be scanned rapidly during the initial transit of the contrast agent. Timing of the delivery of intravenous contrast should be adjusted to the organ system of interest. For example, thoracic CT protocols designed for the detection of pulmonary embolism generally use rather short delays from the time of the beginning of contrast injection to the start of imaging (usually ~20 sec), whereas thoracic CT protocols designed for the evaluation of aortic dissection generally use slightly longer contrast injection delays.

The use of spiral CT and MSCT allows dense vascular opacification to be achieved because of the rapid scan time. In addition, because of the rapid nature of MSCT scanning, the volume of contrast required is less than with single-slice CT. Iodinated contrast materials distribute into the extracellular space rapidly; the time constant varies depending on the amount of contrast material and on the mode of administration, tissue perfusion, capillary permeability, and extracellular fluid volume. Scans obtained after this distribution has occurred are referred to as "equilibrium scans" and generally have less diagnostic value.

Computed Tomography and Radiation

The major drawback of the increased utilization of CT is radiation exposure. In 1980–1982, radiation from medical imaging accounted for approximately 18% of the per-capita effective radiation dose in the United States, but this value increased to 54% by 2006, due largely to increased radiation doses resulting from CT scanning and, to a much lesser extent, nuclear medicine procedures. Currently CT represents about 7% of all radiologic procedures in the world but accounts for more than 40% of the collective dose.[32] Given the continued increased use of CT since 2006, it is likely that these numbers are now even greater.

TABLE 19-1. Typical Radiation Doses Associated Background Sources and Common Thoracic Imaging Applications

Radiation Exposure	Effective Dose (mSv)
United States annual per-capita effective radiation dose 2006 (background/medical/total)	2.4/3.0/5.6[32]
Posteroanterior chest radiograph*	0.05
Ventilation/perfusion scan*	1.4[231]
Standard chest CT*	5–8[231]
High resolution chest CT (1 cm noncontiguous intervals)*	1
Catheter pulmonary angiography*	2.3–4.1
Whole-body ^{18}FDG-PET*	14[231]

*Values may vary according to individual equipment manufacturers, patient size, duration of study, use of dose-reduction techniques, and individual institutional protocols.
CT, computed tomography; ^{18}FDG-PET, [^{18}F]fluoro-2-deoxy-D-glucose positron emission tomography.

The two primary terms for describing the radiation imparted by a CT scan are *adsorbed* and *effective dose*. The adsorbed dose, measured in grays (Gy), is the energy absorbed per unit mass of a specific organ. In other words, it is the radiation imparted to a specific organ, and thus accounts for the future risk of developing a malignancy at that site. Effective dose, measured in sieverts (Sv) is an overall estimate of total-body radiation exposure. This is calculated by summing the individual adsorbed doses to each organ, each of which is multiplied by a weighting factor reflecting their individual radiosensitivities. Effective dose is useful for gross comparisons between different modalities and techniques.

Approximate effective doses for CT are given in Table 19-1. Of note, the values given are representative doses, but in fact, there is a wide range of exposures dependent upon CT technique and method of estimation. Also, indications such as pulmonary embolism, which require thinner sections, may involve greater amount of radiation. In addition, the radiation imparted by MSCT studies is generally higher than that of single-slice spiral CT, often in the range of 30% higher.

No large studies to date have attempted to quantify the cancer risk associated with CT radiation exposure. Most estimates are performed by extrapolating CT doses with reference to data on atomic bomb survivors. A slightly increased risk of malignancy was observed in the atomic bomb survivor group with an exposure of 5 to 20 mSv.[33] CT exposure doses are well within this range. Cancer risk also strongly depends upon age of exposure, with earlier exposure imparting a significantly greater risk.

Interventional Computed Tomography and Percutaneous Lung Biopsy

The indications for and contraindications to transthoracic needle biopsy (TNB) are presented in Tables 19-2 and 19-3.[34] The indications for TNB are changing as more data regarding the utility of alternative approaches to

TABLE 19-2. Indications for Transthoracic Needle Biopsy

Solitary pulmonary nodule or mass
Staging for lung carcinoma or extrathoracic malignancy
Mediastinal mass
Pleural lesion
Chest wall lesion

Focal lung opacity in an immunocompromised patient

TABLE 19-3. Contraindications to Transthoracic Needle Biopsy

Patient unable to cooperate with procedure:
Patient unable to lie in required position
Patient unable to hold breath consistently
Patient unable to give informed consent
Patient unable to follow directions
Coagulopathy: INR > 1.4 or platelets < 50,000/μL
Contralateral pneumonectomy or pneumothorax
Severe obstructive lung disease

INR, International Normalized Ratio for prothrombin time.

the management of thoracic lesions, such as positron emission tomography (PET; see Chapter 21) and video-assisted thoracoscopy (see Chapter 23), become available. Contraindications to TNB are usually relative. With proper evaluation and preprocedural care, the majority of thoracic lesions are amenable to TNB.

TNB procedures should be scheduled through a service dedicated to the performance of invasive procedures. Typically, such a group includes a nurse or nurse practitioner, an office assistant, CT technologists, radiologists experienced in the performance of TNB, and pathologists skilled in cytologic diagnosis. The service may then coordinate obtaining the relevant clinical information and reviewing any pertinent studies prior to the procedure.[34]

Preprocedural laboratory evaluation includes a complete blood count (including platelets), serum creatinine, and a coagulation profile. Abnormal results (see Table 19-3) should be corrected before the procedure is undertaken. Before the day of the procedure, the interventional service should contact the patient by phone to remind him or her of the procedure and to determine if the patient is taking any medications that should be discontinued prior to the procedure. Nonsteroidal anti-inflammatory agents should be discontinued 5 days prior to the procedure, and oral anticoagulants should be converted to shorter-acting parenteral agents, which may then be discontinued 4 to 12 hours before the procedure.[34]

The risks and benefits of the procedure, as well as alternative approaches to TNB, should be discussed with the patient prior to beginning the procedure, and the fact that informed consent was obtained should be documented in the medical record. A complete history and physical examination must be performed and documented if conscious sedation is to be used. Any allergies should be noted, and all questions should be answered before the procedure begins.[35]

Transthoracic lung biopsy may be performed using fine-needle aspiration (FNA) technique with or without the use of cutting needles for core biopsy.[35] Transthoracic FNA provides material for cytologic analysis and is usually sufficient for the diagnosis of carcinomas affecting the lung (primary or metastatic), whereas core biopsy utilizing cutting needles provides histopathologic material and is often required to definitively diagnose spindle cell neoplasms, most benign noninfectious pulmonary lesions, and pulmonary lymphomas and to distinguish certain histopathologic varieties of mesothelioma from metastatic adenocarcinoma affecting the pleura.[35]

Both percutaneous FNA and cutting-needle biopsy of pulmonary, mediastinal, or chest wall lesions may be performed using a single biopsy needle placed directly into the lesion or by using coaxial technique.[35] Either technique may be employed with CT, fluoroscopic, or sonographic guidance. CT-fluoroscopy, a technique that allows real-time CT imaging, provides tangible benefits for lung biopsy procedures compared with either CT or fluoroscopy alone, and is in common use for interventional radiology procedures at a number of centers. TNB performed using needles placed directly into the lesion typically employ 14- to 25-gauge aspiration needles (most often 22-gauge) or 18- to 22-gauge core biopsy devices, whereas biopsies performed using coaxial technique typically employ 22-gauge aspiration biopsy needles or 20-gauge core biopsy needles that are advanced through an outer sheath (often 19-gauge) that is initially placed within the lesion. The latter technique offers the advantage that, once the outer sheath needle is properly placed, repeated sampling of the lesion may be performed without need for additional manipulation of the needles.

All imaging studies should be reviewed prior to beginning the procedure to determine the best approach to the lesion. The best approach is one that is vertical and that does not cross bullae, interlobar fissures, or pulmonary vessels.[34]

Intravenous access should be established and hemodynamic monitoring should be begun before the procedure starts. When TNB is performed using CT guidance, the lesion is localized using narrowly collimated scans, with the patient holding her or his breath at functional residual capacity. The proposed skin entry site is established by identifying a clear path toward the lesion that avoids bullae, interlobar fissures, pulmonary vessels, and the undersurface of ribs and illuminating this site on the patient's skin using the table position laser lights on the CT scanner. The exact skin entry site may then be marked on the patient's skin using a permanent marker. The skin overlying this proposed entry site is cleansed and draped in sterile fashion, and the subcutaneous tissues in this region are liberally infiltrated with lidocaine for local anesthesia. The biopsy or sheath needle is then advanced under imaging guidance into the leading edge of the lesion (Fig. 19-29) during breath-holding.

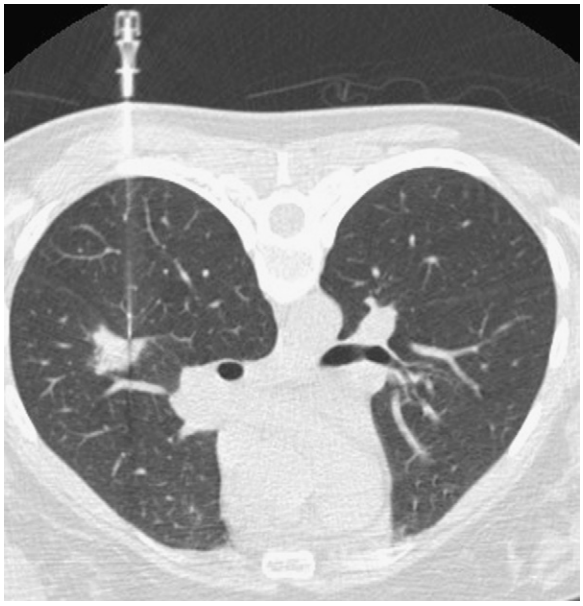

FIGURE 19-29 ■ CT-guided pulmonary nodule biopsy. With the patient in the prone position, a right upper lobe nodule was biopsied first with the placement of a 19-gauge outer sheath, with fine-needle aspiration biopsies performed using a 22-gauge needle placed through the sheath. Hodgkin's lymphoma was diagnosed.

Once the needle is properly positioned, the patient again holds her or his breath, the biopsy is performed, and the specimen is given to the cytopathologist for examination. A similar guidance approach can be used to localize fluid collections or pneumothoraces that are not responding to blindly placed thoracostomy tubes and then to guide percutaneously placed drains into the refractory collections.

Once material sufficient for diagnosis has been obtained, the needle is removed, hemostasis is achieved via local pressure, and the patient is imaged to exclude pneumothorax. Large or symptomatic pneumothoraces should be treated immediately with tube thoracostomy. Small pneumothoraces may be scanned sequentially over several minutes to ensure that the pneumothorax is not rapidly enlarging. Once a small pneumothorax is shown to be stable, the patient may be transferred to a gurney, and a chest radiograph is then obtained to establish the size of the postbiopsy pneumothorax for comparison with subsequent radiographs. The patient is then positioned on the gurney, whenever possible, with the biopsy site dependent to reduce the risk of air leak and to limit endobronchial spread of postbiopsy hemorrhage.[34]

The patient is then transferred to a recovery suite where vital signs and oxygen saturation are monitored for the next 3 hours. Supplemental oxygen may be administered to promote resorption of small pneumothoraces. If the patient remains asymptomatic, chest radiographs are obtained at 1.5 and 3 hours to assess for the development of a pneumothorax or the enlargement of a pneumothorax detected on the CT scanner immediately after biopsy. If no pneumothorax is seen on the 3-hour film, or if the pneumothorax is small, asymptomatic, and stable, the patient may be discharged. If the pneumothorax is enlarging or symptomatic, hospital admission and tube thoracostomy may be required. Assessment of the need for tube thoracostomy and/or hospital admission depends on the patient's underlying cardiopulmonary status, social support system, and proximity to an urgent care facility capable of properly treating the patient in a timely fashion.

The overall accuracy of TNB ranges from 70% to 100%, and approaches 90% to 95% for the diagnosis of thoracic malignancies.[35] The yield for TNB of benign lesions is less than that for malignancy, but may be enhanced with multiple samplings of the lesion, the use of cutting-needle biopsy, and routine culturing of aspirated specimens for biopsies preliminarily interpreted as negative for malignancy by the cytopathologist.[35]

Complications of TNB include pneumothorax, hemorrhage, hemoptysis, systemic air embolism, and malignant seeding of the biopsy tract. The mortality rate associated with TNB is approximately 0.02%, and fatalities are usually related to air embolism or massive hemorrhage. Pneumothoraces occur in approximately 30% of patients undergoing CT-guided procedures, but thoracostomy tube drainage is required in less than half of these patients. Factors associated with an increased likelihood of pneumothorax requiring thoracostomy tube drainage variably include severe COPD, the use of larger-gauge needles, small lesion size, intractable coughing, multiple needle passes through the pleura, the use of cutting needles, and prolonged procedure duration.[34]

Positron Emission Tomography and Positron Emission Tomography Computed Tomography

As with most nuclear medicine techniques, PET imaging begins with the injection of a radionuclide that localizes to a specific site in the body (see also Chapter 21). The most commonly used of these radioactive materials is [^{18}F]fluoro-2-deoxy-D-glucose (^{18}FDG). ^{18}FDG is a glucose analogue transported into metabolically active cells and, once phosphorylated, is fixed within the cell. The radionuclides used in PET imaging release a positron from their nucleus that subsequently undergoes an annihilation reaction with an electron. This process releases two coincidence 511-keV photons. These photons are detected by scintillation crystals in the PET camera. By using many of these coincidence detection events, a cross-sectional image can be obtained that demonstrates regions of activity. The amount of activity in a specific region of interest can be quantified by using a standard uptake value (SUV). The higher the SUV, the more metabolically active the tissue.

Compared to CT, ^{18}FDG-PET scanning is limited by relatively poor spatial resolution. To improve localization within the body, CT images may be obtained during the same scanning period, so-called PET-CT. These two separate data sets can then be colocalized to produce fusion images that contain data from both the PET and

FIGURE 19-30 ■ Whole-body coronal [^{18}F]fluoro-2-deoxy-D-glucose positron emission tomography computed tomography (^{18}FDG-PET-CT) shows intense left upper lobe tracer accumulation (*arrow*) in a patient with bronchogenic carcinoma. Note normal high tracer activity within the brain (*arrowheads*).

the CT portions of the examination (Fig. 19-30). This provides a more precise anatomic localization of the PET data to specific organs or abnormalities within the body.

^{18}FDG, as a glucose analogue, localizes to metabolically active cells. Tumor cells with their active division and growth typically acquire significantly greater amounts of ^{18}FDG than other cells, and thus are conspicuous on PET scanning (see Fig. 19-30). Common indications for PET and PET-CT of the thorax are the differentiation of benign versus malignant nodules and lung cancer staging. It is important to note, however, that active inflammatory processes, such as sarcoidosis, are also metabolically active and may concentrate ^{18}FDG. The final probability that an ^{18}FDG-PET-positive abnormality is malignancy is based upon a synthesis of the PET data, morphologic appearance of the lesion, and clinical presentation of the patient. It is also important to know the normal distribution of ^{18}FDG in the body, such as physiologically high tracer uptake in the heart and brain, and that high levels of activity in specific situations may be occasionally encountered, such as enhanced tracer uptake with muscular contraction.

Prior to the procedure, the patient should fast for at least 6 hours. This prevents competition between injected ^{18}FDG and glucose uptake from the gastrointestinal tract. For the same reason, a diabetic patient's glucose level should be well-controlled before the examination. Both a nonfasting state and hyperglycemia may cause false-negative examination results by producing artifactually low levels of uptake of ^{18}FDG in metabolically active tumors.

MAGNETIC RESONANCE IMAGING

Physical Principles

MRI is performed by magnetizing the patient's tissue slightly, generating a weak electromagnetic signal by applying a radiofrequency pulse, and spatially mapping that signal by manipulating its frequency and phase in a location-dependent manner with magnetic field gradients. Unlike CT, MRI does not require mechanical motions of the scanner and therefore can image directly in nonaxial planes.

Although MRI uses electromagnetic radiation, the energy levels used in MRI are quite low (i.e., nonionizing). MRI appears to be remarkably free of significant bioeffects. Potential safety hazards in MRI relate to the extremely strong static magnetic field and rapidly switched gradient magnetic fields used and to the possibility of tissue heating from radiofrequency energy absorbed by the body. Tissue heating is a theoretic concern but, in practice, is not significant when conventional MRI techniques are used. Theoretically, the rapidly varying gradient magnetic fields could stimulate electrically excitable tissue, but this does not occur with routine MRI techniques. In contrast, the powerful static magnetic field is a major safety hazard because the magnetic forces near a whole-body magnetic resonance (MR) imager are strong enough to cause significant projectile hazards. For example, an ordinary steel oxygen cylinder brought into an MRI examination room will fly into the bore of the magnet with a terminal velocity of about 45 mph. The possibility of displacements or torques on metallic implants within patients also must be considered. Although the margin of safety is high, there are rare documented instances of harm to patients from dislodging intracranial aneurysm clips or intraocular metallic foreign bodies. Finally, the magnetic field can operate reed relays in cardiac pacemakers and cause a change in the pacing mode. Accordingly, strict security around MRI facilities is essential to prevent patients with certain types of metallic implants from entering the scanner and to prevent medical personnel from carrying into the scan room objects that could become projectiles.

MRI produces extremely high contrast between different types of soft tissue. This soft-tissue contrast is based on intrinsic properties of the tissues, but it can be modified and exploited by appropriate use of operator-selectable imaging techniques. The tissue properties normally utilized in MRI are as follows: the concentration of protons available to produce an MR signal ("proton density"), the presence of motion or blood flow, and two properties known as T1 and T2, time constants that describe how quickly an MR signal can be generated

from a tissue (T1) and how quickly the MR signal, once generated, decays away (T2). In general, pathologic tissues have long T1 times and appear dark on those MR images whose appearance is conditioned primarily by T1 effects ("T1-weighted images"). Usually, pathologic tissues also have long T2 times and appear bright on T2-weighted images. The reason for this opposite behavior is that "T1" and "T2" describe processes that have opposite effects on the intensity of the MR signal. Flowing blood also can appear either bright or dark on MR images, depending on the examination technique used. The art of performing an MRI examination depends on appropriate manipulations of imaging techniques to capitalize on differences in proton density, flow, T1, and T2 between normal and pathologic tissue. In addition, the use of gadolinium-based MRI contrast materials, which alter the T1 and T2 of tissues semiselectively, has become important for numerous clinical applications, particularly MR angiography. MRI also can display other tissue properties such as molecular self-diffusion, temperature, and metabolites (MR spectroscopy), but these are less important for thoracic applications, although diffusion imaging and MR spectroscopy have recently shown some promise in lung cancer evaluation and staging.

Techniques

Motion during MRI causes artifacts that can degrade image quality severely. Motion compensation techniques, such as electrocardiographic gating and respiratory compensation, are widely used in thoracic MRI. High-speed techniques permit imaging in a matter of seconds, even fast enough to stop cardiac motion.

Direct MRI in sagittal, coronal, and oblique planes can provide superior depiction of structures that are oriented in the long axis of the body, such as the aorta, and of edges of structures that lie within the axial plane, such as lesions in the aortopulmonary window or lung apex.[36]

Flow has profound effects on the MR image. Two basic types of effects from flow occur in MRI; they are called "time-of-flight effects" and "spin-phase effects." The manifestations of flow effects in MR images strongly depend on the type of flow that is present and on the specific MRI techniques used. The clinical implication of this is that one can make blood in MR images either bright ("white-blood images") or dark ("black-blood images"). Most types of vascular pathology can be demonstrated with either white-blood or black-blood images, but there are usually clinical advantages to using one approach or the other in specific situations. Flow velocity can be estimated with MRI techniques, and thus noninvasive estimates of blood flow are potentially available.

Although high-speed imaging techniques are now available with MRI, it still is not an appropriate method to use for wide-ranging screening examinations of the entire trunk for metastatic disease. Such examinations normally should be performed with modern CT scanners. It usually is more rewarding to ask an anatomically focused question when requesting an MRI study.

APPLICATIONS OF CONVENTIONAL CHEST RADIOGRAPHY

Screening and "Routine" Chest Radiographs

It is now generally agreed that screening chest radiographs are not indicated except in specific high-risk populations.[37] Estimates as to possible iatrogenic disease caused by ionizing radiation from screening examinations, forecasts of possible genetic consequences, and financial concerns outweigh the medical value of such examinations. In 1973, the Department of Health, Education, and Welfare, in conjunction with the American College of Radiology and the American College of Chest Physicians, recommended the discontinuation of screening examinations. In 1985, recommendations of the American College of Radiology were more explicit: chest radiographs obtained for routine examination, preemployment screening, prenatal or obstetric screening, and hospital admission, and repeated examinations of patients with positive tuberculin tests and a negative initial chest radiograph, should be eliminated. From their analysis of over 10,000 chest radiographic examinations obtained in a hospital-based population, Sagel and associates[19] concluded that routine screening examinations done solely because of hospital admission or scheduled surgery are not warranted in patients under the age of 20 years. Even in selected high-risk populations, radiographic screening for carcinoma of the lung has failed to significantly increase longevity.

The value of the routine hospital admission chest radiograph is still controversial. Although the yield is low in asymptomatic patients, the examination can be extremely valuable as a baseline study for comparison with radiographs taken during or after the course of hospitalization in patients who develop pulmonary symptoms.

Detection of Lung Cancer and Assessment of Solitary Pulmonary Nodules

Although chest radiographs are clearly useful in the initial evaluation of patients suspected of having lung cancer, they are of limited accuracy in showing small or early cancers. At the time of their initial diagnosis, it is not uncommon for lung cancers to be visible retrospectively on prior radiographs.[38] Although additional radiographic studies, such as oblique views, are cost-effective for the initial evaluation of "nodular opacities" that do not clearly represent a lung nodule and are often of value in determining that a "nodular opacity" is not a true nodule, studies by CT are superior for the detailed evaluation of a known lung nodule.[39]

Evaluation of Intensive Care Unit Patients

Chest radiography is generally the most common imaging study performed in the most critically ill patients in the hospital—those in the ICU. ICU radiographs are taken with portable and, therefore, suboptimal technique; nonetheless, the information they provide often alters patient management.[9]

The overall incidence of abnormalities found on chest films in ICU patients is quite high; in a study of more than 1000 consecutive medical or surgical ICU films obtained routinely or after a change in clinical status, malposition of a monitoring device or a marked change in apparent cardiopulmonary status was found in 65%.[8] In a study of patients in a respiratory ICU,[40] chest radiographs showed at least one new, clinically unsuspected finding in 35% of patients that, in 29% of these patients, led to a change in management. Significant findings are even more likely when the study is obtained to assess a change in clinical status. In intubated patients in a medical ICU, 43% of radiographs showed significant worsening of a known process or development of a new abnormality.[41]

The value of obtaining chest radiographs on a daily basis in ICU patients is less clear. Strain and colleagues[42] found that routine morning radiographs revealed unsuspected abnormalities that led to a change in management in only about 15% of medical ICU patients, although this percentage was considerably higher (57%) in patients with pulmonary or unstable cardiac disease. Graat and coworkers[43] prospectively assessed the value of 2457 routine chest radiographs performed on patients in a combined medical and surgical ICU and found only 5.8% of routine chest radiographs showed new or unexpected findings; only 2.2% of patients required a change in management. Hall and colleagues[44] found that 18% of mechanically ventilated patients in a medical/surgical ICU had at least one radiograph that showed a clinically significant and unsuspected finding. Based on these results, the American College of Radiology has recommended that daily portable radiographs be obtained routinely in patients with acute cardiopulmonary problems, whereas only initial ICU admission chest radiography, and not routine daily chest radiography, is recommended for patients with stable cardiac disease or stable patients with extrathoracic disease prompting ICU admission. In the latter group of patients, additional chest radiography is recommended only for specific indications.[45]

The use of chest radiographs has also been recommended for assessing the placement of various support and monitoring devices, including endotracheal tubes, tracheostomy tubes, central venous catheters, pulmonary artery catheters, nasogastric tubes, chest tubes, pacemakers, and intra-aortic counterpulsation devices.[19,45] A significant frequency of clinically unsuspected endotracheal tube malposition detected by chest radiography, between 10% and 15%, has been reported.[19,45] In contrast, Hejblum and associates[45a] recently concluded that an on-demand strategy for ordering chest radiographs for mechanically ventilated patients in the intensive care unit is associated with a 32% reduction in the use of chest radiography compared with a routine daily strategy, but both strategies result in a similar rate of therapeutic or diagnostic intervention.

Indications in Acute Lung Disease

Dyspnea

Two studies suggest that chest radiography should be used routinely in patients with acute or chronic dyspnea.[46,47] In one study, new, clinically important radiographic abnormalities requiring acute intervention or follow-up evaluation were identified in 35% of 221 symptomatic patients.[46] Another study found that acute dyspnea was a strong predictor of a radiographic abnormality, but mainly in patients older than 40.[48] In this group, 86% of dyspneic patients had abnormal chest radiographs, whereas radiographs were abnormal in only 31% of patients younger than 40. Only 2% of patients younger than 40 with a normal physical examination had abnormal radiographs indicative of an acute abnormality. The American College of Radiology[49] recommends chest radiography when dyspnea is chronic or severe or when additional risk factors are present, such as age over 40; known cardiovascular, pulmonary, or neoplastic disease; or abnormal physical findings.

Acute Respiratory Symptoms

Opinions are also divided as to the utility of chest radiographs in patients with suspected acute lung disease and symptoms other than dyspnea. In a study of 1102 outpatients with acute respiratory disease, Benacerraf and coworkers[48] found patient age, results of physical examination, and presence or absence of hemoptysis to be important factors in predicting the value of radiographs. Only 4% of patients younger than 40, without hemoptysis and without detectable abnormalities on physical examination, had acute radiographic abnormalities. A much higher incidence of radiographic abnormalities was present if the patient was older than 40, had hemoptysis, or had abnormal physical findings. Heckerling,[50] in a study of 464 patients with acute respiratory symptoms, found a low incidence of pneumonia (3%) in patients with a negative physical examination, except in those with dementia. Whenever pneumonia is suspected in adults, the American Thoracic Society recommends PA (and lateral when possible) chest radiography. In this setting, chest radiography may be useful to determine which patients should be hospitalized and which patients should be classified as having "severe" pneumonia.[51]

Acute Asthma

Chest radiography is uncommonly used to make a diagnosis of asthma; radiographs are often normal, and visible abnormalities in this disease are usually nonspecific.[52] Although Petheram and associates[53] reported that 9% of 117 patients with severe acute asthma had unsuspected

radiographic abnormalities affecting management, the usefulness of radiography in patients with an established diagnosis of asthma who suffer an acute attack is limited. Correlation between the severity of radiographic findings and the severity or reversibility of an asthma attack is generally poor,[52-54] and radiographs provide significant information that alters treatment in 5% or fewer patients with acute asthma.[50,55,56] Although it is difficult to generalize regarding the role of radiographs in both adults and children with acute asthma, chest films should be used to exclude the presence of associated pneumonia or other complications when significant symptoms and/or appropriate clinical or laboratory findings are suggestive.[52,54,56]

Exacerbation of Chronic Obstructive Pulmonary Disease

Chest radiographs are often used in the initial assessment of patients with suspected COPD; however, they are of limited value in patients with known COPD who present with worsening of their disease.[56,57] In a study of 107 patients with COPD presenting with an exacerbation of symptoms, only 17 (16%) had an abnormal chest radiograph, and in only half of these did the radiographic findings result in a significant alteration in management.[56] In another study, including patients with both COPD and asthma, the management of 21% of patients was altered by radiographic findings.[57] It has been recommended that chest radiographs be obtained in patients with COPD only if certain clinical indicators are present; in various studies, these have included a history of heart disease or congestive heart failure, intravenous drug abuse, seizures, immunosuppression, other pulmonary disease, an elevated white blood cell count, fever, chest pain, and peripheral edema. When such indicators are used as a guide, nearly all patients with significant findings will have radiographs performed; however, it should be noted that more than two thirds of patients in one study met inclusion criteria for performing radiography.[57]

In most patients with an established diagnosis of cystic fibrosis, clinical findings and chest radiographs are sufficient for clinical management. Conversely, it should be recognized that patients with cystic fibrosis can have a significant exacerbation of their symptoms with little visible radiographic change.

APPLICATIONS OF CROSS-SECTIONAL IMAGING TECHNIQUES

Solitary Pulmonary Nodules

Assessment of a solitary pulmonary nodule (SPN) seen on chest radiographs is a common indication for CT.[39,58] CT is used to confirm that the SPN is real, to confirm that the SPN is solitary, to attempt further noninvasive characterization of the lesion, to guide percutaneous biopsy of the lesion, and to provide staging information if the SPN is found to represent a carcinoma. As discussed further in Chapter 47, the likelihood of malignancy in such nodules varies from less than 10% in mass screenings to about 50% in resected nodules.

In general, CT of a patient with an SPN should be performed with thin-section volumetric imaging to provide detailed analysis of nodule morphology and to allow identification of the presence of fat or calcium within the nodule, and when the latter is present, the

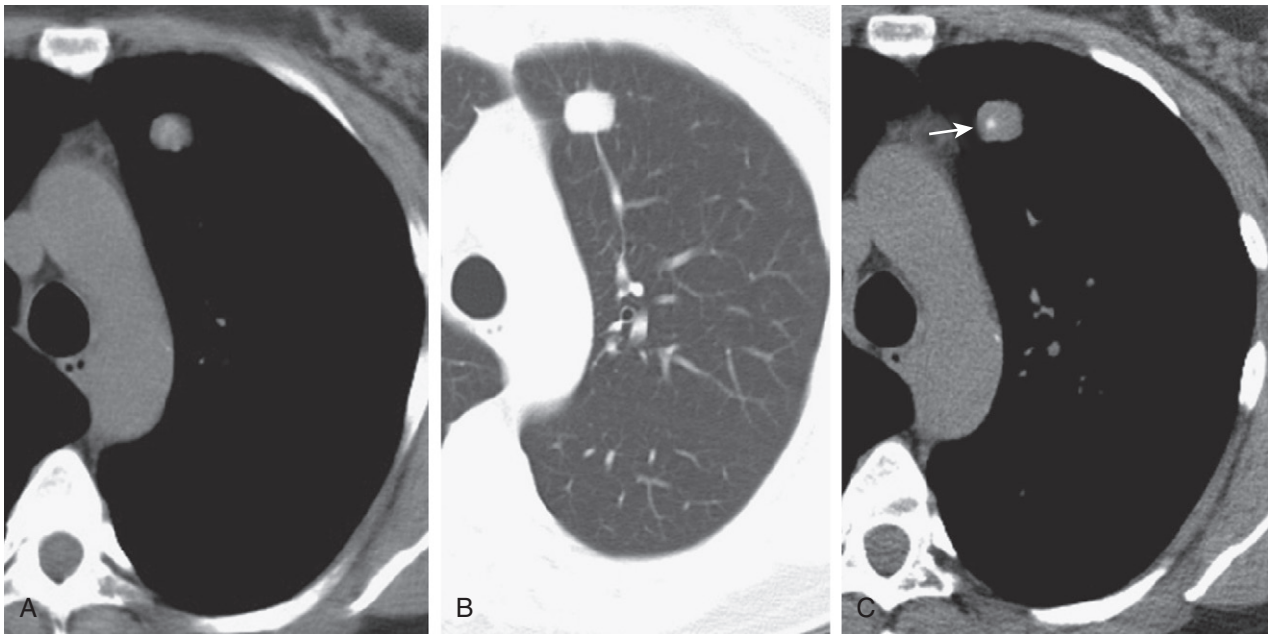

FIGURE 19-31 ■ Volumetric multislice computed tomography (MSCT) imaging of a pulmonary nodule detected at chest radiography. **A,** Axial 5-mm CT image shows a soft-tissue nodule in the left upper lobe. Vaguely increased attenuation is seen within the nodule suggesting calcification, but the finding is not well seen. **B,** Lung window images shows that the nodule is circumscribed. **C,** Thin-section (1-mm) soft-tissue image more clearly shows a small focus of calcification (*arrow*) within the lesion, suggesting a benign etiology.

pattern of calcification (Fig. 19-31); this is now fairly routine in the era of MSCT technology.

In up to 20% of instances, a "lung nodule" visible on chest radiographs actually represents an artifact, chest wall lesion, or pleural abnormality; in some cases, CT is essential to determine the true nature of the opacity. CT can be useful to define the morphology of the SPN and suggest whether it is benign, likely malignant, or indeterminate, having neither benign nor malignant characteristics. In some patients, a specific diagnosis of lesions such as rounded atelectasis (Fig. 19-32), a mucous plug, or arteriovenous malformation can be made based on CT findings, indicating the benign nature of the lesion.[39,58] Other CT appearances suggest the presence of malignancy.[39] These include a spiculated or irregular contour; the presence of air bronchograms within the nodule, bubbly air collections ("pseudocavitation"), or cavities; and a diameter of more than 2 cm (Fig. 19-33).[39,58] The presence of several patterns of calcification can indicate that the SPN is benign; "benign" patterns include diffuse, central, laminated, and "popcorn" calcification (Fig. 19-34).[39,58] In about 30% of benign nodules, calcium invisible on plain radiographs can be seen on thin-section CT. Carcinomas may occasionally show calcification, often in an eccentric or stippled pattern. The presence of fat within an SPN, indicated by a low CT attenuation coefficient (Fig. 19-35), strongly suggests the presence of hamartoma[39,58] or lipoid pneumonia; such nodules can be safely followed with serial radiographs.

Malignant tumors tend to show greater enhancement than benign nodules after the rapid injection of iodinated contrast material.[59–62] Because the degree of enhancement depends on the amount and rapidity of contrast infusion, it is important to use a consistent technique. Using a specific contrast enhancement CT protocol, a threshold for enhancement of 15 H or more typically is

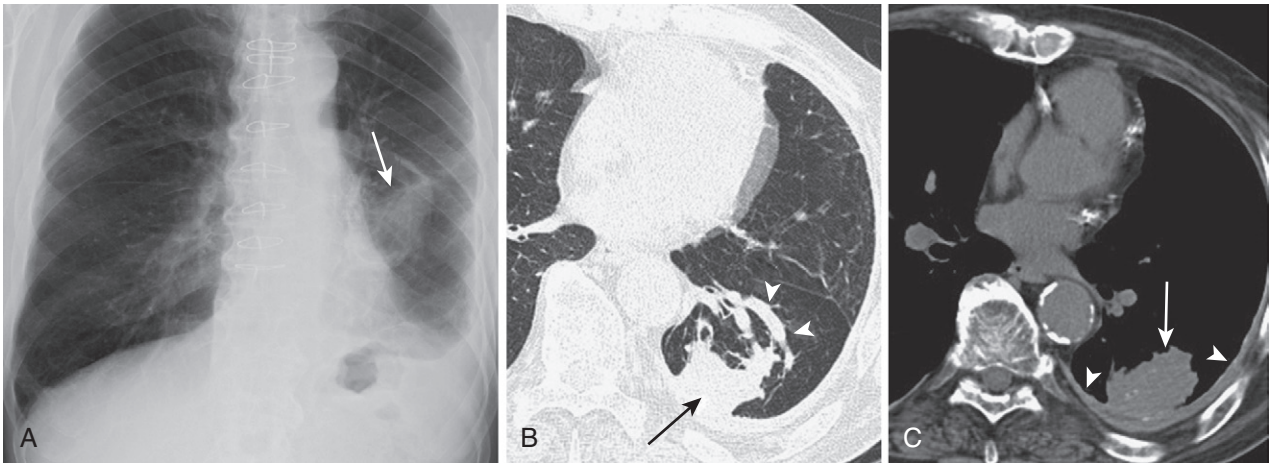

FIGURE 19-32 ■ Thoracic CT shows typical findings of rounded atelectasis. **A,** Frontal chest radiography shows volume loss in the left lower lobe associated with an oblong mass (*arrow*) and left-sided pleural abnormality. **B,** Axial thoracic CT in lung windows shows a subpleural left lower lobe mass (*arrow*) associated with left lower lobe volume loss (posterior displacement of left major fissure, small volume in the left lower lobe). Note "spiraling" appearance of left lower lobe bronchovascular bundles as they extend into the mass (*arrowheads*); this is the so-called comet-tail sign. **C,** Axial thoracic CT displayed in soft-tissue windows shows other features consistent with rounded atelectasis including abnormally thickened pleura (*arrowheads*) and contact of the mass (*arrow*) with the abnormal pleura.

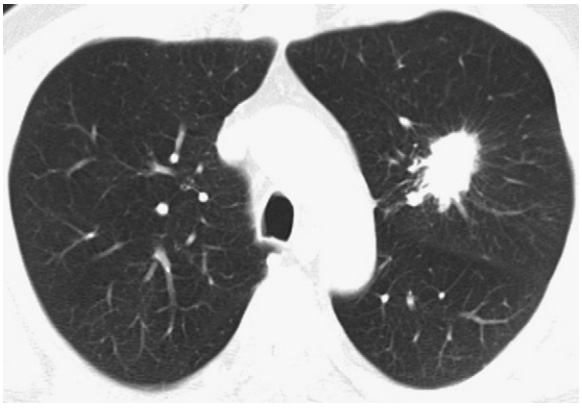

FIGURE 19-33 ■ Thoracic CT of bronchogenic carcinoma. Axial CT displayed in lung windows shows a spiculated lesion within the left upper lobe.

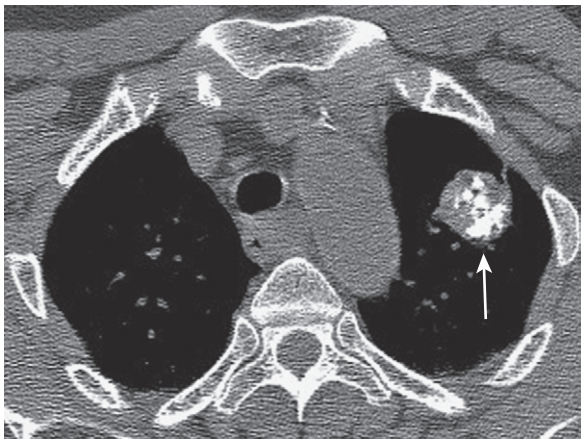

FIGURE 19-34 ■ Thoracic CT showing "popcorn" (chondroid) calcification within a left upper lobe nodule (*arrow*), consistent with hamartoma.

FIGURE 19-35 ■ This patient had a solitary nodule that proved to be a hamartoma. CT image showed low attenuation within the nodule (typical CT numbers within the lesion ranged from –90 to –100 HU), consistent with fat.

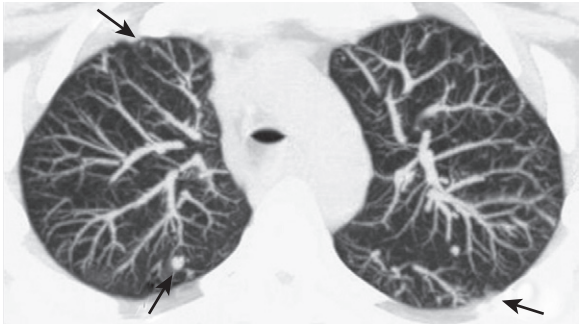

FIGURE 19-36 ■ This patient was diagnosed with metastatic cervical carcinoma. CT shows numerous bilateral pulmonary nodules (*arrows*) that were not visible on chest radiography. CT is more sensitive than radiography for detection of small nodules of any cause.

seen with malignancy, hamartoma, and some inflammatory lesions. Enhancement of less than 15 H almost always indicates a benign lesion, usually a granuloma. Therefore, whereas positive results (enhancement of ≥15 H at any time point during the study) are nonspecific, negative results are quite useful. This technique has been shown to have a sensitivity of 98% and a specificity of 58% in diagnosing carcinoma. More importantly, the negative predictive value of this technique is approximately 96%.[61] CT nodule enhancement studies are most appropriately used for patients who have indeterminate nodules (i.e., those without typical benign or malignant appearances). A similar use for dynamic, contrast-enhanced MRI has been reported, although data are limited.[63] The use of PET imaging (see Chapter 21) has also been shown to be very useful for distinguishing benign from malignant nodules,[64] and is generally favored over contrast-enhanced CT for additional imaging characterization of indeterminate lung nodules.

^{18}FDG-PET imaging may be used to differentiate between benign and malignant pulmonary nodules. In a recent meta-analysis,[63] ^{18}FDG-PET was shown to be 95% sensitive and 82% specific in the differentiation of benign from malignant nodules. The addition of PET-CT tends to increase sensitivity with no change in specificity compared with PET alone.[65] False-positive ^{18}FDG-PET results may be seen with inflammatory processes, particularly granulomatous diseases such as tuberculosis, histoplasmosis, and sarcoidosis. Tumors that may be ^{18}FDG-PET-negative include bronchoalveolar cell carcinoma, adenocarcinoma with predominant bronchoalveolar features, carcinoid tumors, and some metastases (e.g., renal cell carcinoma).[66] In addition, small nodules may not be of a sufficient size to produce a positive result with ^{18}FDG-PET scanning. The sensitivity of ^{18}FDG-PET imaging significantly decreases with nodules measuring less than 8 to 10 mm in diameter. As with any imaging modality, the correlation of the ^{18}FDG-PET results with morphologic features on CT, prior radiographic examinations, and the clinical presentation will improve the determination of the likelihood of malignancy.

Multiple Pulmonary Nodules

CT is the favored procedure for identifying multiple pulmonary nodules or masses. It detects more and smaller metastases (Fig. 19-36) than any other imaging technique, and 2- to 3-mm nodules are routinely visible.[67] This is most pertinent to patients with extrathoracic malignancies, in whom the detection of metastatic disease has a major impact on initial staging and assessment of response to therapy. The major sources of controversy regarding the use of CT for evaluation of possible metastases have been its limited specificity and cost-benefit ratio.[67]

CT is clearly more sensitive than chest radiographs in diagnosing multiple pulmonary nodules in patients with suspected metastasis. The sensitivity of CT for detecting surgically proven nodules ranges from 50% to 75% (i.e., 50%–75% of all resected nodules are seen on preoperative CT scans), whereas the sensitivity of chest radiographs is about 25% and that of conventional tomography about 35%. In some studies, most nodules (55%–60%) seen on CT and subsequently resected have proved to be benign (granulomas, intrapulmonary lymph nodes, and the like).[68] In other studies most CT-detected nodules (80%–95%) have proved to be metastatic lesions.[69] In a study involving radiologic-surgical correlation, Peuchot and Libshitz[69] evaluated 84 patients with previously

documented extrathoracic malignancies and newly identified pulmonary nodules. These authors noted important limitations in both the sensitivity and the specificity of CT. Of a total of 237 nodules resected, CT was able to identify only 173 (73%); 207 (87%) were metastatic tumors, 21 (9%) were benign, and 9 (4%) were bronchogenic carcinomas. Of 65 nodules interpreted as solitary on chest radiographs, CT disclosed multiple nodules in 46%, and 84% of these additional nodules were metastases.

Accordingly, CT results must be interpreted in light of the clinical characteristics of the patient. Primary tumors that commonly spread to the lungs, more advanced malignancies, and the absence of any simulators of metastases (silicosis, sarcoidosis, and prior granulomatous infection) would favor malignancy in pulmonary nodules detected by CT. Furthermore, smaller and less numerous nodules are more likely to be benign. The findings on CT are in themselves not specific, however, and follow-up may be necessary to demonstrate the growth or stability of small nodules.

Lung Cancer Staging

In patients with lung cancer, accurate anatomic staging is essential for planning the therapeutic approach.[70–72] CT is used in both assessment of primary tumor extent and detection of lymph node metastases. However, its accuracy in both situations is limited.[72]

Computed Tomography

The primary goal of CT is to help distinguish patients who likely have resectable tumors from those who do not. Pulmonary malignancy is considered to be likely unresectable (T4) if the primary tumor (1) involves the trachea or carina; (2) invades the mediastinum with involvement of mediastinal structures; (3) invades the chest wall with involvement of great vessels, brachial plexus, or vertebral column; or (4) results in a malignant pleural effusion or pleural implants.[72,73] The presence of satellite nodules in the same lobe as the primary tumor is now designated as T3 in the 7th edition of the TNM Classification of Malignant Tumors, and does not preclude surgical resection.[74]

Tracheal or carinal invasion can be suggested with CT but requires biopsy confirmation. The CT diagnosis of chest wall or mediastinal invasion can be problematic, although a CT scan should be obtained if these diagnoses are suspected. The sensitivity and specificity of CT in diagnosing T4 mediastinal or chest wall invasion are about 60% and 90%,[74] respectively, although some findings (e.g., vertebral body destruction, encasement of mediastinal structures, mediastinal fat infiltration) are virtually diagnostic.[71,74–79] Limited chest wall or mediastinal invasion is considered potentially resectable by many surgeons, but knowledge of tumor extent is nonetheless an important factor when planning therapy.

CT findings suggesting mediastinal invasion[74,76,77] include (1) replacement of mediastinal fat by soft-tissue attenuation, (2) compression or displacement of mediastinal vessels by tumor, (3) tumor contacting more than 90 degrees of the circumference of a structure such as the aorta or pulmonary artery (the greater the extent of circumferential contact, i.e., 180 degrees, the greater the likelihood of invasion), (4) more than 3 cm of contact between tumor and the mediastinum, and (5) obliteration of the mediastinal fat plane normally seen adjacent to most mediastinal structures (see Fig. 19-28). However, individually, these findings are unreliable for differentiating mediastinal invasion from anatomic contiguity.[74]

CT is of little value in the diagnosis of malignant pleural effusion, as this diagnosis requires cytologic confirmation.[80] However, in some patients, CT can show pleural implants with or without effusion or diffuse or nodular pleural thickening.[80,81] ^{18}FDG-PET may show tracer uptake in patients with malignant pleural effusion, even when CT does not show evidence of nodular pleural thickening and when cytologic analysis is negative.[82]

The diagnosis of mediastinal lymph node metastasis by CT is determined purely by node size. By convention, a nodal diameter of more than 1 cm is considered to be abnormal in all node stations (Fig. 19-37)[72,74] except the subcarinal space.[83,84] Tumor cannot be detected in normal-sized lymph nodes by CT, and there are no characteristic appearances allowing benign and malignant causes of nodal enlargement to be distinguished.[85–87] Pooled information from 35 studies published between 1991 and June 2006 evaluating the performance of CT scanning for noninvasive staging of the mediastinum has shown that this size threshold has a sensitivity of only about 51% and a specificity of 86% for diagnosing mediastinal lymph node metastases in patients with lung cancer.[71,88–90] Furthermore, the accuracy of CT for detecting involvement of individual node groups is low, perhaps as low as 40%.[88]

Despite its limited accuracy, CT, particularly in conjunction with ^{18}FDG-PET, is useful in determining the need for preoperative mediastinoscopy. Furthermore, CT may also be useful in guiding mediastinoscopy (e.g., suprasternal vs. left parasternal approach) or suggesting alternate procedures (e.g., needle biopsy, endoscopic ultrasound). If mediastinoscopy is not performed routinely before thoracotomy, CT can significantly reduce the number of thoracotomies performed in patients with gross mediastinal disease, but its use varies with practice patterns at individual institutions.[91]

Perhaps the most important potential contribution of CT to intrathoracic staging is precise mapping of nodes likely to be involved by tumor. For example, ipsilateral mediastinal lymphadenopathy places the patient in stage IIIA (potentially resectable), whereas contralateral lymphadenopathy (see Fig. 19-37B) renders the patient unresectable (stage IIIB). However, CT may have a limited role in this crucial staging distinction. The prognostic significance of N2 metastases appears to correlate with the method of their discovery, with those found at mediastinoscopy associated with only a 10% 5-year survival rate and those found at thoracotomy with a 25% 5-year survival rate.[92,93]

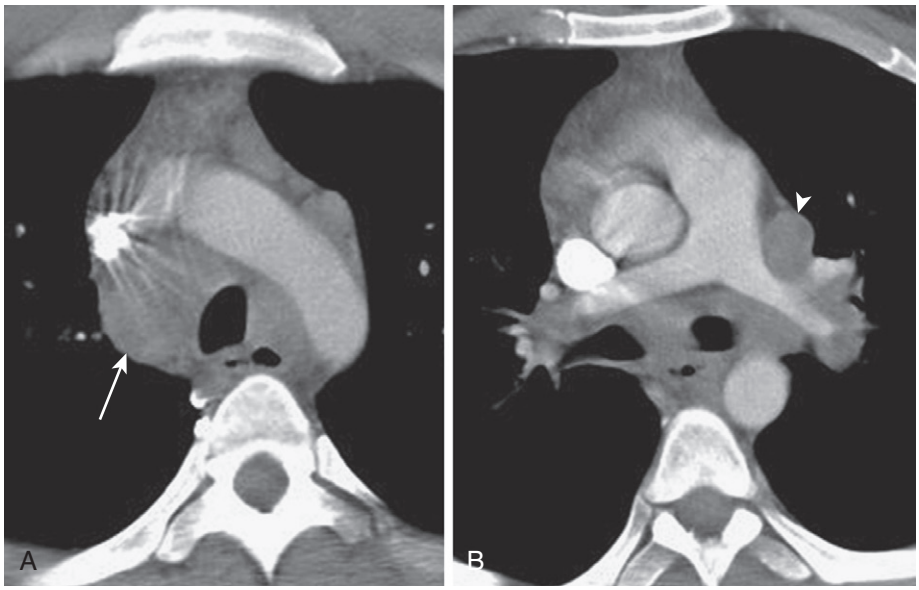

FIGURE 19-37 ■ This patient was diagnosed with non–small cell lung cancer, and CT was performed for staging. **A,** The primary tumor was present at another level in the right lung. Right paratracheal lymphadenopathy (*arrow*) is present; left mediastinal nodes also appear enlarged. **B,** Axial thoracic CT at a slightly lower level than **A** shows left hilar and subaortic (*arrowhead*) lymph nodes, which measure greater than 1 cm in short axis diameter, the most widely accepted size threshold for abnormality, and would be considered suspicious for metastasis. The radiographic staging thus would be IIIB.

Positron Emission Tomography and Positron Emission Tomography Computed Tomography

^{18}FDG-PET imaging has become an integral part of staging for lung cancer. The primary end point for using ^{18}FDG-PET is to increase the sensitivity for the detection of local and distant malignancy: to prevent patients with unresectable disease from undergoing unnecessary surgery. ^{18}FDG-PET and PET-CT are most useful for evaluating the N and M components of staging, although ^{18}FDG-PET activity in the primary tumor (T component) may provide insight into biologic aggressiveness and the chance of future spread of early localized tumors.[94] Characteristics of the primary tumor, however, are typically best evaluated using CT, given its superior spatial resolution.

In a meta-analysis, ^{18}FDG-PET showed a greater sensitivity and specificity for nodal disease compared with CT—79% versus 60% and 91% versus 77%, respectively.[95] The exact role of ^{18}FDG-PET with respect to more invasive diagnostic procedures, such as mediastinoscopy, is yet to be determined. Another recent study demonstrated that ^{18}FDG-PET has a relatively high false-positive rate for lung carcinoma lymph node metastases (26%),[96] suggesting that mediastinoscopy was still required for confirmation of mediastinal metastasis. ^{18}FDG-PET is still quite useful to identify potentially involved mediastinal groups (Fig. 19-38) and to evaluate mediastinal compartments that are typically inaccessible with mediastinoscopy. ^{18}FDG-PET is also useful in the evaluation of distant metastases and has the potential to supplant traditional imaging methods for this purpose. In a study by Weder and coworkers,[97] ^{18}FDG-PET detected unsuspected metastasis in 14% of patients with stage IIIa disease or less and in those who had already undergone CT of the chest and upper abdomen. The majority of these unsuspected metastases were osseous or adrenal in location. It is important to note that ^{18}FDG-PET has a decreased sensitivity for brain metastases compared to traditional techniques (CT and MRI) due to the fact that the high metabolic activity of the brain normally accumulates significant amounts of radiotracer activity.

Magnetic Resonance Imaging

There are few situations in which MRI is the preferred imaging modality for patients with primary lung cancer. The extent of chest wall invasion adjacent to a lung tumor sometimes may best be shown by MRI. However, MRI, like CT, still has imperfect sensitivity and specificity. MRI has been used for delineating additional chest wall involvement in patients with lymphoma.[98] Sagittal or coronal MR images can be advantageous in delineating the extent of tumors at the lung apex (Fig. 19-39).[72,99] Consequently, MRI is more accurate than CT for determining chest wall involvement in superior sulcus tumors; moreover, involvement of the neurovascular bundle[99] is better shown with coronal and sagittal MRI than with axial CT images.

In most patients with primary lung cancer, MRI has no unique information to offer, and CT is the preferred imaging procedure.[72] MRI is similar to CT in its ability to identify mediastinal lymph nodes[72] and to diagnose mediastinal metastases. Although it has been reported that MRI is more accurate than CT in detecting medi-

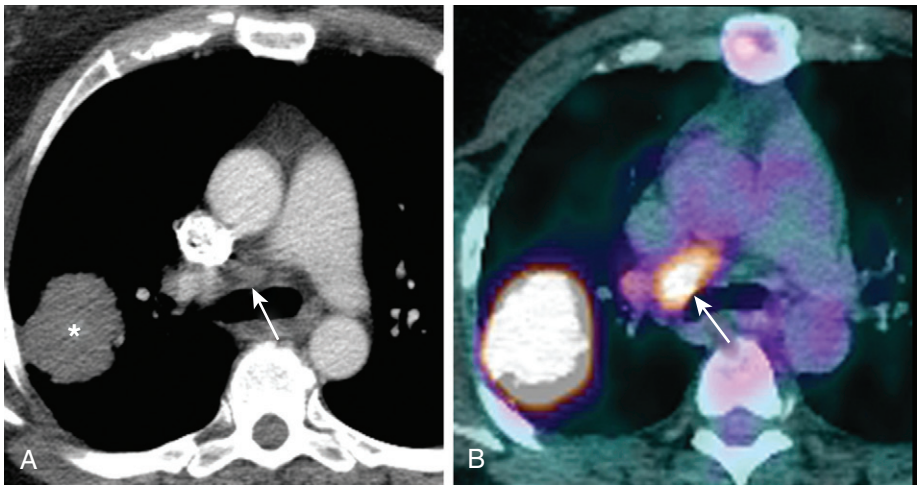

FIGURE 19-38 ■ Utility of PET-CT in the staging of pulmonary malignancy. This patient was diagnosed with non–small cell lung cancer, and CT and PET-CT were performed for staging. **A,** The primary tumor is visible in the peripheral right lung (*). Borderline right paratracheal lymph nodes (*arrow*) are present. **B,** PET-CT shows intense tracer uptake in the primary right lung neoplasm as well as within the right paratracheal lymph nodes (*arrow*). The latter finding prompted mediastinoscopy, which confirmed metastatic nodal disease.

astinal,[71,100] cardiac, or vascular invasion by lung cancer, the reported differences in accuracy are small. In general, the MR properties of benign and tumor-bearing mediastinal lymph nodes do not differ significantly in most patients,[101] and as with CT, node size is usually the only diagnostically useful discriminator. However, recent data with newer MR sequences, particularly diffusion-weighted imaging[102] and short tau inversion recovery imaging (STIR),[103,103a] as well as recent observations regarding findings at T2-weighted thoracic MRI,[103b] which may allow discrimination between benign and malignant lymph node involvement even for lymph nodes with short axis dimensions less than 1 cm. In addition, in some cases, MRI is able to demonstrate masses better than CT by imaging in the coronal or sagittal plane, and in some cases, MRI may be used as a problem-solving tool.

Brachial Plexopathy

Imaging of the brachial plexus is useful for patients with suspected metastatic disease, radiation injury, primary tumor, or traumatic injury. Clinical evaluation can suggest possible etiologies of brachial plexopathy and whether the neurologic deficit is more likely due to a central or a peripheral lesion.[104] However, clinical evaluation cannot demonstrate the pathology and localize precisely the site of involvement.

Metastatic disease and radiation injury are the most common causes of brachial plexopathy, and the clinical distinction between these is difficult, although pain, Horner's syndrome, and lower trunk involvement are characteristic of metastatic involvement.[105,106] CT is of proven value for patients with primary or metastatic tumors,[104,107] but it may be less useful for patients with radiation fibrosis. CT is superior for the detection of osseous involvement due to superior sulcus tumors.[99] Older data clearly indicated that MR is superior to CT for assessment of brachial plexus involvement by lesions within the superior sulcus, primarily due to the multiplanar capabilities of MR. However, as mentioned previously, advances in CT technology now allow imaging reconstruction in any plane, and it is likely that these improvements have enhanced the diagnostic capabilities of CT for assessment of superior sulcus tumors. Nevertheless, MR possesses inherently superior contrast resolution to CT, which is a valuable property for imaging the superior sulcus region. Therefore, MR is still considered the reference standard for evaluation of tumors within the superior sulcus and for assessment of brachial plexus involvement by tumors in this region.[99]

CT myelography, often in conjunction with conventional myleography and MR imaging, is the optimal imaging modality for the assessment of traumatic brachial plexus injury.[108]

Lung Cancer Screening

The utility of CT in screening for lung cancer remains uncertain. As with most screening issues, studies are subject to biases including lead-time bias, length-time bias, and overdiagnosis. Many of the screening studies performed have shown a high percentage of early stage cancers found, suggesting early detection and a greater chance of cure. For instance, in the International ELCAP study,[109] 85% of cancers detected were stage I. As none of these studies have had a control arm, the mortality benefit of early diagnosis assumes that lung cancer is an invariably fatal disease; however, this is not necessarily true. Currently, the National Lung Screening trial, which does include a control arm, is underway in an attempt to settle this debate.

A second potential issue with lung cancer screening is the high incidence of nonmalignant pulmonary nodules detected. According to the Mayo Clinic data,[110] 74% of patients had at least one nodule detected during the

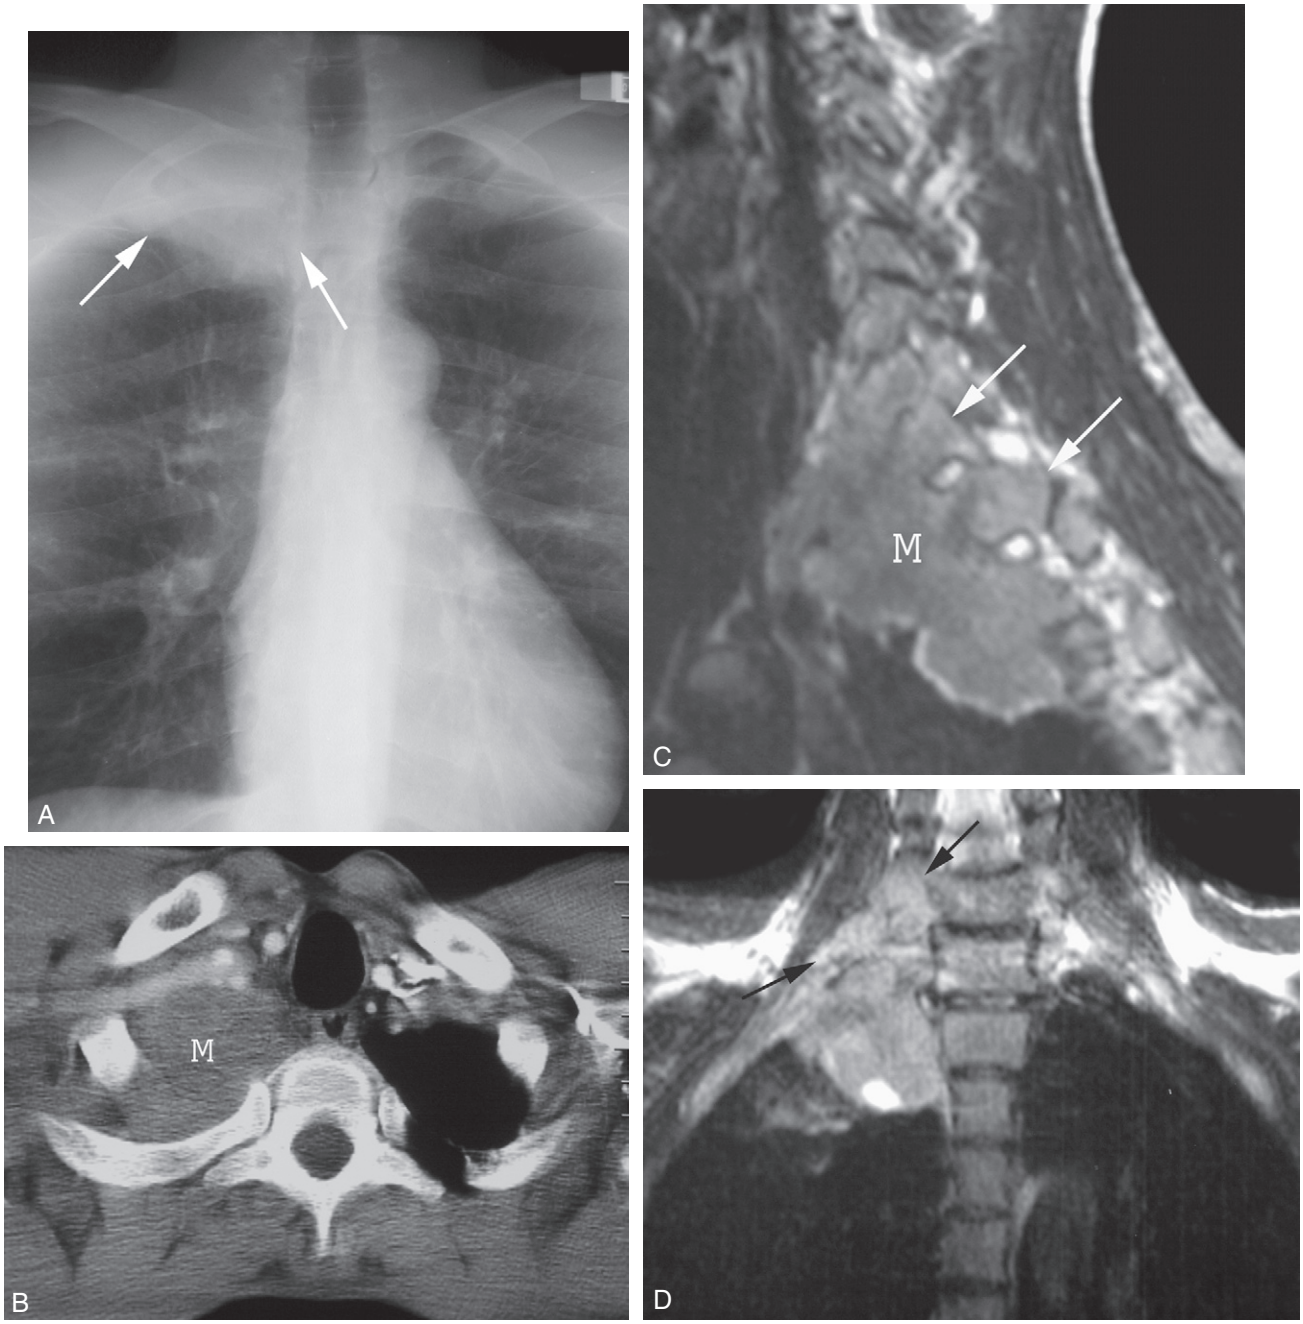

FIGURE 19-39 ■ This patient had primary non–small cell lung cancer with brachial plexopathy. **A,** Frontal chest radiography demonstrates right apical lung opacity (*arrows*) without clear chest wall involvement. **B,** An axial CT image through the lung apex delineates the lung mass (M), but chest wall involvement is not clearly identified. **C,** Sagittal T2-weighted magnetic resonance imaging (MRI) reveals the extension of the mass (M) into the vertebral body neural foramina (*arrows*). **D,** Coronal T2-weighted MRI shows extension of the mass into the right neck (*arrows*), in the region of the brachial plexus.

4-year study period and only 2% of noncalcified nodules were found to be malignant. Given that most patients with nodules are followed with CT to demonstrate 2 years of stability, the acceptance of lung cancer screening would undoubtedly result in a large number of subsequent CT scans that would not have otherwise be performed. This could have a significant impact on the cost-effectiveness of lung cancer screening and radiation exposure to this patient population.

Hilar and Mediastinal Masses

CT is indicated as the primary imaging modality in most patients with suspected hilar or mediastinal masses. The cross-sectional display and tissue discrimination of CT have revolutionized diagnostic imaging of the hilum and mediastinum.

Lesions can be detected with high sensitivity and located precisely to their structure of origin or anatomic

region (Fig. 19-40). By localizing a mass to a particular region of the mediastinum,[111,112] the differential diagnosis can be made more specific, and biopsy procedures can be planned with greater accuracy. In addition to the information gained from the location of the mass, the density discrimination of CT enables soft-tissue abnormalities, fluid collections, and fatty tissue to be distinguished accurately (Fig. 19-41).[113-115] With use of intravenous contrast material, masses and vascular anomalies can be accurately delineated. CT is useful in further evaluating a mass initially detected on chest radiography, in demonstrating pathology that is suspected on the basis of the clinical setting—but not visible on conventional imaging studies—and in precisely delineating the location of lesions for planning therapy.

MRI may be indicated as the primary imaging modality in patients with suspected mediastinal mass when the mediastinal abnormalities are thought to be vascular, with lesions at the thoracic inlet that may be advantageously displayed in the coronal plane, and for evaluation of posterior mediastinal masses and neurogenic tumors, which may have intraspinal components.[116,117] It has also been reported that MRI can be used to distinguish between a tumor mass and a benign fibrous mass[118-120] following radiation therapy, a distinction that can be difficult with CT. However, in practice, the differentiation of tumor from associated inflammation is difficult,[118,119] and ^{18}FDG-PET is generally preferred for this distinction.

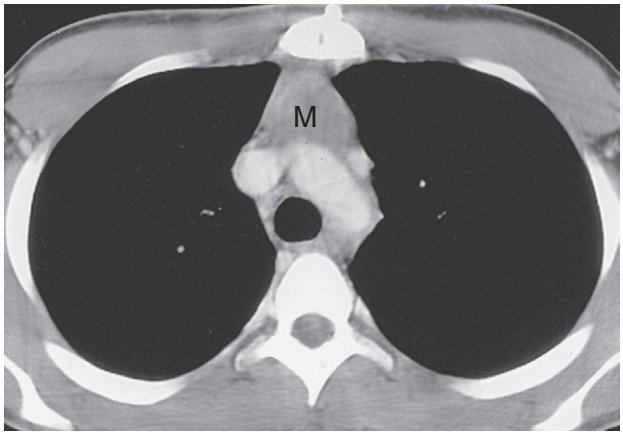

FIGURE 19-40 ■ This axial CT image shows an anterior mediastinal soft-tissue mass (M). There are no characteristic attenuation features (e.g., fat or calcium). The location of the mass, however, is precisely documented, and thus the differential diagnosis was limited and biopsy facilitated. The lesion was a seminoma.

MRI is rarely indicated for imaging hilar masses; CT is usually preferred for this application. Traditionally, contrast-enhanced MR would be considered as an alternative to contrast-enhanced thoracic CT for the assessment of hilar or mediastinal lesions in patients with impaired renal function, but recent recognition of a fibrosing dermopathy, referred to as nephrogenic systemic fibrosis, that may occur following intravenous administration of gadolinium-based contrast agents in patients with impaired renal function[121] gives pause to such an approach. Nevertheless, unenhanced MR, due to its inherent high contrast resolution, may still provide valuable information regarding hilar and mediastinal masses.

Primary and metastatic cardiac tumors usually are often detected initially by echocardiography, but MRI also is an accurate method of delineating such lesions.[122-127] It is thus appropriate as a problem-solving technique for patients with inconclusive ultrasound examinations and is of particular value for resolving false-positive echocardiographic findings, but it is also emerging as a first-line examination for a number of cardiovascular applications. Both MRI and CT can specifically demonstrate fat within cardiac lesions and fluid within pericardial cysts. Intracardiac tumor (Fig. 19-42) and thrombus frequently can be differentiated by MRI, particularly with contrast administration.

Diffuse Lung Disease

The clinical assessment of a patient with suspected diffuse infiltrative lung disease (DILD) can be a difficult

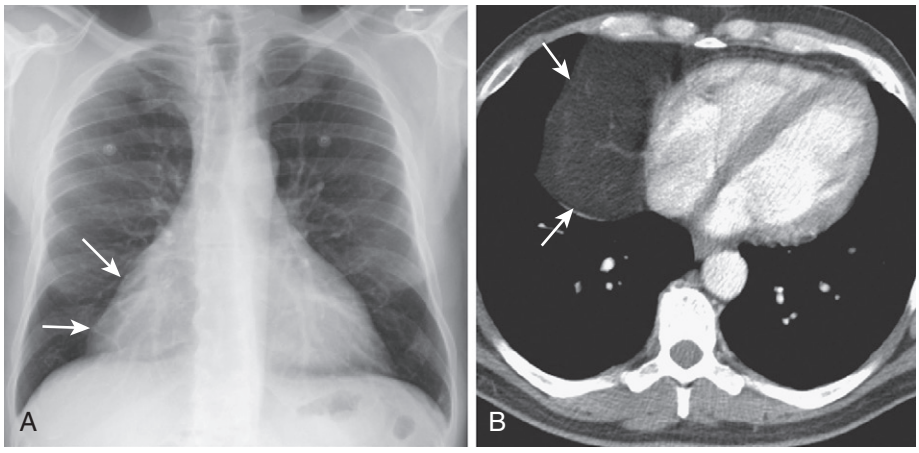

FIGURE 19-41 ■ CT characterization of fatty mediastinal masses. **A,** Frontal chest radiography shows a contour abnormality (*arrows*) along the right inferior mediastinum. **B,** Axial thoracic CT shows a fatty right paracardiac mass (*arrows*), consistent with thymolipoma.

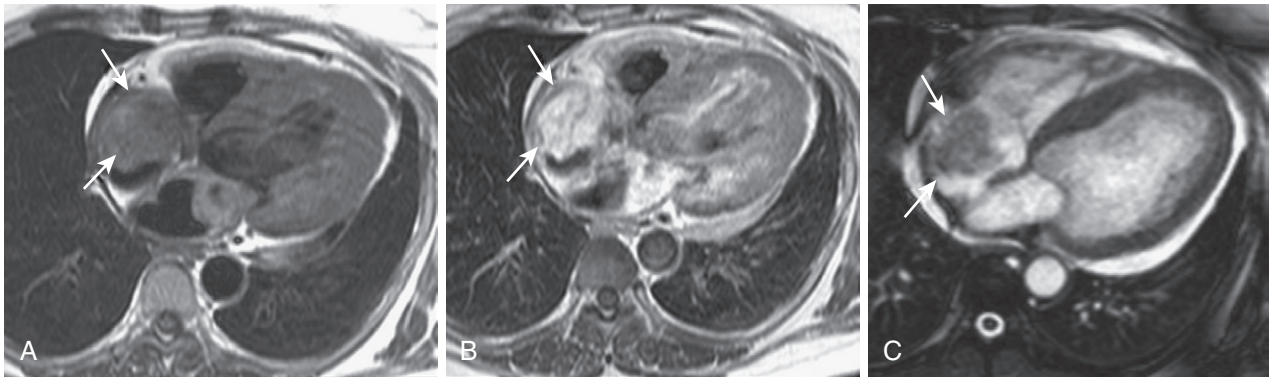

FIGURE 19-42 ■ MRI characterization of cardiac masses. **A,** Axial T1-weighted image shows a soft-tissue intensity mass (*arrows*) within the right atrium. **B,** Contrast-enhanced axial T1-weighted MRI shows intense enhancement of the mass (*arrows*), excluding thrombus as the diagnosis and suggesting neoplasm. **C,** Balanced fast-field echo image (obtained for function) shows the mass as a low-signal lesion (*arrows*) within the right atrium. Resection confirmed right atrial myxoma.

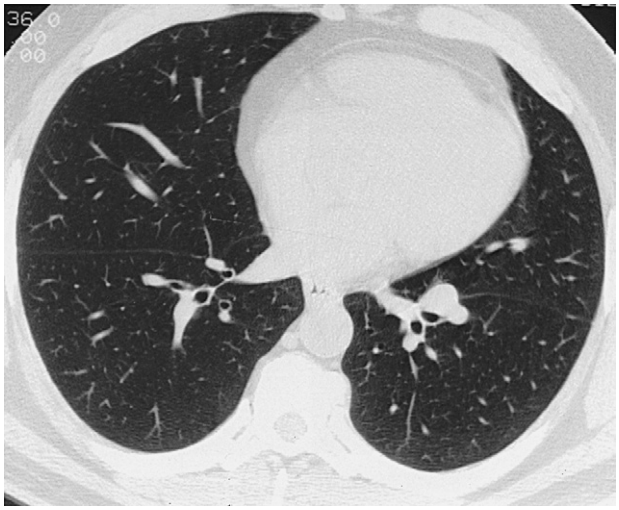

FIGURE 19-43 ■ This normal high-resolution computed tomography (HRCT) image at the level of the inferior pulmonary veins delineates the pulmonary vessels, major fissures, and lower lobe segmental bronchi.

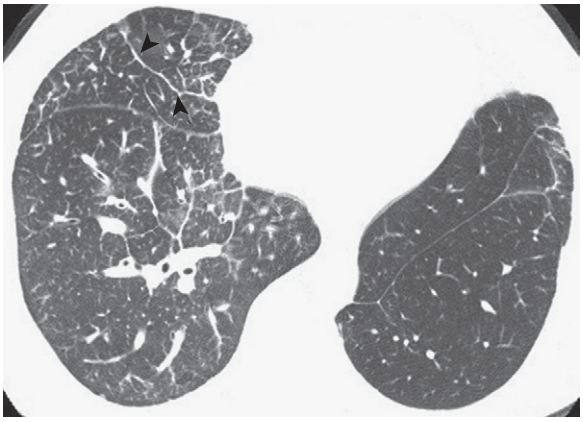

FIGURE 19-44 ■ This HRCT image in a patient with lymphangitic metastasis of breast carcinoma shows smoothly thickened interlobular septa (*arrowheads*); note asymmetry of the process.

and perplexing problem. Imaging studies are often important in reaching a final diagnosis, suggesting appropriate diagnostic procedures, and assessing the patient's course and prognosis.

In clinical practice, the imaging studies most frequently used to evaluate patients with suspected DILD are chest radiographs and HRCT. HRCT is typically used when the diagnosis is uncertain based on chest radiographs and clinical evaluation and further assessment is considered warranted and to assess treatment response in patients with established diagnoses.

HRCT findings in a wide variety of parenchymal diseases have been described, including the idiopathic interstitial pneumonias, sarcoidosis, diffuse neoplasms, pneumoconioses, infections, and numerous other disorders.[90,128–144] These studies have shown that HRCT delineates both normal anatomic structures (Fig. 19-43) and pathologic alterations in lung morphology more clearly than conventional or spiral CT or chest radiographs.[139,140,145,146] In general, HRCT findings of lung disease can be divided into increased lung opacity, including reticular, linear, and nodular opacities, consolidation, and ground-glass opacity; and decreased lung opacities, such as cysts, cavities, emphysema, and mosaic perfusion.[147]

Increased Lung Opacity

Linear and Reticular Opacities. Thickening of the interstitial fiber network of lung by fluid, fibrous tissue, or interstitial infiltration by cells results in an increase in both linear and reticular opacities as seen on HRCT.[147] Interlobular septal thickening occurs in patients with a variety of interstitial lung diseases, but most typically pulmonary edema, lymphangitic spread of tumor (Fig. 19-44),[147] and sarcoidosis, in addition to a small number of rarer causes.[148–150] Septal thickening is not common in patients with interstitial fibrosis, except for those with sarcoidosis and asbestosis.[151] Honeycombing reflects extensive fibrosis with lung destruction and results in a cystic, reticular appearance on HRCT that is characteristic (Fig. 19-45).[147,151] When honeycombing is present,

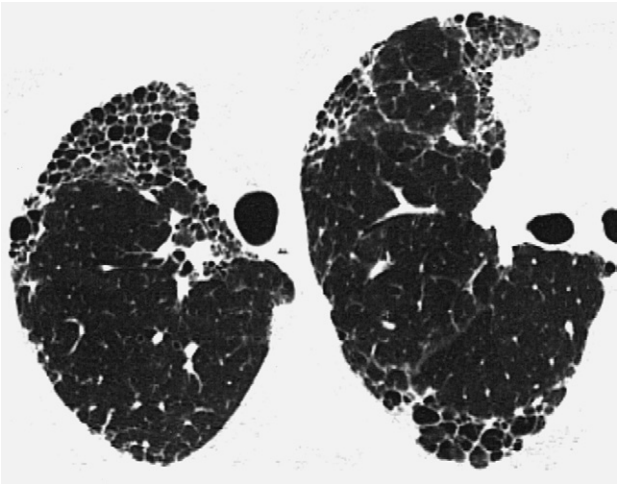

FIGURE 19-45 ■ HRCT at two levels shows rheumatoid lung disease with honeycombing. The appearance of multiple, contiguous, air-filled cystic structures having a subpleural predominance is typical.

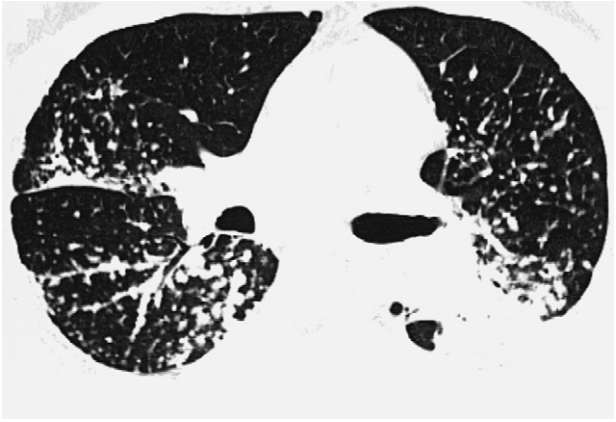

FIGURE 19-46 ■ HRCT in a patient with sarcoidosis shows a perilymphatic distribution of nodules. Note that numerous subpleural nodules are seen in relation to the right major fissure, and nodules also surround arteries in the right lower lobe. These findings, along with the patchy distribution of the nodules, are diagnostic of sarcoidosis in the appropriate clinical setting.

normal lung architecture is distorted, and secondary lobules are difficult or impossible to recognize. The cystic spaces of honeycombing can range from several millimeters to several centimeters in diameter and are characterized by thick, clearly definable, fibrous walls, and are often found stacked in several layers in the subpleural regions of lung.

Nodules. Well-defined nodules, as small as 1 to 2 mm in diameter, can be detected on HRCT in patients with a variety of diseases; these are usually interstitial in origin. Nodules can be classified according to their distribution as perilymphatic, random, or centrilobular according to their distribution within the secondary pulmonary lobule.[147] Recognition of one of these distributions is fundamental to the generation of differential diagnoses.[152,153] Perilymphatic nodules affect the peribronchovascular, interlobular septal, subpleural, and centrilobular interstitial compartments and are typical of sarcoidosis, which tends to have a peribronchovascular and subpleural predominance (Fig. 19-46)[148,152-154]; silicosis and coal worker's pneumoconiosis, which predominate in the subpleural and centrilobular regions[133,149,150]; and lymphangitic spread of tumor, which is usually peribronchovascular and septal.[147] Nodules with a random distribution are most typical of miliary infections (Fig. 19-47)[155] and hematogenous metastases.[147] Well-defined centrilobular nodules can be seen in silicosis and coalworker's pneumoconiosis,[156,157] asbestosis, and Langerhans cell histiocytosis.[158] Poorly defined centrilobular nodules often reflect bronchiolar or peribronchiolar abnormalities,[159] and can be seen in silicosis and coal worker's pneumoconiosis,[156] endobronchial spread of infection,[155] hypersensitivity pneumonitis,[160,161] and pulmonary edema.[159]

Consolidation and Ground-Glass Opacity. Air space consolidation, by definition, occurs when alveolar air is replaced by fluid, cells, or other material.[162] On HRCT, consolidation results in an increase in lung opacity

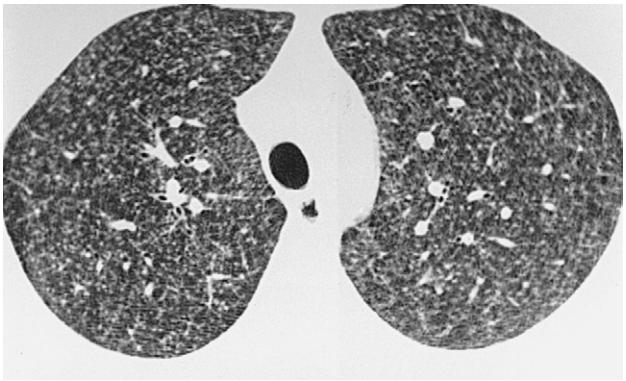

FIGURE 19-47 ■ This human immunodeficiency virus (HIV)–infected patient had miliary tuberculosis. Innumerable small nodules are visible on HRCT. These are evenly distributed throughout the lung in a "random" pattern. Note the dissimilarity to the distribution of nodules in Figure 19-46.

associated with obscuration of underlying vessels. Among patients with chronic DILD, the most common causes of this pattern include chronic eosinophilic pneumonia and cryptogenic organizing pneumonia.[163,164] The term *ground-glass opacity* refers to a hazy increase in lung opacity that is not associated with obscuration of underlying vessels (Fig. 19-48).[162] This finding can reflect the presence of a number of diseases and can be seen in patients with either minimal interstitial thickening or minimal air space filling.[137,140,165-168] It often reflects the presence of active disease, such as pulmonary edema, alveolitis associated with some idiopathic interstitial pneumonias, pulmonary hemorrhage (see Fig. 19-48), infectious pneumonias (particularly *Pneumocystis jirovecii* [formerly *P. carinii*] pneumonia), alveolar proteinosis, hypersensitivity pneumonitis (Fig. 19-49), and sarcoidosis.[169] However, ground-glass opacity may reflect the presence of fibrosis below the resolution of HRCT, particularly when the ground-glass opacity is associated

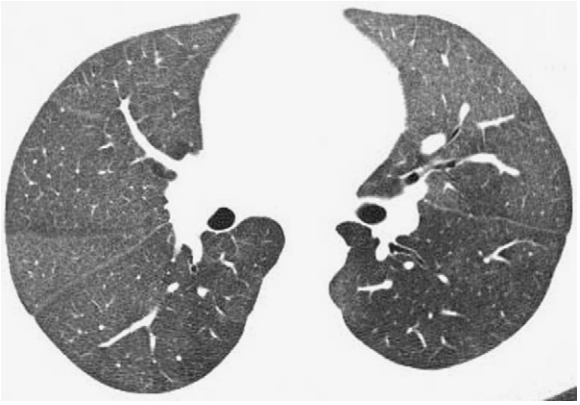

FIGURE 19-48 ■ In this patient with pulmonary hemorrhage in the setting of systemic lupus erythematosus, HRCT shows multifocal areas of geographic areas of opacity. The opacity does not obscure the normal lung markings (e.g., the vascular structures are still well delineated) and thus is considered ground-glass opacity.

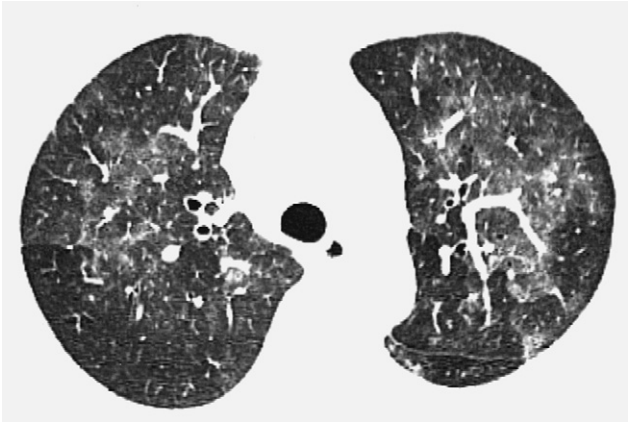

FIGURE 19-49 ■ In this patient with hypersensitivity pneumonitis, patchy ground-glass opacity is visible bilaterally.

with other findings of fibrotic lung disease, such as coarse reticulation, architectural distortion, traction bronchiectasis, and honeycombing.[166] Because of its potential reflection of active lung disease, the presence of ground-glass opacity may lead to surgical lung biopsy, depending on the clinical status of the patient.

Decreased Lung Opacity

Emphysema. Emphysema is accurately diagnosed with HRCT, and HRCT is more sensitive for the detection of emphysema than routine CT or chest radiographs.[141] Emphysema results in focal areas of very low attenuation that can be easily contrasted with surrounding, higher-attenuation, normal lung parenchyma (Fig. 19-50). In patients with centrilobular emphysema, areas of lucency can be seen surrounding the centrilobular artery and have a patchy, upper lobe distribution. In panlobular emphysema, focal areas of lucency are not usually present, but a diffuse simplification of lung architecture and a decrease in lung attenuation are present (see Fig. 19-50). In clinical practice, HRCT is rarely used in an attempt to diagnose emphysema. Usually, the combination of a smoking history, a low diffusing capacity, airway obstruction on pulmonary function tests, and an abnormal chest radiograph showing large lung volumes is sufficient to make the diagnosis. HRCT is useful in evaluating patients with COPD who are being considered as candidates for lung volume-reduction surgery. In addition, some patients with early emphysema can present with clinical findings more typical of infiltrative lung disease or pulmonary vascular disease, namely shortness of breath and low diffusing capacity, without evidence of airway obstruction on pulmonary function tests.[170] In such patients, HRCT can be valuable in detecting the presence of emphysema and excluding an interstitial abnormality. If significant emphysema is found on HRCT, no further workup is necessary; specifically, a lung biopsy is not needed.[171]

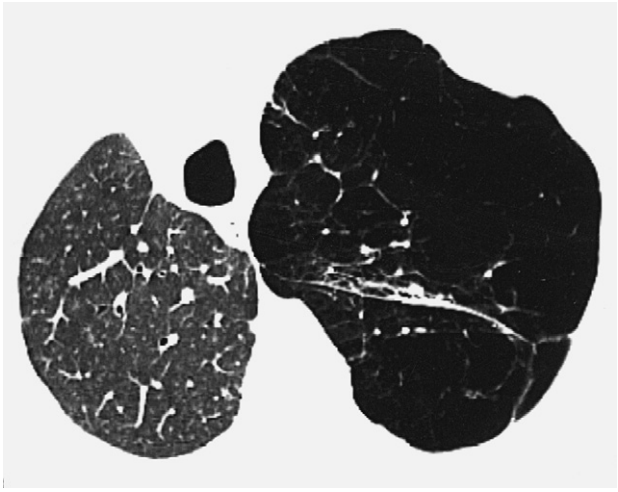

FIGURE 19-50 ■ This HRCT scan is from a patient with panlobular emphysema who underwent right lung transplantation. The emphysematous left lung is easily contrasted with the normal-appearing right lung. The left lung is less dense, is larger in volume, and contains fewer and smaller vessels.

Cystic Pulmonary Diseases. Lymphangiomyomatosis and Langerhans cell histiocytosis often result in multiple lung cysts (Fig. 19-51), which have a distinct appearance on HRCT.[158,172-174] The cysts have a thin but easily discernible wall, ranging up to a few millimeters in thickness. Associated findings of fibrosis are usually absent or much less conspicuous than they are in patients with honeycombing. In these diseases, the cysts are usually interspersed within areas of normal-appearing lung. In patients with Langerhans cell histiocytosis, the cysts can have bizarre shapes and an upper lobe predominance.

Mosaic Perfusion. Decreased lung attenuation not reflecting the presence of cystic lesions or emphysema can sometimes be recognized on HRCT in patients who have diseases that produce air trapping, poor ventilation, or poor perfusion.[141,163,165,167-176] The areas of decreased lung attenuation that are seen on HRCT can be focal, lobular or lobar, or multifocal. The term *mosaic*

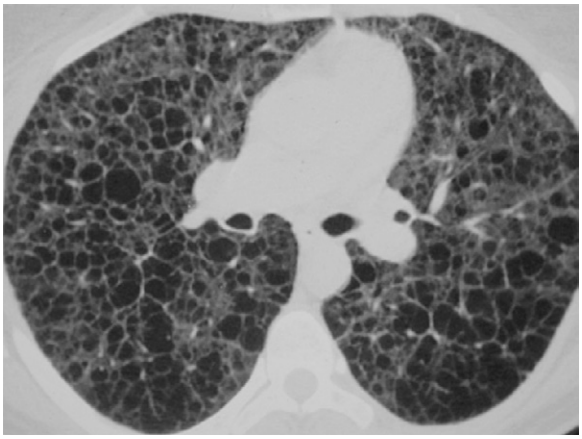

FIGURE 19-51 ■ A patient with lymphangiomyomatosis underwent HRCT. Note that the multiple cystic areas have clearly definable walls, in contrast to the appearance of emphysema (see Fig. 19-50).

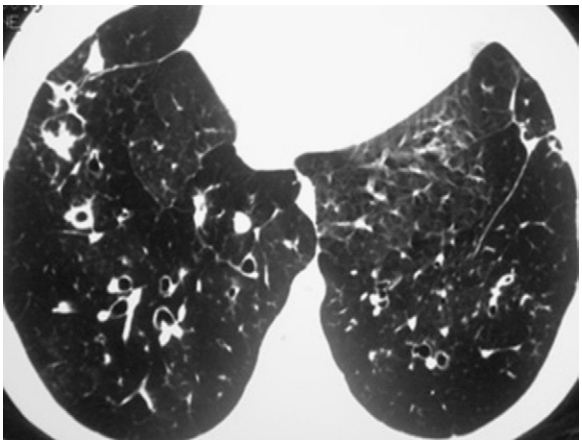

FIGURE 19-52 ■ HRCT in a patient with cystic fibrosis and mosaic perfusion shows inhomogeneous opacity in the lung bases bilaterally, somewhat geographically distributed. The areas of decreased attenuation represent mosaic perfusion, in this patient resulting from a combination of regional air trapping due to large airway disease and hypoperfusion in the affected areas of lung.

perfusion has been used to refer to patchy decreased lung attenuation resulting from perfusion abnormalities (Fig. 19-52). In patients with air trapping, this appearance can be enhanced with expiratory HRCT.[141,176–179]

Diagnostic Utility

The utility of chest radiographs and HRCT in the clinical diagnosis of diffuse lung disease relates to their ability to detect the presence of lung disease (sensitivity and specificity), characterize its nature, assess disease activity, and guide lung biopsy.

Sensitivity and Specificity. It is well documented that chest radiographs are limited in both their sensitivity and their specificity in patients with DILD.[144,180–182] For example, Gaensler and Carrington[181] reported that nearly 16% of patients with pathologic proof of interstitial lung disease had normal chest radiographs. The sensitivity of CT for detecting lung disease has been compared with that of chest radiography in a number of studies; without exception, these have shown that CT, and particularly HRCT, is more sensitive than chest radiography for detecting both acute and chronic diffuse lung diseases.[90,134,144,160,183–185] The average results of several studies show that the sensitivity of HRCT for detecting DILD is approximately 94% compared with 80% for chest radiographs.[182] The sensitivity of HRCT has also proved superior to that of routine CT obtained with wider collimation.[128,168,169]

It is important to note that the increased sensitivity of HRCT is not achieved at the expense of decreased specificity or diagnostic accuracy.[131,133,182] A specificity of 96% for HRCT compared with 82% for chest radiographs was reported by Padley and colleagues[182] in patients with DILD. In other studies, it has been shown that between 10% and 20% of patients with DILD suspected on chest radiographs subsequently prove to have normal lung biopsy results.[180,181] Although HRCT is clearly more sensitive than chest radiographs, its sensitivity in detecting lung disease is not 100%, and a negative HRCT cannot generally be used to rule out DILD. For example, in one study, although HRCT had very high sensitivity and specificity values, 4% of subjects with biopsy-proven lung disease were interpreted as having a normal HRCT.[182]

Diagnostic Accuracy. Even in the presence of definite abnormalities, chest radiographs have limited diagnostic accuracy for patients with DILD. In an attempt to improve the diagnostic accuracy of chest radiographs, McLoud and associates[186] employed a semiquantitative approach to the chest radiographic diagnosis of diffuse lung disease based on a modification of the International Labor Organization/Union Internationale Contre Cancer classification of chest radiographic abnormalities. In an evaluation of 365 patients with open lung biopsy–confirmed DILD, these investigators found that their first two diagnostic choices corresponded to the histologic diagnosis in only 50% of patients; this improved to only 78% when the first three choices were included. Furthermore, there was only 70% interobserver agreement as to the predominant type of parenchymal abnormality or its extent. Numerous reports have shown that HRCT is significantly more accurate than are chest radiographs in diagnosing both acute and chronic diffuse lung disease, usually allows a more confident diagnosis, and is subject to considerably less interobserver variation in its interpretation (Table 19-4).[131–133,141,151,168,187–193]

In an attempt to further refine diagnostic accuracy, Grenier and coworkers[131] used bayesian analysis to determine the relative value of clinical data, chest radiographs, and HRCT for patients with chronic DILD. For this study, two samples from the same population of patients with 27 different diffuse lung diseases were consecutively assessed: an initial retrospectively evaluated set of "training" cases (n = 208) and a subsequent prospectively evaluated set of "test" cases (n = 100) for validation. The results showed that for the test group an accurate diagnosis could be made in 27% of cases based on clinical

TABLE 19-4. Comparative Accuracy of Chest Radiographs and High-Resolution Computed Tomography

	CONFIDENT FIRST CHOICE DIAGNOSIS		CORRECTED FIRST CHOICE DIAGNOSIS WHEN CONFIDENT		CORRECT FIRST CHOICE DIAGNOSIS		CORRECT DIAGNOSIS IN FIRST THREE CHOICES	
Study	CXR	HRCT	CXR	HRCT	CXR	HRCT	CXR	HRCT

CXR, chest radiograph; HRCT, high-resolution computed tomography.

data only, increasing to 53% ($P < .0001$) with the addition of chest radiographs and to 61% ($P = .07$) with the further addition of HRCT scans. In some situations, HRCT findings are sufficiently diagnostic to obviate biopsy.[144,194]

Assessing Disease Activity. In addition to being more sensitive, specific, and accurate than chest radiographs, HRCT may also play a critical role in the evaluation of disease activity in patients with diffuse lung disease.[144,194] Available data suggest that, in certain cases, HRCT may be used to determine the presence or absence, and extent, of reversible (acute or active) lung disease compared with irreversible (fibrotic) lung disease. Furthermore, because HRCT may accurately identify subtle "active" lung disease, it can be used to study patients who are being treated in order to monitor the success or failure of the treatment being employed.[129,144,194–198]

Although a number of HRCT findings have been described as being indicative of active or reversible lung disease in patients with different disease entities, most attention has focused on the potential significance of ground-glass opacity in patients with chronic DILD.[137,166] This finding has been reported in a wide range of DILDs, including usual interstitial pneumonia, desquamative interstitial pneumonitis, lymphoid interstitial pneumonia, sarcoidosis, hypersensitivity pneumonitis, alveolar proteinosis, cryptogenic organizing pneumonia, respiratory bronchiolitis, and chronic eosinophilic pneumonia.[137] Ground-glass opacity also has been described in patients with neoplasms, in particular bronchoalveolar carcinoma, as well as a wide variety of acute lung processes, such as acute interstitial pneumonia; bacterial, fungal, viral, and *P. jirovecii* infections; pulmonary hemorrhage syndromes; and congestive heart failure and other causes of pulmonary edema.

Although ground-glass opacity is a nonspecific finding and can reflect various histologic abnormalities, in patients with chronic DILD, ground-glass opacity may represent active parenchymal inflammation. In a study of 26 patients with DILD in whom histopathologic correlation was obtained, biopsy specimens demonstrated that ground-glass opacity corresponded to inflammation in 24 cases (65%), and in 8 additional cases (22%), inflammation was present but fibrosis predominated[137,166]; in only 5 cases (13%) was fibrosis the sole histologic finding. Similarly, Leung and associates,[165] in a study of 22 patients with a variety of chronic DILDs and evidence of ground-glass opacity as either a predominant or an exclusive HRCT finding, showed that 18 (82%) had potentially active disease identified on lung biopsy.

Ground-glass opacity may also be seen in the presence of interstitial fibrosis without active inflammation.[137,165,166] To strongly suggest that ground-glass opacity indicates active disease, this finding should generally be unassociated with HRCT findings of fibrosis.[137,165,166] In patients with idiopathic pulmonary fibrosis, a significant correlation has been found between the presence of HRCT findings of ground-glass opacity and pathologic findings of active inflammation, the development of pulmonary fibrosis, the patient's prognosis,[142,196,198–200] and the likelihood of response to therapy.[195,196,198] HRCT has also been used to assess disease activity as well as the likelihood of response to therapy in patients with sarcoidosis.[129,138,154,167,197] In most series of patients with sarcoidosis, the main HRCT determinant of disease activity has been the presence and, to a lesser degree, the extent and distribution of small nodules.[138,167]

Guiding Lung Biopsy. Among the many indications for HRCT, perhaps the most important is as a potential guide for surgical lung biopsy. Many "diffuse" lung diseases are quite patchy in distribution, with areas of abnormal lung frequently interspersed among relatively normal areas of lung parenchyma. Furthermore, both active and fibrotic disease can be present in the same lung.[142,144,194,199–201] To establish a specific diagnosis and assess the clinical significance of the abnormalities present, it is critically important to selectively sample those portions of the lung that are the most abnormal and the most likely to be active. This can be accomplished with HRCT. Also, as a direct consequence of its ability to visualize, characterize, and determine the distribution of parenchymal disease, HRCT also provides a unique insight into the likely efficacy of transbronchial or surgical lung biopsy (via thoracotomy or video-assisted thoracoscopy) in patients with either acute or chronic diffuse lung disease. Surgical lung biopsy is often

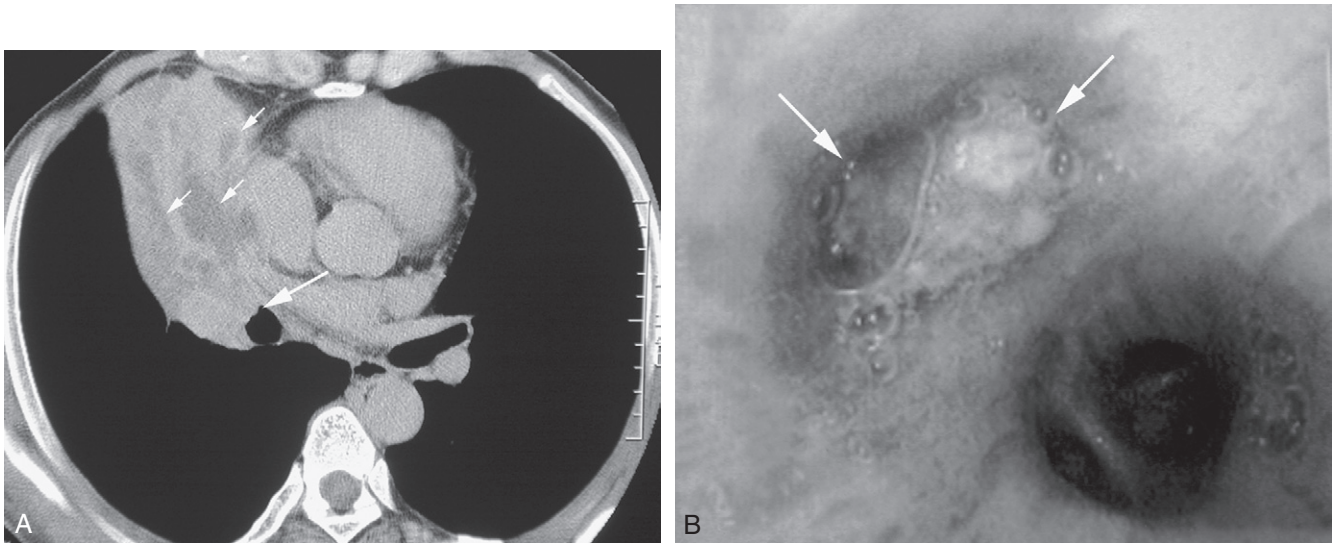

FIGURE 19-53 ■ **A,** Axial CT image shows a squamous carcinoma occluding the right middle lobe bronchial orifice (*large arrow*), producing complete collapse of the right middle lobe. Low-attenuation tubular foci (*small arrows*) visible within the collapsed right middle lobe represent mucus-impacted bronchi. **B,** Bronchoscopic image shows the carcinoma occluding the right middle lobe bronchus and protruding into the bronchus intermedius (*arrows*).

diagnostic, with accuracies greater than 90% generally reported,[144,181,194,202,203] but this procedure is also subject to sampling error. HRCT is of considerable value in determining the most appropriate sites for biopsy.[144,188,194]

Intrathoracic Airway Disease

Previously, spiral CT was used to evaluate the trachea or central airways and HRCT technique is more appropriate for imaging the peripheral airways. With the development of MSCT, volumetric HRCT is now possible, which allows simultaneously optimized evaluation of the central airways combined with HRCT technique for evaluation of the peripheral airways in a single examination.[204]

Central Airways

CT can effectively evaluate lesions (Fig. 19-53) of the trachea and central airways,[205] including strictures and stenoses, inflammatory diseases such as polychondritis (Fig. 19-54), some cases of extrinsic versus intrinsic obstruction,[206] aspirated foreign objects, tracheobronchomalacia, and neoplasms.[205] Multislice CT, with its ability to rapidly acquire images with equal resolution in all planes, is particularly useful in this assessment and can provide detailed three-dimensional analysis of the central airways. The ability to produce excellent quality three-dimensional images aids in the evaluation of subtle airway stenoses and complex airway lesions, particularly when they are oblique with respect to the imaging plane. In the assessment of tracheal and central bronchial neoplasms, CT does not substitute for bronchoscopy and biopsy, but it can be useful to determine the extent of invasion and to direct the bronchoscopist to a particular segment or to a precise location of peribronchial disease. The major value of CT imaging is its ability to visualize the luminal contents, the airway wall, and the surrounding soft tissue. Accordingly, the use of CT carries the greatest benefit in circumstances that require all three of these capabilities.

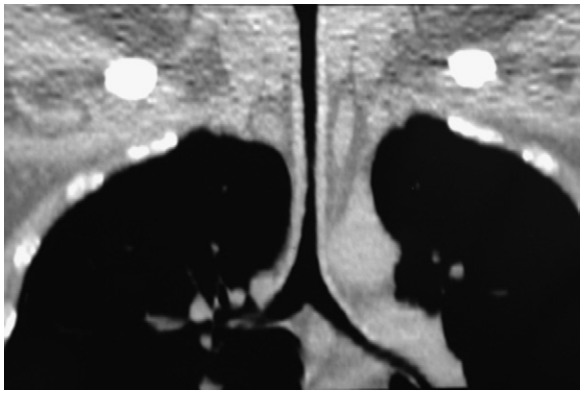

FIGURE 19-54 ■ Value of MSCT for central airway evaluation. Coronally reconstructed image shows diffuse thickening and narrowing of the trachea in a patient with relapsing polychondritis.

Bronchiectasis

CT should be the initial investigation in all patients with suspected bronchiectasis.[207–210] The sensitivity and specificity of HRCT (scans at 1-mm intervals) for diagnosing bronchiectasis to the segmental level are 95% to 98% (Figs. 19-55 and 19-56), whereas the sensitivity and specificity of thick-section CT are only about 80%. In current medical practice, CT has replaced bronchography. A review of the CT criteria for diagnosing bronchiectasis and the technical pitfalls that may intervene has been published.[211] MSCT scanning with narrow collimation

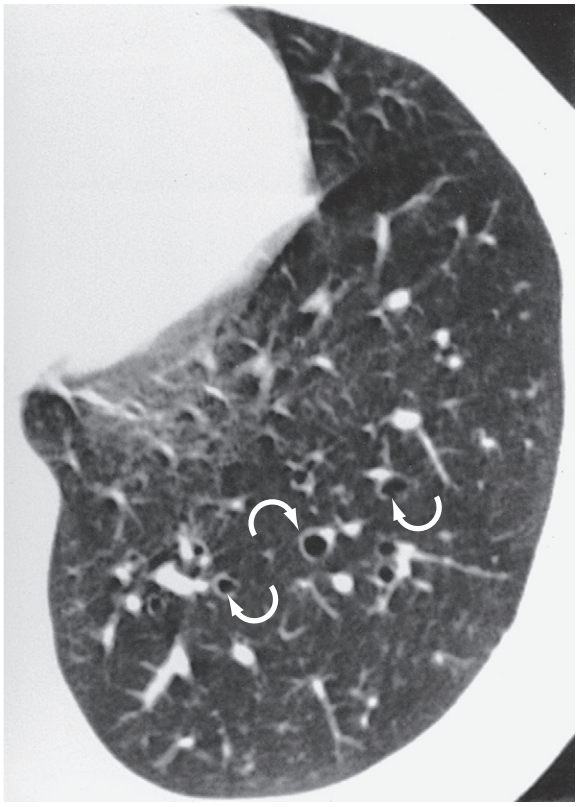

FIGURE 19-55 ■ HRCT image (performed with 1.5-mm collimation) shows obvious bronchiectasis (*arrows*).

(on the order of 1 mm) provides a larger volume of coverage with spatial resolution superior to routine single-slice spiral CT, yet also allows for volumetric imaging and the creation of exquisite reformatted images, including volume rendering.

Small Airway Disease

HRCT has the ability to demonstrate abnormalities of small airways having a diameter of a few millimeters or less.[141,153,159,163,176–178,212] Diagnosable abnormalities include (1) inflammatory forms of bronchiolitis, such as cellular bronchiolitis (usually due to infection, aspiration, or hypersensitivity pneumonitis), respiratory bronchiolitis, follicular bronchiolitis, and panbronchiolitis, and; (2) small airway diseases associated with airflow obstruction (e.g., constrictive bronchiolitis).[212] Cryptogenic organizing pneumonia has been previously classified as a disease of the small airways but is now considered an idiopathic interstitial pneumonia.[144,212] The use of postexpiratory HRCT is particularly important in the diagnosis of small airway diseases because air trapping may be visible in the absence of other abnormalities.[177,178] Postexpiratory HRCT may be performed by imaging after a forced vital capacity maneuver[213] or with lateral decubitus CT.[214] Recent data suggest that postexpiratory CT performed during a forced vital capacity maneuver, called "dynamic expiratory CT," is a more effective technique for the demonstration of subtle or transient air trapping.[213]

Cardiovascular Disease

Pulmonary Thromboembolism

Thoracic MSCT has emerged as the test of choice for the imaging evaluation of suspected pulmonary embolism. Ventilation-perfusion scintigraphy has long been used as the initial test for such patients. Its strengths and its limitations are well known and reviewed in Chapter 21. It is extremely safe, it is widely available, and it is exceedingly sensitive: a normal perfusion scintigram effectively rules out pulmonary embolism. A high-probability scan is quite specific (97% in the Prospective Investigation of Pulmonary Embolism Diagnosis [PIOPED] I study).[23] However, a substantial fraction of perfusion scintigrams yield results that are abnormal but nonspecific. In addition, it has been recognized increasingly that imaging the lower extremity veins can be useful and cost-effective for many patients suspected of having acute pulmonary embolism; thus, a single imaging procedure that evaluates both the lower extremity veins and the pulmonary arteries is quite useful.

Single-slice spiral CT, in pooled data from a number of studies, showed an overall sensitivity and specificity approaching 90% and 96%, respectively. Regardless, criticisms regarding the methodology employed in single-slice CT studies as well as the long-held faith in the diagnostic accuracy of catheter pulmonary angiography for suspected pulmonary embolism led to relatively slow adoption of the use of CT for this application in some centers. Once MSCT technology became available, however, it became clear that MSCT scans could demonstrate smaller vessels and, therefore by inference, should be more sensitive than single-slice CT for the detection of thromboembolic disease. Several studies investigating the incremental value of MSCT over single-slice CT for the diagnosis of thromboembolic disease were conducted shortly after the introduction of this technology, including the PIOPED II trial, the results of which were published in 2006. In PIOPED II, the sensitivity of MSCT for the diagnosis of pulmonary embolism was 83% (95% confidence limits, 76%–92%) and the specificity was 96%. The positive predictive value of a positive MSCT study was 86% and the negative predictive value was 95%. Although the sensitivity of MSCT in the PIOPED II trial has led some investigators to question the utility of MSCT for the evaluation of suspected pulmonary embolism, MSCT is nevertheless in widespread use as the first-line diagnostic modality for the investigation for such patients all across the world.

Ultimately, the main question that must be answered when patients suspected of thromboembolic disease undergo MSCT pulmonary angiography is, "can anticoagulation be safely withheld in such patients?" In other words, what is the negative predictive value of MSCT pulmonary angiography for thromboembolic disease? Several studies have addressed this question, and the negative predictive value of MSCT pulmonary angiography ranges

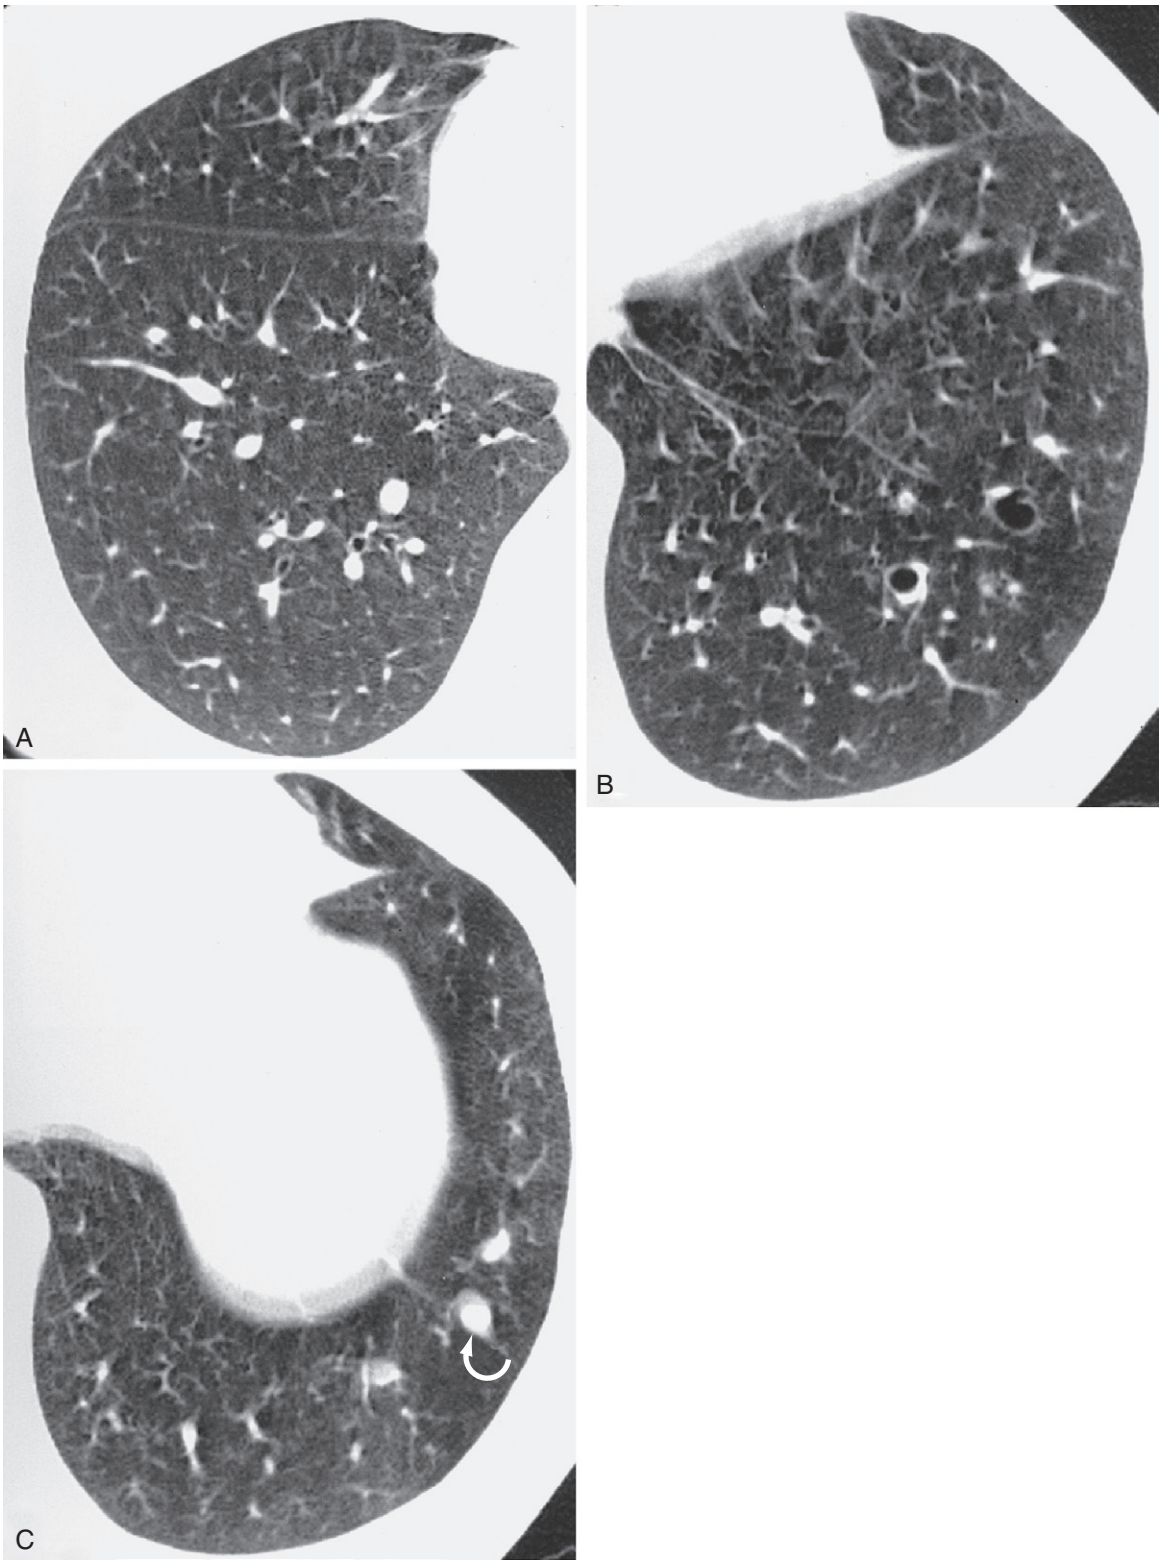

FIGURE 19-56 ■ **A,** HRCT shows the normal appearance of peripheral bronchi in the right lower lobe. In addition, note that there is a pulsation artifact anteriorly (middle lobe) due to transmitted cardiac pulsations. **B,** Focal bronchiectasis is present in the left lower lobe. Again, note that there is a pulsation artifact anteriorly (lingula and lower lobe). **C,** An image lower in the thorax demonstrates mucus-filled ectatic bronchi (*arrow*).

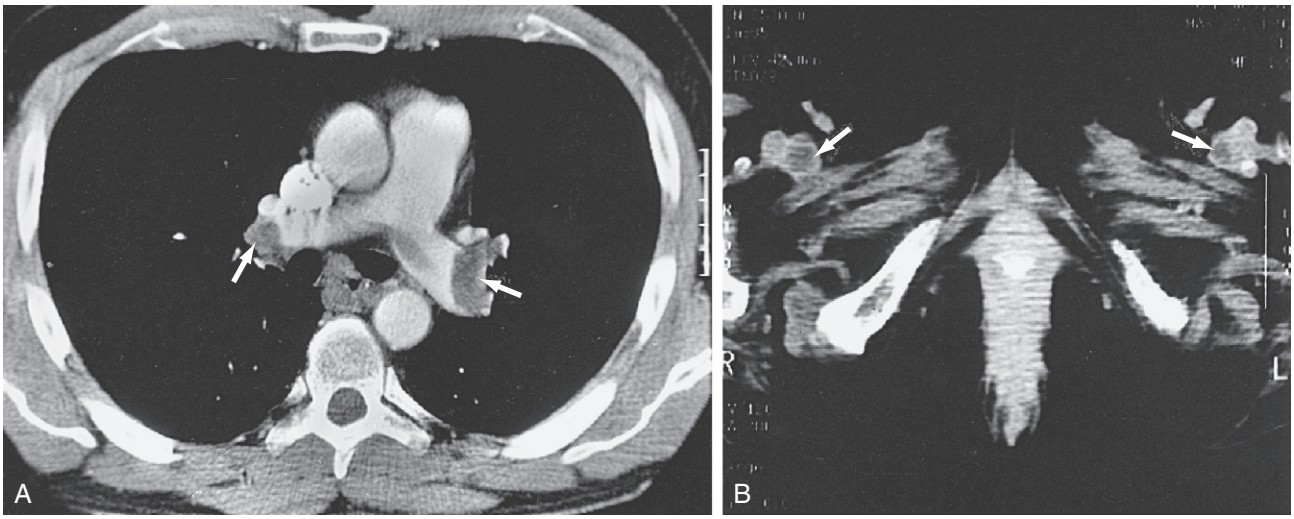

FIGURE 19-57 ■ CT images demonstrate pulmonary embolism and deep vein thrombosis. **A,** Contrast-enhanced helical CT shows bilateral large filling defects consistent with pulmonary emboli (*arrows*). **B,** A pelvic CT image made without additional contrast material shows bilateral filling defects in the common femoral veins consistent with venous thrombi (*arrows*).

from 95% to 99%.[215,216] Importantly, it has been suggested that further diagnostic testing should be pursued when MSCT pulmonary angiography results (with or without indirect CT venography, see later) are discordant with the clinical probability for pulmonary embolism, particularly when MSCT results are negative and the clinical probability of pulmonary embolism is considered high.[215]

Various investigations also suggest that both spiral CT and MSCT may also be able to detect deep venous thrombosis in the proximal leg and pelvic veins without injection of additional contrast material (Fig. 19-57), a technique known as indirect CT venography.[217,218] The addition of CT venography to thoracic MSCT studies obtained for the evaluation of suspected pulmonary embolism allows for the simultaneous evaluation of deep venous thrombosis and pulmonary embolism with a single test. Combining MSCT with CT venography increased the sensitivity for the diagnosis of pulmonary embolism to 90% and the negative predictive value of the combination of the examinations was 97% in the PIOPED II trial.[215]

Like MSCT, MRI can demonstrate pulmonary embolism directly as intravascular filling defects on cross-sectional images (Fig. 19-58).[219] Experience with MRI in patients suspected of having pulmonary embolism is far more limited than that with CT. The two techniques are probably overall roughly similar in accuracy for the detection of pulmonary embolism, although MRI may show more pronounced interobserver variability than CT and may show slightly decreased sensitivity compared with CT at the segmental and subsegmental vascular levels. MRI has been shown to be highly accurate for detecting deep venous thrombosis.[220,221]

The potential advantages of MRI are the lack of need for iodinated contrast material or ionizing radiation, ability to image the pulmonary arteries and deep venous system in a single examination, and potentially, the ability to perform perfusion imaging. The latter point is of particular significance in light of the imperfect sensitivity of CT. The advantages of MSCT are higher spatial resolution, wider availability, fewer artifacts, faster examination time, and simpler, more robust technology as well as, importantly, the availability of alternative diagnoses for patients with negative results. Currently, MSCT is a realistic option in the clinical management of patients with suspected pulmonary embolism; the clinical use of MRI is limited to medical centers with personnel who are highly skilled with advanced MRI technology.

Acquired Aortic Disease

Acquired aortic diseases, such as aortic dissection, can be imaged with aortography, CT angiography, echocardiography, and MRI.[222] Transthoracic echocardiography can assess the ascending aorta, but its limited field of view restricts its utility. Transesophageal echocardiography has produced definitive results,[223] but this technique requires sedation and carries the risk of esophageal injury. Aortography has previously been considered the standard method for demonstrating aortic dissection, but it is invasive, and both false-positive and (more commonly) false-negative results occur.[222] It has largely been replaced by cross-sectional imaging methods for the evaluation of aortic pathology.

CT angiography can accurately identify the intimal flap, the true and false lumens (Fig. 19-59), the vessels involved by dissection, and the presence of end-organ perfusion impairment; thus, CT angiography is used routinely for evaluating aortic dissection. Complications of dissection, such as mediastinal hematoma, hemothorax, and hemopericardium, can also be detected. Limitations of CT include the need for iodinated contrast material and its limited ability to assess aortic valve function (information that some surgeons require and others do not). The latter concern has been alleviated somewhat with the development of retrospectively

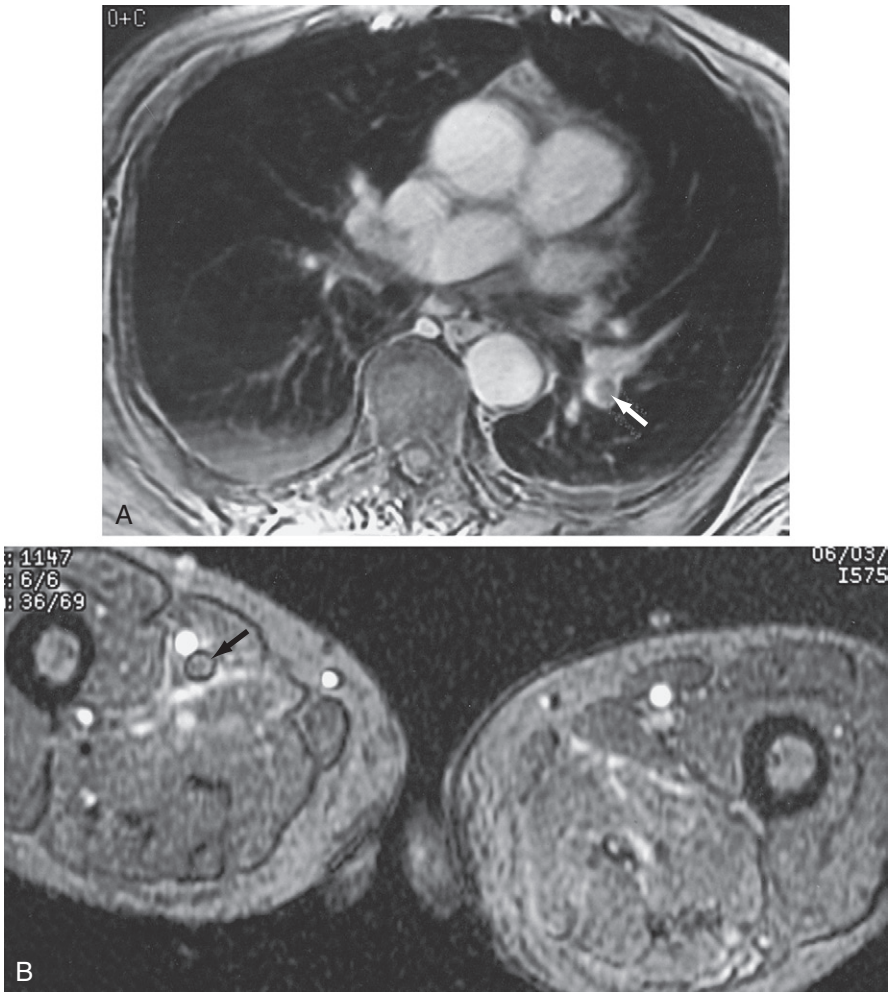

FIGURE 19-58 ■ MRI demonstrates pulmonary embolism and deep vein thrombosis. **A,** This contrast-enhanced magnetic resonance (MR) image shows a filling defect consistent with pulmonary embolus in the left lower lobe artery (*arrow*). **B,** This MR image made without contrast material shows a filling defect in the right superficial femoral vein consistent with venous thrombus (*arrow*), while the contralateral vein is patent and without filling defects.

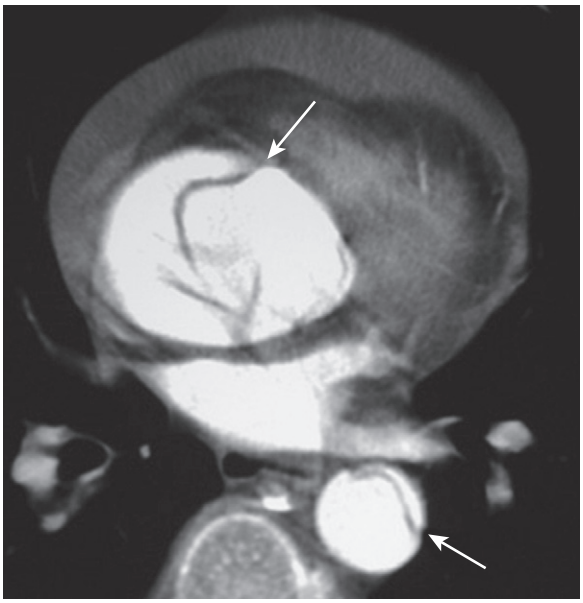

FIGURE 19-59 ■ Thoracic CT angiography in a patient with Stanford type A aortic dissection shows an intimal flap (*arrows*) in the ascending and descending thoracic aorta. Note dilation of the ascending aorta.

electrocardiographic-gated MSCT angiography of the aorta. With this technique, the imaging acquisition is conducted simultaneously with the electrocardiographic tracing, and data can then be reconstructed at any time during the cardiac cycle. Images reconstructed during late diastole often are motion free and allow assessment of the coronary arteries and aortic valve (Fig. 19-60).

MRI has several advantages in suspected aortic dissection. No iodinated contrast material is required (Fig. 19-61), and MRI does not require ionizing radiation. Cine-MRI can assess aortic valve and left ventricular function. However, MRI also has limitations in the assessment of dissections. Some patients are excluded from MRI for safety reasons. MRI examinations usually require more time than MSCT studies for dissection. Artifacts lead to nondiagnostic studies more often with MRI than with MSCT. Greater experience is required to interpret MR images accurately.

The relative accuracy of aortography, transesophageal echocardiography, MSCT, and MRI for detecting and characterizing dissections has not been established by definitive prospective clinical trials. For practical reasons, such a trial is not likely to be conducted. Accordingly, which technique is superior is arguable, and judgment

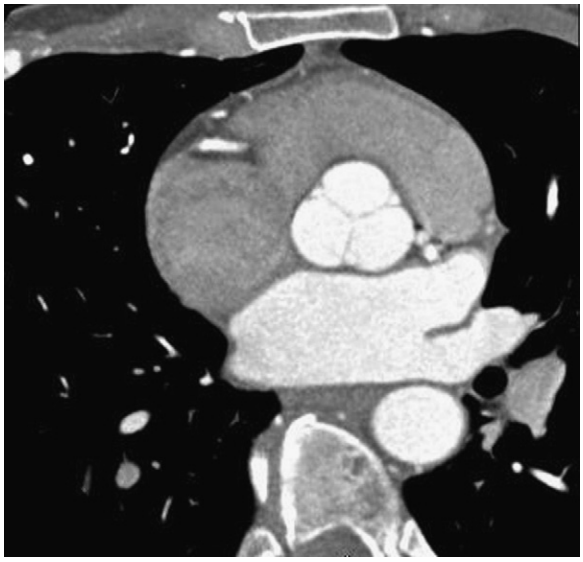

FIGURE 19-60 ■ Value of retrospectively gated thoracic CT angiography for the evaluation of the aorta. Axial CT angiography image obtained with retrospective electrocardiographic (ECG) gating (image reconstructed during diastole) shows a motion-free image. Note clarity of the aortic valve cusps. Compare with the nongated CT angiography image in Figure 19-59.

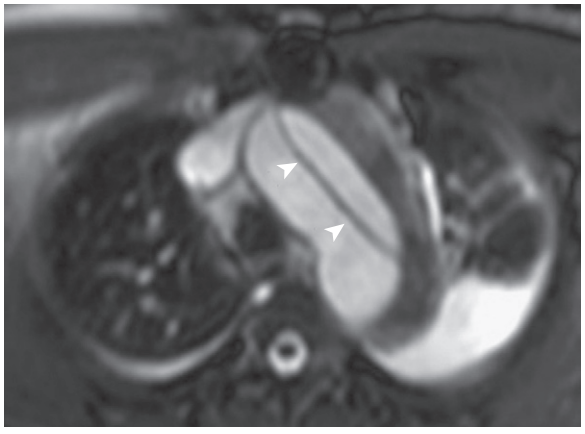

FIGURE 19-61 ■ This patient had symptoms classic for aortic dissection. "White blood" cine MR images show an intimal flap within the aortic arch (*arrowheads*), consistent with aortic dissection.

is required for individual cases. Aortography is the time-tested gold standard, but it is invasive and known to be inaccurate, particularly in cases with thrombosed false lumina, and has largely been replaced by cross-sectional methods. Extensive data indicate that both MSCT and MRI are accurate in evaluating dissections.[224] Our experience is that MSCT and MRI have equivalent accuracy for detecting dissection and that both are more sensitive than aortography. However, no single technique always fulfills all of the requirements for characterization of dissections. Several reports suggest that hemodynamically unstable patients with suspected aortic dissection should be studied with transesophageal echocardiography, whereas stable patients should be evaluated by MSCT or MRI.[223,225] MRI is also recommended for serial studies of patients with chronic dissection.

Both MSCT and MRI have advantages over aortography for evaluating thoracic aortic aneurysms. Both are noninvasive, can document that a mediastinal mass is an aneurysm, can assess the thickness of the aortic wall, and can measure accurately the diameter and longitudinal extent of the aneurysm. In most situations, MSCT is sufficient for diagnosis, and because it is less expensive and faster than MRI, it is the preferred study. MRI is particularly useful for patients with contraindications to iodinated contrast material.

In suspected traumatic aortic rupture, MSCT aortography has replaced catheter aortogtaphy for initial diagnosis.[226] Catheter aortography is generally reserved for indeterminate MSCT studies or problem-solving cases. Although MRI has been reported in this setting, it is not normally used because the problems of monitoring and sustaining the trauma patient are greater with MRI; in addition, MSCT examinations are substantially faster than MR examinations, and time is of the essence in traumatically injured patients. Chronic pseudoaneurysms (Fig. 19-62) in survivors of traumatic or iatrogenic aortic injury can be evaluated with either MRI or MSCT.

Congenital Anomalies of the Thoracic Great Vessels

Echocardiography, MRI, and angiography are commonly chosen modalities for demonstrating great vessel anomalies, associated cardiac malformations, and their physiologic sequelae in children. CT usefully can demonstrate simple vascular anomalies, such as an aberrant subclavian artery and persistence of the left superior vena cava. The vascular supply of sequestrations can be identified by MRI or CT, and angiography now is rarely needed (see Fig. 19-24). In adults with congenital anomalies of the great vessels, MRI is often the procedure of choice because its field of view is wider than that of echocardiography and it is noninvasive, but in complex lesions, these techniques often are complementary. MSCT is also a very effective tool for the investigation of adult and pediatric congenital cardiovascular abnormalities.

Published experience with MRI in developmental anomalies of the great vessels has focused on aortic coarctation and pulmonary artery obstruction, but extensive investigations of the utility of MR techniques for other vascular abnormalities, including extracardiac shunts and partial anomalous pulmonary venous return, have been performed. Coarctation is detected accurately by MRI (Fig. 19-63) or MSCT angiography. Complications of treatment, including restenosis and aneurysm, can be detected,[227,228] and the degree of collateral vascular supply, which affects the risk of surgery, can be established with either technique. The pressure gradient across the coarctation and the relative increase in blood flow distal to the coarctation may be quantified by MRI. Such calculations also provide quantitative data

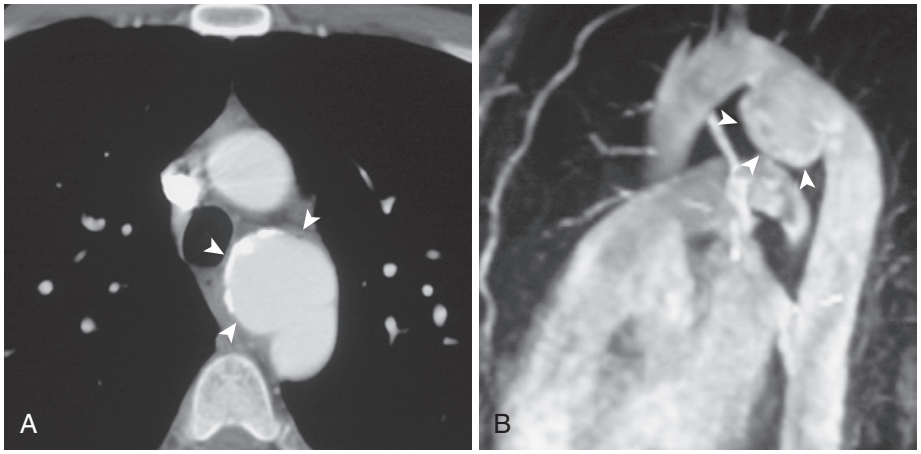

FIGURE 19-62 ■ Chronic pseudoaneurysm in a long-term survivor with undiagnosed traumatic aortic injury 17 years earlier. **A,** Contrast-enhanced CT image at the level of the aortic arch reveals a pseudoaneurysm (*arrowheads*); note calcification along the medial wall of the lesion. **B,** Oblique sagittal three-dimensional MR angiography image shows the pseudoaneurysm (*arrowheads*) to advantage.

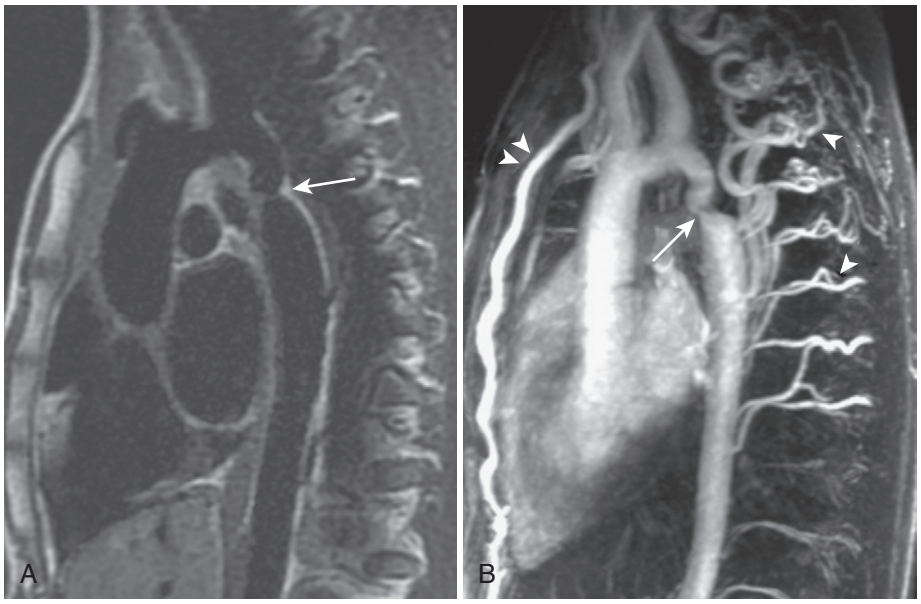

FIGURE 19-63 ■ Value of MRI in the assessment of congenital cardiovascular diseases: aortic coarctation. **A**, Oblique sagittal T1-weighted spin-echo image of the thoracic aorta shows focal, severe narrowing of the proximal descending thoracic aorta (*arrow*) consistent with aortic coarctation. **B,** Oblique sagittal volume-rendered image shows coarctation (*arrow*) as well as collateral vessel formation. The latter derive from intercostal (*single arrowheads*), internal mammary (*double arrowheads*), and chest wall arteries and indicate the presence of a significant pressure gradient across the coarctation.

regarding the efficacy of operative and percutaneous interventions.

MRI is the noninvasive imaging procedure of choice for detecting central pulmonary artery obstruction,[229] evaluating the potential for palliative shunts, and assessing the results of surgery,[228] although MSCT angiography is very useful as well. Comparisons of MRI with transthoracic echocardiography usually have shown MRI to be superior for demonstration of great vessel anomalies. Diagnosis of a variety of other congenital vascular anomalies by MRI and MSCT angiography also has been reported.

Pleural Disease

Most pleural processes can be imaged accurately and cost-effectively with conventional radiography or ultrasonography. However, CT, including single-slice spiral, multislice, and HR, can be useful in several clinical problems relating to the pleura.[24,80,230] These include differentiation of pleural and parenchymal disease (including the distinction between lung abscess and empyema); detection of subtle pleural abnormalities (such as early pleural plaques or small pneumothoraces); location of pleural fluid collections and pleural tumors, including

localization for interventional purposes (e.g., tube drainage or biopsy); determination of the extent of pleural tumors (in particular, metastases and mesothelioma); and occasionally, characterization of pleural lesions (Figs. 19-64 and 19-65; see also Fig. 19-32) or paradiaphragmatic lesions. MRI currently has a limited role in the evaluation of pleural abnormalities.

Type of Fluid

Most effusions appear to be near to water in attenuation. CT numbers cannot be used to predict the specific gravity of the fluid or its cause. One exception, however, is acute or subacute hemothorax. Hemothorax can sometimes appear inhomogeneous in attenuation, with some areas having an attenuation value higher than that of water.

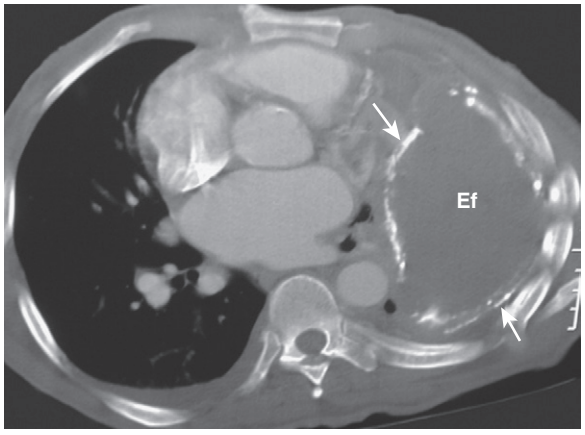

FIGURE 19-64 ■ Thoracic CT performed in a patient with a history of tuberculosis shows pleural thickening and calcification (*arrows*) and a residual pleural effusion (Ef) indicative of empyema.

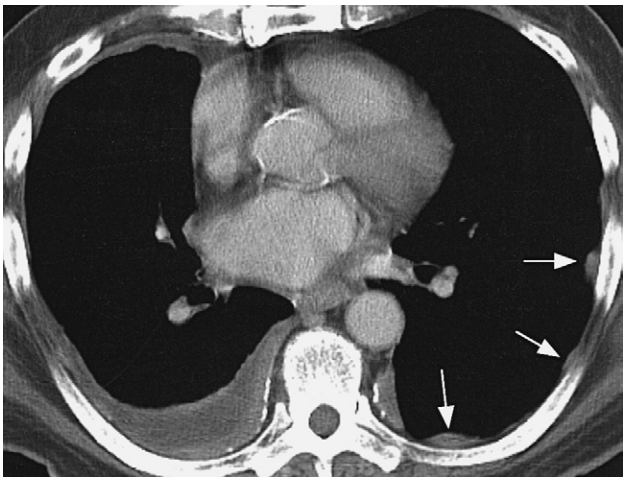

FIGURE 19-65 ■ A patient with prior asbestos exposure has focal areas of pleural thickening or pleural plaques within the left hemithorax (*arrows*). Pleural thickening on the right is associated with pleural effusion. This reflects the presence of early malignant mesothelioma.

The presence of pleural thickening is often of value in predicting the nature of the effusion. In patients with effusion, the presence of pleural thickening on CT indicates that the effusion is an exudate.[80] By definition, the pleura is considered thickened if it is visible on a contrast-enhanced or unenhanced CT. Transudates are never associated with pleural thickening. Conversely, the absence of pleural thickening on contrast-enhanced CT is less helpful. In this case, the effusion can be an exudate or transudate. Only about 60% of exudates are associated with visible pleural thickening. However, the absence of pleural thickening on a contrast-enhanced scan rules out empyema; empyema is always associated with parietal pleural thickening on contrast-enhanced CT.

Pleural versus Parenchymal Disease

Chest radiography may not be able to distinguish between parenchymal disease, pleural disease, and pathology affecting both compartments. CT can be useful in this setting. Pleural lesions typically have obtuse tapering margins and sharp interfaces with adjacent lung parenchyma, whereas parenchymal lesions tend to blend with lung parenchyma and have acute, irregular margins. One of the more common and therapeutically important problems in this category is differentiating lung abscess from empyema. Empyemas typically have smooth outer and inner margins, a lenticular shape, and a sharp interface with underlying lung; they tend to displace pulmonary vessels around them and often display prominent rim enhancement (the "split pleura sign") with intravenous administration of iodinated contrast material (see Fig. 19-64). Lung abscesses are characterized by spherical or polygonal shape, a thick wall with a shaggy or irregular inner margin, and permeation between adjacent pulmonary vessels. None of these features is unique, but when considered together, they permit categorization of the abnormality in most cases.

Early Detection

The contrast resolution and cross-sectional format of CT make it highly sensitive and accurate in detecting pleural thickening and early pleural plaques in patients with asbestos-related pleural disease (see Fig. 19-65).[24,128] Circumscribed plaques often are missed on chest radiographs unless they are calcified or attain a thickness of about 5 mm or more. Furthermore, normal extrapleural soft tissues and fat can be misinterpreted as plaques when they are prominent on chest radiography. Both standard CT and HRCT are accurate for detecting pleural plaques, but HRCT may be more accurate for characterizing subtle plaques.

CT has been shown to be accurate and more sensitive than conventional radiographs in detecting pneumothoraces. This can be of particular importance in trauma patients, who may require intubation and positive-pressure ventilation.

KEY POINTS

- After the medical history and physical examination, radiography is the most commonly used technique in the evaluation of patients with known or suspected thoracic disease.
- Most clinical questions can be answered by careful review of high-quality frontal and lateral chest radiographs. Currently available techniques of digital recording of images offer many interpretive and logistical advantages.
- When needed, higher-quality resolution of known or suspected abnormalities is available by CT, particularly by MSCT, which has rapid acquisition time and greatly improved resolution; MSCT has become the imaging method of choice for further evaluation of pulmonary nodule(s), lung cancer, mediastinal abnormalities, diffuse lung diseases, airway diseases, and suspected pulmonary embolism.
- MRI is useful in evaluating superior sulcus lesions, brachial plexopathy, and certain cardiac and mediastinal abnormalities. MRI is also useful, though less often used than MSCT, for evaluating suspected aortic dissection and pulmonary embolism.
- Further information about the application of radiographic techniques and the results of these studies is presented in the chapters concerning specific pulmonary diseases that appear later in this book.

INTRODUCTION

Ultrasonography is a diagnostic tool with expanding indications in pulmonary medicine. Indications include evaluation of pleural effusions and guidance for catheter insertion into the thorax. The analysis of image artifacts has further increased the range of ultrasound in diagnosing pulmonary pathology such as pneumothorax and pulmonary edema. Using endobronchial ultrasound (EBUS) during bronchoscopy, the airways can also be examined allowing sampling of lymph nodes and peripheral lung lesions. Although complete diagnostic ultrasound imaging of the thorax is still not available as part of a routine clinical examination, ultrasonography is being used to answer specific questions in point-of-care or goal-directed scanning.

Ultrasonography has the potential to revolutionize pulmonary practice by extending bedside diagnostic capabilities. Sonographically guided procedures increase the probability of success of procedures in the pleural space and improve diagnostic yields during bronchoscopy. Complications related to pleural interventions are also likely to be reduced. Ultrasonography is easily mastered once the image acquisition and interpretation, as well as the technical jargon (Table 20-1), are learned. These advantages coupled with the radiation-free, portable, and noninvasive properties of ultrasound place this technology in a position to gain widespread application in pulmonary medicine.

BASICS OF ULTRASOUND

Ultrasound Physics

Ultrasound is nonaudible sound energy used for medical applications in a frequency range of 2 to 20 MHz, frequencies that have been found to provide the best combination of penetration and resolution in the body. These frequencies are more than 1000 times greater than the audible range of sound, up to 20 kHz, but obey the same

TABLE 20-1. Glossary of Ultrasound Terminology

Acoustic enhancement	An artifact showing an increase in echogenicity in a region distal to a fluid collection.
Acoustic impedance	A measure of the "resistance" of the medium to the transmission of sound waves from one tissue to another. The difference in acoustic impedance (mismatch) between two tissues determines the reflection of waves at the interface.
Acoustic window	Pathway of an ultrasound beam between the probe and the target.
Acoustic shadow	Anechoic area behind bony structures.
Attenuation	The progressive reduction of amplitude and intensity of a transmitted signal as it moves through a medium.
Artifacts	Images created by physical effects on sound wave propagation not reflecting the presence of actual tissues.
Artifact lines	
Comet-tail artifacts	*Vertical* hyperechoic lines arising from the pleural line.
B lines	Comet-tail artifacts that spread all the way to the edge of the screen without fading.
Z lines	Comet-tail artifacts that fade quickly without reaching the edge of the screen.
Lines	
A lines	*Horizontal* hyperechoic echoes of the pleural line.
Doppler	Technique for imaging moving particles by the detection of a change in the frequency of the reflected ultrasound energy.
Echogenicity	
Hyperechoic	An appearance that is brighter or more white than that of normal solid organ structures such as the liver or spleen.
Hypoechoic	An appearance that is darker or more black than that of normal solid organ structures.
Lung sliding	The "to-and-fro" twinkling movement of the lung during respiration as it slides past the chest wall at the pleural line.
Modes	The means by which reflected ultrasound energy is displayed on the screen. In each case, the time for the energy to be reflected from an object determines the depth of the resultant image on the screen.
A-mode	Amplitude-mode—reflected energy is shown as peaks of different size; not used in thoracic ultrasound.
B-mode	Brightness-mode—reflected energy is displayed as areas of different brightness; used to generate the standard two-dimensional ultrasound image.
M-mode	Motion-mode—reflected energy is shown as areas of brightness traced from left to right on screen with time on the x-axis.
M-mode signs	
Sinusoid sign	A hyperechoic sinusoidal line deep to a pleural effusion that represents movement of the visceral pleura with respiration adjacent to a pleural effusion.
Seashore sign	A grainy "sandy" image with a few horizontal lines denoting the "sea" at the top, a sign that represents aerated lung.
Stratosphere sign	A series of prominent horizontal straight A lines that represent a pneumothorax.
Lung point	A sudden transition from a "seashore" to a "stratosphere" sign, representing the fleeting appearance of aerated lung expanding in inspiration into a pneumothorax. A positive ultrasound sign for pneumothorax.
Pleural line	Horizontal hyperechoic line that corresponds to the interface between the lung and the chest wall.
Resolution	The ability to display two tissue interfaces that are close to each other as separate images.
Time-variable gain	An amplification or gain of reflected ultrasound energy proportional to the timing of the returning signals to enable deeper objects to be as bright as those closer.

physics. As ultrasound waves travel through tissue, they undergo attenuation and are also deflected by scattering, refraction, and reflection; it is the reflection of the waves that forms the basis of the ultrasound images. Reflection depends on the difference in sound transmission characteristics of the tissue, or the impedance, which is a measure of the resistance to propagation of sound waves from one medium to another. In a completely homogeneous tissue, there would be no reflection; at the boundary between two tissue structures with different impedance (i.e., an impedance mismatch), an ultrasound pulse is partially reflected. The greater the difference in acoustic impedance, the greater will be the strength of the reflected ultrasound signal. The difference between acoustic impedance of air and tissue is very high and, at air-tissue interfaces, almost all energy is reflected back; thus a coupling gel is necessary to remove all air from the interface of the transducer and the body to allow ultrasound energy to enter the body. The more minor differences in impedance between body tissues allow partial reflection of waves to impart information about the location and characteristics of the tissues. Signal processing of the reflected energy into a gray-scale image on a screen forms the basis of ultrasound technology.

An ultrasound pulse is generated by the piezoelectric crystals within the transducer probe. When an alternating current is applied, these crystals vibrate to convert electrical energy into mechanical energy and produce an emitting pulse. After the pulse is transmitted, the system awaits the return of reflected signals, which are received by the same piezoelectric crystals in the transducer. Returning ultrasound energy provides two types of information: the amplitude of the signal, which indicates how much energy is reflected, and the timing of the returning signal, which is related to the distance of the target from the emitting probe.

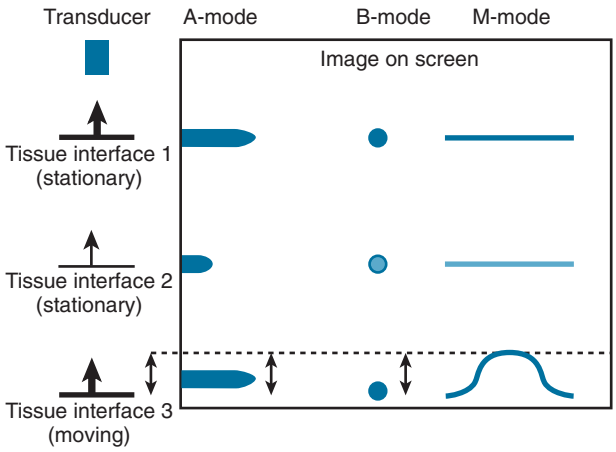

FIGURE 20-1 ■ Generation of images for each ultrasound mode depends on the amplitude of the reflected signal (size of arrow) and the timing of the returning signal (distance from transducer). The amplitude-mode (A-mode) is not currently used in thoracic ultrasonography. The brightness-mode (B-mode) is used to generate the standard two-dimensional image of ultrasound. The motion-mode (M-mode) provides a record of the position over time, allowing the recording of some signs of use in thoracic ultrasound such as the "seashore" sign of normal lung and the "stratosphere" sign of pneumothorax. (Adapted from Stoylen A: Basic ultrasound for clinicians. Available at http://folk.ntnu.no/stoylen/strainrate/Ultrasound. [accessed September 4, 2008].)

Ultrasound Modes

The processing of the reflected signals determines the type of image seen. In the A-mode (or *amplitude* mode), the received amplitude of energy from the transducer is displayed as peaks or waves shown at the distance determined by the depth of the image. This mode is not used currently in thoracic ultrasound. With the B-mode (or *brightness* mode), the amplitude of energy is instead displayed as spots of different brightness, so that a series of B-mode images can be used to produce a conventional two-dimensional ultrasound image. In the M-mode (or *motion* mode), the image of a particular object is traced across the screen by capturing a B-mode image as it sweeps across the screen against a time axis. This provides a single image in which relative positions of images are shown against time on the x-axis (Fig. 20-1).

Transducers

Thoracic ultrasound typically utilizes the 2- to 5-MHz frequency range that provides the optimal compromise between spatial resolution and depth of penetration for thoracic indications. Higher frequencies improve resolution but limit the depth of imaging; lower frequencies visualize with less resolution but to a greater depth. Thoracic ultrasound generally uses curvilinear or convex probes that employ a curved surface to create a scanned field that is wider than the footprint of the probe, producing a sector or fan-shaped image; small footprints can also be achieved with phased array probes with electronic steering. Small footprints enable better access through the narrow acoustic windows available between ribs through which the beam can access deeper tissues. Compared with linear probes, convex transducer probes have a reduced lateral resolution, but the resolution is acceptable for the relative sizes of structures imaged in the chest.

Doppler

Doppler imaging is used to detect motion. Doppler imaging is based on the principle that the frequency of sound increases as the source of sound moves toward an observer and decreases as the source of sound moves away. In pulsed wave Doppler, a pulse is transmitted and the change in frequency of the returning echo is measured at a certain time. Traditionally, a red color on the screen denotes objects moving toward the probe and blue denotes objects moving away from the probe. Optimal imaging for color Doppler is obtained when the transducer is aimed *parallel* to the flow of the target; in contrast, for B-mode and M-mode ultrasound, optimal imaging is produced when the transducer is aimed *perpendicular* to the target.

ULTRASOUND IMAGE ACQUISITION

Positioning of Patients and Probe

In a free pleural space without septations, effusions will collect in the dependent parts of the thorax whereas free air will collect in superior, nondependent locations. Therefore, the positions of the patient and of the ultrasound probe are crucially important to evaluate for these indications. In most thoracic evaluations, the patient is examined sitting upright. Patients who are ill may be examined in the supine or lateral decubitus position but, if so, the patient's position must be taken into consideration when images are interpreted. For systematic evaluation, the hemithorax can be divided into three zones: anterior, lateral, and posterior. These zones are demarcated by the anterior and posterior axillary lines.[1] The anterior zone spans from the anterior axillary line to the sternum, the posterior zone spans the posterior axillary line to the vertebral column, and the lateral zone lies between. For better access to the posterior thorax, supine patients who cannot sit up can be moved to the lateral edge of the bed.

Scan/Probe Orientation

Longitudinal scans through the intercostal spaces (i.e., parallel to the long axis of the body) are preferred to transverse scans both because of convention and because a longitudinal image will generally include the diaphragm for reference. To maintain orientation of the probe and the resulting image, the transducer probe has a ridge or groove. With the groove oriented toward the head of the patient, the resultant image will show the cephalad direction to the left of the screen.

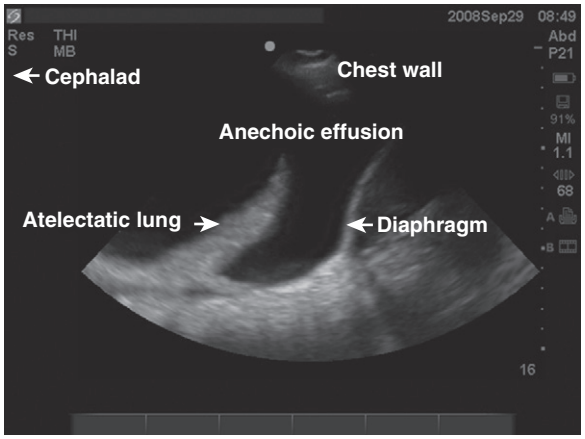

FIGURE 20-2 ■ B-mode image of an anechoic pleural effusion bordered by the hyperechoic diaphragm and an isoechoic atelectatic lung.

Superficial structures will be at the upper part of the screen with deep structures at the bottom of the screen (Fig. 20-2).

Transducer Probe Handling

The probe is held in the dominant hand as one would hold a pen, with the thumb on the orientation groove. The examiner's hand rests against the patient's skin as a support to stabilize the transducer. The probe is moved from intercostal space to intercostal space and moved transversely within intercostal spaces. Because air forms an almost impermeable barrier to ultrasound, air trapping is minimized by using a water-based coupling gel and by holding the probe firmly against the skin. The probe must be kept still during image acquisition to prevent confusion between the movement of the probe and dynamic signs within the thorax.

Image Acquisition

Two parameters need to be adjusted for optimal acquisition of the images: depth and gain. The depth of the field is set according to needs of the ultrasound examination: a 10-cm depth will usually suffice for most thoracic investigations. The gain is set to amplify signals relative to background noise. Increasing the gain makes an image whiter and decreasing the gain makes the image blacker. Time-variable gain enables the operator to amplify ultrasound signals proportional to the depth in order to make deeper structures appear as bright as more superficial structures. Because solid organs such as the normal liver are considered to be of intermediate density (isoechoic), gain can be adjusted with reference to the liver image to make it gray on the screen; other tissues can then be evaluated in comparison to this standard gray image. Although noise filters can improve the quality of imaging solid and liquid structures, the use of such filters can also obliterate the signal artifacts that are crucial to diagnostic analysis of aerated lung.

TABLE 20-2. Basic Interpretation of Ultrasound Images as Either Representing an Anatomic Structure or an Artifact

Image Appearance	Anatomic Structure	Artifact
Black (hypoechoic/ anechoic)	Uncomplicated fluid collection	Acoustic shadows
Gray (isoechoic)	Tissues (e.g., liver, spleen, lymph nodes, consolidation, atelectasis)	Acoustic enhancement (light gray)
	Complicated fluid collections (e.g., hemothorax, empyema)	
White (hyperechoic)	Fat	Aerated lung*
	Calculi	Pneumothorax

*Aerated lung is listed as an artifact in this table because the generated image does not conform to the size or shape of the actual tissue.

DIAGNOSTIC THORACIC ULTRASONOGRAPHY

Two types of images are visualized by ultrasound, either anatomic structures or artifacts[2] (Table 20-2). Anatomic structures are identified based on their location and echogenicity. Echogenicity of body structures can be referenced to solid organs such as the liver that are made to appear gray or isoechoic on the screen. Uncomplicated fluid collections appear darker than these solid organs and are termed "hypoechoic"; if they appear black, they are termed "anechoic." Air appears white and is "hyperechoic." The homogeneity or heterogeneity of echoes also contributes to the recognition of different issues.

Artifacts are images that do not correspond to specific anatomic structures but which can provide useful information if properly recognized. Examples of artifacts are acoustic shadows, acoustic enhancement, and reverberation echoes. Unlike anatomic structures, artifacts tend to move with the movement of the probe and converge toward the near field at the top of the screen. *Acoustic shadows* are anechoic regions that lie behind bony structures such as ribs. Because acoustic shadows provide no ultrasound information, the transducer probe should have an appropriately small footprint to transmit ultrasound pulses between the bony structures and thus avoid them. *Acoustic enhancement* is a hyperechoic region (lighter gray than liver) located distal to a cystic fluid collection; the enhanced region distal to the fluid should not be mistaken for another tissue structure. *Reverberation echoes* are alternating dark and white lines produced when ultrasound beams reflect back and forth between two surfaces, often at an air–soft tissue interface. These echoes produce multiple copy images seen at different depths depending on the number of times the beam was reflected (Fig. 20-3).

Normal Lungs

"Lung sliding" is the key sign used to identify normal lungs[1] (Table 20-3). To identify lung sliding, one first identifies the "pleural line" as a horizontal hyperechoic line located about 0.5 cm below the skin surface corresponding to the interface between the lung and the chest wall.[3] The pleural line is bordered cephalad and caudad by anechoic shadows caused by the ribs. "A lines" are deeper horizontal lines that are reverberation echo artifacts of the pleural line[3] (see Fig. 20-3). Once these lines are identified, lung sliding is seen as the to-and-fro twinkling and movement of the lung adjacent to the pleural line in rhythm with inspiration and expiration. The image above the pleural line on the screen is motionless. Therefore, lung sliding identifies visceral pleura sliding over parietal pleura. An M-mode image of this will show up as a grainy pattern that recedes distally and is termed the "seashore sign"[1] (Fig. 20-4).

Lung sliding is an important sign for identifying normal lung, but it is dependent on technical issues and interpretation. For example, the sign may not be detected

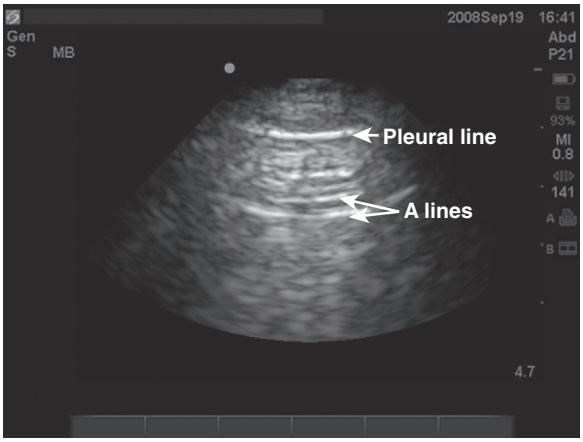

FIGURE 20-3 ■ B-mode image of normal lung with the pleural line and "A lines" indicated. "A lines" are echoes of the pleural line and indicate the presence of an air-soft tissue interface, whether the air is in aerated lung or free in the pleural space (e.g., pneumothorax).

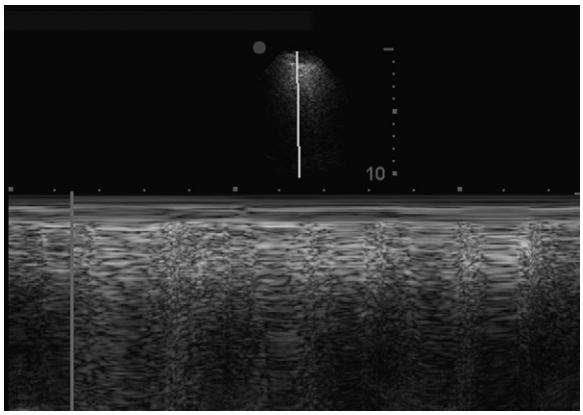

FIGURE 20-4 ■ M-mode image of normal lung show the "seashore sign." The seashore sign is recognized by the grainy texture and is distinguished from the stratosphere sign (see Fig. 20-8) where the grainy quality is absent and only the horizontal lines are seen. *Top,* The B-mode image from which the M-mode is generated.

TABLE 20-3. Ultrasound Signs of the Thorax in Health and Disease

Thoracic Condition	Ultrasound Image
Normal lungs	Lung sliding.
	Isolated comet-tail artifacts (B lines, Z lines).
	A lines.
	Seashore sign on M-mode.
Pleural effusion (free-flowing)	Static, usually anechoic collection that is bordered by the diaphragm, atelectatic lung, and the chest wall.
	Dynamic signs include flapping of atelectatic lung in the effusion and diaphragm movement with respiration allowing an effusion to be distinguished from ascites.
	Sinusoid sign on M-mode showing lung/visceral pleura motion adjacent to an effusion.
Pneumothorax	Absence of lung sliding sign.
	Absence of comet-tail artifacts.
	"Stratosphere" sign and "lung point" on M-mode.
Lung atelectasis/ consolidation	Isoechoic "hepatization" of lung with white lentiform/linear air bronchograms.
	Vascularity within consolidation preserved on color Doppler.
	Atelectasis may present with elevated hemidiaphragm and black (fluid-filled) bronchograms.
Pulmonary edema	Multiple "B lines" seen diffusely throughout thorax.
	Bilateral anechoic pleural effusions.
Diaphragm paresis or paralysis	Diaphragm moving <5 mm or paradoxically in inspiration.
	Loss of lung sliding sign.
	Intrathoracic location of liver or spleen.
Pulmonary embolism	Pulmonary infarcts appearing as peripheral wedge-shaped consolidation with diminished vascularity on color Doppler.
	Ipsilateral hyperechoic (hemorrhagic) effusion.
	(Supportive signs from echocardiography and compression vascular sonography of lower limbs.)

with low-frequency probes below 2.5 MHz.[1] In addition, the amplitude of lung sliding will decrease at the apex of the lung, where movement of the lung is less. Lung sliding can be mimicked by accessory respiratory muscle contractions, although unlike lung sliding, muscle movement will appear superficial to the pleural line. Lung sliding can also be absent in pathologic conditions in which lung motion is impaired such as pleurisy, pleurodesis, pneumothorax, subcutaneous emphysema, apnea and jet ventilation, extreme bronchospasm, extensive pneumonia, and the acute respiratory distress syndrome (ARDS).[3]

Pleural Effusions

Ultrasonography is more sensitive than chest radiography in diagnosing small pleural effusions[4] and is especially effective in distinguishing effusions from lung atelectasis. Pleural effusions can be identified by using both static and dynamic signs. *Static signs* for identifying pleural effusions are the anatomic boundaries of the diaphragm caudally, the chest wall superficially, and atelectatic lung at the bottom of the screen (see Fig. 20-2). Usually, the effusion is a hypoechoic region within these boundaries, but echogenicity cannot be the sole criterion for identifying a pleural effusion. All transudative effusions and some exudative effusions are anechoic in nature, but anechoic regions can also be seen with pleural thickening and abdominal ascites. Echogenic regions cannot be interpreted to mean a lack of effusion because echoes can be seen with complex pleural effusions such as hemothorax or empyema.

Dynamic signs used to identify pleural effusions include movement of the diaphragm adjacent to the effusion and of the lung within the effusion. The diaphragm is identified as a hyperechoic concave structure that descends with inspiration and is bordered caudally by either the liver or the spleen, both isoechoic structures. The position of the diaphragm helps distinguish a pleural effusion from ascites in the hepatorenal recess, where the diaphragm and its movement will not be seen. Of note, caution must be used in interpreting subcostal images because the concave diaphragm has high reflective properties that can lead to artifacts and because the spleen or liver can produce either acoustic shadows, which can be mistaken for effusions, or acoustic enhancement, which can be mistaken for consolidation.[1] Another dynamic sign of pleural effusions that can help avoid these misdiagnoses includes the movement of the lung within the effusion. The flapping of atelectatic lung secondary to cardiac contractions can sometimes be seen. The respiratory movement of the visceral pleura toward the chest wall can be captured on M-mode as a sinusoidal pattern.[1] Sometimes a "curtain" of aerated lung can be seen to slide into and out of smaller effusions.

In the evaluation of pleural effusions, the costal and diaphragmatic pleura should be carefully examined for nodules or masses that may be accessible to percutaneous biopsy (Fig. 20-5). The presence of swirling debris within an effusion in patients with cancer is a predictor of malignant effusions.[5] Color Doppler can be used to enhance the detection of this motion. The presence of pleural septations predicts an increased need for pleural interventions such as fibrinolysis and decortication[6] (Fig. 20-6).

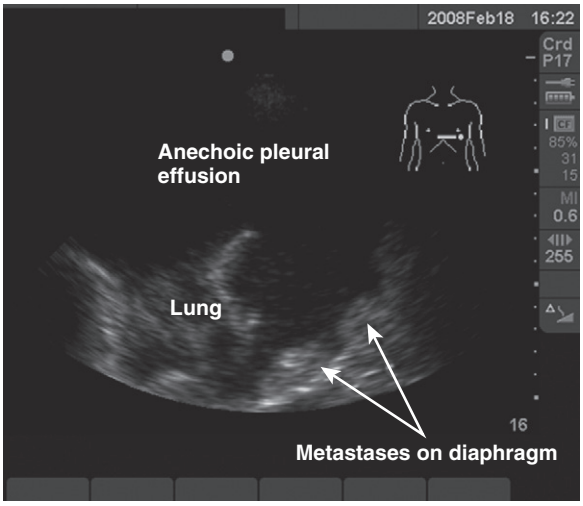

FIGURE 20-5 ■ Diaphragmatic metastases within a large anechoic pleural effusion. The metastases are seen as isoechoic nodules on the diaphragmatic surface.

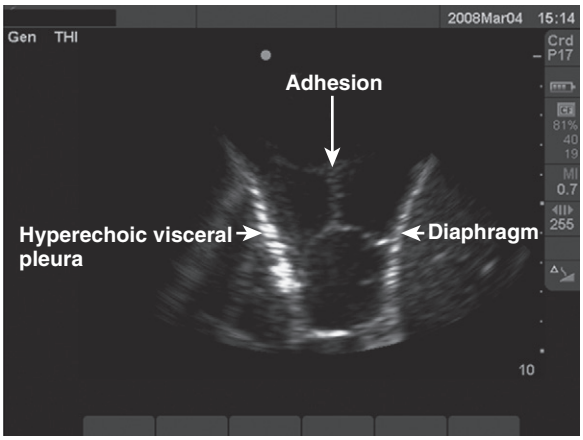

FIGURE 20-6 ■ B-mode image of complicated pleural effusion with adhesions between the hyperechogenic visceral pleura cephalad and the diaphragm caudally.

The use of ultrasonography to quantify the volume of pleural effusions has yet to be established in clinical practice. The size of the thoracic cavity, presence of loculations, position of the diaphragm, and degree of lung collapse all affect ultrasound measurements.[7] Despite these limitations, in supine patients with transverse scans at the posterior axillary line, the distance of maximum separation of parietal and visceral pleura on ultrasound has been shown to correlate better with the volume of thoracentesis drainage than measurements on lateral decubitus chest x-rays.[7,8] For comparison of the size of the same effusion over time, the transducer and the patient must be in exactly the same position for each measurement.

Pneumothorax

Pneumothorax itself has few positive findings; it is generally identified by the absence of the signs of normal aerated lung. As described previously, aerated lung is noted by the presence of the lung sliding sign; the lung is also noted by artifacts called "comet tails," including isolated B lines and Z lines, which are vertical hyperechoic lines that arise from the pleural line and move in synchrony with lung sliding.[1] "B lines" are comet-tail artifacts that spread from the pleural line all the way to edge of the screen without fading[1] (Fig. 20-7). Z lines are similar but, unlike B lines, fade quickly and do not reach the periphery of the screen.[1]

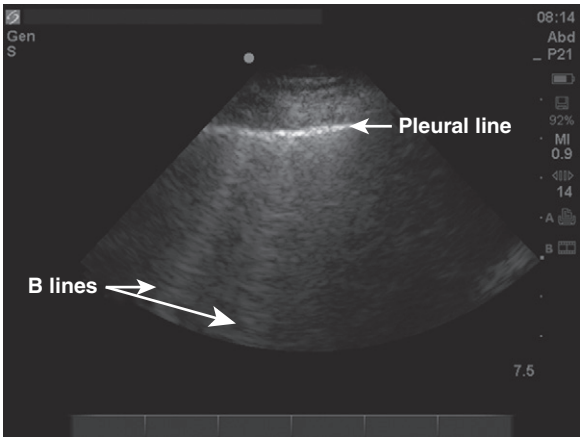

FIGURE 20-7 ■ B-mode ultrasound image shows B-line comet-tail artifacts emanating from the pleural line. Isolated B lines are artifacts found in normal aerated lung; when the B lines are multiple, they are thought to represent increased thickness of the interstitium; when multiple B lines are found diffusely throughout the thorax, they are thought to represent diffuse interstitial thickening as from pulmonary edema, interstitial lung disease, or acute respiratory distress syndrome.

In any ultrasound examination for pneumothorax, the nondependent part of the hemithorax should be scanned. In a pneumothorax, "A lines" representing reverberation echoes of the pleural line will still be seen, but there will be no movement at the pleural line and no evidence of lung sliding or comet-tail artifacts.[9-11] The absence of lung sliding and comet-tail artifacts indicates the presence of pneumothorax with a reported 100% sensitivity and 96.5% specificity.[12] Conversely, the presence of the lung sliding sign basically excludes a pneumothorax, with a reported 100% negative predictive value.[11] In a pneumothorax, multiple accentuated A lines may be seen and this can be captured on M-mode as a series of stratosphere-like horizontal lines (i.e., the stratosphere sign)[1] (Fig. 20-8). The horizontal lines seen in the stratosphere sign characteristic of free air can be contrasted with the grainy pattern prominent in the seashore sign of normal aerated lung (see Fig. 20-4). A pneumothorax can be grossly quantified as large if the loss of both lung sliding and comet tails extends to dependent parts of the thorax. The sudden and fleeting appearance of lung sliding and comet-tail artifacts in an area where they were previously absent may indicate aerated lung expanding intermittently into a moderate-sized pneumothorax. This fleeting appearance if captured on M-mode is termed the "lung point" and has been reported to have 66% sensitivity and 100% specificity for the diagnosis of a pneumothorax.[13] These ultrasound signs when used in combination may diagnose occult pneumothoraces not detected on supine chest x-rays[10,14] and are useful in the evaluation of patients after procedures such as central venous catheter placement, transbronchial lung biopsy, and chest tube clamping. The presence of a pneumothorax must be strongly suspected if comet-tail

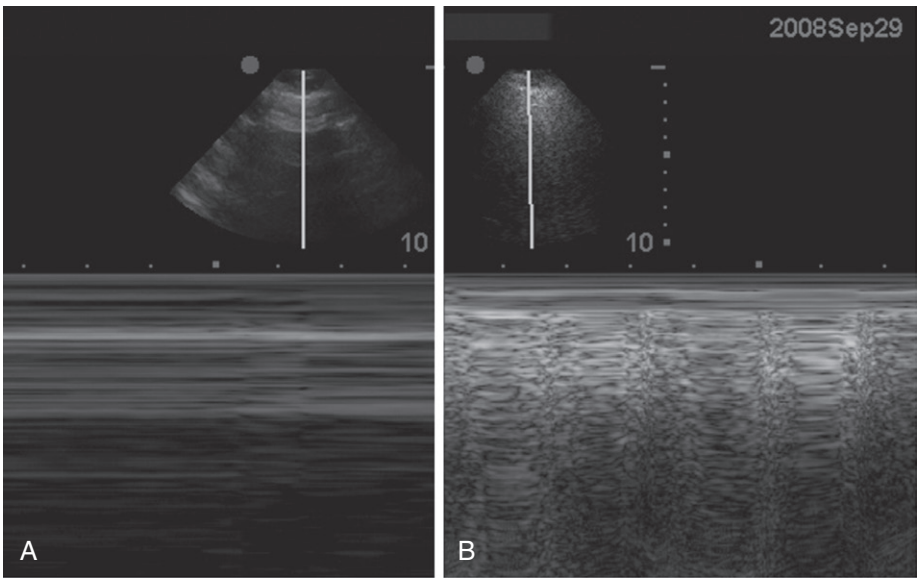

FIGURE 20-8 ■ M-mode image of a pneumothorax shows the "stratosphere sign" (**A**), characterized by multiple horizontal lines without the granularity seen with the normal aerated lung in the "seashore" sign (**B**). *Top,* The B-mode images from which the M-mode images were generated.

artifacts that were present before the procedure are not detected postprocedure.

Errors that can lead to a failure to diagnose pneumothorax include failure to scan in the nondependent parts of the thorax, failure to scan longitudinally, excessive use of noise filters, and an unsteady scanning hand that may give the false impression of lung sliding. A false diagnosis of pneumothorax may arise in patients with chronic obstructive pulmonary disease (COPD), which may mimic pneumothorax on ultrasound. In patients with COPD, the specificity of the diagnosis of pneumothorax is reduced to 71% even among experienced operators, indicating that additional imaging studies are required to confirm a pneumothorax in such patients.[15]

Lung Atelectasis/Consolidation

Alveolar consolidation can be identified on ultrasonography if the area of consolidation extends to the visceral pleura; if not, the intervening aerated lung will generate artifacts that make the diagnosis difficult. In alveolar consolidation, lung sliding will be abolished and a tissue pattern similar to the liver will develop due to the consolidation and "hepatization" of the lung. The superficial boundary of consolidated lung is usually regular and conforms to the visceral pleura whereas the deep border is invariably irregular depending on the extent of consolidation.[16] Air bronchograms may be seen as hyperechoic (white) lentiform or linear shadows that may vary with respiration[17–19] (Fig. 20-9). On color Doppler, branching pulmonary blood vessels may be visualized within the area of consolidation.[20]

These signs together with the absence of a sinusoidal pattern on M-mode indicative of pleural effusion give ultrasound a diagnostic sensitivity of 90% and specificity of 98% in detecting consolidation when compared with computed tomography (CT) scans.[21] A false-positive diagnosis of consolidation may result when complex echogenic pleural effusions or intrathoracic fat is mistaken for consolidation. The size of consolidation is typically smaller on ultrasound than on chest x-rays because the peripheries of a pneumonic area are usually partially air-filled.[22]

Atelectasis is imaged by ultrasound scanning in a way similar to consolidation (see Fig. 20-2). In addition, intercostal spaces may be observed to be narrowed and the hemidiaphragm elevated. If air bronchograms are seen, they do not change size with respiration. If the bronchi are filled with fluid in a postobstructive pneumonia/atelectasis, then fluid bronchograms may been seen as anechoic lentiform shadows within the area of consolidation.[23–25]

Lung abscesses will present as hypoechoic fluid collections with well-defined walls within an area of consolidation.[16] In the center of the abscess, septations or swirling of fluid may be identified.

Pulmonary Edema

The detection of thickened, edematous interlobular septae by ultrasonography can help make the diagnosis of pulmonary edema. Whereas single B lines are found in normal lungs as described, multiple B line comet-tail artifacts are thought to correspond to thickened interlobular septa[1] and multiple B lines that are identified diffusely and bilaterally are very suggestive of pulmonary edema.[16] The diagnosis can be confirmed by the disappearance of this finding with appropriate treatment of heart failure. Finding multiple and diffuse B lines has a diagnostic sensitivity and specificity of 93% when compared with chest radiographs in the diagnosis of alveolar-interstitial pulmonary abnormalities such as pulmonary edema.[26] This ultrasound pattern has also been shown to correlate with NT-ProBNP levels.[27] The total number of B line comet tails in the anterior and lateral chest of supine patients has also been shown to be cor-

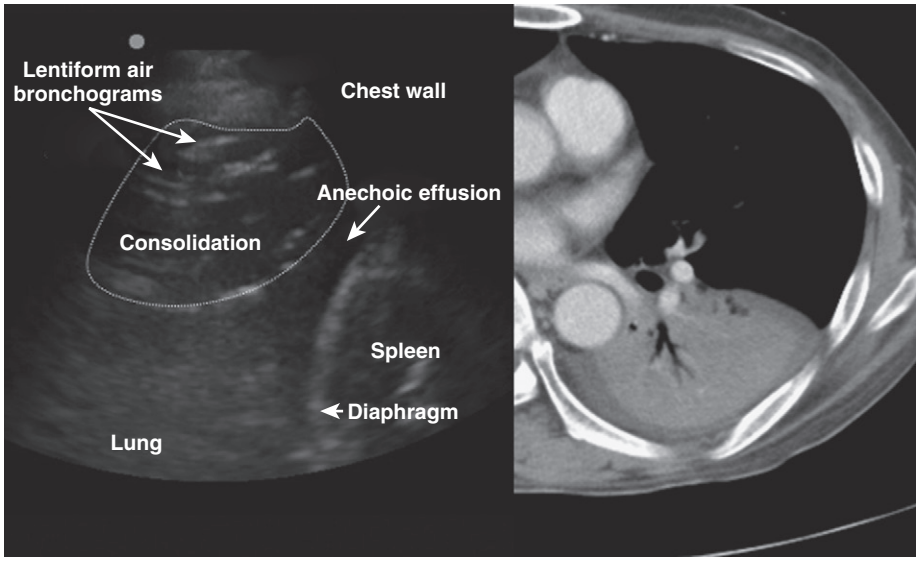

FIGURE 20-9 ■ B-mode image of subpleural consolidation with hyperechoic lentiform shadows corresponding to the air bronchograms seen on the adjacent computed tomography scan of the same patient.

relate with oxygenation levels in patients presenting with high-altitude pulmonary edema.[28]

Nonetheless, other lung diseases such as interstitial lung diseases and ARDS can present with these signs and be mistaken for pulmonary edema[16] because ultrasonography cannot distinguish between interlobular thickening due to edema and thickening due to inflammation or infiltration. Other ultrasonographic findings such as the presence of bilateral anechoic pleural effusions can contribute to the diagnosis of pulmonary edema. Using echocardiography, one can assess cardiac filling pressures, valve function, and left ventricular ejection fraction to confirm the diagnosis and possibly the etiology of the pulmonary edema.

Other Diagnoses

Diaphragmatic dysfunction can be assessed via ultrasound. This can be especially useful in evaluating patients with difficulties in weaning from mechanical ventilation. With inspiration, the normal diaphragm moves caudally 10 to 15 mm.[16] In diaphragmatic dysfunction, the movement of the diaphragm on inspiration may be less than 5 mm and signs of lung motion such as lung sliding may be lost.[16] The diaphragm may also be elevated as identified by an intrathoracic location of either the liver or the spleen.

Pulmonary embolism is suggested by the detection of pleural effusions that may be hyperechoic due to hemorrhage and by peripheral consolidations representing pulmonary infarction. Pulmonary infarcts typically appear as round or triangular pleural-based lesions[29] with evidence of reduced vascularity on color Doppler.[20] Thoracic ultrasonographic findings can be supplemented by compression vascular sonography of the lower limbs to identify deep venous thrombosis. Supportive echocardiographic evaluation would include assessment of right heart function, pulmonary artery pressure, and signs such as McConnell's sign: regional right ventricular dysfunction with akinesia of the mid-free wall but normal wall motion at the apex.[30]

Pulmonary contusion may be diagnosed based on the findings of focal alveolar-interstitial edema (focal area with multiple B lines) in patients within the appropriate clinical context.[31] However, the detection of peripheral parenchymal consolidation may have low sensitivity because the consolidation from contusion varies over time, becoming maximal 24 to 48 hours after the initial injury.[32]

Pleural-based lesions can also be evaluated by ultrasound. In fact, ultrasonography remains one of the best methods to distinguish pleural effusions from pleural thickening.[33] Pleural thickening is visualized as a peel of tissue with no mobile components (i.e., Doppler negative). Calcifications are visualized as hyperechoic regions and may indicate chronic inflammation as from previous tuberculosis. Pleural carcinomatosis is visualized as irregular thickening with isoechoic nodules that may infiltrate the chest wall.[34] In the assessment of patients after pleurodesis, the absence of lung sliding may also help evaluate the efficacy of pleural symphysis.[35]

Ultrasound has been shown to be more accurate than CT scans in assessing chest wall invasion of lung cancers, with a sensitivity and specificity of 89% and 95%.[36] Chest wall involvement can be diagnosed by evidence of tumor growth into the wall, invasion of the ribs with loss of the pleural line in that location, or the absence of lung sliding. Subpleural tumors typically have heterogeneous echogenicity and distorted vascularity as seen on color Doppler imaging.[20,37]

Algorithmic Evaluation of Acute/New-Onset Dyspnea[38] (Fig. 20-10)

Ultrasonography can be used in the evaluation of a patient with new-onset dyspnea. First, the nondependent portions of the thorax should be scanned for lung sliding and comet-tail artifacts as evidence for aerated lung. If absent, then a pneumothorax should be strongly suspected. If lung sliding is present, then the presence of multiple B lines diffusely throughout the thorax would suggest an alveolar-interstitial process such as pulmonary edema or ARDS. Evidence of alveolar consolidation or a large pleural effusion is sought by systematically scanning the thorax. Pulmonary embolism can also be considered based on the surrogate signs described earlier, particularly hyperchoic effusions and peripheral consolidation with decreased vascularity. Although thoracic ultrasound is of limited diagnostic value in airway diseases, there are emerging data supporting its use for diagnosing moderate bronchospasm based on the combination of predominant A lines with the presence of the lung sliding sign.[39] (In severe bronchospasm, lung sliding may be minimal or absent, as described earlier.) Unilateral bronchial intubation results in cessation of aeration

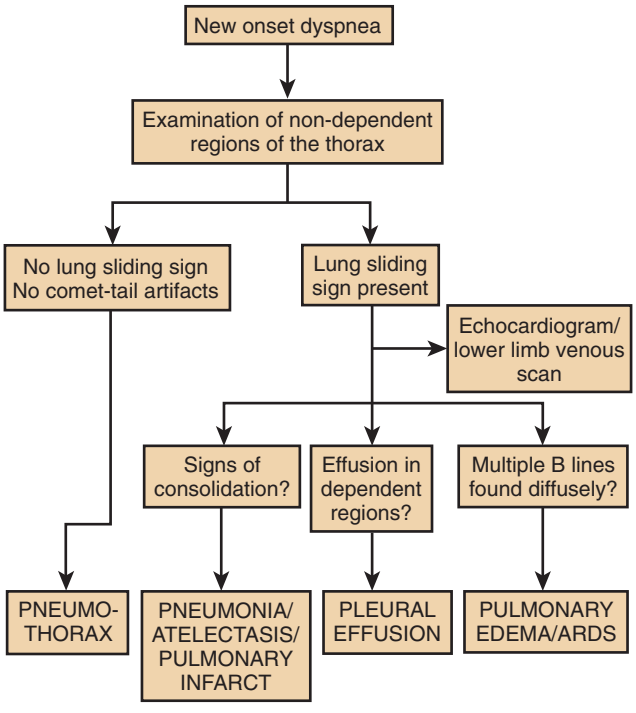

FIGURE 20-10 ■ Algorithmic evaluation of new-onset dyspnea.[38]

to one lung and consequently abolishes lung sliding while causing a transient pulsation of the pleural line in rhythm with cardiac contractions (lung pulse sign), probably caused by the transmission of cardiac contractions through the motionless lung.[40] The thoracic ultrasound evaluation of new-onset dyspnea can be supplemented by lower limb venous thrombosis scanning, as well as echocardiographic evaluation of right and left ventricular function and exclusion of pericardial effusion.

ULTRASOUND-GUIDED INTERVENTIONAL PROCEDURES

Thoracentesis and Pleural Catheter Placement

Ultrasound guidance can be valuable in increasing the success and safety of thoracentesis. Ultrasound-guided thoracentesis can successfully obtain fluid in up to 88% of cases following nonguided "blind" taps that were dry.[41] In the majority of failed blind pleural taps, subsequent examination by ultrasound has shown that the needle had been inserted subdiaphragmatically.[41] By using ultrasound guidance, therefore, operators can avoid puncturing intrathoracic organs such as the lungs, liver, spleen, and heart.[42] Ultrasound guidance can reduce the incidence of iatrogenic pneumothorax from up to 39% in blind thoracentesis to less than 5.4%.[43–48] With ultrasound-guided thoracentesis, the rate of pneumothorax can be kept to as low as 1.3% even in patients on positive-pressure ventilation.[49]

An ultrasonographically-directed thoracentesis is performed by first identifying and marking the target site with the patient positioned comfortably. To reduce the risk of complications, the operator should position the transducer probe so that the thickest portion of the target fluid collection is in the center of the screen. A separation of 10 to 15 mm between the visceral and the parietal pleura is usually deemed adequate to tap safely.[50]

The depth of needle insertion can be estimated on the ultrasound screen but, because the probe compresses near-field soft tissues, this distance can be misjudged. In a real-time procedure, the needle is usually directed at a downward angle of 45 degrees to the long axis of the probe over the rib; the operator attempts to keep the entire length of the needle in view along its trajectory. If the site is marked for a thoracentesis that will be performed at a later time, the patient position must be kept constant to avoid a change in location of the pleural fluid. The patient is then cleaned, draped, and anesthetized and the needle is placed at the same angle as the probe, usually perpendicular, at the target site. The point of entry is ideally superior to the rib to avoid injury to the neurovascular bundle. If catheters are inserted, ultrasonography can be used to confirm the position of catheters. The pleural catheter will appear as a hyperechoic linear structure within an anechoic fluid collection. Postprocedure ultrasound scans of the nondependent chest wall to identify lung sliding and comet-tail artifacts excludes an iatrogenic pneumothorax.[9–12]

Despite ultrasound guidance, taps can occasionally be unsuccessful. Reasons include plugging of the aspiration needle or the presence of loculations or septations preventing free drainage. Operator error due to compression artifacts may result in misjudging the depth of the effusion. The patient may have changed position between the scan and the tap. If a tap is dry, the thoracentesis needle should be withdrawn immediately and the patient rescanned. Repeat scanning enables repositioning of the entry point as well as exclusion of complications such as pneumothorax.

Transthoracic Needle Biopsy

Ultrasound guidance can be used to guide the biopsy of peripheral lung lesions, pleural masses, and anterior mediastinal tumors. Ultrasound enables the identification of the correct angle and depth of biopsy because it can distinguish solid from liquid components of pulmonary lesions. However, transthoracic needle biopsy should be performed only by physicians with expert knowledge both of ultrasonography and of needle biopsy techniques.[51]

Prerequisites for ultrasound-guided transthoracic needle biopsy are the presence of an acoustic window and the absence of overlying structures such as bone or aerated lung. Absolute contraindications include inability of patients to cooperate, to maintain an optimum position, or to control coughing. Uncorrected coagulopathy, thrombocytopenia (platelet count $< 50 \times 10^9$/L), uremia and severe pulmonary hypertension are relative contraindications. Bronchiectatic and chronic cavitary lesions are considered poor candidates for biopsy because of the limited capacity for local tamponade of any bleeding.[51]

The preferred method of biopsy is by the coaxial technique, in which a stylet with an introducer is inserted and biopsies are taken through the introducer when the stylet is removed. Patients are asked to hold their breath when the needle is advanced, during biopsy, and when the introducer is not occluded between biopsies. The needle should be visualized throughout its path, and failure to do so is usually the result of poor angulation. Any undue resistance should raise the suspicion of poor placement. Needle aspirates yield cytologic material; core biopsies for a tissue diagnosis are needed if tumors such as mesothelioma, lymphoma, teratoma, or thymoma are suspected.

Complications of biopsy include pneumothorax, hemoptysis, air embolism, or perforation of other organs. The pneumothorax rate in needle biopsy of lung lesions has been reported in less than 4%,[52–55] a low rate probably because most of the biopsied lesions were abutting the pleura. Air embolism can occur when a swing in intrathoracic pressure draws air into the pulmonary veins via the introducer.

DOCUMENTATION[56]

Appropriate documentation of ultrasonographic findings and interventional procedures is essential for research,

reimbursement, and communicating medical information. Capturing of images enables comparisons with future scans and assessment of a patient's progress. Standard documentation should include patient identification, time and date of procedure, ultrasound operator identification, patient position, transducer type and location, and indications and anatomic extent of the study. Reports should comment on normal findings, pathology, subjective measures of certainty (probable vs. possible), and changes compared with previous scans. Any limitations of the study should also be noted. If interventional procedures were performed, documentation usually includes the site, anaesthesia, specimens obtained, complications, and follow-up instructions.

TRAINING

The American Medical Association[57] has affirmed that ultrasound privileging is within the scope of appropriately trained physicians and that speciality-specific training standards should be developed. Such standards have yet to be developed within pulmonary or critical care medicine but are needed to maintain safety, accuracy, and credibility.[58] Guidelines from the American College of Emergency Physicians[59] suggest that there should be 3 to 4 hours of didactic instruction to cover basic physics and interpretation and 2 to 4 hours of practical demonstration/practice on basic handling, psychomotor skills, and "knobology" (the proper use of the dials on the ultrasound machine). In general emergency ultrasonography, 150 proctored scans are recommended.[59] Thus, for general thoracic ultrasonography, it would seem appropriate that 25 to 50 proctored examinations and logbook documentation would be appropriate for the acquisition of sufficient experience for each indication as, for example, in the diagnosis of pleural effusion. Novices should always be aware of both false-positive and false-negative signs. When scans do not correlate with clinical findings, the scans should be disregarded until confirmed by either an expert opinion or an alternative imaging method such as CT scanning. A realistic understanding of the limits of one's skill and knowledge will ensure continued safety and credibility.

ADVANTAGES AND DISADVANTAGES OF ULTRASOUND

The advantages of ultrasound imaging include bedside availability and the relative ease of performing repeated examinations. Imaging is real-time and free of harmful radiation. There are no documented side effects and discomfort is minimal. Despite the absence of randomized, controlled trials, ultrasonographic guidance for interventional procedures in the thorax is likely to improve diagnostic yield and reduce complications by providing visual guidance.[60] Bedside ultrasonography enables clinicians who understand the clinical context of patients to perform the most appropriate scans directed to address clinically relevant questions.

The disadvantages of ultrasonography are primarily related to the fact that it is heavily operator-dependent. Retrospective review of images provides only limited quality control. There is no scout scan to give a global picture for orientation. In addition, the basic ultrasound evaluation cannot determine the exact position of devices such as the endotracheal tube, central lines, and feeding tubes in the body. Ultrasonography is limited by bones, which prevent penetration of ultrasound waves, and by air, which largely reflects them. Full diagnostic imaging of the thorax can also be time-consuming. Costs include the capital investment for the purchase of the ultrasound machine and operating expenditures of consumables like the gel and sterile sheaths.[60]

The bedside nature of ultrasonography mandates that infection control issues be taken seriously. Portable machines should never be placed on patients' beds and should ideally have independent stands. Sterile sheaths should be employed in all real-time interventional procedures together with standard aseptic techniques. Ultrasound gel can be a culture medium for bacteria,[61] and it is a common courtesy to clean off all gel from the patient's body at the end of the procedure. The ultrasound machine should also be wiped clean between studies, with special attention given to components that may contribute to nosocomial transmission of infection: the transducer probe, cable, and keyboard.

ENDOBRONCHIAL ULTRASOUND

EBUS has revolutionized bronchoscopy because it extends the endoscopist's view beyond the mucosal surface of the airways. It enables a detailed assessment of the airway wall layers and facilitates guided biopsies of lymph nodes and tumors. EBUS is available in two general versions, based on either radial or linear transducer probes.[61a]

Radial EBUS and linear EBUS have contrasting features and applications. The radial EBUS probe produces high-resolution, 360-degree images and is inserted via a standard flexible bronchoscope. It facilitates the detailed evaluation of the central airway walls, as well as of peripheral lung lesions. However, any biopsy procedure guided by radial EBUS is not real-time but directed to the area identified previously by the radial EBUS image. Linear EBUS generates relatively lower resolution sector scans. Because the transducer is built into a dedicated bronchoscope, imaging is confined to lesions around the central airways and transbronchial needle aspirations (TBNA) are performed real-time.

Radial Endobronchial Ultrasound

Radial EBUS has a 20-MHz (12–30 MHz available) rotating transducer (external diameter 1.7–2.0 mm) that can be inserted together with a guidesheath through the working channel of a standard flexible bronchoscope (Fig. 20-11). Owing to the rotation of the transducer, a 360-degree image is produced that is perpendicular to the long axis of the bronchoscope. In the proximal

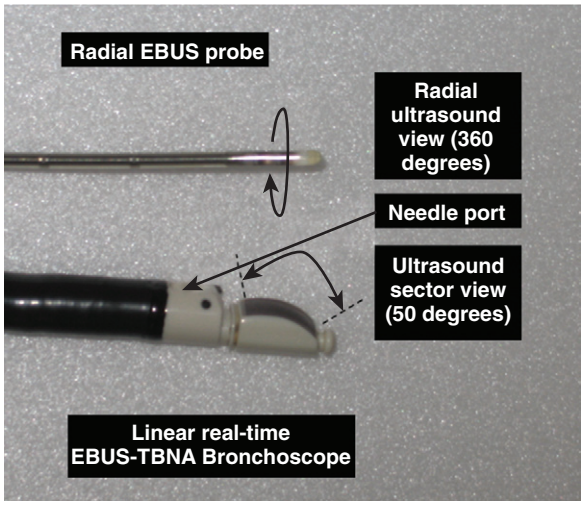

FIGURE 20-11 ■ Radial endobronchial ultrasound (EBUS) probe and linear real-time EBUS-TBNA (transbronchial needle aspiration) bronchoscope. Using a radial EBUS probe, transbronchial biopsies via a guidesheath or needle aspirates of lymph nodes are obtained after the probe is removed whereas, using a linear EBUS bronchoscope, needle aspirates are obtained via a needle advanced through the needle port along a trajectory similar to that shown for the *arrow*.

airways, coupling is achieved by inflating a balloon that surrounds the transducer with sterile water. Saline is avoided because it can result in salt crystallization. In the distal airways, such coupling is unnecessary because the smaller airway caliber allows direct contact between the transducer and the mucosal wall. The resulting scans penetrate to a depth of 4 to 5 cm with a lateral resolution of less than 1 mm.

Radial EBUS is typically performed after a standard bronchoscopic examination of the tracheobronchial tree. To avoid damaging the probe, the endoscopist should not insert the radial probe into the working channel of the bronchoscope when it is actively rotating. Most patients tolerate inflation of the balloon, even in the trachea, for short periods of time without ventilation problems. Once an image is obtained, the ultrasound view needs to be oriented and matched to the endoscopic view using familiar ultrasound landmarks such as major vessels, spine, and esophagus. In the trachea, the orientation of the image with EBUS is similar to that of axial CT scans. However, this orientation becomes more challenging for the operator as the scanning axis changes to an oblique angle in the main-stem bronchi and in more distal airways. Therefore, a detailed understanding of thoracic anatomy is mandatory for the successful use of EBUS.

Airway Assessment

Airway walls can be examined in detail using radial EBUS. Up to seven layers of the wall can be distinguished[62]: the mucosa, endochondium, perichondium, and adventitia are hyperechoic (white) whereas the intervening submucosa, cartilage, and connective tissue layer are hypoechoic (dark gray). Such detail allows assessment of airway invasion; EBUS has been reported to be superior to CT scanning in distinguishing airway wall invasion from extrinsic compression by a tumor.[62] By identifying evidence of tumor invasion into cartilage, patients can be excluded from endoscopic modalities such as photodynamic therapy or brachytherapy in favor of surgical resection.[63,64] EBUS can also guide interventional bronchoscopy: by identification of submucosal tumor involvement and airway malacia, one can avoid undersizing of stents, and by identification of adjacent blood vessels, one can avoid inducing hemoptysis via débridement or thermal ablation.[64,65]

Endobronchial Ultrasound–Guided Biopsies of Lymph Nodes

Radial EBUS can locate lymph nodes and extraluminal tumors relative to the airways. Once the target lesion is identified, the probe is removed and transbronchial biopsy or TBNA can be performed. The reported diagnostic yields with TBNA following radial EBUS range from 72% to 86%.[66–69] The use of EBUS guidance has been shown to improve diagnostic rates of TBNA in mediastinal lymph node stations 2, 3, and 4.[68] Preliminary data are also emerging about the use of Doppler to measure the vascular resistive index of lymph nodes.[70] Compared with normal nodes, malignant nodes may demonstrate a higher vascular resistive index to blood flow because of neovascularization; thus, it may be possible in the future to direct biopsies to those lymph nodes with the greatest likelihood of malignant involvement.

Endobronchial Ultrasound–Guided Biopsies of Peripheral Lung Lesions

Radial EBUS can increase the diagnostic yield of transbronchial lung biopsies of small (<30-mm) peripheral lung lesions[71] with diagnostic yields of 77% to 80%.[71–73a] Biopsy of fluoroscopically invisible nodules has also been possible with diagnostic yields of 70%.[74] The EBUS probe is inserted through a guidesheath into the bronchus where the lesion is suspected. Whereas normal air-filled alveoli produce a whitish snowstorm image with comet-tail artifacts, peripheral lung tumors are isoechoic and more homogeneous. When the image of the lesion is seen all around the probe, the probe is considered to be within the target. The transducer is then removed and a regular biopsy forcep is used to biopsy through the guidesheath. Biopsies of lesions at the site of the probe have been shown to have higher diagnostic rates when the probe is placed within rather than adjacent to the lesions.[75] The use of EBUS-guided transbronchial lung biopsy without fluoroscopic guidance is also safe and effective.[76,77] Electromagnetic navigation bronchoscopy or virtual bronchoscopy can be used to navigate the EBUS probes to peripheral lung lesions to improve diagnostic yields further.[77–79]

Linear Endobronchial Ultrasound–Transbronchial Needle Aspiration Bronchoscope

The linear EBUS probe has been built into a dedicated flexible bronchoscope to enable real-time TBNA biopsies. This EBUS bronchoscope (BF-UC260F-OL8; Olympus Ltd, Tokyo, Japan) has an external diameter of 6.9 mm and so requires insertion via an oral route or via an oral endotracheal tube (see Fig. 20-11). Because the endoscopic viewing optics are at a 30-degree angle from the long axis of the scope, the operator must compensate in order to interpret the view correctly. Particular attention is needed in intubating the trachea and often only the anterior apex of the vocal cords is visible as the scope enters the subglottic space. Usually endobronchial examination is limited and standard bronchoscopy may also be needed to complete a full airway examination. At the time of this writing, the only linear EBUS scope available has a convex 7.5-MHz EBUS transducer and a 50-degree sector view perpendicular to the long axis of the bronchoscope extending 20 to 50 mm in depth. This bronchoscope has a 2.0-mm working channel that can house a dedicated 22-gauge biopsy needle.

After insertion into the trachea, the EBUS-TBNA scope is maneuvered to the approximate location of the target lymph node or paratracheal tumor. The scope is flexed to contact the airway wall and then withdrawn while being rotated from side to side. Although there is a balloon that can be filled with normal saline to facilitate coupling, this is not always needed if good contact can be maintained between the airway mucosal surface and the probe. Simultaneous imaging of the endoscopic and ultrasound images aids localization. Lymph nodes appear more echoic (gray) than blood vessels and Doppler can be used to assist in making the distinction. The needle sheath is then visualized on the endoscopic image before the "jabbing" technique is used to perform TBNA under real-time guidance. Once the TBNA needle is within the target (Fig. 20-12), the stylet of the needle is removed and cellular material aspirated. Most mediastinal and hilar lymph nodes can be reached by the EBUS-TBNA bronchoscope except the aortopulmonary (station 5), subaortic (station 6), paraesophageal (station 8), and pulmonary ligament (station 9) nodes.

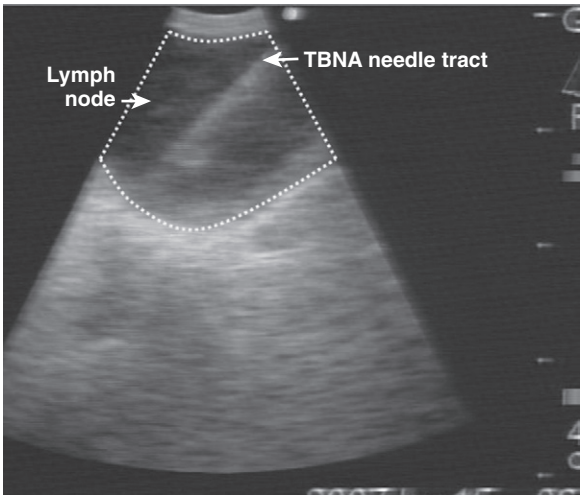

FIGURE 20-12 ■ Linear real-time EBUS-TBNA shows the biopsy needle within the lymph node (*outlined by dotted lines*).

Endobronchial Ultrasound–Transbronchial Needle Aspiration Mediastinal Staging

Compared with blind TBNA, real-time EBUS-TBNA has been shown to have a higher diagnostic yield in mediastinal staging[80] and may be comparable to cervical mediastinoscopy.[81] Even without the presence of rapid on-site cytology, diagnostic yields with definitive histology of 65% to 94% have been reported for real-time EBUS-TBNA.[82-84] The histologic staging of a radiologically normal mediastinum with lymph nodes of 10 mm or less has also been shown to be feasible.[85,86] The dedicated 22-gauge biopsy needle can obtain samples that are sufficient for genetic analysis (e.g., epidermal growth factor receptor mutations).[87] Although the pooled diagnostic sensitivity for EBUS-TBNA is 90% and the specificity is 100%, the false-negative rate can be over 20%.[88] Therefore, all negative results need to be followed up clinically or by alternative diagnostic modalities to confirm that the results are true negatives. When combined with transesophageal endoscopic ultrasound-guided fine needle aspiration (EUS-FNA), EBUS-TBNA can enable complete staging of the mediastinum with access to lymph node stations not accessible by either technique alone (diagnostic sensitivities of 93%–94%).[80,89] Such combined approaches may further extend the diagnostic options for mediastinal staging.

Other Applications

EBUS-TBNA has also been shown to have utility in diagnoses besides lung cancer. In patients with clinically suspected lymphoma, the reported diagnostic sensitivity is 90.9%.[90] In the demonstration of noncaseating granulomatous inflammation, EBUS-TBNA has a reported diagnostic yield for sarcoidosis of 85% to 93.8%.[91-93] Furthermore, real-time guided TBNA can potentially be used in the diagnostic workup of anterior mediastinal masses, paratracheal tumors, and mediastinal cysts.

Setting Up an Endobronchial Ultrasound Service

Training in EBUS covers image interpretation, knobology, orientation of endoscopic and ultrasound views, as well as biopsy techniques. Knowledge of thoracic anatomy and competence in basic flexible bronchoscopy and TBNA are prerequisites. The American College of Chest Physicians[94] recommends at least 50 proctored procedures to gain competence in EBUS and 5 to 10 procedures per year to maintain the skill. The European Respiratory Society and American Thoracic Society joint statement[95] suggests 40 supervised procedures to gain competence and 25 procedures per year to maintain the

skill. These guidelines are for radial EBUS and no similar recommendations are available for linear EBUS-TBNA. Other issues that need to be addressed when starting an EBUS service will be the costs of the equipment and disposables as well as the training of the endoscopy staff. EBUS can add to the time required for endoscopy initially and this has implications for what can be achieved under moderate sedation. However, in expert hands, radial EBUS adds less than 3 minutes to a TBNA procedure and about 60 seconds to the transbronchial biopsy of peripheral lesions.[68,73] Linear EBUS-TBNA has been reported to take a mean of 12.5 (range 8–21) minutes.[84]

ACKNOWLEDGMENTS

The authors thank Dr. Phua Ghee Chee from Department of Respiratory and Critical Care Medicine, Singapore General Hospital, who provided editing and manuscript review.

KEY POINTS

- Ultrasound offers the advantages of real-time, bedside, radiation-free imaging that will extend the possibilities for diagnosis and treatment by pulmonary and critical care physicians.
- Choice of transducer probes depends on frequency (compromise between spatial resolution and depth of scan) and footprint (acoustic window size).
- Patient and probe position must be considered when assessing gravitationally dependent pathology such as pneumothorax and pleural effusion.
- Anatomic structures are identified based on their location and echogenicity.
- Ultrasound-guidance for thoracentesis and pleural catheter placement has the potential to increase the success of these procedures and reduce complications.
- A key disadvantage of ultrasonography is that it is operator-dependent. Retrospective analysis of previously acquired images is limited.
- EBUS increases the diagnostic sensitivity for TBNA of mediastinal lymph nodes and for transbronchial lung biopsy of peripheral lung lesions.

FUTURE DEVELOPMENTS

INTRODUCTION

This chapter describes the two major applications of nuclear medicine techniques in the evaluation of diseases of the thorax: the ventilation-perfusion (V/Q) study to detect pulmonary embolism and [^{18}F]fluoro-2-deoxy-D-glucose (FDG) positron emission tomography (PET) for evaluating patients with suspected or documented lung cancer. Virtually every hospital performs V/Q scans using single-photon–emitting radionuclides. Recently, however, multidetector computed tomographic angiography (CTA) has replaced V/Q imaging in some patients with suspected pulmonary embolism. FDG-PET imaging is being increasingly utilized for evaluation of solitary pulmonary nodules, initial staging of lung cancer, planning radiotherapy, and following lung cancer after treatment.

VENTILATION-PERFUSION IMAGING

The normally functioning lung demonstrates homogeneous patterns of ventilation and perfusion on the scintigraphic study.[1] V/Q imaging can be used to classify abnormalities in ventilation and perfusion according to the probable cause. The pathologic conditions affecting ventilation and perfusion may be divided into four functional categories: (1) the vascular occlusive state, (2) the consolidative state, (3) the obstructive state, and (4) the restrictive state.

Pulmonary emboli, extrinsic vascular compression, and pulmonary vasculitis are examples of the vascular occlusive state. In this state—in the absence of pulmonary infarction—ventilation is preserved within regions of pulmonary arterial vascular occlusion. Thus, most conditions causing a vascular occlusive state result in a V/Q mismatch.

Inflammatory and infectious lung diseases, pulmonary infarction, and atelectasis result in the consolidative state, which has two components. First, these disorders may result in alveolar collapse and atelectasis. Second, leakage of intravascular fluid into the alveolar space may occur secondary to capillary bed damage. In the consolidative state, both ventilation and perfusion are reduced and generally matched.

Acute asthma and chronic lung diseases such as emphysema, bronchitis, and bronchiectasis result in the obstructive state. With emphysema, there is loss of alveolar walls and their capillary beds, which increases alveolar volume and decreases the surface area for gas exchange. Airway obstruction occurs from either narrowing and/or closure of small airways or loss of structural support, excessive bronchial secretions, bronchial spasm, mucosal edema, or foreign bodies. The resultant decrease in alveolar P_{O_2} causes constriction in precapillary arterioles with redistribution of blood to better-ventilated alveoli. Thus, both ventilation and perfusion to involved areas are decreased but remain matched.

Chronic inflammation and fibrosis that eventually obliterate alveoli result in the restrictive state. Local ventilation may be preserved even though regional compliance is decreased. Overall alveolar ventilation is often increased because of associated increased respiratory drive. In the restrictive state, ventilation may be increased relative to perfusion, resulting in a V/Q mismatch.

Techniques

Ventilation imaging is performed using either a radiolabeled gas or a radiolabeled aerosol. The ventilation agent used has not resulted in a difference in the accuracy of V/Q imaging for the detection of pulmonary embolism. Most of the data in the literature are based on the use of xenon-133 (^{133}Xe) gas. The major alternative ventilation imaging agent is technetium-99m (^{99m}Tc)–labeled aerosol, which some institutions find easier to use than a radiolabeled gas.

The ^{133}Xe ventilation studies are performed using commercially available ventilation devices. The patient breathes through either a face mask or a mouthpiece with the nose clamped. A first-breath or breath-hold image is obtained as the ^{133}Xe is administered at the mouthpiece during a deep inspiration and breath-hold. The patient then performs normal tidal breathing while inhaling the ^{133}Xe-air mixture for at least 4 minutes while equilibrium images are obtained. Regions of the lung that appear as areas of decreased accumulation on the breath-hold image may normalize on the equilibrium image because of slow equilibrium through the airways or because of collateral air drift. After the equilibrium images are obtained, washout imaging is performed while the patient breathes in room air and exhales the ^{133}Xe into a storage container or a system that exhausts the radiolabeled gas into the atmosphere. Abnormalities on the breath-hold and equilibrium images are areas of decreased ^{133}Xe accumulation. Abnormalities on the washout phase are determined by asymmetry of the washout images. Focal areas of retained activity represent regional air trapping. ^{133}Xe studies are preferably performed in the sitting position, but the studies can be performed in the supine position. These studies can be performed on patients on a ventilator by using an elastic bag to deliver the gas during the study. Because the photon energy of ^{133}Xe is lower than that of ^{99m}Tc, which is used for the perfusion study, the ventilation study is performed prior to the perfusion study.

Radiolabeled aerosols are also used for imaging regional ventilation and are available commercially in the form of small and efficient aerosol nebulizers. Although several different radiopharmaceuticals have been used, ^{99m}Tc-labeled diethylenetriaminepenta-acetic acid (^{99m}Tc-DTPA) is most commonly used. The radioaerosols are typically between 0.5 and 3 μm in size. For the study, 1.11 GBq (30 mCi) of ^{99m}Tc-DTPA in 3 mL of saline is placed in the nebulizer. Oxygen is used with the nebulizer to produce the aerosol, which is inhaled by the patient through either a face mask or a mouthpiece with a nose clip. The patient inhales the aerosol until 37 MBq (1 mCi) is in the lungs, which generally takes 3 to 5 minutes. The distribution of the aerosol within the lungs is proportional to regional ventilation. The radiolabeled aerosol study is performed prior to the perfusion study. Typically a 200,000- to 250,000-count posterior image is made and the time recorded. Other views are obtained for the same time interval except for the lateral images, which are obtained for shorter periods of time. The count rate for the aerosol ventilation study should be approximately 20% of the count rate for the perfusion study. The advantages of the radioaerosol study over the ^{133}Xe study are that the radioaerosol study requires minimal patient cooperation and it can be performed as a portable study. These studies can also be performed relatively easily in patients on ventilators. A major disadvantage of the radioaerosol study is the central deposition of radioactivity that occurs in patients with chronic obstructive pulmonary disease (COPD). Newer radioaerosols have been developed that overcome some of the limitations of the ^{99m}Tc-DTPA aerosol. These agents include ^{99m}Tc technegas and ^{99m}Tc pertechnegas. These agents, which are not available in the United States at this time, are produced by burning ^{99m}Tc pertechnetate in a carbon crucible at extremely high temperatures, producing an ultrafine aerosol.

Perfusion lung imaging is accomplished by intravenous injection of radiolabeled particles that embolize within the pulmonary vasculature. The number of particles that impact in a volume of the lung is proportional to the pulmonary arterial blood flow to that region. Because the radiolabeled particles are administered intravenously, they are well mixed with venous blood in the right atrium and ventricle before being distributed into the lung in direct proportion to local pulmonary arterial blood flow. Thus, the perfusion images represent regional distribution of pulmonary arterial blood flow at the time of radiopharmaceutical administration.

Technetium-99m–labeled macroaggregated albumin (^{99m}Tc-MAA) is the radiopharmaceutical used for perfusion imaging. More than 90% of the particles are between 10 and 90 μm in size. The typical administered dose is 74 to 148 MBq (2-4 mCi) of ^{99m}Tc (140-keV photon)-MAA that contains approximately 500,000 particles. To obtain an even distribution of the radioactivity in the pulmonary vascular bed, 60,000 or more particles are needed. Because the normal human lung contains approximately 300 million precapillary arterioles, only approximately 0.1% of these vessels are blocked during this study. The pulmonary perfusion study is extremely safe even in patients with severe COPD in whom the precapillary arterioles are smaller in diameter and the number of precapillary arterioles and capillaries is diminished. The biologic half-life of the ^{99m}Tc-MAA in the lung is 2 to 6 hours owing to metabolism of MAA in the lungs. Patients who have right-to-left shunts tolerate the procedure well, even though the presence of a right-to-left shunt has been considered a relative contraindication to the procedure. But there have been no reported consequences of administering the particles in these patients. In fact, radiolabeled particles have been directly injected into a coronary artery or carotid artery without any adverse effects, and as pointed out in Chapter 54, injection of ^{99m}Tc-MAA is a useful way of quantifying the magnitude of right-to-left shunting of blood in patients with pulmonary arteriovenous malformations.

For perfusion scintigraphy, at least eight views of the thorax are obtained, including the anterior, posterior, left and right posterior and anterior obliques, and right and left lateral views. For each view, 750,000 counts are obtained except for the lateral views. The lateral view

with the best perfusion is imaged for 500,000 counts, the time is recorded, and the other lateral view is acquired for the same length of time.

Perfusion scintigraphy is sensitive but not specific for diagnosing pulmonary diseases. Almost all pulmonary diseases cause decrease in pulmonary perfusion to affected lungs zones. Ventilation imaging is used to improve the specificity for diagnosing pulmonary embolism. Pulmonary embolism and other vascular occlusive states result in perfusion abnormalities without abnormalities in ventilation (mismatched defects). In consolidative states, such as pneumonia, ventilation and perfusion are decreased in the same region as the radiographic abnormality (matched defects). Airway obstruction, mucus plugging, atelectasis, and pneumonia may result in ventilation abnormalities larger than the perfusion abnormalities (reverse mismatch).

Pulmonary Embolism

As emphasized in Chapter 51, there is a strong association between pulmonary embolism and deep venous thrombosis (DVT) because pulmonary embolism usually begins with DVT. Patients with suspected pulmonary embolism should have their initial evaluation directed at the chest. Afterward, if the diagnosis remains uncertain, venous imaging can be performed.[2]

Multidetector CTA is being increasingly used to evaluate patients with suspected pulmonary embolism.[2a,2b] The use of CTA has been adopted in clinical practice at many centers, and V/Q scintigraphy is being used in a secondary role. Although the initial studies demonstrated a lower sensitivity for computed tomography (CT) than for perfusion scintigraphy, recent studies with improved CT techniques demonstrate better results. The technical improvements include multidetector scanners with thin collimation and high pitch, which improve the sensitivity of CT for detecting subsegmental emboli. Increasing observer experience will also likely further improve the results.

The second Prospective Investigation Of Pulmonary Embolism Diagnosis (PIOPED II), was a large multicenter study evaluating the accuracy of multidetector CTA in patients with suspected acute pulmonary embolism.[3] The purpose of PIOPED II was to determine the extent to which multidetector CT is an efficacious, minimally invasive test for pulmonary embolism and thereby to reduce the need for pulmonary angiography and V/Q scanning. The added information from computed tomographic venography (CTV) and a validated clinical assessment (the Wells score) were also evaluated. Each patient in the study underwent both a V/Q scan and a multidetector CTA for suspected pulmonary embolism. The final determination of pulmonary embolism status was being made by the combination of V/Q scintigraphy, venous ultrasonography of the lower extremities, pulmonary angiography, and venography. In this study of 824 patients who had a reference diagnosis and CTA, 51 were excluded because of poor image quality. In the remaining patients with adequate CTA, the sensitivity was 83% and the specificity was 96%. The sensitivity for combined CTA-CTV was 90% and the specificity was 95%. A concordant clinical assessment increased the prediction value.

Sostman and coworkers[4] evaluated the sensitivity and specificity of V/Q scintigraphy for detecting acute pulmonary embolism in patients in the PIOPED II study. They used the V/Q scan interpretation of high probability for pulmonary embolism to indicate "pulmonary embolism present," of normal or very low probability as "pulmonary embolism absent," and low or intermediate probability as "nondiagnostic of pulmonary embolism": 27% of patients had nondiagnostic scan interpretations and were excluded. The sensitivity of a pulmonary embolism present scan finding was 78% and the specificity of a pulmonary embolism absent scan finding was 98%. They concluded that in a population similar to that in PIOPED II, V/Q scintigraphy was diagnostically definitive in a majority of patients and could be appropriately utilized in patients in whom CTA may be disadvantageous. Although CTA is the primary procedure that is currently used to evaluate patients with suspected pulmonary embolism at many centers, V/Q scintigraphy still has an important role in the diagnostic workup. The reasons that V/Q scintigraphy is performed instead of CTA are that the patients have renal dysfunction, are allergic to the contrast material, are too large to be scanned in the CT scanner, have low clinical suspicion of pulmonary embolism and a normal chest radiograph, or are young women in whom radiation dose to the breasts is of concern.

Pulmonary angiography has been considered the "gold standard" for clinical diagnosis of pulmonary embolism. The intravascular filling defect seen on pulmonary angiography may be acute, but the actual age of the pulmonary embolus cannot be determined. There are angiographic findings of chronic pulmonary embolism, but the significance of chronic emboli, unless discovered in patients with pulmonary hypertension, is uncertain. The accuracy of pulmonary angiography interpretation has not been adequately studied. In the National Urokinase Pulmonary Embolism Trial,[5] the angiographers agreed that pulmonary embolism was present 94% of the time. In the first PIOPED study,[6] interobserver agreement about the presence of pulmonary embolism was 92%. If the embolus was large and was in the main pulmonary artery or lobar artery, agreement was 98%. The agreement was 80% in segmental arteries and 40% in peripheral arteries.

The PIOPED I study prospectively compared the results of V/Q scintigraphy with the results from pulmonary angiography.[6] None of the patients in the PIOPED study with a normal lung scan interpretation and pulmonary angiography was found to have pulmonary embolism. A normal perfusion study has long been accepted to exclude the diagnosis of pulmonary embolism.[7] Never has a patient had a documented pulmonary embolus with a normal perfusion lung scan. Accordingly, a normal scan stops the evaluation for pulmonary embolism.

Perfusion scintigraphy is not specific for pulmonary embolism because almost all pulmonary diseases produce perfusion abnormalities.[8] The diagnostic accuracy of

scintigraphy for the detection of pulmonary emboli was significantly improved when ^{133}Xe ventilation studies were added to the perfusion lung scan and chest radiograph.[9] The concept of segmental equivalents—that is, that two subsegmental perfusion defects can be added to produce the same diagnostic significance as a single segmental defect—contributed to the diagnostic accuracy of the interpretation of V/Q scintigraphy.[10] Additional studies improved the categorization of perfusion defects matched by ventilatory or radiographic abnormality to reduce the number of intermediate-probability diagnoses.[11,12] The categorization of perfusion defects as small (<25% of the area of an average-sized pulmonary artery segment), moderate (equivalent to 25%=75% of the area of a segment), and large (>75% of a segment) has led to the more accurate criteria that are used to categorize V/Q scans today. Bronchopulmonary segments are typically of different sizes. Although the reader of a V/Q scan could attempt to individualize the evaluation of defect size to the particular segment, in practice, most experienced readers utilize an average, idealized segment to evaluate the defects in any location.

Diagnostic Criteria

Different sets of criteria have been developed for interpreting V/Q scans. Several studies have demonstrated that experienced readers are more accurate in their interpretations when using their experience than when using reference criteria.[13–15] Although the gestalt interpretation works for highly experienced readers, reference criteria are helpful for those readers with less experience in interpreting V/Q scans. The PIOPED I studies have set the standard for reference criteria (Table 21-1). These multicenter studies have been sponsored by the National Heart, Lung, and Blood Institute.[6] In the original study that was performed to evaluate the accuracy of V/Q scanning as compared with contrast angiography, 933 patients were recruited, 931 had V/Q scans, and 755 had pulmonary angiograms. Pulmonary embolism was present in 251 patients (33%). Thus, the prevalence of pulmonary embolism in the population being referred for V/Q scans at multiple large tertiary care medical centers was 33%. When using the PIOPED I criteria for interpreting V/Q scans to determine the likelihood of pulmonary embolism, it is important to consider the prevalence of disease in the population. If the prevalence of disease is less than in the PIOPED I study, then the likelihood of pulmonary embolism in each category would be lower than it was in the PIOPED I study. In the PIOPED II study, Sostman and coworkers[4] found the prevalence of pulmonary embolism to be 18%. Because the number of patients with suspected pulmonary embolism is increasing without a concordant increase in the incidence of pulmonary embolism, the prevalence of pulmonary embolism in patients having imaging studies is decreasing. We estimate the prevalence of pulmonary embolism in the patients being studied at our institution to be 5%.

The interpretations of the V/Q scans were entered into a database so that the major findings could be compared with abnormalities found on the chest radiograph and angiogram. The criteria that had been used for the original interpretations of the PIOPED V/Q scans were then revised based on the findings of the computerized comparisons (see Table 21-1). The revised PIOPED criteria were then compared with the original PIOPED criteria and gestalt interpretations of two experts in a prospective study.[16] In this study of 104 patients who had V/Q scans and pulmonary angiography, the gestalt percent probability estimate was the most accurate for assessing the likelihood of pulmonary embolism, with an area under the receiver operating characteristic (ROC) curve of 0.836. The revised PIOPED criteria had an area under the ROC curve of 0.753, which was larger than the area under the ROC curve using the original PIOPED criteria.

After the publication of the revised PIOPED criteria, they were accepted as the standard criteria for interpreting V/Q scans.[14] The typical finding of pulmonary embolism on V/Q imaging is large, wedge-shaped, peripheral perfusion defects in areas that have normal ventilation and that are normal on plain radiographs. The larger the number of these defects, the more likely it is that the patient has pulmonary embolism. It is important to keep in mind that in patients who have a prior history of pulmonary embolism, the finding of large mismatched defects is not as accurate as in patients who do not have a previous history of pulmonary embolism.[1] For a V/Q scan to be considered high probability (≥80% in the PIOPED study), two or more large mismatched segmental perfusion defects or the equivalent in moderate or large and moderate mismatched defects must be present. Two large mismatched perfusion defects are borderline for high probability, but generally should be categorized as high probability.

Patients who had intermediate-probability V/Q scans had pulmonary embolism detected by pulmonary angiography 20% to 79% of the time. The criteria for an intermediate-probability scan include the following: one moderate to two large mismatched segmental perfusion defects or the equivalent in moderate or large and moderate defects, one matched V/Q defect with a clear chest radiograph, and difficult to categorize as low or high probability.

Patients with a low-probability V/Q scan had a 19% or less probability of having a positive pulmonary angiogram. The criteria for low probability included the following: nonsegmental perfusion defects, perfusion defect with substantially larger abnormality on chest radiography, perfusion defects matched by ventilation abnormality, and any number of small perfusion defects with a normal chest radiograph. Thus, patients with extensive COPD with matched ventilation and perfusion were categorized as low probability.

The normal perfusion study excludes pulmonary embolism (Fig. 21-1). Criteria for normality included no perfusion defects and perfusion outlining exactly the shape of the lungs seen on chest radiograph. Hilar and aortic impressions may be seen, and the chest radiograph, the ventilation scan, or both may be abnormal.

The PIOPED II V/Q scan criteria include revisions from the revised PIOPED criteria based on continuing analysis of the original PIOPED data and the input of the

TABLE 21-1. Ventilation-Perfusion (V/Q) Scan Interpretation Criteria

Revised PIOPED Criteria	PIOPED II Ventilation-Perfusion (V/Q) Scan Criteria
HIGH PROBABILITY (≥80%)	**HIGH SCAN PROBABILITY**
Two or more large mismatched segmental perfusion defects or the equivalent in moderate or large and moderate mismatched defects*	Two or more large mismatched segmental defects or the equivalent in moderate or large and moderate defects
INTERMEDIATE PROBABILITY (20%–79%)	**INTERMEDIATE-INDETERMINATE SCAN PROBABILITY**
One moderate to one and one-half large mismatched segmental perfusion defects or the equivalent in moderate segmental perfusion defects	One-half to one and one-half segmental equivalents
Single matched V/Q defect with clear chest radiograph†	Difficult to categorize as high or low
Difficult to categorize as low or high, or not described as low or high	Solitary moderate or large segmental size triple match in lower lobe (zone)
	Multiple opacities with associated perfusion defects
LOW PROBABILITY (≤19%)	**LOW SCAN PROBABILITY**
Nonsegmental perfusion defects (e.g., cardiomegaly, enlarged aorta, enlarged hila, elevated diaphragm)	A single matched V/Q defect
Any perfusion defect with a substantially larger chest radiographic abnormality	More than three small segmental lesions
Perfusion defects matched by ventilation abnormality† provided that there are (a) a clear chest radiograph and (b) some areas of normal perfusion in the lungs	Probable pulmonary embolism mimic:
Any number of small perfusion defects with a normal chest radiograph	One lung mismatched (whiteout) with absent perfusion
	Solitary lobar mismatch
	Mass or other radiographic lesion causing all mismatch
	Moderate-sized pleural effusion (greater than costophrenic angle but less than one third of pleural cavity with no other perfusion defect in either lung)
	Marked heterogeneous perfusion
	VERY LOW SCAN PROBABILITY
	Nonsegmental lesion (e.g., prominent hilum, cardiomegaly, elevated diaphragm, linear atelectasis, costophrenic angle effusion with no other perfusion defect in either lung)
	Perfusion defect smaller than radiographic lesion
	Two or more V/Q matched defects with regionally normal chest radiograph and some areas of normal perfusion elsewhere in the lungs
	One to three small segmental perfusion defects
	A solitary matched triple defect in the mid or upper lung zone confined to a single segment
	Stripe sign present around the perfusion defect (best tangential view)
	Pleural effusion of one third or more of the pleural cavity with no other perfusion defect in either lung
NORMAL	**NORMAL PERFUSION SCAN**
No perfusion defects—perfusion outlines exactly the shape of the lungs seen on the chest radiograph (note that hilar and aortic impressions may be seen, and the chest radiograph and/or ventilation study may be abnormal)	No perfusion defect. Perfusion scan must outline the shape of the lungs seen on chest radiograph, which could be abnormal (e.g., scoliosis).

*Two large mismatched perfusion defects are borderline for high probability. Individual readers may correctly interpret individual scans with this pattern as high probability. In general, it is recommended that more than this degree of mismatch be present for the high-probability category.
†Very extensive matched defects can be categorized as low probability. Single V/Q matches are borderline for low probability and should be considered for intermediate probability in most cases by most readers, although individual readers may correctly interpret individual scans with this pattern as low probability.
PIOPED, Prospective Investigation of Pulmonary Embolism Diagnosis (study); V/Q, ventilation-perfusion.

PIOPED II nuclear medicine working group (Figs. 21-1 to 21-5). In the PIOPED II criteria, the criteria for high probability have remained the same. The intermediate-probability criteria and the low-probability criteria have been revised, and a very low probability category has been added. These changes result in fewer patients having intermediate-probability scans and provide more definitive diagnoses within the very low probability category, but are not well understood by clinicians.[17]

The revised intermediate-probability criteria include scans that had 0.5 to 1.5 segmental equivalent defects, scans that were difficult to categorize as high or low probability, scans that had a solitary moderate or large segmental size triple match in the lower zone, and multiple opacities with associated perfusion defects.

The revised low-probability criteria include a single matched V/Q defect, more than three small (<25% of a segment) lesions, probable pulmonary embolism mimic, moderate-sized pleural effusion, and marked heterogeneous perfusion pattern. The very low probability criteria

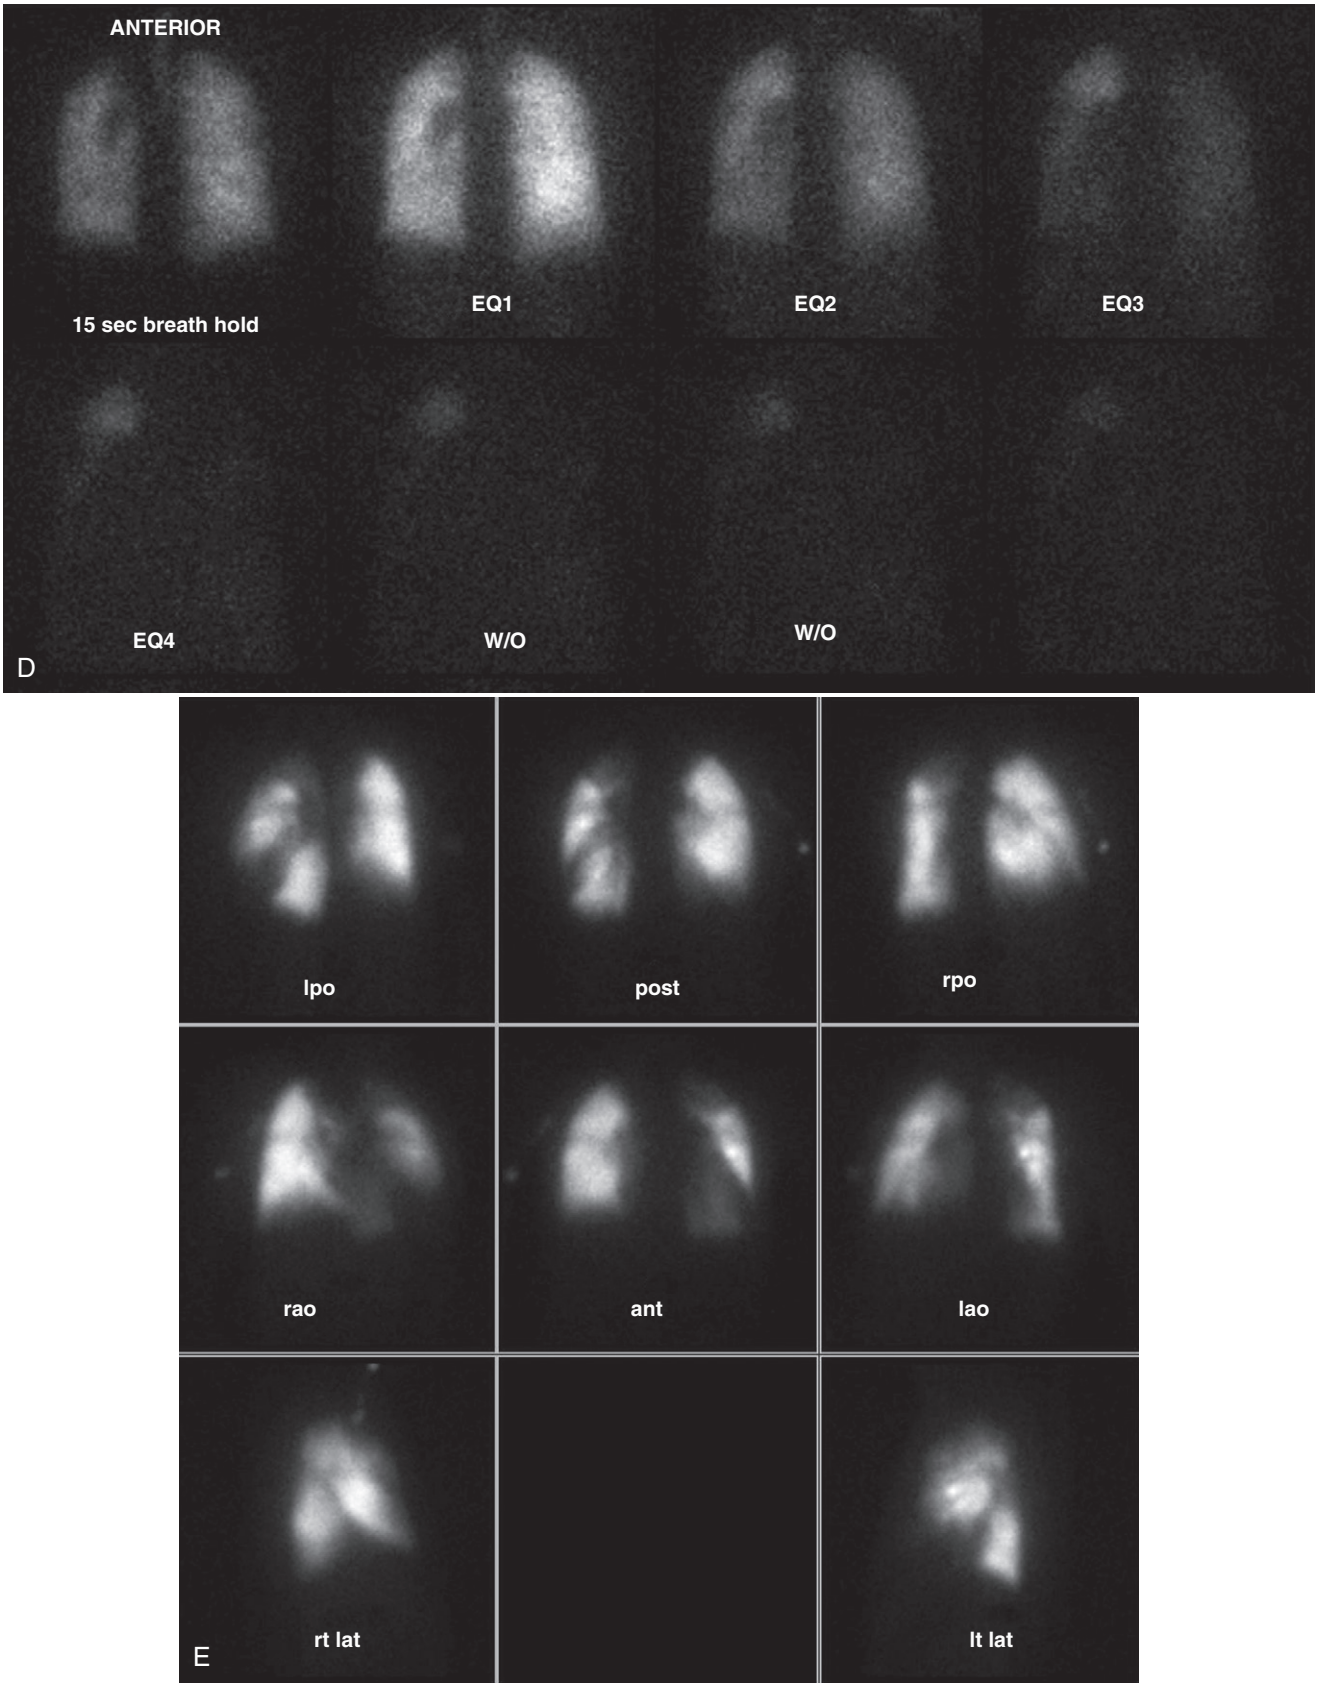

FIGURE 21-5 ■ cont'd. posterior (**D**) ^{133}Xe ventilation images at equilibrium (EQ) and during washout (W/O) reveal evidence of air trapping in the left upper zone. **E,** The ^{99m}Tc-MAA perfusion images reveal multiple bilateral segmental defects.

include the following: nonsegmental lesion, a perfusion defect smaller than a radiographic lesion, two or more V/Q matched defects with regionally normal chest radiograph, one to three small segmental perfusion defects, a solitary triple-matched defect in the mid or upper lung zone confined to a single segment, a stripe sign present around the perfusion defect, and a large pleural effusion.

Pulmonary embolism mimics are included in the low-probability category. These diseases result in V/Q mismatch and are quite uncommon.[18] The disease processes that result in pulmonary embolism mimics involve the pulmonary vessels, producing vascular occlusive physiologic findings including normal ventilation. Most mimics of pulmonary embolism are caused by chronic perfusion deficits from previous pulmonary embolism, intravenous drug abuse, and hilar or mediastinal involvement by bronchogenic carcinoma.[2] Less common causes include vasculitis or other connective tissue disorder, tuberculosis, irradiation, vascular anomalies such as pulmonary arterial agenesis and peripheral coarctation, arteriovenous malformation, surgical pulmonic-systemic shunts, and extrinsic compression of pulmonary arteries or veins from mediastinal malignancy or fibrosis.

Other Diagnostic Patterns

As noted in the PIOPED II criteria (see Table 21-1), a stripe sign results in the defect being considered very low probability for pulmonary embolism. The stripe sign is a rim of activity along the pleura that is greater than the rest of a segmental-appearing defect.[19] This sign has been found to be between 90% and 95% reliable as an indication of nonembolic disease.[20] Another diagnostic pattern on V/Q scans is the segmental contour pattern that is considered to be the result of lymphangitic spread of tumors.[21] The venules and arterioles may also be involved with tumor microemboli. With this pattern, the segments are outlined by the defects, and the defects are not the segments themselves. The pattern of diffuse pulmonary edema on the chest radiograph generally results in minimal, if any, perfusion abnormality.[22] Frequently, whenever a chest radiograph is shown to have diffuse abnormality, it is assumed that the V/Q scan would be intermediate probability for pulmonary embolism. However, in a study of 55 patients with diffuse radiographic opacities, 73% had normal or near-normal perfusion images.[22]

Preoperative Evaluation

Ventilation and perfusion imaging by the methods used to study patients suspected of having pulmonary embolism has also proved useful in the preoperative evaluation of patients with cancer of the lung. Because many patients with newly diagnosed and potentially curable bronchogenic carcinoma have coexisting COPD, both being complications of inveterate cigarette smoking, the issue sometimes arises as to whether the patient can tolerate lung resection and, if so, how much lung can be removed (e.g., lobectomy or pneumonectomy). Scintigraphic studies of regional lung function are probably not warranted if the patient's preoperative forced vital capacity (FVC) is greater than 2 L and the FEV_1 is greater than 50%. Lower values raise questions, however, because the functional limitations of lung resection, in general, begin to affect daily life when postoperative FEV_1 is reduced to 0.8 L or less.

Postoperative lung function can be reasonably well estimated by either ventilation or perfusion lung scanning, but perfusion with ^{99m}Tc-MAA is the preferred method owing to its simplicity and slight theoretical advantage. After summing the radioactivity over each lung in the anterior and posterior views, the postoperative FEV_1 is predicted by multiplying the preoperative value by the ratio of the counts in all the lung to be preserved to the total activity.[23,24] Recently, studies using dynamic perfusion magnetic resonance imaging (MRI) were shown to be as accurate (but more costly and complicated) as perfusion scintigraphy for predicting postoperative lung function in patients with lung cancer.[24]

POSITRON EMISSION TOMOGRAPHY

Imaging evaluation of a thoracic abnormality depends on a variety of factors, including patient symptoms and history. Plain chest radiographs are still the most common radiographic examination as they provide enormous amounts of anatomic information and often dictate whether additional imaging is required. Whereas CT is usually the next study performed, PET with FDG has emerged as an invaluable tool for in patients with suspected cancer. More recently, the combination of CT-PET has been used, primarily to differentiate benign from malignant pulmonary lesions that are indeterminate on conventional studies, to stage non–small cell lung cancer (NSCLC), to assist in planning radiotherapy, and to distinguish recurrent or persistent cancer from post-treatment fibrosis. In early stage NSCLC, FDG uptake correlates with survival and thus provides prognostic information. Most importantly, PET is a new direction for radiology and was the genesis of a molecular imaging approach, complementing more traditional anatomic and morphologic radiographic studies. This section focuses on the current clinical indications and utility of PET imaging in the thorax.[24a]

Differentiating Benign and Malignant Lesions

Diagnostic imaging plays a central role in evaluating patients with or suspected lung cancer, but unfortunately, conventional studies do not always provide the information necessary to establish a diagnosis or plan treatment. The etiology of a lung lesion may be suggested on conventional imaging studies, but further invasive evaluation is often required.[25] Thus, in an effort to improve diagnostic accuracy while reducing the necessity of follow-up studies and biopsies, new noninvasive techniques are constantly being explored. Since the mid 1990s, PET has become a routine procedure for

differentiating benign from malignant lesions. The rationale for using FDG, a glucose analogue, as the imaging probe is that increased glucose metabolism is a fundamental property of malignancies, and that FDG preferentially accumulates in malignant tumors as compared with benign abnormalities.[26,27]

The radiologic manifestations of NSCLC are variable, although it typically presents as a focal pulmonary opacity or solitary pulmonary nodule. However, not all pulmonary lesions are malignant, and differentiating benign from malignant lesions is a common radiologic dilemma. Once an abnormality is detected, comparison with prior radiographs or CT is suggested to determine growth. If the lesion is stable over a 2-year period, then it is highly suggestive of a benign abnormality.[28] Many lesions remain indeterminate, and a decision to follow the lesion for growth, or alternatively to intervene (i.e., biopsy or resection), depends on clinical factors such as age, past medical and smoking history, and suspicious radiologic findings.

PET with FDG is now commonly used for indeterminate pulmonary lesions.[29,30] The results from these studies have been consistent, with an overall accuracy around 85%. Those patients with increased FDG uptake—a positive PET scan—require further attention, as these lesions are considered malignant until proven otherwise (Figs. 21-6 and 21-7). Unfortunately, not all lesions with increased FDG uptake are malignant. False-positive scans (positive PET scans that prove benign) have been reported with a number of entities, including infectious and inflammatory processes such as tuberculosis, histoplasmosis, and rheumatoid nodules.[31–34]

Lesions that do not have increased FDG uptake are usually benign. These patients can be followed with sequential imaging to determine resolution or stability. False-negative studies are unusual, but may be seen with some small (<10 mm) lung cancers, bronchoalveolar cell cancers, or carcinoid tumors.[35,36] If the lesion grows, then it should be considered malignant, and a biopsy or resection is recommended. The rare patient with a negative PET scan who later proves to have NSCLC typically has a biologically indolent tumor. The short delay before a diagnosis is made does not appear to change prognostic outcome.[37,38]

Several studies have shown that a diagnostic strategy that incorporates PET is cost-effective and will reduce

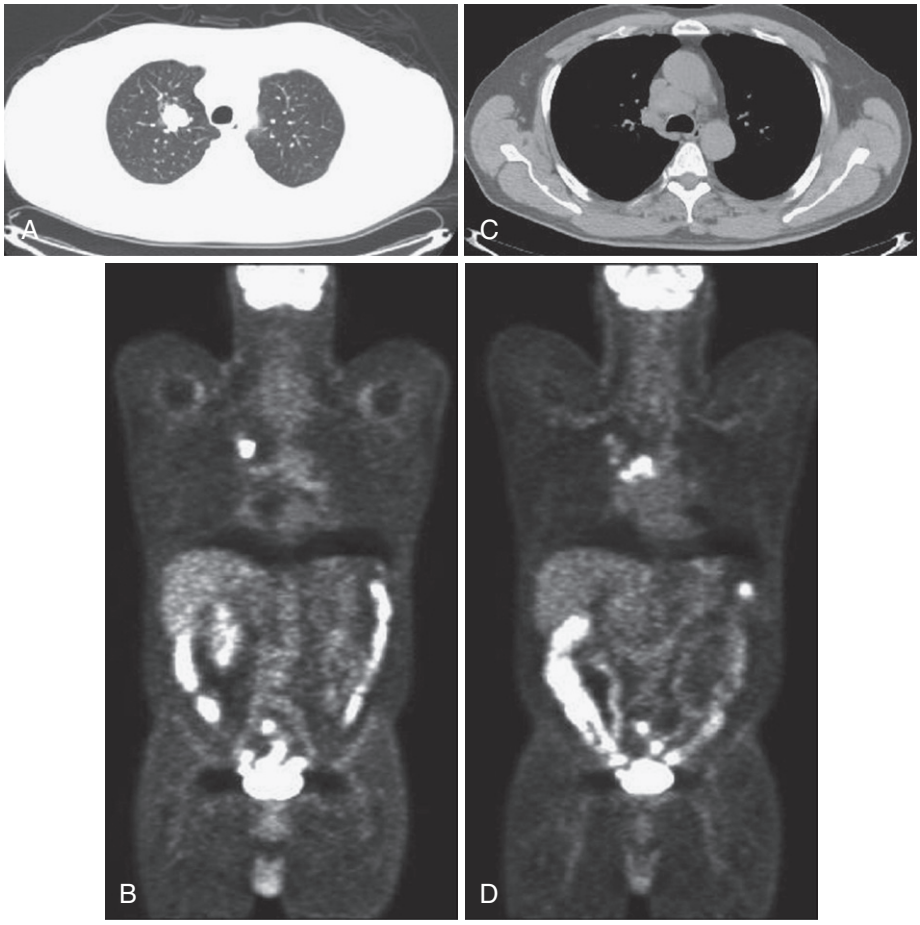

FIGURE 21-6 ■ A 63-year-old man with a right upper nodule on chest radiograph. **A,** Axial computed tomography (CT) image confirms an indeterminate nodule. **B,** Coronal positron emission tomography (PET) image shows increased [^{18}F]fluoro-2-deoxy-D-glucose (FDG) uptake consistent with a malignant lesion. **C,** CT shows enlarged pretracheal lymph nodes. **D,** Coronal PET image demonstrates increased FDG activity in the pretracheal and right paratracheal regions suggestive of lymph node metastasis. Mediasternoscopy confirmed stage IIIA non–small cell lung cancer (NSCLC).

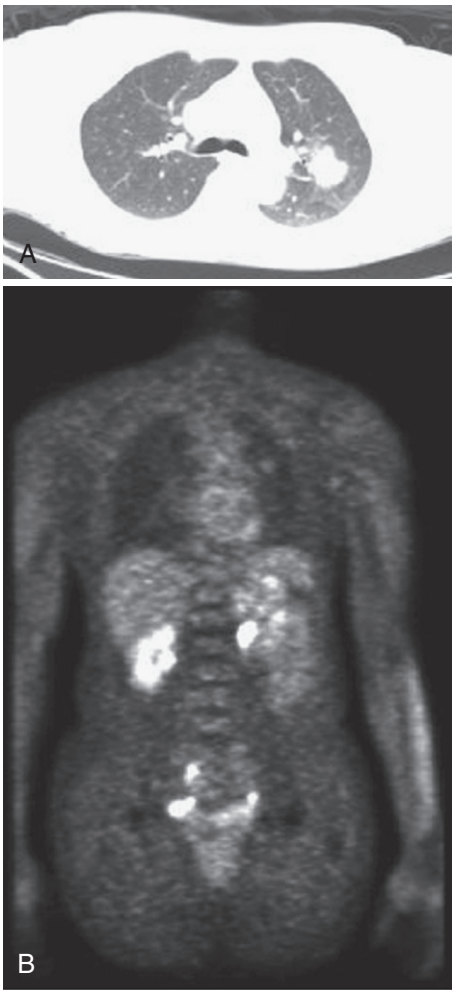

FIGURE 21-7 ■ A 65-year-old woman presented with an irregular left upper lobe mass. **A,** Axial CT confirms the irregular left upper lobe nodule. **B,** Coronal PET shows no significant increased FDG activity consistent with a benign lesion. This was followed for over 2 years and did not change in size consistent with a benign abnormality.

the number of patients who undergo resections of indeterminate lesions that prove to be benign by 15%.[39,40] It was estimated that the combination of PET and CT to evaluate indeterminate focal pulmonary lesions could save almost $1,200 per patient as compared with the use of CT alone.[41,42]

Staging Lung Cancer

Once a diagnosis of lung cancer has been made, accurate staging is essential in determining therapeutic options and prognosis. The primary goal of radiologic studies is to help distinguish those patients in whom the tumor is potentially resectable (stages I to IIIA) from those in whom the tumor is not resectable (stages IIIB and IV). Imaging evaluation typically includes thoracic CT, a radionuclide bone scan, and brain imaging (CT or MRI) in the search for extrathoracic metastases. Unfortunately, despite careful clinical evaluation, conventional staging techniques are suboptimal: some patients are overstaged and others are understaged. Tissue sampling is required for histologic confirmation prior to initiation of therapy, but this is limited by the imaging studies' ability to detect an anatomic abnormality suggestive of tumor.

With the addition of PET, more accurate lung cancer staging can be achieved. Several studies have reported changes in patient management in up to 40% of cases as compared with conventional imaging alone. Some patients first considered to be resectable had more advanced disease, whereas others with anatomic abnormalities suggestive of metastases were found to have localized, resectable disease.[43–46]

The tumor-node-metastasis (TNM) descriptors used to stage tumors were designed for anatomic assessment and are not always applicable to PET imaging. PET assessment of tumor (T) status differs from conventional anatomic imaging in that lung lesions are typically interpreted as either positive or negative for malignancy.

Although CT, and occasionally MRI, is used to evaluate hilar and mediastinal nodes, the accuracy of detecting nodal metastases with conventional studies using a short axis diameter (>1 cm) is approximately 60%.[47] Normal-sized lymph nodes may harbor malignant cells, and enlarged nodes may be benign.[48,49] However, PET is more sensitive and specific than CT alone, with accuracy reported to be greater than 80% (Fig. 21-8).[44,50] In one study, PET correctly changed nodal staging as determined by CT in 24% of presurgical patients. In another report of patients with clinical stage I disease, mediastinoscopy was deemed unnecessary if the PET showed normal mediastinal nodal activity.[51] In those patients with increased FDG uptake in hilar and mediastinal lymph nodes, PET provides a road map for surgical nodal sampling and should reduce the number of patients with unresectable mediastinal nodal metastases who, in the absence of histologic diagnosis, undergo resection.

Lung cancer most commonly metastasizes to the regional lymph nodes, adrenal glands, bones, brain, and liver.[47] Whereas routine radiologic evaluation remains controversial, PET imaging appears to improve the noninvasive detection of extrathoracic disease. Whole-body PET has the capability to stage both intra- and extrathoracic disease in a single examination with more improved accuracy than conventional imaging alone.[46,52]

The adrenal glands are a common site of metastasis in NSCLC.[53] These lesions are occasionally difficult to distinguish from benign abnormalities, as up to two thirds of adrenal lesions detected by CT in patients with lung cancer are benign. Consequently, PET has been advocated to evaluate adrenal masses as the sensitivity and specificity for detecting adrenal metastases in lung cancer patients are reported to be over 80%.[54]

The bones are another common site of metastatic disease, and metastases are found in up to 20% of patients at presentation.[55] At least 20% of these patients are asymptomatic, but bone scans using ^{99m}Tc-MDP are only 60% specific, with a sensitivity of 90%. PET imaging in patients

FIGURE 21-8 ■ A 75-year-old presented with cough and hemoptysis. **A,** Axial CT demonstrates a thick-walled right upper lobe cavitary lesion. **B,** Coronal PET image demonstrates significant FDG activity suggestive of a malignancy. Biopsy revealed NSCLC.

with lung cancer has been shown to detect lesions not found on these other studies. The accuracy, sensitivity, specificity, and positive and negative predictive values for bone metastases are all reported to be over 90%.

Lung cancer also metastasizes to the brain, and up to 12% of patients with brain metastases are asymptomatic at presentation. Either CT or MRI is typically used to search for central nervous system lesions. Because the normal brain has significant glucose uptake, metastases may be difficult to detect on PET.[56] For this reason, PET imaging has a low sensitivity (68%) in detecting brain metastases and should not be used to replace CT or MRI.

Although lung cancer commonly metastasizes to the liver, it is an unusual isolated site of disease, particularly in the absence of metastatic disease to regional lymph nodes. Nevertheless, whole-body PET scanning may be useful in the evaluation of hepatic lesions that are indeterminate by conventional imaging. Several small series have suggested that PET is more specific than CT in detecting liver metastases.[46,57] False-positive PET studies can rarely occur with other lesions, such as liver abscesses or other malignant primary liver lesions (cholangiocarcinoma and hepatocellular carcinoma).[58]

In summary, the use of PET for routine staging of non–small cell lung cancer appears to improve detection of metastases and reduces both cost and morbidity. With the use of PET, preliminary data suggest that bone scintigraphy may be eliminated, although brain imaging is required, if clinically indicated.

Posttreatment Follow-up

After patients have been treated for lung cancer, anatomic changes including airway distortion, focal pulmonary opacities, and soft-tissue abnormalities often develop within the thorax and chest wall. Depending on the therapeutic intervention (surgical or radiation), benign abnormalities including posttreatment scarring and fibrosis may be impossible to distinguish from residual cancer on conventional imaging studies.

Unfortunately, once patients have had first-line therapy, it remains uncertain if detecting early recurrence will improve survival. If therapeutic options improve, it may become important to distinguish benign posttreatment changes from residual or recurrent malignancy. PET studies have shown accuracy of 78% to 98%, sensitivity of 97% to 100%, and specificity of 62% to 100%.[59–62] However, false-positive results may occur immediately following surgery or irradiation. It is therefore recommended that FDG-PET studies in this situation be obtained approximately 4 to 5 months after completion of the therapy, which allows inflammatory changes to subside and provides a more accurate assessment of tumor viability (Fig. 21-9).

Planning Radiotherapy

Planning for radiation treatment traditionally uses conventional imaging, including chest radiographs, CT, or MRI for an anatomic description of the extent of the tumor. This treatment planning relies on morphologic features, which do not always provide a clear distinction between benign and malignant tissue. Several preliminary studies suggest that CT-PET is more accurate than other imaging studies in making this distinction.

Radiation ports are typically planned to treat the primary lesion, with prophylactic doses to the mediastinum to treat microscopic tumor foci not identified by conventional imaging studies.[63–65] It is common to use small margins on CT-defined targets when planning three-dimensional treatment to minimize radiation damage to adjacent normal tissues. The use of CT-PET when planning radiation ports has been shown to influence treatment in approximately 30% of patients, resulting in enlarging portions of the irradiated margins up to 15 cm.[65,66] The use of anatomic imaging alone would have meant inadequate radiation coverage and a higher

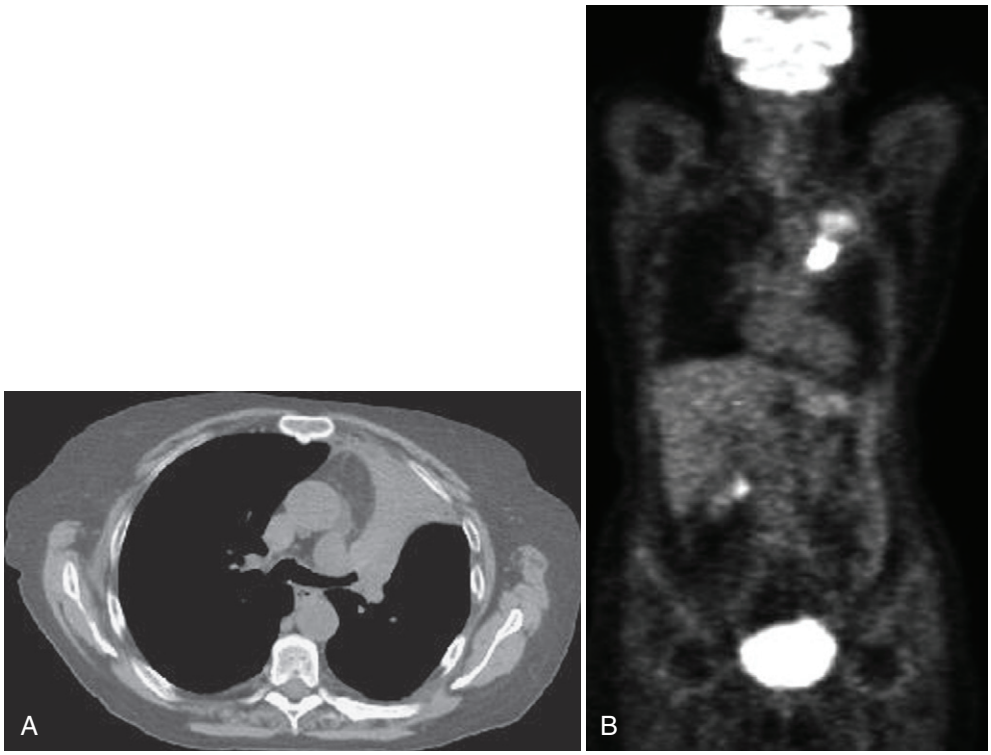

FIGURE 21-9 ■ A 57-year-old man with treated NSCLC presented with increasing cough. **A,** Axial CT image showed obstruction of the left upper lobe bronchus with associated left upper lobe atelectasis. **B,** Coronal PET image demonstrates significant activity in the left hilum consistent with recurrent lung cancer. Bronchoscopy proved recurrent NSCLC.

chance of local recurrence. In addition, in poorly demarcated tumors, PET scans can identify the neoplastic focus to be smaller than suspected by conventional imaging,[67,68] potentially allowing irradiation of smaller portals with less morbidity. Thus, for radiation planning, integrating CT-PET appears to be more accurate than CT alone in defining tumor extent. Future studies will show if this indeed is associated with increased survival and reduced morbidity.

Prognostic Information

Although conventional imaging studies elucidate anatomic detail, there is minimal prognostic information. However, several recent PET studies suggest that PET may be usefully employed as a marker that predicts response to therapy and outcomes.[37,69-71] The amount of FDG uptake in the primary lesion at the time of diagnosis in patients with early-stage NSCLC correlates with survival, but no definite correlation exists between FDG uptake and late-stage disease.[70] Once patients have been treated for lung cancer, a positive PET scan in the thorax is associated with a statistically worse survival than a negative study. Other prospective trials suggest that complete reduction in metabolic activity of the tumor site to background activity (complete response) is indicative of true local remission of the disease.[61,71]

When assessing a patient's operability following induction chemotherapy (stage IIIA-N2), some preliminary studies have suggested PET as a noninvasive method for selecting those patients who should proceed to surgical resection.[72,72a] Repeat mediastinoscopy in irradiated patients is difficult due to fibrosis, and neither the disappearance of lymphadenopathy nor a greater than 50% decrease of the primary tumor diameter on CT was significantly associated with improved survival. Similarly, in a recent study in potentially resectable patients receiving neoadjuvant chemotherapy, a change in FDG activity on PET did not correlate with survival. Therefore, PET to predict long-term response is not indicated in these patients.

FUTURE DEVELOPMENTS

PET provides a new direction for tumor imaging, and with an increased understanding of tumor biology, accompanied by improvements in detection, characterization, and staging, this type of noninvasive molecular assessment of tumors is likely to improve patient outcome. Future developments include technologic improvements in scanner design and resolution, in addition to the design of novel tumor-specific imaging probes. Although FDG has a high sensitivity, the lack in specificity places limits on its clinical utility. A series of tumor-specific probes could then be used to produce a noninvasive "tumor profile." Such molecular imaging characterization of a thoracic abnormality could have significant diagnostic, prognostic, and therapeutic implications.

KEY POINTS

- Although multidetector CTA is being increasingly used to evaluate patients with suspected pulmonary embolism, V/Q scintigraphy plays an important backup role in patients with renal dysfunction, contrast allergy, massive obesity, and low clinical suspicion of embolism and when radiation is contraindicated.
- Newly revised criteria for evaluating V/Q scintigraphic findings in patients with suspected pulmonary embolism show that the sensitivity of a "pulmonary embolism present" interpretation was 77% and that the specificity of a "pulmonary embolism absent" was 98%: thus confirming the diagnostic efficacy of the method.
- V/Q scintigraphy is also useful for predicting the level of pulmonary function that will remain postoperatively in patients with cancer of the lung who have abnormal function to begin with and are being considered for resectional surgery.
- Since the mid 1990s, PET imaging in the thorax has become an invaluable tool in managing patients with cancer. It is particularly valuable in evaluating patients with an indeterminate pulmonary nodule and in staging patients with NSCLC.
- PET appears useful in providing prognostic information in early-stage NSCLC, in suggesting recurrent disease following treatment, and in planning radiotherapy. PET does not appear useful as a prognostic marker in patients with advanced-stage disease nor in predicting survival following neoadjuvant therapy.

INTRODUCTION AND HISTORICAL BACKGROUND

Among the many areas in pulmonary medicine that have been revolutionized by technological advances, flexible bronchoscopy (FB) is one of the prime examples. Today, it has become one of the most frequently performed invasive procedures in pulmonary medicine.

Gustav Killian performed the first bronchoscopy in 1897 to extract a piece of a pork bone from the right main bronchus.[1] From that meager beginning, the technology in bronchoscopy has advanced exponentially. In 1966, the flexible bronchoscope was introduced into clinical practice by Shigeto Ikeda.[2] Currently, this instrument is one of the most important tools for diagnosis and treatment of pulmonary diseases.

Since its introduction the flexible bronchoscope has become the instrument of choice owing to its diagnostic accuracy, safety, and ease of use. The procedure can be easily performed in an outpatient setting, under moderate sedation and local anesthesia. Compared with FB, rigid bronchoscopy is now used only for selective indications such as massive hemoptysis.[3–6]

The indications for fiberoptic bronchoscopy are broad and growing (Table 22-1). Nonetheless, certain conditions are not considered indications for FB. For example, FB is not indicated in patients with cough unless the cough fails to respond to conventional treatment or if there is a change in its character. Similarly, bronchoscopy is not indicated in patients with isolated pleural effusion or atelectasis,[7–9] and its use to remove secretions during acute exacerbations of chronic obstructive lung disease is also considered inappropriate.[10] FB also has little role in finding synchronous lesions in patients undergoing lung resection of a solitary pulmonary nodule suspected to be primary bronchogenic carcinoma.[11] There are also contraindications to its use, both absolute and relative (Table 22-2).

PROCEDURE

FB is usually performed via the oral or the nasal route.[12] Either route provides excellent access to the lower airways. By either route, attention should also be given to the upper airways. In particular, bronchoscopy performed for the evaluation of hemoptysis or wheezing should include a careful evaluation of the upper airways.

The need for sedation during FB remains a matter of some debate in the literature.[13–15] The purpose of

TABLE 22-1. Indications for Diagnostic Flexible Bronchoscopy (Adult)

Hemoptysis
Wheeze and stridor: suspected stricture, upper airway obstruction
Lung infiltrates of unknown cause
- Suspected pulmonary infections not responding to conventional treatment
  (a) Localized
  (b) Diffuse
- Lung infiltrates in an immunocompromised host
- Recurrent or unresolved pneumonia
- Cavitary lesion
- Interstitial infiltrates
- New pulmonary nodule

Unexplained lung collapse
Suspected or known bronchogenic carcinoma
- Positive or suspicious sputum cytology
- Staging
- Follow-up after endobronchial treatments

Mediastinal and hilar lymphadenopathy and masses
Lung transplantation
- Inspect airway anastomosis
- Rejection surveillance

Esophageal cancer evaluation
Endotracheal intubation
- Confirm tube position
- Evaluate for tube-related injury

Evaluation for foreign body aspiration
Chest trauma
- Rule out rupture of central airways
- Examine for aspirated contents

Evaluation following burns or chemical injury to the airways
Unexplained superior vena cava syndrome
Unexplained vocal cord paralysis or hoarseness
Suspected fistulas
- Bronchopleural
- Tracheoesophageal and bronchoesophageal
- Tracheo- or bronchoaortic
- Iatrogenic (postsurgical)

TABLE 22-2. Contraindications for Flexible Bronchoscopy

ABSOLUTE
Uncorrectable hypoxemia
Lack of patient cooperation
Lack of skilled personnel
Lack of appropriate equipment and facilities
Unstable angina
Uncontrolled arrhythmias

RELATIVE
Unexplained or severe hypercarbia
Uncontrolled asthma
Uncorrectable coagulopathy
Unstable cervical spine
Need for a large-size tissue specimen for diagnosis
Debility, advanced age, malnutrition

sedation is to improve patient comfort and add to the ease of the procedure for the bronchoscopist.[16] Although bronchoscopy can be carried out without sedation,[17,18] most are performed under moderate sedation.[19,20] Interestingly, according to some surveys, 16% to 21% of physicians use general anesthesia for FB.[19,21] Intravenous preparations of various sedatives such as diazepam, midazolam, lorezapam, morphine sulfate, fentanyl, and hydrocodone have been used either singly or in combination based on the bronchoscopist's preference and the availability of the drug.[22–27] Fentanyl has a greater analgesic potency than morphine.[23] Hydrocodone has a greater antitussive property than codeine but less than that of morphine.[28] The combination of a benzodiazepine and an opioid has been shown to be safe and synergistic for the purposes of sedation during FB.[26,29] The combination of hydrocodone and midazolam reduces cough during FB without causing significant desaturation and improves the overall well-being of the patient.[26,29] Dextromethorphan can be given orally 90 minutes before the procedure to improve cough suppression.[30] Patients suffering with human immunodeficiency virus (HIV) infection, recipients of stem cell transplantation, lung transplant recipients for cystic fibrosis, and drug abusers usually require higher doses of sedatives than other patients.[31–33]

Although nerve blocks can be used to provide excellent analgesia to the airway, physicians generally rely on topical administration of local anesthetic agents. Lidocaine is the most commonly used drug for the purpose.[34] It offers a relatively wide margin of safety with a rapid onset and sufficient duration of action to allow completion of most bronchoscopic procedures. The gel preparation of lidocaine is preferred over the spray for nasal anesthesia.[35–37] The oropharynx can be anesthetized with 2% to 4% lidocaine applied as a spray, nebulized solution, or gargles. The vocal cords as well as the endobronchial tree are anesthetized by direct instillation of 1% to 2% lidocaine via the working channel of the bronchoscope. The total dose of lidocaine should be limited to 8.2 mg/kg in adults, with extra caution in the elderly or those with liver or cardiac impairments.[22]

Anticholinergic agents such as atropine and glycopyrrolate have been commonly used as premedication for FB[38,39] with the aim to reduce the bronchial secretions and suppress vagal overactivity. Several studies have shown that anticholinergics offer little advantage as premedications and their use should be avoided.[40–42]

MONITORING

To ensure adequate oxygenation (oxygen saturation >92%) and hemodynamic stability, pulse oximetry, heart rate and blood pressure are monitored throughout the procedure. All FB procedures are performed observing universal precautions. Following each procedure, the instrument is thoroughly disinfected or sterilized according to the published consensus statement.[43]

DIAGNOSTIC BRONCHOSCOPY

Examination of the upper airways can be instructive. The vocal cords may be involved with infections (Fig. 22-1) or malignancy or may show paralysis as a result of interruption of the recurrent laryngeal nerve. The trachea may be abnormal owing to either congenital or acquired conditions (Fig. 22-2A and B). The endobronchial mucosa exhibit characteristic changes due to infiltrative or systemic conditions (see Fig. 22-2C and D). Endobronchial lesions may be caused by a multitude of conditions including malignant or infectious disease or by foreign bodies (Fig. 22-3).

Bronchoalveolar Lavage

Bronchoalveolar lavage (BAL) has become an important clinical and investigational tool.[44,45] It is a standard diagnostic procedure in all patients with diffuse lung abnormalities of unknown cause whether an infectious, noninfectious, immunologic, or malignant etiology is suspected.[46] BAL allows the recovery of both cellular and noncellular components of the alveolar lining fluid and epithelial surface of the lower respiratory tract. Components of the BAL fluid represent the inflammatory and immune status of the lower respiratory tract and alveoli[44,47] (Fig. 22-4). BAL, which samples the distal air spaces, differs significantly from a bronchial washing, which samples the large airways via aspiration of small amounts of instilled saline.[48,49] BAL should be considered when the bleeding risk prohibits bronchial

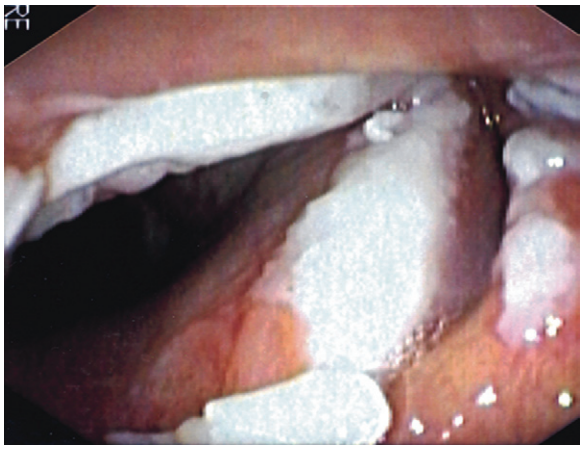

FIGURE 22-1 ■ Vocal cord candidiasis in an immunocompromised host.

brushing, transbronchial biopsy, or transbronchial needle aspiration or when fluoroscopy is not available.

For diffuse infiltrates, any area can be chosen for BAL. Thus, in the case of diffuse abnormalities, the right middle lobe or the lingula is usually sampled because, for a supine patient, gravity assists the recovery of a maximal amount of BAL fluid return.[45,46,50] In the case of localized disease, lavage should be performed from the area of focal radiographic abnormality,[48,50] and for maximal recovery, the patient can be positioned to improve recovery from the desired segment. "Good wedge" position usually means that the bronchoscope is advanced as far as possible without losing the view of the distal lumen. In this optimal position, a slow, gradual, manual aspiration, without allowing the airway walls to collapse, tends to maximize the lavage return.

BAL has significantly improved the diagnostic workup of lung diseases, whether diffuse or localized. In pulmonary alveolar proteinosis, it has both diagnostic and therapeutic value.[46,51-54] In an international statement on the major interstitial lung diseases, BAL is considered to be helpful in strengthening the diagnosis of sarcoidosis in the absence of a tissue diagnosis.[55] BAL and/or transbronchial biopsy (TBB) are considered valuable in excluding other diseases in a patient with suspected idiopathic pulmonary fibrosis who cannot undergo surgical biopsy.[56] BAL may be a useful tool in the diagnosis of peripherally located primary lung cancer, with an overall diagnostic yield range of 33% to 69%, being exclusively diagnostic in 9% to 11% of cases.[57-60] It also has value in patients suspected to have bronchoalveolar cell carcinoma[57,59,61] and lymphangitic carcinomatosis.[62-64] Numerous case reports confirm the ability of BAL to diagnose leukemia and lymphomatous pulmonary involvement as well as plasma cell dyscrasia.[65-67] Finding asbestos bodies in BAL fluid may correlate with occupational exposure, yet in itself, it is not proof of an asbestos-related disease.[68,69] The presence of more than 25% eosinophils in the BAL fluid confirms the diagnosis of eosinophilic lung diseases and the presence of more than 4% $CD1^+$ Langerhans cells confirms a diagnosis of Langerhans cell histiocytosis, albeit with low sensitivity.[70] In chronic beryllium disease, lymphocytes from the BAL proliferate when stimulated in vitro with soluble beryllium salts, with a sensitivity and specificity approaching 100%; this lymphocyte test has become a valuable diagnostic tool for this condition and has replaced open lung biopsy.[71,72] In patients with ventilator-associated pneumonia, a positive quantitative culture ($>10^4$ colony-forming units/mL) on BAL fluid may be clinically useful with a sensitivity of 22% to 93% and a specificity of 45% to 100%, depending upon the clinical status of the patient.[73-80] BAL is also a useful tool in the diagnosis of pulmonary infections in immunocompromised patients with the reported yield as high as 93%[81-87] (Fig. 22-5). Thus, in certain conditions, BAL findings can be diagnostic and thereby avoid the need for either TBB or open-lung biopsy (Table 22-3). In other settings, although not diagnostic, BAL can be used as an adjunct to the diagnosis when interpreted in the context of the entire clinical picture.

TABLE 22-3. Diseases in which Bronchoalveolar Lavage can be Diagnostic

Opportunistic infections (*Pneumocystis jirovecii*, fungi)
Pulmonary alveolar proteinosis
Alveolar hemorrhage syndrome
Malignant infiltrates (solid tumors, lymphoma, leukemia)
Dust exposure
Eosinophilic lung disease
Chronic beryllium disease
Langerhans cell histiocytosis

Bronchial Washings

The utility for bronchial washings is largely for the diagnosis of airway diseases including primary or metastatic lung carcinoma and fungal or mycobacterial infection. Broncial washing is the easiest to perform but has the lowest yield of the various bronchoscopy procedures (sensitivity, 27%–90%),[88-93] with a higher yield for central lesions.[91,94-96] Bronchial washings are an inexpensive adjunct and should be collected during a diagnostic bronchoscopy when appropriate because, even though by a small percentage, they can increase the overall diagnostic yield of the procedure.[91]

Bronchial Brushings

Bronchial Brush Biopsy. Bronchial brush biopsies (BBBs) were analyzed for the first time in 1973 and showed highly suspicious cytology in most of the cases with lung cancer.[97] In general, BBB provides diagnostic material in 72% (range, 44%–94%) of patients with central lung cancers and 45% of patients with peripheral lesions under fluoroscopic guidance.[98] When it is combined with endobronchial biopsy (EBB) of central lesions, the diagnostic yield of FB increases to between 79% to 96%.[99] We usually perform brushing after obtaining all the other bronchoscopy specimens to avoid bleeding or cell distortion interfering with obtaining or interpreting the overall results. The size or the length of the brush has not been shown to affect the diagnostic yield from BBB.

Protected Specimen Brush. Protected specimen brush (PSB) was first described in 1979 by Wimberley and coworkers[100] as a technique to establish an accurate diagnosis in patients with suspected pneumonia. In ventilator-associated pneumonia (VAP), the sensitivity of PSB ranges from 58% to 86% and the specificity from 71% to 100%.[101] For now, the procedure appears to have lost popularity against empiricism for the diagnosis of VAP (see Chapter 33).

Endobronchial Biopsy

EBB is an essential and technically simple tool in the diagnosis of endobronchial neoplasm. It is used for lesions directly visualized during bronchoscopy. It provides histologic specimens, whereas bronchial washing provides only cytologic samples. The reported diagnostic yield from EBB is 80% with a range of 51% to 97% depending upon the patient population.[88,89,98,102] The number of biopsies required for optimal diagnostic yield varies according to the suspected diagnosis. Three biopsy specimens of an endobronchial lesion suspected to be bronchogenic carcinoma can provide a diagnostic yield of over 97%.[103] Biopsies of the surface of endobronchial tumors may be falsely negative if there is peripheral necrosis; in such circumstances, a Wang needle sampling deeper into the mass may be diagnostic.

Transbronchial Biopsy

TBB is the technique by which a piece of lung parenchyma is obtained by using flexible forceps positioned distally via FB. In many instances, TBB can replace open-lung biopsy. TBB is diagnostically useful in 38% to 79% of patients (average sensitivity, 52%) depending upon the underlying disease.[104–108] TBB has a diagnostic yield of 40% to 90% in sarcoidosis,[109] 10% to 40% in Langerhans cell histiocytosis,[110] 88% to 97% in *Pneumocystis jirovecii* pneumonia,[111] and 57% to 79% in lung infections caused by *Mycobacterium tuberculosis*.[112] In patients suspected to have pulmonary alveolar proteinosis, its diagnostic yield has been reported to be as high as 100% (Fig. 22-6). The diagnostic yield of TBB increases with the number of the biopsy specimens obtained.[113]

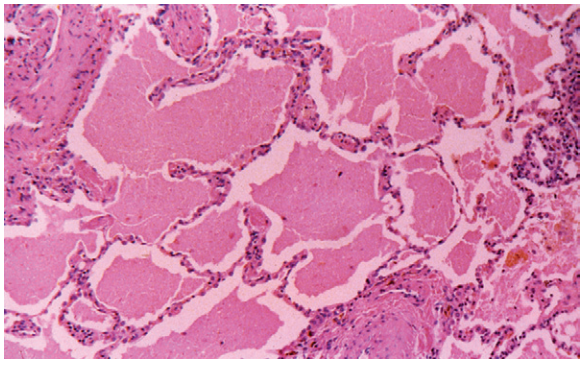

FIGURE 22-6 ■ Transbronchial biopsy specimen confirms the diagnosis of pulmonary alveolar proteinosis. Note periodic acid–Schiff (PAS) stain–positive material filling up the alveolar spaces.

Usually 6 to 10 biopsy specimens are obtained under fluoroscopic guidance. However, use of the fluoroscopy is not mandatory in patients with diffuse parenchymal disease, and biopsies can be obtained by assessing the proximity to the pleura as guided by the patient's perception of chest pain. When performed in association with bronchial brushings and transbronchial needle aspiration (TBNA), TBB adds to the diagnostic yield of FB for peripheral lung cancers.[95,98,114–119]

Pneumothorax and hemorrhage are the most feared complications following TBB, with an incidence of up to 3% of cases.[120] Renal insufficiency (blood urea nitrogen [BUN] > 30 mg/dL [10.7 mmol/L] and creatinine of >3 mg/dL [265 µmol/L]), coagulopathies, and pulmonary hypertension are considered risk factors for bleeding following TBB.[121] TBB can be safely performed while patients are receiving aspirin or nonsteroidal anti-inflammatory drugs; however, use of clopidogrel bisulfate should be withheld for at least 5 to 7 days before the procedure.[122,123]

Transbronchial Needle Aspiration

TBNA is a sensitive, accurate, safe, and cost-effective technique in the diagnosis and staging of lung cancer[119,124–130]; in selected cases, it can also be applied for the diagnosis of benign diseases.[131–135] Despite proven advantages, the practice of TBNA remains underutilized.[136] There is no absolute contraindication for TBNA. Superior vena cava obstruction has been considered as a relative contraindication by some because of a potential increased risk of bleeding[119]; however, the opposite view also exists.[137]

Diagnosis and staging of bronchogenic carcinoma can be established using 21- or 22-gauge cytology needles; diagnosis of benign conditions and lymphomas may require a larger-bore histology (19-gauge) needle.[136,138] The reported sensitivity, specificity, and accuracy of TBNA in lung cancer patients are 60% to 90%, 98% to 100%, and 60% to 90%, respectively.[138–142] The overall sensitivity, specificity, and accuracy of TBNA for mediastinal staging are 50%, 96%, and 78%, respectively.[98] Judicious use of TBNA can thus reduce the need for mediastinoscopy. In the diagnosis of involvement of mediastinal or hilar lymph nodes by sarcoidosis or tuberculosis, TBNA can be useful as well[131–135] (Fig. 22-7). In cases with pulmonary nodules, TBNA increases the diagnostic yield of FB by 25%.[141] TBNA can be safely performed in mechanically ventilated patients.[142]

The procedure of TBNA is safe, with an overall major complication rate of approximately 0.26%. Complications include damage of the working channel of the bronchoscope, fever, bacteremia, and bleeding from the puncture site (Fig. 22-8).[119,136,142] Use of computed tomography (CT), fluoroscopy, and ultrasonic guidance has been shown to improve the TBNA yield[143,144] (see Chapter 20).

Ultrathin Bronchoscopy

The ultrathin bronchoscope currently being studied has an outer diameter of 2.8 mm and an inner channel diam-

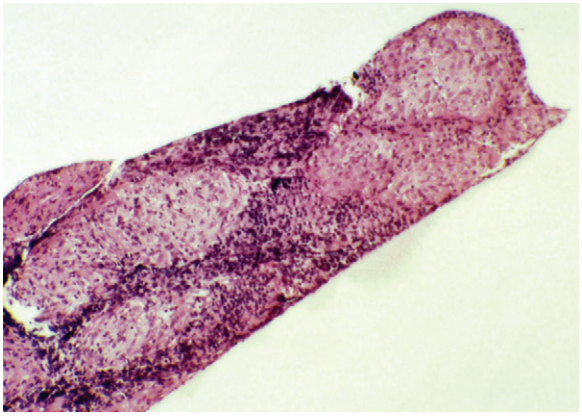

FIGURE 22-7 ■ Transbronchial needle aspiration specimen obtained using a 19-gauge histology needle reveals noncaseating granulomas under high-power magnification (×200) and hematoxylin and eosin stain.

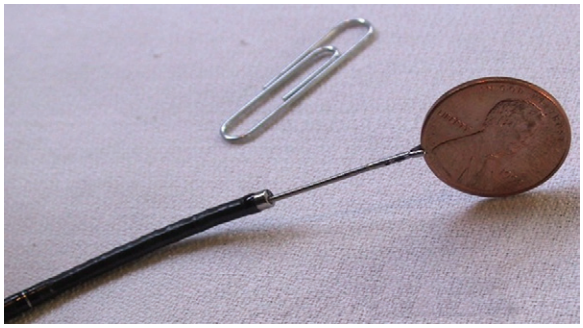

FIGURE 22-9 ■ Ultrathin bronchoscope with a flexible forceps inserted through the working channel. (Courtesy of Dr. Rex Yung.)

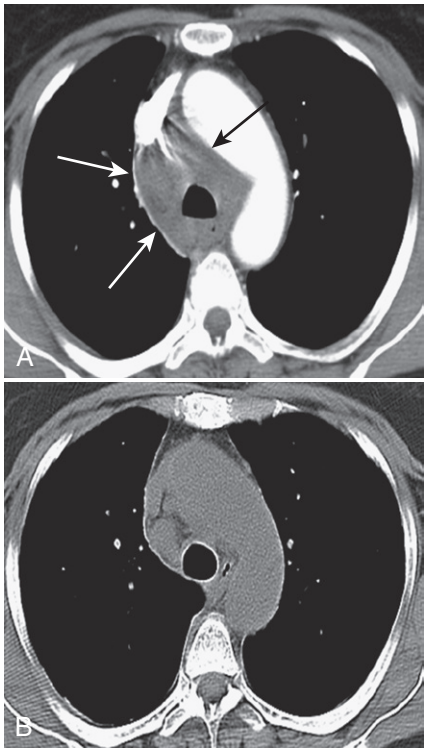

FIGURE 22-8 ■ Complication of transbronchial needle aspiration. **A,** On day 1, mediastinal hemorrhage is noted (*arrows*). **B,** By day 6, the abnormality has resolved. (Courtesy of Dr. Stefano Gasparini.)

eter of 1.2 mm and is made up mainly of fiberoptic bundles. This device has been developed to overcome the low diagnostic yield of FB for small lesions less than 20 mm in diameter.[145-148] Complexities of the distal airway anatomy requires fluoroscopic or CT guidance to maneuver the scope to the peripheral lesions. These bronchoscopes also can be used with ease in mechanically ventilated patients with small endotracheal tubes in place. Ultrathin bronchoscopes help in evaluating the nature and the extent of the upper airway obstruction where there is a risk for completely compromising the airways with standard bronchoscopes.[148] Over time, miniaturization of the instrument is likely to continue (Fig. 22-9).

Confocal Bronchoscopy

Fibered confocal fluorescence microscopy (FCFM) is a new technique that produces microscopic imaging of a living tissue via a 1-mm fiberoptic probe that can be introduced through the working channel of the conventional bronchoscope. In a recent study, bronchial FCFM was performed at 488-nm excitation wavelength on two bronchial specimens ex vivo and in 29 individuals at high risk for lung cancer in vivo; the alterations in fluorescent signal appeared to originate from the elastin component of the basement membrane zone.[149] Alterations of the autofluorescence microstructure were observed in 19 of 22 metaplastic or dysplastic samples, 5 of 5 carcinomas in situ, and 2 of 2 invasive lesions, representing a minimally invasive method to study specific basement membrane alterations associated with premalignant bronchial lesions in vivo. In the future, the technique may be used to study bronchial wall remodeling in nonmalignant chronic bronchial diseases.

Electromagnetic Navigation

Electromagnetic navigation (EMN) can be used to guide the bronchoscopist to lesions that cannot be visualized in the airways, either because they are distal or paratracheal. The EMN creates an electromagnetic field around the chest of a patient undergoing FB, superimposes the field upon previously acquired three-dimensional CT images, and uses a microsensor to determine the

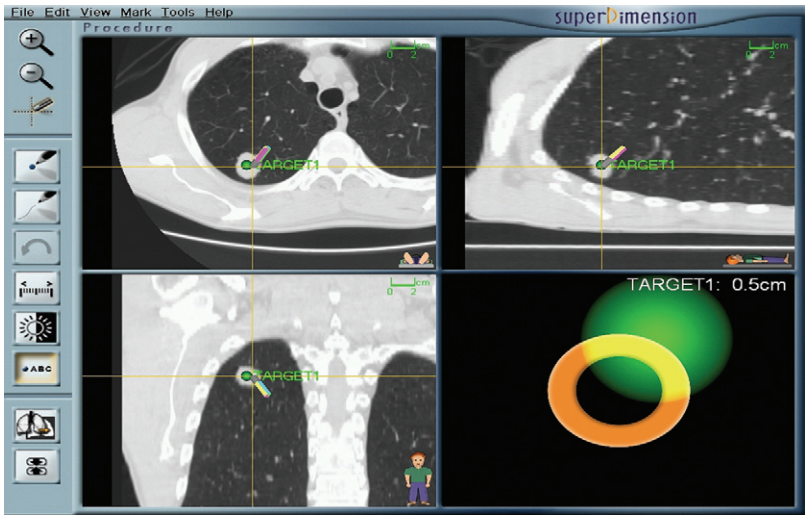

FIGURE 22-10 ■ Electromagnetic navigation monitor. Note: Location of the pulmonary nodule is depicted in three different views. Right lower quadrant image exhibits the position of the microsensor (*orange ring*) in relation to the virtual pulmonary nodule (*green circle*).

bronchoscopist's position within the endobronchial tree. EMN can then guide placement of endoscopic accessories to peripheral lung lesions or to mediastinal lymph nodes. In principle, the device is similar to the global positioning system used in automobiles and air planes.

The diagnostic yield of FB for peripheral lung lesions and solitary pulmonary nodules is limited and dependent upon lesion size and location.[142] Recent studies have shown that EMN increases this yield.[150–157] EMN is well-tolerated and has proved to be both safe and useful in localizing small or fluoroscopically invisible lung lesions with a sufficient level of accuracy (Fig. 22-10).

Autofluorescence Bronchoscopy

In the treatment of lung cancer, the best outcome is achieved if the lesion is discovered in the intraepithelial stage. However, intraepithelial neoplastic lesions are difficult to localize by conventional white-light bronchoscopy (WLB). Autofluorescence bronchoscopy (AFB) has been in use since 1988 as an aid to the diagnosis of bronchial precancerous lesions and early lung cancers.[158–163] In this method, airways are illuminated by blue light. Fluorescence emitted from the mucosal surface is partially quenched in areas of dysplasia, a result that can be enhanced by video signal processing. Normal areas are usually exhibited in a green color whereas the suspicious areas appear in a reddish to brown discoloration (Fig. 22-11). The lesions detected by AFB include squamous cell cancer and the "premalignant" dysplasias of the squamous epithelium.[164] AFB can also capture the endobronchial extent of tumor; thus it is helpful to decide the line of resection preoperatively or plan endobronchial therapies.

However, discrimination between cancerous/precancerous lesions and inflammation is not possible by endoscopic images alone and the histologic diagnosis is still necessary.[158] In a multicenter study, the combination of WLB and AFB had greater sensitivity (82.3%) for detecting dysplasia than WLB (57.9%) alone, although the benefit for detecting carcinoma in situ was not significant.[161] The low specificity of the technique, the lack of evidence for a decrease in disease-specific mortality, and the lack of cost analyses are some of the drawbacks of this technique.[164] Therefore, AFB is not yet considered a screening tool for lung cancer[161,164] (Fig. 22-12).

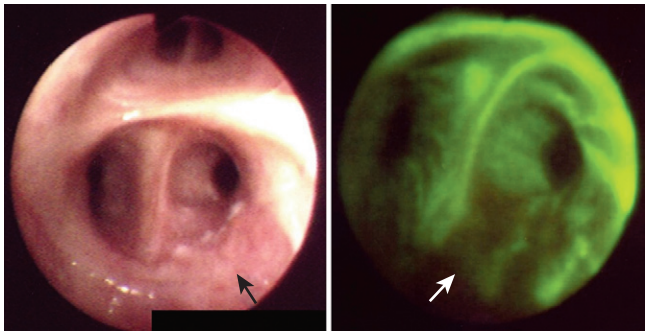

FIGURE 22-11 ■ Autofluorescence bronchoscopy: White-light image (*left*) versus autofluorescent image (*right*). A lesion that is poorly seen using white light (*black arrow, left*) becomes more evident under fluorescent light (*white arrow, right*). This brownish discoloration involving the posterior airway wall depicts an area suspicious for early lung cancer.

Narrow-Band Imaging

Visualizing the vascular pattern of the bronchial epithelial surface promises to advance the understanding of angiogenesis in the early phases of carcinogenesis of lung tissue and to advance the diagnosis of premalignant lesions. Narrow-band imaging (NBI) is a new, alternative light-wavelength capture system that can be used to detect the altered blood vessel morphology of bronchial dysplasia. Wavelengths of light in the visible spectrum (400–700 nm) are filtered to narrow the wavelength to bands in the blue and green spectrum (415 and 540 nm), coinciding with the peak absorption spectrum of oxyhemoglobin and thereby enhancing detection of blood

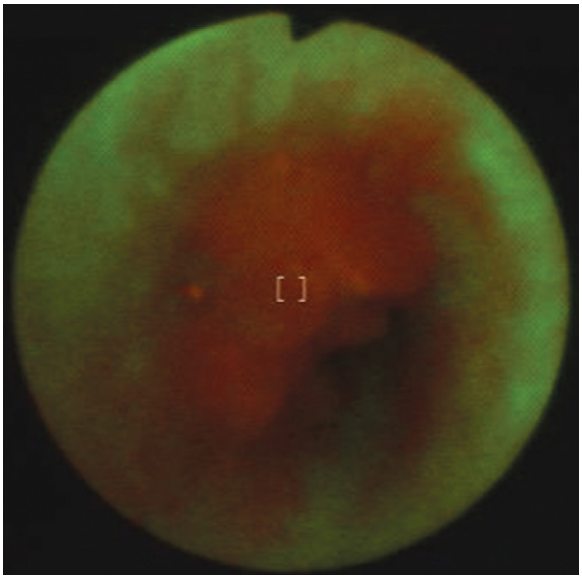

FIGURE 22-12 ■ False-positive autofluorescence bronchoscopy in patients with recurrent respiratory papillomatosis involving the trachea. All endobronchial biopsies from the suspicious areas were negative for malignancy.

TABLE 22-4. Indications for Therapeutic Flexible Bronchoscopy

Removal of central airway neoplasm (malignant/benign)
• Laser photoresection
• Endobronchial electrosurgery
• Argon plasma coagulation
• Brachytherapy
• Cryotherapy
• Photodynamic therapy
Dilation of stricture and stenosis: balloon bronchoplasty
Stent placement
Intralesional injection: cidofovir, mitomycin, steroid
Removal of foreign body, mucous plug, blood clot
Bronchoalveolar lavage for pulmonary alveolar proteinosis
Aspiration of cysts: mediastinal or bronchogenic
Drainage of lung abscess
Hemoptysis
Pulmonary toilet
Difficult endotracheal intubation
Percutaneous dilational tracheostomy
Pneumothorax/bronchopleural fistula (fibrin glue therapy)
Bronchoscopic volume reduction
Gene therapy

vessels. It may be helpful to detect severely dysplastic lesions; it is estimated that invasive carcinoma will develop in 40% to 83% of patients with severely dysplastic lesions.[165,166] NBI in combination with high-magnification bronchoscopy can be useful in characterizing capillary loop patterns of dysplastic airway lesions.[167] Also, NBI may be more specific than AFB for dysplasia when used as an adjunct to AFB to evaluate vascular patterns of autofluorescence-abnormal areas.[156] When NBI is used with WLB, detection of bronchial dysplasia is significantly improved compared with WLB alone. At the same time, NBI requires closer examination both as a stand-alone technology and in comparison with other imaging strategies including AFB in the setting of clinical trials.[168]

Because both AFB and NBI are "technologies in search of an indication," they remain largely research tools and should not be routinely performed outside well-designed clinical trials or special clinical circumstances.[164,168] In one study, high-magnification bronchovideoscopy combined with NBI was found useful in the detection of capillary blood vessels in angiogenic squamous dysplasia lesions at sites of abnormal fluorescence. This may enable the discrimination between angiogenic squamous dysplasia and other preinvasive bronchial lesions.[167]

THERAPEUTIC BRONCHOSCOPY

Even though FB is most often employed for diagnostic indications, its therapeutic spectrum has also expanded significantly since its initial inception (Table 22-4).[169] With the development of fiberoptic bronchoscopy, rigid bronchoscopy has become less popular. Nonetheless, rigid bronchoscopy remains an invaluable tool and should be considered for control of the compromised airway, massive hemoptysis, silicone stent placement, and removal of large foreign bodies, especially in the pediatric age group.[169] There are several therapeutic techniques with overlapping indications, with both advantages and disadvantages, for which the best uses may become clear in the future (Table 22-5).

Therapeutic applications of FB are discussed below.

Foreign Body Removal

Indications

Foreign body aspiration is one of the most common indications for therapeutic bronchoscopy. The diagnosis and removal of foreign bodies has long been performed using a rigid bronchoscope in children as well as in adults; however, in recent years, FB has reduced the need for rigid bronchoscopy, and a trained bronchoscopist can successfully confirm and remove a foreign body in a single sitting using an FB. Moreover, a flexible bronchoscope with a large suction channel may permit suctioning of small foreign bodies from distal airways and allow the retrieval of foreign bodies from deep in subsegmental bronchi.[170-174] In adults, foreign bodies are usually right-sided, but in children, this is not necessarily true owing to the equal size and angulations of the main bronchi. In children, aspiration usually results from their tendency to place objects in the mouth, and also from their use of incisive teeth that forcefully send the object to the back of the throat. Nuts account for the majority of aspirated foreign bodies among children. In adults, removal of foreign bodies was reported in fewer than 9 events out of 4500 bronchoscopies/yr (0.2%).

TABLE 22-5. Advantages and Disadvantages of Various Therapeutic Bronchoscopic Techniques

Treatment	Equipment/Technique	Result	Complications
Mechanical removal	Standard/GA/LA	Short-term, immediate	Bleeding
Electrosurgery	Standard, GA/LA, rigid and fiberscope	Immediate and superficial, very cheap	Endobronchial fire
Argon plasma coagulation	Special probes, GA/LA, fiberscope	Immediate and superficial, effective hemostasis, low cost	Damage to bronchoscope, gas embolism, no vaporization effect
Cryotherapy	Special applicators, GA or LA	Delayed effect, safe for the cartilage	Rare
Nd:YAG laser	Laser, mostly GA, or fiber through rigid	Immediate effect	Perforation, endobronchial fire
Photodynamic therapy	Dye and diode laser, LA	Delayed effect, safe for the cartilage	Skin photosensitivity, secondary necrosis, perforation risk
Brachytherapy	High-dose therapy requires remote control after loading, LA	Delayed effect	Radiation bronchitis, stenosis, fistula

GA, general anesthesia; LA, local anesthesia; Nd:YAG, neodymium:yttrium aluminum garnet.

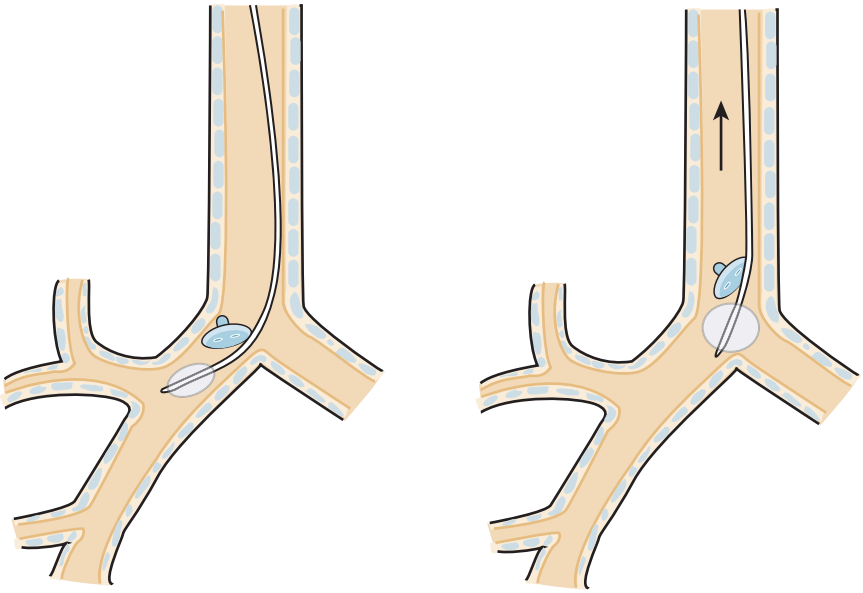

FIGURE 22-13 ■ Schematic representation of the use of a balloon catheter for dislodging a foreign body by a retrograde pull. (Courtesy of Dr. Eric Folch.)

Risk factors for aspiration in adults include alcohol intoxication, sedative and hypnotic drugs, poor dentition, senility, mental retardation, seizure, trauma with loss of consciousness, swallowing impairment, parkinsonism, and general anesthesia.[169,170]

Contraindications, Procedure, Results, and Complications

All contraindications that apply to the routine FB apply to the removal of a foreign body. Lack of experience and lack of availability of all necessary endobronchial accessories are the more important contraindications. Removal of a foreign body using FB should be attempted only by or under the supervision of an expert bronchologist. Acute respiratory distress caused by the foreign body indicates need for rigid bronchoscopy. There are not enough data to support use of FB in infants with foreign body aspiration.[170] Published reports indicate that FB is successful in 87% of patients with foreign body aspiration.[172,173,175–180] FB can thus be used as an alternative to rigid bronchoscopy avoiding the need for general anesthesia and its related cost and complications.[170]

Foreign body removal using FB is carried out in stages: first, dislodging the foreign body, then, grasping or securing the object, and finally, removing it along with the flexible bronchoscope as single unit. A balloon catheter is usually used to dislodge the foreign body from the distal airways and to pull it into the proximal airways (Fig. 22-13). Once the object is grasped and secured with an appropriate accessory, it is kept very close to the tip of the flexible bronchoscope to reduce danger of losing it in the subglottic area or at the level of vocal cords. A variety of ancillary accessories (forceps, grasping claws, snares, baskets [dormia, fishnet], and magnets) are available for foreign body extraction.[169] Once the object is in

the trachea, the patient can also be asked to cough to expel the foreign body. Lasers and cryoprobes can also be used if a significant amount of granulation tissue is present. A cryoprobe passed through the flexible bronchoscope can be used to retrieve the foreign body by placing the tip in contact with the object until the point of contact is frozen, leading to adhesion (cryoadhesion). This allows for en bloc removal of the object with the cryoprobe and the flexible bronchoscope. This approach is especially useful for the removal of blood clots, mucous plugs, friable organic material, and small inorganic objects. Occasionally, laser instruments can assist in the removal of large objects by breaking them up into smaller pieces. Self-expanding metallic stents embedded in the bronchial mucosa can be extracted by fracturing the wires using laser energy.[169]

Serious complications can accompany removal of a foreign body, including central airway obstruction, airway wall perforation, or flooding of the airways with secretions or blood. Other less serious complications are hypoxia, bronchospasm, arrhythmias, laryngeal edema, bacteremia, fever, migration of the object to distal airways, object fragmentation, and loss of the object at the glottis during removal efforts. The key for the success in foreign body removal is airway protection, an experienced operator, adequate equipment, and availability of a rigid bronchoscope for an emergent situation.[181]

Electrosurgery

Endobronchial electrosurgery (ES) is the application of heat produced by high-frequency electrical current to treat tumor tissue using special accessories such as coagulation probes, knives, and snares introduced through a bronchoscope. A small probe functions as an active electrode that focuses heat to a tiny spot at the point of contact, leading to tissue coagulation or vaporization. The electrical current can also cut or blend cutting and coagulation. The degree of tissue destruction depends on the power used, duration of contact, surface area of contact, and water content of the tissue.

To avoid endobronchial ignition, the fractional concentration of oxygen in inspired gas (FIO_2) should be kept below 40%. Insulated bronchoscopes, compatible with ES, are used to prevent leakage of electrical current, avoiding burns or electrical shock to the patient and the bronchoscopist.[182,183]

Indications and Contraindications

ES is used for immediate debulking of intraluminal tumor and has a curative potential in patients with occult carcinomas, benign tumors, or polypoid lesions. Coagulation is achieved by gently touching the tumor tissue and applying 20 to 40W until blanching of the mucosa becomes apparent. The tumor area should be kept free of blood or mucus by continuous suctioning or the electrical current will be conveyed through these liquids. The coagulated tissue can be removed using biopsy forceps. The process can be repeated until the desired lumen size is achieved. In cases of large tumor, ES can be used to coagulate the tumor base to devascularize the lesion and reduce the risk for bleeding while the tumor tissue is débrided mechanically. The procedure is contraindicated in patients with pacemakers and defibrillators to avoid cardiac consequences.[182,183]

Results and Complications

In vivo studies have shown that a monopolar flexible electrocautery probe produces predictable yet superficial coagulative necrosis by blanching the mucosa with relative sparing of cartilage. After a relatively short learning period, the bronchoscopist can create a shallow necrosis of 2 to 3 mm, avoiding damage to the tracheobronchial wall. Moreover, electrocautery is a cost-effective bronchoscopic intervention.[182,184] Coulter and Mehta[185] showed that a high success rate (89%) could be achieved by using ES under local anesthesia in a selected group of the patients with small, polypoid endobronchial lesions. Outcomes of ES in both malignant and benign diseases have been promising.[186–194] Although complications are rare in experienced hands, the most common ones are bleeding (2%–5%), endobronchial ignition while using high FIO_2, and electrical shock to the operator when inappropriate grounding is used. Although airway perforation has not been reported, it is a tangible risk.

Argon Plasma Coagulation

Argon plasma coagulation (APC) uses ionized argon gas to conduct electrical current from the probe to the tissue, transferring heat in a homogeneous but superficial way to the conductive surface lying closest to the probe. The argon gas spreads out into the airway lumen, and the portion that is activated and ionized becomes the plasma jet. A spark through the plasma jet desiccates tissues to a specific depth. Because positively charged argon gas automatically flows toward the negatively charged bleeding tissue, treatment can be directed in an axial, a radial, or a retrograde fashion (Fig. 22-14). As the tissue gets desiccated, it offers more resistance to the electrical current. Argon plasma automatically moves toward untreated areas with lesser degree of tissue resistance, thus producing little vaporization and limiting the depth of penetration.[183,184,195]

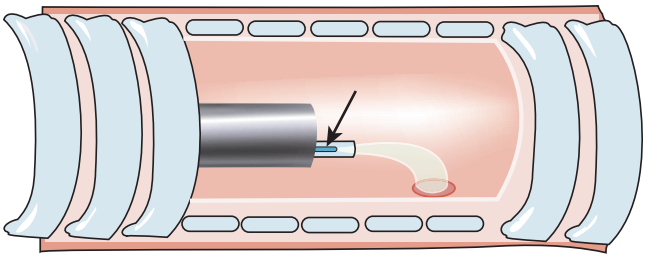

FIGURE 22-14 ■ Schematic presentation of argon plasma coagulation. *Arrow* shows the tungsten carbide electrode. Positively charged argon gas automatically flows radially to the negatively charged bleeding tissue. (Courtesy of Dr. Eric Folch.)

Indications and Contraindications

APC is frequently used for palliation of malignant obstruction as part of multimodality treatment and also in benign conditions such as hemorrhage and treatment of excess granulation tissue (including stent-related granuloma), papillomatosis, and postinfectious airway stenosis.[182-184] The most important advantages of this technique are its ability to treat lesions at sharp angles from the tip of the electrode and to treat lesions in close proximity to airway stents, and its superiority in achieving hemostasis. Its major limitation is the depth of penetration of less than 3 mm, thus limiting its use in large bulky tumors obstructing the airways. Conversely, APC offers good protection against perforation of the airways. Its only absolute contraindication is the presence a pacemaker susceptible to electrical interference.[195]

Results and Complications

APC provides effective hemostasis, self-limited depth of penetration, no damage to uncovered stents, and minimal smoke. In properly selected cases, it provides symptomatic relief in almost 90% of the patients. It is also portable, less expensive than laser, and easy to use with a flexible bronchoscope. The potential complications include gas embolism with argon, bleeding, endobronchial ignition with possible damage to the bronchoscope, postprocedure stenosis, and injury to deeper structures, as previously described for electrocautery (Fig. 22-15). The need for an expensive, disposable probe is also a drawback associated with the procedure. FIO_2 should be kept below 40% during APC. The observed mortality and overall complication rate are 0.4% and 3.7% of cases, respectively.[195,196]

Cryotherapy

Cryotherapy causes freezing of the tissue, leading to extracellular ice crystal formation, hypertonicity, and withdrawal of the intracellular water to cause tissue damage and necrosis. It employs gas decompression or the "Joule-Thompson principle" to cause thermal tissue destruction by direct contact. The three cooling agents (cryogen) available are liquid nitrogen, nitrous oxide, and carbon dioxide (N_2, N_2O, and CO_2). The cryoprobe can be used through rigid or flexible bronchoscopes. When the cryogen is released from very high pressure to the normal atmospheric pressure, at the tip of the cryoprobe, it expands. This expansion lowers its temperature to between –80°C to –160°C at the tip of the probe. The probe is placed in contact with the tissue being treated, reaching tissue temperature as low as –80°C. The temperature increases approximately 10°C per mm from the tip ("warming effect"), so the effective killing zone is approximately 5 to 8 mm. The cryoprobe is activated with a foot pedal and is advanced approximately 5 mm distal from the tip of the flexible bronchoscope. Repeated cycles of freezing and thawing are applied to the endobronchial tissue in a contiguous fashion to cover the entire surface of the lesion. Tissue necrosis and sloughing takes place within 24 to 48 hours, and a "cleanup" bronchoscopy is usually required to remove necrotic tissue. This delayed tissue effect is one of the shortcomings of cryotherapy.[197,198]

FIGURE 22-15 ■ Damage to the tip of the bronchoscope caused during argon plasma coagulation. Note the charred tip along with the frayed rubber sheath. (Image courtesy of Dr. Praveen Mathur.)

Indications and Contraindications

Cryotherapy has been used for the destruction of endobronchial lesions when immediate results are not mandatory and "hot" therapies are contraindicated; for example, cryotherapy is ideal for treating stent-related granulomas when the stent is made of a flammable material. The tissue effects depend upon the length and the duration of the freezing-thawing cycles, temperature attained, and type of the tissue. Skin, nerves, endothelium, granulation tissue, and mucous membranes are sensitive to cryotherapy, and connective and fibrous tissues, nerve sheath, cartilage, and fatty tissue are cryoresistant. Proper selection of the cryosensitive tumor is essential for a successful outcome.[184,197,198] Cryotherapy has been shown to have beneficial effect in conjunction with radiation therapy. Under special circumstances, cryotherapy can be used with excellent results in removing organic foreign objects, blood clots, and mucus plugs by "cryoadhesion," as described earlier. Advantages of cryotherapy include its ability to be used in a high oxygen environment and under local anesthesia and its limited bronchial wall damage.[197,198] Cryotherapy may enhance the effect of chemotherapy in a mouse lung cancer model.[199,199a]

Results and Complications

In most cases, cryotherapy offers a safe and inexpensive alternative for ablation of endobronchial tumor. The most common side effects are airway sloughing requiring a repeat bronchoscopy and a postprocedure fever. On a rare occasion, cryoadhesion to a necrotic tumor can cause excessive damage to the airway wall. Moderate bleeding, mediastinitis, and fistula formation following cryotherapy have also been encountered in few cases.[197,198]

Laser Photoresection

Laser light has three unique characteristics—monochromaticity, coherence, and collimation—that permit a controlled delivery of a well-defined energy. Laser light causes thermal, photodynamic, and electromagnetic changes in the living tissue. Although many types of laser systems exist, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser with an invisible infrared beam exhibits a number of advantages for bronchoscopic use. It can deliver up to 100 W of output in the beam through a flexible quartz fiber. At lower watts, the Nd:YAG laser photocoagulates, whereas at higher settings, it vaporizes tissue. Use of energy higher than 40 W is seldom needed. It is also a durable and reliable laser with minimal maintenance. Another version, neodymium:yttrium-aluminum-perovskite (Nd:YAP), achieves particularly good coagulation owing to its high absorption rate within the tissue (20 times > Nd:YAG).[184,200,201]

Indications

The main indications of laser photoresection (LPR) are relief of central airway obstruction from exophytic obstructive neoplasms and from tracheal stenosis. An ideal lesion for the laser LPR is an endobronchial tumor, less than 4 cm in length, which arises from a single wall of a central airway, has a visible distal lumen, and distal lung collapse of less than 4 to 6 weeks[169,200] (Table 22-6).

Contraindications

Lesions not amenable to LPR are extrinsic or submucosal, primarily involving lobar or segmental bronchi and contiguous with the esophagus. Other contraindications to LPR include abnormal coagulation profile, unstable cardiovascular status, and a high oxygen requirement.[184]

Results and Complications

LPR can restore airway patency with immediate symptomatic improvement in 93% of cases[200–202] (Fig. 22-16). This technique palliates symptoms of cough, dyspnea, and hemoptysis along with documented benefits in radiographic, spirometric, and quality of life parameters. Studies have shown a small survival benefit when emergent LPR is compared with emergent radiotherapy. LPR is associated with the following complications (range, 0%–2.2%): exsanguination (2%), endobronchial ignition, pneumothorax or barotrauma, bronchopleural or bronchoesophageal fistula, and hypoxemia.[201,203] Extensive knowledge of the anatomy of the tracheobronchial tree is mandatory prior to performing the procedure. Accumulation of blood and secretions can lead to rapid desaturation. Tracheobronchial tree perforation can be fatal owing to its close proximity with the great vessels. While performing the procedure, one must take precautions to avoid fire, which can severely damage the airways, bronchoscope, suction catheter, or the endotracheal tube. Care should be taken to avoid ocular (mainly retinal) or skin damage by the direct laser beam.[169,201,203]

Photodynamic Therapy

Photodynamic therapy (PDT) is a three-step process that involves the intravenous administration of a photosensitizing agent known as dihematoporphyrin ether/ester (DHE; Photofrin II), exposure to a laser light of a specific wavelength, and finally, a cleanup bronchoscopy.[169] After 48 hours, the DHE is preferentially retained by tumor cells and cleared from most healthy tissues; the tumor is then exposed to a particular laser light introduced via a flexible bronchoscope. Exposure of DHE to light of a proper wavelength results in tumor destruction caused by a photochemical reaction including generation of oxygen radical species, direct damage to cells and organelles, indirect ischemic effects, apoptosis, and

TABLE 22-6. Factors Influencing Outcome of Nd:YAG Laser Photoresection

Factors	Favorable	Unfavorable
Location	Trachea, main bronchi	Lobar and segmental bronchi
Type of lesion	Endobronchial	Extrinsic
Appearance	Polypoid, exophytic, pedunculated	Submucosal
Extent of involvement	Localized (1 wall)	Extensive (>1 wall)
Length of lesion	<4 cm	>4 cm
Distal lumen	Visible	Not visible
Duration of collapse	<4–6 wk	>4–6 wk
Clinical status		
Hemodynamics	Stable	Unstable
Oxygen requirement	<0.4 FIO_2	>0.4 FIO_2
Coagulation profile	Normal	Abnormal
Pulmonary vascular supply	Intact	Compromised

inflammatory effects. Cleanup bronchoscopy is often necessary to avoid complications such as postobstructive pneumonia or respiratory distress or failure.[169,184,204]

Indications and Contraindications

PDT is indicated for the palliation of advanced obstructing cancers of the tracheobronchial tree and appears to be effective for superficial as well as submucosal disease. Curative treatment for asymptomatic multiple and early lung cancers is another indication for PDT. Occasionally, it is also used preoperatively to reduce the extent of surgical resection by rendering the line of resection free of the disease. In high-risk surgical patients or in those who refuse surgery, PDT may represent an alternative treatment as long as the malignancy satisfies the following criteria: (1) radiographically occult, (2) superficial, less than 3 cm^2 in surface area and 1 mm in depth, and (3) squamous cell carcinoma.

Owing to its delayed effect and possible swelling of the lesion following the therapy, tracheal-carinal lesions and lesions in post-pneumonectomy patients are considered contraindications. PDT is contraindicated if the tumor invades vascular structures or if there is a history of porphyria and/or porphyrin hypersensitivity.[169,204]

Results and Complications

PDT has been used to treat advanced lung cancer,[205] to treat multiple malignancies alone or in combination with surgery,[206] and to pretreat in order to reduce the extent of the surgical resection.[207] In superficial tumors, a complete remission rate between 64% to 98% with PDT has been described.[205,206,208]

PDT has a slow onset of action, requires frequent cleanup bronchoscopies, and mandates that the patient avoid sunlight for 4 to 6 weeks.[209] The most common complications include skin photosensitivity, up to 4 to 6 weeks after the procedure; local airway edema; strictures; hemorrhage; and fistula formation. The major limitation of PDT, as with brachytherapy and cryotherapy, is the delayed response to therapy.[169,184,204]

Brachytherapy

Endobronchial brachytherapy ("brachy" meaning "short"; short-distance radiotherapy) requires implantation or insertion of a radioactive source adjacent to the lesion in a patient's airway. A polyethylene catheter is placed adjacent to the lesion via FB and its position verified by radiography (or fluoroscopy). The catheter is then loaded with the radioactive source, usually radium in capsules for low dose (1–2 gray/hr) or iridium for high-dose radiotherapy (10 gray/hr) reaching the total dose of 500 to 4000 gray directly to the lesion.[210,211]

Indications

Patients with unresectable primary carcinoma of the lung, recurrent carcinoma of the lung, or cancers metastatic to the airway are potential candidates for brachytherapy. The lesion can be either extrinsic or intrinsic to the airway.[210] It may also be benign obstruction such as granulation tissue.[211] The main goal of brachytherapy is palliation of symptoms of airway obstruction caused by tumor. Brachytherapy can also be used as an adjunct to external beam radiotherapy for curative treatment of primary non–small cell tumors. Occasionally, brachytherapy has been used as a curative treatment of a residual tumor following surgery.[210]

Contraindications

A few absolute contraindications for endobronchial brachytherapy exist, such as known fistulas involving the airways. To avoid life-threatening complications, one should exclude tumors directly involving the major arteries and mediastinal structures. CT, magnetic resonance imaging, or digital subtraction angiography of the chest should be performed before instituting endobronchial therapy in patients suspected to have mediastinal extension of tumor. Patients with endotracheal carcinoma causing high-grade obstruction should be treated with Nd:YAG laser and possible placement of stent prior to brachytherapy because of the potential postradiation edema and total airway obstruction.[210]

Results and Complications

The studies that combined external radiation with brachytherapy showed that even if quick airway response was gained, there was no survival benefit[210]; thus, its role is mainly for palliation. High-dose brachytherapy has been used safely for granulation tissue caused by metallic stents[211] and may be more effective when used prophylactically than therapeutically.

Complications include respiratory compromise, massive hemoptysis, fistula formation, radiation bronchitis, airway stenosis, and pulmonary artery erosion. The combined rate of massive hemoptysis and airway-mediastinal fistula formation ranges from 0% to 42%. Risk of late exsanguinations has been found to be high in patients receiving brachytherapy to the right upper lobe, anterior segment area, probably owing to its close proximity to the pulmonary artery.[210,211]

Brachytherapy may be an effective palliative treatment for endobronchial malignancies, but further investigations are necessary to determine the optimal dose and its efficacy in bronchogenic carcinoma alone and in combination with either external beam radiation therapy, surgery, or other endobronchial therapeutics.

Stent Placement

Stents are devices used for the internal splinting of luminal structures.[184] The first stents that were used in the trachea were the T-tubes developed by Montgomery. Though they require a tracheostomy for their placement, these silicone stents are still widely used by otolaryngologists and are considered to be the safest approach in cases with high tracheal stenoses. Westaby and colleagues modified this stent and designed a T-Y

prosthesis, which enabled splinting of the carinal region. Using the same tissue-friendly silicone material, Dumon developed the first stents that could be inserted through a bronchoscope without a tracheostomy. Over the years, several other polymer stents have been developed and commercialized. However, all polymer prostheses require use of a rigid bronchoscope and general anesthesia for their deployment.[184]

A family of stents have been developed that can be inserted using FB. These stents are made from metal, such as steel and nitinol (nickel-titanium), and are the direct offspring of its vascular counterpart. There seem to be many advantages to metal construction over the polymer prostheses; metal stents have thinner walls and are thus easier to place using FB under moderate sedation and local anesthesia as an outpatient procedure.

They are available as self-expanding or balloon expandable versions and as covered or uncovered versions. Covered stents are designed mainly to prevent tumor growth or the prosthesis-related granulation tissue invading the airways (Fig. 22-17A). In recent years, fully covered stents have also been introduced to the armamentarium of the therapeutic bronchoscopist (see Fig. 22-17B).[184]

Indications and Contraindications

Indications for the placement of the SEMS include (1) counteracting extrinsic compression from tumors or lymph nodes; (2) stabilizing airway patency after endoscopic removal of intraluminally growing cancer; and (3) sealing malignant fistulas (e.g., stump dehiscences) or fistulas between the trachea and esophagus.[184,212] The U.S. Food and Drug Administration has issued a warning against use of metallic stents in patients with benign conditions until all therapeutic options, including use of silicone stent and surgery, have been explored.

Results and Complications

Stents can be used temporarily in a multimodality concept of cancer care and as a last palliative measure. The efficacy regarding functional improvement and quality of life has been demonstrated.[184]

Retained secretions, bacterial colonization of stent material, migration, stent fractures, and development of granulation tissue are the frequent complications. Metallic stents have a significantly lower rate of migration than silicone stents. Granulation tissue formation especially at either end of the stents, even months after their insertion, can significantly obstruct the internal lumen; the obstruction can ultimately be worse than the primary disease. Removal of the granulation tissue can be very difficult and require use of laser photoresection, APC, or cryotherapy (in the case of covered stents). On occasion, a granulated stent may need to be permanently removed using rigid bronchoscopy or by surgical methods. It is agreed by all experts that there is currently no ideal endobronchial stent. Newer materials, a better understanding of airway biomechanics, and other approaches, such as bioabsorbable stents, may lead to improvements in stent technology.[169,184,212]

Bronchial Thermoplasty

Recently, Cox and associates[213,214] reported their experience with bronchial thermoplasty in asthmatic patients. This novel technique involves treatment of airways with a specially designed, four-wired, thermoplasty probe that ablates airway smooth muscle. The thermal effect appears to remain confined to the airway wall and the immediate peribronchial area without associated fibrosis. The procedure seems to be well tolerated and patients demonstrate an improvement in airway hyperresponsiveness, quality of life and symptom-free days, and peak flow measurements. Even in patients with severe asthma, thermoplasty has been reported to improve quality of life and to decrease severe exacerbations, emergency department visits and days missed from work for up to 12 months.[215] At this early stage, the procedure remains an intriguing subject for research.

KEY POINTS

- Since its introduction in 1966, FB has replaced rigid bronchoscopy for most diagnostic and therapeutic indications; rigid bronchoscopy has a continued role for a few indications such as massive hemoptysis and removal of large foreign bodies, especially in the pediatric population.
- BAL, which samples the distal air spaces, can diagnose several diseases that involve the air spaces, including opportunistic infections, bronchoalveolar carcinoma, and pulmonary alveolar proteinosis.
- TBB has value in the diagnosis of infiltrative diffuse pulmonary diseases; with the advent of novel guidance techniques, such as EMN, TBB may become accurate at sampling distal focal lesions.
- TBNA has a role in sampling the mediastinal nodes to assist in staging of lung cancer and in making diagnoses of nodal involvement with sarcoidosis or tuberculosis.
- New developments in bronchoscopy, including confocal bronchoscopy, AFB, and NBI bronchoscopy, may prove valuable in evaluating early lesions of the large airways.
- Therapeutic bronchoscopy with the standard flexible bronchoscope has long been used for removal of foreign bodies and stent placement; now, with many new technologies, bronchoscopy can be used for the relief of large airway obstruction.
- Each therapeutic bronchoscopic technique has overlapping indications and its own advantages and disadvantages; it is hoped that, with ongoing research, the best use of these techniques will be determined (see Table 22-5).

DIFFERENCES BETWEEN PLEUROSCOPY AND VIDEO-ASSISTED THORACIC SURGERY (SURGICAL THORACOSCOPY)

INTRODUCTION

Biopsy procedures play an essential role in the diagnostic evaluation of patients with respiratory diseases. Most of the basic techniques we use today were mainly developed and refined during the 20th century. Recently, significant advances in endoscopic technology have provided sophisticated endoscopic instruments and endoscopic telescopes with extremely high optical resolution and small diameters. In addition, developments in anesthesiology offer a wide range of alternatives, from procedures performed under local anesthesia to selective double-lumen intubation under general anesthesia.

As with all medical procedures, the risk-benefit ratio of more invasive methods has to be considered for each individual patient, weighing the risk of morbidity and mortality against the benefit of obtaining an early diagnosis to guide correct therapy. Usually, the more invasive procedures are used if simpler, less invasive methods have failed, if the latter are not very promising for obtaining a reliable diagnosis, or if additional therapeutic options can be combined with the diagnostic approach.

This chapter reviews these more invasive procedures, such as pleuroscopy and medical thoracoscopy. Other biopsy methods, such as bronchoscopic biopsies, thoracentesis, needle biopsy of lung lesions, and closed-needle biopsy of the pleura, are described in other chapters.

PLEUROSCOPY (MEDICAL THORACOSCOPY)

Historical Development

Thoracoscopy was introduced together with laparoscopy in 1910 by Hans-Christian Jacobaeus, who at that time worked as an internist in Stockholm, Sweden. He published his first experiences in a paper entitled "On the possibility to use cystoscopy in the examination of serous cavities."[1] It was recently reported that, as early as 1866, F.-R. Cruise in Ireland had possibly been the first to perform a thoracoscopy, examining the pleural space of a girl with empyema through a pleurocutaneous fistula that had developed after spontaneous pleural drainage.[2] Jacobaeus, in his pioneering paper,[1] mentions two cases of pleuritis exsudativa (tuberculous pleurisy), in which he studied the pleural surfaces after replacing the fluid with air. Although not able to get a clear impression of the pleural changes, he was confident that the method would be successful in the future and might eventually yield prognostic information. Jacobaeus[3] himself initiated the therapeutic application of thoracoscopy for lysis

of pleural adhesions by means of thoracocautery to facilitate pneumothorax treatment of tuberculosis ("Jacobaeus operation"). During the ensuing 40 years, his technique of using a single entry site for the thoracoscope and another for the electrocautery device under local anesthesia was applied worldwide for this specific therapeutic purpose, until antibiotic therapy of tuberculosis was introduced and made the procedure obsolete.[4] Between 1950 and 1960, a generation of chest physicians familiar with the therapeutic application of thoracoscopy began to use the technique for biopsy diagnosis of pleural and even pulmonary disease.[5] Today, pleuroscopy is considered as an integral part of interventional pulmonology.[6]

At the same time, the excellent results of laparoscopic surgery and the tremendous advances in endoscopic technology stimulated many thoracic surgeons almost simultaneously in Europe and the United States to develop minimally invasive techniques, which were termed *therapeutic* or *surgical thoracoscopy*, as well as video-controlled or video-thoracoscopic surgery, or video-assisted thoracic surgery (VATS).[7–10]

To clarify the difference between the two methods, the term *medical thoracoscopy* was introduced.[11] This is performed using the Jacobaeus technique under local anesthesia or conscious sedation, via a single or two sites of entry, by the pulmonary physician in an endoscopy suite using nondisposable rigid instruments.[12] Its main indications are the diagnosis and treatment of recurrent pleural exudative effusions and the treatment of spontaneous pneumothorax. However, because the term *thoracoscopy* is used for both the medical and the surgical procedures, a degree of uncertainty has arisen, which may lead to unnecessary surgical interventions for what are, in fact, medical indications. To avoid confusion in the future, it has been suggested that the old term *pleuroscopy*, as used in 1923[4] and as proposed by Weissberg for the sake of clarity,[4] should be favored over *medical thoracoscopy*.

Finally, in some countries, interventional pulmonologists have broadened their field of expertise to include more elaborate interventions (e.g., sympathectomy, splanchnicectomy, treatment of empyema)[13–15] and to perform thoracoscopy in the operating theater, under total intravenous anaesthesia and spontaneous ventilation (with a laryngeal mask or simple endotracheal tube protecting the airway) or mechanical ventilation. Hence, one can consider "thoracoscopy" to encompass a spectrum of interventions from "simple pleuroscopy," performed under local anesthesia outside the operating theater, to "thoracoscopy," performed by experienced pulmonologists in an operating theater, to "video-assisted thoracic surgery," performed by thoracic surgeons in the operating theater.

In Europe, pleuroscopy/medical thoracoscopy (P/MT) is part of the training program of pulmonary medicine,[16] and it is becoming more popular in the United States. According to a national survey in 1994, pleuroscopy was used frequently by 5% of all pulmonary physicians.[17] Although newer data are not yet available, the interest in the technique seems to be increasing.[18] However, training is lagging: in an American College of Chest Physicians (ACCP) survey of U.S. pulmonary/critical care fellowship programs in 2002/2003, only 12% of the directors stated that P/MT was offered in their programs.[19] In the United Kingdom, where medical thoracoscopy has been underutilized compared with the rest of Europe, there is also growing interest.[20,21] Meanwhile, the technique has been introduced successfully in many Asian countries and in other parts of the world, particularly with the introduction of the semirigid (semiflexible) pleuroscope.[22–24]

Techniques

Pleuroscopy is an invasive technique that should be used to obtain a diagnosis when other, simpler methods are nondiagnostic (in case of pleural exudates) or to achieve pleurodesis (in case of recurrent pleural effusion or pneumothorax).[25] As with all technical procedures, there is a learning curve before full competence is achieved.[26,27] Appropriate training is therefore mandatory.[12,27] The technique is actually very similar to chest tube insertion by means of a trocar, the difference being that, with pleuroscopy, the pleural cavity can be visualized and biopsies can be taken from all areas of the pleural cavity, including the chest wall, diaphragm, mediastinum, and lung under direct visual control. When indicated, talc poudrage can be performed. In general, pleuroscopy is easier to learn than flexible bronchoscopy if sufficient expertise in thoracentesis and chest tube placement has already been gained.[12]

There are two different techniques of diagnostic and therapeutic pleuroscopy, as performed by the pulmonary physician.[12,28] In the first method, as first described by Jacobaeus for diagnostic purposes, a single entry site is usually produced with a 7- or 9-mm trocar for a thoracoscope with a working channel for accessory instruments and optical biopsy forceps; for this technique, local anesthesia is usually employed.[5] This approach can be modified for use of a semirigid pleuroscope.[22–24] In the other technique, as used by Jacobaeus for lysis of adhesions, two entry sites are used: one with a 7-mm trocar for the examination telescope and the other with a 5-mm trocar for accessory instruments, including the biopsy forceps. For this technique, neuroleptic or general anesthesia is preferred.[28]

Equipment

Rigid instruments are still in use, as they were from the beginning. Compared with the rigid thoracoscopes, flexible bronchoscopes or other flexible endoscopes have several disadvantages, mainly less adequate orientation within the pleural cavity and small and frequently inadequate biopsy specimens. A recently modified semirigid pleuroscope with a flexible tip has become an acceptable alternative.[22–24] As mentioned, the single-entry-site technique is usually performed via a 7- or 9-mm diameter trocar and a cannula with valve. Optical devices exist with various fields of view (0, 30, and 90 degrees) (Fig. 23-1). Trocars are also available with diameters of 5 and 3.75 mm for performing thoracoscopy in children. In

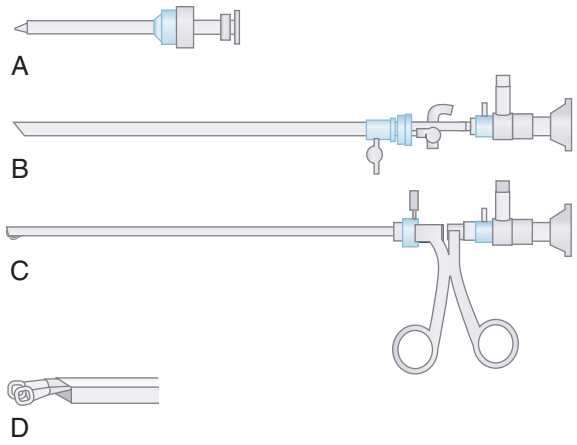

FIGURE 23-1 ■ Instruments for pleuroscopy (medical thoracoscopy). **A,** Trocar and cannula with valve. **B,** Single-incision thoracoscope (9 mm diameter). **C,** Biopsy forceps with straight optics. **D,** Magnified view of optical device and forceps in the thoracoscope shaft ready for biopsy. (A–D, Redrawn from Loddenkemper R: Thoracoscopy—State of the art. Eur Respir J 11:213–221, 1998.)

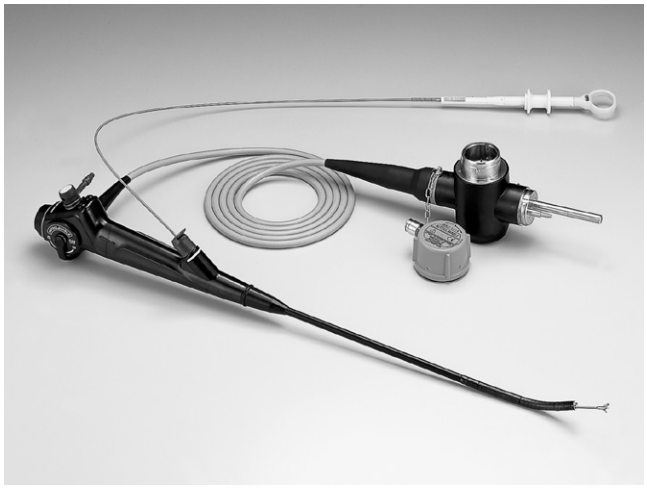

FIGURE 23-2 ■ Semirigid (semiflexible) pleuroscope with biopsy forceps.

infants, instruments similar to those used in rigid bronchoscopy are employed. Biopsy forceps with straight viewing as well as accessory instruments such as puncture needle, cautery electrode, probe, combined suction and cautery cannula with valves, and various biopsy forceps and scissors are available. For talc pleurodesis, a talc atomizer is used.[28]

The two-entry-site technique uses a 7-mm trocar for the first site of entry for appropriate telescopes and forceps and similar accessory instruments. For the second site of entry, a 5-mm trocar is used for insertion of instruments designed for its smaller bore, including a loop for dividing adhesions and a double-lumen insufflator.[28]

As stated earlier, a semirigid (semiflexible) pleuroscope was developed recently.[22–24] The design, including the handle, is similar to that of a standard flexible bronchoscope; however, the proximal 22 cm is stiff and the distal 5 cm is bendable with an angulation of 160 and 130 degrees (Fig. 23-2). The outer diameter of the shaft is 7 mm and a working channel of a diameter of 2.8 mm allows the use of standard instruments available for flexible bronchoscopy. The semirigid pleuroscope has several advantages: The skills involved in operating the instrument are already familiar to the practicing bronchoscopist. Because the shaft is rigid, it can be moved like the rigid thoracoscope without losing the orientation, and it is compatible with the existing video processors and light sources. Its disadvantages compared with rigid thoracoscopic instruments are the smaller biopsy specimens, although its diagnostic yield in pleural disease has been shown to be comparable with that of the conventional rigid thoracoscope.[24] Its flexible tip allows very homogeneous distribution of talc on all pleural surfaces.

The procedure suite should be equipped with monopolar and, if possible, bipolar electrocoagulation as well as equipment for resuscitation and assisted ventilation, electrocardiography, and blood pressure monitoring, and a defibrillator, as well as an oxygen source and vacuum generators.[5,28]

Pleuroscopy can be performed in the operating room or in an environment dedicated to invasive procedures.[11,12,23] The personnel required to perform pleuroscopy include an endoscopy nurse (or an endoscopy assistant) to assist with the instrumentation, an additional assistant outside the sterile field to bring necessary equipment, and the physician performing the pleuroscopy.[27] Ideally, an additional person sits at the patient's head and monitors his or her overall condition. In an emergency, pleuroscopy can be performed with only a physician and a nurse, but this is less efficient and prolongs the procedure.[5]

Indications

Pleuroscopy today is primarily a diagnostic procedure, but it can also be applied for therapeutic purposes (Table 23-1).[11,12,15] Pleuroscopy is mainly used for diagnosis of exudates of unknown etiology, for staging of diffuse malignant mesothelioma or lung cancer, and for treatment by talc pleurodesis of malignant or other recurrent effusions.[29,30] Pleuroscopy is also useful for evaluation and possible treatment of spontaneous pneumothorax and empyema.[11] For those familiar with the technique, pleuroscopy is also indicated for diagnostic biopsies from the diaphragm, lung, mediastinum, and pericardium and for more elaborate procedures.[13–15] As mentioned earlier, there is an overlap of indications between pleuroscopy and VATS (see later discussion and Table 23-1). In addition, pleuroscopy offers a remarkable tool for research as a "gold standard" in the study of pleural effusions.

The diagnosis of pleural effusions is the main and oldest indication for pleuroscopy, as described by

TABLE 23-1. Indications for Pleuroscopy versus Surgical Thoracoscopy (VATS)

Pleuroscopy	Pleuroscopy or VATS (Gray Area)	VATS
Pleural effusions • Pleural effusions of unknown etiology • Staging of lung cancer • Staging of diffuse malignant mesothelioma • Pleurodesis by talc poudrage	Spontaneous pneumothorax • Staging • Pleurodesis by talc poudrage • Decortication • Empyema (stage I/II) • Drainage Diffuse pulmonary diseases • Biopsy Localized lesions • Chest wall, diaphragm Sympathectomy, splanchnicectomy	Lung procedures • Lung biopsy • Lobectomy • Lung volume reduction surgery Pleural procedures • Pleurectomy (pneumothorax) • Drainage/decortication (empyema stage III) Esophageal procedures • Excision of cyst, benign tumors • Esophagectomy • Antireflux procedures Mediastinal procedures • Resection of mediastinal mass • Thoracic lymphadenectomy • Thoracic duct ligation • Pericardial window • Sympathectomy

VATS, video-assisted thoracic surgery.

Jacobaeus himself in his earliest articles.[1,4] However, even in the therapeutic era, publications from many countries emphasized the diagnostic value of pleuroscopy in spontaneous pneumothorax, focal pulmonary disease, diseases of the chest wall, mediastinal tumors, diseases of the heart and great vessels, and thoracic trauma.[4] Later, these indications were expanded to include performing biopsies for localized and diffuse lung diseases.[11,12] Today, the use of pleuroscopy for diagnosis of lung diseases has decreased owing to the improvements in less invasive pulmonary biopsy techniques such as flexible bronchoscopic biopsy and computed tomography (CT)–guided biopsy.[4,12]

In the past, therapeutic pleuroscopy was used extensively for collapse treatment of tuberculosis in order to sever adhesions that prevented a complete artificial pneumothorax.[3] This indication disappeared after the successful introduction of chemotherapy for tuberculosis.[4] Today, the main indication for therapeutic pleuroscopy is talc poudrage in malignant or other chronic and recurrent pleural effusions.[30] The first report on *talcage* was published in 1935[30] and, in 1963, it was first used for treating recurrent effusions.[4] Since then, talc poudrage performed during pleuroscopy for pleurodesis in malignant pleural effusions has been widely applied, especially in Europe.[4] Talc pleurodesis via pleuroscopy has several advantages over pleurodesis via a thoracostomy tube: simultaneous drainage of pleural fluid, visualization of the visceral pleura to ensure that the lung is not encased by pleural thickening or tumor that could prevent reexpansion, and guidance of chest tube placement.[31] In addition, talc pleurodesis can also be used to prevent recurrent pneumothorax.[32]

Other indications for therapeutic pleuroscopy are the drainage of empyema[15] or dorsal sympathectomy in hyperhidrosis patients.[13,14] Anecdotal reports describe its use for removal of foreign bodies, for removal of benign tumors, and for production of pericardial fenestrations.[12]

Contraindications

Contraindications to pleuroscopy are few and rarely absolute. The main limitation is the size of the free pleural space, which must be at least 6 to 10 cm in width.[12] If extensive adhesions prevent the lung from collapsing away from the chest wall, thoracoscopy can still be performed, but this requires special skill and should not be undertaken without special training.[33]

Several factors may make it necessary to postpone pleuroscopy but are rarely prohibitive; these include a persistent cough, hypoxemia, hypocoagulability (prolonged International Normalized Ratio or platelet count less than 40,000–60,000/mm^3), and cardiac abnormalities. Great care should be taken, particularly in the presence of hypercarbia. Depending on the severity of respiratory failure, this may prove to be an absolute contraindication, except in patients with a tension pneumothorax or massive pleural effusion, in whom it can be anticipated that pleuroscopy would provide therapeutic benefit in addition to a possible diagnosis. Under these conditions, premedication should be administered judiciously to minimize respiratory center depression. Even in very ill patients on a ventilator, diagnostic pleuroscopy has been carried out without significant complications.[5,28]

Contraindications for pulmonary biopsy are suspicion of arteriovenous pulmonary aneurysm, vascular tumors, hydatid cysts, and a stiff fibrotic lung.[26,34] Relative contraindications for pulmonary biopsy would include previous systemic steroid or immunosuppressive therapy

because, under these circumstances, bronchopleural fistulas resulting from lung biopsy may heal poorly.

The thoracoscopist must consider the risk-benefit ratio in each case. Pleuroscopy should be performed only after careful evaluation aimed at answering specific questions.

Complications

Pleuroscopy is a safe and effective modality in the diagnosis and treatment of several pleuropulmonary diseases if certain standard criteria are fulfilled.[5,28,35] In the most thorough review, only 1 death occurred among 8000 cases, for a mortality rate of 0.01%.[34] In another series reviewing 4300 cases, the mortality rate was 0.09%.[28] The reported mortality rate of pleuroscopy is thus roughly equivalent to or less than that of transbronchial biopsies. In another report of 817 pleuroscopy procedures using conscious sedation and local anesthesia, the complications were persistent air leak of more than 7 days' duration in 2%, subcutaneous emphysema in 2%, and postoperative fever in 16%.[36] The major complication rate in a series of 102 patients was 1.9% and included ventricular tachycardia responding to resuscitation, subcutaneous emphysema, and persistent air leak.[37] The minor complication rate was 7.5%, including transient air leak, fever, and minor bleeding at a biopsy site. Another large series including 360 patients reported morbidities of fever in 9.8%, empyema in 2.5%, pulmonary infection in 0.8%, and malignant invasion of the scar in 0.3%.[38] Major uncontrollable bleeding requiring thoracotomy was not reported in any of these large series and appears to be extremely rare. During the procedure, cardiorespiratory functions should be monitored. Many complications such as benign arrhythmias, low-grade hypotension, and hypoxemia can be prevented by administration of oxygen.[39] In case of persistent bleeding, electrocoagulation may become necessary.[28]

As much as several liters of pleural fluid can be removed completely during pleuroscopy with little risk of pulmonary edema, because immediate equilibration of pressure is provided by direct entrance of air through the cannula into the pleural space. Following lung biopsies, a bronchopleural fistula may result. Particularly if the lungs are stiff, a fistula may require longer to heal than the usual period of applied pleural suction of 3 to 5 days.[28] Local site infection is uncommon, and empyema has been reported only very rarely.[34] In cases of mesothelioma, the late complication of tumor growth at the site of entry has been observed after pleuroscopy and also after thoracentesis or closed-needle biopsy. Radiotherapy 10 to 12 days after pleuroscopy has been reported to prevent this late complication.[40] The standard use of prophylactic radiotherapy in these cases is controversial, however.[41] After talc poudrage, any postprocedure fever, as a nonspecific inflammatory reaction, and pain can be treated symptomatically. In conclusion, the overall mortality rate with pleuroscopy is low. Morbidity which is mainly due to benign postprocedural fever, is also minimal. Pleuroscopy in the hands of the appropriately trained pulmonologist is safe.[35]

Patient Preparation

Before pleuroscopy, radiologic evaluation should routinely include a posteroanterior and a lateral chest radiograph. Ultrasound for localization of the pleural fluid and for diagnosis of potential fibrinous membranes or adhesions in the pleural space is helpful. A CT scan is not mandatory but can be helpful to localize abnormalities such as loculated empyema or localized lesions (tumors) of the chest wall or diaphragm.

Evaluation of the patient's respiratory status requires, at a minimum, arterial or capillary blood gas analysis. An electrocardiogram should be obtained to exclude recent myocardial infarction or significant arrhythmia. The clinical laboratory will provide the coagulation parameters, serum electrolytes, and blood glucose as well as blood group typing, platelet count, liver function studies, and serum creatinine.

The planned technique, the management of possible postoperative complications, and the expected diagnostic or therapeutic results should be explained to the patient. It is only then that the patient can truly provide informed consent.[5]

The site of introduction of the pleuroscope depends in part on the location of abnormalities to access and the location of potentially hazardous areas to avoid. Pleuroscopy is usually performed with the patient in the lateral decubitus position with the intended procedural site facing upward.[5,11,28,42] A pillow is placed under the patient's flank, causing the spine to flex laterally and widening the intercostal spaces at the procedural site.

Access to the Pleural Space

Because it is impossible to perform the procedure if the pleural cavity is completely obliterated, a sufficiently large pleural space is an essential prerequisite, allowing the introduction of the trocar and thoracoscope/pleuroscope without injuring the lung or other organs.

The simplest access is available in case of a preexisting complete pneumothorax, in which the trocar can be introduced directly into the pleural space without risk of injuring the lung. In the presence of a large pleural effusion, the trocar can also be introduced directly. In case of a smaller pleural effusion, a needle puncture should be performed at the level of greatest opacification/dullness or, ideally, under sonographic or fluoroscopic guidance. When pleural fluid is aspirated, the syringe is removed from the needle and air enters the pleural space either spontaneously or after the patient takes a few deep breaths. The entry of air causes the lung to collapse away from the chest wall and creates a pleural space for safe trocar insertion. Alternatively, if one is certain that the needle is well positioned in the pleural fluid (e.g., not in the lung), air can be injected into the pleural space by means of a syringe. Most often, a few milliliters of air are sufficient to create a good separation of the lung from the chest wall. A greater safety is provided under ultrasound guidance, which allows the operator to localize the pleural effusion and to avoid transecting significant adhesions.[43] Another option is

fluoroscopy "on the table," which can show the air-fluid level caused after injection of air as well as adhesions, if present.

If neither effusion nor pneumothorax is present, an artificial pneumothorax must be created either by the blunt dissection technique using the finger[33] or by the technique of pneumothorax induction. The blunt dissection technique (extended thoracoscopy) involves gentle dissection of the pleural adhesions with a finger in order to advance the pleuroscope into the pleural space.[33,42] If carbon dioxide is introduced instead of air, for faster absorption in case of gas embolism, the pneumothorax should be induced immediately before undertaking P/MT, because the pneumothorax will be absorbed rapidly.[5,12] Some pleuroscopists induce the pneumothorax the day before the procedure, allowing more time to obtain pressure measurements and to determine if the pleural space is patent. It can also reduce the actual time spent in a busy operating/endoscopy room. When general anesthesia is planned, it may also be desirable to induce the pneumothorax on the previous day, so that a general anesthetic is not given unnecessarily to a patient who cannot undergo pleuroscopy owing to an obliterated pleural space.[28]

However, some experienced teams regularly perform pleuroscopy without any form of image-guided induction of a pneumothorax. In one series of more than 700 pleuroscopies conducted without preprocedural imaging of the entry site, induction of a pneumothorax was impossible in only 10 patients, due to extensive adhesions.[44] In this series, no major complications such as bleeding were observed.

Anesthesia

Pleuroscopy by the single-entry-site technique is usually done under local anesthesia with premedication, together with an antianxiolytic, a narcotic, or both (e.g., midazolam and hydrocodone). If necessary, additional pain medication should be given during the procedure, as required. With this conscious sedation, an anesthetist is not needed. Exceptions are rare idiosyncratic or allergic sensitivities to typical anesthetics, very anxious or uncooperative patients including children, and severe hypercarbia. An excellent alternative today is sedation by propofol with or without premedication. General anesthesia with intratracheal intubation and ventilation is used in some centers[45] but is not generally necessary for pleuroscopy.[12,42]

Monitoring devices such as a cardiac monitor, oxygen saturation monitor, and automatic blood pressure monitor are applied. An intravenous line is maintained, both for intravenous sedation as well as possible resuscitation medications.

Pleuroscopic Technique

The site of introduction of the thoracoscope should be chosen to access the location of presumed abnormalities and to avoid potentially hazardous areas such as the midanterior line where one finds the internal mammary artery, the axillary region with the lateral thoracic artery, and the infraclavicular region with the subclavian artery. The region of the diaphragm is unsuitable, not only because adhesions are frequent but also because the liver or spleen may be injured.[5,12,42] The trocar is introduced for general applications in the lateral thoracic region between the mid- and the anterior axillary line in the 4th to 7th intercostal space ("safety triangle"), for pleural effusions in the 6th or 7th intercostal space, and for pneumothorax in the 4th intercostal space. Following preparation with a surgical disinfectant, local anesthesia using 1% or 2% lidocaïne is performed, and after making a small skin incision, the trocar is advanced with a fairly forceful corkscrew motion until the detectable resistance of the internal thoracic fascia has been overcome. The cannula of the trocar should lie at least 0.5 cm within the pleural space. Pleural effusions should be removed by using a suction tube that does not occlude the cannula, so that air may rapidly enter the pleural space to equalize pressures. After complete removal of the effusion, or in cases without effusion, the optical device is introduced through the cannula, and the pleural space is then inspected (Fig. 23-3).

The pleural space can be inspected through the thoracoscope either directly or indirectly by video. Anatomic relationships and intrathoracic structures are usually well recognized. Biopsies of the pleura and, if needed, of the lungs, can be performed easily and safely by means of the lung biopsy forceps. In the presence of undiagnosed pleural effusions, biopsies should be taken from macroscopic lesions at the anterior chest wall, the diaphragm, and the posterior chest wall for histologic evaluation and, if suspicious of tuberculosis, for mycobacterial culture. If no macroscopic abnormalities are visible, several biopsies should be taken from different sites of the parietal pleura. Biopsies from the lung are not taken routinely to avoid creation of a fistula, but may be necessary when the abnormalities are seen only on the lung surface. Especially in cases of inflammatory pleural exudates or when several therapeutic thoracenteses have already been performed, fibrinous membranes or adhesions may be present that hinder examination. These can be severed by using a blunt forceps or by cutting with electrocautery.

Although a single site of entry is generally sufficient, a second site may be useful for biopsies or to coagulate.[28] The position of the second site of entry is determined by viewing through the 50-degree scope while depressing the possible entry site with the index finger. It is sometimes helpful to insert a needle through the same site while viewing its precise location through the thoracoscope. After administration of a local anesthetic, a 5-mm incision is made and the 5-mm trocar is inserted directly. Its cannula will accommodate many instruments designed for its smaller bore.

Talc Pleurodesis

Talc poudrage is the most widely reported method of talc instillation into the pleural space.[30] It is mainly used for pleurodesis in malignant or recurrent pleural

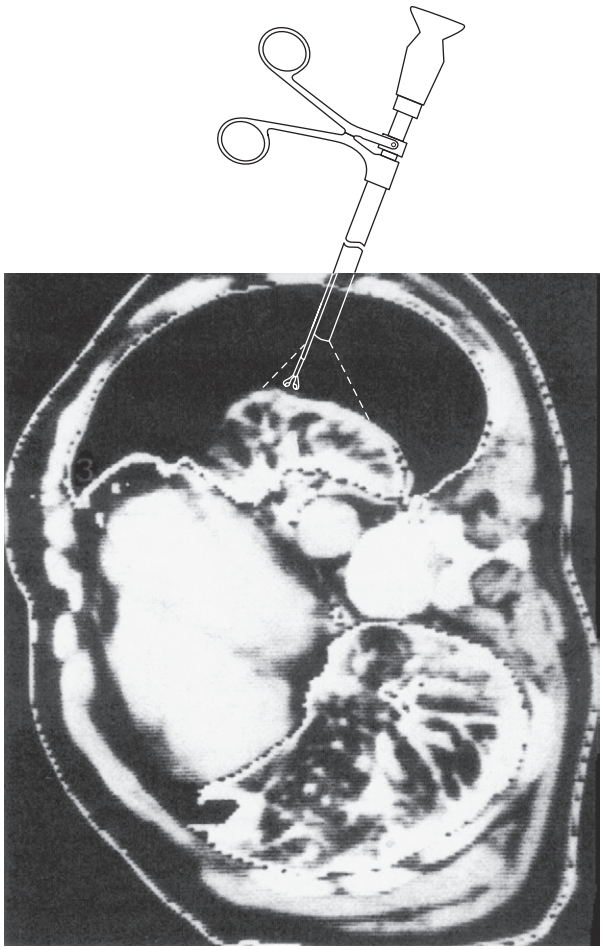

FIGURE 23-3 ■ Computed tomography representation of pleuroscopy in the right thoracic cavity with the patient in the left lateral decubitus position. Visualization of the chest wall, pleura, diaphragm, lung, and anterior (and part of posterior) mediastinum is possible. (From Loddenkemper R: Thoracoscopy—State of the art. Eur Respir J 11:213–221, 1998.)

effusions[23,30,34] but is also used in persistent or recurrent spontaneous pneumothorax.[32] Thoracoscopic talc pleurodesis can be performed under local anesthesia but generally requires additional pain medication.

In cases of pleural effusion, it is important to remove all pleural fluid before spraying with talc. The complete removal of pleural fluid is easily accomplished during pleuroscopy because air promptly enters the pleural cavity, thus creating the desired equilibrium of pressures. Complete collapse of the lung is desirable, because it permits wide and uniform distribution of the talc. A complete lung expansion is necessary for successful pleurodesis.[30,31] A trapped lung caused by thickening of the visceral pleura can be determined at pleuroscopy. The lung can also fail to reexpand if there is main-stem bronchial occlusion by a tumor or extensive pleural tumor infiltration that "traps" the lung. If the chest radiographs fail to show a contralateral mediastinal shift in the presence of a large pleural effusion, an endobronchial obstruction should be suspected and excluded by bronchoscopy before the thoracoscopy.

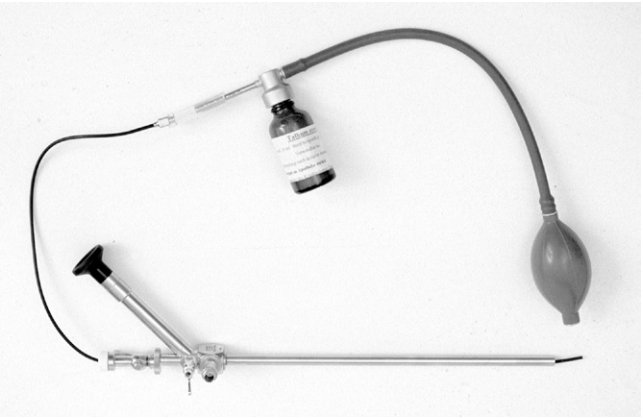

FIGURE 23-4 ■ Insufflator and bottle containing talc powder attached to a catheter that is introduced through the working channel of the rigid thoracoscope (with an angled optic).

The optimal dose of talc for poudrage is not known, but usually a dose of about 5 g is recommended for malignant or recurrent effusions[31] whereas, for pneumothorax patients, 2 g is usually sufficient.[32] The pleural cavity should be inspected during talc insufflation to ensure that the talc is uniformly distributed. For this purpose, one can use a thoracoscope with an angled optical device and a flexible suction catheter that is connected to a small bottle containing talc and to a pneumatic atomizer introduced through the working channel either of the thoracoscope[28,42] (Fig. 23-4) or of the semirigid pleuroscope.[23]

After talc poudrage, an 8- to 10-mm (24- to 30-French) chest tube should always be inserted, and pointed toward the posterior costovertebral gutter in case of effusions or toward the apex in case of pneumothorax. Suction should be applied carefully and progressively (–5 to –20 cm H_2O) to avoid creation of air leaks, which can develop because of diseased, necrotic tissue in the visceral pleura. Following the procedure, the chest tube can be removed when the daily amount of fluid production is less than 100 mL or when an air leak associated with a pneumothorax has stopped. One recent report suggests that the chest tube can be removed within 24 hours without regard to daily fluid production.[46] A potential advantage of talc poudrage via pleuroscopy compared with slurry delivered via chest tubes is the more even distribution of talc over the whole pleural surface.[31] In three head-to-head studies[47–49] comparing talc poudrage with talc slurry instillation, talc poudrage was at least equally and, in some studies, significantly more effective than talc slurry; slurry has never been shown to be superior to poudrage. In patients undergoing pleuroscopy, talc poudrage should therefore be the preferred method. In patients with a poor Karnofsky index, or when thoracoscopy is refused or impossible, talc slurry represents a valid alternative.

Talc is inexpensive and highly effective.[50] Its most common short-term adverse effects include fever and pain. Cardiovascular complications such as arrhythmias, cardiac arrest, chest pain, myocardial infarction, and

hypertension have been noted[51]; whether these complications result from the procedures or are related to talc per se has not been determined.[52] Acute respiratory distress syndrome (ARDS), acute pneumonitis, and respiratory failure have also been reported after talc poudrage and slurry. The development of respiratory failure may be due to the dose and especially to smaller particle sizes of talc, which can distribute via the pleural lymphatics to the rest of the body. The use of size-calibrated, larger-size talc appears to be absolutely safe in the treatment of recurrent pleural effusions and spontaneous pneumothorax.[53,54,54a]

Results

Pleural Effusions

Even after extensive diagnostic workup of the pleural fluid, the etiology of a number of pleural effusions may remain undetermined.[12,55] Blind needle biopsies may establish the diagnosis in some additional cases, particularly in tuberculous pleurisy. In a series by Boutin and colleagues of 1000 consecutive patients with pleural effusion,[26] 215 cases remained undiagnosed after repeated pleural fluid analysis and performance of pleural biopsies. This is in agreement with the results of several other authors who, without the use of pleuroscopy, report that at least 20% to 25% of pleural effusions remain undiagnosed, although this certainly depends strongly on the particular patient populations.[12]

Several studies have tried to determine the diagnostic accuracy of pleuroscopy in the setting of undiagnosed pleural effusion, but the results vary widely, with a range of about 60% to 90%.[26,37,56] Closer evaluation of the study designs reveals that the duration of follow-up was occasionally short and frequently not mentioned at all. One well-designed study of 102 patients reported by Menzies and Charbonneau,[37] with follow-up periods between 1 and 2 years, found a sensitivity of 91%, a specificity of 100%, accuracy of 96%, and a negative predictive value of 93%. Boutin and colleagues[26] reported a false-negative rate of 15% within 1 year of follow-up. In a retrospective study of 709 patients who underwent pleuroscopy for diagnosis of unexplained exudative effusions, Janssen and coworkers[56] also found a 15% false-negative rate in a long-term follow-up (minimum, 24 mo) of 208 patients with initial negative results; the overall sensitivity of pleuroscopy was 91%, the specificity was 100%, the positive predictive value was 100%, and the negative predictive value was 92%.[56] Of note, even thoracotomy can miss the diagnosis. In a study of the results of thoracotomy in patients with pleural effusion of undetermined etiology, even after a pathologic diagnosis of a benign pleural process, 25% of patients were diagnosed with a malignancy.[57] The diagnoses most often missed were malignant pleural mesothelioma and lymphoma (mesothelioma in 10 and lymphoma in 4 out of 31 cases,[56] and lymphoma in 6 and mesothelioma in 4 of 13 cases[57]). Autofluorescence videothoracoscopy may help in the future to avoid some of the false-negative results.[58]

Because of its high diagnostic accuracy, diagnostic pleuroscopy is an excellent option in cases of exudates in which the etiology remains undetermined after pleural fluid analysis.[23,31,34] The procedure allows fast and more definite biopsy diagnosis, including a high yield for tuberculosis cultures, and determination of hormone receptors in some malignancies. Furthermore, staging in lung cancer and diffuse mesothelioma is possible. The exclusion of an underlying malignancy or of *Mycobacterium tuberculosis* is provided with high probability. Surgery, including surgical thoracoscopy, not only is more invasive and expensive but also does not produce better results than pleuroscopy and should therefore be reserved for very selected cases.

Malignant Pleural Effusions

Diagnosis. Malignant pleural effusions are today the leading diagnostic and therapeutic indication for pleuroscopy[12,23,59] (Figs. 23-5 and 23-6). In a prospective comparison of different diagnostic tests performed in the same patients, the diagnostic yield of nonsurgical biopsy methods in malignant pleural effusions was studied simultaneously in 208 patients, including 116 metastatic pleural effusions (from 28 breast cancers, 30 cancers of various other organs, and 58 cancers of undetermined origin); 29 cancers of the lung; 58 diffuse malignant mesotheliomas; and 5 malignant lymphomas.[34] The diagnostic yield of pleural fluid cytology was 62%, of closed pleural biopsy was 44%, and of pleuroscopy was 95%. The sensitivity of pleuroscopy was higher than that of cytology and closed pleural biopsy combined (95% vs. 74%, $P < .001$). The combined methods were diagnostic in 97% of malignant pleural effusions (Fig. 23-7). In 6 of the 208 cases (2.8%), an underlying neoplasm was suspected at pleuroscopy, but confirmed only by thoracotomy or autopsy. Similar results have been reported by a number of other investigators.[21,25,56]

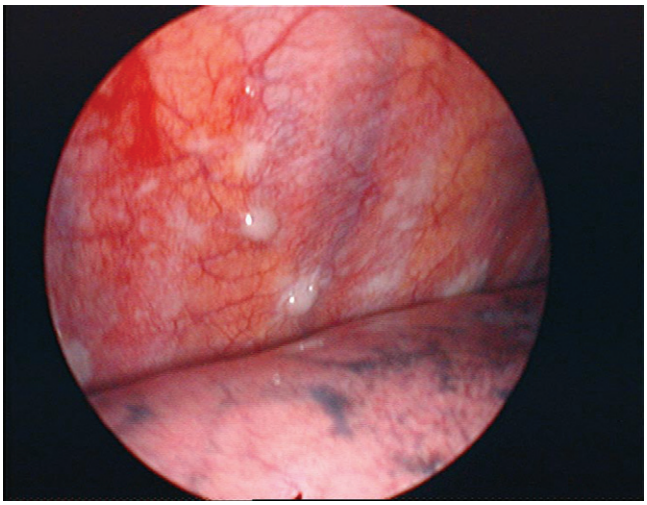

FIGURE 23-5 ■ View through the thoracoscope in a patient with a malignant pleural effusion due to breast cancer. One can see small whitish tumor nodules on the parietal (chest wall) pleura (*upper part of photo*). The lung surface (*lower part of photo*) demonstrates some anthracosis. (From Loddenkemper R, Mathur PN, Noppen M, Lee P: Medical Thoracoscopy/Pleuroscopy: Manual and Atlas. New York: Thieme, 2010.)

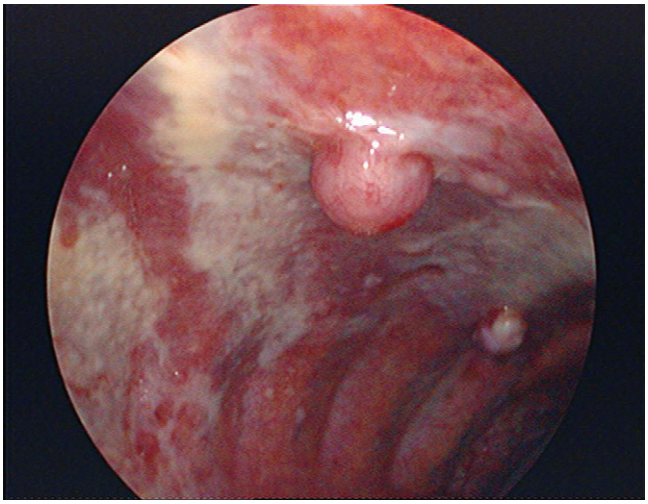

FIGURE 23-6 ■ View through the thoracoscope in a patient with diffuse malignant mesothelioma following occupational asbestos exposure. One can see tumor nodules and whitish areas with pleural thickening on the parietal (chest wall) pleura (*upper part of photo*). Histology revealed a sarcomatoid cell type. (From Loddenkemper R, Mathur PN, Noppen M, Lee P: Medical Thoracoscopy/Pleuroscopy: Manual and Atlas. New York: Thieme, 2010.)

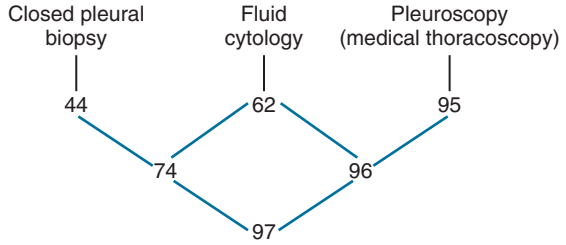

FIGURE 23-7 ■ Sensitivity of different biopsy methods (cytologic and histologic results combined) for the diagnosis of malignant pleural effusions. Numbers represent sensitivity (%) of tests, either alone or combined, in a prospective intrapatient comparison of 208 patients. (Redrawn from Loddenkemper R, Boutin C: Thoracoscopy: Present diagnostic and therapeutic indications. Eur Respir J 6:1544–1555, 1993.)

The reasons for false-negative results of pleuroscopy include insufficient and nonrepresentative biopsies, probably due to lack of experience of the thoracoscopist or the presence of adhesions preventing access to neoplastic tissue.[28,34] Adhesions may often be a consequence of repeated therapeutic removal of large amounts of fluid by thoracentesis.

The diagnostic sensitivity of pleuroscopy is similar for all types of malignant effusion. In one study, the overall yield in 287 cases was 62% for cytology and 95% for pleuroscopy; the relative yields for cytology and pleuroscopy did not vary greatly for lung carcinomas (n = 67), at 67% and 96%, respectively, for extrathoracic primaries (n = 154), at 62% and 95.5%, or for diffuse malignant mesotheliomas (n = 66), at 58% and 92%.[12]

Staging. Pleuroscopy may be useful in staging lung cancer, diffuse malignant mesothelioma, and metastatic cancer. In lung cancer patients, pleuroscopy can help to determine whether the effusion is malignant or paramalignant.[34] As a result, it may be possible to avoid exploratory thoracotomy for tumor staging. Canto and associates[60] found no thoracoscopic evidence of pleural involvement in 8 of 44 patients with lung cancer and pleural effusion; 6 proceeded to resection, where the lack of pleural involvement was confirmed.

In diffuse malignant mesothelioma, pleuroscopy can provide an earlier diagnosis and better histologic classification than closed pleural biopsy because of larger and more representative biopsies and more accurate staging.[61] Earlier diagnosis and staging may have important therapeutic implications either for surgery or for local immunotherapy or local chemotherapy, because better clinical outcomes have been observed for patients detected in the early stages (I and II).[61]

Pleuroscopy is also helpful in the diagnosis of benign asbestos-related pleural effusion by excluding mesothelioma or malignancies. Fibrohyaline or calcified, thick, and pearly white pleural plaques may be found, indicating possible asbestos exposure.[61] Thoracoscopic pulmonary biopsies and even biopsies from special lesions on the parietal pleura may demonstrate high concentrations of asbestos fibers, and thereby provide further support for a diagnosis of asbestos-induced disease.[62]

A further advantage of pleuroscopy in metastatic pleural disease is that biopsies of the visceral and diaphragmatic pleura are possible under direct observation. In addition, the larger size of pleuroscopic biopsies may provide easier identification of primary tumor, including hormone receptor determination in breast cancer,[63] and improved morphologic classification in lymphomas.[64,64a] In addition, the extent of intrapleural tumor spread can be described using a scoring system that has been shown to correlate well with survival[65] and with response to talc poudrage.[66]

Therapy. In malignant pleural effusions, talc pleurodesis achieves success rates of more than 90% as reported in several series.[31] Although there is a lack of randomized, controlled studies, talc poudrage seems to be the most efficient method of pleurodesis.[31] Diacon and colleagues,[67] in a prospective randomized trial, compared pleuroscopic talc poudrage under local anesthesia to bleomycin instillation. In 36 patients, they found much lower recurrence rates of effusion after talc poudrage (13% compared with 41% with bleomycin after 30 days; 13% and 59%, respectively, after 90 days; and 13% and 65%, respectively, after 180 days). A cost estimation also favored talc poudrage, both for initial hospitalization and with regard to recurrences. Boutin and associates[28] randomly compared talc poudrage and tetracycline instillation in 40 patients. The success rate after 1 month was 90% for talc and 80% for tetracycline. However, after 9 months, talc pleurodesis persisted whereas, with tetracycline, malignant effusions recurred in 50% of cases. Fentiman and coworkers[68] found talc superior to tetracycline for control of pleural effusions secondary to breast cancer. Viallat and associates,[38] in a retrospective study of over 300 patients, found that talc poudrage achieved a 90% success rate at 1 month and, in 82%, produced a lifelong symphysis. The success rate in metastatic cases was higher than in mesothelioma cases. Weissberg and BenZeev[69] reported similar results

in another large series with 360 cases. Aelony,[70] in a case series, observed prolonged survival averaging 22.4 months after treatment with talc poudrage pleurodesis. In vitro studies suggest that talc produces apoptosis in human malignant mesothelioma cells and might therefore have an antitumor[71] as well as an antiangiogenic effect.[72]

In chylothorax due to lymphoma, Mares and Mathur[73] showed excellent results of talc poudrage, all in cases refractory to chemotherapy or radiation therapy. All 19 patients with 24 hemithoraces involved had no recurrence after 30, 60, and 90 days (8 patients died during the 90 days of follow-up).

Tuberculous Pleural Effusions. Although the diagnostic yield of pleural fluid *M. tuberculosis* culture combined with closed-needle biopsy is quite high, there may be indications for pleuroscopy in otherwise uncertain pleural effusions[12,29] (Fig. 23-8). The diagnostic accuracy of pleuroscopy is almost 100% because the pathologist is provided with multiple, selected biopsies and there is a higher likelihood of obtaining the tubercle bacilli on culture.[12,34] In this prospective intrapatient comparison, an immediate diagnosis of *M. tuberculosis* infection in 100 cases was established histologically in 94% with pleuroscopy, but in only 38% with needle biopsy.[12,34] This may be of clinical importance, because a proper histopathologic diagnosis allows antituberculous chemotherapy to be started without delay. The combined yield of histology and bacteriologic culture was 99% for pleuroscopy and 51% for needle biopsy, increasing to 61% when culture results from effusions were added (Fig. 23-9). The percentage of positive *M. tuberculosis* cultures from pleuroscopic biopsies (78%) was twice as high as that from pleural fluid and needle biopsies combined (39%), allowing bacteriologic confirmation of the diagnosis and, importantly, drug susceptibility testing. In 5 of the 78 positive cases (6.4%), resistance to one or multiple antituberculous drugs was found and influenced therapy and prognosis.

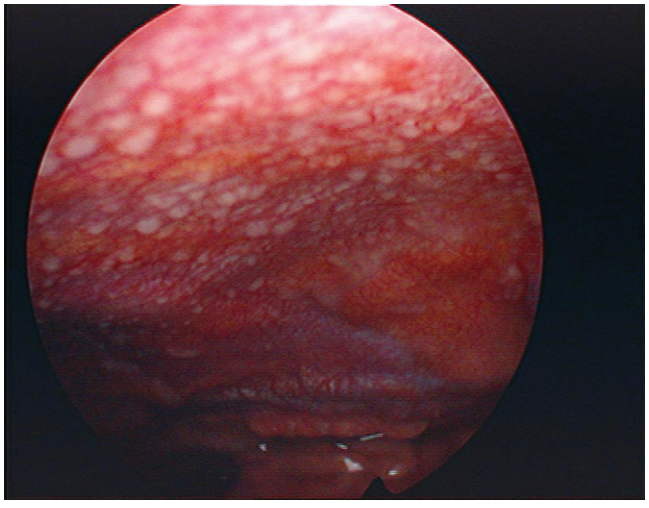

FIGURE 23-8 ■ View through the thoracoscope in a patient with a tuberculous pleural effusion. Note the numerous small whitish nodules on the parietal (chest wall) pleura (*upper part of photo*). The histology revealed florid exudative tuberculous pleurisy with epithelioid cell granulomas, numerous multinucleated giant cells of the Langerhans type, and necrosis. *Mycobacterium tuberculosis* cultures from the biopsies were positive, whereas those from the effusion were negative. (From Loddenkemper R, Mathur PN, Noppen M, Lee P: Medical Thoracoscopy/Pleuroscopy: Manual and Atlas. New York: Thieme, 2010.)

Closed-needle biopsy can have high yield in areas with a high prevalence of tuberculosis but, even then, pleuroscopy can have other benefits. In a prospective study of 40 cases from South Africa, pleuroscopy had a diagnostic yield of 98% in comparison with an 80% diagnostic yield from pleural biopsies performed with an Abrams needle.[74] The value of blind pleural biopsy for diagnosis was confirmed by another prospective study that demonstrated a high diagnostic accuracy with a high pleural fluid adenosine deaminase, differential lymphocytic cell count, as well as closed-needle biopsy in an area with a high incidence of tuberculosis.[75] However, pleuroscopy can lead to complete drainage of the effusion; initial complete drainage of the effusion, performed during and after pleuroscopy, was associated with greater symptomatic improvement than any subsequent therapy.[76] The positive role of early removal of the pleural fluid has also been shown recently in a double-blind, randomized, placebo-controlled trial from Taiwan.[77] No studies are known that compare the potential benefits of pleuroscopy, allowing early diagnosis, complete drainage, and early drug treatment, with drug treatment alone.

It is debatable whether to treat patients with antituberculous drugs merely on the suspicion of tuberculous pleurisy if they present with a high lymphocyte count in the pleural fluid and a positive skin test. At least in countries with a low prevalence of tuberculosis, where other laboratory tests such as adenosine deaminase may not be specific, pleuroscopy may be indicated when needle biopsies show negative results, in order to prove or exclude tuberculosis. In addition, the high yield for positive tuberculosis cultures from pleuroscopic biopsies increases the possibility of obtaining susceptibility tests, which, in cases of drug resistance, may influence therapy and prognosis.[12,75]

Other Pleural Effusions. In cases with effusions that are neither malignant nor tuberculous, pleuroscopy may give visual clues to the etiology such as by revealing

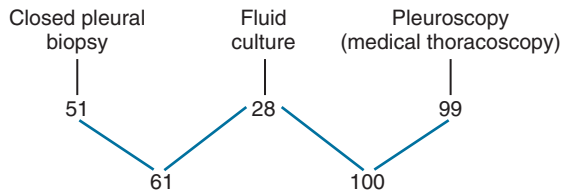

FIGURE 23-9 ■ Sensitivity of different biopsy methods (histologic and bacteriologic results combined) for the diagnosis of *Mycobacterium tuberculosis* infection. Numbers represent sensitivity (%) of tests, either alone or combined, in a prospective intrapatient comparison of 100 patients. (Redrawn from Loddenkemper R, Boutin C: Thoracoscopy: Present diagnostic and therapeutic indications. Eur Respir J 6:1544–1555, 1993.)

the thick white fibrin deposits seen in rheumatoid effusions, calcifications in effusions following pancreatitis, dilated veins in liver cirrhosis, or signs of trauma.[5,34] Although, in these entities, the history, pleural fluid analysis, and physical and other examinations are usually helpful, pleuroscopy may be indicated to confirm the clinical suspicion.[55] If pleural effusion is secondary to underlying lung diseases such as pulmonary infarct or pneumonia, the diagnosis can frequently be made on visual examination and be confirmed by biopsy of the lung.[5,28,34] As already mentioned, pleuroscopy is well suited for diagnosis of benign asbestos-related pleural effusion, which, by definition, is a diagnosis of exclusion.[61]

In other undiagnosed pleural effusions, when the cause is unsuspected, the main diagnostic value of pleuroscopy lies in its ability to exclude malignant and tuberculous disease.[12,55] By means of pleuroscopy, the proportion of so-called idiopathic pleural effusions usually falls below 10%, whereas, in studies that have not used pleuroscopy, failure to obtain a diagnosis can exceed 20% of cases.[53] However, this certainly also depends on the selection of patients and on the definition of "idiopathic." Even after surgical exploration—the gold standard—there are still undiagnosed effusions.[57,78]

Dense pleuropulmonary adhesions may prevent successful pleuroscopy. If so, multiple closed-needle biopsies should be performed or more invasive surgical procedures should be considered.

Talc pleurodesis can be considered in some cases of nonmalignant pleural effusions that are recurrent and symptomatic and do not respond to medical therapy. Such effusions may include those due to hepatic and renal hydrothorax, chylothorax, and systemic lupus erythematosus.[79–81] In such patients with recurrent benign undiagnosed effusions, Vargas and colleagues[82] achieved successful pleurodesis in 20 of 22 by talc insufflation using a thoracoscopic technique with a mediastinoscope performed under general anesthesia.

Empyema

Pleuroscopy can also be used in the management of early empyema, mainly to achieve early and complete drainage.[15,28,83,84] Intermediate between tube thoracostomy and VATS, pleuroscopy is effective and, compared with surgical drainage, costs significantly less and avoids general anesthesia. It is particularly advisable for frail patients at high surgical risk.[15,84a] In cases with multiple loculations, it is possible to open these spaces to remove the fibrinopurulent membranes by forceps and to create a single cavity that can then be successfully drained and irrigated.[85] If performed for this indication, pleuroscopy should be carried out early in the course of empyema, before the adhesions become too fibrous and adherent to perform pleuroscopy. Thus, if the indication for placement of a chest tube is present and if the facilities are available, pleuroscopy can be performed at the time of chest tube insertion. Overall, pleuroscopy is a procedure similar to chest tube placement but one that enables the creation of a single pleural cavity, allowing much better local treatment.[83,85] However, prospective studies on the role of pleuroscopy in the treatment of early empyema in adults have not yet been published.

Spontaneous Pneumothorax

In spontaneous pneumothorax, pleuroscopy has both diagnostic and therapeutic purposes[5,28,32,34,86–88] (Fig. 23-10). In particular, if a chest tube is introduced by the trocar technique, it is easy to use an optical device for visual inspection of the lung and pleural cavity, before insertion of the chest tube through this cannula. By inspection during pleuroscopy, the underlying lesions can be directly assessed according to the classification of Vanderschueren and coworkers[87]: stage I, with an endoscopically normal lung; stage II, with pleuropulmonary adhesions; stage III, with small bullae and blebs (<2 cm in diameter); and stage IV, with numerous large bullae (>2 cm in diameter). In 1047 cases of pneumothorax in which pleuroscopy was used by three different teams, pathologic lesions were detected in about 70%, with similar percentages for stages II through IV.[12] Blebs and bullae were detected in 45% to 62% of cases. Although the detection rates of blebs and bullae are reported to be higher (76%–100%) in series using VATS or thoracotomy,[87] it is unlikely that large bullae and blebs or fistulas would be overlooked during pleuroscopy.

Pleuroscopy offers the possibility of combining chest drainage with treatment by electrocautery of blebs and bullae if the site of the air leak is visible and by pleurodesis using talc poudrage.[32,86] Sattler in Vienna in 1937 was the first to use pleuroscopy to treat pneumothorax

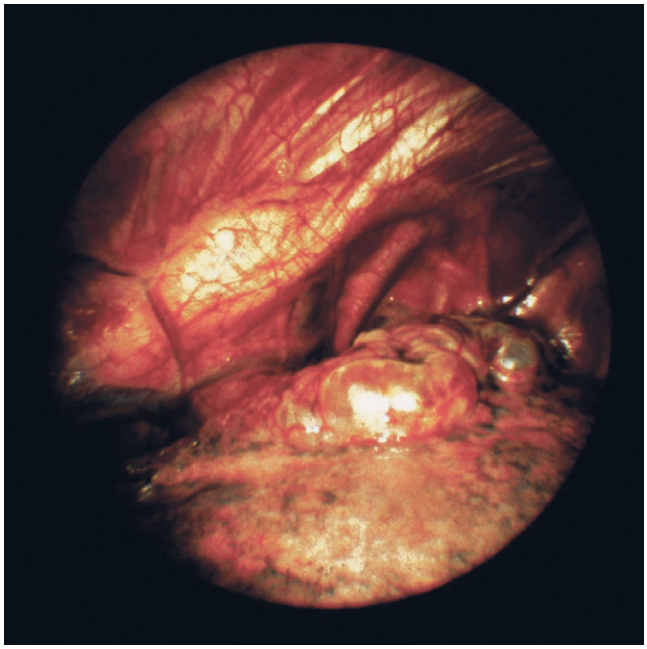

FIGURE 23-10 ■ View through the thoracoscope in a patient with a spontaneous pneumothorax. On the surface of the lung (*lower part of photo*), large apical blebs are visible.

by cauterization of adhesions that prevented the closure of bronchopleural fistulas.[4] Talc poudrage achieves excellent results, with recurrence rates reported below 10%.[32] A prospective study showed that, for complicated pneumothorax, defined as recurring or persistent pneumothorax, simple talc poudrage under local anesthesia prevented a recurrence of pneumothorax.[89] In a prospective, randomized, multicenter comparison, talc poudrage for primary spontaneous pneumothorax proved more efficient (only 1 of 61 patients with talc poudrage had a recurrence, compared with 10 of 47 with simple pleural drainage) and more cost-effective than drainage alone.[90] In stage III/IV cases with numerous blebs or bullae, usually there is an indication for VATS or thoracotomy in order to perform a bullectomy or stapling of blebs/bullae, and these patients should be transferred directly to the surgical department after insertion of a chest tube.[86] Other types of pneumothorax treated successfully by pleuroscopy have included those due to *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia, metastatic osteosarcoma, pleural endometriosis, lymphangioleiomyomatosis, and cystic fibrosis.[55]

In talc poudrage for pneumothorax, a mere 2 to 4 mL of talc can be sufficient for effective pleurodesis.[32] No long-term sequelae were observed 22 to 35 years after talc poudrage. Total lung capacity averaged 89% of the predicted value in 46 patients, whereas it was 97% of the predicted value in 29 patients treated with tube thoracostomy alone.[91] None of the poudrage group developed mesothelioma over the 22- to 35-year follow-up. Although talc poudrage may result in minimally reduced total lung capacity, as well as pleural thickening on chest radiography, these changes appear to be clinically unimportant.[54,92] Talc poudrage may be relatively contraindicated for patients who may become candidates for lung transplantation, although currently it is not considered an absolute contraindication to lung transplantation.[93]

Therefore, if the facilities are available, pleuroscopy may be performed in all patients with spontaneous pneumothorax in whom tube drainage is indicated. Several advantages are offered: precise assessment of underlying lesions under direct visual control, choice of best (conservative or surgical) treatment measures, direct treatment by electrocautery of small blebs and bullae, and severing of adhesions, if necessary, followed by talc poudrage, as well as selection of the best location for subsequent chest tube placement.[34]

Diffuse Pulmonary Diseases

Diffuse lung diseases provide a good indication for diagnostic pleuroscopy[5,28,34,93–95] (Fig. 23-11). An overview of the entire lung surface, assisted by the magnification of the thoracoscope, allows harvesting of representative samples of abnormal areas of parenchyma. In a review of the literature, the sensitivity of pleuroscopic lung biopsies was 93% in 1031 cases with varying etiologies.[28] In a large series of 419 patients with diffuse lung diseases, the overall sensitivity was 85% with different yields depending upon the underlying disease: 98% in sarcoidosis stage II and III, 88% in malignant diseases, 85% in diffuse pulmonary fibrosis/interstitial pneumonia and 42% in histiocytosis X.[34] Pleuroscopy has also been used with a high diagnostic yield in immunocompromized patients.[94]

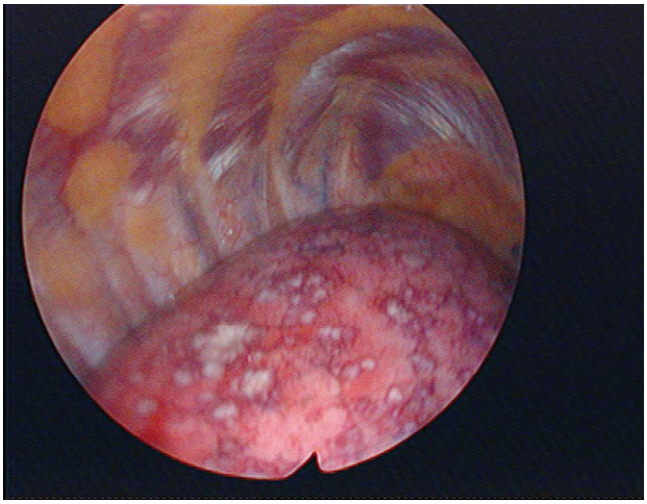

FIGURE 23-11 ■ A view through the thoracoscope in a patient with multiple pulmonary metastases due to ovarian cancer (*lower part of photo*).

In comparison with bronchoscopy, pleuroscopy is more invasive (see "Contraindications") but presents several advantages. It provides significantly larger samples and allows the physician to choose the biopsy site. Unlike transbronchial biopsy, pleuroscopy enables electrocautery, so that bleeding following pleuroscopic parenchymal biopsy can be managed without difficulty. With regard to sensitivity and invasiveness, pleuroscopy ranks between transbronchial biopsy and open-lung biopsy.[34]

Localized Diseases

Localized abnormalities of the chest wall, diaphragm, and thoracic spine may be diagnosed using pleuroscopy if the pleural space is not obliterated.[5,34] Hyaline pleural plaques, localized pleural mesothelioma, lipoma, neurinoma, rib metastasis, rib erosions, and the like can be examined and, if necessary, biopsied. Very discrete metastases are sometimes found in the region of the diaphragm and the posterior chest wall, with or without associated pleural effusion. Chest wall lesions may be easier to diagnose than lung lesions: In a retrospective study in which 109 cases with chest wall lesions of different etiologies were analyzed, the diagnostic sensitivity was 83%[34] whereas, in solitary lung lesions, the overall diagnostic sensitivity was only 46%.

Currently, the application of pleuroscopy has decreased substantially for localized disease due to better imaging techniques such as CT, magnetic resonance imaging, and ultrasound, which allow image-guided biopsies. For example, such biopsies have proved useful for diagnosis of pleural plaques, lipomas, and cysts.[12]

Alternatively, surgical thoracoscopy, or VATS, may now be used for these indications, because the technique not only is diagnostic but also allows the removal of benign or malignant lesions.

Use of Pleuroscopy/Medical Thoracoscopy for Research

Pleuroscopy/medical thoracoscopy (P/MT) is a valuable tool for research in pleural diseases. It allows microscopic inspection of the whole pleural cavity including the surface of the lungs, selective sampling of biopsies from the pleura or lung under visual control, and thus can diagnose or exclude several pathologies with high sensitivity and specificity. P/MT is the pulmonologist's gold standard for diagnosis of pleural effusions.

Research domains for pleuroscopy in normal subjects include performance of pleural lavage in otherwise normal subjects undergoing pleuroscopy for reasons other than pleuropulmonary diseases (e.g., for treatment of essential hyperhdrosis), which enables the examination of the normal pleura and its contents,[96–98] as well as the examination of pleural changes in pleuropulmonary diseases not associated with pleural effusions (e.g., spontaneous pneumothorax).[99]

There are numerous examples of the research value of P/MT in the diagnosis of pleural effusions. Prospective studies have been performed in malignant pleural effusion,[12,26,60] which showed the high diagnostic yield compared with pleural cytology and closed-needle biopsy. Prospective studies in tuberculous pleurisy have also shown the superiority of P/MT in comparison with pleural fluid examinations and closed pleural biopsies.[12,74,75]

P/MT is also superior in the diagnosis of diffuse malignant mesothelioma.[34,61] The technique of autofluorescence thoracoscopy is evaluated for the improved detection of otherwise invisible pleural lesions.[58] P/MT allows better staging and has prognostic implications in malignant mesothelioma.[34,61] P/MT allows the grading of pleural involvement, which is correlated with survival[65] and also with the success of talc pleurodesis.[30,49,66] It allows us to study the mechanisms of talc pleurodesis in malignant pleural effusion.[66,71,72]

Research on the role of P/MT in the management of pneumothorax has been performed,[32,87–90] including the role of talc poudrage in comparison with other pleurodesis techniques.[32,87,90] New techniques have expanded our understanding of the abnormalities associated with pneumothorax, such as fluorescein-enhanced autofluorescence thoracoscopy.[100]

Future Areas of Research

- Prospective studies of the diagnostic accuracy of pleuroscopy for so-called idiopathic pleural effusions.
- The value of new visualization methods such as autofluorescence or narrow-band imaging in the early diagnosis of malignant pleural effusions, particularly when diffuse malignant mesothelioma is suspected.[101,102]
- Prospective studies of the role of pleuroscopy in tuberculous pleurisy for early diagnosis, complete drainage, and early drug treatment compared with drug treatment alone.
- Prospective studies on the role of pleuroscopy in the management of empyema.
- Potential role of pleuroscopy for intrapleural gene therapy.

DIFFERENCES BETWEEN PLEUROSCOPY AND VIDEO-ASSISTED THORACIC SURGERY (SURGICAL THORACOSCOPY)

As described in the preceding sections, P/MT is used mainly for diagnosis of pleural diseases. The most common indications for pleuroscopy are diagnosis of pleural effusion with inspection of the pleural cavity, combined with biopsies from the parietal and visceral pleura, as well as treatment of malignant or other therapy-refractory effusions by talc pleurodesis (poudrage). It is a relatively simple and inexpensive technique because it can be performed in an endoscopy room, under local anesthesia or conscious sedation through a single entry site with nondisposable instruments.

VATS, conversely, which takes its roots from pleuroscopy, has now been technically developed to the point that it can replace thoracotomy for most indications, if certain limitations such as dense pleural symphysis are not present. VATS requires an operating room, general anesthesia with single-lung ventilation, more than two (usually three) entry sites, and complex instruments. Overall, it is a more invasive and expensive technique with a higher risk than pleuroscopy; however, in experienced hands and in the proper setting, VATS is less invasive, is less expensive, and has a lower risk than open procedures.

The different clear-cut indications for either pleuroscopy or VATS are listed in Table 23-1. However, there remains a gray area of indications for which either method can be used (see Table 23-1). Gray areas include treatment of pneumothorax stages I to III, drainage of empyema stages I and II, biopsies in diffuse parenchymal lung diseases, and sympathetic interventions. For these indications, the choice of the medical or the surgical approach depends on local expertise, availability of the technique, and performance status and prognosis of the patient.

The choice of the medical or the surgical approach depends on local expertise, availability of the technique, and performance status and prognosis of the patient. More details are given in the book Manual and Atlas of Medical Thoracoscopy/Pleuroscopy.[103]

KEY POINTS

- P/MT is less invasive than surgical thoracoscopy (VATS) because it is performed under local anesthesia and conscious sedation, most commonly through a single entry. It is also less expensive because it can be performed in an endoscopy suite, using nondisposable rigid or semirigid endoscopes, and usually does not require an anesthesiologist.
- P/MT is used today mainly for diagnostic purposes, in particular in pleural effusions of otherwise indeterminate origin, owing to its high sensitivity and specificity for the diagnosis of malignant and tuberculous etiologies.
- P/MT is useful in staging diffuse malignant mesothelioma and lung cancer with pleural effusion.
- P/MT allows talc poudrage, which is today the most successful conservative method for pleurodesis in malignant and recurrent pleural effusions.
- P/MT can be useful for treatment of spontaneous pneumothorax; the introduction of the scope by the trocar technique is similar to the introduction of a chest tube, and an optical device can be used to inspect the pleural space followed by coagulation of blebs and bullae and talc poudrage.
- P/MT can be used in the management of early empyema, for biopsy diagnosis of diffuse pulmonary diseases as well as for sympathectomy in hyperhidrosis patients. As an invasive procedure, it should be used only if other, simpler methods fail or are not available.
- P/MT is a safe procedure that is even easier to learn than flexible bronchoscopy, if sufficient expertise in thoracentesis and chest tube placement has already been gained. As part of interventional pulmonology, it should be included in the training program of pulmonologists.

INTRODUCTION

Pulmonary function tests (PFTs) are an integral part of diagnosing and managing patients with respiratory disease. PFTs play an important role in respiratory medicine but they are only one piece of the puzzle and are not diagnostic of any given disease: many pathologic processes share similar pulmonary function patterns. PFTs are most useful when interpreted in conjunction with other clinical information including history, physical examination, imaging studies, and laboratory data.

PFTs provide clinically useful information under the following conditions: (1) measurements are accurate and precise, (2) patient data are compared with high-quality reference values appropriate for the patient population, (3) the interpretation is made according to a standardized interpretation strategy, (4) the report is configured to highlight important data and to avoid interpretive errors.

The commonly performed and most clinically useful PFTs are discussed: spirometry, diffusing capacity, lung volume tests, tests of respiratory muscle strength, and bronchial provocation tests.

SPIROMETRY

Spirometry is the most useful and readily available PFT. It is an essential tool for any health care provider who cares for patients with respiratory disease. Even tests as well established as spirometry are not entirely straightforward. This section addresses those controversies along with the practicalities of performing and interpreting the test.

Indications

The common clinical indications for spirometry are listed in Table 24-1. Spirometry is a valuable screening test for evaluating respiratory symptoms (cough, wheeze, dyspnea, and chest tightness), abnormal physical examination findings (wheeze, crackles, cyanosis, hyperinflation) and abnormal laboratory tests (chest radiographs, arterial blood gases, oximetry). It is also useful in diagnosing and monitoring many common respiratory diseases including asthma, chronic obstructive pulmonary disease (COPD), various diffuse parenchymal lung diseases, and neuromuscular disorders.

The role of spirometry in populations without respiratory symptoms or pulmonary disease is less clear. A number of proposals have recommended screening asymptomatic smokers and ex-smokers with spirometry, although there is no clear evidence of benefit. The concept is controversial. The U.S. Preventive Services Task Force recommends against screening spirometry for asymptomatic adults including smokers and ex-smokers[1] because it found no evidence that lung function testing improved health care outcomes. In contrast, the National Lung Health Education Program recommends spirometry for all current and past smokers over age 45 years.[2] Their rationale is not evidence based. Screening spirometry would be beneficial if the results encouraged asymptomatic smokers to quit. Studies are conflicting as to whether performing spirometry results in increased smoking-cessation rates.[3,4]

The appropriate use of preoperative spirometry for risk stratification is also controversial. There are good data that spirometry is valuable in predicting postoperative pulmonary complications in patients undergoing thoracic surgery[5]; there is no such evidence for patients undergoing extrathoracic surgery.[6,7] There is no defined threshold at which surgical risk is prohibitive, and spirometry alone should not preclude extrathoracic surgery.[7] Spirometry should be performed in patients undergoing lung resection surgery and cardiac surgery and in selected patients undergoing extrathoracic surgery who have respiratory symptoms or known lung disease.[8]

Spirometry is a safe test with minimal associated risks and there are few contraindications to its performance. Inability to follow technician instructions due to altered mental status or patient unwillingness and subjective discomforts such as pain and nausea may affect test quality and are relative contraindications. Testing should be terminated if the patient develops significant lightheadedness or syncope. Testing should also be terminated if sequential spirometric measurements show a greater than 20% reduction in FEV_1 that is not explained by procedural problems, suggesting maneuver induced bronchoconstriction.[8a]

TABLE 24-1. Indications for Spirometry

Evaluate respiratory symptoms, signs, abnormal laboratory or radiographic findings
Assist in diagnosing respiratory diseases
Monitor respiratory disease activity and response to therapy
Determine respiratory disease prognosis
Evaluate the pulmonary effects of occupational, environmental, and drug exposures
Provide objective assessment of impairment or disability
Evaluate risk prior to lung resection surgery
Assist in smoking-cessation efforts

Spirometry Measurements

Although spirometry measures many physiologic parameters, the important clinical measures are the forced vital capacity (FVC) (the maximal volume of air forcefully exhaled after a maximal inspiration) and forced expiratory volume in 1 second (FEV_1) (the amount of air exhaled during the first second of a FVC maneuver). Both FVC and FEV_1 are expressed in liters at body temperature (37°C) and ambient pressure saturated with water vapor (BTPS). Many other measurements can be obtained from the FVC maneuver. Two of these include the mean forced expiratory flow between 25% and 75% of the FVC ($FEF_{25\%-75\%}$) and peak expiratory flow (PEF), which is the maximum flow achieved during forced exhalation. Both are measured in liters per second. There is evidence that a reduction in $FEF_{25\%-75\%}$ is a spirographic manifestation of small airway dysfunction.[9] However, $FEF_{25\%-75\%}$ is a highly variable test that is dependent on exhalation time and is not specific for small airway disease in individual patients.[10] PEF reflects the caliber of the large airways and is highly effort dependent. Although PEF is attractive because it can be measured using inexpensive handheld devices, it is a more variable measure than FEV_1 and the correlation between PEF and FEV_1 in patients with airway obstruction is poor.[11,12] Neither $FEF_{25\%-75\%}$ or PEF offers any advantage over FEV_1.

Spirometry Performance

Spirometry is commonly performed in the primary care setting and can be completed in less than 15 minutes. Robust testing devices costing less than $2,000 are available for office use. Equipment performance standards and quality control recommendations are discussed in detail elsewhere.[13] The volume accuracy of the spirometer should be checked at least daily with a 3-L syringe.[13] The instrument should display both flow-volume and volume-time tracings, and inspections of these tracings are needed for optimal quality control. Figure 24-1 provides examples of flow-volume and volume-time

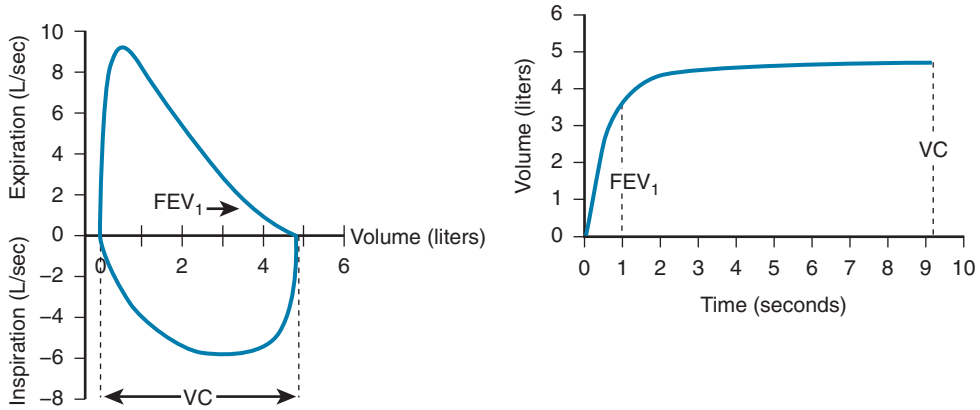

FIGURE 24-1 ■ Examples of flow-volume (*left*) and volume-time (*right*) tracings for a healthy subject are illustrated. FEV_1, forced expiratory volume in 1 second.

TABLE 24-2. Spirometry Acceptability (Within-Maneuver) Criteria

1. Good start of test
   a. Sharp take-off without hesitation
   b. Extrapolated volume < 5% or 0.15 L, whichever is greater
2. Meet end-of-test criteria
   a. Complete exhalation to RV
   b. Plateau on volume-time curve
   c. Exhalation time ≥ 6 seconds (3 sec for children)
3. Absence of artifacts
   a. Cough, especially during first second of exhalation
   b. Glottis closure
   c. Hesitation or submaximal effort
   d. Air leak
   e. Obstructed mouthpiece

RV, residual volume.

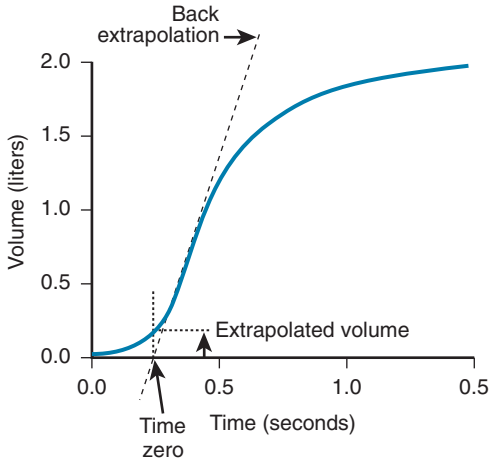

FIGURE 24-2 ■ The back extrapolation method for determining time zero (the adjusted start time) and extrapolated volume are illustrated. The extrapolated volume must be less than 5% of the FVC or 0.150 L, whichever is greater.

tracings. An adequate FVC maneuver requires (1) maximal inspiration to total lung capacity (TLC); (2) an abrupt, maximally forceful exhalation; and (3) exhalation continuing to residual volume. In older patients and in patients with airway obstruction, an unforced or slow vital capacity (SVC) may be useful. In these patients, the SVC may be larger than the FVC due to dynamic air trapping with the forced maneuver. The largest vital capacity (VC) obtained should be used for interpretation.[14,15]

The initial step in spirometry interpretation is to assess test acceptability and repeatability. The American Thoracic Society/European Respiratory Society (ATS/ERS) Task Force on Standardization of Lung Function Testing[13] provides clear guidelines for assessing test acceptability and repeatability. An acceptable study requires the visual examination of each individual effort to determine whether specific within-maneuver criteria are met (Table 24-2). This should include direct inspection of both the volume-time and the flow-volume tracings. Based on this examination, the technician can adjust coaching for the next maneuver. Poorly performed or submaximal maneuvers may mimic disease patterns, leading to interpretive errors.

The start of test criteria requires an abrupt, sharp rise in flow with no hesitation. This is quantified by assessing the back extrapolated volume as illustrated in Figure 24-2. At the onset of forced exhalation, inertial forces must be overcome; PEF is not achieved until approximately 150 msec after the exhalation maneuver begins. The extrapolated volume, calculated using the new "time zero," must be less than 5% of the FVC or 0.150 L, whichever is greater.[13] Most modern spirometers provide rapid computerized feedback to alert the technician when start-of-test criteria are not met. An inaccurate "start-of-test" with a large back extrapolated volume could overreport FEV_1 relative to FVC, resulting in an increased FEV_1/FVC ratio, possibly missing an obstructive pattern.

The end-of-test criteria ensures that the patient has exhaled completely to residual volume (RV). The end-of-test criteria are met at an exhalation time of greater than 6 seconds (3 seconds for children < 10 years of age) or

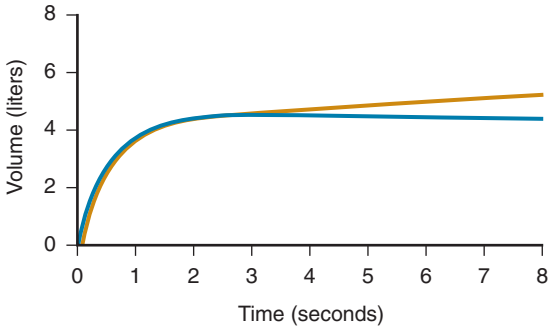

FIGURE 24-3 ■ Premature closure of the glottis is exhibited. This will result in an underestimation of FVC.

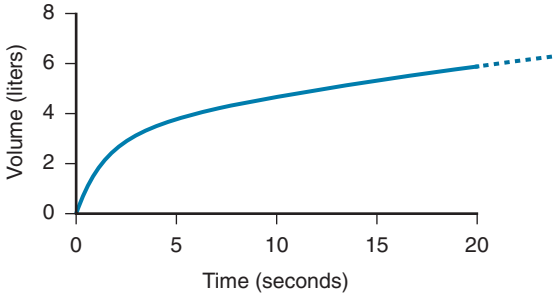

FIGURE 24-4 ■ A volume-time tracing for a patient with COPD who does not meet end of test criteria despite an exhalation time exceeding 20 seconds.

a plateau on the volume-time curve (defined as a change in volume < 25 mL for the last second of exhalation). Most currently available spirometers alert the technician if end-of-test criteria are not met. Visual inspection of the tracings is necessary to exclude a trial with premature closure of the glottis, because this can erroneously be reported as meeting end-of-test criteria (Fig. 24-3). Two situations exist in which end-of-test criteria may not be met despite being acceptable maneuvers. Patients with severe airway obstruction may not meet the plateau end-of-test criteria despite very long exhalations, often exceeding 15 seconds (Fig. 24-4). Prolonged exhalations in this setting generally do not result in misinterpretation and may cause unnecessary discomfort, lightheadedness, or, rarely, syncope.[16] Young children and adults with severe restriction may have difficulty meeting the specified exhalation time requirements. Visual inspection of the volume-time curves is useful in these situations to confirm the presence of a plateau. The technician can use this information to stop the test.

Failing to adhere to the end-of-test criteria and complete exhalation to RV will result in a falsely low FVC. This may have two consequences. A restrictive ventilatory defect may be suggested and lead to further testing.[17] A low FVC can falsely elevate the FEV_1/FVC ratio, which could obscure an obstructive abnormality.[18]

Other elements of an acceptable test include the absence of cough, glottic closure, or hesitation during the maneuver; an air leak from the mouth or nose; and obstruction of the mouthpiece. Maximal effort throughout the maneuver is suggested, although the consequences of a submaximal effort are not clear-cut. Some

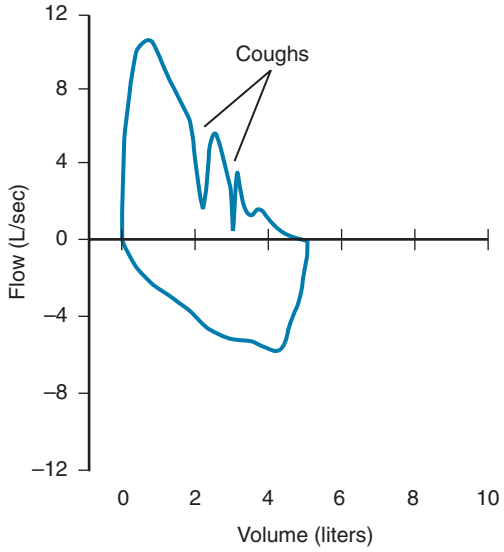

FIGURE 24-5 ■ An unacceptable spirogram due to coughing. Useful information may be obtained from spirograms with cough. If the cough occurs after the first second of exhalation, FEV_1 will be reliable.

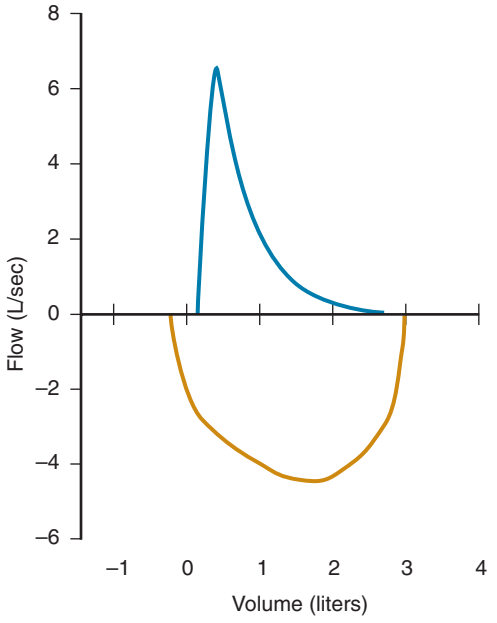

FIGURE 24-6 ■ An unacceptable spirogram due to expiratory leak. Note expiratory vital capacity is less than inspiratory vital capacity.

patients exhibit "negative effort dependence" in which maximal effort is associated with a reduced FEV_1 due to thoracic gas compression.[11,19] Negative effort dependence is classically seen in disease processes in which there is a loss of cartilage in the trachea or bronchi such as tracheomalacia, although it can also be observed in individuals without airway pathology. Reducing the effort after approximately 2 to 3 seconds of forceful exhalation does not appear to change the results and lessens discomfort and the risk of syncope.[20] Examples of unacceptable tests are shown in Figures 24-5 to 24-10.

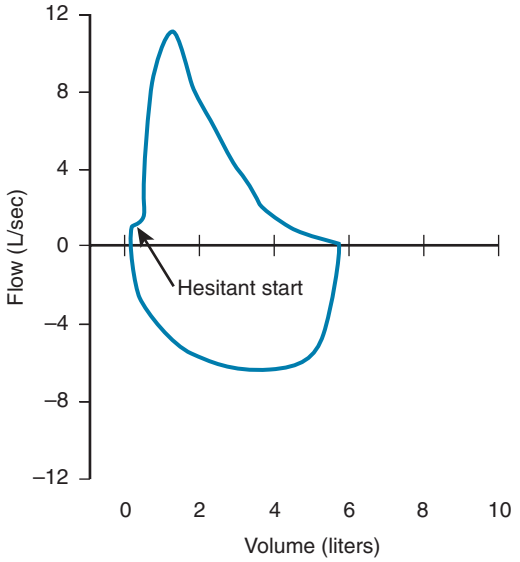

FIGURE 24-7 ■ An unacceptable spirogram due to hesitant start. This will result in an underestimation of FEV_1.

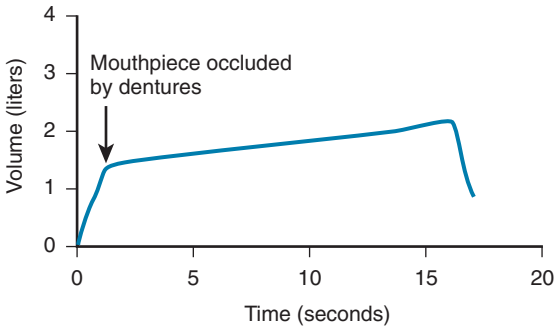

FIGURE 24-8 ■ An unacceptable spirogram due to partial mouthpiece obstruction by denture.

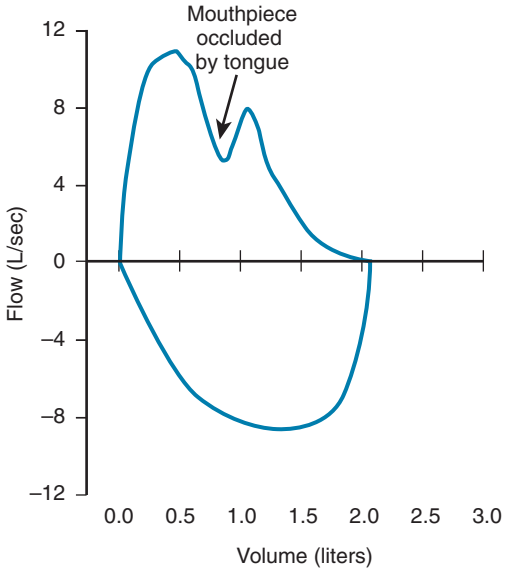

FIGURE 24-9 ■ An unacceptable spirogram due to transient occlusion of mouthpiece by tongue.

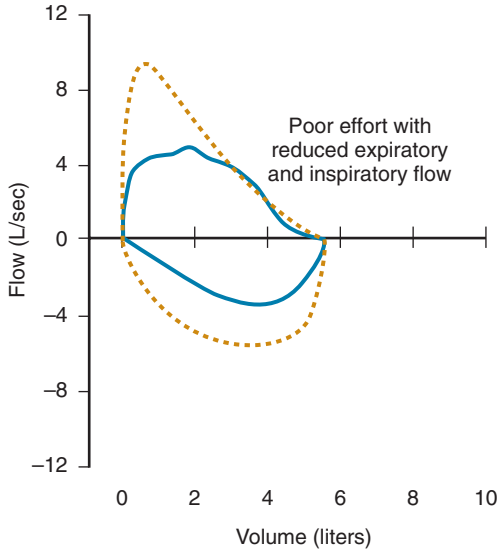

FIGURE 24-10 ■ An unacceptable spirogram due to submaximal effort is illustrated. Flattening of both the inspiratory and the expiratory limbs (*solid line*) is present. Inspiratory limb flattening due to submaximal effort is a common problem and needs to be distinguished from upper airway obstruction. A normal spirogram is superimposed (*dotted line*).

TABLE 24-3. Spirometry Repeatability (Between-Maneuver) Criteria

After three acceptable spirograms, apply the following criteria:

1. Are the two largest values of FVC within 0.15 L of each other?
2. Are the two largest values of FEV_1 within 0.15 L of each other?

If both criteria are met, conclude test session.

If criteria are not met, continue testing until criteria are met, patient is fatigued, or eight tests have been performed.

FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.
Modified from Miller MR, Hankinson J, Brusasco V, et al: Standardisation of spirometry. Eur Respir J 26:319–338, 2005.

An adequate test requires a minimum of three acceptable maneuvers, that is, maneuvers that meet the criteria described previously. The next step in interpretation is to determine whether the repeatability or between-maneuver criteria are met (Table 24-3). Specifically, the two largest values of FVC and FEV_1 must be within 0.15 L of one another. If the FVC value is less than 1.0 L, the highest and next highest FVC and FEV_1 should be within 0.10 L. In a study of 18,000 consecutive patients, 95% met these repeatability criteria and repeatability was not significantly influenced by patient characteristics such as sex, age, height, and smoking status.[21] If the repeatability criteria are not met after three acceptable tests, testing should continue until repeatability criteria are met or eight attempts have been made.[13] More than eight maneuvers is generally not useful.[22,23] From all acceptable tests, the largest FVC (or SVC if larger than FVC) and FEV_1 are selected for analysis, even if they come from different maneuvers. At least three maneuvers that meet the acceptability and repeatability criteria should be

saved. If the tests do not meet the acceptability and repeatability criteria, they may still have some clinical utility. The interpreting physician needs to comment in the report that the data should be considered minimum values for the patient.

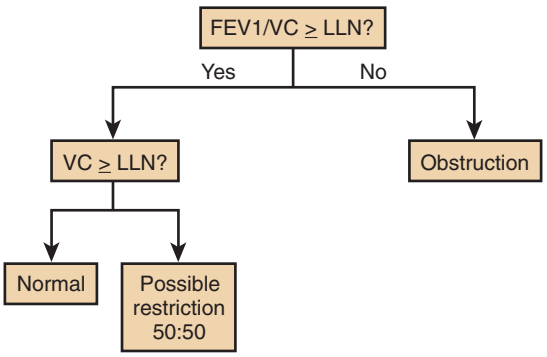
Spirometry Interpretation

After acceptable and repeatable studies are obtained, interpretation can proceed using a systematic approach. Using the FVC, FEV_1, and FEV_1/FVC ratio, an obstructive, restrictive, or normal pattern is determined. A simple approach for interpreting spirometry is shown in Figure 24-11. The first step is to assess the FEV_1/FVC ratio. Narrowing of either the large or the small airways will result in a larger reduction in FEV_1 relative to FVC, resulting in a reduced FEV_1/FVC ratio. The pathophysiologic processes in asthma and COPD primarily affect the mid to smaller airways and show a proportionally greater reduction in flow in the middle and later parts of exhalation. This produces the characteristic concave shape on the flow-volume curve.

Whereas obstruction is always defined as a low FEV_1/FVC, the definition of "low" is not consistent. The ATS/ERS Task Force on Standardization of Lung Function Testing[14] defines an obstructive ventilatory defect as a FEV_1/FVC ratio below the 5th percentile of the predicted value—a statistically defined lower limit of normal (LLN). The Global Initiative for Chronic Obstructive Lung Disease (GOLD) defines airway obstruction as a post-bronchodilator FEV_1/FVC less than 70%.[24] Both approaches use the FEV_1 percent predicted to grade the severity of airway obstruction. The ATS/ERS Task Force and GOLD criteria for defining and classifying airflow obstruction are listed in Figure 24-12.

The GOLD guidelines advocate the use of the fixed ratio for FEV_1/FVC for reasons of simplicity and ease of remembrance, while acknowledging that the FEV_1/FVC decreases with age and may result in the overdiagnosis of COPD in the elderly.[24] The process of aging results in a loss of elastic recoil; FEV_1 decreases more rapidly than FVC, resulting in a progressive reduction in the FEV_1/FVC ratio with advancing age. Figure 24-13 provides examples of flow-volume curves for normal subjects aged 20, 50, and 80 years. The ATS/ERS Task Force[14] emphasizes the importance of using the 5th percentile LLN to prevent overdiagnosis in the elderly and underdiagnosis in the younger population. This is depicted graphically in Figure 24-14. Using National Health and Nutrition Examination Survey (NHANES) III reference equations for white males for FEV_1/FVC, the LLN is less than 70% at ages older than 41 years. For white females, the LLN is below 70% at ages older than 52 years.[25] The risk of overdiagnosing an obstructive ventilatory pattern when using the fixed ratio of FEV_1/FVC less than 70% is evident in two studies both showing approximately 20% of elderly subjects misidentified as abnormal with the fixed ratio compared with the 5th percentile LLN method.[26,27] In our laboratory, we interpret the presence and severity of obstruction using the ATS/ERS criteria to avoid the misclassification of older and younger patients.

Another controversy arises in classifying those whose FEV_1/FVC ratio is reduced but the FEV_1 is in the normal range. Patients with this pattern have been identified as obstructed[14] or a "normal physiologic variant" when FEV_1 was greater than 100% of predicted.[28] Accurate interpretation of subjects with a reduced FEV_1/FVC ratio and a preserved FEV_1 requires clinical information, because it depends on the prior probability of obstructive disease. In healthy individuals, this pattern may represent unequal



Severity classification	FEV1 % predicted
Normal physiologic variant	>100
Mild	70–100
Moderate	60–69
Moderately severe	50–59
Severe	35–49
Very severe	<35

FIGURE 24-11 ■ A simple algorithm for interpreting spirometry beginning with the FEV_1/FVC ratio is shown. A reduced FEV_1/FVC ratio, less than the lower limit of normal (LLN), is diagnostic of obstruction, and the severity of obstruction is determined by the FEV_1 percent predicted. Restriction is suggested if the FVC is reduced, although a reduced FVC is not specific for a restrictive pattern.

DEFINITION OF OBSTRUCTION AND CLASSIFICATION OF SEVERITY BY SPIROMETRY

ATS/ERS FEV_1/FVC <LLN		GOLD FEV_1/FVC <0.70	
FEV_1 % predicted			FEV_1 % predicted
>70	Mild	Stage I: Mild	≥80
60–69	Moderate	Stage II: Moderate	<80
50–59	Moderately severe	Stage III: Severe	<50
35–49	Severe		
<35	Very severe	Stage IV: Very severe	<30

FIGURE 24-12 ■ The American Thoracic Society and European Respiratory Society (ATS/ERS) defines obstruction as an FEV_1/FVC ratio below the lower limit of normal (LLN) defined as below the 5th percentile of the predicted value. The Global Initiative for Chronic Obstructive Lung Disease (GOLD) defines obstruction as a FEV_1/FVC ratio less than 0.70. Both grade the severity of obstruction based on the FEV_1 percent predicted.

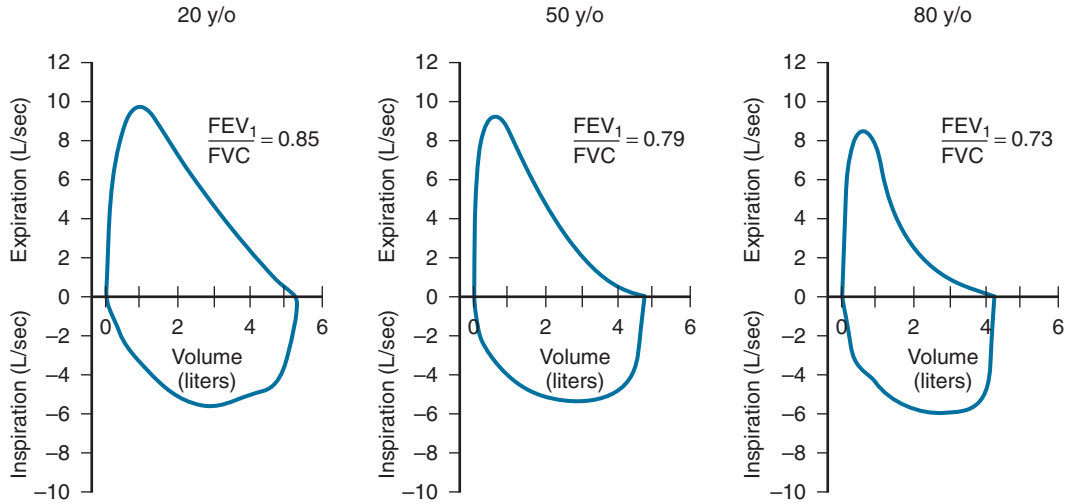


FIGURE 24-13 ■ Examples of flow-volume curves for healthy subjects aged 20, 50, and 80 years. The FEV_1/FVC ratio decreases with age, primarily due to a loss of elastic recoil. The changes in flow with ageing are most evident at lower lung volumes.

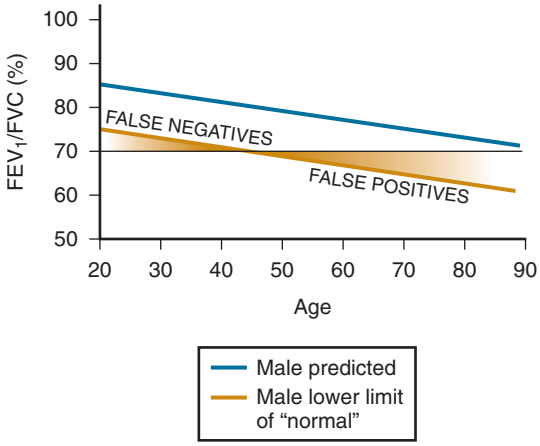

FIGURE 24-14 ■ The reduction in FEV_1/FVC with age for a white male is represented graphically. The *blue line* represents the predicted value and the *brown line* represents the LLN. After approximately age 41, the lower limit of normal is less than the 70% limit that the GOLD guidelines recommend as the threshold for obstruction. The *dark area* represents false positives and false negatives associated with using the 70% limit.

growth of the airways relative to the lung parenchyma, but in people with respiratory symptoms or exposures, it probably represents airway obstruction.

A restrictive ventilatory defect is defined as a total lung capacity (TLC) below the 5th percentile of the predicted value.[14] Because spirometry is much more readily available, technically easier, and less costly to perform than measurements of lung volumes (plethysmography, nitrogen washout, or inert gas techniques), FVC is often used as a surrogate for TLC to diagnose a restrictive abnormality. Spirometry-based algorithms can exclude a restrictive process with greater than 95% accuracy if the FVC is normal.[17,29] However, a low FVC cannot reliably diagnose restriction. A reduced FVC has a positive predictive value of only approximately 50% for confirming a restrictive process with only modest improvements in accuracy if reserved for patients with a normal FEV_1/FVC ratio.[30-32] Spirometry is helpful in excluding but not predicting a restrictive defect. VC will be reduced despite a normal TLC if inspiratory or expiratory efforts are submaximal and if there is air trapping associated with small airway closure or noncommunicating bullae.

It is not uncommon to identify patients with a reduced FEV_1 and FVC with a normal FEV_1/FVC ratio and normal TLC. This has been referred to as a "nonspecific pattern" and was found in approximately 10% of patients in a large academic PFT lab.[32a] The majority of patients with this pattern had either airway hyperresponsiveness or abnormalities that restrict the normal expansion of the lung or thorax such as obesity.

A mixed or combined ventilatory defect is present when both the FEV_1/FVC ratio and the TLC are below the 5th percentiles of their predicted values. A reduced FVC associated with a reduced FEV_1/FVC ratio is most likely due to hyperinflation, although a concomitant restrictive process cannot be ruled out without measurement of TLC by plethysmography. In a study of nearly 5000 patients with airway obstruction, approximately 40% had a reduced VC; less than 10% of this subgroup met the definition of restriction (reduced TLC measured with plethysmography).[33]

Though the FEV_1/FVC ratio is the spirometric standard for diagnosing obstruction, the FEV_1/FEV_6 ratio is an acceptable surrogate. The FEV_6 maneuver, which allows cessation of exhalation after 6 seconds, has several advantages over the standard FVC maneuver. It is less physically demanding for the patient. It simplifies spirometric testing for the technician, shortens testing time, and has superior reproducibility.[34] The FEV_1/FEV_6 ratio performs well in categorizing patients with obstruction with a sensitivity and specificity greater than 90% compared with the FEV_1/FVC ratio.[16,34,35,35a] Based on these findings, the National Lung Health Education Program has recommended replacement of FVC with FEV_6.[2] However, FEV_6 is not as sensitive as FVC at determining the presence of a restrictive respiratory impairment (sensitivities 83%-88%).[16,36] Reference values are available for FEV_1/FEV_6 and FEV_6.[25]

Bronchodilator Testing

Bronchodilator administration in the pulmonary function laboratory is commonly performed to determine acute reversibility of airflow limitation. The ATS/ERS Task Force[13] recommends the administration of four separate puffs at 30-second intervals of the short acting β_2-agonist albuterol (total of 400 mcg) using a spacer device. For pre- and postbronchodilator spirometry studies, a minimum of three acceptable and repeatable tests should be obtained at baseline and 15 minutes after bronchodilator administration. If the short-acting anticholinergic drug ipratropium bromide is used, testing should be repeated 30 minutes after administration. The combination of albuterol and ipratropium produces a greater response than either medication alone.[37] The ordering physician's purpose is paramount in determining the conditions of testing: If the aim of the study is to determine whether there is any evidence of reversible airflow obstruction, the patient should not take short-acting bronchodilators for 4 to 6 hours prior to testing and long-acting bronchodilators 12 to 24 hours before testing. However, if the goal is to determine whether lung function can be improved above that achieved with baseline treatment, medications should be taken as prescribed.[13]

There is no consensus as to what defines acute reversibility in patients with airflow limitation. Certainly, improvement in lung function must exceed the changes observed in healthy individuals administered bronchodilator. The 95th percentile for percent change from baseline in healthy nonsmokers for FEV_1 is 9%.[38] The ATS/ERS Task Force[14] defines a positive bronchodilator response as an increase in FEV_1 and/or FVC greater than or equal to 12% and 200 mL of the baseline value.

The clinical utility of acute bronchodilator testing is not well defined. The National Asthma Education and Prevention Program Expert Panel Report 3[39] recommends measuring pre- and postbronchodilator pulmonary function in asthmatics. The GOLD guidelines[24] recommend the use of postbronchodilator spirometry for diagnosis and staging of COPD. It is not clear how an acute response to bronchodilator in the laboratory influences the management of patients with asthma or COPD. One reported benefit of bronchodilator testing is to distinguish between asthma and COPD. Reversible airflow obstruction is the hallmark for asthma and irreversible obstruction is often a characteristic of COPD.[40] However, it is not uncommon for patients with COPD to respond acutely to bronchodilator; some studies report more than 50% of subjects met criteria for reversibility.[41–43] There is significant overlap between response to bronchodilator for patients with asthma and those with COPD, and it cannot reliably differentiate between asthma and COPD.[37] There are some quantitative and qualitative patterns more commonly associated with one than the other. In general, asthmatics have a larger absolute increase in FEV_1 than patients with COPD. In COPD patients who respond to bronchodilator, there often is an increase in FVC, whereas individuals with asthma more often respond with an increase in FEV_1.[44] Asthma is a disease characterized by variability in bronchial responsiveness and in bronchodilator reversibility. Similarly, bronchodilator responsiveness in COPD patients is not static. In one study, 52% of COPD patients changed their responder/nonresponder status over an 8-week period.[45] Bronchodilator reversibility cannot be the sole criteria for differentiation of asthma from COPD, and clinical information is necessary for making this distinction.

Another possible benefit of bronchodilator testing is the association between bronchodilator reversibility and prognosis. In asthma, larger responses to bronchodilator have been associated with an increased risk of accelerated loss of lung function and the development of fixed airflow obstruction.[46] For COPD patients, the importance of bronchodilator reversibility with regard to lung function decline and mortality is not clear; some studies suggest that it is a marker of more rapid disease progression[43,50] and others find no effect[47–49] or a positive impact on disease progression.[51]

Bronchodilator testing is not useful in predicting symptomatic improvement in patients with obstructive lung disease treated with bronchodilator therapy. The absence of a response to a bronchodilator given in the laboratory should not preclude a trial of bronchodilator medications.[52] The reason for the lack of correlation between traditional acute bronchodilator response (increase in FEV_1 and in FVC) and subsequent clinical benefit with use of bronchodilator may be due to a reduction in hyperinflation with bronchodilator use. Obstructed patients treated with bronchodilators have less hyperinflation, as measured by increased inspiratory capacity. The beneficial effect on hyperinflation is especially prominent with exercise.[53] A 10% improvement in inspiratory capacity with bronchodilator is a better predictor of improvement in dyspnea and in exercise tolerance in patients with COPD than is an improvement in FEV_1 or FVC.[54–57] Bronchodilator responses exhibiting an improvement in FEV_1 and FVC and an improvement in inspiratory capacity without an improvement in expiratory flows are illustrated in Figure 24-15. A positive bronchodilator response in COPD patients does not distinguish those patients who will clinically improve when treated with inhaled steroids from those who will not.[41]

Spirometry in Upper Airway Obstruction

The upper airway extends from the nose or mouth to the main carina of the trachea. The upper airway is further subdivided into the extrathoracic and intrathoracic components. The extrathoracic airway includes the nose, mouth, pharynx, larynx, and the 2 to 4 cm of the trachea cephalad to the thoracic inlet. The intrathoracic component comprises the 6 to 9 cm of trachea extending from the thoracic inlet caudal to the main carina. Spirometry is very useful in identifying upper airway obstruction (UAO).[58] UAO may present in a similar manner to the more common causes of airway obstruction such as asthma and COPD. Differentiating UAO from these more common causes of airway obstruction is important because treatment is very different and confirmatory diagnostic tests are required.

The flow-volume loop is the single best PFT for diagnosing UAO. The importance of the flow-volume tracing in diagnosing UAO was demonstrated by Miller and

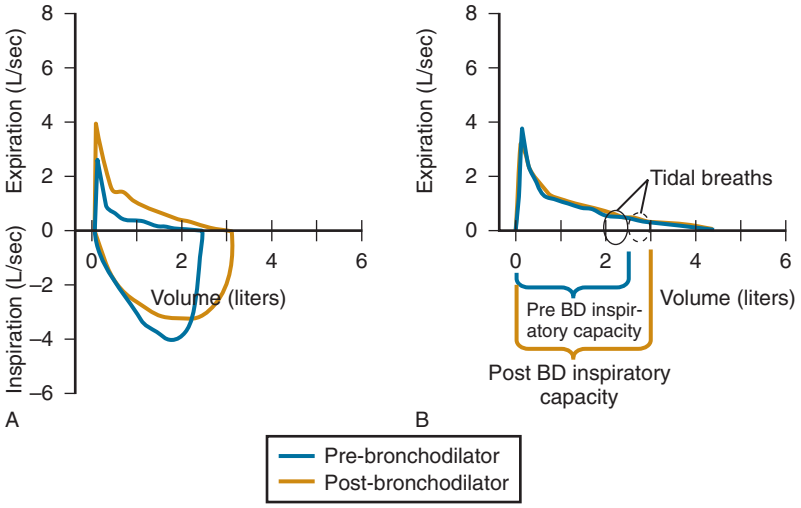

FIGURE 24-15 ■ Patients with airflow obstruction may improve following the administration of bronchodilator in two ways: FEV_1 and/or FVC may improve by 12% and 200 mL (**A**), or there may be a reduction in hyperinflation manifest by an increase in inspiratory capacity (**B**). A reduction in hyperinflation is associated with clinical improvement.

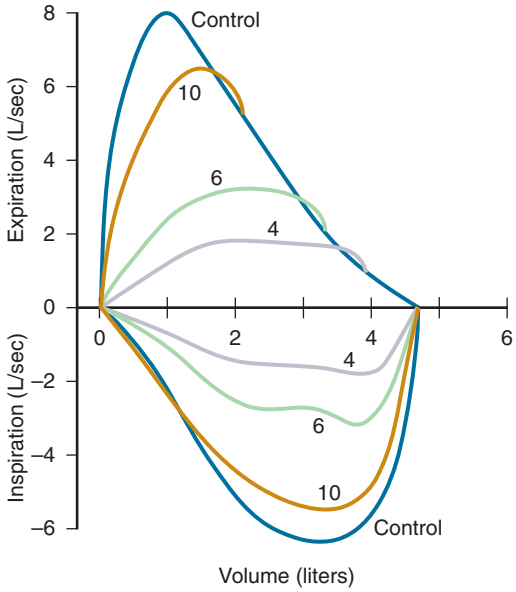

FIGURE 24-16 ■ Reductions in inspiratory and expiratory flows with a healthy subject breathing through progressively smaller calibrated fixed orifices (from 10 mm to 4 mm) are shown. Breathing through the orifices did not affect FVC and FEV_1 remained above 90% of control value until the 6 mm orifice was used. (Modified from Miller RD, Hyatt RE: Obstructing lesions of the larynx and trachea: Clinical and physiologic characteristics. Mayo Clin Proc 44:145–161, 1969.)

Hyatt.[59] They obtained flow-volume tracings with normal volunteers breathing through calibrated orifices. With decreasing orifice diameter, a prominent plateau was noted throughout inhalation and exhalation as shown in Figure 24-16. Their study also confirmed the poor sensitivity of FVC and FEV_1 for detecting UAO and affirmed the need to examine the flow-volume curve when UAO is suspected. FVC was not affected by the orifices and FEV_1 remained above 90% of the control value until the 6-mm orifice was used.[59]

Three patterns of UAO can be identified by examining the inspiratory and expiratory components of the flow-volume tracing.[59–61] The UAO pattern is determined by the location of the obstruction (intrathoracic or extrathoracic) and whether the obstruction is fixed or variable. Reviewing the physiologic principles that govern air movement into and out of the airways can identify the pattern of obstruction observed with the flow-volume curve. Transmural pressure gradients develop across the upper airway wall with inhalation and exhalation. Whether the transmural pressure is positive or negative depends on the phase of respiration (inhalation or exhalation) and on the location of the obstruction. Under normal circumstances, the integrity of the airway wall prevents crimping or expansion, preserving airflow. With variable extrathoracic obstruction, as depicted in Figure 24-17, transmural pressure is negative with inhalation, resulting in crimping of the airway at the site of the lesion, reducing airflow and flattening the inspiratory limb of the flow-volume tracing. With exhalation, transmural pressure is positive, decreasing the degree of obstruction and improving flow. Patient effort is especially important when using the flow-volume curve to diagnose UAO. In our experience, the most common cause of inspiratory limb flattening is submaximal inspiratory effort. Causes of extrathoracic UAO include tracheomalacia; vocal cord abnormalities (paralysis, edema, neoplasms, vocal cord dysfunction); thyroid tumors; laryngeal edema (angioedema, post-extubation, burns); epiglottitis, tonsillar, and retropharyngeal abscesses; and foreign bodies.[62] While the reduction in inspiratory flow is most pronounced with these causes of variable extrathoracic obstruction, PEF is also decreased but to a smaller degree. The flow-volume curve reveals a more pronounced decrease in the inspiratory limb flattening than in the expiratory limb. The exception is extrathoracic tracheomalacia, which exhibits only inspiratory limb flattening with a normal expiratory limb.

Variable intrathoracic obstruction is shown in Figure 24-18. Transmural pressure is negative with exhalation as pleural pressure exceeds intratracheal pressure, crimping the airway downstream of the site of the lesion, reducing airflow and flattening the expiratory limb of the flow-volume curve. With inhalation, tracheal pressure exceeds surrounding pleural pressure, no compression

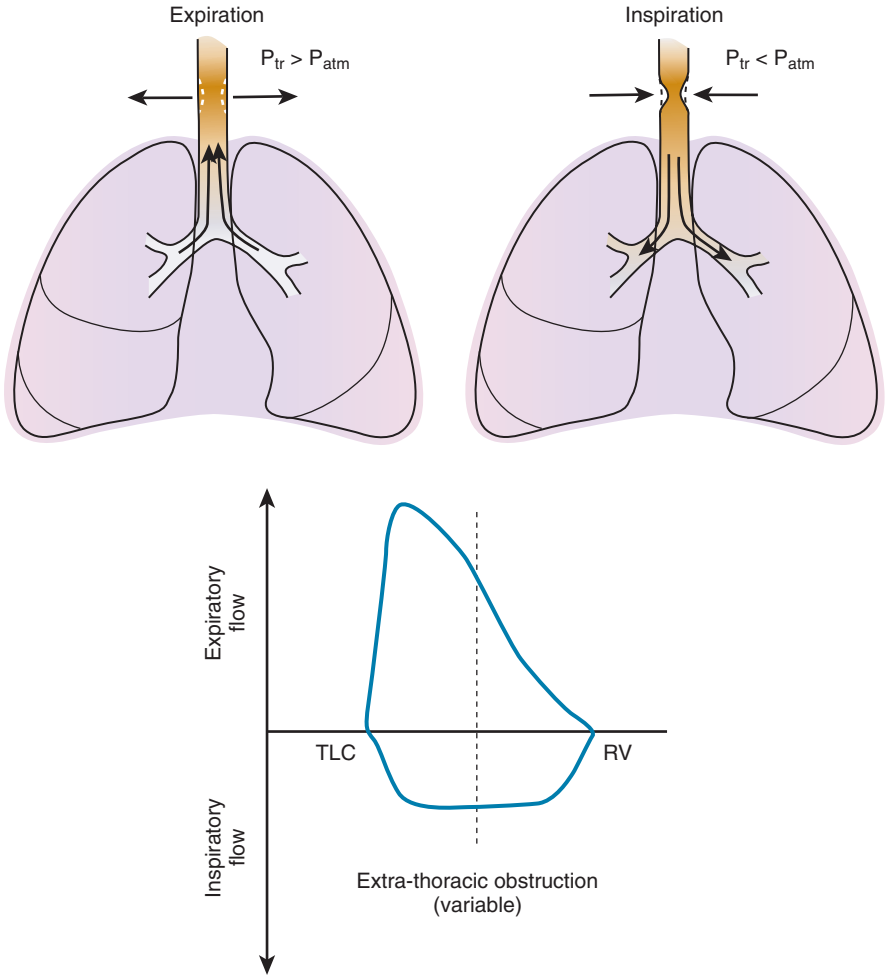

FIGURE 24-17 ■ Characteristic changes in upper airway diameter with variable extrathoracic obstruction. Inspiratory limb flattening is seen on the flow-volume curve. Forced expiratory flow at 50% of lung volume ($FEF_{50\%}$) is greater than forced inspiratory flow at 50% of lung volume ($FIF_{50\%}$).

downstream occurs, resulting in greater inspiratory flow. Causes of variable intrathoracic obstruction include tracheomalacia, tracheal tumors, tracheal inflammatory processes (Wegener's granulomatosis, tracheitis), and mediastinal adenopathy.[62] Similar to variable extrathoracic obstruction discussed previously, most causes of variable intrathoracic obstruction result in reductions of both expiratory and inspiratory flows with more pronounced reductions in expiratory flows. The exception is intrathoracic tracheomalacia, which exhibits only expiratory limb flattening with a preserved inspiratory limb. Fixed lesions of the upper airway are firm and relatively resistant to the effects of transmural pressure changes. They do not change significantly with the phase of respiration and both the inspiratory and the expiratory limbs of the flow-volume curve are similarly flattened (as illustrated in Fig. 24-19). The most common cause of fixed UAO is subglottic stenosis from prior intubation or tracheostomy. Other causes include benign and malignant tumors anywhere in the upper airway, large thyroid goiters, and large foreign bodies.[62] Tracheomalacia located at the thoracic inlet will also result in near-equal reduction in both inspiratory and expiratory flows.

The ratio of forced expiratory flow at 50% of lung volume to forced inspiratory flow at 50% of lung volume (FEF_{50}/FIF_{50}) is a simple test for determining the type of UAO. Miller and Hyatt[60] documented the following ratios for $FEF_{50\%}/FIF_{50\%}$: normal individuals of 1.0 or greater; fixed upper airway obstruction 0.9; variable extrathoracic UAO 2.2; and variable intrathoracic obstruction 0.3.

The diagnosis of UAO is more difficult when there is concomitant "lower" airway obstruction associated with asthma or COPD.[63] Rotman and coworkers[64] found four variables derived from the FVC maneuver to be useful in distinguishing UAO from normal subjects and patients with COPD. These included: $FIF_{50\%}$ of 100 L/min or less; $FEF_{50\%}/FIF_{50\%}$ of 1.0 or greater; FEV_1/PEF of 10 mL/L/min or greater; and $FEV_1/FEV_{0.5}$ of 1.5 or greater. However, there was significant overlap between the groups, and others have proposed measuring the maximum voluntary ventilation (MVV) and then using the MVV/FEV_1 ratio of 25 or less as a criterion for diagnosing UAO or concomitant UAO and COPD.[65,66] However, MVV is highly dependent on patient effort and more variable, making this test less clinically useful.

While spirometry is very helpful in evaluating UAO, visual inspection of the flow-volume curve or any of the values derived from the FVC maneuver can be misleading when patient effort is submaximal and when there is concomitant obstructive lung disease. Confirmatory tests such as ultrafast cinetomographic computed

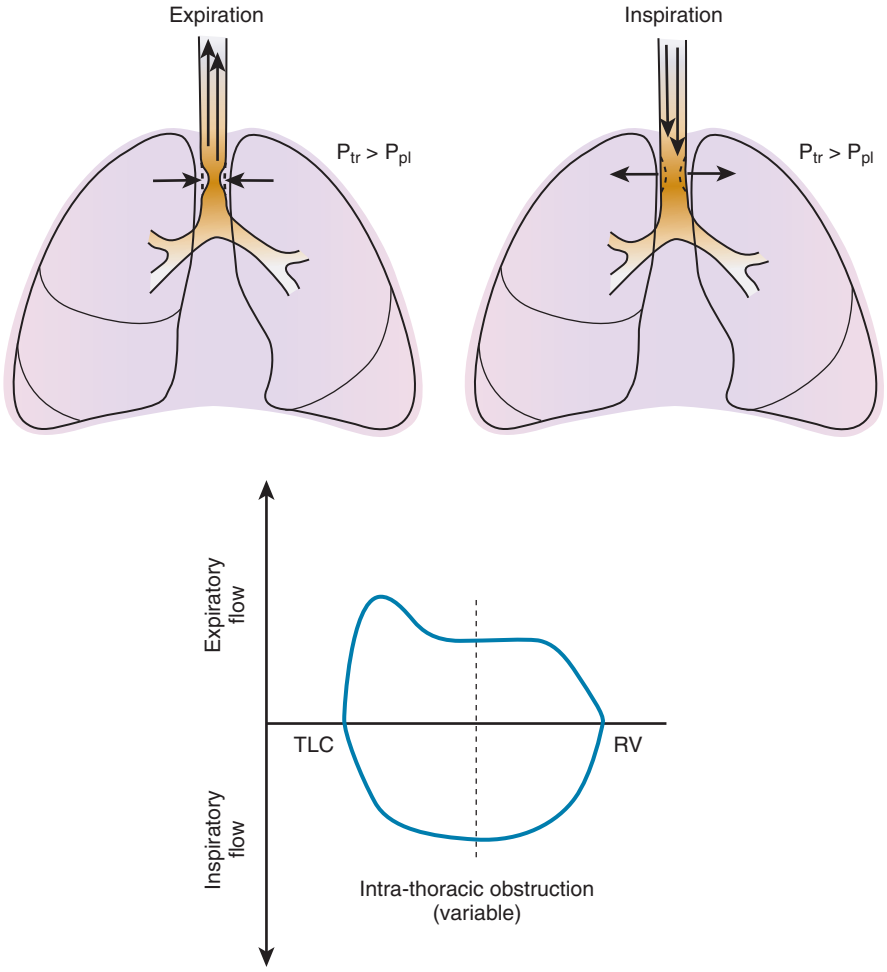

FIGURE 24-18 ■ Characteristic changes in upper airway diameter with variable intrathoracic obstruction. Expiratory limb flattening is seen on the flow-volume curve. $FEF_{50\%}$ is less than $FIF_{50\%}$.

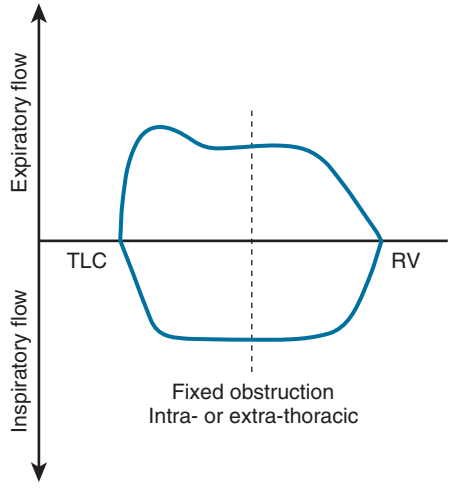

FIGURE 24-19 ■ With fixed upper airway obstruction, there is flattening of both the inspiratory and the expiratory limbs of the flow-volume curve. $FEF_{50\%}$ is approximately equal to $FIF_{50\%}$.

tomography (cine-CT) and laryngoscopy or bronchoscopy are necessary to confirm the diagnosis.

DIFFUSING CAPACITY

The diffusing capacity for carbon monoxide (D_{LCO}) is a common and clinically useful test that provides a quantitative measure of gas transfer in the lungs. D_{LCO}, along with spirometry, is a core PFT used to evaluate and manage patients with respiratory diseases. Diffusing capacity is often abnormal in patients with interstitial lung disease, pulmonary vascular disease, and COPD. Because D_{LCO} is a measure of the transfer of gas from the airways to the reaction with hemoglobin in the pulmonary capillaries, D_{LCO} has been called a "window on the pulmonary microcirculation."[67] Diffusing capacity is influenced by processes in addition to diffusion and is usually obtained at rest when it is submaximal so it is not a true capacity measurement. Transfer factor (T_{LCO}), the term commonly used outside of North America, is technically a more accurate name for the test. However, because of its historical use and for the sake of uniformity, the ATS/ERS Task Force[68] continues to endorse the term D_{LCO}.

Diffusing Capacity Physiology

Measuring $D_{L_{CO}}$ provides information on the transfer of gas from the airways to hemoglobin. This is depicted in Figure 24-20. The gas essential to cellular metabolism is O_2 but CO is used in the test. Why is the diffusion of CO measured rather than the diffusion of O_2? Both CO and O_2 readily diffuse across the alveolar capillary membrane and bind tightly with hemoglobin. However, CO has a binding affinity for hemoglobin 200 to 250 times greater than that of O_2. Because of the high affinity combined with the abundance of CO binding sites on the hemoglobin molecule, the pulmonary capillary CO tension remains near zero when low concentrations of CO are inhaled. The CO uptake is therefore diffusion limited. In contrast, the pulmonary capillary O_2 tension or partial pressure rises along the length of the capillary, creating appreciable back tension (Fig. 24-21). Oxygen is perfusion-limited in normoxic conditions and perfusion and diffusion-limited in hypoxic conditions. Despite the fact that O_2 is the primary gas of interest, technical factors preclude measurement of $D_{L_{O_2}}$. At the present time, CO is the best gas to measure the diffusion properties of the lung.

Fick's law describes the diffusion of a gas through tissue. The amount of gas transferred across a membrane is directly proportional to the tissue surface area, diffusion constant, and the difference in gas partial pressure and is inversely proportional to the tissue thickness. The diffusion constant is proportional to the solubility of a gas and is inversely proportional to the square root of the molecular weight of the gas. This relationship is shown in Figure 24-22. It is not possible to determine the tissue area or thickness of the alveolar capillary membrane for the entire lung so area, thickness, and the diffusion constant are replaced by a single constant, D_L, which represents the diffusing capacity for the lung.

$$\dot{V}_{gas} = D_L \times (P_1 - P_2)$$

where D_L is the diffusing capacity of the lung and P_1 and P_2 are the gas concentrations in the alveolus and pulmonary capillary, respectively. When CO is the gas being

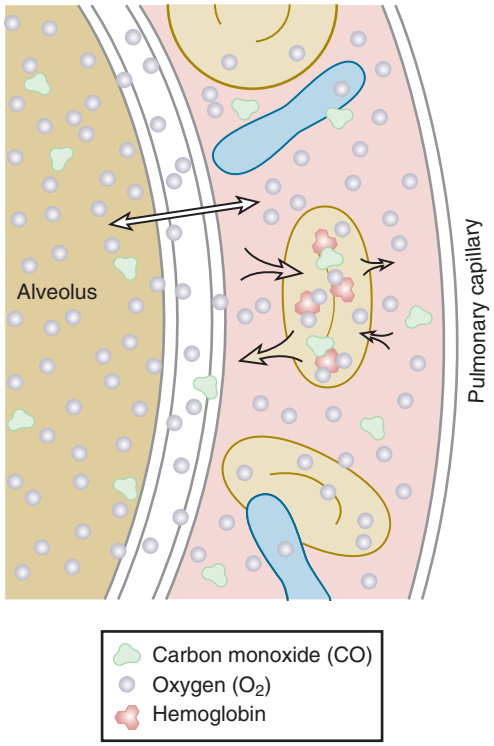

FIGURE 24-20 ■ The transfer of carbon monoxide and oxygen molecules across the alveolar-capillary membrane, through plasma, across the red blood cell membrane and the reaction with hemoglobin is represented.

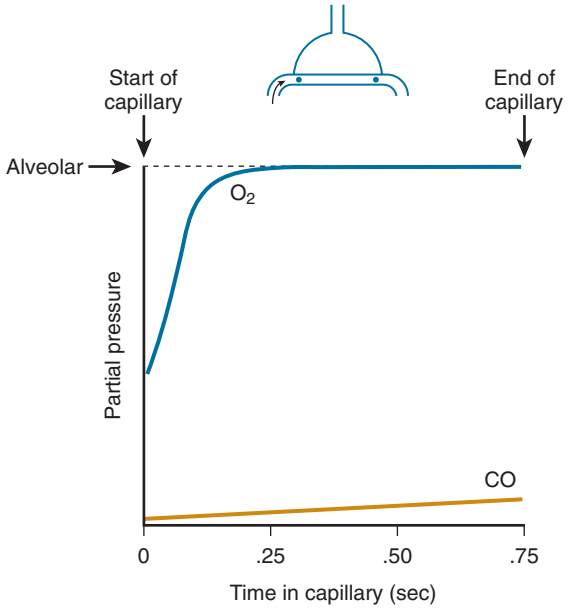

FIGURE 24-21 ■ This figure illustrates why oxygen (O_2) uptake is perfusion limited under most clinical circumstances, because the capillary partial pressure of O_2 rapidly increases along the length of the pulmonary capillary, while the capillary partial pressure of carbon monoxide, at low concentrations, remains near zero and its uptake is limited by diffusion.

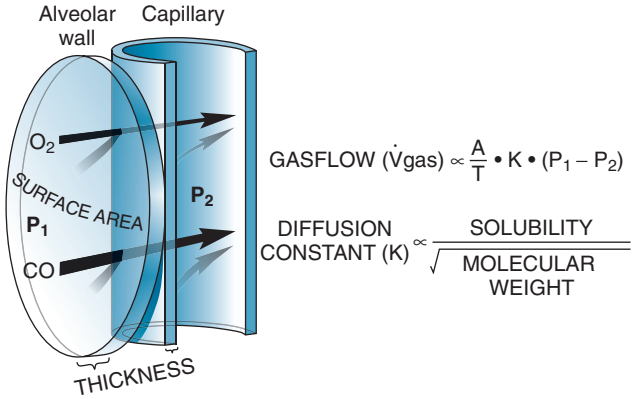

FIGURE 24-22 ■ Fick's law describes the factors that determine diffusion of a gas ($\dot{V}_{GAS}$) through tissue including tissue surface area (A), a diffusion constant (K), the difference in gas partial pressure across the tissue ($P_1 - P_2$) and tissue thickness (T).

measured, P_2 is assumed to be small and is ignored. The equation then becomes

$$D_{L_{CO}} = \dot{V}_{CO} / P_{A_{CO}}$$

Or, in words, the quantity of CO transferred from the alveolar gas to the capillary blood, or the $D_{L_{CO}}$, is equal to the volume of CO transferred per minute per millimeter of mercury of alveolar partial pressure of CO. The traditional units for $D_{L_{CO}}$ are millimeters CO at STPD (standard temperature, pressure, and dry) conditions/min/mm Hg; SI units are moles CO/min/kPa.[68]

As illustrated in Figure 24-20, the pathway for diffusion of CO and O_2 involves diffusion across the alveolar capillary membrane (consisting of the alveolar cell, the basement membrane, a potential interstitial space, and the capillary endothelium), across a thin layer of plasma, across a red blood cell membrane, and within the red blood cell until they bind with hemoglobin. Roughton and Forster[69] simplified this process into two stages: (1) diffusion of CO from the alveolus to the red cell interior, described as the membrane component (D_M), and (2) the rate of uptake of CO by binding with hemoglobin in the red cells per mm Hg CO tension (θ) and the blood volume of the pulmonary capillary bed (V_C). The basic equation for $D_{L_{CO}}$ is a conductance, flow divided by pressure change ($\dot{V}/\Delta P$). The reciprocal of conductance is resistance and resistances can be added in series. Roughton and Forster[69] proposed the following equation to describe the diffusion of CO in the lung:

$$1/D_{L_{CO}} = 1/D_M + 1/\theta V_C$$

The relative contribution of each component can be determined by measuring $D_{L_{CO}}$ with high concentrations of inspired O_2. With increasing partial pressure of O_2, CO competes with O_2 for hemoglobin binding, reducing the θV_C component. While this is conceptually important in determining the pathophysiologic mechanism for reduced $D_{L_{CO}}$ in various conditions, it has not been found to be clinically useful because of technical difficulties and poor reproducibility.[70]

Diffusing Capacity Test Performance

The single-breath technique is the most common method for measuring $D_{L_{CO}}$ and is the focus of this discussion. Its advantages are that it has been standardized by the ATS/ERS Task Force, there are well-defined reference values for healthy subjects, and the majority of clinical studies have used this method.[68] Diffusing capacity can be measured using other techniques including the steady state, rebreathing, intrabreath, and multiple inert gas methods. These are more technically demanding and are reviewed elsewhere.[71]

The single-breath $D_{L_{CO}}$ technique requires a subject to inhale a gas mixture containing a low concentration of CO and an inert gas, usually helium, methane, or neon. The inert gas is essentially insoluble and cannot cross the alveolar capillary membrane. Because the inhaled concentration of inert gas is known, the alveolar volume (VA) can be determined by measuring the exhaled concentration. The initial alveolar concentration of CO (PA_{CO}) can be determined by making the assumption that CO is diluted to the same extent as the inert gas. The advantage of this method is that it only requires knowing the concentrations of the inhaled CO and inert gas and the concentrations of the same gases in an alveolar sample. This method allows the measurement of VA as well as $D_{L_{CO}}$.

The measurement of the single-breath $D_{L_{CO}}$ measurement is more complex than spirometry. It requires a higher level of commitment and expertise for test performance, maintenance, and quality control. In addition, the instrument is considerably more expensive than a spirometer, often costing more than $30,000. For these reasons, $D_{L_{CO}}$ is not commonly performed in the outpatient office setting. The basic instrument consists of a source of test gas, a device for measuring inspired and expired volume, and gas analyzers. The test gas is usually a mixture of 0.3% CO, an inert gas (often either 0.3% methane, 10% helium, or 0.5% neon), 17% or 21% O_2, and the balance nitrogen. At altitudes above sea level, gas mixtures with a higher concentration of O_2 are often used to achieve an inspired O_2 partial pressure similar to that at sea level.[72,73] The gas analyzer can be a single-sample slow-responding analyzer or a continuous high-speed analyzer. The high-speed analyzers allow the washout volume and alveolar sample volume to be adjusted and appear to improve the accuracy and reproducibility of $D_{L_{CO}}$ measurements.[74]

Performance standards for $D_{L_{CO}}$ equipment and quality control measures are discussed in detail elsewhere.[68] The methods for determining instrument accuracy vary from instrument to instrument, and specific instructions provided by the manufacturer must be followed. Standard recommendations suggest that before each test, the gas-analyzer should be zeroed. Each day, volume accuracy should be tested with a 3-L syringe. In addition, the system should be tested weekly with a biologic control or a commercially available $D_{L_{CO}}$ simulator (Hans Rudolph, Inc., Kansas City, MO).

Standardizing test performance is important to minimize variability. The patient should be instructed not to smoke or exercise vigorously on the day of the test, and if clinically safe, supplemental oxygen should be discontinued 10 minutes prior to testing. The patient should inspire the test gas in less than 4 seconds. The inhaled volume should be at least 85% of the largest known VC. The patient then holds his or her breath for 10 (±2) seconds, maintaining near-atmospheric pressure during the breath-hold (performing neither a Valsalva nor a Müller maneuver). Breath-hold time is calculated using the Jones-Meade method (two thirds of the time for inspiration and continuing until halfway through the sample collection).[75] After the breath-hold, the patient is instructed to exhale smoothly without hesitation. Total exhalation time for clearing the washout volume and collecting the alveolar sample should not exceed 4 seconds. Measurement of $D_{L_{CO}}$ requires an adequate alveolar sample. The alveolar sample is the gas volume obtained after the anatomic and mechanical dead-space volumes are cleared or "washed out." It is the volume of gas used to analyze the CO and tracer gas concentrations.

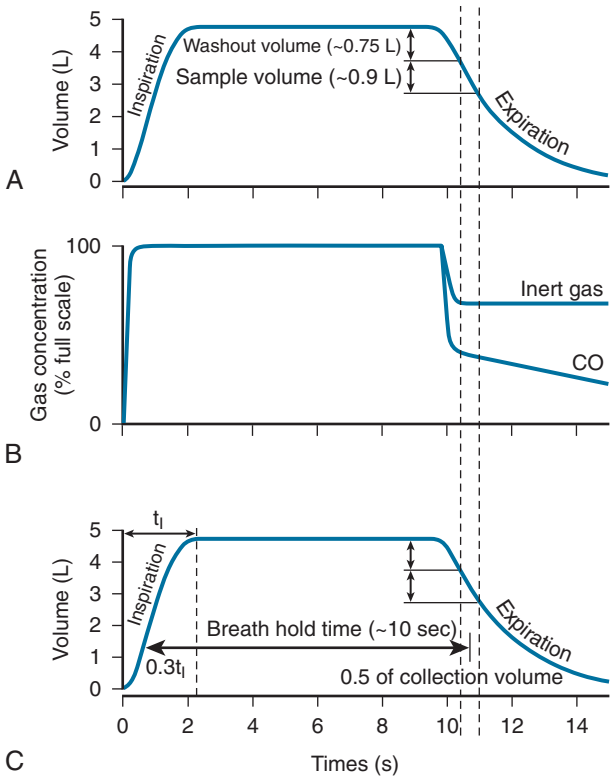

FIGURE 24-23 ■ Diffusing capacity tracings are represented including lung volumes (**A**) with washout and sample volumes; inert gas and carbon monoxide (CO) concentrations (**B**); and Jones-Meade method for calculating breath-hold time (**C**), which begins at 0.30 of inspiratory time and continues to 0.50 of sample collection.

The washout volume needed to clear the dead space confidently is 0.75 to 1.0 L.[74] In patients with a VC of less than 2.0 L, the washout volume may be reduced to 0.50 L. If all lung units emptied simultaneously, it would not matter where the alveolar sample was collected as long as the dead space was appropriately cleared. However, in patients with lung units that empty with different time constants, a suitable volume is needed to represent multiple lung units. The recommended alveolar sample gas volume collected for analysis is 0.50 to 1.00 L. In patients with a VC of less than 2.0 L, an alveolar sample gas volume of less than 0.50 L is acceptable if the dead-space volume has been adequately cleared. This can be done by visually adjusting the alveolar sample collection at a point where the inert gas concentration has started to plateau. It requires a system with a rapid gas analyzer. The single-breath DL_{CO} maneuver is illustrated in Figure 24-23.

The DL_{CO} maneuver should be repeated until there are at least two technically acceptable and repeatable tests or until five tests have been performed. The ATS/ERS Task Force suggests the average of at least two acceptable tests be reported. The tests should be repeatable within 3 mL CO (STPD)/min/mm Hg of each other or within 10% of the highest value.[68] Many laboratories require a higher degree of intrasession repeatability. See the section on "Interpreting Change in Lung Function," later. A DL_{CO} maneuver checklist is included as Table 24-4.

TABLE 24-4. DL_{CO} Maneuver Checklist

V_I is at least 85% of largest VC
Rapid inspiration – V_I inspired in <4.0 seconds
Breath-hold time of 10 ± 2 seconds; no evidence for air leak during breath-hold
Intrapulmonary pressure during breath-hold is near atmospheric; no Valsalva or Müller
Smooth unforced exhalation in < 4 seconds
Washout (dead-space) volume is 0.75 to 1.0 L (0.50 L is acceptable if VC < 2.0 L)
Sample (alveolar) volume is 0.50 to 1.0 L and collected on plateau of inert gas tracing (<0.50 L is acceptable if VC < 2.0 L)
A minimum of two acceptable tests within two units

DL_{CO}, diffusing capacity for carbon monoxide; VC, vital capacity; V_I, inhaled volume.

Variability in Diffusing Capacity Measurements

Many technical and physiologic factors influence DL_{CO} variability. These sources of variability must be minimized to obtain clinically useful results. As noted previously, the ATS/ERS Task Force recommended that two acceptable tests be within 3 mL CO (STPD)/min/mm Hg of each other or within 10% of the highest value and laboratories should strive to meet a repeatability criteria of 2 mL CO (STPD)/min/mm Hg. Strict adherence to guideline recommendations will reduce variation. Interlaboratory variability for DL_{CO} can be very large and comparing results from different laboratories should be done cautiously.[76] If technical factors are tightly controlled, intra-individual variability can be within 5%. This is comparable with the accepted intra-individual variability for FVC and FEV_1.[77–79]

The most important technical sources of variation in the measurement of DL_{CO} include the inspired volume of test gas, rate of inspiration, breath-hold duration, method of calculating breath-hold time, the condition of the breath-hold, dead-space washout volume, and gas analysis. The measurement of inspired and expired volumes must be accurate. Inspiratory volume should be within 85% of another independent measure of VC. A submaximal inspiratory volume will reduce the DL_{CO}[80] as will prolonging inspiration beyond 4 seconds. Breath-hold time should be 10 ± 2 seconds using the Jones-Meade method described earlier. An underreported breath-hold time will result in an overestimation of DL_{CO}. During the breath-hold, intrapulmonary pressure should be near atmospheric[81]; a Valsalva maneuver (expiratory efforts against a closed airway) will decrease venous return and thoracic blood volume, resulting in a decrease in DL_{CO} of

up to 17%.[82] A Müller maneuver (inspiratory efforts against a closed airway) will have the opposite effect on venous return and thoracic blood volume and may increase DL_{CO} up to 6%.[82] If the dead-space volume is not cleared, the resulting contamination of the alveolar gas sample will result in an underestimation of DL_{CO}. Gas analyzer instability is a frequently unrecognized technical source of increased variability.

Physiologic sources of variability may be more difficult to control than technical sources of variability but must be considered when interpreting changes in an individual's DL_{CO}. The most important physiologic sources of variability in the measurement of DL_{CO} are listed in Table 24-5. Cross-sectional reference studies have shown that DL_{CO} is primarily influenced by age, height, sex, and race.[72,83] Diffusing capacity is lower with advancing age and shorter height. It is lower in women than in men for any given height and hemoglobin level. In African Americans, DL_{CO} is lower by an average of 1.96 mL CO (STPD)/min/mm Hg compared with whites for a given height.[84] Reduced hemoglobin (anemia) results in a reduction in DL_{CO} and an adjustment for hemoglobin concentration is important for interpretation.[68] An elevated carboxyhemoglobin level lowers DL_{CO} by reducing the available hemoglobin binding sites and by increasing the back-pressure of CO in alveolar capillary blood. In general, a 1% increase in carboxyhemoglobin reduces the measured DL_{CO} by 1%.[68] Because cigarette smoking is the most common reason for increased carboxyhemoglobin, patients should not smoke on the day of the test. Changes in inspired O_2 concentration (increased with the use of supplemental O_2, decreased at higher altitude) affect DL_{CO}. Diffusing capacity increases with lower inspired O_2 pressure (P_{O_2}), because O_2 and CO compete for the same binding sites on the hemoglobin molecule. The altitude effects on DL_{CO} can be corrected by either increasing the test gas O_2 concentration or by using an altitude adjustment equation.[73] For example, in Salt Lake City, UT (altitude 1400 m), 25% O_2 is commonly used in the DL_{CO} test gas mixtures to produce a PO_2 similar to that at sea level (150 mm Hg).[72]

TABLE 24-5. Physiologic Sources of Variability in Measurement of DL_{CO}

Age

Body position
Bronchodilation

Other physiologic conditions can affect DL_{CO}. Diffusing capacity decreases from morning to evening, a finding likely explained by small changes in hemoglobin during the course of the day.[85] Diffusing capacity can vary about 9% throughout a woman's menstrual cycle, with the highest level occurring just before menses and the lowest occurring 5 to 10 days after the onset of menses. This monthly variation is not explained by changes in hemoglobin concentration.[86] Current and former cigarette smokers have small reductions in DL_{CO} compared with never smokers that is proportional to the number of pack-years.[84] The effects of exercise on DL_{CO} are complex. During exercise, DL_{CO} increases and is associated with increased capillary blood flow.[87,88] Following intense exercise, DL_{CO} falls below preexercise levels, perhaps representing a redistribution of pulmonary capillary blood volume to peripheral muscles.[89] Diffusing capacity decreases as a patient moves from the supine to sitting to standing positions,[87] and it is recommended that patients be sitting at least 10 minutes prior to testing and remain sitting during testing. Bronchodilator administration increases DL_{CO} as much as 6% in patients with obstructive lung disease.[90] The use of bronchodilator drugs prior to testing should be noted in the interpretation.

Diffusing Capacity Interpretation

As with all PFTs, the first step in interpreting a DL_{CO} study is to review and comment on test quality and repeatability. The results from two acceptable tests should be within 3 mL CO (STPD)/min/mm Hg of each other and the mean value reported. Adjustments for hemoglobin and carboxyhemoglobin should be reported. The test is judged abnormal if it is below the lower 5th percentile of the reference population. The ATS/ERS Task Force criteria[14] for grading the severity of reductions in DL_{CO} are listed in Table 24-6.

A common practice is to adjust or "correct" DL_{CO} for lung volume by using DL_{CO}/VA. The clinical utility of this measurement is questionable primarily because the relationship between DL_{CO} and VA is not linear. In some circumstances, including postpneumonectomy patients and normal subjects with incomplete inhalation, the reduction in DL_{CO} is less than the concomitant decrease in VA and the DL_{CO}/VA will be increased. In patients with pulmonary vascular disease and in some patients with

TABLE 24-6. Degree of Severity of Decrease in DL_{CO}

Degree of Severity	DL_{CO} % Predicted
Mild	>60% and <LLN
Moderate	40%–60%
Severe	<40%

DL_{CO}, diffusing capacity for carbon dioxide; LLN, lower limits of normal.
Modified from Pellegrino R, Viegi G, Brusasco V, et al: Interpretative strategies for lung function tests. Eur Respir J 26:948–968, 2005.

hyperinflation, the reduction in D_{LCO} is greater than the concomitant change in VA, resulting in a decrease in D_{LCO}/VA.[80,91] When ventilation is maldistributed and VA is altered, it cannot be assumed that the diffusion properties of the maldistributed lung units are the same as the more normal lung units. In summary, the measurement D_{LCO}/VA is commonly misleading and cannot be relied upon to make clinical decisions.

The single-breath D_{LCO} test requires the measurement of VA. VA minus dead-space volume approximates TLC. However, VA is determined by the inert gas dilution method and measures only those areas of the lung that communicate with the mouth. Lung units that contain "trapped" gas are not measured. In patients with obstructive lung disease, VA results in a significant underestimation of TLC as compared with a TLC measured by body plethysmography.[92,93] Relying on VA to assess lung volumes may wrongly classify patients with obstructive lung disease as having a mixed obstructive/restrictive abnormality (see "Techniques for Measuring Lung Volumes," later).

Clinical Utility of Diffusing Capacity

The main objective of pulmonary function testing is to provide useful information to help answer the clinical question for which the test was ordered. Diffusing capacity interpretation is most clinically useful when it is performed in conjunction with measurements of spirometry and lung volumes. A low D_{LCO} with normal spirometry suggests the presence of pulmonary vascular disease, early interstitial lung disease, emphysema associated with a restrictive lung process, anemia (reduced hemoglobin), or elevated carboxyhemoglobin level. Pulmonary vascular diseases such as idiopathic pulmonary artery hypertension, pulmonary embolism, chronic thromboembolic pulmonary hypertension, and pulmonary vasculitis should be considered in a patient with a significant reduction in D_{LCO} and normal spirometry and lung volumes.[94,95] Early interstitial lung disease can cause mild to moderate reductions in D_{LCO} before the development of abnormal spirometry and lung volumes. A reduced D_{LCO} is often an early manifestation of interstitial lung disease, and a low D_{LCO} in a patient with dyspnea should lead to further evaluation such as a high-resolution CT scan of the chest.[96] Emphysema with a concomitant restrictive process such as idiopathic pulmonary fibrosis, amiodarone-induced interstitial lung disease, and hypersensitivity pneumonitis has been associated with a reduced D_{LCO} and normal spirometry and lung volumes.[97]

A low D_{LCO} in the setting of obstruction, defined as a FEV_1/FVC ratio below the LLN, suggests a diagnosis of emphysema. In emphysema, the magnitude of the reduction in D_{LCO} correlates with the severity of airway obstruction, exercise capacity, and the degree of emphysema scored pathologically or radiologically with CT scans.[98–100]

The clinical value of D_{LCO} in diagnosing COPD in an individual patient is limited because patients can have early emphysema while D_{LCO} is preserved and the chronic bronchitis phenotype is often associated with a normal D_{LCO}.[98] In addition, D_{LCO} has not been proved to be better than FEV_1 in predicting symptoms or mortality. In children and young adults, a low D_{LCO} in the presence of airway obstruction should raise the possibility of cystic fibrosis or alpha$_1$-antitrypsin deficiency. One of the uses of D_{LCO} measurement in patients with obstructive lung disease is distinguishing asthma from COPD: diffusing capacity is preserved and often elevated in asthma.[101,102] This is probably due to improved ventilation-perfusion relationships in the apices of the lungs.[103]

A low D_{LCO} in the setting of restriction, defined as an FVC or TLC below the LLN, is seen in various interstitial lung diseases, neuromuscular disease, chest wall abnormalities, and severe congestive heart failure. Most interstitial lung diseases, such as idiopathic pulmonary fibrosis,[104] nonspecific interstitial pneumonitis,[104] sarcoidosis,[105] cryptogenic organizing pneumonitis,[106] and drug-induced pulmonary toxicity (e.g., amiodarone, bleomycin, cyclophosphamide, methotrexate, and nitrofurantoin),[107,108] are associated with a disproportionately larger reduction in D_{LCO} than in lung volumes. Pulmonary processes associated with significant restriction that do not affect the lung parenchyma, such as neuromuscular disease, chest wall abnormalities, and pleural abnormalities, generally cause only a small reduction in D_{LCO}.

Diffusing capacity is valuable in monitoring disease progression in patients with idiopathic pulmonary fibrosis and sarcoidosis.[109,110] While commonly used to screen patients for amiodarone pulmonary toxicity, serial D_{LCO} measurement may not be effective due to poor specificity.[111]

Congestive heart failure has variable effects on both D_{LCO} and lung volumes depending on disease severity. In advanced heart failure, D_{LCO} and lung volumes are often reduced.[112] In early heart failure, lung volumes are preserved and D_{LCO} is also usually normal, although it may be mildly elevated because of increased pulmonary capillary blood volume.[113]

Most disease processes reduce D_{LCO}. A few disorders are associated with an elevated D_{LCO}, defined as a D_{LCO} greater than 140% of predicted value. The most common cause of an elevated D_{LCO} is obesity, probably due to increased pulmonary capillary blood volume.[114] Other disease processes associated with an elevated D_{LCO} include pulmonary hemorrhage syndromes (e.g., Wegener's granulomatosis, Goodpasture's syndrome, idiopathic pulmonary hemosiderosis), polycythemia, left-to-right intracardiac shunts, and asthma.[114–116]

LUNG VOLUMES

Lung volumes are useful for detecting and physiologically characterizing the nature and severity of lung diseases.[117] While spirometry measures inhaled and exhaled lung volumes, the term "lung volumes" is generally reserved for the measurements TLC, functional residual capacity (FRC), and RV.[117] A reduced TLC defines a restrictive pattern.[14] Four techniques are commonly used to measure lung volumes: body plethysmography, nitro-

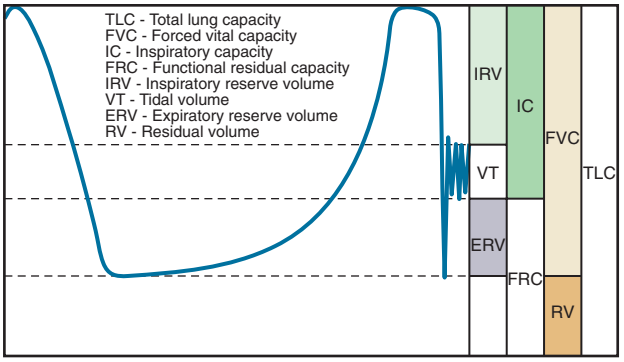

FIGURE 24-24 ■ The four basic lung volumes are: inspiratory reserve volume (IRV), tidal volume (VT), expiratory reserve volume (ERV), and residual volume (RV). The four basic lung capacities are: total lung capacity (TLC), forced vital capacity (FVC), inspiratory capacity (IC), and functional residual capacity (FRC).

gen washout, inert gas dilution, and radiographic imaging methods.

Definitions of "Volumes" and "Capacities"

TLC can be divided into several subdivisions grouped as "volumes" and "capacities." Two or more "volumes" make up a "capacity." The four basic volumes are tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume. The four basic capacities are TLC, VC, inspiratory capacity, and FRC. Figure 24-24 illustrates the most commonly measured lung volumes and capacities.

TLC is the amount of air in the lungs at the end of a maximal inhalation. It is attained when the recoil forces of the lung and chest wall counterbalance the maximal inspiratory muscle force. RV is the amount of air in the lungs at the end of a maximal exhalation. It is determined by the balance of the forces tending to reduce lung volume (maximal expiratory muscle force and inward lung recoil) against the outward recoil of the chest wall. VC is the volume of air that can be exhaled after a maximal inhalation. TLC is, therefore, the sum of RV and VC. Inspiratory capacity is the amount of air that can be inhaled from the end of a tidal exhalation. FRC is the volume of air in the lungs at the end of a relaxed exhalation and is the critical measurement obtained with lung volume testing. Expiratory reserve volume is the volume of air that can be exhaled from the end of a tidal exhalation; inspiratory reserve volume is the volume of air that can be inhaled from the end of a tidal inspiration.

Indications for Lung Volume Testing

Lung volumes are indicated to confirm a restrictive pattern in a patient with a reduced VC. As noted in the "Spirometry" section, a reduced VC suggests restriction but has a poor positive predictive value for confirming a restrictive process.[29,30,32] That is, a normal VC excludes a restrictive process but a reduced VC accurately predicts restriction in only approximately 50% of patients.[14]

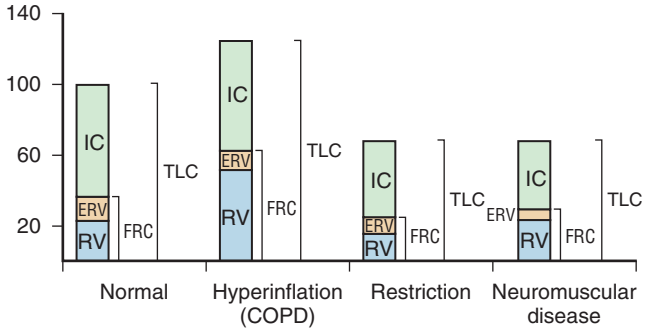

FIGURE 24-25 ■ Four basic lung volume patterns are illustrated: normal, hyperinflation, restriction, and neuromuscular disease.

Four basic lung volume patterns can be identified based on pathophysiology: normal, hyperinflation, restriction, and associated with neuromuscular disease. These are illustrated in Figure 24-25. Measurement of lung volumes is necessary to definitively characterize these patterns. In young healthy adults, RV constitutes about 25% of TLC and FRC about 40% of TLC. In hyperinflation, often present in patients with COPD, decreased elastic recoil results in an increased TLC, RV, and FRC.[53] Restrictive processes are characterized by reduced lung or chest wall compliance and appear as proportional reductions in TLC, RV, and FRC. Neuromuscular diseases also cause a restrictive pattern. The characteristic pattern of neuromuscular disease is a reduced TLC associated with an increased RV.[118,119]

Clinical Utility of Lung Volume Testing

While lung volume measurements are necessary to confirm a restrictive pattern and to characterize pathophysiologic processes,[120] their role in clinical management is unclear.[117] Lung volume measurements are often helpful in the evaluation of patients with a reduced VC. A restrictive pattern caused by decreased lung compliance is seen in patients with interstitial lung disease and lung volume measurements are suggested in the evaluation of patients with interstitial lung disease.[121,122] A restrictive pattern is also seen in patients with decreased chest wall compliance.[119] Decreased chest wall compliance is present in many different disease processes including kyphoscoliosis, ankylosing spondylitis, pleural effusions, fibrothorax, thoracoplasty, and morbid obesity.[119] Neuromuscular diseases also result in a restrictive pattern.[118] Expiratory muscle weakness causes an increase in RV, while inspiratory muscle weakness limits inspiration to TLC.[123]

All of these restrictive processes have characteristic lung volume patterns, and measuring lung volumes may help determine the specific pathophysiologic process. Lung volume measurement may be useful when more than one abnormality is suspected. For example, while obesity does cause restriction by reducing chest wall compliance, the TLC is not reduced below the LLN until the weight-to-height ratio (calculated as kg/cm) is greater than 1.0.[124] Obese patients whose weight-to-height ratio is less than 1.0 and who have a low TLC should be

evaluated for other causes of restriction, such as intrinsic lung disease.

Measurement of lung volumes can be clinically useful in patients with COPD. A reduced VC is common in patients with COPD. The causes of this reduction include submaximal effort or air trapping associated with small airway closure or noncommunicating bullae.[33] Measuring TLC with plethysmography in patients with COPD and a reduced VC can exclude a concomitant restrictive process.[33] Moderate to severe airway obstruction is associated with air trapping, which leads to hyperinflation. Hyperinflation causes dyspnea at rest that worsens with even mild exertion. Air trapping and overinflation of the lungs reduces inspiratory capacity and is a primary hallmark of hyperinflation. In patients with COPD, inspiratory capacity predicts symptoms, quality of life, and exercise capacity better than spirometry.[54-56] Hyperinflation, manifested by a reduced IC/TLC ratio is an independent risk factor for mortality in patients with COPD.[125] The IC/TLC ratio is a better predictor of mortality than FEV_1 and it predicts mortality independent of the multi-dimensional grading system that includes the body mass index, measure of airflow obstruction, dyspnea score and exercise capacity commonly referred to as the BODE index.[125] An IC/TLC threshold of 25% provides the best power to predict mortality; an IC/TLC ratio less than 25% was associated with an all-cause mortality of 70% in a cohort of COPD patients followed for a median of 34 months.[125]

Abnormal lung volume values may help focus the diagnostic evaluation of patients with respiratory symptoms. A restrictive pattern in a patient with dyspnea should lead to further diagnostic testing to evaluate for interstitial lung disease even if the chest radiograph is normal.[96]

The clinical utility of serial measurements of lung volumes in disease processes other than COPD has not been established. Lung volume measurements are not as useful as spirometry or diffusing capacity for following disease activity or response to therapy in idiopathic pulmonary fibrosis or sarcoidosis.[109,110]

Techniques for Measuring Lung Volumes

All techniques used to measure lung volumes have technical limitations. The laboratory-based tests require a two-step process. FRC is measured with body plethysmography, nitrogen washout, or inert gas dilution techniques. The inspiratory capacity obtained from spirometry is added to FRC to determine TLC. In healthy subjects and patients with interstitial lung disease, all three methods provide similar results. However, in patients with obstructive lung disease, nitrogen washout and gas dilution methods will significantly underestimate the lung volume obtained with body plethysmography.[117,126] In patients with severe obstructive lung disease, the difference in TLC can exceed 3 L. A comparison of lung volumes measured by the various techniques in healthy subjects, patients with interstitial lung disease, asthma, and mild and severe COPD are reported in Table 24-7.

Body plethysmography is considered the "gold standard" technique for measuring lung volumes. The test can be performed quickly, and repeated measurements can be obtained in a single session. It is, however, technically demanding and requires expensive, complex, and space-consuming instruments, and for these reasons, it is usually not performed in physician's offices. Measurement technique, equipment, and quality control are reviewed in detail elsewhere.[117,127] Plethysmography measures compressible gas volume in the chest based on Boyle's law (i.e., at a constant temperature, the product of gas volume and pressure is a constant). The patient sits in a sealed box connected to a mouthpiece and gently pants against a closed shutter at FRC. The panting frequency should not exceed 1 pant/sec. If the pants are too rapid, mouth pressure and alveolar pressure will not equilibrate and TLC will be overestimated. The thoracic gas volume is calculated from the slope of

TABLE 24-7. Total Lung Capacity by Five Methods in 100 Persons*

	Healthy Subjects	Interstitial Lung Disease	Asthma	Slight COPD	Severe COPD
N	23	17	25	21	14
Male/female	4.8	1.4	2.1	6.0	1.8
Age (yr)	29.1 ± 7.9	43.1 ± 17.5	21.1 ± 11.4	50.9 ± 10.4	53.0 ± 10.7
Height (inches)	69.5 ± 3.3	67.4 ± 4.1	67.7 ± 2.8	67.4 ± 3.2	65.4 ± 4.3
Average D_{LCO} mL/min/mm Hg	32.2 ± 5.31	17.4 ± 6.2	30.0 ± 6.6	19.2 ± 6.44	13.1 ± 5.65
TLC METHOD (DATA IN L)					
Plethysmographic	6.71 ± 1.20	4.90 ± 1.16	6.78 ± 1.23	6.52 ± 1.23	7.40 ± 1.45
7-Minute helium	6.61 ± 1.21	4.68 ± 1.06	5.99 ± 0.75	6.11 ± 1.35	5.91 ± 1.14
Single-breath helium	6.31 ± 1.06	4.40 ± 1.04	5.66 ± 0.99	5.54 ± 1.08	4.62 ± 1.23
Nitrogen single breath	6.25 ± 0.99	4.12 ± 0.96	5.38 ± 0.84	5.31 ± 1.03	4.31 ± 1.21
Radiographic	6.19 ± 1.23	4.89 ± 1.15	6.49 ± 1.04	6.22 ± 1.24	6.28 ± 1.44

*TLC measured by five methods (plethysmography, single breath and 7-minute helium dilution, nitrogen single breath and radiographic) in 100 persons.
D_{LCO}, diffusing capacity for carbon monoxide; TLC, total lung capacity.

the pressure-volume curve obtained by the compression and decompression of the gas in the chest during the panting maneuver. A total of three to five loops should be recorded with similar slopes. The interpreting physician must examine the slopes that are determined automatically by computerized systems. The criteria for an adequate test are at least three plethysmographic FRC values that agree within 5%; the mean value is reported.[117]

Inert gas dilution techniques are another common technique used to measure lung volumes. These tests use the mass balance approach to calculate lung volumes. The patient inhales a known concentration and volume of an inert gas, usually helium, methane, or neon, and the gas is allowed to mix. Because the initial volume and concentration of the inert gas are known, determining the exhaled concentration of the inert gas allows the calculation of the volume present in the patient's lungs at the moment tracer gas breathing began. The major limitation of this method is that it measures only the gas volume in the lungs that directly communicates with the mouth. Unlike body plethysmography, which measures total thoracic gas volume, inert gas dilution methods can underestimate TLC in obstructed patients with "air trapping."[126,128–130] Testing technique, equipment, and quality control are discussed in detail elsewhere.[117]

Gas dilution methods can be performed with either a single- or a multiple-breath technique. The single-breath technique is usually performed in conjunction with diffusing capacity measurement (see "Diffusing Capacity" section). It requires inhalation to TLC and a 10-second breath-hold. After gas from the dead space is cleared, the exhaled gas is collected and alveolar volume measured. Alveolar volume minus dead-space volume approximates TLC.

The multiple-breath technique requires the patient to rebreathe the inert gas mixture (usually helium) at FRC until helium reaches equilibrium in the lungs, a process that takes less than 10 minutes in most patients. FRC is determined based on the stable concentration of helium. The multiple-breath technique requires minimal patient effort and coordination. Usually only a single measurement will be made because a waiting period of at least 15 minutes is required between tests in patients without airway obstruction and up to 1 hour in patients with airway obstruction. TLCs measured by the single-breath and multiple-breath techniques show good agreement in patients without airway obstruction, but the single-breath technique significantly underestimates the TLC obtained by the multiple-breath technique when the FEV_1/FVC ratio is less than 0.70.[92]

A third method for determining lung volumes is nitrogen washout. Nitrogen washout techniques also use a mass balance approach to estimate TLC and, as with the inert gas dilution techniques, the test measures only the lung gas volume that communicates directly with the mouth. Trapped gas is not measured and TLC is underestimated in patients with obstructive lung disease.[93,126] The testing method is described in detail elsewhere.[117] Nitrogen washout lung volumes can be obtained using either a single-breath or a multiple-breath technique. The single-breath technique requires the inhalation of 100% O_2 with measurement of the nitrogen concentration in the exhaled gas. The single-breath technique allows the determination of closing volume. This was thought to have potential as a sensitive test for early airway disease but has not been found to be clinically useful.[131] The single-breath technique significantly underestimates TLC compared with the multiple-breath technique. Most laboratories that use nitrogen washout rely on the multiple-breath technique to determine lung volumes.[132] In the multiple-breath nitrogen washout method, the patient breathes 100% O_2 at FRC with continuous collection and monitoring of the exhaled nitrogen gas. FRC is calculated based on the assumption that the mass of displaced nitrogen is equal to the mass of nitrogen in the lungs at the beginning of the test and that the initial concentration of nitrogen in the lungs was 80%. The multiple-breath nitrogen washout test requires minimal patient effort and coordination. It is very sensitive to leaks in the system. A prolonged waiting period is required before the test can be repeated in patients with airflow obstruction, making it difficult to perform more than one measurement in a test session.

TLC can also be calculated from a standard posteroanterior and lateral chest radiograph. The calculation can be done rapidly using a computerized algorithm and the result is comparable with those of plethysmography and gas dilution techniques in many clinical settings.[133–135] However, radiographic TLC does not correlate well with gas dilution techniques in patients with interstitial lung disease and is dependent on complete inhalation.[136] The technique is not widely used and obtaining a chest radiograph for the sole purpose of measuring TLC cannot be justified. However, the radiographic method can be quite useful to evaluate change in lung volumes over time, because prior chest radiographs are often available and can provide lung volume information from a patient's past.

REFERENCE VALUES FOR PULMONARY FUNCTION TESTS

Reference values play a role in pulmonary function testing that is as important as making high-quality measurements. Interpretation of lung function tests requires the selection of appropriate reference values and their limits. The patient's results are compared with the reference values to determine whether the patient's values are normal (within boundaries established for healthy subjects) or abnormal (outside the statistically defined limits of the nomal subject range).

Defining the Lower Limits of Normal

In pulmonary function testing, reference values are typically calculated from equations using test results from a reasonably large sample of healthy individuals. The reference ranges are set statistically, assuming gaussian distributions. This assumption is correct for most lung function measurements. The lower limit of the "normal" range is

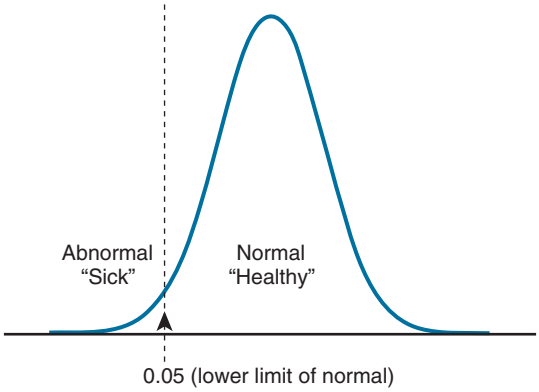

FIGURE 24-26 ■ In pulmonary function testing, the LLN is defined as the lower 5th percentile: Patients with values below the 5th percentile are reported as abnormal.

commonly defined as the lower 95% confidence interval or the lower 5th percentile. The practice of using 80% of the predicted mean value for the LLN can lead to interpretive errors, especially when age and height diverge from the average, and should be avoided.[28] As represented in Figure 24-26, patient values above the 5th percentile are labeled normal or "healthy" and those below are labeled abnormal. The terms "normal" and "abnormal" are problematic because they carry a connotation of health or disease. It is important to note that 5% of a healthy reference population is categorized as "abnormal." Using only an LLN is appropriate for spirometry because the clinical question being asked is whether the measured value is too low. For lung volumes and diffusing capacity, the clinical questions involve values that are both larger and smaller than the predicted value and both upper and lower limits of normal should be available.

Use of Reference Values in Interpretation

When the prior probability of disease is low (i.e., healthy individuals), increasing the number of tests will increase the likelihood of errors in interpretation. One study detected a false-positive rate of 24% when a full set (14 comparisons) of PFTs was applied to healthy individuals.[137] With results near the threshold, the clinician needs to be cautious with interpretation (Fig. 24-27). Clinical information and the prior probability of disease need to be considered to avoid errors near the lower or upper limit of normal.

Reference comparisons can be made using a representative sample of healthy subjects for which a reference range has been determined (reference equations) or, even better, by comparison with a patient's own prior measurement as illustrated in Figure 24-28. For an individual, the ideal reference comparison is a good-quality baseline test obtained when she or he is healthy. Such a reference allows the comparison to be switched from group to self.[138] As illustrated in Figure 24-29, most reference values have a distribution that is roughly ± 20%

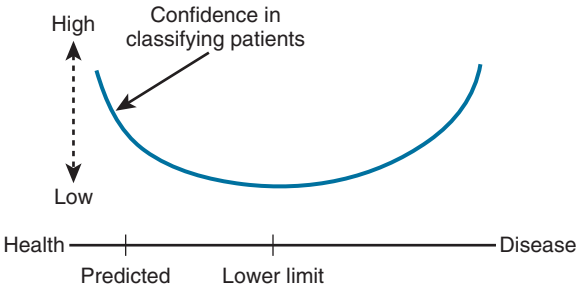

FIGURE 24-27 ■ Confidence in classifying patients as normal ("healthy") or abnormal ("diseased") increases the further the test deviates from the LLN.

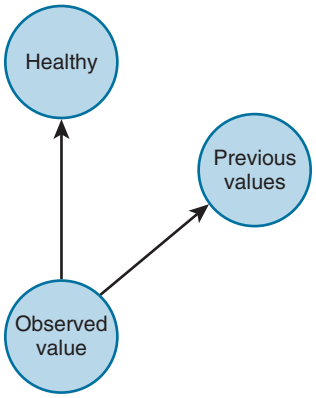

FIGURE 24-28 ■ The patient's test result (observed value) is ideally compared with a previous value obtained using similar technique or to a representative sample of healthy "normal" subjects.

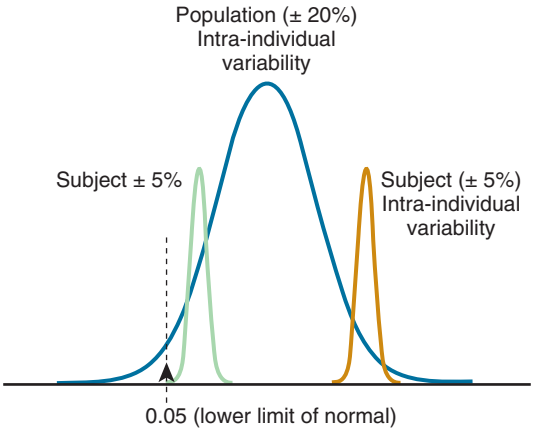

FIGURE 24-29 ■ It is preferable to compare the patient's result with a prior measurement, because the intra-individual variability is much less than the population variability.

(a 40% range) of predicted about a mean of 100%. A person who started at 120% of predicted would have to lose 33% of her or his lung function before the values fell off the "cliff of abnormality." In contrast, a person whose baseline lung function is near the LLN would be classified as abnormal with a trivial decrease in her or his lung function simply because the baseline numbers

are near the lower limit threshold of the normal distribution.[139] Once an individual's baseline has been established, intra-individual variability may be as little as ± 5% and decline is more easily detected. Therefore, if it is important to assess change over time or change with a response to an exposure or a therapy, baseline tests are critical. Although it is not practical to obtain baseline measurements for everyone, measurement of baseline values is reasonable for individuals at risk for respiratory illness or injury, including workers exposed to potential lung toxins and patients receiving treatments that may cause lung injury.

Criteria for Selecting Reference Values

Pulmonary function laboratories should select reference values based on the following principles:

1. The reference population must be biologically similar to the population of patients likely to be tested in the laboratory. Critical elements are gender, age, height, weight, and ethnic considerations.
2. Test quality in the reference population must be high. Instruments and procedures used to generate reference values should meet current standards.
3. The sample size in the reference study must be reasonably large because uncertainty in a comparison increases when the number of subjects in the reference value study is small.
4. Appropriate statistical limits of the normal range should be used. Fixed limits such as 80% of predicted should not be used unless they have been demonstrated to work on a study population that is appropriate for the individual being tested.
5. Reference equations should not be extrapolated beyond the reported ranges of the age and stature of the reference population. This is especially important when choosing reference values for children.[140]

A model for a study designed to create reference equations for spirometry is the NHANES III reported by Hankinson and colleagues.[25] Their reference values are based on a very large (7429 participants, ages 8-80) random sample of the United States that included three ethnic groups: whites, African Americans, and Mexican Americans. Spirometry was measured with high-quality instruments and procedures. Equations were created to predict "normal" values and lower limits of the normal range for an individual. An advantage of this study is the availability of race-/ethnic-specific reference equations. Race-/ethnic-specific equations are not available or as robust for lung volume measurements and diffusing capacity. Although adjustment factors have been reported, these are not as accurate as specific race/ethnic equations.[14] Limitations of the NHANES equations are the lack of information for Asian Americans and for children younger than 8 years of age. Reference equations for spirometry, lung volume measurements, and diffusing capacity for various populations are listed in the ATS/ERS Task Force publication.[14]

INTERPRETING CHANGE IN LUNG FUNCTION TESTS

In patients with lung disease, lung function measurements are often repeated over time to monitor disease activity or to assess response to therapy. Important clinical decisions are made based on changes in lung function. To determine whether a change in lung function is significant, the variability or reproducibility of the lung function test must be known. Sources of variability include (1) technical factors from either the instrument, the technician, or the subject; (2) biologic factors; and (3) disease-related changes.[141] It is essential to determine whether a change in lung function represents a change related to the disease or treatment (signal) rather than technical or biologic sources of intra-individual variability (noise). Lung function variability increases over time and is generally greater in subjects with disease than in normal subjects.

Within-Session Repeatability

Within-session test repeatability recommended by the ATS/ERS Task Force is listed in Table 24-8.[14,68,117] Our laboratory deviates from these recommendations only for DL_{CO}. Based on the results from two large studies that found that more than 91% of DL_{CO} tests had two results within 2.0 mL/min/mm Hg of each other. Our laboratory requires this level of reproducibility.[77,142]

Intersession Variability

Significant changes in PFTs when obtained weeks, months, and years apart have not been extensively studied in normal subjects or patients with underlying lung diseases. The information on variability over time comes from several sources and inconsistencies are present due to limited data, varied technical quality, and varied patient populations. Changes can be expressed as an absolute value or as a percentage change from an earlier measurement. Table 24-9 provides clinically significant changes over time in common PFTs for normal subjects and for patients with COPD. The limits provided in Table 24-9 roughly indicate the 90% to 95% confidence limits of the intersession variation of the tests.[78,142–144] Changes greater than those listed in Table

TABLE 24-8. Within-Session Repeatability Criteria per ATS/ERS Task Force

FVC	FEV_1	DL_{CO}	TLC_{PL}
150 mL (100 mL if FVC < 2 L)	150 mL (100 mL if FVC < 2 L)	3.0 mL CO/min/mm Hg	5%

ATS/ERS, American Thoracic Society/European Respiratory Society; DL_{CO}, diffusing capacity for carbon monoxide; FVC, forced vital capacity; FEV_1, forced expiratory volume in 1 second; TLC_{PL}, total lung capacity measured with plethysmography.

TABLE 24-9. Clinically Significant Changes in FEV_1, FVC, DL_{CO}, and TLC_{PL} over Time

	FVC	FEV_1	DL_{CO}	TLC_{PL}
Week to week				
Normal subjects	11%	12%	3 units	8%
COPD patients	20% or 400 mL	20% or 225 mL	4 units	↑
Year to year				
Normal subjects	15%	15%	10%	NA

COPD, chronic obstructive pulmonary disease; DL_{CO}, diffusing capacity for carbon monoxide; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; TLC_{PL}, total lung capacity measured with plethysmography.

24-9 over the specified time period are outside the expected variability of the test measurement and imply a clinically relevant change in pulmonary function.

Spirometry is more variable over time in patients with COPD than in normal subjects. In normal subjects, a change in FEV_1 over weeks to months greater than 12% is significant; for COPD patients, the threshold is a change of greater than 20%.[143] More recent data from the Lung Health Study and National Emphysema Treatment Trial reported that more than 90% of participants had an intersession (averaging 25–86 days) FEV_1 difference less than 225 mL.[144]

Data regarding significant changes in DL_{CO} are relatively weak. Variability in DL_{CO} in normal subjects for weeks to months involved 11 subjects. In well-performing instruments, a change in DL_{CO} over 24 weeks of greater than 3.0 mL/min/mm Hg was significant.[78] Approximately 40% of the variability was attributed to the instrument and the remainder to the subject. A change in DL_{CO} of greater than 10% was significant in eight normal subjects tested over 1 year with well-performing equipment.[145] In COPD patients tested over 1 week, a change in DL_{CO} of greater than 4.0 mL/min/mm Hg was significant.[79]

Data from the same laboratory with a well-maintained, constant instrument are likely to be associated with less variability over time. Observed changes over time are more likely to represent clinically significant changes rather than noise from technical factors. In the setting of a stable laboratory environment, a smaller change over time may be considered clinically important. Also, it is more likely that a significant change has occurred when more than two measurements are made over time.

TESTS OF RESPIRATORY MUSCLE STRENGTH

Measurements of respiratory muscle strength are important in the evaluation and management of patients with neuromuscular disease and selected patients with unexplained dyspnea. Respiratory muscle dysfunction is common in a variety of neuromuscular disorders. Identifying respiratory muscle weakness is clinically important. It predicts adverse clinical sequelae and may lead to interventions that improve outcomes.

A number of tests are available to assess respiratory muscle strength. These are usually used in conjunction with standard PFTs. Multiple tests are recommended to make a confident diagnosis of respiratory muscle weakness, because single tests of respiratory muscle strength tend to overdiagnose respiratory muscle weakness.[146] The advantages and disadvantages of the respiratory muscle function tests are listed in Table 24-10.

Spirometry

Spirometry with examination of the flow-volume loop should be performed on all patients with suspected respiratory muscle weakness. A reduced VC is a sensitive test for diagnosing moderate to severe respiratory muscle weakness, and serial testing is useful for monitoring disease progression.[147] Spirometry findings are not specific for respiratory muscle weakness and are less sensitive in mild disease than measures of maximum mouth pressures; respiratory muscle strength needs to decrease by approximately 50% before VC is significantly reduced.[123,147] Measurement of upright and supine VC is useful for diagnosing diaphragm weakness. In normal subjects, VC is less than 10% lower in the supine than in the upright position. A reduction of greater than 30% suggests severe diaphragm weakness.[147] The maximum flow-volume loop also exhibits characteristic changes with moderate to severe respiratory muscle weakness as illustrated in Figure 24-30. The contour of the expiratory limb is blunted with a decreased PEF and decreased slope of the ascending limb, abrupt cessation of flow occurs near RV, and pronounced flattening of the inspiratory limb is seen.[147,148] This pattern may be confused with extrathoracic UAO.

Maximal Inspiratory and Expiratory Pressures

The primary tests for assessing respiratory muscle strength in the laboratory are maximal inspiratory pressure (MIP) or P_{Imax} (also referred to as negative inspiratory force[99]) and maximal expiratory pressure (MEP) or P_{Emax}. P_{Imax} and P_{Emax} are obtained at the mouth with use of either a flanged mouthpiece or a tube mouthpiece that is connected to a mechanical pressure gauge. The system requires a small leak (1- to 2-mm hole) to prevent glottis closure and to reduce the use of buccal muscles.[147] The inspiratory or expiratory pressure should be maintained for at least 1.5 seconds and the maximum pressure sustained for 1 second recorded. The maneuver should be repeated at least five times with the maximum value of three maneuvers that vary by less than 20% reported.[147] Although the criteria permit variation of up to 20%, intrasession repeatability of less than 5% is achievable and preferable.[149] The lung volume at which the maneuver is performed is critically important. P_{Imax} is a measure of the diaphragm and other inspiratory muscles and is highest when obtained from residual volume. P_{Emax} reflects the strength of the expiratory muscles (primarily

TABLE 24-10. Tests of Respiratory Muscle Weakness: Advantages and Disadvantages

Test	Advantages	Disadvantages
VC	• Widely available • Easy to perform • Inexpensive • Reproducible • Supine and upright measurement sensitive for diaphragm weakness	• Poor specificity • Less sensitive for early weakness than P_{Imax} or P_{Emax} • Difficult to perform with bulbar dysfunction
P_{Imax}	• Widely used • Noninvasive • Can obtain at bedside • Reference values available • Predicts clinical consequences • Good negative predictive value	• Effort and technique dependent • Poor positive predictive value • Difficult to perform with bulbar dysfunction • Low values occur with lung hyperinflation
P_{Emax}	• Widely used • Noninvasive • Can obtain at bedside • Reference values available • Predicts clinical consequences	• Effort and technique dependent • Poor positive predictive value • Difficult to perform with bulbar dysfunction
SNIP	• Noninvasive • Can obtain at bedside • Easier than P_{Imax} or P_{Emax} with severe disease or bulbar dysfunction • Predicts outcomes in ALS	• Effort dependent • Provides no information about expiratory muscle strength • Unreliable if upper airway distortion/nasal obstruction
MVV	• None	• No advantage over VC • Poor specificity • Highly effort dependent • Uncomfortable to perform
Esophageal, gastric, transdiaphragmatic pressure measurements; phrenic nerve stimulation pressure measurements	• Best measures of respiratory muscle strength • Improves specificity compared with P_{Imax} or P_{Emax}	• Invasive • Difficult to perform • Performed only at specialty centers

ALS, amyotrophic lateral sclerosis; MVV, maximum voluntary ventilation; P_{Emax}, maximal expiratory pressure; P_{Imax}, maximal inspiratory pressure; SNIP, sniff nasal inspiratory pressure; VC, vital capacity.

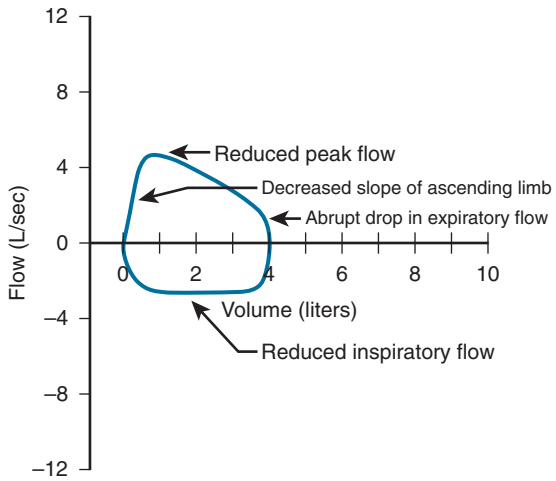

FIGURE 24-30 ■ The characteristic changes in the flow-volume curve with moderate or severe respiratory muscle weakness are illustrated. The slope of the ascending segment of the expiratory limb is reduced, peak expiratory flow is reduced, there is an abrupt drop in expiratory flow near the end of exhalation, and inspiratory flow is reduced.

abdominal muscles) and is highest when obtained at TLC. Because P_{Imax} and P_{Emax} are dependent on lung volumes, they are altered by diseases that affect lung volumes. For example, COPD results in an increase in RV due to hyperinflation, and P_{Imax} may be reduced in COPD because of the change in lung volume and not because of respiratory muscle weakness. Similarly, in restrictive disorders of the lung or chest wall such as kyphoscoliosis and pulmonary fibrosis, TLC is decreased, resulting in a reduced P_{Emax} even in the absence of muscle weakness. These tests are also dependent on maximum effort and proper technique. As in most PFTs, maximum effort and proper technique are critical. Patients with bulbar dysfunction may not be able to obtain a good seal on the mouthpiece, which will reduce maximum mouth pressures. Because of these factors, the positive predictive value of P_{Imax} and P_{Emax} is relatively low. Normal values exclude significant respiratory muscle weakness, but low values may reflect poor effort or technique or may be due to alterations in lung volumes rather than respiratory muscle dysfunction.

Definitive reference values for P_{IMAX} and P_{EMAX} have not been established. Differences in technique, mouth-

TABLE 24-11. Reference Values with Lower Limits of Normal for Maximal Inspiratory Pressure and Maximal Expiratory Pressure

Age (yr)	P_{Imax} (cm H_2O) (LLN)	P_{Emax} (cm H_2O) (LLN)
20–54	Male: 124 (80)	Male: 233 (149)
	Female: 87 (55)	Female: 152 (98)
55–59	Male: 103 (71)	Male: 218 (144)
	Female: 77 (51)	Female: 145 (105)
60–64	Male: 103 (71)	Male: 209 (135)
	Female: 73 (47)	Female: 140 (100)

	Female: 57 (45)	Female: 116 (90)

LLN, lower limits of normal; P_{Emax}, maximal expiratory pressure; P_{Imax}, maximal inspiratory pressure.

piece design and lung volumes at which the measurement was obtained contribute to differences in published reference ranges.[150–155] Our laboratory uses the references ranges determined by Black[150] for ages less than 65 years and Enright for ages greater than 65 years, because they are based on well designed trials and standardized technique[152] (Table 24-11).

Though not diagnostically definitive, measurement of P_{Imax} and P_{Emax} are clinically useful in many different neuromuscular diseases. Serial monitoring of pulmonary function in Guillain-Barré syndrome predicts the development of respiratory failure and need for mechanical ventilation.[156] Specifically, respiratory failure is likely when VC is less than 20 mL/kg; P_{Imax} is less negative than (–)30 cm H_2O; and P_{Emax} is less than 40 cm H_2O (the "20–30–40 rule").[156] P_{Imax} and P_{Emax} less than 30% of normal predicts respiratory failure in patients with other neuromuscular disorders.[157,158] A P_{Emax} less than 60 cm H_2O predicts an ineffective cough.[159]

Sniff Nasal Inspiratory Pressure

Sniff nasal inspiratory pressure (SNIP) is another noninvasive test for assessing inspiratory muscle strength. It is a technically simple test to perform. A plug, connected to a pressure transducer, is wedged into one nostril. The patient is instructed to make short, sharp, maximal inspiratory efforts (sniffs) through the unobstructed nostril.[147] Up to 10 maximal sniffs should be obtained until a consistent value is achieved. SNIP correlates well with sniff transdiaphragmatic pressures and LLN are available.[160–162] Significant inspiratory muscle weakness is unlikely if the values are greater than (–) 70 cm H_2O for males and (–) 60 cm H_2O for females.[147] The SNIP is easier to obtain than P_{Imax} or P_{Emax} in patients with bulbar dysfunction. It is useful in monitoring respiratory muscle strength in patients with amyotrophic lateral sclerosis (ALS)[160,163]; a value less than 40 cm H_2O is a sensitive test for predicting mortality.[160] Combining the SNIP measurement with P_{Imax} reduces the number of false-positive diagnoses of inspiratory muscle weakness by 19%.[146] The SNIP test is unreliable in patients with upper airway distortion and nasal congestion.

Maximum Voluntary Ventilation

The MVV is commonly used for assessing respiratory muscle strength. The test can be performed on most office spirometers. The patient is instructed to breathe as deep and fast as he or she can for 15 seconds. The respiratory rate should be 70 to 110 breaths/min with a tidal volume approximately 50% of VC. The maximal ventilation in 12 seconds is calculated and multiplied by 5. If MVV divided by $FEV_1 \times 41$ is less than 0.80, the test is abnormal and suggests neuromuscular weakness or poor effort.[164] MVV was once touted as a specific test for respiratory muscle weakness. However, it is highly effort dependent and is influenced by factors other than respiratory muscle function (these include airway resistance and respiratory system compliance).[123] In those patients who do have respiratory muscle weakness, MVV is reduced in proportion to VC. Because it is a difficult and strenuous test to perform and adds little to more simple tests such as VC, it is no longer recommended in the evaluation and management of patients with respiratory muscle weakness.[147]

Invasive Tests for Measuring Respiratory Muscle Strength

Several invasive tests are available to more precisely determine the presence of respiratory muscle weakness. These tests overcome the inherent problems associated with measuring mouth or nasal pressures by directly measuring esophageal or gastric pressures with a balloon catheter. Pressures can be measured with the patient sniffing or coughing or by electrically stimulating the phrenic nerve.[146,162,165] Measuring sniff esophageal or sniff transdiaphragmatic pressures reduces the number of patients diagnosed with inspiratory muscle weakness by approximately 30% to 40% compared with P_{Imax} alone.[146,162] Measuring cough gastric pressure reduces the number of patients diagnosed with expiratory muscle weakness by approximately 40% compared with P_{Emax} alone.[165] Measuring twitch transdiaphragmatic or twitch gastric pressure by electrically stimulating the phrenic nerve further improves diagnostic accuracy.[146] Although these are the gold standard for diagnosing respiratory muscle weakness, the tests are invasive and difficult to perform. They are only performed in specialized laboratories and are not widely used clinically.

BRONCHIAL PROVOCATION TESTS

Bronchial provocation (bronchoprovocation) tests are performed to assess bronchial hyperresponsiveness (BHR). They involve the administration of a stimulus that causes airway narrowing in susceptible patients. Bronchoprovocation tests are primarily used to confirm a diagnosis of asthma but are most clinically useful when the diagnosis is not clear-cut. Asthma is a chronic

disorder of the airways characterized by variable and recurring symptoms, airflow obstruction, BHR, and underlying inflammation.[39] The diagnosis of asthma is most often made with a history of intermittent respiratory symptoms in combination with variable airflow obstruction. While BHR is a key feature of asthma, bronchoprovocation tests are not often necessary to establish the diagnosis.

Indications

Indications for bronchoprovocation include

1. Establishing a diagnosis of asthma when atypical features are present: Asthma symptoms with normal spirometry, a presumptive diagnosis of asthma that does not improve with asthma therapy, or nonspecific asthma symptoms such as persistent cough are common reasons to obtain the test.[166]
2. Evaluating the possibility of occupational asthma: Bronchoprovocation testing is generally a sensitive but not specific test for diagnosing occupational asthma.[167,168]
3. Excluding a diagnosis of asthma in patients for whom an erroneous diagnosis has significant social impact (military recruits, divers, firefighters, and other high-risk occupations).[169,170]
4. Monitoring asthma therapy: Symptoms and lung function may normalize despite ongoing airway inflammation; BHR correlates well with airway inflammation, and adjusting therapy based on BHR may improve outcomes.[171,172]
5. Identifying specific asthma triggers. It is rarely necessary to perform specific bronchial challenge testing with the suspected offending agent, although it may be performed for research or legal purposes.
6. Objectively assessing asthma severity.[173]

Contraindications

Contraindications to bronchoprovocation testing are listed in Table 24-12. Bronchoprovocation can elicit severe bronchoconstriction in susceptible individuals. In patients with severely reduced lung function at baseline, worsening airway obstruction can be dangerous. An FEV_1 less than 50% of predicted (or <1.0 L) is an absolute contraindication and a FEV_1 less than 60% to 70% of predicted (or <1.5 L) is a relative contraindication to test performance.[166,173] Because of the potential to precipitate severe airway obstruction, trained personnel and medications to treat bronchospasm (albuterol and ipratropium) should be immediately available.

A relative contraindication for performing bronchial challenge tests is the failure of patients to withhold medications that may affect the test result, causing a false-negative study. Medications affecting the test should be held for an appropriate period of time determined by the drugs' duration of effect.[166] Short-acting β-agonists (albuterol) should be held for 8 hours; medium-acting bronchodilators (ipratropium) should be held for 24 hours, and long-acting bronchodilators (salmeterol, formoterol, and tiotropium) should be held for 48 hours. Theophylline preparations should be held for 12 to 48 hours depending on the duration of effect. Leukotriene modifiers should be held for 24 hours. Antihistamines have a variable effect of BHR and should be held for 24 to 72 hours depending on their duration of effect. Coffee, tea, cola drinks, and chocolate have small effects on BHR and should be withheld on the day of the study.[174]

TABLE 24-12. Contraindications for Bronchial Provocation Testing

ABSOLUTE
Severe airflow limitation (FEV_1 < 50% predicted or <1.0 L)
Acute coronary syndrome or stroke within 3 months
Severe hypertension (systolic BP > 200 mm Hg or diastolic BP > 100 mm Hg)
Cerebral or aortic aneurysm
RELATIVE
Moderate airflow limitation (FEV_1 < 60% predicted or <1.5 L)
Inability to perform acceptable and repeatable spirometry
Pregnancy*
Nursing mothers*
Current use of cholinesterase inhibitor medication for myasthenia gravis*
Significant hypoxemia (Pa_{O_2} < 60)
Recent upper or lower respiratory tract infection (within 6 wk)
Failure to withhold medication that may affect test results
Vigorous exercise on day of test

*Relative contraindications for methacholine administration.
BP, blood pressure; FEV_1, forced expiratory volume in 1 second; Pa_{O_2}, arterial oxygen pressure.
Modified from Crapo RO, Casaburi R, Coates AL, et al: Guidelines for methacholine and exercise challenge testing—1999. This official statement of the American Thoracic Society was adopted by the ATS Board of Directors, July 1999. Am J Respir Crit Care Med 161:309–329, 2000.

Categories of Bronchoprovocation Tests

There are three broad categories of bronchoprovocation tests. Bronchial hyperreactivity can be elicited using specific airway irritants, "direct" stimuli using nonspecific pharmacologic agents (methacholine and histamine), and "indirect" stimuli (exercise, eucapnic voluntary hyperventilation, cold air hyperventilation, hypertonic saline, mannitol, and adenosine monophosphate [AMP]). The direct airway challenges cause airway narrowing via a direct effect on airway smooth muscle whereas indirect airway challenges cause airflow obstruction by acting on airway inflammatory and neuronal cells, which release mediators or cytokines that provoke bronchoconstriction.[173]

Specific inhalation challenge tests with substances found in the workplace are considered the gold standard for confirming or diagnosing occupational asthma.[167,175] However, a negative test may not definitively exclude the diagnosis of occupational asthma if the wrong agent or too low a concentration is used. Moreover, these tests require specialized equipment and have the potential to trigger severe life-threatening asthmatic reactions. They should be performed only at specialized centers and are not widely available.

Methacholine Inhalation Challenge

Methacholine inhalation challenge testing is the most widely used method to assess BHR. Methacholine acts by directly stimulating specific receptors on bronchial smooth muscle, causing bronchoconstriction and airway narrowing. Histamine is an alternative direct bronchial smooth muscle stimulant that gives similar results but is not commonly used because it is not U.S. Food and Drug Administration (FDA) approved and causes more side effects, including headache, hoarseness, and flushing.[166] Methacholine inhalation challenge is a sensitive test (sensitivity 85%-90%) for diagnosing asthma, including occupational asthma, cough variant asthma, and exercise-induced bronchoconstriction.[166,167,176–178] The sensitivity of the test is probably even greater than reported because the gold standard for asthma diagnosis in most studies is clinical improvement with specific asthma therapy. The problem with using response to therapy as the definitive test for diagnosing asthma is that eosinophilic bronchitis is similar to asthma in clinical presentation and responds favorably to inhaled corticosteroids but is not associated with variable airflow obstruction or BHR.[179,180] It is likely that some of the "false-negative" methacholine tests represent eosinophilic bronchitis. The specificity of methacholine testing is relatively poor, especially in general population studies.[181] Allergic rhinitis, COPD, patients who smoke, cystic fibrosis, bronchiectasis, bronchiolitis, and recent respiratory tract infections can all result in false-positive tests.[166,173]

Standardized protocols for methacholine testing are available.[166] The test consists of performing spirometry at baseline and then after each dose of nebulized methacholine. An initial methacholine concentration of 0.031 mg/mL or 0.0625 mg/mL is used and subsequent doses are increased by two- to fourfold until the FEV_1 falls by 20% from the baseline value or a concentration of 16 mg/mL is reached. If the FEV_1 falls by 20% from the baseline value, bronchodilator (albuterol 2 puffs) should be administered and the FEV_1 repeated in 10 minutes. The technician should record the patient's symptoms during the test. The reproduction of the symptoms that prompted the study is especially important (e.g., cough, dyspnea) as this suggests the symptoms are due to asthma. Methacholine can be administered using the 2-minute tidal-breathing method or the five-breath dosimeter protocol.[166] The 2-minute tidal breathing method appears to be more sensitive.[182]

Change in FEV_1 is the primary outcome measure for methacholine challenge testing. Spirometry must be acceptable and reproducible for the test to be meaningful. Maximal inspiratory maneuvers need to be performed if vocal cord dysfunction is being considered. If the patient cannot perform spirometry adequately, body plethysmography can be used to determine specific airway conductance. Plethysmography is more complicated than spirometry and does not improve test accuracy.[166] If plethysmography is used, the outcome measurement is specific airway conductance, and a reduction of 35% to 40% defines a positive result.

The provocative concentration that results in a 20% reduction in FEV_1 (PC_{20}) is determined by interpolation.[166] The categorization of BHR based on PC_{20} is listed in Table 24-13. The results are most accurately interpreted if clinical information is available. When the pretest probability of asthma is between 30% and 70%, a PC_{20} less than 1.0 mg/dL strongly suggests asthma. Conversely, a PC_{20} greater than 16 mg/dL suggests the patient does not have asthma and alternative diagnoses need to be considered. Results in the borderline area (between 4.0 and 16 mg/mL) require clinical information for meaningful interpretation.[183] Many laboratories use a threshold of 8 mg/mL for diagnosing asthma when the clinical index of suspicion is moderate. However, the positive predictive value of a PC_{20} less than 8 mg/dL was less than 50% when histamine challenge was performed in a sample of the general population.[181] Direct bronchoprovocation studies are highly sensitive when current asthma symptoms are present but are not specific.

TABLE 24-13. Categorization of Bronchial Responsiveness for Methacholine Inhalation Challenge

PC_{20} (mg/mL)	Interpretation
>16	Normal BHR
4.0–16	Borderline BHR
1.0–4.0	Mild BHR (positive test)
<1.0	Moderate to severe BHR

BHR, bronchial hyperresponsiveness; FEV_1, forced expiratory volume in 1 second; PC_{20}, provocative concentration that results in a 20% reduction in FEV_1.

Modified from Crapo RO, Casaburi R, Coates AL, et al: Guidelines for methacholine and exercise challenge testing—1999. This official statement of the American Thoracic Society was adopted by the ATS Board of Directors, July 1999. Am J Respir Crit Care Med 161:309–329, 2000.

Indirect Bronchoprovocation Tests

Bronchoprovocation testing can be performed using indirect challenges that act by stimulating inflammatory cells and sensory nerves to release mediators that result in bronchial smooth muscle contraction and airway narrowing.[171,173] Indirect challenges include exercise, eucapnic voluntary hyperventilation (EVH), cold air hyperventilation, hypertonic saline, mannitol, and AMP. Indirect challenges may be less sensitive than direct challenges for the diagnosis of asthma but are more specific.[173,184–186] Some asthmatics, especially those with mild BHR, respond to direct challenges but not indirect challenges.[173] Indirect challenges are better tests for assessing airway inflammation and determining response to an inhaled corticosteroid than methacholine testing.[171,173,186,187] In asthmatics, symptoms and lung function improve rapidly with inhaled corticosteroid therapy despite ongoing airway inflammation. An improvement in BHR to indirect stimuli correlates well with airway inflammation and may be a useful target for titrating the dose of inhaled corticosteroid.[171] While BHR to direct stimuli also improves with inhaled corticosteroid use, it is not as sensitive a marker of airway inflammation, and BHR persists even after there has been significant improvement in airway inflammation.[188]

Of the indirect methods, standard exercise tests are less useful for diagnosing asthma. Exercise testing is most commonly performed in the evaluation of exercise-induced bronchospasm. In this setting, it is less sensitive than other indirect challenge tests and direct challenge tests.[178,189–192] The lack of sensitivity is likely due to the inability of some patients to achieve adequate exercise levels due to deconditioning, musculoskeletal limitations, or submaximal effort. Exercise testing is highly specific in differentiating asthma from normal.[173]

If exercise is chosen as the provoking agent, testing can be performed in the laboratory, using a treadmill or bicycle ergometer, or performing specific exercise tests in the field. Whichever method is used, the patient should exercise for a total duration of 6 to 8 minutes with 4 to 6 minutes of exercise at near-maximum levels.[166] The minute ventilation should achieve 50% to 60% of MVV and the heart rate should reach 90% of predicted maximum.[173] Sensitivity improves if dry air, rather than ambient air, is inhaled.[193] FEV_1 is the primary outcome variable and it should be obtained 5, 10, 15, 20, and 30 minutes postexercise. A reduction in FEV_1 of 10% compared with baseline is considered a positive test.[166]

EVH is a useful test for diagnosing asthma.[184,194] It is the most sensitive test for diagnosing exercise-induced bronchospasm.[178,189–191] The test is performed by having the patient breathe deep and fast a gas mixture of 5% CO_2 and the balance room air for 6 to 8 minutes. A target minute ventilation is set at $30 \times FEV_1$.[195] Spirometry is measured immediately, 5, 10, and 20 minutes after the hyperventilation. A positive test is defined as a 10% reduction in FEV_1.

Hypertonic saline and mannitol are indirect challenge tests that cause an increase in airway osmolarity, resulting in mediator release and bronchoconstriction.[173,185] Hypertonic saline challenge tests involve the nebulization of 4.5% saline. Mannitol capsules are inhaled using a dry powder inhaler that has recently been FDA approved for bronchoprovocation testing. Spirometry is performed serially after inhalation of these agents at 0, 5, 10, and 20 minutes, and a 10% reduction in FEV_1 compared with baseline is considered a positive study.[173] Mannitol may be more sensitive than the other indirect challenges for detecting mild BHR.[196] Inhalation of hypertonic saline or mannitol is a sensitive stimuli for provoking exercise-induced bronchospasm.[197,198] Mannitol is a more clinically useful test than is histamine for determining improvement with inhaled corticosteroids.[185]

AMP is a purine nucleotide that acts as an indirect bronchoprovocation agent. Airway response to adenosine appears to be a sensitive marker of mast cell priming; atopic asthmatics are more responsive to AMP than to methacholine.[173] There are limited data comparing AMP with other indirect agents and with methacholine. However, AMP appears to be more specific than methacholine for distinguishing pediatric asthma from other obstructive diseases such as bronchiectasis and bronchiolitis obliterans. It may also be useful in separating nonsmoking adults with COPD from those with asthma. Methacholine is often positive in both groups whereas AMP is more often positive only in the patients with asthma.[199] AMP is administered with a nebulizer using either the five-breath dosimeter or 2-minute tidal breathing technique. Similar to methacholine challenge testing described previously, the concentration of inhaled AMP is gradually increased, with measurement of FEV_1 after each dose. A 20% reduction in FEV_1 is considered a positive test. AMP is not FDA approved for bronchoprovocation.

KEY POINTS

- Pulmonary function testing plays an important role in the diagnosis and management of patients with respiratory disease. The major types of PFTs are spirometry, diffusing capacity, lung volume, respiratory muscle strength, and bronchoprovocation tests.
- Spirometry is the most commonly performed and clinically useful PFT. FEV_1 and FVC are the primary measurements obtained during spirometry and a reduced FEV_1/FVC ratio is necessary to diagnose airflow obstruction.
- DL_{CO} provides a quantitative measure of gas transfer in the lungs and is an important test in managing patients with interstitial lung disease.
- Lung volume testing allows the measurement of TLC, which is required to confirm the presence of a restrictive pattern.
- Pulmonary function testing interpretation requires examination of the tracings to determine acceptability and repeatability. Meaningful interpretation also requires comparison with a patient's prior result or an appropriate reference value.
- Bronchial provocation testing is clinically useful in confirming a diagnosis of asthma when atypical features are present.
- Measurement of P_{Imax} and P_{Emax} are sensitive but not specific tests for detecting respiratory muscle weakness as low values may be due to poor technique or effort and alterations in lung volumes.

Organization of Exercise Data and Comparison with Normal Values

Interpreting Exercise Data to Quantify Exercise Capacity

Interpreting Exercise Data for Diagnostic Purposes: Typical Response Patterns

Interpretive Strategies

INTRODUCTION

Many chronic conditions that affect lung function, either directly or indirectly, are first manifest as symptoms or limitations during exercise. Examinations performed at rest may fail to identify the defect, or may inadequately predict the impact of organ system impairment on the overall ability to perform work. Exercise tests have thus long been part of medical practice, both as diagnostic tools and as means of assessing functional capacity. These range from simple functional performance measures to standardized graded profiles of work with measurement of multiple physiologic variables. An appreciation of the physiologic processes subserving exercise and their integrated function provides a basis for applying data from exercise tests to the evaluation and management of patients.

PHYSIOLOGY OF EXERCISE

Any physical activity in which work is performed by skeletal muscle can be regarded as exercise. A broad distinction is made between resistance and endurance exercises, resistance exercise referring to activities consisting of brief periods of muscle contraction at high forces, such as weight lifting, and endurance exercise referring to lower intensity contractions performed rhythmically for extended periods of time, such as in walking or running. Though both forms of exercise are relevant to clinical assessments of disability and rehabilitation, it is endurance, also referred to as aerobic, exercise that is the primary focus of most clinical exercise testing, and of this discussion.

Overview of Cellular Energetics Relevant to Clinical Exercise Testing

Oxygen Uptake as a Measure of Exercise

Contraction of skeletal muscle is accomplished by the ratcheting of overlapping segments of actin and myosin filaments relative to one another within muscle fibers, powered by hydrolysis of adenosine triphosphate (ATP). The major pathway for ATP generation is aerobic metabolism in the mitochondria via the Krebs tricarboxylic acid cycle and electron transport chain, as illustrated in Figure 25-1. Carbon dioxide (CO_2) is generated from breakdown of substrate, and oxygen (O_2) is consumed in the final step of the electron transport chain. Under steady-state conditions, the ratio of CO_2 production to O_2 consumption (respiratory quotient, or RQ) reflects substrate utilization, ranging from 0.7 for fat to 1.0 for carbohydrate. Glycogen is the predominant substrate

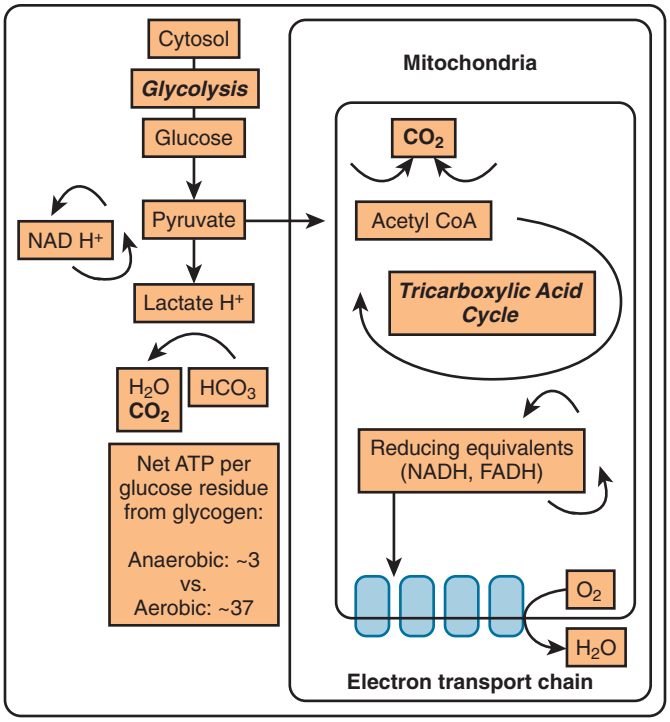

FIGURE 25-1 ■ Simplified schematic of cellular energetics and gas exchange. Glycolysis is the splitting of 6 carbon glucose equivalents into 3 carbon pyruvate molecules. Complete oxidation (*blue arrows*) to CO_2 and water is accomplished by transport of pyruvate into the mitochondria after conversion to acetyl CoA (also derived from lipid metabolism, not shown) to enter the tricarboxylic acid cycle. As each carbon is removed from pyruvate, CO_2 is released as a by-product and hydrogen ions are complexed to the cofactors nicotinamide adenine dinucleotide (NAD) and flavin adenine dinucleotide (FAD) for delivery to the electron transport chain on the inner mitochondrial membrane. Hydrogen ions are passed through a series of four complexes and concentrated in the intermembrane space, forming the electrochemical gradient that drives ATP synthase. This process is called oxidative phosphorylation because oxygen is required to serve as the final electron acceptor in the electron transport chain. In its absence, the upstream reactions cannot proceed and pyruvate is instead converted to lactate (*orange arrows*) to regenerate the cofactor NAD, allowing glycolysis to continue anaerobically. The resulting lactic acid is buffered by bicarbonate, with the evolution of CO_2. Energy released at multiple steps in these processes is captured in the form of ATP, though the net gain per molecule of glucose is far lower for anaerobic glycolysis than for complete oxidation.

utilized during short-duration exercise, so that O_2 and CO_2 are exchanged in roughly equal volumes in muscle during short bouts of moderate exercise. Ultimately this cellular gas exchange must be matched by similar levels of gas exchange in the lung.

The relationship between the amounts of oxygen consumed and work performed is predictable within a relatively narrow range. And since the body has limited capacity for storing oxygen, the rate of *oxygen uptake* at the lung ($\dot{V}O_2$) can be taken as the rate of cellular *oxygen consumption.* $\dot{V}O_2$ is thus proportional to the external work of physical activities, as illustrated by the examples in Table 25-1, though the exact relationships are complicated by factors such as biomechanical economy and body weight, which can alter the actual oxygen cost of an exercise task. Progressively higher rates of exercise work require higher $\dot{V}O_2$, and the maximum $\dot{V}O_2$ that an individual can attain is the conventional expression of exercise capacity.

Lactate or Anaerobic Threshold

Though most energy for endurance exercise is derived from oxidative metabolism, it has long been recognized that there is a critical or threshold level of work above which exercise is associated with a systemic lactic acidosis,[1] indicative of nonoxidative glycolysis. Among healthy individuals, the threshold for lactate accumulation occurs at $\dot{V}O_2$ values averaging around 50% to 60%, but ranging widely from 40% to over 80% of maximum $\dot{V}O_2$. The magnitude of cardiac and ventilatory stress that a task represents and its tolerability to the patient are affected by whether the work is above or below the individual's lactate threshold. The lactate threshold is therefore an important characteristic of exercise function that is relevant to the clinical evaluation of patients.

Lactate is the product of anaerobic glycolysis in the myocyte cytosol (see Fig. 25-1). This is a rapidly available source of ATP for muscle contraction, but it is an inefficient source of energy for endurance exercise, because the energy yield is only a fraction what is possible by full oxidation of carbohydrate to CO_2 and water. To sustain glycolysis in the absence of oxygen, the cofactor nicotinamide adenine dinucleotide (NAD) is regenerated during the conversion of pyruvate to lactate. The occurrence of progressive lactic acidosis is a marker of exercise that cannot be sustained for very long; however, lactate per se is not what causes the muscle to fatigue, and in fact, there are local effects of the acidosis that appear important for exercise performance.[2] In particular, oxygen delivery is enhanced by the Bohr effect, by which a fall in pH causes rightward shift of the oxyhemoglobin dissociation curve and a release of oxygen from hemoglobin. This is illustrated in Figure 25-2, which shows that venous P_{O_2} remains constant but hemoglobin unloads oxygen and reduces oxygen saturation as the pH drops during lactic acidosis–inducing exercise.[3]

Despite extensive investigation over a period of many decades, the mechanisms[4-6] and effects[2,7] of lactic acid accumulation during exercise continue to be debated. Conflicting interpretations of this process are reflected in the varied nomenclature for its description. The term *anaerobic threshold,* introduced by Wasserman and McIlroy in 1964,[8] reflects the view that lactate production occurs when a critical rate of oxygen delivery is reached relative to oxygen demand.[9,10] This view is consonant with a large body of data showing that the lactate threshold can be experimentally shifted by factors altering oxygen availability,[11] such as hemoglobin concentration, arterial P_{O_2}, and blood flow, and that it occurs at a low level of exercise when oxygen delivery is impaired by cardiac dysfunction, or utilization is impaired due to metabolic defects.[4]

TABLE 25-1. Estimated Metabolic Costs for Selected Physical Activities* and the Corresponding $\dot{V}O_2$ Values for a 70-kg Adult of Normal Body Habitus

	Activities	Estimated METs	$\dot{V}O_2$ for ~70-kg Adult (mL/min)
Walking, Running, Climbing	Rest, seated	1.0	250
	Walking slowly with children while pushing stroller	2.5	625
	Walking, 3 mph on level ground	3.3	825
	Walking, 3 mph carrying load of <25 lbs	4.0	1000
	Jogging, <5 mph	7.0	1750
	Running, 7 mph	11.5	2875
	Walking up stairs or climbing ladder	8.0	2000
	Running up stairs	15.0	3750
Home and Self-Care	Dressing and undressing	2.0	500
	Grooming: washing, shaving, hairstyling	2.0–2.5	500–625
	Light cleaning, dusting	2.5	625
	Vacuuming	3.5	875
	Sweeping garage or sidewalk	4.0	1000
	Mowing lawn, walking power mower	5.5	1375
Occupational and Recreational	Light work standing: bartending, filing	2.3	575
	Pressing clothes	4.0	1000
	Playing golf, general	4.5	1125
	Machine tool operation	2.5–5.0	625–1250
	Swimming leisurely	6.0	1500
	Playing tennis, general	7.0	1750
	Shoveling, digging dirt	6.0–8.5	1500–2125
	Firefighting: climbing ladder with gear	11.0	2750

*Expressed as multiples of the resting metabolic rate (METs, defined as 3.5 mL/min/kg), METs values were abstracted from The Compendium of Physical Activities,[147,148] a compilation of data derived from various sources, including questionnaires, laboratory simulations, and field measurements.
mph, miles per hour.

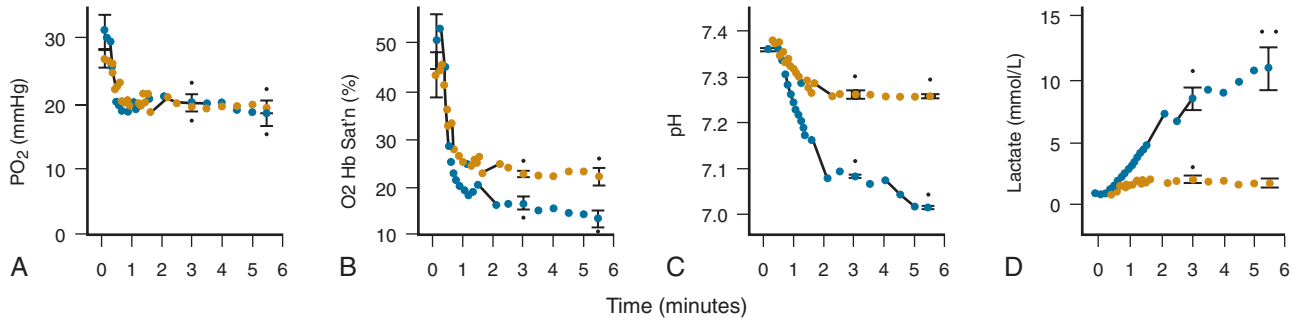

FIGURE 25-2 ■ Femoral blood P_{O_2}, S_{O_2}, and pH during constant work rate exercise at moderate- and high-intensity work rates. In each panel, mean values for five subjects are shown; orange symbols are for moderate-intensity and blue symbols high-intensity exercise; Bars indicate SE for samples drawn at 3-minute and 6-minute time points. **A,** Venous P_{O_2} fell from rest during exercise and reached stable values, which were similar for both exercise intensities. **B,** S_{O_2} and O_2 content were lower during high-intensity compared to moderate-intensity exercise. This was due to a right shift in the oxyhemoglobin dissociation induced by lactic acidosis (Bohr effect) **(C and D).** (Modified from Stringer W, Wasserman K, Casaburi R, et al: Lactic acidosis as a facilitator of oxyhemoglobin dissociation during exercise. J Appl Physiol 76:1462–1467, 1994.)

Alternative perspectives challenge the notion that oxygen availability determines the lactate threshold, since lactate accumulation begins at levels well below maximum $\dot{V}O_2$. Some attribute the rise of lactate to progressive changes in muscle fiber types being recruited as exercise intensity increases, with highly oxidative type I fibers recruited at low levels of exercise and type II fibers with greater glycolytic capacity increasingly recruited at higher work rates.[12] From this observation, it has been inferred that lactate accumulation results from increasing flux of substrate through glycolytic pathways in type II fibers, independent of oxygen availability. Rate limitation of oxygen utilization by enzymatic steps prior to the electron transport chain[13] or saturation of mechanisms for clearance of lactate have also been proposed as the basis for lactate accumulation.[5] The increase in the ratio

of lactate to its precursor pyruvate in blood,[14] and in the ratio of nicotinamide adenine dinucleotide, reduced (NADH) to NAD in muscle,[15] indicates a change in the cellular redox state associated with lactic acidosis, which argues against it resulting solely from greater flux through nonoxidative pathways or impaired clearance.

The lack of consensus concerning its mechanism has given rise to a variety of terms to describe the onset of exercise lactic acidosis, including "ventilatory threshold," "gas exchange threshold," and "lactic acidosis threshold." Importantly, neither its significance as a parameter of exercise function nor its utility in clinical exercise testing is diminished by these differences in perspective. The terms *lactate threshold* and *anaerobic threshold* are used in this chapter when referring to the underlying metabolic processes, and the resulting changes in respiratory gas-exchange variables, respectively.

Domains of Exercise Intensity

In diagnostic testing, the significance of the lactate threshold lies in its relationship to oxygen delivery processes, and in the assessment of function, its significance lies in its relationship to endurance ability.[16] Exercise below the lactate threshold can be continued for prolonged periods of time without discomfort or fatigue, but exercise above this level is associated with systemic acidosis and augmented ventilatory demand. Consistent with this, there is a very limited range above the lactate threshold for which steady-state responses for oxygen transport and utilization can be established. Above this, exercise leads to fatigue and inability to continue exercise due to reaching physiologic limits (see Fig. 25-3). It is thus possible to define discrete domains of exercise intensity,[17,18] with exercise below the lactate threshold designated as "moderate," above the lactate threshold as "heavy," and exercise unsustainable because it leads to attainment of physiologic limits termed "very heavy" or "severe." Although the concept of different intensity domains is relevant to the clinical evaluation of patients, the kind of testing required to precisely distinguish between heavy and very heavy exercise is not well suited to clinical exercise testing. The anaerobic threshold is readily determined using standard testing protocols,

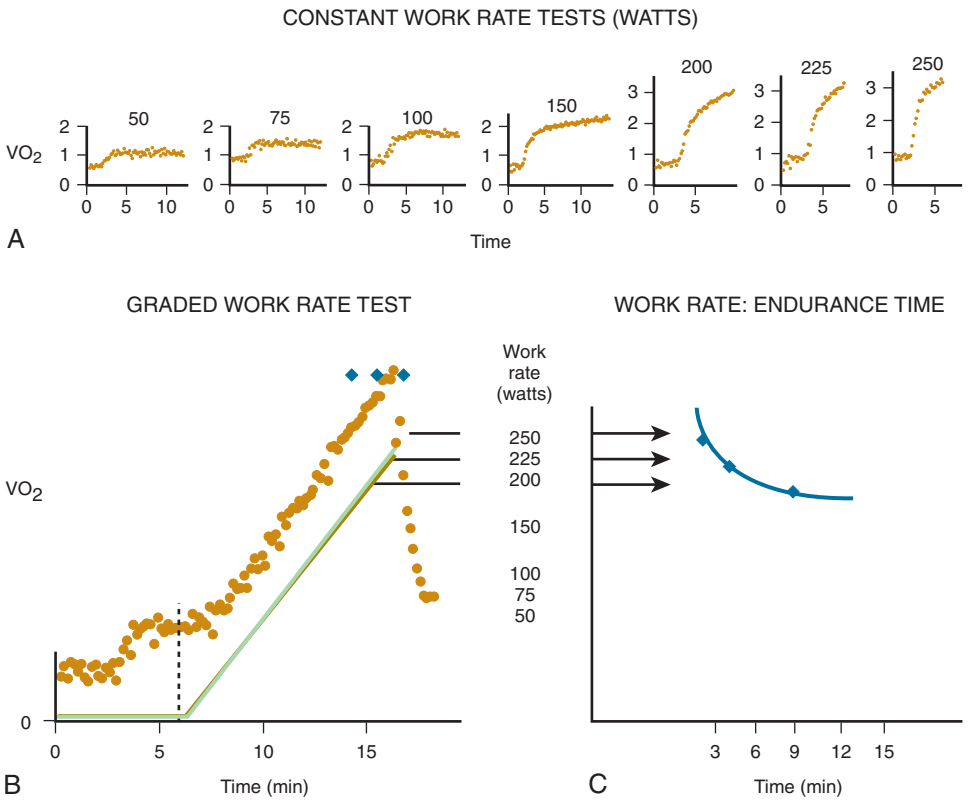

FIGURE 25-3 ■ Data from a healthy man showing relationships between $\dot{V}O_2$, work rate, and time during constant work rate and graded exercise tests. **A,** The profile of $\dot{V}O_2$ for a series of constant work rates ranging from 50 to 250 watts, each test targeted to be 10 minutes long. The lowest three work rates were moderate intensity (i.e., below lactate threshold), and resulted in $\dot{V}O_2$ reaching a steady state within 2 to 3 minutes. The 150-watt work rate represented heavy intensity, slightly above lactate threshold, and attaining a steady state $\dot{V}O_2$ took longer. The three highest work rate tests were very heavy intensity, and all were ended prior to the targeted time due to the subject reaching his maximum $\dot{V}O_2$. **B,** $\dot{V}O_2$ and work rate increased as function of time during a graded test consisting of 3 minutes of rest, then 3 minutes of unresisted cycling, followed by a progressive increase in work rate (*solid line*). Peak $\dot{V}O_2$ reached on the graded test was similar to the end exercise $\dot{V}O_2$ values for the three very heavy constant work rate tests (*blue diamonds*). **C,** The curvilinear relationship of endurance time for these three work rates. The lower intensity tests would not result in maximal $\dot{V}O_2$ and would be sustainable for extended times.

however, and provides a facile measure of endurance capacity.

Organ Systems Supporting Exercise and Limiting Functions

Integrated function of multiple organ systems is required to successfully support exercise while maintaining other vital functions. Impairment in any of these systems can limit maximal exercise or can impose increased requirements on other systems, altering the overall efficiency of exercise. Discrimination of these effects and their contribution to functional impairment is a central goal of clinical exercise testing. The major organ systems supporting exercise are briefly outlined in this section.

Skeletal Muscle

When a small enough mass of muscle is exercised that the cardiac output is not maximally stressed, the maximal oxygen consumption of the muscle is determined by its metabolic capacity. During exercise involving a large muscle mass, however, such as running or cycling, the ability of the active muscle to utilize oxygen exceeds the capacity of the cardiovascular system for oxygen delivery.[19] For the kind of exercise used in clinical exercise testing, therefore, skeletal muscle is viewed as having a "metabolic reserve" and is not normally the proximal limiting factor to maximum $\dot{V}O_2$. Despite this, exercise training is associated with structural and functional adaptations in muscle that allow a given level of work to be accomplished using a lower proportion of the cellular metabolic capacity and with more rapid adjustments to changes in metabolic state. These adaptations include increases in mitochondrial and capillary densities, and increases in the activity of oxidative enzymes.

The existence of a metabolic reserve in the muscle is conditional on there being sufficient muscle mass to accept the increased blood flow of maximal cardiac output and on the muscle having normal metabolic function. Muscle disorders that are limiting to exercise function are diverse and include conditions characterized by decreased mass, impaired capacity for activation or contraction, or decreased energy metabolism. In addition, it is increasingly recognized that reduced muscle mass or function can complicate many chronic disease states,[20,21] such as chronic obstructive pulmonary disease (COPD),[22,23] and their treatments (e.g., corticosteroid therapy), and can contribute importantly to exercise impairment.

Cardiovascular System

The direct relationship between exercise capacity and hemodynamic capacity is underscored by expressing $\dot{V}O_2$ in the terms of the Fick relationship for oxygen:

$$\dot{V}O_2 = \dot{Q} \times C(a-v)O_2$$

where $\dot{Q}$ represents cardiac output and $C(a-v)O_2$ the arterial-venous difference in oxygen content. The increase in exercise cardiac output is coordinated with mechanisms that direct increased blood flow to exercising muscle and minimize flow to less metabolically active tissues, while maintaining blood pressure and flow to vital organs.[24,25] Factors initiating the increase in cardiac output at exercise onset include an augmented venous return due to the action of the skeletal muscle pump and neurally mediated changes in heart rate. Heart rate increases initially by withdrawal of resting parasympathetic tone, and subsequently by progressive sympathetic stimulation. Peak heart rate is dependent on age, with maximal values decreasing by an average of 1 beat/min per year. Stroke volume increases primarily through the Starling mechanism of augmented contractility associated with the stretch of myocardium by higher venous return along with sympathetic augmentation of contractility. Most of the increase in stroke volume occurs relatively early in graded exercise such that increasing cardiac output becomes increasingly dependent on heart rate during heavy exercise.[26] Stroke volume may actually peak prior to maximal exercise and decrease at the highest levels of work due to limited diastolic filling time at high heart rates.[27]

These changes result in systemic blood flow increasing nearly linearly with $\dot{V}O_2$ at a rate of 5 to 6 liters of blood flow for each increment of 1 L/min in $\dot{V}O_2$, with little variation by age or fitness level.[28] For healthy young adults, maximal exercise cardiac output may be in the range of 25 or 30 L/min, and for highly trained endurance athletes, up to 35 to 40 L/min. Most of the exercise-induced increase in cardiac output is attributable to heart rate, which increases two- to threefold, while stroke volume only increases by 20% to 50%. As training does not affect maximum heart rate, training-related increases in cardiac output are mediated entirely by augmented stroke volume. After training stroke volume is higher, and heart rate is lower, at a given $\dot{V}O_2$. The linear decrease in $\dot{V}O_2$ with normal aging is due at least in part to the age-related decline in maximal heart rate and cardiac output. Because cardiac output is normally the limiting factor to maximal aerobic capacity, any attenuation of cardiac function reduces exercise capacity.

Hematologic and Neuroendocrine Systems

The Fick relationship identifies the maximal $C(a-v)O_2$ as the other factor, along with cardiac output, determining maximal $\dot{V}O_2$. This factor is largely a function of hematologic and neuroendocrine processes. While it is not routinely measured during clinical exercise testing, studies of normal subjects and patients with heart failure show that $C(a-v)O_2$ increases linearly across the range of exercise capacity of an individual, reaching peak values at maximum $\dot{V}O_2$.[29]

In health, the arterial oxygen content is primarily a function of hemoglobin concentration, so is lower in women than men, accounting for some of the gender difference in exercise capacity. Additional factors determining mixed venous oxygen content are the distribution of cardiac output and the extraction of oxygen

by perfused tissues. Local extraction of oxygen from capillary blood is a function both of muscle's metabolic capacity and of the microvascular structures that determine diffusion distance from capillary to mitochondria. Distribution of blood flow to and within the muscle is mediated by increases in sympathetic outflow to vascular beds of nonexercising tissues and paracrine factors in exercising muscle mediating local vasodilation.[30] Despite the number of factors contributing to peripheral oxygen extraction, there is far less variability in maximal $C(a-v)O_2$ among healthy persons than there is in maximal cardiac output, with small systematic differences reported due to gender, age, and training status. Consequently the most common clinical disorders limiting $C(a-v)O_2$ are those reducing arterial concentration of oxygen, namely anemia and hypoxemia. Less commonly, extraction of oxygen at the tissue level can be impaired due to metabolic defects in the muscle, or due to disturbances of distribution of blood flow resulting from autonomic dysfunction or regional vascular disease.

Pulmonary System

Control of Breathing. During moderate exercise, the volume per time of pulmonary ventilation ($\dot{V}_E$) matches the rate of carbon dioxide output at the lung ($\dot{V}_{CO_2}$) so closely that there are no more than trivial changes in arterial P_{CO_2} and pH despite large excursions in $\dot{V}_{CO_2}$, $\dot{V}_E$, and venous P_{CO_2}. During higher intensity exercise, lactic acidosis induces a partially compensatory respiratory alkalosis.[31] Although the subject of investigation for over a century, the integration and hierarchy of the factors that contribute to the precise control of $\dot{V}_E$ during exercise remain incompletely understood.[32–35] Ventilatory stimuli originating in the central nervous system and reflexes triggered by mechanical and metabolic processes in exercising limbs and vascular structures are postulated to contribute to the rapid adaptation of ventilation to the start of exercise. The importance of mechanisms related to chemo-sensing processes for "fine-tuning" ventilatory control is evidenced by the remarkable consistency of arterial acid-base homeostasis during rest and exercise.

Breathing Mechanics. In healthy persons, $\dot{V}_E$ may increase 20-fold or more relative to resting levels at maximal exercise. Tidal volume (V_T) increases predominately at low levels of exercise, followed by progressive increases in breathing frequency. V_T approaches, but usually does not reach, inspiratory capacity (IC), and breathing frequencies greater than 50 per minute are unusual. The combination of V_T and breathing frequency at any level of $\dot{V}_E$ appears to be chosen to optimally utilize lung and chest wall mechanics to minimize work of breathing.[36] The increases in V_T result primarily from increases in the volume inspired above resting functional residual capacity, with smaller incursions during exhalation into expiratory reserve volume (ERV)[37] (see Fig. 25-8). Healthy nonathletes generally use less than 75% of breathing capacity, represented by maximal voluntary ventilation (MVV) at peak exercise, and so are not limited by their breathing mechanics. The difference between MVV and $\dot{V}_E$ at peak exercise during a graded exercise test has been termed the exercise "breathing reserve."

Increasing the capacity of the cardiovascular system by training allows healthy persons to attain levels of exercise requiring more of their breathing capacity, so that breathing reserve may be reduced or exhausted.[38] Diseases reducing breathing capacity or increasing breathing requirements can also reduce the normal breathing reserve and, if severe enough, impose limits to exercise due to inability to ventilate sufficiently to keep pace with the rate of CO_2 production.

Gas Exchange. As noted earlier, arterial P_{CO_2} normally remains very close to resting levels during moderate exercise, decreasing at higher intensities due to metabolic acidosis. Because $\dot{V}_E$ increases disproportionately to cardiac output during exercise, the overall ratio of ventilation to perfusion ($\dot{V}/\dot{Q}$) is higher during exercise than at rest. Despite this, the relative efficiency of CO_2 elimination is improved as reflected by the decrease in the ratio of $\dot{V}_E$ to $\dot{V}_{CO_2}$ and decrease in effective dead space–to–tidal volume ratio (V_D/V_T) calculated from the modified Bohr equation. The alveolar-arterial difference in P_{O_2}, or $P(A-a)O_2$, increases during exercise; however, arterial P_{O_2} remains similar to resting levels, almost always above 80 torr at sea level, in healthy nonathletes.[39,40]

Endurance-trained individuals may demonstrate decreased arterial P_{O_2} during high levels of exercise, attributed to both $\dot{V}/\dot{Q}$ mismatch and diffusion limitation due to rapid pulmonary capillary transit time.[41] Thus, the capacity for pulmonary gas exchange, like breathing mechanics, may become limiting to exercise in athletes.

EXERCISE TESTS

Types of Exercise Tests

Functional Performance Tests

A wide assortment of low-complexity or field tests have been devised to test the ability to perform tasks that mimic activities important to home life or to occupation. In clinical contexts, these most commonly simulate elements of activities of daily living using measures such as walking speed, balance, and time required (e.g., to rise from a chair or ascend a flight of stairs). These can be predictive of success in independent living or need for various levels of assistance.[42] In the context of occupation and work fitness, functional tests might instead involve carrying a fire hose up a ladder or running a mile within predetermined times, and are used to predict capacity for job performance.

Walk Tests

Less task-specific tests involving walking on a course or track are applied more broadly to clinical populations with chronic diseases or disabilities.[43] Examples include timed walking tests for which the distance covered in a set time is measured, and fixed-distance tests in which the time required to cover a defined course is measured. Incremental walking tests cue the patient to walk at a

progressively faster pace, and so have the profile of graded exercise tests commonly used in diagnostic laboratories. Because they require little equipment, walking tests are inexpensive to perform and are adaptable to many different environments.

The 6-minute walk test is the most widely used and well-characterized of the walking tests and is frequently utilized in clinical research trials.[44] It and other self-paced tests are subject to "ceiling effects" and may be expected to be relevant primarily to patients whose disease is severe enough to interfere with maintaining a normal or brisk walking pace. In some conditions, such as pulmonary hypertension, these tests have been shown to elicit maximal or near-maximal physiologic responses.[45] In this population, the 6-minute walk test has proven to be sensitive in discriminating between-subject differences in prognosis,[46] and for identifying within-subject changes in performance associated with interventions.[47] Experience with the responsiveness of the 6-minute walk test to change in some other clinical populations, including chronic heart,[48] lung,[44] and kidney[49] diseases, has been less consistent. Published recommendations for administering the 6-minute walk test[50] highlight the importance of standardizing test procedures to account for effects of learning, verbal encouragement, and variations in course layout. Because physiologic measures are not generally made during this kind of testing, these tests have little or no role in diagnostic evaluations.

Laboratory-Based Exercise Testing

Testing in a laboratory allows more extensive monitoring of clinical variables and use of specialized equipment for physiologic measures. *Cardiopulmonary exercise testing* is the term applied to testing when ventilation and pulmonary gas exchange are measured in addition to the electrocardiogram (ECG) and blood pressure, and is the focus of discussion in the following sections. A wide range of other diagnostic instruments may be used to compliment these basic measurements for specific clinical purposes.

APPLICATIONS OF EXERCISE TESTING

Applications of exercise testing can be broadly classified under the headings of tests done for quantitative purposes—that is, to measure exercise capacity or the degree of impairment in persons with known conditions—and tests done for diagnostic purposes (Table 25-2).

Exercise Testing to Quantify Capacity or Impairment

Objective measures of exercise capacity are useful for determining disability, for assessing prognosis, for grading and longitudinal tracking of disease severity, and

TABLE 25-2. Clinical Applications of Cardiopulmonary Exercise Testing with Selected Examples

Category	Goal	Examples
Quantitative Assessments	Quantify functional capacity	• Athletic training assessment
		• Disability assessment
		• Disease severity rating
		• Evaluation of response to therapy or disease progression
	Establish prognosis	• Cardiac transplantation priority and timing
		• Preoperative risk assessment for lung resection
		• General preoperative risk assessment
	Exercise prescription	• Pulmonary rehabilitation
		• Weight loss or other health benefits
	Pacemaker evaluation	• Optimize settings
Diagnostic Assessments	Confirm a suspected disorder	• Document dynamic hyperinflation in chronic obstructive pulmonary disease
		• Provoke exercise-induced bronchoconstriction
		• Evaluate for ischemia as cause of chest pain
	Attribute symptoms or limitation to a cause	• Distinguish between two or more established diagnoses as cause of change in symptoms
	Evaluate significance of abnormal finding on resting study	• Echocardiogram finding of uncertain significance
		• Abnormal pulmonary function test
	Evaluate exercise intolerance: Specific diagnoses	• Cardiac ischemia
		• Heart rate insufficiency
		• Ventilatory limitation
	Evaluate exercise intolerance: Narrow differential diagnosis	• Distinguish between cardiovascular, pulmonary, or metabolic pattern of abnormality
	Evaluate exercise intolerance: Limit diagnostic workup	• Confirm normalcy of age- or weight-referenced responses

for prescribing exercise training. Disability assessment of patients with lung disease is addressed in Chapter 27 of this text and is not discussed here. Similarly, exercise testing to guide athletic training of healthy persons is beyond the scope of this discussion.

Prognosis

Exercise capacity is an independent predictor of survival in many different clinical populations, including apparently healthy persons and patients with chronic cardiovascular conditions.[51–55] Exercise capacity also provides prognostic information for patients with chronic lung diseases, including COPD,[56] cystic fibrosis,[57,58] and parenchymal lung diseases.[59,60,60a]

The prognostic value of exercise capacity has proven to have utility in clinical decision making in a number of contexts. The most extensively studied is the estimation of prognosis among patients with chronic heart failure for the purpose of prioritizing heart transplant waiting lists. Early reports of this application used a peak $\dot{V}O_2$ value of less than 14 ml/min per kg of body weight as a criterion for consideration of transplantation, based on demonstration that patients referred for transplantation with exercise capacity above this level had 2-year survival rates similar to those of transplant recipients.[61,62] Since then, additional exercise variables have been found to add to the prognostic value of peak $\dot{V}O_2$ in this population,[63,64] and important covariants affecting their interpretation have been identified.[65,66] Tailoring of other advanced therapies for heart failure to individual patients is likely to incorporate a number of variables measured during exercise testing.

There is relatively less experience with the use of exercise data for decision making regarding lung transplantation. The 6-minute walk distance has been found to predict mortality among patients awaiting lung transplantation,[60,67,68] and has been used in allocation algorithms. Similarly, the National Emphysema Treatment Trial found peak exercise work rate to be a key factor identifying those patients with severe emphysema who could benefit from lung volume reduction surgery.[69] These contexts are analogous to that of heart transplantation, in that exercise capacity is used to identify a subset of patients whose disease puts them at sufficiently high risk to justify the risk of aggressive interventions.

Another application of the prognostic value of exercise data is in preoperative risk assessment. In contrast to the decision making related to transplants, here low exercise capacity is used to identify those for whom the risk of surgery may be considered prohibitive. Among patients with anatomically resectable lung cancer, peak $\dot{V}O_2$ values less than 12–15 mL/min/kg predict increased risk of perioperative morbidity and mortality.[70,70a] As a result, exercise testing is included in algorithms for guiding the choice and extent of lung cancer surgery, especially for patients with marginal pulmonary function.[71,72] Because unresected lung cancer has a poor prognosis itself, in this context exercise capacity serves more to inform the risk-benefit discussion than as an absolute criterion of operability.[73] Fewer data are reported for the use of exercise testing in preoperative assessment for nonthoracic surgery.[73a] An anaerobic threshold of less than 11 mL/min/kg has been reported to predict increased risk of mortality following elective abdominal procedures, and has been used effectively to plan the intensity of perioperative care for patients who are elderly or have comorbid conditions.[74]

Grading and Tracking of Disease Severity

When disease limits exercise function, it is rational to grade the severity of disease by the degree of exercise impairment. Weber and colleagues in 1982 demonstrated the predicted relationship between peak cardiac output and peak $\dot{V}O_2$ among patients with chronic heart failure and proposed a functional severity classification (termed classes A through D) based on stratifying peak $\dot{V}O_2$ at 20, 16, and 10 mL/min/kg.[75] The validity of this approach is borne out by the relationship of Weber class to prognosis and to the New York Heart Association symptom-based classification.[76] In addition, longitudinal changes in peak $\dot{V}O_2$ appear to accurately reflect changes in status of patients with heart failure referred for transplantation.[77] Functional capacity is increasingly used in the grading of severity of chronic lung disease as well. Exercise capacity, expressed as either 6-minute walk distance or peak $\dot{V}O_2$, is used along with body mass index, airflow obstruction, and dyspnea scores to calculate the BODE index of COPD severity,[78] and among patients with moderate to severe disease, longitudinal changes in this index identify changes in clinical status and mortality risk.[79] Longitudinal exercise testing is also an important tool in clinical research trials evaluating interventions, including drugs or rehabilitation, aimed at improving physical function.

Exercise Prescription

Quantifying exercise capacity is an integral component of exercise prescription.[80] Pre–pulmonary rehabilitation testing is used to identify maximal capacity and anaerobic threshold as measures of baseline impairment, select initial work rates for training, and calibrate training guides such as heart rate or symptoms to physiologic targets.[81] In addition to these quantitative measures, the nature of exercise limitation can be confirmed and patients screened for exercise hypoxemia or adverse responses to exercise that should be addressed prior to exercise conditioning.[82]

Exercise Testing for Diagnostic Purposes

Historically the most common diagnostic use of exercise testing has been to identify exercise-induced myocardial ischemia as the cause of exertional chest pain. An extensive literature defines the utility of exercise testing for this purpose and is not reviewed here. Like stress testing for coronary disease, cardiopulmonary testing is sometimes performed to verify a specific condition as a cause

of symptoms. This may be the case, for example, if a condition such as exercise-induced bronchoconstriction is suspected. Design of the test protocol to optimize the chance of provoking that abnormality, and use of specific ancillary measurements to identify it, enhance the test's diagnostic specificity.

Often cardiopulmonary exercise testing is performed to evaluate patients with unexplained exercise intolerance without the a priori intent of confirming a specific condition.[83] Standardized test protocols that span the range of an individual's capability allow exercise function to be characterized in terms of major parameters and response patterns.[84] The results are then compared with normal reference values and interpreted in the context of the patient's history and symptoms. In some cases a specific diagnosis will be established by the finding of a unique abnormality. The underlying causes of dyspnea and exercise intolerance are diverse, however,[85,86] and not all potential diagnoses have unique findings in the measurements made using standard test protocols. Often, therefore, diagnostic exercise testing aims to narrow the differential diagnosis and provide a focus for further evaluations based on the patterns of exercise responses.[87] No less important, in some cases support for limiting further diagnostic testing can be obtained by finding normal results or by exclusion of specific conditions that would otherwise require more invasive testing to evaluate. A general approach to diagnostic testing is discussed below in the section on clinical exercise data and interpretation.

CONDUCTING CARDIOPULMONARY EXERCISE TESTS IN CLINICAL PRACTICE

Practice Standards and Risks

The risk of serious complications during medical exercise testing has been estimated in the range of less than 1 to 5 per 10,000 tests, and the risk of death at 0.5 per 10,000 tests based on surveys of laboratory testing in patients with known or suspected cardiac disease.[88,89] This means that exercise testing is a relatively safe procedure, but not without risk. Consensus recommendations published by several professional societies[40,80,90] include guidelines for reducing risk by setting standards related to contraindications to testing, monitoring procedures, criteria for interrupting a test, and availability of emergency resources. Absolute contraindications to maximal exercise testing include temporal proximity to acute myocardial infarction or other major event, decompensated state of chronic disease, acute infectious illness, or instability of cardiac rhythm or hemodynamics. Additional relative contraindications may apply in the context of the indication for testing and the staffing of the laboratory. There is presently no certification process required for physicians to perform exercise tests, but minimal training and skills needed for supervising tests and interpreting the ECG are published.[91]

Instrumentation and Measurements

Instruments for conducting clinical cardiopulmonary exercise tests have become widely available. Specific methods and performance characteristics of equipment vary between devices, but all use similar component measurements for calculation of gas exchange. Patients breathe through either a mask or a mouthpiece, and ventilatory and gas-exchange variables are calculated from analyses of expired breath from a mixing chamber or breath-by-breath.[92] Respired volumes are derived from volume or flow transducers interfaced with the breathing apparatus, and partial pressures of CO_2 and O_2 in the exhalate are measured by gas analyzers with rapid response times.[40] Measurements must be precisely time-aligned for accurate calculation of gas-exchange rates. Calibration routines therefore include calibrating signals from the flow or volume transducer and gas analyzers, and determining transit and analysis times and environmental factors such as temperature and humidity.

Calculation of gas exchange is based on mass balance equations having the general form:

$$\dot{V}_{O_2} = \dot{V}_E \times (F_{I_{O_2}} - F_{E_{O_2}})$$

and

$$\dot{V}_{CO_2} = \dot{V}_E \times F_{E_{CO_2}}$$

with correction factors to adjust for water vapor and other factors.[10] By convention, $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are expressed at standard temperature and pressure, dry (STPD) because they reflect metabolic processes and so are most meaningful as molar equivalents. For the above calculations, therefore, $\dot{V}_E$ is expressed in STPD and $F_{E_{CO_2}}$ and $F_{E_{O_2}}$ are fractional concentrations of the dry exhaled gas volumes. When reporting $\dot{V}_E$, however, it is expressed at body temperature and pressure, fully saturated with water vapor (BTPS), because this is the form in which air is breathed, and the significance of $\dot{V}_E$ is more related to the mechanical requirements of breathing than to the molar equivalents of the gases. Profiles of instantaneous measures of gas tension, flow, and volume over individual breaths may also be recorded.

Heart rate is determined from the 12-lead ECG, which is monitored continuously for changes in rhythm or repolarization. Blood pressure is determined intermittently by cuff, and arterial saturation is estimated by pulse oximetry. Periodic assessment of ratings of perceived exertion and dyspnea are frequently included in test procedures. Arterial blood may be sampled for blood gas analyses either from an indwelling catheter or by discrete punctures. In addition to blood gas tensions, this allows calculation of $P(A-a)_{O_2}$ from the alveolar gas equation and V_D/V_T from the modified Bohr equation,[10,40] which represent the most sensitive measures of the efficiency of pulmonary gas exchange routinely available for clinical assessments.

Test Design Issues

Ergometers

The most commonly used ergometers are treadmills and stationary cycles. Treadmills offer the advantage of

simulating a universal component of daily activities. For most subjects, treadmill exercise also elicits a slightly higher peak $\dot{V}O_2$ than cycling, and so a more likely true physiologic maximum. Conversely, cycles offer the practical advantages of less motion artifact in signals from monitoring devices, easier performance of blood draws or other procedures, and lesser chance of injury due to falls. Because seated exercise allows very low initial work rates and the ability to discontinue work at any time, cycles may be favored in laboratories that frequently evaluate very frail patients. In addition, the imposed work rate is more accurately defined for cycling because the biomechanics are relatively less complicated than those of walking. Portable gas-exchange measurement systems make it feasible to use other modalities of exercise simulating occupational or sports activities, or to accommodate populations for whom conventional ergometers may not be appropriate.

Protocols

Both fixed work rate and graded work rate protocols have utility in clinical testing. The relationship between the responses of $\dot{V}O_2$ to these two different profiles of work is illustrated in Figure 25-3, page 557.

Graded or Incremental Exercise. Graded tests begin with a low level of difficulty and work rate is progressively increased until maximal tolerance is reached or some other end point occurs. Numerous graded protocols have been developed for cycles or treadmills.[40,84,93] Work rate is increased on a cycle by raising resistance to pedaling and on a treadmill by changes in grade and/or speed. Some protocols call for a specific series of ergometer settings, though individualizing the settings allows targeting the incremental portion of the test to an 8- to 12-minute duration, increasing the likelihood of optimal patient performance.[94] Because physiologic responses take time to fully develop, measurements of $\dot{V}O_2$ and other variables during graded tests lag behind the steady-state requirements of the instantaneous work rate being performed. Despite this, key variables such as the anaerobic threshold—as well as $P(A-a)O_2$ and V_D/V_T, reflecting gas-exchange efficiency—are similar to those obtained during steady-state exercise.[95] In most cases too, the $\dot{V}O_2$ at peak exercise of a graded exercise test is comparable to the maximal $\dot{V}O_2$ that is classically derived from having subjects perform a series of very-heavy-intensity fixed work rate tests to exhaustion.[18,96] The term *peak* $\dot{V}O_2$ is customarily used to distinguish the results of a graded test from the latter, more rigorously defined, maximum $\dot{V}O_2$.

Constant Work Rate Exercise. Though graded tests are most common in clinical testing, fixed or constant work rate tests are also useful. Constant work rates elicit markedly different responses depending on the intensity that work rate represents to the patient.[97,98]

Work rates of moderate intensity result in most measured variables reaching steady states within a few minutes and are appropriate, for example, for assessing the need for ambulatory oxygen therapy in patients with COPD. Tests of higher intensity with measurement of endurance time as the primary variable are increasingly used in clinical research trials, particularly in COPD. With appropriate selection of the testing work rate, changes in endurance time are more responsive to changes in function induced by rehabilitation[99] or drug therapy[100] than are parameters from graded testing. This results from the complex dynamic pattern of cardiorespiratory responses to heavy and very heavy exercise, as shown in Figure 25-3. In these ranges, $\dot{V}O_2$ and other variables do not reach new steady states in the 2 to 3 minutes required to adapt to moderate exercise; in fact, the trajectory of $\dot{V}O_2$ paradoxically extends to a higher level than would be expected if the exercise were only a moderate stress. The basis for this is incompletely understood.[101] The consequence, however, is that in this range of exercise, maximal $\dot{V}O_2$ is approached asymptotically over an extended period of time. Interventions increasing maximal $\dot{V}O_2$ or the lactate threshold by even small amounts can substantially prolong the time required to reach physiologic limits at that work rate. Aside from providing a useful form of testing in clinical trials, this observation underscores how a modest increment in exercise capacity (e.g., due to exercise training) can disproportionately improve tolerance for exercise in the range of work rates around a patient's lactate threshold.

CLINICAL EXERCISE DATA AND INTERPRETATION

Organization of Exercise Data and Comparison with Normal Values

Results of exercise function tests include discreet values, such as peak $\dot{V}O_2$, and slopes or ratios of variables reflecting their interrelationships and dynamic changes occurring with exercise. Interpreting these data includes comparisons with reference values from healthy populations (Table 25-3). As is the case for pulmonary function tests, comparative data for all variables of interest are rarely available from a single source, so reference data are selected from a number of sources.[40] For some measured variables, normal responses are relatively invariant, whereas others are affected by demographic, genetic, and behavioral factors and have wide ranges within healthy populations. For the latter, which include peak $\dot{V}O_2$ and anaerobic threshold, predicted values vary considerably depending on the characteristics of the population sample on which the regression equations are based. Equations derived from volunteers tend to predict higher values than those derived from randomly selected sedentary subjects. Selection and use of reference sets therefore requires consideration of the characteristics of the patient population being tested as well as the methodology of the laboratory. Graphical displays are used to identify the anaerobic threshold and facilitate identification of patterns of responses in other variables that are characteristic of different clinical conditions (Figs. 25-4, 25-5, and 25-6).

Table 25-3. Normal Values for Variables from Clinical Exercise Testing and Factors Contributing to Their Variability Among Healthy Adults*

		OTHER FACTORS CONTRIBUTING TO VARIABILITY†				
	Normal Values or Equations	Age	Gender	Fitness	Effort	References
Peak $\dot{V}O_2$‡ (ml/min)				+++	+++	39, 113, 149, 150
Men	= (Height [cm] − age [yr]) × 21					
Women	= (Height [cm] − age [yr]) × 14					
	LLN: 83% of predicted					
Anaerobic threshold $\dot{V}O_2$	= 50–60% of normal peak $\dot{V}O_2$	+	+	+++		39, 113, 150
	LLN: 40–55% of normal peak $\dot{V}O_2$					
$\Delta\dot{V}O_2/\Delta WR$ (ml/min/watt)	= 10.0					104, 151
	LLN: 8.5					
Peak HR (beat/min)	= (220 − age [yr])				+++	40, 150
	LLN: (predicted − 20 beats/min)					
Peak $\dot{V}O_2$/HR (ml O_2/beat)	= Predicted peak $\dot{V}O_2$ ÷ Predicted peak HR			++	++	113
	LLN: ~ (predicted − 2.7)					
$\dot{V}E/\dot{V}CO_2$ @ AT§	LLN: 28–32	+	+			39, 152
Breathing reserve (L/min)	28% of MVV			+	+++	39, 153
	LLN: 11 L/min					
PaO_2, heavy exercise (mm Hg)	>80	+				39
$P(A-a)O_2$, heavy exercise (mm Hg)	<34	+				39
VD/VT, rest	<0.4	+				39
VD/VT, heavy exercise	<0.3 *and* lower than VD/VT at rest	+				39

*Representative values or equations for sedentary adults are shown. Values expressed as "<" or ">" represent estimates of the upper or lower limits of normal; otherwise values are averages with lower limits of normal (LLN) indicated where available. Sources and selected alternatives can be found in the references listed.

†Potential sources of significant variability in the values of healthy persons represented by the listed ranges or not accounted for in the reference equations, with +, ++, and +++ indicating increasing magnitude of the potential effect.

‡Equations for peak $\dot{V}O_2$ are simplified equations based on unpublished analyses (J.E. Hansen, personal communication). See references cited for detailed regressions.

§Ratio of $\dot{V}E$ to $\dot{V}CO_2$ measured at the anaerobic threshold (AT).

Heavy exercise, exercise above anaerobic threshold; HR, heart rate; MVV, maximal voluntary ventilation measured at rest; VD/VT, dead space–to–tidal volume ratio calculated by the Enghoff modification of the Bohr equation using arterial PCO_2 and simultaneous measures of $\dot{V}CO_2$ and respiratory exchange ratio (RER).

Interpreting Exercise Data to Quantify Exercise Capacity

Variables for Quantifying Exercise Capacity

Exercise capacity can be quantified by the amount of external work performed, expressed as watts or as the stage of a standard test protocol, or by the level of metabolic work (i.e., $\dot{V}O_2$) that can be attained. Which of these is of greater relevance depends on context. Capacity for external work may be most relevant to occupational ability assessment, but normalcy of cardiorespiratory capacity for metabolic work is the focus of tests assessing disease severity or prognosis. Ergonomic efficiency may alter the expected relationship between external and metabolic work. In addition, the peak work rate attained on a graded test is affected by the rate at which the work rate is increased, and so is only meaningful in the context of a standardized protocol.

Maximal or peak $\dot{V}O_2$ is the standard metabolic expression of exercise capacity. It is systematically higher in men than women, declines linearly with age throughout adulthood, and is modified by activity level, so reference equations typically include some or all of these factors.[40] The common practice of expressing peak $\dot{V}O_2$ in ml/min/kg of body mass as means of normalizing for size has the advantage of combining an expression of cardiorespiratory capacity with an expression of the weight that needs to be supported during ambulatory activities. The quotient may be low if either peak $\dot{V}O_2$ is abnormally low or weight is abnormally high, however, with obvious differences in clinical implications.

The anaerobic threshold is the $\dot{V}O_2$ above which gas exchange and ventilation reflect an accelerated rate of $\dot{V}CO_2$ due to the buffering of lactic acid. It is most readily determined graphically from a plot of $\dot{V}CO_2$ against $\dot{V}O_2$ (see Fig. 25-4). It is expressed in milliliters per

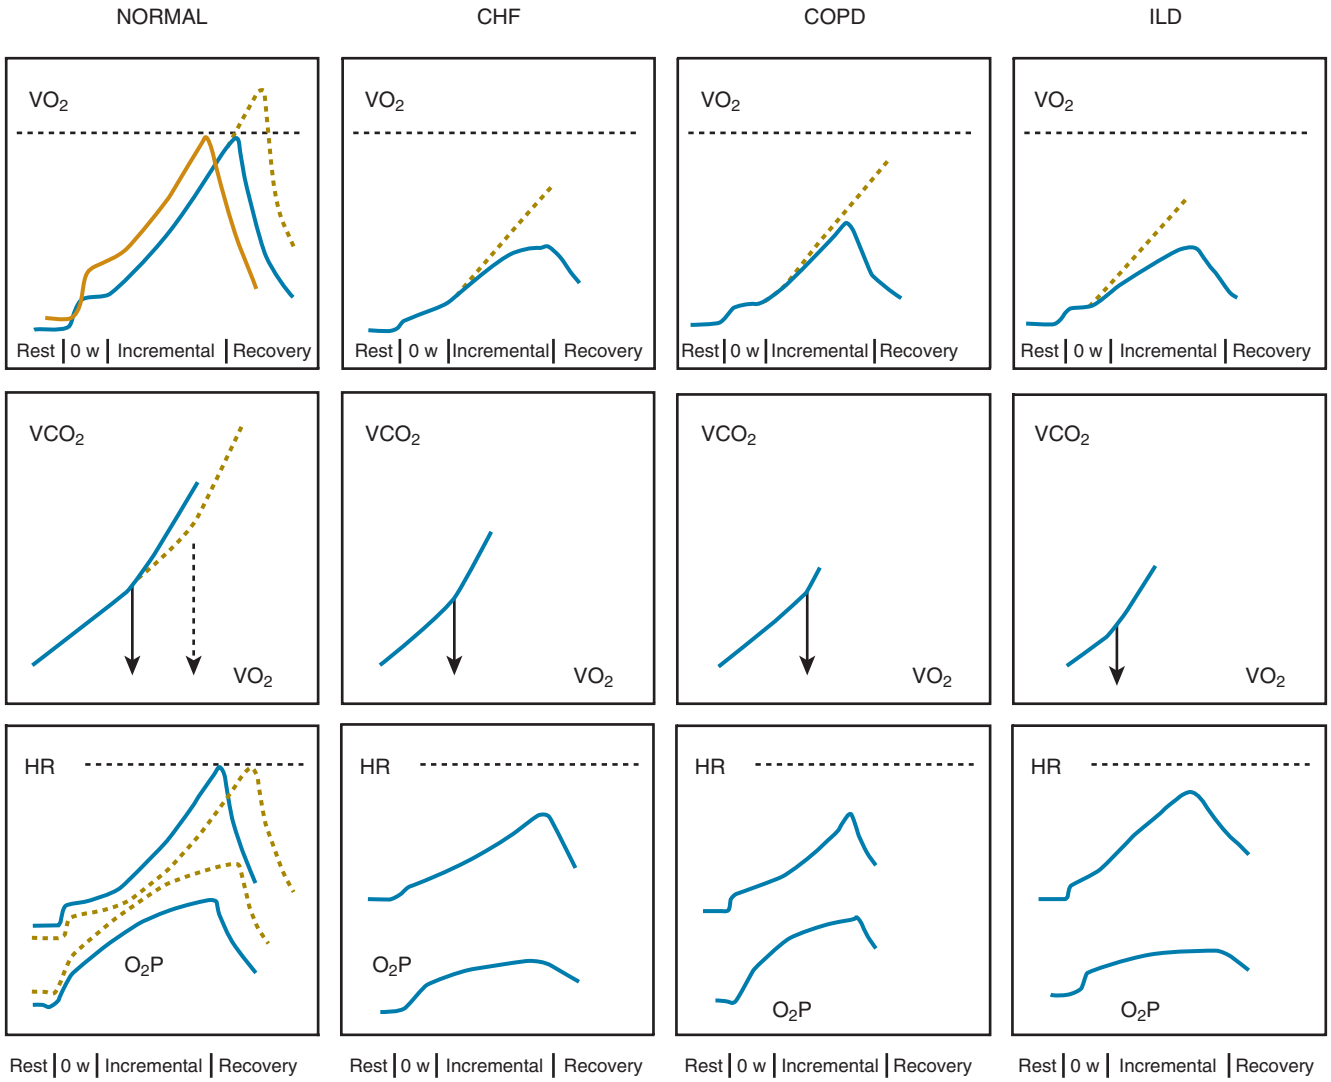

FIGURE 25-4 ■ Typical response patterns to graded cycle exercise test performed by a normal subject compared to sample patients with chronic heart failure (CHF), chronic obstructive pulmonary disease (COPD), and interstitial lung disease (ILD), all scaled identically: Variables reflecting oxygen delivery and utilization. *Top row,* $\dot{V}o_2$ as a function of time for a protocol consisting of 3 minutes of rest, 3 minutes of unresisted cycling (0 watts), incremental increase in work rate, and recovery. *Horizontal dashed lines* indicate predicted maximal $\dot{V}o_2$, which is approached as a linear function of work rate in the normal subject (*left panel, solid blue line*). A more fit subject (*dashed line*) demonstrates the same relationship between work rate and $\dot{V}o_2$ but reaches higher values for both, whereas an obese subject (*solid orange line*) has a higher $\dot{V}o_2$ at any given work rate. In the patients with CHF and ILD, the rate of increase in $\dot{V}o_2$ relative to work rate is lower than normal (*dashed lines*) due to impaired cardiac output response, and recovery of $\dot{V}o_2$ following exercise is also slower. *Middle row,* $\dot{V}co_2$ is plotted as function of $\dot{V}o_2$ (omitting data from rest and recovery) to identify the anaerobic threshold[154] as the $\dot{V}o_2$ above which there is a disproportionate increase of $\dot{V}co_2$ (*vertical arrows*) indicating buffering of lactic acid. Anaerobic threshold is higher $\dot{V}o_2$ in the fit subject (*first panel, dashed line*), and is lower in the patients with CHF and ILD, though relatively normal in the COPD patient, for whom it thus is a high percentage of peak $\dot{V}o_2$. *Bottom row,* Heart rate (HR) and oxygen pulse (O_2P, calculated as $\dot{V}o_2$/HR) as a function of time. *Horizontal dashed lines* indicate predicted maximal HR. Both normal subjects reach the same peak HR, but HR is lower and O_2P higher for the fit subject (*dashed lines*) at a given work rate. In the patient with CHF, peak HR is reduced and O_2P is low and reaches an asymptote early, reflecting limited increase in stroke volume. Peak HR and O_2P are also low in the patient with COPD, though the pattern is closer to normal with truncation of the test prior to reaching peak cardiovascular responses. The ILD pattern reflects reduced oxygen delivery due to limited right ventricular stroke volume and arterial hypoxemia, and so resembles CHF more than COPD.

minute (mL/min) or as a percentage of maximal $\dot{V}o_2$. For middle-aged men it should be at least 40% peak $\dot{V}o_2$, and for women a slightly higher percentage. The anaerobic threshold declines less steeply with aging than peak $\dot{V}o_2$, so it becomes a progressively higher percentage of peak with age. In clinical testing, both the predicted and measured anaerobic thresholds are expressed as a percentage of the *predicted* peak $\dot{V}o_2$ to avoid misinterpreting a low value as normal because of a concomitant decrease in maximal capacity or an underestimation of peak $\dot{V}o_2$ due to submaximal effort or some other factor.

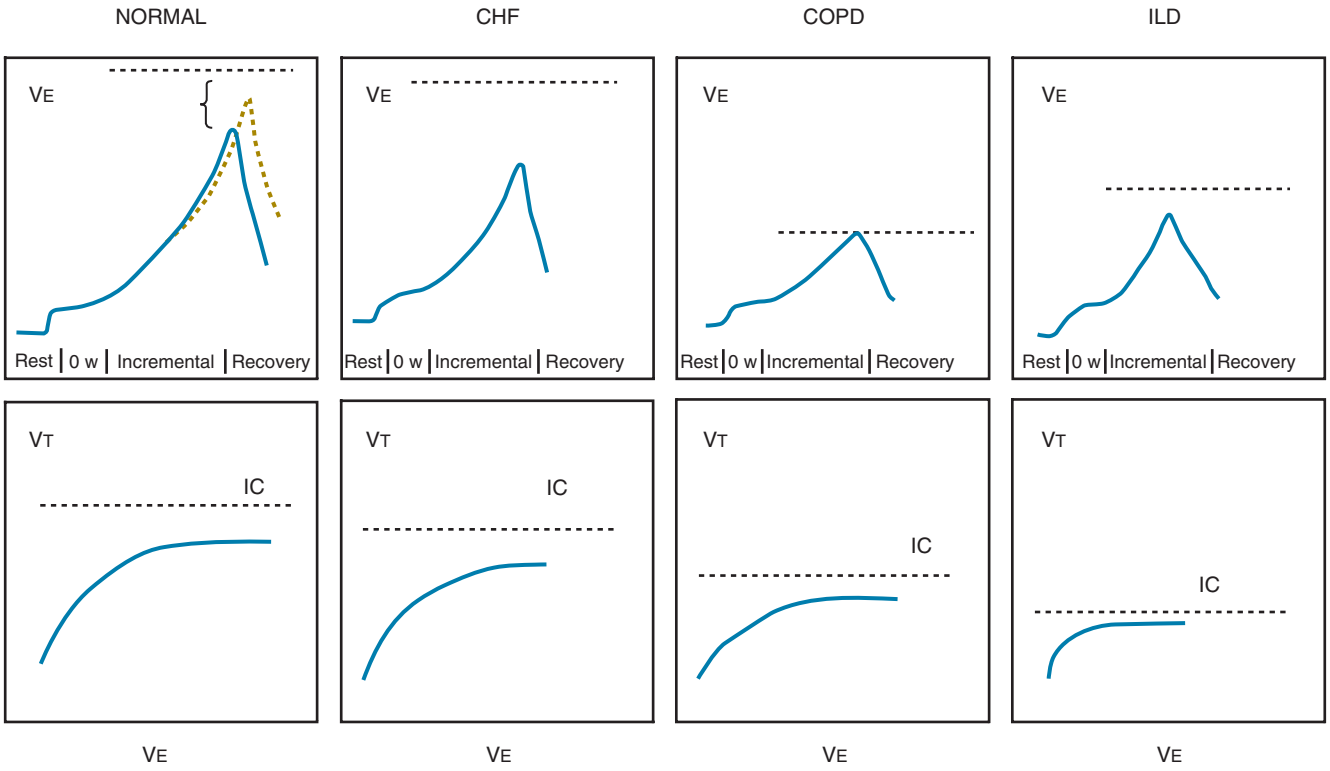

FIGURE 25-5 ■ Exercise variables reflecting ventilatory variables for the same protocol and subjects shown in Figure 25-4. *Top row,* $\dot{V}_E$ as a function of time. *Horizontal dashed lines* indicate the subjects' MVV values. The normal subject has a breathing reserve (*bracket*) at end exercise, which is smaller for the fit individual (*dashed line*), who reached a higher peak $\dot{V}_E$ but had lower $\dot{V}_E$ at a given work rate in the range above the anaerobic threshold. The COPD patient has no breathing reserve and ends exercise on reaching MVV. *Bottom row,* Tidal volume (V_T) as a function of $\dot{V}_E$. *Horizontal dashed lines* indicate subjects' inspiratory capacities (IC). All subjects increase tidal volume early in exercise, with V_T approximating IC early in exercise in the patient with ILD.

Utilizing Data from Quantitative Testing

Prognosis. Using exercise data in the estimation of prognosis requires comparison with data from the relevant clinical population. For example, peak $\dot{V}_{O_2}$ predicts mortality risk in both COPD and idiopathic pulmonary fibrosis (IPF), but for a given value, mortality is higher in IPF. Testing modality and protocol should also be comparable to those used in the reference studies. The treatment of data of obese patients can be problematic in this context. Using actual weight to define peak $\dot{V}_{O_2}$ in ml/min/kg lowers values for obese subjects independent of disease severity and should be avoided, for example, in transplantation assessments, where the value of peak $\dot{V}_{O_2}$ presumably derives from its relationship to cardiac function. The appropriate approach in preoperative risk assessments is less clear as obesity may constitute a component of the estimated risk.

Exercise Training. Prescriptions for endurance training include elements of exercise frequency, duration, and intensity. Exercise tests are particularly helpful in guiding selection of a work rate matching the desired intensity. Prescribing guidelines often define intensity in terms of percentages of peak heart rate, $\dot{V}_{O_2}$, or work rate,[80] though referencing the work rate to the anaerobic threshold results in more uniform training stimulus. Work rates corresponding to the subject's anaerobic threshold are effective and are usually tolerated for the 30- to 45-minute durations commonly targeted in the prescriptions. Higher intensities, up to about midway between anaerobic and peak, are also suitable and can result in greater effects for a given time.

Longitudinal Assessments. Using exercise tests to monitor changes in patients' condition over time depends on an appreciation of the repeatability of the key variables. The within-subject coefficient of variation for peak $\dot{V}_{O_2}$ is reported to be in the range of 4% to 8% for a number of clinical populations.[102,103] Somewhat more variability is usually reported for determination of the anaerobic threshold from gas-exchange variables, despite it being independent of maximal effort. There appear to be minimal learning effects on the results of graded tests. Six-minute walk distance, in contrast, is systematically longer on the second compared to the first trial, with subsequent tests showing progressively less change and coefficients of variation in the range of 6% to 8%.[50]

Interpreting Exercise Data for Diagnostic Purposes: Typical Response Patterns

For tests targeting the confirmation of a specific diagnosis, interpretation may be based on ancillary measures

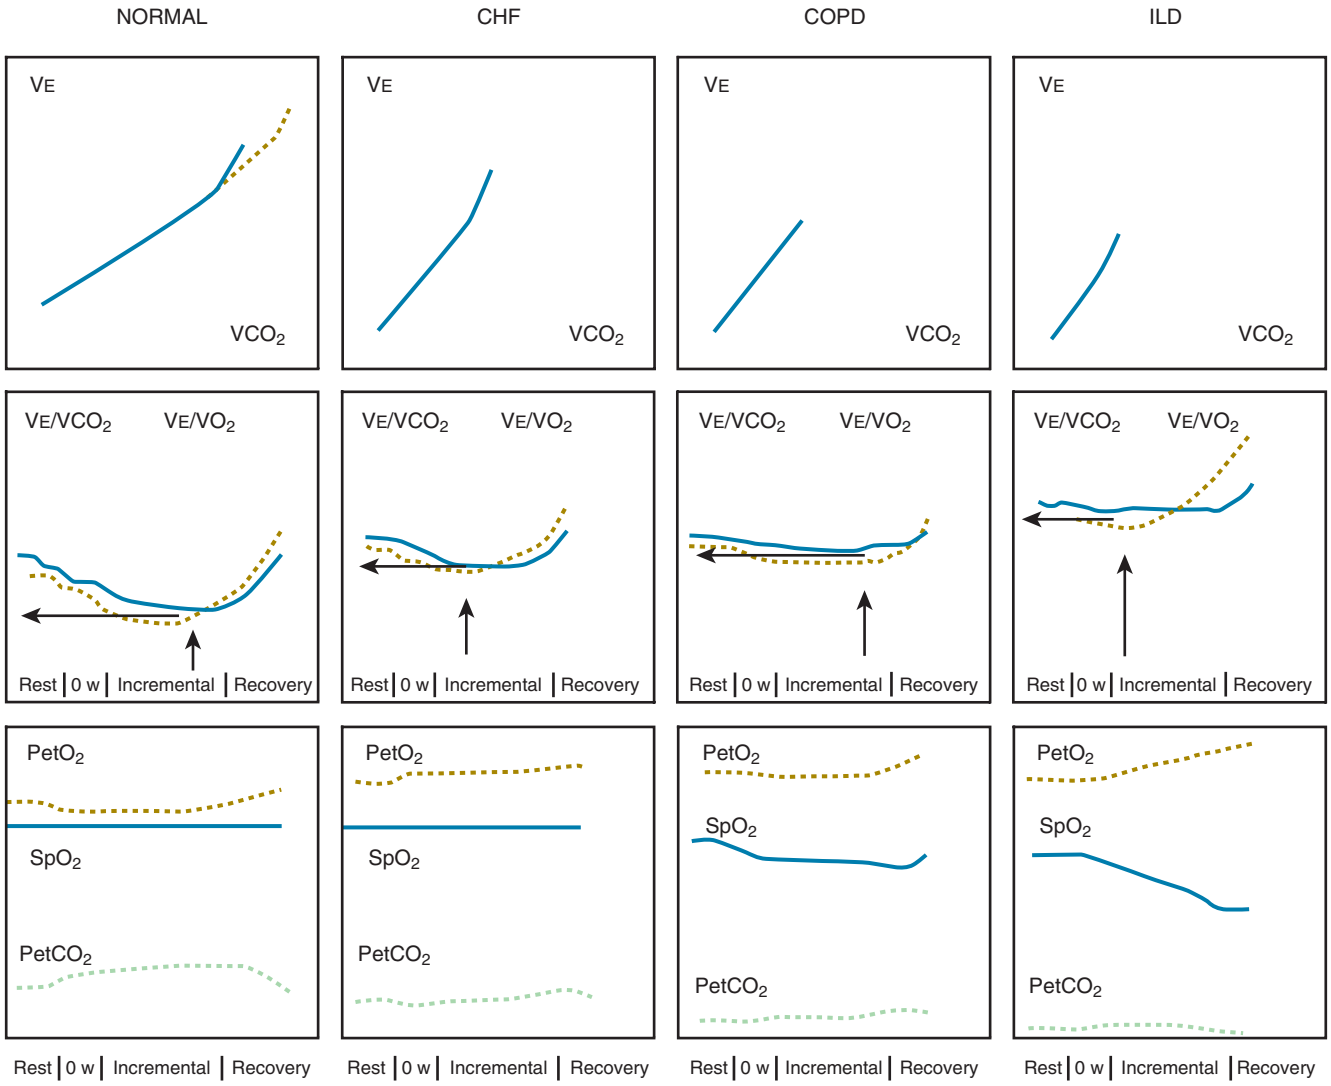

FIGURE 25-6 ■ Exercise variables reflecting gas-exchange efficiency for the same protocol and subjects as in Figure 25-4. *Top row,* $\dot{V}_E$ as a function of $\dot{V}_{CO_2}$. $\dot{V}_E$ and $\dot{V}_{CO_2}$ are linearly related over most of exercise, but the slope is steeper for all patient groups shown due to the effects of high ventilation-to-perfusion relationships in the lung. Late in exercise, an increase in slope marks ventilatory compensation for metabolic acidosis, which may not be evident in patients with reduced chemoresponsiveness or severe ventilatory limitation, or when exercise is limited soon after the anaerobic threshold, as shown for COPD. *Middle row,* $\dot{V}_E/\dot{V}_{CO_2}$ (*solid blue lines*) and $\dot{V}_E/\dot{V}_{O_2}$ (*dotted brown lines*) ratios as a function of time. An increase in $\dot{V}_E/\dot{V}_{O_2}$ marks the anaerobic threshold (*vertical arrows*); the $\dot{V}_E/\dot{V}_{CO_2}$ at this point (*horizontal arrows*) is an index of efficiency of gas exchange. *Bottom row,* End-tidal P_{O_2} (P_{ETO_2}, *dashed brown lines*) and P_{CO_2} (P_{ETCO_2}, *dashed blue lines*) and pulse oximeter O_2 saturation (S_{PO_2}, *solid blue lines*). Arterial desaturation is often progressive and more severe in ILD than COPD, but is not typical of CHF.

such as posttest spirometry or cardiac imaging. In the more broadly focused evaluation of dyspnea or exercise intolerance, interpretation focuses on classifying responses as characteristic of cardiovascular, ventilatory, or metabolic abnormalities. Patterns of findings in test variables that are typical of some common cardiorespiratory disorders are illustrated in Figures 25-4 through 25-6 and further described below.

Limitation due to Cardiovascular Disorders

Any condition abnormally limiting cardiac output reduces peak $\dot{V}_{O_2}$ and can affect other $\dot{V}_{O_2}$-related variables. The anaerobic threshold is often low, and the slope of change of $\dot{V}_{O_2}$ relative to work rate ($\Delta\dot{V}_{O_2}/\Delta WR$) may be less than normal, particularly in the range above anaerobic threshold.[104] This reflects an abnormal reliance on anaerobic metabolism due to failure of cardiac output to appropriately respond to the oxygen requirement,[105] resulting in an abnormal "oxygen deficit" as evidenced by a delayed recovery of $\dot{V}_{O_2}$ and heart rate to resting levels when exercise ends.[106] Impairments in stroke volume require an augmented heart rate response reflected in a steeper slope of the linear relationship of heart rate (HR) to $\dot{V}_{O_2}$. Conversely, the ratio $\dot{V}_{O_2}$/HR, termed the *oxygen pulse,* is lower. This expression has

units of milliliters of oxygen (mL O_2)/heart beat and by derivation from the Fick relationship is equal to the product of stroke volume and $C(a-v)O_2$. Normal values at peak exercise vary by the same factors affecting peak $\dot{V}O_2$, depend on effort, and are increased when heart rate is limited by pharmacologic agents, so the pattern of change is often more informative than the peak value. Attainment of a constant value prior to the end of a graded test implies attainment of maximal values for both stroke volume and $C(a-v)O_2$.[29] Decreasing values as work rate progresses are distinctly abnormal but may be seen in settings in which stroke volume falls during exercise, such as in hypertrophic cardiomyopathy or exercise-induced cardiac ischemia.

Chronic Heart Failure. Reduction of peak $\dot{V}O_2$ and anaerobic threshold are characteristic of heart failure. A rather unique finding of afterload dependence of left ventricular function sometimes observed is a transient rise in $\dot{V}O_2$ and $\dot{V}O_2$/HR in the early seconds of recovery following cessation of exercise, as the acute reduction in systemic vascular resistance allows stroke volume to increase above peak exercise levels. Peak heart rate is frequently low in chronic heart failure (termed *chronotropic incompetence*), even in the absence of therapeutic β-adrenergic blockade.

Heart failure is also associated with inefficiency of pulmonary gas exchange manifest as high levels of $\dot{V}E$ for a given metabolic rate. This can be characterized as the slope of the relationship of $\dot{V}E$ to $\dot{V}CO_2$, ($\Delta\dot{V}E/\Delta\dot{V}CO_2$) or the ratio of $\dot{V}E/\dot{V}CO_2$ measured at the anaerobic threshold, both of which have upper limits of normal in the range of 28 to 32. High ventilatory requirements do not result solely from the early onset of lactic acidosis, but are due at least in part to increased effective VD/VT. In contrast, arterial oxygenation and the $P(A-a)O_2$ are usually normal in heart failure in the absence of concomitant lung disease. A proportion of patients with severe left heart failure demonstrate an oscillatory pattern of pulmonary gas exchange and ventilation, having a periodicity of 45 to 60 seconds similar to Cheyne-Stokes respiration. Values of peak $\dot{V}O_2$ and $\Delta\dot{V}E/\Delta\dot{V}CO_2$, and findings of chronotropic incompetence and oscillatory breathing all have prognostic significance in chronic systolic heart failure. Diastolic heart failure is characterized by many of these same findings.[107,108]

Pulmonary Vascular Disease. Pulmonary vascular diseases limit cardiac output due to constraints on right ventricular performance with a resulting reduction of peak $\dot{V}O_2$. Because the gas-exchanging structures themselves are often affected, evidence of pulmonary V:Q abnormalities are almost universal.[109,110] If VD/VT is calculated, it may be normal or high at rest but generally does not decrease normally during exercise. This gas-exchange inefficiency is reflected in $\dot{V}E/\dot{V}CO_2$, which remains abnormally high at the anaerobic threshold. In contrast to the findings in left ventricular failure, impaired oxygenation is common. There are several potential mechanisms for exercise hypoxemia in pulmonary vascular disease, including V:Q mismatch, diffusion limitation, and intra-atrial shunting through a patent foramen ovale. The latter may be suspected from a characteristic pattern of acute changes in ventilatory variables induced by hyperventilation of the alveolar capillary blood to compensate for right-to-left shunting of venous CO_2.[111,112]

Deconditioning. Though normal reference data sets often include measurements of subjects characterized as sedentary, the degree of inactivity in clinical populations may be more extreme than represented in many reference samples.[113] Conditioning involves changes in cardiac stroke volume and peripheral vascular structures, so it is not surprising that it can be difficult to distinguish between deconditioning and mild cardiovascular disease on the basis of peak $\dot{V}O_2$ and anaerobic threshold. In deconditioning alone, the $\Delta\dot{V}O_2/\Delta WR$, measures of gas-exchange efficiency, and the ECG and blood pressure responses to exercise should be normal, however, so that abnormalities in these variables warrants further cardiovascular evaluation.

Limitation due to Ventilatory Disorders

Because there is normally some reserve function of the lung, exercise capacity may be maintained in early pulmonary disease. As lung impairment increases, whether due to obstructive or parenchymal disorders, exercise may be limited by the combined effects of impaired lung mechanics, reducing breathing capacity, and impaired gas exchange, increasing breathing requirements, as illustrated in Figure 25-7. Cardiovascular responses may also be constrained by the secondary effects of lung disease on the pulmonary circulation, respiratory muscle blood flow, and altered intrathoracic pressures. Alterations in work of breathing and gas exchange can precipitate dyspnea disproportionate to the level of exercise, which can cause patients to stop exercise due to symptoms. Which of these various factors has the dominant effect on exercise varies among different disorders, and among patients with a given lung disease.

Chronic Obstructive Pulmonary Disease. Typical findings on exercise with COPD include elevated $\dot{V}E$ relative to $\dot{V}CO_2$, reflecting high pulmonary V:Q relationships as described previously for heart failure and pulmonary vascular disease. Abnormally high ventilatory requirements and reduced ventilatory capacity can result in patients reaching their maximal capacity to breathe at relatively low levels of exercise. Exercise must be limited at this point because progressively higher rates of CO_2 production and O_2 consumption without corresponding increases in $\dot{V}E$ would rapidly lead to intolerable derangements of arterial blood gases. Such ventilatory limitation is readily evident if exercise is terminated at the point at which the patient approaches maximum breathing capacity, as represented by the MVV.[114] The MVV does not necessarily represent a physiologic breathing pattern, however, and some patients are limited by dyspnea at $\dot{V}E$ levels below MVV, indicating a need for additional ways of identifying limitation of exercise by ventilatory factors.

Analysis of the flow-volume relationship during tidal respiration by patients with COPD often demonstrates attainment of the patient's maximal expiratory flow rates even at low levels of exercise.[115] While this does not necessarily cause exercise to be terminated, further

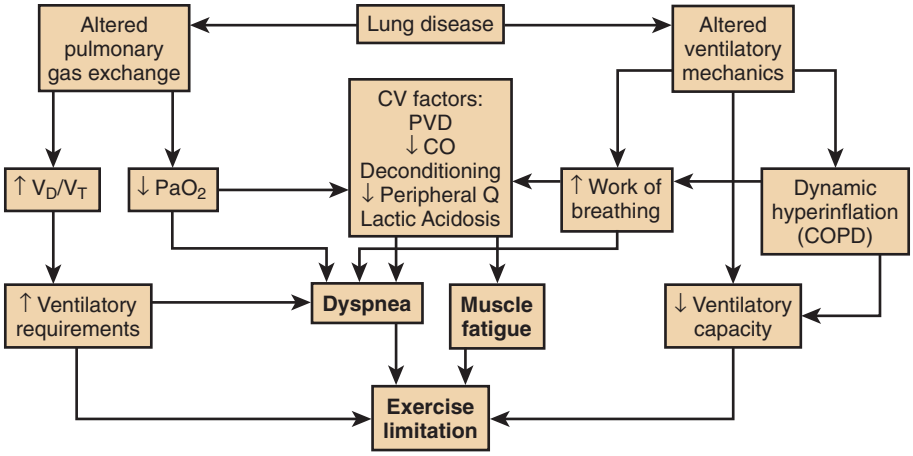

FIGURE 25-7 ■ Interaction of pulmonary and cardiovascular factors contributing to exercise intolerance in lung disease. In simplest terms, lung diseases lead to exercise limitation due to dual effects of altered gas-exchange efficiency and altered breathing mechanics, which increase ventilatory requirements and decrease ventilatory capacity, respectively. This leads to exercise limitation when the limits of ventilation are attained. Cardiovascular and skeletal muscle effects can contribute to exercise limitation by a number of mechanisms. Cardiac output may be limited by the presence of secondary pulmonary vascular disease, or the effects of lung mechanics on systemic venous return. Altered breathing mechanics also increase work of breathing, which can distribute more cardiac output to the muscles of respiration and away from locomotor muscles. These effects, together with deconditioning or other muscle dysfunction associated with lung disease, result in early onset of lactic acidosis, further increasing ventilatory requirements. Symptoms of dyspnea and muscle fatigue (not illustrated) arise from multiple of the processes shown, and can limit the tolerability of exercise even at levels below absolute physiologic limitation.

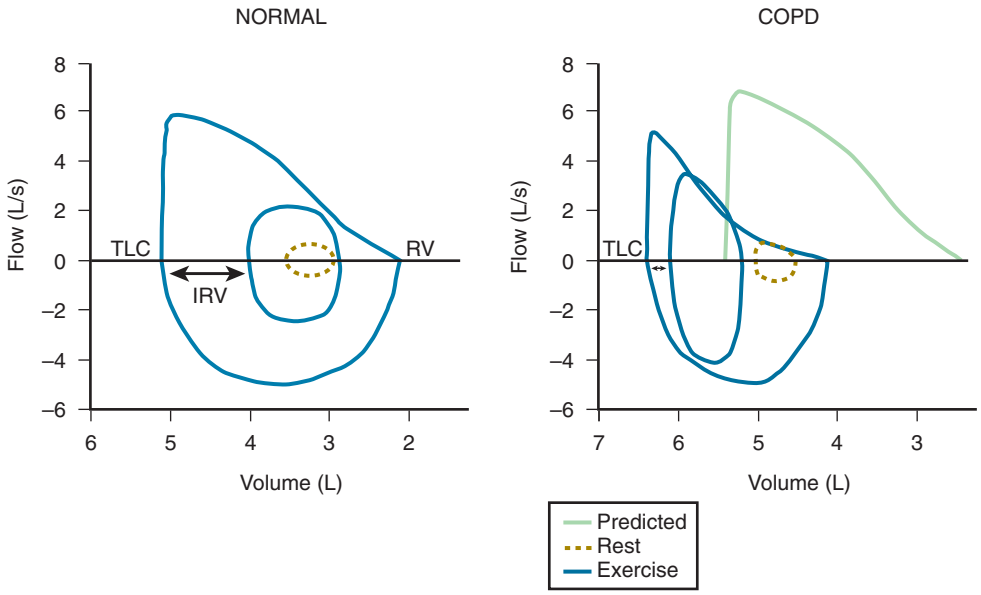

FIGURE 25-8 ■ Flow-volume relationships for tidal breathing during exercise compared with the maximal flow-volume loop measured at rest prior to exercise. Placement of the tidal loops on the horizontal axis is based on periodic measures of IC during exercise. *Left,* Data from a normal subject showing the normal expansion of tidal volume within the maximal flow-volume loop over the range of exercise. *Right,* Similar data from a patient with COPD demonstrating marked increase in end-expiratory lung volume, or dynamic hyperinflation, during exercise with attainment of maximal expiratory flow rates over much of exhalation and reduction of inspiratory reserve volume (IRV). (Modified from O'Donnell DE, Banzett RB, Carrieri-Kohlman V, et al: Pathophysiology of dyspnea in chronic obstructive pulmonary disease: a roundtable. Proc Am Thorac Soc 4:145–168, 2007.)

increases in $\dot{V}_E$ can require or induce a shift to higher end-expiratory lung volumes, which has been termed *dynamic hyperinflation,* as illustrated in Figure 25-8. The higher operational lung volumes place the respiratory muscles in less favorable operating length, which can increase the work of breathing and predispose to respiratory muscle fatigue, particularly in patients with COPD who have hyperinflation at rest. O'Donnell and colleagues have demonstrated the importance of dynamic hyperinflation to exercise intolerance in COPD by showing that the severity of dyspnea in this population is closely related to encroachment on inspiratory reserve

volume (IRV), with marked increases in dyspnea occurring once IRV is less than 500 mL.[116] It may thus be useful to identify these findings in patients with COPD whose symptoms seem disproportionate to abnormalities of resting lung function. Expiratory flow limitation and increases in end-expiratory lung volume have also been demonstrated in patients without COPD, including obese persons, who have low ERV at rest, and the elderly, who have relatively low expiratory flow rates at low lung volumes. The relationship of these findings to dyspnea and exercise impairment in conditions other than COPD is not well defined, and their measurement during clinical testing of unselected populations is not routine.[117]

Patients with COPD also have variable degrees of exercise hypoxemia and, less commonly, may develop hypercapnia and/or blunted ventilatory response to metabolic acidosis. Despite the predisposition to ventilatory limitation and gas-exchange abnormalities, a significant proportion of patients with COPD report leg fatigue, rather than dyspnea, as their primary symptom limiting exercise.[118] Reductions in muscle mass and function are increasingly recognized as intrinsic or confounding impairments in COPD.[22,119] These may be the proximal cause of exercise limitation[119] and/or contribute to ventilatory limitation due to the increased ventilatory requirements represented by early onset of lactic acidosis. Recognition of muscular impairment in patients with lung disease is important because it represents a treatable target for exercise training, an integral component of pulmonary rehabilitation.[120]

COPD can also limit cardiovascular responses to exercise.[121] Loss of recruitable pulmonary capillary bed predisposes to exaggerated increases in pulmonary artery pressures during exercise, and elevated intrathoracic pressures can impair venous return, either of which may constrain cardiac output. The augmented work of breathing associated with abnormal breathing mechanics obligates a higher blood flow to the respiratory muscles, potentially reducing available blood flow to the locomotor muscles.[122]

A general correlation between exercise capacity and the degree of resting lung function abnormalities can be demonstrated in patients with moderate to severe COPD.[123] However, prediction of functional impairment for individual patients from resting measurements is imperfect. This is in keeping with the heterogenous abnormalities in ventilatory, cardiovascular, and muscular function already referred to that can occur in this condition.[124] Thus, while diagnosis of COPD is based on resting lung function, exercise testing can be diagnostically helpful in the differential diagnosis of how a particular patient's disease impacts exercise tolerance.[82]

Episodic Airflow Obstruction: Asthma and Laryngeal Dysfunction. Provocation of bronchoconstriction by exercise is an important diagnostic application of clinical testing. Commonly used graded protocols may not be the most effective for inducing bronchoconstriction, however, which is associated with airway cooling or dehydration during high levels of ventilation. Protocols recommended for exercise broncho-provocation utilize a rapid increase in work rate to attain a heart rate of 80% to 90% maximal and a $\dot{V}_E$ of 40% to 60% of MVV, which are then maintained for a minimum of 4 minutes.[125,126] Prolonged protocols and lower intensities are avoided as they may induce a refractory state in which there is resistance to bronchoconstriction. Exercise-induced bronchoconstriction is typically manifest in the postexercise period, identified by a 10% or greater decrease in forced expiratory volume in 1 second (FEV_1) relative to the preexercise period. FEV_1 is measured serially every 5 minutes postexercise for 30 minutes or until a positive result is obtained and reversed with β-agonists. When well-controlled, asthmatics can have normal responses to graded exercise testing, though flow limitation and dynamic hyperinflation have been demonstrated even with relatively normal resting spirometry and may reduce exercise tolerance.[127]

Graded exercise protocols have been reported to be effective for precipitating symptoms in patients with exercise-associated upper airway dysfunction as a cause of dyspnea.[128] In contrast to asthma, upper airway obstruction is more likely to occur during exercise rather than recovery, and is associated with stridor. It may be possible to differentiate these conditions from abnormal inspiratory flow rates on exercise flow-volume loops, though definitive diagnosis and identification of the structures involved are based on visualizing the upper airway by laryngoscopy.

Interstitial Lung Disease. As is the case for COPD, diffuse parenchymal lung disease is marked by abnormalities in both breathing mechanics and gas exchange. Restrictive lung mechanics result in exercise tidal volumes that approach the resting measure of IC early in exercise. End-expiratory lung volume is usually maintained at resting levels.[129] Even though breathing capacity may be significantly reduced, exercise limitation often appears consequent to the secondary effects of interstitial disease on cardiovascular responses,[130] or the effects of hypoxemia, rather than due to ventilatory mechanics. Consistent with this, the patterns of abnormalities in $\dot{V}_{O_2}$ and related variables during graded testing may be indistinguishable from those of intrinsic pulmonary vascular disease, described above. Both oxygenation and CO_2 elimination are abnormal, reflected in high $\dot{V}_E/\dot{V}_{CO_2}$ and V_D/V_T and widened $p(A-a)O_2$. The latter measures may be the earliest abnormalities in exercise responses related to interstitial disease.[131,132] Although a feature of any condition altering V:Q, isolated abnormalities of $p(A-a)O_2$ or V_D/V_T, in the absence of clinical findings of chronic heart failure or airflow obstruction to account for them, suggests either interstitial or pulmonary vascular disease. Among patients with established interstitial disease, hypoxemia tends to be more severe than in COPD. The degree of exercise impairment varies both within and between conditions, with more severe impairment reported among patients with idiopathic interstitial fibrosis than among those with a similar degree of restriction due to chronic pneumoconiosis.[133] Extrapulmonary manifestations of conditions such as collagen vascular disease may dominate exercise findings.

Hyperventilation Syndromes. Hyperventilation syndromes are reported among the conditions leading to

referral for evaluation of dyspnea, and in some series represent a substantial proportion of patients undergoing exercise testing for this reason.[134] Erratic patterns of tidal volume and frequency are suggestive of this condition, but the sensitivity of this finding is not clear. Precipitation of typical symptoms in conjunction with evidence of acute hyperventilation, with no other apparent abnormality, is supportive of the diagnosis. One study has reported systematically higher respiratory rate and smaller tidal volumes during exercise among patients believed to have hyperventilation syndromes compared to controls, but the differences were small.[135]

Limitation due to Muscle or Metabolic Factors

Among the systemic and metabolic conditions that may affect exercise function, obesity and muscle metabolic disorders are frequently under consideration in the differential diagnosis of unexplained dyspnea.

Obesity. Obesity increases the metabolic cost of weight-bearing exercise and thus decreases the amount of external relative to internal work that can be performed. This is reflected in higher values for $\dot{V}O_2$ at a given work rate compared to lean individuals (see Fig. 25-3), but does not alter the relationship between the increment in $\dot{V}O_2$ for a given increment in work rate ($\Delta\dot{V}O_2/\Delta WR$), or relationships between $\dot{V}O_2$ and other variables. Similarly, the relationship between $\dot{V}E$ and $\dot{V}CO_2$ is normal. In addition to incurring higher $\dot{V}O_2$ due to the work of supporting excess weight, the work of breathing may be increased due to effects on chest wall mechanics.[136,137] Exercise testing may be useful in the evaluation of the obese patient for exclusion of other coexisting conditions causing exercise intolerance.

Metabolic Myopathies. Muscle metabolic disorders include a spectrum of conditions that may sometimes present in adolescence or adulthood as exertional dyspnea with, or instead of, muscle-specific symptoms. These are classified as defects in carbohydrate metabolism, fat metabolism, or mitochondrial oxidation.

The prototypic disorder of carbohydrate metabolism is McArdle's syndrome, in which a deficiency of myophosphorylase prevents metabolism of glycogen. This results in dependence on fatty acids or circulating glucose as substrate and is identified by the unique inability to produce lactate under ischemic conditions, such as hand grip exercise performed with a blood pressure cuff inflated to a suprasystolic level. During lower extremity exercise, peak $\dot{V}O_2$ is limited to levels that would correspond to a normal lactate threshold, but with little or no increase in blood lactate. The $C(a-v)O_2$ fails to widen normally, so the cardiovascular response to exercise is hyperdynamic,[138] reflected in a high heart rate relative to $\dot{V}O_2$.

Disorders of fatty acid metabolism, such as defects in carnitine palmitoyltransferase, result in dependence on carbohydrate metabolism. Symptom of muscle pain and cramping occur under conditions of fasting or prolonged exercise. Short-duration tests commonly used in clinical testing can be supported by carbohydrate metabolism, so peak $\dot{V}O_2$ and other responses to graded testing may be normal.[139]

Mitochondrial myopathies constitute diverse conditions resulting from defects of any of the nuclear- or mitochondrial DNA–encoded proteins involved in oxidative phosphorylation.[140] They are most readily recognized when presenting as characteristic syndromes affecting multiple tissues with high energy needs. Clinical findings vary from one patient to another, however, due to differing burdens of affected mitochondria between and within tissues, so exercise intolerance may occur as an apparently isolated finding without a recognizable syndrome. In one clinical series,[141] mitochondrial defects were reported to account for over 8% of patients undergoing exercise testing to evaluate unexplained dyspnea. Common exercise findings include a high heart rate and cardiac output relative to $\dot{V}O_2$ due to impaired oxygen extraction in the muscle. Peak $\dot{V}O_2$ is reduced in proportion to the mutational burden in muscle,[142] and lactate concentrations may be elevated at rest or early in exercise. In addition, $\dot{V}E$ has been reported to be high relative to metabolic rate,[141,143] although the basis for this in these conditions is not established.

Interpretive Strategies

A number of strategies have been proposed for the diagnostic interpretation of exercise data. These are based on comparison of the patient's response patterns with those that are typical of patients with known disorders either using a series of categorical assessments or a stepwise algorithm.[10,144,145] Limited data are available to define the diagnostic yield of these analyses for each of the conditions potentially causing dyspnea. It is widely agreed, however, that exercise testing is useful for distinguishing between cardiac and pulmonary disorders[83] and so narrowing the differential diagnosis and providing direction for further evaluation.[146]

An approach to systematically summarizing test results is shown in Table 25-4, which organizes the test data into four components.

Summary of Overall Quality of the Test and Peak Exercise Performance

Peak $\dot{V}O_2$ is expressed in absolute terms and in comparison to reference values. The symptom or finding that limited exercise is identified and an assessment made of whether the test can be interpreted as a valid measure of the patient's exercise capacity. The latter can be based on several lines of evidence, including the tester's impression of the patient's effort. Objective evidence of maximal or near-maximal exercise includes reaching or approaching any physiologic maxima, such as $\dot{V}E$ greater than 80% of MVV, heart rate within 10 beats/min (1 standard deviation) of predicted maximum, or a plateau of $\dot{V}O_2$ or heart rate in the face of increasing work rate. An approximation of maximum is also implied by findings that the patient did exercise in the very-heavy-intensity range, that is, well beyond the lactate threshold. Peak exercise respiratory exchange ratio (RER) values

TABLE 25-4. Approach to Organization of Exercise Test Data for Summary and Interpretation*

General Areas of Analysis	Specific Questions	Variables	Relevant Conditions
Test quality and performance	Does the test represent maximal capacity?	Peak HR and RER	
		AT	
		Symptoms	
	What was the limiting symptom? Were the patient's complaints reproduced?	Symptoms	Diagnostic value may be reduced if symptoms not reproduced
	What is maximal capacity? How does it compare with reference values?	Peak $\dot{V}O_2$	
	Is metabolic requirement higher than normal?	Peak $\dot{V}O_2$	Obesity
		Peak WR	
	Is endurance capacity low?	AT	Deconditioning
			Cardiovascular disease
			Myopathy
Ventilatory mechanics	Is there limitation due to lung mechanics?	$\dot{V}E$ Exercise IC	COPD
			Respiratory muscle weakness
			ILD
	Is the pattern of breathing abnormal?	VT	Hyperventilation syndrome
		Respiratory rate	
		Flow-volume relationship	Laryngeal dysfunction
		Postexercise FEV_1	Exercise-induced bronchoconstriction
Efficiency of gas exchange	Is $\dot{V}E$ high relative to metabolic rate?	$\dot{V}E/\dot{V}CO_2$	Chronic heart failure
			Chronic lung disease
			Pulmonary vascular disease
			Acid-base disturbance
	Are there other findings of abnormal pulmonary gas exchange?	SpO_2	ILD
		ABGs	COPD
		$P(A-a)O_2$ and VD/VT	Pulmonary vascular disease
Oxygen delivery and utilization	Is endurance capacity abnormal?	AT	Cardiovascular disease
			Myopathy
			Severe deconditioning
	Does $\dot{V}O_2$ increase appropriately?	$\Delta\dot{V}O_2/\Delta WR$	Cardiovascular disease
			Myopathy
	Does heart rate increase as expected relative to $\dot{V}O_2$?	High $\dot{V}O_2/HR$	Chronotropic insufficiency
		Low $\dot{V}O_2/HR$	Low SV
			Reduced HbO_2 content
			Impaired O_2 extraction
	Are there abnormalities of ECG or blood pressure?	ECG	Myocardial ischemia
		BP	Arrhythmia
			Hypertension
			Autonomic dysfunction

*Four major areas of analysis are shown along with examples of the form of questions used in analyzing each area, the pertinent exercise variables, and examples of relevant clinical conditions.

ABGs, arterial blood gases; AT, anaerobic threshold; BP, blood pressure; COPD, chronic obstructive pulmonary disease; ECG, electrocardiogram; HbO_2, oxyhemoglobin; HR, heart rate; IC, inspiratory capacity; ILD, interstitial lung disease; RER, respiratory exchange ratio; SpO_2, pulse oximeter O_2 saturation; SV, stroke volume; WR, work rate.

above 1.10 or 1.15 imply significant lactic acidosis, and have been used as criteria of effort, but since peak RER depends on the resting value and the rate of increase of work rate, no single value can be defined as a necessary criterion of an adequate test. Since the lactate threshold is usually in the midrange of exercise, however, a peak $\dot{V}O_2$ that exceeds the anaerobic threshold by 80% or more supports a high degree of effort.

Description of Ventilatory Response and Assessment of Whether or Not Breathing Mechanics Limited Exercise Performance

An absent breathing reserve indicates ventilatory limitation, and a low reserve (<20% of MVV) is suggestive of the same. It has been proposed that the degree to which ventilation is constrained during exercise be

quantified as the percentage of exhaled tidal volume that reaches or exceeds maximal flow rates.[115] As noted previously, the utility of this practice in clinical testing has not been systematically evaluated. Changes in breathing mechanics occurring during exercise are not reflected in the calculated breathing reserve, however, so that findings on flow-volume loop or physical examination, such as inspiratory stridor or reduction of IC and IRV, indicate potential ventilatory limitation even if breathing reserve appears normal. Erratic patterns of tidal volume and frequency suggest hyperventilation or malingering.

Analysis of Efficiency of Pulmonary Gas Exchange

Inefficiency of oxygenation is identified by abnormally low arterial $P_{A}O_2$ or high $P(A-a)O_2$, and inefficiency of CO_2 elimination by failure of V_D/V_T to decrease normally. These measures are based on analyses of exercise arterial blood gases. Inefficient gas exchange may alternatively be inferred from pulse oximetry findings of desaturation by more than 3% or by abnormally high $\dot{V}_E$ relative to $\dot{V}CO_2$. Because noninvasive oximetry is not always precise and high $\dot{V}_E/\dot{V}CO_2$ relationships can reflect acute or chronic hyperventilation (e.g., due to anxiety or compensation for chronic metabolic acidosis), an exercise arterial blood gas can be useful in confirming or excluding defects in gas exchange when the noninvasive measures are unexpectedly abnormal.

Analysis of Oxygen Delivery and Utilization

Abnormalities of oxygen delivery and/or utilization are reflected in the responses related to $\dot{V}O_2$, including low anaerobic threshold, low $\Delta\dot{V}O_2/\Delta WR$, or plateau of $\dot{V}O_2/HR$. Any cardiovascular disorder or muscle metabolic disorder can cause these abnormalities, so attribution of the findings to a particular condition involves consideration of history, physical findings, ECG, and blood pressure responses. For example, the onset or progression of cardiac arrhythmias, failure of blood pressure to increase, or ST segment displacement on ECG all suggest myocardial ischemia. Similarly, examination and ECG findings can provide clues to valve stenosis as the cause of $\dot{V}O_2$ abnormalities. The association of abnormal $\dot{V}O_2$ responses with impaired pulmonary gas exchange is characteristic of pulmonary vascular disease, including idiopathic pulmonary hypertension. Pulmonary venous hypertension can result in an identical pattern of findings, so when the patient is at risk for diastolic dysfunction, distinguishing between these conditions requires measurement of central circulatory pressures by right heart catheterization. Although the same constellation of exercise findings is typical of systolic heart failure, this is usually readily distinguished by clinical or echocardiogram findings.

Peripheral processes can also impair the $\dot{V}O_2$ response to exercise. Muscle symptoms are typical of both myopathies and peripheral arterial disease, but the latter may be suspected by risk factors and is confirmed or excluded by measurement of the ankle-brachial pressure index. Metabolic myopathies may be suggested by a history of rhabdomyolysis, use of myotoxic drugs, or family history compatible with mitochondrial disorder. Confirmation ultimately depends on histologic and biochemical analysis of a muscle biopsy specimen. Disorders of the regulation of blood flow distribution to muscle are suggested by blood pressure abnormalities or other manifestations of autonomic dysfunction.

KEY POINTS

- Exercise capacity and tolerance for exercise tasks are determined by the integrative function of multiple organ systems and so can be adversely affected by diverse diseases.
- Clinical exercise testing protocols range from simple task-based performance tests to more comprehensive procedures that quantify the imposed work rate and the associated physiologic responses.
- Cardiopulmonary exercise testing combines measures of ventilation, pulmonary gas exchange, electrocardiogram, and blood pressure to quantify exercise function and to characterize the range and pattern of cardiorespiratory adaptations to the exercise stress.
- Major parameters of exercise function derived from cardiopulmonary exercise testing include maximum oxygen uptake ($\dot{V}O_2$), which is the conventional measure of exercise capacity, and the lactate or anaerobic threshold, which is a marker of endurance capacity.
- Exercise testing is indicated to quantify exercise capacity for the purpose of defining functional capacity or impairment, grading the severity of cardiovascular diseases, assessing prognosis in chronic heart or lung disease, and designing exercise prescriptions for rehabilitation.
- Exercise testing is useful diagnostically in the evaluation of patients with unexplained dyspnea or exercise intolerance by identifying or excluding certain specific conditions, or helping direct further diagnostic evaluations.

Lung Volume Reduction Surgery

INTRODUCTION

Until recently, few studies had rigorously evaluated the ability of preoperative variables to predict postoperative pulmonary complications (PPCs). Recent investigations supplemented by a meta-analysis of the perioperative outcomes of large numbers of patients, however, now allow generation of indices that can better predict a patient's risk for mortality.[1-5] New investigations have also improved the ability to predict an individual's risk of developing postoperative pneumonia and respiratory failure (see Tables 26-1 and 26-2 as an example).

PPCs rival cardiovascular complications as a cause of perioperative morbidity in high-risk surgical procedures in patients with lung disease. Because surgical procedure–related risk factors contribute to overall risk, modifying the surgical approach may help reduce this risk (see later discussion on laparoscopic procedures as an example). Although patients with lung disease, even when it is quite severe, tend to tolerate anesthesia and surgery without excessive mortality or excessive morbidity, and although postoperative complications can be minimized by identifying high-risk patients preoperatively and treating them aggressively,[6,7] postoperative care should include approaches designed to reduce PPCs in all patients, regardless of their potential risk.

This chapter discusses the importance of the assessment of cardiac disease in patients with lung disease, the recent modifications in surgical and perioperative practices that have improved perioperative outcome, and preoperative assessment of patients with lung disease for specific procedures.

ASSESSMENT OF CARDIAC RISK IN PATIENTS WITH LUNG DISEASE

One of the most important risk factors predicting perioperative mortality after noncardiac surgery in patients with lung disease, especially lung disease due to smoking, is myocardial ischemia and infarction in the immediate postoperative period.[8,9] Many investigations have characterized the risk factors for perioperative cardiac events.[8,9] Practice guidelines have been published by the American College of Cardiology, the American Heart Association,[5] and the American College of Physicians.[10] The specific guidelines for preoperative assessment are designed to identify preexisting heart disease, to define the severity and stability of that disease, and to determine the risk of having a cardiac event (e.g., myocardial infarction, congestive heart failure, death) when the patient undergoes a specific surgical procedure.[6,10] To summarize the guidelines[5] briefly, there are defined clinical predictors of increased cardiovascular risk. Notably, pulmonary disease would influence these predictors if the patient had associated pulmonary hypertension, coronary artery disease, arrhythmias, or a low functional status. Surgical procedures have been classified as to

their risk of causing cardiac death or nonfatal myocardial infarction. High-risk procedures are those that have a 5% or higher risk of these cardiac events, intermediate procedures have a risk of more than 1% but less than 5%, and low-risk procedures have a risk less than 1%.[5,10]

Reduction of cardiac risk involves medical therapy with perioperative β-blockers, such as metoprolol, the administration of a central-acting α-agonist, such as clonidine or dexmedetomidine, and possibly statin medication.[11–15]

Although not shown in all studies,[12] several investigations have documented the efficacy of perioperative β-blockade or α-agonist therapy in decreasing perioperative ischemia and cardiac mortality.[11–15] In fact, investigations have shown that β-blockers can be administered to patients with chronic obstructive lung disease (COPD) without increasing airway obstruction.[14,16] Atrial arrhythmias are frequently observed in patients with COPD,[14–18] especially after cardiac operations[19,20]; and they are associated with prolonged hospitalization and an increased incidence of strokes, poorer cognitive dysfunction, and death.[19,20] These atrial arrhythmias can be prevented by perioperative administration of β-blockers.[19,21] Patients with COPD and elderly patients who have had previous myocardial infarctions have a 40% increase in survival if β-blockers are administered, but because of physician bias, these patients are often not treated with these lifesaving medications.[22] Therefore, current data still suggest that β-blockers should be used in patients with COPD who are at risk for cardiac events perioperatively or in patients who have had myocardial infarctions.

Long-acting inhaled β-agonists may have adverse cardiac effects in patients with COPD, particularly if these patients have preexisting cardiac arrhythmias, hypoxemia, or left ventricular systolic dysfunction.[23] Patients were found to have increased heart rates and more supraventricular and ventricular premature beats when they were given 24 mg of formoterol.[23] In patients hospitalized for heart failure, there was an increased, dose-response–related risk between the use of inhaled β-agonists and all causes of mortality.[16] Patients with hypoxemic COPD can have an autonomic neuropathy, which has been associated with a prolonged QTc interval and an increased risk of ventricular arrhythmias and death.[24,25] The QTc interval can be further prolonged by more severe hypoxemia, and β-agonists can increase hypoxemia transiently, in some instances by worsening ventilation-perfusion heterogeneity.[25] The incidence of perioperative arrhythmias in patients given long-acting β-agonists has not been compared with those occurring in patients receiving shorter-acting β-agonists. Long-acting β-agonists should, however, be utilized with caution in COPD patients who are having arrhythmias or ischemia.[16]

CHANGES IN ANESTHETICS AND SURGICAL PRACTICES

Anesthesia and Analgesia

Atelectasis has been noted in 90% of the patients given any anesthetic except ketamine and epidural anesthetics.[26] The atelectasis develops whether the patient is breathing spontaneously or is paralyzed and ventilated mechanically.[27] The atelectasis occurs in the dorsal, caudal lung regions in supine patients and can comprise 10% of the total lung tissue.[27] It is attributed to compression of lung tissue by mediastinal organs and abdominal pressure, is reduced by phrenic nerve stimulation, and is believed to result from loss of inspiratory muscle tone, changes in thoracic geometry, and alterations in diaphragm position and motion.[26–28] The atelectasis persists for up to 2 days after major surgery (see later) but resolves within 24 hours after laparoscopy in nonobese patients.[26–28] Morbidly obese patients have more atelectasis than nonobese patients, and the atelectasis persists longer.[29] A vital capacity maneuver (i.e., applying an airway pressure of 40 cm H_2O for 8 sec) reexpands atelectactic lung tissue, alleviates the atelectasis (as seen on computed tomography [CT] scans), and improves oxygenation.[29,30] Greater pressures and even the beach-chair position[31] as well as using pressure-controlled ventilation intraoperatively[32] may be needed in obese patients and those with low abdominal and/or chest wall compliance. Newer volatile anesthetics (i.e., desflurane, sevoflurane) with a shorter half-life are now utilized.[33] Within 10 minutes after discontinuing either desflurane or sevoflurane, patients have normal ventilatory responses.[33] These agents may not be associated with the same changes seen with older volatile anesthetics.[33]

Despite the documented effects of the volatile anesthetics on pulmonary function, there is no clear evidence that regional anesthesia results in better intraoperative or postoperative pulmonary function.[34–36] A number of investigators report preserved lung compliance and arterial oxygenation with use of epidural anesthesia. Others, however, find a decrease in the expiratory reserve volume and cough efficacy with both spinal and epidural anesthesia.[34–36]

A number of studies have compared the effects of regional and general anesthesia in patients with lung disease. Ravin[35] examined 20 patients with a maximal voluntary ventilation (MVV) value of less than 68 L/min and a residual volume–to–total lung capacity ratio greater than 45% who underwent lower abdominal surgery. Intraoperatively and postoperatively, there was no difference in arterial P_{O_2} between patients receiving spinal anesthesia and those given general anesthesia. Similar results were obtained by Boutros and Weisel.[36] Thus, there does not appear to be an advantage in using regional anesthesia to maintain intraoperative or immediate postoperative arterial blood gas values. Postoperative respiratory failure, however, may possibly occur less frequently in selected patients receiving epidural analgesia.[37] Furthermore, there does not seem to be any difference in other organ function, including cognition, after regional anesthesia compared with general anesthesia.[37,38] At a minimum, it appears that epidural analgesia can produce superior pain relief, particularly if it is initiated prior to the surgical incision,[39] and it may be associated with fewer complications and a lower incidence of respiratory failure than parenteral narcotics in selected patients. Thus, the decision to use regional or general

anesthesia should be made on the basis of the location of the surgery, the surgical technique (laparoscopy), and whether controlling the airway is advantageous.

Abdominal Surgeries

Upper abdominal surgery carries more risk for pulmonary complications than does lower abdominal surgery (which, in turn, carries more risk than peripheral surgery). Diaphragm dysfunction induced by upper abdominal surgery has been identified as an important factor in the development of postoperative pulmonary problems.[40] The pulmonary dysfunction observed after open upper abdominal surgery is characterized by a long-lasting decrease in lung volumes, leading to the development of atelectasis and hypoxemia.[40] Postoperatively, patients use rib cage breathing rather than abdominal breathing. These abnormalities have been attributed to dysfunction of the diaphragm and/or the phrenic nerve. A number of studies indicate, however, that phrenic nerve stimulation generates normal transdiaphragmatic pressures after upper abdominal surgery. Accordingly, the nerve seems to work, and the strength of the diaphragm seems to be normal. These findings imply that the activity of the nerve may be reduced by transmission of inhibitory signals resulting from visceral or somatic afferents. In support of this idea is the observation that administering local anesthetics to the epidural space improves diaphragmatic function after upper abdominal surgery. Other investigators, however, found that epidural and subarachnoid administration of opiates achieved pain relief but did *not* improve diaphragmatic function.[41,42] Although pain relief and/or postoperative maneuvers designed to improve lung volumes (e.g., intermittent positive-pressure treatments, incentive spirometry, deep-breathing exercises) seem to decrease the incidence of postoperative pulmonary dysfunction, neither intervention completely prevents the problem.[41,42] It appears that most of the maneuvers designed to increase lung volumes and expand atelectatic lung segments are equally effective,[43] but intermittent positive-pressure breathing seems to be less comfortable and is more expensive.[43]

Laparoscopic procedures were introduced to the U.S. military hospitals in 1990; within 2 years, 87% of the cholecystectomies performed were done laparoscopically with only a 10% or less conversion rate to an open procedure.[44] The number of complications observed after laparoscopic procedures depends on the experience of both the surgeon and the institution with the procedure. The number of perioperative complications decreases after approximately 20 procedures, and the risk of adverse outcomes stabilizes after 50 laparoscopic procedures have been performed at an institution.[45,45a]

The advantages of the laparoscopic technique are that much smaller abdominal incisions are made, less postoperative pain is created, there is less disruption of diaphragmatic or abdominal muscle activity, and the patients can often leave the hospital within 1 day of the surgery.[46] Patients with lung disease who would have had difficulty with the PPCs associated with open abdominal procedures have now successfully undergone laparoscopic abdominal procedures.[46]

Cardiac Surgeries

The postoperative period following cardiac surgery is characterized by a high incidence of respiratory complications.[47] Atelectasis is more prominent when cardiopulmonary bypass is used, occurring even more commonly than after thoracotomy. A randomized investigation of 78 patients undergoing cardiopulmonary bypass documented that the delivery of positive end-expiratory pressure up to 15 cm H_2O (until a peak inspiratory pressure of 40 cm H_2O was reached) resulted in significant improvement in oxygenation during the first hour after bypass; however, the improvement was not sustained.[30]

Intraoperative variables that have been associated with severe atelectasis include the number of grafts, longer bypass times, and use of internal mammary grafts, which requires opening the pleural space.[47] Phrenic nerve paralysis is not commonly found in these patients (<10%) and is therefore not a common cause of atelectasis after cardiac surgery.[48] The mechanisms for the atelectasis may be that the blood supply to the alveolar epithelium is inadequate during cardiopulmonary bypass. Lungs that are ventilated without positive end-expiratory pressure and that are exposed to the atmosphere tend to develop atelectasis. The cold temperature used in these surgical procedures may also produce abnormalities in surfactant production or function.

The patients undergoing cardiac surgery in the current decade are older and have more comorbidities than patients in the 1990s.[49] However, the perioperative mortality rate for this procedure has decreased to 3% in 1999 from nearly 4% in 1990.[49] Short-term mortality after coronary artery bypass graf (CABG; <30 days) is primarily affected by cardiac variables, including age, history of previous heart operation, prior myocardial infarction, extent of noncardiac comorbidity, and urgency of the operation.[50,51] In contrast, intermediate-term survival (>30 days postoperatively) is affected by noncardiac variables, including functional status, COPD, and renal dysfunction.[50]

Recently, CABG procedures are being done off cardiopulmonary bypass (OPCAB). Retrospective analyses suggest that these patients had fewer perioperative myocardial infarctions and shorter ICU stays.[51-53] The Octopus Study Group documented the equivalence of off-pump and on-pump bypass surgery with respect to perioperative and 1-year survival; however, only low-risk patients were assessed.[54] Furthermore, cognitive declines and the incidence of atrial fibrillation were not different between the patients who had been on bypass and those who had been OPCAB.[54,55] Therefore, preliminary data do not document a superiority of OPCAB compared with the conventional bypass procedure.

Thoracic Surgeries

The atelectasis seen after thoracic surgery seems to have different mechanisms. Cardiopulmonary bypass is not

routinely used for thoracic surgery, so it is not a cause of the atelectasis. Diaphragm dysfunction does not appear to be a problem, although the maximal strength of the diaphragm may be somewhat reduced after thoracotomy.[56] Phrenic nerve dysfunction is not uncommon after thoracotomy, but the abnormalities are usually mild and account for only half of the diaphragmatic motion disturbances.[57] Pleural or mediastinal drainage tubes do not appear to contribute to postoperative lung dysfunction.[58] Mechanical compression of the lung, accumulation of secretions, increased lung water, alterations in chest wall mechanics due to the thoracotomy itself, and reduced surfactant activity may lead to atelectasis of the lung after thoracotomy.

Esophagectomy is associated with an extremely high risk of PPCs. A multicenter prospective study of 1777 patients undergoing surgical resection of the esophagus reported a 21% incidence of pneumonia and a 16% incidence of respiratory failure.[59] Preoperative factors associated with PPCs were increasing age, dyspnea, diabetes mellitus, COPD, alkaline phosphatase greater than 125 U/L, lower serum albumin concentrations, increased complexity scores, and decreased functional status. Intraoperative risk factors included the need for blood transfusion and longer operative time. A trial of 220 patients with adenocarcinoma of the mid-to-distal esophagus or the gastric cardia involving the distal esophagus randomized to esophagectomy via transhiatal versus a transthoracic approach showed lower incidence of PPCs (27% vs. 57%, $P < .001$) with the transhiatal approach.[60]

PREOPERATIVE EVALUATION OF HIGH-RISK PATIENTS

Patients Who Smoke

Patients with moderate to severe COPD, and smokers without demonstrable airflow limitation are at high risk for PPCs. Patients with asthma should also be carefully evaluated. This section considers these three groups of patients.

One third of all patients who undergo surgery are smokers.[61] Chronic exposure to cigarette smoke produces profound changes in physiology that may alter responses to perioperative interventions and contribute to perioperative morbidity and mortality, mainly because of the effects of smoking on the cardiovascular and respiratory systems.[61,61a] Such alterations may also predispose to postoperative renal failure in smokers with severe COPD.[62]

Smokers may have increased levels of carboxyhemoglobin as a function of their brand of cigarette, how deeply they inhale, the number of puffs they take, and the level of ventilation during smoking.[63] The level of carboxyhemoglobin in smokers usually ranges from 3% to 15%, and the major effects are (1) to reduce the amount of hemoglobin available to bind with oxygen (which decreases arterial oxygen content) and (2) to shift the oxygen-hemoglobin saturation curve to the left (which facilitates loading of oxygen onto hemoglobin but impairs unloading at the tissues). Smoking has been shown to increase the carboxyhemoglobin measured during surgery, even after the initiation of mechanical ventilation.[64] Smokers have decreased oxygen delivery and increased tissue oxygen extraction, manifested by a reduced mixed venous oxygen content. Patients at greater risk for elevated carboxyhemoglobin levels are those who smoke avidly late at night and then undergo an early morning operation. Therefore, it is recommended that smokers stop smoking 12 to 18 hours preoperatively (if not permanently) to allow three half-lives of time for carboxyhemoglobin clearance.

Nicotine has concentration-dependent effects on the cardiovascular system. It can cause systemic vasoconstriction and increase both heart rate and systemic blood pressure. Abstinence from smoking for 20 minutes is followed by a decrease in heart rate, blood pressure, and systemic catecholamine levels.[65] These cardiovascular effects of nicotine may contribute to perioperative morbidity in smokers, and short-term abstinence may be beneficial.

Several investigators have evaluated PPCs in smokers.[61,66,67] These studies suggest that smoking may be associated with increased pulmonary complications when the patient is older, has smoked longer, is currently smoking, and perhaps already has significant underlying lung disease. Several investigators have documented that an optimal period of abstinence is 8 weeks prior to surgery, as this duration of cessation is associated with fewer pulmonary complications, better wound healing, and shorter length of stay in the ICU.[61] Also, patients who stop smoking before or immediately after percutaneous cardiac revascularization have a lower risk of Q-wave infarctions and death.[67] A smoking-intervention program targeted at smokers who are hospitalized for surgery produces higher long-term quit rates.[68] Accordingly, the preoperative evaluation of smokers should include enrolling them in smoking-cessation programs[68] or, at a minimum, provide a time when a serious discussion can occur regarding smoking. At least 12 to 24 hours of preoperative abstinence should be sought to achieve possible cardiovascular benefits and perhaps optimally 6 to 8 weeks of preoperative abstinence to decrease the incidence of PPCs.[61]

Patients with Obstructive Sleep Apnea and Chronic Obstructive Pulmonary Disease

Risk factors for PPCs are related to general health and nutritional status and include advanced age, COPD, congestive heart failure, lower albumin level, dependent functional status, and weight loss.[69] Obesity itself has not been clearly identify as a risk factor for PPCs. Pulmonary problems associated with PPCs include COPD, pneumonia, and sleep apnea.[69] Patients with obstructive sleep apnea (OSA) patients have a higher incidence of (mainly respiratory) PPCs than those who do not.[70] In a more defined surgical population, 39% of patients with OSA

who had hip or knee replacements developed PPCs or cardiac complications compared with 18% of patients without OSA; 24% of the patients with OSA required ICU admissions compared with 9% of patients without OSA.[71] Few investigations have identified the perioperative risks for OSA surgical patients,[72,72a] but left heart failure or right heart dysfunction due to pulmonary hypertension should be sought. Pulmonary hypertension is particularly associated with a significant perioperative risk.[73,74] As cardiovascular dysfunction in OSA patients can be modified by treatment,[75–77] it seems important to identify patients not known to have OSA and have them treated. However, to date, owing to lack of appropriate studies, it is not known whether establishing the diagnosis of OSA prior to surgery and instituting/optimizing therapy will improve perioperative outcomes.

A large retrospective observational review of patient data (mainly men) in Veterans Affairs hospitals allowed risk stratification for postoperative pneumonia and postoperative respiratory failure. Each risk factor was assigned a point value, and the total number of points was associated with a predicted probability for the development of these complications.[1,3] For example, a history of COPD conferred 5 points for the risk of postoperative pneumonia and 6 points on the respiratory failure risk index. Pulmonary function tests were not done for these investigations, and the investigators stated that "pulmonary function tests do not appear to predict PPCs."[69] Accordingly, the diagnosis of COPD was based on clinical assessment. Having more than 55 points on the Postoperative Pneumonia Risk Index gave the patient a predicted probability of pneumonia of 15% and of perioperative mortality of about 25%.[3] A point total over 40 on the Respiratory Failure Risk Index was associated with a predicted probability of 31% of respiratory failure.[1] Of note, the newer study from Arozullah's group[2] is more broadly applicable becaue it was developed in patients from the private sector as well as from the Veterans Affairs hospitals and involved patients undergoing vascular and general surgical operations. Although individual point scores differed from the original study, a similar incidence of postoperative respiratory failure was found compared with the original risk model. This congruence between the studies validates the original study and, notably, still identifies COPD as a relevant risk factor for postoperative respiratory failure (Tables 26-1 and 26-2).

Preoperative spirometry or other pulmonary function tests have not been uniformly useful in identifying those who will develop severe pulmonary complications.[78–81] The presence of preoperative hypoxemia identified those who required mechanical ventilation postoperatively in two studies (Fig. 26-1),[80,81] and intraoperative blood administration was associated with those who require mechanical ventilation and develop postoperative pneumonia.[82] Perioperative transfusions are associated with increased mortality, postoperative pneumonia, and hospital length of stay.[82]

TABLE 26-1. Independent Predictors of Respiratory Failure after General and Vascular Surgery

Effect	Odds Ratio (95% CI)	Score
ASA class (3 vs. 1–2)	2.88 (2.46–3.36)	3
ASA class (4–5 vs. 1–2)	4.90 (4.11–5.85)	5
Emergency	2.42 (2.17–2.69)	2
Work RVU (10–17 vs. <10)	2.30 (1.94–2.73)	2
Work RVU (>17 vs. <10)	4.45 (3.72–5.31)	4
Preop albumin (<3.5 vs. >3.5)	1.49 (1.34–1.64)	1
Integumentary versus hernia	1.14 (0.87–1.50)	1
Respiratory versus hernia	3.12 (2.18–4.47)	3
Heart versus hernia	2.31 (1.67–3.20)	2
Aneurysm versus hernia	1.55 (1.20–2.00)	2
Mouth, palate versus hernia	6.64 (4.78–9.21)	7
Stomach, intestines versus hernia	2.13 (1.66–2.73)	2
Endocrine versus hernia	1.54 (0.99–2.38)	2
Preop sepsis	2.00 (1.71–2.34)	2
Preop creatinine > 1.5	1.65 (1.49–1.82)	2
History of severe COPD	1.52 (1.36–1.69)	2
Ascites	1.85 (1.50–2.28)	2
Dyspnea (yes vs. no)	1.32 (1.19–1.46)	1
Impaired sensorium	1.50 (1.22–1.84)	1
Preop bilirubin > 1.0	1.21 (1.08–1.35)	1
>2 alcoholic drinks/day	1.30 (1.14–1.49)	1
Bleeding disorders	1.25 (1.07–1.46)	1
Age (40–65 vs. <40 yr)	1.70 (0.86–3.37)	2
Age (>65 vs. <40 yr)	2.06 (1.54–2.77)	2
Preop WBC (<2.5 vs. 2.5–10)	1.48 (0.89–2.47)	1
Preop WBC (>10 vs. 2.5–10)	1.20 (1.09–1.33)	1
Preop serum sodium (>145)	1.56 (1.21–2.03)	2
Weight loss > 10%	1.26 (1.10–1.44)	1
Preop acute renal failure	1.51 (1.17–1.94)	2
Gender (male vs. female)	1.19 (1.06–1.35)	1
CHF < 30 days before operation	1.30 (1.09–1.55)	1
Smoker	1.15 (1.05–1.26)	1
Preop platelet count < 150	1.21 (1.06–1.38)	1
CVA with neurologic deficit	1.27 (1.10–1.47)	1
CVA without neurologic deficit	1.23 (1.02–1.48)	1
Wound class (clean/contaminated)	1.16 (1.02–1.30)	1
Wound class (contaminated)	1.36 (1.15–1.61)	1
Wound class (infected)	1.25 (1.04–1.50)	1
Preop SGOT > 40	1.16 (1.04–1.30)	1
Preop hematocrit < 38	1.11 (1.01–1.23)	1

ASA, American Society of Anesthesiologists; CHF, congestive heart failure; CI, confidence interval; COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident (stroke); Preop, preoperative; RVU, relative value unit; SGOT, serum glutamic-oxalacetic transaminase; WBC, white blood count.

Patients with Asthma

Patients with acute bronchospasm are rarely subjected to elective surgery, and they are almost certainly at

increased risk for perioperative complications. Unfortunately, there are no data available on how long after resolution of an acute exacerbation of asthma that patients remain at increased risk. Giving anesthesia to, and performing surgery on, stable, well-treated asthmatic patients is associated with a low incidence of complications.[83]

Several maneuvers associated with anesthesia may aggravate bronchospasm, particularly if the patient has a history of severe asthma. First, tracheal intubation can initiate bronchospasm.[84] Thus, in moderate to severe asthmatics, regional anesthesia should be considered. When general anesthesia is necessary, endotracheal intubation should be avoided, if possible. Shnider and Papper[85] showed that patients who received general anesthesia but were not intubated had an incidence of bronchospasm similar to that of patients who received regional anesthesia compared with a 6% to 7% incidence of bronchospasm in those who were intubated.

All of the volatile anesthetics are effective in preventing[86] and reversing bronchospasm. However, the volatile agents do not have a normal bronchodilatory effect when the epithelium is disrupted, as their bronchodilatory effects appear to depend at least in part on prostanoid and nitric oxide generation from the epithelium.[87] Halothane is associated with ventricular arrhythmias when toxic aminophylline levels are present. Therefore, if there is any concern about the aminophylline level, halothane should probably be avoided. Sevoflurane has proved to be a safe clinical alternative to halothane.

Some of the fixed agents used for anesthesia induction improve bronchomotor tone. Ketamine prevents antigen-induced increases in pulmonary resistance in experimental models of asthma[88] and decreases calcium influx into airway smooth muscle.[89] In contrast, thiopental has no effect on bronchomotor tone. Propofol decreases respiratory resistance in nonasthmatic patients who smoke and is associated with lower respiratory resistance than either thiopental or etomidate in these patients.[90] However, propofol was not compared with ketamine and is probably not as good a bronchodilator as ketamine.

Narcotics have not been well studied regarding their effects on asthmatics. Because morphine has been associated with histamine release, some investigators have recommended against its use in patients with asthma.[84] Some have also advised against using the nondepolarizing neuromuscular blocking agent *d*-tubocurarine because it also releases histamine.[84]

TABLE 26-2. Respiratory Risk Index for Respiratory Failure after General and Vascular Surgery

Risk Level	Score Range*	Respiratory Failure (%)
Low	<8	0.08
Medium	8–12	0.84
High	>12	6.75

*Score derived from independent predictors of respiratory failure (see Table 26-1).

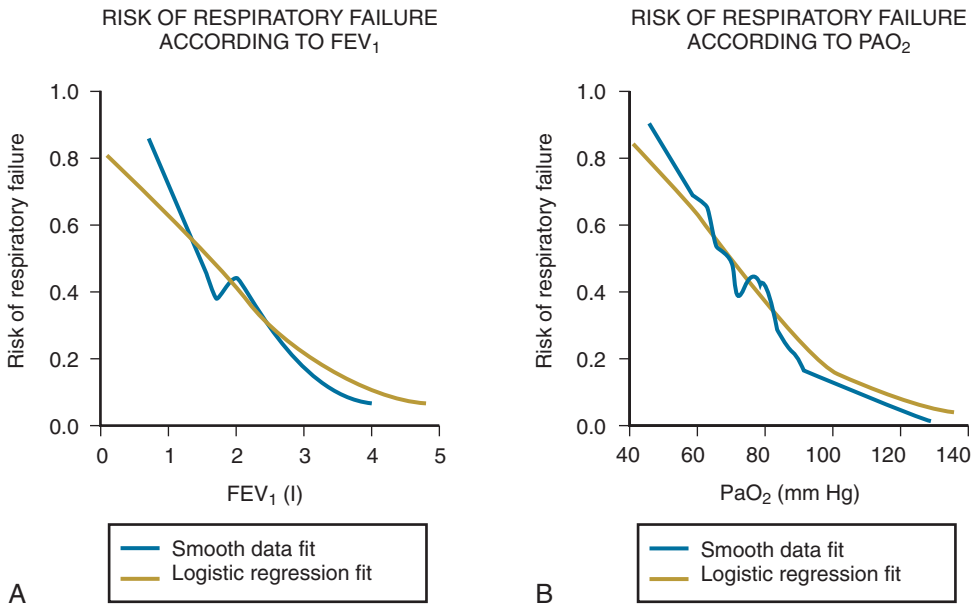

FIGURE 26-1 ■ The risk for postoperative respiratory failure after thoracoabdominal aorta surgery. Assessment of risk was done by testing the forced expiratory volume in 1 second (FEV_1) (**A**) as well as testing preoperative arterial oxygen tension (Pa_{O_2}) (**B**). The *blue lines* have been generated from a smooth fit of the data, and the *brown lines* have been generated from a univariate logistic linear regression analysis of the data. Note the similarities between the two preoperative tests in predicting subsequent respiratory failure. (Redrawn from Svensson LG, Hess KR, Coselli JS, et al: A prospective study of respiratory failure after high-risk surgery on the thoracoabdominal aorta. J Vasc Surg 14:271–282, 1991.)

PULMONARY RESECTION

Surgery remains the only chance for a cure of lung cancer and is especially useful for patients with stage IA or IB non–small cell malignancies, as 5-year survivals that range as high as 77% and 60%, respectively, have been reported (see Chapter 47). Lung resection surgery can now be done with smaller incisions (2 cm for closed thoracoscopy), muscle-sparing incisions (8 cm), less rib damage (no rib spreader utilized), and thoracoscopy. These new surgical techniques have decreased the mortality, morbidity, and length of stay associated with thoracic surgery.[91,92] In several reports, for example, the surgical mortality rate for elderly patients (≥70 years) who underwent thoracic procedures was 1.5%, the median length of stay was 4 days, and the conversion rate to open thoracotomy was low, 1%.[93–95] Although the risks associated with these surgeries have decreased, there has not been a direct comparison of minimally invasive versus standard thoracotomy on the long-term outcome of patients with lung cancer. Accordingly, many suggest that thoracotomy should be the preferred approach in those without underlying comorbidities, indicating an increased risk of the operation. The preoperative evaluation required for the newer techniques has yet to be defined.

The morbidity and mortality associated with standard lung resection procedures have also improved; operative mortality overall for lung resection is now 3.7% in some medical centers, whereas in the 1980s, the mortality was 6.2% for pneumonectomy.[95] High-volume hospitals have better outcomes than do medical centers where fewer procedures are performed,[96,97] but a more recent study suggests that the number of procedures done by an individual physician is not correlated with hospital mortality.[98]

Physiologic Changes Postresection

A number of physiologic changes occur after pneumonectomy. Hsia and colleagues[99–101] exercised three conditioned foxhounds before and 6 to 12 months after pneumonectomy and found postoperative impairment of ventilatory responses to carbon dioxide at all levels of work along with arterial hypoxemia during heavy exercise. The physiologic mechanism in part responsible for the latter abnormality was an increase in exercise-induced ventilation-perfusion heterogeneity and a diffusion limitation. Together, these problems accounted for 58% of the hypoxemia. Cardiac output was also reduced after pneumonectomy, and the hemoglobin concentration increased to compensate for the decrease in oxygen delivery. Further studies that were designed to determine why removing 42% of the total lung tissue (the left lung) decreased the diffusing capacity by only 30% suggested that the remaining lung increases its diffusing capacity by recruiting new vessels.[101] Interestingly, there is a greater degree of diffusion capacity compensation with right versus left pneumonectomy. Mechanisms proposed to explain the recruitment of new vessels implied by these compensatory changes include the effects of the resulting pulmonary hypertension and/or the expansion of the remaining lung that occurs, which could open new alveolar septal and corner capillaries, respectively.

Patients have a 15% decrease in vital capacity after lobectomy, and a 35% to 40% decrease following pneumonectomy.[102] The decrease in lung function is usually less than expected from the number of segments removed, suggesting that the tumor decreased the function of the resected lung and/or that the remaining lung expanded. Patients also have a decrease in oxygen consumption, arterial P_{O_2}, cardiac output, stroke volume, and heart rate at maximum exercise, and they are not able to achieve their preoperative maximal workload and they have a decrease in stroke volume at all levels of exercise and an increase in systemic vascular resistance.[102] The patients who had had a lobectomy had changes similar to those seen in patients with a pneumonectomy, but the differences were less pronounced.

Resection Procedures

Preoperative assessment of patients in need of pulmonary resectional surgery should address two questions: (1) Is the likelihood of perioperative mortality or a postoperative complication so high that the surgery should not be performed? (2) Will the postoperative pulmonary function be sufficient to allow reasonable quality of life?

Is the Likelihood of Perioperative Mortality or a Postoperative Complication So High the Surgery Should Not Be Performed? Because most pulmonary resectional surgery is done with the hope of curing lung cancer, the risks of postoperative complications would have to be extraordinarily high before they would dissuade most patients, or their physicians, from undertaking the operation.[103] Not surprisingly, no studies have suggested that preoperative evaluation aids in making this decision.

The mortality associated with lobectomy and pneumonectomy may be increased in patients over 70 years of age (4%–7% and 14%, respectively), although the effect of age is debated.[104,105] The suggestion has been made that the increased risk is related to increased comorbidities rather than to age alone. Data on patients over age 80 are limited, but selected patients also seem to be reasonable surgical candidates. Lobectomy should not be excluded solely on the basis of age alone. The British Thoracic Society guidelines[106] indicate that age should be taken into account when considering pneumonectomy.

Because of the combined morbidities attributable to smoking, patients who are candidates for pulmonary resection require complete cardiac and pulmonary evaluation. There are numerous clinical predictors of coronary artery disease, and its presence certainly increases the risk of death or of having a nonfatal myocardial infarction within 30 days of surgery. With appropriate pre- and perioperative management, however,

these risks may be reduced considerably. Nonetheless, patients with unstable coronary syndromes, unstable or severe angina, a recent myocardial infarction with residual ischemic risk, decompensated congestive heart failure, uncorrectable life-threatening arrhythmias, or severe valvular disease can generally be excluded from surgery, as their 5-year survival is much more likely to depend on their cardiac abnormalities than on the lung cancer. To expand on this concept further, coronary angioplasty and stenting like conventional CABG surgery are problematic because of the time restrictions limiting the management of bronchogenic carcinoma. Combining conventional CABG surgery with the lung surgery has led to increased risk of morbidity and mortality.[107] However, one small study that looked at minimally invasive ("off-pump") direct coronary artery bypass concurrently with the lung resection surgery found that complications were comparable with resection alone and noted no postoperative myocardial infarctions or episodes of myocardial ischemia.[108] Thus, in certain instances, it may soon be possible to approach some patients with coexisting significant coronary artery disease that would have been previously excluded from lung resection surgery, if further studies confirm these findings.

In reviewing older studies done to predict PPCs after lung resection, it becomes clear that patients develop both pulmonary and cardiac complications (e.g., arrhythmias, myocardial infarction, pulmonary embolism, pneumonia, empyema) that can influence the duration of mechanical ventilation and outcome. Although none of these complications can be accurately predicted by preoperative studies of pulmonary function, a mortality rate under 5% can be expected if the preoperative postbronchodilator forced expiratory volume in 1 second (FEV_1) is more than 1.5 Ls in patients scheduled for lobectomy. A similar mortality rate, about 5%, should be seen if patients scheduled for pneumonectomy have a preoperative postbronchodilator FEV_1 of more than 2 L. Accordingly, if the FEV_1 exceeds these limits (in the absence of symptoms, dyspnea, or chest radiographic evidence of interstitial lung disease), the British Thoracic Society recommends that no additional pulmonary testing is needed. There has been increased use of preoperative exercise studies in an attempt to detect patients likely to have postoperative complications; but there are, as yet, no convincing data that this approach is more sensitive or specific. Mortality from respiratory problems is somewhat more common in older patients who have more serious airflow limitation.

Will the Postoperative Pulmonary Function Be Sufficient to Allow Reasonable Quality of Life? Fear of creating pulmonary insufficiency by lung resection is an important concern; and, accordingly, numerous studies have been conducted to find the lowest limit of pulmonary function that allows surgery to be performed while maintaining adequate pulmonary function postoperatively. Many older studies compared pulmonary function before and after operations for pulmonary tuberculosis.[109] More recent studies have examined patients with bronchogenic carcinoma. Boushy and associates[110] followed 142 patients for 3 months postoperatively and found that 10 died in the immediate postoperative period from myocardial infarction or pulmonary emboli. As would be expected, these patients had pulmonary function studies similar to those of patients who survived their operations.

Recent consensus statements suggest that all patients should have their FEV_1 measured. Those who have no dyspnea on exertion or interstitial lung disease on chest radiographs, and those who have an FEV_1 of more than 1.5 L are deemed suitable for a lobectomy. Those with an FEV_1 of more than 2.0 L are deemed at low risk for a pneumonectomy. Patients whose FEV_1 values are below these limits, and those who have dyspnea on exertion or interstitial lung disease on chest radiographs (regardless of their FEV_1) should have their diffusing capacity for carbon monoxide (DL_{CO}) measured along with pulse oximetry.[106,111] The postoperative DL_{CO} and FEV_1 should then be estimated by multiplying the preoperative FEV_1 by the percentage of lung segments that will remain in the scenario of the most extensive resection possible. The method of estimation is based on the number of segments in each lobe.

Lobe	*Segments*
Right upper	3
Right middle	2
Right lower	5
Left upper	3
Lingula	2
Left lower	4
Total	19

If the expectation is that the right lower lobe will be resected, the remaining segments would be 19 – 5 = 14, which represents 74% of the segments (14/19). The predicted postoperative FEV_1 would thus be 74% of the preoperative value. The postoperative FEV_1, can then be used to predict operative risk and to aid in decision making in the fashion[106] outlined in Table 26-3. Expressing the postoperative data as a percent predicted, rather than a raw value, avoids any possible bias that

TABLE 26-3. Postoperative FEV_1 and DL_{CO} for Predicting Operative Risk and Aiding in Decision Making

Predicted Postoperative FEV_1 and DL_{CO}	Risk	Recommendation
>40% predicted	Average	No further testing needed
<40% predicted	High	16%–60% mortality
		Consider less extensive resection
		Consider radiotherapy
Any other combination	Intermediate	Exercise testing needed

DL_{CO}, diffusing capacity for carbon monoxide; FEV_1, forced expiratory volume in 1 second.

might result for older patients, patients of small stature, and women who might tolerate a lower FEV_1 after surgery while still having these values exceed 40% predicted.

Other ways to estimate the degree of functional lung that might remain following resectional surgery include measuring differential lung function by bronchospirometry, perfusion lung scanning, or more recently, xenon radiospirometry. The latter technique involves intravenous injection of radioactive xenon that has been dissolved in sodium chloride. Because of its low solubility in blood, xenon escapes from pulmonary capillary blood into accessible alveoli as blood flows through the lungs. A gamma camera detects the isotope, and the relative distribution to each lung may be calculated.[112] Using this method, Kristersson and coworkers[113] compared preoperative and postoperative pulmonary function in 19 supine patients who underwent pneumonectomy. They concluded that xenon radiospirometry predicted postoperative ventilatory capacity as well as did the older technique of bronchospirometry. Other studies have compared regional ventilation and perfusion studies with standard lung scanning methods and found a similar good correlation between predicted and actual postoperative pulmonary function. In fact, little difference was found when either ventilation or perfusion was used as the basis for the postoperative prediction of postoperative pulmonary function.[112] Accordingly, radionuclide perfusion lung scanning is also accepted as a useful and simple method with which to predict postoperative function. It does not, however, seem to offer any better ability to predict outcome than the simpler calculation of remaining segments described previously. Quantitative CT scans may provide this data[107] as well as delineate the extent and distribution of emphematous lung changes that often accompany the lung cancer. Using such data in patients with resectable lung cancer situated in the area of the severe emphysema (i.e., those with favorable anatomy) may allow combined resection and lung volume resection surgery. This approach has been shown to carry an acceptable risk and give long-term survival in patients that might otherwise have been excluded on the basis of poor lung function.[114]

Both of the more recently published guidelines agree that cardiopulmonary exercise testing allows accurate stratification of postoperative complications.[106,111] A summary of numerous studies indicates that patients with maximum oxygen consumption ($\dot{V}o_2max$) of more than 20 mL/kg (and possibly >15 mL/kg) have no increased risk of death or of developing postoperative complications, whereas those with a $\dot{V}o_2max$ of less than 10 mL/kg have an extremely high risk of death (as high as 50%).

Pulmonary arterial pressure measurements, with occlusion of the pulmonary artery supplying the lung to be resected, have also been used to predict outcome but do not appear to give any better indication of which patients will not tolerate resection.[115]

Combined cardiopulmonary risk indices have also been proposed for the purpose of predicting both pulmonary and cardiac complications.[116] Neither these indices nor spirometry seems to accurately predict complications, however.[117]

Lung Volume Reduction Surgery

The effects of lung volume reduction surgery (LVRS) on the morbidity and mortality of patients with emphysema have been described. The initial report of the National Emphysema Treatment Trial (NETT)[118] found that in 69 patients with an FEV_1 of 20% or less of the predicted value, and either a homogeneous distribution of emphysema or a DL_{CO} of 20% or less of the predicted value, the 30-day mortality was 16% compared with 0% in 70 patients treated medically ($P < .001$). In addition, those treated surgically had little functional improvement. Accordingly, patients meeting these criteria were subsequently excluded from the ongoing trial.[118,118a]

The report of the completed trial of 1078 patients indicated that exercise capacity, dyspnea, and quality of life improved in those randomized to undergo surgery compared with those treated medically, but no survival benefit was observed.[119] Secondary analyses indicated that the beneficial effects were strongest in patients with predominantly upper lobe disease who had low exercise capacity (i.e., ≤25 W for females and ≤40 Ws for males) measured preoperatively, at the end of a 6- to 10-week period of rehabilitation. Conversely, those with predominantly lower lobe emphysema and an exercise capacity *exceeding* these limits had a greater risk of death if treated surgically.

Based on these findings, the Centers for Medicare and Medicaid Services (CMS) issued a national coverage analysis indicating that LVRS is not indicated, and will not be included as a covered procedure, for the high-risk group described previously. CMS also stated that they intend to cover LVRS for non–high-risk patients who (1) satisfy the entry criteria of the NETT and who present with severe upper lobe emphysema, or (2) have severe *non*–upper lobe emphysema along with a low exercise capacity. LVRS will *not* be a covered benefit for patients with severe non–upper lobe emphysema who have an exercise capacity exceeding the previously discussed limits. CMS also stipulated that the procedure will be covered only at one of the facilities that participated in the NETT and at sites that have previously been approved for lung transplantation.

KEY POINTS

- Patients with pulmonary disease are at increased risk of postoperative cardiovascular, renal, and pulmonary complications.
- Indices are available to identify patients at risk for postoperative complications after abdominal, cardiac, and pulmonary resection surgeries.
- High-risk patients include those who smoke and/or have COPD, sleep apnea, and/or uncontrolled asthma.
- The incidence of complications, especially pulmonary, is influenced by the type, site, and duration of the surgical procedure (i.e., procedure-related factors).
- Postoperative pulmonary complications (PPCs) in all types of procedures can be reduced in ALL patients, regardless of risk, by optimizing medical therapy preoperatively, by modifying anesthetic/surgical approach when indicated, and by delivering aggressive postoperative care with emphasis on analgesia and lung expansion.

INTRODUCTION

Respiratory impairment refers to an alteration in lung structure and/or lung function that results in decreased or limited functional ability and is usually manifested by dyspnea on exertion. Many respiratory diseases may cause impairment, from airways disease such as asthma and chronic obstructive pulmonary disease (COPD) to interstitial lung diseases. A pulmonary physician may be asked to evaluate impairment and/or disability, either for his or her own patients or for others in the context of an independent medical examination through a benefits or compensation program.

This chapter reviews the elements of an impairment evaluation and then provides an overview of the major programs in the United States and how disability and/or impairment is determined under each. Impairment ratings are described using the framework for the assessment of respiratory impairment set forth by the American Thoracic Society (ATS)[1,2] along with the most commonly used rating methodology contained in the American Medical Association (AMA) *Guides to*

the Evaluation of Permanent Impairment, hereafter referred to as the AMA *Guides*. However, the AMA *Guides* are not used by every system. It is incumbent on the evaluating physician to be sure she or he understands and follows the rules and specific requirements of the program under which the patient is being evaluated. The final determination on the award is usually made by personnel in the program or a judge, but the thoroughness of the medical report and its consistency with the program requirements will increase the weight given to the physician's medical opinion.

DEFINITIONS

There is a critical distinction between the terms *impairment* and *disability*. The terms *impairment* and *disability* are often used interchangeably, perhaps made more confusing by the fact that different benefits and compensation programs may use both terms but focus on one more than the other. *Impairment* occurs at the organ or organ system level. *Whole-person impairment* refers to the loss relative to the functioning of the body as a whole. *Disability*, in contrast, refers to the person in terms of limitation in the ability to perform normal activities, including personal, social, and work activities.

Physicians should understand that such determinations are medicolegal decisions, and they can have additional ramifications for the patient beyond that of providing a diagnosis. The physician may be asked to address causation; that is the physician may need to opine whether the respiratory condition was caused or at least aggravated by a certain factor, most commonly work, on a more-likely-than-not basis.

Although several of these terms are related, it is important that each term be applied in accordance with its precise definition. The definitions that follow are those based on the traditional World Health Organization's (WHO's) International Classification of Impairment, Disability, and Handicap (ICIDH) model, which has formed the classic paradigm through which these terms have been defined since 1980.[3] It is important to note that although this model is no longer used by the WHO, programs within the United States are only just beginning to recognize the paradigm shift put forth in the revised International Classification of Functioning, Disability, and Health (ICF).[4] Because most of the existing U.S. programs continue to use the traditional ICIDH definitions, these are reviewed first. To avoid confusion, the International Classification of Functioning, Disability, and Health (ICF) is described later in the chapter under the "Future Directions" section.

Impairment

Impairment refers to the degree of loss of normal use or function of a body part or organ. It was defined by the WHO as "any loss or abnormality of psychological, physiologic, or anatomic structure or function."[3] It was defined by the AMA as "a loss, loss of use, or derangement of any body part, organ system or organ function."[5a]

The essential elements that make up an impairment evaluation will vary to some degree according to the program or system through which the evaluation is being performed. Standard components typically include history, with occupational and environmental history and description of limitations in activities of daily living (ADLs); physical examination; and review of medical records and diagnostic test results that establish the respiratory condition.

Whereas pulmonary function test (PFT) results are the primary factor that determine the presence and degree of pulmonary impairment, some systems will specify that particular tests should be used for assessment of impairment or disability, whereas others allow physician discretion in choosing another test if he or she believes it to be a more accurate reflection of the patient's true respiratory impairment. Some programs will only allow physicians with certain qualifications to perform impairment ratings. Additional elements that may need to be addressed can include delineation of permanent work restrictions, outline of future medical treatment requirements, and/or consideration of apportionment.

Before a physician can determine that a condition has resulted in permanent impairment or disability, the diagnosis should be well defined, the condition stable, and medical treatment either optimized or reasonable options exhausted. When these criteria are met, this is termed *maximum medical improvement* (MMI).

Disability

Disability refers to any resulting alteration in the individual's capacity to perform customary activities. It was defined by the WHO as "any restriction or lack of ability to perform any activity within the range considered normal for a human being."[3] The AMA defined *disability* as an "alteration of an individual's capacity to meet or perform personal, social, or occupational demands or statutory or regulatory requirements because of an impairment."[5a]

Although the degree of impairment frequently correlates with the degree of disability, this is not always the case. The classic example of this is the loss of the fifth finger of the nondominant hand. Under the typical impairment rating system, the loss of this finger would be associated with a very small impairment of the whole person. For the average person, this small impairment would result in a correspondingly small disability. For a concert pianist, this small impairment would be associated with significant disability, particularly in the context of work activities.

Handicap

Handicap refers to the societal disadvantage caused by the impairment or disability. It was defined by the WHO as "a disadvantage for a given individual that limits or prevents fulfillment of that person's normal role depending on sex, age, social and cultural factors."[3]

Additional Terms

Temporary impairment refers to impairment that exists only for a limited period of time after an injury or illness.

Temporary disability insurance covers partial compensation for loss of wages due to a non–work-related injury or illness. Partial compensation for lost wages as well as medical benefits are covered by Workers' Compensation for work-related injuries and illness.

Permanent impairment can be assessed only once the patient has reached MMI. MMI is defined in the AMA *Guides*, Sixth Edition,[6a] as the "point in time in the recovery process … when further formal medical or surgical intervention cannot be expected to improve the underlying impairment" and "symptoms can be expected to remain stable with the passage of time, or can be managed with palliative measures that do not alter the underlying impairment substantially." This is termed "permanent and stationary" in some systems.

W*hole-person impairment* refers to the alteration in the functioning of the body as a whole, so can range from 0% (no impairment) to 100% (essential cessation of all body functions).

Permanent partial impairment is the numeric percentage of the loss of body functioning due to the loss or limitation in the functioning of the organ or organ systems affected. For most respiratory conditions, the primary organ involved is the lung, but at times, the pulmonary arteries or nose and throat may be affected.

Permanent total disability is the medicolegal determination that a person's impairment precludes future gainful employment.

CLINICAL APPROACH TO IMPAIRMENT EVALUATIONS

Although the term *impairment rating* is sometimes used interchangeably with the term *impairment evaluation*, the impairment rating itself is but a small part of what should be a comprehensive medical evaluation[7] (Table 27-1). The physician must first fully understand the purpose and the requirements of the program for which the evaluation is being conducted. The initial goal of the impairment evaluation should be to confirm the medical diagnosis,[2] through a thorough, detailed patient history, physical examination, and review of diagnostic testing results that established the diagnosis. The diagnosis or diagnoses should be clearly stated, along with extrapulmonary conditions that may be contributory to symptoms, limitations in ADLs, and/or impairment. A statement of MMI is often required. Factors important to the impairment rating itself include items from history, physical examination, and diagnostic testing results that reflect disease severity, including impact on normal ADLs,[5a] and current treatment requirements. The physician may be asked to make a statement on causation or apportionment. An outline of reasonably anticipated future medical course and treatment requirements should be given. The following sections describe the various aspects of an impairment evaluation, including the history to be taken, the examination to be conducted, and the testing to be obtained depending on the diagnosis considered and the type of evaluation being performed.

TABLE 27-1. Components of a Respiratory Impairment Evaluation

1. Clear understanding of the rules and specific requirements of the program under which the individual is being evaluated.
2. Complete medical history
   a. Complete occupational and environmental exposure history
   b. Limitations in activities of daily living (ADLs)
3. Physical examination
4. Diagnostic testing
   a. Tests that establish the diagnosis
   b. Tests that identify extra-pulmonary conditions contributing to impairment
   c. Results used in the assessment of impairment
      i. Pulmonary function tests
         A. Spirometry
         B. Single-breath diffusing capacity (DL_{COsb})
      ii. Cardiopulmonary exercise test (when indicated)
      iii. Arterial blood gas measurement (when indicated)
5. Diagnosis
   a. Assessment of causation, usually relationship to work (when indicated)
6. Impairment assessment
   a. Statement of maximum medical improvement (MMI)
   b. Impairment rating
   c. Ability to work/work restrictions (when indicated)
   d. Apportionment (if requested)
   e. Future medical treatment

History

The history of present illness (HPI) is the standard, detailed respiratory history used by most pulmonologists, including symptoms of cough, cough with phlegm, wheeze, chest tightness, and shortness of breath. If present, details should be provided that include when the symptom started, exacerbating and alleviating factors along with temporal relationship, progression over time and current status including frequency, severity, and response to any medication that is used. A scale for the rating of dyspnea is suggested in the AMA *Guides*, based on the Epidemiology Standardization Project,[8] which also provides standardized questions for the assessment of other symptoms. Questions about conditions such as chronic rhinitis, postnasal drip, gastroesophageal reflux disease, cardiac disease, and other lung diseases, including smoking-related lung disease, may help the physician understand other possible contributors to respiratory symptoms. Although dyspnea is the primary limiting symptom of respiratory impairment, dyspnea can also result from nonpulmonary causes including, cardiovascular disease, obesity, and deconditioning. Frequency, severity, treatment requirements, and duration of

periodic exacerbations of diseases such as asthma and bronchiectasis should be well documented. Medications used or tried in the past for the treatment of the respiratory conditions should be described, along with a description of the relief afforded.

Constitutional symptoms are relevant in the HPI in patients with certain diseases, such as fever, sweats, chills, and fatigue in patients with hypersensitivity pneumonitis, chest pain, weight loss, and malaise in patients with asbestos-related lung disease, and night sweats and fatigue in patients with chronic beryllium disease.

A standard detailed past medical and surgical history, list of medications and allergies, family history, and review of systems will provide a good understanding of the patient as a whole. It will also allow the physician to identify other possible diseases that may be contributory to the patient's current status, as well as assess potential treatment-related side effects. The standard social history should include smoking history, including amount, duration, and current smoking status.

An element that may be new to most pulmonologists is the need to obtain a detailed occupational and environmental history. This is necessary to help the physician address whether there is a relationship between a respiratory condition and past or ongoing workplace exposures. The occupational history is most easily performed in chronological order starting from childhood. Details about the period of time spent at each job, the job title, description of the work performed, and details about jobs or processes that may have produced dust, fumes, gas, or smoke should be described, including estimation of intensity, frequency, and duration of exposure. Questions about ventilation and use of respiratory protection can provide helpful clues, as well as whether or not there were any immediate symptoms noted. Chemical exposures, particularly any heavy exposures or exposures that resulted in symptoms, should be detailed. If available, the Material Safety Data Sheet (MSDS) may be reviewed, as it can provide helpful information on the components of the chemicals used in the workplace and potential associated health effects. Unfortunately, MSDSs are not required to provide complete information, and thus some are more reliable than others.

An environmental history includes questions about heating, cooling, and humidification sources; pets including birds; hot tubs; water-damaged areas; and exposures from hobbies should also be obtained to determine whether there is a relationship between the disease and any environmental exposures.

In addition to the just-discussed components, the history should also include a description of how the condition affects the person's ability to perform normal *activities of daily living* (ADLs). Questions most relevant to patients with pulmonary disease include ability to perform basic self-care such as showering; ability to walk, including estimated distance at own pace and at a fast pace or up a hill, estimated pace compared with others one's own age, and number of flights of stairs that can be climbed; and ability to perform indoor and outdoor home maintenance chores, as well as customary hobby, exercise, and job-related activities. There are a number of standardized methods by which to assess ability to perform ADLs, some of which are disease-specific. A list of ADLs suitable for all conditions is outlined in the AMA *Guides*.[5a] Symptoms and limitations in ADLs that are consistent with the lung disease and objective testing data provide useful supporting information for the impairment rating. Dyspnea scales are often used, and can be a helpful way to summarize the relative degree of symptomatology or activity limitation.[8] However, the degree to which dyspnea correlates with objective measures of pulmonary function and exercise performance is variable.[9–12]

Physical Examination

A complete physical examination should be performed, with focus on the respiratory and cardiovascular systems.[2,6,7] A detailed description of the chest should be made, including any deformities or scars, abnormal motion, respiratory rate and effort, breath sounds, and percussion, which can help support the diagnosis. Vital signs should be documented including blood pressure and heart rate, which may affect ability to perform pulmonary function and exercise tests, as well as height and weight, as obesity can cause PFT and exercise test abnormalities and contribute to pulmonary symptoms. Signs of hypoxemia, such as cyanosis and clubbing, should be documented. Signs of cor pulmonale, such as jugular venous distention, right ventricular heave, and liver engorgement, and peripheral edema provide evidence of severe respiratory impairment in patients with respiratory disease.[2]

Diagnosis, Causation, and Maximum Medical Improvement

Any available or provided medical records should be summarized, with focus on the results of the diagnostic testing that help establish the diagnosis and/or severity of the condition. Medicolegal cases may often involve the review and summarization of large volumes of records. Some independent medical examinations require that only the records provided through the program be reviewed.

The list of medical diagnoses should start with the diagnosis of the condition for which the patient is being evaluated, including disease severity. The diagnosis of asthma associated with workplace exposures may fall under one of three different diagnoses: occupational asthma (new-onset asthma caused by a workplace exposure), work-aggravated asthma (existing asthma aggravated by a workplace exposure), and reactive airways dysfunction syndrome (RADS), which can result from a single high-level exposure irritant exposure. Other diagnoses that may be contributory to symptoms, limitations in activities of daily living, or testing abnormalities should be clearly delineated.

If relevant, the diagnosis should also include a statement on *causation*, the physician's opinion as to whether or not a given workplace exposure has caused

or aggravated an illness. This is a medicolegal determination, also known as attribution, made on a medically probable basis, also known as a "more-likely-than-not" basis. That is, the physician should be able to opine with greater than 50% certainty that the exposure(s) in the workplace caused the respiratory condition or worsened an underlying condition based on objective criteria, such as change in treatment requirements. This criterion is less rigorous than would be required for scientific proof of a hypothesis (i.e., 95% certainty). This is important, because in cases of respiratory illness, there may be multifactorial causation, frequently a long latency between initial exposure and clinical onset of disease, nonspecific clinical manifestations, incomplete understanding of dose-response relationships from epidemiologic studies, and lack of individual exposure data. Although recognition of these limitations is necessary, causation can be attributed in most cases on a more-probable-than-not basis by simply applying reasonable judgment. This process is easier when the exposure is known, the dose-response relationship is well characterized, and competing diagnoses are unlikely. The physician should clearly describe the specific substances at the workplace; their known health effects according to the medical literature; the relative dose, in terms of estimated intensity, frequency, and/or duration of exposure; and finally, why it is medically probable that the exposure(s) caused or resulted in permanent aggravation of the diagnosed medical condition in this worker. When one or more of these conditions are not met, attribution should be based on the answers to the following questions.

- Is the diagnosis clearly established, and is it biologically plausible (or consistent with the available epidemiologic data) that the disease could have been caused or aggravated by the exposure in question?
- Have competing diagnoses been adequately considered?
- Is the exposure of sufficient intensity and duration to have caused or aggravated the disease?
- Has there been an adequately long latent period, or is there a temporal relationship between onset of exposure and clinical manifestation of disease?

Some systems, such as most state workers' compensation and a Department of Labor Program, the Energy Employees Occupational Illness Compensation Program (EEOICP) require the physician to make a statement that the patient has reached MMI before performing an impairment rating. If the examining physician believes the condition is not stable or believes that there may be additional treatment reasonably likely to improve the condition, it is medically prudent to state this. What will happen logistically following determination of the MMI will depend on the specific program requirements. The examining physician should be aware of the ramifications of making these medicolegal determinations. For example, in the state workers' compensation system, determination of MMI will allow the worker to be awarded permanent impairment, but will also result in the cessation of temporary benefits such as compensation for lost wages, as the case is closed by the workers' compensation insurance company.

GUIDES TO RESPIRATORY IMPAIRMENT RATINGS

American Thoracic Society Guidelines for Evaluation of Impairment or Disability

There are a number of systems that have been used to determine respiratory impairment. Most base impairment primarily on lung function. In their "Guidelines for the Evaluation of Impairment/Disability Secondary to Respiratory Disorders," the ATS recommends that impairment due to most lung diseases be rated based on PFT results.[2] The results of the ATS impairment system, based on PFTs, places individuals into four impairment categories. Each of these categories provides a corresponding description of the associated ability to perform job demands (Table 27-2). This system does not lend itself

TABLE 27-2. American Thoracic Society Impairment Categories, with Corresponding Description of Ability to Perform Job Demands

Category	Criteria	Ability to Perform Job Demands
Normal	FVC ≥ 80% of predicted, ***and*** FEV_1 ≥ 80% of predicted, ***and*** $FEV_1/FVC \times 100 \geq 75\%$, ***and*** DL_{COsb} ≥ 80% of predicted	
Mildly impaired	FVC 60%–79% of predicted, ***or*** FEV_1 60%–79% of predicted, ***or*** $FEV_1/FVC \times 100$ 60% to 74%, ***or*** DL_{COsb} 60%–79% of predicted	Usually not correlated with diminished ability to perform most jobs
Moderately impaired	FVC 51%–59% of predicted, ***or*** FEV_1 41%–59% of predicted, ***or*** $FEV_1/FVC \times 100$ 41% to 59%, ***or*** DL_{COsb} 41%–59% of predicted	Progressively lower levels of lung function correlated with diminishing ability to meet the physical demands of many jobs
Severely impaired	FVC ≤ 50% of predicted, ***or*** FEV_1 ≤ 40% of predicted, ***or*** $FEV_1/FVC \times 100 \leq 40\%$, ***or*** DL_{COsb} ≤ 40% of predicted	Unable to meet the physical demands of most jobs, including travel to work

DL_{COsb}, single-breath diffusing capacity; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

to use in most compensation systems, in which monetary awards are typically based on a numerically derived percentage of whole-person impairment, as it does not provide such a paradigm.

American Medical Association Guides to the Evaluation of Permanent Impairment

The most commonly used methodology by which to calculate an actual numeric value for permanent partial impairment is set forth in the AMA *Guides*. Although the Fifth Edition is no longer the most current edition since the recent publication of the Sixth Edition in 2008, most compensation systems have not yet adopted the Sixth Edition. Therefore, the methodology of the still widely used AMA *Guides*, Fifth Edition, is presented in this section. The methodology of the Sixth Edition is described under "Future Directions."

The AMA *Guides*, Fifth Edition and earlier, delineate methodology similar to ATS by which to place individuals into one of four impairment categories, as shown in Table 27-3, but also provide an associated range of percentage whole-person impairment: Class 1 impairment is equal to 0% whole-person impairment, Class 2 impairment ranges from 10% to 25% impairment, Class 3 ranges from 26% to 50% impairment, and Class 4 ranges from 51% to 100% whole-person impairment. The physician can then determine a final numeric percentage whole-person impairment, based on where the test results fall within that range of impairment, as well as other factors, including impact of the respiratory condition on the ability to perform ADLs. Because a person can never have more than 100% impairment of the body, impairment in any additional organ system needs to be combined rather than added to the respiratory impairment. The AMA *Guides* contain a special combining table for this purpose.

Classification of Impairment Resulting from Specific Pulmonary Diseases

In the classification of impairment, the greatest weight should be placed on objective data.

Asthma

Rating asthma according to the standard respiratory disorder methodology can both under- and overestimate impairment, given the episodic and variable nature of airflow limitation and bronchial hyperresponsiveness.[13] The AMA *Guides*, Fifth Edition, incorporated the methodology of the ATS Guidelines for the Evaluation of Permanent Impairment and Disability updated in 1993,[1] to more accurately reflect the true impairment due to this condition. First, a worker with objectively confirmed asthma must be determined to be at MMI or to have achieved optimal therapeutic goals (i.e., minimum medication that obtains the best overall outcome).[6b] To rate asthma impairment according to the AMA *Guides*, Fifth Edition, a postbronchodilator forced expiratory volume in 1 second (FEV_1), reversibility (% change with bronchodilator), or methacholine challenge results (provocative concentration of methacholine inducing a 20% drop in FEV_1 [PC_{20} mg/mL]), and minimum medications required to maintain this status are needed (Table 27-4).

Bronchiectasis

Rating conditions such as bronchiectasis by the standard pulmonary function testing methods also can underestimate impairment, as it is the recurrent episodes of infection and inflammation that cause intermittent respiratory symptoms, respiratory dysfunction, and limitations in ADLs, often with normal lung function in between episodes. The AMA *Guides*, Fifth Edition, acknowledge that this method will be applicable only in "limited cases,"

TABLE 27-3. American Medical Association Classification of Respiratory Impairment

Class 1, 0%–9%: No Impairment of the Whole Person	Class 2, 10%–25%: Mild Impairment of the Whole Person	Class 3, 26%–50%: Moderate Impairment of the Whole Person	Class 4, 51%–100%: Severe Impairment of the Whole Person
FVC ≥ lower limit of normal,* ***and*** FEV_1 ≥ lower limit of normal,† ***and*** FEV_1/FVC ≥ lower limit of normal ***and*** D_{LCO} ≥ lower limit of normal,‡ ***or*** $\dot{V}O_2$max > 25 mL/kg/min	FVC between 60% and lower limit of normal, ***or*** FEV_1 between 60% and lower limit of normal, ***or*** $\dot{V}O_2$max between 20 and 25 mL/kg/min	FVC between 51% and 59% of predicted, ***or*** FEV_1 between 41% and 59% of predicted, ***or*** $\dot{V}O_2$max between 15 and 20 mL/kg/min	FVC ≤ 50% of predicted, ***or*** FEV_1 ≤ 40% of predicted, ***or*** D_{LCO} ≤ 40% of predicted, ***or*** $\dot{V}O_2$max < 15 mL/kg/min

*Lower limit of normal FVC for men is predicted normal FVC—1.115 L; lower limit of normal FVC for women is predicted normal FVC—0.676 L (adapted from Crapo et al[19]).
†Lower limit of normal FEV_1 for men is predicted normal minus 0.842 L; lower limit of normal FEV_1 for women is predicted normal minus 0.561 L (adapted from Crapo et al[19]).
‡Lower limit of normal D_{LCO} from men is predicted normal—8.2 mL/min/mm Hg; lower limit of normal D_{LCO} for women is predicted normal—5.74 mL/min/mm Hg (adapted from Crapo et al[22]).
D_{LCO}, diffusing capacity for carbon monoxide; FVC, forced vital capacity; $\dot{V}O_2$max, maximal oxygen consumption.

TABLE 27-4. American Medical Association Impairment Classification for Asthma Severity

A. POSTBRONCHODILATOR FEV_1*

Score	FEV_1 (% predicted)
0	Lower limit of normal
1	70–Lower limit of normal
2	60–69
3	50–59
4	<50

B. REVERSIBILITY OF FEV_1 OR DEGREE OF AIRWAY HYPERRESPONSIVENESS*

Score	% FEV_1 Change	PC_{20}† (mg/mL)
0	<10	>8
1	10–19	8–>0.6
2	20–29	0.6–>0.125
3	>30	≤0.125

C. MINIMUM MEDICATION NEED‡

Score	Medication
0	No medication
1	Occasional bronchodilator, not daily, and/or occasional cromolyn, not daily
2	Daily bronchodilator and/or daily cromolyn and/or daily low-dose inhaled steroid (<800 µg beclomethasone or equivalent)
3	Bronchodilator on demand and daily high-dose inhaled steroid (>800 µg beclomethasone or equivalent) or occasional course (1–3/yr) systemic steroid
4	Bronchodilator on demand and daily high-dose inhaled steroid (>1000 µg beclomethasone or equivalent) and daily or every other day systemic steroid

D. SUMMARY OF IMPAIRMENT RATING CLASSES§

Impairment Class	Total Score	% Impairment of the Whole Person
I	0	0–9
II	1–5	10–25
III	6–9	20–50
IV	7–9	51–100
V	10–11 or asthma not controlled despite maximal treatment (i.e., FEV_1 remaining < 50% despite use of ≥ 20 mg prednisone/day)	

*When the postbronchodilator FEV_1 value is above the lower limit of normal, the PC_{20} value should be determined and used for rating impairment; when the postbronchodilator FEV_1 value is less than 70% of the predicted value, the degree of reversibility should be used; when the FEV_1 value is between 70% of the predicted value and the lower limit of normal, either the degree of reversibility of FEV_1 or the PC_{20} can be used.

†PC_{20}, the provocative concentration of methacholine that causes a 20% decrease in FEV_1 from the prechallenge baseline.

‡The need for minimum medication should be demonstrated by the treating physician (e.g., previous records of exacerbation when medications have been reduced).

§The impairment rating is calculated as the sum of the patient's scores from parts A, B, and C.

FEV_1, forced expiratory volume in 1 second.

but will allow the physician to assign a rating based on the extent and severity of these episodes and their impact on ADLs, with objective supporting evidence documented.[5b]

Lung Cancer

The AMA *Guides*, Fifth Edition, recommends one of two methods be used for rating permanent impairment due to lung cancer.[5b] All individuals with lung cancer are considered severely impaired at the time of diagnosis. At 1 year after diagnosis, if there is still evidence of tumor or tumor recurrence, the person is considered to be severely impaired. If there is no residual tumor or recurrence, the impairment rating is performed according to the standard rating methodology for respiratory diseases.

Diseases of the Pulmonary Arteries

This category includes pulmonary artery hypertension, cor pulmonale, and pulmonary emboli. The rating is determined by the presence or absence of physical examination signs (right ventricular heave, increased pulmonic component [P_2] of the second heart sound [S_2], peripheral edema) and symptoms of right heart failure (dyspnea), as well as the observed pulmonary artery pressure (PAP), as shown in Table 27-5.

Conditions of the Upper Airway

The AMA *Guides*, Fifth Edition,[5d] contain methodology by which to assign impairment due to obstruction of the upper airway, larynx, trachea, and/or bronchi, based on degree and location(s) of the obstruction, nature of the activities that trigger dyspnea, as well as need for ventilation. There is also methodology for the rating of voice/speech impairment, based on audibility, intelligibility, and functional efficiency.

ROLE OF DIAGNOSTIC TEST RESULTS IN IMPAIRMENT RATINGS

Radiographic Data

Documentation of chest radiograph or computed tomography (CT) scan abnormalities consistent with the lung disorder is frequently required to establish evidence of disease, particularly for diseases like pneumoconiosis. The chest imaging findings may correlate poorly with the physiologic findings, especially in patients with obstructive lung disease.

Some programs require that chest x-rays be read by a National Institute of Occupational Safety and Heath (NIOSH)–certified B-reader and classified according to the International Labour Organization's (ILO's) classification system.[14] This radiographic interpretation system was devised to attempt to objectively and consistently report the presence, appearance, and extent of radiographic changes consistent with pleural and parenchymal evidence of pneumoconiosis. Chest radiograph

TABLE 27-5. Criteria for Rating Permanent Impairment Due to Pulmonary Hypertension

Class 1 0%–9% Impairment of the Whole Person	Class 2 10%–29% Impairment of the Whole Person	Class 3 30%–49% Impairment of the Whole Person	Class 4 50%–100% Impairment of the Whole Person
No symptoms or signs of right heart failure and mild pulmonary hypertension (P_{PA} 40–50 mm Hg) or a Doppler echocardiography–derived peak tricuspid velocity of 3.0–3.5 m/sec	No symptoms or signs of right heart failure and moderate PA hypertension (P_{PA} 51–75 mm Hg)	Moderate pulmonary hypertension (P_{PA} < 75 mm Hg) ***and*** Signs and symptoms of right HF ***or*** Symptoms of mild limitation (class 2) with any degree of pulmonary hypertension	Severe pulmonary hypertension (P_{PA} > 75 mm Hg) ***or*** Symptoms of severe limitation (class 3 or 4) with any degree of pulmonary hypertension

PA, pulmonary artery; P_{PA}, pulmonary artery pressure.
From the American Medical Association: Cocchiarella L, Andersson GBJ (eds): The cardiovascular system: Systemic and pulmonary arteries. *In*: Guides to the Evaluation of Permanent Impairment, Fifth Edition. Chicago: AMA Press, 2001, pp 65–86.

findings of opacities with an ILO profusion score of at least 1/0 are "consistent with" asbestosis and will be accepted for compensation purposes by programs such as the Department of Labor for that condition. If the opacities are small and irregular (classified as "s" and "t") and are found predominantly in the middle and lower lobes or are found in conjunction with pleural plaques, these findings are highly consistent with a diagnosis of asbestosis.

Whereas the ILO interpretation may help raise suspicion of pneumoconiosis, or provide sufficient evidence of disease in the correct clinical situation, the physician needs to determine on a clinical basis whether additional testing is needed to definitively establish a medical diagnosis and determine whether treatment is needed. The physician should note that additional testing may or may not be covered by the benefits or compensation program. Because of the variability in the extent of radiographic findings and the degree of physiologic impairment, none of the major programs or rating systems uses radiographic findings in the assessment of impairment due to the lung disease. The NIOSH website provides a search tool by which to find certified B-readers by state and country.[15]

Pulmonary Function Testing

PFTs are the most important tests, both from a diagnostic standpoint and in their use to determine impairment for most respiratory conditions. Both the ATS[2] and the AMA *Guides*,[5,6] specify the use of forced vital capacity (FVC), FEV_1, FEV_1/FVC, and single-breath diffusing capacity (DL_{COsb}). Some programs mandate that pulmonary function testing be performed pre- and postbronchodilator and should be done in patients with low FEV_1 or diagnoses of reversible airflow limitation. The ATS specifies that individuals should be evaluated only after they have received an accurate diagnosis and while they are receiving optimal therapy.[2] This is consistent with the AMA *Guides'* requirement that the patient be at MMI, as described previously.[5] Measurement of height in stocking feet is recommended, as is use of arm span (distance from the tips of the middle fingers with arms outstretched) in cases of spinal deformity.[2,16]

Both ATS and the AMA *Guides* emphasize the importance of only using test results that meet the quality standards defined in the latest ATS statement "Standardization of lung function testing."[17] This document governs the equipment, quality assurance, and technique that should be used to perform lung function testing, in addition to the assessment of the quality of the test and the method of interpretation. If a physician has concern that the PFTs were not performed in a manner consistent with the ATS Guidelines, including acceptability and reproducibility, then she or he should request that a repeat test be obtained. One exception is when a patient has consistently demonstrated less than optimal technique on past tests despite language-appropriate education and encouragement. This consistent unacceptable test performance may be due to overall debilitation, pain, or language barrier, and it is unlikely that repeating the test will yield improved results. Test results that are markedly worse than those of prior tests raise concern for an exacerbation of the underlying condition and that the patient is not at MMI, or it may be that the patient gave less than full effort; regardless, such results would not be considered to reflect the patient's permanent impairment status. Options include informing the subject of the discrepancy and repeating the test or using the results "as a subsidiary and not the main criterion."[18]

When evaluating PFTs for impairment, the normal values of the laboratory performing the test should not be used, but rather the normal values of the impairment rating system. For example, the ATS and AMA *Guides*, Fifth Edition, reference population normal values derived from Crapo and coworkers,[19] while the AMA *Guides*, Sixth Edition, reference National Health and Nutrition Examination Survey (NHANES) III–derived prediction equations.[20]

DL_{COsb}, measured by the single-breath method of Ogilvie and colleagues[21] and interpreted according to Crapo and Morris,[22] is suggested by both ATS and the AMA *Guides*. Both recommend correction by the methodology of others for factors including hemoglobin, carboxyhemoglobin,[2,5b] and altitude and alveolar volume,[2] but correction methodology and interpretive strategies are not explicitly described in the rating criteria. The

most recent ATS statement on DL_{COsb} describes explicit criteria for evaluating acceptability and repeatability, as well as adjustment for hemoglobin, supplemental oxygen, altitude, carboxyhemoglobin, while noting that further study is needed before specific recommendations for lung volume adjustment can be made.[23] In a separate statement, the ATS has noted that low DL_{COsb} along with low DL_{COsb} corrected for alveolar volume (DL_{COsb}/VA) suggests parenchymal abnormalities as the cause of the impairment, but recommends examining the two separately.[17] Neither the ATS nor the AMA *Guides* utilize DL_{COsb}/VA in assessing impairment.

Maximal voluntary ventilation (MVV) and FEV_{25-75} are not recommended for use by ATS or the AMA *Guides* in impairment evaluation. ATS defines a restrictive ventilatory defect as a reduction in total lung capacity (TLC) below the fifth percentile of the predicted value, with a normal FEV_1/FVC ratio.[17] TLC is not included in the standard rating criteria in either the ATS or the AMA *Guides*. Although the AMA *Guides*, Sixth Edition, caution that a true restrictive defect may not be present even with a reduced FVC in the setting of a normal or increased FEV_1/FVC,[6] FVC continues to be the test used in the rating of impairment. Low FVC can be caused by submaximal inspiratory or expiratory effort and/or patchy peripheral airflow obstruction.[17] One study showed the predictive value of reduced FVC to be less than 60% for the presence of true restrictive deficit.[24] Others report concern about reduced lung function test results, including FVC, in obesity,[25,26] but there are no established criteria by which to account for obesity in testing.

Cardiopulmonary Exercise Testing

Neither the ATS nor the AMA *Guides* recommend the routine use of exercise test results in the determination of permanent impairment, but do note that maximal exercise test results, specifically $\dot{V}O_2max$, should be used in specific circumstances. ATS recommended that exercise test results be used in cases where the static PFTs do not reflect the true impairment present.[2] For example, studies have demonstrated that alveolar-arterial oxygen pressure difference ($P(A—a)O_2$) during exercise is a better reflection of impairment due to gas exchange abnormality than DL_{COsb}.[27] Although exercise limitation does not necessarily correlate with static lung function testing,[28,29] exercise testing can be very helpful in cases where there is a large discrepancy between symptoms and resting physiology,[27] providing a more precise measurement of work capacity.[30]

Airflow limitation and gas exchange abnormality help define the relative degree to which respiratory disease is contributing to exercise limitation. When exercise limitation is present, nonrespiratory causes of exercise limitation should be considered as well, including cardiovascular disease, deconditioning, and neuromuscular disease.[31] The ATS guidelines for respiratory impairment note that exercise testing can be used as a valid measure of respiratory impairment when the following criteria are met: (1) if exercise testing is not terminated for other nonpulmonary reason, (2) if there is low breathing reserve at termination, and (3) if there is absence of or erratic overventilation at submaximal levels with failure to achieve anaerobic threshold. However, there are no details provided on how these criteria should be met and the AMA *Guides* do not delineate a specific methodology. The reason for test termination should be noted, as tests terminated early due to nonrespiratory causes such as excessive blood pressure, cardiac abnormality, or leg pain do not reflect maximum exercise tolerance.

To determine work capacity, and thus impairment, ATS requires use of $\dot{V}O_2max$ to place workers into one of three categories of work tolerance, assuming that workers can comfortably perform sustained work at 40% of $\dot{V}O_2max$ and that $\dot{V}O_2$ requirements of the workers' job are known (Table 27-6). Major limitations to this approach include the following: (1) little published data that substantiate its use; (2) heterogeneous methods of assessing maximal oxygen uptake[32]; (3) the fact that actual work performed by workers with the same job title can vary markedly from employer to employer or among employees with differing seniority at the same employer; (4) the questionable relationship between exercise tolerance on the treadmill or bicycle and performance on the job[33]; and (5) the lack of consideration of modifying factors such as the need to talk or use personal protective equipment (PPE) while performing the work.[34] The average energy requirements of a number of jobs are listed in Table 27-7. The AMA *Guides*, Fifth and Sixth Editions, both consider a $\dot{V}O_2max$ greater than 25 mL/kg/min to place one into the lowest (least) category of impairment (class 1 and class 0, respectively), and a $\dot{V}O_2max$ less than 15 mL/kg/min to place one into the highest (greatest) category of impairment (class 4). The use of exercise testing and $\dot{V}O_2max$ overestimates impairment in older workers. As an alternative,

TABLE 27-6. American Thoracic Society Interpretation of Exercise Test Results Using $\dot{V}O_2max$

$\dot{V}O_2max$	METS	Estimated Work Ability
≥25 mL/kg/min	≥7.1	Continuous heavy exertion throughout an 8-hour day in all but the most physically demanding jobs
15–25 mL/kg/min ***and*** Metabolic demands of the work ≤ $\dot{V}O_2max$		Able to perform that job comfortably, assuming there are no frequent or extended periods (5 min) requiring exertion substantially >40% $\dot{V}O_2max$
≤ 15 ml/kg/min	≤4.3	Unable to perform most jobs because they would be uncomfortable traveling back and forth

METS, the energy demand in liters of oxygen consumption per minute/basal oxygen consumption (3.5 mL/kg/min); $\dot{V}O_2max$, maximal oxygen consumption.

TABLE 27-7. Energy Requirements Expressed as Oxygen Uptake ($\dot{V}O_2$) of Various Types of Work

Level of Work	$\dot{V}O_2$ (APPROXIMATE)		
	mL/kg/min	L/min	METS
Light to moderate work (sitting)			
Clerical	5.6	0.42	1.6
Using repair tools	6.3	0.47	1.8
Operating heavy equipment	8.8	0.66	2.5
Heavy truck driving	12.6	0.95	3.0
Moderate work (standing)			
Light work, own pace	8.8	0.66	2.5
Janitorial work	10.5	0.79	3.0
Assembly line (lifts ≥ 45 lb)	12.3	0.92	3.5
Paper hanging	14.0	1.05	4.0
Standing and/or walking (arm work)			
General heavy labor	15.8	1.19	4.5
Using heavy tools	21.0	1.58	6.0
Lift and carry 60–80 lb	26.2	1.97	7.5

METS, the energy demand in liters of oxygen consumption per minute/basal oxygen consumption (3.5 mL/kg/min); $\dot{V}O_2$max, maximal oxygen consumption.
Adapted from Becklake M: Organic or functional impairment. Am Rev Respir Dis 129:S96-S100, 1984.

it has been proposed that $\dot{V}O_2$max be expressed as percent of predicted,[35] although this is not in standard use at this time. Although advances have been made, the recent ATS Statement on Cardiopulmonary Exercise Testing[31] noted a comprehensive updated framework for impairment/disability is urgently needed.

Blood Gas Analysis

Arterial blood gas analysis is not used for impairment rating purposes on a routine basis. Resting arterial P_{O_2} does not correlate with exercise capacity. As a result, arterial hypoxemia at rest is, by itself, not evidence of severe impairment in exercise tolerance. ATS recommends it only be used in "selected patients" under "rigidly controlled laboratory conditions," and should be documented on at least two occasions separated by at least 4 weeks.[2] They consider hypoxemia to be evidence of severe impairment only when accompanied by evidence of cor pulmonale. Arterial blood gas analysis was also considered to be a test infrequently indicated in the evaluation of impairment in the AMA *Guides*, Fifth Edition.[5b] It is not included in the Sixth Edition.

Addressing Discrepancies between Objective and Subjective Data

A description of the severity of the disease or condition should be given. This can be difficult when there is a discrepancy between the severity reported by the patient and the severity of the disease based on the results of the diagnostic testing. It is important that the physician distinguish between data that are *objective* (findings evident to the examiner in a reproducible manner and not dependent on only the patient's perceptions), including physical signs and diagnostic testing results, and the *subjective* data, which are reported by the patient, such as symptoms perceived by the patient only and not evident to the examiner. Normally, the two will be very similar, making the history, physical examination, and diagnostic testing findings all helpful in the assessment of true functional impairment. If the subjective complaints are not consistent with the objective findings, the physician should first be sure there is no coexisting disease process responsible for the symptoms. For example, dyspnea may also be caused by nonrespiratory disorders such as cardiac disease and anemia. *Organic impairment* refers to the presence of objective findings of respiratory dysfunction or disease. *Functional impairment* refers to dyspnea for which an objectively measured abnormality of organ function cannot be identified. Recognizing that tests for organic impairment are not perfectly sensitive, the contribution of functional impairment can range from "negligible" to "perhaps accounting for the entire extent of a patient's dyspnea." When there is a discrepancy between the subjective and the objective data, and other medical conditions have been excluded as possible contributors to the subjective complaints, there are several steps that should be taken. The first and foremost is to review the purpose of the evaluation with the patient to ensure that a lack of comprehension of either questions or performance of PFTs does not exist. Second, an evaluation of test performance, including cooperation and the results of effort-independent tests such as functional residual capacity, may be of some use. Examination of test results for comparability over time may show evidence of consistency or the lack thereof. Finally, exercise testing may shed considerable light on a patient's level of effort by demonstrating the relationships of heart rate and ventilatory rate at workloads actually achieved to the predicted maximal values.

Dyspnea due to functional impairment may result from subconscious effects on the perception of symptoms or from outright malingering. Because of the inability of PFTs and other tests to be perfectly sensitive in diagnosing organic causes of impairment, the diagnosis of malingering should be made with caution. The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR), classifies malingering as a condition "that may be a focus of clinical attention."[36] Furthermore, malingering is described as "the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives." Specific listed examples of these external incentives include avoiding work and obtaining financial compensation. The DSM-IV-TR recommends that malingering should be strongly suspected if any combination of the following is noted: (1) there is a medicolegal context of presentation, (2) a marked discrepancy between the person's claimed stress or disability and the objective findings is noted, (3) a lack of

cooperation during the diagnostic evaluation and compliance with the prescribed treatment regimen are observed, and (4) there is the presence of antisocial personality disorder. Malingering is differentiated from a factitious disorder in that the motivation for the symptom production is external, rather than an intrinsic need to maintain the sick role. Malingering may also be differentiated from conversion disorder and other somatoform disorders by the intentional production of symptoms and the obvious external incentives associated with it.

Although it is important to identify frank malingering, which represents fraud, it must be emphasized that malingering is relatively rare and should remain a diagnosis that is made through exclusion and with extreme caution.

WORK RESTRICTIONS, APPORTIONMENT, AND FUTURE MEDICAL TREATMENT

Work Restrictions

Some compensation systems, such as workers' compensation, require a statement on ability to work, that is, are there any physical activities or exposures the worker should avoid? Inability to work may be due to inability to perform a specific physical activity, perform it safely on a sustained or repeated basis, and/or perform it in the presence of certain dust, fume, gas, chemical, and/or antigen exposures, as in the case of occupational allergic asthma and hypersensitivity pneumonitis.

The NIOSH recommends the following hierarchical approach to reducing workplace exposures: elimination; substitution; engineering controls, such as improving ventilation or enclosing exposures; and administrative controls, before using personal protective equipment, such as respirators.[37] Medical clearance for the use of respirators is mandated by the OSHA, either through their standard questionnaire or through a comparable medical examination.[38] Before using a respirator, the worker should undergo fit testing with the specific make and model of the respirator to be used, to ensure proper fit and protection. Fit testing is also regulated by OSHA.

In order for the physician to determine whether or not the worker can perform the full scope of the job tasks, both the physical requirements of the job and the worker's capabilities need to be known. Exercise testing, with its limitations noted previously, is a standard approach used in this assessment. Although submaximal testing has been used, and does have some advantages in terms of administration and merits in terms of demonstrating a workers' ability to sustain activity at a predetermined level of exertion, maximal exercise testing is normally used. Accuracy of exercise testing to predict functional performance can be increased by combining exercise testing with measures of pulmonary function[28] and with heart rate monitoring during the performance of work activities.[39] Actual simulation of work may be performed by a physical or occupational therapist, called a Functional Capacity Evaluation (FCE). Interpretation of results and formulation of formal work restrictions should be performed in a manner consistent with Americans with Disabilities Act (ADA) considerations, including suggesting possible methods of reasonable accommodation in the workplace.

Apportionment

When multiple disease processes are present that may contribute to respiratory impairment, the physician may be asked to apportion, or make a statement of the relative contribution of each disease process to the total impairment. This is usually performed in the context of workers' compensation in an effort to limit the amount of the monetary award to that specifically attributed to the workplace exposure or event. It does not typically reduce medical treatment benefits or wage compensation. Unfortunately, the scientific basis for this level of precision is rarely present and thus must be acknowledged as arbitrary even if required by the entitlement system.

Cigarette smoking and its sequelae is the most common condition taken into account when considering apportionment of respiratory impairment. For example, much has been written about the difference in symptoms and physical limitations in smoking compared with nonsmoking asbestos workers,[40] and the observation that the most common cause of exercise limitation in one group studied was the cardiovascular system rather than the respiratory system.[41] Specific methods for apportionment have been proposed,[42] but none has been validated scientifically or considered generally accepted. If objective evidence of prior impairment exists, such as diagnostic testing results performed before the work-related exposure or development of disease, some states will allow apportionment to be performed by subtracting the preexisting impairment from the current total impairment.

Expected Future Medical Treatment

A description of the expected natural history of the condition, that is, if the condition is expected to remain stable or potentially deteriorate over time, should be provided. In addition, the recommended medical follow-up and anticipated treatment requirements can provide a helpful measure of reasonably anticipated future medical expenses. This is of value to the worker, as well as insurance adjusters and attorneys.

MAJOR STATE AND FEDERAL BENEFIT AND COMPENSATION PROGRAMS

Most impairment and disability evaluations will be performed under the context of a particular state or federal program. A number of different programs exist for individuals and workers in specific employment settings. Most programs reference both impairment and disability. In some programs, the primary determination to be made by the physician is disability, usually in the context

of making the dichotomous determination of "disabled" or "not disabled." Systems in which the primary role of physicians is to determine impairment will also be discussed. Most major compensation systems require physicians undergo special training and/or approval before they are permitted to perform these evaluations for benefits programs. A few of the larger programs are reviewed in the following sections.

Programs in Which Physicians Primarily Determine Disability

These are programs that provide benefits to individuals who are determined to be unable to work due to a medical condition. The role of the physician is to determine if there is evidence of an illness and, if so, provide medical evidence that supports the determination that the worker cannot engage either in a particular occupation or in any type of gainful employment. These are typically all or none systems; either the worker is totally disabled due to the condition or he or she is not. No benefits are awarded unless the worker is determined to be totally disabled.

Federal Black Lung Program

The Federal Black Lung Program is a medical treatment program for miners, administered through the Department of Labor (DOL).[43] It arose out of the Federal Coal Mine and Safety Act of 1969, with amendments made in 1977, 1981, and 2000. The Act established mandatory safety and health standards in mines, and included provisions for research and training. Title IV of the Act established black lung benefits, recognizing that there are many coal miners who are disabled or deceased because of mining-related lung disease, primarily pneumoconiosis. The amendments that followed the initial act broadened the scope of workers covered and lung diseases. A *miner* is now defined as "any person who works or has worked in or around a coal mine or coal preparation facility in the extraction, preparation or transportation of coal, and any person who works or has worked in coal mine construction or maintenance in or around a coal mine or coal preparation facility." In addition, the amendments also broadened the disease covered, so that *pneumoconiosis* is now defined as any "chronic dust disease of the lung and its sequelae including respiratory and pulmonary impairments, arising out of coal mine employment." Thus, the Federal Black Lung program covers not only coal miners with silicosis or coal worker's pneumoconiosis but also airways disease due to coal mining, such as chronic airways obstruction.

Benefits are awarded to the miners or to their *surviving dependents*, defined as the wife or dependent child, parents, or siblings of the miner. Each miner who applies for benefits is afforded the opportunity to undergo a medical evaluation paid for by the DOL to ascertain if she or he is eligible for benefits. The testing must be performed in the manner outlined in the Federal regulations. Only physicians who have been approved by the DOL may perform the examination; they cannot be related to the miner or have examined or treated the miner within the preceding 12 months. Miners may apply for benefits under state workers' compensation as well.

There are strict eligibility requirements. This normally requires the miner to have been employed for a minimum of 10 years in underground mine work. Once determined to be eligible, the physician must then determine if the miner has lung disease due to mining, as defined by the statute. This is most commonly determined on the basis of chest x-ray findings of pneumoconiosis, specifically large or small opacities of profusion 1/0 or greater, read by a NIOSH-certified B-reader and classified according to the ILO's classification system.[14] A determination may also be made by biopsy or autopsy evidence of pneumoconiosis, or through a reasoned medical opinion that there was a condition that would be reasonably expected to yield the previously discussed chest x-ray or pathology findings. The regulations also specify criteria for posthumous determinations.

The physician will next determine if the miner meets the definition of *totally disabled*, defined as being unable to work as a miner or perform comparable work due to respiratory impairment. The medical criteria that establish total disability are pulmonary function test results with FVC, FEV_1, or MVV below values listed in the tables contained in the regulations (60% of predicted), FEV_1/FVC ratio 55% or less, or ABG analysis based on a P_{O_2} at or below a value specified for concurrently measured P_{CO_2}, listed in one of three tables provided for different ranges of altitude. If these criteria are met, the physician must also establish that the miner is unable to perform his or her usual job in the coal mine, or unable to be employed in the area of their residence with the skills used in the mines over a period of time. The specific tables noted previously may be accessed at the U.S. DOL's Division of Coal Mine Workers Compensation page[44] through the Pulmonary Functions Standards and Tables link. This website also contains a link to the specific standards that must be used for the administration and interpretation of PFTs contained in the legislation.

If not covered under state workers' compensation, medical treatment expenses for black lung–related conditions, including medication, will be covered. Home oxygen, pulmonary rehabilitation, and home health care may be covered after special approval.

Social Security Disability

Amendments to the Social Security Act in 1950 established the first legislation for financial assistance "to aid the permanently and totally disabled." Numerous changes in this system have occurred since that time. The Social Security Administration (SSA) oversees two programs: the Social Security Disability Insurance (SSDI) program, which pays monthly cash benefits to former workers now unable to work for at least a year due to disability; and the Supplemental Security Income (SSI) program, which provides benefits to disabled persons who meet financial need criteria. Former workers are eligible for

SSDI if they have earned a sufficient number of work credits while working in the past, based on past contributions made to Social Security. What constitutes a credit is variable, as is number of credits required, and with workers aged 62 years or older requiring the greatest number of credits to qualify.

In this program, the physician must first determine whether an applicant is disabled. *Disability* is defined as not being able to do any substantial gainful work activity because of a medically determined physical or mental impairment, which is expected to last at least 12 months or which may result in death. The determination may be made based on information submitted by treating physicians and/or through an evaluation by an approved physician. There are strict eligibility criteria. The categories of impairments of the respiratory system and an overview of the impairment criteria are listed in Table 27-8. The SSA outlines the specific tests and testing criteria, including quality considerations, which form the basis for the determination as to whether or not the degree of impairment would be expected to prevent an individual from working. Up-to-date Blue Book information can be freely accessed at the SSA website (http://www.ssa.gov/disability/professionals/bluebook/).

Programs in Which Physicians Primarily Determine Impairment

In addition to the programs outlined previously, there are programs that compensate workers for permanent impairment remaining after treatment of a medical condition that developed as a direct result of a workplace exposure or activity. A description of a few of these programs follows.

Workers' Compensation

State workers' compensation systems are state-specific, as they are governed by the rules and laws of each individual state. States began to adopt this European "no-fault" model in the early 1900s in a piecemeal manner.[45]

TABLE 27-8. Social Security Administration Respiratory System Impairment Categories and Criteria by Which to Establish Sufficient Impairment to Result in Disability

Category		Impairment Rating Criteria to Establish Disability
Chronic pulmonary insufficiency	Obstructive disease, any cause	Based on FEV_1 in liters (BTPS) and height without shoes (Table I)[1]
	Restrictive disease, any cause	Based on FVC in liters (BTPS) and height without shoes (Table II)[2]
	Pulmonary disease causing gas exchange abnormality	DL_{CO} < 10.5 ml/min/mm Hg, or DL_{CO} < 40% predicted, or ABG result based on P_{O_2} for a specified P_{CO_2}, at rest or steady state exercise ≤5 METS[3]
Asthma		Based on Table I criteria, or based on frequency of attacks[4]
Cystic fibrosis		As per COPD or based on frequency of infections or exacerbations[5] or based on infection treatment requirements[5]
Pneumoconiosis		Based on Table II criteria
Bronchiectasis		Based on Table II criteria or based on frequency of infections or exacerbations[6]
Mycobacterial, mycotic, or other chronic infection		Based on Table II criteria
Cor pulmonale	Secondary to pulmonary vascular hypertension	Mean pulmonary artery pressure > 40 mm Hg Arterial hypoxemia[3] or based on Section 4.02 (chronic heart failure)
Sleep disorders		As per cor pulmonale
Lung transplant		

ABG, arterial blood gas; BTPS, body temperature, ambient pressure, saturated with water vapor; COPD, chronic obstructive pulmonary disease; DL_{CO}, diffusing capacity for carbon monoxide; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; P_{CO_2}, pressure of carbon dioxide; P_{O_2}, pressure of oxygen.
Adapted from the Social Security Administration. Updated Blue Book information can be obtained on the SSA website (http://www.ssa.gov/disability/professionals/bluebook/) under the links to the Adult Listings, and the link to Section 3.00 Respiratory system.
[1]SSA Blue Book Section 3.02 Table I.
[2]SSA Blue Book Section 3.02 Table II.
[3]SSA Blue Book Section 3.02 Table III-A, III-B, or III-C, depending on altitude.
[4]Frequency of attacks, defined as occurring every 2 months or at least six times a year despite treatment. Attacks requiring in-patient hospitalizations are counted as two attacks.
[5]Infection treatment requirements, defined as persistent infection accompanied by bacterial infections occurring at least once every 6 months requiring intravenous or nebulization antimicrobial therapy.
[6]Frequency of infections or exacerbations, defined as number of episodes of bronchitis, pneumonia, hemoptysis, or respiratory failure requiring treatment occurring at least every 2 months or six times per year. In-patient hospitalizations are counted as two episodes.

This system affords employees the right to guaranteed treatment and benefits for an injury or illness that occurs "in the course and scope" of their work, regardless of fault, but in exchange for the ability to sue their employers for negligence.[46] The determination that a worker has a work-related condition is usually made by a physician on a medically probable basis, that is, it is at least 51% likely that work event caused or substantially worsened the condition or illness. Whereas the state workers' compensation systems remain highly variable from state to state, commonalities include employer funding of the system; coverage of medical treatment expenses; temporary wage replacement compensation, usually about two thirds of salary; vocational rehabilitation training (some states only); and compensation for permanent impairment that remains after the worker has completed medical treatment, that is, is at MMI. There is usually a statute of limitation, or a time period that a claim must be made after the worker has received a diagnosis of a work-related disease. In many states, the statute of limitations is 2 years.

The monies a worker may be paid in compensation for persistent permanent impairment of the respiratory system are usually based on the impairment rating provided by the physician. Most states designate the specific system by which permanent impairment is to be determined. Forty-four states and two commonwealths use the AMA *Guides*.[6a] Some states mandate the use of the "most recent" or "most current" edition, whereas others specifically mandate that the Fifth Edition, the Fourth Edition, or the Third Edition, revised be used. Some states, such as Minnesota, have developed their own guidelines for the rating of permanent impairment. Some states, such as Colorado, require that a physician have undergone training and become "accredited" before performing impairment evaluations. Because of the variability of the systems used, as well as concerns for validity and internal consistency within some editions of the *Guides* themselves,[47] significant variability exists in impairment ratings performed across the country.[48] Physicians should consult their state regulations or workers' compensation agencies to learn about the system and statutes used in their state.

There are other workers' compensation programs that cover specific workers groups. For example, the Office of Workers' Compensation (OWCP) administers medical treatment and benefits to current federal workers through the Federal Employees' Compensation Program, Department of Energy (DOE) workers through the EEOICP (as described in the next section), and through the Longshore and Harbor Workers' Compensation Program for workers in these industries. Under the Federal Employers' Liability Act (FELA), enacted in the beginning of the 20th century, federal railroad workers must establish that negligence of the railroad or other railroad personnel contributed to the injury or illness through a legal claim before full treatment and other benefits are awarded. If there is "contributory negligence" on the part of the worker, partial benefits are awarded. The Merchant Marine Act (Jones Act) is a similar system.

Veterans Administration

Department of Veterans Affairs provides medical care for military personnel who have a service-connected condition. Veterans who meet the service requirements and were discharged under other than dishonorable conditions may apply for compensation for disability due to service-connected conditions, defined as injury or illness incurred or aggravated during active military service. Veterans with disabilities can qualify for severance with disability pay or monthly disability compensation. Those veterans who are permanently and totally disabled or 65 years of age and older, had wartime service, and meet the financial eligibility requirement may receive a monthly pension.

Disability ratings are performed according to the Rating Schedule that contains over 700 diagnostic codes under 14 different body systems.[49] Although it is called a disability rating, the listed criteria reflect symptoms, impairment, and treatment requirements by which the rater determines the rating, given in 10% increments ranging from 0% to 100%, rather than a determination of ability or inability to work.

The respiratory system is divided into diseases of the nose and throat, diseases of the trachea and bronchi, and diseases of the lung and pleura. Veterans Affairs–affiliated and –designated physicians review medical records, and are asked to provide medical history, including current treatment requirements, physical examination findings, and results of diagnostic and clinical tests that support the diagnosis along with any associated conditions, and PFT results. The major criteria that the raters use in the determination of the disability rating for the specified respiratory diseases are shown in Table 27-9, adapted from the U.S. Department of Veteran's Affairs Web Automated Reference Materials Systems (WARMS) website, which contains the up-to-date Book C Schedule for Rating Disabilities.[49] Specific illnesses and medical conditions are presumed to be service-connected for select groups of veterans, including prisoners of war, veterans exposed to radiation, Vietnam veterans exposed to agent orange or other herbicides, and Gulf War veterans. These veterans are eligible for disability compensation for those conditions without burden of proof.

Energy Employees Occupational Illness Compensation Program

This is a federal program available as an adjunct or alternative to state workers' compensation for workers who were or are employed by or were subcontractors at DOE sites or who worked for businesses that functioned as vendors providing services or goods for the DOE. The compensation program is outlined in the EEOICP Act of 2000, as amended (EEOICPA or Act), which also established the DOL's responsibility for the administration of this program.[50] Part B of the Act provides compensation to current and former workers who meet DOL criteria for beryllium sensitization, chronic beryllium disease

TABLE 27-9. Veterans Administration: Specific Lower Respiratory Diseases for Which Veterans May Be Eligible for Service-Related Disability and General Criteria Used

Disease	Rating Based on the Following Criteria
Bronchitis, chronic	FEV_1, FEV_1/FVC, DL_{CO}
Bronchiectasis	Cough frequency, number and frequency of infections requiring antibiotics and incapacitating episodes per year
Bronchial asthma	Frequency and type of treatment, physician visits, severity of attacks, FEV_1, FEV_1/FVC
COPD, emphysema	FEV_1, FEV_1/FVC, DL_{CO}, $\dot{V}O_2$max (with cardiorespiratory limit), use of oxygen, evidence of secondary cardiovascular dysfunction[4]
TB	Active vs. inactive disease, respiratory status, x-ray findings, residual lung disease, thoracoplasty
Pulmonary vascular disease	Pulmonary embolism with residual symptoms, ongoing treatment needs, IVC surgery, evidence of secondary cardiovascular dysfunction[4]
Neoplasm	If in remission 6 months after ending treatment, rating will be reassessed and may decrease from 100% based on residuals.
ILD[1]	FVC, DL_{CO}, $\dot{V}O_2$max (with cardiorespiratory limit), evidence of secondary cardiovascular dysfunction,[4] use of oxygen
Mycotic lung disease[2]	Active vs. inactive disease, respiratory symptoms, constitutional symptoms
Restrictive lung diseases[3]	FEV_1, FEV_1/FVC, DL_{CO}, $\dot{V}O_2$max (with cardiorespiratory limit), use of oxygen, evidence of secondary cardiovascular dysfunction[4]
Sarcoidosis	Radiographic involvement, frequency and type of treatment, cardiac involvement, respiratory and systemic symptoms
Sleep apnea	Sleep study results, symptoms, CPAP treatment, respiratory failure

[1]ILD: diffuse interstitial fibrosis, DIP, pulmonary alveolar proteinosis, drug-induced pulmonary pneumonitis and fibrosis, radiation-induced pulmonary pneumonitis and fibrosis, HP, pneumoconiosis (silicosis, anthracosis), asbestosis.

[2]Mycotic lung disease: histoplasmosis, coccidiomycosis, blastomycosis, cryptococcosis, aspergillosis, mucormycosis.

[3]Restrictive lung diseases: diaphragm paralysis/paresis, spinal cord injury with respiratory insufficiency, chest wall deformities, postsurgical residua, chronic pleural fibrosis or effusions.

[4]Evidence of secondary cardiovascular dysfunction: evidence of cor pulmonale, RVH, or pulmonary hypertension.

COPD, chronic obstructive pulmonary disease; CPAP, continuous positive airway pressure; DIP, desquamative interstitial pneumonia; DL_{CO}, diffusing capacity for carbon monoxide; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; HP, hypersensitivity pneumonitis; ILD, interstitial lung disease; IVC, inferior vena cava; RVH, right ventricular hypertrophy; TB, tuberculosis; $\dot{V}O_2$max, maximal oxygen consumption.

Veteran's Affairs Web Automated Reference Materials Systems (WARMS) website: http://www.warms.vba.va.gov/regs/38CFR/BOOKC/PART4/S4_97.DOC (Accessed June 15, 2008).

TABLE 27-10. EEOICPA Part B Requirements for Eligibility and Diagnosis under the Act for Beryllium-Related Illness and Silicosis*

Condition	Eligible Workers	Requirements for Diagnosis under Part B
Beryllium sensitization	See Chronic beryllium disease	Abnormal Beryllium Lymphocyte Proliferation test (BeLPT) performed on blood or BAL cells
Chronic beryllium disease	Employees of the DOE, its predecessor agencies, contractors, and subcontractors, designated atomic weapons workers, and beryllium vendors.	For diagnoses made on or after 1/01/1993† An abnormal BeLPT and at least one of the following: 1. Lung biopsy showing a process consistent with CBD. 2. A CT scan showing changes consistent with CBD. 3. A pulmonary function or exercise tolerance test showing pulmonary deficits consistent with CBD.
Chronic silicosis	DOE employee or contractor who worked at least 250 days in underground tunnel operations at the Nevada or Alaska nuclear test sites.	One of the following: 1. A chest x-ray B-reading confirming pneumoconiosis with a profusion score of 1/0 or greater. 2. Results from a CT or other imaging study consistent with silicosis. 3. A lung biopsy consistent with silicosis.

*The final decision as to whether or not the patient meets the requirements is made by the Department of Labor.

†If the diagnosis was made before 1/01/1993, at least three of the following must be documented: characteristic chest radiograph or CT scan denoting abnormalities; a test showing restrictive, obstructive, or diffusion abnormality; lung pathology consistent with CBD; a clinical course consistent with a chronic respiratory disorder; an immunologic test showing beryllium sensitivity (skin patch test or beryllium test preferred).

BAL, bronchoalveolar lavage; CBD, chronic beryllium disease; CT, computed tomography; DOE, U.S. Department of Energy; EEOICPA, Energy Employees Occupational Illness Compensation Program.

Adapted from U.S. Department of Labor Medical Requirements under the Energy Employees Occupational Illness Compensation Program Act OMB No. 1215-0197 Expiration date: 08/31/2010 Form EE-7 April 2005.

(CBD) and silicosis (Table 27-10). Individuals with beryllium sensitization are awarded medical monitoring for possible progression to CBD, whereas those with CBD and silicosis are awarded medical evaluation to follow-up and monitor disease, and coverage of medications and consequential illness evaluation and treatment as needed, along with a one-time lump-sum payment of $150,000.

DOE employees, contractors, and subcontractors and atomic weapons employees diagnosed with cancer are compensated in a manner similar to that of CBD and silicosis, if that cancer is determined to have developed

as a result of working at a covered facility, based on DOL criteria. Members of special cohorts, composed of workers at specific sites during certain time periods, are afforded compensation for specific cancers without further burden of proof. The Radiation Exposure Commission Act (RECA) provides compensation to individuals who develop these specific cancers and other serious diseases as a result of exposure to radiation during above-ground nuclear weapons testing or during work as uranium miners, millers, and ore transporters. Eligibility is largely determined on the basis of having worked in certain locations during specified periods of time, a minimum duration of exposure, and having a specific type of cancer. A lump-sum payment and medical expenses will be awarded to individuals who have been awarded compensation by the Department of Justice (DOJ). Because the DOL makes the final determination as to whether or not the worker meets the requirements for the diagnosis, the evaluating physician should clearly document the history of the claimed illness(es), physical examination findings, the clinical testing data supporting the diagnosis, and the date the illness was first documented. Consequential illness or injury may be accepted if sufficient medical documentation of its relationship to the covered illness is submitted. There are provisions for survivor eligibility provided as part of this compensation program.

The EEOICP Act established Part E, and replaced Part D, a program that had been administered by the DOE in which panels of physicians made medical determinations as to whether or not a particular illness was related to DOE work. Under Part E, DOE employees, contractors, and subcontractors, as well as eligible RECA claimants, are awarded payment of medical expenses, as well as a maximum of $250,000 compensation for permanent impairment and loss of wages, if they are determined to have developed an illness as a result of occupational exposure to a toxic substance at a covered DOE facility. Workers with conditions accepted under Part B will be automatically accepted under Part E for compensation for impairment. Unfortunately, DOE vendors are eligible under Part B but are not eligible for compensation under Part E. There is survivor eligibility provided under Part E. Impairment ratings may be performed by physicians who are certified by the American Board of Independent Medical Examiners (ABIME) or American Academy of Disability Evaluating Physicians (AADEP), or who are otherwise considered by the DOL to have the requisite experience or knowledge. Not all physicians approved to provide care for workers under Part B of the program are eligible to provide impairment ratings under Part E. Physicians will be asked to submit such credentials for approval by the DOL to confirm their ability to provide impairment ratings. Alternatively, medical consultants to the DOL may perform the ratings. Currently, the ratings are still performed under the AMA *Guides*, Fifth Edition, which had been the most recent edition at the time the legislation was passed. Each percent whole-person impairment determined through an impairment rating is compensated $2,500. Compensation for lost wages is based on the number of years that the employee was unable to work or sustained a reduction in wages because of the illness up to 65 years of age.

The Americans with Disabilities Act

The ADA of 1990 prohibits discrimination against a qualified individual with a *disability*, defined as "a physical or mental impairment that substantially limits a major life activity."[51] Some, but not all, individuals with permanent respiratory impairment will meet the ADA definition of disability, depending on whether or not the impairment is severe enough to "substantially limit a major life activity." "Substantially limits" means being unable to perform or significantly restricted in performing a major life activity that the average person in the general population can perform.[52] Major life activities include, but are not limited to, functions such as caring for oneself, performing manual tasks, walking, seeing, hearing, speaking, breathing, learning, and working. The act applies to individuals who have, have a record of, or are regarded as having a physical or mental impairment. A qualified individual is a person who has the requisite skills and experience to do the job and "can perform the essential job tasks with or without reasonable accommodation" without risk of direct threat to self or others. Knowing what the essential job tasks are and what is required to do them physically is essential for the physician to be able to make this determination. This information is often contained in the workers' position description. The worker's job title typically provides insufficient information.

Essential job tasks are defined as the specific functions that an individual in that position must be able to perform without aid or with the assistance of reasonable accommodation. Factors involved in determining whether or not a job activity is an "essential function" include whether or not all employees in the position are required to perform the task, the position exists to perform the function, the frequency and duration of the job function, and whether or not there are other employees available and qualified to perform the function. A "preemployment" physical is not permitted under the ADA; an employer may not ask questions about disability or require a medical examination until after a conditional job offer has been made. A postoffer, preplacement medical evaluation is permitted, as long as: the employer does this for all employees entering the same job category; if doing so is job-related and consistent with business necessity, based on objective evidence that a worker will be unable to perform essential job functions or will pose a direct threat because of a medical condition; or when an employer receives a request for reasonable accommodation and the disability or the need for the accommodation is not obvious.

Reasonable accommodation is defined as a modification or adjustment to the job, work environment, or the way things are usually done that enables a person with a disability to perform the essential job function. Physicians may suggest means by which reasonable accommodation may be made, but the employer decides whether or not the accommodation is reasonable on a case-by-case basis. Examples of reasonable accommoda-

tion for individuals with respiratory impairment can include modification of the workstation to allow use of a wheelchair, scooter, or oxygen equipment; decreasing the need to travel distances, lift or push objects; and/or allowing written rather than lengthy verbal communication. A direct threat occurs when an individual poses a significant risk of substantial harm to the health or safety of herself/himself or others, and the risk cannot be reduced to an acceptable level with reasonable accommodation. The risk needs to be defined in terms of the specific behavior or physical limitation that would pose the direct threat, the duration of the risk, the nature and severity of the potential harm, and the likelihood and imminence of the potential harm. An example of direct threat would be use of oxygen in an area with open flames or sparking materials.

FUTURE DIRECTIONS

International Classification of Functioning, Disability, and Health

The WHO's ICIDH model was recognized as problematic in a number of respects, including an implied unidirectional relationship from impairment to handicap, limited definition of the role of the environment, and focus on the disablement, rather than on factors that may enable. The WHO put forth the International Classification of Functioning, Disability, and Health (ICF) in 2001,[4] designed to be used in conjunction with International Classification of Diseases (ICD)–10 codes to put forth a uniform description of health and well-being in two parts.

Part 1 is the part most relevant to most physicians, and combines the consideration of body structure and function, activities, and participation into a unified concept. Essentially, the term *functioning* combines the positive aspects of body functions, activities, and participation, whereas the term *disability* is now used to describe the combination the negative aspects of functional loss (impairment), activity limitation (disability), and participation restriction (handicap).

Part 2 consists of Contextual Factors, divided into personal factors, such as age, education, attitudes, and environmental factors. *Facilitators* are contextual factors that enhance functioning and *barriers* are contextual factors that restrict or limit functioning. As its purpose is to serve as a method to describe functioning and disability in a uniform manner across a wide range of medical disorders on the international level, it certainly holds promise as a system that may improve the reliability, accuracy, and validity of determinations of impairment compared with the systems currently in use, although the only major impairment rating system that references the ICF is the AMA *Guides*, Sixth Edition, which is not yet in widespread use.

American Medical Association *Guides*, Sixth Edition

The methodology for rating general respiratory impairment in the AMA *Guides*, Sixth Edition, is shown in Table 27-11. Based on the "key factor," which is an objective test result (spirometry, DL_{CO}, or $\dot{V}o_2max$), the individual is placed into one of five classes of impairment and assigned the default amount of impairment in the middle of that category. "Non-key factors," such as functional history and physical examination, are then considered, which may or may not serve to move the individual into the higher or lower range of impairment for that category, which determines the final percent whole-person impairment. One major change is that the maximum whole-person impairment for most respiratory disorders is 65% whole-person impairment, rather than 100% whole-person impairment in previous editions, although this impairment may still be combined with impairment in other organ systems.

Americans with Disabilities Act Amendments Act of 2008

The ADA Amendments Act of 2008[53] has just been implemented. This amendment effectively expands the

TABLE 27-11. Overview of AMA *Guides*, 6th Edition, Impairment Rating Scheme, Based on the WHO International Classification of Functioning, Disability, and Health (ICF) Model

Class	Description	Default Impairment (% Whole Person)*	Range of Impairment (% Whole Person)†
0	No symptoms or intermittent symptoms not requiring treatment	0	0
1	Minimal	6	2,4,6,8,10
2	Mild	17	11,14,17,20,23
3	Moderate	32	24,28,32,36,40
4	Severe	55	45,50,55,60,65

*Based on "Key Factor" (spirometry, DL_{COsb}, or $\dot{V}o_2max$).
†Possible final impairment after consideration of "Non-key Factors" (functional history and physical examination findings).
AMA, American Medical Association; DL_{COsb}, single-breath diffusing capacity; $\dot{V}o_2max$, maximal oxygen consumption; WHO, World Health Organization.

number of workers who will qualify for coverage under the Act. While retaining the original definitions of disability, it expands the definition of "major life activities," to include activities such as sleeping, standing, lifting, bending, concentrating, communicating, thinking, and working.[54] A list of "major bodily functions" are now included, such as functions of the immune system, normal cell growth, and respiratory. A disease that causes intermittent impairment or that is in remission is considered a disability if it would substantially limit a major life activity when active. The impact of these changes on Equal Employment Opportunity Commission (EEOC) enforcement guidance and the resulting changes in the workplace have yet to be determined.

KEY POINTS

- *Impairment* refers to the degree of loss of normal use or function of a body part or organ.
- *Disability* refers to any resulting alteration in the individual's capacity to perform customary activities.
- *Handicap* refers to the societal disadvantage caused by the impairment or disability, unless obstacles to performing customary activities can be overcome by means of accommodation or compensation.
- *MMI* is the time at which permanent impairment can be assessed. It is achieved when the diagnosis has been well defined, the condition is stable, and medical treatment has either optimized or reasonable options have been exhausted.
- The *Americans with Disabilities Act of 1990* prohibits discrimination against a qualified individual with a disability, defined as "a physical or mental impairment that substantially limits a major life activity." The definition of major life activities was greatly expanded and a list of "major bodily functions" was added through the ADA Amendments Act of 2008.
- *Reasonable accommodation* is defined as a modification or adjustment to the job, work environment, or the way things are usually done that enables a person with a disability to perform an essential job function.
- An *impairment evaluation* is a medical evaluation. The essential elements that compose an impairment evaluation will vary to some degree according to the program or system through which the evaluation is being performed. Standard components typically include history, including a detailed occupational and environmental history and description of limitations in ADLs; physical examination; and review of medical records and diagnostic test results that establish the respiratory condition. If the worker is at maximum medical improvement (MMI), a permanent impairment rating can be performed. The physician may be asked to address causation, which is usually the disease relationship to workplace exposures, the need for work restrictions, future medical needs, and possibly apportionment of impairment.
- An *impairment rating* is a numeric value from 0% to 100% that represents the percent loss of total body function due to the respiratory system. This numeric value helps form the basis for the monetary award given to workers with permanent impairment that remains after reaching MMI.
- *Workers' compensation* is the system through which employees are afforded guaranteed treatment and benefits for an injury or illness that occurs "in the course and scope" of their work. Whereas the state workers' compensation systems remain highly variable from state to state, commonalities include employer funding of the system; coverage of medical treatment expenses; temporary wage replacement compensation, usually about two thirds of salary; vocational rehabilitation training (some states only); and compensation for permanent impairment. Separate federal workers' compensation programs exist, which also vary considerably program to program.
- Specific benefit and compensation programs exist for certain groups of workers, including miners, DOE workers, veterans, and radiation-exposed workers.

Role of Exercise Training in Relieving Dyspnea

Relief of Dyspnea in End-Stage Lung Disease

INTRODUCTION

Dyspnea (Greek *dys,* meaning "painful," "difficult," and *pneuma,* meaning "breath") is a clinical term for the sensation of breathlessness or shortness of breath experienced by both normal subjects and patients with diseases affecting the respiratory system. Its importance has been recognized by the release of an American Thoracic Society Statement[1] and, more recently, a roundtable discussion by experts in the field.[2] Dyspnea assumes clinical significance when it occurs at a level of exertion that is unacceptably low for the individual. It is increasingly regarded as an important outcome for both prognostic and therapeutic purposes across a wide range of clinical conditions and principally chronic obstructive pulmonary disease (COPD),[3] heart failure,[4] and advanced cancer.[5]

There are no precise data on the prevalence of dyspnea.[6] A recent meta-analysis suggests a worldwide prevalence of 10% for COPD in adults older than 40 years,[7] making its cardinal symptom, dyspnea, a substantial cause of morbidity, especially in older people. A greater prevalence of dyspnea due to all causes is indicated by a survey of 4900 middle-aged and older adults with 27.2% reporting dyspnea relative to 12.5% reporting COPD.[6] A survey of 1556 seriously ill patients admitted to hospital 49% reported dyspnea compared with the 51% reporting pain.[8] Morbidity associated with dyspnea is variable, ranging from minor annoyance to functional incapacity.[9] Moreover, it is now clear that dyspnea is a strong independent predicator of mortality in both COPD[10] and heart failure.[11] Compared with pain, dyspnea is relatively refractory to effective symptom management, likely affecting not only patients but also their care providers (including health professionals) during terminal or severe chronic conditions.[12]

Dyspnea encompasses a variety of sensations experienced when breathing feels uncomfortable, labored, and unsatisfying,[1] sensations likely to be linked to discrete physiologic mechanisms.[13] It is distinct from objective findings associated with physical examination, such as tachypnea, hyperinflation, and cyanosis. Dyspnea is multifactorial, and although it results from some pathophysiologic event, it is likely to be influenced by such factors as psychological state, bodily preoccupation, level of awareness, usual level of physical activity, body weight, state of nutrition, and medications. These many modifying factors may explain the variable correlation between dyspnea ratings and airflow limitation or exercise performance.[13] Because most diseases in

which dyspnea occurs are essentially irreversible (e.g., chronic lung disease, heart failure, cancer), management of the dyspnea to improve quality of life is a desirable goal.

DEFINITION OF DYSPNEA

Over the years, there have been many attempts to define dyspnea and these have shared a common theme of an uncomfortable perception associated with the act of breathing. However, the more formalized definition given in the consensus statement of the American Thoracic Society is now widely accepted and has provided a sound basis for researchers and clinicians concerned with understanding and managing this symptom.[1] This states that "*Dyspnea* is a term used to characterize a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiological, psychological, social, and environmental factors, and it may induce secondary physiological and behavioral responses."

LANGUAGE OF DYSPNEA

When patients complain of being short of breath, they are usually reporting sensations with which they are familiar but that have become noticeable on low levels of exertion. When questioned further, patients may volunteer comments such as "hard to breathe," "can't get enough air," or "feeling tight" but often have difficulty being more specific. Overlaying this, cultural or language differences may result in patients using different words to describe the same sensory experience.[14] Modeled on the proven clinical utility of evaluating the language of pain (e.g., assessing ischemic heart disease), researchers have begun to ask if the language of dyspnea might be similarly useful.

Since the early 1980s, studies in healthy subjects and dyspneic patients have identified distinctive clusters of descriptors from commonly used expressions of breathing discomfort. In general, four primary categories of breathing discomfort can be identified: "tightness," "need or urge to breathe," (often labeled "air hunger"), "work or effort of breathing," and "depth and frequency of breathing." In patient populations, "tightness" appears to be clearly associated with asthma, whereas "urge to breathe" and "effort of breathing" are more characteristic of chronic lung disease. The perception of changes in breathing depth and frequency probably relates more to awareness of chest wall movement than to awareness of breathing discomfort but may nonetheless be worrisome to the patient.

Although there are few cross-cultural studies of the language of dyspnea, the basic categories of phrases noted previously appear consistent across countries.[13] A summary of studies that have defined and explored the utility of qualitative descriptors of dyspnea has recently been published.[13] Recently, the pain model of symptom attributes has been further applied to explore the importance of the affective component (i.e., unpleasantness) of dyspnea in addition to its intensity and quality. One publication has summarized existing research in this area and reported that for a given intensity of dyspnea, that with a greater "air hunger" component is perceived as a substantially more unpleasant experience than that with a strong "work/effort" component.[15] These authors have developed a multidimensional profile for dyspnea, based on an analogous instrument for pain, which should be useful in better understanding the affective component of dyspnea with a view to developing more targeted therapeutic approaches.[15] In conclusion, it seems that a more careful consideration of the language and emotional impact of dyspnea by health practitioners might yield important diagnostic insights or improved management of breathless patients.

MECHANISMS OF DYSPNEA

The neurophysiologic mechanisms that give rise to the perception of dyspnea are incompletely understood (Fig. 28-1). Current thinking suggests that the discomfort of dyspnea comprises two primary components: (1) an "urge to breathe" (often referred to as "air hunger") and (2) a "sense of excessive effort" associated with breathing. Although sensations of effort and urge to breathe normally increase together, they can be separated experimentally.[16] A third quality of respiratory discomfort, chest tightness, is commonly reported by asthmatics.[17] Dyspnea in an individual patient may well represent

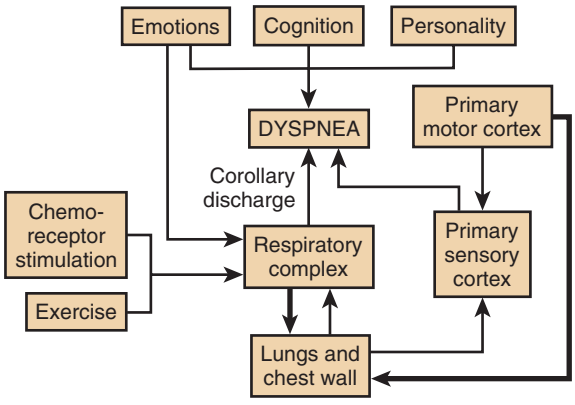

FIGURE 28-1 ■ The respiratory complex in the brain stem is central to our understanding of dyspnea. Activation of the respiratory complex by afferent input from a variety of receptors or by emotions, with input from the lungs and chest wall, determines the efferent command to breathe to the lungs and chest wall. The brain is made aware of this as dyspnea by a simultaneous corollary discharge. Alternatively, ventilation may occur as a result of voluntary output from the primary motor cortex with coactivation of the primary sensory cortex, which contributes to dyspnea. The primary sensory cortex also receives input from the lungs and chest wall that may affect the perception of dyspnea. The central experience of dyspnea may also be affected by emotions, cognition, and personality.

a combination of these component sensations and account for the different qualities of dyspnea mentioned previously.

As with all sensations, the experience of dyspnea must result from changes in neural activity within the cortical structures of the brain that are responsible for sensory perception. Unlike localized sensations, such as touch and temperature, that arise predominantly from peripheral receptor stimulation, dyspnea is a vague visceral sensation analogous to thirst or hunger, sensations that are more dependent on neural activity arising from within the central nervous system. Indeed, dyspnea arises in situations (e.g., exercise, breath-holding, anemia) that do not have a common pattern of peripheral receptor stimulation. Because dyspnea is a perception, studies on its mechanisms must be confined to humans and are limited by the difficulty of measuring a subjective experience and the neural activity that underlies it. New technologies, principally positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), allow imaging of brain function associated with sensory, motor, and cognitive processes, and in recent years, these have been applied to identify the neural basis of dyspnea perception in healthy subjects. Different investigators have induced dyspnea in different ways, with varying degrees of "urge to breathe" and "sense of effort." Despite this, a consistent pattern of neural activity associated with dyspnea perception is emerging from these studies. Of particular note is the activation of limbic and paralimbic structures, especially the anterior insular cortex, anterior cingulate gyrus, amygdale, and cerebellum. Activation of these phylogenically ancient regions of the cerebral cortex has been seen in brain imaging studies of pain,[18] thirst,[19] and hunger[20] and is consistent with the idea that dyspnea is a primal experience associated with behaviors intended to counteract a threat to survival.[21,22] This body of work has been the subject of a review.[23]

There is good evidence that the "urge to breathe" component of the dyspnea sensation depends to a large extent on the degree to which respiratory-related neurons in the brain stem are stimulated. Stimulation of ventilation with exercise, hypoxia, hypercapnia, and metabolic acidosis induces dyspnea[24,25] whereas a voluntary increase in ventilation induces little dyspnea, even in patients with respiratory mechanical limitation.[26] Moreover, dyspnea is felt strongly when respiratory stimulation occurs in the absence of a possible ventilatory response, as with transaction experimental respiratory muscle paralysis.[27,28] By contrast, the "sense of effort" aspect of dyspnea is likely to reflect efferent activity from the motor area of the cerebral cortex to respiratory muscles, as has been demonstrated for perception of peripheral muscle function in general.[13]

The role of afferent feedback from the lungs and chest wall in the genesis of dyspnea is complex. Conditions thought to activate lung irritant receptors and/or pulmonary C-fibers (e.g., pulmonary edema, atelectasis, congestive heart failure) may well contribute to dyspnea via vagal nerve afferents either directly or by modulating other sensory inputs that give rise to dyspnea.[28] Conversely, physiologic activation of slowly adapting stretch receptors (SARs) during lung inflation may inhibit the central respiratory drive and in this way ameliorate dyspnea. The immediate relief of dyspnea observed with thoracic movements following breath-holding but without improvements in blood gas status is consistent with this concept.[29]

In their recent review of the roles of airway nerves in inflammatory airway disease, Undem and Nassenstein[28] implicate vagal mechanisms in the production of dyspnea, both directly by neural signaling and indirectly by increasing the work of breathing via the release of acetylcholine (which stimulates airway smooth muscle contraction and mucus secretion). Nishino[30] suggested that vagal mechanisms associated with coughing affected the sensation of dyspnea, although the author agreed that other neural mechanisms could play roles. Further support for this comes from the observation in quadriplegic patients (lacking afferent information from the chest wall) that carbon dioxide–induced dyspnea is reduced as the tidal volume is increased without any change in blood gas levels.[31] Moreover, recent studies of inhaled furosemide (which potentiates SAR activity in an animal model) on experimental dyspnea in healthy subjects[32] and exertional dyspnea in COPD patients[33] have shown evidence of amelioration of the dyspneic sensation. With respect to "sense of effort" proprioceptive feedback from muscle, joint, and metaboreceptors probably integrates with the motor cortical output in the genesis of this perception.[13]

In light of the previous discussion, exertional dyspnea in patients with lung disease can usefully be considered a manifestation of the increased central respiratory drive necessary to achieve adequate ventilation by a mechanically constrained respiratory apparatus. This concept fits with the observation that in COPD patients, progressive hyperinflation is associated with increasing dyspnea as ventilatory demands require greater respiratory muscle activity to overcome increased elastic work at high lung volumes and to offset the foreshortening of inspiratory muscles that places them at a mechanical disadvantage.[13] Following from this, the lessening of dyspnea that follows successful lung volume reduction surgery is consistent with improvement in both lung and respiratory muscle mechanics. Support of this concept comes from a study showing that a decrease in dyspnea after volume reduction was associated with alleviation of hyperinflation of the lungs and a decrease in neural drive to the diaphragm.[34] Moreover, the concept is supported by the observation that noninvasive ventilatory support during exercise relieves dyspnea in patients with COPD,[34] presumably by reducing the work of breathing and consequently the efferent neural activity to respiratory muscles. The utility of this concept of dyspneogenesis extends to conditions in which lung disease is not the primary problem. In particular, the dyspnea of heart failure might be accounted for in terms of a heightened respiratory drive secondary to expiratory flow limitation[35] or peripheral muscle dysfunction.[36] A similar phenomenon may occur with deconditioning. The benefits of exercise training for those with dyspnea may be mediated in

part by changes in peripheral muscle function. Other conditions in which dyspnea in the absence of lung disease could be accounted for by increased respiratory drive include motoneuron disease/respiratory muscle weakness,[37] late-stage pregnancy,[38] anemia,[39] thyroid disorders, panic disorder, and anxiety.[40]

The sensation of dyspnea, like pain, has a psychological dimension.[41] An individual's emotional state, personality, previous experience, and cognitive function are likely to influence the experience and reporting of dyspnea. Dyspnea is worse when it is unexpected, when it occurs in inappropriate situations, and when it is perceived by the patient to be dangerous.[42] Studies in both healthy subjects and patients with underlying disease have suggested that perception of the intensity of breathlessness may be influenced by prior experience of the sensation.[43,44] Whether such observations are related to the frequency of prior experience of dyspnea (e.g., with exercise) or to some ill-defined psychological factor is unknown. In patients with the hyperventilation syndrome, both dyspnea and ventilation may dramatically increase in the absence of any known physiologic stimulus to breathe.[40] Dyspnea is a particular problem in patients with panic attacks. An Internet-based survey found that 95% of the respondents reported breathing problems during panic attacks, and 68% reported "remarkable" dyspnea.[45] An interesting example of clinically significant activity-related breathlessness in healthy human pregnancy is reported.[46] Jensen and colleagues[46] reported that variability in perceptual response to exercise could not be explained by variation in central ventilatory drive or in respiratory mechanical/muscular factors, but ultimately reflected a difference in awareness of increased ventilation. The source of that variation in perception is not clear. O'Donnell and coworkers[2] have recently reviewed the role of "higher center" neural processing on dyspnea perception and its relevance to self-management of this symptom.

In sum, dyspnea may occur when there is (1) increased central respiratory drive secondary to hypoxia, hypercapnia, or other afferent input; (2) augmented requirement for the respiratory drive to overcome mechanical constraints or weakness; and (3) altered central perception.

ASSESSMENT OF DYSPNEA

Clinicians generally rely on a combination of patients' reports and physiologic measurements (e.g., forced expiratory volume in 1 second [FEV_1]) to evaluate dyspnea. By assessing the nature and severity of symptoms, such as dyspnea, physicians quickly gain an advantage in the decision-making process. With a better understanding of the physiologic basis of symptoms, physicians can target the types and extent of diagnostic testing as well as the urgency with which a diagnosis must be made. Understanding the mechanisms of dyspnea or the responses to interventions, however, requires objective measurement of the symptom. Although primarily used for clinical investigation, there is increasing interest in applying dyspnea measurements to clinical practice.[47] For a recent review of factors that limit exercise performance in COPD and the identification of factors that contribute to the variability in dyspnea during exercise, see Stendardi and associates.[48] O'Donnell and coworkers[13] present a hypothetical model for exertional dyspnea based on current neurophysiologic concepts that were developed to explain the origins of "effort," "air hunger," and the accompanying affective "distress" response.

Exercise Performance as an Indication of Dyspnea

Exercise testing is commonly used to better understand dyspnea,[49] although there are discrepancies in the available diagnostic algorithms.[50] This form of testing focuses more on physiologic limitations than on the symptoms that limit exercise and might not be necessary for all patient groups. Two widely used field tests are the 6-minute walk distance and shuttle walking tests,[51] which are easy to perform, requiring minimal equipment; more sophisticated cardiopulmonary exercise testing (CPET) can be particularly helpful when it is unclear whether the patient is limited by the respiratory versus the cardiovascular system.[52]

Exercise Limitation Due to Dyspnea

Early attempts to evaluate the severity of dyspnea involved patient assessments of their own exercise tolerance (e.g., the five-point Medical Research Council [MRC] scale[53] and its modified version the American Thoracic Society [ATS] scale). Although such scales are simple, they are insensitive, require individuals to make comparisons with others, and cannot readily measure changes with therapeutic interventions. The Baseline Dyspnea Index, a rater-administered test, was developed to rate patients with regard not only to the "magnitude of the task" that elicits dyspnea (e.g., hills compared with level ground) but also to the impact of dyspnea on activities of daily living and the effort expended before dyspnea occurs.[54] Measurements can be repeated over time or in response to interventions. A number of easy-to-use self-administered questionnaires to assess functional limitation due to dyspnea have been developed but in general have not found widespread use.[55]

Quality of Life and Dyspnea

The negative impact of dyspnea on an individual's quality of life has been increasingly recognized since the mid 1980s and now is an important outcome measure in studies of therapeutic intervention for COPD/dyspnea. Two questionnaires, the St. George's Respiratory Questionnaire (SGRQ) and the Chronic Respiratory Disease Questionnaire (CRQ), are the most used. The CRQ is a rater-administered questionnaire with 20 items that focus on four aspects of illness: dyspnea, fatigue, emotional function, and the patient's feeling of control over

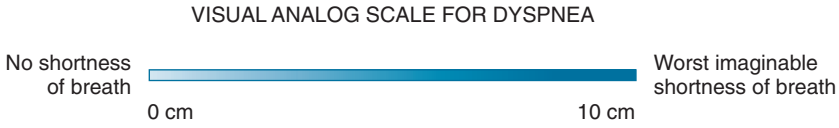

FIGURE 28-2 ■ Visual analogue scales, such as the horizontal one shown here, can be used for measuring dyspnea during an activity (e.g., exercise testing) or in response to questions. Such scales may be depicted vertically as well. On request, the subject marks a point on the line in response to a question (e.g., How short of breath are you right now?). The score is determined by the length of the line from "no shortness of breath" to the point marked by the patient. The scales are usually 10 cm long to facilitate scoring, and electronic scales may be used to allow online scoring (e.g., during exercise testing). Instructions about what is meant by the terms used to describe a sensation (e.g., "extremely breathless") must be clear and must be presented in a uniform fashion to provide meaningful result.

the disease.[56] Dyspnea is evaluated on a seven-point scale in relation to the five most important activities provoking dyspnea during the previous 2 weeks. The SGRQ is a self-administered questionnaire with 76 items addressing symptoms, activity, and the impact of disease on daily life. Dyspnea is not evaluated specifically but is included with other respiratory symptoms such as cough, sputum, and wheezing.[57] These instruments have been shown to be reasonably reproducible, to correlate with each other, and to relate appropriately to physiologic measurements.[58–60] Although important for clinical investigation, these tools are somewhat demanding to use, often requiring trained health personnel, and are of unproven value for routine clinical care.

Psychometric Measurement of Dyspnea

Several instruments are available for rating the symptom dyspnea directly; they allow reasonably reproducible rating of the intensity of dyspnea on a simple linear or numeric scale during exercise or in response to specific questions. The visual analogue scale (VAS) is a horizontal or vertical line, usually 10 cm long, anchored at either end with words such as "no dyspnea" and "maximal dyspnea" (Fig. 28-2). In response to a question (e.g., "How short of breath are you?"), the subject marks a point along the line so the length reflects the intensity of the sensation. The Borg Scale is a 10-point scale with extremes of "nothing at all" and "maximal."[61] Unlike the VAS, the Borg Scale (Table 28-1) includes verbal descriptors (e.g., "slight," "severe") to assist in rating the symptom. Both scales demonstrate good reproducibility,[62,63] but the proximity of the terms "slight" and "severe" on the Borg scale may reduce its sensitivity and discourage subjects from using the whole scale as they do with the VAS.[64] A valid approach, which has perhaps better clinical utility, has been to employ a simple numeric rating scale ranging from 0 to 10.[65] Additional scales continue to be developed.[55] Any of these validated instruments may be appropriate when designing research studies, but it is critical that they be administered in a standardized way. Recently, researchers have begun to extend dyspnea assessment beyond the intensity domain to explore the qualitative and affective components using a multidimensional dyspnea profile instrument,[15] modeled on an approach widely used in pain research.

TABLE 28-1. Modified Borg Category Scale for Rating Dyspnea

Rating	Intensity of Sensation
0	Nothing at all
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight
3	Moderate
4	Somewhat severe
5	Severe
6	
7	Very severe
8	
9	Very, very severe (almost maximal)
10	Maximal

DIAGNOSTIC APPROACH TO THE PATIENT WITH DYSPNEA

Overview: Physiologic Categories of Dyspnea

The differential diagnosis of dyspnea includes neuromuscular, renal, endocrine, rheumatologic, hematologic, and psychiatric diseases, as well as diseases of the lungs, heart, and chest wall. The diagnostic approach is determined by the acuity of the problem. For acute dyspnea, the differential diagnosis is relatively narrow and the cause is generally easily identified (e.g., pneumonia, pulmonary embolism, congestive heart failure, asthma), although psychogenic dyspnea or hyperventilation syndrome can pose a diagnostic challenge.[66] For subacute or chronic dyspnea, a systematic, physiologically based approach enables one to make sense of what otherwise becomes a long list of potential diagnoses.

At its core, the goal of the respiratory and cardiovascular systems is to take oxygen from the air we breathe, transfer it to hemoglobin, deliver it to metabolically active tissue, and transport carbon dioxide, the primary product of metabolism, back to the lung, where it can be eliminated. Dyspnea arises when this goal has not been met (and the patient becomes hypoxemic,

hypercapnic, and/or acidemic with consequent stimulation of the chemoreceptors), when achieving this goal produces stress within the cardiorespiratory system (e.g., increased work of breathing or elevated left ventricular and pulmonary capillary pressures, secondary to pathologic abnormalities), or because of direct stimulation of pulmonary receptors (e.g., irritant receptors, again resulting from a pathologic process). Ultimately, dyspnea can be conceived as originating from the respiratory or cardiovascular systems, including derangements in oxygen delivery, such as in anemia, and problems with uptake and utilization of oxygen, such as in mitochondrial disorders.

To facilitate a systematic approach to this problem, one can divide the process of respiration into three components:

1. A controller, which determines the rate and depth of breathing;
2. A ventilatory pump, which facilitates the movement of gas into and out of the alveolus; and
3. A gas exchanger, which consists of the pulmonary vasculature and the alveolus (Table 28-2).

Abnormalities in any one of these elements can lead to dyspnea. Similarly, one can consider the derangements of the cardiovascular system within three categories: conditions characterized by high cardiac output, normal cardiac output, and low cardiac output.

Diseases that mechanically interfere with ventilation (i.e., derangements of the ventilatory pump) increase the effort of breathing, whether because of narrowing of the airway or because of a change in the elastic properties of the lungs or chest wall. If the respiratory muscles are weakened, the effort of breathing seems greater because a larger fraction of maximal available muscle force is required. (This is analogous to peripheral muscle function, in which, for example, it would be more difficult to lift a weight after an arm has just been liberated from being in a cast.) Any stimulus of ventilation (e.g., exercise, hypoxia, acidosis, interstitial edema, pulmonary hypertension), which can be considered abnormalities of the controller, may provoke the sensation of dyspnea. Psychological dysfunction may cause or exaggerate dyspnea and is thought to be an alteration in behavioral control of breathing.[67] In many conditions, the origin of dyspnea is only partially understood (e.g., pulmonary embolism without hypoxemia) or is due to multiple factors (e.g., abnormalities of the ventilatory pump and gas exchanger in a patient with COPD).

History

A comprehensive medical history is important for a diagnosis of dyspnea.[68] It is important to identify

TABLE 28-2. Diseases that Cause Dyspnea Grouped by Physiological Mechanism of Action*

VENTILATORY CONTROLLER AND GAS EXCHANGER—INCREASED RESPIRATORY DRIVE
Simulation of Chemoreceptors
Conditions leading to acute hypoxemia
Impaired gas exchanger (e.g., asthma, pulmonary embolism, pneumonia, congestive heart failure†)
Environmental hypoxia (e.g., altitude, contained space with fire)
Conditions leading to increased dead space and/or acute hypercapnia
Impaired gas exchanger (e.g., acute, severe asthma, exacerbations of COPD, severe pulmonary edema)
Impaired ventilatory pump (see below) (e.g., muscle weakness, airflow obstruction)
Metabolic Acidosis
Renal disease (renal failure, renal tubular acidosis)
Decreased oxygen carrying capacity (e.g., anemia)
Decreased release of oxygen to tissues (e.g., hemoglobinopathy)
Decreased cardiac output
Stimulation of Pulmonary Receptors (Irritant, Mechanical, Vascular)‡
Interstitial lung disease
Pleural effusion (compressive atelectasis)
Pulmonary vascular disease (e.g., thromboembolism, idiopathic pulmonary hypertension)
Congestive heart failure
Mild asthma
Behavioral Factors
Hyperventilation syndrome, anxiety disorders, panic attacks
VENTILATORY PUMP—INCREASED EFFORT OR WORK OF BREATHING
Muscle Weakness
Myesthenia gravis, Guillain-Barré, spinal cord injury, myopathy, postpoliomyelitis syndrome
Decreased Compliance of the Chest Wall
Severe kyphoscoliosis, obesity, pleural effusion
Airflow Obstruction (Includes Increased Resistive Load from Narrowing of Airways and Increased Elastic Load from Hyperinflation)
Asthma, COPD, laryngospasm, aspiration of foreign body, bronchitis

*Some diseases appear in more than one category. They act via several physiologic mechanisms.
†Heart failure includes both systolic and diastolic dysfunction. Systolic dysfunction may produce dyspnea at rest and with activity. Diastolic dysfunction typically leads to symptoms primarily with exercise. In addition to the mechanisms noted above, systolic heart failure may also produce dyspnea via metaboreceptors; these are receptors that are postulated to lie in muscles and are stimulated by changes in the metabolic milieu of the tissue that result when oxygen delivery does not meet oxygen demand.
‡These conditions probably produce dyspnea by a combination of increased ventilatory drive and primary sensory input from the receptors.
COPD, chronic obstructive pulmonary disease.

activities that precipitate it and to understand its impact on the patient's life. Because decreased exercise tolerance may go unrecognized by the patient owing to alterations in lifestyle (e.g., a patient who develops dyspnea climbing stairs may move from a two-story house to a single-level apartment) that do not tax the respiratory and cardiovascular systems, input from close acquaintances may be helpful. Although most patients with severe lung disease report that their activities are limited by dyspnea, some patients are actually more limited by fatigue, weakness, joint pain, or chest pain than by dyspnea.

The key areas of inquiry are (1) quality of the symptom, (2) persistence or variability of the symptom, (3) aggravating or precipitating symptom. As noted previously (in the section on "Mechanisms of Dyspnea"), the sensation of "chest tightness" is commonly associated with bronchoconstriction, an increased sense of "effort or work of breathing" is typical of derangements of the ventilatory pump, and a sense of "air hunger" or "urge to breathe" is characteristic of problems that stimulate the respiratory controller. The sense of difficulty getting a deep breath may be associated with hyperinflation due to obstructive lung disease or with the hyperventilation syndrome.

Intermittent dyspnea is probably due to reversible conditions (e.g., bronchoconstriction, congestive heart failure, pleural effusion, acute pulmonary emboli, hyperventilation syndrome), whereas persistent or progressive dyspnea is more characteristic of chronic conditions (e.g., COPD, interstitial fibrosis, chronic pulmonary emboli, dysfunction of the diaphragm or chest wall). Nocturnal dyspnea may be brought on by asthma, congestive heart failure, gastroesophageal reflux,[69] obstructive sleep apnea, or even nasal obstruction. Dyspnea in the recumbent position is classically associated with left ventricular failure but may also occur with abdominal processes (e.g., ascites) or diaphragmatic dysfunction. Dyspnea that worsens in the upright position (i.e., platypnea) may be related to orthodeoxia, a decrease in arterial oxygen pressure (P_{O_2}) in the upright position, which occurs with cirrhosis, pulmonary arteriovenous malformations, or interatrial shunts.[70–73] Physical activity generally accentuates dyspnea of physiologic origin, as when ventilation is stimulated by lactic acid production at relatively low levels of exercise (e.g., anemia, cardiac disease, deconditioning). Dyspnea after exercise may be affected by a number of factors (e.g., activity, time of day, position, exposures, meals, medications). To the extent that post-exercise dyspnea may be mitigated by warm-up activities or use of inhaled bronchodilators, exercise-induced asthma should be considered. Although emotional states may affect dyspnea of any cause,[66] psychogenic dyspnea should be suspected when dyspnea varies on a daily or hourly basis, especially when it is unrelated to exertion or if litigation is involved.[67]

Recognition of factors that may precipitate (e.g., cigarettes, allergens, smog) or relieve (e.g., position, medications) breathlessness is helpful. Obesity may aggravate dyspnea because of increased metabolic and ventilatory demands as well as mechanical interference with chest movement.[74] Severe weight loss may weaken the respiratory muscles.[75] Symptoms of right ventricular failure (e.g., abdominal swelling, edema of the extremities) suggest hypoxemia, pulmonary vascular problems (e.g., pulmonary hypertension of any cause, obstructive sleep apnea), or left ventricular failure. Neuromuscular diseases, such as amyotrophic lateral sclerosis (ALS), may present with dyspnea as a result of respiratory muscle weakness.[76] Raynaud's phenomenon alone or in combination with skin, joint, or swallowing problems suggests collagen vascular disease.

Physical Examination

Pattern of breathing (e.g., splinting, use of pursed lips or accessory muscles), body habitus (e.g., cachexia, obesity), posture (e.g., leaning forward on elbows to recruit pectoralis muscles as ventilatory muscles, as in COPD), skeletal deformity, and emotional state may be important clues to the diagnosis. Cough on deep inspiration or expiration suggests asthma or interstitial lung disease. A generalized decrease in the intensity of breath sounds suggests emphysema or moderate to severe bronchoconstriction, whereas a localized decrease may occur in pneumothorax, pleural effusion, localized airway obstruction, or elevated hemidiaphragm of any cause. Forced expiratory maneuvers may elicit focal or diffuse wheezing. Cardiac examination may suggest pulmonary hypertension (e.g., right ventricular heave or prominent P_2) or right ventricular failure (e.g., jugular venous distention, right-sided S_3 gallop). Clubbing of the digits is an easily overlooked sign of many processes, notably cancer or purulent lung disease (e.g., bronchiectasis). Cyanosis, a bluish coloration of the perioral region or nails, indicates there are 5 gm of deoxygenated hemoglobin/100 mL of blood (note: hypoxemia in the presence of significant anemia may not cause cyanosis because of insufficient hemoglobin). Edema of the lower extremities suggests congestive heart failure if symmetrical and thromboembolic disease if asymmetrical. Assessment of the patient's emotional status may be helpful.[66]

If a patient's history includes a report that he or she develops dyspnea walking a short distance (e.g., ≤200 yards), one should consider walking the patient in a corridor near the examination room to elicit his or her symptoms. When dyspnea occurs, observe the patient, repeat the vital signs, reexamine the chest and heart, and check the oxygen saturation with pulse oximetry. The development of an abrupt increase pulse-pressure product, basilar crackles, or acute wheezing suggests a rapid increase in pulmonary capillary pressure and interstitial edema. Rapid shallow breathing may be a sign of stiff lungs or chest wall. Occasionally, the patient will walk farther than one would expect from the history; motivation and the inability of the patient to tolerate any respiratory discomfort may, in fact, be the cause of the patient's limitation. It is not uncommon for patients who lead extremely sedentary lives, especially if they have been told they have a condition that may cause shortness of breath, to equate any increase in ventilation as pathologic.

Laboratory Assessment

The laboratory is only occasionally of help in the diagnosis of dyspnea. Anemia of any cause may contribute to dyspnea. Polycythemia may be the only clue to chronic hypoxemia. Elevation of the erythrocyte sedimentation rate may suggest occult infection or autoimmune disease. A chemistry panel may reveal occult renal disease or acid-base derangement. More elaborate screening may uncover collagen vascular or thyroid disease. A new laboratory test, measurement of B-type natriuretic peptide (BNP), is finding wide acceptance in the differential diagnosis of acute dyspnea,[77,78] primarily in the emergency department setting.[79] The ventricle secretes BNP in response to elevated pressure. Therefore, it is usually elevated in patients with left ventricular failure or cor pulmonale but not in patients with exacerbations of obstructive lung disease. It has been shown to be more accurate than echocardiography in recognizing left ventricular dysfunction as a cause of acute dyspnea.[80]

The database should include chest radiography, spirometry, and possibly electrocardiography. Chest roentgenograms are useful when abnormal but are insensitive for detecting early obstructive and interstitial diseases; approximately 10% of patients with interstitial disease will have a normal chest radiograph. Computed tomography (CT) angiogram has become the standard modality for assessment of suspected thromboemoblic disease. Although it is not recommended as a general screening test, it can be used to assess for both occult interstitial lung disease and thromboemoblic disease in patients with evidence of gas-exchange abnormalities, for example, low diffusing capacity and/or hypoxemia at rest or with exercise (desaturation on exercise oximetry), or pulmonary hypertension on echocardiography.

Spirometry is a useful screening test for both airway and parenchymal disease. Because airway obstruction in asthma may be intermittent, monitoring of peak flow at home or in the workplace may be productive. The yield of routine electrocardiography is low, although it may reveal previously unsuspected coronary artery disease, occult valvular disease, or diastolic dysfunction, and can suggest pulmonary hypertension (i.e., if signs of right ventricular hypertrophy or tricuspid regurgitation are present).

Special Studies (Including Pulmonary Function Tests)

An array of special studies may be required for diagnosis of dyspnea (Table 28-3).[1] Pulmonary function tests are useful but correlate only moderately with the severity of the dyspnea.[81] In the patient with episodic dyspnea, but normal spirometry, methacholine inhalation testing can aid in the diagnosis of asthma. Patients with dyspnea characterized as "chest tightness" are most likely to have a positive study.[82]

Pulse oximetry may reveal previously unrecognized hypoxemia, a possible clue to many diseases; because the lungs have significant reserve capacity for diffusion at rest, exercise oximetry may be necessary to elicit hypoxemia in patients with abnormalities of the gas exchanger. Oximetry should always be assessed in patients with a low diffusing capacity, which may be seen in individuals with emphysema, pulmonary vascular disease, and interstitial lung disease. Orthodeoxia (i.e., hypoxemia worse in the upright position) leads to a search for one of the many causes of this unusual condition.[72,73,83]

If ventilatory muscle weakness is suggested by the patient's history, physical examination, or measurement of lung volumes, ventilatory muscle strength should be assessed. Maximal inspiratory and expiratory pressures can be measured easily and followed sequentially over time.

Cardiopulmonary exercise testing (CPET) helps determine whether exercise is limited by the pulmonary, cardiovascular, or musculoskeletal system.[52] To the extent that patients with lung disease are frequently at risk for or have concurrent cardiac problems due to cigarette smoking, CPET can be very useful. Unfortunately, exercise testing is insensitive for distinguishing cardiac disease from deconditioning.[84] Therefore, additional cardiac evaluation may be required. Spiral CT scanning of the chest with iodinated contrast has replaced ventilation-perfusion lung scanning as the screening procedure of choice for the diagnosis of pulmonary embolic disease.[85–90] One should remember that patients

TABLE 28-3. Special Studies for Evaluation of Dyspnea

PSYCHOLOGICAL ASSESSMENT

CT, computed tomography; D_{LCO}, diffusing capacity for carbon dioxide.

with chronic thromboemoblic disease often present with gradually worsening dyspnea in the absence of episodic breathlessness characteristic of acute pulmonary embolism.

If exercise testing suggests cardiac dysfunction, echocardiography, radionuclide scanning, measurement of BNP, or even cardiac catheterization (preferably combined with supine exercise) may identify unsuspected ventricular dysfunction, valvular disease, or pulmonary hypertension.[80,91] Diastolic dysfunction, characterized by normal ventricular pressures at rest but marked elevations during exercise, is a common cause of heart failure but is frequently missed as the etiology of exertional dyspnea. In a patient with a history of hypertension and/or left ventricular hypertrophy, this diagnosis should be considered, even in the presence of normal systolic function on an echocardiogram. A stage III CPET (with pulmonary artery catheter in place) might be necessary to confirm the role of diastolic dysfunction in the patient's symptoms.

Gallium and high-resolution CT scanning are sensitive but not specific for occult infectious and inflammatory lung disease.[90]

It is clear that a cascade of special studies might be necessary before reaching a specific diagnosis. If extensive testing is unrevealing, psychiatric evaluation may be valuable, especially if there is a strong psychological component. However, it is more likely that the patient has an early stage of an as-yet-undiagnosed condition that serial testing may reveal.

TABLE 28-4. Symptomatic Treatment of Dyspnea

REDUCE SENSE OF EFFORT AND IMPROVE RESPIRATORY MUSCLE FUNCTION
Energy conservation (e.g., pacing)
Breathing strategies (e.g., pursed-lip breathing)
Position (e.g., leaning forward)
Correct obesity or malnutrition
Inspiratory muscle exercise
Respiratory muscle rest (e.g., cuirass, nasal ventilation, transtracheal oxygen)
Medications (e.g., theophylline)
DECREASE RESPIRATORY DRIVE
Oxygen
Opiates and sedatives
Exercise conditioning
Vagal nerve section (not done)
Carotid body resection (not done)
ALTER CENTRAL NERVOUS SYSTEM FUNCTION
Education
Psychological interventions (e.g., coping strategies, psychotherapy, group support)

USE EXERCISE TRAINING ALONE OR WITH PULMONARY REHABILITATION
Enhance self-esteem and self-confidence in ability to perform
Improve efficiency of movement
Desensitization to dyspnea (e.g., from repeated exercise)

SYMPTOMATIC TREATMENT OF DYSPNEA

Dyspnea can be most effectively alleviated by treatment of the underlying disease and its complications. The focus should be on alleviating symptoms as well as improving pulmonary function.[92] Lung volume reduction surgery for relief of dyspnea in advanced emphysema deserves special mention. Removal of multiple bullous or emphysematous portions of the lungs reduces hyperinflation and improves lung recoil, potentially leading to dramatic improvement in pulmonary function and dyspnea for some individulas.[93] As experience with this approach continues to develop, it is likely that increasing numbers of patients will gain substantial benefit as optimal selection criteria are refined.

When dyspnea persists despite optimal treatment of the underlying disease, treatment should focus on the symptom rather than the disease and particularly on the specific mechanisms contributing to an individual's dyspnea (e.g., respiratory muscle dysfunction, hypoxemia, anxiety).[1] Until guidelines for specific therapy are established, one must take a generic approach to treatment, with a focus on improving respiratory muscle function, thereby decreasing the sense of effort, decreasing the drive to breathe, altering the central experience, and instituting exercise training (Table 28-4 and Fig. 28-3).

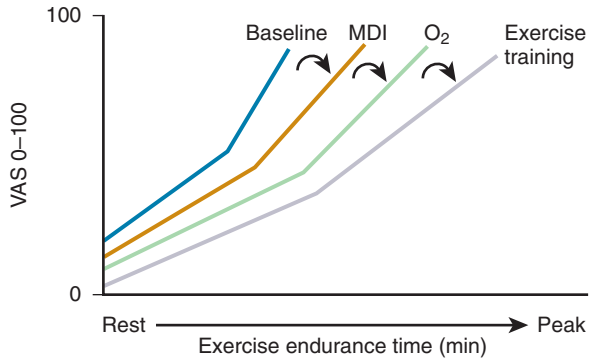

FIGURE 28-3 ■ The cumulative effects of treatment on exercise endurance time at a set workload and dyspnea measured by a visual analogue scale (VAS) are depicted here. The endurance time gradually improves with cumulative treatment using a bronchodilator by metered-dose inhaler (MDI), oxygen (O_2), and exercise training. Dyspnea relative to the workload is gradually relieved both at rest and relative to time on the treadmill, even though maximum dyspnea remains about the same. Improvement on exercise testing should translate into improvement with activities of daily living so the patient should experience less dyspnea with activities of daily living.

Reducing Respiratory Effort and Improving Respiratory Muscle Function

Energy conservation techniques reduce physical effort (e.g., walking more slowly) so less ventilatory effort is necessary. Breathing techniques (e.g., pursed lips) may reduce respiratory discomfort by slowing breathing, reducing hyperinflation, and improving oxygen saturation.[94] If ventilation limits exercise, strengthening the respiratory muscles should improve maximal ventilation and exercise performance, thereby alleviating the dyspnea. Unfortunately, the results of this approach have been inconsistent,[95,96] although one meta-analysis concluded that it can be of value especially in patients with documented respiratory muscle weakness.[97]

Nutritional repletion of cachectic patients can improve respiratory muscle strength and decrease dyspnea, although the clinical effectiveness of this therapy is unclear.[95,98] It is intuitively appealing to "rest" chronically "fatigued" respiratory muscles with mechanically assisted ventilation (positive or negative pressure) so they perform better with less dyspnea, and although not all studies have shown much benefit,[99] there is increasing evidence in support of this management strategy in patients with exacerbations[100] or respiratory failure.[101] In less acute circumstances, a meta-analysis concluded that acute noninvasive ventilatory support during exercise does relieve dyspnea and improves exercise performance in COPD.[34] Studies of medications to relieve dyspnea by increasing muscle contractility have been unconvincing.[102]

Decreasing the Respiratory Drive

Because dyspnea is so closely related to the respiratory drive, treatments that reduce the drive should reduce dyspnea. Supplemental oxygen can reduce carotid body activation and decrease dyspnea by decreasing ventilation and reducing hyperinflation during exercise.[103] Other benefits of oxygen that may decrease dyspnea include improved ventilatory muscle function,[104] stimulation of left ventricular contractility and reduced pulmonary artery pressure.[105] The amount of oxygen should be titrated to prevent desaturation below 90%, although even higher amounts may be advantageous for preventing dyspnea and improving exercise performance. Indeed, oxygen supplementation can improve exercise capacity in individuals without exercise hypoxaemia.[106] Oxygen supplementation is recommended for use during pulmonary rehabilitation programs.[96]

Treatments aimed at peripheral receptors or reflex pathways have shown some positive results. In healthy subjects, topical anesthesia of airway receptors[107] or buccal mucosa[108] reduced experimentally induced breathlessness. Inhalation of furosemide, proposed to potentiate activity of SARs, has been shown to reduce dyspnea in some individuals with COPD.[32,33] In studies in COPD patients, a fan blowing air on the face has been shown to decrease dyspnea[109] and chest wall vibration[110] has been shown to reduce exertional dyspnea, raising hope for treatments directed at peripheral receptors. More drastic surgical approaches, including vagal nerve section and carotid body resection, have always been controversial and are not currently available.

Altering Central Perception

The experience of dyspnea is affected by many factors, including education, cultural background, knowledge, emotional state, bodily preoccupation, and prior experience. Some recent studies of dyspnea relief emphasize the importance of central processes in decreasing dyspnea.[111] Altering the central experience of dyspnea may be helpful even when physiologic approaches are inadequate.[1] Education, including specific coping strategies (e.g., muscle relaxation[112]), helps patients understand their disease and develop feelings of mastery over it.[113] Sharing experiences with others or psychotherapy may reduce the intensity of the dyspnea and the distress associated with it.[114,115] These educational and psychosocial strategies for symptom management have been comprehensively reviewed and their use, in conjunction with exercise training, is recommended.[96]

Most discussions of centrally acting drugs for dyspnea focus on opiates. Opiates do have pharmacologic effects that should reduce the severity of the dyspnea (including reduction in ventilation), and it is likely that opiates would affect an individual's experience of dyspnea as they do pain.[116] However, fear of side effects, especially respiratory depression, has discouraged their use in patients with COPD.[117–120] Nonetheless, laboratory studies in COPD patients has produced modest improvement in exercise performance and dyspnea scores and only slight and infrequent side effects (e.g., drowsiness) with benefits that have been related both to decreases in ventilatory requirements for a given workload and to reductions in the perception of breathlessness at each level of ventilation.[116,121] Conversely, placebo-controlled outpatient studies have shown inconsistent benefits and frequent side effects.[117,119,122,123] For example, in a 14-week controlled crossover study of 16 patients with severe stable COPD,[122] long-acting morphine produced no relief of the dyspnea as measured by the CRQ or during walking. Moreover, there was a deterioration in the CRQ Mastery subscale and in the 6-minute walk distance. Almost all of the subjects experienced significant, although not life-threatening, side effects, although the authors emphasized that one subject had a "spectacular" response and continued treatment. Thus, opiates may be appropriate for dyspnea in an occasional carefully selected patient with far-advanced disease.[124]

Opiates are less controversial for palliation of dyspnea in terminal malignant disease or chronic respiratory failure. In this setting, the importance of relieving suffering despite the risk of shortening life is more widely accepted. Recent systematic reviews clearly demonstrate the efficacy of this approach in the palliation of refractory dyspnea.[125,126]

Based on the concept of opiate receptors in the airways, inhalation of opiates has been examined as a

way of relieving dyspnea without the side effects seen with systemic administration. Despite earlier reports of that inhaled opiates increased submaximal exercise endurance time in patients with severe COPD[127] and reduced dyspnea in patients with terminal lung disease and heart failure,[128] recent systematic reviews based on controlled trials have failed to demonstrate any real benefit of administering opiates by this route.[125,126]

Centrally acting pharmacologic agents have a limited role in the treatment of dyspnea, although controlled studies of unselected COPD patients have shown no benefit of anxiolytics on dyspnea.[117,129] Similarly, there is little experimental evidence to support the use of antidepressants in the management of dyspnea, although positive results have been reported in case studies.[130,131] Despite a lack of evidence, there is widespread recognition that there are clear clinical associations between dyspnea, anxiety, and depression, and a view that individual patients with chronic dyspnea can benefit by targeting psychomorbidity with appropriate therapies.[132,133]

Role of Exercise Training in Relieving Dyspnea

There is now convincing evidence that pulmonary rehabilitation programs, along with improving exercise capacity and health-related quality of life, improve the symptom of dyspnea in patients with COPD.[96] Exercise training appears to be a critical part of pulmonary rehabilitation programs for reduction of dyspnea and, although one randomized, controlled study reported a better outcome with high-intensity compared with moderate-intensity training,[134] further studies are needed to clarify the impact of training intensity on dyspnea outcomes. Although most studies have employed endurance training using treadmills or cycles in supervised clinical environments, there is accumulating evidence that pulmonary rehabilitation programs can yield dyspnea-related benefits with (1) interval training,[135] (2) strength training,[136] and (3) home-based exercise training.[137] It is not certain how important the educational component of pulmonary rehabilitation is in relieving dyspnea. A program of dyspnea management (including relaxation, breathing retraining, pacing, self-talk, and panic control) without an exercise component was compared with general health education; neither measure alleviated the dyspnea or improved the 6-minute walking distance.[138] By contrast, it has been shown that treadmill training with or without nurse coaching is equally effective in reducing dyspnea during exercise testing and activities of daily living.[139] Despite uncertainty about the impact of education per se on dyspnea outcomes, current recommendations strongly endorse the inclusion of an educational component as part of a pulmonary rehabilitation program.[96]

Exercise training may relieve dyspnea by many mechanisms. Neither pulmonary mechanics nor respiratory muscle strength is usually affected.[96,140] True conditioning with decreased lactate production and resulting decreased stimulation of ventilation may occur even in patients with severe disease.[141] Relaxation and increased mechanical efficiency (e.g., longer stride length[142]) may lower oxygen consumption and ventilation for a given activity.[143] Exercise training may improve self-confidence, thereby reducing anxiety and dyspnea.[144,145] Repeated exercise may result in desensitization to the symptom (i.e., the same ventilatory stimulus results in less dyspnea[43,139,146,147]). In any one patient, it is difficult to know which of these mechanisms is operant, but for clinical purposes, it may not matter.

Relief of Dyspnea in End-Stage Lung Disease

Dyspnea is one of the most devastating symptoms known to human beings. In no area of medicine is relief more important than when dealing with dyspnea in end-stage lung disease. The severity of this symptom is well recognized in terminal malignancy, interfering with both physical and psychological function.[148] More than half of patients dying of cancer described their dyspnea as moderate or worse.[148] This awareness is lacking in other areas of terminal lung disease, where most information is anecdotal.[149] One exception is the treatment of the terminal phase of ALS. The value of opiates and anxiolytics for relief of symptoms (especially dyspnea) in the last 24 hours of life of patients with ALS has been documented by postmortem telephone interviews with family members in both the United Kingdom and Germany.[150]

Although patients with chronic lung disease are normally encouraged to exercise to maintain their state of fitness, there comes a time when a different approach is required and the focus shifts from prolongation of life to relief of distress.[149] When dyspnea with exertion is extreme, it may be more appropriate to restrict activity and to focus on modifying treatments such as oxygen, opiates, and anxiolytics. Palliative treatment may include partial ventilatory support or, under rare circumstances, a tracheostomy with mechanical ventilation. Such dramatic steps to relieve dyspnea must be taken with full understanding of the ramifications and complications. Some patients might choose a morphine drip to allow a comfortable death, whereas others might choose an aggressive approach focused on prolongation of life as well as relief of discomfort. It is up to the health care provider to help the individual patient understand these choices.

KEY POINTS

- Dyspnea is a complex symptom arising from the central processing of information relayed from the respiratory complex, with modifying information from numerous afferent sources.
- The information is integrated within the psychological and intellectual makeup of the individual. It is still unclear whether there is a final common pathway for the sensation.
- Dyspnea may be due to diseases in virtually any organ system, whether caused by interference with breathing, increased demand for breathing, or weakening of the respiratory pump. In most cases, however, one is dealing with a disorder of the respiratory or cardiovascular system.
- Diagnosis of dyspnea requires a comprehensive database. Cardiopulmonary exercise testing may be particularly useful when a patient has concomitant cardiopulmonary diseases or when cardiovascular deconditioning is suspected.
- When the cause is not obvious, a series of studies analyzing cardiopulmonary function at rest and with exercise usually uncovers a specific diagnosis. Sophisticated studies of the heart, pulmonary vascular bed, lung parenchyma, and even esophagus may be necessary.
- Treatment of dyspnea is most effective when it is based on a specific diagnosis. When treatment of the underlying disease is inadequate, treatment should focus on the symptom.
- A combination of education, exercise training, oxygen, and muscle strengthening aids most patients; but in far-advanced disease, compassion may require the use of agents that directly blunt the sensation even though they may shorten life.

Narcotic and Non-narcotic Antitussives

Local Anesthetics

Expectorants and Mucolytics

Potential New Antitussives

INTRODUCTION

Cough is a symptom that has been experienced by every human and is an essential innate protective mechanism that ensures the removal of mucus, noxious substances, and infections from the larynx, trachea, and large bronchi. Cough also minimizes the inhalation of toxic material. Impairment or absence of coughing can be harmful or even fatal in disease. Cough may also be a sign of disease in or outside the airways and lungs and a useful indicator for both patient and physician for initiating diagnosis and treatment of disease processes. When cough itself is persistent and excessive, it can be harmful and deleterious and may need to be suppressed directly.

Because cough is a normal defensive mechanism, it is a symptom experienced by healthy individuals. Epidemiologic surveys have shown that between 11% to 18% of the general population report a persistent cough,[1-3] but it is not known how much this cough is "normal" or is associated with disease. This reporting of chronic cough may be due to the presence of cigarette smokers in these surveys or to the exposure of an urbanized population to environmental indoor and outdoor irritants and air pollution. There may also be undiagnosed illnesses associated with cough within these populations. The potential contribution of irritants to cough is illustrated by the report of excessive cough in New York firefighters who worked in the dust fall-out of the World Trade Center bombing on September 11, 2001.[4] Cough is also a common presenting symptom to the clinician. In the United States, cough is the most common complaint for which patients seek medical attention and the second most common reason for a general medical

consultation; patients with persistent cough constitute about 10% to 38% of a chest specialist outpatient practice. In the United Kingdom, about 3 million prescriptions are written annually for cough preparations by general practitioners, representing a cost of $3 million; this is an underestimate because a vast number of cough mixtures are also bought over-the-counter without a medical prescription. Cough medicines represent $1 billion yearly sales in the world.

Recent books,[5,6] reviews,[7,8] reports from expert groups on cough management[9,10] and symposium proceedings[11,12] provide excellent accounts of the physiology, pathology, and clinical science of cough in healthy subjects and in those with airway diseases.

DEFINITION OF COUGH

Cough is usually initiated as a series of respiratory maneuvers that lead to a characteristic cough sound. It usually starts as a deep inspiration, followed by a strong expiration against a closed glottis, which then opens with an expulsive flow of air, followed by a restorative inspiration; these are the inspiratory, compressive, expulsive, and recovery phases of cough (Fig. 29-1). The first cough sound is heard during the expulsive phase. This definition is valuable but may be restrictive for several reasons: (1) In the expulsive phase of cough, there may be a secondary closure of the glottis, which generates the second cough sound; this is usually present in airway disease, but may be absent in health. Its mechanisms are unknown. (2) The initial inspiration of cough may be followed by a series of expiratory efforts, with closures of the glottis but not intervening inspirations—a "cough bout." (3) Punctate mechanical stimulation of the trachea or larynx causes a brief but strong expiratory effort—the "expiration reflex"—and, in the case of the glottis, reflex glottal closure[13–15]; these reflexes presumably act to prevent or minimize entry of foreign material into the trachea and lungs. Throat clearing, as in postnasal drip, consists more of this expiration reflex or "huff" than a full cough.

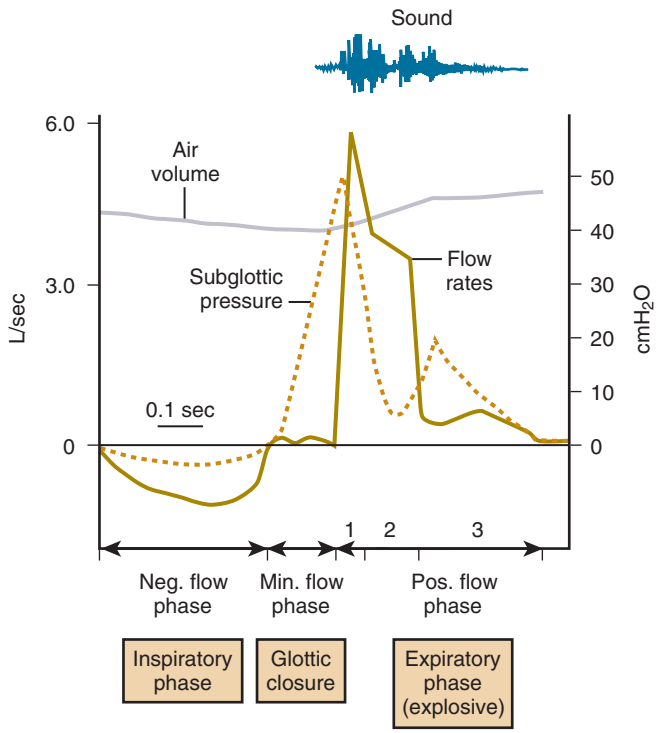

FIGURE 29-1 ■ Diagrammatic representation of the changes of the following variables during a representative cough: sound level, lung volume, flow rate, subglottic pressure. During inspiration, the flow rate is negative; at the glottic closure, the flow rate is zero; and during the expiratory phase, the flow rate is positive. The last phase can be divided into three parts: growing, constant, and decreasing. (Redrawn from Bianco S, Robuschi M: Mechanisms of cough. *In* Braga PC, Allegra L [eds]: Cough. New York: Raven, 1989, pp 29–36.)

Not only are there different patterns of "cough," but these patterns may be differently affected by pharmacologic and physiologic inputs.[13–15] The picture is complicated by the use of different semantics for cough components. Thus, the second phase may be called "expulsive," "explosive," or "expiratory," the second cough sound may be called "voiced" or "glottal," and a cough bout may be called an "epoch," "burst," or "peal." The confusion is probably not important provided the terms are clearly defined. Cough sounds may have clear harmonic patterns,[16] but the basis of these patterns has been little analyzed, and their significance, if any, has not been established. Induced cough is usually preceded by an "urge-to-cough,"[17] involving activation of the cerebral cortex.[18] Voluntary cough and habit cough presumably originate in the cortex. Once a cough has been induced, there will be secondary feedbacks both from the lungs and from the higher parts of the brain, which do not seem to have been analyzed.

Thus, the definition of cough may need to be extended to embrace, or at least consider, these different patterns and neural circuits. This consideration is not a semantic quibble. The reflexes have different afferent and central nervous pathways, but clinical descriptions of cough have seldom differentiated between them. Antitussive drugs could have selective actions on the different afferent pathways.

PHYSIOLOGY

Experimentally, involuntary coughing appears to be initiated only from those structures innervated by the vagus nerve and its branches.[13,19] These are especially the larynx and the proximal tracheobronchial tree, but they also include the lower part of the oropharynx and the smaller bronchi, as well as the tympanic membrane and the external auditory meatus. Irritation of all these sites can cause coughing. The one clear exception to vagally mediated coughing is that caused voluntarily[20,21] (Fig. 29-2); of all the highly complex defense mechanisms, cough is the only one that we can mimic voluntarily and accurately. We can also inhibit it voluntarily. Most patients can suppress their cough for 5 to 20 minutes if they try hard.[20]

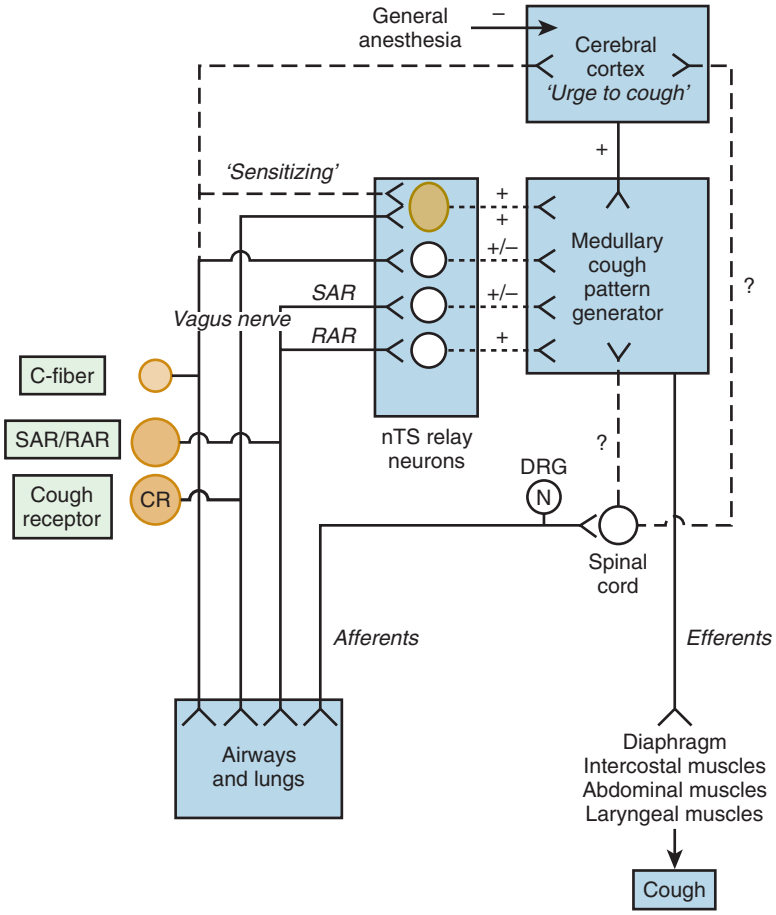

FIGURE 29-2 ■ Model illustrating the afferent and efferent pathways in the control of cough. Rapidly adapting receptors (RARs), slow-adapting receptors (SARs) and C-fibers may modulate the cough responses, and a distinct set of cough receptors has been described in the guinea pig. There may be promotion of coughing through interactions with cortical and brain-stem structures, in addition to putative contributions via spinal airway afferents. The cough pattern generator coordinates the output to muscles and effectors that results in the cough response. DRG, dorsal root ganglion; nTS, nucleus tractus solitarius; +, enhancing; –, inhibitory; ?, putative. (Adapted from Mazzone SB: Sensory regulation of the cough reflex. Pulm Pharmacol Ther 17:361–368, 2004.)

Spontaneous coughing can be initiated by a wide variety of inflammatory or mechanical changes in the airways and by inhalation of a large number of chemical and mechanical irritants. Rapid and large changes in lung volume can cause cough, as can psychological effects such as laughter. The extremely wide variety of stimuli that can trigger cough points to a similarly wide range of properties of the sensory receptors that are the starting point of the cough reflex.[13,19,22]

Receptors for the Cough Reflex

The most sensitive sites for initiating cough are the larynx and the tracheobronchial tree, especially the carina and the points of bronchial branching.[13,19,22–24] Inhaled materials impinge on these points. In experimental animals and humans, it is difficult or impossible to induce coughing from the smaller airways and alveoli. This is teleologically understandable because in the smaller airways even a vigorous cough would not move gas fast enough to cause turbulence and shearing forces at the airway wall, so the cough would be ineffective. In view of the wide range of stimuli for coughing, one would expect the sensory nerve receptors to be "polymodal" (i.e., to respond to a variety of chemical and pharmacologic mediators and to mechanical stimulation). Such receptors are found throughout the respiratory tract.

Larynx and Pharynx

Nerve receptors (or perhaps better termed "sensors") in the laryngeal mucosa are activated by the mechanical and chemical stimuli for cough; their fibers run mainly in the superior and recurrent laryngeal nerves before joining the vagus nerves. Many studies of laryngeal afferent innervation suggest that the sensors for cough belong to the broad group of "rapidly adapting 'irritant' receptors" (RARs) found there and in the tracheobronchial tree.[25–27] The RARs are normally silent, as would be expected and, when activated, cause rapidly adapting discharges with an irregular pattern that are conducted in fast-velocity vagal myelinated (Aδ) fibers. Their many stimuli include cigarette smoke, ammonia, ether vapor, acid and alkaline solutions, hypotonic and hypertonic saline, and mechanical stimulation by catheter, mucus, or dust; all these stimuli can provoke cough. Although strong cough can be induced from the larynx, its denervation or bypass makes little difference to the strength of cough caused by inhaled irritants. As with many protective/defensive mechanisms, the cough reflex displays much "redundancy"—that is, a doubled sensory input for cough does not result in a doubling of the motor response.

Activation of receptors in the larynx or pharynx may cause either a "typical" cough, starting with an inspiration, or the expiration reflex, starting with an expiratory

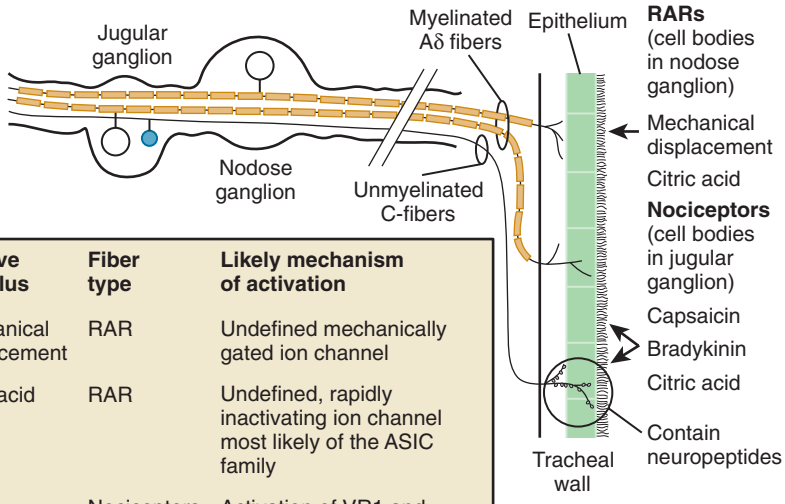
effort.[13–15] The difference is presumably due to various types of cough sensors in the mucosa. Although cough induced from the pharynx may seem to be the exception to the vagal rule, in that the pharynx is supplied mainly by the glossopharyngeal nerve, there is a small pharyngeal branch of the superior laryngeal (vagal) nerve that could mediate cough, and this seems to be especially active in humans.[28] Furthermore, postnasal drip associated with, for example, inflammation due to nasopharyngitis and sinusitis, can induce cough possibly due to spread of inflammatory mediators into the larynx.

Tracheobronchial Tree

Similar RARs are found in the trachea and large bronchi of those species that cough. The sensors have nerve terminals under or within the epithelium (Fig. 29-3), concentrated at points of airway branching; some of them lie close (1 μm) to the epithelium.[29–31] Their appearance and location suggest that they might be sensitive to intraluminal irritants. They are activated, like those in the larynx, by an extremely wide range of chemical and mechanical irritants and by many inflammatory and immunologic mediators, such as histamine, bradykinin, prostaglandins, and substance P. In experimental animals, RAR activity is enhanced by pulmonary congestion, atelectasis, bronchoconstriction, and decreases in lung compliance, all of which can cause cough in patients.

Although the evidence that the RARs are primarily responsible for coughing is convincing, other lung reflexes may interact with them. C-fiber receptors, which have thin nonmyelinated vagal afferent fibers, are found in the laryngeal, bronchial, and alveolar walls. They are activated by much the same range of stimuli as are the RARs, but their responses, at least for those in the alveolar walls, do not include cough.[22,31,32] The C-fiber receptors may release tachykinins, such as substance P, which in turn stimulate RARs to cause cough and can also cause neurogenic inflammation by an axon reflex. This may explain the effect of tachykinin antagonists in inhibiting cough. However, there is no convincing evidence that C-fiber receptors can be a primary sensory input to the cough reflex. A new group of Aδ-nociceptors has been identified in the guinea pig, and electrophysiologic and immunohistochemical studies indicate that this may represent an airway afferent nerve subtype distinct from RARs and C fibers that play an essential role in regulating the cough reflex, termed "cough receptors."[33] Airway C-fiber receptors have been differentiated into two groups.[30,34] The precise actions of these new groups of sensors on cough have not yet been determined.

Thus, the fact that the other receptors, such as the C-fiber endings, also respond like RARs to many of the same stimuli suggests that the total pattern of cough may be due to the interaction of several reflexes. This view,



Tussive stimulus	Fiber type	Likely mechanism of activation
Mechanical displacement	RAR	Undefined mechanically gated ion channel
Citric acid	RAR	Undefined, rapidly inactivating ion channel most likely of the ASIC family
	Nociceptors	Activation of VR1 and activation of undefined ASIC
Capsaicin*	Nociceptors	Activation of VR1 channels
Bradykinin	Nociceptors	B2 receptor-mediated activation of VR1 channels. This may involve protein kinase C and lipoxygenase enzymes

*Capsaicin activates RAR indirectly by including neuropeptides release; neuropeptide-mediated smooth muscle contraction and increase in vascular permeability activate RAR.

FIGURE 29-3 ■ Vagal afferent innervation of guinea pig trachea. Mechanism of sensory nerve stimulation by various cough-inducing stimuli (*inset*). ASIC, acid-sensing ion channel; RAR, rapidly adapting receptors; VR-1, transient receptor vanniloid-1. (Redrawn from Undem BJ, Carr MJ, Kollarik M: Physiology and plasticity of putative cough fibers in the guinea pig. Pulm Pharmacol Ther 15:193–198, 2002.)

together with the variety of physiologic patterns of sensitivities and responses of RARs in various parts of the respiratory tract, could explain the great divergence of cough patterns in different conditions and in different patients. The effectiveness of antitussive drugs that act at peripheral sites (e.g., by the inhalation of anesthetic aerosols) may depend on their relative actions on the different groups of receptors that affect cough or on their central connections.

Plasticity of the Cough Sensors

In disease, the sensory receptors for cough can show an exaggerated response to stimuli that would normally be harmless or mildly irritating. This increase in sensitivity of RARs and C-fiber receptors can be caused, inter alia, by allergen challenge, viral infections, ozone, cigarette smoke, and a variety of inflammatory mediators.[35] RARs can also be sensitized by mucus in the airways, underlying smooth muscle contraction, and mucosal edema.[31,32,36–38] Structural changes in the nervous receptors, in particular in their intracellular mediators, have been related to the increases in sensitivity. Similar changes have been seen in the nerve cell bodies in the jugular and nodose ganglia and in the afferent pathways entering the brain stem (see later). The relevance of these plasticity changes to human airway disease is apparent.

Membrane Receptors/Channels on Sensory Endings for Cough

The last decade has seen extensive studies on the membrane/channel receptors in sensory nerves involved in coughing.[31,35,38–40] The details are complex and most conclusions tentative, so they are summarized only briefly; however, the results are of considerable importance not only in indicating how coughing may be induced but also by pointing to possible future targets in antitussive therapy.

Cough sensors, especially the RARs and Aδ-nociceptors, are stimulated by touch and stretch and are thought to have stretch-activated membrane channels, as do similar receptors elsewhere (e.g., baroreceptors). In addition, they have voltage-gated sodium channels that can be activated by acid and belong to the acid-sensing ion channel (ASIC) family. However, the RAR membranes lack transient receptor potential vanilloid (TRPV-1) receptors, which are found in C- and Aδ-nociceptors. The TRPV-1 receptors are activated especially by capsaicin, much used as a tussive agent, and are sensitized or activated by (inter alia) heat, protons, bradykinin, arachidonic acid derivatives, adenosine triphosphate (ATP) and phosphokinase C. Recently, cannabinoid (CB2) membrane receptors have also been identified.[41] Thus, the way in which a large variety of tussive stimulants activate the sensory nerves responsible for cough is beginning to be clarified. The membrane receptors on cough sensors have been studied mainly in experimental animals,[35,42] but their relevance to human cough is still unclear.

Central Nervous System Control

A (possible) circuit diagram for the interaction of cough inputs and outputs and the respiratory rhythm generator in the brain stem has been proposed.[43–46] Coughing is integrated in the medulla oblongata where the afferent fibers for coughing first relay in or near the nucleus of the tractus solitarius; the motor outputs are in the nucleus retroambigualis, sending motoneurons to the respiratory muscles, and in the nucleus ambiguous, sending motoneurons to the larynx and bronchial tree. In the cat, brain-stem pathways for the expiration reflex differ from those for a typical cough,[46,47] and pathways for cough from the larynx differ from those from the tracheobronchial tree.[48] These observations, if true for humans, point to different antitussive agents appropriate to the two sites.

The voluntary control of coughing can probably bypass these integrative centers[20,21] (see Fig. 29-3), because some patients with brain-stem damage lack a spontaneous cough reflex but can consciously induce coughing to clear the airways.[49] Greater understanding of the central control of coughing is desirable because most antitussive drugs act centrally, and we know little about how they do this. However, research has shown that central nervous membrane receptors for cough include serotonin, gamma-animobutyric acid, *N*-methyl-D-aspartate, neurokinins, and dopamine, results that could have considerable therapeutic implications.[43,50] Studies with functional magnetic resonance imaging of the human cerebral cortex and upper brain during induced cough and the urge-to-cough are delineating those areas involved[18,51] (Fig. 29-4).

The central nervous pathways for cough show interactions and plasticity, as do the peripheral mechanisms already described.[37,52,53] For example, afferent fibers from RARs and C-fiber receptors converge in the nucleus of the solitary tract. Neurokinins released from the latter potentiate the activity of the former, especially cough and reflex bronchoconstriction, and this potentiation is enhanced by continued C-fiber activity. An example of such central plasticity may also be seen in some cases of gastroesophageal reflux (GER), where activity in esophageal afferents, which do not normally cause cough, may activate the cough reflex when sensitization takes place.

Motor Outputs

Although glottic closure is usually regarded as an essential and definitive component of cough, in both human and experimental animals, the closure may be incomplete or even absent, and this does not seem greatly to limit the effectiveness of the cough in terms of airway clearance. In addition, the glottal closure reflex has a lower threshold to irritants than does the expiration and cough reflexes and may therefore depend on different pathways.[23,24]

Coughing is associated with respiratory actions other than those of the respiratory skeletal muscles.[13,19,22] There is usually bronchoconstriction, although this may be masked or reversed by the dramatic changes in lung

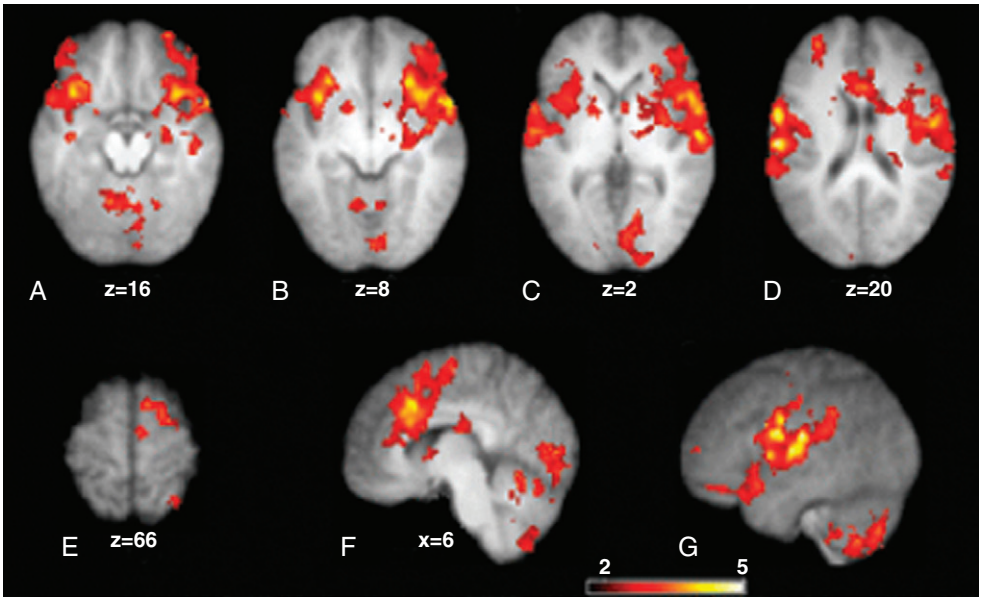


FIGURE 29-4 ■ Activation of brain pathways associated with inhalation of capsaicin to cause an "urge-to-cough" shown by functional magnetic resonance imaging. The majority of regional activations were distributed in both hemispheres, including the orbitofrontal cortex (**A**), inferior frontal gyrus (**A** and **B**), anterior insula (**B** and **C**), superior temporal gyrus (**C**), and primary motor and somatosensory cortices (**D** and **G**). Midline capsaicin activations include the supplementary motor area (**E**) and the anterior midcingulate cortex (**F**). The locations of capsaicin activations in the primary motor and somatosensory cortices were at the caudal end of the central sulci in both hemispheres (**D**) and are clearly discernable on the three-dimensional rendering of the left hemisphere. (A-G, From Mazzone SB, McLennan L, McGovern AE, et al: Representation of capsaicin-evoked urge-to-cough in the human brain using functional magnetic resonance imaging. Am J Respir Crit Care Med 176:327–332, 2007.)

volume. The afferent mechanisms for reflex cough and reflex bronchoconstriction may be different. Cough may be caused mainly by RARs and Aδ-nociceptors and the bronchoconstriction mainly by C-fiber sensors. In practice, coughing, like laughter, can precipitate an attack of asthma, and asthma attacks are often associated with a hyperreactive cough reflex. The possibility of vicious circles exists. Bronchoconstriction would increase linear velocity of airflow and lessen the inflow of irritant and tussigenic material to deeper parts of the airways.

The afferent sensors for cough also cause reflex secretion of mucus from airway submucosal glands.[13,19,22,54] Mucus entraps inhaled particles and irritant chemicals, and the material is thus cleared from the airways by mucociliary transport and by the cough itself. Mucus could also act as a physicochemical barrier between the luminal irritants and the airway wall. However, an increase in mucus secretion in conditions associated with cough has never been accurately measured, perhaps because of lack of appropriate methods.

Mechanics of Coughing

The inspiratory phase of cough consists of a deep inspiration through a widely opened glottis. The inhaled volume varies greatly, from a nearly complete vital capacity to much lower values. The inspiration may draw material into the lungs; however, the large lung volume provides a better mechanical efficiency for the expiratory muscles of cough because they are initially stretched, because their stretch reflex is activated, and because there is a stronger elastic recoil of the lung to aid expiration. Furthermore, the deep inspiration opens the airways in preparation for their clearance during the expiratory phase.[52]

In the compressive phase of cough, which lasts about 200 ms, the glottis closes while the expiratory muscles contract, and the intrapleural and intra-alveolar pressures rise rapidly to values as high as 300 mm Hg (40 kPa).[52,55] The expulsive phase follows when the glottis opens. The expiratory flow rate depends both on air leaving the central airways during dynamic collapse as a result of the high intrathoracic pressure and on the effect of high alveolar pressure, increased during the compressive phase and maintained at a high level by the contraction of the expiratory muscles. The expulsive phase of coughing may be long-lasting, with a large expiratory tidal volume, or it may be interrupted by glottic closures into a series of short expiratory efforts, each having a compressive and an expulsive phase. What determines which pattern of coughing has not been established, but may depend on the anatomic site of origin of the cough, on the different nerve types of receptor activated, and on the strength of their activation.

Maximum expiratory flow is effort-independent because it is limited by dynamic compression of the airways.[52] This compression starts immediately downstream from the "equal pressure point" at which intraluminal and extraluminal pressures around the bronchial wall are equal, so that transbronchial pressure is zero. The effectiveness of cough depends on peak airflow and will therefore be greater with a larger elastic recoil of

the lung and a greater elasticity of the central airways. Dynamic compression of the airways downstream from the equal pressure point increases velocity, kinetic energy, and turbulence of the air passing through the proximal airways. Thus, the clearing capacity of the cough is improved. If cough consists of a series of expiratory efforts, with lung volume decreasing with each effort, dynamic compression is predicted to move into the more peripheral bronchi, which will be progressively cleared of intraluminal material. However, at present this description is largely theoretical and needs to be established experimentally. Determinants of maximal airflow are discussed in Chapter 24.

Whereas mucociliary transport is the major method of clearing the airway lumen in healthy subjects, cough is an important reserve mechanism, especially in patients with lung disease. In many lung diseases, mucociliary clearance is impeded and cough is necessary to remove the increased amount of secretions and debris. Healthy subjects have twice the mucociliary clearance rate of that in patients with chronic bronchitis, but when cough is permitted or encouraged, the patients increase their clearance by 20%, whereas healthy subjects increase their clearance by only 2.5%. As would be expected, all studies point to the fact that cough is effective in causing clearance if there is hypersecretion of mucus; by definition, a dry cough is an unproductive one.

APPROACH TO THE PATIENT WITH COUGH

In the management of a patient with cough, the first step is to identify the cause of the cough and then treat the cause. Cough may be indicative of trivial to very serious airway or lung diseases and also of extrapulmonary processes. Often, the cause may not be delineated or treatment of the putative cause may not lead to suppression or improvement of the cough, or there is no effective treatment of the cause available. Therapy that suppresses cough by inhibiting the cough pathway without treating the cause ("symptomatic," "nonspecific," or "indirect" antitussives) is needed if the cough is very severe, if treatment of the cause does not lead to sufficient cough suppression, or if treatment of the cause is not possible or successful.

The differential diagnosis of cough is extensive and includes infections, inflammatory and neoplastic conditions, and many pulmonary as well as extrapulmonary conditions (Table 29-1). The protocol for investigating a chronic cough that has persisted for more than 3 weeks takes into account several factors pertaining to the pathophysiology of cough and the most common causes of cough. Persistent cough may be due to the presence of excessive secretions, to airway damage and infection, or to the establishment of a hypersensitive cough reflex. A protocol based on systematic evaluation using history, examination, and laboratory investigations focusing at the anatomic sites of cough receptors that constitute the afferent limb of the cough reflex is a most widely advocated approach to diagnosis and treatment.[9,10]

The foremost consideration for the clinician at the first visit is to (1) determine the severity, (2) assess the cause of the cough, and (3) plan investigations and treatment. Various indicators in the history and examination of the patient may provide clues to the diagnosis, although these may not be entirely reliable or specific and may be absent in many cases.

A period of 3 weeks has been taken as a cutoff point for an acute cough usually due to an upper respiratory virus infection, although some postviral coughs may persist for many weeks or months. The only caveat to this is that sometimes such a cough may last for more than 3 weeks and many patients with an "idiopathic" cough often state that their cough originated during an upper respiratory tract infection. A cough that has lasted for more than 2 to 3 months is less likely to be due to an upper respiratory tract infection, and further investigations in terms of other associated causes must be looked for.

Cough with sputum production usually points toward conditions such as chronic bronchitis and bronchiectasis or other causes of bronchorrhea. The diagnostic value of knowing that the cough is productive is probably limited. One study indicates that similar causes are often found for both productive and dry cough.[56] In addition, the volume of sputum produced is difficult to estimate accurately (usually depending on sputum cups and block of salivary contamination), and coughing itself leads to sputum production. The concept of a dry versus a productive cough as delineating a cough secondary to an increased cough reflex for the former and a cough secondary to excessive mucus production for the latter is not entirely correct. An enhanced cough reflex may be present in both productive and nonproductive cough. Features that are associated with an increased cough reflex include cough triggered by taking a deep breath, laughing, inhalation of cold air, and prolonged talking. Therefore, the diagnostic approach remains similar as to whether the cough is productive or not.

The characteristics of the cough may sometimes help. Throat clearing may be associated with a postnasal drip, a predominantly nocturnal cough may be attributed to asthma rather than to other causes, or cough after meals may be related to coexistent GER. However, the predictive values of these characteristics are low.[57] A cough with a "honking" or "barking" quality, particularly in a child, has been associated with a psychogenic or habit cough.

Many cigarette smokers have a chronic cough, but rarely seek medical advice regarding their cough as they expect the irritant effect of cigarette smoke is the cause of their cough. A change in the pattern or characteristics of their cough, such as an increase in intensity (usually after an upper respiratory tract infection), or accompanying hemoptysis may force a smoker to seek medical attention. A chest radiograph is mandatory in this situation.

Measuring Cough

Assessment of cough frequency and severity rests mainly on history taking. In very severe cough, complications arising from cough such as vomiting, rib fractures, tiredness, incontinence, and syncope may be experienced (Table 29-2), and their presence indicates that the chronicity and intensity of the cough are severe. The effect of cough on the patient's lifestyle and psychological well-being may also provide an idea of the severity of the cough. Questionnaires that are specifically devised to measure these effects have been developed.[58,59] For the assessment of the response of the cough to various treatment modalities, tools to measure the frequency and severity of cough have also been developed.[16,60,61] In many published studies, the effectiveness of particular interventions have been determined qualitatively at the clinic, but use of more quantitative tools is gradually being introduced.

Cough can be measured in several ways: (1) The severity of cough can be judged by the patient recording her or his perception on a visual analogue scale ranging from mild to severe or on a nominal scale from 0 to 10; (2) cough-specific health-related quality of life questionnaires can provide a quantitative measure of the impact of chronic cough on the patient; (3) measurement of the cough reflex can be done by counting the cough responses to inhalation of tussive agents such as capsaicin, the pungent extract of peppers, or citric acid– or low-chloride–content solutions; and (4) quantitative ambulatory recording of the frequency and intensity of cough.[62] What should be the "gold standard" for measuring the severity of the cough is not clear yet, but it will need to be a combination of both subjective and objective measurements and, ideally, should include both frequency and intensity of cough and the extent to which it is divided into individual cough and cough epochs. All these features are of concern to the patient.

Measurement of the Cough Reflex

Persistent cough may result from an increase in the sensitivity of the cough sensors. This can be measured with inhalation of an aerosol of capsaicin or of citric acid. Most patients with a persistent cough due to a range of

causes have an enhanced cough reflex to capsaicin when compared with healthy noncoughing subjects.[63] Successful treatment of the primary condition underlying the chronic cough (specific or disease-orientated treatment) often leads to a normalization of the cough reflex.[64] The degree of the cough responsiveness to inhaled capsaicin may be a reflection of the severity of the cough, but this has not been examined yet. Of relevance to the evaluation and treatment strategies for persistent dry cough is the fact that the cough response can be augmented by various mediators of inflammation such as the prostaglandins PGE_2 and $PGF_{2\alpha}$ and bradykinin through a process of sensitization.[65,66] Measurement of the cough reflex response to such agents may be useful in confirming the presence of a persistent cough or in assessing the response to treatment. At the moment, only centers with an interest in cough use it for clinical and research purposes.

Measurement of Cough Frequency and Intensity

Advances in computer technology and in digital sound recording have led to the development of ambulatory systems for audio or audiovisual recording of cough, with the ultimate objective of automatically obtaining cough counts and possibly intensity in a real-life setting. Several devices have been described.[16,61,67] Although none has been tested in the context of treatment studies, their availability represents a major progress in the assessment of cough. A recent study indicated that the number of cough sounds and the cough seconds, a measurement of the time of coughing, correlated strongly with scores on a Leicester Cough Questionnaire (LCQ) and cough visual analogue scale.[16]

Although the methods are valuable in counting the number of expiratory efforts associated with cough, they do not allow assessment of cough intensity (because this need not correlate with intensity of expiratory sound). They can be used to differentiate between individual coughs and those associated with a cough epoch, although the definition of the distinction is arbitrary. Both intensity of cough efforts and whether they occur are groups are features of importance to the patient. Nor do current methods allow a distinction between a "true" cough and an expiration reflex, a feature that should be important to the investigator.

Quality of Life Questionnaires

Quality of life questionnaires specific for the evaluation of the impact of chronic cough[59] provide subjective measurements that are likely to reflect the severity of cough from the viewpoint of the patient. Such measurements integrate both the impact of frequency and the intensity of cough. The LCQ uses a seven-point Likert response scale for 19 items from three domains (physical, psychological, and social) and is shown to be repeatable and responsive in patients with chronic cough.[68] This is increasingly becoming a useful clinical tool.

Diagnosis and Investigations of Chronic Cough

The history and examination will sometimes indicate likely associated diagnosis or diagnoses, and the timing of various investigations may vary according to presentation (Table 29-3). Initial investigations may be limited to a chest radiograph, particularly in a cigarette smoker. Abnormalities have been reported in 10% to 30% of chest radiographs of cigarette smokers, although the yield of tumors is likely to be lower. Further investigations (e.g., computed tomography or fiberoptic bronchoscopy) may be pursued despite a "normal" chest radiograph.

Patients on angiotensin-converting enzyme (ACE) inhibitor therapy should discontinue such therapy, with replacement by other appropriate treatments. A period of observation of 3 to 4 weeks in a patient who provides a good history of an upper respiratory tract infection prior to further investigation or therapeutic trial is adequate, although institution of an anti-inflammatory therapy such as inhaled corticosteroids can be useful in controlling this type of cough.

Postnasal drip ("nasal catarrh" or "upper airway cough syndrome"), asthma, and GER are the three most common conditions associated with a chronic cough, and a diagnostic approach to exclude these conditions first is sensible. Examination of the nose and sinuses with a computed axial tomogram of the sinuses may be indicated with a history of postnasal drip or rhinosinusitis, with ambulatory esophageal pH monitoring to exclude GER. The diagnosis of asthma is supported by the

TABLE 29-3. Diagnostic Evaluation of Chronic Cough

1. History and physical examination.
2. Chest radiograph, particularly in smokers.
3. Initial evaluation may lead to diagnosis of chronic bronchitis in cigarette smokers and of angiotensin-converting enzyme inhibitor cough. Discontinue cigarette smoking and offending drug.
4. Further diagnostic evaluation on basis of initial evaluation:
   i. If suggestive of postnasal drip, order a computed tomographic scan of sinuses, and allergy tests
   ii. If suggestive of asthma, request a record of peak expiratory flow measurements at home for 2 weeks and a bronchoprovocation test with histamine or methacholine and/or a trial of antiasthma treatment.
   iii. If suggestive of gastroesophageal reflux disease, request 24-hr pH monitoring and, if necessary, an endoscopic examination of the esophagus or a barium swallow series.
   iv. If the chest radiograph is abnormal, consider examination of sputum and a fiberoptic bronchoscopy. A high-resolution computed tomographic scan of the thorax and further lung function evaluation may be necessary.
5. Treat specifically for associated conditions. The cause(s) of cough is (are) determined when specific therapies eliminate or improve the cough. There may be more than one associated cause for the cough.

presence of diurnal variation in peak flow measurements, bronchial hyperresponsiveness to histamine or methacholine challenge, and the presence of eosinophils in sputum. Under the umbrella of "asthma" would also be included cough-variant asthma and eosinophilic bronchitis. However, a therapeutic trial may be the best initial approach, particularly when the history and examination provide supportive clues. It is important that effective doses of medication over a sufficient period of time are given. Often, a longer-than-usual period of treatment is necessary to control the cough. Postnasal drip is an often overlooked condition and aggressive treatment consists of corticosteroid nasal drops together with an antihistamine, with the possibility of adding antibiotic therapy and a short period of treatment with a nasal decongestant. Often, more than one of these conditions may coexist and cough may respond only with concomitant treatment of these. For example, inhaled steroid therapy and gastric acid suppression with a proton pump inhibitor or H_2-histamine blockers would be indicated for the coexistence of asthma and GER.

Bearing in mind that there are a myriad of other less common causes of a chronic cough, investigations must proceed further if the just-discussed causes have been excluded. Lung function tests to include lung volumes and gas transfer factor, and a computed axial tomogram of the lungs should be considered in case of bronchiolar or parenchymal disease or unsuspected bronchiectasis. Fiberoptic bronchoscopy should be considered and, apart from excluding small central tumors, provides mucosal biopsies for histologic examination.

CAUSES AND TREATMENT OF ACUTE AND CHRONIC COUGH

Acute Cough

Acute cough is usually due to a viral or bacterial upper respiratory tract infection. The cough of the common cold is usually self-limiting and accompanies the cold in the majority of sufferers within the first 48 hours.[69] Other symptoms of postnasal drip, throat-clearing, irritation of the throat, sore throat, nasal obstruction, and nasal discharge also accompany the cough, which usually resolves within 2 weeks, although it can be sometimes prolonged. Pertussis should be considered in the differential diagnosis, particularly with a whooping characteristic of the cough, and is often associated with vomiting. Other causes of acute cough are pneumonia, congestive cardiac failure, exacerbation of chronic obstructive pulmonary disease (COPD), aspiration, or pulmonary embolism. These conditions are usually accompanied by other symptoms such as shortness of breath and fever, but cough may be the predominant or, rarely, the only symptom.

Patients with the common cold usually self-medicate with over-the-counter antitussive preparations. A Cochrane review reported no good evidence for or against the effectiveness of over-the-counter medicines such as antitussives and antihistamines in acute cough. "Satisfactory" responses to pediatric cough syrups was reported in 46% and 56% of children compared with 21% of children in the placebo group.[70] Codeine was ineffective compared with placebo against the acute cough of the common cold,[71] while dextromethorphan has some effect in a meta-analysis,[72] but not in two smaller studies.[73,74] In a study of 100 children, dextromethorphan or diphenhydramine given as a single dose before bedtime was found to be no better than placebo in providing nocturnal symptom relief for children with cough and sleep difficulty from an upper respiratory tract infection.[75] Instead, a subsequent study showed that buckwheat honey provided symptomatic relief,[76] but a placebo effect was not excluded. The American Academy of Pediatrics has highlighted the fact that the efficacy of antitussive preparations in children is lacking and that these medications may be potentially harmful.[77] Their recommendation is that cough due to acute viral airway infections is self-limiting and may be treated with fluids and humidity.

A first-generation antihistamine and decongestant has been proposed for the treatment of cough associated with a postnasal drip in acute cough,[69] but a study using a newer-generation antihistamine, loratidine, in combination with a decongestant showed no effect.[78] The rhinitis associated with the common cold may become mucopurulent, but this is not an indication for antibiotic therapy unless this persists for more than 10 to 14 days.

Chronic Cough

Chronic cough (cough that persists for more than 3 weeks) can be caused by many diseases, but according to several series, it is most commonly due to asthma, GER, postnasal drip (rhinosinusitis), chronic bronchitis, and bronchiectasis.[64,79]

Postnasal Drip (Rhinosinusitis, Upper Respiratory Tract Syndrome)

Postnasal drip has been reported as being the most common cause of chronic cough.[79,80] The strong association between postnasal drip and chronic persistent cough is based on epidemiologic evidence and on a prospective study in adults. Postnasal drip ("nasal catarrh") is characterized by a sensation of nasal secretions or of a "drip" at the back of the throat, accompanied very often by frequent need to clear the throat ("throat-clearing"). There may be a nasal quality to the voice due to concomitant nasal blockage and congestion, and there may be hoarseness of the voice. Physical examination of the pharynx is often unremarkable although a "cobblestoning" appearance of the mucosa and draining secretions may be observed. Computed tomography of the sinuses may reveal mucosal thickening or sinus opacification and air-fluid levels. Extrathoracic variable upper airway obstruction is not invariably present.[81] Testing for allergens may be helpful, and the presence of allergy to pollens supports the presence of seasonal allergic rhinitis.

Topical administration of corticosteroid drops in the head-down position is the best treatment, often with the concomitant use of antihistamines. Topical steroids offer a local effect with the minimum of side effects. Occasionally, severe symptoms may be controlled initially by a short course of oral steroids, followed by topical therapy. A topical anticholinergic spray to the nose (such as ipratropium bromide) to dry excessive nasal secretions may provide additional benefit. Topical decongestant vasoconstrictor sprays may be useful adjunct therapy for a few days, but rebound nasal obstruction may occur after prolonged use. Antibiotic therapy is necessary in the presence of acute sinusitis involving bacterial infection with the presence of mucopurulent secretions that has persisted for at least 10 days.

Asthma and Associated Eosinophilic Conditions

Chronic cough may occur in asthma under different clinical settings. Asthma may present predominantly with cough, often nocturnal, and the diagnosis is supported by the presence of reversible airflow limitation and bronchial hyperresponsiveness.[82] This condition of "cough-variant" asthma is a common type of asthma in children. Elderly asthmatics may also give a history of chronic cough prior to a diagnosis of asthma made on the basis of episodic wheeze. Cough as the only presenting symptom of asthma has been reported in up to 57% of patients and is often its most prominent symptom.[83] Atopic cough is recognized in Japan as an isolated chronic cough characterized by an atopic background, sputum eosinophilia, cough hypersensitivity, normal pulmonary function, and airway hyperresponsiveness.[84]

Eosinophilic bronchitis is characterized by cough without asthma symptoms or bronchial hyperresponsiveness but with eosinophilia in sputum.[85] Cough may also occur as a first sign of worsening of asthma usually presenting first at night, associated with other symptoms such as wheeze and shortness of breath with falls in early morning peak flows. Some patients with asthma may also develop a persistent dry cough despite good control of their asthma with antiasthma therapy.

Patients with asthma do not usually have an enhanced cough reflex, although a subgroup with a persistent cough may do so.[86] In these latter patients, cough sensors may be sensitized by inflammatory mediators such as bradykinin, tachykinins, and prostaglandins. Cough in asthma may also be due to bronchial smooth muscle contraction, which may activate cough receptors through physical deformation. Indeed, in some patients with cough-variant asthma, β-adrenergic bronchodilators are effective antitussives.[87] A predominance of eosinophils in induced sputum and bronchial biopsies, together with a thickened basement membrane and bronchial hyperresponsiveness, is present in cough-variant asthma. In eosinophilic bronchitis, conversely, cough responsiveness to capsaicin is increased without bronchial hyperresponsiveness, but the immunopathologic abnormalities are similar to those of asthma.[88]

Cough associated with asthma should be treated with antiasthma medication including inhaled corticosteroid therapy and bronchodilators such as β_2-adrenergic agonists. Such treatment should be given over a prolonged period of time (3–6 months) at a minimum dose that controls the cough. Often, a trial of oral corticosteroids (e.g., prednisolone 40 mg/day for 2 weeks) may be recommended, particularly in those asthmatics that have had a cough despite being on adequate antiasthma medication. A combination of inhaled corticosteroids and a long-acting β-agonist is now the best available maintenance treatment for moderate-to-severe asthma. Leukotriene receptor antagonists may control cough-variant asthma. Eosinophilic bronchitis responds well to inhaled or oral corticosteroid therapy.

Gastroesophageal Reflux

GER, the movement of acid and other components of gastric contents from the esophagus into the larynx and trachea, is one of the most commonly associated causes of chronic cough in all age groups. GER may lead to symptoms of physical complications such as heartburn, chest pain, a sour taste, or regurgitation, and also a chronic persistent cough. There may also be no symptoms associated with GER or impaired clearance of esophageal acid. Prolonged exposure of the lower esophagus to acid may lead to esophagitis, Barrett's esophagus, esophageal ulceration and stricture, and bleeding. An esophageal-tracheobronchial cough reflex mechanism has been proposed on the basis of studies in which distal esophageal acid perfusion induced coughing episodes in such patients that was suppressed by local distal esophageal perfusion of lidocaine and by an inhaled anticholinergic agent, ipratropium bromide.[89] Over 90% of the cough episodes have been shown to be temporally related to reflux episodes. Significant reflux occurs in both supine and upright positions. A high proportion of patients with GER also appear to have gastrohypopharyngeal reflux, and there may be a direct effect of acid reflux on cough receptors in the larynx and trachea. Coughing itself may precipitate reflux, setting a vicious circle of acid inducing–cough that in turn induces acid reflux. Continuous monitoring of tracheal and esophageal pH in patients with symptomatic GER has demonstrated significant increases in tracheal acidity with pH's falling down to 4 or less during episodes of reflux.[90] Other components of the refluxate, apart from acid, such as the content of pepsin or other enzymes may also contribute to cough, but the importance of this contribution is not yet established.

There is no particular specific pattern of the cough of GER. The cough may be long-standing and may be productive. In the presence of reflux and microaspiration, laryngeal symptoms may be present with dysphonia, hoarseness, and sore throat; often, posterior vocal cord laryngeal inflammation is visible. There may be associated esophageal dysmotility characterized by heart burn, water brash, and oral regurgitation, worse in the supine position. Esophageal dysmotility may occur in the absence of acid reflux.[91]

The most specific test for GER is a 24-hour ambulatory esophageal pH monitoring examining for episodes of pH below 4 and for the temporal relationship between cough and falls in pH. However, there is a low frequency of acid reflux episodes associated in time with cough with only up to 13% of coughs occurring shortly after an acid reflux episode.[92] Positive predictive values for the use of esophageal pH monitoring are reported to be between 68% and 100%, and a negative test nearly excludes GER as the cause of cough. Other tests that may be used are esophageal manometry to measure dysmotility, particularly associated with reflux episodes; upper gastrointestinal contrast series to detect reflux of barium into the esophagus; or an upper gastrointestinal endoscopy. A trial of antireflux treatment with a proton pump inhibitor or a histamine H_2-antagonist may be used in patients as a diagnostic measure where ambulatory 24-hour pH esophageal monitoring is not available. This may also be indicated in patients with chronic cough that remains unexplained after diagnostic workup or exclusion of other associated causes.

The aim of treatment of GER is to decrease the frequency and duration of the events. Conservative measures such as weight reduction; high-protein, low-fat diet; elevation of the head of the bed; avoidance of coffee and smoking should be advocated. Reduction of acid production by the stomach can be achieved with either H_2-histamine blockers or proton pump inhibitors, but there have been no comparative studies. Given the increasing use of proton pump inhibitors and their superior effect in acid suppression and in treating GER, these drugs will remain the preferred choice. Although initial uncontrolled studies have provided very optimistic effects of histamine H2-receptor antagonists or proton pump inhibitors in controlling the cough associated with GER, double-blind placebo studies[93,94] report more limited effects. Of 17 patients with a positive pH test, 6 had improvement or resolution of cough with omeprazole treatment for 12 weeks within the first 2 weeks of treatment.[93] In another trial, omeprazole 40 mg/day for 8 weeks partly relieved GER-related cough.[94] A 3 months, treatment at the highest recommended dose of a proton pump inhibitor is usually advocated. Not all patients respond and, in some, the response is only partial. One of the reasons for this failure may be the effect of the nonacid refluxate. Antireflux surgery such as open or laparoscopic fundoplication may be considered for patients with proven GER disease whose cough has failed to respond to medical therapy.[95] The effect of specific treatments for esophageal dysmotility is not known.

Chronic Bronchitis/Chronic Obstructive Pulmonary Disease

Although 30% to 40% of the community smokes, chronic bronchitis is only reported in 5% of the patients seeking medical attention for cough. Chronic bronchitis should be considered in a patient who produces sputum on most days over at least 3 consecutive months, particularly during the winter months, over at least 2 consecutive years. In a smoker, the presence of chronic bronchitis may be predictive of progressive irreversible airflow obstruction.[96] The cough of chronic bronchitis may result from excessive sputum production associated with mucus cell hyperplasia and bronchiolar inflammation. The presence of airflow obstruction diagnosed on the basis of a ratio of forced expiratory volume in 1 second to forced vital capacity (FEV_1/FVC) of less than 70% or of an FEV_1 of less than 70% of the predicted value indicates the onset of COPD.[97]

The productive cough in chronic bronchitis is exacerbated by upper respiratory infections with common viruses or by exposure to irritating dusts or environmental pollutants. Other causes of productive cough should be excluded such as bronchiectasis or postnasal drip. It is important to exclude also the presence of an endobronchial tumor. Cessation of cigarette smoking is usually accompanied by a reduction in cough, occurring most often within 4 to 5 weeks.[98] Various adjuncts such as nicotine replacement or bupropion or varenicline, a nicotine receptor partial agonist, may help smoke cessation.[99] Treatment of any associated chronic airflow obstruction with short-acting or/and long-acting β_2-adrenoceptor agonists and anticholinergic agents should be considered particularly in the presence of dyspnea. Suppression of the inflammatory process in the small airways may be tried with the combination of inhaled corticosteroids and long-acting β-agonist. Oral or systemic corticosteroids are effective in the treatment of exacerbations of COPD. Mucolytic therapy may reduce the incidence of exacerbations. Use of indirect (symptomatic) antitussive therapies is not recommended but may be needed in excessive coughing.

Bronchiectasis

The cough of bronchiectasis is associated with overproduction of airway secretions together with a reduced clearance, often with a vicious circle of recurrent bacterial infections. Usually, the patient produces 30 mL or more of mucoid or mucopurulent sputum per day, sometimes accompanied by fever, hemoptysis, and weight loss. In early cases of bronchiectasis, the condition may be present only with a persistent productive cough. Bronchiectasis may be associated with postnasal drip and rhinosinusitis, asthma, GER disease, and chronic bronchitis. Common pathogens cultured from sputum include *Haemophilus influenzae*, *Staphyloccocus aureus*, and *Pseudomonas aeroginusa*. The chest radiograph may show increased bronchial wall thickening, particularly in the lower lobes in advanced cases, but thin-section computed axial tomography of the chest can reveal early changes of intrapulmonary airway wall thickening, dilation, and distortion, with mucus plugging, and evidence of bronchiolitis.[100]

Cough in bronchiectasis is the most effective mechanism for clearing airway secretions. In addiction, there is an increased capsaicin cough response in bronchiectasis.[101] Cough during infective exacerbations of bronchiectasis may become a tiring symptom, and specific treatment of the exacerbation leads to a reduction of

cough. The cough due to bronchiectasis may be controlled with inhaled β_2-agonists that improve mucociliary clearance and reverse any associated bronchoconstriction by postural drainage of airway secretions and by the use of intermittent antibiotic therapy. Use of antitussives is not recommended, but in the context of severe cough, some suppressive effect may be clinically beneficial.

Angiotensin-Converting Enzyme Inhibitor Cough

ACE inhibitors are often prescribed for the treatment of hypertension and heart failure, and cough has been observed in 2% to 33% of patients.[102,103] The cough is typically described as "dry," associated with a tickly irritating sensation in the throat. It may appear within a few hours of taking the drug, but may also become apparent only after weeks or even months. The cough disappears within days or weeks following withdrawal of drug. Patients with ACE inhibitor cough demonstrate an enhanced response to capsaicin inhalation challenge. Accumulation of bradykinin and prostaglandins, which sensitize cough receptors directly, has been implicated. The best course of action for ACE inhibitor cough is to discontinue the treatment and to replace it with alternative therapies such as angiotensin II receptor antagonists, which are not associated with cough.

Postinfectious Cough

Postinfectious cough has been reported from 11% to 25% of patients with chronic cough.[104,105] A persistent cough occurs in 25% to 50% of patients following *Mycoplasma* or *Bordetella pertussis* infection.[106] *B. pertussis* infection has now been increasingly recognized as a cause of both acute and chronic cough, particularly in older children and in adults.[107] In children, other respiratory infections associated with chronic cough include viruses (respiratory syncytial virus and parainfluenzae), *Mycoplasma*, and *Chlamydiae*.[108] The cough of *B. pertussis* usually lasts for only 4 to 6 weeks, is spasmodic with a typical whoop, but can last for a longer period of time. In most patients with a postinfectious cough, the initial trigger is usually an upper respiratory tract infection, and cough that is expected to have lasted for only a week at most persists for many months, often severe. Such patients are often referred to a cough clinic and are usually investigated for the more commonly associated cause of cough. It is assumed that there may have been persistent damage to the airways containing the cough sensors or persistent airway inflammation induced initially by the virus. Bronchial epithelial inflammation and damage are present in children with chronic cough following lower respiratory tract illness. Irritants may penetrate more readily through the damaged epithelium. This may represent a vicious circle of events of coughing-induced damage that maintains and triggers further cough. Inhaled corticosteroids are often prescribed, but with variable success. Oral steroids may be successful.[104] Inhaled ipratropium bromide was reported to be effective in a small study.[109] Macrolide antibiotics or trimethoprin/sulfamethoxazole are effective in eliminating *B. pertussis* but do not alter subsequent clinical course.[110]

Other Conditions

Other conditions causing cough include bronchogenic carcinoma, metastatic carcinoma, sarcoidosis, chronic aspiration, interstitial lung disease, or left ventricular failure, conditions that can usually be excluded by performing a chest radiograph. Psychogenic or habit cough is not uncommon particularly in children, and is usually a diagnosis arrived at after exclusion of other causes. Habit cough is a throat-clearing noise made by a person who is nervous and self-conscious. Cough may be associated with a depressive illness and long-standing cough may cause depression. In the pediatric population, other cough etiologies specific for this age group need to be considered such as congenital abnormalities, for example, vascular rings, tracheobronchomalacia, pulmonary sequestration or mediastinal tumors, foreign bodies in the airway or esophagus, aspiration due to poor coordination of swallowing or esophageal dysmotility, and heart disease.

Chronic Persistent Cough of Unknown Cause ("Idiopathic" Cough)

Identification of a potential cause of cough has been reported in 78% to 99% of patients presenting at a cough clinic, and specific treatment of identifiable causes has also been reported to be successful in up to 69% to 99% of cases.[79,111] However, more recent series have identified 7% to 46% of patients with chronic cough as having idiopathic cough, despite undergoing thorough diagnostic evaluation.[8] The high success rates reported in some centers versus the lower success rates in others remain unexplained, but possibly relates to the definition of successful treatment and the case mix. The patient with idiopathic cough should be diagnosed as such only after an intensive diagnostic evaluation with empirical trial of therap(ies) has (have) been carried out.

These patients with a persistent cough of unknown cause or not responding to treatment of associated causes present in a similar way as others in terms of their cough symptoms where a cause has been identified. However, it is reported that they tend to be middle-aged women who frequently give a history of cough onset at the menopause and can have associated autoimmune disorders such as autoimmune hypothyroidism.[112] An enhanced cough reflex is usually found, and this usually improves when the associated cause has been successfully treated. Patients with an enhanced cough reflex often complain of a persistent tickling sensation in the throat that often leads to paroxysms of coughing. This sensation can be triggered by factors such as changes in ambient temperature, taking a deep breath, laughing, talking over the phone for a few minutes, and exposure to cigarette smoke or other irritants such as aerosol sprays or perfumes or to certain odors. Mucosal biopsies taken from a group of nonasthmatic patients with idiopathic cough showed evidence of increased mast cells

and of airway wall remodeling features such as increased subbasement membrane thickening, increased airway smooth muscle mass, goblet cell hyperplasia, and increased blood vessels.[113] These changes could represent the sequelae of chronic trauma to the airway wall following intractable cough, and could in turn lead to sensitization of the cough reflex. There is an increase in neural profiles that express the neuropeptide, calcitonin gene–related peptide (CGRP), and the calcium channel, TRPV1, in the airway epithelium of chronic coughers that could contribute to the increased cough reflex.[114,115]

COUGH SUPPRESSION THERAPIES

"Symptomatic," "Indirect," or "Nonspecific" Antitussives

When the treatment of the cause of cough is not effective or not available, therapies directed at eliminating the symptom of cough irrespective of the cause of the cough may be tried (Table 29-4). These therapies are also termed "symptomatic," "indirect," or "nonspecific" antitussives. This is particularly relevant to patients with lung cancer with a persistent cough, of whom 50% rate their cough as moderate to severe,[116] and in many other conditions with chronic cough where specific therapies do not lead to cough control or do not exist. Drugs that affect the complex mechanism of the cough reflex may act by inhibition of central mechanisms within the brain stem or of peripheral mechanisms on the cough sensors in the airways. Because of the relative low efficacy of current antitussives, several new classes of antitussives are being developed, based on our understanding of the cough reflex and of the membrane receptors and channels on cough sensors.[7,117,118] A summary of the existing direct and indirect antitussives and their potential modes and sites of actions are shown in Figure 29-5.

TABLE 29-4. Treatments for Cough

1. TREATING THE SPECIFIC UNDERLYING CAUSE(S)	
Asthma, cough-variant asthma	Bronchodilators and inhaled corticosteroids
Eosinophilic bronchitis	Inhaled corticosteroids; leukotriene inhibitors
Allergic rhinitis and postnasal drip	Topical nasal steroids and antihistamines
	Topical nasal anticholinergics (with antibiotics, if indicated)
Gastroesophageal reflux	Conservative measures
	Histamine H_2 antagonist or proton pump inhibitor
Angiotensin-converting enzyme inhibitor	Discontinue and replace with alternative drug such as angiotensin II receptor antagonist
Chronic bronchitis/COPD	Smoking cessation.
	Treat for COPD
Bronchiectasis	Postural drainage. Treat infective exacerbation and airflow obstruction.
Infective tracheobronchitis	Appropriate antibiotic therapy
	Treat any postnasal drip
2. SYMPTOMATIC TREATMENT (ONLY AFTER CONSIDERATION OF CAUSE OF COUGH)	
Acute cough likely to be transient (e.g., upper respiratory viral infection)	Simple linctus
Persistent cough particularly nocturnal	Opiates (codeine or pholcodeine)
Persistent intractable cough due to terminal incurable disease	Opiates (morphine or diamorphine)
	Local anesthetic aerosol
Cough in children	Simple linctus (pediatric)

COPD, chronic obstructive pulmonary disease.

Narcotic and Non-narcotic Antitussives

Opiates including morphine, diamorphine, and codeine are the most effective antitussive agents.* At their effective doses, they cause physical dependence, respiratory depression, and gastrointestinal colic. Morphine and diamorphine are reserved for the control of cough and pain of terminal bronchial cancer patients, but codeine, dihydrocodeine, and pholcodeine can be tried in other cases of chronic cough. Codeine is the methylether of morphine and has long been the standard centrally acting antitussive drug against which the pharmacologic and clinical effects of newer drugs have been measured. Codeine is probably the most commonly prescribed antitussive. It has some antitussive activity, compared with placebo when given orally. Although codeine possesses antitussive activity against pathologic cough[118] and against induced cough in normal volunteers,[119] a recent study suggested, contrary to earlier evidence, that it had little effect on cough in selected COPD patients[120] or against acute cough of the common cold[71] compared with placebo.

It should be used cautiously in patients with reduced hepatic function, but it can be used without dose modification in patients with renal failure. Drowsiness may be an incapacitating side effect, together with nausea, vomiting, and constipation. Rarely, allergic cutaneous reactions such as erythema multiforme have been described. Codeine can cause physical dependence, but on a smaller scale than morphine. Dihydrocodeine has no particular advantage over codeine and may cause more addiction than codeine. Pholcodeine is also as effective as codeine but has little or no analgesic effect.

Morphine and diamorphine should be used only for severe distressing cough that cannot be relieved by other less potent antitussives and are therefore usually confined to patients with terminal illness such as bronchial carcinoma. These opioids also relieve anxiety and pain. They cause sedation, respiratory depression, and constipation. Opioids can exacerbate wheezing through the release of histamine, but this is rare. Diamorphine may be preferred to morphine because of its lower incidence

*Diamorphine is not prescribable in the United States.

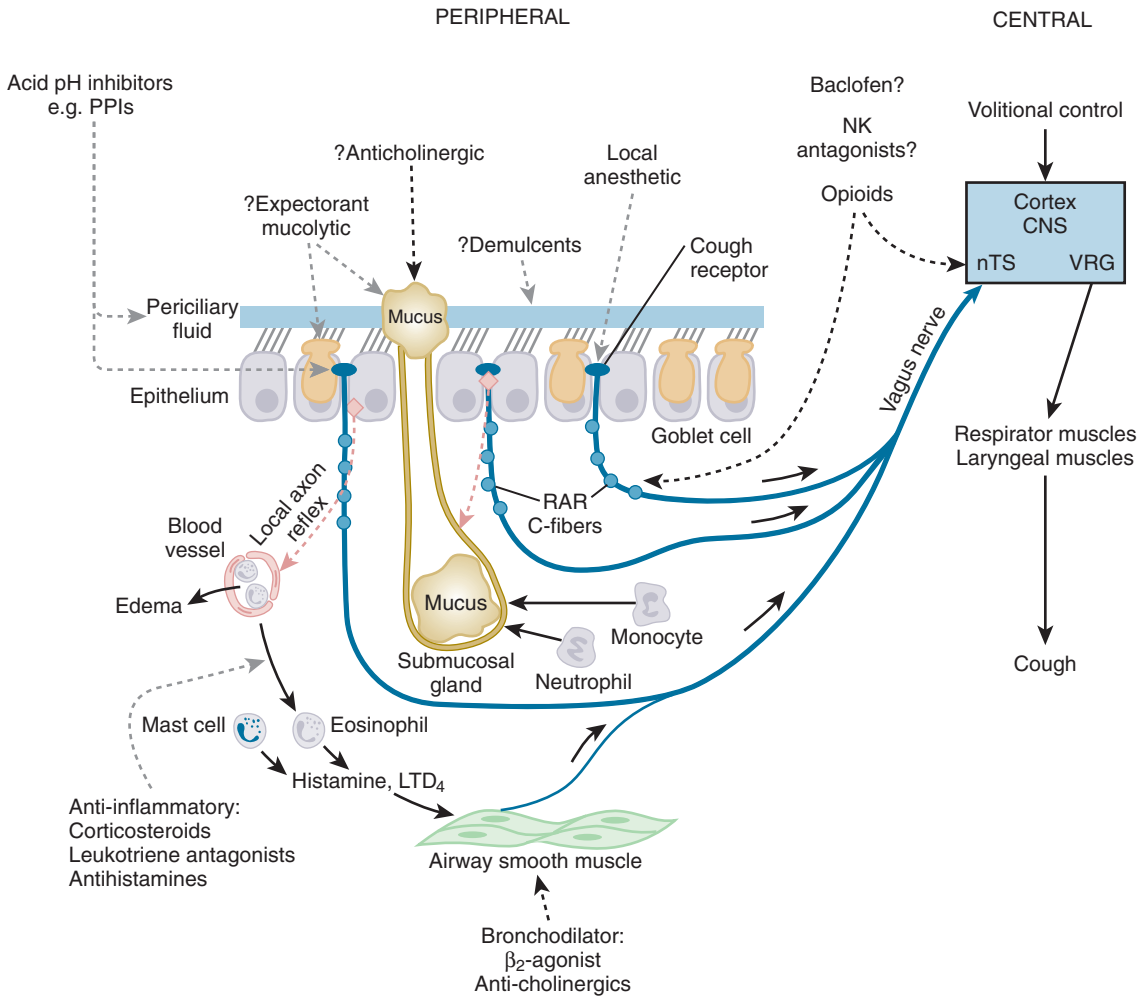

FIGURE 29-5 ■ Afferent pathways of the cough reflex and some potential sites of action of direct and indirect antitussive drugs. Drugs may be divided according to their peripheral effects on airways or to their central effects in the central nervous system (CNS). LTD_4, leukotriene D_4; NK, neurokinin; nTS, nucleus tractus solitarius; PPI, proton pump inhibitor; RAR, rapidly adapting receptors; VRG, ventral respiratory group. (Redrawn from Chung KF: Management of cough. *In* Chung KF, Widdicombe JG, Boushey HA [eds]: Cough: Causes, Mechanisms and Therapy. Oxford: Blackwell, 2003, pp 283–297.)

of nausea and vomiting. Morphine is usually given as a slow-release oral preparation, and has been shown to be efficacious in severe intractable cough.[121] Diamorphine is preferably given by injection.

Dextromethorphan is a non-narcotic antitussive, a synthetic derivative of morphine with no analgesic or sedative properties, and is usually included as a constituent of many compound cough preparations sold over the counter. It is as effective as codeine in suppressing acute and chronic cough when given orally,[122,123] with one study showing its superiority over codeine.[124] Antitussive efficacy of a single 30-mg dose has been demonstrated against cough associated with upper respiratory tract infections.[72] However, in children, dextromethorphan has been shown to be ineffective in providing any symptomatic relief in cough due to upper respiratory tract infections.[75,76] It is commonly used as a constituent of many compound cough preparations that are sold over the counter. Side effects are few at the usual dose, but at higher doses, dizziness, nausea, vomiting, and headaches may occur. It should be avoided in patients with hepatic insufficiency as it undergoes metabolic degradation in the liver. The American Academy of Pediatrics has highlighted the potential adverse effects and overdosage associated with antitussive preparations containing dextromethorphan in children,[77] where dextromethorphan has been shown to be ineffective in cough due to upper respiratory tract infections.[75,76] Dextromethorphan should be used with caution also in patients on monoamine oxidase inhibitors as cases of central nervous depression and death have occurred.

Other non-narcotic preparations include noscapine and levopropoxyphene, although their antitussive efficacy has not been proved. Levodropropizine, a nonopioid antitussive with peripheral inhibition of sensory cough receptors, has a favorable benefit/risk profile compared with dextromethorphan.[125] Other drugs acting on cough receptors include benzonatate, which inhibits vagal stretch lung receptors, with a possible central effect.

Of the potentially new antitussives is baclofen which is an agonist of gamma-aminobutyric acid, an inhibitory neurotransmitter. It showed demonstrable inhibitory effects in two patients with chronic cough[126] and against ACE inhibitor cough,[127] but there have been no clinical trials yet.

Local Anesthetics

Lidocaine aerosol inhaled from a nebulizer has been administered to cases of intractable cough with variable results, and should be reserved for such individual cases.[128] It works by inhibiting sensory neural activity, but also removes reflexes that protect the lung from noxious substances. Its effects are transient and they should be avoided in patients with asthma or a past history of asthma because they can induce severe bronchoconstriction. There have been no controlled trials of local anesthetics, but their efficacy in controlling cough is not ideal because of their short duration of effect.

Expectorants and Mucolytics

Expectorants and mucolytics may alter the volume of secretions or their composition. Despite the lack of proof, mucolytic agents such as acetylcysteine, carbocisteine, bromhexine, and methylcysteine are often used to facilitate expectoration by reducing sputum viscosity in patients with chronic bronchitis. A small reduction in the exacerbation of bronchitis has been reported with oral acetylcysteine, accompanied by small improvement in cough, a decrease in volume of sputum, and some ease of expectoration. Aromatic agents such as eucalyptus and menthol have decongestant effects in the nose and can be useful in short-term relief of cough. Menthol inhibits capsaicin-induced cough in normal volunteers[129] and acts on a cold-sensitive receptor. Demulcents also form an important component of many proprietary cough preparations and may be useful because the thick sugary preparation may act as a protective layer on the mucosal surface.

Potential New Antitussives

The medical literature contains reports of potential antitussive activities of several existing drugs marketed for other purposes. Positive reports of the effects of the tricyclic antidepressant amitriptyline in open studies have been reported, but a proper blind, placebo-controlled study is needed. The antidepressant paroxetine, a serotonin reuptake inhibitor, the antiepileptic therapies gabapentin and carbamazepine, and the antispasticity agent baclofen, an agonist of the $GABA_B$ receptor have also been reported to be beneficial in some reports. New cough suppressants[130] are also being developed that include new opioids or blockers of TRPV-1 and other vanniloid receptors[117,131] or of specific sodium channels.[132] The search for newer effective antitussives is ongoing.

KEY POINTS

- Cough may also be a sign of disease in or outside the airways and lungs and a useful indicator for both patient and physician for initiating diagnosis and treatment of disease processes.
- Impairment or absence of coughing can be harmful or even fatal in disease.
- When cough itself is persistent and excessive, it can be harmful and deleterious and may need to be suppressed directly.
- The most sensitive sites for initiating cough are the larynx and the tracheobronchial tree.
- In the management of a patient with cough, the first step is to identify the cause of the cough and then treat the cause.
- Many cigarette smokers have a chronic cough, a change in the pattern or characteristics of their cough such as an increase in intensity (usually after an upper respiratory tract infection), or accompanying hemoptysis may force a smoker to seek medical attention. A chest radiograph is mandatory in this situation.
- Patients on ACE inhibitor therapy should discontinue such therapy, with replacement by other appropriate treatments.
- Postnasal drip, asthma, and GER are the three most common conditions associated with a chronic cough, and a diagnostic approach to exclude these conditions first is sensible.
- When the treatment of the cause of cough is not effective, therapies directed at eliminating the symptom of cough irrespective of the cause of the cough may be tried (see Table 29-4).

INTRODUCTION

Pain is a complex subjective experience that varies from person to person in its quality, intensity, duration, location, frequency, and associated features. Its perception is influenced by a subject's culture, emotional and cognitive contributions, socioeconomic status, familial background, prevailing psychological factors, anticipation and previous experience, and the context in which the symptom occurs.

Chest pain is characterized by an unpleasant sensation that is either localized to the thorax or believed to originate from structures located in the latter. It may announce the presence of severe, occasionally life-threatening, disease. Diagnosis of chest pain is often complicated by the vague presentations and indistinct anatomic localization of many of its causes.

EPIDEMIOLOGY

There are uncertainties about the exact prevalence of chest pain. In a study of 500 randomly selected households in Burlington, Canada, 16% of 827 respondents reported experiencing pain within the 2 weeks preceding the survey.[1] Persistent pain was approximately twice as common as temporary pain, and chest pain was the fifth most common type of temporary pain. In studies of acute pain that was sufficient to warrant medical attention, chest pain is always an important factor.

A survey of 1016 randomly selected enrollees of a health care plan in Seattle, Washington, revealed a high incidence of pain that lasted a whole day or more or that occurred several times during the previous 6 months[2]; the most common complaint was back pain, followed by headache, abdominal pain, facial pain, and chest pain. Chest pain accounted for 12% of the reported cases, but was the most common site of pain that prompted respondents (35%) to seek medical attention. Pain is also a common reason for persons to visit hospital emergency departments. In a survey of 36,271 random evaluations, stomach pain, other abdominal pain, and chest pain were the most often cited reasons; they occurred with almost equal frequency and, together, accounted for 10.7% of all emergency department visits.[3]

NEUROBIOLOGY OF PAIN

Pain is not a simple sensation. The neurobiologic and functional components of the sensory channels for pain are neither fixed nor immutable. The nervous system, from the level of the nociceptor (the receptor that responds to noxious stimuli) to the supraspinal sites of integration, is characterized by its dynamic response (plasticity) to tissue insult.

Pain arising from visceral organs (e.g., heart or gastrointestinal tract) differs in many ways from that arising from somatic structures, such as the skin. Visceral pain is difficult to localize, is diffuse in character, and is typically referred to somatic structures. In addition, it is often associated with greater autonomic and motor responses than is somatic pain. These differences between somatic and visceral pain are associated with characteristic features of sensory innervations that are unique to the viscera.

SOMATIC PAIN

Somatic structures, such as the skin, are invested with a wide variety of nociceptors, each with selective sensitivities to mechanical, thermal, or chemical stimuli, in addition to the polymodal nociceptor that responds to multiple modalities of noxious stimuli.[4,5] Cutaneous nociceptors are characterized by high activation thresholds, very infrequent or no spontaneous discharges, an ability to encode stimulus intensities in the noxious (but not innocuous) range, and most importantly, sensitization. *Sensitization* refers to an increase in the magnitude of response after tissue insult, sometimes associated with an increase in spontaneous activity as well as a decrease in response threshold. This attribute of nociceptors contributes to development of hyperalgesia, or an increased response to a stimulus that is normally painful.

When a tissue is injured, a host of sensitizing chemicals are synthesized at the site of injury or released from circulating cells that are attracted to the site of injury. These include amines (e.g., histamine and serotonin), peptides (e.g., substance P and calcitonin gene–related peptide), kinins (e.g., bradykinin), neurotrophins, cytokines, prostaglandins, leukotrienes, excitatory amino acids (e.g., glutamate), and free radicals. However, it is unlikely that any one putative chemical mediator is responsible for nociceptor sensitization. Although substance P, for example, is contained in most nociceptor cell bodies, it is also present in a significant number of non-nociceptor cell bodies. Similarly, other peptides, such as calcitonin gene–related peptide, somatostatin, and galanin, are found more commonly in small to intermediate-sized dorsal root ganglion cell bodies.

VISCERAL PAIN

Whether visceral nociceptors exist is uncertain. Input to the central nervous system (CNS) from aortic baroreceptors, gastric chemoreceptors, and pulmonary stretch receptors is rarely perceived. Nevertheless, it is evident that visceral afferents possess many of the characteristics of nociceptors.

All viscera possess a dual innervation. Organs of the thoracic cavity are innervated by vagal afferent fibers with cell bodies in the nodose and jugular ganglia as well as by spinal afferent fibers with cell bodies in thoracic dorsal root ganglia. Unlike their somatic counterpart, spinal visceral afferent fibers typically traverse either or both prevertebral and paravertebral ganglia en route to the spinal cord. Thus, in contrast to somatic input to the CNS, which has a single, usually spinal, destination, input to the CNS from organs in the thoracic cavity arrives at two locations, namely the brain-stem nucleus tractus solitarii (vagal afferent input) and the thoracic spinal cord. Accordingly, the potential exists for interaction in the CNS of inputs from the same thoracic organ. The esophagus and heart also possess an intrinsic nervous system with cell bodies in the organ wall or in ganglia in the epicardial fat.[6]

Further differences between somatic and visceral innervation relate to the density of innervation and spinal pattern of termination. In general, the number of visceral afferent fibers is disproportionately less than the number of somatic afferent fibers, although the rostrocaudal spread of visceral afferent fiber terminals in the spinal cord is considerably greater than the spread of central terminals from somatic afferent fibers. Although this means that there are fewer central visceral terminals in the spinal cord, visceral afferent fiber terminals have many more terminal swellings (suggestive of synapses) than somatic nociceptor terminals and they spread over several spinal cord segments.[7] The obvious consequence of the low number of visceral afferents and greater intraspinal spread is loss of spatial discrimination, consistent with the diffuse, difficult-to-localize, nature of visceral pain.

The axons of visceral sensory neurons are, with rare exception, either thinly myelinated Aδ fibers or unmyelinated C fibers. Generally, the proportion of C fibers in visceral sensory nerves is greater than the proportion of Aδ fibers. However, high-threshold fibers are not uniformly C fibers, and low-threshold fibers are not uniformly Aδ fibers.

Unlike tissue-damaging stimuli that produce pain in somatic structures, tissue injury is not required for production of pain in the viscera. For the lower airways, irritants contained in smoke, ammonia, and other inhaled substances are capable of producing discomfort and pain. For the heart and mesentery, ischemia can be an adequate stimulus.[8] For hollow organs of the gastrointestinal tract, the adequate stimulus is typically distention of the lumen of the organ, which activates stretch and tension receptors in the smooth muscles.

Hollow viscera, including the esophagus, are innervated by two populations of mechanosensitive afferent fibers, namely a larger group (70%–80%) of fibers that have low thresholds for response (i.e., within the physiologic range), and a smaller group (20%–30%) of fibers that have thresholds for response that fall in the noxious range.[9] All mechanosensitive visceral afferent fibers may function in some circumstances as nociceptors, and low- and high-threshold mechanosensitive fibers contribute to discomfort and pain that arise from the viscera.

"*Silent nociceptors,*" a relatively new category of receptor/afferent fibers, may also contribute to altered sensations from somatic structures. Silent nociceptors have no spontaneous activity and do not respond to acute, high-intensity mechanical stimulation in normal circumstances. After tissue insult, these afferent fibers typically begin to discharge spontaneously and acquire sensitivity to mechanical stimulation. However, the contribution of such "silent" or "sleeping" afferent fibers to altered sensations that arise from the viscera is uncertain at present.

HYPERALGESIA

Some individuals are uniformly more sensitive (i.e., have lowered thresholds for stimulus-produced pain) than others. *Hyperalgesia*, the enhanced response to a stimulus that is normally noxious, consists of primary and secondary components. *Primary hyperalgesia* refers to enhanced sensitivity to stimuli applied at the site of tissue injury (e.g., an incision). *Secondary hyperalgesia*, conversely, pertains to enhanced sensitivity to stimuli applied to uninjured tissue adjacent to the site of injury. Both peripheral mechanisms (sensitization of nociceptors and afferent fibers innervating the insulted tissue) and central mechanisms (changes in the excitability of spinal and supraspinal neurons) contribute to primary and secondary hyperalgesia. Afferent fibers that innervate the pelvic viscera have been shown to sensitize when organs are experimentally inflamed. Both low-threshold and high-threshold mechanosensitive afferent fibers in the pelvic nerve exhibit exaggerated responses to distention relative to responses of the same afferent fibers before inflammation. This change in neuron excitability is believed to arise principally through the action of glutamate at the *N*-methyl-D-aspartate (NMDA) receptor. Contributions of non-NMDA receptors, AMPA or kainite, and of the receptor at which substance P acts (neurokinin 1 [NK1] receptor) are also likely.[10] Glutamate and substance P are co-contained in many small-diameter dorsal root ganglion cells and presumably are concurrently released in the spinal dorsal horn, where NMDA receptors on nociceptor terminals may act as autoreceptors to facilitate the further release of both glutamate and substance P.[11] In addition, there is evidence that substance P can act synergistically with glutamate to enhance the responses of spinal neurons.[12]

Virtually all spinal cord neurons that receive a visceral input also receive input from somatic structures, including the skin, muscle, and joints. This convergence of inputs in the spinal dorsal horn includes both viscerosomatic and visceravisceral pathways and is believed to be the basis of referred sensation that characterizes visceral pain. Such convergence also suggests that injury to somatic tissue could lead to visceral hyperalgesia and, conversely, that injury to a viscus could lead to somatic hyperalgesia.

Spinal nociceptive transmission can be modulated by electrical or chemical stimulation in the midbrain or medulla.[13] Both inhibitory and facilitatory influences on spinal nociceptive transmission are present and likely play an important role in the maintenance of secondary hyperalgesia.[14] Electrical activation of vagal afferent fibers similarly engages descending facilitatory and inhibitory modulation of spinal nociceptive transmission. Responses of neurons in the thoracic dorsal horn to either esophageal distention[15] or lower airway irritation caused by ammonia or smoke[16] are altered when the cervical spinal cord is blocked or transected or when the vagi are cut. It would be expected that responses to esophageal or respiratory stimulation would increase when the cervical spinal cord was blocked because tonic descending inhibitory influences are usually present; unexpectedly, responses were more commonly reduced, suggesting the presence of a descending facilitatory influence that is associated with vagal input to the brain stem. In a related work, both vagal afferent input and cardiac sympathetic afferent inputs contribute to the sensation of cardiac pain, particularly referral of such pain to the neck and jaw.[17]

MEASURING PAIN

Pain has proved to be both hard to define as well as difficult to measure. Because pain can only be quantified indirectly, it has been difficult to determine the optimal measuring tool for all types of pain sensations. Two widely used techniques, namely rating scales and questionnaires, are often used in clinical and epidemiologic studies of chest pain.

Rating scales constitute the simplest measurement of pain. One of the easiest to use is the quantification of pain intensity by a graded rating scale, such as the popular Visual Analogue Scale.[18] However, the sensation of pain has many more components than just its intensity; thus, a single dimensional rating scale leaves many aspects of the sensation undocumented.

To address the multidimensional qualities of pain, questionnaires have been developed.[19] The McGill Pain Questionnaire, the most widely used method in the

English language for studying the epidemiology of pain, was developed in the 1970s[20] and has been shown to be reliable and useful.[21] Although questionnaires are a powerful way of obtaining data on both the qualitative and the quantitative aspects of pain, it is not always possible to compare the results of studies with the same questionnaire because of differences in the way they have been employed.

CHEST PAIN SYNDROMES

Pain arising from the various viscera in the thoracic cavity and from the chest wall is often qualitatively similar and exhibits overlapping patterns of referral, localization, and quality, given the proximity of the various organs and the vagaries of perception of pain of visceral origin. This leads to difficulty in the differential diagnosis of chest pain (Table 30-1). Nevertheless, many chest pain syndromes are sufficiently distinctive clinically such that diagnostic efforts often rely on accurate description of the characteristic pattern of pain. The importance of the medical history in unraveling the various causes of chest pain cannot be overemphasized.

PLEUROPULMONARY DISORDERS

The lung parenchyma and visceral pleura are considered to be insensitive to ordinary painful stimuli, but pain does arise from stimulation of the mucosa of the trachea and main bronchi.[22] The lungs and bronchi are populated with mechanoreceptors that respond to stretch (inflation or deflation of the lungs) as well as chemoreceptors called J receptors that respond to a variety of algogenic chemicals, including bradykinin, prostaglandins, serotonin, and capsaicin.[23,24] Inhalation of irritant substances, such as ammonia, can trigger a cough reflex and can produce a sense of rawness, tightness in the chest, and pain. In addition, rapidly adapting mechanoreceptors that respond to lung deflation are also "irritant receptors" and signal respiratory pain. J receptors have been proposed to contribute to discomfort and pain that accompanies breathlessness.[23–25]

These receptors are, in turn, innervated by vagal and sympathetic afferent fibers. Nerve fibers that travel in the vagus nerves, including myelinated axons that carry impulses from slowly adapting stretch receptors in the conducting airways, myelinated axons that lead from rapidly adapting irritant cough receptors in the trachea and bronchi, and unmyelinated axons that subserve the extensive network of C fiber receptors (e.g., "pulmonary" J receptors and "bronchial" C fibers), are, by far, more important.[26]

The pulmonary causes of chest pain may be related to the pleural tissue, pulmonary vessels, or lung parenchyma. Causes of chest pain related to the lung parenchyma include infection, cancer, or chronic diseases such as sarcoidosis. These are discussed in more detail elsewhere in the textbook.

Pleurisy

Pleurisy results from inflammation of the parietal pleura. The visceral pleura is not innervated by nociceptors, but inflammatory processes in the periphery of the lung that involve the overlying visceral pleura (e.g., pneumonia) frequently cause inflammation of the adjacent parietal pleura that, in turn, provokes pleuritic pain conveyed by somatic nerves. The parietal pleura that lines the interior of the rib cage and covers the outer portion of each hemidiaphragm is innervated by the neighboring intercostal nerves; when pain fibers in these regions are

TABLE 30-1. Common Causes of Chest Pain

PLEUROPULMONARY DISORDERS
- Pleurisy
  - Infection
  - Pulmonary embolism
  - Spontaneous pneumothorax
  - Collagen vascular disease
  - Sickle cell disease
  - Familial Mediterranean fever
  - Malignancy (e.g., mesothelioma)
- Pulmonary hypertension
  - Pulmonary embolism
  - Primary pulmonary hypertension
  - Eisenmenger's syndrome

TRACHEOBRONCHITIS
- Infection
- Inhalation of irritants
- Malignancy

INFLAMMATION OR TRAUMA OF THE CHEST WALL
- Rib fracture
- Muscle injury (myalgia)
- Infection
- Malignancy
- Sickle cell disease
- Neuritis-radiculitis
- Herpes zoster infection

CARDIOVASCULAR DISORDERS
- Angina pectoris
- Variant angina
- Myocardial infarction
- Aortic valve disease
- Mitral valve prolapse
- Hypertrophic cardiomyopathy
- Pericarditis
- Cocaine toxicity

DISORDERS OF THE AORTA
- Aortic dissection

GASTROINTESTINAL DISORDERS
- Reflux esophagitis
- Esophageal motility disorders
- Cholecystitis
- Peptic ulcer disease
- Pancreatitis
- Disorders of intestinal motility

MISCELLANEOUS CAUSES OF CHEST PAIN
- Thoracic outlet obstruction
- Mediastinal emphysema
- Iatrogenic

stimulated, pleuritic pain is localized to the cutaneous distributions of the involved neurons over the chest wall. In contrast, the parietal pleura that lines the central region of each hemidiaphragm is innervated by fibers that travel with the phrenic nerves; when this portion of the diaphragm is stimulated (e.g., by contiguous inflammation), the resulting pain is referred to the ipsilateral shoulder or neck.

Because of the somatic innervation of the parietal pleura as well as the localization of most diseases of the lungs or chest wall to one hemithorax or the other, pleuritic pain tends to be limited to the affected region rather than be diffuse, with the exception of referral to the ipsilateral neck or shoulder. Pain may be variously described as "sharp," "dull," "achy," "burning," or simply a "catch." There is a distinctive and unmistakable relationship to breathing movements, and taking a deep breath typically aggravates pleuritic pain.[27] Coughing and sneezing can cause intense distress. Movements of the trunk, such as bending, stooping, or turning in bed, worsen pleuritic pain, so much so that patients often prefer the body position in which motion of the affected region is least.

An immediate onset of pleuritic pain suggests traumatic injuries or spontaneous pneumothorax. A sudden onset, often associated with dyspnea and tachypnea, also characterizes the clinical presentation of pulmonary embolism.[28] A slower but still acute onset over minutes to a few hours often heralds the development of community-acquired bacterial (typically pneumococcal) pneumonia, especially when accompanied by fever and chills. Recurrent acute pleuritic pain is a feature of familial Mediterranean fever.[29] Finally, a gradual onset over days or weeks, often associated with features of chronic illness, such as low-grade fever, weakness, and weight loss, suggests tuberculosis or malignancy.

Pulmonary Hypertension

Persons with pulmonary hypertension may experience crushing or constricting substernal pain that, at times, radiates to the neck or arms, thus resembling the pain of myocardial ischemia.[30] Pain from pulmonary hypertension has been reported in patients with both acute (e.g., multiple or massive pulmonary emboli) and chronic (e.g., Eisenmenger's syndrome, pulmonary vasculitis, or mitral stenosis) conditions. In addition, about half of the patients with primary pulmonary hypertension may have precordial chest pain.[31]

In acute pulmonary hypertension resulting from massive pulmonary embolism, the pain may be caused by sudden distention of the main pulmonary artery and stimulation of mechanoreceptors.

In primary pulmonary hypertension, chest pain may be related to either (1) right ventricular ischemia because coronary blood flow is unable to meet the metabolic needs of the overloaded right ventricular muscle mass as the latter strives to maintain sufficient systolic and diastolic pulmonary arterial pressures[32] or (2) compression of the left main coronary artery by the dilated pulmonary artery trunk.[33]

Although precordial pain related to the sudden onset of pulmonary hypertension can develop in cases of acute pulmonary embolism, embolism-associated pain is much more likely to be pleuritic in character, whether or not pulmonary infarction occurs.[34]

Pulmonary artery stenosis may also cause substernal pain, presumably by the same pressure-overload mechanism through which pulmonary hypertension with right ventricular hypertrophy provokes pain.[35]

TRACHEOBRONCHITIS

Pain of tracheal origin is generally felt in the midline, anteriorly, from the larynx to the xyphoid. Conversely, pain from either main bronchus is felt in the ipsilateral anterior chest near the sternum or in the anterior neck near the midline.[22] Whatever its origin, pain related to tracheobronchitis is typically described as "raw" or "burning" but may be "dull" or "achy," and exaggerated by deep breathing. This type of discomfort usually denotes the presence of viral or bacterial tracheobronchitis or, less often, a malignancy, but can also be experienced during exposure to noxious gases. Tracheobronchial pain is thought to be mediated by bronchial C fibers. Experimentally induced tracheal pain can be abolished by vagal blockade[36] or by vagotomy.[37]

INFLAMMATION OR TRAUMA OF THE CHEST WALL

Inflammation of, or trauma to, the joints, muscles, cartilages, bones, and fasciae that constitute the thoracic cage can cause chest pain.[38–40] Fibromyalgia, fibrositis, and other rheumatologic disorders of the thoracic cage, such as ankylosing spondylitis, are known to cause pain and discomfort in the chest.[41] Acute or chronic inflammation of the xyphoid process (xyphodynia)[42] and superficial "jumping" thrombophlebitis of the chest wall (Mondor's syndrome)[43] may also be uncommon sources of chest pain. Occasionally, pain related to respiration may be experienced along the costal margins after vigorous exercise.[44] In addition, metastatic malignancy may present as painful lesions of the chest wall, sometimes with spontaneous rib fractures. Another confusing source of chest pain is infectious arthritis of the sternoclavicular joint or costochondral junctions, which is an increasing problem among injection drug users.[45]

With *costochondritis*, chest wall pain arises from the costochondral cartilaginous junctions. It is usually described as "dull with a gnawing, aching quality." There is little, if any, relationship to respiratory or other body movements. Tenderness to palpation is clearly localized to one or more of the costal cartilages.[46] There may be redness, swelling, and enlargement of the costal bridges (Tietze's syndrome). The most common sites of costosternal perichondritis are the second, third, and fourth cartilages, but any part of the large cartilaginous shield along the central and lower portions of the anterior thoracic cage may be involved.

The pain of *intercostal neuritis* or *radiculitis*, which often originates from disorders of the cervicodorsal spine or nerve roots, is usually perceived in the rib cage. The superficial, spontaneous lancinating or electric shock–like pain of intercostal neuritis is typically felt over the cutaneous distribution of the involved nerves and may be worsened by taking deep breaths, coughing, and sneezing; unlike pleurisy, neuritic pain is usually not aggravated by ordinary breathing; the diagnosis is supported by the presence of hyperalgesia or anesthesia on examination of the skin. In some patients with neuritis/radiculitis, the diagnosis becomes evident 2 or 3 days later with the development of the characteristic vesicular rash of herpes zoster over the involved dermatome. Painful radiculitis is also recognized as an important early manifestation of Lyme disease.[47]

Injuries to the ribs (fracture) and thoracic cage muscles (strain, tears, or hematoma) are common causes of localized chest pain. The relationship of the pain to trauma is obvious in most instances, but diagnosis may be elusive, particularly if the inciting event is relatively minor (e.g., unnoticed episode of coughing) or when onset of pain is delayed.

CARDIOVASCULAR DISORDERS

Mechanosensitive and chemosensitive afferent fibers are present in the myocardium.[23,48] Chemical stimuli are believed to be the most important actuators of cardiac pain, but mechanical distention or distortion may also play a role.[49] Sensory fibers travel from the heart to the spinal cord through the several cardiac nerves, the upper five thoracic sympathetic ganglia, and finally, the upper five thoracic dorsal roots; afferent fibers also reach the brain through the vagus nerves.[50] Cardiac pain is likely associated with activity in afferent fibers contained in the sympathetic afferent innervation of the heart.

Myocardial Ischemia

Angina pectoris due to myocardial ischemia is typically described as severe "pressure," "squeezing," or "constriction" with maximal intensity retrosternally or over the left parasternal border. Radiation to the neck, jaw, shoulder, or down the inner aspect of one or both arms may be present. It is usually induced by exercise but may be provoked by heavy meals, excitement, or extreme emotion. Pain tends to recur with repeated provocation, although its severity may vary. Pain usually subsides within 2 to 10 minutes with rest, and relief is accelerated by treatment with sublingual nitroglycerin.[51] A majority of patients with stable angina pectoris have significant reduction of at least one major coronary artery.[52] Prinzmetal's or variant angina is similar in quality and location to typical angina pectoris but occurs at rest rather than during exercise or increased myocardial oxygen needs.[53] In this syndrome, the imbalance between myocardial oxygen supply and demand is postulated to arise from epicardial coronary artery vasospasm, usually superimposed on noncritical atheromatous vessel narrowing. Pain does not always accompany myocardial ischemia, and many electrocardiographically detectable episodes of ischemia in patients with stable angina pectoris are asymptomatic ("silent" ischemia).[54] Conversely, many individuals with angina-like chest pain have normal or nearly normal coronary arteries when studied by arteriography. As many as 30% of these noncoronary cases are classified as "syndrome X,"[55] with the development of chest pain attributed to either coronary microvascular spasm or heightened pain perception.[55,56]

The pain of *acute myocardial infarction* is similar in location to that of angina pectoris, but is typically much more severe in intensity, is not relieved by rest or nitroglycerin, often requires large doses of opiates for control, and is frequently associated with profuse sweating, nausea, dyspnea, and profound weakness.[51] During episodes of myocardial ischemia, the involved myocardium stiffens; when severe, this decrease in compliance may increase left ventricular end-diastolic filling pressure sufficiently to raise left atrial and pulmonary vascular pressures and to cause pulmonary edema. Massive myocardial infarction may also lead to intractable hypotension and shock. Acute myocardial infarction may also be silent,[57] especially in patients with diabetes mellitus.[58]

Valvular Heart Disease

Chest pain can also arise from other *non-coronary artery disorders*, including mitral valve prolapse, myocarditis,[51] pericarditis, and hypertrophic cardiomyopathy.[59] It can also be related to cocaine use.

Patients with aortic stenosis may complain of angina-like pain on exertion. The frequency of chest pain is higher with aortic stenosis than with any other valvular heart disease and occurs in two thirds of patients with severe disease.[51] Whenever a patient presents with progressive angina, dyspnea, or syncope, aortic stenosis should be considered.

Patients with mitral stenosis or pulmonic stenosis infrequently experience chest pain.

Pericarditis

The pain of *pericarditis* is most commonly pleuritic and arises from spread of the inflammatory process across the pericardium to the adjacent parietal pleura. Typically, pain is worse in the recumbent position and while lying on the left side and is partially or completely relieved by sitting up, leaning forward, or lying on the right side. Occasionally, pericardial pain may be confused with anginal pain, but radiation to the arms is uncommon. Although there are few afferent nociceptors in the pericardium, there appear to be some pain receptors in the diaphragmatic portion of its parietal layer, which is innervated by sensory axons that travel in the phrenic nerves.[60] Stimulation of these fibers causes pain that may be sharp and steady and referred to the upper margins (ridge) of the trapezius muscles. Pain in this location is claimed to be specific for pericarditis because other diseases seldom cause discomfort in that area.[51]

Pericardial friction rubs, presumably indicating underlying pericarditis, occur more often than pericardial pain during the first few days after acute myocardial infarction and with worsening uremia.[51,61] Other causes of pericarditis, usually associated with pericardial pain, are infections, often viral but also bacterial,[62] and connective tissue diseases (e.g., lupus erythematosus). Pericarditis, usually with fever, also occurs after open heart surgery (post-pericardiotomy syndrome) and after myocardial infarction (Dressler's syndrome), both of which are considered to be autoimmune disorders.[63] Often, no diagnosis can he made and pericarditis is considered idiopathic.

Cocaine Toxicity

Cocaine toxicity is associated with more visits to the emergency department for adverse reactions than any other illicit drug, and chief among the presenting complaints is chest pain.[64] Cocaine-associated chest pains typically begin about 60 minutes after injection or inhalation of the substance and lasts for 120 minutes.[65] The pain is most frequently substernal in location and pressure-like in character; it may be accompanied by shortness of breath and diaphoresis. Interestingly, clinical presentation may not differ among persons who develop myocardial infarction documented by biochemical markers and those who do not.

Cocaine-induced chest pain is undoubtedly provoked by the combined effects of an increase in myocardial oxygen demand owing to an increase in heart rate and in systolic and mean arterial pressures and a decrease in myocardial oxygen supply due to vasoconstriction of the epicardial coronary arteries.[66]

Despite its widespread use and the frequent causal association (even among casual users), patients with chest pain who are seeking medical assistance are seldom queried about recent use of cocaine. Consequently, in the setting of cardiac symptoms, identification of cocaine exposure is a legitimate goal of cardiovascular history taking. In addition this is an important question to ask because there is consensus that β-adrenergic blocking agents, which are indicated in acute coronary artery syndromes, may aggravate cocaine-induced myocardial ischemia and that nitroglycerin and calcium-channel blocking drugs (e.g., verapamil) constitute the treatments of choice. Cessation of cocaine use is essential for secondary prevention.

Disorders of the Aorta

Dissection of the aorta is usually associated with pain that is nearly always sudden and extremely severe at onset. Pain may be described, aptly, as "tearing" or "ripping" and often spreads widely, to the neck, throat, jaw, back, or abdomen, as the dissection extends from its point of origin.[67] Frequent associated features are drenching sweats, nausea and vomiting, and lightheadedness. Angina-like chest pain can also arise secondary to reduced coronary artery blood flow as a result of syphilitic aortitis or Takayasu's vasculitis.

NONCARDIAC CHEST PAIN

The term *noncardiac chest pain* is used to describe an entity that in the United States has an estimated annual incidence as high as 450,000 cases and that causes considerable long-term morbidity and health care utilization. There are three main categories of extracardiac disease that cause angina-like chest pain: (1) musculoskeletal disorders of the chest wall (see previous section), which may account for 10% to 20% of cases[125]; (2) a variety of esophageal disorders, particularly gastroesophageal reflux, which may cause 30% to 40%; and (3) psychiatric disorders (discussed later), which may explain 30% to 50% of the total.

Gastrointestinal Disorders

Receptors are present in the esophagus and may cause pain when activated by mechanical (spasm), chemical (acid reflux), or thermal (hot liquids) stimuli. Afferent nerves travel in both vagal and sympathetic (T3 to T12) pathways.[68] Pain originating from the esophagus is usually referred to midline structures, such as the throat, neck, and sternal regions, but may involve the arms as well. Stimulation of the distal end of the esophagus can cause pain directly over the heart.

Chest pain may arise either from esophageal reflux (the most common identifiable esophageal cause of chest pain) or from disorders of esophageal motility, such as diffuse esophageal spasm, achalasia, hyperactive lower esophageal sphincter, or nutcracker esophagus.[69,70] Esophageal pain may mimic angina pectoris by its radiation to the neck and arms as well as relief by nitroglycerin.[51] Chest discomfort that lasts an hour or more, that leaves a residual dull achy discomfort, or that is associated with pyrosis, odynophagia, or dysphagia should suggest pain of esophageal origin. Clinical history alone, however, cannot reliably distinguish pain originating from the esophagus from cardiac pain.

Lastly, other gastrointestinal disorders, such as cholecystitis, peptic ulcer disease, and acute pancreatitis, may present with pain that is perceived in the lower thorax.[60]

Miscellaneous Causes of Chest Pain

Obstructive lesions at the thoracic outlet may compress the brachial plexus and subclavian artery and can cause pain in the anterior chest and arms. *Thoracic outlet syndrome* is usually caused by compression of the neurovascular bundle by a cervical rib or a structural abnormality of the 1st rib or clavicle. Associated neuronal abnormalities have been described,[71] and electrophysiologic studies are useful not only to assist with the diagnosis but also to define which patients will respond to surgical decompression.[72] Chest pain may also arise from *iatrogenic causes*, such as pneumothorax following bronchoscopy or central venous catheter malposition.[73]

Psychological Factors

Many patients experience chest pain for which no cause is ever found even after careful and thorough evaluation. Psychological factors clearly affect each person's interpretation of bodily sensations, and a psychiatric cause should be excluded in undiagnosed cases of chest pain.

An association between noncardiac chest pain and anxiety disorders, particularly panic disorder, has been reported. This is particularly well described in patients with mitral valve prolapse.[74] Patients with demonstrable heart disease may also have panic attacks. Alternatively, persons with chest pain may have psychological distress that is related to the panic syndrome and not the cardiac condition.

EVALUATION AND TREATMENT OF CHEST PAIN

Given the wide variety of causes and seriousness of chest pain, considerable clinical judgment is required to decide which patients should be thoroughly evaluated and which tests should be used in the workup. In many instances, empirical therapy may need to be initiated even as evaluation proceeds, with subsequent readjustments in treatment protocols as more information is obtained that clarifies the clinical picture.

The evaluation of chest pain begins with a complete medical interview. The history may reveal nuances in the quality, location, duration, provoking events, and relieving measures, which serve to accurately focus the subsequent evaluation. However, with few exceptions, such as evident injury to the chest wall, a specific diagnosis cannot be made with complete confidence from the clinical history alone. Physical examination may reveal evidence of pleural, lung parenchymal, or airway disease; localized chest wall involvement; or signs of mitral valve prolapse, aortic valve stenosis, or other cardiac abnormalities.

For adults who present to the emergency department with new-onset chest pain, the immediate concern is to properly identify and characterize potentially life-threatening condition, such as myocardial infarction, acute pulmonary embolism, or tension pneumothorax, that requires urgent management. Some diagnostic features are listed in Table 30-2.

A standard 12-lead electrocardiogram (ECG), appropriate chest imaging, measurement of oxygen saturation and arterial blood gases, and blood chemistry profiles (e.g., troponin, D-dimer) often provide important data. In the appropriate clinical setting, some patients may require echocardiography or pulmonary function testing. Many other noninvasive or invasive tests are available for the evaluation of pain believed to be of respiratory, cardiac, or gastrointestinal origin. If diagnosis remains uncertain, admission to chest pain observation units that offer a safe and effective means of care for patients with possible unstable angina who are considered to be at intermediate risk for cardiovascular events may be considered.

TABLE 30-2. Differential Diagnosis of Chest Pain

Diagnosis	Pain	Characteristics	ECG	CXR	Associated Features
Angina pectoris	Substernal, constricting	Transient, effort-related	Local ST depression; occasional elevation	Normal	Relief with NTG
MI	Substernal, crushing	Persistent, severe	Local ST elevation or depression	Possible vascular congestion or cardiomegaly	Relief with opiates; possible hypotension; ↑ troponin
Pulmonary embolism	Pleuritic	Sudden onset with dyspnea	Nonspecific; occasional RV strain	Normal or opacities ± small pleural effusion	Risk factor/s for venous thrombosis
Pulmonary artery hypertension	Gradual onset	Associated with dyspnea, fatigue and edema	Tall right precordial R waves, right axis deviation, RV strain	Prominent pulmonary arteries	Exclude pulmonary thromboembolism and interstitial lung disease
Bacterial pneumonia	Pleuritic	Onset in minutes to hours	Normal	Consolidation	Fever, productive cough
Pneumothorax	Sharp, unilateral	Sudden onset with dyspnea	Normal	Collapsed lung	Asthenic habitus, recurrence
Pericarditis	Pleuritic	Either side; gradual onset	Generalized ST elevation	Possible enlarged silhouette	Friction rub
Aortic dissection	Substernal, severe	Radiation to the back	Nonspecific; LVH or inferior MI	Widened mediastinum	Prostration, loss of pulse, aortic insufficiency
Esophageal spasm/reflux	Substernal	May mimic angina; burning	Normal or ST-T changes	Normal	Relief with NTG or antacids
Costochondritis	Dull-achy, localized	↑ by cough or deep breath	Normal	Normal	Localized tenderness
Herpes zoster	Sharp, unilateral	Dysesthesia	Normal	Normal	Vesicular rash

CXR, chest x-ray; ECG, electrocardiogram; LVH, left ventricular hypertrophy; MI, myocardial infarction; NTG, nitroglycerin; RV, right ventricular.

The most definitive treatment for chest pain, whatever its origin, is to find its cause and to cure it. The general principles of therapy of respiratory, cardiac, musculoskeletal, esophageal, and panic disorders are available and the clinician is encouraged to refer to them. Chronic noncardiac chest pain is more difficult to manage, especially when its trigger cannot be found. Because of the complexities and difficulties in dealing with those few patients who have chronic, severe, and often refractory pain, referral to special pain centers staffed by a multidisciplinary team of specialists is recommended. At times, psychiatric consultation for specific treatment may be helpful.

Cardiac Ischemia

Evaluation of patients with suspected *unstable angina or non-ST elevation myocardial infarction* should include a 12-lead ECG (serial tests may be considered if the initial ECG is not diagnostic), and biomarker determination (creatine kinase-MB, myoglobin, or cardiac-specific troponin [preferred]). Other helpful tests include B-type natriuretic peptide (BNP), stress testing (if ECG and cardiac biomarker measurements are normal),[75] noninvasive coronary imaging tests (cardiac computed tomography [CT] or magnetic resonance imaging [MRI] techniques), echocardiography, radionuclide angiography, or coronary angiography. The indication for stress echocardiography has recently been clarified and includes the evaluation of acute chest pain and other chest pain syndromes, such as anginal equivalent, with or without heart failure, as well as risk assessment in symptomatic patients following revascularization procedures.[76,76a]

Acute ECG changes, such as ST segment deviations or deep T wave inversions, positive cardiac biomarkers or stress test results, or hemodynamic instability should prompt admission to an intensive care unit. Hospital admission may also be considered if diagnosis remains uncertain despite initial limited evaluations. Available risk stratification models, such as the Thrombolysis in Myocardial Infarction (TIMI) score, may aid diagnosis and management. Aspirin, preferably non–enteric-coated formulations, should be provided unless contraindicated or already taken by the patient. Other medications that may be useful in the acute management of ischemic heart disease include nitroglycerin (sublingual or intravenous), β-blockers, angiotensin-converting enzyme (ACE) inhibitors, non-dihydropyridine calcium channel blocker, morphine sulfate (for persistent chest discomfort), antiplatelet agents (clopidogrel or GP II/IIIa inhibitor), and anticoagulant therapy (e.g., unfractionated heparin, enoxaparin, or fondaparinux). Patients should be placed on strict bed rest and supplemental oxygen should be provided, particularly if the patient is in respiratory distress or if oxygen saturation is less than 90%. Every patient with acute coronary syndrome should be evaluated for possible reperfusion therapy (fibrinolytic agents) or revascularization (coronary artery bypass graft surgery or percutaneous coronary intervention) unless contraindicated.[75–81b] A recently published meta-analysis revealed that management of non–ST segment elevation acute coronary syndromes by early invasive therapy improves long-term survival and reduces adverse cardiovascular events (late myocardial infarction and rehospitalization for unstable angina) compared with a more conservative approach.[82]

Evaluation and management of *variant* or *Prinzmetal's angina* consists of coronary angiography in patients with chest pain accompanied by transient ST segment elevation. Nitrates and calcium channel blockers may be given if no obstructive coronary artery lesions are evident on coronary angiography, with percutaneous coronary intervention reserved for those with significant coronary artery stenosis. Provocative testing may be considered in cases of diagnostic uncertainty if no contraindications exist.[77]

For cardiac ischemic chest pain related to the use of *cocaine* or *methamphetamine*, nitroglycerin and calcium channel blockers or may be considered as are immediate coronary angiography (preferred) or fibrinolytic therapy (if coronary angiography is not possible) if electrocardiographic ST elevation (or new ST segment depression or T wave changes) persists despite pharmacologic intervention. A combined α- and β-blocking agent, such as labetalol, may be helpful in patients with sinus tachycardia related to cocaine use if a vasodilator (nitroglycerin or calcium channel blocker) has been administered within the previous hour.[77]

Patients with *cardiovascular syndrome X* may also benefit from medical intervention with nitrates, calcium channel blockers, and/or β-blockers. Intracoronary ultrasound, coronary angiography, 24-hour ambulatory ECG, provocative testing, or coronary flow reserve measurement may be considered to aid with diagnosis.[77]

Risk stratification with exercise ECG (using the Bruce protocol or Duke treadmill score), exercise perfusion imaging, or exercise echocardiography should be considered for patients with symptomatic chronic stable angina who are able to exercise and have no contraindications to such testing. For those who are unable to exercise, myocardial perfusion imaging with dipyridamole or adenosine or dobutamine echocardiography is recommended unless contraindications to such testing exist.[83]

Pulmonary Embolism

Pulmonary embolism is a life-threatening feature of venous thromboembolism and most frequently originates from deep venous thrombosis in the lower extremities.

Patients with acute pulmonary embolism who have elevated levels of troponin are at high risk for short-term mortality and adverse outcome events.[84] A recent meta-analysis of the different diagnostic strategies for suspected pulmonary embolism disclosed the positive likelihood ratios for high-probability ventilation-perfusion (V/Q) lung scan (18.3), spiral CT (24.1), and lower extremity venous ultrasonography (16.2). The corresponding negative likelihood ratios were 0.05 for a normal or near-normal lung scan, 0.04 for a negative

spiral CT along with a negative result on ultrasonography, and 0.08 for a D-dimer concentration less than 500 μg/L by quantitative enzyme-linked immunosorbent assay. With these tests, the posttest probability of pulmonary embolism was greater than 85% in patients with a moderate or high pretest probability and below 5% in patients with a low or moderate pretest probability. Because of higher negative likelihood ratios, spiral CT alone, a low-probability V/Q lung scan, magnetic resonance angiography, a quantitative latex D-dimer test, and hemagglutination D-dimers can only exclude pulmonary embolism in those with a low pretest probability.[85] Patients with pulmonary embolism can be treated with either unfractionated heparin or low-molecular-weight heparin. Anticoagulation is maintained either for 3 to 6 months for events related to a transient risk factor or for greater than 12 months for recurrent venous thromboembolism.[86]

Pericardial Disease

Acute pericarditis is often, but not always, accompanied by pericardial effusion that can be detected by echocardiography. Therapy of acute pericarditis involves identification and management of any underlying cause/s of the condition (e.g., infection or malignancy). In constrictive pericarditis, echocardiography can demonstrate the presence of pericardial thickening and calcification that limits diastolic filling of the ventricles (restrictive filling) and causes a characteristic biphasic pattern of venous return with a diastolic component that is equal to or greater than the systolic component. In selected patients, pericardectomy is a highly effective treatment for constrictive pericarditis.[87]

Cardiac Tamponade

Cardiac tamponade is diagnosed by the presence of cardiac compression by fluid within the pericardial sac. This, in turn, impairs ventricular diastolic filling and gives rise to the sensation of chest pain, dyspnea, tachycardia, falling systemic blood pressure, elevated venous pressure (characteristic loss of the atrial Y descent with maintenance of both the systolic atrial filling wave and the X descent), and pulsus paradoxus (an exaggerated inspiratory decrease in arterial systolic pressure > 10 mm Hg). Cardiac tamponade should be suspected whenever a patient presents with unexplained hypotension or pulsus paradoxus, especially following myocardial infarction, chest trauma, percutaneous coronary intervention, or cardiac surgery. Other risk factors include anticoagulation therapy, malignancy, or an underlying connective tissue disease. A pericardial rub may be appreciated during physical examination. ECG changes compatible with acute pericarditis may be present as is an enlarged cardiac silhouette on chest films. Diagnosis is generally determined by two-dimensional echocardiography that demonstrates an inspiratory increase of right ventricular dimensions and decrease of left ventricular dimensions, compression of the right atrium, right ventricular diastolic collapse, and a heart that swings with cardiac contractions. Left atrial collapse is less common than right atrial collapse but is very specific of cardiac tamponade. There is commonly also an abnormal inspiratory increase of blood flow velocity through the tricuspid valve accompanied by a decrease in mitral valve flow velocity as well as dilation of the inferior vena cava with lack of inspiratory collapse. Rapid infusion of fluid and percutaneous or surgical pericardial fluid drainage leads to immediate relief of chest discomfort, dyspnea, venous hypertension, and pulsus paradoxus.[87,88]

Pulmonary Arterial Hypertension

Evaluation of suspected pulmonary arterial hypertension generally consists of ECG, an arterial blood gas, a chest radiograph, pulmonary function testing, exercise capacity (6-min walk test), noninvasive Doppler echocardiography (with and without contrast), V/Q scanning (to rule out chronic thromboembolic disease), pulmonary angiography, and right heart catheterization to both confirm the diagnosis as well as identify any associated disorders. Testing for connective tissue disease or human immunodeficiency virus (HIV) infection may be considered in patients with suggestive clinical histories for these disorders.[89] Acute vasoreactivity testing (using intravenous epoprostenol or adenosine or inhaled nitric oxide) should be performed for patients with idiopathic pulmonary arterial hypertension. Polysomnography is indicated for patients with a clinical history suggestive of obstructive sleep apnea. Current and investigational agents for pulmonary arterial hypertension include potent vasodilators such as prostacyclin and its analogues (iloprost and treprostinil), endothelin receptor antagonists (bosentan and ambrisentan), sildenafil, a cylcic guanosine monophosphate (cGMP)–specific phosphodiesterase type 5 inhibitor, and high-dose calcium channel blockers. Pulmonary thromboendarterectomy may benefit patients with chronic thromboembolic pulmonary hypertension. Lung (preferably bilateral) transplantation or heart-lung transplantation may be considered for selected patients with New York Heart Association functional class III and IV symptoms.[90]

Thoracic Aortic Dissection

Rapid diagnosis and management are critical for patients with thoracic aortic dissection. Aortography, as a method of diagnosing thoracic aortic dissection, has been replaced by less invasive imaging techniques, such as transesophageal echocardiography, helical CT, and MRI, all of which yield clinically reliable data for both confirming as well as ruling out this condition. In one review, pooled sensitivity (98%–100%) and specificity (95%–98%) from 16 studies involving 1139 patients were comparable between these three less invasive imaging tools. Pooled positive likelihood ratio was higher for MRI than for transesophageal echocardiography or helical CT. The posttest probability of thoracic aortic

dissection following a positive result of each of these imaging tests is 93% to 96% if a patient has a high-risk (i.e., 50%) pretest probability of the condition, and 0.1% to 0.3% if a patient has a low-risk (i.e., 5%) pretest probability following a negative result from each of the imaging tests.[91]

Pneumothorax

Spontaneous pneumothorax can be either primary or secondary. Patients with small primary pneumothoraces may be observed closely for either progression or resolution if they are clinically stable. Chest catheter or tube insertion is indicated if the pneumothorax enlarges or if clinical deterioration occurs, as well as in patients with large primary or secondary pneumothoraces. Patients with small secondary spontaneous pneumothoraces who are clinically stable may be either observed or managed with a chest tube depending on clinical severity and course of the pneumothorax.[92,93]

Tension Pneumothorax

A tension pneumothorax is a life-threatening condition that requires urgent management. High intrathoracic pressures develop because of ingress of air into the pleural space via a one-way valve process, which, in turn, prevents egress of air; this gives rise to vena caval compression, reduction in venous return, and diminished cardiac output. Radiographically, a tension pneumothorax presents as a collapse of the ipsilateral lung, depression/flattening of the ipsilateral hemidiaphragm, and shift of the mediastinum to the contralateral hemithorax. Therapy consists of emergency percutaneous aspiration or chest tube insertion.[93]

Pancoast Tumors

Pancoast's (superior sulcus) tumors require a definitive tissue diagnosis prior to initiation of therapy, which may, in selected patients, include resection and/or chemoradiotherapy. MRI, both mediastinal and extrathoracic, is frequently performed to rule out involvement of adjacent neurovascular structures (brachial plexus, vertebral column, or subclavian vessels) that will influence surgical approaches.[94]

Chest Trauma

Blunt and penetrating chest trauma can give rise to chest pain related to hemothorax (bleeding into the pleural space), pneumothorax, rib, sternal or clavicular fractures, or injury to the chest wall musculature.

As little as 5 mL of hemothorax can be appreciated on a decubitus chest radiograph, but a size of about 200 mL is required for it to be readily identified on an upright chest radiograph, where it will appear as blunting or, with greater volume of bleeding, a concave upward sloping of the fluid, in the ipsilateral costophrenic angle. The presence of an air-fluid level indicates a hemopneumothorax. Chest CT is more sensitive than chest radiographs in detecting a small hemothorax; in addition, it may occasionally offer clues to the origin of the bleeding.

Rib fractures may be associated with injuries to the brachial plexus and subclavian veins (upper rib fractures) or spleen and liver (lower rib fractures). A flail chest resulting from at least two fracture sites on at least three consecutive ribs can create regional chest wall instability and respiratory distress. A sternal fracture occurs most commonly at the body or manubrium, generally following direct trauma to the anterior chest or from deceleration. Significant posterior displacement of the sternum may be associated with trauma to the underlying cardiovascular structures. Chest CT is more sensitive than plain chest radiographs for detecting rib and sternal fractures.[93]

Gastroesophageal Reflux

Dyspepsia secondary to gastroesophageal reflux can be managed with proton pump inhibitors, histamine$_2$ receptor antagonists, or prokinetic agents. An empirical trial with these medications may be considered if the clinical history strongly supports the diagnosis of gastroesophageal reflux and if the patient is not at high risk for a gastrointestinal malignancy. Risk factors, such as use of nonsteroidal anti-inflammatory agents, should be investigated. Endoscopy may be necessary in some patients with unexplained dyspepsia and persistent symptoms. Recommendations for eradication therapy of *Helicobacter pylori*–positive dyspepsia have been published.[95]

Pancreatitis

Common causes of acute pancreatitis include gallstone disease (about 50% of cases) and alcohol abuse (20%–25%). Patients typically complain of abdominal pain and vomiting, but chest pain may develop as well. Lipase determination, with its higher sensitivity and specificity over amylase, is preferred over the latter for the diagnosis of acute pancreatitis; the former is produced only by the pancreas. In addition, the half-life of lipase is longer than that of amylase. Other helpful laboratory tests include liver chemistries, triglyceride, and calcium. When diagnostic doubt exists, abdominal imaging by contrast enhanced CT may be beneficial. In additional to supportive measures, therapeutic endoscopic retrograde cholangiopancreatography (ERCP) may be considered, particularly if the acute pancreatitis is severe, due to gallstones, or when cholangitis, jaundice, or a dilated common bile duct is present. The presence of cholangitis is an indication for endoscopic sphincterotomy or duct drainage by stenting. Image-guided fine-needle aspiration is recommended for patients with significant pancreatic necrosis, who may require débridement if infection is present.[96,97]

KEY POINTS

- Chest pain is characterized by an unpleasant sensation that is either localized to the thorax or believed to originate from structures located in the latter. It may announce the presence of severe, occasionally life-threatening, disease.
- Pain arising from visceral organs (e.g., heart or gastrointestinal tract) differs in many ways from that arising from somatic structures, such as the skin. Visceral pain is difficult to localize, is diffuse in character, and is typically referred to somatic structures. It is also often associated with greater autonomic and motor responses than is somatic pain.
- Somatic and visceral innervations differ in relation to the density of innervations and spinal pattern of termination. In general, the number of visceral afferent fibers is disproportionately less than the number of somatic afferent fibers, although the rostrocaudal spread of visceral afferent fiber terminals in the spinal cord is considerably greater than the spread of central terminals from somatic afferent fibers. The low number of visceral afferents and greater intraspinal spread is responsible for loss of spatial discrimination, consistent with the diffuse, difficult-to-localize, nature of visceral pain.
- Pain is both hard to define as well as difficult to measure. Two widely used techniques, namely rating scales and questionnaires, are often used in clinical and epidemiologic studies of chest pain. Although rating scales constitute the simplest measurement of pain, the sensation of pain has many more components than just its intensity; thus, a single-dimensional rating scale leaves many aspects of the sensation undocumented.
- Pain arising from the various viscera in the thoracic cavity and from the chest wall is often qualitatively similar and exhibits overlapping patterns of referral, localization, and quality, given the proximity of the various organs and the vagaries of perception of pain of visceral origin. This leads to difficulty in the differential diagnosis of chest pain.

CHAPTER 31

VIRAL INFECTIONS

F. Eun-Hyung Lee, MD • John Treanor, MD

INTRODUCTION
Classification
Transmission
Pathogenesis of Infection

CLINICAL SYNDROMES
Common Cold
Pharyngitis
Acute Bronchitis
Influenza-like Illness
Croup
Bronchiolitis
Pneumonia

MAJOR VIRAL PATHOGENS
Adenoviruses
Coronaviruses
Cytomegalovirus
Hantaviruses
Herpes Simplex Viruses
Influenza Viruses
Measles Virus
Metapneumoviruses
Parainfluenza Viruses
Respiratory Syncytial Virus
Rhinovirus
Varicella-Zoster Virus

INTRODUCTION

Viral infections are important causes of disease of the respiratory tract. The common cold is the most frequently encountered infectious syndrome of humans, while influenza continues to be a major cause of mortality and serious morbidity on a worldwide basis. Respiratory viral infections frequently complicate the course of patients with chronic obstructive pulmonary disease and asthma. As the number of immunocompromised persons in the population has increased, infections due to cytomegalovirus and other herpesviruses, adenoviruses, and paramyxoviruses have assumed increasing importance in pulmonary medicine. Finally, recent years have seen the continuing emergence of new viral respiratory pathogens, including hantaviruses, human metapneumovirus, avian and porcine influenza A viruses, and the SARS coronavirus. This introductory section outlines general concepts of respiratory viral infections and their associated clinical syndromes. The following sections then provide a review of the major viral pathogens infecting the respiratory tract.

Classification

Viruses of importance in the respiratory tract (Table 31-1) include both those considered to be principal respiratory viruses—whose replication is generally restricted to the respiratory tract—and others in which respiratory involvement is part of a generalized infection. Virus classification depends in part on the type and configuration of the nucleic acids in the viral genome, the characteristics of the viral structural proteins, and the presence or absence of an envelope surrounding the virus particle. The number of distinct antigenic types within each virus family also varies.

Transmission

The routes by which the different respiratory viruses spread from person to person are variable and include combinations of contact, droplet, and aerosol transmission. For example, rhinovirus and respiratory syncytial virus are primarily spread by direct contact with contaminated skin and environmental surfaces, followed by self-inoculation of virus onto the nasal mucosa or conjunctiva. Others viruses, such as measles and varicella-zoster viruses, spread as small-particle aerosols. Other viruses may spread by means of larger-particle aerosols over short distances (1 meter). The relative importance of the various transmission routes under natural conditions for each virus varies and in many cases is unknown.

TABLE 31-1. Viral Infections of the Respiratory Tract

Group	Nucleic Acid	Envelope	Types	Disease/Syndrome*
Adenovirus	DNA	No	1–47	Common cold; bronchitis; bronchiolitis; pharyngoconjunctival fever; acute respiratory disease (ARD) in military recruits; pneumonia
Coronavirus	RNA	Yes	229E, OC43, HuCoV-SARS	Common cold, severe acute respiratory syndrome (SARS)
Hantavirus	RNA	Yes	Multiple	Acute respiratory distress, pneumonitis
Orthomyxovirus	RNA	Yes		
Influenza virus			A, B, C	Influenza; common cold; pharyngitis; croup; bronchitis; bronchiolitis; pneumonia
Paramyxoviruses	RNA	Yes		
Measles virus				Measles; pneumonia; bronchiectasis
Parainfluenza virus			1–4	Common cold; croup; bronchitis; bronchiolitis; pneumonia
Respiratory syncytial virus			A, B	Common cold; croup; bronchitis; bronchiolitis; pneumonia
Human metapneumovirus			A, B	Bronchiolitis, common cold
Picornaviruses	RNA	No		
Enterovirus				
Coxsackievirus			1–24	Type A21 (Coe virus) colds and ARD; others (types 2, 4, 5, 6, 8, 10); herpangina
Echovirus			1–34	Common cold (importance uncertain)
Rhinovirus			1–100	Common cold
Herpes viruses	DNA	Yes		
Herpes simplex virus			1, 2	Acute pharyngitis in normal persons; chronic ulcerative pharyngitis; tracheitis; pneumonia in immunosuppressed patients
Cytomegalovirus			1	Mononucleosis; acute and chronic pharyngitis; pneumonia in immunosuppressed patients
Varicella-zoster virus			1	Pneumonia in normal persons and immunosuppressed patients
Epstein-Barr virus			1	Mononucleosis; acute and chronic pharyngitis
Human herpesvirus 6			1	Pneumonia in immunosuppressed patients
Filovirus	RNA	Yes	Marburg; Ebola 1, 2	Pharyngitis as an early manifestation of hemorrhagic fever
Human immunodeficiency virus	RNA	Yes	1, 2	Pharyngitis with primary infection; secondary pulmonary infections
Papillomavirus	DNA	No	>60	Laryngeal and tracheobronchial papillomatosis

*Bacterial infections, including sinusitis, otitis media, and pneumonia, complicate respiratory virus infection. Also, infection with the respiratory viruses may precipitate attacks of asthma and cause exacerbations in patients with chronic obstructive pulmonary disease.

Pathogenesis of Infection

The initial sites of infection and pathogenesis differ for the various virus groups. Some, such as rhinovirus, are associated mainly with upper respiratory tract involvement. Others, such as influenza, commonly invade the lower airways and sometimes the pulmonary parenchyma in addition to causing upper airway disease. The viruses also differ in the extent that virus-induced cell damage and host immune response and inflammation contribute to the clinical manifestations of disease.

An additional important feature of respiratory virus infections is their effect on the resident bacterial flora of the upper airways. Respiratory virus infections have been found to alter bacterial colonization patterns, increase bacterial adhesion to respiratory epithelium, and reduce mucociliary clearance and phagocytosis. These impairments of host defenses by virus allow colonization by pathogenic bacteria and invasion of normally sterile areas, such as the paranasal sinuses, middle ear, and lower respiratory tract, often resulting in secondary infection.

CLINICAL SYNDROMES

As shown in Table 31-1, infection by one of the respiratory viruses may result in more than one clinical syn-

drome. Similarly, a particular syndrome can result from infection with one of several different viruses. The poor correlation of agent and syndrome makes specific etiologic diagnosis on clinical grounds inaccurate, although knowledge of the seasonal patterns of infection may be helpful. Moreover, infection with a single virus may cause disease at multiple levels of the respiratory tract.

Common Cold

There is no universally accepted, standard definition of a "cold," but the term is usually used to refer to acute rhinitis with variable degrees of pharyngitis. Systemic complaints are absent or modest in severity, and fever is unusual. Allergic diseases of the upper airway often have clinical manifestations similar to those of colds. Colds are frequently associated with involvement of the middle ear, presumably due to eustachian tube dysfunction. Colds are associated with symptomatic otitis media in approximately 2% of cases in adults, and in a higher proportion in young children. Colds are frequently associated with sinus mucosal thickening or secretions on computed tomography (CT) scans, but rarely result in symptomatic sinusitis. Vertigo associated with viral labyrinthitis may also be seen.

The common cold syndrome is caused by any one of a large number of antigenically distinct viruses found in four principal groups (Table 31-2). Epidemiologic studies have indicated that, on an annual basis, any one antigenic type of virus is responsible for less than 1% of all colds. Since the discovery of the respiratory viruses in the 1960s, rhinovirus has emerged as the prototype common cold virus (Fig. 31-1).

The recommended treatment for colds is to use individual remedies to treat specific symptoms. Nasal sprays containing decongestants should be used for no more than 3 days to prevent a rebound vasomotor rhinitis. Cough syrups containing expectorants are of unproven value in common colds. Symptoms of sneezing and rhinorrhea can be alleviated with nonselective sedating antihistamines such as brompheniramine, chlorpheniramine, or clemastine fumarate,[1] but treatment with selective histamine$_1$ inhibitors is not effective. Studies of pseudoephedrine have demonstrated measurable improvements in nasal airflow consistent with a decongestant effect.[2] Nonsteroidal anti-inflammatory drugs such as naproxen moderate the systemic symptoms of rhinovirus infection. However, the use of the decongestant phenylpropanolamine has been shown to be associated with an increased risk of hemorrhagic stroke.[3] Topical application of ipratropium, a quaternary anticholinergic agent that is minimally absorbed across biologic membranes, reduces rhinorrhea significantly in naturally occurring colds. This agent probably exerts its major effect on the parasympathetic regulation of mucous and seromucous glands. Importantly, most over-the-counter cough and cold remedies have not been studied in pediatric populations, in which they may be associated with significant side effects.[4]

TABLE 31-2. Viruses Associated with the Common Cold

Virus	Percentage of Cases*
Rhinovirus	40
Coronavirus	10
Parainfluenza virus Respiratory syncytial virus Influenza virus Adenovirus	10–15
Other viruses (enterovirus, rubeola, rubella, varicella)	5
Presumed undiscovered viruses	20–30
Group A β-hemolytic streptococci†	5–10

*Estimated percentage of colds annually.
†Included because differentiation of streptococcal and viral pharyngitis is not possible by clinical means.

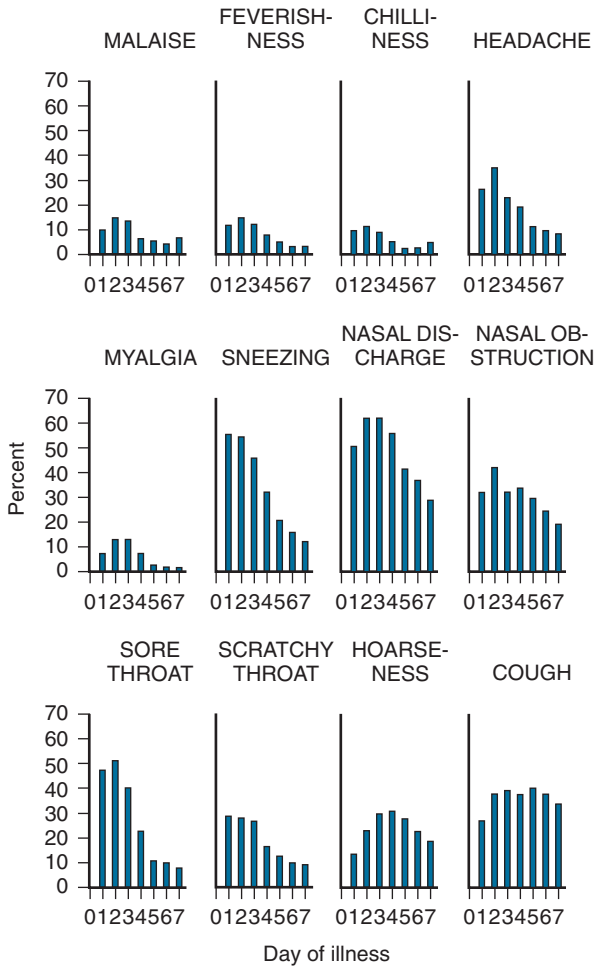

FIGURE 31-1 ■ Graphs showing the clinical features of rhinovirus colds (139 natural infections). (Adapted from Gwaltney JM Jr, Hendley JO, Simon G, Jordan WS Jr: Rhinovirus infections in an industrial population. II. Characteristics of illness and antibody response. JAMA 202:494–500, 1967.)

Pharyngitis

Pharyngitis occurs most often as part of the common cold syndrome and thus is usually associated with the same viruses that cause colds. In some cases, pharyngeal symptoms predominate to a degree that overshadows other complaints; the soreness may be attributable to the presence of kinins, which are potent stimulators of pain nerve endings. High levels of bradykinin and lysylbradykinin are present in nasal secretions of patients with rhinovirus colds; furthermore, intranasal application of bradykinin promotes sore throat and nasal symptoms in volunteers, supporting a role for these agents in the pathogenesis of cold symptoms.[5]

The respiratory viruses causing pharyngitis can be divided into two groups: those associated with a pharyngeal or tonsillar exudate and those in which such an exudate does not occur (Table 31-3). Pharyngitis is often a prominent complaint with adenovirus and influenza virus infection. Also, some viruses are associated with other types of enanthema, such as vesicles and ulcers. Coxsackie A viruses are associated with the condition herpangina, a painful, often febrile pharyngitis of children and young adults characterized by vesicular lesions of the soft palate.

Viruses in the herpes family cause a small proportion of cases of pharyngitis. Primary infection with herpes simplex virus manifests as an acute vesiculoulcerative pharyngitis or gingivostomatitis that may have an exudative character. In immunocompromised patients, herpes simplex virus causes large, shallow ulcers of the mucosa that are chronic and progressive if untreated (Fig. 31-2). Epstein-Barr virus mononucleosis characteristically has an acute exudative pharyngitis. Mononucleosis due to cytomegalovirus infection may have a nonexudative pharyngitis that is acute or chronic, and cytomegalovirus also rarely causes oral ulcerations in immunosuppressed patients. Pharyngitis occurs in primary infection with human immunodeficiency virus (HIV). Viruses in the hemorrhagic fever group produce an acute pharyngitis that occurs early in the disease, before skin lesions appear. Also, exudative pharyngitis is a common clinical manifestation in Lassa fever.

TABLE 31-3. Important Microbial Agents Associated with Acute Pharyngitis

Pharyngitis with colds and influenzal illness (no exudate)	Rhinovirus Influenza virus Coronavirus Respiratory syncytial virus
Exudative pharyngitis (exudate is not present in all cases)	*Streptococcus pyogenes* (group A β-hemolytic streptococcus) Mixed anaerobic infection (Vincent's angina and peritonsillar abscess) Adenovirus Herpes simplex virus Epstein-Barr virus *Corynebacterium diphtheriae* (pseudomembrane)

Typically, sore throat accompanied by nasal symptoms is more likely to be viral in nature. Infection with mixed anaerobic bacteria (Vincent's angina) or with *Corynebacterium diphtheria* are also in the differential diagnosis of exudative pharyngitis. The treatment of most cases of viral pharyngitis is symptomatic.

Acute Bronchitis

The diagnosis of acute bronchitis is usually applied to cases of acute respiratory disease with severe and prolonged cough that continues after other signs and symptoms of the acute infection have subsided. Cough occurs during the first week of illness in 30% of rhinovirus colds in young adults and in 80% or more of cases of influenza A virus infection, in which it is often prolonged. Adenovirus infections characteristically involve the tracheobronchial tree, with resultant bronchitis, which in military populations is part of the syndrome of *acute respiratory disease.*

The mechanisms of cough production in viral infection are not well understood, but may include direct damage to the respiratory mucosa, release of inflammatory substances in response to the infection, increased production and/or decreased clearance of respiratory secretions, and stimulation of airway irritant receptors. Intranasal application of several prostaglandins also produces cough in uninfected volunteers.[5] Infection may also enhance airway reactivity, leading to increased sensitivity to cold air and pollutants such as cigarette smoke.

The differential diagnosis of acute bronchitis includes nonviral infections and noninfectious etiologies such as cough-variant asthma. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* infections cause prolonged cough; *Bordetella pertussis* infection should also be considered in the differential diagnosis. In otherwise healthy persons, workup of acute cough should be directed toward determining the presence of pneumonia; if this

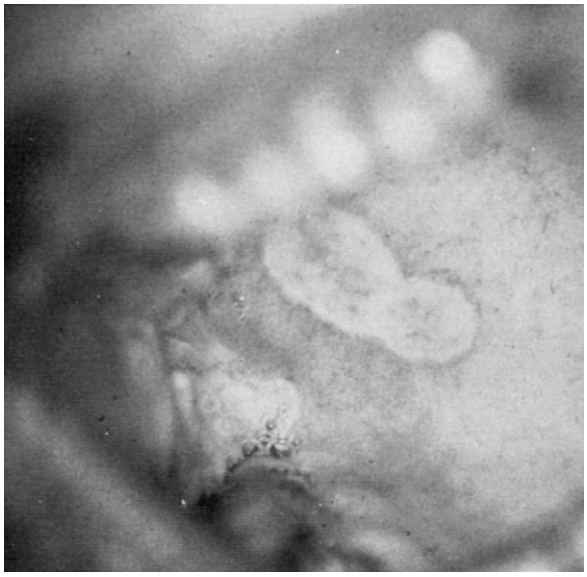

FIGURE 31-2 ■ Chronic herpetic ulcerations overlying the hard palate in an immunosuppressed patient.

is not present, then treatment with antibacterial agents is of no benefit.[6] Symptomatic treatment is directed at the suppression of cough. In children, a single nocturnal dose of honey is as effective as dextromethorphan in suppressing nighttime coughing.[7]

Influenza-like Illness

The clinical syndrome of influenza is characterized by the rapid onset of constitutional symptoms, including fever, chills, prostration, muscle aches, and headache, concurrent with or followed by upper and lower respiratory tract symptoms. Systemic symptoms tend to dominate the first several days of illness, whereas respiratory complaints, particularly cough, predominate later in the first week of illness. Photophobia, excess tearing, and pain with eye movement are common early in the illness. Mild conjunctivitis, clear nasal discharge without obstruction, pharyngeal injection, and small, tender cervical lymph nodes are frequently present. Fever, peaking at 39°C to 40°C or higher, may occur and can last for 1 to 5 days. Persistent nonproductive cough, easy fatigability, and asthenia are common in the second week of illness.

Influenza type A and B viruses are the most important causes of the influenza syndrome, particularly when it occurs in epidemic form. However, the syndrome can occur in association with infection by other viruses, including adenoviruses, parainfluenza viruses, and respiratory syncytial virus. The characteristic clinical features of influenza and its epidemic nature permit the practitioner to make an accurate diagnosis in most cases seen during recognized epidemics of influenza virus infection, particularly if cough and fever are present.[8] Specific antiviral therapy is effective if given early in the course of the illness (see the section on influenza viruses). Symptomatic treatment (bed rest, oral hydration, antipyretics, and antitussives) is also beneficial. Fever should be treated in certain clinical situations, such as in children with previous febrile convulsions or patients with preexisting cardiac disease. Because of its possible association with Reye's syndrome, aspirin should be avoided in pediatric patients.

Croup

The croup syndrome of children is characterized by an unusual brassy or barking cough that may be accompanied by inspiratory stridor, dyspnea, and hoarseness. The symptoms are often preceded by several days of upper respiratory illness and are typically worse at night. Croup is seen primarily in children under the age of 6 years. The term *acute infectious croup* or *laryngotracheobronchitis* is applied to a contagious disease that affects otherwise healthy children and that is often associated with a respiratory illness in the family. The term *acute spasmodic croup* is applied to a similar syndrome that is most common in young children who are prone to recurrent attacks, which may be precipitated by respiratory viral infections and possibly allergic or other factors. In these children, fever is frequently absent, and symptoms often abate within several hours.

Most children with acute laryngotracheobronchitis have symptoms of decreasing intensity over several days and can be managed at home. However, increasing laryngeal obstruction can be associated with respiratory insufficiency, which is manifested by restlessness, air hunger, stridor at rest, use of accessory muscles, and intercostal retractions, and which may be followed by development of exhaustion with severe hypoventilation, cyanosis, and cardiovascular collapse. A fluctuating course is typical.

Radiologic examination of the upper airway shows glottic and subglottic edema (Fig. 31-3) and helps to differentiate the disorder from acute bacterial epiglottitis.

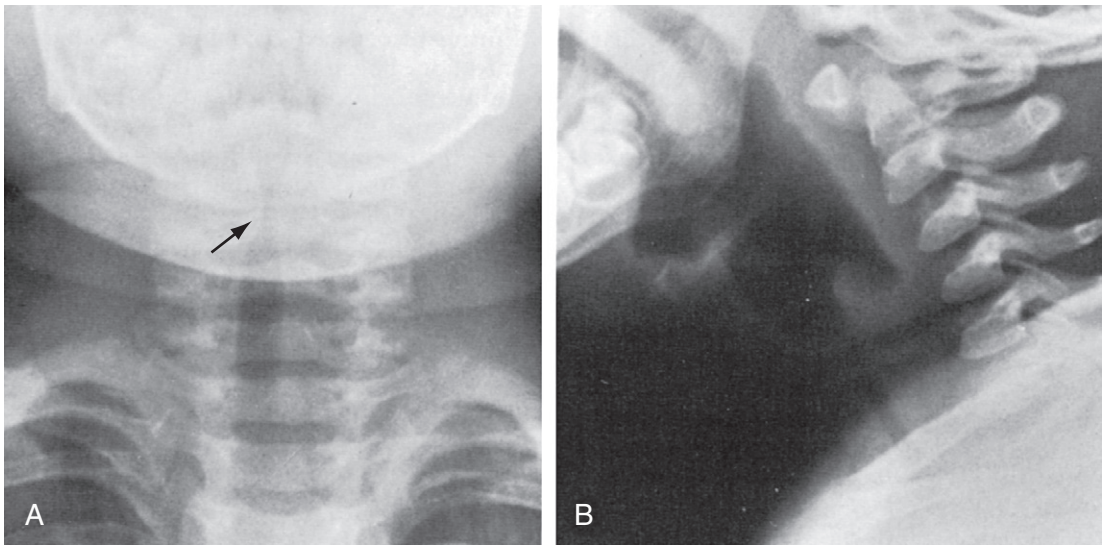

FIGURE 31-3 ■ Anteroposterior **(A)** and lateral **(B)** neck roentgenograms of a 2-year-old child with croupy cough, inspiratory stridor, and fever. The anteroposterior view shows subglottic narrowing in the steeple pattern (*arrow*) characteristic of laryngotracheobronchitis caused by parainfluenza virus. The lateral view shows ballooning of the hypopharynx resulting from laryngeal obstruction. (Courtesy of Joan McIlhenny, MD, Department of Radiology, University of Virginia Medical Center, Charlottesville, Virginia.)

However, radiographs are limited in accuracy, and when the diagnosis is uncertain, radiologic and pharyngeal examination should be avoided because of the risk of cardiorespiratory arrest in acute epiglottitis. Emergency assessment by an otolaryngologist or an anesthesiologist is indicated in this situation.

The acute infectious croup syndrome has been associated principally with infection by one of the parainfluenza viruses, as well as respiratory syncytial virus, influenza A and B viruses, adenoviruses, and rhinovirus. Measles is an important cause of severe croup in the developing world, and influenza A epidemics also are associated with severe croup. The differential diagnosis of croup includes acute bacterial epiglottitis, diphtheritic croup, asthma, and intrinsic or extrinsic upper airway obstruction related to an aspirated foreign body, allergic angioedema, and retropharyngeal abscess.

Because the majority of hospitalized children are hypoxic, oxygen is the mainstay of treatment for severe disease. Humidified air or mist therapy is commonly used, but the value of mist therapy has not been proven, and removal of the child from the parents and placement in a mist tent can be more distressing to the child than beneficial.

Nebulized racemic epinephrine is commonly used for symptomatic relief in croup. It is believed that α-adrenergic stimulation by this drug causes mucosal vasoconstriction, leading in turn to decreased subglottic edema. The onset of action is rapid, often within minutes, but the duration of relief is also limited, lasting 2 hours or less. Therefore, treated subjects should be observed closely for clinical deterioration. While symptomatic relief is considerable, use of epinephrine is not associated with improvements in oxygenation. Steroids have been shown to confer significant benefits in the management of mild, moderate, and severe croup, including more rapid improvement in symptoms, reduced length of hospital stay, and reduced rates of intubation. Administration of single-dose steroid therapy in this setting has not been associated with significant side effects, and should probably be used in any patient with significant enough illness to require an emergency room or clinic visit.[9]

Antiviral agents have not been tested for efficacy in this situation, although the potential benefit of the use of an antiviral in the typical self-limited course of croup would likely be limited. Because croup is a viral illness, antibiotic therapy is of no benefit.

Bronchiolitis

Bronchiolitis is an acute inflammatory disorder of the small airways characterized by obstruction with air trapping, hyperinflation of the lungs, and atelectasis that typically occurs in children under the age of 2 years. After a several-day prodrome of mild upper respiratory tract symptoms, patients typically present with inspiratory and expiratory wheezing. The clinical features, which include tachypnea, intercostal and suprasternal retractions, nasal flaring, hyperresonant chest, wheezing, and inspiratory crackles, usually lead to an accurate clinical diagnosis. The infant is often afebrile, and in mild cases symptoms resolve within several days. Chest roentgenograms show hyperinflated lungs with flattening of the diaphragms, peribronchial thickening, and often atelectasis or parenchymal consolidation indicative of concurrent bronchopneumonia (Fig. 31-4). The white blood cell count and differential count are usually within normal limits.

The majority of cases in which an etiologic agent has been demonstrated are associated with respiratory syncytial virus. Other viruses associated with bronchiolitis include human metapneumovirus, parainfluenza viruses, influenza A and B viruses, adenoviruses, measles virus, and rhinovirus. The major differential diagnostic consideration is asthma, which is uncommon under the age of 1 year.

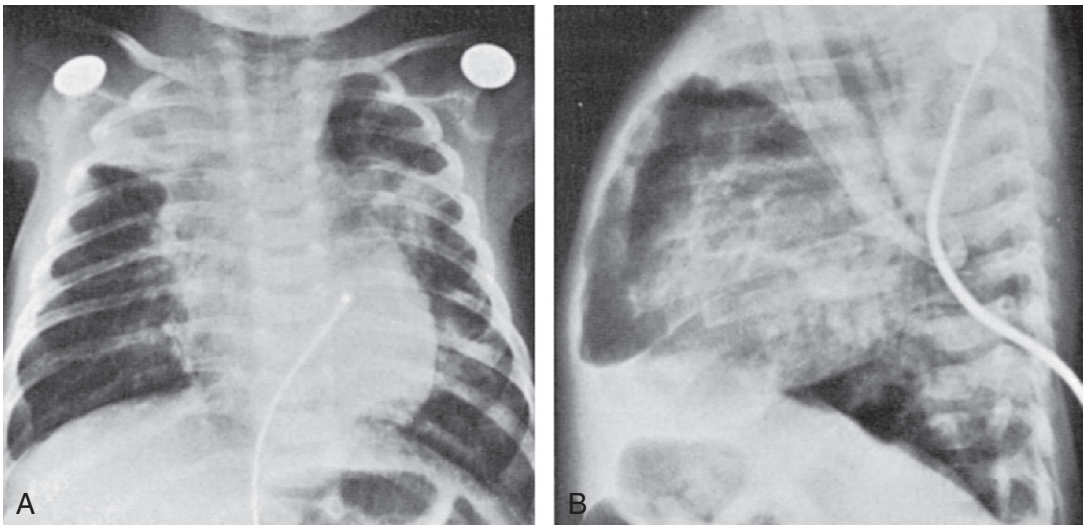

FIGURE 31-4 ■ Anteroposterior **(A)** and lateral supine **(B)** chest roentgenograms of a 1-month-old child with respiratory syncytial virus pneumonia. Note the marked overexpansion and patchy infiltrates in both upper and left lower lung zones. (Courtesy of Thomas Lee Pope, Jr., MD, Department of Radiology, University of Virginia Medical Center, Charlottesville, Virginia.)

Correction of hypoxemia is the most important aspect of managing lower respiratory tract disease. Studies of corticosteroid therapies have found no consistent benefit, and bronchodilating drugs are not effective and may contribute to increased restlessness and cardiovascular stress. Because of the dehydrating effect of tachypnea and reduced oral intake in some hospitalized infants, parenteral rehydration is often needed, but care must be taken to avoid inducing hyponatremia. Aerosol treatment with the synthetic nucleoside ribavirin has been associated with reductions in virus titers but inconsistent clinical benefits.

Pneumonia

Viruses are important causes of pneumonia in both adults and children. They have been associated with up to 40% of radiographically proven pneumonias in hospitalized adults and are estimated to cause 16% of total pneumonias in pediatric outpatients and up to 49% in hospitalized infants. These figures may underestimate the importance of viral infections as a cause of pneumonia, particularly in outpatients, because of the insensitivity of viral diagnostic methods and because of the lack of chest roentgenograms in many patients with acute viral infections. Also, because viral infections may be complicated by secondary bacterial pneumonias, invasive procedures would be needed to accurately differentiate among pure viral pneumonias, secondary bacterial pneumonias, and mixed viral and bacterial infections.

Normal Host

The relative importance of the different viruses as causes of pneumonia in otherwise healthy people depends on the season in which illness occurs and the age distribution of the population under study. During outbreaks, influenza virus accounts for over 50% of viral pneumonia in adults. In addition, respiratory syncytial virus, adenoviruses, parainfluenza viruses, and varicella virus can all cause pneumonia in healthy adults. Unusual viruses continue to emerge in epidemics of severe acute pneumonitis, including hantaviruses, coronavirus (that causing severe acute respiratory syndrome [SARS]), and both avian and porcine influenza A viruses.

In children, respiratory syncytial virus, parainfluenza viruses, and adenoviruses—in addition to influenza viruses—are the most important causes of pneumonia. Measles virus pneumonia occurs in children and adults during epidemics in susceptible populations. There are reports of cases of pneumonia in adults and children attributable to rhinovirus, but the evidence that these viruses are definite causes of pneumonia is circumstantial.

The clinical and radiographic features of sporadic cases of viral pneumonia are usually not sufficiently characteristic to permit specific viral diagnosis or differentiation from bacterial pneumonias on clinical grounds alone. Exceptions include measles and varicella pneumonia, in which the associated rash establishes the diagnosis. Therefore, attention is first directed at excluding primary or secondary bacterial pneumonia. If available, viral cultures of respiratory secretions and tests to detect viral antigens or nucleic acids may provide a specific diagnosis. Serologic testing may be useful.

Treatment of viral pneumonia in the normal host is supportive in nature and is directed at early antimicrobial therapy of secondary bacterial infections. Specific antiviral therapy may be beneficial and is discussed with the individual pathogens later in the chapter. Viral pneumonias with extensive involvement of lung tissue may require prolonged ventilatory assistance and pulmonary rehabilitation. Some cases of viral pneumonia have a rapid and relentless fatal course, with generalized alveolar and interstitial infiltrates, development of the acute respiratory distress syndrome (ARDS), and progressive respiratory failure.

Immunocompromised Host

Viral pneumonia is an important problem in the increasing number of persons in the population who have deficiencies in immunity as the result of cytotoxic chemotherapy, organ transplantation, and the acquired immunodeficiency syndrome (AIDS). The major respiratory viruses that affect healthy persons may also cause pneumonia in immunodeficient hosts, and severe and prolonged pneumonias due to adenovirus, respiratory syncytial, influenza, measles, or parainfluenza viruses may develop in such patients. In addition, these individuals may develop pneumonia due to viruses that rarely cause lower respiratory tract disease in normal hosts, such as cytomegalovirus, which causes severe primary viral pneumonia as well as predisposing patients to bacterial and fungal superinfections because of its added immunosuppressive effects. Also, varicella-zoster and herpes simplex virus pneumonias are relatively uncommon but serious infections in immunosuppressed patients.

MAJOR VIRAL PATHOGENS

Adenoviruses

Adenoviruses are medium-sized (65 to 80 nm), nonenveloped viruses with a genome composed of linear double-stranded deoxyribonucleic acid (DNA)[10] (Fig. 31-5). Currently, 47 antigenic types of adenovirus are associated with human infection, although not all types have been associated with human disease. The protein coat of the virus is composed of 252 hexagonal and pentagonal capsomeres in an icosahedral array with long projecting fibers at each vertex. These fibers are thought to be the site of host cell attachment. Adenovirus types 2 and 5 and Coxsackie B viruses utilize the same receptor, designated the Coxsackie-adeno receptor (CAR). Interaction of the penton base with α_5 integrins also promotes virus entry into the cell. Type-specific antigens, which give rise to neutralizing antibody, are present on the hexons and fibers of the capsid. The hexons also contain a complement fixation antigen with cross reactivity among the mammalian adenoviruses.

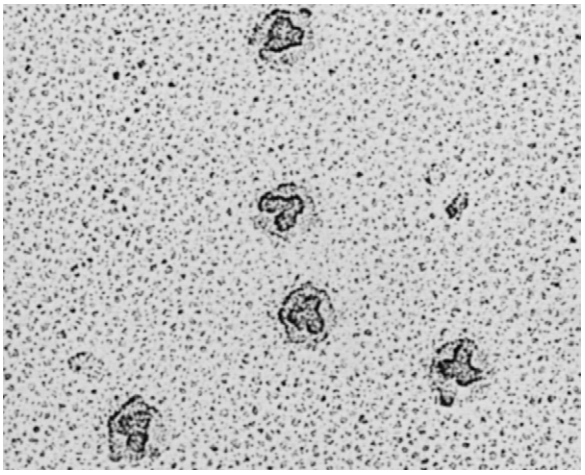

FIGURE 31-5 ■ Photoelectron micrograph showing human adenovirus type 2. Each virion contains a lobulated group of three adenosomes, which are composed of DNA and protein. Full virion particles contain a total of 12 adenosomes, each of which is found below one vertex of the icosahedral capsid. (Courtesy of J. Brown and W. Newcomb, University of Virginia, Charlottesville, Virginia.)

Epidemiology and Transmission

Humans are the reservoir of the adenoviruses that cause human disease, although nonhuman adenoviruses are found in other species. Some serotypes, especially types 1 and 2, routinely infect infants and young children, who then have prolonged asymptomatic viral shedding from the respiratory and gastrointestinal tracts. Other types, including those that have been most often implicated in respiratory disease (e.g., types 3, 4, and 7), are acquired later in life, characteristically in epidemic settings. In most instances, viral transmission probably occurs by direct contact with infectious secretions. However, the explosive nature of adenoviral acute respiratory disease in military recruits probably reflects airborne spread.

Most community adenovirus respiratory disease has been recognized in the summer months in association with outbreaks or sporadic cases of febrile pharyngitis or bronchitis. Nosocomial outbreaks of adenovirus infection have occurred in hospital wards, special care units, and psychiatric facilities. Since 1996, a specific variant of adenovirus type 7 (Ad7d2) has been responsible for several civilian outbreaks and a large military outbreak.[11] The appearance of this new Ad7 genotype may herald a shift in the predominant strains with greater disease impact.

Pathogenesis

Adenoviruses have been isolated from the upper airway, eye, urine, stool, and, rarely, blood. The incubation period for naturally acquired adenovirus disease of the respiratory tract is in the range of 4 to 7 days but may be up to 2 weeks.

Cytopathologic changes have also been observed in bronchial epithelium cells,[12] and crystalline arrays of virus particles have been found in alveolar lining cells of infected persons with severe illness.[13] The extent of damage to the respiratory tract in nonfatal adenovirus respiratory disease is not well defined, but may result from a combination of virus-related cytopathology and host-related inflammatory responses to infection. In cases of fatal adenovirus pneumonia, bronchial epithelial necrosis, bronchial obstruction, and interstitial pneumonia have been seen.[14] Cells containing large basophilic, intranuclear inclusions—so-called smudge cells—appear to be characteristic (Fig. 31-6). In lung transplant recipients, a necrotizing bronchocentric pneumonia with diffuse alveolar damage has been reported.[15]

Clinical Illness

Adenovirus Respiratory Disease. The nonpneumonic respiratory syndromes associated with adenovirus infection include acute respiratory disease of military recruits and *pharyngoconjunctival fever* of civilians, which have similar characteristics (Fig. 31-7). Adenovirus respiratory disease typically involves the pharynx as a moderate to severe, sometimes purulent, pharyngitis. Also characteristic of this disease is marked tracheitis, bronchitis, or tracheobronchitis, plus rhinitis and conjunctivitis. Conjunctivitis is not a feature of infection with the other major respiratory viruses and therefore, when present, is a useful diagnostic finding in adenovirus respiratory disease. With adenovirus respiratory disease, the conjunctivitis is typically mild and follicular, although some adenovirus types also cause the more severe condition, epidemic keratoconjunctivitis. Fever, chills, myalgia, and prostration are prominent features of adenovirus infection, so it is often perceived by the patient as a "flulike" illness or an unusually severe cold.

Cases of acute respiratory disease tend to have more tracheobronchitis, perhaps reflecting acquisition of infection by the airborne route. Conversely, in pharyngoconjunctival fever, the infrequency of cough and other tracheobronchial complaints in some outbreaks may reflect infection contracted by pharyngeal and/or conjunctival inoculation with virus from contaminated

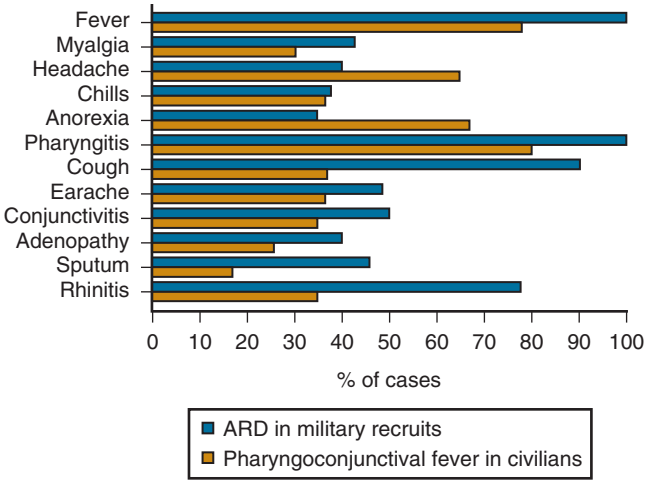

FIGURE 31-7 ■ Graph showing comparison of the clinical characteristics of acute respiratory disease (ARD) of military recruits and pharyngoconjunctival fever of civilians. (Adapted from Dascomb HE, Hilleman MR: Clinical and laboratory studies in patients with respiratory disease caused by adenoviruses. Am J Epidemiol 111:229–237, 1980.)

water. The two syndromes are associated with the same viral serotypes, and in civilian populations, both occur as sporadic cases. In young children, adenovirus infection has been associated with both mild and febrile respiratory illness; concomitant otitis media occurred in approximately 40% of these cases.

Adenovirus Pneumonia. Adenovirus was first recognized as a cause of viral pneumonia in military recruits and has since been recognized as a rare cause of pneumonia in civilian adults and children. The clinical characteristics of adenovirus pneumonia are similar to those of other pneumonias, so that it is difficult to make an accurate etiologic diagnosis on the basis of clinical features. In fatal cases there has been extensive pulmonary damage, with death occurring 2 to 3 weeks into the illness. Intravascular coagulopathy has also been a late feature of some cases, and a septic-shock picture has been described.[16] Adenoviruses cause a particularly aggressive form of pneumonia in neonates, characterized by necrotizing bronchiolitis and alveolitis.[17] Viral acquisition from the mother, perhaps via the birth canal, may occur. Long-term sequelae of adenovirus infection may include persistent radiographic abnormalities, abnormal pulmonary function tests, bronchiectasis, and hyperlucent lung.

Adenovirus Infection in Persons with Impaired Immunity. Adenoviruses can cause fatal pneumonia and disseminated infection, with hepatitis, hemorrhagic cystitis, and renal failure, in transplant patients and other persons with immunodeficiency.[18] A variety of immunotypes have been recovered from these patients (Table 31-4), including higher numbered serotypes that are only seen in such patients. Types seen with particular frequency include 1, 2, 5, 6, 7, 11, 21, 31, 34, and 35. The clinical importance of the recovery of an adenovirus from these patients, particularly from stool samples, is often difficult to determine because of the multifactorial nature of their disease.

Diagnosis

Diagnosis may be achieved either by virus isolation or by direct detection of viral antigens or nucleic acids from appropriate specimens of respiratory secretions, conjunctival swabs, stool, and urine, depending on the clinical syndrome. Rapid detection of viral antigens in clinical specimens by enzyme-linked immunosorbent

assay or immunoflorescence and of viral DNA by nucleic acid amplification techniques is increasingly used, because of the fastidiousness of some serotypes and the slow rate of isolation. Quantitative measurement of adenovirus DNA levels in plasma may be useful for diagnosis and response to therapy.[19]

Frozen specimens (−70°C) are satisfactory for testing because of the relative stability of adenoviruses. Cytopathic effect usually appears in cell culture in 3 to 7 days, but may take several weeks. The time required to detect virus in cell culture can be shortened to as little as 2 days by employing centrifugation culture systems. Serodiagnosis has relied primarily on testing for a group-specific complement fixation antibody response, using acute and convalescent serum specimens. Infection with some adenovirus types is not detected by the complement fixation test. In biopsy specimens, the appearance of characteristic intranuclear basophilic inclusion bodies seen by light microscopy or of crystalline arrays of virus seen by electron microscopy are useful in histopathologic diagnosis.

Treatment and Prevention

Antiviral treatment of proven value for adenovirus infection is not available. Both the broad-spectrum antiviral agents ganciclovir and cidofovir, and ribavirin for group C adenoviruses, are active in vitro, and an increasing number of reports indicate that intravenous gancyclovir may be useful in seriously ill patients, although at the expense of significant renal toxicity.[20] Cidofovir has also been used for preemptive therapy in high-risk immunocompromised patients.[21] While intravenous ribavirin[22] or ribavirin combined with immunoglobulin[23] has been administered in individual patients, failures are common.[24] Donor leukocyte infusions have also been tried.

Because of the prominent fever and systemic complaints associated with adenovirus respiratory disease, analgesics, such as aspirin and acetaminophen, are needed more often than with a milder coryzal illness such as a rhinovirus cold. Warm saline gargles are helpful for relieving throat pain, which does not usually require narcotics. The presence of pharyngeal exudate may sometimes lead to an incorrect diagnosis of streptococcal pharyngitis, resulting in the initiation of antimicrobial therapy.

Effective and safe live oral vaccines for adenovirus types 4 and 7 were developed for military use, and, when delivered in enteric-coated capsules, controlled acute respiratory disease in recruit populations. Of note, use of these vaccines was not associated with replacement by nonvaccine serotypes. Because the manufacturer no longer produces these vaccines, they are not currently used in the military. Consequently, adenoviruses have reemerged as important causes of lower respiratory tract disease in this population.

Coronaviruses

Coronaviruses are enveloped viruses containing a single-stranded, positive-sense ribonucleic acid (RNA) genome of approximately 29,000 nucleotides. Distinctive club-shaped projections are present on the virus surface, giving the appearance of a crown or corona, from which it derives its name. Coronaviruses can be classified into three main groups, two mammalian (I and II) and one avian (III), based on genetic and antigenic differences. The group I strains include coronavirus strain 229E (HCoV 229E) and HCoV NL63, while group II includes strains HCoV OC43 and HKU1. In addition, the novel coronavirus responsible for *severe acute respiratory syndrome* (SARS), denoted HuCoV-SARS, is also a member of group II.

The virus contains five structural proteins: spike or Sprotein, hemagglutinin-esterase (HE), M (matrix), E (envelope), and N (nucleocapsid). The S protein is the major envelope glycoprotein and mediates both attachment to cells and fusion with the cell membrane. Antibodies to the spike protein are thought to be associated with protection and thus candidates for therapeutic and vaccine targets. A second envelope protein, HE, is only found in some coronavirus strains, but is not present on HuCoV-SARS. Nonstructural proteins such as the viral replicases and proteinases, particularly the 3C-like proteinase, are also antiviral targets.

Epidemiology and Transmission

Human coronaviruses OC43 and 229E have been recognized as causes of the common cold for many years and cause frequent reinfections throughout life. In adults these viruses have accounted for 4% to 15% of acute respiratory disease annually and up to 35% during peak periods. Annual illness rates in children reach 8%, with peak rates of up to 20%.[25] The reported frequency of infection in adults for 229E and OC43 viruses has ranged from 15 to 25 per 100 persons per year, with up to 80% of infections occurring in persons with prior antibody to the infecting virus.[26] Coronaviruses usually circulate during winter and early spring, but can be detected year-round.[27]

For all coronaviruses, transmission involves inoculation of the respiratory tract with infectious secretions via large droplets and close contact, as demonstrated in human challenge experiments for OC43[28] and animal studies for HuCoV-SARS.[29] In the spring of 2003, the emergence of HuCoV-SARS occurred in southern China, and the virus rapidly spread worldwide.[30] Virus shedding for HuCoV-SARS peaked at day 10 of symptom onset, which was at the height of disease severity.[31] This phenomenon accounted for the preponderance of transmission in hospitals. The incubation period for SARS is estimated from 2 to 10 days, and for conventional human coronaviruses 3 to 4 days.

Pathogenesis

Conventional coronavirus antigen has been detected in epithelial cells shed from the nasopharynx of infected volunteers,[32] and during experimental infection, nasal airway resistance, mucosal temperature, and the albumin content of nasal secretions increase.[33] However, relatively little is known about the pathogenesis of

the common cold induced by conventional human coronaviruses.

The hallmark of the pulmonary pathology in fatal cases of SARS was diffuse alveolar damage,[34] type II pneumocyte hyperplasia, squamous metaplasia, and multinucleated giant cells. Hemophagocytosis has been reported, potentially as a consequence of cytokine dysregulation.[35] Furthermore, virus was detected within pulmonary epithelial cells.[36] From these findings, it is postulated that disease pathogenesis involves direct damage to pulmonary epithelia by the virus in combination with an overly enthusiastic host immune response.

Clinical Illness

Conventional human coronaviruses produce a typical coryzal illness that is indistinguishable from colds due to other viruses. Coronaviruses have also been linked with acute otitis media, exacerbations of asthma in children, and exacerbations of chronic bronchitis and pneumonia in adults.

In contrast, SARS has a nonspecific presentation that is difficult to distinguish from other viral acute respiratory illnesses, particularly influenza. Common symptoms on presentation are fever, chills and/or rigors, myalgias, and occasionally diarrhea. Cough and dyspnea are the predominant respiratory symptoms but may not be present initially. Respiratory disease becomes more severe over 4 to 7 days, and about 20% of patients require respiratory support. SARS fatality rates were 11% for all ages but much higher in older adults[37]; children generally had mild disease.[38] SARS laboratory abnormalities include elevations in lactate dehydrogenase, transaminases, and creatine kinase, and hematologic abnormalities, particularly lymphopenia (depletion of CD4 and CD8 T cells), and thrombocytopenia.

Common findings on chest CT include unilateral or bilateral ground-glass opacifications, and interlobular septal and intralobular interstitial thickening. In most patients, peripheral involvement in the lower lung zones has been observed. In some cases, after recovery from acute illness, pulmonary fibrosis has developed.[39] Clinical features predictive of poor outcomes included the presence of bilateral disease at presentation, peak level of lactate dehydrogenase, older age, and other comorbid conditions.

Diagnosis

The main site of viral replication of HuCoV-SARS appears to be the lower respiratory tract[36]; therefore, polymerase chain reaction (PCR) detection is the most reliable in the sputum, but virus can also be detected in the blood and stool.[40] Serum antibodies rise within 2 to 3 weeks of illness, although measurements at 4 weeks have become the standard to exclude SARS.

Treatment and Prevention

Current available human antiviral treatments for HuCoV-SARS include chloroquine, protease inhibitors, ribavirin, type I interferons, niclosamide, and anti-inflammatory agents such as indomethacin.[41–43] Ribavirin, a purine nucleoside analogue, was used early during the SARS epidemic. Then, ribavirin in combination with lopinavir/ritonavir (protease inhibitors commonly used in HIV disease) was associated with a lower incidence of adverse outcomes compared to historical controls of ribavirin alone. Nelfinavir, another protease inhibitor, also has demonstrated in vitro antiviral activity. Other targets for controlling SARS viral replication have included interferons. In an uncontrolled clinical study, the use of corticosteroids with interferon alfacon-1 (synthetic interferon-α) demonstrated improvements in oxygenation.[44] Although the mechanisms are unknown, chloroquine, niclosamide, and indomethacin all have activity inhibitory to HuCoV-SARS in vitro.[45–47] Neutralizing antibodies to the S1 protein contained in convalescent plasma (stocked by the Hong Kong Red Cross) may also be important in preventing viral entry.[43]

For conventional coronoviruses, immunity is short lived. Epidemiologic studies of coronovirus infection have demonstrated high reinfection rates.[48] In human volunteer experiments, infection with a 229E-like coronavirus only induced effective immunity short term because rechallenge with homotypic virus, the 229E serotype, resulted in infection and illness.[49] In addition, under certain circumstances, vaccines against animal coronaviruses have led to enhanced disease.[50] Thus, efforts to derive a coronavirus vaccine for humans may be difficult.

Cytomegalovirus

Cytomegalovirus (CMV) is a member of the gammaherpesvirus subfamily of the herpesviruses and has the same structural and biochemical characteristics, which include an internal core containing linear double-stranded DNA, an icosadeltahedral capsid containing 162 capsomeres, and an envelope derived from the host-cell nuclear membrane. However, the large size of the CMV virion (200 nm) and larger genome distinguish it from the other human herpesviruses. There is approximately 80% homology between the genomes of various strains of CMV, but sufficient differences exist to permit strain identification by restriction endonuclease analysis. The CMV genome codes for approximately 33 structural proteins, the functions of many of which are currently unknown. In addition, clinical isolates often encode multiple gene products not seen in laboratory strains. Envelope glycoproteins B and H have been identified as a major antigens eliciting neutralizing antibody. Glycoprotein B may also be a target for cytotoxic T-lymphocyte responses,[51] while multiple proteins serve as targets for T-cell responses. Cytomegalovirus-specific, cytotoxic T-cell responses are an important host defense mechanism that has been shown to be associated with survival from CMV infection in bone marrow transplant recipients.[52] However, CMV uses multiple mechanisms, including down-regulation of human leukocyte antigen on the cell surface and interference with antigen processing, to evade recognition by the host.

Epidemiology and Transmission

Infection with CMV, whether disease associated or asymptomatic, is followed by prolonged excretion of virus in urine, saliva, stool, tears, breast milk, vaginal secretions, and semen. Thus, the major community reservoir for CMV is asymptomatic infected persons. Virus shedding persists for years in children with congenital and perinatal CMV infections. Transmission of the virus is believed to occur by direct contact, especially under conditions of intimacy such as found in child care centers[53] and the family setting. Thus, the rate of acquisition of infection is greater in populations with high density, leading to infection at an early age. In addition to transmission by sexual intercourse, passage through a contaminated birth canal, and ingestion of breast milk, CMV infection can be acquired from transfused blood products and from transplanted organs. No seasonal patterns of CMV infection have been observed.

Pathogenesis

In human fibroblast cell cultures, CMV produces a slowly progressive lytic infection. Infected cells contain large irregular basophilic intranuclear inclusions and also eosinophilic inclusions in paranuclear areas. The intranuclear inclusions are a hallmark of CMV infection and have been found in cells of a number of organs, including kidney, liver, lung, and the gastrointestinal tract (Fig. 31-8). In the lung, fibroblasts, epithelial cells, endothelial cells, and smooth muscle cells are all targets for CMV infection.[54]

In immunocompetent persons, most infections are subclinical. If symptoms occur, the most typical manifestation is acute pharyngitis with features similar to mononucleosis. In immunocompromised hosts there may be a variety of clinical syndromes, whose severity is affected by whether infection is acquired de novo or represents reactivation of endogenous virus. The risk of severe disease is particularly high in transplant patients when a CMV-seronegative recipient receives an organ from a seropositive donor.

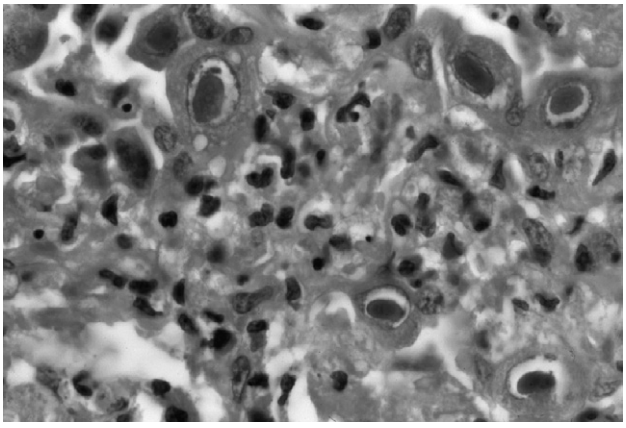

FIGURE 31-8 ■ Photomicrograph of lung tissue from an individual with CMV pneumonia, showing eosinophilic intranuclear inclusions.

The pathogenesis of CMV pneumonia is partly related to viral replication but also is thought to have an immunopathologic basis.[55] The development of CMV pneumonitis reflects a complex interaction between viral infection and graft-versus-host disease, particularly in marrow transplant recipients.[56,57] Two patterns of histopathology have been described in the lung tissue of bone marrow transplant patients with serious pneumonia.[58] One is a miliary pattern, with multiple focal lesions showing extensive cytomegaly with localized necrobiosis, alveolar hemorrhage, fibrin deposition, and neutrophilic response (see Fig. 31-8). The other is of interstitial character, with alveolar cell hyperplasia, interstitial edema, lymphoid infiltration, and diffusely distributed cytomegalic cells.

Clinical Illness

Cytomegalovirus causes a variety of human diseases, including congenital and perinatal infections, infectious mononucleosis, hepatitis, posttransfusion infection, and invasive infection in patients with impaired immunity. In transplant populations, CMV infection often involves multiple organ systems in conjunction with other opportunistic infectious agents.

The main impact of CMV is as a respiratory pathogen is in immunocompromised patients because the virus rarely causes pneumonia in healthy hosts. In recipients of allogeneic bone marrow transplants, CMV is recognized as the most common infectious cause of interstitial pneumonia and, untreated, is responsible for the highest fatality rate. The risk of CMV pneumonia is greatest between 30 and 90 days after bone marrow transplantation. However, late occurrence of CMV syndromes posttransplantation (i.e., at >180 days) has been increasingly recognized with effective control of earlier onset disease.

Risk factors for the disease include advanced age, the presence of acute graft-versus-host disease, intensive conditioning regimens, and allografts. Cytomegalovirus infection and pneumonitis also develop in the majority of isolated lung transplant recipients who are serologically at risk, usually in the transplanted lung.[59] In these patients, CMV pneumonitis may be a factor in the development of *bronchiolitis obliterans* reactions, a serious posttransplantation complication. Cytomegalovirus can also be a primary pathogen in persons with AIDS, although it is more often encountered in conjunction with other pulmonary pathogens.

Characteristically, patients with CMV pneumonia have sustained fever, nonproductive cough, and dyspnea. Crackles and tachypnea are often present, and marked hypoxemia is an indicator of life-threatening infection. Pneumonitis may be accompanied by mild neutropenia, thrombocytopenia, and elevated liver enzymes, which may be helpful in differential diagnosis. Chest radiographic changes are usually bilateral, with diffuse or focal haziness involving the middle and lower lung fields. Both miliary and interstitial radiographic patterns have been described (Fig. 31-9). Patients with a miliary pattern of lung pathology may have a sudden onset of tachypnea, severe respiratory distress, and hypoxemia resulting in a

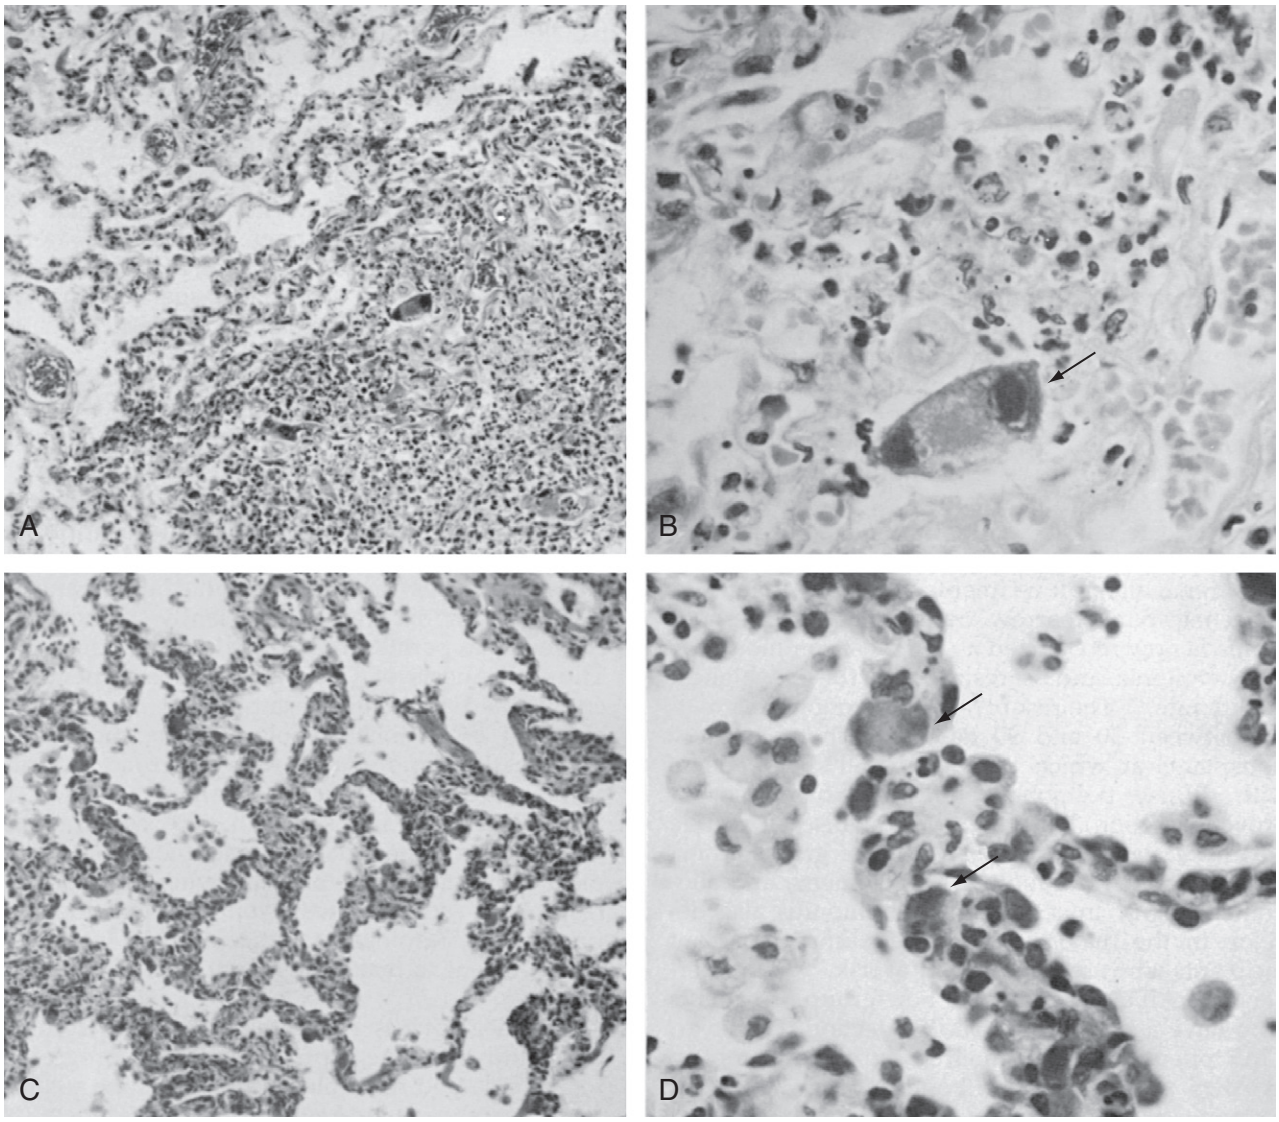

FIGURE 31-9 ■ Multifocal or miliary pattern and diffuse interstitial pneumonitis patterns of CMV pneumonia. **A,** The multifocal pattern has well-circumscribed lesions adjacent to relatively normal pulmonary tissue. **B,** Within these lesions are numerous cells with cytomegaly and intranuclear inclusions (*arrow*), a neutrophilic response, and cellular necrosis. **C,** The diffuse interstitial pneumonitis pattern of CMV pneumonia shows alveolar cell hyperplasia, interstitial thickening, and mild mononuclear cell infiltrate. **D,** Interspersed with the alveolar lining cells are cells with characteristic cytomegaly (*arrows*). (Hematoxylin and eosin stain; **A** and **C,** magnification ×150; **B** and **D,** ×600.) (Courtesy of W. E. Beschorner, Johns Hopkins University, Baltimore, Maryland.)

rapidly fatal course,[60] whereas patients with an interstitial pattern of disease often have an insidious onset of pneumonia with slowly progressive hypoxemia. In these patients, pulmonary infiltrates may be initially localized, with bilateral spread over days or weeks. Often the perihilar distribution of the infiltrate is suggestive of pulmonary edema.[59] Common CT scan findings include small nodules, consolidation, and ground-glass attenuation.[61]

Reactivation of CMV recently has been demonstrated to play a role in critically ill previously immunocompetent patients. During the critical illness, some recent evidence suggests a transient and vulnerable period of "immunoparalysis," indicating reactivation and not exogenous infection of CMV. In these patients, CMV viremia occurred with frequencies of 33% and was associated with prolonged hospitalization and death.[62] At this time, however, it is unclear if CMV prophylaxis would be beneficial.

Diagnosis

Cytomegalovirus pneumonia should be in the differential diagnosis for any immunosuppressed patient with unexplained lower respiratory complaints or pulmonary infiltrates. However, the clinical assessment of patients with suspected CMV pneumonia is complicated by their frequently having simultaneous pulmonary infections with other microbial agents and because the clinical features and radiographic appearance of CMV pneumonia are not

sufficiently characteristic to permit an accurate etiologic diagnosis. Because of its generally immunosuppressive properties, CMV predisposes to infections with bacterial[63] and fungal pathogens, such as *Aspergillus.*[64] In addition, noninfectious pulmonary conditions are also common in the population at risk for CMV pneumonitis, including pulmonary malignancy or hemorrhage and posttransplant lymphoproliferative disorder. Culture and pathologic examination of specimens obtained by bronchoalveolar lavage and biopsy are diagnostic. However, the detection of virus in respiratory secretions, urine, or blood does not establish with certainty that CMV is responsible for a particular clinical syndrome. This is particularly true in patients with AIDS, in whom detection of CMV in bronchoalveolar lavage fluid is often not associated with pulmonary pathology. However, in transplant recipients, detection of CMV in blood does increase the risk of subsequent development of CMV pneumonia, and may be useful in guiding preemptive therapy.

The time required for appearance of viral cytopathic effect in cell culture depends on the quantity of virus in the specimen tested and ranges from 2 to more than 35 days, with a median of approximately 1 week. Laboratory diagnosis can be expedited by a technique of centrifugation of the specimen onto cell monolayers in shell vials coupled with immunofluorescent staining for viral antigen. However, direct detection of the CMV antigen (pp67 antigen) in leukocytes or plasma, as well as detection of viral DNA or messenger RNA by nucleic acid amplification, are the most rapid and sensitive techniques.[65] The CMV viral load by quantitative PCR is a good predictor of development of CMV disease in transplant recipients. Serologic testing has no role in diagnosis of acute infection and is used only to determine the serologic status of donors and recipients prior to transplantation.

Treatment and Prevention

Once CMV pneumonitis is established, particularly in allogeneic bone marrow transplant patients, it is very difficult to treat. Ganciclovir is highly active against CMV in vitro, but monotherapy is not effective in pneumonitis in bone marrow transplant recipients. The combination of ganciclovir therapy and intravenous CMV immune globulin can reduce mortality from approximately 90% to 50% or lower in these patients.[66] The effect of the immune globulin in this situation may mostly be to ameliorate graft-versus-host disease. Whether combination therapy is required in solid organ transplant recipients with CMV pneumonia is uncertain. Cidofovir and foscarnet are other antiviral drugs with activity against CMV; both have been used to successfully treat CMV retinitis, but their effectiveness for treating CMV pneumonia has not been established. All of the available CMV antivirals have serious side effects that limit their usefulness.

Guidelines for reducing the risk of CMV disease in stem cell transplant recipients have recently been published.[67] Transplant candidates should be screened for evidence of CMV immunity, and CMV-seronegative recipients of allogeneic stem cell transplants from CMV-seronegative donors should receive only leukocyte-reduced or CMV-seronegative red blood cells and/or leukocyte-reduced platelets. In mismatched solid organ transplant recipients (donor+/recipient−), posttransplant prophylaxis with oral ganciclovir or its prodrug valganciclovir significantly reduces the risk of CMV disease, although late-onset disease still occurs.[68] Another strategy is preemptive therapy with ganciclovir or another anti-CMV agent when screening detects infection, but before disease develops. This strategy requires the use of sensitive and specific laboratory tests for diagnosis.

No vaccines are available for prevention of CMV infection or disease, although several strategies are being actively pursued, including live, attenuated virus vaccines and inactivated subunit vaccines.

Hantaviruses

Hantaviruses are members of the Bunyavirus family and include a number of genetically diverse viruses. By electron microscopy, one of the hantaviruses—Sin Nombre virus (SNV)—is roughly spherical, with a mean diameter of 112 nm. The virions contain a dense envelope, surrounded by fine surface projections. Filamentous nucleocapsids are present within the virions. The genome consists of negative-sense single-stranded RNA arranged in three physically discrete gene segments. The smallest segment (S) encodes the nucleoprotein; the middle-sized segment (M), the two envelope glycoproteins, G1 and G2; and the largest (L), the putative polymerase protein.[69]

These viruses are difficult to isolate from clinical material in cell culture, and grow slowly. Viral entry into the cell is mediated by a variety of cell surface integrins,[70] which may be related to the patterns of pathogenicity of the virus. The genome is segmented, and genetic reassortments in dually infected cells are common. It is believed that new pathogenic strains arise by this mechanism.

Epidemiology and Transmission

The *hantavirus pulmonary syndrome* (HPS) is a zoonosis in which rodents experience prolonged asymptomatic infection, and humans experience severe, often fatal disease. Each of the individual hantavirus strains appears to be associated with a specific rodent host: for example, SNV with the deer mouse (*Peromyscus maniculatus*), Bayou virus with the rice rat (*Oryzomys palustris*), Black Creek Canal virus with the cotton rat (*Sigmodon hispidus*), New York virus with the white-footed mouse (*Peromycus leucopus*), and so on. The features that are associated with maintenance of these viruses in rodent populations and with rodent-to-rodent transmission are unclear. However, serologic studies suggest that hantaviral infection of feral rodents is widespread throughout North America.[71]

Transmission to humans is presumed to be the result of contact with infected rodent excreta. Virus can be

isolated from urine, feces, and wet cage bedding for as long as 150 days postinfection in asymptomatic cotton rats.[72] Risk factors for acquisition of HPS include peridomestic cleaning, agricultural activities, and other forms of occupational exposure to rodent droppings, as well as high densities of rodents in the household. In the Four Corners region, the occurrence of El Nino–southern oscillation events have been linked to increased rainfall, rodent population densities, and thus cases of hantavirus cardiopulmonary syndrome (HCPS).[73]

Person-to-person transmission was not seen in the North American outbreaks.[74] In contrast, a recent outbreak of HPS in South America has suggested that, under certain circumstances, person-to-person transmission can occur.[75] Whether this feature is unique to the particular hantavirus implicated in that outbreak (Andes virus) or will be a feature in future outbreaks is unknown at present.

Pathogenesis

Infection with SNV or other agents of HPS have relatively long incubation periods (approximately 8 to 20 days), and antibody and cellular responses in humans are usually detectable at the time of presentation.[76] Neutralizing antibody is directed against the surface glycoproteins G1 and G2, and lower titers on presentation correlate with greater disease severity.[77] Viremia is detectable at presentation and declines promptly after resolution of fever.

Pathologic findings in fatal cases include pleural effusions, alveolar edema and fibrin, and interstitial mononuclear cell infiltrate[78] with little necrosis or polymorphonuclear leukocyte infiltration. These findings are believed to be most consistent with a capillary leak syndrome with subsequent noncardiogenic pulmonary edema as the major mechanism of disease. Immunopathologic responses play a major role in HCPS.[79] Infection of humans with SNV and other hantaviruses results in widespread expression of viral antigens in endothelial cells of pulmonary and cardiac tissues,[80] and CD8 T-cell responses peak at the time of maximal clinical symptoms, implicating these responses in the pathogenesis of disease.[81] Myocardial depression has also been ascribed to induction of nitric oxide and locally secreted cytokines in response to infection.[82] Evidence has also suggested a role for antagonism of the host innate immune response by the hantavirus G1 tail as a pathogenic mechanism.[83]

Clinical Features

Presentation of HPS begins with a prodrome of fever, chills, and myalgias, occasionally accompanied by abdominal discomfort and gastrointestinal symptoms, and generalized malaise. Upper respiratory symptoms are usually absent. After a variable period of several days, the patient presents with mild, nonproductive cough and progressive dyspnea resulting from leakage of high-protein edema fluid into the alveoli. On physical examination, patients are febrile, with tachypnea and tachycardia with mild hypotension. Examination of the chest may reveal crackles but is otherwise unremarkable.

Laboratory studies generally reveal hemoconcentration, mild thrombocytopenia, and mildly elevated liver function test results. The triad of thrombocytopenia, left shift with circulating myeloblasts, and circulating immunoblasts is highly suggestive of HPS.[84] Multivariate analysis has identified dizziness, nausea, and the absence of cough as clinical symptoms predictive of HPS, as well as thrombocytopenia, elevated hematocrit, and decreased serum bicarbonate as features that help distinguish HPS from other causes of acute respiratory distress such as pneumococcal pneumonia and influenza.[85] Mild renal abnormalities may be detected, but unlike hantavirus-related *hemorrhagic fever with renal disease syndrome* (HFRS), do not progress to renal failure. Renal dysfunction may be more common in HPS associated with Bayou virus than with other hantaviruses.[86]

Chest radiographs are typical of pulmonary edema, without consolidation. Pleural effusions are present in most cases. Early in the course of HPS these effusions are transudative, while later they develop higher fluid protein content and in severe cases have the protein characteristics of plasma.[87] Cardiopulmonary manifestations in severe cases include a shock state with low cardiac index, low stroke volume index, and high systemic vascular resistance.[87] Progression is associated with worsening cardiac dysfunction and development of lactic acidosis. The case-fatality rate averages approximately 30% to 40%. In those patients who survive, recovery is usually complete, but some patients have manifested long-term pulmonary and cognitive dysfunction.[88]

Diagnosis

Patients universally have detectable serum immunoglobulin M (IgM) and immunoglobulin G antibody at the time of admission, and serologic techniques are the mainstay of diagnosis. In low-prevalence areas, a positive IgM antibody test is diagnostic.[89] Virus can also be detected in blood by reverse transcriptase–PCR during the first 10 days of illness.[90] In contrast, isolation of virus from tissue is laborious and time-consuming and must be undertaken in suitable containment facilities, and so is not useful diagnostically.

Treatment and Prevention

Treatment is supportive, and requires careful management of fluid status to maintain perfusion without exacerbating pulmonary edema. It has been suggested that high-dose steroid therapy may be useful[79] because of the pathogenesis of the disease and the use of steroids in systemic capillary leak syndrome. In severe cases, extracorporeal membrane oxygenation has been shown to be potentially beneficial.[91] The broad-spectrum antiviral agent ribavirin is active against hantavirus in vitro, and was demonstrated to be effective in HFRS in Korea. However, trials of ribavirin in HPS have not supported efficacy in this situation.[92]

Herpes Simplex Viruses

Both herpes simplex viruses (HSV) types 1 and 2 belong to the alphaherpesvirus subfamily of herpesviruses and share the same basic structural features. HSV-1 is most commonly associated with respiratory infection, while HSV-2 is more commonly associated with genital infection. The two HSV types were originally differentiated by neutralization assay and have been found to differ in a number of biologic and biochemical properties as well. Infection with either type results in production of both type-specific and cross-reactive antibodies, with higher concentrations of antibodies being produced against the homologous type.

Epidemiology and Transmission

Humans are the reservoir for HSV-1 and HSV-2 viruses. With primary infection, infectious virus is produced in the skin and mucous membranes, being present in vesicle fluid and cellular debris from herpetic ulcers. After establishment of latency in nerve ganglia, virus is intermittently shed in respiratory, vaginal, and urethral secretions in the absence of clinical disease. Asymptomatic respiratory tract shedding can be detected in about 1% to 2% of seropositive children and adults.

HSV-1 spreads by means of transfer of virus-containing respiratory secretions, vesicle fluid, and cell debris under conditions of close personal contact. The portal of entry for primary infections is the mucous membranes of the oropharynx and possibly the eye. Virus deposited onto areas of burned or abraded skin, and exogenous inoculation or autoinoculation of virus, also lead to clinical lesions. Cases of HSV-1 occur sporadically throughout the year and occasionally in small clusters. HSV-1 infection is usually acquired in childhood or adolescence, with epidemiologic surveys showing a prevalence of HSV antibody of 30% to 100% in adults.

Pathogenesis

Primary HSV infection has a mean incubation period of approximately 1 week. The events involved in primary infection occur at a local site and are related to viral replication in parabasal and intermediate epithelial cells, with resultant cell destruction and initiation of host inflammatory responses. Cells containing characteristic nuclear inclusions and sometimes multinucleation may be observed in lesions. In normal individuals, clinical involvement of regional lymph nodes may occur during primary infection, but otherwise the disease is usually contained at the primary site by the host's natural defenses. In neonates and others with deficient or impaired immune systems, local infection may be followed by viremic spread to multiple organs, including skin, liver, brain, adrenals, and lungs. Disseminated disease may also occur in such individuals following reactivation of latent infection. Visceral infection is characterized by a highly destructive coagulation necrosis of involved sites.[93] In a series of fatal cases of HSV pneumonia, inflammatory infiltrates, parenchymal necrosis, and hemorrhage are found in lung tissue at autopsy.[94] Patients with associated herpetic laryngotracheitis have necrotizing lesions in these areas.

Latent infection is established in sensory nerve ganglia, and is followed by lifelong recurrences of virus shedding and often lesions on skin and mucous membranes of the involved dermatomes. Cellular immunity is of primary importance in controlling HSV infection, although the specific responses are under study. In animal models, the stage of maturity of macrophages, interferon production, and the presence of natural killer cells and of sensitized killer lymphocytes have all appeared to be involved in resistance to infection.

Clinical Illness

Acute Gingivostomatitis and Pharyngitis. Herpetic disease of the oral cavity and pharynx is the most common overt manifestation of primary infection with HSV-1. Scattered or clustered vesicles and ulcers of various sizes (3 to 7 mm) are located on the buccal mucosa, tongue, gingiva, or floor of the mouth. Individual lesions usually appear as a shallow, white-based ulcer surrounded by a thin rim of erythema. Pain is prominent in involved areas of the mouth and pharynx, and regional nodes are tender and enlarged, particularly with pharyngitis. Fever, malaise, and reduced oral intake may add to the overall severity of these illnesses, which last up to 2 weeks.

Chronic Ulcerative Pharyngitis and Laryngotracheitis. In immunocompromised patients, including those with AIDS, both primary and recurrent HSV infection may present as a chronic erosive process of the mucous membranes of the oral cavity and upper airway. Characteristically, the lesions appear as large (5- to 15-mm) individual ulcerations that are slowly progressive and may coalesce when present in adjacent sites (see Fig. 31-2). The base of the ulcer is white or gray. Although shallow, the lesions are usually painful and may reduce oral intake. Herpetic lesions are sometimes present on the lips and the skin of the face. Infection may spread to the esophagus and lower airway, possibly facilitated by instrumentation, resulting in the development of similar lesions at these sites. Clinical features of herpetic tracheobronchitis include dyspnea, cough, fever, chills, diaphoresis, chest pain, wheezes, hypotension, and hypoxemia.[95] Herpetic tracheobronchitis has also been reported to occur in elderly patients presenting with bronchospasm who did not have histories of chronic lung disease or of immunosuppression.[96]

Pneumonia. Herpes simplex virus causes pneumonia in neonates with congenital and peripartum infections and in patients with malignancy, burns, organ transplantation, and other conditions leading to mechanical ventilation and impaired immunity. Neonatal herpes simplex pneumonia has been reported to occur between the 3rd and 14th days of life and to be associated with prominent hila and central interstitial infiltrate on radiographs.[97] Other associated findings have been thrombocytopenia, disseminated intravascular coagulation, abnormalities in liver function, vesicular skin lesions, and

deterioration during antimicrobial treatment. The pathologic findings in infants, children, and adults suggest that the disease may occur either as the result of direct extension of infection from the tracheobronchial tree to the lung or as the result of hematogenous dissemination of virus from mucocutaneous lesions of the upper airway or genitourinary tract. CT scan findings include multifocal segmental and subsegmental ground-glass opacities, but are not distinctive.[98] In one study, more than one half of the patients had concomitant pulmonary infection with other microorganisms, including bacterial, candidal, and *Aspergillus* species and cytomegalovirus.[94] Histologic evidence of herpetic esophagitis was present in 10 of 16 patients with herpes pneumonia in whom esophageal examination was performed. Many cases are nosocomially acquired.[99]

Herpes simplex virus infection of the lower airway has also been found in association with ARDS. The relationship of HSV infection to ARDS is unclear, but the presence of HSV in the lower respiratory tract was associated with the need for prolonged respiratory support and an increased late mortality. Isolation of HSV from lower respiratory tract secretions has also been common in mechanically ventilated patients and may be associated with a poor outcome,[100,101] although it is unclear whether this represents reactivation as a consequence of overall illness or whether the virus plays a direct role in mortality.[102]

Diagnosis

The clinical features of herpetic gingivostomatitis are sufficiently characteristic to permit accurate diagnosis in most cases. Other conditions with similar oral lesions are limited and include herpangina, aphthous stomatitis, Stevens-Johnson syndrome, and other enanthems resulting from infection and drug sensitivities. In herpangina, the lesions are smaller (1 to 3 mm), more often vesicular, and usually localized to the soft palate. The ulcers in aphthous stomatitis are few, relatively deep, and well circumscribed. Aphthosis is characterized by periodic recurrence, whereas acute herpetic gingivostomatitis and pharyngitis are limited to a single occurrence. Herpetic pharyngitis, when exudative, must be distinguished from pharyngitis due to *Streptococcus pyogenes,* adenovirus, Epstein-Barr virus, and diphtheria. Laboratory confirmation of the diagnosis of acute herpetic disease of the oropharynx can be made by examination of Giemsa- or Wright-stained smears of scrapings from the base of a fresh lesion (Tzanck test) and by culture of scrapings or swab specimens. Techniques for the rapid detection of viral antigens or DNA are widely available.

Chronic ulcerative pharyngitis due to HSV has a characteristic clinical appearance that is highly suggestive of the diagnosis (see Fig. 31-2). The white color of the candidal lesion may lead to confusion, but the lesion of thrush is an easily removable plaque, not an ulcer. Thrush and chronic herpetic pharyngitis may coexist in the same patient. The lesions of aphthous stomatitis are not characteristically found in the back of the oropharynx and are relatively small (2 to 5 mm), with a fixed diameter.

The diagnosis of herpetic laryngotracheitis may be difficult because of the inaccessibility of the lesions. The disease should be suspected in any immunocompromised patient with herpetic lesions of the mouth, upper airway, or skin of the face, especially if endotracheal intubation has been performed. In such patients, bronchoscopic examination is indicated for sampling of suspected areas for cytology and viral culture.

The diagnosis of HSV pneumonia should be suspected in any immunocompromised patient with unexplained pulmonary infiltrates, especially in the presence of herpetic laryngotracheitis or herpetic lesions of other mucocutaneous sites, including the genital area. Definitive diagnosis of HSV pneumonia depends on obtaining a sample of involved lung for viral culture and testing for HSV antigen or nucleic acids. Limited experience with lung biopsy in patients with HSV pneumonia suggests that obtaining adequate samples for culture and histologic examination may be a problem[94] and that, when possible, generous biopsy specimens should be obtained.

Treatment and Prevention

No vaccines of proven value are currently available. Primary HSV gingivostomatitis in immunocompetent persons responds to oral acyclovir treatment. Specific therapy of herpes simplex pneumonia has not been evaluated in controlled trials, but most clinicians would use intravenous acyclovir in this situation. In immunosuppressed patients with chronic mucocutaneous HSV infection, including pharyngitis and laryngotracheitis, prompt treatment with acyclovir is recommended both to control the local infection and to prevent possible dissemination to the lung. Valacyclovir, the valine ester prodrug of acyclovir, and famciclovir, the prodrug of penciclovir, are orally administered drugs that are also effective for mucocutaneous HSV.

Antiviral susceptibility testing should be considered in patients with serious HSV infection who do not respond to initial treatment with oral valacyclovir or intravenous acyclovir. Foscarnet is probably the best available alternative therapy. Prophylactic intravenous and oral acyclovir regimens have been shown to be effective in preventing recurrences of mucocutaneous HSV infection in seropositive patients undergoing intense periods of immunosuppression, such as bone marrow transplant recipients or patients receiving combination chemotherapy for leukemia.

Influenza Viruses

Influenza viruses belong to the family Orthomyxoviridae, and are classified into three distinct types, influenza A, influenza B, and influenza C virus, based on major antigenic differences. All three viruses share the presence of a host cell–derived envelope, envelope glycoproteins important for entry and egress from cells, and a segmented negative-sense, single-stranded RNA genome. The standard nomenclature for influenza viruses includes the influenza type, place of initial isolation, strain designation, and year of isolation. For example, an influenza

A virus isolated from a patient in Puerto Rico in 1934 is given the strain designation A/Puerto Rico/8/34, sometimes referred to as "PR8" virus.

The envelope glycoproteins are hemagglutinins (HAs) and neuraminidases (NAs). At least 15 highly divergent, antigenically distinct HAs have been described in influenza A viruses (H1 to H15) as well as at least 9 distinct NAs (N1 to N9). Influenza A viruses are further divided into subtypes based on the hemagglutinin (H) and neuraminidase (N), e.g., H1N1 or H3N2. Infection with influenza virus results in long-lived resistance to reinfection with the homologous virus. Infection induces both systemic and local antibody, as well as cytotoxic T-cell responses, each of which plays a role in recovery from infection and resistance to reinfection.

Epidemiology and Transmission

Influenza virus infection is acquired by transfer of virus-containing respiratory secretions. Both small-particle aerosols and droplets probably play a role in this transmission, but for infection control purposes influenza is generally considered to be transmitted by droplets. In temperate climates in either hemisphere, epidemics occur almost exclusively in the winter months (generally October to April in the Northern hemisphere and May to September in the Southern hemisphere), while influenza may be seen year round in the tropics.

Influenza epidemics are regularly associated with excess morbidity and mortality, usually expressed in the form of excess rates of pneumonia and influenza-associated hospitalizations and deaths, with potentially as many as 51,000 deaths annually in the United States.[103] Attack rates are generally highest in the young, whereas mortality is generally highest in the elderly. Excess morbidity and mortality are particularly high in those with medical conditions including pulmonary conditions such as asthma or COPD. Rates of influenza-related hospitalizations are particularly high in healthy children under 2 years of age, in whom rates approach those of older children with high-risk conditions.[104,105]

A high frequency of antigenic variation is a unique feature of influenza virus that helps to explain why this virus continues to cause epidemic disease. Antigenic variation involves principally the two external glycoproteins of the virus, HA and NA, and is referred to as "antigenic drift" or "antigenic shift," depending on whether the variation is small or great. Antigenic drift refers to relatively minor antigenic changes that result from amino acid changes in one or more of the five identified major antigenic sites on the HA molecule.[106] Antigenic shift refers to the complete replacement of the HA or NA with a novel HA or NA. These viruses are "new" viruses to which the population has no immunity. When such a new virus is introduced into a population, a severe, worldwide epidemic, or pandemic, of influenza results. Recent pandemics of influenza include the H1N1 pandemic of 1918, the H2N2 pandemic of 1957, and the H3N2 pandemic of 1968. Extensive surveillance and sequence information suggests that these new HA and NA genes are introduced into viruses circulating in humans from resident populations of influenza A viruses in birds.[107]

In the spring of 2009, a novel H1N1 influenza A virus emerged in Mexico and the United States. This triple-reassortant swine influenza A (H1) virus contains genes from avian, human and swine influenza viruses and is causing the pandemic of 2009, which has already infected millions of people worldwide.[107a-107c] Unlike seasonal influenza viruses, which cause greatest morbidity and mortality in infants and the elderly, high-risk populations for the novel H1N1 virus appear to be infants, young children, previously healthy adults ages 24–49 years, women who are pregnant or postpartum (28 days), and patients who are immunocompromised.[107d] Other conditions such as obesity, diabetes mellitus, COPD and asthma have also been described among hospitalized patients with this infection.[107e,107f]

Pathogenesis

Infection with influenza virus in humans is generally limited to the respiratory tract. After inoculation, the incubation period is thought to be from 18 to 72 hours, depending in part on the inoculum dose. Virus shedding is maximal at the onset of illness and may continue for 5 to 7 days or longer in children.

Bronchoscopy of individuals with typical, uncomplicated acute influenza typically reveals diffuse inflammation of the larynx, trachea, and bronchi, and a range of histologic findings (Fig. 31-10), from vacuolization of columnar cells with cell loss, to extensive desquamation of the ciliated columnar epithelium down to the basal layer of cells.[108,109] Generally, the tissue response becomes more prominent as one moves distally in the airway. Recovery is associated with rapid regeneration of the epithelial cell layer, and pseudometaplasia.

Abnormalities of pulmonary function are frequently demonstrated in otherwise healthy, nonasthmatic young adults with uncomplicated (nonpneumonic) acute influenza. Demonstrated defects include diminished expiratory forced flow rates, increased total pulmonary resistance, and decreased density-dependent forced flow rates consistent with generalized increased resistance in airways less than 2 mm in diameter,[110,111] as well as hyperresponsiveness to bronchoprovocation.[110] In addition, abnormalities of carbon monoxide diffusing capacity[112] and increases in the alveolar-arterial oxygen difference[113] have been seen. Of note, pulmonary function defects can persist for weeks after clinical recovery. Influenza in asthmatics or patients with COPD with influenza may result in acute declines in forced vital capacity or forced expiratory volume in 1 second. Individuals with acute influenza may be more susceptible to bronchoconstriction from air pollutants such as nitrates.[114]

Clinical Illness

Typical uncomplicated influenza often begins with an abrupt onset of symptoms after an incubation period of 1 to 2 days. Systemic symptoms include feverishness, chilliness or frank shaking chills, headaches, myalgia,

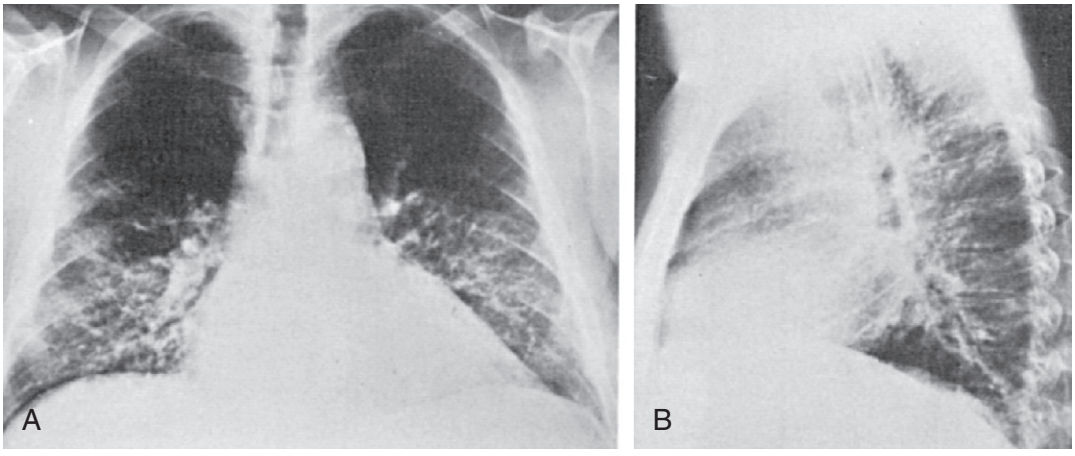

FIGURE 31-11 ■ Posteroanterior **(A)** and lateral **(B)** chest roentgenograms of a 55-year-old man with febrile illness showing bilateral diffuse reticulonodular infiltrates with a lower zone predominance and some hyperexpansion. These findings are typical, although not specific, for influenza viral pneumonia. (Courtesy of Thomas L. Pope, Jr., MD, Department of Radiology, University of Virginia School of Medicine, Charlottesville, Virginia.)

malaise, and anorexia. Typical respiratory symptoms include dry cough, severe pharyngeal pain, and nasal obstruction and discharge. Elderly individuals may simply present with fever, lassitude, and confusion without the characteristic respiratory complaints, which may not occur at all. There is a wide range of symptomatology, but the presence of fever plus either sore throat or cough is predictive of positive culture results in adults.

The syndrome of primary influenza viral pneumonia was first well documented in the 1957–1958 outbreak. The illness begins with a typical onset of influenza, followed quickly by a rapid progression of fever, cough, dyspnea, and cyanosis. Physical examination and chest radiographs (Fig. 31-11) reveal bilateral findings consistent with ARDS. Gram staining of the sputum fails to reveal significant bacteria, and bacterial culture yields

sparse growth of normal flora, whereas viral cultures yield high titers of influenza A virus. Such patients do not respond to antibiotics, and their mortality is high.

Secondary bacterial pneumonia has primarily been described in patients who are elderly or who have chronic pulmonary, cardiac, and metabolic or other disease. The classic description is of an influenza illness followed by a period of improvement lasting usually 4 to 14 days. Recrudescence of fever is associated with symptoms and signs of bacterial pneumonia such as cough, sputum production, and an area of consolidation detected on physical examination and chest radiographs. The most common bacterium implicated is *Streptococcus pneumoniae,* with a significantly increased frequency of *Staphylococcus aureus.*[115,116] Many patients present with mixed viral and bacterial pneumonia. Bacterial superinfections of influenza have been postulated as a major cause of death during the pandemic of 1918.[117]

Similar to previously circulating seasonal influenza virus, most cases of infection with the novel H1N1 influenza virus result in mild disease. However, severe disease in hospitalized patients due to pneumonia and acute respiratory distress syndrome has been reported during this H1N1 pandemic, from both viral pneumonitis and superinfections with bacterial pneumonia.[107e,107f] In agreement with seasonal influenza virus infections, the most common complicating bacterial organisms include *Streptococcus pneumoniae, Staphylococcus aureus*, and Group A streptococci. Mortality rates in hospitalized patients with the novel H1N1 influenza infection range from 7% to 17%.[107d,107e] Interestingly, in one small study of 10 patients in Intensive Care Units in Michigan, nearly 50% had evidence of thromboembolic disease.[117a]

Diagnosis

Virus can be isolated readily from nasal swab specimens, nasal aspirates, or combined nose and throat swab specimens. Virus can also be isolated readily from sputum or endotracheal aspirate samples. Over 90% of positive cultures can be detected within 3 days of inoculation.[118] Immunologic detection of influenza antigens in respiratory samples can be used for rapid diagnosis, and a large number of such tests are commercially available. The reported sensitivities of each test in comparison to cell culture has varied between 40% and 80% and is somewhat dependent on the nature of the samples tested and the patients from whom they were derived. In general, sensitivities in adults and elderly patients tend to be lower than those reported in young children, who shed much larger quantities of virus in nasal secretions and therefore have much higher concentrations of antigen in their samples.[119] Similarly, sensitivity is likely to be higher early in the course of illness, when viral shedding is maximal. PCR techniques have also been developed and are highly sensitive and specific.

Diagnosis of the novel H1N1 influenza virus can be made by rapid antigen detection, viral culture and PCR methods. The current rapid diagnostic tests have not been very sensitive in identifying H1N1 virus infections, and are worse in adults than in pediatric cases,[119a] which means that many influenza-like illnesses due to the novel H1N1 are not being confirmed. By contrast, PCR-based tests for the virus are highly sensitive and specific but may not always be readily available.[119b]

Treatment and Prevention

Vaccines. Two types of vaccine are available for prevention of influenza. Inactivated virus vaccines consist of either inactivated purified virions (whole virus vaccines) or partially purified HA and NA preparations (split-product or subvirion vaccines). These vaccines are administered intramuscularly without adjuvant and are intended to induce formation of antibody against the viral HA and NA, which are associated with protection. Cellular immune responses also occur, and may also be associated with protection. Inactivated vaccines are well tolerated in all age groups, although hypersensitivity to hens' eggs, in which the vaccine virus is grown, is a contraindication to vaccination. Generally, if persons can eat eggs or egg-containing products, vaccination is safe. If necessary, individuals with anapylaxis can be desensitized and safely vaccinated.[120]

Increases in HAI antibody are seen in about 90% of healthy adult recipients of vaccine. Only a single dose of vaccine is required in individuals who been previously vaccinated or who have experienced prior infection with a related subtype, but a two-dose schedule is required in unprimed individuals. This includes children up to age 9 who have not previously been vaccinated or who were vaccinated for the first time with only a single dose in the previous season.[121] Diminished responses are seen in elderly and immunocompromised populations.

The protective efficacy of inactivated influenza vaccine is estimated to be in the range of 70% to 90% in healthy adults and children when there is a good antigenic match between vaccine and epidemic viruses.[122,123] Relatively few prospective trials of protective efficacy have been conducted in high-risk populations. In one placebo-controlled prospective trial, inactivated vaccine was approximately 58% effective in preventing laboratory-documented influenza among adults over 60, and 29% in those over 70.[124] Retrospective cohort studies have shown vaccine to be protective against influenza- and pneumonia-related hospitalization in the elderly, and to be associated with decreases in all-cause winter mortality.[125] However, these results have been called into question, and doubts remain regarding the level of effectiveness of inactivated vaccine in this age group.[126]

Live, attenuated vaccine induces a limited, asymptomatic infection of the upper respiratory tract and induces a variety of immune response designed to mimic the protective immunity induced by natural infection.[127,128] The vaccine is well tolerated and highly effective in children, but is associated with an increased frequency of wheezing in children under the age of 2 years. Live vaccine is protective in adults as well, resulting in decreased laboratory-confirmed influenza in challenge studies and reduced frequencies of influenza-like illness in the field.[129] Although the vaccine is well tolerated in the elderly and in those with chronic lung disease,

immune responses are very infrequent in older recipients, and the vaccine is therefore not licensed for use in those over 49 years.

Although vaccine virus can be recovered from vaccinated individuals, particularly children, for several days following vaccine, transmission is extremely unusual.[130] Live vaccine can be administered safely to health care workers except for those caring for immunosuppressed individuals requiring barrier precautions.

Randomized controlled comparisons of the efficacy of inactivated and live, attenuated vaccine in children have consistently shown that live vaccine provides superior efficacy in this population, with an approximately 50% lower cumulative incidence of influenza in those receiving live vaccine.[131] Similar comparisons in adults have suggested slightly superior efficacy of inactivated vaccine,[132] and large cohort studies are also consistent with the interpretation that inactivated vaccine has slightly better efficacy than live vaccine in adults, particularly in those who have received vaccines in previous years.[133]

Current target groups for influenza vaccination[121] are focused on two complementary strategies: targeting vaccine to those at the highest risk for influenza-related complications, and preventing transmission of influenza to such individuals by vaccinating their close contacts, including health care workers (Table 31-5).

TABLE 31-5. Target Groups for Influenza Immunization

PERSONS AT INCREASED RISK FOR COMPLICATIONS

- Persons > 65 years of age
- Residents of nursing homes and other chronic care facilities
- Adults and children with chronic pulmonary or cardiovascular diseases, including asthma
- Adults and children with chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including human immunodeficiency virus infection)
- Children and adolescents receiving long-term aspirin therapy
- Women who will be in the second or third trimester of pregnancy during the influenza season
- Children ages 6–23 months

PERSONS AGES 50–64 YEARS

- Influenza vaccine has been recommended for this entire age group to increase vaccination rates among persons in this age group with high-risk conditions.

PERSONS WHO CAN TRANSMIT INFLUENZA TO THOSE AT HIGH RISK

- Physicians, nurses, and other personnel in both hospital and outpatient care settings, including medical emergency response workers
- Employees of nursing homes, assisted living facilities, and other chronic care facilities who have contact with patients or residents
- Persons who provide home care to persons in groups at high risk
- Household contacts (including children) of persons in groups at high risk
- Household contacts of children ages 0–23 months

In the fall of 2009, vaccines to the novel H1N1 virus became available as a single inoculation separate from the seasonal trivalent vaccine. Due to limited supply of the new vaccine, priority has been given to populations at high risk of developing influenza-related complications, including pregnant women, caretakers who live with or care for infants younger than 6 months, health care and emergency medical personnel, infants and young adults age 6 months through 24 years, and adults from 25 to 64 years with chronic medical conditions that put them at high risk of influenza-related complications.

Antivirals. Two classes of antiviral agents are currently available for the treatment and prevention of influenza, the M2 inhibitors (M2Is) amantadine and rimantadine, and the neuraminidase inhibitors (NIs) oseltamivir and zanamivir. The M2Is are active against all strains of influenza A virus in a variety of cell culture systems and animal models. However, these drugs have no activity against influenza B viruses, and resistance to their antiviral effects emerges readily. The NIs are active against both influenza A and B viruses. Antiviral resistance has emerged as an important problem for these agents as well.

The most common side effects of amantadine are minor and reversible central nervous system (CNS) side effects such as insomnia, dizziness, or difficulty in concentrating. These dose-related side effects may be more troublesome in the elderly, in whom confusion is noted in about 18% of recipients.[134] In addition, amantadine use has been associated with seizures in individuals with prior seizure disorder. The CNS effects of amantadine are increased when these drugs are coadministered with anticholinergics or antihistamines, or drugs such as trimethoprim-sulfamethoxazole that inhibit tubular secretion of amantadine and increase the potential for CNS toxicity.[135] There are no other known significant drug interactions with amantadine. Rimantadine is associated with a considerably reduced rate of CNS side effects.[136] There are no known drug interactions that significantly affect the levels or metabolism of rimantadine.

When used as therapy, the M2Is are effective in reducing the severity and duration of illness due to susceptible strains of influenza A virus in both adults and children. Treatment with amantadine also results in significantly more rapid improvement in small airways dysfunction in previously healthy adults with uncomplicated H3N2 influenza.[110,137] Effective use of these drugs requires that they be administered within 48 hours of symptom onset, when viral replication is at its peak. The M2Is are also effective in prevention of influenza when administered prior to exposure, either by giving the drug throughout the influenza season or by giving short courses of prophylaxis upon exposure in an institutional or family outbreak. In this latter setting, it is important to avoid both treatment and prophylaxis to prevent the emergence and transmission of resistant viruses.

Resistance is the result of single point mutations in the membrane-spanning region of the M2 protein, and confers complete cross-resistance between amantadine and rimantadine.[138] Resistant viruses emerge in the

majority of treated individuals, particularly children,[139] and prolonged shedding of resistant viruses may occur in immunocompromised patients even after therapy is terminated.[140] While resistant viruses were initially detected very infrequently in untreated patients in the years following introduction of these drugs, the first decade of this century has seen the emergence and spread of resistant influenza A (H3N2) viruses such that almost all such viruses isolated worldwide exhibit resistance to the M2Is.[141] The novel H1N1 viruses causing the 2009 pandemic are also resistant.

Neuraminidase inhibitors (NIs) are potent inhibitors of influenza virus in vitro and in vivo. Influenza B viruses are somewhat less sensitive than influenza A viruses but are well within clinically achievable concentrations. Activity against influenza viruses includes avian viruses with all nine known NA subtypes. While zanamivir and oseltamivir have an identical mechanism of action and similar profile of antiviral activity, they have differing pharmacologic properties. Zanamivir is not orally bioavailable and is administered as a dry powder for oral inhalation, using the so-called diskhaler device. Oseltamivir phosphate is an orally bioavailable ethyl ester prodrug that is rapidly absorbed from the gastrointestinal tract and is converted in the liver by hepatic esterases to the active metabolite, oseltamivir carboxylate. The metabolite is excreted unchanged in the urine by tubular secretion, with a serum half-life of 6 to 10 hours. Administration of the drug with food may improve tolerability without impacting drug levels.

The major adverse effects reported for oseltamivir have been gastrointestinal upset in about 10% to 15% of recipients, probably due to irritation as a result of rapid release of the drug in the stomach. Rates of nausea can be substantially reduced if the drug is taken with food. Adverse effects in individuals treated with zanamivir have occurred at essentially the same rate as in placebo recipients. However, postmarketing surveillance has found that inhaled zanamivir may be very uncommonly associated with bronchospasm, sometimes severe or fatal, in influenza patients, particularly those with underlying airways disease.

Because zanamivir has no significant systemic absorption, there are no recommended dosage reductions. The dose of oseltamivir should be reduced to 75 mg once daily in individuals with renal impairment (i.e., with creatinine clearance of less than 30 mL/min). No data are available regarding the use of the drug in individuals with more significant levels of renal impairment. Likewise, no information is available regarding the use of oseltamivir in individuals with hepatic impairment. Clinically significant drug interactions have not been reported. Because the drug is eliminated by tubular secretion, probenecid increases serum levels of the active metabolite approximately twofold. However, dosage adjustments are not necessary in individuals taking probenecid. Coadministration of cimetidine, amoxacillin, or acetaminophen has no effect on serum levels of oseltamivir or oseltamivir carboxylate.[142]

Both NIs are effective in the treatment of influenza due to either influenza A or B virus if administered within the first 48 hours of symptom onset, with reduced duration of illness and earlier return to work or normal activities. Meta-analysis of results of these trials has also suggested that early treatment may reduce the frequency of influenza-related complications, with reductions in the use of antibacterials and in hospitalization.[143] Only oseltamivir is currently licensed for use in children under 5. Administration of oseltamivir liquid at a dosage of 2 mg/kg/dose twice daily for 5 days was well tolerated and resulted in a 36-hour reduction in the duration of symptoms in children with influenza A.[144] NIs have also been used successfully for seasonal or contact prophylaxis.

Mutations within the catalytic framework of NA that abolish binding of the drugs have been described.[145,146] Depending on the location of the mutation, these viruses may be specifically resistant to only one inhibitor.[147] Resistance mutations in NA may be associated with altered characteristics of the enzyme, with significantly reduced activity.[148,149] Drug-resistant viruses are most commonly isolated from treated children.[150] Viral fitness appears to be less compromised by oseltamivir resistance mutations in the N1 neuraminidase.[151] N1-resistant viruses have emerged and become predominant among N1 viruses isolated worldwide, while N2 viruses remain sensitive to oseltamivir. Both N1 and N2 viruses are sensitive to zanamivir.

In the fall of 2009, the CDC reported that most circulating strains of the novel H1N1 influenza A virus were sensitive to the neuraminidase inhibitors oseltamivir and zanamivir, but that nearly all strains were resistant to the amantadines. Although antiviral therapy is not recommended for mild influenza infections, early treatment of hospitalized patients within 2 days of the onset of symptoms suggested clinical benefit.[107e] Therefore, antiviral drugs should be considered in seriously ill patients with both confirmed and suspected H1N1 viral infections. Reports of oseltamivir-resistance in H1N1 virus with the H275Y mutation have recently appeared[151a]; resistance has also cropped up in several countries and is being monitored closely for its clinical impact. Intravenous formulations of peramivir, a neuraminidase inhibitor, have been released though not approved by the FDA and can be considered for patients unable to take oral or inhaled medications.

Measles Virus

Measles virus is classified in the *Morbillivirus* genus of the Paramyxoviridae family and is structurally similar to parainfluenza viruses and respiratory syncytial virus. Its surface glycoproteins include a hemagglutinin responsible for attachment to cells, as well as a fusion (F) protein responsible for cell membrane fusion and virus penetration of cells, but no neuraminidase. The cell surface molecule SLAM (signaling lymphocyte activation molecule) serves as a receptor for entry of the virus into susceptible cells.[152] In addition, the membrane cofactor CD46 can also serve as a receptor, particularly for the vaccine strain.[153] Only one serotype of wild measles virus is recognized, although minor antigenic differences are

detectable by monoclonal antibodies. The human is the natural host for measles virus.

Epidemiology and Transmission

Measles occurs worldwide, but epidemic patterns vary depending on population density and levels of acquired immunity. Prior to vaccine use, measles occurred in epidemics of 3 to 4 months in duration every 2 to 5 years in temperate regions.[154] Except in isolated areas, most people experienced infection by 20 years of age, and 90% of reported cases occurred in those less than 10 years of age. Infection confers lifelong protection against measles, although asymptomatic reinfections may occur.

Measles virus infection is highly contagious and can spread despite high levels of acquired immunity in the population. Airborne transmission via small-particle aerosols and possible spread by fomites appear to account for its high communicability. The virus remains infectious in small-particle aerosols for several hours at low relative humidity and has caused secondary infections in the absence of face-to-face contact with an index case.[155] The incubation period is usually 9 to 14 days but may be longer in adults. Patients are most infectious during the late prodrome, when respiratory involvement contributes to creation of infectious aerosols. The virus may be shed for several days after the onset of rash in normal hosts.

Measles-associated mortality in developed countries is usually 0.1% or less but approaches 2% of cases in the developing world. Case-fatality rates have been as high as 25% in some areas. Most deaths result from respiratory tract involvement, neurologic complications, or both and are related to various combinations of malnutrition, young age, and immunosuppression induced by measles virus infection.

Pathogenesis

The respiratory tract and possibly the conjunctival epithelium are the portals of entry and initial sites of replication of measles virus, as well as subsequent target organs of disease expression. An initial viremic phase leads to infection of reticuloendothelial cells, and a second phase of viremia, corresponding to the prodromal stage of illness, results in dissemination of virus to the epithelial cells of the skin, respiratory tract, gut, bile duct, and bladder and to lymphoid organs.

Measles-induced giant cells may be present in the tonsils, appendix, other lymphoid organs, and various epithelial surfaces, including those of the respiratory tract. The effects of infection on the lymphoid system include leukopenia and immune suppression manifested by cutaneous anergy and depressed natural killer cell activity for weeks after the onset of the rash.[156] The mechanisms by which measles induces immunosuppression are incompletely understood, but infection of dendritic cells and suppression of the interleukin (IL)-12 response are thought to play an important role.[157]

The onset of the rash correlates temporally with the development of host immune responses and subsequent termination of virus shedding. Skin rash develops in agammaglobulinemic patients with measles, whereas progressive giant cell (measles virus) pneumonia without rash may occur in those with deficient cell-mediated immune function. The pathologic changes in involved organs include lymphoid hyperplasia, mononuclear cell infiltration, and the presence of multinucleated giant cells. Lower respiratory tract involvement may be associated with the destruction of ciliated respiratory epithelium, interstitial pneumonia, epithelial cell hyperplasia, and syncytial cell formation.

Clinical Illness

Typical Measles. The prodrome of typical measles lasts 2 to 8 days and is characterized by fever, malaise, anorexia, cough, coryza, and conjunctivitis. Koplik's spots, which are erythematous macular lesions with central white-yellow or gray puncta, appear on the buccal or labial mucous membranes toward the end of the prodromal period. The maculopapular, erythematous eruption begins about the face and neck and progresses to involve the upper body, trunk, and extremities. The rash typically disappears after 5 to 6 days in the order in which it appeared. Defervescence and symptom improvement occur several days after the appearance of the rash, although persistent cough is common. Leukopenia is common during the prodromal and early exanthematous stages of measles. Pronounced leukopenia (less than 2000 cells/μL) is associated with a poor prognosis. The development of neutrophilic leukocytosis suggests the possibility of bacterial superinfection or other complications.

Lower respiratory tract complications develop in 4% to 50% of patients. These include bronchitis, pneumonia, and, less often, croup or bronchiolitis. In young adults, a multilobar reticulonodular infiltrate is the most common radiographic abnormality.[158] In the absence of bacterial superinfection or atypical measles, pleural effusion or lobar consolidation is uncommon. In patients with altered cell-mediated immune function, and rarely in apparently normal persons, infection by wild measles virus can cause a lethal giant-cell pneumonia with or, in about 30% of patients, without rash.[159] Severe virus-induced pneumonia has been recognized during measles in pregnant women[160] and in those infected with HIV.[161] In hospitalized patients, mortality rates are approximately 70% in oncology patients and 40% in HIV-infected patients.[159]

Secondary bacterial infection has been found in 30% to 50% of young adults with measles-related pneumonia. Symptoms and signs indicative of bacterial infection usually begin 5 to 10 days after onset of the rash. One study employing transtracheal aspiration found a range of bacterial pathogens in adults, most commonly *Haemophilus influenzae, Neisseria meningitidis,* and *S. pneumoniae.*[158] Up to 30% of cases are complicated by otitis media or sinusitis. Acute nonrespiratory complications include hepatitis, encephalitis, keratitis, and

mesenteric adenitis, as well as a high rate of severe diarrheal disease in children in developed countries. Measles infection or vaccination may be followed by conversion of a positive tuberculin skin reaction to negative for weeks. Measles may exacerbate active tuberculosis, but whether measles reactivates dormant tuberculosis is unresolved.[162]

Atypical Measles. An unusual clinical syndrome has been recognized in adolescents and young adults who received the inactivated measles vaccine between 1963 and 1968 and who have been subsequently reexposed to the wild virus. The illness begins abruptly, with high fever, headache, myalgia, vomiting, abdominal pain, and nonproductive cough. Respiratory symptoms, including dyspnea, coryza, sore throat, and pleuritic chest pain, are common. A polymorphous eruption, which may include vesicles, petechiae, purpura, and urticarial lesions, begins typically on the distal extremities and spreads proximally over 3 to 5 days. Although Koplik's spots are absent, conjunctivitis and glossitis with strawberry tongue have been described.

Pulmonary abnormalities occur in most cases, and acute respiratory failure has been described. Chest radiographic changes include patchy, diffuse, or dense lobar infiltrates, pleural effusions, and hilar adenopathy.[163] Residual nodular pulmonary infiltrates may persist for years and lead to diagnostic confusion. The fever and other symptoms usually resolve in 1 to 3 weeks. The pulmonary function changes in atypical measles include transient hypoxemia and significantly reduced lung volumes.

Diagnosis

Measles virus may be isolated from the blood, urine, or respiratory secretions during the prodrome and up to several days after the exanthem appears. Isolation of virus from clinical specimens has been performed in several types of human and monkey cell cultures but is slow and inefficient. Respiratory and conjunctival secretions or urine sediment stained by various techniques reveals multinucleated giant cells in most cases. Immunofluorescent staining of skin biopsy specimens, cells from combined nasopharyngeal and throat swab samples, and, less often, exfoliated cells in the urine demonstrates measles virus antigens early in the disease.

Treatment and Prevention

The treatment of measles involves supportive care and specific therapy for bacterial complications. No antiviral agents have proven clinical value, but aerosol and intravenous ribavirin and immunoglobulin have been used in treating measles pneumonia.[160,164] Vitamin A therapy reduces morbidity and mortality in severe measles in children.[165] Patients suspected of having measles should be placed in respiratory isolation.

The live, attenuated measles vaccine currently used in the United States provides durable immunity in over 90% of recipients. The vaccine is safe, and it has been conclusively shown to have no association with autism.[166,167]

Metapneumoviruses

The human metapneumoviruses (hMPV) are pleiomorphic particles with short envelope projections, resembling other paramyxoviruses.[168] These viruses are closely related to the pneumoviruses (of which respiratory syncytial virus [RSV] is the human example), differing only by the absence of two nonstructural proteins and a slightly different arrangement of gene order on the negative-sense, single-stranded RNA genome. The basic virology of these viruses closely resembles that of RSV. Envelope glycoproteins include the SH (sulfhydryl), F (fusion), and G (glycosylated) proteins, although there is little sequence homology in these genes between RSV and hMPV.[169] By analogy, it is expected that antibody to the F and G proteins of hMPV would play a role in protection against reinfection. At least two major genetic groups have been identified, roughly corresponding to subgroups A and B of RSV.[170] Sequential infections of the same individual tend to involve different genogroups. The role of cell-mediated immunity in this infection is largely unexplored.

Epidemiology and Transmission

Human metapneumovirus infections are distributed worldwide, and have been documented in about 12% of children with lower respiratory tract illness in an outpatient setting[171] and in about 6% to 7% of hospitalized children during the winter respiratory season.[172] As with many other respiratory viruses, infection is linked to daycare attendance.[173] The peak age incidence is 11 months, and serologic studies suggest that essentially all children have been infected by age 5.[168] Similar to the case with RSV, disease has also been documented in adults and in the elderly,[174] although asymptomatic infection is also common in adults. The mode of transmission has not been documented, but is likely to be via droplet spread as with RSV. There is a clear seasonal variation in incidence, with the majority of cases occurring during the winter months.[171]

An interesting feature of the epidemiology of these viruses is that children with hMPV are often coinfected with other respiratory viral pathogens, especially RSV.[175] Dual infections with both viruses may result in more intense bronchiolitis in some infants.[176] hMPV was also detected in many cases of SARS, but did not appear to exacerbate this illness.[177]

Clinical Features

Human metapneumoviruses appear to be responsible for a spectrum of acute respiratory illnesses ranging from very mild or asymptomatic infection to severe bronchiolitis and pneumonitis. The clinical picture most closely resembles that of RSV, and bronchiolitis is the major manifestation in children.[171,178] Clinical features include wheezing and hypoxia in hospitalized children.[179] A variety of other lower and upper respiratory tract syndromes are also associated with hMPV infection, including croup and pneumonitis.[171,172] There are no clinical

features that can reliably distinguish between disease caused by hMPV and RSV, although in general RSV is more severe.

Symptomatic infection in adults and in the elderly has also been described.[174] hMPV infections of young adults had features of the common cold, with nasal congestion, rhinorrhea, cough, and hoarseness predominating. Frail elderly and high-risk adults had lower rates of hMPV infection than healthy adults but more severe clinical symptoms, with significantly higher frequencies of dyspnea and wheezing, and more prolonged illness.[174] Elderly patients with hMPV infection were hospitalized with diagnoses of COPD, bronchitis, and pneumonia. hMPV appears to be a leading cause of respiratory tract infection after lung transplantation.[180] In one study, hMPV was the most commonly detected RNA virus in bronchoalveolar lavage samples from immunocompromised patients.[181]

Pathogenesis

Relatively little is known about the pathogenesis of this disease. In hospitalized children with hMPV, levels of nasal secretion of the RANTES (regulated on activation, normal T-cell expressed and secreted) chemokine have been reported to be suppressed, while levels of nasal IL-8 were increased.[182] The immune responses elicited by hMPV are similar to those of RSV but often less vigorous.[183]

Diagnosis

Viral culture is slow and unpredictable. Most infections have been detected by nucleic acid amplification techniques.

Prevention and Treatment

Treatment is supportive. No antiviral agents or vaccines are currently licensed for treatment or prevention of hMPV infections, and this is unlikely to change in the near future. Ribavirin is as active in vitro against hMPV as it is against RSV.[184]

Parainfluenza Viruses

Parainfluenza viruses belong to the *Paramyxovirus* genus of the Paramyxoviridae family, which includes mumps virus and important veterinary pathogens. This group of medium-sized (150 to 200 nm), pleomorphic, enveloped viruses has a nonsegmented, single-stranded RNA genome contained in a helical nucleocapsid. The human parainfluenza viruses are separated into types 1 to 4, and type 4 is further divided into subtypes A and B, on the basis of antigenic differences. One envelope glycoprotein (HN) has hemagglutinin and neuraminidase activity and mediates for adsorption of virus to host cell receptors and release. The F glycoprotein has membrane-fusing activity and is responsible for viral penetration into cells and for the formation of multinucleated syncytial cells. Antibody against the HN and F proteins is involved in protective immunity.

Epidemiology and Transmission

Parainfluenza viruses have a worldwide distribution, and almost all persons are infected initially during childhood. Infections by parainfluenza type 3 virus may occur in infancy, whereas infections by type 1 and 2 viruses appear to be prevented by maternal antibody and usually occur later. National surveillance has demonstrated distinct seasonality for type 1 viruses, occurring in biennial outbreaks in the fall of odd-numbered years. In contrast, yearly outbreaks of type 3 virus occurred annually in the spring, with smaller fall outbreaks in those years when type 1 outbreaks did not occur. Type 2 viruses are detected much less frequently, but appeared to be more prevalent in the fall; type 4 does not exhibit notable seasonality.[185]

Parainfluenza viruses appear to be transmitted from person to person by direct contact with infectious respiratory secretions or by large-particle aerosols. The incubation period is approximately 3 to 6 days. Transmission occurs readily in families. Outbreaks of infection have occurred in closed populations, such as nurseries, daycare centers, and hospitals, in which high attack rates (40% to 80%) occur in susceptible persons.

Parainfluenza virus infections, most commonly type 1 virus, are associated with approximately 40% of croup cases and up to 75% of those with a documented viral cause, with smaller proportions of pneumonia or bronchiolitis cases in children. The incidence of croup and lower respiratory tract disease due to type 1 or 2 infections is highest between 6 months and 3 years of age, whereas parainfluenza type 3 is an important cause of bronchiolitis or pneumonia in infants less than 6 months old. Reinfections with parainfluenza viruses are common and may occur within several months of each other in young children. Parainfluenza virus type 1 infections are estimated to account for up to 28,900 annual hospitalizations in the United States, and parainfluenza virus type 3 for up to 52,000.[186]

Pathogenesis

Although viremia has been described, replication of the virus is generally restricted to the respiratory tract mucosa. The quantity of virus shed in respiratory secretions tends to parallel the severity of illness.[187] Virus shedding commonly continues for periods of 8 to 10 days in initial infections but may last for 3 weeks or longer. Prolonged shedding (months) of parainfluenza virus type 1 or 3 has been reported in apparently normal hosts,[188] as well as in immunodeficient children.[189]

The pathologic findings in fatal cases are typical of other viral pneumonias and include peribronchiolar and alveolar lymphocytic infiltration.[190] Infection of the tracheal epithelium with localized edema and fibrinous exudate contributes to airway narrowing in croup. The reasons for the laryngotracheal localization of parainfluenza virus–induced disease are unresolved. Virus–host

cell interactions (specifically cleavage of the F protein) and other host factors, including the nature of the immune response, are postulated to play contributory roles in the pathogenesis of croup. The nasopharyngeal secretion concentrations of parainfluenza virus–specific immunoglobulin E and of histamine and leukotriene C4, and cellular responses to viral antigen, are higher in patients with wheezing than in those with upper respiratory tract illness alone.[191]

Clinical Illness

Primary infections are usually symptomatic and associated with the most severe forms of illness. Initial infections with parainfluenza virus types 1 to 3 cause febrile rhinitis, pharyngitis, laryngitis, and bronchitis in children. Depending on the serotype causing infection, 50% to 80% of primary infections are associated with fever, and up to one third of children have evidence of lower respiratory tract involvement. In parainfluenza virus type 1 and 2 infections, lower respiratory disease is principally manifested as croup, whereas type 3 infection has been associated with croup, bronchiolitis, and pneumonia.

In adults and older children, reinfections are frequently asymptomatic. Symptomatic infections are manifested as common colds, usually without fever, and less often pharyngitis, tracheobronchitis, or influenza-like illness. Pneumonia and exacerbations of COPD have been described following parainfluenza virus infection in adults and the elderly.[192]

Although uncommon, parainfluenza viruses can cause serious lower respiratory tract disease, including fatal pneumonia with or without giant cells, in children with immunodeficiency or leukemia, and in adults and children who are bone marrow or stem cell transplant recipients.[193] Nosocomial outbreaks in immunosuppressed patients have been reported.[194] Because upper respiratory illness may be absent and nasopharyngeal cultures negative, bronchoalveolar lavage is often required for diagnosis.

Diagnosis

Throat and nasopharyngeal secretions contain the virus at the onset of symptoms. Virus can be isolated as early as 3 days and usually within 10 days after inoculation of cell culture with specimens from infants and children. Virus replication in cell culture is usually detected by hemadsorption of guinea pig erythrocytes or immunofluorescence. Rapid diagnosis by detection of parainfluenza antigens in respiratory secretions or PCR-based tests has also been developed.

Treatment and Prevention

There are currently no available antiviral agents of proven effectiveness against parainfluenza virus. Ribavirin is active against parainfluenza viruses in vitro, and would theoretically be expected to be active in vivo as well. Anecdotal reports in immunodeficient children with severe parainfluenza virus infections suggest that aerosolized ribavirin may be associated with antiviral effects and clinical benefit,[195] although delayed treatment with aerosolized ribavirin was not associated with improved survival in bone marrow transplant recipients.[196]

Initial attempts to develop vaccines for the prevention of parainfluenza virus infections involved use of formalin-inactivated virus. However, these vaccines failed to provide protection in field trials carried out in the 1960s, despite being modestly immunogenic. In contrast to RSV vaccines, the use of formalin-inactivated parainfluenza virus vaccine was not associated with enhanced disease upon subsequent infection. Several approaches have been explored subsequently to develop an effective parainfluenza vaccine, including use of subunit vaccines and development of live, attenuated viruses as potential parainfluenza virus vaccines.[197]

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is classified in the *Pneumovirus* genus of the Paramyxoviridae family. Similar in structure to parainfluenza viruses, RSV is a pleomorphic (150 to 300 nm), enveloped virus with a single-stranded, nonsegmented RNA genome. The surface proteins include the F protein responsible for fusion of the viral envelope with the host cell membranes and formation of syncytium, and the G protein, a heavily glycosylated protein responsible for attachment to cells. Antibodies against the F and G proteins neutralize RSV in vitro, but antibodies against the G protein do not do not prevent syncytium formation. Two major antigenic groups (designated A and B) are distinguished primarily by differences in the G glycoprotein.[198] The clinical and epidemiologic importance of strain variation are under study, but infections by group A strains appear to be more severe.[199] Further antigenic subgroups and genomic heterogeneity are recognized among circulating RSV strains.

Epidemiology and Transmission

Respiratory syncytial virus is worldwide in distribution and, in temperate climates, causes annual outbreaks of infection in the late fall, winter, or spring. Epidemics are associated with increases in pediatric hospitalizations and deaths due to lower respiratory tract illness in infants and young children.[200] Nearly 50% of children are infected within the first year, and almost all within 3 years of age. Reinfections in children and adults are quite common even with the same strain, suggesting immunity is only partial at best.[201] Epidemiologic factors related to serious illness in infected infants include low socioeconomic status, crowding, maternal smoking, lack of breastfeeding, daycare center attendance, and history of allergic disease. RSV is also recognized as a cause of severe disease in older adults,[202] and may result in a greater total burden of mortality in the elderly than in infants.[103]

Virus spreads by large-particle aerosols during close personal contact and by hand contamination with infectious secretions and subsequent self-inoculation of the

eye or nose. RSV is a major nosocomial pathogen on pediatric wards, and high attack rates occur during outbreaks in hospitals, transplantation units, daycare centers, and geriatric residential homes. Attack rates in children have approached 100% during outbreaks in daycare centers and are commonly 20% to 50% in hospital staff and patients during epidemic periods. In the family setting, secondary infection develops in approximately one half of infants and up to one third of adult contacts after introduction of virus by an older sibling.[203]

Pathogenesis

Viral replication generally begins in the upper respiratory tract with gradual (4- to 5-day) progression to involve the lower respiratory tract. In normal children, the duration of viral shedding ranges from 1 to 3 weeks. Clinical signs of bronchiolitis include air trapping and wheezing. Pathologic findings in RSV bronchiolitis include necrosis of bronchiolar epithelium, loss of ciliated epithelial cells, and marked peribronchiolar mononuclear inflammation.[204] Virus-induced cytopathology and associated submucosal edema lead to obstruction of smaller bronchioles, particularly in infants, with distal collapse or air trapping.

Both serum and mucosal antibody responses occur but are associated with only partial protection. The magnitude of the antibody response is related to the age at primary infection, with infants less than 8 months of age having approximately 10-fold lower antibody levels than older ones.[205] Reinfection may occur within weeks after primary infection and as early as 8 weeks in adults with secondary infections.[201] Increasing levels of circulating and mucosal antibody occur with each successive infection and appear to be associated with milder illness. High titers of serum neutralizing antibody are generally associated with a lower risk of severe illness in infants and children.[206]

Cell-mediated immunity appears to be important in viral clearance, and may also be involved in pathogenesis. For example, adult bone marrow transplant populations are at high risk of severe lower respiratory disease from RSV, which is likely due to prolonged periods of decreased cellular immunity.[207,208] In contrast, in AIDS patients with decreased cellular immunity, viral shedding can continue for up to 6 months with only mild disease.[209]

Studies investigating the association of severe RSV disease in infants with genetic polymorphisms have implicated several candidate innate and adaptive immune genes, including surfactants, TLR4, and several cytokine and chemokine genes, as modulating the severity of RSV disease.

Clinical Illness

The clinical manifestations of infection are dependent upon both the age and the immunologic state of the host. In infants and young children, upper respiratory illness accompanied by fever and otitis media is common. Respiratory syncytial virus is the major cause of lower respiratory tract illness in infants and young children and accounts for 45% to 90% of bronchiolitis, up to 40% of pneumonia, and smaller proportions of croup and bronchitis cases in this age group. Most severe infections occur in infants less than 6 months of age, and almost all primary infections are symptomatic, with 40% or more associated with bronchiolitis or pneumonia. Approximately 1% to 2% of infections result in hospitalization, and about one tenth of hospitalized infants require ventilatory support.

The risk of hospitalization and severe bronchiolitis is particularly high in infants with congenital heart disease, chronic lung disease, or immunodeficiency. In addition, infants born prematurely are also at risk for severe disease because they lack maternal antibody. Mortality is usually 0.5% to 1.5% in previously healthy infants hospitalized with RSV disease but is 15% to 40% in those with primary immunodeficiency, cancer chemotherapy, or pulmonary and heart disease; pulmonary hypertension, in particular, is associated with poor outcome. Severe disease in children has also been associated with a family history of asthma, and those exposed to cigarette smoke in the family household.[210]

Radiographic findings in lower respiratory tract disease include bronchial wall thickening, peribronchial shadowing, air trapping, and, in pneumonia, multilobar patchy shadowing or poorly defined nodularity (see Fig. 31-4). Although no radiographic pattern is specific, air trapping, alone or with other abnormalities, is highly associated with RSV infection in hospitalized children.[211]

The most common physiologic abnormality is hypoxemia that may persist for weeks after apparent recovery.[212] Prolonged pulmonary function abnormalities, including increased airway resistance, peripheral airway obstruction, and decreased arterial oxygen saturation, have been detected in children years after bouts of RSV-related bronchiolitis.[213] Bronchiolitis in infancy has also been associated with an increased risk of subsequent recurrent wheezing and cough and airway hyperreactivity. However, whether or not adults develop asthma after severe RSV disease during infancy has not been established.

One half or more of recurrent infections in adults are associated with upper respiratory tract illness. Adults typically experience coryza, pharyngitis, and cough, sometimes accompanied by low-grade fever. Bronchitis, influenza-like illness, pneumonia, and exacerbations of asthma and chronic bronchitis have also been described in adults with RSV infection. In the United States, approximately 170,000 hospitalizations and over 10,000 deaths are associated with RSV annually in adults over 65 years of age.[103] In elderly adults, the clinical features of RSV infection can mimic those of influenza, although fever is less and wheezing is more frequent.[214] In one study, rates of RSV infection were from 3% to 7% among healthy elderly and 4% to 10% in high-risk adults, and compared to influenza, intensive care unit (ICU) admissions were higher and mortality similar at 7% to 8%.[202] RSV also plays a substantial role in causing exacerbations of COPD, with rates from 5% to 10%.[215]

Respiratory syncytial virus, often nosocomially acquired, causes severe lower respiratory tract disease in immunosuppressed children and adults. Upper respiratory tract illness usually precedes the development of pneumonia, and complicating sinusitis and otitis media are common. Two thirds or more of the bone marrow transplant recipients who develop RSV pneumonia succumb without treatment.

Diagnosis

Respiratory syncytial virus grows well in several human cell lines, in which it causes formation of characteristic syncytia. Virus can be detected as early as 2 days and usually within 7 days on primary isolation from specimens collected from children. A variety of antigen detection tests have been developed for more rapid diagnosis. The sensitivity of such techniques is dependent on the quality of the nasopharyngeal specimen, with nasopharyngeal aspirates superior to brushings or swabs.[216] In addition, sensitivity is related to the amount of antigen being shed, and so is generally greater in children than adults. In transplant patients with suspected RSV pneumonia, samples of the lower respiratory tract by bronchoalveolar lavage are more sensitive than throat swabs for detection of RSV antigens.[217] A PCR-based respiratory viral multiplex assay for detection of RSV and other respiratory viruses has also been approved by the Food and Drug Administration.

Treatment and Prevention

Correction of hypoxemia is the most important aspect of managing RSV lower respiratory tract disease. Ribavirin is highly active against RSV in vitro, and aerosolized ribavirin has been shown to reduce viral shedding and shorten the course of illness in some but not all studies. Aerosolized ribavirin is currently recommended for use only in selected infants and young children who are at high risk for serious RSV disease.[218]

In immunosuppressed patients, particularly human stem cell transplant recipients, both aerosolized ribavirin and high-dose oral ribavirin have been used for early treatment to prevent progression to pneumonia.[219] Once RSV pneumonia has developed, intravenous ribavirin alone is ineffective, but combinations of aerosolized ribavirin with intravenous immune globulin (RSV-IVIG), and particularly paluvizumab (see later), may be beneficial if treatment is initiated prior to the onset of respiratory failure.[220,221]

Vaccines for prevention of RSV have not been developed. In a study of formalin-inactivated RSV vaccine conducted in the 1960s, vaccinated infants developed more severe disease compared to unvaccinated children.[222] The mechanism of this enhancement remains unknown, although an unbalanced immune response in which the majority of immunity is directed against nonprotective and/or denatured epitopes generated by the inactivation process, a lack of antibody maturation, and enhanced immune complex deposition are some current hypotheses.[223,224]

In contrast, passive transfer of antibody to the RSV F protein has been shown to be a highly effective means to prevent RSV morbidity in high-risk children. The currently commercially available product, paluvizumab, is a humanized monoclonal antibody to the F protein.[225] Administration of paluvizumab to infants with prematurity or bronchopulmonary dysplasia resulted in a 55% reduction in RSV-related hospitalizations, and a lower incidence of ICU admissions.[226] In a second trial, administration of paluvizumab to infants and children with hemodynamically significant congenital heart disease was well tolerated and resulted in a 45% decrease in RSV-associated hospitalizations.[227] A new higher affinity anti-RSV monoclonal antibody, motavizumab, is in clinical trials for RSV prophylaxis of high-risk infant populations.

Prophylaxis with paluvizumab should be considered for infants younger than 24 months old with chronic lung disease severe enough to require medical therapy within 6 months of the anticipated start of the RSV season.[228] Prophylaxis with paluvizumab (and not RSV-IVIG) should be given to infants with hemodynamically significant congenital heart disease and infants born before 32 weeks of gestation. Prophylaxis for infants born between 32 and 35 weeks of gestation should depend on the presence of other RSV risk factors, such as tobacco smoke, attendance at daycare, school-aged siblings, and congenital airway abnormalities. Paluvizumab has not been shown to be effective in the therapy of established RSV disease.

Recommendations for interruption of nosocomial transmission include handwashing, decontamination of surfaces and inanimate objects, and isolation of infected patients. Use of disposable eye-nose goggles by pediatric staff reduces the risk of nosocomial RSV infection in both staff and patients.[229] Regular use of gowns, gloves, and possibly masks by hospital staff caring for infected children may also reduce the risk of nosocomial RSV spread. Protective isolation of high-risk infants or deferring their elective admission has been recommended during institutional outbreaks of RSV.

Rhinovirus

The rhinovirus (RV) virion is a nonenveloped particle 30 nm in diameter with four major structural proteins. The genome of RV consists of single-stranded RNA of approximately 2.5×10^6 daltons and codes for a 240-kD protein that is cleaved into the structural units of the virion. Rhinovirus genomes have been found to have 45% to 62% homology with poliovirus genomes. Poliovirus and RV differ, however, in the construction of their protein shells: that of RV being loosely packed with a resultant sensitivity to inactivation at low pH, and that of poliovirus being tightly packed, providing the virion with resistance to acid inactivation. The acid sensitivity of RV and its optimum growth at 32°C to 34°C are thought to account for its replication in the nasal passages (and possibly large airways) but not in the gastrointestinal tract.

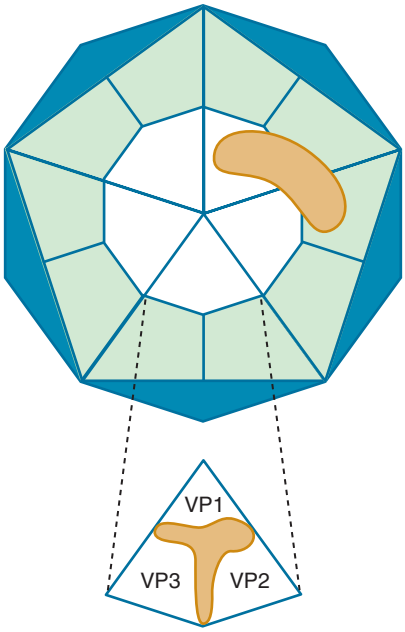

FIGURE 31-12 ■ Organization of rhinovirus shell drawn to scale with attached antibody molecule. *Top,* The protein shell is built of 12 pentamers, one of which is highlighted (*white*). Each of the five wedge-shaped subunits of the pentamer is called a "protomer." The antibody molecule (*beige*) bridges protomers of two adjacent pentamers. *Bottom,* Surface organization of the protomer. Three of the polypeptide chains (VP1, VP2, VP3) making up each protomer are exposed on the virus surface, while the smallest polypeptide (VP4) is buried at the bottom of the protomer. The host-cell receptor is thought to bind near the base of the cleft formed by antigenic plateaus forming VP1, VP2, and VP3. The blunt-nosed binding site of the antibody is too wide to fit into the base of the cleft. (Courtesy of Roland Rueckert, MD, University of Wisconsin, Madison, Wisconsin.)

Three of the four proteins in the RV shell (VP1, VP2, and VP3) react with neutralizing antibody, forming the basis on which 100 antigenic types and one subtype have been numbered. The presence of neutralizing antibody in serum and nasal secretions correlates with protection from infection. X-ray diffraction studies of RV have disclosed the presence of a large depression on the surface of the virus shell at a junction between the plateaus of the three proteins (Fig. 31-12).[230] This depression contains the recognition site for the host cell receptor, which is intracellular adhesion molecule-1 (ICAM-1) for 91 of 102 known rhinovirus serotypes.[231] Rhinovirus serotypes that do not bind to ICAM-1 are referred to as the minor receptor group viruses, and appear to utilize the low-density lipoprotein receptor.[232] Manipulations of these receptor proteins have been explored as a potential control measure for rhinovirus infection.

Epidemiology and Transmission

Rhinoviruses are worldwide in distribution. In the United States, RV has been observed to cause 0.74 to 0.77 infections per person per year in adults. Rhinovirus is believed to produce even higher infection rates in children, leading to acquisition of antibody to the different RV types throughout childhood and adolescence, with peak antibody prevalence occurring in young adults. Immunity to rhinovirus is type specific and relatively solid following infection, although second infections with the same virus type can occur. The different immunotypes circulate in a given population in an apparently random manner. In the United States, RV infections are most prevalent in the early fall and late spring.

The major reservoir for RV is schoolchildren, who transmit RV infection among their peers in the classroom and introduce it into their homes, infecting other family members. Studies of experimental RV colds in volunteers have shown that RV is most efficiently spread by contaminated fingers accidentally depositing virus into the nose or eye. Also, experimental RV transmission has been achieved by the airborne route, presumably by large-particle aerosol. The relative importance of these two routes of RV transmission under natural conditions has not been determined.

Pathogenesis

Approximately two thirds of both natural and experimental RV infections result in overt illness. The incubation period of RV colds is usually 2 days but may be up to a week. Symptoms begin within 1 day following experimental infection. Small doses of RV instilled into the nose or eye of susceptible volunteers regularly lead to infection, indicating that mucociliary clearance is not effective against the virus. During the period of illness, sloughed ciliated epithelial cells containing viral antigen are present in nasal secretions.[233]

In general, the number of RV-infected cells in the nasopharynx appears to be quite limited,[234] and infection does not lead to detectable damage to the epithelium of the nasal passages. These results have suggested that virus-induced cellular injury is not the direct cause of symptoms in rhinovirus colds, and that inflammatory mediators play an important role. Nasal secretions during the initial response to rhinovirus infection are predominantly the result of increased vascular permeability, as demonstrated by elevated levels of plasma proteins in nasal secretions; glandular secretions (lactoferrin, lysozyme, and secretory immunoglobulin A) predominate late in colds.[235] In contrast to the situation in allergic rhinitis, histamine does not appear to play a role in the induction of symptoms in colds. Nasal secretion kinin levels correlate with symptoms in natural and experimental colds, and intranasal administration of bradykinin causes increased nasal vascular permeability, rhinitis, and sore throat.[236] Interleukin-1, -6, and -8 levels also increase in experimental rhinovirus colds and correlate well with symptom severity.[237] Enhanced synthesis of proinflammatory cytokines and cell adhesion molecules in the middle ear may also contribute to the pathogenesis of otitis media associated with colds.[238]

Clinical Illness

Rhinovirus colds vary in severity from mild episodes characterized by a day or two of coryza or scratchy throat to full-blown illnesses with profuse and prolonged rhinorrhea, pharyngitis, and bronchitis. The profile of a typical RV cold, based on composite results from young adults with natural infection, is shown in Figure 31-1. The median length of illness is 1 week, with symptoms lasting up to 2 weeks in one quarter of cases. Peak symptoms are usually seen on the second and third days of illness. The characteristics of RV illness are not distinctive enough to permit its differentiation from colds due to other respiratory viruses. Rhinovirus is among the respiratory viruses implicated in the development of acute sinusitis and represents about half of all viruses recovered from middle ear effusions in children with acute otitis media.[239] Recently, a clinical presentation indistinguishable from that of influenza has also been reported in healthy adults.[240]

Rhinovirus alone or in combination with bacteria has been recovered from aspirates obtained by direct puncture of the maxillary sinuses of patients with acute sinusitis.[241] Mucosal thickening and/or sinus exudates have been observed in as many as 77% of subjects with acute colds.[242] These abnormalities are transient, and in uncomplicated cases resolve within 21 days. However, clinically manifest acute bacterial sinusitis is seen in a small (0.5% to 5%) proportion of individuals with naturally occurring colds. It is presumed that the RV infection impairs mucociliary clearance and other local defenses in the sinus cavity, allowing secondary bacterial invasion.

There is increasing evidence for an important role of rhinoviruses in lower respiratory tract disease in adults and children. Rhinovirus is the second most frequently recognized agent associated with pneumonia and bronchiolitis in infants and young children and commonly causes exacerbations of preexisting airways disease in older patients with COPD or cystic fibrosis.[243] Colds are generally more severe in atopic individuals, and rhinoviruses are major causes of asthma exacerbation.[244] Children with a history of wheezing/asthma had significantly more RV-associated hospitalizations than those without such history.[245]

Rhinovirus infections may also be associated with severe lower respiratory tract disease in transplant recipients,[246] and in some cases can be associated with prolonged viral shedding.[247] These viruses can also be detected in lower respiratory tract disease in individuals with hematologic malignancy, often in conjunction with other pathogens.[248]

Diagnosis

Rhinoviruses can be isolated in cell culture, usually within 2 to 7 days after inoculation. Virus is present in nasopharyngeal secretions in highest concentrations during the first and second days of illness but may be shed for as long as 3 weeks. Identification of the specific serotype of a rhinovirus isolate is made by neutralization test. Rapid tests for detecting RV antigen or nucleic acids by PCR have been developed and are more sensitive than culture.

Treatment and Prevention

The only effective therapy for RV colds currently available is symptomatic treatment of individual complaints. Remedies recommended for such treatment are described in the section on the common cold earlier in this chapter. As mentioned, the plethora of rhinovirus serotypes suggests that an effective vaccine will not be forthcoming in the foreseeable future. Advances in understanding of the structural and molecular biology of the rhinoviruses has led to development of a number of strategies for antiviral intervention, including receptor blockade and capsid-binding agents. However, none of these agents has reached approval for clinical use.

Varicella-Zoster Virus

Varicella, or *chickenpox,* is a highly contagious childhood disease that typically causes community outbreaks in late winter and early spring months in temperate regions. Varicella spreads rapidly to household contacts, with an attack rate of nearly 90% within 2 weeks. Consequently, most adults in temperate areas have experienced infection during childhood, but a high proportion of adults in semitropical and tropical areas remain susceptible to primary infection.[249] Herpes zoster, or *shingles,* is nonseasonal in occurrence and is seen in persons of all ages, although its incidence increases almost linearly over the age of 30 years. About 10% to 20% of adults experience zoster, typically as a single episode after the fifth decade of life. Clinically apparent reinfections with varicella-zoster virus (VZV) may occur.

Although the virus has been infrequently recovered from respiratory secretions of varicella patients, epidemiologic evidence indicates that the virus is spread from person to person through airborne transmission. Cutaneous lesions may be the source of infectious virus. Infection of susceptible persons has occurred after contact with patients with varicella, or, less often, herpes zoster. Prior to the implementation of vaccination, VZV was an important cause of nosocomial outbreaks on pediatric wards, during which spread could occur by small-particle aerosols.

Pathogenesis

The incubation period of varicella averages 2 weeks, and almost all cases of varicella develop within 11 to 20 days after exposure. The initial portal of infection is the respiratory tract, with viremic dissemination leading to the extensive cutaneous and mucous membrane lesions. Following infection, VZV establishes latency in the posterior dorsal root ganglia. Reactivation of virus replication and centrifugal spread along sensory nerves lead to the unique dermatomal distribution of shingles (zoster). Viremic dissemination to other sites may occur in immunocompromised hosts with zoster.

Clinical Illness

Varicella. In normal children, varicella is usually not associated with significant systemic or respiratory manifestations. The exanthem typically begins around the scalp and head, with subsequent involvement of the trunk and extremities. Lesions progress through various stages (erythematous macules, vesicles, pustules, crusts), so that an area will have lesions in different stages of evolution. In contrast, in smallpox, a disease with which varicella was often confused, lesions begin on the face and spread outwardly to the extremities, and adjacent lesions are at the same stage of development.

In children and susceptible adults who are immunocompromised, particularly those with defects in cell-mediated immune function, including HIV infection,[250] varicella follows a more severe course. Continued lesion development particularly involving the extremities, high fever, and visceral involvement with pneumonia, meningoencephalitis, and hepatitis are common. Severe pneumonia occurs in approximately 10% of varicella cases during pregnancy.

Viral pneumonia is the major complication of varicella in previously healthy adults, in whom it occurs with an estimated 25-fold higher frequency than in children.[251] Smoking is a significant risk factor. Pneumonia associated with varicella is usually apparent 1 to 6 days after the onset of rash. Symptoms include cough, dyspnea, pleuritic chest pain, and hemoptysis. Physical findings other than fever and tachypnea are often modest. The intensity of the rash does not necessarily correlate with the severity of pneumonia. The characteristic radiographic pattern is that of diffuse nodular (1- to 10-mm) infiltrates (Fig. 31-13), which may resolve with miliary calcific densities.[252] Hilar adenopathy, pleural effusions, and peribronchial infiltrates are frequently present. Pulmonary infarction may complicate the clinical picture. Pulmonary function studies have found normal spirometric values but decreased carbon monoxide diffusing capacity, which may persist for months. However, many individuals with radiographic changes are relatively asymptomatic.

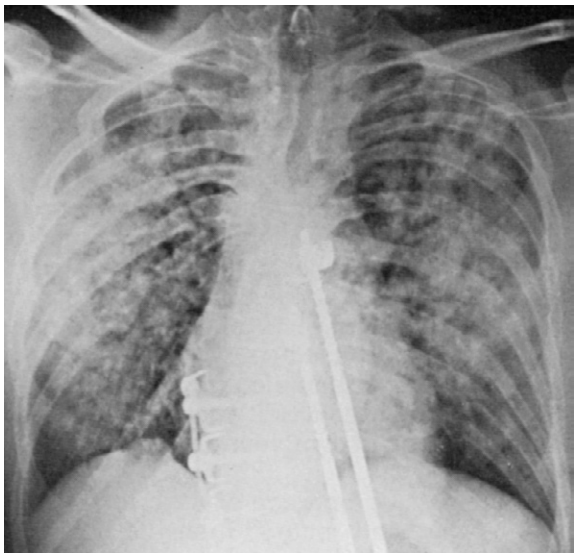

FIGURE 31-13 ■ Anteroposterior chest roentgenogram of a 23-year-old paraplegic man showing bilateral fluffy infiltrates ("pulmonary edema" pattern) with areas of nodular coalescence. This patient died of varicella pneumonia. (Courtesy of Thomas L. Pope, Jr., MD, Department of Radiology, University of Virginia School of Medicine, Charlottesville, Virginia.)

Herpes Zoster. Zoster represents reactivation of latent virus along one to three dermatomes, and in adults is usually associated with acute pain in the involved areas. The thoracic dermatomes are involved in about one half of cases. Prolonged severe pain, or *postherpetic neuralgia,* occurs with increased frequency in those over the age of 50 years.

Zoster occurs more often in those receiving immunosuppressive therapy or combination chemotherapy for malignancies and at anatomic sites irradiated for treatment of malignancies. Depending on the degree of immunosuppression, herpes zoster occurs in 30% or more of patients. Cutaneous dissemination (defined as more than 20 lesions outside the primary dermatome) occurs in 25% to 50% of immunosuppressed patients and in up to 2% of apparently healthy patients with zoster. It is associated with visceral involvement, including pneumonitis as well as hepatitis, meningoencephalitis, and uveitis, in approximately one half of those affected. Mortality depends on the degree of immunosuppression and has ranged from zero to 10%.

Diagnosis

The virus is very labile but can be isolated from vesicular fluid during the first 3 days of varicella in normal hosts and for up to 10 days in immunocompromised hosts or patients with disseminated zoster. Direct inoculation of vesicular fluid onto monolayers of cell culture (human embryonic lung fibroblasts) at the bedside increases the likelihood of isolation. A rapid diagnosis of herpes group infection can be established by cytologic examination of lesion scrapings (Tzank smear and others), which has a sensitivity of 70% to 85% when lesions are in the vesicular stage. Direct immunofluorescence for VZV antigen in lesions is the most sensitive rapid laboratory test.

Treatment and Prevention

Live, attenuated varicella vaccine generates neutralizing antibody in over 95% of recipients, and long-lived cytotoxic T-lymphocyte responses against varicella virus.[253] Vaccination of immunosuppressed children, mostly those with leukemia, is also safe, although a small proportion of children will experience a mild, varicella-like clinical syndrome approximately 1 month after vaccination.[254] In both healthy and immunosuppressed children, the vaccine is highly effective at preventing varicella, with efficacy rates of 50% to 90%. Two doses of varicella vaccine administered subcutaneously are recommended for children 12 months and older, adolescents, and adults without evidence of prior immunity.[255] Second-dose catch-up vaccination is recommended for those who previously received only a single dose of vaccine.

A higher dose live vaccine effectively restimulates cellular immunity in adults and can reduce the frequency of reactivation as well as the clinical severity of zoster.[256] The high-dose live vaccine is recommended as a single dose in all healthy individuals 60 and above.[257]

Although uncomplicated varicella in children usually requires no specific treatment, oral acyclovir initiated within 24 hours of rash onset reduces the number of lesions, duration of fever, and healing time compared with placebo in children, adolescents, and adults.[258] In certain circumstances, sequential intravenous and oral acyclovir has been used in therapy of varicella in immunocompromised children.[259] In immunocompromised patients with localized zoster, intravenous acyclovir has been found to halt dissemination. In addition, oral acyclovir, valacyclovir, and famcyclovir are effective for the treatment of zoster, and may reduce the duration of postherpetic neuralgia in healthy adults.[260] Intravenous acyclovir (10 mg/kg every 8 hours for 5 to 7 days) appears efficacious in varicella pneumonia in previously healthy adults if started early.[261]

KEY POINTS

- Viral infections are extremely important causes of disease of the respiratory tract, which are associated with considerable morbidity and, at times, mortality.
- Clinical syndromes—such as the common cold, pharyngitis, acute bronchitis, influenza-like illness, croup, bronchiolitis, and pneumonia—may be caused by several different viruses, and most of the major respiratory viruses may cause more than one clinical syndrome.
- Adenoviruses of many antigenic types cause sporadic, epidemic, or nosocomial disease both in previously healthy children and adults and in persons with impaired immunity.
- Human coronaviruses have long been recognized as causes of the common cold, and a novel strain was identified as the cause of the recent pandemic of severe acute respiratory syndrome (SARS).
- In immunocompetent persons, infection with cytomegalovirus is usually asymptomatic, but severe pneumonia and extrapulmonary disease occur in immunocompromised patients.
- Hantaviruses cause severe, often fatal pneumonia in addition to a cardiopulmonary and hemorrhagic fever with renal disease syndrome.
- Herpes simplex virus, especially type 1, causes acute gingivostomatitis and pharyngitis in healthy persons and chronic ulcerative pharyngitis and laryngotracheitis and pneumonia in immunocompromised patients.
- Influenza virus, especially types A and B, regularly causes seasonal epidemics of pneumonia, which are associated with substantial excess morbidity and need for hospitalization that are at least partially preventable by vaccination.
- Measles virus occurs worldwide but has largely been curtailed by vaccination in industrialized countries; in resource-poor countries, death from associated pneumonia is common.
- Human metapneumoviruses and respiratory syncytial virus (RSV) both cause a spectrum of acute respiratory illnesses ranging from mild or asymptomatic infection to severe bronchiolits and pneumonia. Disease from RSV is generally more severe than from metapneumoviruses, and may also occur in adults, especially those with chronic lung disease or immunosuppression.
- Parainfluenza viruses occur worldwide and commonly infect young children, who may present with croup or, less often, bronchiolitis or pneumonia.
- The numerous strains of rhinovirus are the most common cause of the common cold.
- Varicella-zoster virus causes two distinct clinical syndromes, varicella, which in adults is often associated with pneumonia, and zoster, a painful skin eruption that is common in immunocompromised patients and increases with age in otherwise healthy adults. Effective vaccines are available for each condition.

CHAPTER 32

PYOGENIC BACTERIAL PNEUMONIA AND LUNG ABSCESS

Antoni Torres, MD • Rosario Menéndez, MD • Richard Wunderink, MD

INTRODUCTION

PATHOPHYSIOLOGY

EPIDEMIOLOGY
Community-Acquired Pneumonia
Hospital-Acquired (Nosocomial) Pneumonia
Health Care–Associated Pneumonia

CLINICAL PRESENTATION
"Typical" versus "Atypical" Pneumonia

PATIENT EVALUATION
Clinical Evaluation
Laboratory Evaluation
Radiographic Evaluation
Microbiologic Evaluation
Invasive Diagnostic Techniques
Differential Diagnosis

THERAPEUTIC APPROACH TO PNEUMONIA
Assessment of Severity

Strategies to Prevent Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia

INTRODUCTION

There are an estimated 4 million cases of community-acquired pneumonia (CAP)/yr in the United States that result in approximately 10 million physician visits, 1 million hospitalizations, and 45,000 deaths.[1] The mortality of CAP in hospitalized patients is 14% but increases to 20% to 50% in patients who require intensive care unit (ICU) care. In addition, pneumonia is the second most common and most frequently fatal nosocomial infection among hospitalized patients.

A clinical diagnosis of pneumonia can usually be readily established on the basis of signs, symptoms, and chest radiographs, although distinguishing CAP from conditions such as congestive heart failure, pulmonary embolism, and chemical pneumonia from aspiration is sometimes difficult. Unfortunately, defining an etiologic agent is much more challenging. Although early empirical therapy is often necessary, it is still important to identify the causative pathogen in order to confirm the appropriateness of therapy and reduce unnecessary antimicrobial use. In hospitalized cases, up to 10% of patients do not respond to initial antibiotic therapy.

Adequate diagnosis and management of pneumonia is complicated by the growing proportion of aged and comorbid, debilitated, institutionalized, and immunocompromised individuals, by the increasingly diverse array of microorganisms that cause pneumonia, and by evolving antimicrobial resistance.

PATHOPHYSIOLOGY

Inhalation pneumonia is most often due to microorganisms that (1) survive long enough while suspended in the air to be transported far from the initial source, (2) have a size less than 5 μm and carry a high inoculum, and (3) evade local host defenses.

In contrast, aspiration of oropharyngeal secretions is the main mechanism of contamination of lower airways by large bacteria. While a person is awake, normal glottal reflexes prevent aspiration; however, during sleep, 50% of normal persons aspirate small volumes of pharyngeal secretions. Healthy adults have 10 to 100 million bacteria/mL of oropharyngeal secretions. This may increase 100- to 1000-fold in patients with periodontal disease. Therefore, aspiration of 0.001 mL may carry an inoculum of greater than 100,000 microorganisms.

Normal oropharynx is predominated by a mixed flora of low virulence. The ability of virulent microorganisms such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* to colonize the oropharynx is determined by the interaction of specific microbial adhesins with cellular receptors. For example, glycoproteins such as fibronectin in oral mucus promote the adherence of viridans streptococci and prevent colonization of the oropharynx by gram-negative bacilli. Colonization by gram-negative bacilli is increased in persons with lower levels of salivary fibronectin, which occurs consequent to alcoholism, diabetes, malnutrition, and other severe comorbidities. The presence of local immunoglobulins (particularly immunoglobulin A [IgA]), complement, and normal flora also prevents colonization of the oropharynx by more virulent organisms. Antimicrobial-mediated depression of the normal oral flora facilitates colonization by resistant gram-negative bacilli. Gram-negative bacillus colonization also occurs when new receptors appear in the surface of epithelial cells. This occurs following influenza infection or in chronic obstructive pulmonary disease (COPD).

Complex interactions between the virulence and quantity of inhaled or aspirated microorganisms and the integrity of mechanical barriers as well as of innate and adaptive immunity determine whether pneumonia develops.[2] Disruption of the factors that regulate bacterial adherence to mucosal surfaces facilitates oropharyngeal colonization by more pathogenic microorganisms. Aerosolization is the route of infection by intracellular bacteria such as *Mycoplasma pneumoniae*, *Chlamydophila* spp., and *Coxiella burnetii*, whereas disease due to *S. pneumoniae*, *Haemophilus influenzae*, gram-negative bacilli, and related organisms is due to aspiration. Aside from inhalational pneumonia due to *Legionella* or contaminated medical aerosols, aspiration is the cause of hospital-acquired pneumonia (HAP),[2] especially in intubated patients. Biofilms are a well-recognized reservoir of bacteria that facilitate the development of HAP.[2,2a]

EPIDEMIOLOGY

Community-Acquired Pneumonia

The true incidence of CAP is uncertain because the illness is not reportable and only 20% to 50% of patients require hospitalization. Estimates of the incidence of CAP range from 2 to 15 cases/1000 persons/yr, with substantially higher rates in the elderly.[3]

For any given pathogen, the severity of disease is largely determined by the subject's age and the presence and type of any coexisting illness.[4–7] Nevertheless, the likely microbial causes of CAP differ according to the severity of disease at clinical presentation. *S. pneumoniae*, *M. pneumoniae*, *Chlamydophila pneumoniae*, and viruses are likely to cause mild CAP (Table 32-1),

whereas in patients with CAP severe enough to warrant hospitalization, *S. pneumoniae* is the most commonly identified etiologic agent followed by *H. influenzae* and *M. pneumoniae* (Table 32-2).[7,8] Gram-negative enteric bacilli, *S. aureus*, *Legionella* spp., and respiratory viruses other than the influenza virus are uncommon, with an incidence of less than 5%. Polymicrobial infections account for 10% to 20% of episodes.

The most frequently identified pathogens causing severe CAP (i.e., CAP requiring immediate ICU care) include *S. pneumoniae*, *Legionella pneumophila*, *H. influenzae*, gram-negative bacilli, *S. aureus*, *M. pneumoniae*, and respiratory tract viruses (Table 32-3).[7,9,10] *P. aeruginosa* infection is relatively uncommon except in patients with specific risk factors (previous antibiotic treatment and severe pulmonary comorbidity, especially bronchiectasis, cystic fibrosis, and severe COPD).[7,9] Up to 20% of severe CAP episodes are caused by polymicrobial infection; however, even if extensive diagnostic procedures are performed, the responsible pathogen is not isolated in up to 50% to 60% of patients with severe CAP.

Methicilin-resistant *Staphylococcus aureus* (MRSA), originally a nosocomial pathogen, appeared in recent times in the community and are referred to community-acquired MRSA. Community-acquired MRSA can lead to severe pulmonary infections, including necrotizing and hemorrhagic pneumonia.[11]

The likely etiology of severe CAP in differing patient populations is shown in Table 32-4.[12-14]

Age-Related Factors

Pneumonia remains one of the major causes of morbidity in children. In Europe, more than 2.5 million cases of childhood pneumonia occur yearly, which account for around 50% of hospital admissions for children. Radiographically defined pneumonia is present in 7.5% of febrile illnesses in infants up to 3 months old and in 13% of infectious illnesses during the first 2 years of life. In children younger than 2 years, *S. pneumoniae* and respiratory syncytial virus (RSV) are the most frequent microorganisms, whereas *M. pneumoniae* is a leading

cause of pneumonia in older children and young adults.

In adults, increased age is associated with a change in the distribution of microbial causes and an increase in the frequency and severity of pneumonia.[15] The annual incidence of CAP in noninstitutionalized elderly people is estimated to be between 18/1000 and 44/1000 compared with 4.7/1000 and 11.6/1000 in the general population.[3,16] Although the elderly are particularly at risk for pneumococcal pneumonia, they also have increased rates of pneumonia due to group B streptococci, *Moraxella catarrhalis*, *H. influenzae*, *L. pneumophila*, gram-negative bacilli, *C. pneumoniae*, and polymicrobial infections.[3,9,17] Moreover, although the absolute rate of infection by *M. pneumonia* does not decrease with age, this pathogen accounts for a smaller proportion of pneumonia in the elderly than in younger populations. In patients older than 80 years, there is a higher incidence of aspiration pneumonia and lower incidence of *Legionella* spp. than in patients younger than 80 years.[18]

Personal Habits

Alcohol consumption is an important risk factor for CAP owing to its immunosuppressive effects and its potential to lower consciousness level, thus, increasing the risk of aspiration pneumonia. Alcoholism per se has been shown to be an independent risk factor for an increased rate and severity of pneumonia, especially that due to *S. pneumoniae*.[19,20] This predisposition persists several months after cessation of alcohol consumption.[21]

Smoking is one of the most important risk factors for CAP. It is also associated with an increased frequency of CAP due to *S. pneumoniae*, *L. pneumophila*, and influenza.[15] Smoking alters mucociliary transport and humoral and cellular defenses, affects epithelial cells, and increases adhesion of *S. pneumonia* and *H. influenzae* to the oropharyngeal epithelium.

Comorbidities

The most frequent comorbidity associated with CAP is COPD. Patients with COPD have an increased risk for CAP. Microorganisms frequently colonize the lower airways of patients with COPD. In addition, such patients have important alterations in mechanical and cellular defenses. Although the etiology of CAP may not generally be different in patients with COPD, persons with severe COPD (forced expiratory volume in 1 second [FEV_1] < 30% of predicted) and bronchiectasis have an increased risk for pneumonias caused by *H. influenzae* and *P. aeruginosa*.[9]

In COPD patients treated with oral corticosteroids for long periods, the risk of infection by *Aspergillus* spp. is increased.[22]

Bronchitis and pneumonia remain the major causes of morbidity and mortality in patients with cystic fibrosis. During the first decade of life, *S. aureus* and nontypeable *H. influenza* are the most common pathogens, although *P. aeruginosa* is occasionally isolated in infants. By 18 years of age, 80% of patients with cystic fibrosis harbor *P. aeruginosa* and 3.5% harbor *Burkholderia cepacia*.[23] *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, and nontuberculous mycobacteria are emerging pathogens in this population.[24]

Other comorbidities associated with increased rates of CAP and subsequent mortality include congestive heart failure, chronic kidney or liver disease, cancer, diabetes, dementia, cerebrovascular diseases, and immunodeficiency states (e.g., neutropenia, lymphoproliferative diseases, immunoglobulin deficiencies, human immunodeficency virus [HIV] infection).

Susceptibility to infection is increased by a number of malnutrition-related phenomena such as a decreased level of secretory IgA, a failure of macrophage recruitment, and alterations in cellular immunity. As a result, the frequency of respiratory tract colonization by gram-negative bacilli is increased in patients with malnutrition and the incidence and severity of respiratory infections are increased.

Geographic and Occupational Considerations

Geographic setting, seasonal timing, travel history, and occupational or unusual exposures modify the risk of various microbial etiologies of CAP. For example, an increased frequency of *S. pneumoniae* occurs in soldiers, painters, and South African gold miners. *Burkholderia pseudomallei* (melioidosis) is endemic in the rural tropics.[25] Animal exposure may prompt a diagnostic evaluation for agents of zoonotic pneumonia including psittacosis (birds) and *Rhodococcus* (horses). Rodent contact suggests the possibility of infection by *Yersinia pestis* (plague) in the rural southwestern United States[26] and *Francisella tularensis* (tularemia) in rural Arkansas or Nantucket, Massachusetts.[27] Exposure to sheep, dogs, and cats may prompt evaluation for *C. burnetii* (Q fever) in Nova Scotia, Australia, or the Basque region of Spain.[28] The role of seasonal timing is illustrated by the increased incidence of lower respiratory tract infections due to *S. pneumoniae* and *H. influenzae* in winter months. More recently, pneumonia caused by a novel coronavirus causing the severe acute respiratory syndrome (SARS) has emerged in epidemic form in southeast Asia.[29,30] Sporadic human infections by avian influenza A/H5N1 in various places in the world increase the risk of future pandemics.[31] Finally, the infectious agents that cause anthrax, tularemia, and plague may be used for bioterrorism or biowarfare purposes and cause lower respiratory tract infections.[32–34]

Hospital-Acquired (Nosocomial) Pneumonia

Early-onset HAP (<5 days of hospitalization) is most often due "community" microorganisms such as *S. pneumoniae*, *H. influenzae*, and anaerobes. Late-onset HAP (>5 days of hospitalization) is mainly caused by MRSA, enteric gram-negative bacilli, *P. aeruginosa*, nonfermenters such as *Acinetobacter baumanii* and *S. maltophilia*,

and polymicrobial infections.[35] Factors that increase the risk of HAP include antibiotic exposure, old age, severe comorbidities, underlying immunosuppression, colonization of the oropharynx by virulent microorganisms, conditions that promote pulmonary aspiration or inhibit coughing (e.g., thoracoabdominal surgery, endotracheal intubation, insertion of nasogastric tube, supine position), and exposure to contaminated respiratory equipment.

Health Care–Associated Pneumonia

Health care now reflects a continuum of care with many traditional inpatient services provided in outpatient settings. In each of these instances, physicians often categorize new infections in such subjects as "community-acquired." Data indicate, however, that these health care associated infections have a unique epidemiology more like that of traditional hospital-acquired infections. Accumulating evidence pointing to the potential impact of health care–acquired pneumonia (HCAP) results in its recognition as a separate entity by the American Thoracic Society (ATS) and Infectious Diseases Society of America (IDSA).[36] Results from a large database of culture-positive pneumonia justify this new category. *S. aureus* (both methicillin-sensitive and -resistant) and *P. aeruginosa* were the most frequent microorganisms. Compared with CAP, HCAP patients have more severe disease, higher mortality, greater length of stay, and increased cost.[37] Although there is no doubt that HCAP has to be classified differently from CAP, risk factors and particularly the microbiology of HCAP are not consistent when comparing the United States and other countries outside the United States.

CLINICAL PRESENTATION

Pneumonia is characterized by the presence of fever, altered general well-being, and respiratory symptoms such as cough (90%), expectoration (66%), dyspnea (66%), pleuritic pain (50%), and hemoptysis (15%). In elderly and immunocompromised patients, the signs and symptoms of pulmonary infection may be muted and overshadowed by nonspecific complaints. Fever higher than 38.5°C or accompanied by chills should never be attributed to bronchitis without examining a chest radiograph.

Occasionally, there is a "classic" history, such as that of the patient with pneumococcal infection who presents with sudden onset of rigor followed by pleuritic chest pain, dyspnea, and rusty sputum. Similarly, a patient with *Legionella* pneumonia may complain predominantly of diarrhea, fever, headache, confusion, and myalgia. For *M. pneumoniae* infection, extrapulmonary manifestations such as myringitis, encephalitis, uveitis, iritis, and myocarditis may be present. However, only rarely does the clinical history clearly suggest a specific etiologic diagnosis.

Unfortunately, information obtained from the clinical history and physical examination is not sufficient to confirm the diagnosis of pneumonia. A definitive diagnosis requires the presence of new opacity on the chest radiograph.

In elderly patients, especially those with multiple comorbidities, pneumonia may present with general weakness, decreased appetite, altered mental status, incontinence, or decompensation due to underlying diseases. The presence of tachypnea may precede other signs of pneumonia by 1 to 2 days. Tachycardia is another common initial sign but is less frequent and specific than tachypnea. Fever is absent in 30% to 40% of patients. Owing to the lack of specific symptoms, the diagnosis of CAP is frequently delayed in the elderly.[3,17] Elderly patients with pneumonia who present with altered mental status without fever have a delay in receiving antibiotics by more than 4 hours after arrival, and this delay affects mortality.[38]

"Typical" versus "Atypical" Pneumonia

The division of CAP into typical and atypical syndromes has been used to predict the likely pathogens and select appropriate empirical therapy.[4–7] The clinical picture of "typical" CAP is that of disease characteristically caused by bacteria such as *S. pneumoniae*, *H. influenzae*, and *K. pneumoniae*. The initial presentation is frequently acute, with an intense and unique chill. Productive cough is present, and the expectoration is purulent or bloody. Pleuritic pain may be present and it is a very specific finding of *S. pneumoniae*. Physical examination reveals typical findings of pulmonary consolidation. There is leukocytosis with neutrophilia and the presence of band forms. Chest radiography shows lobar condensation with air bronchograms.

In contrast, the syndrome of gradual onset of fever, nonproductive cough, and a relatively normal white blood cell count in a patient without a demonstrable bacterial pathogen has been called "atypical pneumonia." Frequently, systemic complaints are more prominent than the respiratory ones. The atypical syndrome is characteristic of infections by pathogens such as *M. pneumoniae*, *Chlamydophila* spp., *C. burnetii*, and viruses. Unfortunately, several studies, including one that included patients with mild CAP treated on an outpatient basis,[39] have found that neither the clinical symptoms nor the radiographic manifestations are sufficiently sensitive or specific to reliably guide pathogen-directed antibiotic treatment against "typical" versus "atypical" microorganisms.[39] Therefore, current guidelines do not emphasize the use of the typical versus atypical classification to determine initial empirical antibiotic treatment for CAP.[4–7,40]

PATIENT EVALUATION

Clinical Evaluation

The clinical findings that best differentiate CAP from other acute respiratory tract infections are cough, fever, tachypnea, tachycardia, and pulmonary crackles.[41] CAP

is present in 20% to 50% of persons who have all four factors.[41] Specific signs of pulmonary consolidation are present in only one third of the cases that warrant hospitalization and are less frequently observed in less ill patients. Early in the evolution of disease, pain and cough may be absent and the physical examination may be normal other than the presence of fever. In debilitated elderly patients, vague clinical manifestations of pneumonia are common and the presence of fever with no apparent source, especially when accompanied by confusion or tachypnea, justifies obtaining a chest radiograph.

Clues to the etiologic diagnosis may lie outside the respiratory tract. Bradycardia in relation to the amount of fever (pulse should increase by 10 beats/min/°C of temperature elevation) has been associated with pneumonia secondary to *Legionella*, *Chlamydophila psittaci*, *Mycoplasma*, and tularemia. Specifically *M. pneumoniae* may present with a variety of extrapulmonary manifestations including arthralgia, cervical lymphadenopathy, bullous myringitis, diarrhea, myalgia, myocarditis, hepatitis, nausea, pericarditis, and vomiting.[42] Skin lesions of erythema multiforme or erythema nodosum suggest *Mycoplasma* infection (as well as tuberculosis and fungal infection), whereas lesions of ecthyma gangrenosum are seen most commonly with *P. aeruginosa* infection. Finally, the examiner must look for the presence of complications such as pleural effusion, pericarditis, endocarditis, arthritis, and central nervous system involvement, which may necessitate further diagnostic procedures and, potentially, a change in therapy.[43]

Laboratory Evaluation

Once the patient is found to have pneumonia, laboratory studies should be performed that include blood cell counts, serum glucose and electrolyte measurements, and pulse oximetry or arterial blood gas assays.[4–7] These data provide a logical basis for making decisions regarding the need for hospitalization. HIV testing should be offered to hospitalized adults with CAP in areas where the rate of newly detected HIV infection exceeds 1/1000 hospital discharges.

Marked leukocytosis with leftward shift is more often encountered with infections caused by *S. pneumoniae*, *H. influenzae*, and gram-negative bacilli than with infections by *M. pneumoniae*, *Chlamydophila* spp., *Coxiella*, or nonbacterial causes of pneumonia. Leukopenia may be seen with overwhelming pneumococcal or gram-negative bacillary pneumonia. The serum level of C-reactive protein and the erythrocyte sedimentation rate are increased to higher values with bacterial than with viral pneumonias.

New promising information suggests that procalcitonin, a precursor of calcitonin, is released into the blood of persons with bacterial infections. This biomarker measured in blood has been useful to evaluate the severity and prognosis of the patients and to deescalate antibiotic treatments.[44,45] The routine use of procalcitonin in the initial evaluation of CAP needs further evaluation.

Radiographic Evaluation

Radiographic evaluation is necessary to establish the presence of pneumonia, because there is no combination of historical data, physical findings, or laboratory results that reliably confirms the diagnosis.[4,7,41,46] Limitations of chest radiography include suboptimal specificity, particularly in patients with the acute respiratory distress syndrome (ARDS), and interobserver variability.[7] Frequently, the emergency department admissions with radiographic pneumonia are subsequently proved not to have pneumonia. Conversely, the sensitivity of the chest radiograph is decreased in (1) patients with emphysema, bullae, or structural abnormalities of the lung, who may present with delayed or subtle radiographic changes; (2) obese patients, in whom it may be difficult to discern the existence of pneumonia; and (3) patients with very early infection, severe dehydration, or profound granulocytopenia. Failure to detect an abnormal opacity on the plain chest radiograph essentially rules out pneumonia,[41] even though computed tomography (CT) of the chest provides a more sensitive means of detecting minor radiographic abnormalities.[41] In routine clinical practice, a thoracic CT scan is not recommended for patients with suspected pneumonia who have an apparently normal chest radiograph.[7]

Although several radiologic patterns have been associated with pneumonia caused by specific microorganisms, this is not a reliable method for diagnosing a specific pathogen.[47,48] Nonetheless, the presence of air bronchograms and a lobar or segmental pattern is more characteristic of typical than atypical causes of pneumonia. In contrast, a mixed pattern (alveolar and interstitial disease) is more frequently observed with atypical pneumonias. Pneumonia complicating aspiration (frequently from anaerobes) most often involves the superior segment of the right lower lobe or posterior segment of the right upper lobe, or both, as well as the corresponding segments on the left. Infections developing from hematogenous seeding often appear as multiple rounded shadows sometimes with cavities in the greatest distribution of blood flow. Demonstration of a lung abscess, cavitation, or necrotizing pneumonia suggests infection by anaerobes, *S. aureus*, or gram-negative bacilli. Pleural effusion frequently accompanies pneumonia and has management implications. The size of pleural effusion on the chest radiograph helps decide whether to perform a thoracentesis.

Microbiologic Evaluation

Identification of the infecting microorganism serves to verify the clinical diagnosis of infection and facilitates the use of specific therapy instead of unnecessarily broad-spectrum antimicrobial agents. Although the utility of sputum examination is much debated (see later), pleural fluid (if present) and two sets of blood cultures should be obtained in patients hospitalized for CAP. Optimization of culture results require that specimens be obtained before initiation of antimicrobial therapy. Sputum samples must be carefully collected,

TABLE 32-5. Recommended Microbiologic Evaluation in Patients with Community-Acquired Pneumonia

PATIENTS WHO DO NOT REQUIRE HOSPITALIZATION

None*

PATIENTS WHO DO REQUIRE HOSPITALIZATION

- Two sets of blood cultures
- Gram stain and culture of a valid sputum sample
- Urinary antigen test for detection of *Legionella pneumophila* (in endemic areas or during outbreaks)
- Stain for acid-fast bacilli and culture of sputum (if tuberculosis is suggested by clinical history or radiologic findings)
- Fungal stain and culture of sputum, and fungal serologies (if infection by an endemic mycosis is suggested by the clinical history or radiologic findings)
- Sputum examination for *Pneumocystis jirovecii* (if suggested by clinical history or radiologic findings)
- Serologies for *Mycoplasma pneumoniae, Chlamydophila pneumoniae, Chlamydophila psittaci, Coxiella burnetii, Legionella* spp., and respiratory viruses (in endemic areas or during outbreaks)
- Culture and microscopic evaluation of pleural fluid (if significant fluid is present)

PATIENTS WHO REQUIRE TREATMENT IN AN ICU

- Gram stain and culture of valid sputum sample, endotracheal aspirate, or bronchoscopically obtained specimens using a protected specimen brush or BAL
- Other procedures as for other hospitalized patients

*Gram stain and culture should be strongly considered in patients with risk factors for infection by an antimicrobial-resistant organism or unusual pathogen.

BAL, bronchoalveolar lavage; ICU, intensive care unit.

TABLE 32-6. Recommended Microbiologic Evaluation in Patients with Hospital-Acquired Pneumonia

Two sets of blood cultures

Gram stain and culture of a valid sputum sample*

Urinary antigen test for detection of *Legionella pneumophila* (in endemic areas or during outbreaks)

*Gram stain and culture of valid sputum sample, endotracheal aspirate, or bronchoscopically obtained specimens using a protected specimen brush or bronchoalveolar lavage (if patient is intubated).

transported, and processed in order to optimize the recovery of common bacterial pathogens. These recommendations are summarized in Tables 32-5 and 32-6.

Examination of the Sputum

Microscopic examination of expectorated sputum is the easiest and most rapidly available method of evaluating the microbiology of lower respiratory tract infections. A valid expectorated sputum specimen can be obtained from about 40% of patients hospitalized with CAP. When interpreting sputum cultures, it is crucial to ensure that oropharyngeal materials do not unduly contaminate the specimens. The presence of more than 10 squamous epithelial cells per low-power field (×100 magnification) indicates excessive oropharyngeal contamination; consequently, the specimen should be discarded because it is not representative of the pulmonary milieu.[4] A specimen with few or no squamous cells and many polymorphonuclear white blood cells (>25 cells/low-power field) is ideal (see Fig. 32-3). These criteria may not be reliable in patients who are granulocytopenic.[49] Gram-stained acceptable expectorated sputum specimens should be carefully examined using ×1000 magnification (oil immersion lens). In addition, specific fluorescent antibodies can be used to help evaluate sputum or other respiratory tract specimens for the presence of *Legionella*.

When valid sputum is obtained, the specificity of the Gram stain for pneumococcal pneumonia is estimated to be greater than 80%.[50] Because the fastidious nature of *S. pneumoniae* and *H. influenzae* leads to the death of these organisms, the sensitivity of sputum culture is less than that of sputum Gram stain examination for *S. pneumoniae* (50%–60%) and *H. influenzae*. The reverse is true for *S. aureus* and gram-negative bacilli because these bacteria are much hardier and may proliferate during sputum transport and processing. Because of contamination by oral flora, true pneumonia due to *S. aureus* and gram-negative bacilli is doubtful if the Gram stain of a valid sputum specimen does not corroborate the presence of these bacteria. In good quality gram-stained sputum, the presence of a single or a preponderant morphotype of bacteria (+90%) is diagnostic. Sputum with a mixed flora in the Gram stain has no diagnostic value. In contrast with widely held opinion, sputum culture results are convincing only when the organism isolated is compatible with the morphology of the organism present in greater than 90% of the Gram stain. In the absence of an informative Gram stain, the predictive value of sputum culture is very low.

The last IDSA/ATS guidelines[40] recommend to obtain a sputum sample for stain and culture in hospitalized patients with the clinical indications listed in Table 32-7 but are optional for patients without these conditions.

For patients with HAP or ventilator-associated pneumonia (VAP), the range of potential pathogens is so broad and antimicrobial susceptibility patterns so diverse that vigorous diagnostic measures are justified. In ventilated patients, the equivalent of sputum is the endotracheal aspirate. The criteria for a valid sample are the same as those for sputum. Unfortunately, although the Gram stain and qualitative cultures of endotracheal aspirates have excellent sensitivity, they have poor specificity.[51] Quantitative cultures of endotracheal aspirate samples, with a threshold of more than 10^5 colony-forming units (CFU)/mL to distinguish colonization from infection, have been recommended in the diagnosis of VAP.[52] The diagnostic value of the quantitative cultures of endotracheal aspirates is similar to quantitative cultures of invasive techniques.

Some bacterial agents of pneumonia cannot be cultivated on conventional laboratory media. For example, *Legionella* requires special charcoal yeast extract agar

TABLE 32-7. Clinical Indications for More Extensive Testing in Community-Acquired Pneumonia

Intensive care unit admission

for isolation, whereas recovery of *Chlamydophila* spp. and *C. burnetii* requires culture in tissue systems. When necessary, specimens can be referred to specialized or reference laboratories for appropriate handling. Culture of certain rare agents of bacterial pneumonia poses major health risks to laboratory workers (e.g., *F. tularensis*, *Bacillus anthracis*, *C. burnetii*). Specimens suspected to harbor one of these agents should be dealt with carefully in a biologic safety hood, and isolation of the pathogens should be reserved for specialized laboratories.

Blood and Pleural Fluid Cultures

Although the overall yield of blood cultures is probably less than 20% in patients hospitalized for CAP, a positive culture of blood or pleural fluid definitively establishes the etiologic diagnosis of pneumonia.[53] Not only are sputum cultures frequently contaminated by oral flora, but *S. pneumoniae* is successfully recovered from sputum cultures in only 40% to 50% of cases of bacteremic pneumococcal pneumonia.[54] Not surprisingly, the detected rate of bacteremia is reduced in patients with mild CAP and higher in patients with severe CAP, especially those warranting ICU care. The latest IDSA/ATS guidelines[40] recommend obtaining blood samples for culture in hospitalized patients with the clinical indications listed in Table 32-9 but are optional for patients without these conditions.

In up to 40% of CAP, an accompanying pleural effusion may be present. Although specificity of pleural exudates culture is very high, the sensitivity is low because of the low incidence of invasion of the pleura. Gram stain or cultures yielding bacterial pathogens from pleural fluid are likely to be an accurate reflection of the microbial cause of pneumonia. Diagnostic thoracentesis should, therefore, be performed when a significant pleural effusion is present. Gram stain of pleural fluid may produce an indication of the nature of the infecting organisms within 1 hour, with culture and identification requiring 24 to 48 hours.

Antigen Detection

Commercial assays can be used to rapidly detect capsular polysaccharide antigens of *S. pneumonia* or *L. pneumophila* serogroup 1 in urine.[50,55,56] The sensitivity of these tests is little affected by prior antibiotic treatment. Indeed, results may remain positive several weeks after successful treatment. These assays require less than 1 hour, although the diagnostic value improves after further processing (centrifuging the urine), which can delay test results for at least 2 additional hours. For *L. pneumophila* serogroup 1, the sensitivity is 60% to 80%, and the specificity is greater than 95%.[57] Urinary antigen testing is currently the most helpful rapid test for the diagnosis of *Legionella* infections. The major limitation of urinary antigen tests is that currently available tests are intended to detect *L. pneumophila* serogroup 1 antigen only, although this is the most common cause of *Legionella* infection.

The sensitivity of the *S. pneumoniae* urinary antigen kits is 50% to 80% and the specificity 90%.[58] The effect of pretreatment with antibiotics resulted in contradictory reports. The urinary antigen test may also be applied on pleural fluid with a sensitivity and specificity of almost 100%. There is a relation between the degree of positivity for the *S. pneumoniae* urinary antigen test positivity and the Pneumonia Severity Index (PSI).[59] Urine specimens of children, frequent carriers of *S. pneumoniae* in the nasopharynx, may test positive in the absence of evidence of pneumonia, and the test should therefore be interpreted with caution in children.[60]

The most recent IDSA/ATS guidelines[40] recommend *S. pneumoniae* and *L. pneumophila* urinary antigen detection in hospitalized patients with the clinical indications listed in Table 32-11 but are optional for patients without these conditions.

Antigens for the many common respiratory viruses, influenza virus, RSV, adenovirus, and parainfluenza viruses can be detected by direct immunofluorescence or by commercially available enzyme immunoassay. A rapid antigen detection test for influenza can also provide an etiologic diagnosis within 15 to 30 minutes. Test performance varies according to the test used, sample type, duration of illness, and patient age. Most show a sensitivity ranging from 50% to 70% in adults and a specificity approaching 100%. The sensitivity for immunofluorescence can be increased by inoculation of the clinical sample on appropriate cells, followed by immunofluorescence after 48 hours.[40]

Nucleic Acid for Amplification Tests

Culture procedures for viruses and fastidious bacteria, *M. pneumoniae, C. pneumoniae, L. pneumophila*, and *Bordetella pertussis*, which normally do not colonize the human respiratory tract, are too insensitive and too slow

to be therapeutically relevant and should be detected by nucleic acid amplification tests. Their sensitivity is almost superior to that of the traditional procedures and are considered as the "gold standard."[61] Traditional tests that require at least 1 to 2 days produce results that are unavailable in time to have any impact on patient management. Real-time multiplex polymerase chain reaction (PCR) assays detect respiratory viruses in both immunocompetent and immunosuppressed hosts.[62]

Serologic Evaluation

Serologic techniques are often the most practical means to establish a microbiologic diagnosis for pneumonia caused by pathogens that cannot be readily cultured. Examples include common pathogens such as *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila*; less common causes of pneumonia such as those caused by the agents of tularemia, brucellosis, and psittacosis; and viral infections. Diagnosis usually requires that a convalescent specimen demonstrate a fourfold rise in IgG titer above that present in an acute specimen. These tests are not usually helpful in initial patient management but are of greater utility in detecting epidemics and defining the epidemiology of the pertinent infectious agents. Because IgM antibodies appear earlier than IgG antibodies, the detection of IgM in serum is a widely used approach for the early serologic diagnosis of many acute infections. It should be realized that IgM antibodies are often not produced in children younger than 6 months of age. The IgM response may also appear late and wanes with age. Because the microorganisms mentioned previously rarely cause HAP, serologies are not indicated in this type of respiratory infection, except when *Legionella* spp. is suspected.

Invasive Diagnostic Techniques

Because of problems encountered with the use of expectorated sputum, it may be necessary to perform an invasive procedure to obtain suitable material for microscopy and cultures. This may be important in the management of patients with life-threatening CAP in whom diagnostic materials cannot otherwise be obtained rapidly, patients with progressive pneumonia despite seemingly appropriate antimicrobial therapy, immunocompromised patients, and patients with HAP, especially in the setting of endotracheal intubation.[43,63]

Bronchoscopic Samples

The reliability of using bronchoscopic procedures to determine the microbial etiology of pneumonia depends on the technique used and the organism sought. When compared with sputum cultures, routinely processed bronchoscopic specimens demonstrate improved sensitivity and equal specificity for the culture of pathogenic fungi and mycobacteria. However, such materials have unacceptably poor specificity for routine bacterial cultures owing to oropharyngeal contamination. In contrast, semiquantitative or quantitative cultures of materials obtained bronchoscopically with a protected sheath brush or through bronchoalveolar lavage (BAL) and by direct lung aspiration have been successfully used for aerobic and anaerobic bacterial cultures[64–66] (see Chapter 22).

For protected sheath brush cultures, a threshold of 10^3 CFU/mL has been recommended to distinguish colonization from infection. However, 14% to 40% of duplicate samples yield disparate quantitative results, which might lead to differences in patient management. The quality of these samples can be determined by the number of epithelial squamous cells in nonintubated patients.

BAL fluid can be cultured quantitatively for bacteria and qualitatively for fungi, mycobacteria, and viruses. A concentrate can be stained for histochemical and fluorescence evaluation.[66] The recommended threshold of 10^4 CFU/mL for diagnosing bacterial pneumonia shows excellent correlation with diagnoses based on protected sheath brush results and histologic examination of the lung.[67] BAL permits identification of contaminated specimens (i.e., those with >1% squamous epithelial cells), the immediate diagnosis of infection (i.e., intracellular bacteria in >2%–5% of examined polymorphonuclear leukocytes), and the exclusion of infection (i.e., <50% polymorphonuclear leukocytes among the recovered cells).[68]

Other procedures that have been used to diagnose VAP include quantitative cultures of materials obtained by nondirected ("blind") protected sheath brush and nondirected ("mini") BAL.[69] The advantages of both procedures are the ease of performance, greater availability, decreased costs, and fewer side effects. Finally, although qualitative culture of materials obtained by endotracheal suction has excellent sensitivity (>85%), the specificity of such cultures is poor (<35%); thus, overreliance on these cultures may lead to antibiotic overtreatment.[52] In some studies, quantitation with a threshold of 10^5 CFU/mL has improved the specificity of endotracheal suction specimens, but this has been at the cost of decreased sensitivity.[52,70]

Although semiquantitative protected sheath brush and BAL procedures have sensitivities and specificities in the range of 60% to 90%, the sensitivity of bronchoscopic procedures is substantially reduced by the prior administration of antimicrobial agents.[71] Furthermore, the use of a sophisticated algorithm (i.e., Clinical Pulmonary Infection Score) increases the diagnostic accuracy of clinical judgment.[72] Finally, measurement of inflammatory markers such as the triggering receptor expressed on myeloid cells (TREM-1) may provide powerful, independent diagnostic information.[73]

The use of quantitative cultures obtained by protected sheath brush and BAL, compared with qualitative cultures of endotracheal aspirates and clinical evaluation, was associated with lower 14-day mortality rates, earlier reversal of organ dysfunction, and less antibiotic use. However, other randomized trials on the use of quantitative cultures of protected sheath brush and BAL specimens, rather than quantitative cultures of endotracheal aspirates, in patients with VAP have not replicated these findings.[74,75]

In conclusion, the place of quantitative cultures and endotracheal aspirates in determining whether to initiate or withdraw antimicrobial therapy in patients with VAP is unsettled.[76] Currently, two different strategies are proposed: (1) The *clinical strategy* is to administer broad-spectrum antibiotics if new pulmonary radiographic opacities are accompanied by two of three clinical parameters (fever, leukocytosis or leukopenia, purulent secretions) or when the Clinical Pulmonary Infection Score is higher than 6.[73] (2) The *quantitative strategy* is to withhold antimicrobials in patients with suspected VAP if a Gram stain of material obtained at bronchoscopy does not support the diagnosis of pneumonia; or if antibiotics have been started, the quantitative culture results are used to either withdraw the antibiotics or adjust therapy to specifically treat the recovered pathogen.[77]

Transthoracic Lung Aspiration

Transthoracic lung aspiration obtains specimens suitable for microbiologic and cytologic examination directly from lung parenchyma. It is a more successful method for diagnosing malignant pulmonary lesions than infectious diseases, for which, in immunocompetent hosts, the diagnostic yield by transthoracic lung aspiration is approximately 50%. For diagnosis of pulmonary infections, the false-positive rate is 5% to 20% with a sensitivity of 35% to 82%. The variable sensitivity may be due to the small volumes of material retrieved on aspiration, the inevitable aeration of the specimen and consequent loss of viable anaerobes, or poor localization of the site to be aspirated. Serious complications of transthoracic lung aspiration include pneumothorax (2%–5%) and hemoptysis (2%–5%), which occur even when small-gauge needles are used.

Differential Diagnosis

Several diseases may present with fever and chest radiographic opacities and mimic CAP (Table 32-8)[41]; such diseases should be suspected when the chest radiographic resolution is unusually quick or when there is a lack of response to initial or subsequent antibiotic treatments. In patients with HAP, and particularly in those with VAP, the classic signs and symptoms of pneumonia (including new radiographic changes, fever, leukocytosis or leukopenia, and purulent pulmonary secretions) are neither sufficiently sensitive nor specific to confirm the presence of a pulmonary infection. In patients suspected of having VAP, the presence of chest radiographic opacities plus two of the clinical signs mentioned previously has a sensitivity of 30% to 70% and a specificity of 70%. Atelectasis, pulmonary hemorrhage, ARDS, and pulmonary embolism—among others—are causes that may mimic pneumonia. In patients with suspected HAP or VAP, the microbiologic confirmation of pneumonia is important in order to avoid unnecessary treatments and a potential future increase of microbial resistance.

TABLE 32-8. Noninfectious Causes of Fever and Radiographic Changes That May Mimic Community-Acquired Pneumonia

Pulmonary edema
Pulmonary infarction
Acute respiratory distress syndrome
Pulmonary hemorrhage
Lung cancer or metastatic cancer
Atelectasis
Radiation pneumonitis
Drug reactions involving the lung
Extrinsic allergic alveolitis
Pulmonary vasculitis
Pulmonary eosinophilia
Bronchiolitis obliterans and organizing pneumonia

THERAPEUTIC APPROACH TO PNEUMONIA

Once the diagnosis of pneumonia has been made, the clinician must decide whether the patient can be managed in the outpatient setting. Applying a prediction rule can facilitate this decision. The second key decision is selection of the initial antimicrobial therapy.[78]

Assessment of Severity

The PSI (Table 32-9) is a point scoring system derived from a retrospective analysis of a cohort of 14,199 patients with CAP in 1989 and prospectively validated in a separate cohort of 38,039 patients with CAP in 1991. Age is the most significant risk factor, with 1 point given for each year of age (−10 points in women). Other risk factors include patient demographics, comorbid conditions, physical examination findings, and laboratory results. Prospective studies in community and teaching hospitals have shown that the PSI may be safely and effectively applied in clinical practice.[79–81] Because these criteria are less useful at the extremes of age, aged-based criteria have been developed for assessing the severity of pneumonia in children and the elderly.

Patients who have a PSI score of 70 or less (class I or II) have an attributable risk of death within 30 days of less than 1% and outpatient treatment is recommended. Patients with a PSI score of 71 to 90 (class III) have a 30-day mortality rate of up to 2.8% and may benefit from brief hospitalization. Hospital care is appropriate for patients with scores of 91 to 130 (class IV), who have a 30-day risk of death of 8.2% to 9.3%, and for patients with a score of more than 130 (class V), who have a 30-day risk of death of 27.0% to 31.1%.

Similar rules for grading the severity of CAP have been developed by the British Thoracic Society.[10,82] Their algorithm assigns 1 point for each of the following findings upon presentation: (1) confusion; (2) urea higher than 7 mmol/L; (3) respiratory rate of 30/min or more; (4) low systolic (<90 mm Hg) or low diastolic (≤60 mm Hg) blood pressure; and (5) age 65 years or older. The 30-day mortality rates for patients with scores of 0 or 1 (group

TABLE 32-9. Scoring System for Determining Risk of Complications in Patients with Community-Acquired Pneumonia*

Patient Characteristic	Points Assigned
DEMOGRAPHIC FACTORS	
Males	Age (in yr)
Females	Age (in yr) −10
Nursing home residents	Age (in yr) +10
COMORBID ILLNESSES	
Neoplastic disease	+30
Liver disease	+20
Congestive heart failure	+10
Cerebrovascular disease	+10
Renal disease	+10
PHYSICAL EXAMINATION FINDINGS	
Altered mental status	+20
Respiratory rate 30/min or more	+20
Systolic blood pressure < 90 mm Hg	+20
Temperature < 35°C or ≥40°C	+15
Pulse 125/min or more	+10
LABORATORY FINDINGS	
pH < 7.35	+30
BUN > 10.7 mmol/L	+20
Sodium < 130 mEq/L	+20
Glucose > 13.9 mmol/L	+10
Hematocrit < 30%	+10
Po_2 < 60 mm Hg or O_2 saturation < 90%	+10
Pleural effusion	+10

*A risk score is obtained by summing the patient's age in years (age −10 for females) and the points for each applicable patient characteristic. Patients with a score < 50 are candidates for outpatient treatment, whereas those with scores > 90 warrant hospitalization. Proper management of patients with scores of 70–90 requires careful application of clinical judgment.

BUN, blood urea nitrogen; Po_2, oxygen pressure.

TABLE 32-10. American Thoracic Society Criteria for Admission of Patients with Community-Acquired Pneumonia to an Intensive Care Unit

MINOR CRITERIA

Respiratory rate ≥ 30 breaths/min

Pao_2/Fio_2 ratio < 250

Multilobar radiographic involvement

Confusion or disorientation

Uremia (BUN level > 20 mg/dL)

Leukopenia (WBC count < 4000 cells/dL)

Thrombocytopenia (platelet count < 100,000 cells/dL)

Hypothermia (core temperature < 36°C)

Hypotension requiring aggressive fluid resuscitation

MAJOR CRITERIA

Invasive mechanical ventilation

Septic shock with need for vasopressors

BUN, blood urea nitrogen; Fio_2, fractional concentration of oxygen in inspired gas; Pao_2, arterial oxygen pressure; WBC, white blood cell.

1), 2 (group 2), and 3 to 5 (group 3) are 1.5%, 9.2%, and 22%, respectively.[10] Outpatient treatment is recommended for group 1, brief inpatient or supervised outpatient care is recommended for group 2, and hospitalization is recommended for group 3 (with consideration of ICU care for group 3 patients with scores of 4 or 5).

The IDSA and the ATS have published ICU admission criteria for patients with CAP.[40] According to these criteria (Table 32-10), ICU admission is warranted for patients who fulfill three minor criteria or one major criterion. Management of severe CAP per these guidelines has been associated with decreased mortality.[83]

Selection of Antimicrobial Agents

Whenever possible, the initial treatment for pneumonia should be pathogen-directed. Unfortunately, pathogens are rarely identified at the time of presentation, especially when patients are seen in the outpatient setting. Because optimal outcomes are associated with rapid initiation of treatment, the initial antibiotic treatment for patients with pneumonia must often be empirical. When selecting initial empirical antimicrobial therapy, physicians should consider the setting in which the pneumonia occurs (e.g., community, hospital, nursing home), the severity of the disease, the age of the patient, the presence of comorbidities and immunosuppression, previous antimicrobial therapy, and specific clinical manifestations of the illness. Geographic and facility-specific factors such as the endemicity of specific microorganisms (e.g., *C. burnetii*, *L. pneumophila*, endemic mycoses, antimicrobial-resistant pathogens) may also affect the initial treatment choice.

In hospitalized patients, specimens for cultures of blood, sputum, and pleural fluid (if present) should be obtained prior to treatment. On occasion, a brief delay in starting therapy while awaiting the results of an invasive diagnostic procedure is reasonable in patients who are not severely ill. However, delays of more than 8 hours, which unfortunately are common, have been shown to be associated with increased mortality and may otherwise increase the length of hospitalization.[84,85]

Community-Acquired Pneumonia

CAP may be defined as pneumonia occurring in patients who have not been hospitalized or living in a nursing home during the 2 weeks prior to the onset of symptoms.[4] *S. pneumoniae* is the most common pathogen in moderate to severe CAP[7] and accounts for up to 60% of all bacteremic pneumonia. Therapy should be effective against penicillin-resistant *S. pneumoniae* unless there are specific epidemiologic or clinical characteristics that strongly suggest pneumonia due to an "atypical" organism (e.g., mild CAP warranting outpatient care in a previously healthy individual), mixed aerobic-anaerobic flora due to aspiration, or the presence of gram-negative

bacilli or *P. aeruginosa* in a patient with specified risk factors.[4–7,86,87] The ATS,[6] Canadian Infectious Diseases Society/Canadian Thoracic Society,[7] and IDSA[5] also recommend that any empirical regimen for CAP should be active against "atypical" pathogens such as *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila*. Where the guidelines vary most is in the specific criteria warranting more aggressive care and preferences for the use of specific antimicrobial agents. It is important to recognize that all these guidelines are based on broad epidemiologic considerations that may not pertain to all locations.[88] If the epidemiology of antimicrobial resistance within a facility is such that drug resistance is known to be rare, less aggressive selection of antimicrobial therapy may be appropriate.[89]

The appropriate role of fluoroquinolones in the treatment of CAP has attracted particular attention and controversy. Some experts recommend that use of respiratory fluoroquinolones should be strictly limited to adults for whom another regimen has already failed (e.g., an oral agent for outpatient management of CAP), those who are allergic to alternative agents, or those for whom there are no other effective treatment options.[87] Fluoroquinolone resistance and subsequent treatment failures are well reported in patients with community-acquired pneumococcal pneumonia.[90–94] Widespread fluoroquinolone use, especially in subtherapeutic doses, has been associated with pneumococcal-fluoroquinolone resistance rates of up to 13% in Hong Kong.[25]

Retrospective analyses of patients hospitalized with CAP indicate that regimens that cover "atypical" pathogens and those that follow recommendations made by the ATS and the IDSA are associated with improved clinical outcomes.[4,6,83,89,95] There have been no prospective, randomized, head-to-head studies that directly compare the utility of these guidelines. Summaries of the outpatient and inpatient CAP antibiotic recommendations are presented in Tables 32-11 and 32-12, respectively.[96]

Hospital-Acquired Pneumonia

Hospital-acquired, or nosocomial, pneumonia is defined as pneumonia occurring 48 hours or more after admission to the hospital.[6] Severe HAP is defined by the concomitant occurrence of sepsis syndrome, respiratory failure, rapid progression of chest radiographic shadows, multilobar involvement, or cavity formation.[6] VAP is a subset of HAP and is defined as pneumonia in a mechanically ventilated patient that occurs more than 48 hours after intubation.

Antibiotic regimens recommended for the empirical treatment of HAP typically include expanded-spectrum β-lactam agents, often given in combination with aminoglycosides or vancomycin. If aspiration is likely, specific treatment for anaerobes (e.g., metronidazole, clindamycin) must be strongly considered. Unless *Legionella* is known to be endemic in the institution, targeted therapy for this pathogen is seldom necessary

Infectious Diseases Society and Canadian Thoracic Society

Standard: (cefotaxime, ceftriaxone or β-lactam–β-lactamase inhibitor) (fluoroquinolone* or macrolide**)

Pseudomonas risks††: Ciprofloxacin (antipseudomonal β-lactam‡‡ or aminoglycoside) *or* antipseudomonal β-lactam‡‡ aminoglycoside macrolide**

*Antipneumococcal fluoroquinolones include levofloxacin, gatifloxacin, and moxifloxacin.

†Advanced macrolides are azithromycin and clarithromycin.

‡Modifying factors include those considered to increase the risk of infection by a penicillin-resistant pneumococcus (age > 65 yr, exposure to a β-lactam antimicrobial within the prior 3 mo, alcoholism, prior immunosuppressive therapy, multiple medical comorbidities, exposure to a child in a daycare center or to infection by an enteric gram-negative bacillus (residence in a nursing home, underlying cardiopulmonary disease, multiple comorbidities, or recent antimicrobial therapy).

§Preferred regimen may be determined by whether the patient has received antibiotics within the prior 3 mo.

‖Antianaerobic agents include clindamycin, metronidazole, and β-lactam–β-lactamase inhibitor combinations.

¶Acceptable cephalosporins include second-generation agents (e.g., cefuroxime, cefamandole), third-generation agents (cefotaxime or ceftriaxone), or fourth-generation agents (cefepime or cefpirome, neither of which is available in the United States).

**Second-choice agent.

††American Thoracic Society risk factors for *Pseudomonas aeruginosa* are structural lung disease (i.e., bronchiectasis, cystic fibrosis), corticosteroid use (>10 mg prednisone/day), broad-spectrum antibiotic therapy for more than 7 days in the past month, or malnutrition. The Infectious Diseases Society of American risk factors for *P. aeruginosa* include only structural lung disease or recent completion of a course of antibiotics or steroids. The Canadian risk factors include only structural lung disease, recent antibiotic therapy, or recent hospitalization in an intensive care unit.

‡‡Antipseudomonal β-lactams include ceftazidime, cefepime, imipenem, meropenem, mezocillin, piperacillin, and piperacillin-tazobactam.

in the treatment of HAP. Empirical therapy for VAP is necessarily broad because the range of potential pathogens is large and mortality is significantly increased when the responsible pathogen is resistant to the initial antibiotic regimen (Table 32-13).

Nursing Home–Acquired Pneumonia

The etiology of bacterial pneumonia in nursing home residents is diverse and includes HAP-associated pathogens (e.g., aerobic gram-negative rods, *S. aureus*), CAP-associated pathogens (e.g., *S. pneumoniae*, *H. influenzae*, "atypicals"), and anaerobes (due to the aspiration risk in these patients).[3,12,97] Consequently, treatment recommendations for acute pneumonia in nursing home patients represent a hybrid between recommendations for CAP and HAP.[4–7] Particular attention should be paid to providing adequate treatment for *S. pneumoniae* in all patients and to gram-negative bacilli, especially in patients with severe CAP in the setting of significant medical comorbidities or recent antimicrobial therapy.

Other Pneumonia Syndromes

On initial presentation, a variety of other infectious pulmonary syndromes may not be readily differentiated

TABLE 32-13. Guidelines for Empirical Antibiotic Treatment of Nosocomial Pneumonia*

Setting	Core Pathogens	Antimicrobial Choices
2–5 DAYS IN HOSPITAL		
Mild to moderate pneumonia Severe pneumonia "low-risk"	Enterobacteriaceae *Streptococcus pneumoniae* *Haemophilus influenzae* Methicillin-sensitive *Staphylococcus aureus*	β-Lactam–β-lactamase inhibitor† *or* ceftriaxone *or* fluoroquinolone‡ All ± an aminoglycoside
≥5 DAYS IN HOSPITAL		
Mild to moderate pneumonia	As above	As above
≥5 DAYS IN HOSPITAL		
Severe HAP "low risk"	*Pseudomonas aeruginosa, Enterobacter* spp., *Acinetobacter* spp.	Carbapenem *or* β-lactam–β_1-lactamase inhibitor† *or* cefepime All plus amikacin or fluoroquinolone‡
≥2 DAYS IN HOSPITAL		
Severe HAP "high risk"	As above	As above
SPECIAL CIRCUMSTANCES§		
Recent abdominal surgery *or* witnessed aspiration	Anaerobes	As per Table 32-14
Other sites of infection with MRSA or prior use of antistaphylococcal antibiotics	MRSA	As per Table 32-14
Prolonged ICU stay or prior use of broad-spectrum antibiotics or structural lung disease (cystic fibrosis, bronchiectasis)	*Pseudomonas aeruginosa*	As per Table 32-14
Endemicity within facility *and* either impaired cell-mediated immunity or failure to respond to antibiotics	*Legionella*	As per Table 32-14

*High-risk criteria include age ≥ 65 years, pancreatitis, chronic obstructive pulmonary disease, central nervous system dysfunction (stroke, drug overdose, coma, status epilepticus), congestive heart failure, malnutrition, diabetes mellitus, endotracheal intubation, renal failure, complicated thoracoabdominal surgery, alcoholism, and pancreatitis. All other patients are considered to be at low risk.
This protocol does not address the treatment of neutropenic or HIV-infected persons.
Severe pneumonia requiring care in an ICU is characterized by rapid radiographic progression, multilobar disease, or cavitation. All other cases of nosocomial pneumonia are considered *mild to moderate.*
†Ticarcillin-clavulanate and piperacillin-tazobactam are the preferred β-lactam–β-lactamase inhibitors for the treatment of nosocomial pneumonia. Ampicillin-sulbactam lacks adequate activity against many nosocomial enteric gram-negative bacilli.
‡Levofloxacin (IV or PO), gatifloxacin (IV or PO), moxifloxacin (IV or PO), or gemifloxacin (PO only) are preferred for *Streptococcus pneumoniae*. When used for severe HAP, levofloxacin should be dosed at 750 mg IV daily. Ciprofloxacin has the best in vitro activity against *Pseudomonas aeruginosa*.
§Antimicrobial treatment should also be sufficient to cover core pathogens.
HAP, hospital-acquired pneumonia; HIV, human immunodeficiency virus; ICU, intensive care unit; MRSA, methicillin-resistant *Staphylococcus aureus*.
Modified from American Thoracic Society: Hospital-acquired pneumonia in adults: Diagnosis assessment of severity, initial antimicrobial therapy, and preventative strategies. Am J Respir Crit Care Med 153:1711–1725, 1995.

from acute bacterial pneumonia. Examples include influenza A, SARS,[29,30] and hantavirus pulmonary syndrome.

Concerns about potential bioterrorism or biowarfare require that attention be paid to the epidemiologic, clinical, and microbiologic significance of pneumonia due to *B. anthracis* (anthrax),[33] *F. tularensis* (tularemia),[34] and *Y. pestis* (plague).[32] These infectious agents are individually discussed later in this chapter. Further information may be obtained from organizations such as the Centers for Disease Control and Prevention (www.cdc.gov), IDSA (www.idsociety.org), and the World Health Organization (www.who.org).

Adjustments in Antimicrobial Therapy

Organisms recovered from normally sterile sites, such as blood, pleural fluid, cerebrospinal fluid, or transthoracic lung aspiration specimens, are presumed to be pathogens. Because of problems introduced by contamination with oropharyngeal secretions, expectorated sputum culture results must be interpreted in light of the quality of the specimen, correlation with pathogens identified by Gram stain, and the clinical impression.

If the etiologic agent of pneumonia has been reliably identified, the initial antimicrobial regimen should be adjusted based on the results of in vitro susceptibility testing. The ideal drug for a known pathogen has the narrowest spectrum of activity and is the most efficacious, least toxic, and least costly. Pathogen-based modification of therapy is particularly important in HAP because prolonged use of broad-spectrum empirical agents promotes the emergence of pathogens with multidrug resistance.[98] Recommendations for specific drug choices and duration of therapy for specific microorganisms are discussed under the sections devoted to individual microorganisms and are summarized in Table 32-14.

TABLE 32-14. Agents for Specific Therapy of Selected Respiratory Pathogens

Type of Infection	Preferred Agent(s)	Alternative Agent(s)
COMMUNITY-ACQUIRED PNEUMONIA		
Streptococcus pneumoniae		
PCN-susceptible	Penicillin G, amoxicillin, clindamycin, doxycycline, telithromycin	Cephalosporin, macrolide,* (MIC < 2.0 g/mL) fluoroquinolone,†
PCN-resistant	Agents identified using in vitro susceptibility tests, including cefotaxime, ceftriaxone, vancomycin, and fluoroquinolone†	Telithromycin (MIC ≥ 2.0 g/mL)
Mycoplasma	Doxycycline, macrolide	Fluoroquinolone,† telithromycin
Chlamydophila pneumoniae	Doxycycline, macrolide	Fluoroquinolone,† telithromycin
Legionella	Azithromycin, fluoroquinolone (including ciprofloxacin),† erythromycin (± rifampin)	Doxycycline ± rifampin
Haemophilus influenzae	Second- or third-generation cephalosporin, clarithromycin, doxycycline, β-lactam/β-lactamase inhibitor, trimethoprim/sulfamethoxazole, azithromycin, telithromycin	Fluoroquinolone†
Moraxella catarrhalis	Second- or third-generation cephalosporin, trimethoprim-sulfamethoxazole, macrolide doxycycline, β-lactam–β-lactamase inhibitor	Fluoroquinolone†
Neisseria meningitidis	Penicillin	Ceftriaxone, cefotaxime, cefuroxime, chloramphenicol, fluoroquinolone†
Streptococci (other than *S. pneumoniae*)	Penicillin, first-generation cephalosporin	Clindamycin (susceptibility should be confirmed), vancomycin
Anaerobes	Clindamycin, β-lactam–β-lactamase inhibitor, β-lactam plus metronidazole	Carbapenem
Staphylococcus aureus Methicillin-susceptible	Oxacillin, nafcillin, cefazolin; all ± rifampin or gentamicin‡	Cefuroxime, cefotaxime, ceftriaxone, fluoroquinolones,† clindamycin, vancomycin
Methicillin-resistant	Vancomycin‡ ± rifampin or gentamicin	Linezolid, quinupristin-dalfopristin; trimethoprim-sulfamethoxazole, fluoroquinolones,† and tetracyclines may also show activity (in vitro testing required)
Klebsiella pneumoniae and other Enterobacteriaceae (excluding *Enterobacter* spp.)	Third-generation cephalosporin or cefepime (all ± aminoglycoside) carbapenem	Aztreonam, β-lactam–β-lactamase inhibitor,§ fluoroquinolone†
HOSPITAL-ACQUIRED INFECTIONS		
Enterobacter spp.	Carbapenem, β-lactam–β-lactamase inhibitor,§ cefepime, fluoroquinolone; all + aminoglycoside in seriously ill patients	Third-generation cephalosporin + aminoglycoside
Pseudomonas aeruginosa	Anti-pseudomonal β-lactam‖ + aminoglycoside, carbapenem + aminoglycoside	Ciprofloxacin + aminoglycoside, ciprofloxacin + antipseudomonal β-lactam‖
Acinetobacter	Aminoglycoside + piperacillin or a carbapenem	Doxycycline, ampicillin-sulbactam, colistin
LESS COMMON PATHOGENS		
Nocardia	Trimethoprim-sulfamethoxazole	Imipenem ± amikacin, doxycycline or minocycline, sulfonamide ± minocycline or amikacin
Coxiella burnetii (Q fever)	Doxycycline	Fluoroquinolone
Chlamydophila psittaci (psittacosis)	Doxycycline	Erythromycin, chloramphenicol
Eikenella corrodens	Penicillin	Tetracyclines, β-lactam–β-lactamase inhibitor, second- and third-generation cephalosporins, fluoroquinolones

*Azithromycin (IV or PO) is the preferred macrolide; clarithromycin (PO) or erythromycin (IV or PO) may also be used.
†Levofloxacin (IV or PO), gatifloxacin (IV or PO), moxifloxacin (IV or PO), or gemifloxacin (PO only) are preferred for *Streptococcus pneumoniae*. Ciprofloxacin has the best in vitro activity against *Pseudomonas aeruginosa*.
‡Rifampin and gentamicin should be reserved for cases of bacteremic *Staphylococcus aureus* pneumonia, empyema formation, or lung abscesses. Activity of rifampin and gentamicin requires laboratory confirmation for methicillin-resistant *S. aureus*.
§Ticarcillin-clavulanate and piperacillin-tazobactam are the preferred β-lactam–β-lactamase inhibitors for the treatment of nosocomial pneumonia due to Enterobacteriaceae. Ampicillin-sulbactam lacks adequate activity against many nosocomial enteric gram-negative bacilli.
‖Antipseudomonal β-lactams ceftazidime, cefepime, imipenem, meropenem, mezlocillin, piperacillin, or piperacillin-tazobactam.
MIC, minimum inhibitory concentration.
Modified from Bartlett JG, Dowell SF, Mandell LA, et al: Practice guidelines for the management of community-acquired pneumonia in adults: Infectious Diseases Society of America. Clin Infect Dis 31:347–382, 2000.

If a pathogen is not identified, reevaluation of the initial therapeutic regimen must take into account the patient's response to therapy. Failing empirical antibiotic regimen warrants complete reappraisal. Usually, a more aggressive effort to obtain respiratory specimens is needed along with a search for empyema or other complications of pneumonia. If still no diagnosis is established, empirically broadening the spectrum of antimicrobial coverage may be wise.

The change from parenteral to oral antimicrobial therapy can safely be made in CAP patients who are clinically stable and able to absorb effective oral antimicrobials[99,100]; often, this is achieved within 3 days of the initiation of parenteral therapy in hospitalized patients. No clinical benefit is found for in-hospital observation after switching from intravenous to oral antibiotics for CAP patients. Because HAP pathogens are frequently resistant to all available oral antimicrobial agents and because the severity of illness is so much greater, oral antimicrobial therapy is much less frequently appropriate.

COMMON CAUSES OF PYOGENIC PNEUMONIA

Streptococcus pneumoniae (Pneumococcal Pneumonia)

Epidemiology

S. pneumoniae is the most frequent cause of CAP among patients who require hospitalization.[7,8,100a] The overall incidence of pneumococcal pneumonia is approximately 200 cases/100,000 persons/yr, with 9 to 14 cases/100,000 cases of bacteremia. This infection accounts for 40,000 deaths annually in the United States. Risk factors for infection include male sex, chronic liver or kidney disease, congestive heart failure, age younger than 2 years or older than 65 years, African American or Native American ancestry, heavy alcohol use, cigarette smoking, malnutrition, dementia, institutionalization, COPD, immunoglobulin deficiency, HIV infection, and organ transplantation.[101–103] Organisms are transmitted by aerosolized droplets and direct physical contact.[104] Therefore, increased rates of carriage occur under circumstances of crowding and inadequate ventilation. Pneumococcal infections occur predominantly in the winter and early spring and are often associated with prior infection by influenza or RSV.[105]

Clinical Manifestations

The classic presentation of pneumococcal pneumonia consists of a single rigor followed within a few hours by sustained fever and the development of cough, dyspnea, and production of rusty or mucoid sputum. Severe pleuritic chest pain is common. Chest examination may find localized crackles and focal decreased breath sounds at early stages of infection. Eventually, signs of consolidation evolve. Neutropenia may occur in patients with overwhelming infection. The radiographic appearance of pneumococcal pneumonia is often either lobar consolidation or patchy bronchopneumonia (Fig. 32-1). Bacteremia is more likely with lobar opacities than with multilobar or bilateral disease. Cavitation rarely if ever develops. Small, sterile parapneumonic effusions are frequently found.

Microbiologic Diagnosis

Although Gram stain of purulent sputum that reveals numerous, characteristic "lancet-shaped" diplococci with blunted ends (commonly seen in pairs and short chains) in the absence of other predominant flora is strongly suggestive of the diagnosis (Fig. 32-2), a valid sputum specimen cannot always be obtained.[106,107] The organism is recovered from sputum culture in fewer than half of the cases. Even a single dose of antibiotics affects the yield of sputum cultures, the likely explanation for the discrepancy between sputum Gram stain and culture results. Furthermore, pneumococci may be part of the oral flora. Blood cultures are positive in 10% to 30% of hospitalized patients.[6] The rapid, commercial urinary antigen *S. pneumoniae* test has a sensitivity of 50% to 80% and a specificity of approximately 90%; the sensitivity is higher in bacteremic cases.

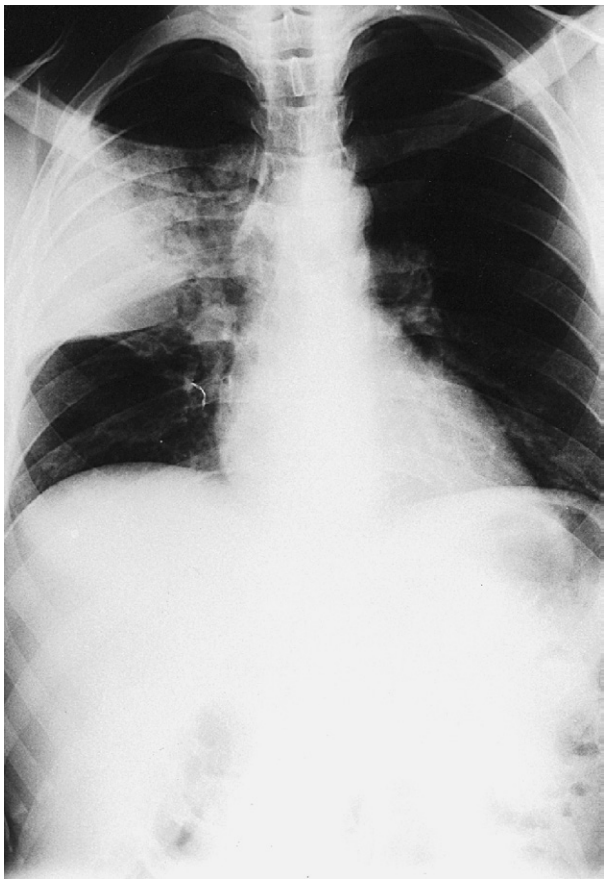

FIGURE 32-1 ■ Pneumococcal pneumonia presenting with lobar consolidation.

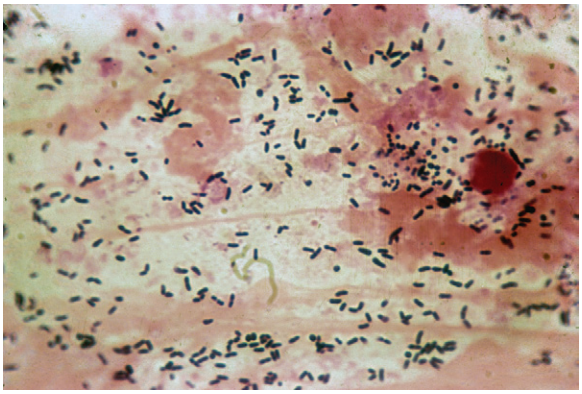

FIGURE 32-2 ■ Gram stain of sputum from a patient with pneumococcal pneumonia. The predominant organisms are gram-positive, lancet-shaped diplococci.

Clinical Course

With an appropriate antibiotic, a salutary clinical response usually occurs within 24 to 48 hours. Fever may persist for up to 5 days without signifying therapeutic failure or complication of the infection. Resolution of radiographic changes usually occurs within 4 to 8 weeks, but up to 12 weeks may be required in patients with extensive underlying lung disease. Complications such as empyema, purulent pericarditis, meningitis, endocarditis, arthritis, and cellulitis are uncommon in the modern era. In asplenic individuals, fulminant septicemia and disseminated intravascular coagulation may be the first signs of pneumococcal pneumonia. The overall mortality of bacteremic pneumococcal pneumonia is 11% to 20%,[108] increasing to 20% to 40% in persons over 65 years of age.

Treatment

Antimicrobial resistance, particularly to penicillin, has complicated the treatment for *S. pneumoniae* in much of the world.[109] For nonmeningeal isolates of *S. pneumoniae*, the recent redefinition of full susceptibility as a minimum inhibitory concentration (MIC) of penicillin 2.0 μg/mL or less and high-level resistance as an MIC 8.0 μg/mL or higher has dramatically changed the incidence of penicillin resistance. This redefinition was driven by the discordance between the previous lower MIC levels and clinical success rates. Resistant isolates are more commonly isolated from attendees of daycare centers, residents of long-term care facilities, and persons who have received antimicrobial therapy within the preceding 3 months. In recent years, the rates of penicillin resistance have stabilized or even started to decrease.[110] Several explanations for this trend exist, including the effect of the pediatric conjugate vaccine and a shift in the outpatient antibiotic prescription patterns away from β-lactams.

Resistance to other β-lactams is due to alterations in penicillin-binding proteins of *S. pneumoniae* rather than to β-lactamase production. Unlike other β-lactams, cefotaxime, ceftriaxone, and cefepime retain activity against 75% to 95% of nonmeningeal isolates of *S. pneumoniae*.[111–113] *S. pneumoniae* resistance rates to other antimicrobials are up to 30% for trimethoprim-sulfamethoxazole (TMP-SMX), 16% for tetracyclines, 26% for macrolides, and 9% for clindamycin; these rates are higher among penicillin-resistant pneumococci.[109,112] Failures of azithromycin treatment of *S. pneumoniae* isolates expressing moderate-level macrolide resistance (MIC ≤ 32 μg/mL or less) are well documented.[114–116] High-level resistance with MIC greater than 64 μg/mL (MLSB [macrolides, lincosamides, or streptogramin B] phenotype) is more common in Europe[117] and has been associated with in vitro resistance to clindamycin. *S. pneumoniae* resistance to fluoroquinolones has also emerged (with rates of ≤13% in Hong Kong) with resultant clinical treatment failures.[25,90–94]

The potential for resistance to all the major classes of antibiotics complicates the choice of empirical antibiotic for suspected *S. pneumoniae*. By far the most important determinant of appropriate therapy is to avoid antibiotics used in the prior 90 days.[118] Severity of illness also may play a role. Whereas only limited data are available and the number of documented *S. pneumoniae* cases is small, combination therapy appears to have slightly better outcomes than fluoroquinolone monotherapy requiring ICU admission.[119] Retrospective and prospective observational studies have suggested a benefit to treating severely ill patients with proven pneumococcal infections with both a β-lactam and a macrolide agent.[57,110,120–122] Although this warrants further validation,[110,122] the most likely explanation is that the macrolides exert a immunomodulatory effect. Improved outcome for bacteremic CAP cases due to pathogens not usually susceptible to a macrolide supports the findings of these studies.[123]

Other Streptococci

Epidemiology

S. pyogenes (group A β-hemolytic streptococcus) can be found in the oropharynx of over 20% of children and a smaller percentage of adults. In the United States, the incidence of pneumonia due to *S. pyogenes* was 0.15 to 0.35/100,000 persons/year, accounting for 0.3% of CAP cases with an identified pathogen.[124,125] Carriage rates increase greatly during epidemics and in crowded conditions.[104,126] The organism is easily transferred between contacts, leading to epidemics of group A streptococcal pneumonia in military recruits, nursing homes, and other crowding situations.[124,126] Pneumonia due to *S. pyogenes* most often occurs during the late winter and spring months, may follow an episode of influenza, measles, or varicella, and has been associated with increased age, alcohol abuse, diabetes mellitus, cancer, and HIV infection.[124]

Group B streptococci (*S. agalactiae*) are a major cause of neonatal sepsis and pneumonia. Pneumonia accounts for approximately 15% of adult infections by group B streptococcal infections in adults.[127] Most adults with group B streptococcal pneumonia are debilitated and develop pneumonia as a consequence of aspiration.[127] Diabetes, hepatic cirrhosis, stroke, breast cancer,

decubitus ulcer, and neurogenic bladder are also risk factors.[127]

The *Streptococcus milleri* group C streptococci (which include *S. intermedius*, *S. anginosis*, and *S. constellatus*) have emerged as significant respiratory pathogens, predominantly causing empyema and lung abscesses. Infections with this group share many of the features of anaerobic infections, including increased risk in males, periodontal disease, and alcoholism. Viridans and microaerophilic streptococci (α-hemolytic, nonpneumococcal) are rarely the sole pathogens in patients with pneumonia. They are more commonly found mixed with other facultative and anaerobic organisms in cases of aspiration pneumonia.

Clinical Manifestations

CAP from these pathogens is nearly identical to pneumococcal pneumonia. Exudative pharyngitis may be evident and unilobar involvement is common with group A streptococcal pneumonia.[126] Pleural effusions in group A streptococcal pneumonia are frequent, may be large, accumulate rapidly, and appear early in the course of the disease. Pneumonia caused by other β-hemolytic streptococci is usually less abrupt and milder; pleural effusions are uncommon, and lung tissue necrosis is rare[127] despite frequent bacteremia.[124] Disease resulting from α-hemolytic streptococci resembles aspiration pneumonia. *S. milleri* infection is predominantly empyema, with or without concomitant pneumonia.[128] Pneumothorax at the time of initial presentation appears to be more common with *S. milleri* than with other streptococcal empyemas. Lung abscesses can also be found.

Microbiologic Diagnosis

Because the organisms are indistinguishable from streptococci in the normal oral flora, documentation of infection from these organisms requires isolation from a culture of blood, pleural fluid, or respiratory specimen obtained by means of an invasive procedure (Fig. 32-3). Pleural fluid cultures of children with *S. pyogenes* pneumonia are frequently positive.[129] PCR technology holds great promise for aiding diagnosis, especially of group A streptococcal infections[130] and *S. milleri* empyema.[131]

Clinical Course

Empyema and/or pericarditis occur in 5% to 30% of patients with group A streptococcal pneumonia[124,126]; other complications include pneumothorax, mediastinitis, and bronchopleural fistula formation. The only classic nonsuppurative complication that follows *S. pyogenes* pneumonia is glomerulonephritis. The overall mortality rate is 24% to 38%, with an 18% mortality rate in previously healthy patients.[124,125]

Treatment

Most of these streptococci are susceptible to penicillin G, ampicillin, and many cephalosporins. α-Hemolytic streptococci may require high dosage (8–18 million units/day). Because resistance to clindamycin and erythromycin is found in up to 15% to 20% of isolates,[132] susceptibility testing is advisable before therapy with a macrolide or clindamycin.[133] Drainage of empyema fluid is an important part of therapy.

Haemophilus influenzae

Epidemiology

H. influenzae is the third most common cause of CAP requiring hospitalization in adults and accounts for approximately 1.2 cases/100,000 adults/yr in the United States.[7] Chronic lung disease, malignancy, HIV infection, and alcoholism are among the most common predisposing conditions to *Haemophilus* pneumonia. Active smoking appears to particularly increase the risk of *H. influenzae* pneumonia. Because unvaccinated young children lack specific immunity to capsular material, they are prone to bacteremic pneumonia with encapsulated strains as well as noninvasive (nonbacteremic) infection by unencapsulated (or nontypeable) strains. Noninvasive infection by unencapsulated strains is the most common *H. influenzae* pneumonia in adults.

Clinical Manifestations

The clinical presentation of *Haemophilus* pneumonia is indistinguishable from other bacterial pneumonias.

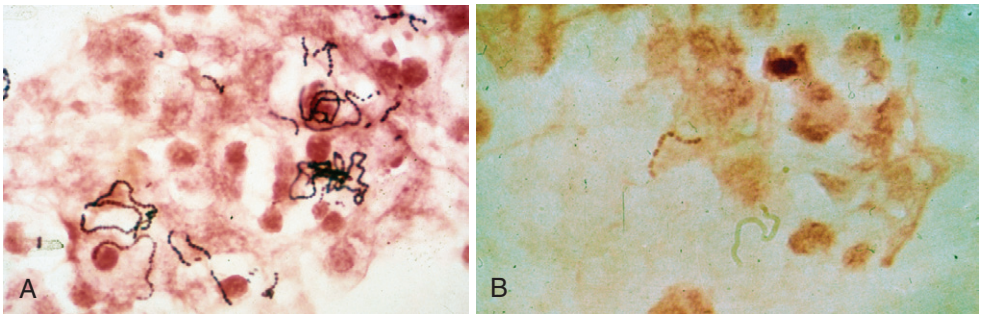

FIGURE 32-3 ■ **A,** Group A streptococcus (*Streptococcus pyogenes,* β-hemolytic streptococcus). **B,** Group B streptococcus (*Streptococcus agalactiae*) are indistinguishable from *Streptococcus pneumoniae* on Gram stain.

Bacteremia is more common in children than in adults. On radiographs, *Haemophilus* pneumonia may be multilobar, patchy bronchopneumonia or have areas of frank consolidation. Spherical radiographic shadows ("round pneumonia") have been described but cavitation is uncommon. Small parapneumonic effusions may occasionally progress to empyema.

Microbiologic Diagnosis

Diagnosing *H. influenzae* pneumonia by a Gram stain of sputum is difficult. The small, pleomorphic coccobacilli are often overlooked or are misidentified as *S. pneumoniae* because of poor staining. Culture of expectorated sputum reveals *H. influenzae* in only half of well-documented cases of pneumonia. Moreover, asymptomatic colonization with nontypeable strains in COPD patients complicates analysis of Gram stain and sputum cultures (Fig. 32-4).

Clinical Course

The overall mortality rate of *H. influenzae* pneumonia is 5% to 7% but is much higher in patients with bacteremia or extrapulmonary disease. Associated foci of infection, such as empyema, meningitis, arthritis, pericarditis, and epiglottitis are more common with infection by encapsulated organisms.

Treatment

About 20% to 50% of *H. influenzae* isolates produce β-lactamase and are therefore resistant to ampicillin. Consequently, patients with serious respiratory tract infections requiring parenteral therapy should be empirically treated with a cephalosporin, or a β-lactam–β-lactamase inhibitor combination. Azithromycin, fluoroquinolones, tetracyclines, and telithromycin also have excellent activity against *H. influenzae*. About 7% to 10% of isolates are resistant to TMP-SMX.

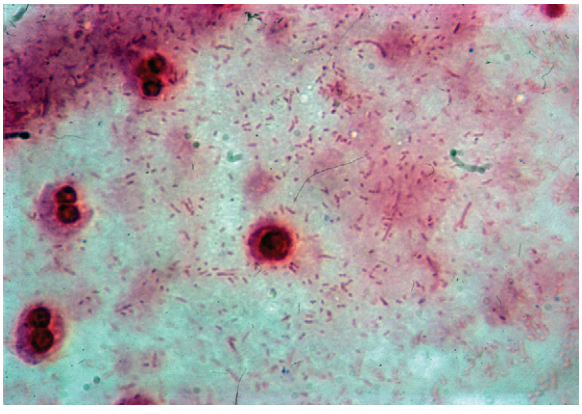

FIGURE 32-4 ■ Gram stain of *Haemophilus influenzae* shows small pleomorphic coccobacilli that can be missed on sputum examination.

Mycoplasma pneumoniae

Epidemiology

M. pneumoniae accounts for up to 37% of CAP in persons treated as outpatients and 10% of pneumonia in persons requiring hospitalization.[6,8] An estimated 2 cases/yr/1000 individuals occur in the United States. *Mycoplasma* infections occur year-round, but outbreaks are most common in the fall. The frequency of *M. pneumoniae* CAP appears to vary from year to year. Because *Mycoplasma* is readily transmitted from person to person via aerosolized respiratory droplets, outbreaks are common in families or closed populations.[134]

Clinical Manifestations

The clinical picture of *M. pneumoniae* pneumonia is the paradigm of atypical CAP[4,7] as described previously. Chest auscultation may be normal. Sometimes crackles and decreased breath sounds are present. Pharyngitis and cervical adenopathy may be encountered. Bullous myringitis is not more common with *Mycoplasma* pneumonia than with pneumococcal pneumonia/otitis. A wide variety of exanthems, including maculopapular eruptions, urticaria, erythema multiforme, and erythema nodosum, occur in 10% to 25% of patients. Laboratory studies may reveal mild to moderate leukocytosis. The chest radiograph usually shows an interstitial or a mixed pattern that is often more striking than would be expected based on chest physical findings (Fig. 32-5).

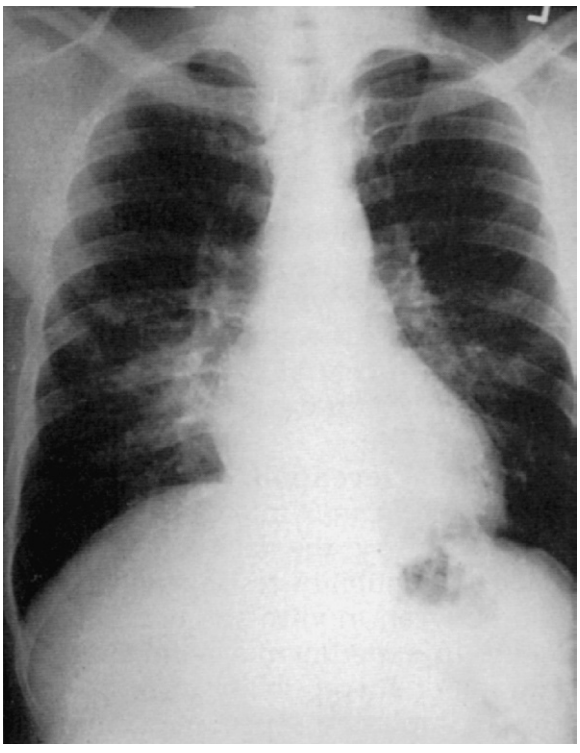

FIGURE 32-5 ■ Radiographic findings in *Mycoplasma pneumoniae* pneumonia are nonspecific. Bilateral bronchopneumonia occurred in this patient.

Small pleural effusions may occur. There are many reports of other radiologic presentations as well.

Microbiologic Diagnosis

Acute *Mycoplasma* pneumonia may stimulate cold agglutinin production in a titer 1:32 or greater. This nonspecific finding also occurs in various other infectious and noninfectious conditions including pneumonia due to *Legionella*, adenovirus, and influenza.[4] When obtained, sputum generally displays moderate numbers of polymorphonuclear leukocytes without a predominant organism. Recovery of *M. pneumoniae* from culture of clinical specimens requires special cultures and takes approximately 10 days. Demonstration of a fourfold rise in specific *M. pneumoniae* complement fixation titer for paired acute and convalescent serum samples confirms the diagnosis. The results of culture and serologic tests are rarely helpful in clinical management but are useful for epidemiologic purposes. A DNA probe test for rapid detection of *M. pneumoniae* in sputum is available, but its role in patient management is still ill-defined.[135]

Clinical Course

Mycoplasma pneumonia is usually a benign, often self-limited infection with an excellent prognosis for complete recovery. ARDS and death have been reported but are rare. Other complications of *M. pneumoniae* infection include fulminant intravascular hemolysis, the Stevens-Johnson syndrome, aseptic meningitis, meningoencephalitis, pericarditis, and myocarditis.[136]

Treatment

Antimicrobial therapy with a tetracycline, macrolide, or fluoroquinolone shortens the course of clinical symptoms and hastens resolution of radiographic abnormalities. To prevent clinical relapse, 2 weeks is the minimum recommended duration for treatment.[4] Early in the course of illness, patients with *Mycoplasma* pneumonia should be isolated to prevent transmission of the organism by respiratory droplets. Azithromycin prophylaxis can prevent infection in close contacts of patients.[137] Despite adequate therapy and resolution of symptoms, *M. pneumoniae* may persist in sputum cultures of infected patients for many weeks but do not appear to readily transmit infection.

Chlamydophila pneumoniae (Formerly *Chlamydia pneumoniae*)

Epidemiology

C. pneumoniae accounts for 5% to 15% of cases of CAP and is generally the second most common cause of CAP requiring hospitalization.[8] Seroepidemiologic studies suggest that *C. pneumoniae* infection eventually occurs in 40% to 50% of the general population, including nursing home residents. Acquisition of *C. pneumoniae* occurs via airborne transmission of infected respiratory droplets.[137a]

Clinical Manifestations

Primary infection by *C. pneumoniae* is usually asymptomatic. An acute, mild respiratory tract infection is observed in only 10% of infected adolescents and young adults. Bronchitis, sinusitis, laryngitis, tonsillitis, or exacerbations of asthma may occur with or without associated pneumonia. Sore throat with hoarseness is often severe and may precede pneumonia by up to a week and resolve prior to pneumonia onset, resulting in a biphasic illness. Diarrhea is common in hospitalized patients. The erythrocyte sedimentation rate is elevated, but there is little leukocytosis. Chest radiographs often reveal nonspecific alveolar opacities. Pleural effusions are rare.

Microbiologic Diagnosis

C. pneumoniae cannot be visualized by Gram stain, and tissue culture is required to grow the pathogen. Criteria for serologic diagnosis of acute infection are a microimmunofluorescence IgM titer of 1:16 or higher, IgG titer of 1:512 or higher, or a fourfold rise in antibody titer following acute infection. IgG may not be elevated until 3 to 6 weeks after the onset of illness.[4] Many patients are concomitantly infected by *C. pneumoniae* and other pathogens (especially *S. pneumoniae*).

Clinical Course and Treatment

Complete recovery following *C. pneumoniae* infection is the rule.[138] When associated with an exacerbation of asthma, *C. pneumoniae* can cause a prolonged recovery time. A minimum of 2 weeks treatment with a macrolide, tetracycline, doxycycline, or fluoroquinolone is recommended.[4,139] Fatalities occur principally in patients with mixed infection and preexisting illness. Reinfection by *C. pneumoniae* in older patients is associated with more severe symptoms, perhaps due to antigenic sensitization.

Staphylococcus aureus

Epidemiology

S. aureus accounts for less than 10% of cases of CAP[7] but is the second or third most common etiology in patients with CAP requiring ICU admission. *S. aureus*, especially MRSA, accounts for up to 30% of nosocomial pneumonias.[12] Nasal or skin colonization is the major source for pneumonia: 30% to 50% of healthy adults carry the organism transiently in the anterior nares. Patients who develop MRSA pneumonia have nasal colonization on admission in 67% of cases whereas noncolonized patients have less than a 5% risk of subsequent MRSA pneumonia.[140] Health care workers may have even higher carriage rates. The organism is easily transferred from person to person by direct hand contact.

A community-acquired strain of MRSA has recently become an important CAP pathogen in the United States.

In addition to antibiotic resistance, the DNA cassette containing the mecA gene also included other virulence factors, such as the Panton-Valentine leukocidin (PVL). The combination of antibiotic resistance and increased virulence factors has been associated with significantly higher mortality.[141] Typical hospital-acquired strains of MRSA have also caused episodes of CAP but usually occur in patients with risk factors for HCAP.[142] The ability to differentiate clinically between nosocomial- and community-acquired cases is increasingly difficult because risk factors, such as prior antibiotic therapy, often overlap.

Factors that predispose patients to acquire staphylococcal pneumonia include underlying pulmonary disease (e.g., COPD, carcinoma, cystic fibrosis), chronic illness (e.g., diabetes mellitus, renal failure), or viral infection (e.g., influenza, measles). *S. aureus*, including community-acquired MRSA, is second in frequency to *S. pneumoniae* as a cause of postinfluenza bacterial pneumonia. Postinfluenza CAP due to community-acquired MRSA is particularly virulent. Pneumonia caused by hematogenous spread of *Staphylococcus* usually occurs as a consequence of intravenous drug abuse or septic embolization in the setting of endocarditis or an infected vascular site.

Clinical Manifestations

In cases of acquired hematogenously, signs and symptoms related to the underlying endovascular infection predominate; if pulmonary infarction results from a septic embolism, pleuritic chest pain and hemoptysis are often noted. Otherwise, respiratory tract symptoms are mild or absent despite radiographic evidence of multiple pulmonary opacities. Severe manifestations, including high-grade fever, massive hemoptysis, neutropenia, pulmonary necrosis, and mortality, are more common among persons infected by *S. aureus* organisms that carry the PVL toxin.[143,144] These toxin-producing strains often demonstrate cavitary disease already at the time of presentation, initially causing confusion with lung abscess or hematogenous spread of *S. aureus*. Rapid progression of pulmonary opacities and massive pleural effusions is also common. The chest radiograph in patients with hematogenous staphylococcal pneumonia often reveals multiple, discrete, and often cavitary shadows with a predilection for the lower lobes (Fig. 32-6).[144a]

Microbiologic Diagnosis

Purulent sputum with multiple clusters of large gram-positive cocci, particularly if intracellular, is strongly suggestive of *S. aureus* pneumonia (Fig. 32-7). The organism is easily recovered from sputum cultures. The absence of MRSA, even after several doses of antibiotics, is strong evidence that MRSA is not the causative pathogen. Less than 25% of infections due to aspiration are associated with positive blood cultures. In contrast, staphylococcal pneumonia resulting from hematogenous spread usually yields multiple positive blood cultures. This is especially true when MRSA causes CAP. Pleural effusions are often watery rather than grossly purulent but are still high yield on culture. An important clue is a concomitant skin lesion, which is often positive on Gram stain.

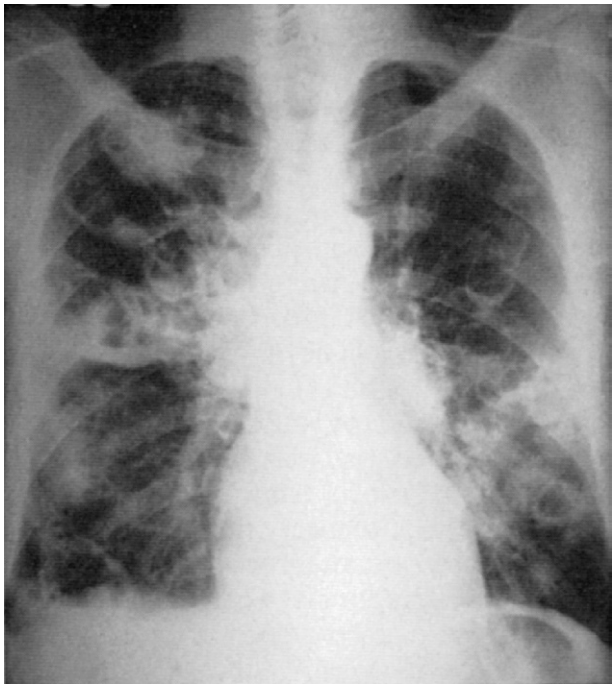

FIGURE 32-6 ■ Chest radiograph shows hematogenous staphylococcal pneumonia associated with bacterial endocarditis. The pneumonia is characterized by many cavities.

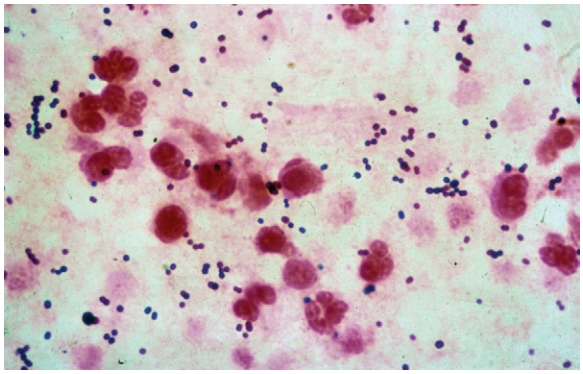

FIGURE 32-7 ■ Gram stain of sputum from a patient with staphylococcal pneumonia shows abundant large, round gram-positive cocci in clusters.

Clinical Course

Local complications of staphylococcal pneumonia include empyema and abscess formation. Metastatic infection to the central nervous system, bones, joints, skin, and kidneys occurs in association with hematogenous infection. Most of these manifestations are due to strains secreting PVL or one of the other large numbers of exotoxins produced by *S. aureus*. Even with appropriate antibiotics, the duration of fever and need for ICU

care is often prolonged. Cavities may prevent adequate local antibiotic levels, whereas unrecognized or incompletely drained empyema may prolong fever. Pleuroscopy or decortication is required in a large percentage of cases. The mortality of *S. aureus* CAP is generally higher than most etiologies, with the mortality in methicillin-sensitive strains about 30%. *S. aureus* CAP following influenza has a reported mortality of greater than 60%, even if not methicillin-resistant.[2]

Treatment

The treatment of choice for methicillin-susceptible *S. aureus* (MSSA) pneumonia is a penicillinase-resistant penicillin (e.g., oxacillin 8–12 g/day) or a first-generation cephalosporin. Duration of therapy of 7 to 10 days is adequate in uncomplicated cases, but 4 to 6 weeks of treatment has been suggested for patients with bacteremia or cavitation. In the penicillin-allergic patient, clindamycin or linezolid can be used.

Treatment is increasingly problematic because of the increasing incidence of CAP caused by both nosocomial MRSA and community-acquired MRSA strains.[144,145] Although outright resistance to vancomycin is still rare, the MIC has been shifting upward and MICs of greater than 1 μg/mL have been associated with frequent clinical failure. In higher-risk patients, such as those with VAP or with underlying renal insufficiency, linezolid may be a better choice for treatment. For community-acquired MRSA, vancomycin therapy alone has been associated with a significant failure rate,[141] most likely because it does not block exotoxin production.[146] Addition of clindamycin or use of linezolid has been associated with improved outcomes in small case series. Clindamycin monotherapy is probably not adequate because of the rapid development of resistance, especially with the high inoculum in cavitary disease. Although often sensitive to other antibiotics such as fluoroquinolones, TMP-SMX, and aminoglycosides, these antibiotics are unreliable in severe community-acquired MRSA cases.

Tricuspid valve débridement may be required in patients with recurrent septic pulmonary emboli. Infected vascular access lines and grafts must be removed.

Gram-Negative Bacillary Pneumonia

The term *gram-negative bacillary pneumonia* refers to infections caused by members of two groups, the Enterobacteriaceae and Pseudomonaceae and other aerobic, nonfermentative gram-negative bacilli. Infections caused by *Haemophilus*, *Legionella*, and anaerobes are usually excluded from this categorization.

Enterobacteriaceae

Epidemiology. Although more common in HAP, gram-negative bacilli also cause 5% to 10% of CAP.[7,9] CAP due to gram-negative bacilli is often severe and frequently requires ICU care. At least 40% to 45% of HAPs are caused by Enterobacteriaceae, such as *Escherichia*, *Klebsiella*, *Proteus*, *Morganella*, *Enterobacter*, *Providencia*, *Serratia*, *Salmonella*, and *Citrobacter*. Patients in an ICU, and especially those undergoing mechanical ventilation, have the highest risk of developing gram-negative bacillary pneumonia.

The Enterobacteriaceae normally colonize the digestive tract, and pneumonia usually results from aspiration of oropharyngeal flora. Although uncommon in healthy, nonhospitalized individuals, the prevalence of oropharyngeal colonization by gram-negative bacilli is greatly increased by serious comorbidities, hospitalization, antimicrobial use, and risk for aspiration, such as cerebrovascular accidents, seizures, or anesthesia.[9] Occasionally, use of contaminated home respiratory therapy equipment directly introduces gram-negative rods into the respiratory tract. Finally, Enterobacteriaceae pneumonia may result from hematogenous seeding from infection at other anatomic sites.

Among the Enterobacteriaceae, *Escherichia coli* is the single most frequent cause of CAP.[9] The classic cause of community-acquired gram-negative bacillary pneumonia, *K. pneumoniae* (Friedlander's pneumonia), causes fewer than 10% of CAPs, but more than 20% of nosocomial pneumonias. Alcohol abuse is the most common underlying condition, with some contribution from diabetes mellitus and chronic pulmonary disease, for community-acquired *K. pneumoniae* pneumonia because it colonizes the pharynx in up to 30% of ambulatory alcoholics.

Clinical Manifestations. The classic clinical features of Enterobacteriaceae pneumonia are abrupt onset of dyspnea, fever, chills, and cough in an older patient who is either hospitalized or chronically ill. In CAP due to *Klebsiella* pneumonia, pleuritic chest pain, hemoptysis, and bloody sputum (occasionally with a "currant jelly" appearance) may be noted. With *Serratia* pneumonia, sputum occasionally is pink or red as a result of bacterial pigments (so-called pseudohemoptysis). However, these classic findings are often absent, and the epidemiology and clinical manifestations of Enterobacteriaceae pneumonias are not sufficiently unique to distinguish these infections from pneumonias due to other causes.[9] Most laboratory abnormalities are nonspecific but neutropenia is an ominous sign. Chest radiographs often demonstrate lower lobe bronchopneumonia, which is often bilateral. A classic radiographic appearance of *Klebsiella* pneumonia is that of lobar consolidation with a predilection for the upper lobes (especially on the right) (Fig. 32-8) with a bulging or bowed fissure due to the heavy gelatinous exudate.

Microbiologic Diagnosis. Enterobacteriaceae pneumonia should be suspected when expectorated sputum is purulent and the Gram stain reveals large numbers of uniform-appearing gram-negative rods (Fig. 32-9). Sputum culture alone is notoriously nonspecific for Enterobacteriaceae in endotracheal intubated patients and is one of the major reasons for interest in quantitative culture diagnosis. Even in nonintubated patients, gram-negative bacilli found in the sputum may represent contamination by oropharyngeal contents rather than being the cause of the pneumonia. Polymicrobial infections involving gram-negative bacilli, anaerobes,

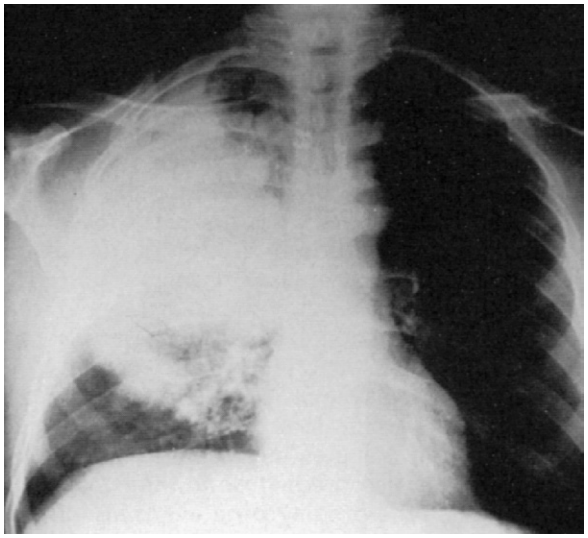

FIGURE 32-8 ■ Dense infiltration of the right upper lobe produced the radiographic appearance of a "bowed" fissure in this patient with *Klebsiella pneumoniae* pneumonia.

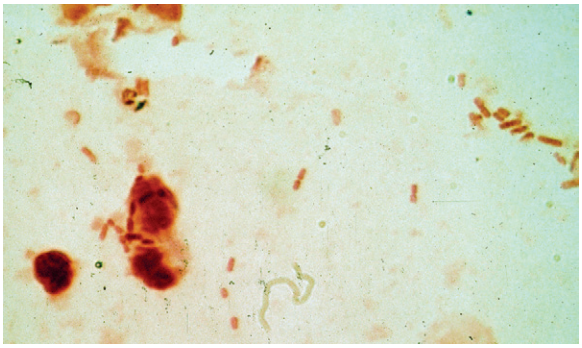

FIGURE 32-9 ■ Large gram-negative rods seen in the sputum of a patient with *K. pneumoniae* pneumonia.

streptococci, and *S. aureus* are common. Severe Enterobacteriaceae pneumonia is accompanied by bacteremia in 20% to 30% of patients.[9]

Clinical Course. Enterobacteriaceae pneumonia fatality rates are 25% to 50%.[9] Presence of bacteremia, neutropenia, and old age points to a poor prognosis. Respiratory failure is a common complication. Destruction of pulmonary alveolar septa may lead to cavitation and, at worst, lobar gangrene.

Treatment. Treatment of serious infections due to Enterobacteriaceae is complicated by the emergence of multidrug antimicrobial resistance. *Enterobacter* spp., *Citrobacter freundii*, *Serratia* spp., and *Providencia* spp. often possess type I chromosomal β-lactamases that mediate resistance to third-generation cephalosporins, cephamycins (e.g., cefoxitin) and β-lactam–β-lactamase combinations. These β-lactamases may be induced by prior use of third-generation cephalosporins and, to a lesser extent, piperacillin. In addition, *K. pneumoniae* and *E. coli* may harbor extended-spectrum β-lactamases that inactivate third- and fourth-generation cephalosporins (i.e., cefepime). Many of these isolates also carry determinants for fluoroquinolone and aminoglycoside resistance, and some are resistant to β-lactam–β-lactamase combinations. Emergence of extended-spectrum β-lactamases has been linked to the widespread use of ceftazidime. Only the carbapenems (imipenem and meropenem) and aminoglycosides (especially amikacin) are consistently active in the presence of both type I chromosomal β-lactamases and extended-spectrum β-lactamases.

Considering the range of antimicrobial resistance, initial therapy of life-threatening pneumonia thought to be due to Enterobacteriaceae must be carefully selected. In patients with serious infection, a two-drug regimen of an aminoglycoside with a broad-spectrum β-lactam or carbapenem is recommended for empirical treatment. Monotherapy may be reasonable for immunocompetent patients with mild to moderate diseases who are known or likely to be infected by susceptible strains of *Proteus*, *Morganella*, *K. pneumoniae*, or *E. coli*. The excellent absorption of oral fluoroquinolones allows these agents to be used as follow-up to initial intravenous therapy when active against the relevant pathogens. Recommendations for empirical therapy for HAP are provided in Table 32-13.

Pseudomonas aeruginosa *and Related Organisms*

Epidemiology. *P. aeruginosa* is an uncommon cause of CAP. Although one large Spanish study found that 7% of CAP was due to *P. aeruginosa*, most studies have found substantially lower rates.[9] The major risk factor for *Pseudomonas* CAP is structural lung disease, such as cystic fibrosis, bronchiectasis, and severe COPD (FEV_1 < 30%). Another common risk factor with these outpatient entities is frequent antibiotic use. Very rarely, such infections develop in normal hosts, perhaps related to aerosols of contaminated water.[7,9,23,49,147,148]

In contrast, *P. aeruginosa* is a leading cause of nosocomial pneumonia and a particularly frequent cause of VAP.[149] Prolonged endotracheal intubation and prior antibiotic therapy, especially with broad-spectrum antibiotics, are the primary risk factors for *Pseudomonas* VAP. Pneumonia may also occur following the administration of aerosols produced by contaminated respiratory therapy equipment. Other nonfermenters, such as *S. maltophilia* and *B. cepacia*, carry the same nosocomial risk factors, most commonly cause pneumonia in patients after prolonged broad-spectrum antibiotic therapy, and are associated with a high mortality rate. *B. cepacia* is also found in outpatients with cystic fibrosis.[150]

Clinical Manifestations. The clinical picture of pneumonia due to *P. aeruginosa* is largely indistinguishable from that of pneumonia due to one of the Enterobacteriaceae. Patients with bacteremic pneumonia appear much more toxic. Physical examination may reveal ecthyma gangrenosum, and leukopenia is common. The chest radiographic appearance is often that of bilateral patchy bronchopneumonia in the lower lobes. Because of its propensity to invade vascular tissue, the clinical and laboratory manifestations of *Pseudomonas*

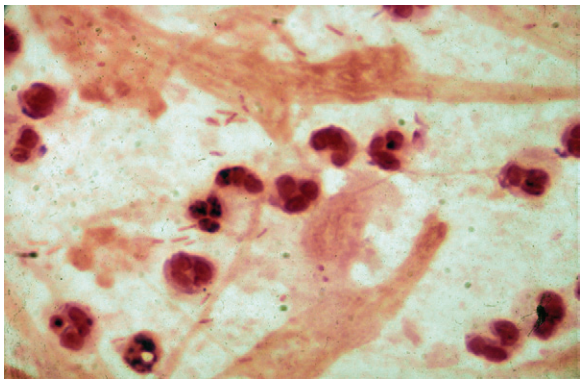

FIGURE 32-10 ■ Gram stain of sputum of *Pseudomonas* seen as slender gram-negative bacilli.

bacteremic pneumonia may resemble pulmonary thromboembolism. *Pseudomonas* HAP is the most common cause of cavitary pneumonia in hospitalized or immunocompromised patients, and empyema is not uncommon.

Microbiologic Diagnosis. Gram stain of sputum from patients with *Pseudomonas* pneumonia typically shows purulence and many slender, gram-negative bacilli (Fig. 32-10). Colonization of the oropharynx in hospitalized or debilitated patients complicates the Gram stain interpretation. In endotracheally intubated patients, absence of *Pseudomonas* on culture is strong evidence that it is not involved in the pneumonia. An invasive diagnostic procedure is especially useful in immunocompromised or neutropenic patients, in whom sputum may be minimal or nondiagnostic.[49] Blood cultures are often positive in neutropenic patients.

Clinical Course. Mortality from community-acquired *P. aeruginosa* pneumonia is up to 28%[9]; and in persons with VAP due to *P. aeruginosa*, mortality rates are 40% to 70%.[151] The prognosis in neutropenic patients with *P. aeruginosa* pneumonia is particularly poor.[152,152a]

Treatment. *P. aeruginosa* pneumonia should initially be treated with two potentially synergistic antimicrobial agents, such as an aminoglycoside and an antipseudomonal β-lactam antibiotic; this is especially true for bacteremic or neutropenic patients.[152] Amikacin is the most reliably active aminoglycoside. The β-lactam antibiotics, in order of probable activity against *P. aeruginosa*, are the carbapenems (imipenem and meropenem), the acylureidopenicillins (e.g., piperacillin), ceftazidime, and cefepime.[153] Although fluoroquinolones (particularly ciprofloxacin) possess good intrinsic activity against *P. aeruginosa*, resistance is common, making empirical monotherapy hazardous. Specific antibiotic choices can be changed when the in vitro susceptibility pattern is known. Emergence of resistance during the course of monotherapy is common.

S. maltophilia is inherently resistant to most standard antibiotics.[154] TMP-SMX is the most reliable agent, and fluoroquinolones or ticarcillin-clavulanate occasionally have activity.[152] Isolates of *S. maltophilia* may become resistant in the face of seemingly effective therapy. *B. cepacia* isolates may be susceptible to acylureidopenicillins, ceftazidime, TMP-SMX, fluoroquinolones, minocycline, and chloramphenicol. Resistance rates are higher in isolates from patients with cystic fibrosis.

Acinetobacter baumanii

Epidemiology. *A. baumanii*, a member of the family Achromobacteriaceae, is a gram-negative bacillary cause of pneumonia that may be either community- or hospital-acquired. In the United States, *Acinetobacter* CAP is most commonly seen in men who abuse alcohol. *Acinetobacter* has also been associated with CAP in hot climates, both dry[155] and humid.[156] Additional risk factors include old age, alcoholism, and severe medical comorbidities.[25] Nosocomial pneumonia is not uncommon and results from aspiration of endogenous flora or by exposure to contaminated respiratory equipment. In the United States, the overall risk of *Acinetobacter* pneumonia is 7.6/10,000 ventilator-days. Nosocomial infections caused by *Acinetobacter* show seasonal variation, peaking in late summer.

Clinical Manifestations. Patients with community-acquired *Acinetobacter* pneumonia often present with the acute onset of severe respiratory distress, tachypnea, fever, productive cough, and pleuritic pain.[25] Leukopenia, pleural effusions, and empyema are common. Nosocomial *Acinetobacter* pneumonia has a less dramatic presentation, similar to those of other hospital-acquired gram-negative bacillary pneumonias.[25]

Microbiologic Diagnosis. Examination of expectorated sputum, which is usually purulent, may reveal a predominance of paired gram-negative coccobacilli that resemble *Neisseria*, *Haemophilus*, and *Moraxella* spp. Bacteremia more often complicates community-acquired than nosocomial *Acinetobacter* pneumonia.

Clinical Course. The mortality rate of community-acquired *Acinetobacter* pneumonia is close to 50%.[25] Patients at greatest risk of death are those with leukopenia or empyema. The fatality rate for nosocomial *Acinetobacter* pneumonia is determined by the severity of underlying disease.

Treatment. Amikacin, tobramycin, ceftazidime, carbapenems, and doxycycline are active against most community isolates.[157] Nosocomial *Acinetobacter* spp. are resistant to most β-lactams and aminoglycosides and therefore are most reliably treated with carbapenems.[158] Some investigators have reported successful treatment of highly resistant isolates with ampicillin-sulbactam or colistin.[159,160] Unfortunately, resistance to β-lactam antimicrobials, carbapenems, aminoglycosides, and fluoroquinolones, and even polymyxin B and colistin[159] is increasingly common among nosocomial isolates.

Legionella

Epidemiology

L. pneumophila causes both epidemic and sporadic infections; both patterns may occur in the community or in hospitals. Outbreaks have been linked to contaminated potable water systems, ultrasonic mist devices,

whirlpool baths, air-conditioning condensates, and water-evaporative systems.[161] Recent travel is the most significant historical clue to the possibility of *Legionella* CAP. The route of transmission is probably through both inhalation of contaminated aerosols and aspiration. Sporadic cases of *L. pneumophila* pneumonia (50%–80% of which are due to serogroup 1) account for 2% to 6% of CAPs in immunocompetent hosts.[7] Importantly, *L. pneumophila* is one of the most common causes of severe CAP. Risk factors include immunosuppression, male gender, cigarette use, diabetes, cancer and end-stage renal disease, alcohol use, and exposure to contaminated drinking water. Infection by *L. pneumophila* is more common in some specific geographic regions, such as the Mediterranean or western Pennsylvania.

In addition to *L. pneumophila*, 40 other *Legionella* species have been identified. The species *L. micdadei*, *L. bozemanii*, *L. dumoffi*, *L. gormanii*, *L. longbeachae*, *L. jordanis*, and *L. wadsworthii* produce a pneumonic illness indistinguishable from that of *L. pneumophila*. Much less is known about the epidemiology of nonpneumophila *Legionella* infections, but they also appear to be water-related. Immunosuppressed patients are predominantly affected.

Clinical Manifestations

The incubation period for *Legionella* pneumonia is 2 to 10 days. Early complaints of lethargy, headache, fever, recurring rigors, anorexia, and myalgias are frequent. After several days, the cough becomes more pronounced; occasionally, watery or purulent sputum develops. Dyspnea becomes prominent in half of the cases, and one third of patients complain of pleuritic chest pain. Hemoptysis may occur. Among the myriad common extrapulmonary manifestations that may completely overshadow the respiratory complaints, gastrointestinal (watery diarrhea, nausea, vomiting, abdominal pain) and neurologic complaints (headache, confusion, obtundation, seizures, hallucinations) are particularly noteworthy.

Patients appear acutely ill. Temperatures reach 40.5°C in one third of patients, are typically sustained, and may be accompanied by relative bradycardia. Physical findings are usually limited to the chest. Crackles and rhonchi are prominent early but usually give way to impressive signs of consolidation. Pleural friction rubs are not unusual. Generalized abdominal tenderness, hepatomegaly, splenomegaly, cutaneous rash, nuchal rigidity, and focal neurologic deficits have all been described.

The sputum becomes more purulent as the disease progresses. Hyponatremia and hypophosphatemia are present in more than half of severe cases. Mild elevations of serum creatinine, creatine phosphokinase, and liver enzymes are also common, as are hematuria and proteinuria. Leukocytosis with a shift to the left is characteristic, but leukopenia and thrombocytopenia occur in severely ill patients. Cold agglutinins may be present.

Chest radiographic findings typically lag behind the early clinical illness. An alveolar pattern with lobar, nodular, or subsegmental involvement that spares the apices is most common (Fig. 32-11). Small pleural effusions are found in 50% of patients and may precede development of the parenchymal process. Frank cavitation rarely occurs.[47]

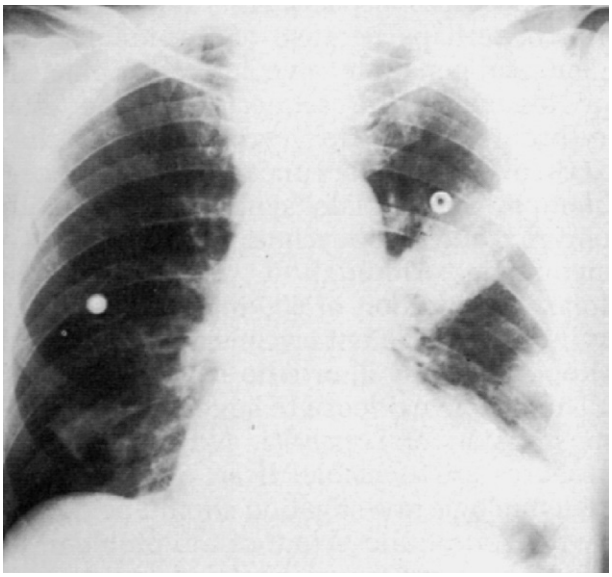

FIGURE 32-11 ■ Multilobar involvement occurring with *Legionella pneumophila* pneumonia.

Microbiologic Diagnosis

Legionella are obligatory aerobic, fastidious, gram-negative bacilli that do not stain well with the ordinary Gram stain or grow well on conventional media. *L. micdadei* and some other *Legionella* spp. may stain weakly acid-fast. Early in the infection, a Gram stain of sputum from patients with *Legionella* pneumonia discloses few or no polymorphonuclear leukocytes. Furthermore, despite use of appropriate media, the sensitivity of cultures of respiratory specimens in clinical practice is as low as 10%. The diagnosis of *L. pneumophila* infection often requires invasive procedures to obtain respiratory secretions, because at least 25% of patients with *Legionella* infection do not produce sputum.[57] Rarely, *Legionella* has been recovered from blood, pleural fluid, and other extrapulmonary sites. The *Legionella* urinary antigen test has a sensitivity of 60% to 80% and specificity of greater than 95% for *L. pneumophila* serogroup 1.[57] The sensitivity of the direct fluorescent antibody (DFA) assay for sputum ranges from 33% to 68%, with specificity greater than 95%,[57] but its use is hindered by the expertise required for interpretation and the multiplicity of *Legionella* spp. and serogroups that require specific antiserum. PCR-based assays for sputum have greater than 80% sensitivity and greater than 90% specificity.[57] A fourfold rise in antibody titer occurs in most patients within 8 weeks of the onset of illness.[57] Even in appropriate clinical circumstances, a single acute titer of 1:256 has a positive predictive value of only 15%.

Clinical Course

A dramatic clinical response to appropriate antibiotic therapy is usually observed within the first 48 hours. In contrast, radiographic findings may temporarily continue to progress despite observed clinical improvement and may take months to resolve.[47] Acute renal failure and oliguria, often independent of shock and myoglobinuria, are noted in approximately 10% of patients and dialysis may be transiently required. Many patients note lingering fatigue and weakness for months following *Legionella* pneumonia. The mortality of community-acquired cases is approximately 15%. Clinical outcome is related primarily to the host immunocompetence, presence of preexisting comorbidities, early initiation of appropriate therapy, and development of complications. The need for ventilatory support or dialysis is a grim determinant of a poor outcome.

Treatment

Azithromycin and fluoroquinolones are superior to erythromycin and clarithromycin. Although it should never be used alone, the addition of rifampin is advised for patients who are severely ill or immunocompromised, especially if the primary therapy is not with azithromycin or a fluoroquinolone.[4] Antibiotics should be continued for 10 to 21 days in immunocompetent patients to decrease the rate of relapse.[4]

Anaerobic Bacteria

Epidemiology

Mixed aerobic and anaerobic infection is usually a complication of macroaspiration of oropharyngeal contents. Rare causes include rupture of the esophagus and intra-abdominal abscesses. Underlying pulmonary conditions such as malignancy, bronchiectasis, and pulmonary infarction are present in 20% of patients who have an anaerobic lung infection. Although acute complications of macroaspiration are largely due to a chemical injury pneumonitis (Mendelson's syndrome) and/or infection by pathogenic aerobes in the oral flora, many of these episodes later result in the clinical emergence of mixed aerobic and anaerobic pneumonia.

Clinical Manifestations

Important clues to the diagnosis of anaerobic pleuropulmonary infection are predisposition to aspiration, the presence of periodontal disease, a subacute or chronic presentation, foul-smelling sputum or empyema fluid, involvement of dependent lung segments, and the presence of lung cavitation. These infections present as four different syndromes: pneumonitis, necrotizing pneumonia, lung abscess, and empyema (which almost always overlaps one of the other syndromes). These entities are probably different expressions of the same fundamental pathologic process and may be regarded as a continuum of changes.

Anaerobic pneumonitis is characterized by the acute onset of fever, cough (often dry), and pleuritic pain. The foul sputum and hemoptysis that are characteristic of anaerobic lung abscess are often absent in cases of uncomplicated pneumonitis. Physical findings may include evidence of chronic alcoholism, pharyngeal dysfunction, or periodontal disease. Crackles and decreased breath sounds are localized over the involved lung fields. Chest radiographs demonstrate bronchopneumonic shadows, but usually not lobar consolidation, in the aspiration-prone segments of the lung (e.g., posterior segment of the right upper lobe and superior segment of the right lower lobe).

Necrosis and suppuration of lung parenchyma characterize *anaerobic necrotizing pneumonia*. These patients tend to be toxic, with prominent complaints of fever, dyspnea, pleuritic pain, and productive cough. Sputum is often purulent. Most patients have tachycardia, tachypnea, and temperatures well above 39°C. Chest radiographs demonstrate dense segmental opacification with multiple small lucent areas of lung necrosis (<2 cm in diameter), usually without air-fluid levels (Fig. 32-12). Multilobar involvement may occur.

In the absence of appropriate treatment, anaerobic pneumonitis may evolve into a *primary lung abscess*. Patients commonly experience fatigue, low-grade fever, weight loss, and productive cough for several weeks after an episode of loss of consciousness and before seeking medical attention. Approximately half of the patients describe putrid sputum, and hemoptysis may occur. On examination, patients appear chronically ill, with temperatures up to 39°C. Breath sounds may be either diminished or amphoric. Anemia of chronic disease is frequent. In most patients, a single lung abscess of more than 2 cm in diameter is detected in a dependent lung segment on radiography (Fig. 32-13). The abscess may be multilocular; occasionally, multiple abscesses are located in different lung segments.

Empyema commonly complicates each of the preceding three syndromes. The incidence of anaerobes as a cause of community-acquired empyema is generally overestimated and is only present in 20%.[131] Most primary empyemas are due to *S. milleri/intermedius*. When anaerobic empyema occurs in the absence of parenchymal lung infection, the presence of a subphrenic or other intra-abdominal abscess is suggested.

Microbiologic Diagnosis

Distinguishing aspiration pneumonia (infection) from aspiration pneumonitis (Mendelson's syndrome), which represents chemical injury by acidic gastric contents,[162] is important. Gram stain of sputum or examination of a bronchoscopically obtained specimen from a patient with anaerobic infection reveals numerous polymorphonuclear leukocytes with an abundance of intracellular and extracellular bacteria. Typically, the microorganisms present a variety of Gram stain reactions and morphologies that may include pale-staining gram-negative rods with tapered ends (suggestive of *Fusobacterium nucleatum*), small, pale-staining gram-negative coccobacilli,

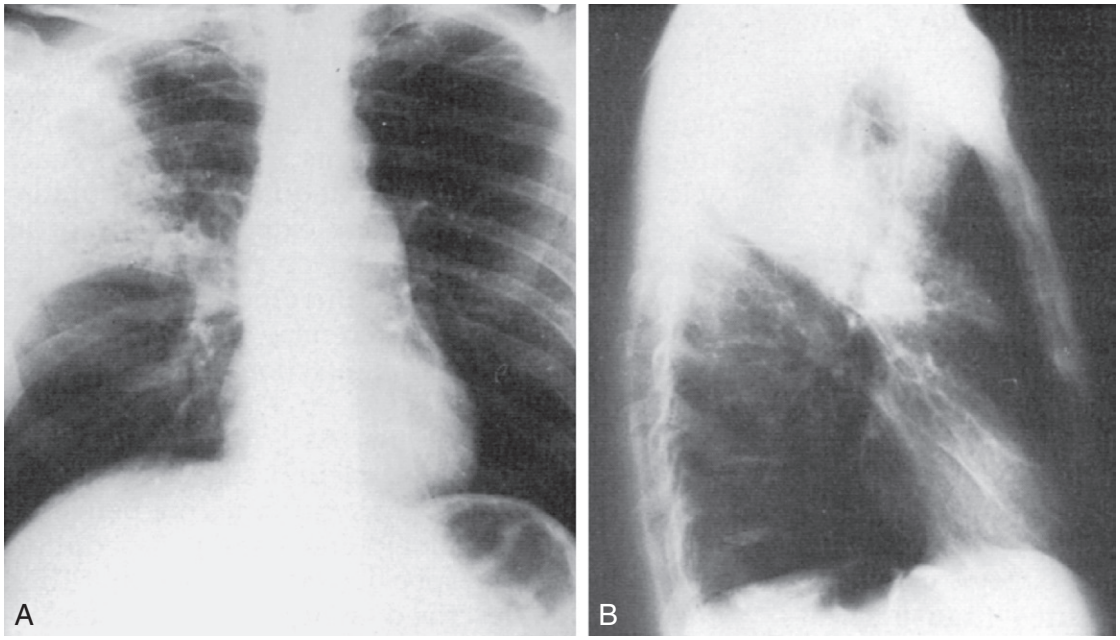

FIGURE 32-12 ■ Anaerobic necrotizing pneumonia following aspiration of oropharyngeal secretions. Multiple, small (<2 cm) radiolucencies are seen throughout the posterior segment of the right upper lobe on the posteroanterior (**A**) and lateral (**B**) projections.

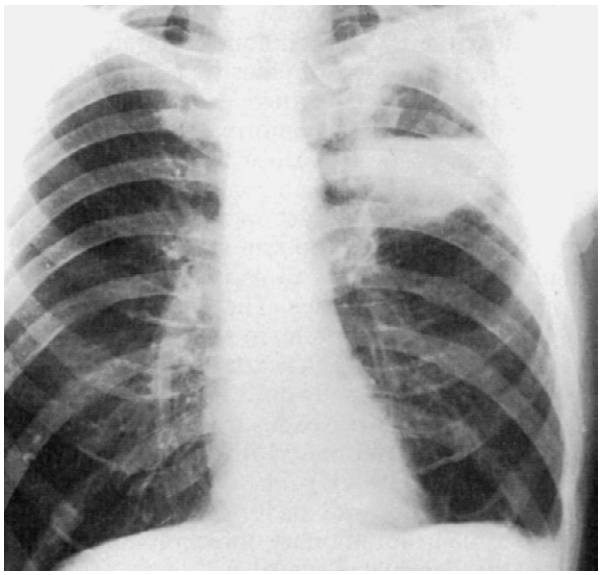

FIGURE 32-13 ■ A single parenchymal cavity with an air-fluid level typifies an anaerobic lung abscess. Most often, these lesions are located in the dependent, aspiration-prone lung segments (superior segment of the right lower lobe and left lower lobe and posterior segments of the upper lobes). This patient also has a small left empyema.

and chains of tiny gram-positive cocci. Because the indigenous flora of the upper respiratory tract consists predominantly of anaerobic bacteria, cultures of expectorated sputum are not appropriate for diagnosis of anaerobic infections. With careful attention to technique, recovery on average of 3.2 bacterial isolates/case of aerobic/anaerobic pneumonia, of which 80% are anaerobes, is possible. The most commonly encountered anaerobes in pleuropulmonary infections include *F. nucleatum*, *Prevotella*, *Porphymonas*, *Peptostreptococcus*, and microaerophilic *Streptococcus*. The major aerobic and facultative organisms recovered in conjunction with anaerobes are *Streptococcus* spp. Although *S. aureus*, various enteric gram-negative bacilli, and *Pseudomonas* may also be isolated, their significance is often questionable. Use of molecular techniques can often identify anaerobes in culture negative cases.[131]

Clinical Course

Uncomplicated pneumonitis generally responds promptly to appropriate antibiotics. Fever should resolve within a few days, and the chest radiograph normalizes within 3 weeks. Fever resolves more slowly in the other types of anaerobic pleuropulmonary infection. Closure of abscess cavities and resorbtion of empyema collections may require many months. Fatality rates are low in adequately treated patients, except those with necrotizing pneumonia, in which mortality approaches 20%.[131] Chronic lung abscess may be complicated by brain abscess, other metastatic abscess, secondary amyloidosis, life-threatening hemoptysis, or bronchopleural fistula. Inadequately treated acute empyema may result in chronic empyema or *empyema necessitans* (rupture through the chest wall).

Treatment

Emergence of β-lactamase–mediated resistance indicates that penicillin G and ampicillin are no longer the drugs of choice for treatment of patients with serious anaerobic pleuropulmonary infection. Such resistance occurs not only among *Bacteroides* spp. but also among

Prevotella and even some *F. nucleatum* strains. Empirical treatment for serious anaerobic pleuropulmonary infection therefore requires the use of a β-lactam–β-lactamase inhibitor (e.g., ampicillin-sulbactam, ticarcillin-clavulanate, or piperacillin-tazobactam) or metronidazole combined with either penicillin or ampicillin. Because of the very frequent presence of aerobes, metronidazole monotherapy is not adequate for suspected anaerobic pneumonia. For mild to moderate disease, clindamycin or an antianaerobic cephalosporin can suffice, although occasional pulmonary isolates are resistant to one or more of these agents. For example, *Eikenella corrodens* is resistant to clindamycin. Carbapenem monotherapy is also effective but generally provides unnecessarily broad coverage. When complete identification and susceptibility testing of anaerobes are available, therapy can be specifically tailored. Ten days of total treatment is usually adequate for uncomplicated pneumonitis. Necrotizing pneumonia, abscess, and empyema require prolonged parenteral therapy to achieve clinical improvement; and extended courses of oral therapy, often requiring several months, may be required for cure.

Standard drainage of empyema fluid is required. Percutaneous drainage or surgical resection of anaerobic lung abscess is almost never indicated. Bronchoscopy is useful for excluding an underlying malignancy in patients without other risk factors for development of lung abscess, such as edentulous patients.

OTHER LESS COMMON CAUSES OF PNEUMONIA

A variety of less common pathogens can cause pneumonia. These agents are usually suspected by either unique risk factors or presentations or are diagnosed by surprising results on culture. The unique aspects of these pneumonia pathogens are discussed.

Actinomycoses

A variety of species within the two genera of the Actinomycetaceae family (*Actinomyces* and *Propionibacterium*), which normally are harmless commensals in the oropharynx, can cause subacute to chronic pulmonary infections that are virtually indistinguishable. Pulmonary actinomycosis infection follows aspiration of oropharyngeal material. Periodontitis and other dental disease clearly increase the risk of cervicofacial invasion and likely also for pneumonia. Most patients are 30 to 60 years old. Cases in men outnumber those in women by four to one. Bronchiectasis and COPD are common underlying conditions.

Patients with actinomycosis appear chronically ill but not toxic. Constitutional symptoms, including fatigue, weight loss, and low-grade fever, may be present for weeks to months prior to diagnosis and often mimic the presentation of chronic fungal infection, tuberculosis, and malignancy. Fever may be absent. Most patients gradually develop productive cough and pleuritic chest pain, but hemoptysis and putrid sputum are unusual.

The classic physical finding of actinomycoses is a sinus tract on the chest with discharge of characteristic "sulfur granule" –containing pus. These distinctive 2 mm, gritty, yellow granules consist of masses of intertwined filaments of *Actinomyces* or *Propionibacterium* that have been mineralized by host-derived calcium phosphate. Cervicofacial involvement is rarely observed in patients with thoracic involvement. Radiographic findings most commonly demonstrate fibrotic changes confined to a single lobe with one or more small cavitary lesions. In advanced cases, the findings are more distinctive, with penetration through the chest wall, destruction of adjacent bone tissue, or direct extension through an interlobar fissure. Laboratory abnormalities are often limited to those of anemia of chronic disease.

Members of the *Actinomyces* and *Propionibacterium* genera are gram-positive, diphtheroidal or filamentous, branching bacilli. Most strains grow best in anaerobic conditions, although some also grow aerobically. In patients with a cutaneous chest wall sinus, the best means of establishing a diagnosis of actinomycosis is the sulfur granules that, when crushed and stained, form a characteristic pattern of gram-positive, branching filaments (Fig. 32-14). The organism can usually be recovered from culture of this material, provided anaerobic conditions are maintained for the specimen. Diagnosis of an actinomycotic parenchymal lesion is more difficult. Sulfur granules are rarely present in sputum, and recovery of the organism in sputum cultures is unreliable because

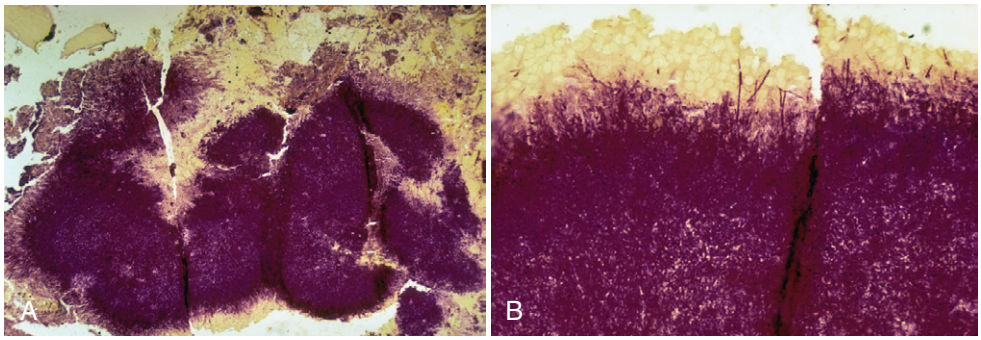

FIGURE 32-14 ■ Gram stain of an actinomycotic sulfur granule. **A,** ×100, **B,** ×400.

colonization without invasion may occur along any mucosal surface. Definitive diagnosis depends on demonstrating the characteristic histopathology and culture from a sterile body fluid or tissue biopsy. It is common to identify other organisms, including *Haemophilus (Actinobacillus) actinomycetemcomitans* and *Prevotella*, in addition to *Actinomyces* or *Propionibacterium*.

Complications of pulmonary actinomycosis relate to its ability to invade across anatomic barriers. Pleural empyema, cutaneous thoracic sinuses, mediastinitis, pericarditis, and vertebral osteomyelitis are not infrequent. Metastatic infection, including brain, skin, and bone, occurs more commonly with pulmonary actinomycosis than with other variants (e.g., cervicofacial disease) but is still unusual. With adequate therapy, death from actinomycosis is rare.

Prolonged antibiotic treatment is the key to curing actinomycosis. *Actinomyces* are universally susceptible to penicillin G, which should be given in intravenous doses of 12 to 20 million units daily for 4 to 6 weeks. Ceftriaxone has also been successfully used to provide prolonged parenteral therapy. This should be followed by at least 6 months of oral penicillin V or ampicillin. In cases with polymicrobial infection, the presence of other organisms may require modification of therapy. If β-lactamase–producing anaerobes are present, treatment choices as described for anaerobic pneumonia are recommended. On occasion, clindamycin fails because of concomitant infection by *H. actinomycetemcomitans*.

Chlamydophila psittaci (Formerly *Chlamydia psittaci*)—Psittacosis

Exposure to birds is the classic risk factor for psitticosis. Multiple species harbor the organism, but most cases have been acquired from canaries, parakeets, cockatiels, parrots, and pigeons. Although infected birds are typically ill, asymptomatic fecal carriage is well reported. *C. psittaci* can be detected in blood, tissues, feathers, and feces of infected birds. The organism is acquired by humans via inhalation of contaminated bird excreta. Although approximately 50% of cases are reported in owners of infected pet birds, 25% of sporadic cases and occasional outbreaks occur without a history of bird exposure. Psittacosis is also an occupational hazard in poultry business workers, especially those exposed to turkeys.

The symptoms of psittacosis may develop abruptly, with high fever and chills, or they may evolve slowly. Headache, arthralgia, and painful myalgia (especially in the head and neck) are prominent features. A severe cough develops that may be either dry and hacking or productive of mucoid sputum. Chest pain and dyspnea are present with extensive pulmonary involvement. Temperatures are 38°C to 40°C and are frequently accompanied by relative bradycardia. Splenomegaly or occasionally a pale macular rash (Horder's spots) can be seen. Laboratory findings are nonspecific, except occasionally for findings consistent with granulomatous hepatitis. The chest radiograph shows unilateral or bilateral bronchopneumonia in the lower lobes, often seeming to radiate out from the hilar areas.

C. psittaci is an obligate intracellular parasite that does not stain by the Gram method but can be seen as large intracytoplasmic inclusions in infected cells when stained with Giemsa stain. Cultivation of the organism, which requires tissue culture for growth, poses a threat to laboratory personnel and should be performed only in specialized facilities. The diagnosis of psittacosis is best made by demonstrating a fourfold rise in complement-fixing antibodies in paired acute and convalescent serum samples. A single titer of 1:16 or greater can be considered presumptive evidence of infection in a patient with compatible illness. Cross reaction of the antibody with *C. burnetii* or *Brucella* may occur.

The case-fatality rate is about 1% with antimicrobial therapy. Unusual complications include respiratory failure, encephalitis, hepatitis, disseminated intravascular coagulation, renal failure, and endocarditis. Treatment with doxycycline is recommended, but the clinical response may be slow. Because of the risk of relapse, therapy should be given for a minimum of 2 weeks after fever has resolved. Chloramphenicol, erythromycin, azithromycin, and moxifloxacin have shown in vitro activity.

Coxiella burnetti—Q Fever

Q fever occurs worldwide and is a particular public health problem in farming communities in Europe, North America, and Australia. *C. burnetii* asymptomatically infects a wide variety of domestic and wild animals as well as insects. The organism is highly resistant to drying and maintains infectivity after months of dormancy in contaminated soil. Transmission to humans occurs primarily via exposure to the urine, feces, placenta, or unpasteurized milk of an infected animal: cows, sheep, and goats are most common. Outbreaks have occurred in tanneries, dairies, and wool-rendering plants, among laboratory personnel, and in household members exposed to an infected cat or dog during parturition.[163,164]

Following an incubation period of 2 to 4 weeks, 10% to 20% of infected persons develop an atypical pneumonia syndrome.[163] On examination, high fever (≥40°C), relative bradycardia, conjunctivitis, hepatosplenomegaly, and chest crackles may be detected. Unlike other rickettsial infections, a rash is typically absent.[164] Laboratory studies often show a normal white blood cell count, decreased platelet count, and liver function tests suggestive of granulomatous hepatitis.[163] Chest radiography often reveals segmental opacities.

C. burnetii is a small, obligate intracellular bacterium that cannot be cultured on standard media or visualized with the Gram stain. Because of the high infectivity of the organism, cultures should be attempted only by experienced personnel in Biosafety Level 3 laboratory facilities. Diagnosis usually relies on demonstrating a fourfold rise in specific antibody titer from acute to convalescent serum samples or on pathologic findings, which may be augmented by immunohistochemical detection techniques or DNA amplification.

Although patients may be acutely ill on presentation, the disease is rarely fatal and generally runs its course in 1 to 2 weeks.[163] Some patients, however, particularly the elderly, have a very prolonged illness. Tetracyclines, especially doxycycline, are first-line therapy for Q fever. Quinolones have excellent in vitro activity and may be advantageous in the treatment of meningoencephalitis.[164] No special isolation procedures are recommended.

Nocardioisis

Although several other species (e.g., *Nocardia brasiliensis*) have also been associated with human infection, *N. asteroides* is the etiologic agent in over 80% of pulmonary or disseminated cases. The organism is widespread in nature, primarily in soil. The respiratory tract, skin, and gastrointestinal tract are portals of infection. Dysfunction of cell-mediated immunity and, to a lesser extent, immunoglobulin defects are predisposing factors. Thus, the rate of disease appearance is increased in patients who have a lymphoreticular malignancy, Cushing's disease, or acquired immunodeficiency syndrome (AIDS) or who are receiving immunosuppressive medications. Most reported cases recently have occurred in transplant patients, with the greatest risk in lung or heart transplant recipients and stem cell transplants. Persons with pulmonary alveolar proteinosis are also at increased risk. Nonetheless, approximately half of the patients who develop nocardiosis have no known underlying medical disorder.

Although nocardiosis and actinomycosis are clinically similar infections of the lower respiratory tract, nocardiosis can be distinguished by a lesser proclivity for sinus tract formation and a greater tendency for hematogenous dissemination in both healthy and impaired hosts. Dissemination occurs and may involve almost every organ system, but the central nervous system and skin are most commonly involved.[165] Many patients with pulmonary nocardiosis have low-grade fever, fatigue, weight loss, productive cough, and pleuritic chest pain for weeks prior to seeking medical attention. However, some immunosuppressed patients present with acute, fulminant pneumonia. Physical examination is nonspecific unless sites of dissemination are obvious. Neurologic signs of a mass lesion may be present. Cutaneous dissemination appears as multiple subcutaneous abscesses with or without sinus tracts. Chest radiographs commonly demonstrate localized bronchopneumonia or lobar consolidation, but solitary, multiple, or miliary nodules, abscesses, and pleural effusion also occur.

Nocardia spp. are gram-positive bacilli that appear as beaded, branching filaments. Unlike the anaerobic Actinomycetaceae, *Nocardia* requires aerobic growth conditions and is usually weakly acid-fast when stained by the modified Ziehl-Neelsen method with 1.0% sulfuric acid as the decolorizing agent (Fig. 32-15). Although the organism can be cultivated on conventional blood agar or Sabouraud medium, growth may not be apparent for 3 to 21 days. Although the organism occasionally colonizes the upper respiratory tract, recovery of *Nocardia* from a culture of sputum or invasively obtained material is highly predictive of the diagnosis. Extension of the pulmonary infection to the pleural cavity, with or without chest wall involvement, occurs in 10% of patients.

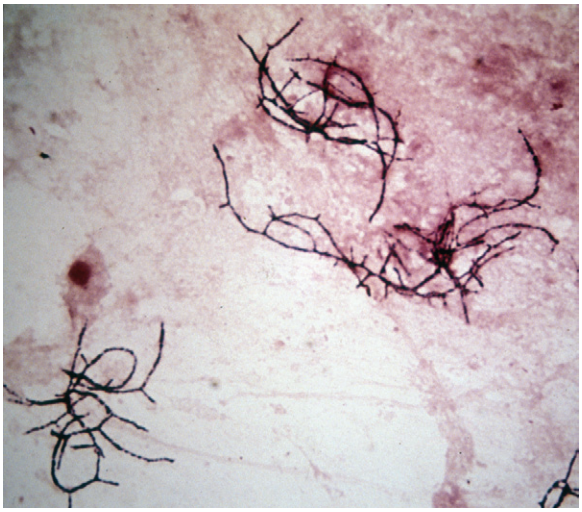

FIGURE 32-15 ■ Modified acid-fast stain of sputum containing *Nocardia asteroides* shows filamentous branching organisms.

Mortality approaches 50% in those with central nervous system lesions but is less than 10% in those with only pulmonary disease.[165] Because of in vitro synergy, TMP-SMX has become the standard treatment.[165] In case of sulfa allergy or a resistant organism, minocycline, amikacin, cefotaxime, imipenem, or linezolid may be useful, but choices should always be guided by the results of susceptibility testing.[165,166] Therapy must be prolonged to prevent relapses. Adequate drainage or excision of abscesses and empyema is a crucial adjunct to antimicrobial therapy.

Melioidosis (*Burkholderia pseudomallei*)

In the most highly endemic areas, melioidosis may be the most common cause of severe CAP.[167] *B. pseudomallei* is found in soil, vegetation, and water throughout tropical regions between latitudes 20°N and 20°S, especially in Southeast Asia.[28,168] In the indigenous population of northern Australia, the yearly incidence is 25 cases/100,000.[169] Acquisition of the organism is through cutaneous inoculation or inhalation.[28] The incubation period of acute pneumonia is 1 to 21 days.[168] The infection may remain latent for months to years.[168] Risk factors for clinical disease include diabetes, alcohol-related problems, and renal disease. Meteorologic conditions, such as typhoons or episodic heavy rain, may increase the risk of acute fulminant pneumonia.

Melioidosis can produce either acute fulminant pneumonia or indolent, cavitary disease. Clinical manifestations of acute melioidosis include high fever, prostration, dyspnea, pleuritic chest pain, purulent sputum, and hemoptysis. Cellulitis and lymphangitis often occur at the site of cutaneous inoculation. Concomitant bacteremia is common.[167] The chest radiograph typically shows

diffuse miliary nodules, which may expand and cavitate. Subacute or chronic *B. pseudomallei* pneumonia is milder and often occurs after a period of latency. Patients may be entirely asymptomatic (e.g., disease demonstrated by radiograph only), or they may present with an illness that is clinically and radiographically indistinguishable from chronic pulmonary tuberculosis.

B. pseudomallei is an aerobic, gram-negative bacillus that grows readily on routine culture media. Specific IgM to *B. pseudomallei* can be demonstrated by indirect immunofluorescence in the serum of patients who have active infection. Fourfold rises in hemagglutination and complement fixation antibodies are other serologic aids for diagnosing melioidosis. Low-titer hemagglutinating antibodies may be found in persons with prior exposure to soil and water in endemic areas. Without evidence of active infection, such persons do not warrant therapy.

Despite improvements in recognition and treatment, melioidosis is still associated with high morbidity and mortality.[167] *B. pseudomallei* is usually susceptible to carbenems, ceftazidime, piperacillin-tazobactam, tetracyclines, sulfonamides, chloramphenicol, and TMP-SMX. Optimal treatment for disseminated or life-threatening melioidosis requires initial intensive therapy with a carbapenem or ceftazidime followed by 3 months of TMP-SMX.[28,167]

Rhodococcus equi

Rhodococcus equi may cause lung abscess and pneumonia. Most cases occur in the setting of impaired cell-mediated immunity (e.g., high doses of corticosteroids, HIV infection, solid organ transplantation),[170] and a history of animal exposure is common. Illness develops subacutely, mimicking mycobacterial or fungal infection. Bacteremia can occur despite the intracellular location. Chest radiographs often show nodules that gradually cavitate.

The organism is a gram-positive bacillus. It may stain weakly acid-fast but is much smaller than mycobacteria. The most effective regimens appear to be vancomycin or erythromycin. The addition of rifampin may be useful. Development of resistance has occurred with β-lactam antibiotics. Prolonged therapy is necessary to prevent relapse.

Anthrax (*Bacillus anthracis*)

Although *B. anthracis* is detected in many agricultural regions, anthrax is a rare infection in the developed world. The spores are the transmissible agent of infection. Spores reside in soil, water, and vegetation and primarily infect large herbivorous animals (e.g., cows, sheep, and horses). Humans are often infected via contact with contaminated animals or animal products (e.g., animal hides and wools).[33] Ominously, anthrax has become a proven agent of bioterrorism.[171–173]

The manifestations of anthrax are cutaneous, gastrointestinal, and inhalational (woolsorters' disease). The inhalational form is the most severe. Disease follows inhalation and germination of *B. anthracis* spores and production of toxin. Clinical illness begins insidiously with fever, malaise, nonproductive cough, and precordial pain. This stage is followed by rapid pulmonary deterioration with dyspnea, stridor, chest pain, tachypnea, cyanosis, nausea, vomiting, and drenching night sweats. Diffuse edema of the neck and anterior chest may be evident. Meningitis is a common complication.

Radiographically, the lung parenchyma is initially clear. A widened mediastinum and bilateral pleural effusions are clues to the diagnosis of inhalational anthrax. Mediastinal widening occurs in 100% of inhalational anthrax cases but only 8% of control CAP patients.[174] CT scans of the chest may be required to define these characteristics.[33] Later findings include vascular engorgement and lung parenchymal opacities, although usually not a typical bronchopneumonia.

B. anthracis is a large, facultative, gram-positive rod that forms centrally located spores. The organism grows readily on routine culture media and can be rapidly recovered from cultures of blood, sputum, and pleural fluid. In advanced disease, the organism can be demonstrated by Gram stain of peripheral blood.[33] Anthrax can be detected in nasal swabs of persons exposed to anthrax spores. However, the predictive value of this test for diagnosing clinical disease is ill-defined.[33]

Treatment recommendations for inhalational anthrax may be affected by resistance patterns and the potential need to treat mass casualties. Current recommendations for inhalational anthrax call for initial treatment with ciprofloxacin plus one or two additional antibiotics that have in vitro activity, such as clindamycin, vancomycin, imipenem, meropenem, chloramphenicol, penicillin, ampicillin, rifampin, and clarithromycin.[175] If the recovered isolate is susceptible, therapy can be changed from the fluoroquinolone to maximum doses of penicillin G or doxycycline. Intravenous therapy may be converted to oral therapy once the patient's condition stabilizes for 60 days total. Although the reported mortality rate has been as high as 90%, 6 of 11 patients with inhalational anthrax survived during the 2001 anthrax attacks in the United States.[33]

Tularemia (*Francisella tularensis*)

Although *F. tularensis* has been recovered from numerous insects and species of wild or domestic mammals throughout the temperate zones of the Northern Hemisphere, fewer than 200 cases of tularemia/yr are reported in the United States.[34] Humans acquire infection following direct contact with tissues of an infected animal (as when skinning or eating an infected animal), through the bite of an infected tick or deerfly, or by inhalation of contaminated aerosols.[27,34,176] Persons who engage in landscaping or agricultural activities that generate aerosols in highly endemic areas are at particular risk of developing pneumonic tularaemia.[27] Because of the efficiency of aerosol transmission, *F. tularensis* is regarded as a potential biowarfare weapon.[34]

Pneumonia occurs as a consequence of inhalation of contaminated aerosols or as a complication of bacteremia. Clinical manifestations of inhalational pneumonia

typically begin abruptly with fever, chills, malaise, and headache. Shortly thereafter, dyspnea, cough, and chest pain develop.[34] Chest radiographs are usually normal at the onset of systemic symptoms (i.e., 3 to 5 days following aerosol exposure) but ultimately show diffuse bronchopneumonia, often with hilar adenopathy.[34] Pleural effusion is relatively common and may occur without parenchymal involvement.[34]

F. tularensis is a fastidious, pleomorphic, gram-negative bacillus that is rarely visualized on Gram stain of sputum and requires specially enriched media for optimal recovery by culture. Because of the hazardous nature of the organism, culture is best undertaken by reference laboratories. The organism can also be rapidly identified in tissues, secretions, and exudates by use of immunohistochemical techniques.[34] Retrospective diagnosis can be accomplished by demonstrating a fourfold rise in agglutinating titers. A single titer of 1:160 or greater is compatible with past or current infection.

Mortality can be as high as 60% if pneumonic tularemia is not suspected and treated appropriately. Although gentamicin has been used successfully, streptomycin remains the preferred therapy.[34] Ciprofloxacin is an acceptable alternative agent, but doxycycline and chloramphenicol are associated with higher relapse rates and require a longer duration of therapy.[34] Ceftriaxone is unsatisfactory despite its demonstrated in vitro activity. In the event of known aerosol exposure to *F. tularensis*, antimicrobial prophylaxis with doxycycline or ciprofloxacin for 14 days is recommended.[34]

Plague (*Yersinia pestis*)

Zoonotic plague is typically associated with ground squirrels, rabbits, prairie dogs, rats, and other small ground animals. Rodent fleas are responsible for transmission of the organism between animal hosts. Humans become infected when bitten by an infected rodent flea, by handling an infected animal carcass, or less frequently by inhaling an aerosol from a human or animal with pulmonary involvement. Most cases of plague in the United States occur in rural regions of New Mexico, Arizona, and California.[26] Because of the disease severity and potential for aerosol transmission, *Y. pestis* is regarded as a potential biowarfare weapon.[32]

Three clinical forms of infection exist: bubonic, septicemic, and pneumonic. Although the latter presents as a primary pneumonia, pulmonary involvement may also complicate bubonic and septicemic infections. Plague pneumonia may develop 2 to 7 days after the initial exposure. Fever and toxicity occur early, followed by chest pain, productive cough, dyspnea, and hemoptysis. The hemoptysis causes confusion with the hantavirus pulmonary syndrome, which overlaps with plague geographically in the United States. If pulmonary disease complicates bubonic plague, painful adenopathy is also noted. In the septicemic form, the patient may show only signs of septic shock in association with pneumonia. Chest radiographs commonly reveal bilateral lower lobe alveolar opacities, but nodules, adenopathy, and pleural effusions have been described.

Y. pestis is a short, nonmotile, gram-negative rod. Most patients with plague have positive blood cultures. In addition, the organism can be recovered from sputum and lymph node aspirates by routine bacteriologic techniques. Fluorescent antibody staining of sputum and tissues facilitates the rapid diagnosis of plague but is available only in specialized laboratories.

Because of the potential for person-to-person transmission, all patients with plague pneumonia should be isolated. Recommended treatment consists of gentamicin or doxycycline.[32,177] Alternative treatments include fluoroquinolones, streptomycin, or chloramphenicol. For all regimens, the duration of treatment should be at least 10 days.

Moraxella catarrhalis

M. catarrhalis causes pneumonia, acute exacerbations of COPD, otitis media, and maxillary sinusitis.[178] Pneumonia typically occurs in patients with underlying COPD, although alcoholism, malnutrition, increased age, congestive heart failure, and malignancy are also frequent accompaniments.[178]

Moraxella pneumonia is heralded by several days of dyspnea and cough before pneumonia is diagnosed. Pleuritic chest pain and blood-tinged sputum may occur. High fever, toxic states, and empyema are uncommon.[178] Chest radiographs show bronchopneumonia or lobar pneumonia that usually involves a single lobe. Pleural effusion and cavitation may occur.

Because *M. catarrhalis* may be a part of the normal upper respiratory tract flora, only adequately screened sputum samples provide useful diagnostic information. A purulent specimen that contains many intracellular Gram-negative diplococci and yields heavy growth of *M. catarrhalis* is highly suggestive of true pneumonia. Blood cultures are rarely positive.[178]

The mortality of *M. catarrhalis* is approximately 10% and is attributable primarily to exacerbations of severe underlying pulmonary disease.[178] Effective agents include TMP-SMX or a cephalosporin, macrolide, tetracycline, quinolone, or β-lactam–β-lactamase inhibitor combination. Virtually all isolates are resistant to penicillin and ampicillin because of β-lactamase production.

Neisseria meningitidis

Neisseria meningitidis pneumonia is often a surprise culture diagnosis because clinical manifestations of meningococcal pneumonia resemble those of pneumococcal pneumonia or an acute exacerbation of COPD. The estimated incidence of sporadic primary meningococcal pneumonia is 0.4 cases/100,000 adults/yr; pneumonia also complicates 5% to 15% of invasive meningococcal infections.[179] Rates of asymptomatic carriage vary according to the season and are increased under conditions of crowding.[179] Person-to-person transmission occurs largely through droplet aerosols. Nosocomial clusters of meningococcal pneumonia are well described.

The Gram stain appearance of *Neisseria* in sputum is similar to that of *Moraxella* and *Acinetobacter*. Rates of

isolation of the organism from blood, cerebrospinal fluid, and pleural fluid from patients with meningococcal pneumonia are highly variable.

Aqueous penicillin G for 10 days, in daily doses of 4 to 6 million units intravenously, is adequate therapy for isolated pneumonia. Coexistence of septicemia or meningitis warrants increasing the dose to 18 to 24 million units/day. Chloramphenicol remains a useful drug in developing countries.[179] Isolates with decreased susceptibility to penicillin are not yet a significant problem in the United States.[180]

Because meningococci can be transmitted from patients with pneumonia to susceptible contacts, respiratory droplet isolation should be implemented during the initial days of treatment. Chemoprophylaxis with rifampin is advised for household and other intimate contacts of the patient. Alternative regimens for prophylaxis include ceftriaxone or ciprofloxacin. These prophylaxis recommendations are based on those for meningitis; however, the epidemiology of meningococcal infections suggests that a similar benefit can be derived by prophylaxis of pneumonia contacts.

Pasteurella multocida

Pasteurella multocida is part of the normal oral flora of many domestic and wild mammals. Although skin and soft tissue infections following a cat or dog bite are more common manifestations of human disease, sporadic cases of pneumonia, lung abscess, and empyema occur in patients with chronic respiratory diseases, including COPD, carcinoma, and bronchiectasis. Most patients recall prior exposure to animals.

Pasteurella pneumonia is indistinguishable from other etiologies of CAP, although empyema may occur more frequently with it. The organism is a small, gram-negative coccobacillus that cannot be distinguished from other gram-negative rods by Gram stain of sputum. Identification of the organism by sputum culture is easily accomplished. Blood and pleural fluid may also yield the organism.

The treatment of choice for *P. multocida* pneumonia is penicillin G, 4 to 12 million units daily for 10 to 14 days. Tetracycline, amoxicillin-clavulanate, second- and third-generation cephalosporins, TMP-SMX, fluoroquinolones, and chloramphenicol are also active.

LUNG ABSCESS

Lung abscesses are pus-containing necrotic lesions of the lung parenchyma that often contain an air-fluid level. A similar process with multiple small cavities less than 2 cm in diameter has been designated necrotizing pneumonia by some clinicians. Lung abscess may be associated with infections caused by pyogenic bacteria, mycobacteria (see Chapters 34 and 35), fungi (see Chapter 36), and parasites (see Chapter 37). Lung abscess, often infected but sometimes bland, may also complicate pulmonary infarction (see Chapter 51), primary and metastatic malignancies (see Chapters 47 and 49), and the necrotic conglomerate lesions of silicosis and coal miners' pneumoconiosis (see Chapter 65). Empyema is covered in Chapter 74. Information about treatment of lung abscess is covered in a previous section of this chapter.

CAUSES OF NONRESPONDING PNEUMONIA

The causes of nonresponding pneumonia are classified according to the etiology as infectious, noninfectious, and of unknown origin.[181] Table 32-15 shows common infectious and noninfectious causes.

Infectious Causes

In hospitalized CAP, infections are responsible for 40% of nonresponding CAP. The most frequent microorganisms found are *S. pneumoniae*, *Legionella*, *P. aeruginosa* and *S. aureus*. Microorganisms found may show resistance against antibiotics prescribed. Resistance, although infrequent, may also develop during treatment specially related to the new fluoroquinolones, levofloxacin, and macrolides.[114] Recently, pleuropulmonary complications PVL-positive community-acquired MRSA pneumonia have been reported.[141]

Patients with CAP or HAP may also fail to respond adequately because of an unusual microbial etiology not adequately covered with the standard empirical therapeutic regimens. For example, *P. aeruginosa* causes

TABLE 32-15. Causes of Nonresponding Pneumonia

INFECTIOUS PNEUMONIA
Resistant microorganisms
Community-acquired pneumonia (e.g., *Streptococcus pneumoniae*, *Staphylococcus aureus*)
Nosocomial pneumonia (e.g., *Acinetobacter*, MRSA, *Pseudomonas aeruginosa*)
Uncommon microorganisms (e.g., *Mycobacterium tuberculosis, Nocardia* spp., fungi, *Pneumocystis jirovecii*)
Complications of pneumonia

Drug-induced pulmonary disease
Pulmonary vasculitis

MRSA, methicillin-resistant *Staphylococcus aureus.*

about 10% of cases of nonresponding CAPs, whether due to persistent infection or to subsequent nosocomial superinfection.[182] Similarly, the most common causative organisms in an elderly nursing home population with CAP who failed to respond to treatment after 72 hours of antimicrobial therapy were MRSA (33%), enteric gram-negative bacilli (24%), and *P. aeruginosa* (14%).[183] In nonresponding VAP, up to 50% of the episodes are caused by multiresistant microorganisms, with the most frequent being MRSA, *P. aeruginosa*, and *Acinetobacter* spp.[184,185]

Unusual microorganisms to be considered in patients who fail to respond to initial antimicrobial therapy include *Mycobacteria*, *Nocardia* spp., anaerobes, fungi, *Pneumocystis jirovecii*, and other microorganisms requiring specific antibiotic treatment other than that recommended in the guidelines for CAP or HAP. Investigation of the etiology of some of these microorganisms requires exhaustive review to search for risk factors, including epidemiology, personal habits (e.g., illicit drug use), environmental factors, professional, leisure, pets, and journeys.

Local or metastatic infectious complications also contribute to a clinical response. The incidence of metastatic infections such as endocarditis, arthritis, pericarditis, meningitis, or peritonitis is greater in bacteremic pneumonia. Empyema is one of the most frequent complications in pneumonia and is thus a common cause of nonresponse that must be ruled out with thoracentesis when a pleural effusion is present. Another cause of nonresponse is abscess formation or necrotizing pneumonia because antibiotics have a decreased activity in necrotic tissues.

Last, it should be recognized that in 30% of the cases, no specific cause for lack of response can be identified despite adequate antibiotic treatment. This may be due to the presence of comorbidities or to an exaggerated or diminished inflammatory response.

Noninfectious Causes

Noninfectious diseases with acute involvement of the pulmonary parenchyma may simulate pneumonia. This category includes neoplasms, pulmonary infarction, pulmonary hemorrhages, bronchiolitis obliterans and organizing pneumonia, eosinophilic pneumonia, hypersensitivity pneumonitis, and drug-induced lung disease. Alveolar cell lung cancer may be particularly difficult to distinguish radiographically from pyogenic pneumonia. The frequency of noninfectious etiologies has been reported to be 22% in CAP and 19% in nosocomial pneumonia. Table 32-15 summarizes infectious and noninfectious causes of nonresponding pneumonia.

Diagnostic Evaluation

In patients with nonresponding or progressive pneumonia, complete reevaluation of the history, physical examination, and laboratory studies is required.[181] In the evaluation of possible causes, important epidemiologic clues mentioned elsewhere in this chapter may suggest unusual microorganisms, unexpected resistance to antimicrobials, or host immune disorders such as HIV infection.

Microbiologic Studies

The microbiologic investigation requires comprehensive culture and microscopic examination of the sputum, urinary antigen detection, blood cultures, and serum antibody detection (Table 32-16).

If simpler procedures do not provide a rapid diagnosis, invasive techniques (i.e., bronchoscopy) are recommended in most cases of nonresponding pneumonia. Both protected sheath brush and BAL sampling should be done during the same procedure. Quantitative bacterial cultures of these samples are preferred. The sensitivity is around 40% in the context of nonresponding CAP and 70% in nosocomial ICU pneumonia[185]; sensitivity is reduced by the previous administration of antibiotics.[71] In patients undergoing mechanical ventilation, the tracheal aspirate provides a good diagnostic yield in nonresponding pneumonia (sensitivity of 93% and specificity of 80% for a cutoff of 10^5 CFU/ml). Gram stain of cytocentrifuged BAL fluid can rapidly identify intracellular microorganisms and may guide decisions regarding changes in antimicrobial therapy. As with sputum, comprehensive microbiologic studies should be performed

(Table 32-17). Complete processing of BAL cells may provide other useful information. DNA amplification and hybridization procedures may be warranted. When present, pleural fluid should be obtained and subjected to a full array of studies.

Imaging Studies

In nonresolving pneumonia, a simple chest radiograph may demonstrate pleural effusion, cavitation, or new changes. In progressive pneumonia, clinical deterioration and the extension of the radiographic image may appear during the first 72 hours after the initiation of satisfactory treatment.

Pulmonary CT scans provide a more detailed study of the parenchyma, interstitium, pleura, and mediastinum. In the right clinical setting, the appearance of nodular images with the halo sign (i.e., a nodule surrounded by a halo of ground-glass attenuation, especially near the pleura) on CT scan is suggestive of pulmonary aspergillosis or mucormycosis.[186,187] Nodules of similar appearance have also been described in cytomegalovirus infection, Wegener's granulomatosis, Kaposi's sarcoma, and hemorrhagic metastasis. Chest radiography of *P. jirovecii* pneumonia shows characteristic ground-glass opacities consistent with interstitial pneumonia. Infection by *Nocardia* spp., *M. tuberculosis*, or Q fever may result in nodules or multiple masses with or without cavitation. Diffuse or mixed interstitial and alveolar opacities may be due to viral infections or *M. pneumoniae*.

Other imaging studies, such as perfusion-ventilation scintigraphy, may be performed according to the clinical suspicion of pulmonary embolism. Spiral CT scans and pulmonary arteriography complement this diagnostic procedure.

Therapeutic Management

Correction of Host Abnormalities

Defects related to the host's immune system may impede recovery from pneumonia. Immunodeficiency may occur as a complication of cancer chemotherapy, immunosuppressive therapy, or corticosteroid use; or it may result from a congenital (e.g., agammaglobulinemia) or acquired (e.g., HIV infection) immune defect. Many of these immune system deficiencies are not remediable; however, drug-related immunosuppression may be improved by discontinuing the offending agent. Even if complete discontinuation is not medically feasible, tapering or intermittent dosage may improve immune function, particularly with corticosteroids.

Granulocytopenia (absolute granulocyte count << 500/μL) has been associated with fulminate, antibiotic-unresponsive pneumonia. Although the use of granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor has not been shown to decrease infectious mortality in patients with established infections,[188] use of these agents is reasonable in the treatment of profoundly neutropenic patients with severe pneumonia unresponsive to antimicrobial therapy.[189] Administration of activated protein C has been shown to improve survival in selected critically ill patients with septic shock.[190]

Antimicrobial Adjustment

Unless there is undrained pus, infectious causes of nonresponding pneumonia require a diagnostic evaluation and adjustment in empirical treatment.[181] The ideal time to make these changes is unknown, although it has been suggested that one should wait until 72 hours after the initiation of treatment except in the presence of severe clinical deterioration or dramatic progression as determined by chest radiology. Prior to initiating the new therapeutic schedule, new samples should be obtained for microbiologic studies.

In nonresponding CAP, strong consideration should be given to extending the antibacterial spectrum to ensure coverage of resistant *S. pneumoniae*, *P. aeruginosa*, *S. aureus*, and anaerobes. Such broad-spectrum therapy should be undertaken after all abscesses or empyemas have been drained, the results of all previous cultures are reviewed, and whenever possible, vigorous new efforts have been made to identify the offending microorganisms. The specific antimicrobial regimen chosen depends on patient risk factors, disease severity, and the local epidemiology of antimicrobial resistance. In community MRSA (PVL strains), antimicrobial treatments may include, depending on susceptibility tests, linezolid or clindamycin plus vancomycin.[4,7,141]

In nonresponding nosocomial pneumonia, combinations of up to three antibiotics may be necessary to cover *P. aeruginosa*, MRSA, and the endemic flora of each hospital, such as *Acinetobacter* spp. or other microorganisms.[184] Occasionally, empirical coverage against *Aspergillus* spp. should be considered (i.e., severe

COPD, significant immunosuppressive therapy, corticosteroids treatments), especially if supported by clinical, radiologic,[186] or laboratory data.[191]

PREVENTION

Vaccinations

Prevention of pneumonia may be possible by administering the pneumococcal and influenza (during flu season) vaccines for eligible patients. Criteria for administration of pneumococcal and influenza[192] vaccines are presented in Tables 32-18 and 32-19, respectively. The recommendations for administration of live, attenuated influenza vaccine are healthy persons from 5 to 49 years including health care providers and household contacts of high-risk patients. This intranasally live vaccine is an alternative for healthy persons and must be avoided in high-risk persons with chronic underlying diseases or immunodeficiencies.[40] Data from meta-analyses of randomized, controlled trials show that pneumococcal vaccination reduces the incidence of definitive and presumptive pneumococcal pneumonia but differ as to the degree to which this benefit occurs in the elderly (i.e., ≥65 yr) or other high-risk patients.[193] Data from randomized clinical trials also demonstrate that the influenza vaccine reduces the incidence of clinical influenza in the elderly, and a meta-analysis of other trials and a population-based analysis show that the influenza vaccine reduces mortality and hospitalizations for any cause in the elderly.[194]

Strategies to Prevent Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia

The most successful strategies to prevent HAP are those that increase staff handwashing, ensure aseptic

TABLE 32-18. Recommendations for Administration of Polysaccharide Pneumococcal Vaccine*†

Indications	Revaccination
Age > 65 yr	If the patient < 65 yr at the time of the initial vaccination, provide the second vaccination dose ≥5 yr after the first dose. If the patient ≥ 65 at the time of initial vaccination, revaccination is not recommended.
Age 2-64 yr with: sickle cell disease, asplenia, or immunocompromised state (HIV infection, leukemia, lymphoma, multiple myeloma, generalized malignancy, chronic renal failure, nephrotic syndrome, organ or bone marrow transplant, or receiving immunosuppressive therapy).	For patients ≤ 10 yr, provide revaccination 3 yr after the previous dose. For patients > 10 yr, provide a single revaccination dose ≥5 yr after the previous dose.
Age 2-64 yr with: chronic cardiopulmonary disease (CHF, cardiomyopathy, COPD, emphysema), diabetes mellitus, alcoholism, chronic liver disease, cerebrospinal fluid leak, or from high-risk ethnic community (e.g., Alaska Natives)	No revaccination

*Although there is no specific precaution, the currently available polysaccharide vaccine generally lacks efficacy in persons < 2 yr of age.
†Although the safety of the currently available polysaccharide vaccine has not been assessed during the first trimester of pregnancy, no adverse consequences have been reported.
CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus.
Modified from Centers for Disease Control and Prevention: Prevention of pneumococcal disease: Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Morb Mortal Wkly Rep 46:1–24, 1997.

TABLE 32-19. Recommendations for Administration of Influenza Vaccine*

Age ≥ 50 yr
Nursing home resident
Chronic cardiopulmonary disease (including asthma)
Chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies
Immunosuppression (including immunosuppressive therapy and HIV)
Children and adolescents (aged 6 months to 18 years) receiving long-term aspirin therapy
Women who will be in the second or third trimester of pregnancy during the influenza season
Health care workers (primarily to avoid transmission of influenza virus to high-risk patients)
Close contacts of high-risk persons (primarily to avoid transmission of influenza virus to high-risk patients)

**Note*: Avoid giving vaccine to patients with anaphylactic allergy to eggs or to other influenza vaccine components. The optimal period for vaccination is October to November. However, it is acceptable to provide vaccine from September up to early March.
Modified from Bridges CB, Harper SA, Fukuda K, et al: Prevention and control of influenza: Recommendations of the Advisory Committee on Immmunization Practices (ACIP). MMWR Recomm Rep 52:1–34, 2003.

suctioning techniques, and prevent aspiration. The greatest attention and highest-quality studies have focused on patients undergoing mechanical ventilation in whom elevation of the head of the bed, aspiration of subglottic secretions, and use of oscillating beds for surgical and neurologic patients may prevent VAP.[195] Although selective gut decontamination with antibiotics may also decrease the incidence of VAP, it has not been consistently associated with a shorter duration of ventilation or ICU stay or with better survival.[196] This strategy is not generally recommended, because this approach may increase antimicrobial resistance.[195]

The choice of an antimicrobial agent for treating pneumonia should target the likely causative organism, which may be identified by Gram stains and cultures of sputum, pleural fluid, other respiratory tract specimen and blood.

However, it is often not possible to determine the etiology of pneumonia on clinical grounds and bodily fluid samples. The clinical presentation, risk factors, and epidemiology considerations as well as Gram stain of sputum may not be diagnostic. Thus, prompt initiation of effective antimicrobial therapy often requires the use of empirical regimens. Once the offending pathogenic organism has been identified and its antimicrobial susceptibility determined, more specific therapy should be given unless there are compelling clinical contraindications. Thoughtful application of these simple principles can minimize the morbidity, mortality, and socioeconomic cost of pyogenic bacterial pneumonias.

KEY POINTS

- All patients with suspected pneumonia should have a chest radiograph. Gram stains and cultures of blood, sputum, and other sites should be obtained in hospitalized patients prior to treatment. Specialized serologic or urinary markers are essential for certain microbial infections. *S. pneumoniae* and *L. pneumophila* urinary antigens can make an etiologic diagnosis with reasonable sensitivity and specificity.
- Infection by the aerosolization route occurs with the intracellular bacteria such as *M. pneumoniae*, *Chlamydophila* spp., and *C. burnetii*, whereas infection occurs by aspiration with *S. pneumoniae*, *H. influenzae*, gram-negative bacilli, and other organisms. Aside from inhalational pneumonia due to *Legionella* or contaminated medical aerosols, aspiration is the cause of HAP, especially in intubated patients.
- Culture procedures for viruses and fastidious bacteria, *M. pneumoniae, C. pneumoniae, L. pneumophila*, and *B. pertussis* are too insensitive and too slow to be therapeutically relevant and should be detected by nucleic acid amplification tests.
- In elderly and immunocompromised patients, the signs and symptoms of pneumonia may be muted and overshadowed by nonspecific complaints. Fever higher than 38.5°C or accompanied by chills should never be attributed to bronchitis without examining a chest radiograph. Elderly patients with pneumonia who present with altered mental status without fever have a delay in receiving antibiotics and this delay affects mortality.
- The treatment for pneumonia should be pathogen-directed, but pathogens are rarely identified initially. Therefore, the setting in which the patient resides (e.g., community, hospital, nursing home), the severity of the disease, the age of the patient, the presence of comorbidities and immunosuppression, previous antimicrobial therapy, and specific clinical and radiologic manifestations of the illness must be considered.
- If the etiologic agent has been reliably identified, the antimicrobial regimen should be adjusted based on the results of in vitro susceptibility testing. The ideal drug for a known pathogen has the narrowest spectrum of activity and is the most efficacious, least toxic, and least costly.

PREVENTION
Conventional Infection Control Approaches
Specific Prophylaxis against VAP
Implementing a Structured Prevention Policy

INTRODUCTION

Ventilator-associated pneumonia (VAP) is the most frequent intensive care unit (ICU)–acquired infection among patients who are treated with mechanical ventilation.[1,2] In contrast to infections of other organs (e.g., urinary tract and skin), for which mortality ranges from 1% to 4%, the mortality rate for VAP, defined as pneumonia occurring more than 48 hours after the onset of mechanical ventilation, ranges from 20% to 50%, and can even be higher when lung infection is caused by high-risk pathogens.[1–3] Although the attributable mortality rate for VAP is still debated, good evidence indicates that VAP prolongs the duration of mechanical ventilation and the ICU stay.[1,2] Approximately 50% of all antibiotics prescribed in an ICU are administered for respiratory tract infections.[4] Because several studies have shown that appropriate antimicrobial treatment of patients with VAP significantly improves outcome, rapid identification of infected patients and accurate selection of antimicrobial agents are important clinical goals.[1] Agreement is lacking, however, about the appropriate diagnostic, therapeutic, and preventive strategies for VAP.

PATHOGENESIS

Normally, a variety of defense mechanisms protect the normal human respiratory tract from infection. Examples include anatomic barriers, such as the glottis and larynx; cough reflexes; constituents of tracheobronchial secretions; mucociliary clearance; epithelial lining fluid and surfactant components; cell-mediated and humoral immunity; a phagocytic system that involves alveolar macrophages and recruited neutrophils; and both humoral and cell-mediated immunity.[5,6] When these coordinated components function properly, invading microbes are eliminated and clinical disease is avoided. When these defenses are impaired, however, or if they are overcome by virtue of a high inoculum of organisms or organisms of unusual virulence, pneumonitis results.

As suggested by the infrequent association of VAP with bacteremia, most of these infections appear to result from aspiration of potential pathogens that have colonized the mucosal surfaces of the oropharyngeal airways, the dental plaque, and/or the paranasal sinuses.[6] Endotracheal intubation not only compromises the natural barrier between the oropharynx and trachea, but also facilitates the entry of bacteria into the lungs by pooling and leakage of contaminated secretions around the endotracheal tube cuff from the subglottic area below the true vocal cords.[7] This phenomenon occurs in most intubated patients, whose supine position may facilitate its occurrence.[8] Moreover, biofilm formation on the inner and outer surfaces of the endotracheal tube provides a protected environment for pathogens. Bacterial aggregates in biofilm dislodged during suctioning are

dangerous for the lung, because they are difficult to clear by host immune defenses and difficult to eradicate with antibiotics.

Tracheobronchial colonization with gram-negative bacilli (GNB) usually precedes the onset of VAP. Risk factors for tracheobronchial colonization appear to be the same as those that favor pneumonia and include advanced age, more severe illness, longer hospitalization, prior or concomitant use of antibiotics, malnutrition, endotracheal intubation, depressed level of consciousness, immune suppression from disease or medication, azotemia, underlying pulmonary disease, and longer duration of mechanical ventilation.[1,9,10] Experimental studies have linked some of these risk factors with changes in adherence of GNB to respiratory epithelial cells. Although formerly attributed to losses of cell surface fibronectin, these changes in adherence also reflect alterations of cell surface carbohydrates. Bacterial adhesins and prior antimicrobial therapy appear to facilitate the process. Interestingly, Enterobacteriaceae usually appear in the oropharynx first, whereas *Psuedomonas aeruginosa* more often appear first in the trachea.[11]

Although the stomach can be a reservoir for pneumonia pathogens, the gastropulmonary route of infection is not always the primary route of infection in critically ill patients.[12] Progression of colonization from the stomach to the upper respiratory tract with subsequent episodes of VAP could not be demonstrated in several studies, and efforts to eliminate the gastric reservoir with antimicrobial therapy without decontaminating the oropharyngeal cavity have generally failed to prevent VAP.[13] In fact, there is more than one potential pathway for colonization of the oropharynx and trachea in such a setting, including cross infection from the hands of health care personnel, and contaminated respiratory therapy equipment. Patient care activities, such as bathing, oral care, tracheal suctioning, enteral feeding and tube manipulations, provide many opportunities for transmission of pathogens when meticulous infection control practices are not followed.

EPIDEMIOLOGY

Incidence

The exact incidence of VAP varies widely depending on the case definition of pneumonia and the population being evaluated. For example, the incidence may be up to two times higher in patients diagnosed by qualitative or semiquantitative sputum cultures compared to quantitative cultures of lower respiratory tract secretions. However, all studies confirmed that nosocomial pneumonia is considerably more frequent in ventilated patients than in other ICU patients, with the incidence increasing by as much as 6- to 20-fold in this subset of patients.[14,15] VAP occurs in 9% to 27% of all intubated patients, and its incidence increases with duration of ventilation.[10] The risk of VAP is highest early in the course of the hospital stay, and is estimated to be 3% per day during the first 5 days of ventilation, 2% per day during days 5 to 10 of ventilation, and 1% per day after this.[10] Since most mechanical ventilation is short term, approximately half of all episodes of VAP occur within the first 4 days of mechanical ventilation. In a large epidemiologic study, independent predictors of VAP retained by multivariate analysis were a primary admitting diagnosis of burns, trauma, central nervous system disease, respiratory disease, or cardiac disease; mechanical ventilation during the preceding 24 hours; witnessed aspiration; and use of paralytic agents. Exposure to antibiotics conferred protection, but this effect was attenuated over time.[10] According to four studies, the VAP rate was higher in patients with acute respiratory distress syndrome (ARDS) than other ventilated patients, affecting between 34% and greater than 70% of patients with ARDS and often leading to the development of sepsis, multiple organ failure, and death.[16–19]

Attributable Mortality, Morbidity, and Costs

Mechanically ventilated patients in the ICU with VAP appear to have a 2- to 10-fold higher risk of death as compared with patients without pneumonia. Although these statistics indicate that VAP can be lethal, previous studies have not demonstrated clearly that pneumonia is responsible for the higher mortality rate of these patients. It is often difficult to determine whether ICU patients with severe underlying illness would have survived if VAP had not occurred. VAP, however, has been recognized in several case-control studies or studies using multivariate analysis as an important prognostic factor for different groups of critically ill patients.[20–24]

Other factors beyond the simple development of VAP, such as the severity of the disease or the responsible pathogens, may be more important determinants of outcome for patients in whom pneumonia develops. Indeed, it may be that VAP increases mortality only in the subset of patients with intermediate severity of illness,[24] when initial treatment is inappropriate,[25–29] and/or in patients with VAP caused by high-risk pathogens, such as *P. aeruginosa.*[30] Patients with very low severity and early-onset pneumonia caused by organisms such as *Haemophilus influenzae* or *Streptococcus pneumoniae* have excellent prognoses with or without VAP, whereas very ill patients with late-onset VAP occurring while they are in a quasi-terminal state would be unlikely to survive.

All studies have shown clearly that patients with VAP have prolonged duration of mechanical ventilation and lengthened ICU and hospital stay as compared with patients who do not have VAP.[1,2] Summarizing available data, VAP appears to extend the ICU stay by at least 4 days, with the attributable ICU length of stay being longer for medical than surgical patients and for patients infected with "high-risk" as opposed to "low-risk" organisms.[31] The prolonged hospitalization of patients with VAP underscores the considerable financial burden

imposed on the health care system by the development of VAP.[32,33]

Etiologic Agents

Microorganisms responsible for VAP differ according to the population of ICU patients, the durations of hospital and ICU stays, and the specific diagnostic method(s) used to establish the responsible pathogens. A number of studies have shown that GNB cause many of the respiratory infections in this setting.[1,2] The data from 24 studies conducted on ventilated patients, for whom bacteriologic studies were restricted to uncontaminated specimens, confirmed these results: GNB represented 58% of recovered organisms (Fig. 33-1). The predominant GNB were *P. aeruginosa* and *Acinetobacter* spp., followed by *Proteus* spp., *Escherichia coli, Klebsiella* spp., and *H. influenzae.* A relatively high rate of gram-positive pneumonias was also reported in those studies, with *Staphylococcus aureus* involved in 20% of the cases. Many episodes of VAP are caused by multiple pathogens.[34]

Underlying diseases may predispose patients to infection with specific organisms. Patients with chronic obstructive pulmonary disease are at increased risk for *H. influenzae, Moraxella catarrhalis,* or *S. pneumoniae* infections; cystic fibrosis increases the risk of *P. aeruginosa* and/or *S. aureus* infections, while trauma and neurologic disease increase the risk for *S. aureus* infection. Furthermore, the causative agent for pneumonia differs among ICU surgical populations, with 18% of the nosocomial pneumonias caused by *Haemophilus* or pneumococci, particularly in patients with trauma, but not in patients with malignancy, transplantation, or abdominal or cardiovascular surgery.[1,2]

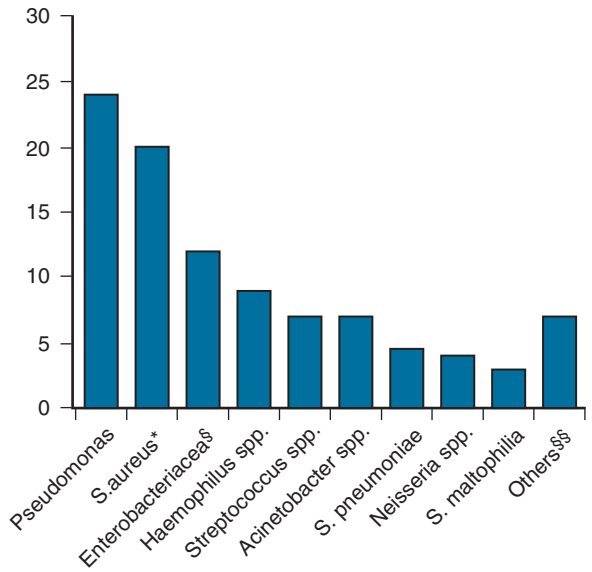

FIGURE 33-1 ■ Etiology of VAP as documented by bronchoscopic techniques in 24 studies for a total of 1689 episodes and 2490 pathogens. *Methicillin-resistant *Staphylococcus aureus* (MRSA), 56%; methicillin-sensitive *S. aureus* (MSSA), 44%. §*Klebsiella* spp., 16%; *Escherichia coli,* 24%; *Proteus* spp., 22%; *Enterobacter* spp., 19%; *Serratia* spp., 12%; *Citrobacter* spp., 5%. §§Including *Corynebacterium* spp., *Moraxella* spp., and *Enterococcus* spp. (Adapted from Chastre J, Fagon JY: Ventilator-associated pneumonia. Am J Respir Crit Care Med 165:867–903, 2002.)

Despite somewhat different definitions of early-onset pneumonia, varying from onset of less than 3 to less than 7 days, high rates of *H. influenzae, S. pneumoniae,* methicillin-sensitive *S. aureus,* or susceptible Enterobacteriaceae were constantly found in early-onset VAP, whereas *P. aeruginosa, Acinetobacter* spp., methicillin-resistant *S. aureus* (MRSA), and multiresistant GNB were significantly more frequent in late-onset VAP.[1] The different pattern of distribution of etiologic agents between early- and late-onset VAP is linked to prior antimicrobial therapy in many patients with late-onset VAP. When multivariate analysis was used to identify risk factors for VAP caused by potentially drug-resistant bacteria such as MRSA, *P. aeruginosa, Acinetobacter baumannii,* and/or *Stenotrophomonas maltophilia* in 135 consecutive episodes of VAP, only three variables remained significant: duration of mechanical ventilation of longer than 7 days before onset of VAP, prior antibiotic use, and prior use of broad-spectrum drugs (third-generation cephalosporins, fluoroquinolones, and/or imipenem).[35] Not all studies have confirmed this distribution pattern, and in some studies the most common pathogens associated with early-onset VAP were *P. aeruginosa*, MRSA, and *Enterobacter* spp., with similar pathogens associated with late-onset VAP.[36,37] These findings might be explained in part by prior hospitalization and the use of antibiotics prior to transfer to the ICU.

Legionella species, anaerobes, fungi, viruses, and even *Pneumocystis jirovecii* should be mentioned as potential causative agents, but these microbes are not commonly found when pneumonia is acquired during mechanical ventilation. Several of these causative agents might be more common than reported, because of difficulties with the diagnostic techniques used to identify them, including viruses.[38,39] Isolation of fungi, most frequently *Candida* species, at significant concentrations poses interpretative problems. Invasive disease has been reported in VAP, but yeasts are isolated more frequently from respiratory tract specimens in the absence of apparent disease. Based on current data,[40] the use of the commonly available respiratory sampling methods (bronchoscopic or nonbronchoscopic) in ventilated patients is not sufficient to make the diagnosis of *Candida* pneumonia, and evidence of bloodstream invasion is also needed.

DIAGNOSIS

Two diagnostic algorithms can be used when VAP is suspected, typically when a patient has new or progressive radiographic infiltrates and clinical findings suggesting infection, such as the new onset of fever, purulent sputum, leukocytosis, and a decline in arterial oxygenation. The first option is to treat every patient clinically suspected of having a pulmonary infection with new

antibiotics, even when the likelihood of infection is low, arguing that several studies showed that immediate initiation of appropriate antibiotics was associated with reduced mortality.[41] The second option is to use an invasive diagnostic strategy based on quantitative cultures of distal respiratory specimens obtained using bronchoscopic or nonbronchoscopic techniques, such as bronchoalveolar lavage (BAL) or a protected specimen brush (PSB), in order to improve the identification of patients with true VAP and facilitate decisions about whether or not to treat with antibiotics.[2,42,43] Although no consensus exists on the best diagnostic strategy for patients clinically suspected of having VAP, the goals are early, appropriate use of antibiotics in patients with true VAP and withholding them in others.[1,2]

The Clinical Strategy

Using this strategy, all patients suspected of having VAP are treated with new antibiotics. The selection of appropriate empirical therapy is based on risk factors and local microbiologic and resistance patterns, and involves qualitative testing to identify possible pathogens. The initial antimicrobial therapy is adjusted according to culture results or clinical response (Fig. 33-2). Antimicrobial treatment is discontinued if and only if the following three criteria are fulfilled on day 3: (1) clinical diagnosis of VAP is unlikely (there are no definite infiltrates found on chest radiography at follow-up and no more than one of the three following findings is present: temperature greater than 38.3°C, leukocytosis or leukopenia, and purulent tracheobronchial secretions) or an alternative noninfectious diagnosis is confirmed; (2) tracheobronchial aspirate culture results are nonsignificant; and (3) severe sepsis or shock is not present.[44]

This clinical approach has two undisputable advantages: first, no specialized microbiologic techniques are required, and, second, the risk of missing a patient who needs antimicrobial treatment is minimal when all suspected patients are treated with new antibiotics.

While the simple qualitative culture of endotracheal aspirates (EAs) is a technique with a high percentage of false-positive results due to bacterial colonization of the proximal airways in many ICU patients, recent studies using quantitative culture techniques suggest that the diagnostic accuracy of EA cultures is similar to the accuracy of more invasive techniques.[45] The inherent advantages of these techniques are that they are less invasive, they are available to nonbronchoscopists, they are less expensive than bronchoscopy, they are less likely to compromise gas exchange, and they can be performed in patients with small endotracheal tubes. The disadvantages include the potential sampling errors inherent in a blind technique and lower specificity for distinguishing airway colonization from true pneumonia.

Another option when using the clinical approach is to follow the strategy described by Singh et al., in which decisions regarding initial antibiotic therapy are based on a clinical score constructed from seven variables, the Clinical Pulmonary Infection Score (CPIS).[46] Patients with a CPIS greater than 6 are treated as having VAP with antibiotics for 10 to 21 days, and antibiotics are discontinued after 3 days if the CPIS is 6 or less (Fig. 33-3). Such an approach avoids prolonged treatment of patients who have a low likelihood of infection, while allowing immediate treatment of patients who are more likely to have VAP. Two conditions must be fulfilled when using this strategy. First, the selection of initial antimicrobial therapy should be based on the most common microbes responsible for VAP at each institution. For example, ciprofloxacin would not be the right choice in hospitals with a high prevalence of MRSA infections. Second, physicians should reevaluate antimicrobial treatment on day 3, when susceptibility patterns of the microorganism(s) recovered from pulmonary secretions are available, in order to select treatment with a narrower spectrum antibiotic.

The Invasive Strategy

This strategy uses quantitative cultures of lower respiratory secretions (BAL or PSB collected with or without a bronchoscope) to define both the presence of pneumonia and the etiologic pathogen. Growth above a threshold concentration is required to make a diagnosis of VAP and determine the causative microorganism(s).[47] Growth below the threshold is assumed to be due to colonization or contamination. Using this strategy, therapeutic decisions are tightly protocolized, using the results of direct examination of distal pulmonary samples and results of quantitative cultures in deciding whether to start antibiotic therapy, which pathogens are responsible for infection, which antimicrobial agents to use, and whether to continue therapy (Fig. 33-4).

Quantitative cultures of BAL and/or PSB specimens consistently yield fewer microorganisms growing above the diagnostic threshold than are present in qualitative cultures of tracheal aspirates.[2,48] Thus, when therapeutic decisions have been based on these data, fewer patients have been treated with antibiotics, and a potentially narrower spectrum of therapy was used, as compared with the clinical approach, thereby limiting the emergence and dissemination of drug-resistant strains and minimizing antibiotic-related toxicity.[43,49]

Another compelling argument in favor of the invasive strategy is that this approach directs attention away from the lungs as the source of fever when BAL/PSB quantitative culture results are negative. Many ICU patients with negative bronchoscopic cultures have other potential sites of infection that need to be identified in order to avoid delays in initiating appropriate treatment.[50]

The accuracy of bronchoscopic techniques is questionable in patients who have received prior antibiotics, particularly when new antibiotics have been introduced after the onset of the symptoms suggestive of nosocomial pneumonia and before pulmonary secretions were collected. However, several investigators have found that cultures of respiratory secretions are not modified in a major way when pneumonia develops in patients who have been receiving systemic antibiotics for several

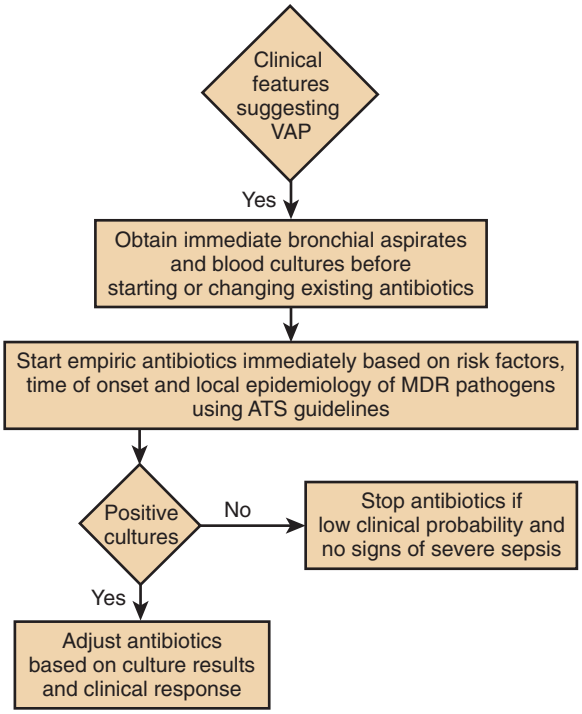

FIGURE 33-2 ■ Diagnostic and therapeutic strategy applied to patients managed with the "clinical" strategy.

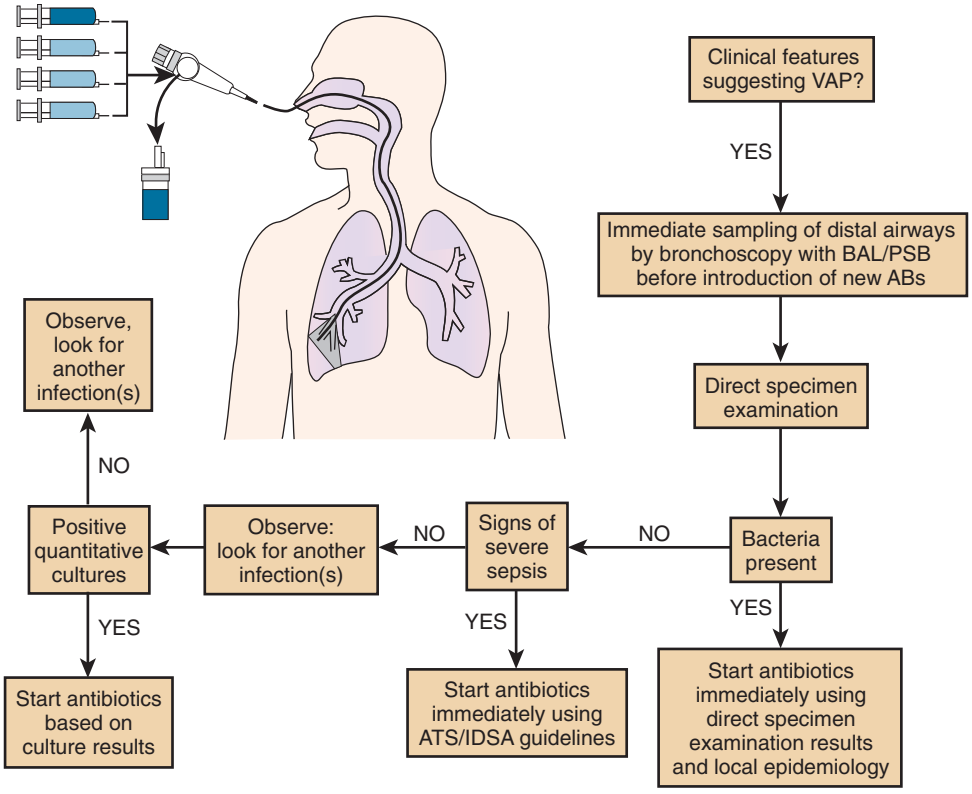

FIGURE 33-4 ■ Diagnostic and therapeutic strategy applied to patients with a clinical suspicion of VAP managed according to the "invasive" strategy.

days before the appearance of the new pulmonary infiltrates. The reason for this appears to be that the bacteria responsible for the new infection are likely to be resistant to the antibiotics that have been used.[51,52] The problem with performing microbiologic cultures of pulmonary secretions after initiation of new antibiotics in patients suspected of having VAP is that the antibiotics can increase the number of false-negative results, regardless of the way in which these secretions are obtained.[52-54]

One major technical problem with all bronchoscopic techniques is proper selection of the sampling area in the tracheobronchial tree. The sampling area is usually selected based on the location of the radiographic infiltrate, or the bronchoscopic identification of a pulmonary segment that has purulent secretions.[55] In patients with diffuse pulmonary infiltrates or minimal new changes in a previously abnormal chest radiograph, determining the correct segment to sample can be difficult. In such cases, sampling should be directed to the area where endobronchial abnormalities are maximal. Because autopsy studies indicate that VAP frequently involves the posterior portion of the right lower lobe, this area should probably be given priority for sampling.[56]

Summary of the Evidence

Aside from decision-analysis studies[57,58] and a single retrospective study,[59] five trials have used a randomized scheme to assess the effect of a diagnostic strategy on antibiotic use and outcome in patients suspected of having VAP.[26,27,43,60,61] In three randomized studies conducted in Spain, no differences were found in mortality and morbidity when either invasive (PSB and/or BAL) or noninvasive (quantitative endotracheal aspirate cultures) techniques were used to diagnose VAP.[26,27,60] These studies were relatively small, ranging from 51 to 88 patients. Antibiotics were continued in all patients despite negative cultures, thereby offsetting the potential advantage of the specific diagnostic test in patients with suspected VAP. Several prospective studies have concluded that antibiotics can be stopped in patients with negative quantitative cultures, without adversely affecting the recurrence of pneumonia and mortality.[42,62,63]

In a French study in which 413 patients were randomized, those receiving bacteriologic management using BAL and/or PSB had a lower mortality rate on day 14, lower sepsis-related organ failure assessment scores on day 3 and 7, and less antibiotic use.[43] Pertinently, 22 nonpulmonary infections were diagnosed in the bacteriologic strategy group and only 5 in the clinical strategy group, suggesting that overdiagnosis of VAP can lead to errors in identifying nonpulmonary infections. A recent randomized trial conducted by the Canadian Critical Care Trials Group investigated the effect of different diagnostic approaches on outcomes of 740 patients suspected of having VAP.[61] There was no difference in the 28-day mortality rate in patients in whom BAL was used, versus those in whom endotracheal aspiration was used as the diagnostic strategy. The BAL group and the endotracheal aspiration group also had similar rates of targeted antibiotic therapy on day 6, days alive without antibiotics, and maximum organ dysfunction scores. Unfortunately, information about how the decision algorithms were followed in the two diagnostic arms once cultures were available was not provided, raising uncertainties about how de-escalation of antibiotic therapy was pursued in patients with negative BAL cultures. Obviously, the potential benefit of using a diagnostic tool such as BAL for safely restricting unnecessary antimicrobial therapy in such a setting can only be obtained when decisions regarding antibiotics are closely linked to bacteriologic results, including both direct examination and cultures of respiratory specimens.

TREATMENT

Antimicrobial therapy of patients with VAP is a two-stage process. The first stage involves administering broad-spectrum antibiotics to avoid inappropriate treatment in patients with true bacterial pneumonia.[1] The second stage focuses on trying to achieve this objective without overusing or abusing antibiotics. In general, the first goal can be accomplished by identifying patients with pneumonia in a rapid fashion and starting therapy with an empirical regimen that is likely to treat the most common etiologic agents in a particular institution. This requires that the initial antibiotic choice be driven by knowledge of the likely etiologic pathogens, and the local patterns of antimicrobial resistance. The second goal involves stopping therapy in patients with a low probability of VAP, focusing and narrowing treatment once the etiologic agent is known, switching to monotherapy after day 3 whenever possible, and shortening the duration of therapy to 7 to 8 days in most patients, as determined by the patient's clinical response and information about the bacteriology (Table 33-1).

Initial Treatment

Failure to initiate prompt appropriate therapy (i.e., using an agent to which the etiologic organism is sensitive, with the optimal dose and route of administration) has been consistently linked with increased mortality in patients with VAP.[28,41,64] Due to the emergence of multiresistant GNB, such as *P. aeruginosa* and/or extended-spectrum β-lactamase–producing Enterobacteriaceae in many institutions and the increasing role of gram-positive bacteria, such as MRSA, empiric treatment with broad-spectrum antibiotics is justified in most patients with a clinical suspicion of VAP.[2,3] The choice of agents should be based on local patterns of antimicrobial susceptibility and anticipated side effects, and should also take into account the antibiotics that the patients have received within the prior 2 weeks, striving not to use the same antimicrobial classes, if possible.[65,66] Having

TABLE 33-1. Proposed Strategy for Conducting Antimicrobial Therapy in Patients with VAP

Proposed Strategy	Rationale
Step 1: Start therapy using broad-spectrum antibiotics	Due to the emergence of multiresistant GNB, such as *P. aeruginosa* and ESBL-producing GNB in many institutions, and the increasing role of MRSA, empiric treatment with broad-spectrum antibiotics is justified in most patients with a clinical suspicion of VAP.
Step 2: Stop therapy if the diagnosis of infection becomes unlikely	The goal is to ensure that ICU patients with true bacterial infection receive immediate appropriate treatment. However, this can result in more patients receiving antimicrobial therapy than necessary, because clinical signs of infection are nonspecific.
Step 3: Use narrower spectrum antibiotics, once the etiologic agent is identified	For many patients with VAP, including those with late-onset infection, therapy can be narrowed once the results of respiratory tract and blood cultures are available, either because an anticipated organism (such as *P. aeruginosa* and *Acinetobacter* spp. or MRSA) was not recovered, or because the organism isolated is sensitive to a more narrow-spectrum antibiotic than used in the initial regimen.[63,64]
Step 4: Use pharmacokinetic-pharmacodynamic data to optimize treatment	Clinical and bacteriologic outcomes can be improved by optimizing the therapeutic regimen according to pharmacokinetic and pharmacodynamic properties of the agent(s) selected for treatment.
Step 5: Switch to monotherapy on days 3–5	There are no clinical benefits to using a regimen combining two antibiotics for more than days 3–5, provided that initial therapy was appropriate, the clinical course appears favorable, and microbiologic data do not point to a very difficult-to-treat microorganism.
Step 6: Shorten the duration of therapy	Reducing duration of therapy in patients with VAP has led to good outcomes with less antibiotic use. Prolonged therapy leads to colonization with antibiotic-resistant bacteria, which may precede a recurrent episode of VAP.

ESBL, extended-spectrum β-lactamase; GNB, gram-negative bacteria; ICU, intensive care unit; MRSA, methicillin-resistant *Staphylococcus aureus;* VAP, ventilator-associated pneumonia.

current knowledge about local bacteriologic patterns can increase the likelihood that appropriate initial antibiotic treatment will be prescribed.[67] Only patients with early-onset infection and no specific risk factors, such as prolonged duration of hospitalization, admission from a health care–related facility, and recent prolonged antibiotic therapy, can be treated with a relatively narrow-spectrum drug, such as a nonpseudomonal third-generation cephalosporin.[1]

Several published reports have shown a relationship among serum concentrations of β-lactams or other antibiotics, the minimal inhibitory concentration (MIC) of the infecting organism, and the rate of bacterial eradication from respiratory secretions in patients with lung infection.[68–70] Consequently, clinical and bacteriologic outcomes can be improved by optimizing the therapeutic regimen according to pharmacokinetic properties of the antimicrobial(s) selected for treatment. Development of dosing algorithms based on a drug's MIC, the patient's creatinine clearance and weight, and pharmacokinetic-pharmacodynamic parameters might be a way to improve treatment of these patients, because this overall approach is more precise than current guidelines for use of antimicrobial agents.

Avoiding the Overuse of Antibiotics

The need to ensure that ICU patients with true bacterial infections promptly receive an appropriate antibiotic regimen can lead to many more patients receiving antimicrobial therapy than is actually necessary, because clinical signs of infection are relatively nonspecific. Thus, when a clinical approach to VAP is used, it is important to perform serial clinical and microbiologic evaluations, and reevaluate therapy after 48 to 72 hours so that therapy can be stopped if infection is unlikely. To accomplish this, all diagnostic strategies that are designed for managing patients with a clinical suspicion of VAP should make explicit the decision tree that is used to identify patients with a low probability of infection, in whom therapy can be stopped when infection appears improbable.

For many patients with VAP, including those with late-onset infection, therapy can be narrowed once the results of respiratory tract and blood cultures are available, because a resistant organism (such as *P. aeruginosa* and *Acinetobacter* spp. or MRSA) is not recovered or because the organism isolated is sensitive to a narrower spectrum antibiotic than used in the initial regimen. For example, vancomycin and linezolid should be stopped if MRSA is not identified, unless the patient is allergic to β-lactams or has developed an infection caused by a gram-positive microorganism. Very-broad-spectrum agents, such as carbapenems, piperacillin-tazobactam, and/or cefepime, should also be restricted to patients with infection caused by pathogens that are only susceptible to these agents. Clinicians must be aware that the emergence of resistant mutants may lead to treatment failure when third-generation cephalosporins are chosen to treat infections caused by *Enterobacter, Citrobacter, Morganella morgannii,* indole-positive *Proteus,* and *Serratia* spp., even if the isolate is initially susceptible.

The most common reason to use combination therapy in initial management of patients with VAP is to achieve synergy in treating *P. aeruginosa* or other difficult-to-treat GNB. However, antibiotic synergy has only been

shown to be valuable in vitro and in patients with neutropenia[71] or bacteremic infection,[72] which is uncommon in VAP. A recent meta-analysis evaluated all prospective randomized trials of β-lactam monotherapy as compared with β-lactam/aminoglycoside combination regimens in 7586 patients with sepsis, of whom at least 1200 patients had VAP.[73] The clinical success rates were similar with monotherapy versus combination therapy, and combination therapy had no advantage in the treatment of *P. aeruginosa* infections. Importantly, combination therapy did not prevent the emergence of antimicrobial resistance during treatment, but it was associated with a significantly higher rate of nephrotoxicity. Based on these data, therapy could be switched to monotherapy in most patients after 3 or 5 days, provided that initial therapy was appropriate, the clinical course is favorable, and microbiologic data do not identify a difficult-to-treat microorganism with a high in vitro MIC, as is found with some lactose-nonfermenting GNB.

Efforts to reduce the duration of therapy for VAP are justified by studies of the natural history of the response to therapy. Most patients with VAP who receive appropriate antimicrobial therapy have a good clinical response within the first 6 days.[74–76] Prolonged therapy leads to colonization with antibiotic-resistant bacteria, which may precede a recurrent episode of VAP. A multicenter, randomized, controlled trial in 401 patients with microbiologically proven VAP showed that the clinical outcomes of patients who received appropriate empiric therapy for 8 days were similar to those of patients who received therapy for 15 days.[77] A trend to greater rates of relapse for short-duration therapy was seen if the etiologic agent was *P. aeruginosa* or *Acinetobacter* spp., but the clinical outcomes were exactly the same. These results have been confirmed in two later studies, including a prospective, randomized trial of 290 patients evaluating an antibiotic discontinuation policy.[78,79]

PREVENTION

Because VAP is associated with increased morbidity, longer hospital stay, increased health care costs, and higher mortality rates, prevention is a major challenge for all ICU personnel.[1,80,81]

Conventional Infection Control Approaches

Conventional approaches should be the first steps taken in all prevention programs. The design of the ICU has a direct effect on the potential for nosocomial infections. Adequate space and lighting, properly functioning ventilation systems, and appropriate handwashing facilities all lead to lower infection rates.[82] It is important to note, however, that upgrading the physical environment does not reduce the infection rate unless the attitudes and practices of health care personnel are also improved. In any ICU, one of the most important factors is the health care staff, including the number, quality, and motivation of medical, nursing, and ancillary members. The team should include a sufficient number of nurses to minimize their movement from one patient to another and to avoid having them work under constant pressure.[83–85] The importance of personal cleanliness and attention to aseptic procedures must be emphasized at every opportunity. It is clear that careful monitoring, decontamination, and compliance with guidelines for the use of respiratory equipment all reduce the incidence of nosocomial pneumonia.[86] In particular, handwashing and handrubbing with alcohol-based solutions remain the most important components of effective infection control practices in the ICU.[87,88]

Environmental and patient-oriented microbiologic monitoring facilitates the early recognition of colonization and infection, and has been associated with significant reductions in nosocomial infection rates.[89] The focal point for infection control activities in the ICU is a surveillance system designed to establish and maintain a database that identifies endemic rates of nosocomial infections. This information facilitates the recognition of epidemics, when infection rates rise above the endemic threshold for a specific type of nosocomial infection.

Adoption of an antibiotic policy that restricts the prescription of broad-spectrum agents and inappropriate antibiotics is of major importance. Better use of antibiotics in the ICU can be achieved by implementing strict guidelines, avoiding the treatment of patients who do not have bacterial infections, using narrow-spectrum antibiotics whenever possible, and reducing the duration of treatment.[90,91] Similarly, transfusion of red blood cells and other allogenic blood products should follow a strict policy, because several studies have identified exposure to allogenic blood products as a risk factor for postoperative infection and pneumonia.[92,93]

Specific Prophylaxis against VAP

Specific strategies aimed at reducing the duration of mechanical ventilation (a major risk factor for VAP), such as improved methods of sedation,[94] use of protocols to facilitate and accelerate weaning,[94–96] using adequate levels of positive end-expiratory pressure,[97] and also using intensive insulin therapy to control blood glucose[98] should be considered as integral parts of any infection control program. All are based on the application of strict protocols. Similarly, noninvasive positive-pressure ventilation using a face mask should be employed whenever possible.[99]

Some very simple, safe, inexpensive, and logical measures may have major effects on the frequency of VAP in mechanically ventilated patients.[1,88] These include avoiding nasal insertion of endotracheal and gastric tubes[100]; maintaining the endotracheal tube cuff pressure above 20 cm H_2O to prevent leakage of bacteria around the cuff

into the lower respiratory tract[101]; promptly reintubating patients who are likely to fail extubation[102]; keeping patients in the semirecumbent position, especially when enteral nutrition is used[103]; removing tubing condensate[104]; and providing meticulous oral hygiene[105] or using an antiseptic such as chlorhexidine.[106]

Continuous or intermittent suctioning of oropharyngeal secretions using a specially designed endotracheal tube with a separate lumen that opens into the subglottic region has been proposed as a means to avoid chronic aspiration of secretions around the endotracheal cuff of intubated patients.[107,108] While most studies that have evaluated this approach demonstrated that VAP development was delayed, the incidence of VAP caused by *P. aeruginosa* or Enterobacteriaceae did not differ with or without subglottic suctioning, and no difference in mortality rates was observed. Recent data from animal models and randomized human studies, including a large trial, support the hypothesis that an endotracheal tube coated externally and internally with a potent antiseptic product such as silver has a sustained antimicrobial effect in the proximal airways, blocking biofilm formation at its surface and significantly reducing the VAP rate.[109–112]

Gastric colonization by potentially pathogenic organisms increases with decreasing gastric acidity.[113] Thus, medications that decrease gastric acidity (antacids, histamine$_2$ [H_2] blockers) can increase the gastric bacterial burden and increase the risk of VAP. In contrast, medications that do not affect gastric acidity (e.g., sucralfate) do not appear to increase this risk. Several meta-analyses of more than 20 randomized trials have evaluated the risk for VAP associated with methods used to prevent gastrointestinal bleeding in critically ill patients.[114] The largest randomized trial comparing ranitidine to sucralfate showed that ranitidine was superior in preventing gastrointestinal bleeding and did not increase the risk of VAP.[115] Therefore, despite the potential advantage of sucralfate (potentially less VAP with more gastrointestinal bleeding) over H_2 blockers (potentially more VAP with less gastrointestinal bleeding) in preventing VAP, stress ulcer prophylaxis with H_2 blockers appears to be safe in patients who are at high risk for bleeding as well as VAP.

Several groups have used topical prophylactic antibiotics for selective decontamination of the oropharynx and digestive tract (SDD) in patients at high risk for nosocomial pneumonia. The SDD regimen usually includes a short course of systemic antibiotic therapy, such as cefotaxime, trimethoprim, or a fluoroquinolone, combined with nonabsorbable local antibiotic prophylaxis, consisting of a combination of an aminoglycoside, polymyxin B, and amphotericin. Since the original study published by Stoutenbeek et al. in 1984,[116] which demonstrated a decrease of the overall infection rate in patients receiving the SDD regimen, more than 40 randomized, controlled trials, and 7 meta-analyses have been published.[117,118] All seven meta-analyses reported a significant reduction in the risk of VAP, and four reported a significant reduction in mortality. No mortality benefit was seen with topical prophylaxis alone. A clear consensus as to the effectiveness of SDD has not developed, however, because of discordances among the meta-analyses related to limitations and methodologic deficiencies of the analyzed studies. Particular problems include the use of clinical diagnosis of pneumonia as a study end point, the heterogeneity of the populations studied, the wide variety of oral regimens, the inconsistent addition of systemic antibiotics (cefotaxime or ceftazidime), and differences in analytic methods.[80,81] Recently, De Jonge et al. were able to show, in a large, prospective, randomized, unblinded clinical trial of 934 patients, that SDD decreases ICU and hospital mortality and colonization with resistant aerobic GNB in settings with a low prevalence of vancomycin-resistant enterococci and MRSA.[119]

Implementing a Structured Prevention Policy

The application of consistent evidence-based interventions to prevent VAP has been highly variable from one ICU to another, and often suboptimal. Furthermore, no single preventive measure can succeed alone, emphasizing the need to use multifaceted and multidisciplinary programs to prevent VAP. Such programs are frequently referred to as "care bundles." A care bundle is a set of readily implementable interventions that are required to be undertaken for each patient on a regular basis.[120] The key goal is that every intervention must be implemented for every patient on every day of his or her stay in the ICU. Compliance is assessed for the bundle as a whole, so failure to complete even a single intervention means failure of the whole bundle at a particular assessment. The interventions need to be packaged in such a way that they are easy to assess for compliance, which usually means that no more than five interventions are included in each care bundle. The performance goal is to routinely achieve over 95% compliance. Care bundles make it possible to introduce evidence-based preventive measures, including appropriate nurse staffing levels, hand hygiene with alcohol-based formulations, standardized weaning protocols and daily interruption of sedation, oral care with chlorhexidine, and keeping patients who receive enteral nutrition in a semirecumbent position.[121] All of these measures can be consistently applied to all patients in a coordinated way. Recent experience confirms the positive effects of these approaches in reducing the frequency of VAP.[122–125] The newer emphasis on care bundles in the ICU is shifting the focus from the diagnosis and treatment of VAP to the more important goal of preventing VAP from occurring in the first place.

KEY POINTS

- VAP is associated with mortality in excess of that caused by the underlying disease alone, particularly in the case of infection due to high-risk pathogens, such as *P. aeruginosa* and MRSA.
- The predominant organisms responsible for infection are *S. aureus, P. aeruginosa,* and Enterobacteriaceae, but etiologic agents widely differ according to the population of hospital patients, the duration of hospital stay, and prior antimicrobial therapy.
- Because even a few doses of a new antimicrobial agent can negate results of microbiologic cultures, pulmonary secretions in patients suspected of having developed VAP should always be obtained before new antibiotics are administered.
- Antimicrobial therapy of patients with VAP should follow a two-stage process. The first stage involves administering broad-spectrum antibiotics to avoid inappropriate treatment in patients with true bacterial pneumonia.
- The second stage focuses on trying to achieve this objective without overusing and abusing antibiotics, combining a number of different steps, such as stopping therapy in patients with a low probability of VAP, streamlining treatment once the etiologic agent is known, switching to monotherapy after days 3 to 5, and shortening duration of therapy to 7 to 8 days, as dictated by the patient's clinical response to therapy and information about the bacteriology of the infection.
- Some very simple, no-cost measures, such as maintaining the endotracheal tube cuff pressure above 20 cm H_2O to prevent leakage of bacteria around the cuff into the lower respiratory tract, promptly reintubating patients who are failing extubation, oral care with chlorhexidine, keeping patients in the semirecumbent position especially in the case of enteral nutrition, removal of ventilator tubing condensates with minimal exposure to patients, and reducing the duration of ventilation have an important effect on decreasing the frequency of VAP.

CHAPTER 34

TUBERCULOSIS

Philip C. Hopewell, MD • Midori Kato-Maeda, MD

INTRODUCTION

CHARACTERISTICS OF *MYCOBACTERIUM TUBERCULOSIS*

EPIDEMIOLOGY

TRANSMISSION OF *MYCOBACTERIUM TUBERCULOSIS*
Source Case
Environmental Factors
Circumstances of Exposure
Host Factors

PATHOGENESIS
Events in the Nonimmunized Host
Immunologic Responses to *Mycobacterium tuberculosis*
Exogenous Versus Endogenous Infection

RISK FACTORS

TUBERCULOUS INFECTION
Tuberculin Skin Test
Interferon-γ Release Assays

PULMONARY TUBERCULOSIS
History, Physical, and Laboratory Examinations
Radiographic Features
Bacteriologic Evaluation
Treatment

EXTRAPULMONARY TUBERCULOSIS
Disseminated Tuberculosis
Lymphatic Tuberculosis
Pleural Tuberculosis
Genitourinary Tuberculosis
Bone and Joint Tuberculosis
Central Nervous System Tuberculosis
Abdominal Tuberculosis
Pericardial Tuberculosis

LATENT TUBERCULOUS INFECTION
Indications for Treatment
Current Treatment Regimens
Management of Exposure to Drug-Resistant Organisms
Immunization with Bacille Calmette-Guérin

TACKLING CURRENT PROBLEMS

INTRODUCTION

Mycobacteria have played an extremely important role in influencing society throughout history. Tuberculosis and Hansen's disease (leprosy), the two most prominent mycobacterial diseases, have been recognized as scourges of humanity since antiquity. Whereas leprosy was most apparent as a metaphor for the destitute, disabled, and disfigured, tuberculosis was the "captain of all these men of death," according to John Bunyan, a plague that carried away the young and talented members of society. Currently, although the resurgence of tuberculosis in industrialized countries that began in the mid-1980s has subsided, the disease continues to ravage much of the developing world and to kill or disable many young, productive members of society.[1–3] Because of the frequency with which both pulmonary and extrapulmonary tuberculosis occur together, and because the general manifestations and microbiologic features are the same with all sites of disease, this chapter addresses both pulmonary and extrapulmonary tuberculosis.

Because tuberculous infection is so prevalent throughout much of the developing world, the conflicts and upheavals that result in immigration from low-income to developed countries will have a continuing influence on the incidence of tuberculosis everywhere. For this reason, tuberculosis must be viewed as a global problem, one that is not contained by national boundaries and

whose effects are felt in all countries regardless of their state of development.[4] More recently, in addition to human immunodeficiency virus (HIV) infection, drug resistance is providing new challenges to tuberculosis control efforts.[5] Both multidrug-resistant (MDR) tuberculosis (caused by organisms resistant to at least isoniazid and rifampin) and extensively drug-resistant (XDR) tuberculosis (caused by MDR organisms that are also resistant to one of the fluoroquinolones and to at least one of the injectable second-line agents) pose significant difficulties for tuberculosis control programs in most of the world.

CHARACTERISTICS OF *MYCOBACTERIUM TUBERCULOSIS*

The main defining characteristic of the genus *Mycobacterium* is the property of "acid-fastness," the ability to withstand decolorization with an acid-alcohol mixture after coloration with such stains as Ziehl-Neelsen or auramine O (Fig. 34-1).[6] In addition to their being acid fast, the mycobacteria are primarily intracellular parasites, have slow rates of growth (except for the "rapid grower" category), are obligate aerobes, and in normal hosts induce a granulomatous response in tissue (see Chapter 15, Fig. 15-4C).

Details about the means of obtaining specimens for studies of mycobacteria and their differentiation are provided in Chapter 18. *Mycobacterium tuberculosis* produces characteristic buff-colored colonies. Biochemical testing or deoxyribonucleic acid (DNA) probes serve to identify the species. Ninety-nine percent of *M. tuberculosis* strains produce niacin.[7] In radiometric systems, a culture of *M. tuberculosis* can be identified by testing for resistance to *para*-nitro-acetylamino-hydroxypropiophenone (NAP), a precursor in the synthesis of chloramphenicol.[8] Growth of *M. tuberculosis* is not inhibited by this antimicrobial compound, in contrast with other mycobacterial species that do not grow in its presence.

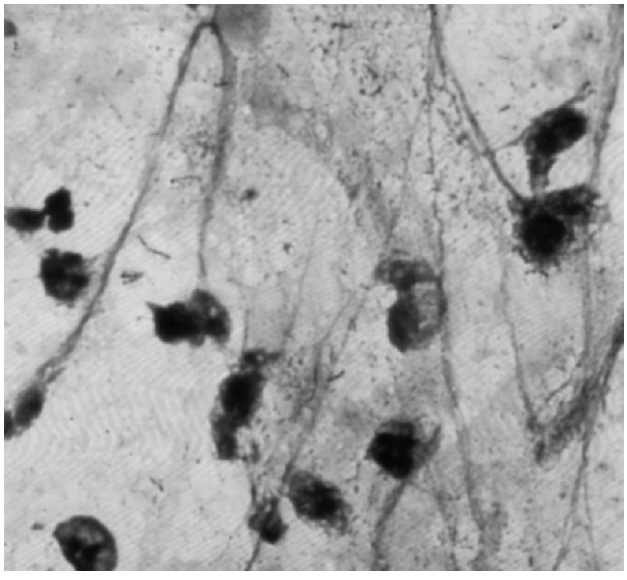

FIGURE 34-1 ■ Ziehl-Neelsen–stained smear of sputum showing acid-fast bacilli (in this instance *Mycobacterium tuberculosis*). (Original magnification ×960.)

Tuberculosis is caused by any one of three mycobacterial pathogens that form part of the *M. tuberculosis* complex: *M. tuberculosis, Mycobacterium bovis,* and *Mycobacterium africanum. Mycobacterium microti, Mycobacterium pinnipedii,* and *Mycobacterium caprae* are also members of the *M. tuberculosis* complex but only rarely cause disease in humans. Because *M. bovis* and *M. africanum* produce relatively few cases of human tuberculosis, they are not considered separately in this chapter.

The complete genomes of six *M. tuberculosis* strains have been sequenced, including two laboratory strains: H37Rv,[9] the first strain to be sequenced, and H37Ra,[10] the attenuated strain; the genome of H37Rv is composed of 4.41 million base pairs containing 4009 genes (http://genolist.pasteur.fr/TubercuList/). The *M. tuberculosis* genome differs from other bacterial genomes in that it contains a large number of genes for enzymes involved in lipogenesis and lipolysis that are presumably related to synthesis and maintenance of the bacterial cell wall. Functions have been attributed to approximately 52% of the predicted proteins encoded by the genes, and similarities were found with other genes for an additional 39%.[11] The remaining 9% may represent genes encoding proteins with *M. tuberculosis*–specific functions and, thus, are of particular interest. It is clear from the genetic makeup of the organism that it has the potential to survive in a variety of environments, including those with very low oxygen tension. This latter capability is consistent with the ability of the organism to remain viable but dormant in sequestered sites in the body, only to again become active under the proper conditions. The potential for developing new drugs, vaccines, and diagnostic tests on the basis of the knowledge of the complete array of genes in *M. tuberculosis* is enormous and is only beginning to be realized.[12,13] It is anticipated that additional information about virulence factors, drug and vaccine targets, and the pathogenesis of latency and active disease will be provided by the analysis and comparison of the whole-genome sequences.[10,14,15]

EPIDEMIOLOGY

For most of recorded history, tuberculosis has been a problem of enormous dimensions worldwide—and it still is. The World Health Organization (WHO) estimates that nearly one third (1.9 billion people) of all the people in the world are infected with *M. tuberculosis.* According to the latest (2009) WHO Global report,[3] in 2007 there were an estimated 9.27 million new cases, of which 4.1 million (44%) were sputum smear positive for acid-fast bacilli and, therefore, highly infectious; the total number of prevalent cases (new and old) in the world was estimated to be 13.7 million, from which there were an estimated 1.78 million deaths. Most of the persons with clinically active tuberculosis (>95%) and nearly all

of those who die from it (98%) reside in developing countries.

Since 1990 there has been a progressive decrease in the incidence of tuberculosis in all nine WHO regions of the world except Eastern Europe and Africa, although rates in both of these areas have recently begun to show a downward trend.[3] Because of the limitations in the global surveillance and reporting system for tuberculosis, only 5.3 of the estimated 9.2 million new cases were actually reported to WHO in 2007.[3] In 2004 (the last year for which worldwide information is available), tuberculosis accounted for approximately 2.5% of all deaths in the world, nearly 20% of deaths of persons between 15 and 59 years of age, and 26% of avoidable adult deaths.[16]

Also in 2007, it was estimated that there were 1.37 million new cases and 456,000 deaths from tuberculosis in persons with HIV infection.[3] The distribution of persons with coexisting HIV and tuberculosis varies considerably around the world, but the great majority (79%) live in sub-Saharan Africa. Although the rates of tuberculosis in Africa have increased steeply since 1992,[3] with the rapid spread of HIV infection in Asia, a similar—perhaps even greater—impact of HIV infection on the incidence of tuberculosis will almost certainly occur there, too.

In spite of the staggering impact of tuberculosis in developing countries, it was believed that the disease was well on its way to being eliminated in most of the developed world, including the United States, where from at least the beginning of the 20th century, tuberculosis death rates were steadily decreasing, a decline that was accelerated by the introduction of antituberculosis chemotherapy in the late 1940s. Following the introduction of effective chemotherapy, rates of new cases of tuberculosis decreased steadily at an average annual rate of approximately 5%. However, from 1984 to 1992, the number of tuberculosis cases increased by 20%. With renewed effort and considerably increased funding, case rates once again began to decline in 1993, as shown in Figure 34-2. In 2008, 12,898 cases of tuberculosis (4.2 cases per 100,000 population) were reported in the United States, the lowest number since systematic national reporting began in 1953. However, the rate of decline in cases has slowed since 2000: from an average annual decline of 7.3% from 1993 to 2000 to 3.8% from 2000 to 2008.[17]

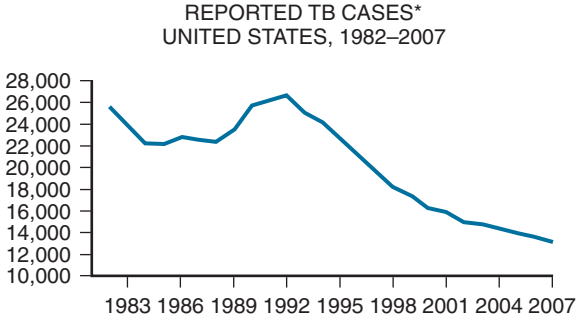

FIGURE 34-2 ■ Reported cases of tuberculosis in the United States, 1982–2007. (From Centers for Disease Control and Prevention: Reported Tuberculosis in the United States, 2007. Atlanta: Centers for Disease Control and Prevention, 2008.)

The reasons for the resurgence of tuberculosis in the late 1980s and early 1990s in the United States, as well as in western Europe, are complex but revolve largely around two major factors: the epidemic of infection with HIV and the deterioration of public health systems.[18] Interacting with and amplifying these two major factors were two additional circumstances: (1) socioeconomic conditions, particularly homelessness that led to crowding; and (2) immigration of persons from countries in the world where the prevalence of tuberculous infection was high. Although the prevalence of HIV infection has decreased in the United States and the use of antiretroviral therapy has diminished the risk of tuberculosis among persons with HIV infection, the conditions that fueled the resurgence of tuberculosis remain largely unchanged.[4,19] Notably, while the number of cases of tuberculosis decreased overall by 49% from 1993 to 2008,[17] the reduction occurred mainly among the U.S.-born population, in which cases decreased by 72%. In 2008, 58.8% of newly diagnosed cases of tuberculosis in United States were reported among foreign-born persons. A recent review demonstrated that, among this group, the rates of tuberculosis are the highest during the first 2 years after entry into the country, regardless of age, with annual rates especially high (>250/100,000 persons) among immigrants from sub-Saharan Africa and Southeast Asia.[4] By contrast, in the United States and other developed countries, tuberculosis case rates in persons born in these countries tend to increase with increasing age, because the older a person is, the more likely he or she is to have acquired tuberculous infection, having lived during a time when the disease was far more prevalent than it is today.

TRANSMISSION OF *MYCOBACTERIUM TUBERCULOSIS*

Knowledge of the factors that govern transmission of *M. tuberculosis* from a source case and of the sequence by which the disease develops in a potential new host is vital, both for devising strategies for tuberculosis control and for evaluating the risk of a person becoming infected after exposure to a patient with tuberculosis.[20] Transmission of *M. tuberculosis* is influenced by features of the source case, particularly the bacillary load, the closeness of the potential recipient of the organism to the source, and the condition of the environmental air they share. A possible additional factor is the infectivity of the organism: the degree to which *M. tuberculosis* has the ability to establish itself within the lung or other sites in the new host once transmission has occurred.

Source Case

Transmission of *M. tuberculosis* is a classic example of an airborne infection.[21] In nearly all instances, tuberculous infection is acquired by inhalation of one or more

tubercle bacilli contained in an airborne particle small enough (1 to 5 μm) to reach an alveolus. For a person with tuberculosis to be infectious, the organisms must have access to environmental air and be aerosolized. By and large, this means that only patients with pulmonary tuberculosis can be regarded as infectious. However, respirable particles containing *M. tuberculosis* may rarely be generated from other sources: for example, irrigation of a tuberculous abscess.[22] After aerosolized respiratory secretions are expelled from the nose or mouth, their water content evaporates rapidly, leaving only a small residue of solid matter—the *droplet nucleus*—which may include tubercle bacilli and which may remain suspended in the air for several hours.[23] A single bacillus in a tiny droplet nucleus is more hazardous than several bacilli in larger airborne particles, which when inhaled deposit in airways rather than alveoli and which then are quickly removed by mucociliary clearance.

Coughing is the most effective mechanism for generating aerosols that create droplet nuclei. Forced expiratory maneuvers other than coughing—such as sneezing, yelling, singing, and loud talking—all involve, to a greater or lesser extent, the sudden acceleration of air required to disrupt a liquid surface or mucous strands, thereby aerosolizing particles. Thin, watery secretions are more easily fragmented into small respirable droplets than is more viscous mucus. In general, the greater the volume of respiratory secretions, the greater the number of potentially infectious droplets.

Riley and coworkers[24] demonstrated marked variability in the infectious potential of tuberculosis patients that, in part, could be related to the severity of coughing. One patient with exceptionally infectious disease not only had severe pulmonary tuberculosis but tuberculous laryngitis as well. It was calculated that this patient was as contagious as a child with measles is to other susceptible children. Similar studies by Escombe and coworkers,[25] which described the infectiousness of HIV-infected patients with tuberculosis, reported that infectiousness was very heterogeneous. Of 97 patients (118 admissions) hospitalized in an HIV-tuberculosis ward, 10 caused 90% of the infections in guinea pigs exposed to air exhausted from the ward. Of the 10 infectious patients, 6 had MDR tuberculosis that was inadequately treated; in addition to having MDR tuberculosis, being sputum smear positive and being on suboptimal treatment both contributed to the degree of infectiousness.

Simple maneuvers, such as covering the mouth while coughing, can reduce formation of droplet nuclei by deflecting droplets from the air stream. Similarly, a mask worn by the patient is effective because particles are trapped while they are still large, before the water content has evaporated. Masks (disposable particulate respirators) worn by persons exposed to an infectious source are less effective than are masks worn by patients, because most airborne droplet nuclei are much smaller than their parent droplets. However, properly constructed, well-fitting masks are very efficient in removing respirable particles of 1 to 5 μm.[26]

An important factor to be considered in determining infectiousness is the number of organisms contained in the lungs of the source case. This can be inferred from the extent and morphology of the disease, as determined by the chest roentgenogram and more directly estimated by microscopic examination of sputum. Canetti[27] demonstrated that the bacillary population of tuberculous lesions varies greatly, depending on the morphology of the lesion. The number of bacilli in solid nodular lesions ranges from 10^2 to 10^4 organisms, whereas in cavitary lesions, populations are on the order of 10^7 to 10^9 bacilli. Loudon and Spohn,[28] among others, demonstrated that the prevalence of tuberculin reactors among young contacts of patients with newly discovered tuberculosis increased as the radiographic extent of involvement increased. Thus, in tuberculosis control, the contacts of persons with more extensive tuberculosis should be accorded a higher priority for epidemiologic investigations than should the contacts of persons with less severe disease.

The most direct means of estimating bacillary population is microscopic examination of properly stained sputum smears. An average viable bacillary population of 5000 to 10,000 organisms per milliliter of sputum is required for the organisms to be seen in an acid-fast–stained sputum smear.[29] Data from a variety of sources consistently demonstrate that contacts of patients who have organisms present in sputum smears have a much higher prevalence of infection than do contacts of patients with negative smears and either positive or negative cultures.[30] However, it should be noted that the contacts of sputum smear–negative patients may acquire tuberculous infection and develop tuberculosis. Transmission from smear-negative patients was estimated to be the cause of approximately 17% of newly diagnosed cases in San Francisco.[31]

A third important factor in determining the infectiousness of a source case is the use of chemotherapy. In a series of studies designed to identify and quantify factors influencing transmissibility of *M. tuberculosis,* Sultan and associates[32] and Riley and coworkers[24] noted that patients who had positive sputum smears but who were receiving antituberculosis drugs were much less infectious for guinea pigs than were untreated patients. By their calculations, the relative infectiousness of untreated patients in comparison with treated patients was 50 : 1. Escombe and coworkers,[25] as already noted, came to a similar conclusion. Consistent with these experimental observations, a substantial body of clinical data has accumulated that indicates that, once treatment to which the organisms are susceptible is begun, transmission of *M. tuberculosis* decreases quickly. The quantification of the infectiousness of cough-generated aerosols has shown the same result—that the major factor associated with persistent culture-positive aerosols was lack of effective treatment during the previous week.[33]

The most important mechanism by which chemotherapy reduces infectiousness is the direct effect of the drug on the bacillary population in the lungs. Hobby and associates[29] found that, after an average of 15.6 days of multidrug chemotherapy, there was a reduction in the number of tubercle bacilli per milliliter of sputum of at least 2 logs, from approximately 10^6 to approximately

10^4, or a 99% decrease. These data are similar to those reported by Jindani and coworkers,[33] who demonstrated a reduction in colony counts of nearly 2 logs per milliliter of sputum in the first 2 days of treatment, and a further reduction of 1 log during the next 12 days. Thus, in the initial 2 weeks of treatment, there was a decrease from approximately 10^7 to 10^4 organisms per milliliter of sputum, or a reduction of 99.9%. However, even with this profound reduction in the bacillary population, the remaining number of organisms (10,000 per milliliter of sputum) would still be sufficient to produce a positive acid-fast sputum smear. In addition to reducing the number of viable bacilli, chemotherapy also promptly decreases coughing. Loudon and Spohn[28] noted that coughing was reduced by 40% after 1 week of treatment and by 65% after 2 weeks.

The sum of these effects is that, once a patient with tuberculosis is placed on effective therapy, transmission of tubercle bacilli ceases to be a concern. The decline in infectiousness is caused mainly by the rapid reduction in bacillary population in the lungs as a result of antituberculosis chemotherapy, particularly isoniazid. Drug regimens that do not include isoniazid probably should not be expected to render the patient noninfectious as rapidly as do those containing isoniazid. Likewise, the prompt reduction in infectiousness cannot be assumed to occur in patients harboring organisms that are resistant to isoniazid.

The operational implications of these assumptions concerning infectiousness should be modified in accordance with the patient's living and working circumstances. The general principles of infection control entail an assessment of the vulnerability to tuberculous infection of persons who will potentially be exposed and the consequences should those who are exposed become infected.

Data from several sources indicate that strains of *M. tuberculosis* resistant to isoniazid may be less pathogenic than fully susceptible organisms.[34,35] Molecular epidemiologic studies suggest that the mutation conferring resistance may have a role in the pathogenicity of *M. tuberculosis,* especially mutations associated with isoniazid resistance.[36] Isolates harboring the most common mutation, *katG* S315T and the *inhA* promoter 15c-t, were able to cause secondary cases of tuberculosis (defined by genotyping of strains in a population). In contrast, mutations in *katG* other than the common S315T mutation did not cause secondary cases. Although more information is needed to confirm this association, this finding may explain the different results regarding the pathogenicity of drug-resistant strains. It is also clear that the lesser pathogenicity can easily be offset by a prolonged period of infectiousness, as might occur with ineffective treatment, as suggested by Escombe and associates,[25] or by exposure of an immunocompromised host. Outbreaks of tuberculosis caused by MDR and XDR strains of tubercle bacilli have taken place in hospitals or correctional facilities and largely have involved HIV-infected persons.[37] Through the use of DNA fingerprinting, nosocomial transmission has been clearly documented. However, the outbreak described by Reves and associates[38] did not involve persons with evident immunocompromise. Moreover, in the outbreak that was described by Nardell and colleagues,[39] the patients were homeless and, though many of them were alcoholic, no other potential cause of immunodeficiency was recognized.

Environmental Factors

The physical laws that apply to aerosolized particles, described in detail in Chapter 12, dictate that droplet nuclei essentially become part of the environmental air; thus, environmental factors are of extreme importance in influencing transmission of tubercle bacilli. Studies by Loudon and associates[40] showed that, under standard conditions of temperature and humidity indoors, 60% to 71% of aerosolized *M. tuberculosis* organisms survived for 3 hours, 48% to 56% for 6 hours, and 28% to 32% for 9 hours. Apart from the natural death rate, the only factors influencing the infectiousness of organisms in a droplet nucleus under ordinary circumstances are its removal by venting or filtering and the death of the organisms from exposure to ultraviolet light. Environmental factors may be manipulated to dilute the concentration of tubercle bacilli, mainly removing them by effective filtration, killing them with ultraviolet light, or both.[41]

The influence of the concentration of organisms in environmental air in transmission of *M. tuberculosis* has been well illustrated in several microepidemics in which recirculation of air played an important role. The most dramatic example occurred on board a U.S. Navy vessel that had a closed, recirculating ventilation system.[42] The index case had a positive sputum smear and a brisk cough and therefore was highly infectious. As a result of this one case, 53 of 60 persons (88%) in his berthing compartment acquired tuberculous infections, and 6 developed tuberculosis. In a second compartment connected to the same ventilation system, 43 of 81 persons (53%) became infected and 1 developed tuberculosis. Smaller epidemics, one caused by a patient who underwent bronchoscopy in an intensive care unit, have been described.[43,44]

Since early in the 20th century, it has been known that exposure to ultraviolet radiation kills tubercle bacilli. Riley and coworkers,[24] in their classic studies of infectiousness in a series of patients, demonstrated that ultraviolet irradiation of air passing through an air-conditioning duct completely eliminated transmission of *M. tuberculosis* to guinea pigs housed beyond the ultraviolet lights. The major usefulness of ultraviolet lights is in hospital areas or clinics where patients with untreated tuberculosis are likely to be encountered. This is especially important in open areas such as waiting rooms, where ventilation may not be adequate to remove infectious particles, and within ventilation systems.[41]

Circumstances of Exposure

The conditions under which the exposure occurs have a major influence on the number of infectious particles inhaled. If the exposure is of long duration and takes

place under conditions that would be associated with a high concentration of droplet nuclei in the air inhaled by the contact, there is obviously a greater likelihood that transmission will occur. This is simply a restatement of what has been known for many years: crowding and intimacy of contact are important determinants of transmission of *M. tuberculosis.*[45] This is reflected in data from the United States showing that rates of both clinical tuberculosis and tuberculin reactivity are much higher among close (generally household) than among nonclose (generally out-of-household) contacts.[17] In general, the rate of tuberculosis is in the range of 15 per 1000 close contacts and 3 per 1000 nonclose contacts examined. Of close contacts, approximately 30% are infected, in comparison with approximately 15% of nonclose contacts. Because the risk of tuberculosis is higher among close contacts, they should also be considered high-priority candidates for isoniazid preventive therapy.

Host Factors

It has generally been thought that risk factors for acquisition of tuberculous infection have been exogenous to the contact; in other words, the likelihood of becoming infected with *M. tuberculosis* is related mainly to features of the index case and of the environment shared by the index case and the contact. Nevertheless, endogenous factors, especially the immune responsiveness of the newly infected person, do influence whether or not tuberculosis will develop. For example, the data indicating that the risk of acquiring tuberculous infection is greater among blacks than among whites, given equal levels of exposure,[46] suggest endogenous factors play a role in affecting the response to an encounter with *M. tuberculosis.* This may be true of HIV-infected persons as well. The possible factors have not yet been defined, although in the presence of HIV infection, any of several abnormalities could account for an increased likelihood of infection.

Once viable *M. tuberculosis* organisms have been deposited in the lungs, both nonimmunologic and immunologic factors defend the potential host against the development of infection. Of these, the more potent by far is the specific immunologic response mounted after the first successful invasion of tubercle bacilli.[47,48] The most commonly measured evidence of this response is reactivity to tuberculoprotein, assessed by the tuberculin skin test or by a positive interferon-γ (IFN-γ) release assay. In immunocompetent persons, the cell-mediated immune response to the first tuberculous infection generally checks the proliferation of the organisms. In addition, external challenges from inhaled mycobacteria are met with substantially increased resistance that greatly reduces the likelihood that any new exogenous infection will occur. For this reason, an already infected person who is in contact with an infectious case is less likely to acquire a new infection than is a previously uninfected contact. The cell-mediated immunity that develops in response to mycobacterial infection is species-specific for the infecting organisms. However, sensitization with heterologous mycobacterial antigens, such as the bacillus of Calmette and Guérin (BCG) or nontuberculous mycobacteria, increases the responsiveness of lymphocytes and macrophages to *M. tuberculosis* and, thus, may afford some protection against subsequent infection with *M. tuberculosis.*[49]

In people with impaired immune responses, such as those with HIV infection, the mechanisms by which infection, both initial and latent, is contained are substantially less effective than in those with normal immunity, which explains why persons with HIV infection who acquire a new tuberculous infection so often develop tuberculosis. Moreover, previous tuberculous infection in an HIV-infected person is less likely than in healthy persons to provide protection against a new exogenous infection.[50] The risk of reinfection in persons with HIV infection is higher among those with a CD4 cell count less than 200 cells/μL.[51] It has also been demonstrated that the risk of reinfection is higher in areas where the incidence of tuberculosis is high.[52]

Although there are specific genetic defects, such as polymorphisms in the genes for the natural resistance-associated membrane protein-1 (NRAMP-1) and the vitamin D receptor, that have been found to predispose to mycobacterial diseases, their contribution to the total burden of tuberculosis appears to be small in relationship to the much more dominant social and environmental factors.[53]

PATHOGENESIS

The genesis of the pathologic reactions in tuberculosis is inextricably linked with the response of the host to the invading tubercle bacillus. In most individuals infected with *M. tuberculosis,* the host response—both nonspecific and specific—restricts the growth of the pathogen, thereby containing the infection.[48,54] Paradoxically, however, a major component of the tissue damage associated with tuberculosis is thought to result from the immunologic responses to *M. tuberculosis.* The near absence of cell-mediated immunity that occurs in patients with advanced HIV infection is assumed to be responsible for the atypical presentations of tuberculosis in HIV-infected patients. Such patients tend not to have cavitary lung lesions and to have multisystem involvement with tuberculosis. Although the lack of immune response minimizes tissue necrosis, the organism is not met with an effective protective response; thus, proliferation and dissemination are facilitated.

Figure 34-3 describes schematically the pathogenesis of tuberculosis. As can be seen, the process occurs in two phases: the acquisition of tuberculous infection and the subsequent development of tuberculosis. Tuberculosis may develop as a direct progression from infection to disease (3% to 10% probability within 1 year of infection) or from late progression occurring many years after infection (up to 5% probability for the lifetime of an infected person after the first year of infection).[55] These percentages were derived from data collected before the HIV epidemic. In HIV-infected populations, the rate of developing disease is considerably higher.

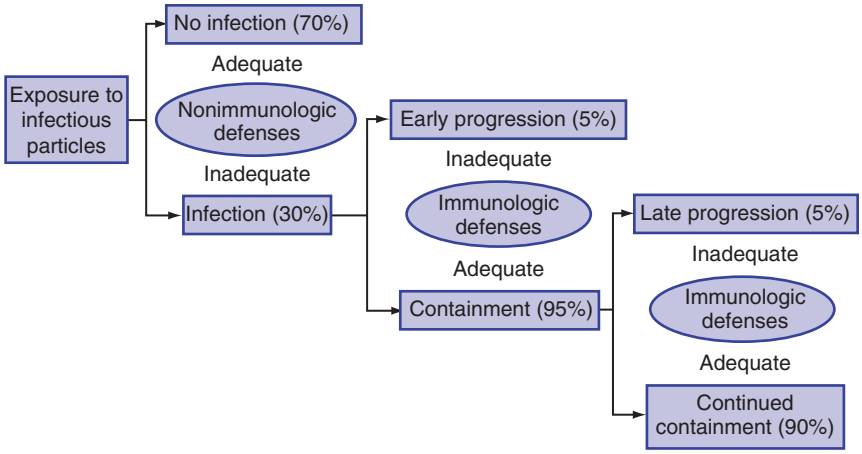

FIGURE 34-3 ■ Consequences of exposure to an infectious source case of tuberculosis. Exposure to a patient with infectious tuberculosis causes tuberculous infection in approximately 30% of those exposed. Of those who are infected, 3% to 10% develop tuberculosis within 1 year of their becoming infected. Beyond 1 year, an additional 3% to 5% develop tuberculosis during the remainder of their lifetimes.

Events in the Nonimmunized Host

Tiny droplet nuclei are efficient vehicles for conveying *M. tuberculosis* deeply into the lungs owing to their aerodynamic properties, which enable them to avoid the mechanical barriers that prevent larger particles from penetrating beyond conducting airways (see further discussion in Chapter 12). Tubercle bacilli within particles that reach the respiratory bronchioles and alveoli are generally ingested by alveolar macrophages and removed from the alveolar space by migration of the phagocytes along the alveolar surface to the origin of the mucociliary transport system. Macrophages, even from individuals with no prior immunologic experience with mycobacterial infection, possess some killing or growth-inhibiting capability. Thus, once alveolar macrophages phagocytose a small number of invading mycobacteria, killing and digestion of the organism probably follow in the majority of exposures to *M. tuberculosis.*

Clearance by alveolar macrophages may completely eradicate all the bacilli—if only a few organisms are implanted on the alveolar surface; however, when many infected droplet nuclei are deposited, the number of bacilli ingested by an individual macrophage can overwhelm the microbicidal system of the phagocyte. When the nonspecific defenses are insufficient to kill all of the organisms, the surviving bacilli multiply, causing a localized tuberculous pneumonia. In general, after the development of specific cell-mediated immune response, this lesion heals spontaneously, leaving only a calcified parenchymal focus (*Ghon lesion*), which may be accompanied by calcification in hilar nodes, the two lesions together forming the *Ranke complex.*

During the phase of tissue invasion, *M. tuberculosis*–laden macrophages enter the bloodstream via the lymphatics, which then provides access to all organs of the body; this invariable dissemination sets the stage for the development of pulmonary and extrapulmonary tuberculosis that occurs by reactivation many years later. It has been postulated that the sites in which the organisms thrive best are those in which the prevailing oxygen tension is high. Support for this theory comes from the observations that the apical portions of the lungs, the most favored location of persistence and subsequent proliferation of tubercle bacilli, are known to have the highest oxygen tension in the body, whereas organs such as the heart and spleen have much lower values and are seldom clinically involved.

Immunologic Responses to *Mycobacterium tuberculosis*

The principal immune response associated with protection against tuberculosis in experimental animals and presumably humans is cell-mediated immunity involving T lymphocytes and macrophages.[47,48,54] Studies in BCG-immunized animals indicate that, although immunization does not prevent infection with *M. tuberculosis,* the growth of the organism within macrophages is reduced by several orders of magnitude. In dramatic contrast, immunodeficiency, such as that produced by HIV infection or selective depletion of T cells or cytokines—especially IFN-γ—in experimental animals, results in a weakening of defenses against *M. tuberculosis.*[48] However, because *M. tuberculosis* is a virulent organism, little if any immunodeficiency is necessary for disease to develop. Thus, tuberculosis, which commonly occurs with a lesser degree of immunodeficiency than other HIV-associated "opportunistic" infections, has become a sentinel disease for the presence of HIV infection.

Once *M. tuberculosis* antigens are internalized, the macrophages digest them into small fragments. Particular fragments (epitopes) are able to bind to the major histocompatibility complex (human leukocyte antigen) molecules of infected macrophages and other antigen-presenting cells, which can transport the epitopes to the macrophage surface for presentation to T cells. With time, the number of T cells with specificity for antigens and epitopes of *M. tuberculosis* expands and establishes a state of delayed-type hypersensitivity in most healthy individuals.[48] Delayed-type hypersensitivity to the antigens of *M. tuberculosis* is measured by a person's ability to produce an indurated reaction to the intracutaneous injection of tuberculin purified protein derivative (PPD) or a positive IFN-γ release assay. Specific $CD4^+$ T cells secrete a characteristic pattern of lymphokines, including interleukin-2, a growth factor for T cells that stimulates their clonal expansion, and IFN-γ, a major mediator of

macrophage activation.[48] It is known that IFN-γ is necessary for the activation of microbicidal mechanisms in macrophages. One of the major cytotoxic mechanisms of phagocytic cells is the production of reactive oxygen intermediates from molecular oxygen, the most potent of which are hydrogen peroxide and the hydroxyl radical. Not surprisingly for a pathogen with a preference for growth in the lungs, tubercle bacilli are found to be extraordinarily resistant in vitro to the cytotoxic activity of reactive oxygen intermediates.[56] The production of reactive nitrogen intermediates, particularly nitric oxide, is also thought to play an important role in killing *M. tuberculosis*. Evidence indicates that murine macrophages that produce nitric oxide both inhibit growth and actually kill virulent human tubercle bacilli in vitro.[57,58] Nitric oxide is produced by murine macrophages activated by two cytokines, IFN-γ, and tumor necrosis factor-α (TNF-α). $CD4^+$ T cells produce IFN-γ, and mycobacteria-infected macrophages produce large amounts of TNF-α.

Lymphokines and cytokines also have the ability to organize granulomas that then serve to wall off the infection, kill or reduce the growth of bacilli, and restrict the mobility of infected macrophages and the spread of the infection within the body.[56,59] In immunodeficient individuals or animals deprived of TNF-α, there is a lack of organized granulomas and generally unrestricted spread of infected macrophages throughout the body, which may explain the pathogenesis of miliary tuberculosis. Essentially, each macrophage that cannot kill its internalized bacilli becomes an infectious seed enabling the growth and spread of bacilli.

Similarly, it is becoming increasingly clear that activated T cells, activated macrophages, and production of a variety of lymphokines and cytokines are also involved in tissue damage in tuberculosis. If the macrophages fail to kill or contain the organisms initially, antigens diffuse from the cells, leading to a greater influx of blood monocytes to the site of the lesion, increased macrophage activation, a larger granuloma, and ultimately greater necrosis. At some point in sensitized individuals, there is killing of the infected macrophages by products of the intracellular tubercle bacilli or possibly cytotoxic T lymphocytes. This killing results in release of tissue-dissolving enzymes that can cause caseous necrosis and cavitation. The extracellular liquid milieu serves as an ideal culture medium in which tubercle bacilli can proliferate to very large numbers.

Exogenous Versus Endogenous Infection

One of the historical controversies in tuberculosis has been the extent to which clinical tuberculosis can be attributed to new infection by recently inhaled exogenous organisms (i.e., from the environment) as opposed to a reactivation of viable bacilli that have been maintained for many years in a dormant or growth-restricted state within the body.[60] Data related to this issue are largely inferential; however, the concept is very important in that, as discussed subsequently, current tuberculosis control efforts are based largely on the idea that most tuberculosis in low-incidence areas is the result of endogenous reactivation. Thus, prevention entails identification of infected persons and giving them preventive therapy with isoniazid.

Stead,[60] after an extensive review of the literature, concluded that the data provided strong—albeit inferential—evidence that chronic (so-called adult) pulmonary tuberculosis results from proliferation of organisms in foci that were seeded during primary infection. The data presented showed that, in tuberculin-negative persons, rates of tuberculosis were proportional to the degree of exposure (49.4 cases per 1000 person-years of observation with heavy exposure and 10.8 cases per 1000 person-years in those "not particularly exposed"). In contrast, rates of disease in persons known to be tuberculin-positive at the beginning of the observation period were not so clearly related to exposure (7.6 cases per 1000 person-years with heavy exposure and 4.3 cases per 1000 person-years in those "not particularly exposed"). If exogenous reinfection were the predominant mechanism by which tuberculosis developed, rates of disease should have varied with the degree of exposure in both the tuberculin-positive and tuberculin-negative groups. This obviously was not the case.

DNA restriction fragment length polymorphism (RFLP) analysis has provided more direct evidence on transmission pathways and on the question of reinfection. For example, isolates of tubercle bacilli from HIV-positive individuals, in health care facilities or correctional institutions, frequently show identical DNA fingerprints (Fig. 34-4), indicating that these individuals were prob-

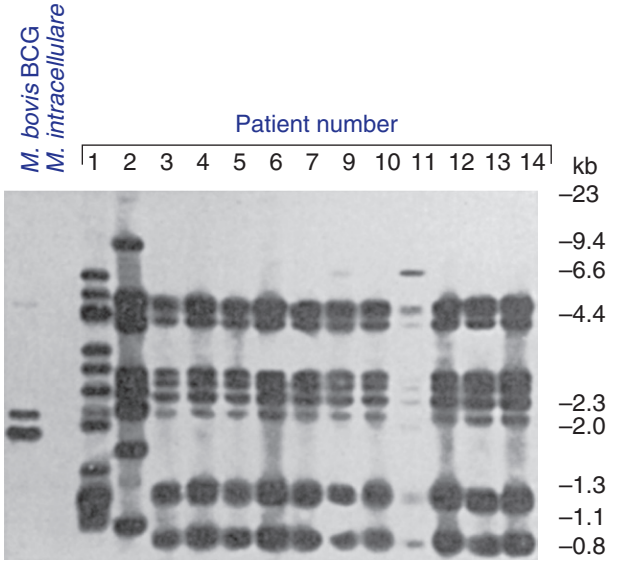

FIGURE 34-4 ■ Gel electrophoresis of DNA extracted from organisms isolated from patients in an outbreak of tuberculosis in San Francisco. Cases 3 through 14 were linked epidemiologically, whereas cases 1 and 2 were not. This is an example of the use of restriction fragment length polymorphism analysis to track strains of *Mycobacterium tuberculosis*. (From Daley CL, Small PM, Schecter GF, et al: An outbreak of tuberculosis with accelerated progression among persons infected with the human immunodeficiency virus: An analysis using restriction fragment length polymorphisms. N Engl J Med 326:231–235, 1992.)

ably infected by the same source.[50,61,62] Thus, molecular technology—by identifying organisms that are genetically related—can suggest the source of infection. Regarding reinfection, the results of a study using RFLP analysis conducted in a high-incidence community showed that exogenous reinfection accounted for 75% of the cases of recurrent tuberculosis in persons who had had apparently curative treatment.[63] However, this study was limited by a relatively low sampling rate of recurrent cases. Molecular epidemiologic analyses from other areas have shown lower rates of apparent reinfection.[64,65] Thus, although it is clear that reinfection does occur and may account for a certain proportion of cases, the magnitude of the contribution to the overall incidence of tuberculosis is not known, but probably varies considerably depending on local epidemiologic circumstances.

The overall implication of the results of experimental infection in animals, results of clinical studies, and epidemiologic data is that specific immunity to antigens of the tubercle bacillus provides considerable resistance against disease, but protection is incomplete. Heavy exposure to tubercle bacilli may result in new disease, even in individuals who are tuberculin-positive and, hence, have considerable immunologic protection. Lapses or deficiencies in immune responses can lead to reactivation or endogenous infection.

RISK FACTORS

Although the factors involved in the pathogenesis of tuberculosis, described previously, apply in all instances in which the disease develops, not all persons are at equal risk of developing disease after acquiring an infection. Many conditions that either influence the likelihood of tuberculosis or serve as markers of increased risk have been identified. As noted previously, in generally healthy populations the risk of developing tuberculosis is much higher during the first year after infection has occurred; between 3% and 10% of newly infected persons develop tuberculosis during this period. The two factors presumably involved are the adequacy of the host response in countering the invasion and the dose of bacilli implanted in the lungs. The "inoculum effect" has not been clearly demonstrated in humans but is strongly suggested by results of animal experiments.[21] Presumably, beyond the first year after infection has taken place, the immune response has matured and the number of organisms present has been substantially reduced.

Among persons with tuberculous infection, case rates vary markedly with age. Rates are considerably increased in infants and relatively increased in adolescents and young adults.[66] The reasons for the variations are as yet undetermined but may relate to age-dependent influences on the effectiveness of the immune response.

Clearly, the most potent condition that increases the risk of tuberculosis is infection with HIV. Selwyn and coworkers[67] found that 8 of 212 HIV-infected intravenous drug users developed tuberculosis in a 2-year period of observation, a case rate of 8 per 100 person-years of observation. Of these, 7 cases developed within a subset of 49 persons who were known to be tuberculin-positive. Thus, the case rate for persons who were dually infected with both HIV and *M. tuberculosis* was 7.9 per 100 person-years. This exceeds the lifetime risk of a person with tuberculous infection who is not HIV-infected. It also appears that the risk of rapid progression of tuberculosis among persons who are infected with HIV and who then become infected with *M. tuberculosis* is tremendously increased, as has been demonstrated in descriptions of two such outbreaks.[61,68] The reported rates of tuberculosis in cohorts of persons with HIV infection vary widely, and depend on the prevalence of tuberculosis in the environment, particularly the presence of infectious cases; the frequency with which treatment for latent tuberculous infection is used; the severity of immune compromise within the HIV-infected group; and whether dually infected persons are receiving antiretroviral therapy, which substantially reduces the risk.[69,70]

The only study conducted to address the incidence of tuberculosis prospectively in a broad-based group of persons with HIV infection in the United States—before the widespread use of combined antiretroviral therapy—was the Pulmonary Complications of HIV Infection study.[71] In this cohort, drawn from six centers across the country, the rate of tuberculosis was 0.71 per 100 person-years of observation. In multivariate analyses, the factors that were associated with increased rates were residence in New York City or Newark (the two East Coast centers), being tuberculin positive (reaction > 5 mm), and having a $CD4^+$ cell count below 200 cells/μL.

In persons with both HIV and tuberculous infections, antiretroviral therapy and preventive treatment with isoniazid substantially decrease the incidence of tuberculosis. In a retrospective analysis of the incidence of tuberculosis among persons with HIV infection in Rio de Janeiro, Brazil, among patients who received neither antiretroviral treatment nor isoniazid preventive therapy, the incidence of tuberculosis was 4.01/100 person-years.[72] Among patients who received antiretroviral therapy, the incidence was 1.90/100 person-years (95% confidence interval [CI], 1.66 to 2.17), and those treated with isoniazid had a rate of 1.27/100 person-years (95% CI, 0.41 to 2.95). The incidence among patients who received both antiretroviral therapy and isoniazid was 0.80/100 person-years (95% CI, 0.38 to 1.47). Overall, there was a 76% reduction in tuberculosis risk among patients receiving both antiretroviral treatment and isoniazid. (Isoniazid preventive therapy is discussed in a later section.)

Other conditions or therapies that interfere with cell-mediated immunity also increase the risk of tuberculosis. These relationships, although well described and generally accepted, are poorly quantified. Examples of these disorders include hematologic malignancies and cancer chemotherapy. In addition, conditions such as diabetes mellitus and uremia are thought to fit into this general category of risk-enhancing diseases, although the basis for this effect is not established. The risk of tuberculosis is also increased considerably in persons with silicosis,[73]

presumably owing to the effect of silica on the function of alveolar macrophages.

Genetic factors had been suggested by twin studies in which there was a greater concordance of disease in monozygotic than in dizygotic twins.[74] However, it is difficult to separate them from linked environmental factors. Case rates among persons infected with *M. tuberculosis* living in Denmark in the 1950s were only 28 per 100,000 per year.[75] This contrasts strikingly with annual rates of 1500 to 1800 per 100,000 in Eskimo populations in Alaska and Greenland.[76] Genetic differences are also suggested by the pattern of tuberculosis noted among Filipinos in the U.S. Navy.[77] Their rate of disease tended to increase with duration of enlistment rather than to decrease, unlike the pattern seen in blacks and whites. The apparently decreased ability of Filipinos to develop potent cell-mediated immunity is also suggested by their increased rates of developing symptomatic coccidioidomycosis.

Undernutrition is known to interfere with cell-mediated responses and thus is thought to account for the increased frequency of tuberculosis in malnourished persons.[78] In addition to overt malnutrition, other factors related to specific but poorly defined nutritional deficiencies may also be associated with an increased risk of tuberculosis. For example, observations suggest that risk is increased in persons who have had a gastrectomy or an intestinal bypass procedure for weight control.[79] Body build has also been related to the risk of disease among infected persons. In U.S. Navy personnel, rates of tuberculosis were nearly three times greater among men who were thin for their height; the increased incidence of tuberculosis did not appear to be related to nutritional status.[77]

In spite of the number of risk factors for developing tuberculosis that have been identified, the majority of cases diagnosed each year have none of these abnormalities or characteristics.

TUBERCULOUS INFECTION

As indicated previously, infection may or may not follow exposure to *M. tuberculosis* in otherwise healthy individuals, but when infection occurs, it causes a cell-mediated immune response to the organisms whose presence can then be identified by a positive response to testing with an appropriate skin test antigen or INF-γ release assay. Until recently, the only standardized test available to identify this reactivity was the tuberculin skin test utilizing tuberculin PPD. Although the tuberculin skin test remains the "gold standard" for detecting latent tuberculous infection in persons who do not have clinical tuberculosis, tests that measure release of INF-γ from whole blood in response to exposure to specific *M. tuberculosis* antigens are now available commercially.[80]

Tuberculin Skin Test

Tuberculin was first prepared by Robert Koch in 1890 and was touted by him as being therapeutic for tuberculosis. Shortly thereafter, the diagnostic capabilities of the material were recognized through its use in animals. In 1934, Seibert and Glenn[81] prepared the first batch of a much more purified preparation, which they termed *purified protein derivative.* The antigen is prepared in liquid form containing the detergent Tween 80 to decrease adsorption of protein to the glass of the vial. The standard intermediate tuberculin test consists of the intracutaneous injection (Mantoux's method) of 0.1 mL of material, which contains 0.0001 mg of PPD (5 TU). The site usually chosen is the volar surface of the forearm, but any accessible area can be used. A short-beveled 26- or 27-gauge needle should be used with a 1-mL graduated syringe. A properly placed intracutaneous injection should cause a well-demarcated wheal 6 to 10 mm in diameter in which the hair follicles form dimples. Conventionally, the reading is done 48 to 72 hours after the injection, but it may be delayed for up to 1 week.[82]

In persons such as hospital employees, who are likely to be tested repeatedly—if tuberculin-negative at the outset—a two-step testing procedure is recommended to avoid confusing a boosted reaction with a true conversion.[83] Boosting occurs when a person who was infected and would have tested positive in the past loses skin test reactivity over the course of several years. When this occurs, a single tuberculin test is falsely negative, but the test itself is capable of recalling (i.e., boosting) the waned reactivity. A subsequent test would then elicit a positive reaction and may cause the person tested to be classified as a tuberculin converter. To elicit the boosted response and to categorize the person more accurately as infected or not infected, a second 5-TU tuberculin test is applied within 1 to 2 weeks of the first (spuriously negative) test. If the second test shows a positive reaction, it is interpreted as a boosted response indicative of prior infection; if the reaction remains negative, it is assumed to be truly negative.

The reaction to the test should be read by inspecting and palpating the area where the tuberculin was injected. The reaction size is determined by measuring the diameter of any induration with a ruler. The amount of erythema should not be taken into account; only the extent of induration is important. Readings must be recorded accurately in millimeters.

The interpretation of tuberculin tests requires clinical judgment as well as understanding of the test. In a population in which the only mycobacterial species causing infection was *M. tuberculosis,* the curve describing the distribution of reaction sizes in otherwise healthy infected persons given 5-TU PPD would be bell shaped, having a mode of 17 to 18 mm, with very few reactions less than 10 mm. Thus, defining the minimum reaction size indicative of tuberculous infection would be simple.[84] Unfortunately, in many parts of the world, a portion of the population is infected with nontuberculous mycobacteria, which induce some degree of sensitization to tuberculin; inoculation with BCG, for many years the world's most commonly used vaccination, has the same enhancing effect on tuberculin reactivity. Although these reactions are on the whole smaller than

those caused by *M. tuberculosis,* they nevertheless smudge the distinction between reactions in persons infected with *M. tuberculosis* and those not infected. On the basis of a large amount of epidemiologic data and skin testing with antigens prepared from nontuberculous mycobacteria, the best compromise between false-positive and false-negative readings to 5-TU PPD tuberculin tests is 10 mm. Thus, under most circumstances, a reading of 10 mm or more is considered indicative of infection with *M. tuberculosis.* However, in some situations, smaller reactions should be taken to indicate tuberculous infection. For example, a reaction of 5 mm in a child who is a contact of a person with smear-positive tuberculosis would probably indicate tuberculous infection and be considered positive. Likewise, a 5-mm reaction in a person with known HIV infection should be considered positive. In the United States, the history of BCG administration is generally ignored in interpreting the results of the tuberculin skin test.[85]

There are several reasons why the tuberculin reaction may be interpreted as negative in the presence of tuberculous infection. These include errors in application or reading of the test result, usually related to the inexperience of the tester/reader, and should be easily correctable with proper training. Problems with the antigen are infrequent unless it has been improperly handled. Many disease states, especially HIV infection, interfere with cell-mediated immune responses. Lymphoreticular malignancies such as Hodgkin's disease are potent suppressors of cell-mediated immunity. Corticosteroids and immunosuppressive drugs decrease tuberculin reactivity if the patient is on a sufficient dose for a sufficient period of time. For corticosteroids, the minimum dose is 15 to 20 mg of prednisone or the equivalent of another preparation, given daily for 2 to 3 weeks.[86] As stated previously, advancing age is associated with loss of tuberculin reactivity, although it may be recalled.[82] Malnutrition also may cause defects in cell-mediated immunity with consequent diminished tuberculin reactivity. Finally, overwhelming tuberculosis itself may cause diminished or absent tuberculin responsiveness.

Even when the test is applied and the result is read with particular care in patients with proven tuberculosis and no apparent immunosuppression at the time they are admitted to a hospital, only 80% to 85% have reactions of 10 mm or more to 5-TU PPD.[87] Thus, a negative tuberculin test result cannot be used to exclude tuberculosis as a diagnostic possibility.

The interpretation of tuberculin skin test results in persons with HIV infection is particularly problematic, because of the progressive immunosuppression that occurs as HIV disease advances. Individuals infected with HIV are less likely to have a positive tuberculin reaction. In a cross-sectional study of persons with HIV infection and a wide range of $CD4^+$ lymphocyte counts, anergy—defined as lack of any reaction to tuberculin (5 TU) plus mumps and *Candida* antigens—occurred more frequently when the $CD4^+$ count was less than 400 cells/μL.[88]

Interferon-γ Release Assays

Two INF-γ release assays are currently approved for marketing in the United States, the QuantiFERON-TB test and the T-Spot TB test. The QuantiFERON-TB (Cellestis Limited, Carnegie, Victoria, Australia) test, specifically QuantiFERON-TB Gold and QuantiFERON-TB Gold In-tube, measure the amount of INF-γ released from sensitized lymphocytes in whole blood incubated overnight with mixtures of *M. tuberculosis* antigens, early secreted antigenic target (ESAT)-6 and culture filtrate protein (CFP)-10.[80] The other approved test, the T-Spot TB (or ELISPOT), utilizes an elispot format to quantify the number of cells in peripheral blood that secrete INF-γ when stimulated with ESAT-6 and CFP-10 (Oxford Immunotec, Abingdon, United Kingdom).[89]

Compared with the tuberculin skin test, the INF-γ release assays have the advantage of being accomplished with one patient visit, being more specific in the presence of BCG vaccination or infection with nontuberculous mycobacteria, having less reader variability, and not recalling waned immunity (the booster reaction described earlier).[89] A recent systematic review showed that the INF-γ release assays have excellent specificity and are not affected by BCG vaccination.[90] The sensitivity to diagnose infection (using culture-positive *M. tuberculosis* cases as the reference) was variable in the different studies, but T-SPOT TB appeared to be more sensitive than QuantiFERON-TB Gold and QuantiFERON-TB Gold In-tube and the tuberculin skin test.[90,91] In patients with HIV infection, the responses to TST and QuantiFERON-TB Gold In-tube correlated with the degree of immunodeficiency, whereas results of the T-SPORT TB are independent of the level of CD4 T-cell depletion,[91a] which may explain the variable results of the different INF-γ-release assays and TST among patients with HIV infection.[91b]

INF-γ release assays have disadvantages that include the need to draw blood and process it within a specific time and there being far less experience with the test than with PPD and, therefore, much less evidence to characterize the performance of the test for diagnosing latent tuberculous infection and for epidemiologic studies. The risk factors for conversion and reversion were different for ELISPOT and the tuberculin skin test.[92] The authors attributed these findings to a lack of understanding of the dynamics of the INF-γ response to ESAT-6 and CFP-10. Also, because there is no knowledge about the time required for the INF-γ release assays to become positive after the onset of infection, the interpretation of a negative ELISPOT requires caution, especially when there is no reference point in time for exposure to *M. tuberculosis.*

Other authors, who also found a substantial proportion of reversions, attributed their findings to the decrease of the bacterial load due to treatment, and to the natural resolution of the infection.[93] In a study in the United Kingdom, Wilkinson et al.,[94] using ELISPOT, showed an early rise in spot-forming counts in patients given isoniazid and rifampin, then a reduction at month 3. No changes were observed in those without treatment. In

India, Pai et al.[95] followed 216 nursing and medical students and observed that 9 (24%) of the 38 individuals with an initial positive QuantiFERON Gold In-tube test had reversion, which was associated with an initial tuberculin skin test negative result. Interestingly, those with skin test conversion also had increase in levels of INF-γ, Taken together, these data underscore the uncertainty regarding the interpretation of the INF-γ release assays in providing information about the outcome of infection with *M. tuberculosis,* both treated and untreated.

Currently, the CDC recommends using the QuantiFERON-TB Gold test for the same indications as the tuberculin skin test: for evaluating persons suspected of having tuberculosis and for screening, including contacts of an infectious case of tuberculosis, children younger than 17 years of age, pregnant woman, and persons at increased risk of tuberculosis, particularly those with HIV infection, recent immigrants who have had BCG vaccination, and health care workers. The QuantiFERON-TB Gold test usually can be used in place of—and not in addition to—the tuberculin skin test.[96]
