Currently, in the United States approximately 71% of new cases of tuberculosis involve the lungs only, 20% involve extrapulmonary sites only, and 8% involve both locations.[17] Although extrapulmonary involvement is common in persons with HIV infection, the lungs are also involved in 60% to 70% of such patients.[97]

History, Physical, and Laboratory Examinations

Cough is the most common symptom of pulmonary tuberculosis. Early in the course of the illness it may be nonproductive, but subsequently, as tissue necrosis ensues, sputum is usually produced. Inflammation of the lung parenchyma adjacent to a pleural surface may cause pleuritic pain without evident pleural disease. Spontaneous pneumothorax may also occur, often with chest pain and perhaps dyspnea. *Dyspnea* that results from parenchymal lung involvement is unusual unless there is extensive disease, which may occur, however, and may be associated with severe respiratory failure. *Hemoptysis* usually occurs with more extensive involvement but does not necessarily indicate an active tuberculous process. Hemoptysis may also result from bronchiectasis left as a residual of healed tuberculosis; from rupture of a dilated vessel in the wall of an old cavity (*Rasmussen's aneurysm*); from bacterial or fungal infection (especially in the form of a fungus ball [*aspergilloma* or mycetoma]) in an old residual cavity (Fig. 34-5); or from erosion of calcified lesions into the lumen of an airway (*broncholithiasis*).

The systemic features of tuberculosis include fever in approximately 35% to 80%[98,99]; malaise and weight loss; a variety of hematologic abnormalities, especially leukocytosis and anemia[100]; and metabolic disorders, including hyponatremia, which in one series was found to occur in 11% of patients.[101] Subsequently, hyponatremia was determined to be caused by production of an antidiuretic hormone–like substance found within affected lung tissue.[102]

Physical findings are not particularly helpful. Crackles may be heard in the area of involvement, along with bronchial breath sounds, when lung consolidation is close to the chest wall. Amphoric breath sounds may be indicative of a cavity.

Radiographic Features

In developed countries, radiographic examination of the chest is usually the first diagnostic study undertaken, after the history and physical examination. In resource-limited settings, a chest radiograph is not necessarily included as part of the routine evaluation because of cost, complexity, and nonspecificity of the findings.[103] Pulmonary tuberculosis nearly always causes detectable abnormalities on the chest film, although in patients with HIV infection, a normal chest radiograph occurred in as many as 11% of patients with positive sputum cultures.[71] In primary tuberculosis, occurring as a result of recent infection, the process is generally seen as a middle or lower lung zone infiltrate, often associated with ipsilateral hilar adenopathy (Fig. 34-6). Atelectasis may result from compression of airways by enlarged lymph nodes. If the primary process persists beyond the time when specific cell-mediated immunity develops, cavitation may occur (so-called progressive primary tuberculosis).

Tuberculosis that develops many years after the original infection (endogenous reactivation) usually involves the upper lobes of one or both lungs. Cavitation is common in this form of tuberculosis. The most frequent

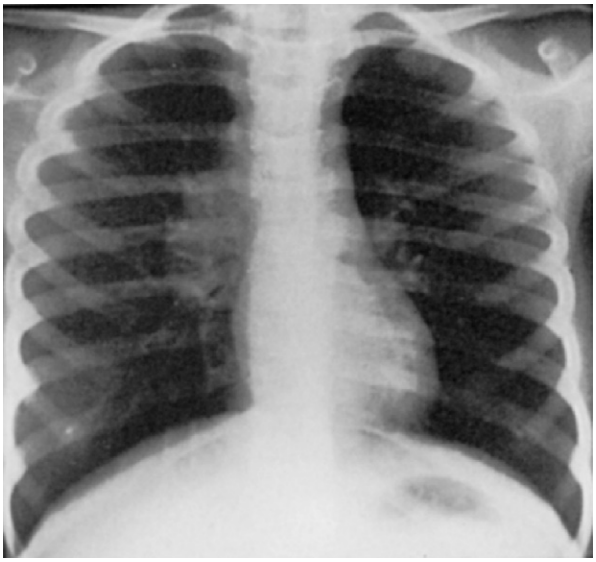

FIGURE 34-6 ■ Frontal-view chest roentgenogram showing right hilar adenopathy from primary tuberculosis.

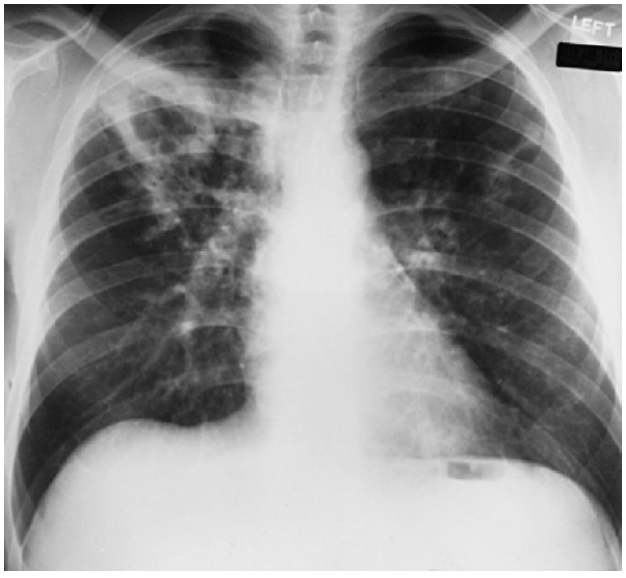

FIGURE 34-7 ■ Frontal-view chest film showing upper lobe cavitary lesion typical of endogenous reactivation tuberculosis.

sites are the apical and posterior segments of the right upper lobe (Fig. 34-7) and the apical-posterior segment of the left upper lobe. Healing of the tuberculous lesions usually results in development of a fibrotic scar with shrinkage of the lung parenchyma and, often, calcification. Involvement of the anterior segments alone is unusual. In the immunocompetent adult with tuberculosis, intrathoracic adenopathy is uncommon. When the disease progresses, infected material may be spread via the airways (i.e., "bronchogenic" spread) into the lower portions of the involved lung or to the other lung. Erosion of a parenchymal focus of tuberculosis into a blood or lymph vessel may result in dissemination of the organism and a miliary pattern on the chest film (Fig. 34-8).

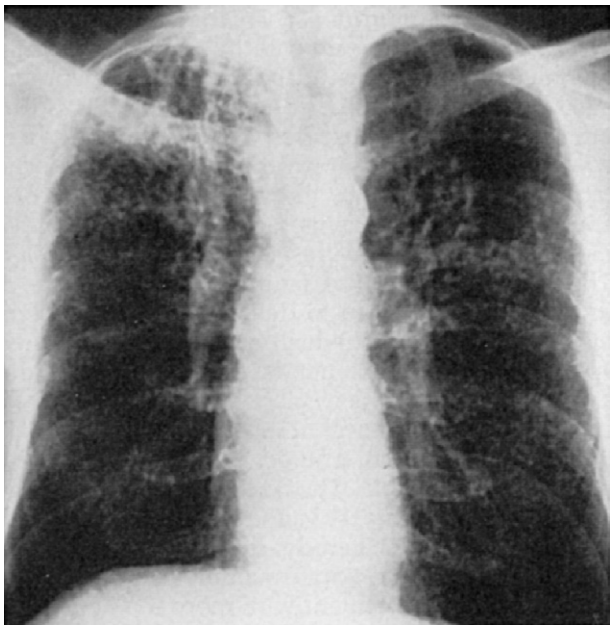

FIGURE 34-8 ■ Frontal-view chest film showing focal infiltration in the right upper lobe and scattered miliary lesions throughout both lungs.

Radiographic findings in HIV-infected patients are affected by the degree of immunosuppression. As further explained and illustrated in Chapter 80, tuberculosis occurring relatively early in the course of HIV infection tends to produce typical radiographic findings with predominantly upper lobe infiltration and cavitation.[104] With more advanced HIV disease, the radiographic findings become more "atypical": cavitation is uncommon, and lower lung zone or diffuse infiltrates and intrathoracic adenopathy are frequent (Fig. 34-9). Surprisingly, a substantial number of HIV-infected patients with pulmonary tuberculosis had normal radiographs at the end of their course of treatment.[105]

The activity of a presumed tuberculous process cannot be determined simply from a single radiographic examination of the chest. A cavity might be a sterile residual of an old infection, whereas a fibrotic-appearing lesion may be active. Conversely, not all radiographic worsening of the residua of prior tuberculous lesions can be ascribed to reactivation of the disease, although such worsening should always be of concern. Superimposed infections with other organisms or bleeding from bronchiectasis or from residual cavities may cause new infiltrations to appear. In addition, carcinomas may arise from within the area of scarring (so-called scar carcinomas) and be the cause of radiographic changes.

From this discussion, it should be obvious that the chest radiograph, although extremely valuable, cannot provide a definitive diagnosis of tuberculosis. Because of the radiographic similarities among the other disorders in the differential diagnosis, and because of the uncertainties in assessing disease activity and in determining the reasons for progressive radiographic changes, careful microbiologic evaluation is always indicated. A nondiagnostic microbiologic evaluation should prompt

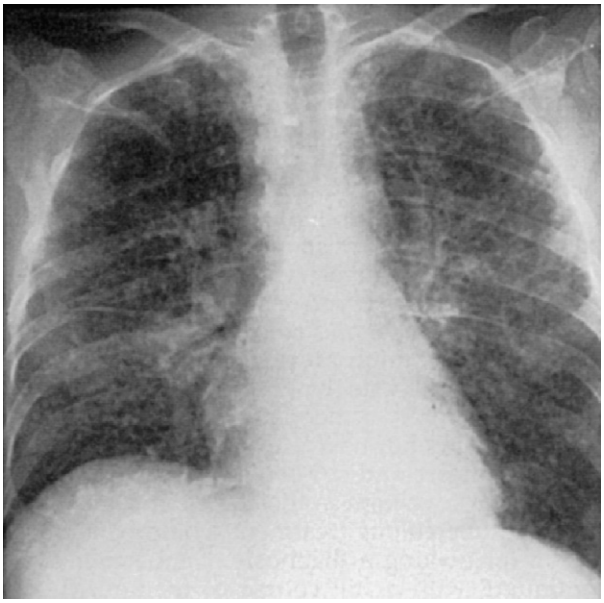

FIGURE 34-9 ■ Frontal-view chest film in a patient with acquired immunodeficiency syndrome and tuberculosis. Note the diffuse lung involvement and the bilateral hilar and right paratracheal adenopathy.

a careful assessment for other causes of the radiographic abnormality.

Bacteriologic Evaluation

As noted previously, a definitive diagnosis of tuberculosis can be established only by isolation of tubercle bacilli in culture or identification of specific nucleic acid sequences. Obviously, when the lung is involved, sputum is the initial specimen of choice. Sputum specimens should be collected at the time of the initial evaluation, and if they are found to be negative by microscopy, additional specimens should be collected. Single early-morning specimens have a higher yield and a lower rate of contamination than do pooled specimens.[106] Collecting more than two sputum specimens increases the yield only slightly.[107]

There are several options for obtaining specimens from patients who are not producing sputum. The first and most useful in terms of yield and avoidance of patient discomfort is inducing sputum production by the inhalation of a hypertonic (3% to 5%) saline mist generated by an ultrasonic nebulizer. Sputum induced by this technique is clear and resembles saliva; thus, it must be properly labeled or it may be discarded by the laboratory. This is a benign and well-tolerated procedure, although bronchospasm may be precipitated in asthmatic patients.

Sampling of gastric contents via a nasogastric tube has a lower yield than sputum induction and is more complicated and uncomfortable for the patient. However, in children and some adults, gastric contents may be the only specimen that can be obtained. Gastric lavage should be performed early in the morning before the patient has gotten out of bed, eaten, or brushed teeth. Once the specimen is obtained, prompt neutralization of the gastric acid is necessary to ensure a maximum yield.

Depending on the clinical circumstances, if the sputum is negative or cannot be obtained, the next diagnostic step is usually fiberoptic bronchoscopy with bronchoalveolar lavage, and in some instances transbronchial lung biopsy. The yield of bronchoscopy has been high in miliary tuberculosis and in local disease as well.[108,109] Bronchoscopic procedures have been especially helpful in the diagnostic evaluations of patients with HIV infection.[110,111] Needle aspiration biopsy may also provide specimens from which mycobacteria are isolated, but the technique is especially suited to the evaluation of peripheral nodular lesions for which there is a suspicion of malignancy.

In some situations, a therapeutic trial of antituberculosis chemotherapy may be indicated before more invasive studies are undertaken.[112] For example, in a tuberculin-positive person who is under 40 years of age, is a nonsmoker, and comes from a country where there is a high prevalence of tuberculosis, either current or past tuberculosis is much more likely than a neoplasm to be a cause for a radiographic abnormality, even in the presence of negative smears and cultures of sputum. In such a patient, improvement in the chest film concomitant with antituberculosis treatment would be sufficient reason for making a diagnosis of tuberculosis and continuing with a full course of therapy. If a response is going to occur, it should be seen within 2 months of starting treatment. If no improvement is noted, the abnormality is the result of either old tuberculosis or another process. An algorithm illustrating this approach is shown in Figure 34-10.

Because of the potentially disastrous consequences of delays in diagnosis of tuberculosis, it is essential that the identification of *M. tuberculosis* be performed rapidly and the results be reported promptly. Waiting days for the results of microscopic examinations, weeks for culture results, and months for speciation and susceptibility studies, as has commonly been the practice, is no longer acceptable.

Acid-Fast Staining

A systematic review of the different diagnostic tests for tuberculosis was recently published.[113] As pointed out, the first step in the diagnostic sequence is nearly always staining and examining readily available specimens for acid-fast bacilli (AFB). Finding AFB is very specific for mycobacteria (except in rare instances), but provides no information about species. In addition, the sensitivity of microscopic examination is relatively low; the level of detection is approximately 10,000 bacilli per milliliter of secretions, if 100 oil immersion microscopic fields are examined. In practice, 40% to 70% of patients with *M. tuberculosis* isolated in culture have positive smears.[114]

Sensitivity of detection of AFB is increased by about 10% when using a fluorochrome staining procedure with auramine O, a fluorescent stain.[115] This procedure requires use of a fluorescent microscope but is faster

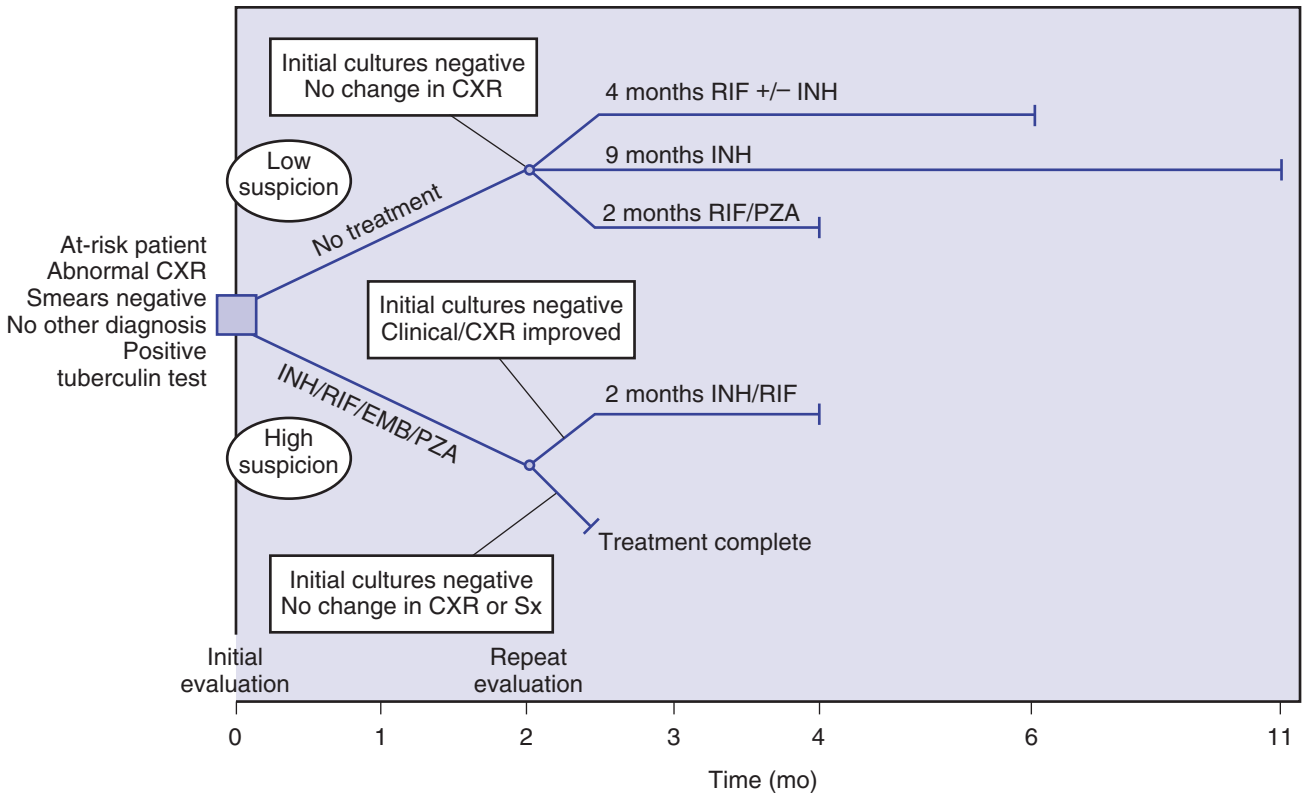

FIGURE 34-10 ■ Treatment algorithm for active, culture-negative pulmonary tuberculosis and inactive tuberculosis. The decision to begin treatment for a patient with sputum smears that are negative depends on the degree of suspicion that the patient has tuberculosis. If the clinical suspicion is high (lower portion of figure), then multidrug therapy should be initiated before acid-fast smear/culture results are known. If the diagnosis is confirmed by a positive culture (see Fig. 34-11), treatment can be continued to complete a standard course of therapy. If initial cultures remain negative and treatment has been with multiple drugs for 2 months, then there are two options depending on repeat evaluation at 2 months (lower portion of figure). In option 1, if the patient demonstrates symptomatic or radiographic improvement without another apparent diagnosis, then a diagnosis of culture-negative tuberculosis can be inferred. Treatment should be continued with isoniazid and rifampin alone for an additional 2 months. In option 2, if the patient demonstrates neither symptomatic nor radiographic improvement, then prior tuberculosis is unlikely, and treatment is complete once treatment including at least 2 months of rifampin and pyrazinamide has been taken. In low-suspicion patients not initially on treatment (upper portion of figure), if cultures remain negative, the patient has no symptoms, and the chest radiograph is unchanged at 2 to 3 months, there are three treatment options: (1) isoniazid for 9 months; (2) rifampin with or without isoniazid for 4 months; or (3) rifampin and pyrazinamide for 2 months. (See later discussion of latent tuberculous infection.) CXR, chest radiograph; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; Sx, symptoms. (From Blumberg HM, Burman WJ, Chaisson RE, et al, for the American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: Treatment of tuberculosis. Am J Respir Crit Care Med 167:603–662, 2003.)

than acid-fast staining because the intensity of the fluorescent signal enables slides to be scanned at lower magnification. Smears generally are interpreted as negative, or, if positive, are reported as rare (3 to 9 organisms per slide), few (10 or more per slide), or numerous (1 or more per high-power oil immersion field). A limitation of this method is the need of a short-arc mercury vapor lamp (MVP) used as the excitatory light source. This has a limited lifespan (200 to 300 hours), is costly, requires high maintenance, and is potentially toxic due to its mercury content. Recently, a light-emitting diode (LED) has been substituted as the light source. The LED has a life span of more than 50,000 hours, and a recent study demonstrated that its performance was similar to the MVP-based microscopy; because of its considerably lower cost, the LED is a feasible option for laboratories with limited resources.[116]

In most situations in which acid-fast organisms are detected by microscopy, they should be assumed to be *M. tuberculosis* until proven otherwise. Assuming the patient has tuberculosis will trigger the appropriate prompt responses from the physicians responsible for treatment and from public health agencies.

Mycobacterial Culture

Although definitive identification of *M. tuberculosis* can be accomplished by rapid amplification tests, determination of drug susceptibility generally still requires isolation of the organism in culture. However, rapid polymerase chain reaction (PCR)–based tests that identify resistance-conferring mutations have recently been developed and validated, although they are not yet marketed in the United States.[117] Many of the mutations that cause drug

resistance have been identified, but there have not yet been evaluations of the utility of tests designed to detect these mutations in routine clinical practice.[118]

Culturing of mycobacteria from clinical specimens requires a higher level of technical capability than that needed for microscopy. The need for infection control precautions, constant-temperature incubators, and a constant power supply restricts the use of culture in many developing countries. At a minimum, laboratories performing culture should be able to identify *M. tuberculosis.* Isolates that are not *M. tuberculosis* or are of questionable identity should then be sent to a more specialized laboratory for definitive speciation.

Solid Media. Culture of sputum usually involves digestion, decontamination, and concentration of the specimen before inoculating media. This process enables more uniform plating of the specimen and decreases bacterial overgrowth. For specimens other than sputum, digestion and decontamination are not required. It is generally recommended that two different kinds of media be inoculated: usually an egg-based one, such as Löwenstein-Jensen, and an agar-based one, such as Middlebrook-Cohn 7H10. Egg-based media are generally regarded as the reference standard and may result in a larger number of positive cultures, whereas agar-based media enable earlier detection of growth.[119] *Mycobacterium tuberculosis* colonies appear in 2 to 6 weeks. Cultures showing no growth at 6 weeks are reported as negative, although they generally are kept for another 2 to 4 weeks before being discarded.

Liquid Media with Radiometric and Colorimetric Detection Systems. Because early identification of patients with tuberculosis is important and because of concern regarding multidrug-resistant organisms, radiometric or colorimetric detection and sensitivity test systems should be used in hospitals in which large numbers of patients with tuberculosis are managed. Radiometric culture systems incorporate ^{14}C-labeled palmitic acid into a liquid culture medium[8]; accordingly, as mycobacteria grow in this medium, they liberate $^{14}CO_2$ that can be measured by the detection device. The increased sensitivity of the system enables growth to be detected sooner, usually in 10 to 14 days. As noted earlier, a positive NAP test or DNA probe testing confirms an isolate as being *M. tuberculosis.* A limitation of the method is the need for safe disposal of the radioactive waste. Therefore, currently, it is more common to see nonradiometric methods based on fluorescent or colorimetric (based on the reduction of a colored redox indicator present in the culture medium) signals.[120]

Nucleic Acid Amplification Tests. Nucleic acid amplification tests include those that involve PCR amplification, transcription-mediated amplification, strand-displacement amplification, ligase chain reaction, Q Beta replicase amplification, transcription-mediated amplification, and peptide nucleic acid assay.[120] Each of these approaches has strengths and weaknesses, descriptions of which are beyond the scope of this discussion. In each test, either DNA or ribonucleic acid (RNA) within as few as 1 to 10 organisms is amplified to detectable levels. Currently, rapid amplification tests are mainly used with specimens in which AFB have been found, although one available test has been licensed for use with AFB smear-negative specimens. The updated recommendations by the CDC indicate that a nucleic acid amplification test should be performed on at least one specimen, preferably the first diagnostic specimen, and that the results should be available within 48 hours of collection. The recommended interpretation algorithm includes the use of clinical judgment when the nucleic acid amplification test is negative.[121] This limitation has been applied because the sensitivity of the tests for specimens that are smear negative but culture positive is not sufficiently high to exclude *M. tuberculosis* with a negative result of a rapid test.[113,121]

Other Diagnostic Methods

Several antigens, including highly purified and recombinant antigens specific for *M. tuberculosis* complex, have been used in serologic antibody tests with variable results. A recent systematic review found that the results of serologic tests are highly variable, but there is no commercial test that is better than the sputum smear microscopy; therefore, the use of these methods is very limited.[122]

Drug Susceptibility Testing

Determination of susceptibility to antimicrobial agents is of considerable clinical importance. Because of concerns regarding tuberculosis caused by drug-resistant organisms, drug susceptibility testing is recommended for all initial *M. tuberculosis* isolates. Although several techniques are used for determining resistance, the proportion method remains the reference standard.[123] This involves inoculating one or more dilutions of cultured mycobacteria on drug-free media and on media containing appropriate concentrations of antimycobacterial agents. Resistance is generally considered to be present when the growth on the drug-containing medium is 1% or more of the control growth. The standard drug concentrations used for defining resistance of *M. tuberculosis* to the first-line drugs are as follows: isoniazid, 0.2 g/mL; rifampin, 1.0 g/mL; ethambutol, 5.0 g/mL; and streptomycin, 2.0 g/mL. Susceptibility testing for pyrazinamide has been done mainly in a radiometric system,[124] and more recently with nonradiometric methods, which have shown comparable results.[125] Testing for susceptibility to second-line drugs is generally performed only in reference laboratories and recommended mainly for MDR strains. Rapid radiometric measurements have been used to determine drug susceptibility and can provide results much more quickly than from cultures on solid media,[124] but definitive results still take weeks.

Recent studies have demonstrated that the Microscopic-Observation Drug Susceptibility (MODS) assay is a simple, fast, and reliable method to detect *M. tuberculosis* and determine the drug susceptibility at the same time.[126] MODS incorporates the antituberculosis drugs from the beginning of the assay. The method uses a

sealed 24-well tissue-culture plate with liquid culture media containing different antibiotics and controls that are examined periodically under an inverted light microscope. When compared with culture on Löwenstein-Jensen medium and an automated mycobacterial culture system (MBBacT), the sensitivity to detect *M. tuberculosis* growth was 97.5% to 97.8% for MODS, 89% for MBBacT, and 84% for Löwenstein-Jensen. The median times for a positive culture were 7, 22, and 68 days, respectively. The agreement with the proportional method for susceptibility test was 100% for rifampin, 97% for isoniazid, 95% for ethambutol, and 92% for streptomycin.[126,127]

Molecular methods that provide results much more quickly than conventional tests are now available and attracting increasing attention.[121] These techniques are based on the detection of drug-resistant associated mutations that are present in 90% to 95% of the isolates that are phenotypically resistant to isoniazid and rifampin. Currently there are several commercial methods. The Genotype MTBDR*plus* (Hain Lifescience, Nehren, Germany) is a PCR-based reverse hybridization assay to detect rifampin and isoniazid resistance directly in smear-positive sputum.[128] A recent study in South Africa demonstrated that 97% of the specimens gave a useful result within 1 to 2 days, with a sensitivity of 98.8% and specificity of 100% for the detection of multidrug resistance when compared with conventional results. Interestingly, the assay performed well on contaminated cultures, which cannot be used for susceptibility test by conventional methods.[129] The INNO-LiPA Rif.TB kit (Innogenetics, Gent, Belgium) is also based on PCR and hybridization of the PCR product on strips that identify *M. tuberculosis* as well as the mutations responsible for the resistance to rifampin.[130] Other methods based on real-time PCR using different probes, such as the molecular beacons and bacteriophage-based assays, are promising but currently are not commercially available.[131,132]

Genetic Polymorphisms

As noted earlier in this chapter, analysis of the genetic polymorphisms in genomic DNA of *M. tuberculosis* has been shown to be a useful tool for studying the epidemiology and transmission dynamics of tuberculosis.[34,50,67,133–135] RFLP analysis is based on the finding that tubercle bacilli possess repetitive DNA sequences. Of these sequences, IS*6110* is found in 2 to 25 copies per individual isolate or strain with enough polymorphism to study the dynamics of the transmission of tuberculosis in a population. The polymorphism based on IS*6110* is considered the standard method; however, secondary typing methods such as spoligotyping, mycobacterial interspersed repeat unit (MIRU) typing, and polymorphic guanine cytosine-rich sequence (PGRS) are required to increase the resolving power when the number of IS*6110* bands is less than 6.[62] The IS*6110* and PGRS are based on determining RFLPs and involve extracting DNA from cultured *M. tuberculosis,* digesting it with restriction endonucleases, separating the resulting fragments by gel electrophoresis, and using Southern blot analysis with labeled components of these sequences to create a unique, strain-specific DNA fingerprint.

Spoligotyping is a PCR-based method that detects polymorphisms in the direct repeat locus, and has enabled the demonstration that different genotypes of *M. tuberculosis* predominate in different parts of the world.[136] This technique is relatively simple, highly reproducible, and suited to high-throughput approaches. A second PCR-based genotyping method, MIRU typing, is based on minisatellite-like loci containing a variable number of tandem repeats (VNTR) present in different loci in the genome.[137] Like spoligotyping, MIRU/VNTR typing is highly reproducible. In contrast to RFLP, spoligotyping, and MIRU/VNTR typing, single nucleotide polymorphisms (SNPs) and large sequence polymorphisms represent unique event polymorphisms especially suited for inferring evolutionary history,[138] and are easily incorporated into high-throughput formats. However, except for the comparison of a few whole-genome sequences,[139–141] SNP data are still very limited in *M. tuberculosis.*[142]

Treatment

Further information about the introduction and development of chemotherapy for pulmonary tuberculosis is provided in Appendix 1 for this chapter, which can be found in the electronic version of this textbook on its Website. The Appendix also provides important details about the means of action, genetic basis of resistance, and chief adverse effects of each of the main first- and second-line antituberculosis agents that are currently in use; also included is Table 34A.1, which lists the available preparations and their recommended doses.

Current Standard Regimens

The treatment regimens that are recommended currently by the American Thoracic Society, the CDC, and the Infectious Diseases Society of America are shown in Table 34-1.[143]

The recommended basic treatment regimen for previously untreated patients with pulmonary tuberculosis consists of an initial phase of isoniazid, rifampin, pyrazinamide, and ethambutol given for 2 months, followed by a 4-month continuation phase of isoniazid and rifampin.[143,144] As shown in Table 34-1, there are several variations in the pattern of administration of the basic regimen, which are largely designed to enable health care personnel (or their surrogates) to provide closer supervision of treatment.

Several caveats apply to these recommendations for treatment to be successful. First, the organisms must be susceptible to the drugs used. Second, patients must take all or nearly all of the prescribed treatment. Third, success should be documented by bacteriologic evaluation; that is, sputum cultures should be negative by the end of 3 months of treatment. If the sputum still contains *M. tuberculosis* after 2 to 3 months of therapy, the patient should be reassessed carefully to determine whether a change in treatment is necessary.

Table 34-1. Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

INITIAL PHASE			CONTINUATION PHASE			Range to Total Doses (Minimum Duration)	RATING* (EVIDENCE)†	
Regimen	Drugs	Interval and Doses‡ (Minimum Duration)	Regimen	Drugs	Interval and Doses‡§ (Minimum Duration)		HIV+	HIV−
1	INH RIF PZA EMB	Seven days/wk for 56 doses (8 wk) or 5 days/wk for 40 doses (8 wk)§	1a	INH/RIF	Seven days/wk for 126 doses (18 wk) or 5 days/wk for 90 doses (18 wk)§	182–130 (26 wk)	A (I)	A (II)
			1b	INH/RIF	Twice weekly for 36 doses (18 wk)	92–76 (26 wk)	A (I)	A (II)¶
			1c**	INH/RPT	Once weekly for 18 doses (18 wk)	74 or 58 (26 wk)	B (I)	E (I)
2	INH RIF PZA EMB	Seven days/wk for 14 doses (2 wk) then twice weekly for 12 doses (6 wk) *or* 5 days/wk for 10 doses (2 wk)§ then twice weekly for 12 doses (6 wk)	2a	INH/RIF	Twice weekly for 36 doses (18 wk)	62–58 (26 wk)	A (II)	B(II)¶
			2b**	INH/RPT	Once weekly for 18 doses (18 wk)	44 or 40 (26 wk)	B (I)	E (I)
3	INH RIF PZA EMB	Thrice weekly for 24 doses (8 wk)	3a	INH/RIF	Thrice weekly for 54 doses (18 wk)	78 (26 wk)	B (I)	B (II)
4	INH RIF EMB	Seven days/wk for 56 doses (8 wk) or 5 days/wk for 40 doses (8 wk)§	4a	INH/RIF	Seven days/wk for 217 doses (31 wk) or 5 days/wk for 155 doses (28 wk)§	273–195 (39 wk)	C (I)	C (II)
			4b	INH/RIF	Twice weekly for 62 doses (31 wk)	118–102 (39 wk)	C (I)	C (II)

Definitions of evidence ratings:
*A, preferred; B, acceptable alternative; C, offer when A and B cannot be given; E, should never be given.
†I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.
‡When directly observed therapy (DOT) is used, drugs may be given 5 days/wk and the necessary number of doses adjusted accordingly. Although there are no studies that compare 5 with 7 daily doses, extensive experience indicates this would be an effective practice.
§Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (28-week; either 196 doses [daily] or 56 doses [twice-weekly]) continuation phase.
§Five-day-a-week administration is always given by DOT. Rating for 5-day-a-week regimens is AIII.
¶Not recommended for human immunodeficiency virus (HIV)–infected patients with $CD4^+$ cell counts less than 100 cells/μL.
**Options 1c and 2b should only be used in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on the initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture at 2 months, treatment should be extended an extra 3 months.
EMB, ethambutol; INH, isoniazid, PZA, pyrazinamide, RIF, rifampin, RPT, rifapentine.
Modified from Blumberg HM, Burman WJ, Chaisson RE, et al, for the American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: Treatment of tuberculosis. Am J Respir Crit Care Med 167:604–662, 2003.

Because of concerns with drug resistance, initial isolates from patients with tuberculosis should have drug susceptibility tests performed and the results should be used to guide treatment. Drug susceptibility tests should be repeated for specimens that are positive after 3 months of treatment.

The recommendation of a four-drug intensive phase is based, in part, on findings of the British Medical Research Council[145,146] concerning the outcome in countries or regions where the prevalence of initial resistance to isoniazid is likely to be high, in which case treatment regimens should include a 2-month, four-drug initial phase, and a 4-month continuation phase of rifampin plus isoniazid. However, a recent meta-analysis of clinical trials indicates that treatment failures and relapses are inordinately high when there is initial isoniazid resistance, suggesting that ethambutol should be continued for the duration of the regimen.[147] The risk of not taking this approach is the development of rifampin resistance.

Several factors have been found to be predictive of a poor therapeutic outcome, including extensive tuberculosis and a large population of bacilli, the rapidity or slowness with which sputum becomes negative after treatment is begun, and several factors associated with adherence.[143,148–150] In U.S. Public Health Service Study 22, the presence of cavitation on the initial chest film and sputum culture positivity at the end of the 2-month

intensive phase of treatment were highly predictive of an adverse outcome—either treatment failure or relapse.[148] For this reason, in patients with cavitation on the initial chest film and who have positive sputum cultures at the end of the initial phase of treatment, prolongation of the continuation phase to 7 months, making a total of 9 months of treatment, is recommended.[143] Factors that have been associated with poor clinic attendance and, therefore, with a less likely chance of favorable response, include use of alcohol, younger age (but above 18 years), and unmarried status. Patients with any of these characteristics should be monitored especially carefully. Although directly observed therapy (DOT) is labor intensive, the improved outcomes shown in retrospective analyses justify its use in preventing treatment failure and relapse, both of which have striking cost as well as public health implications.[151–153]

Special Situations

The algorithm shown in Figure 34-11 presents the approach to treatment of pulmonary tuberculosis in patients with *M. tuberculosis* isolated from sputum, and Figure 34-10 shows a treatment algorithm for patients with radiographic evidence of tuberculosis but negative bacteriologic examinations. In the absence of bacteriologic confirmation, treatment depends first on the degree of suspicion of active disease, and second on whether or not initial treatment causes clinical or radiographic improvement.

HIV Infection. The recommended treatment regimen for HIV-infected patients with tuberculosis consists of the same 6-month regimen as described for non–HIV-infected persons, although there are several important areas in which therapy may differ. Although

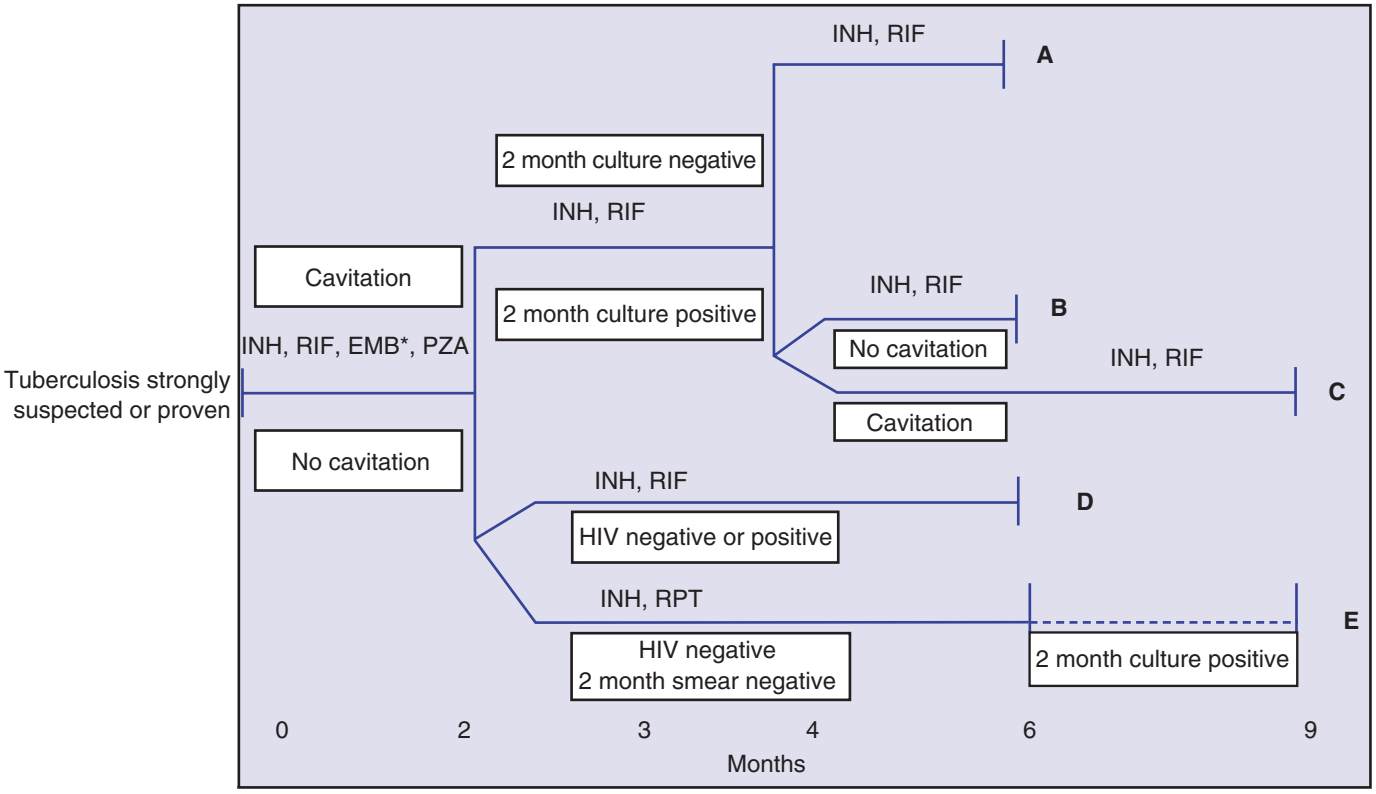

FIGURE 34-11 ■ Treatment algorithm for patients with sputum-culture positive tuberculosis. Patients in whom tuberculosis is proven or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide, and ethambutol daily or thrice weekly for the initial 2 months (*intensive phase*). A repeat smear and culture should be performed at the time 2 months of treatment is completed. The *continuation phase* of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment (arm A of figure). If the patient has HIV infection and the $CD4^+$ cell count is less than 100/μL, the *continuation phase* should consist of daily or thrice-weekly isoniazid and rifampin. Twice-weekly therapy should not be used for patients with advanced HIV infection. If the culture at completion of 2 months of treatment is positive but there was no cavitation on the initial chest film or the culture is negative (with or without cavitation on the initial film), a 4-month continuation phase should be used (arms B and D of figure). If cavitation was present on the initial chest radiograph and the culture from the time of completion of 2 months of therapy is positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment—arm C of figure). In non–HIV-infected patients having *no* cavitation on chest radiograph *and negative* acid-fast smears at completion of 2 months of treatment, the *continuation phase* may consist of either once-weekly isoniazid and rifapentine, or daily or twice-weekly isoniazid and rifampin, to complete a total of 6 months of treatment (arm D of figure). Patients receiving isoniazid/rifapentine whose 2-month cultures are positive should have treatment extended by 3 additional months (total of 9 months of treatment—arm E of figure). EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine. (Modified from Blumberg HM, Burman WJ, Chaisson RE, et al, for the American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: Treatment of tuberculosis. Am J Respir Crit Care Med 167:603–662, 2003.)

rates of relapse are not increased among HIV-infected patients who take a standard 6-month regimen in the United States, there is an association with acquiring rifampin resistance.[154–156] In sub-Saharan Africa, however, where different regimens are often used, the likelihood of death, especially during the first 2 months of therapy, and of relapse following apparently successful treatment is considerably higher in HIV-infected than in non–HIV-infected patients.[157] The cause of rifampin monoresistance is not clear but has been associated with the use of once- or twice-weekly drug administration in the continuation phase and prior use of rifabutin as prophylaxis for *Mycobacterium avium* complex infections.[154,156,158] For this reason, the rifapentine once-weekly regimen is contraindicated for all patients with HIV infection, and a twice-weekly regimen is not recommended for HIV-infected patients with $CD4^+$ counts less than 100 cells/μL.[143]

An important concern in treating tuberculosis in patients with HIV infection is the potential for interactions with other drugs, especially antiretroviral agents, as discussed in detail in Chapter 80. The most practical means of minimizing the effects of interactions is to use a regimen consisting of two nucleoside reverse transcriptase inhibitors plus efavirenz or, in pregnant women, nevirapine in the HIV treatment regimen, and rifabutin in place of rifampin in the antituberculosis regimen. Monitoring of serum drug concentrations may be useful in avoiding the adverse consequences of the interactions. The timing of initiation of an antiretroviral regimen in patients being treated for tuberculosis has not been determined. The general recommendation is that, for patients with tuberculosis and HIV infection having a $CD4^+$ count less than 200 cells/μL, an antiretroviral regimen should be started[159]; for patients with $CD4^+$ counts of 200 to 350 cells/μL, the possible benefits are less clear, but treatment should be considered. However, this is an area that is changing rapidly.

Another feature of the treatment of tuberculosis, as well as of other opportunistic infections, is the paradoxical worsening that may occur in HIV-infected persons who are also receiving antiretroviral therapy, a clinical phenomenon known as the immune reconstitution inflammatory syndrome (IRIS). The frequency of tuberculosis-related IRIS varies depending on the study, mainly because of the different case definitions used. Recently, the International Network for the Study of HIV-associated IRIS published the case definitions for the two main syndromes of tuberculosis.[160] The more common syndrome is the paradoxical tuberculosis–associated IRIS, which occurs within the first weeks or months after the start of antiretroviral therapy in patients already being treated for tuberculosis. Characteristic features include new or exacerbated symptoms or signs of tuberculosis and worsening of its radiologic manifestations; usually, the syndrome is self-limiting, with a median duration of 2 months. Risk factors for the development of this form of IRIS include advanced HIV disease, disseminated and extrapulmonary tuberculosis, and a short interval between starting antituberculosis and antiretroviral treatments.

The second IRIS syndrome, known as antiretroviral therapy–associated tuberculosis, occurs when tuberculosis (or some other lurking undiagnosed HIV-linked complication) is "unmasked" and flares up not long after beginning antiretroviral therapy and, therefore, can be diagnosed.

Drug Resistance. Patients who do not have a favorable bacteriologic response early during treatment present a difficult problem. After 3 months of chemotherapy, more than 90% of patients taking regimens containing isoniazid and rifampin should have negative sputum cultures. Failure of the sputum to become negative generally means that either the organisms are resistant to the agents being used or the patient is not taking the drugs. Patients who continue to have *M. tuberculosis* in their sputum after 2 to 3 months of treatment should be started on DOT, if not already being supervised, and should have drug susceptibility testing performed. If resistance is found, the regimen should be modified accordingly. If sputum samples are still positive after 4 months of therapy, the regimen should be considered to have failed and a new regimen should be begun, ideally based on recent drug susceptibility test results. A list of possible regimens for non-MDR tuberculosis is shown in Table 34-2.

The basic principle of treatment for patients whose organisms are resistant to one or more of the first-line drugs is the administration of at least two (but generally three or four) agents to which there is demonstrated sensitivity.[143,161] Unfortunately, there are no data to provide evidence-based guidelines as to the relative effectiveness of various regimens and the necessary duration of treatment. Clearly, if the organism is susceptible to isoniazid and rifampin, a usual regimen can be expected to be successful. In the presence of resistance to isoniazid, treatment with rifampin and ethambutol, supplemented by pyrazinamide, also is likely to be successful. There are data that suggest that 12 months of treatment with rifampin and ethambutol is sufficient[162]; however, in patients with organisms resistant to isoniazid, such decisions should be made on a case-by-case basis.

The fourth Global Drug Resistance Surveillance Project conducted between 2002 and 2007 by the WHO and the International Union Against Tuberculosis and Lung Disease included 91,577 patients from 81 countries, representing 35% of the global notified new smear-positive cases.[163] Drug resistance was found in all countries surveyed, except for Iceland, with a weighted mean of 17% of new cases having resistance to at least one antituberculosis drug and 2.9% having multiple drug resistance (resistance to at least isoniazid and rifampin). According to the most recent WHO estimates, in 2007, 511,000 cases of MDR tuberculosis occurred worldwide: 289,000 (3.1%) among all new, never-treated patients, and 221,000 (19%) among all previously treated patients.[3] There were areas of the world in which rates of multiple drug resistance are truly alarming, such as Baku, Azerbaijan, where 56.3% of new cases were resistant to any drug and 22.3% were MDR,[163] a considerable worsening since the previous report.[164]

Table 34-2. Selected Treatment Regimens for non-MDR Drug-Resistant Tuberculosis

Resistance to	Treatment Regimen	Duration of Therapy	Comments
Isoniazid (± streptomycin)	Rifampin Ethambutol Pyrazinamide	6–9 months	A fluoroquinolone may strengthen the regimen for patients with extensive disease.
Isoniazid and pyrazinamide	Rifampin Ethambutol Fluoroquinolone*	9–12 months	A longer duration of treatment should be used for patients with extensive disease.
Isoniazid and ethambutol	Rifampin Pyrazinamide Fluoroquinolone	9–12 months	A longer duration of treatment should be used for patients with extensive disease.
Rifampin	Isoniazid Ethambutol Fluoroquinolone plus at least 2 months of pyrazinamide	12–18 months	An injectable drug may strengthen the regimen for patients with extensive disease.
Rifampin and ethambutol (± streptomycin)	Isoniazid Pyrazinamide Fluoroquinolone plus injectable drug† for at least the first 2–3 months	18 months	A longer course (6 months) of the injectable may strengthen the regimen for patients with extensive disease.
Rifampin and pyrazinamide (± streptomycin)	Isoniazid Ethambutol Fluoroquinolone plus injectable drug for at least the first 2–3 months	18 months	A longer course (6 months) of the injectable may strengthen the regimen for patients with extensive disease.
Isoniazid, ethambutol pyrazinamide (± streptomycin)	Rifampin Fluoroquinolone plus an oral second-line agent,‡ plus injectable drug for at least the first 2–3 months	18 months	A longer course (6 months) of the injectable may strengthen the regimen for patients with extensive disease.
Pyrazinamide	Isoniazid, rifampin plus at least 2 months of ethambutol	9 months	Most commonly seen in *M. bovi* infection.

*Fluoroquinolones: levofloxacin or moxifloxacin.
†Injectable drugs: streptomycin, amikacin, kanamycin, or capreomycin.
‡Oral second-line drugs: ethionamide, cycloserine, or *p*-aminosalicylic acid.
From Francis J, for the Curry National Tuberculosis Center and California Department of Public Health, Drug-Resistant Tuberculosis: A Survival Guide for Clinicians, 2nd ed. Sacramento: California Department of Public Health, 2008, pp 34–35.

Patients with MDR tuberculosis should be treated with a minimum of 4—and preferably more—drugs to which the isolate is susceptible, including any susceptible first-line agents, a fluoroquinolone, an injectable aminoglycoside, and oral second-line drugs to create a regimen of 4 to 6 agents. Treatment should be directly observed, either in the hospital or domiciliary setting.[164a]

The outcome of treatment in persons with tuberculosis caused by MDR organisms is generally less good than that of treatment of disease caused by susceptible organisms, although data are sparse. At least in part, the outcome depends on the number of agents to which the organisms are susceptible, the promptness and appropriateness of therapy, the number of previous courses of therapy, and the HIV status of the patient. For example, in a group of patients with MDR tuberculosis who had undergone multiple previous courses of chemotherapy, the rate of successful outcome was only slightly better than 50%.[164] However, both in New York and in San Francisco, non–HIV-infected patients with MDR tuberculosis who had not been extensively treated previously had a much better rate of success (92% and 97%, respectively), albeit with a much shorter follow-up time.[165,166] In the report from San Francisco, the prognosis for patients with HIV infection and MDR tuberculosis was very poor: all 11 patients died during the period of the study, although no patients received antiretroviral therapy,[165] but whether or not it would have improved the outcome is unknown.

In 2006, XDR tuberculosis—defined as tuberculosis caused by *M. tuberculosis* that are not only MDR but resistant as well as to any one of the fluoroquinolones and to at least one of three injectable second-line drugs (amikacin, capreomycin, or kanamycin)—was identified and was rapidly recognized as a serious emerging threat to global public health.[37,167] Subsequent reports have identified XDR tuberculosis in all regions of the world, with countries from the former Soviet Union reporting as high as 24% XDR tuberculosis among the MDR cases.[163] The two strongest risk factors for XDR tuberculosis are failure of a tuberculosis treatment regimen that contains second-line drugs, including an injectable agent and a fluoroquinolone, and close contact with an individual with documented XDR tuberculosis or with an individual for whom treatment with a regimen including second-line drugs is failing or has failed.

The outcome of treatment of patients with XDR tuberculosis is generally less good than the outcome for

patients with MDR disease.[168] In one cohort from KwaZulu-Natal, 98% of XDR tuberculosis patients coinfected with HIV died, with a median time of death of only 16 days from time of specimen collection.[37] Rates of successful completion of treatment among patients with XDR tuberculosis but without HIV infection range from approximately 30% to 60%. Consultation with an expert is advised in treating patients with MDR/XDR tuberculosis, because the regimen chosen often represents the last best chance for cure, and treatment must be done correctly. The regimen should be based on the results of drug susceptibility tests when available. In most instances, however, the results are not known until several weeks after therapy is started. In such instances, treatment should be determined on the basis of the patient's history of prior therapy, avoiding reliance on agents taken previously, and on the prevailing resistance patterns in the community or subpopulation of which the patient is a member.

Children. The basic principles that apply in the management of adults with pulmonary tuberculosis are equally applicable in children. Although children have been excluded from nearly all clinical trials of short durations of chemotherapy, there are several reports documenting the usefulness of 6- and 9-month regimens in children.[143,169,170] The most frequent difference between treating children and adults is the more limited use of ethambutol. Because children tend to have forms of tuberculosis that are associated with lower bacillary populations, the likelihood of drug resistance is less. Moreover, young children generally cannot have visual acuity testing performed accurately, and thus cannot be monitored for toxicity. However, if ethambutol is used, the dose is 20 mg/kg because of differences in pharmacokinetics between adults and children.[171]

At least in younger children, sputum specimens for bacteriologic evaluations cannot usually be obtained. Consequently, the response to treatment is assessed by clinical and radiographic criteria. For this same reason, drug susceptibility or resistance often must be inferred from the pattern of the presumed source case or community data rather than being determined in the laboratory.

Pregnancy and Breast-feeding. Active untreated tuberculosis represents a far greater hazard to a pregnant woman and her fetus than does treatment for the disease. Pregnant women or mothers of young infants, therefore, should be started on treatment with isoniazid, rifampin, and ethambutol. Pyrazinamide is included in recommendations for treating tuberculosis in pregnant women by the WHO, but it has not been included in recommendations in the United States because of insufficient information about possible harm to the fetus.[143,144] Streptomycin, which interferes with development of the ear and may cause congenital deafness, is the only antituberculosis drug documented to have harmful effects on the fetus.[172] This potential is presumably shared by amikacin, kanamycin, and capreomycin; however, there is little or no information about the effects of these drugs on the fetus, or about the potential hazards of cycloserine, ethionamide, and pyrazinamide.

Although several antituberculosis drugs are present in breast milk, their concentrations and the total amounts that could possibly be ingested by a nursing infant are such that adverse effects would be unlikely. Thus, no modifications of treatment regimens are necessary for nursing mothers.[143]

Associated Conditions. Tuberculosis commonly occurs in association with other conditions, either because an underlying disease or its treatment alters immune responsiveness, thereby predisposing to tuberculosis (e.g., HIV infection, hematologic or reticuloendothelial malignancies, chronic renal disease or type 2 diabetes mellitus), or because the accompanying condition occurs frequently in the same social and cultural milieu as tuberculosis, particularly alcoholism and all its complications and other forms of substance abuse. Because all of these conditions may affect the response to and outcome of treatment, therapeutic decisions must be made on an individualized basis, and when possible, steps must be taken to correct the immunosuppression.

In patients with impaired renal function, streptomycin, kanamycin, amikacin, and capreomycin should be avoided if at all possible or given two to three times per week in the usual dose. If there is severe impairment of renal function, reduction in frequency of administration of ethambutol and pyrazinamide to two to three times per week may be necessary.[143]

Liver disease, particularly alcoholic hepatitis and cirrhosis, is commonly associated with tuberculosis. In general, the complications of potentially hepatotoxic antituberculosis drugs have not been greater in patients with liver disease.[173] However, detecting such adverse effects if they occur may be difficult because of the preexisting disorder of hepatic function. Moreover, what in a person with normal liver function would be minor hepatotoxicity could have major consequences in a patient with severe liver disease. Options in treating patients with severe liver disease include treatment without isoniazid, using rifampin, ethambutol, and pyrazinamide for 6 months; treatment without pyrazinamide for a total duration of 9 months; treatment with only one potentially hepatotoxic drug, usually retaining rifampin and adding ethambutol and a fluoroquinolone for a total of 12 to 18 months; and treatment with a regimen that contains no hepatotoxic drugs, such as streptomycin, ethambutol, a fluoroquinolone, and perhaps another second-line drug for 18 to 24 months.[143] In patients with severe liver disease, routine testing of liver function should be performed at baseline and during treatment.

Finally, in patients with psychiatric disorders, close supervision of treatment with DOT of all medications is essential.

Adjuctive Therapy

Currently, the adjunctive therapies for pulmonary tuberculosis include surgery and corticosteroid treatment. Although surgery was once a mainstay of treatment for pulmonary tuberculosis, since the advent of chemotherapy it has rarely been indicated. Artificial pneumothorax,

pneumoperitoneum, phrenic nerve interruption, plombage, and thoracoplasty—procedures designed to collapse portions of the lung and close cavities—were common interventions until the 1960s,[174] but then rendered obsolete by the effectiveness of chemotherapy. Rarely, patients with MDR pulmonary tuberculosis are treated with either pneumoperitoneum or thoracoplasty.

Resection. Currently, surgical resection may be indicated in several situations. In patients with tuberculosis caused by MDR or XDR organisms that is anatomically limited within the lung, resection may be an effective therapeutic option.[175] Before operating on such patients, the bacillary population should be reduced as much as possible with drugs to which the organism is susceptible. However, the timing of surgery can be difficult, in that the effectiveness of a limited second-line drug regimen cannot always be predicted. Resection may also be necessary because of massive hemoptysis associated with current or old tuberculosis, because of residual lung damage (e.g., bronchiectasis) exacerbated by recurrent bacterial infections, or because of a bronchopleural fistula with (usually) a tuberculous empyema. In addition to these therapeutic indications for surgery, tuberculosis is sometimes diagnosed by examination of a pulmonary mass or nodule that was resected owing to suspicion of malignancy.

In any situation involving possible lung surgery in patients with or suspected of having tuberculosis, including the resection of a solitary nodule in a patient with a positive tuberculin reaction, it is desirable for the patient to have been receiving adequate antituberculosis chemotherapy before the operation. This will minimize the possibility of spread of tuberculosis within the lung and of bronchial stump infection and empyema. The optimum amount of time before operation that treatment should be given is not clear, but in emergencies, such as massive hemoptysis, at least single doses of the drugs should be given, whereas with elective procedures, it is desirable to wait at least until the sputum smear is negative. If the sputum smear is negative to begin with, 2 weeks of treatment is reasonable.

Corticosteroids. The use of corticosteroids in pulmonary tuberculosis has been and remains controversial. In view of the well-known effects of corticosteroids in decreasing cell-mediated immune responses, it seems counterintuitive that these same agents could be beneficial. Nevertheless, corticosteroids, by interfering with the tissue-damaging immune response, may minimize the adverse effects of the inflammatory reaction. For this reason, corticosteroids may under certain conditions be of benefit in patients with pulmonary tuberculosis who are receiving adequate chemotherapy. These conditions were defined by a controlled trial reported by Johnson and colleagues[176] in which all patients were treated with effective antituberculosis chemotherapy (although rifampin was not yet available) and were assigned at random to receive either methylprednisolone or placebo. This study demonstrated that corticosteroid treatment most benefited the seriously ill patient (defined by low serum albumin concentration, low body weight, and severe weight loss) who had extensive tuberculosis. This benefit was evidenced mainly by an increase in the rate of radiographic clearing; there was no adverse effect on the bacteriologic response. In less severely ill patients, methylprednisolone either was of no benefit or actually decreased the speed of sputum conversion. These data suggest that the major role of corticosteroid treatment is in patients with severe tuberculosis and severe systemic effects.

Although not considered in the study by Johnson and colleagues, steroids may also be of benefit in patients with marked abnormalities of gas exchange and respiratory failure.[177] A more recent systematic review examined the results of clinical trials of corticosteroids as adjunctive therapy for pulmonary tuberculosis and came to essentially the same conclusions as the Johnson et al. study (which was included in the review).[178] In addition, dexamethasone is recommended in tuberculous meningitis and, although the evidence is less persuasive, corticosteroids are often given in tuberculous pericarditis.

EXTRAPULMONARY TUBERCULOSIS

Extrapulmonary tuberculosis presents more of a diagnostic and therapeutic problem than does pulmonary tuberculosis. In part this relates to its being less common and therefore less familiar to most clinicians.[179,180] In addition, extrapulmonary tuberculosis involves relatively inaccessible sites, and often, because of the vulnerability of the areas involved, much greater damage can be caused by fewer bacilli. The combination of small numbers of bacilli in inaccessible sites causes bacteriologic confirmation of a diagnosis to be more difficult, and invasive procedures are frequently necessary to establish a diagnosis. In addition to the need for invasive diagnostic procedures, surgery may be an important component of management.

In 2007 in the United States, 20% of newly reported cases of tuberculosis involved extrapulmonary sites only.[181] The proportion of patients with extrapulmonary involvement is greater among patients with HIV infection. In one large retrospective study of tuberculosis occurring in patients with HIV infection, approximately one third of the patients had only extrapulmonary sites of involvement, one third had both pulmonary and extrapulmonary disease, and one third had only pulmonary involvement.[97] Because of the frequency of extrapulmonary tuberculosis among HIV-infected patients, diagnostic specimens from any suspected site of disease should be cultured for mycobacteria, including blood and bone marrow from patients who do not have an obvious localized site of disease but who are febrile.

Disseminated Tuberculosis

Miliary tuberculosis, although it nearly always involves the lungs, is considered among the extrapulmonary forms of the disease because of the multiplicity of organs affected. In the past, miliary tuberculosis occurred mainly in young children, as an early consequence of initial infection and bacillemia; currently, however, except among HIV-infected persons, it is more common

among older persons, as a result of endogenous reactivation and bloodstream invasion. The shift in age-specific incidence presumably has been caused at least in part by the paucity of new infections in relation to the number of endogenous reactivations that take place in the United States. The incidences in both sexes are nearly equal except in the HIV-infected population, in which the disease predominates among men.

The term *miliary* is derived from the similarity of the lesions to millet seeds. Grossly, these lesions are 1- to 2-mm yellowish nodules that on histologic examination are granulomas (see Chapter 15, Fig. 15-4C). As noted previously, HIV-infected patients may not be able to form granulomas; thus, discrete individual lesions may not be present, but a diffuse uniform pattern of infiltration is seen.

Because of the multisystem involvement in disseminated tuberculosis, the clinical manifestations are protean. Initial screening laboratory studies are not particularly helpful either. The chest film, however, is abnormal in most but not all patients with disseminated tuberculosis: the frequency of a classic military pattern has ranged from 50% to 90%. Overall, it appears that, at the time of diagnosis, approximately 85% of patients have the diffuse tiny nodules characteristic of miliary tuberculosis. Other abnormalities may be present as well. These include upper lobe infiltrates with or without cavitation, pleural effusion, and pericardial effusion. In patients with HIV infection, the radiographic pattern is one of diffuse infiltration rather than discrete nodules.

Autopsy series have shown the liver, lungs, bone marrow, kidneys, adrenal glands, and spleen to be the organs most frequently involved in miliary tuberculosis, but any organ can be the site of disease.[182] Because of the multiplicity of sites involved, there are many potential sources of material to provide a diagnosis. Acid-fast smears of sputum are positive in 20% to 25% of patients, and *M. tuberculosis* is cultured from sputum in 30% to 65%.[183–185] Smears of induced sputum may be positive when the patient is not expectorating spontaneously. In a patient with an abnormal chest film and negative sputum examinations, bronchoscopy should be the next step. Combinations of bronchoalveolar lavage and transbronchial biopsy would be expected to have a high yield.[109] Other potential sites for biopsy include liver and bone marrow, each of which has a high likelihood of showing granulomas (70% to 80%), but only a 25% to 40% chance of providing bacteriologic confirmation; urine is easy to obtain, and cultures may be positive in up to 25% of patients.[184,185] Selection of other potential sources of diagnostic material should be guided by specific findings.

The role of rapid nucleic acid amplification tests for identification of *M. tuberculosis* in patients with miliary tuberculosis has not been defined, and neither of the two tests licensed by the U.S. Food and Drug Administration is approved for nonrespiratory specimens. The reported data are difficult to interpret because, often, the results of specimens from different sites are combined, patients are selected by a variety of criteria, and test performance varies.[186–188]

In the prechemotherapy era, disseminated tuberculosis was uniformly fatal. With treatment, however, the reported case-fatality rates vary, ranging from 29% to 64%, depending in part on the frequency of meningitis in the series.[185] When meningitis is present, the duration of standard chemotherapy should be extended from 6 to 9 or 12 months.[143] Corticosteroids may be useful, as discussed previously, for severe pulmonary disease with respiratory failure and if there is involvement of the central nervous system.[189]

Lymphatic Tuberculosis

Lymphatic tuberculosis accounts for approximately 42% of the cases of extrapulmonary tuberculosis in the United States.[181] Although the basic descriptive epidemiology of tuberculosis applies to lymphatic tuberculosis, there are a few differences. This form of tuberculosis is relatively more common among children than adults. In addition, lymphatic tuberculosis differs from the overall pattern in that it occurs more frequently in women. It also appears to be more common among Asians and Pacific Islanders than among blacks and whites. Among HIV-infected persons, the incidence of tuberculous lymphadenitis increases as the level of $CD4^+$ T cells decreases.[190]

Tuberculous lymphadenitis usually presents as painless swelling of one or more lymph nodes (Fig. 34-12). The nodes most commonly involved are those of the posterior or anterior cervical chain or those in the supraclavicular fossa. Frequently the process is bilateral, and other noncontiguous groups of nodes can be involved. At least initially, the nodes are discrete and the overlying skin is normal. With ongoing disease, the nodes may become matted and the overlying skin inflamed. Rupture of the node can result in formation of a sinus tract, which may persist for years. Intrathoracic adenopathy may compress bronchi, causing atelectasis, thereby leading to lung infection and perhaps bronchiectasis. Although rare, upper airway obstruction may result from cervical node enlargement. Both chylous pleural effusion and ascites have occurred because of intrathoracic or abdominal node involvement with obstruction of retroperitoneal lymphatics or the thoracic duct.

The diagnosis of tuberculous lymphadenopathy is established by lymph node biopsy or aspiration with histologic examination, including stains for acid-fast organisms and culture of the material. Smears show acid-fast organisms in approximately 25% to 50% of biopsy specimens, and *M. tuberculosis* is isolated in approximately 70% of instances in which the final diagnosis is considered to be tuberculosis.[191] Caseating granulomas are seen in nearly all biopsy specimens from immunocompetent patients. In immunodeficiency states, granulomas may be poorly formed or absent.[192]

The rate of response of tuberculous lymphadenitis to the standard 6-month regimen is much slower than that of pulmonary tuberculosis. Nodes may enlarge, new nodes may appear, and fistulas may develop during treatment that ultimately proves effective, but true bacteriologic relapse after completion of therapy is unusual.[193]

FIGURE 34-12 ■ Tuberculous lymphadenitis. There is swelling of an anterior cervical node and a chronic sinus tract with cutaneous scarring in the supraclavicular area. (Courtesy of Dr. Austin Brewin, University of California, San Francisco.)

Corticosteroid treatment has been used to shrink intrathoracic nodes and relieve bronchial obstruction, primarily in children. In a controlled study, Nemir and coworkers[194] demonstrated that corticosteroids increase the rate of resolution of radiographic changes thought to be due to bronchial narrowing by lymph nodes or endobronchial lesions in children with primary tuberculosis. Apart from this indication, there is no clear role for corticosteroids in lymphatic tuberculosis.

Surgical intervention may be necessary to make a diagnosis of tuberculous lymphadenitis, and on occasion surgical incision and drainage are needed to prevent spontaneous drainage and fistula formation. Surgical excision of involved nodes, strictly as an adjunct to chemotherapy, is associated with perhaps a slightly worse outcome than medical treatment with aspiration of the node or medical treatment alone.[195]

Pleural Tuberculosis

Although the pleural space is within the thorax, it is considered an extrapulmonary site of tuberculosis. Tuberculous pleuritis accounts for 17% of the extrapulmonary cases in the United States.[181] The epidemiology of pleural tuberculosis parallels that of the overall pattern for tuberculosis, being more common among men and increasing in incidence with increasing age between ages 5 and 45 years. As noted previously, this epidemiologic pattern is modified by the occurrence of HIV infection, although pleural involvement seems relatively less frequent among HIV-infected persons.

There are two mechanisms by which the pleural space becomes involved in tuberculosis. The difference in pathogenesis results in different clinical presentations, approaches to diagnosis, treatment, and sequelae. The first mechanism occurs early in the course of a tuberculous infection—a few tubercle bacilli may gain access to the pleural space and, in the presence of cell-mediated immunity, can cause a hypersensitivity response.[196,197] This form of tuberculous pleuritis commonly goes unnoticed, and the process resolves spontaneously. However, in some patients, the tuberculous involvement of the pleura is manifested as an acute illness with fever and pleuritic pain.[198] If the effusion is large enough, dyspnea may occur, although the effusions are generally rather small and are rarely bilateral.

The diagnosis of pleural tuberculosis is generally established by analysis of pleural fluid and pleural biopsy. In a patient with a pleural effusion that might be tuberculous, a diagnostic thoracentesis should be performed. Sufficient fluid should be obtained for cell count, cytologic examination, biochemical analysis, and microbiologic evaluation (all described in detail in Chapter 73), but enough fluid should be left to allow a needle biopsy to be performed if the original specimen proves to be exudative and no diagnosis is evident. The fluid is nearly always straw-colored, although it may be slightly bloody. Leukocyte counts are usually in the range of 100 to 5000 cells/μL.[199] Early in the course of the process, polymorphonuclear leukocytes may predominate, but mononuclear cells soon become the majority. The fluid is exudative, with a protein concentration greater than 50% of the serum protein concentration, and the glucose level may be normal to low. The presence of more than 10% eosinophils or 5% mesothelial cells is evidence against a tuberculous etiology.[200]

Adenosine deaminase has been shown to have high sensitivity, except in HIV-infected patients, but variable specificity, for diagnosing tuberculous pleural effusion.[201] Interferon-γ has been reported to have both high sensitivity (0.99) and high specificity (0.98) and to be equally reliable in HIV-infected and -uninfected patients[202,203]: further studies are needed to define the diagnostic role of this potentially useful test. Because few organisms are present in the pleural space, acid-fast smears of pleural fluid are rarely positive, and *M. tuberculosis* is isolated by culture in only 20% to 40% of patients with proven tuberculous pleuritis.[198,204] A single closed-needle biopsy

of the pleura with a Cope or an Abrams needle, with collection of three or four specimens for histologic examination, acid-fast staining, and culture of the tissue, confirms the diagnosis in approximately 65% to 75% of patients in whom tuberculous pleuritis is ultimately diagnosed. A second set of specimens in patients whose initial biopsy is negative increases the yield to 80% to 90%.[204] The results of thoracoscopy are nearly always diagnostic, but the procedure is invasive, costly, and not always available. In a patient with an exudative mononuclear pleural effusion that remains undiagnosed after a full evaluation, including pleural biopsy, and who has a positive tuberculin reaction, antituberculosis treatment should be initiated.

Treatment of the hypersensitivity variety of tuberculous pleural effusion consists of standard antituberculosis drug regimens.[143] Drainage via tube thoracostomy is rarely necessary, although repeat thoracenteses may be required to relieve symptoms. The use of corticosteroids may increase the rate of resolution and decrease the residual fluid, but such treatment is rarely indicated.[205]

The second variety of tuberculous involvement of the pleura, which is much less common than tuberculous pleurisy with effusion, is a true empyema that follows the spilling into the pleural space of a large number of organisms, usually from rupture of a cavity or an adjacent parenchymal focus via a bronchopleural fistula.[206] Tuberculous empyema is usually associated with evident pulmonary parenchymal disease on chest films. In this situation the fluid generally is thick and cloudy and may contain cholesterol, which causes the fluid to look like chyle (pseudochylous effusion). The fluid is exudative and usually has a relatively high white blood cell count, nearly all of which are lymphocytes. Acid-fast smears and mycobacterial cultures are usually positive, making pleural biopsy unnecessary.

In addition to standard antituberculosis chemotherapy, surgical drainage with an ordinary thoracostomy tube is often necessary and may be required for a prolonged period of time. In selected patients, creation of an Eloesser flap, in which a small portion of rib overlying the empyema space is resected and the skin is sutured to the pleura, is the procedure of choice.[207]

Genitourinary Tuberculosis

The epidemiologic pattern of genitourinary tuberculosis parallels that of tuberculosis in general, with the exception of HIV-infected patients. The pathogenesis appears to be one of seeding of the kidney at the time of the initial infection and bacillemia. This mechanism is supported by the finding that, with careful study, tuberculous lesions can be found in both kidneys in 90% of patients with renal tuberculosis, even though the disease is clinically evident in only one kidney.[208] Lower genitourinary tract involvement is thought to represent spread from the kidneys, but hematogenous seeding may also occur. Genital lesions were reported by Medlar and coworkers[209] in 13% of men with disseminated renal lesions, 52% of those with caseating lesions, and 100% of those with cavitary lesions in the kidney. Genital involvement without renal involvement occurred in 11%.

In patients with genitourinary tuberculosis, local symptoms predominate and systemic symptoms are less common.[210,211] Dysuria, hematuria, and frequent urination are common, and flank pain may also be noted. However, in general the symptoms are very subtle, and often there is advanced destruction of the kidneys by the time a diagnosis is established.[212] In women, genital involvement is more common without renal tuberculosis than in men and may cause pelvic pain, menstrual irregularities, and infertility as presenting complaints.[211] In men, a painless or only slightly painful scrotal mass is probably the most common presenting symptom of genital involvement, but symptoms of prostatitis, orchitis, or epididymitis may also occur.[210] A substantial number of patients with any form of genitourinary tuberculosis are asymptomatic, and the disease is detected because of an evaluation for an abnormal routine urinalysis. In patients with renal or genital tuberculosis, urinalyses are abnormal in more than 90%, the main finding being pyuria, hematuria, or mixed pyuria and hematuria. The finding of pyuria in an acidic urine with no organisms isolated from a routine urine culture should prompt an evaluation for tuberculosis. Occasionally, when there is an isolated genital focus of disease or when a tuberculous kidney is blocked by a ureteral stricture, the urinalysis may be normal and cultures may be sterile.

The suspicion of genitourinary tuberculosis should be heightened by the presence of abnormalities on the chest film. In most series, 50% to 75% of patients have chest radiographic abnormalities, although many of these may be the result of previous, not current, tuberculosis.[210,211]

When genitourinary tuberculosis is suspected, at least three first-voided early morning urine specimens should be collected and stained for AFB and cultured for mycobacteria. In men, saprophytic *Mycobacterium smegmatis* may cause a positive smear. However, in the presence of abnormalities suggesting tuberculosis, the finding of a positive smear should be interpreted as confirming the diagnosis of genitourinary tuberculosis until the results of cultures are known. *M. tuberculosis* is isolated from the urine in 80% to 95% of cases of genitourinary tuberculosis.[210,211] Diagnosis of isolated genital lesions usually requires biopsy, because the differential diagnosis often includes neoplasia as well as other infectious processes.

Positive urine cultures may occur in the absence of any clinical, laboratory, or radiographic findings on intravenous pyelograms, which suggests concomitant genitourinary tuberculosis in patients with other forms of tuberculosis. Bentz and coworkers[213] found unanticipated positive urine cultures in 21% of patients with other extrapulmonary forms of tuberculosis and in 5% of those with pulmonary tuberculosis alone.

Renal tuberculosis, at least as indicated by a positive urine culture, may occur in patients with HIV infection. In one series, positive urine cultures were found in 12 (71%) of 17 cultures submitted in patients with tuberculosis and advanced HIV infection, although this was not a systematic sampling.[97]

There are several treatment considerations for genitourinary tuberculosis apart from standard chemotherapy. Nephrectomy, formerly a mainstay of therapy for renal tuberculosis, now is seldom indicated; however, in patients who have tuberculosis caused by MDR organisms and who can tolerate removal of a kidney, nephrectomy may be indicated. Nephrectomy may also be indicated for patients who have recurrent pyogenic bacterial infections in a kidney destroyed by tuberculosis, for patients with persistent pain, and for those with massive hematuria. Surgical or endoscopic procedures may also be necessary to correct ureteral strictures and to augment the capacity of a contracted bladder.

Bone and Joint Tuberculosis

The incidence of tuberculosis involving the joints and bones increases with increasing age and is equally frequent among men and women. In comparison with blacks and whites, other racial groups are less likely to have skeletal involvement. Skeletal tuberculosis does not appear to be particularly frequent in persons with HIV infection.

It is presumed that most osteoarticular tuberculosis results from endogenous reactivation of foci of infection seeded during the initial bacillemia, although spread from paravertebral lymph nodes has been postulated to account for the common localization of spinal tuberculosis to the lower thoracic and upper lumbar vertebrae. It is also postulated that the predilection for tuberculosis to localize in the metaphyses of long bones is due to the relatively rich blood supply and scarcity of phagocytic cells in this portion of the bone.[214] After beginning in the subchondral region of the bone, the infection spreads to involve the cartilage, synovium, and joint space. This produces the typical findings of metaphyseal erosion and cysts and loss of cartilage with narrowing of the joint space. Typically, in the spine these changes involve two adjacent vertebrae and the intervertebral disk (Fig. 34-13). An interesting observation was made in 103 cases of spinal tuberculosis: an "atypical" form of spondylitis without evidence of disk involvement occurred in slightly more than half (52%) of the patients.[215–217] Paravertebral or other para-articular abscesses may develop with occasional formation of sinus tracts. Although weight-bearing joints are the most common sites for skeletal tuberculosis, any bone or joint may be involved.[214] In most series of osteoarticular tuberculosis, tuberculosis of the spine (Pott's disease) makes up 50% to 70% of the cases reported. In adults the lower thoracic and upper lumbar vertebrae are most commonly involved, whereas in children the upper thoracic spine is the most frequent site. The hip or knee is involved in 15% to 20% of cases, and shoulders, elbows, ankles, wrists, and other bones or joints also make up 15% to 20%. Usually only one bone or joint is involved, but occasionally the process may be multifocal. Evidence of either previous or current pulmonary tuberculosis is found in approximately half the reported patients, and other extrapulmonary sites may be involved as well.

The first diagnostic test undertaken is usually a radiograph of the involved area. Early in the process, the only abnormality noted may be soft-tissue swelling. Computed tomography (CT) scans and magnetic resonance imaging of the spine are considerably more sensitive than routine films and should be obtained when there is a high index of suspicion of an infectious process. Radionuclide bone scanning with technetium-99m can demonstrate occult skeletal involvement in patients with normal radiographs. Likewise, gallium-67 scanning may define unsuspected sites, especially soft-tissue involvement not seen on the bone scan.

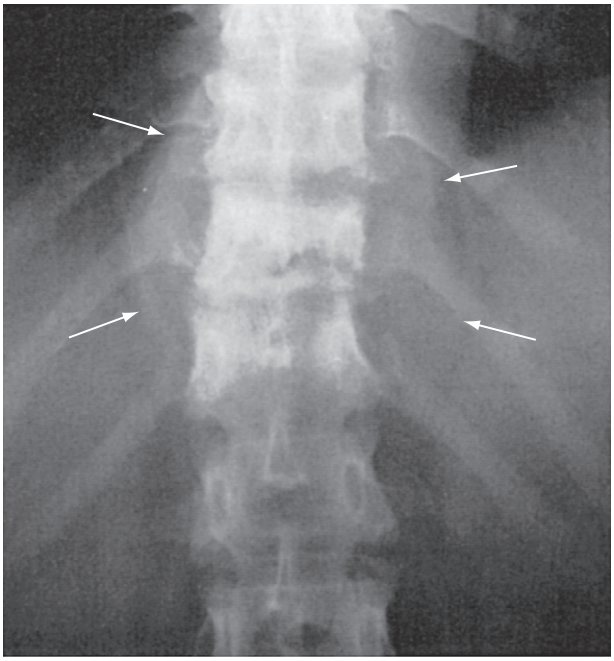

FIGURE 34-13 ■ Radiograph of lower thoracic and upper lumbar spine, showing tuberculous involvement of the 10th, 11th, and 12th thoracic vertebrae and a paraspinous abscess (*arrows*). Note loss of intervertebral disk space.

Confirmation of the diagnosis is obtained by aspiration of joint fluid or periarticular abscesses or by biopsy of bone or synovium with histologic and microbiologic evaluation of the material obtained. Acid-fast stains are positive in 20% to 25% of samples of joint fluid, and *M. tuberculosis* is isolated in approximately 60% to 80% of them.[214] Biopsy specimens of synovium or bone have a higher yield and enable histologic examination as well. Evidence of granulomatous inflammation even in the absence of bacteriologic proof of the diagnosis is sufficient evidence of tuberculosis to begin therapy unless another cause is found.

Standard chemotherapy of 6 to 9 months' duration is highly successful in skeletal tuberculosis, but surgery is occasionally a necessary adjunct.[215] The longer duration of treatment has been suggested because of the difficulties in assessing response. Several controlled studies have documented that chemotherapy conducted largely on an ambulatory basis is effective in curing spinal tuberculosis without the need for immobilization.[216] The role of emergency spinal cord decompression in patients with Pott's disease and early neurologic findings is not clear, and, if paraplegia is already present, the benefit of surgical intervention is even less clear. Moreover, there

is no well-defined surgical procedure of choice. An "all-or-none" approach has been advocated by several surgeons,[217–219] which means that surgery is not performed except in patients with progressive neurologic deterioration unresponsive to chemotherapy—in whom all affected bone is removed and an anterior spinal fusion is performed; there is no role for simple débridement other than for diagnosis. Surgery may be indicated in other forms of articular tuberculosis when there is extensive destruction of the joint or surrounding soft tissues, in which case synovectomy and joint fusions may be necessary.

Central Nervous System Tuberculosis

Meningitis is the most frequent form of central nervous system tuberculosis; solitary or multiple tuberculomas occur less commonly. The epidemiologic pattern of central nervous system tuberculosis is quite different from that of either pulmonary or other forms of extrapulmonary tuberculosis, in that the peak incidence is in infants and children up to 4 years of age. Although an appreciable number of cases occur in adults, meningitis accounts for only approximately 6% of all cases of extrapulmonary tuberculosis, which are equally divided between males and females.[181]

Central nervous system tuberculosis, especially tuberculomas, seems to occur with greater frequency among HIV-infected persons. Central nervous system tuberculomas have been reported even in patients who are receiving what should be adequate chemotherapy.[220] Because tuberculomas may be indistinguishable on CT scan from the lesions of toxoplasmosis, specific diagnosis is necessary.

Meningitis presumably can result from direct meningeal seeding and proliferation during a tuberculous bacillemia either at the time of initial infection or at the time of reactivation of an old pulmonary focus, or it can also result from reactivation of an old parameningeal focus with rupture into the subarachnoid space.[221] The consequences of the subarachnoid space contamination include diffuse meningitis, a localized arteritis, encephalitis, and myelitis. The symptoms depend primarily on which of these processes predominates. With meningitis, the process is primarily located at the base of the brain.[222] Symptoms therefore include those related to cranial nerve involvement in addition to headache, decreased level of consciousness, and neck stiffness. The duration of illness before diagnosis is quite variable and is related partly to the presence or absence of other sites of involvement. In a large series of patients, the average duration of illness was 12 days.[223] In most series, over 50% of patients with meningitis have abnormalities on chest film that are consistent with an old or current tuberculous process, often miliary tuberculosis. At autopsy, disseminated disease is found in a very high percentage of patients with meningitis. In patients with tuberculous meningitis, sputum cultures have been positive in 40% to 50%; thus, a substantial number of patients have pulmonary and systemic symptoms in addition to those referable to the central nervous system. Patients in whom arteritis is the predominant manifestation of meningitis can present with a variety of focal central nervous system ischemic syndromes in addition to the symptoms already described.

In tuberculous meningitis, the lumbar puncture usually shows increased opening pressure, and the cerebrospinal fluid (CSF) usually contains between 100 and 1000 cells/μL.[179,223] In approximately 65% to 75% of patients, lymphocytes predominate, whereas polymorphonuclear leukocytes predominate in the remainder, generally early in the course of the illness. The protein concentration is elevated in nearly all patients. Very high (>3300 mg/dL) protein concentrations have been associated with a poor prognosis; the glucose concentration in CSF is usually low, but not as low as that often found in pyogenic bacterial meningitis.[223] Acid-fast organisms are seen on smears of CSF in only 10% to 20% of patients, and the rate of culture positivity varies from 25% to 80%, but is generally in the lower end of the range.[223] In a substantial number of patients, *M. tuberculosis* is isolated from other sources, which, in the presence of compatible CSF findings, is sufficient to diagnose tuberculous meningitis. In view of the severity of tuberculous meningitis, a presumptive diagnosis justifies empirical treatment if no other diagnosis can be established promptly. Because of the difficulty with establishing a diagnosis of tuberculous meningitis by bacteriologic methods, Thwaites and associates[223] developed and validated a clinical scoring system by which tuberculous meningitis could be separated from pyogenic bacterial meningitis. Younger age (<36 years), lower white blood cell count (<15,000/μl), longer duration of illness (>6 days), lower CSF white blood cell count (<900/μL), and lower percentage (<75%) of neutrophils in the CSF were associated with a greater likelihood of a tuberculous etiology.

A recent meta-analysis of 14 studies of nucleic acid amplification tests for the diagnosis of tuberculous meningitis found a combined sensitivity of 56% and a specificity of 98%.[187] Thus, when a nucleic acid amplification test is positive, one can assume that the etiology is tuberculous, but a negative result does not exclude the diagnosis.

If there are no epidemiologic indicators of possible resistance, a treatment regimen of isoniazid, rifampin, pyrazinamide, and ethambutol should be effective. The recommended length of the continuation phase is at least 7 months, for a total treatment duration of 9 to 12 months, although there are no clinical trials that serve to define the optimum treatment duration.[143]

Corticosteroid treatment has a beneficial effect in patients with tuberculous meningitis and cerebral edema,[189] and decreases the frequency of adverse sequelae in children with less advanced disease.[224] Given the poor prognosis of tuberculous meningitis, the reasonably good data supporting corticosteroid use in more severe forms of the disease, and the paucity of information in patients with less advanced disease, corticosteroid treatment, specifically with dexamethasone, is recommended for all patients[189] at a dosage of 12 mg/day for 3 weeks, then decreased gradually during the next 3 weeks. Even with effective chemotherapy and corticosteroids, however, both the mortality rate and

rate of residual neurologic abnormalities from tuberculous meningitis remain high.

The other major central nervous system form of tuberculosis, the tuberculoma, presents a more subtle clinical picture than does tuberculous meningitis.[225] The usual presentation is that of a slowly growing focal lesion, although a few patients have increased intracranial pressure and no focal findings. The CSF is usually normal, and the diagnosis is established by CT scanning or magnetic resonance imaging and subsequent resection, biopsy, or aspiration of any ring-enhancing lesion. The response to antituberculosis chemotherapy is good, and corticosteroids are indicated only if there is an increase in intracranial pressure.

Abdominal Tuberculosis

Tuberculosis can involve any intra-abdominal organ as well as the peritoneum. The age distribution of abdominal tuberculosis shows a relatively higher incidence in young adults and a second peak in older persons. Men and women have similar incidences. The abdomen is a relatively common site of disease in HIV-infected persons.

Abdominal tuberculosis presumably results from seeding at the time of initial infection and then either direct or late progression to clinical disease. Peritonitis can also be caused by rupture of tuberculous lymph nodes within the abdomen, and intestinal tuberculosis may result from direct implantation in the gut of ingested tubercle bacilli. Before the advent of chemotherapy, tuberculous enteritis was common in patients with advanced pulmonary tuberculosis, presumably being caused by swallowed bacilli from the lungs. In a prospective study conducted between 1924 and 1949, intestinal abnormalities compatible with tuberculous enteritis were found by contrast radiography in 1%, 4.5%, and 24.7% of patients with minimal, moderately advanced, and far advanced pulmonary tuberculosis, respectively.[226]

The clinical manifestations of abdominal tuberculosis depend on the areas of involvement. In the gut itself, tuberculosis may occur in any location from the mouth to the anus, although lesions proximal to the terminal ileum are unusual. The most common sites of involvement are the terminal ileum and cecum; other portions of the colon and the rectum are involved less frequently.[227] In the terminal ileum or cecum, the most common manifestations are pain (which may lead to a misdiagnosis of appendicitis) and intestinal obstruction. A palpable mass may be noted that, together with its radiographic appearance, can easily be mistaken as a carcinoma. Rectal lesions usually present as anal fissures or fistulas or perirectal abscesses. In addition to carcinoma, the differential diagnosis of these findings includes inflammatory bowel disease. Because of the concern regarding carcinoma, the diagnosis often is made through surgery.[228]

Tuberculous peritonitis commonly causes pain as its presenting manifestation, often accompanied by abdominal swelling. Fever, weight loss, and anorexia are also common. Active pulmonary tuberculosis is uncommon in patients with tuberculous peritonitis. Because the process frequently coexists with other disorders, especially cirrhosis with ascites, the symptoms of tuberculosis may be obscured. The combination of fever and abdominal tenderness in a person with ascites should always prompt an evaluation for intra-abdominal infection, and paracentesis should be performed. Ascitic fluid in tuberculous peritonitis is exudative and contains between 50 and 10,000 leukocytes per microliter, the majority of which are lymphocytes, although polymorphonuclear leukocytes occasionally predominate.[229] Acid-fast organisms are rarely seen on smears of the fluid, and cultures are positive in only approximately 50%, although the yield increases if a large volume of fluid is submitted for culture. Because of the generally low yield from culture of the fluid, laparoscopic biopsy is often necessary to confirm the diagnosis.

Standard chemotherapy is quite effective in abdominal tuberculosis. Corticosteroids have been advocated in tuberculous peritonitis to reduce the risk of adhesions causing intestinal obstructions, but this recommendation is controversial because of the low frequency of obstruction. As discussed previously, surgery is often necessary to establish a diagnosis and, in addition, may be necessary to relieve intestinal obstruction.

Pericardial Tuberculosis

The descriptive epidemiology of pericardial tuberculosis is not well defined, but in general it tends to occur among older persons, particularly nonwhites and men. The pericardium may become involved during the initial bacillemia, with early progression to clinically evident disease or recrudescence after a quiescent period. Hematogenous seeding may also occur during the course of endogenous reactivation. Alternatively, there may be direct extension of an adjacent focus of disease from the lung parenchyma, pleura, or tracheobronchial lymph nodes into the pericardium. Like the pleura, the pericardium is a serosal surface capable of exuding large amounts of fluid in response to inflammation. As presumably occurs in tuberculous pleuritis with effusion, it is likely that tuberculin hypersensitivity plays a role in producing the intense inflammatory response and abundant effusion in the pericardium. This would account for the relative infrequency of isolation of tubercle bacilli from pericardial fluid, the nonpurulent nature of the fluid, and the generally prompt response to antituberculosis chemotherapy in most instances. Conversely, rupture of a caseous lymph node into the pericardium may cause contamination with a much greater number of organisms; a greater inflammatory response with thicker, more purulent fluid; and a greater likelihood of either early or late hemodynamic effects.

The most common form or stage of tuberculous pericarditis is characterized by pericardial effusion with little pericardial thickening or epicardial involvement. Because in most instances the fluid accumulates slowly, the pericardium can expand to accommodate very large

volumes (2 to 4 L) with little apparent hemodynamic compromise. Symptoms of cardiopulmonary origin tend to occur later and include cough, dyspnea, orthopnea, ankle swelling, and chest pain. The chest pain may occasionally mimic angina but usually is described as being dull, aching, and often affected by position and by inspiration.

The fluid itself is usually serosanguineous or occasionally grossly bloody, is exudative, and has a white blood cell count ranging from 500 to 50,000 cells/μL, with an average of 5000 to 7000 cells/μL.[230] The cells are predominantly mononuclear, although polymorphonuclear leukocytes occasionally predominate. Tubercle bacilli have been identified in pericardial fluid in approximately 25% to 30% of cases (smear and culture combined).[230] Biopsy of the pericardium with both histologic and bacteriologic evaluation is much more likely to provide a diagnosis, although a nonspecific histologic pattern and failure to recover the organisms do not exclude a tuberculous cause.

Although not well documented, it appears that, if the patient survives the subacute phase without treatment, chronic fibrotic pericarditis nearly always follows. Before the advent of antituberculosis therapy, 88% of one series of patients who had tuberculous pericarditis developed evidence of chronic constriction.[231] Constriction has also been observed to develop during the course of antituberculosis chemotherapy, although this appears to be uncommon in patients who have had symptoms for less than 3 months; it is frequent in patients who have had symptoms for more than 6 months.

The fibrotic reaction progresses to complete fusion of visceral and parietal pericardium and encasement of the heart in a rigid scar that often becomes calcified. Impairment of coronary circulation is common. At this point the histologic pattern is usually nonspecific; thus, confirmation of a tuberculous etiology is infrequent.

The definitive diagnosis of tuberculous pericarditis requires identification of tubercle bacilli in pericardial fluid or tissue. Although not conclusive, demonstration of caseating granulomata in the pericardium and consistent clinical circumstances provide convincing evidence of a tuberculous etiology. Less conclusive but still persuasive evidence is the finding of another form of tuberculosis in a patient with pericarditis of undetermined cause. Approximately 25% to 50% of patients with tuberculous pericarditis have evidence of other organ involvement, particularly pleuritis, at the time pericarditis is diagnosed.[232] Still less direct and more circumstantial evidence of a tuberculous etiology is the combination of a positive intermediate-strength tuberculin skin test reaction and pericarditis of unproved cause.

Because of the potentially life-threatening nature of pericardial tuberculosis, treatment with antituberculosis agents should be instituted promptly once the diagnosis is made or strongly suggested. It appears that the likelihood of constriction is greater in patients who have had symptoms longer; thus, early therapy may reduce the incidence of this complication. Several studies have suggested that corticosteroids have a beneficial effect in treating both tuberculous pericarditis with effusion and constrictive pericarditis.[233–235] However, a meta-analysis of studies examining the effects of corticosteroids in tuberculous pericarditis concluded that, although steroids could have an important effect, the studies were too small to be conclusive.[233] Nevertheless, patients with proven tuberculous pericarditis who are receiving adequate antituberculosis therapy and who have no major contraindications should receive corticosteroids. The optimum regimen is not known, but daily prednisone, 60 mg/day for 4 weeks, followed by 30 mg/day for 4 weeks, 15 mg/day for 2 weeks, and 5 mg/day for 1 week, is the recommended regimen.[143] Corticosteroid therapy should not be used if there is a strong suspicion that the infection is caused by a drug-resistant organism unless adequate antituberculosis chemotherapy can be ensured.

In general, if hemodynamic compromise occurs, pericardiectomy is necessary. Although pericardiocentesis generally improves the circulatory status, the improvement is usually temporary. Pericardial windows with drainage into the left pleural space also generally provide only temporary relief. The criteria for selecting patients for pericardiectomy are not clear, apart from those patients who have refractory hemodynamic compromise.

LATENT TUBERCULOUS INFECTION

The concept of latent tuberculous infection and the observations on which its treatment are based were made in the 1950s during the course of experimental studies on the chemotherapeutic effect of isoniazid: animals given isoniazid before being challenged by *M. tuberculosis* had a much lower frequency of tuberculosis.[236] Subsequently, it was found that isoniazid given to children with primary tuberculosis nearly eliminated extrapulmonary spread of the disease.[237] These results provided the rationale for several large U.S. Public Health Service studies of the effectiveness of isoniazid in preventing tuberculosis. These studies were double-blind, placebo-controlled clinical trials that involved approximately 70,000 participants who were in a number of different settings and who had a variety of different risk factors for tuberculosis. The design and results of these studies are described in detail by Ferebee.[238] The findings were remarkably similar in all groups studied; participants given isoniazid had a reduction of approximately 80% in the incidence of tuberculosis during the year the medication was given, in comparison with those given placebo. The protective effect decreased during subsequent years, but the treated groups still showed approximately 50% less tuberculosis than did the control groups each year after the medication year through 10 to 12 years of observation. Overall, isoniazid reduced the incidence of tuberculosis by approximately 60%.

The effectiveness of antituberculosis drugs in preventing tuberculosis is presumably a result of the reduction of the viable population of sequestered bacilli in inactive

or radiographically invisible lesions in the lungs and elsewhere. However, on occasion treatment may be given to persons who have been exposed to tuberculosis but do not have a positive tuberculin reaction. In this situation, treatment is assumed to prevent the establishment of a tuberculous infection, an example of "primary prophylaxis."

Indications for Treatment

The recommendations for testing for and treatment of latent tuberculous infection reflect the concept that only persons who are at increased risk of tuberculosis should be tested for latent infection; thus, any person who is tested and is found to have a positive test should be considered for treatment.[239] The two broad categories of persons in whom the risk of tuberculosis is substantially higher than that of the general population of the United States are persons who are either known or presumed to have been recently infected with *M. tuberculosis* and persons who have clinical conditions that increase the risk of progressing from latent infection to active tuberculosis. The specific groups in which treatment is indicated are as follows (in order of decreasing degree of risk for developing tuberculosis).

Persons with HIV Infection

Several studies have shown that the rates of tuberculosis among persons who are infected with both *M. tuberculosis* and HIV are extremely high, ranging from 3% to 10% per year.[67,240–245] The effectiveness of preventive therapy among persons with HIV infection has been examined in 11 trials with a total of 8130 randomized participants.[241,244,245] Preventive therapy with any antituberculosis drug versus placebo was associated with a lower incidence of active tuberculosis (relative risk [RR], 0.64; 95% CI, 0.51 to 0.81). Among persons with a positive tuberculin skin test, the reduction in risk was even greater (RR, 0.38; 95% CI, 0.25 to 0.57) compared with persons having negative skin test, in whom the reduction was not statistically significant (RR, 0.83; 95% CI, 0.58 to 1.18). The efficacy was similar for all regimens, regardless of drug type, frequency, or duration of treatment. However, compared to isoniazid monotherapy, short-course multidrug regimens were much more likely to require discontinuation of treatment due to adverse effects.

Pape and colleagues[241] reported a rate of 1.7 cases per 100 person-years among HIV-infected, tuberculin-positive (>5-mm induration) adults given isoniazid, 300 mg/day for 12 months, in comparison with a rate of 10.0 cases per 100 person-years in those given placebo. Whalen and associates[244] reported similar rates (1.1 per 100 person-years) among tuberculin-positive, HIV-infected Ugandan adults given isoniazid, 300 mg/day for 6 months, in comparison with a rate of 3.1 cases per 100 person-years in those given placebo. In neither of these studies was benefit found among anergic subjects. The study by Pape and colleagues[241] also demonstrated a reduction in the rate of progression to AIDS and in death rates among those tuberculin-positive subjects given isoniazid. The lack of benefit for anergic subjects was subsequently corroborated in a study conducted in the United States by Gordin and coworkers.[245] Although the optimum duration of preventive therapy with isoniazid in persons with HIV infection is not known, 9 months is currently recommended.[239]

Close Contacts of New Cases

Two percent to 4% of these persons develop tuberculosis in the year after exposure has occurred.[246,247] In young children and adolescents, the risk is perhaps twice that in adults. Because the tuberculin reaction may be negative if infection has recently occurred, all close contacts should be treated.[239] Those with a reaction of 5 mm or more should be considered to be infected and should receive a full course of preventive therapy. Close contacts who have negative tuberculin reactions should be retested 2 to 3 months after the index case has ceased being infectious or after contact has been broken. If the tuberculin reaction at that time is less than 5 mm, isoniazid can be discontinued, and if the reaction is 5 mm or more, the drug should be continued for a full course. Contacts who are known to be HIV-infected should be treated even if the tuberculin test result is negative.

Persons with Recent Infection

As discussed in the section describing the pathogenesis of tuberculosis, the risk of developing tuberculosis is greatest during the initial 1 to 2 years after acquisition of the infection. Any person who is documented to have had a conversion of the skin test reaction from negative to positive should be considered newly infected and receive treatment. A skin test conversion is defined as an increase in reaction size of 10 mm or more within a 2-year period for persons under 35 years of age and a 15-mm or more increase for persons over 35 years of age. Tuberculin skin test reactors younger than 5 years of age should be accorded a high priority for preventive therapy, both because they obviously have been infected relatively recently and because of the potential for severe disease in this age group.

Persons with Stable Radiographic Findings Consistent with Previous Tuberculosis

This group includes persons with a history of tuberculosis who never received chemotherapy or who were not treated adequately, and persons with no known history of the disease. The rate at which new episodes of tuberculosis develop in these groups ranges from approximately 0.4% to 3.5% per year.[238,248–250] The risk is lowest in persons with small lesions that have been stable for a long period.[250] In persons with radiographic abnormalities, it is essential that current tuberculosis be excluded by a careful clinical and bacteriologic evaluation. Because exclusion of active tuberculosis might not be feasible or possible at the initiation of therapy, an alternative

approach is to begin therapy with multiple drugs: isoniazid, rifampin, and pyrazinamide, sometimes with ethambutol. If active disease is present as determined by a positive culture or by radiographic improvement, therapy should be continued for 6 months. If there is no suggestion of active disease, therapy can be stopped after 4 months and the course of treatment will be sufficient for preventive purposes.[239]

Persons with Other Conditions That Increase the Risk of Tuberculosis

Although the risk of tuberculosis is not always quantifiable, there is sufficient evidence to warrant preventive therapy in certain situations[239]: silicosis or coal worker's pneumoconiosis; prolonged therapy with adrenocorticosteroids (usually 15 mg or more of prednisone daily, or its equivalent, for more than 2 to 3 weeks); immunosuppressive therapy; hematologic or reticuloendothelial malignancies, and perhaps certain solid tumors; end-stage renal disease; clinical conditions associated with rapid weight loss (including intestinal bypass for obesity and inadequate nutritional intake); after gastrectomy; and after treatment with anti-TNF agents.[251] In addition, even in the absence of any of these risk factors, persons in the following circumstances who have tuberculin skin test readings of 10 mm or more should be considered for preventive therapy[239]: foreign-born persons from areas of high tuberculosis prevalence; medically underserved, low-income populations, including high-risk racial and ethnic groups; residents of long-term care facilities (e.g., correctional institutions and nursing homes); and other groups that, on the basis of local epidemiologic patterns, have been shown to have a high incidence of tuberculosis (e.g., migrant workers, homeless persons).

Current Treatment Regimens

Three regimens are currently recommended for treating latent tuberculous infection in adults.[239] The regimen that is supported most strongly is isoniazid given daily for 9 months. A 6-month regimen has also been shown to produce considerable protection and may provide the best balance between cost and benefit. Both the 6-month and the 9-month isoniazid regimens may be given twice weekly under direct observation. A regimen of rifampin and pyrazinamide given daily for 2 months was recommended as an alternative to isoniazid,[252] but owing to its significantly greater risk of hepatotoxicity than isoniazid alone, currently it is recommended only for persons thought not likely to complete a 6- to 9-month course of therapy and who can be monitored closely.[253,254] A third option, although the supporting data are not so strong, is rifampin given daily for 4 months.

Isoniazid is given in a single daily dose of 300 mg for adults and 5 to 10 mg/kg body weight (up to 300 mg/day) for children. The drug may also be given in doses of 15 mg/kg twice a week, which may facilitate direct observation of treatment. The minimum duration of treatment is 6 months; 9 months of treatment is considered optimum. Rifampin is given in a single dose of approximately 10 mg/kg body weight for both adults and children, up to a total daily dose of 600 mg. The same dose is used when the drug is given twice weekly. If rifabutin is substituted for rifampin, the dose is 5 mg/kg/day or 300 mg/day.

Treatment of latent tuberculous infection with isoniazid or rifampin should not be undertaken in persons who have active, unstable liver disease. Stable chronic liver disease is not a contraindication, but such patients deserve careful consideration regarding the indications and need close attention during the course of treatment. Other persons who should be monitored especially closely during the administration of preventive therapy include persons over 35 years of age; those taking other medications with which there may be interactions (such as phenytoin, disulfuram, or antiretroviral drugs); and persons with other disorders such as alcoholism, diabetes mellitus, or renal insufficiency that may increase the risk of adverse reactions, mainly hepatitis and peripheral neuropathy.

Pregnancy is not a contraindication to isoniazid; however, in view of the concern with elective administration of any drug during the course of pregnancy, it is generally prudent to wait until after delivery to give isoniazid. The exceptions to this generality are women who have a documented tuberculin conversion during pregnancy or who are HIV-infected and have a positive tuberculin reaction.

Management of Exposure to Drug-Resistant Organisms

Providing preventive therapy for persons exposed to MDR or XDR organisms is especially problematic because there are no regimens of proven efficacy. The options that are available include observation only and administration of two drugs to which the source case isolate was shown to be susceptible (e.g., a 6-month regimen of ethambutol and pyrazinamide or of pyrazinamide and a fluoroquinolone).[239] It should be noted that there are no data to guide the choice of an option. In such situations consultation should be obtained. Regardless of the approach that is chosen, if evidence suggesting tuberculosis arises, the patient should be treated promptly with a multidrug regimen to which the organism would be predicted, on the basis of susceptibility testing of the index case isolate, to be susceptible.

Immunization with Bacille Calmette-Guérin

Administration of BCG vaccine has been the major preventive technique used for many years throughout much of the world, and yet no vaccine has been the subject of greater controversy.[49] BCG is an attenuated tubercle bacillus (*Mycobacterium bovis*) that was created beginning in 1908 by Calmette and Guérin in France and that

was found to protect a variety of animal species against tuberculosis. It was first used in humans in 1921 and has since become the most widely used vaccine in the world: As many as 80% of infants in developing countries receive BCG immunizations. The controversy related to results in prevention of tuberculosis in adult populations should not obscure the fact that BCG has been demonstrated to prevent disseminated and miliary tuberculosis and tuberculosis meningitis in children. Controversy stems from the fact that, of eight controlled clinical trials of BCG against pulmonary tuberculosis in adults, protection has ranged from 0 to 70%.[49] Interestingly, when two different vaccines were used in a Medical Research Council Trial in the United Kingdom, one of which produced only very poor tuberculin skin test reactivity, equal degrees of protection were seen. Conversely, no protection was seen in the South Indian Trial of over 200,000 people monitored for 15 years, although all patients who developed tuberculosis had been converted to skin test positivity by the vaccine.[255] It is unclear why BCG appears to be effective in some parts of the world and not in others (a finding that is also evident in protection against leprosy). Clearly, there is a great deal that has yet to be elucidated about the nature of protective host immune responses, host genetic factors, variations in pathogenicity of tubercle bacilli, and the role of exposure to environmental nontuberculous mycobacteria that may provide resistance or enhance susceptibility.

There are many variables that potentially could account for the discordant results. These include variations in potency of the strains of BCG used, technique of administration, handling of the vaccine, and prevalence of infection with nontuberculous mycobacteria, which may in themselves confer some degree of protection.[256] Partly because of these factors, it is now generally accepted that BCG is not a tool that can be used to decrease the overall incidence of tuberculosis in a population. However, it appears that BCG reduces the likelihood of the more severe forms of the disease in children, and it is with this goal in mind that it continues to be a component of WHO immunization recommendations for developing countries.

In the United States, BCG has very limited applicability. It is recommended only for tuberculin-negative persons who are repeatedly exposed to potentially infectious patients who are being ineffectively treated. In general, the recommendation is limited to children. BCG should not be given to immunocompromised persons, including those with symptomatic HIV infection, or to pregnant women.

TACKLING CURRENT PROBLEMS

Tuberculosis is becoming a more complicated disease globally because of the occurrence of MDR and XDR organisms and the increasing frequency of comorbidities, particularly HIV infection but also other risk-enhancing factors such as diabetes, renal insufficiency, immunosuppressive drugs, and tobacco and other substance addiction. No longer can it be said that tuberculosis control is mainly a management issue rather than a technical problem. Nor can it continue to be said that all that is needed to solve current problems is more assiduous application of the tools that are already widely available. Yet, the most extensively used diagnostic methods around the world, both for active tuberculosis (sputum smear microscopy) and for latent tuberculosis (tuberculin skin test), were invented at end of the 19th century. Similarly, BCG vaccine, despite its wide use, does not provide the needed protection. Today's standard treatment with four drugs (isoniazid, rifampin, ethambutol, and pyrazinamide) has remained unchanged for more than 30 years and is insufficient to treat patients with MDR or XDR tuberculosis. Although there are new diagnostic methods, all of them are either an improvement of the old techniques or based on the detection of nucleic acids. Neither are point-of-care diagnostic tests as are urgently needed.

The increase of drug-resistant tuberculosis and the detection of XDR cases underscores the need for new drugs as well as means to decrease the risk of developing resistance to new drugs.[257] Also high on the list is the availability of a test for the rapid detection of drug resistance suitable for field use. The current technology has identified drug targets and has enabled testing of new compounds with high-throughput screening methods. Several drugs for active tuberculosis are now being tested in clinical trials.[258,259] Some of them are candidates for first-line drugs that can reduce the treatment time, such as moxifloxacin. Others drugs have less drug-drug interaction, with the potential benefit of being used with antiretroviral drugs such as rialazil. Other drugs have a different target, such as TMC207.[260–262] However, we are still far from having a truly short treatment (currently the term *short course* is used for the 6-month regimen!).

Better understanding of the protective immune response to *M. tuberculosis* and of the pathogenesis of the disease, the availability of whole genomic sequences of several clinical strains of *M. tuberculosis,* and the recent evidence of the importance of the coevolution of the host and organism have led to the design of different vaccination approaches.[263,264] Although substantial knowledge has been developed as a consequence of vaccine research, we are still far from having an understanding of why the natural immune system (which prevents 90% of persons infected from developing active tuberculosis) fails in 10% of those infected, and why the adaptive immune response in tuberculosis does not protect us from repeated infections. In spite of these gaps in knowledge, several vaccine candidates are now being tested.[12]

Although important scientific advances have been made recently, major gaps in understanding the basic biology of the organism and the human response to infection with *M. tuberculosis* remain. The rapidly emerging new challenges to the care and control of tuberculosis, such as HIV, MDR tuberculosis, and more recently XDR tuberculosis, may outstrip the advances and threaten our ability to control the disease.

Appendix can be found on Expert Consult

KEY POINTS

- Although tuberculosis cases and case rates are consistently declining in high- and most middle-income countries, the disease continues to be highly prevalent in low- and some middle-income countries.
- The epidemic of HIV infection, especially in sub-Saharan Africa, is leading to extremely high tuberculosis case rates.
- Both HIV infection and resistance to antituberculosis drugs, especially multidrug resistance and extensive drug resistance, present major problems in worldwide tuberculosis control.
- Adequate treatment for tuberculosis, both drug susceptible and drug resistant, is the major intervention for decreasing transmission of *M. tuberculosis.*
- Assuming an adequate regimen is prescribed, patient adherence is the critical factor that determines the success of treatment.
- The treatment of extrapulmonary tuberculosis is largely the same as the treatment of pulmonary tuberculosis. The exceptions are central nervous system tuberculosis and tuberculosis involving bones and joints, in which treatment of longer duration is recommended.
- Treating latent tuberculous infection in persons at increased risk of progressing to active tuberculosis significantly reduces the risk of disease.

CHAPTER 34
APPENDIX

ESSENTIALS OF CHEMOTHERAPY

INTRODUCTION

The development of successful chemotherapy for tuberculosis must rank as one of the greatest achievements of medical science. Beginning in the late 1940s, chemotherapy began to slow down—little by little—the centuries' long and ever-growing toll from the incurable "captain of all these men of death," John Bunyan's name for the plague that has killed an estimated 2 billion human beings: more, by far, than any other disease. Notable victims included kings and princes, cardinals, famous poets, writers, musicians, and artists, and, of course, countless anonymous poor people. Finding a cure for this scourge did not happen easily, quickly, or by serendipity. It was the cumulative work over decades by many men and women dedicated to that single purpose, and—keep this in mind—these efforts are ongoing. The history of the initial taming of tuberculosis and why the task remains unfinished makes fascinating reading, especially in the accounts of Dubos and Dubos,[1] Ryan,[2] and Daniel.[3]

Even though effective treatment has been available for more than 50 years, tuberculosis continues to plague vulnerable regions of the world. More and more strains of disease-producing *Mycobacterium tuberculosis* are resistant to standard antituberculosis regimens: some strains are resistant to nearly all available agents. A glance at the most recent statistics—an estimated 9.27 million new cases; 1.3 million deaths among human immunodeficiency virus (HIV)–uninfected persons and 456,000 among HIV-infected persons; and 511,000 cases of multiresistant disease in the year 2007—reveals how much work remains to be done.[4]

BEGINNINGS

To understand where we currently stand and to appreciate the enormity of the task ahead, this appendix provides a brief chronology of the use of chemotherapy for treating tuberculosis, starting with streptomycin, the original breakthrough agent, which was first injected into a desperately ill young woman in November 1944. To everyone's astonishment and relief, she did not die but slowly began to recover. Then, miraculously, so did others.[5]

But within a few years, after many more patients with tuberculosis had been treated with streptomycin, it became apparent that the striking clinical and radiographic improvement observed initially did not always last; after several months of treatment, patients began to worsen and the reason was immediately obvious: their tubercle bacilli had become resistant to streptomycin.[6] The findings of clinical failure and emergence of drug resistance served to define the major bacteriologic principle on which successful chemotherapy for tuberculosis depends: bacillary populations are not uniform in their susceptibility to antituberculosis agents; hence, it is always necessary to treat active disease with more than one drug to which the organisms are susceptible.

The concept of multiple-drug chemotherapy was first validated in 1950 by a British Medical Research Council study in which streptomycin was partnered with *para*-aminosalicylic acid, better known as PAS: long-lasting success occurred because PAS prevented organisms from becoming resistant to streptomycin and vice versa, and two drugs have more clinical clout than only one.[7] Since that time, treatment with more than one drug has been standard in the management of patients with tuberculosis. Although the combination of streptomycin and PAS was effective, neither agent was well tolerated and clinical improvement was slow and hampered by side effects. The long-sought solution to antituberculosis chemotherapy arrived in 1952 with the introduction of isoniazid, a powerful drug that was not only highly effective, but well tolerated and inexpensive.[8] However, once again it was learned that single-drug treatment with isoniazid was inadequate because resistance to the agent developed quickly. The solution was clear: combine isoniazid with both streptomycin and PAS. This triple therapy became the standard treatment for tuberculosis until 1967, when a new antituberculosis agent, ethambutol, an easily tolerated and minimally toxic drug, was welcomed as a substitute for PAS.[9]

Subsequent experiments have shown that, in any wild strain of *M. tuberculosis,* the frequency of drug-resistant mutants is 1 in 3.5×10^6 for isoniazid, 1 in 3.8×10^6 for streptomycin, 1 in 3.1×10^8 for rifampin, and 1 in $0.5 \times$

10^4 for ethambutol.[10] Thus, a bacillary population of more than 10^{12} organisms would be required before one would expect to find (statistically) a single bacillus resistant to both isoniazid and streptomycin.

Once optimum doses of each component were established, wide use of triple therapy revolutionized the care of patients with tuberculosis. Springett[11] reviewed death rates from tuberculosis for cohorts of patients in Birmingham, England, for the years 1947, 1950, 1953, 1956, and 1959. With increasing use of antituberculosis chemotherapy, deaths decreased dramatically during the 10 years after diagnosis, and nearly all of the reduction was accounted for by improvements in survival during the first year after diagnosis. In addition, not only were survivors more numerous, but among survivors, far fewer than in the prechemotherapy era continued to be potential sources of new infections. In the Springett study, both the decrease in mortality rate and the reduction in the prevalence of chronically infectious patients reached their maximum in 1956, with no further improvement in 1959.

The next major advance in chemotherapy for pulmonary tuberculosis resulted from the discovery of rifampin (or rifampicin, as it is known in many parts of the world) and the demonstration that the combination of isoniazid and rifampin, generally with ethambutol or streptomycin, could dramatically shorten the necessary duration of treatment.[12] In a series of important studies from East Africa during the 1970s, the British Medical Research Council established that a 6-month regimen consisting of isoniazid, streptomycin, and rifampin was as effective as the standard regimen used at the time in developing countries (18 months of isoniazid and thiacetazone, plus streptomycin given during the first 2 months).[13]

A critical factor influencing the effectiveness of chemotherapy was, and continues to be, the adherence (or lack thereof) of patients to the prescribed regimen, a fact well documented both in the United States and in developing countries.[14,15] In spite of initial high rates of success elsewhere, the results of a U.S. Public Health Service multicenter cooperative trial indicated that a 6-month regimen of isoniazid and rifampin did not have an acceptable rate of favorable outcome.[16] Positive cultures were found in 6.1% of the patients between 3 and 6 months after treatment began. Of greater importance was that 9.2% experienced relapse after completion of treatment. Strikingly, 16.8% of the patients were withdrawn from the study because they had been delinquent about clinic visits during the 6 months of treatment. This outcome was a setback for efforts to shorten the duration of treatment to 6 months, which—assuming equal effectiveness and tolerance—would have considerable clinical and logistical advantages over 18- to 24-month regimens.

Studies of chemotherapy then began to focus on the possible benefits of pyrazinamide.[17] Dickinson and coworkers[18] demonstrated that streptomycin, rifampin, and isoniazid are quickly bactericidal for rapidly growing *M. tuberculosis* in vitro. The in vitro conditions could be likened to the conditions under which the extracellular organisms in tuberculous lesions are living. Although both rifampin and isoniazid are rapidly bactericidal, Mitchison and Dickinson[19] demonstrated that rifampin is more effective in killing organisms that grow in spurts rather than continuously. Although both isoniazid and rifampin are effective in killing intracellular organisms, pyrazinamide is especially effective for this purpose, suggesting that the addition of pyrazinamide would strengthen the isoniazid-rifampin combination. Subsequently, two studies substantiated the fact that the addition of pyrazinamide for 2 months to a regimen of isoniazid and rifampin does indeed improve the effectiveness of a 6-month regimen.[20,21] Thus, a 6-month regimen of isoniazid and rifampin supplemented by pyrazinamide and ethambutol for the initial 2 months is now recommended as standard treatment for most patients with newly diagnosed pulmonary tuberculosis.[22,23]

DRUGS IN CURRENT USE

As shown in Table 34A-1, 10 drugs currently are approved by the U.S. Food and Drug Administration for treating tuberculosis, and 6 other drugs are effective but not approved for this indication. The table lists both first- and second-line drugs, the available preparations, and the doses currently used to treat tuberculosis.

First-Line Drugs

Isoniazid is the most widely used of all antituberculosis agents. It is very effective, specific for some mycobacteria, relatively nontoxic, easily administered, and inexpensive. Isoniazid is highly active against *M. tuberculosis:* most strains are inhibited by concentrations of 0.05 to 0.20 μg/mL, and it has profound early bactericidal activity. The drug is readily absorbed from the gastrointestinal tract; peak blood concentrations of approximately 5 μg/mL occur 1 to 2 hours after administration of 3 to 5 mg/kg of body weight. The serum half-life varies depending on whether a person is a rapid or slow acetylator: half-lives are 2 to 4 hours in slow acetylators and 0.5 to 1.5 hours in rapid acetylators.[24] The drug penetrates well into all body fluids and cavities, producing concentrations similar to those found in serum. Isoniazid presumably exerts its effect by inhibiting an enzyme, mycolate synthetase. The genetic bases for the action of isoniazid and for microbial resistance to the drug have been at least partially explained. Zhang and coworkers[25] and Heym and associates[26] demonstrated that the gene for the catalase-peroxidase enzyme (*katG*) was deleted in some isoniazid-resistant strains of *M. tuberculosis,* which suggests that isoniazid requires intracellular conversion to an active form by the enzyme. However, subsequent studies have shown that most isoniazid-resistant strains have not lost the *katG* gene. Rather, a number of *katG* polymorphisms have been identified, at least some of which are associated with isoniazid resistance.[27,28]

Mutations in the *inhA* gene provide a second genetic mechanism for isoniazid resistance. The product of this gene is thought to be an enoyl reductase that is involved

TABLE 34A-1. Doses* of Antituberculosis Drugs for Adults and Children†

Drug	Preparation		Daily	WEEKLY 1×	WEEKLY 2×	WEEKLY 3×
FIRST-LINE DRUGS						
Isoniazid	Tablets (50 mg, 100 mg, 300 mg); elixir (50 mg/5 mL); aqueous solution (100 mg/mL) for IV or IM injection.	Adults (max.)	5 mg/kg (300 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)
		Children (max.)	10–15 mg/kg (300 mg)	—	20–30 mg/kg (900 mg)	—
Rifampin	Capsule (150 mg, 300 mg). Powder may be suspended for oral administration. Aqueous solution for IV injection.	Adults‡ (max.)	10 mg/kg (600 mg)	—	10 mg/kg (600 mg)	10 mg/kg (600 mg)
		Children (max.)	10–20 mg/kg (600 mg)	—	10–20 mg/kg (600 mg)	—
Rifabutin	Capsule (150 mg)	Adults‡ (max.)	5 mg/kg (300 mg)	—	5 mg/kg (300 mg)	5 mg/kg (300 mg)
		Children	Appropriate dosing for children is unknown.			
Rifapentine	Tablet (150 mg film coated)	Adults	—	10 mg/kg (continuation phase) (600 mg)	—	—
		Children	The drug is not approved for use in children.			
Pyrazinamide	Tablet (500 mg scored)	Adults	20–30 mg/kg (2 g)	—	40–50 mg/kg (4 g)	30–45 mg/kg (3 g)
		Children (max.)	15–30 mg/kg (2 g)	—	50 mg/kg (4 g)	—
Ethambutol	Tablet (100 mg, 400 mg)	Adults	15–20 mg/kg (1.6 g)	—	40–50 mg/kg (2.4 g)	25–35 mg/kg (2.4 g)
		Children§ (max.)	20 mg/kg daily (1 g)	—	50 mg/kg (4 g)	—
SECOND-LINE DRUGS						
Cycloserine	Capsule (250 mg)	Adults (max.)	10–15 mg/kg/day (1.0 g in two doses), usually 500–750 mg/day in two doses¶	There are no data to support intermittent administration.		
		Children (max.)	10–15 mg/kg/day (1.0 g/day)	—	—	—
Ethionamide	Tablet (250 mg)	Adults (max.)	15–20 mg/kg/day (1.0 g/day), usually 500–750 mg/day in a single daily dose or two divided doses¶	There are no data to support intermittent administration.		
		Children (max.)	15–20 mg/kg/day (1.0 g/day)			

*Dose per weight is based on ideal body weight. Children weighing more that 40 kg should be dosed as adults.
†For purposes of this document, adult dosing begins at age 15 years.
‡Dose may need to be adjusted when there is concomitant use of protease inhibitors or non-nucleoside reverse transcriptase inhibitors.
§The drug can likely be used safely in older children but should be used with caution in children under 5 years, in whom visual acuity cannot be monitored. In younger children, ethambutol at the dose of 15 mg/kg/day can be used if there is suspected or proven resistance to isoniazid or rifampin.
¶It should be noted that, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimum dose for a given patient.
¶The single daily dose can be given at bedtime or with the main meal.

continued

TABLE 34A-1. Doses* of Antituberculosis Drugs for Adults and Children†—cont'd

Drug	Preparation		Daily	WEEKLY 1×	WEEKLY 2×	WEEKLY 3×
Streptomycin	Aqueous solution (1-g vials) for IM or IV administration.	Adults (max.)	15 mg/kg/day (1 g), and 10 mg/kg in persons >59 years of age (750 mg). Usual dose 750 mg–1.0 g IM or IV typically given as a single dose 5–7 days a week and reduced to 2–3 times a week after first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.			
		Children (max.)	20–40 mg/kg/day (1.0 g)	—	20 mg/kg	—
Amikacin/ Kanamycin	Aqueous solution (500-mg and 1-g vials) for IM or IV administration.	Adults (max.)	15 mg/kg/day (1 g), and 10 mg/kg in persons >59 years of age (750 mg). Usual dose 750 mg–1.0 g IM or IV typically given as a single dose 5–7 days a week and reduced to 2–3 times a week after first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.			
		Children (max.)	15–30 mg/kg/day (1.0 g) IM or IV as a single daily dose	—	15–30 mg/kg	—
Capreomycin	Aqueous solution (1-g vials) for IM or IV administration.	Adults (max.)	15 mg/kg/day (1 g), and 10 mg/kg in persons >59 years of age (750 mg). Usual dose 750 mg–1.0 g IM or IV typically given as a single dose 5–7 days a week and reduced to 2–3 times a week after first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.			
		Children (max.)	15–30 mg/kg/day (1.0 g) as a single daily dose	—	15–30 mg/kg	—
***para*-Aminosalicylic Acid (PAS)**	Granules (4-g packets) can be mixed with food. Tablets (500 mg) are still available in some countries, but not in the United States. A solution for IV administration is available in Europe.	Adults	8–12 g/day in 2 or 3 doses	There are no data to support intermittent administration.		
		Children	200–300 mg/kg/day in 2–4 divided doses (10 g)			
Levofloxacin	Tablets (250 mg, 500 mg, 750 mg); aqueous solution (500-mg vials) for IV injection.	Adults	500–1000 mg daily	There are no data to support intermittent administration.		
		Children	The long-term (>several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both isoniazid and rifampin. The optimal dose is not known.			
Moxifloxacin	Tablets (400 mg); aqueous solution (400 mg/250 mL) for IV injection.	Adults	400 mg daily	There are no data to support intermittent administration.		
		Children	The long-term (>several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.			
Gatifloxacin	Tablets (400 mg); aqueous solution (200 mg/20 mL; 400 mg/40 mL) for IV injection.	Adults	400 mg daily	There are no data to support intermittent administration.		
		Children	The long-term (>several weeks) use of gatifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.			

Drugs in **bold** are approved by the U.S. Food and Drug Administration for treatment of tuberculosis.
Modified from Blumberg HM, Burman WJ, Chaisson RE, et al: American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: Treatment of tuberculosis. Am J Respir Crit Care Med 167:604–662, 2003.

in mycolic acid biosynthesis. Mutations of *inhA* usually are associated with low-level resistance to isoniazid and resistance to ethionamide as well, which suggests that the *inhA* product is also a target for ethionamide.[27]

When isoniazid is used alone, a population of organisms resistant to the drug emerges rapidly. This was demonstrated in an early clinical trial in which 11%, 52%, and 71% of patients to whom isoniazid alone was given developed resistant strains after 1, 2, and 3 months of treatment, respectively.[29]

Hepatitis is the major toxic effect of isoniazid.[22,30,31] Asymptomatic elevations of aminotransferase—up to five times the upper limit of normal—occur in 10% to 20% of persons receiving isoniazid alone for treatment of latent tuberculous infection.[32] The enzyme levels usually return to normal even with continued administration of the drug. Recent data indicate that the incidence of clinical hepatitis is lower than was previously thought. In 11,141 patients managed in an urban tuberculosis control program who were receiving isoniazid alone as treatment for latent tuberculous infection, hepatitis occurred in only 0.1% to 0.15%.[33] A meta-analysis of six studies estimated the rate of clinical hepatitis in patients given isoniazid to be only 0.6%.[34] The rate of clinical hepatitis was 1.6% when isoniazid was given with other agents, *not* including rifampin.[34] When isoniazid was given in combination with rifampin, the rate of clinical hepatitis averaged 2.7% in 19 reports. For isoniazid alone, the risk increases with increasing age; it is uncommon in persons under 20 years old but is nearly 2% in persons ages 50 to 64 years.[35] The risk may also be increased in persons with underlying liver disease, in those with a history of heavy alcohol consumption, and in the postpartum period, particularly among Hispanic women.[35,36] A large survey estimated the rate of fatal hepatitis to be 0.023%,[37] but more recent studies suggest the rate is substantially lower.[33] The risk may be increased in women. Death has been associated with continued administration of isoniazid well after the onset of symptoms of hepatitis.

Peripheral neuropathy, the second most frequent adverse reaction associated with isoniazid administration, occurs especially in persons with other disorders that may cause neuropathy (HIV infection, diabetes mellitus, uremia, and alcoholism). The neuropathy can be prevented or reversed by administration of pyridoxine 25 mg/day.

Rifampin is also rapidly bactericidal for *M. tuberculosis.* The drug is easily administered and is relatively nontoxic. It is quickly absorbed from the gastrointestinal tract; serum concentrations of 6 to 7 μg/mL occur 1.5 to 2 hours after ingestion. The half-time in blood is 3 to 3.5 hours, although this may be decreased in persons who have been taking the drug for several weeks.[38] The half-time increases with increasing doses of the drug. For sensitive strains of *M. tuberculosis,* the minimum inhibitory concentration of rifampin is approximately 0.5 μg/mL, although there is variation among strains.[39] Approximately 75% of the drug is protein bound, but it penetrates well into tissues and cells. Penetration through noninflamed meninges is poor; however, therapeutic concentrations are achieved in cerebrospinal fluid when the meninges are inflamed.[40]

Among susceptible strains of *M. tuberculosis,* the rate of mutation seems to be less for rifampin than for isoniazid. David[10] reported the rate of mutation to rifampin resistance to be approximately 10×10^{10} per bacterium per generation. In spite of this rather low rate of in vitro mutation, resistance rapidly develops when rifampin is used alone in vivo.[41] Resistance to rifampin unaccompanied by resistance to other antituberculosis drugs has been reported to occur almost exclusively among patients with HIV infection, particularly among patients being treated with once- or twice-weekly intermittent regimens.[42–44]

Rifampin exerts its effect by binding to the β-subunit of RNA polymerase.[27] For this reason, it has activity against many bacteria other than *M. tuberculosis.* Resistance to rifampin results from mutations in the *rpoB* gene, the product of which is the β-subunit of RNA polymerase. Although many different mutations may be involved, alterations in *rpoB* have been shown to account for approximately 96% of the rifampin-resistant strains isolated from patients in many different parts of the world.[27] The mechanism for resistance in the remaining 4% is not known.

Adverse reactions to rifampin when it is given daily include rashes, hepatitis, gastrointestinal upset, and, rarely, thrombocytopenia. The rates of these reactions have been variable, but in general are quite low.[22] Hepatitis occurred in 3.1% of the patients in the U.S. Public Health Service study of 6-month isoniazid-rifampin treatment.[16] Intermittent (twice-weekly) administration of higher doses of rifampin is associated with several immunologically mediated reactions, including thrombocytopenia, an influenza-like syndrome, hemolytic anemia, and acute renal failure.[45]

Drug-drug interactions due to induction of hepatic microsomal enzymes by rifampin are relatively common and are of particular concern in patients with HIV infection. The rifamycins—rifampin, rifabutin, and rifapentine—interact with the protease inhibitor and nonnucleoside reverse transcriptase inhibitor classes of antiretroviral agents.[22] The interaction of these classes of drugs is bidirectional: protease inhibitors decrease clearance of rifamycins, and rifamycins accelerate clearance of protease inhibitors by inducing hepatic P-450 cytochrome oxidases.[46] Of the rifamycin derivatives, rifabutin has the least effect on the concentration of antiretroviral agents. The practical implications of these interactions on treatment regimens are discussed in both Chapters 34 and 80. Rifampin induces the metabolism of a number of other drugs, including methadone, warfarin, oral contraceptives, digoxin, macrolide antibiotics, and ketoconazole.[22] (A complete list of interactions with the rifamycins is found in Blumberg and colleagues.[22]) Doses of these drugs need to be adjusted when rifampin is given. Ketoconazole and, to a lesser extent, fluconazole interfere with absorption of rifampin, thereby decreasing its serum concentration.

Rifabutin, although not approved by the U.S. Food and Drug Administration for the treatment of tuberculo-

sis, may be used as a substitute for rifampin in most treatment regimens.[22] Because of its lesser propensity to induce cytochrome P-450 enzymes, rifabutin is generally reserved for patients who are taking any medication for which there are unacceptable interactions with rifampin. It may also be used for patients who are intolerant of rifampin. There is nearly complete cross-resistance among the rifamycins for *M. tuberculosis.* The toxicity profile of rifabutin is similar to that of rifampin except that, in some studies with HIV-infected patients, neutropenia has been reported and uveitis has been described when the drug is given with a macrolide antibiotic that reduces rifabutin clearance.[22]

Rifapentine, which has the longest serum half-life of the rifamycins, has been shown to be effective in combination with isoniazid given once weekly in the continuation phase of treatment for pulmonary tuberculosis.[47] However, it should be emphasized that this regimen is *not* to be used for patients with HIV infection, patients who have cavitary lesions on chest film, or patients who have positive sputum smears at the end of the 2-month initial phase of treatment. The toxicity profile is similar to that of rifampin.

Ethambutol in usual doses of 15 mg/kg of body weight is generally considered to have a static effect on *M. tuberculosis.* The drug is easily administered and has a low frequency of adverse reactions. Its main effect is to reduce the risk of rifampin resistance in patients with tuberculosis caused by strains that have primary resistance to isoniazid. Peak plasma concentrations occur 2 to 4 hours after ingestion. With doses of 15 mg/kg, the peak concentration is approximately 4 μg/mL.[48] The concentration increases proportionally with increasing doses. In persons with normal renal function, the half-time in blood is approximately 4 hours. Minimum inhibitory concentrations of the drug for *M. tuberculosis* range from 1 to 5 μg/mL. Protein binding is minimal, but penetration into cells is thought to be poor. Cerebrospinal fluid concentrations of ethambutol, even in the presence of meningeal inflammation, are low, averaging 1 to 2 μg/mL after a dose of 25 mg/kg.[49] Like isoniazid, ethambutol appears to exert its effect by interfering with cell wall biosynthesis. Specifically, the target for ethambutol is thought to be an arabinosyltransferase. Mutations in the *embB* gene that, together with *embA* and *embC,* codes for arabinosyltransferases are found in approximately 70% of ethambutol-resistant strains.[27]

Retrobulbar neuritis is the main adverse effect of ethambutol. Symptoms include blurred vision, central scotomata, and red-green color blindness. This complication is dose related, occurring in 15% of patients given 50 mg/kg, 1% to 5% of those given 25 mg/kg, and less than 1% in those given 15 mg/kg.[22] The frequency of ocular effects is increased in patients with renal failure, presumably owing to increased serum concentrations of the drug.

Streptomycin is rapidly bactericidal, although its effectiveness is inhibited by an acid pH.[22] Because the drug is not absorbed from the gut, it must be given parenterally. Peak serum concentrations occur approximately 1 hour after an intramuscular dose. With a dose of 15 mg/kg, the peak concentration is in the range of 40 μg/mL. The half-time in blood is approximately 5 hours. Sensitive strains of *M. tuberculosis* are inhibited by streptomycin in a concentration of 8 μg/mL. The drug has good tissue penetration; however, it enters the cerebrospinal fluid only in the presence of meningeal inflammation. Streptomycin and ethambutol have been found to be of approximately equal effectiveness in combination regimens; however, because of a relatively high prevalence of resistance to streptomycin, particularly in patients from developing countries, its usefulness is limited. For this reason and because it requires parenteral administration, streptomycin is no longer considered a first-line agent in treating tuberculosis.[22]

Streptomycin exerts its effect by interfering with ribosomal protein synthesis. This effect is mediated by binding of the drug to 16S ribosomal RNA (rRNA), thereby inhibiting initiation of translation. Mutations in the genes that code for 16S rRNA (*rrs* and *rpsL*) have been found in 65% to 77% of resistant strains. Mutations in *rpsL* have been associated with high-level streptomycin resistance, whereas low-level resistance has been associated with *rrs* mutations.[27] More recently, mutations in the gene *gid*B were found to be associated with low-level streptomycin resistance. This gene encodes a methyltransferase specific for the 16S rRNA. The available data indicate that *gid*B mutations emerge spontaneously at a high frequency of 10^{-6}.[50]

The most serious adverse effect of streptomycin is ototoxicity.[22] This usually results in vertigo, but hearing loss may also occur. The risk of ototoxicity is related both to cumulative dosage and to peak serum concentrations. In general, peak concentrations of greater than 40 to 50 μg/mL should be avoided, and the total dose should not exceed 100 to 120 g.[22] Because of its effect on fetal auditory system development, streptomycin is contraindicated in pregnancy. Streptomycin should be used with caution in patients with renal insufficiency, in whom dosing frequency should be reduced to two to three times a week, because of increased risk of nephrotoxicity and ototoxicity.[22]

Pyrazinamide is active against *M. tuberculosis* at an acid pH, which suggests that the drug is activated under these conditions.[51] The drug is particularly active against dormant or semidormant *M. tuberculosis* in macrophages or in the acidic environment within areas of caseation, and is rapidly bacteriostatic but only slowly bactericidal. Absorption from the gastrointestinal tract is nearly complete; peak serum concentrations occur approximately 2 hours after ingestion. Concentrations generally range from 30 to 50 μg/mL with doses of 20 to 25 mg/kg. The serum half-life is 9 to 10 hours. At a pH of 5.5, the minimal inhibitory concentration of pyrazinamide for *M. tuberculosis* is 20 μg/mL. Penetration of the drug into cells and tissues seems to be fairly good, although data with regard to tissue concentrations are limited. Data suggest that there is no specific cellular target but that pyrazinamide disrupts the membrane energetics and acidification of cytoplasm.[52]

The genetic mechanism of mycobacterial resistance to pyrazinamide appears to be any of a large number of

mutations in the *pncA* gene, which encodes the enzyme pyrazinamidase. This enzyme appears to be necessary for the intracellular conversion of pyrazinamide to its active form. Mutations in the *pncA* gene are found in approximately 70% of pyrazinamide-resistant strains.[27,52]

The most important adverse reaction to pyrazinamide is liver injury. This appears to be a dose-related occurrence. In a large U.S. Public Health Service study in which pyrazinamide was given in a dose of 25 mg/kg daily for 6 months, hepatotoxicity occurred in 2% to 3% of patients.[53] At a dose of 40 mg/kg per day, also given for 6 months, 6% of patients developed hepatitis. All patients were also receiving isoniazid and PAS in addition to pyrazinamide. An increased frequency of hepatotoxicity has been reported in studies of pyrazinamide combined with rifampin in a 2-month treatment regimen for latent tuberculous infection in persons without HIV infection; accordingly, the indications for this regimen are very limited.

Because pyrazinamide impairs renal urate clearance, hyperuricemia occurs in nearly all patients taking the drug. Clinical gout is not common, but diffuse arthralgias, apparently unrelated to the hyperuricemia, occur frequently. The drug may also cause nausea and vomiting and skin rashes, especially photosensitive dermatitis.

Second-Line Drugs

Four additional agents approved for treating tuberculosis are available in the United States: PAS, ethionamide, cycloserine, and capreomycin. In addition, the fluoroquinolones, amikacin, and kanamycin have antituberculosis effects and have been used to a greater or lesser extent, generally in treating patients with tuberculosis caused by drug-resistant organisms. All these second-line drugs have important limitations—effectiveness, toxicity, and cost—that interfere with their general applicability in treating tuberculosis.[22]

Of the second-line drugs, the fluoroquinolones—levofloxacin, moxifloxacin, and gatifloxacin—are the most widely used, because all three agents possess good in vitro bactericidal activity and gatifloxacin and moxifloxacin have good in vivo bactericidal activity against *M. tuberculosis.*[54,55] The fluoroquinolones should not be considered as first-line agents but should be reserved either for patients with drug-resistant organisms or those who cannot tolerate first-line drugs.[22] A systematic analysis of the randomized controlled trials published until July of 2007 concluded that ciprofloxacin cannot be recommended for treating tuberculosis, and that information regarding other fluoroquinolones was too limited to make any recommendation.[56] However, results from a recent clinical study showed that an intensive phase with isoniazid, rifampin, pyrazinamide, and moxifloxacin was associated with a greater likelihood of negative culture after 4 weeks of treatment than the standard regimen of isoniazid, rifampin, pyrazinamide, and ethambutol, although the culture status at 2 months was similar in both groups.[57]

The target of the fluoroquinolones is DNA gyrase, an enzyme that operates to increase coiling of DNA. Resistance to these agents is mediated by mutations in *gyrA* and *gyrB* genes that encode for DNA gyrase.[27] Not many strains have been sequenced, but *gyrA* mutations have been found in 42% to 85% of resistant isolates.[27,58]

The quinolones are generally well tolerated. The most frequent adverse effects include nausea, vomiting, dizziness, anxiety, and other central nervous system effects. Photosensitivity and arthropathy may also occur. There are few clinical studies of the usefulness of quinolones in multiple-drug regimens. Optimal dosages and durations of quinolone administration are not known.

All of the other oral agents are difficult to administer because of adverse effects. It is strongly recommended that consultation with an expert be obtained before treatment with these drugs is undertaken.[22] Administration of PAS causes a high frequency of gastrointestinal upset plus hypersensitivity reactions in another 5% to 10% of patients. In addition, the usual dose of 10 to 12 g/day requires ingestion of 20 to 24 tablets, although administration has been made somewhat easier by the availability of a granular formulation. Ethionamide likewise causes a high frequency of gastrointestinal side effects, often necessitating discontinuation of the drug. Cycloserine causes behavioral disturbances, ranging from irritability and depression to frank psychosis, in a large percentage of patients taking the drug; moreover, seizures and peripheral neuropathy occur, especially with high doses and when cycloserine and isoniazid are given together. In addition to the adverse effects of PAS, ethionamide, and cycloserine, none of these drugs is particularly potent against *M. tuberculosis.* Kanamycin, amikacin, and capreomycin are not absorbed from the gastrointestinal tract and thus necessitate parenteral administration. All three drugs may cause hearing loss related both to peak concentrations and to cumulative doses and, in addition, may impair renal function.

Other unapproved but possibly useful antituberculosis agents include the β-lactam imipenem, the β-lactam/β-lactamase combination amoxicillin-clavulanate, and linezolid.[59-61] These agents have been used in small numbers of patients with tuberculosis caused by multidrug-resistant organisms. However, their role in the treatment of tuberculosis has not been precisely determined. The currently available compounds of the macrolide class of agents, which are useful against *Mycobacterium avium* complex, do not have antituberculosis effects.

PROGRAMMATIC CONSIDERATIONS

The availability of powerful antituberculosis medications made it possible to cure around 95% patients with disease caused by susceptible organisms, but it soon became apparent that drugs alone are insufficient: they are but one key element in a comprehensive tuberculosis control program. As far back as 1959, at the landmark Arden House Conference, the basic components of a national public health program were defined with, as a long-range goal, the eradication of tuberculosis in the United States.[62] Twenty years later, another conference

reviewed and refined the objectives and proposed new control strategies.[63] At practically the same time, effective national tuberculosis control programs were introduced into resource-poor countries by the International Union Against Tuberculosis and Lung Disease[64]; much later, the concepts that made these programs so efficacious were adopted, updated, and promoted by the World Health Organization (WHO) under the rubric Directly Observed Treatment Short-course, more familiarly known as DOTS.

Not surprisingly, the lessons from all these activities were similar. Among them, the most important programmatic principle is the obligation of the health care system or treating physician to provide effective supervision of therapy *from beginning to end.* Because of inadequacies both in the provision of tuberculosis control services and in private physician supervision of treatment, completion of therapy is often problematic.[65] As perhaps an extreme example, at Harlem Hospital in New York during the late 1980s, 89% of patients with tuberculosis who had been started on appropriate treatment were lost to follow-up after discharge, in large part owing to cutbacks in funding of outpatient services.[66] Obviously, failure to continue medications precludes successful therapy and promotes the emergence of drug-resistant organisms as, in fact, occurred in New York City.

Even in well-organized tuberculosis control programs, ensuring patient adherence to therapy often presents a difficult problem. The reasons for poor adherence are complex and numerous. Prediction of who will be compliant and who will not is difficult and generally unreliable. To improve adherence, a number of modifications in the organization of treatment have been tried, with varying degrees of success.[67] These include setting clinic hours to suit the patient's schedule; directly observing treatment in the clinic, the patient's home, or another location; and offering incentives and enablers, such as meals and transportation reimbursements.[22] Although all of these approaches, as well as others, have had their successes, it is obvious that compliance will remain a major problem as long as treatment regimens continue to be lengthy and cumbersome. It has come to be generally accepted that the best means of ensuring completion of therapy is giving the drugs under "directly observed therapy," or DOT,[22,23] which is one of the essential elements of the WHO's DOTS global tuberculosis control strategy, mentioned earlier.[68] Globally it was estimated that, in 2007, 93% of the world's population had access to DOTS services but only 63% of the estimated total number of smear-positive cases were reported by DOTS programs.[4] The use of the DOTS strategy has been associated with improved treatment outcomes in several cohort analyses.[15,69,70] However, a Cochrane review of 11 trials with 5609 patients did not show a significant difference in the cure of patients who were treated with observed therapy compared with self-administration.[71] These results highlight the fact that simply observing medication ingestion does not ensure successful completion of treatment and that the full range of measures for supporting patients in completion of treatment must be employed.[72]

Because of heightened public health concerns regarding transmission of *M. tuberculosis* by noncompliant patients and, in particular, concern about multidrug-resistant organisms, public health statutes that could require DOT or, in some instances, confinement until treatment is completed were strengthened in the early 1990s.[73,74] A review of the use and usefulness of these laws in New York City has shown that they were not abused and added significantly to the ability of health authorities to improve treatment outcome and minimize spread of tuberculous infection.[74]

IMPORTANCE OF COMPLETION

Effective chemotherapy is the major mechanism by which the spread of tuberculous infection is halted; thus, treatment of tuberculosis serves as an important public health measure.[72] For antituberculosis chemotherapy to be effective in this public health role, it must be carried out properly. Tuberculosis is one of the few diseases for which a little treatment may be worse than no treatment. Grzybowski and Enarson[75] reviewed the literature and determined the outcome of treatment for tuberculosis in three groups of patients who had positive acid-fast bacillus (AFB) smears: patients who had no chemotherapy at all; patients who were treated in poorly organized programs; and patients who were treated individually with the best available regimens. Among untreated patients, approximately 50% died in 4 to 5 years; 25% remained chronically ill with positive sputum smears and thus continued to be infectious; and the disease resolved spontaneously in the remaining 25%. The outcome in poorly organized programs differed in that the death rate was decreased, but the percentage of patients who continued to have *M. tuberculosis* in their sputum was actually increased; because poor treatment is a major factor in causing drug resistance, it is likely that a large proportion of the patients with chronically positive sputum had drug-resistant organisms. Top-notch programs, in contrast, hugely reduced both the death rate from tuberculosis *and* the number of chronically infectious patients with AFB-positive sputum.

HEALTH CARE–ASSOCIATED NTM DISEASE AND PREVENTION OF NTM INFECTIONS

INTRODUCTION

Soon after the discovery of *Mycobacterium tuberculosis* in 1882 by Robert Koch, several other species of mycobacteria were described. It was not until half a century later, however, that these mycobacteria were recognized to cause disease in humans, and by the 1980s they were recognized as causing a broad spectrum of disease.[1] Over the years, these organisms have gone by many names, including "mycobacteria other than tuberculosis," "environmental mycobacteria," "anonymous or atypical mycobacteria," and "nontuberculous mycobacteria" (NTM), the preferred term in the United States. The epidemic of the human immunodeficiency virus (HIV) heralded a new awareness of NTM infections because of the highs rates of disseminated infections due to *Mycobacterium avium* complex[2] (or, as commonly abbreviated, MAC) and other species.[3] On the one hand, disseminated NTM infections have declined significantly in HIV-infected populations following the advent of antiretroviral drugs; on the other hand, rates of NTM disease in HIV-uninfected populations appear to be on the increase.

NTM represent a broad array of organisms that are ubiquitous in our environment. They have been isolated from natural and drinking waters as well as soil, and exposure to these reservoirs is thought to be the source of human infection. At least 140 species of NTM have been identified, and many of these have been reported to cause disease in both immunocompetent and immunocompromised patients. Unlike *M. tuberculosis,* NTM do not appear to be transmitted from human to human, they vary greatly in their ability to cause disease, and evidence for latency is lacking. Unfortunately, NTM are difficult to treat because of high levels of in vitro resistance to antimicrobial drugs, which requires long courses of therapy with relatively poor outcomes when compared to tuberculosis. To date, our lack of understanding of the transmission and pathogenesis of these increasingly important infections has limited out ability to develop public health measures aimed at preventing infection.

TAXONOMY

In 1997, approximately 50 species of NTM had been identified, with approximately 13 described as respiratory pathogens.[4] Currently, there are more than 140 identified NTM species with at least 40 that are associated with lung infection[5] (Table 35-1). Thus, it is reasonable to ask why there appears to be such a profusion of NTM species in general and those associated with lung disease in particular.

The primary explanation can be found in the mycobacteriology laboratory. Prior to the era of DNA sequencing for organism identification, NTM were identified

based on their morphologic and biochemical characteristics as well as in vitro susceptibility patterns. The inadequacy or insensitivity of these techniques was reflected in the number of organisms that were grouped as "complexes," such as the "*Mycobacterium fortuitum* complex," which included multiple rapidly growing species such as *M. fortuitum, Mycobacterium chelonae,* and *Mycobacterium abscessus.* Although, it was apparent that multiple species were present with similar growth and morphologic properties, standard laboratory techniques were not adequate to reliably separate them to the species level.

Currently, there are multiple techniques for NTM species identification, including DNA probes for the most commonly isolated NTM species and high-performance liquid chromatography (HPLC).[5] HPLC has been especially useful in the identification of new NTM species but lacks the sensitivity of molecular techniques. The revolutionary change in NTM identification was the advent of readily available DNA sequencing, especially the sequencing of the 16S ribosomal RNA gene, which is highly conserved so that 1% or greater differences in this gene sequence can define an NTM species. Publicly available databases of 16S ribosomal RNA gene sequences allow relatively easy comparison of mycobacterial isolates to determine if a new NTM species is present. Alternatively, sequences of the heat shock protein 65 (hsp65) gene, or the entire genomic DNA sequence of an NTM species, can be compared to other publicly available gene sequence databases. For practical purposes, anyone with access to DNA sequencing can potentially identify a new sequence and species of NTM.

The expansion of new NTM species in the past 15 years is, therefore, primarily a consequence of more sensitive identification techniques capable of separating closely related NTM species rather than a proliferation of new NTM species. Predictably, many of these newly identified species have microbiologic properties very similar to other closely related NTM, so that identification of the new NTM species may not be associated with any new or surprising clinical properties. It remains to be seen if this revolution in NTM species identification will have an equally profound impact on clinical NTM disease. What is certain, however, is that clinicians will have to become familiar with many more NTM species names as new NTM species are identified by increasingly more laboratories.

EPIDEMIOLOGY

Incidence and Prevalence

The epidemiology of NTM disease has been difficult to determine because reporting is not mandatory in most countries and differentiation between infection and disease is often difficult. The incidence and prevalence of NTM infections have varied significantly across studies, partially because the studies have used different methodologies and studied different populations.[6] Although not definitive, the existing data suggest that the incidence and prevalence of NTM infections are increasing.

Epidemiologic studies of NTM infection and disease use one of three approaches: (1) the use of antigens to examine the reactivity to delayed-typed hypersensitivity; (2) the reported isolation rate of NTM from laboratories; or (3) the use of both clinical and laboratory data to define disease more accurately.[6] Studies utilizing delayed-type hypersensitivity reaction to subcutaneously injected mycobacterial antigens have estimated that 11% to 33.5% of the population in the United States has been exposed to NTM.[6–8] A recent study used data from the National Health and Nutritional Examination Survey (NHANES) cohort to describe skin reactivity to purified protein derivative-B (PPD-B) during two time periods. For the years 1971–1972 and 1999–2000, rates of a positive skin

test were 11.2% and 16.6%, respectively.[9] Skin test reactivity was noted to increase between the two time periods in foreign-born but not in U.S.-born individuals, suggesting a higher rate of exposure and infection in the foreign-born individuals.

Laboratory-based studies utilize consecutive isolates from a well-defined catchment area to estimate the frequency of infection. Survey data from state laboratories in the early 1980s estimated a prevalence of NTM infection of 1 to 2 cases per 100,000 population.[10] A similar follow-up survey from 1993 to 1996 reported an annual case rate of 7 to 8 per 100,000, documenting an increase in isolation of NTM when compared to the previous survey.[11] Although these surveys reported an increase in the number of isolates of NTM between the two time periods, it is important to point out that laboratory-based surveys suffer from the fact that they provide isolate-based information but may not take into account the number of patients and whether or not the patients have disease.

Studies that combine cultural and clinical data may be more useful for estimating disease incidence and prevalence. Studies since the 1950s from Czechoslovakia,[12] Wales,[13] Ireland,[14] Australia,[15] and the United States[10] have reported increases in incidence or prevalence. In some reports, the increase in the rate of NTM infection was associated with a decline in the rate of tuberculosis. For example, in Japan from 1971 to 1984, the incidence of pulmonary tuberculosis decreased from 133.1 to 46.3 per 100,000 while the incidence of NTM pulmonary disease increased from 0.89 to 2.15.[16] Similarly, in Switzerland, the incidence of pulmonary tuberculosis decreased from 16.2 to 13.2 per 100,000 over 6 years while the incidence of pulmonary NTM increased from 0.4 to 0.9 per 100,000.[17] Marras and coworkers[18] reported an increase in the number of pulmonary NTM isolates in Ontario from 9.1 per 100,000 in 1997 to 14.1 per 100,000 in 2003 (Fig. 35-1); during this same time period, the rate of tuberculosis declined. In a subsequent analysis of these data, Iseman and Marras[19] noted that the prevalence was likely to be in the range of 14 to 35 per 100,000, far exceeding the prevalence of tuberculosis in Ontario. A recent study reported a significant increase in the annual prevalence of NTM pulmonary disease in patients hospitalized in 11 states between 1998 and 2005.[19a] Annual prevalence increased among men and women in Florida (3.2%/year and 6.5%/year, respectively) and among women in New York (4.6%/year) but there was no significant increase in California. While not all studies have documented an increase in NTM prevalence,[20] the preponderance of evidence suggests that pulmonary disease due to NTM is increasing.

The reasons for the increase in incidence and prevalence have not been explained, although increased awareness of the disease and improved diagnostic techniques could be a factor. A true increase in incidence could be related to changes in the host such as an aging population, an increased prevalence of chronic lung disease, or an increase in the number of immunocompromised individuals. The observation of a decreased incidence of pulmonary tuberculosis and an increased incidence of pulmonary NTM, as noted previously, could be explained by cross-immunity between mycobacterial species. Finally, an increase in the prevalence or virulence of environmental organisms or changes in human behavior that would lead to increased exposure to organisms could be contributing factors.

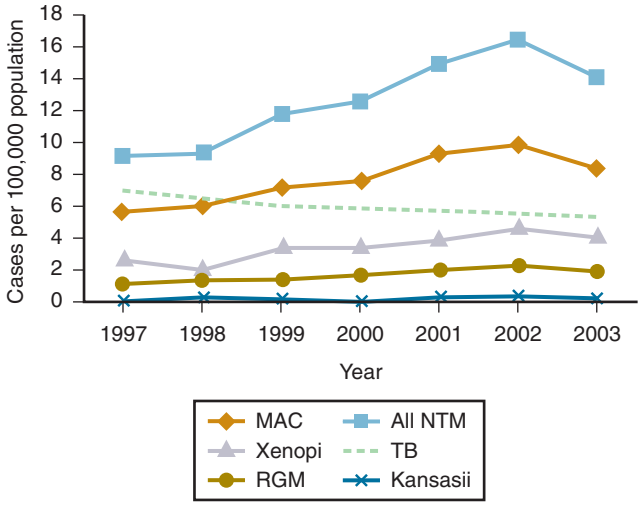

FIGURE 35-1 ■ Prevalence of pulmonary nontuberculous mycobacteria (NTM) infections and tuberculosis (TB) case rates in Ontario, 1997–2003. All NTM prevalence rates increased significantly (all $P \leq 0.001$). Tuberculosis rates were calculated from the total number of tuberculosis cases and population data from Statistics Canada for 1999–2003 (from http://www.statcan.ca/english/Pgdb/demo02.htm, accessed October 4, 2004) and estimated by back-extrapolation for 1997 and 1998. Geographic Distribution and Variation

NTM have been reported to cause pulmonary disease around the globe, although there is marked variation in the prevalence of disease and in which species predominates. In the United States, the southeastern region seems to have the highest rates of infection.[10,21,22] NTM have been recovered with higher frequency from water samples in the southeastern versus northern United States, so exposure is likely higher in these regions.[23] The predominant species in North America have been MAC, followed by *Mycobacterium kansasii, M. abscessus, M. fortuitum, M. chelonae,* and *M. scrofulaceum.*[10,21] MAC has also been reported as the predominant species in Central and South America, Europe, and Asia. *Mycobacterium xenopi* is common in Europe and Canada, whereas *Mycobacterium malmoense* is more common in Northern than Southern Europe. Populations of miners in Czechoslovakia[12] and South Africa[24,25] have been reported to have high rates of *M. kansasii* infection.

TRANSMISSION AND PATHOGENESIS

Transmission

NTM are ubiquitous in the environment and have been found in natural and drinking waters, biofilms, soil, and aerosols.[26] The presumed source of infection is exposure to these environmental reservoirs because human-to-human transmission has never been documented. Studies using genotyping techniques, such as pulsed-field gel electrophoresis, have been able to isolate the same strains of NTM from patients and their environment.[27–29] Although, the mechanism by which an environmental exposure eventually leads to pulmonary infection is poorly understood,[30] it has been hypothesized that exposure to infected aerosols can lead to infection and possibly disease. In at least two cases, the same strain of MAC was isolated from the patients' respiratory specimens and water from their shower head.[27,28] In another report, the patient's strain of MAC was isolated from potting soil in the home.[29] There have also been reports of outbreaks in which patients' isolates matched environmental isolates of NTM.[31] Extrapulmonary NTM infections are usually the result of a puncture wound or surgery.

Factors Associated with Infection

A prospective study using skin testing data from Palm Beach, Florida, reported that 32.9% of 447 participants in a population-based random household survey had a positive reaction to *M. avium* sensitin.[32] Independent predictors of a positive reaction included black race, birth outside the United States, and more than 6 years' cumulative exposure to soil. Exposure to water, food, and pets was not associated with skin test reactivity. Using NHANES data, investigators reported similar findings with regard to sensitization to *Mycobacterium intracellulare*[9]: male gender, non-Hispanic black race, and birth outside the United States were each independently associated with sensitization. The highest rate of skin test reactivity occurred in persons who were 20 to 39 years of age, and among individuals who were 20 years of age and older, working in agriculture or construction was strongly associated with sensitization. These two studies are interesting in that skin test reactivity to either *M. avium* or *M. intracellulare* sensitin was associated with factors likely associated with soil exposure and were more common in men and foreign-born individuals. However, disease seems to be more common in older women and, at least in the United States, in U.S.-born individuals. Thus, it is likely that the risk factors for exposure and infection are different from those associated with disease.

Factors Associated with Disease

Most NTM are significantly less pathogenic than *M. tuberculosis* and likely require some degree of host impairment to establish infection. A number of risk factors for disease have been described, and these can be subdivided broadly into three groups: (1) factors impairing host immunity, (2) factors leading to impaired local (lung) immunity, and (3) factors relating to host demographics. Increasing age has been consistently described as a risk factor for pulmonary NTM, in patients both with and without underlying lung disease.[8,10,33,34] The most consistently reported risk factor is male gender, though there is also a population of elderly females who are at risk for nodular bronchiectatic lung disease. Perhaps the most important risk factor for the development of pulmonary NTM disease is underlying chronic lung disease. NTM disease has been described in association with cystic fibrosis, chronic obstructive pulmonary disease (including alpha$_1$-antitrypsin deficiency), cavitary lung disease, pneumoconiosis, bronchiectasis, prior tuberculosis, and pulmonary alveolar proteinosis.[35] Studies have documented a high prevalence of NTM in sputum cultures from patients with cystic fibrosis, with estimates ranging from 3% to 19.5%, the majority of which were MAC.[36,37]

Patients with NTM lung disease often have associated gastroesophageal reflux disease (GERD) or other esophageal disorders. Historically, it has been reported that patients with rapidly growing mycobacteria often have associated esophageal disorders[38–40]; recent reports have also described a high frequency of GERD in patients with MAC lung disease.[41,42] In a report from South Korea that used pH probes to diagnose GERD, the authors reported the prevalence of GERD was 26%, although only 27% of the patients were symptomatic.[41] Patients with *M. abscessus* infection were more likely to have GERD than those with MAC, although the difference did not reach statistical significance.

One of the most interesting patient populations to develop NTM pulmonary disease consists of postmenopausal women who often have certain associated morphologic features. This constellation was first described by Prince and colleagues[33] in 1989 and later referred to as the "Lady Windermere syndrome," after the lead in Oscar Wilde's play *Lady Windermere's Fan,* who was characterized by her fastidious behavior.[43] The morphologic features such as pectus excavatum, scoliosis, thin body habitus, and mitral valve prolapse were described subsequently by Iseman and others.[44] Recently, investigators reported that women with pulmonary NTM disease were taller and thinner and weighed less than matched control subjects[45] (Fig. 35-2): 51% had scoliosis, 11% pectus excavatum, and 9% mitral valve prolapse, all significantly more common than in reference populations. Another interesting feature of this syndrome is the predilection for right middle lobe and lingular bronchietasis. To date, extensive evaluation of the immune system of these patients has been unrevealing, but mutations in the cystic fibrosis transmembrane regulator (CFTR) gene are common.[45,46]

NTM in acquired immunodeficiency syndrome (AIDS) most commonly causes disseminated disease that presents with nonspecific symptoms such as fever, night sweats, diarrhea, abdominal pain, and lymphadenopathy, with MAC being the most frequent isolate.[47] Despite the fact that MAC is isolated from the sputum in up to

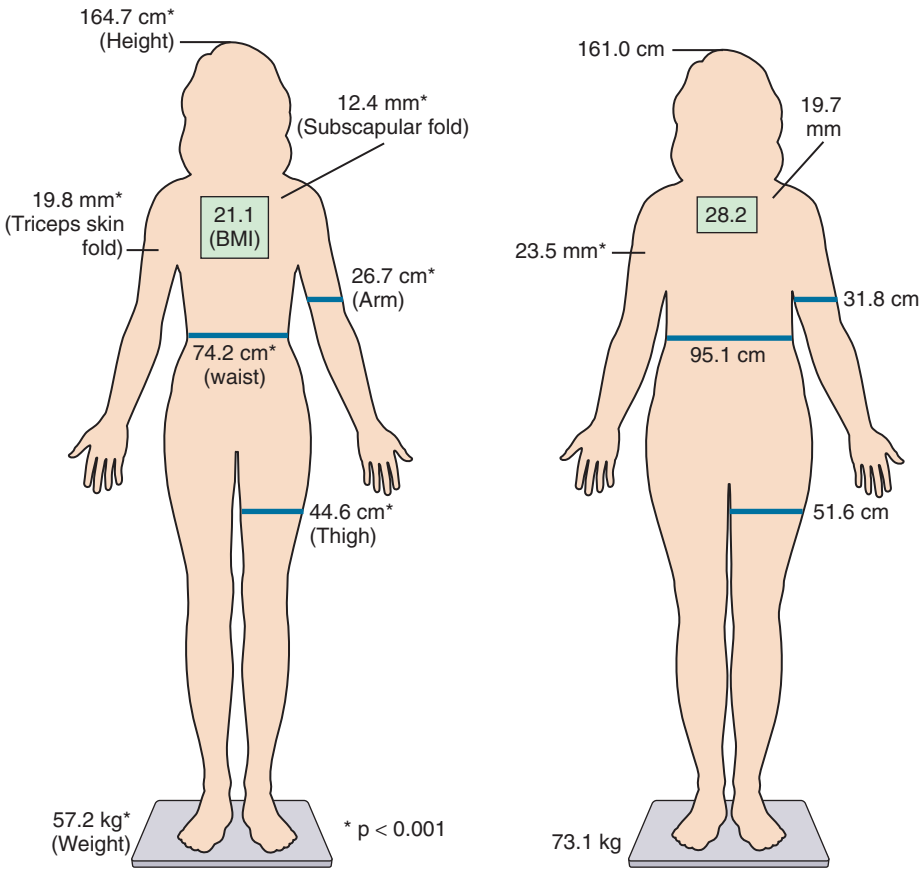

FIGURE 35-2 ■ Schematic depiction of the anthropometrics of women with pulmonary nontuberculous mycobacterial disease (n = 60) (*left*) compared with National Health and Nutrition Examination Survey age-, sex-, and race-matched control subjects (*right*). *P < 0.001. (Reproduced with permission from Kim RD, Greenberg DE, Ehrmantraut ME, et al: Pulmonary nontuberculous mycobacterial disease: Prospective study of a distinct preexisting syndrome. Am J Respir Crit Care Med 178:1006–1074, 2008.)

10% of AIDS patients with CD4 T-cell counts less than 50 cells/μL, pulmonary disease due to MAC is uncommon.[48] Pulmonary disease been reported in 2.5% to 8% of patients with disseminated MAC[49] and, rarely, has also been reported in the absence of dissemination.[49,50] Patients with pulmonary disease tend to have higher CD4 counts and focal alveolar infiltrates, which rarely cavitate. *Mycobacterium kansasii* can also cause disease in patients with HIV and AIDS. In one study, the risk for infection with *M. kansasii* was increased 150-fold in HIV-infected patients and 900-fold in those with AIDS.[51] In contrast to MAC, *M. kansasii* only rarely causes indolent disease and should almost always be treated as a pathogen.[52]

Pulmonary disease due to NTM has been described in several other immunocompromised patient populations, including transplant recipients. Rates may be as high as 6.5% following heart or lung transplantation,[53] and 2.9% following bone marrow transplantation,[54] but are probably much lower in patients following liver or kidney transplantation.[55,56] *Mycobacterium abscessus* infection in patients with cystic fibrosis who have undergone lung transplantation has been associated with severe and sometimes fatal disease.[57–59]

Multiple cytokines are necessary for granuloma formation and eventual containment of mycobacterial infections. The most important among these are interferon-γ (IFN-γ), interleukin-12 (IL-12), and tumor necrosis factor-α (TNF-α). Patient populations with defects in each cytokine are susceptible to infection with NTM. Mutations in IFN-γ receptor 1 (IFN-γR1), IFN-γ receptor 2, IL-12 p40, and the IL-12 receptor have all been shown to lead to human disease.[60] The dominant and recessive IFN-γR1 deficiencies have distinct clinical presentations.[60] Large numbers of patients with inflammatory bowel disease, rheumatoid arthritis, or psoriatic arthritis are treated with infusions of the TNF-α inhibitors. Although initially demonstrated to predispose to tuberculosis,[61] recent reports have linked these therapies to NTM infections as well.[62] Patients with suspected or known mycobacterial infections should not receive these medications without proper antimycobacterial therapy.

Most studies have focused on evaluating possible host abnormalities that could lead to NTM disease, although microbial factors are likely to be important as well. Recent studies have identified isolates and phenotypes associated with increased virulence in in vitro

models.[62a,62b] Moreover, a recent population-based assessment of the clinical significance of NTM in a region of the Netherlands demonstrated a wide range of pathogenicity among different NTM species.[62c]

DIAGNOSIS AND MANAGEMENT OF SPECIFIC PATHOGENS

NTM lung infection presents with diverse manifestations (Table 35-2). This chapter focuses on the most common clinical presentations in the immune-competent host: chiefly, tuberculosis-like (cavitary) disease and disease associated with nodules and bronchiectasis (nodular/bronchiectatic disease). The diagnostic evaluation usually consists of (1) assessment for the presence of one or more compatible symptoms, which are usually insidious in onset (cough, sputum production, fatigue, weight loss, fever, hemoptysis); (2) radiographic evaluation, which frequently includes high-resolution computed tomography (HRCT) scans of the chest; and (3) microbiologic evaluation, which usually consists of three or more sputum specimens for microscopy and mycobacterial culture and/or collection of specimens bronchoscopically. The most important diagnosis for exclusion is tuberculosis.

The diagnosis of NTM lung disease can be challenging. Unlike pulmonary tuberculosis, in which a single positive culture of sputum or bronchoscopic specimen, barring laboratory contamination, establishes the diagnosis, confirmation of the diagnosis of NTM lung disease usually requires repeated isolation of a particular NTM species. Diagnostic criteria have been developed—and recently revised—to aid the clinician in the diagnostic evaluation of persons suspected of having pulmonary NTM disease.[5] The NTM diagnostic criteria outlined in Table 35-3 are based on experience with common and well-described respiratory pathogens such as MAC, *M. kansasii,* and *M. abscessus.* However, it is important to note that because of the varying pathogenicity among the many NTM species, no single diagnostic approach will work for all cases.[62c] Diagnostic criteria that are too sensitive promote overdiagnosis and the unnecessary exposure of patients to potentially toxic antimicrobial medications. By contrast, overly rigid diagnostic criteria put patients at risk for undertreatment and progressive NTM disease. Fortunately, NTM lung disease is usually sufficiently indolent for a careful patient assessment to determine with confidence the presence or absence of significant disease.

The difficulty in determining the clinical significance of an NTM respiratory isolate results from several factors. NTM isolates can contaminate clinical specimens, usually from environmental sources. Many NTM species, such as *Mycobacterium gordonae,* are generally nonpathogenic and almost invariably represent specimen contamination rather than true infection. NTM can be found in potable (municipal or tap) water (*M. kansasii,* MAC, *Mycobacterium simiae, M. abscessus, M. xenopi*), so that their presence in a clinical specimen can be due to waterborne contamination of the specimen, even if the isolated species is sometimes associated with significant clinical disease. And sometimes, the recovery of even potentially virulent and pathogenic NTM may not be associated with active or progressive disease, for reasons that are not understood. Unfortunately, no easily applied algorithm addresses all NTM species in all clinical circumstances. The clinician must have not only some knowledge of the disease-producing potential of NTM species, but also an awareness of the circumstances associated with the isolation of the NTM species.

A single positive sputum culture for NTM is usually regarded as indeterminate for the diagnosis of NTM lung disease. In contrast, when two or more sputum cultures are positive, the diagnosis of disease is more likely. For example, 98% of patients with two or more positive sputum cultures for MAC had evidence of progressive disease during follow-up in a study from Japan.[63] A single positive NTM culture from bronchoscopy can be diagnostic for disease (see Table 35-3), but the clinician must keep in mind those NTM species that are usually respiratory contaminants (especially *M. gordonae*) and those NTM species that can be found in tap water (discussed earlier) since "pseudo-outbreaks" of NTM disease can be

TABLE 35-2. Diversity of NTM Pulmonary Disease

- Tuberculosis-like (cavitary) disease
- Disease associated with nodules/bronchiectasis
  - Disease associated with genetic airway abnormalities and abnormal airway clearance (cystic fibrosis, primary ciliary dyskinesia, alpha$_1$-antitrypsin deficiency)
- Hypersensitivity-like lung disease
- Disease associated with esophageal motility disorders
- Disease associated with disseminated disease and immune suppression
  - HIV/AIDS
  - Defects in interferon-γ and interleukin-12 pathways
  - Tumor necrosis factor-α antagonists

TABLE 35-3. Microbiologic Criteria for Diagnosis of NTM Lung Disease

At least three sputum results available	• Two positive cultures regardless of the results of AFB smear
Single available bronchial wash or lavage	• One positive culture regardless of the results of AFB smear
Tissue biopsy	• Compatible histopathology (granulomatous inflammation) and a positive biopsy culture for NTM • Compatible histopathology (granulomatous inflammation) and a positive sputum or bronchial wash culture for NTM

AFB, acid-fast bacillus; NTM, nontuberculous mycobacteria.
Data from Griffith DE, Aksamit T, Brown-Elliott BA, et al: An official ATS/IDSA statement: Diagnosis, treatment, and prevention of nontuberculous mycobacterial diseases. Am J Respir Crit Care Med 175:367–416, 2007.

the consequence of bronchoscopic equipment that has been inappropriately rinsed with tap water.[64] This latter criterion does not mean that bronchoscopy has a better yield for detection of NTM, but rather that it would be inappropriate to subject a patient to multiple bronchoscopic procedures simply to obtain multiple respiratory specimens. Patients who are suspected of having NTM lung disease but do not meet the diagnostic criteria should be followed clinically until the diagnosis is either firmly established or excluded, a process that can literally take months to years.

Making the diagnosis of NTM lung disease does not necessitate the institution of therapy, which is a decision based on potential risks and benefits of therapy for individual patients. Factors that might influence the decision to treat NTM lung disease include the virulence of the NTM pathogen and the potential for disease progression, the severity (or lack of severity) of symptoms and radiographic findings, the presence of known indolent disease, and the presence of advanced age and/or severe comorbid conditions (with limited life expectancy); another factor is the inability to tolerate the prolonged and sometimes toxic antimicrobial regimens for NTM disease. Again, there is no substitute for physician familiarity with NTM pathogens and the individual patient for optimal management of NTM lung disease.

Other clinical manifestations of NTM infection include lymphadenitis, disseminated disease, and skin, soft tissue, and bone disease. Lymphadenitis is the most common NTM disease manifestation in children and is usually due to MAC or, less commonly, *M. scrofulaceum.*[65] The most important differential diagnosis is tuberculosis lymphadenitis, although NTM account for approximately 90% of mycobacterial lymphadenitis in American children (but only 10% in adults).[66] Symptoms are usually minimal, with frequent unilateral involvement of submandibular, submaxillary, preauricular, or cervical lymph nodes. Skin and soft tissue infections are usually due to the "rapidly growing mycobacteria," *M. abscessus, M. fortuitum, M. chelonae,* or *M. marinum,* and are the result of direct inoculation after either trauma or surgery.[1,67] Dissemination of NTM pathogens is most often associated with the severe immunosuppression of advanced AIDS and is caused by MAC.[47,68–70] Disseminated NTM infections can occur in other immune-compromised states, such as organ transplantation, or in association with indwelling foreign bodies such as venous catheters, dialysis catheters, or other prosthetic devices.[71–74]

Laboratory Diagnosis

The diagnosis of NTM disease is based on isolation of these organisms from diagnostic specimens. Cultures should include both solid and broth media for detection of mycobacteria, and a semiquantitative reporting of colony counts is recommended.[5] The optimal temperature for growth of most NTM species is between 28°C and 37°C, although some species require either higher or lower temperatures for optimal growth and some species require special supplementation for recovery from culture.[5] Most NTM grow within 2 to 3 weeks of subculture but the group of rapidly growing NTM appear within 7 days of subculture.

Identification of specific species can be based on phenotypic, chemotaxonomic, and molecular methods.[5] NTM can be categorized by their growth rate and pigmentation, although these characteristics are not specific enough for final speciation. In addition, biochemical testing can be used to help speciate the NTM. However, none of these procedures is sufficient to differentiate all NTM, particularly some of the newly identified species.

Additional techniques for speciation include nucleic acid probes, polymerase chain reaction and other amplification methods, HPLC, and nucleic acid sequencing.[75–80] The commercially available AccuProbe technology (GenProbe, San Diego, CA) is currently recommended for identification of *M. tuberculosis* complex, *M. avium* complex (as well as *M. avium* and *M. intracellulare* separately), *M. kansasii,* and *M. gordonae.* HPLC, which analyzes the chromatographic profile of the mycolic acids extracted from the bacterial cell wall, can be used to speciate a large number of NTM.[81] Identification of mycobacteria by 16S ribosomal DNA sequencing[75,76] provides more accurate determination of the species, although neither HPLC nor 16S ribosomal DNA sequencing can differentiate all species of NTM.

The clinical usefulness of drug susceptibility testing in the management of patients with NTM disease remains controversial, stemming from the fact that in vitro results do not correlate well with clinical outcomes for some mycobacterial species. No single susceptibility method is recommended for all species of slowly growing mycobacteria. For MAC, a broth-based culture method—with both microdilution and macrodilution methods—is considered acceptable.[5] Initial isolates should be tested for response to clarithromycin, as should isolates from treatment failures and relapses, patients who have taken macrolides previously, and AIDS patients who develop bacteremia on macrolide prophylaxis. Isolates of *M. kansasii* should be tested for response to rifampin (rifampicin) because resistance to rifampin is associated with treatment failure or relapse. If rifampin resistance is documented, additional drugs should be tested.[5] Broth microdilution minimal inhibitory concentration (MIC) determination for susceptibility testing is recommended for rapidly growing mycobacteria.

Slowly Growing Mycobacteria

Although there are fewer species of slowly growing NTM than rapidly growing species, the slow growers are more common causes of lung disease (see Table 35-1). The slow growers include over 40 species with a wide range of pathogenicity, from organisms such as *M. kansasii* that are probably second only to *M. tuberculosis* in terms of disease-producing capability to *M. gordonae,* which rarely causes lung disease.

Mycobacterium avium *Complex*

Mycobacterium avium complex includes the NTM species *M. avium,* of which there are several subspecies,

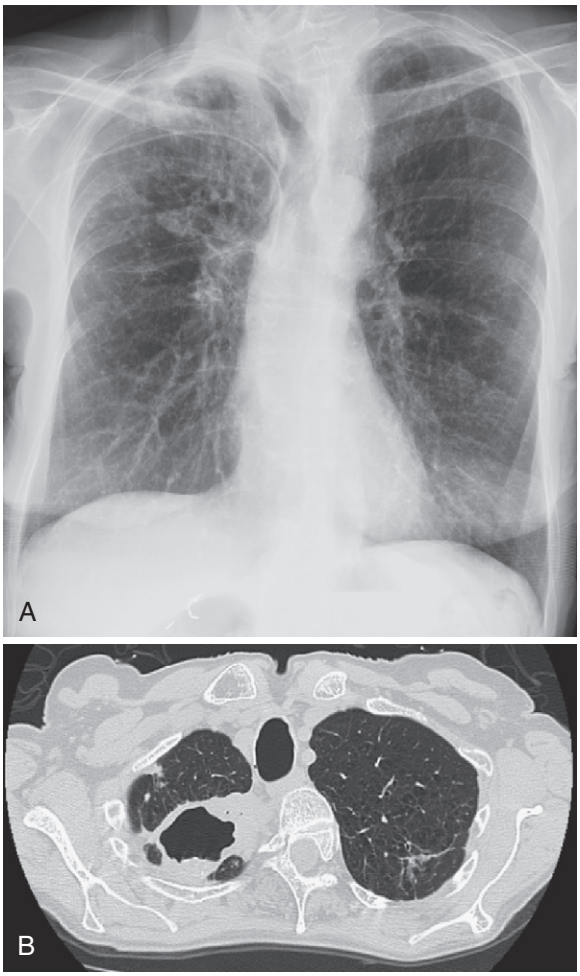

FIGURE 35-3 ■ A 63-year-old female smoker with cavitary MAC lung disease. The patient, who presented with cough, fatigue, weight loss, and intermittent hemoptysis, was diagnosed with MAC in 2004. She failed two courses of multidrug therapy, and her sputum remains strongly culture positive for MAC. **A,** Chest radiograph showing cavitary consolidation in the right apex and scattered nodular and reticulonodular densities in both lungs. **B,** Computed tomography scan showing large cavity in right upper lung field.

as well as *M. intracellulare* and some as yet poorly described species, which explains why MAC has sometimes also been referred to as *Mycobacterium avium-intracellulare* (MAI). Differentiation of the separate MAC species is not possible with routine laboratory techniques, although DNA probes are available for *M. avium* and *M. intracellulare.* Currently, in most circumstances, the differentiation of *M. avium* and *M. intracellulare* does not make a significant difference clinically or therapeutically (although *M. avium* is more often seen with disseminated disease, and in the United States *M. intracellulare* is more often isolated as a respiratory pathogen).

The traditionally recognized presentation of MAC lung disease has been as apical fibrocavitary lung disease similar to tuberculosis, sometimes with large cavities, usually in males but also in females in their fifth and sixth decades who have a history of cigarette smoking and alcohol abuse (Fig. 35-3). If left untreated, this form of disease is generally progressive and can result in extensive cavitary lung destruction.

MAC lung disease also presents with nodular and interstitial nodular infiltrates, which frequently involve the right middle lobe or lingula, predominantly in postmenopausal nonsmoking white females (Fig. 35-4). This form of disease, termed *nodular/bronchiectatic disease,* tends to have a much slower progression than cavitary disease, such that long-term follow-up may be necessary to demonstrate clinical or radiographic changes. Even with this more indolent form of disease, however, death may result from progressive disease.[33] Nodular/bronchiectatic MAC lung disease is radiographically characterized by HRCT findings that include multiple small peripheral pulmonary nodules centered on the bronchovascular tree and cylindrical bronchiectasis (see Fig. 35-4). The HRCT pattern of these predominantly peripheral small nodular densities has been described as "tree-in-bud," and reflects inflammatory changes including bronchiolitis.

Patients with nodular/bronchiectatic MAC lung disease often have additional microbiologic findings associated with bronchiectasis, including respiratory

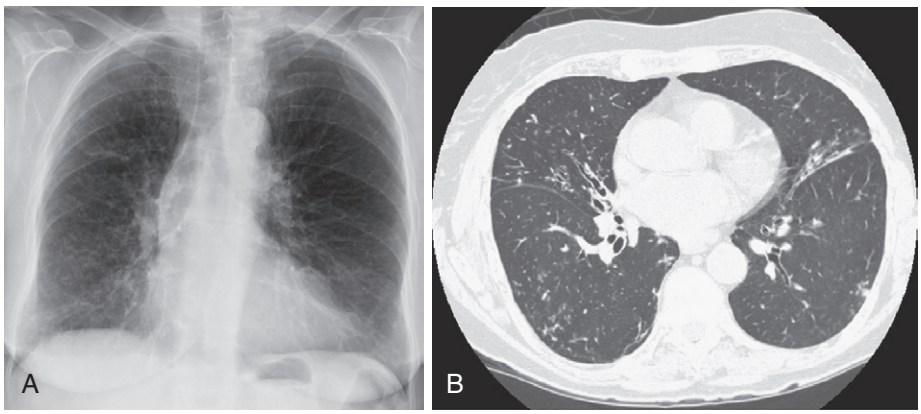

FIGURE 35-4 ■ A 78-year-old nonsmoking female with a several-year history of cough and increasing fatigue. Her sputum was consistently culture positive for MAC. **A,** Chest radiograph showing bilateral, primarily mid–lung field reticular and reticulonodular densities; **B,** Chest computed tomography (CT) scan showing bilateral small nodules and "tree-in-bud" appearance and bronchiectasis in the right middle lobe and lingula.

cultures positive for *Pseudomonas aeruginosa, Nocardia* species, and occasionally other NTM such as *M. abscessus.* Nonmycobacterial exacerbations of bronchiectasis often complicate the assessment and management of MAC disease such that strategies aimed at treatment of the bronchiectasis may improve patients' symptoms.

For many patients, perhaps the majority of patients with nodular/bronchiectatic disease, it is unknown if bronchiectasis is the result of the mycobacterial infection or due to some other process that predisposes to subsequent mycobacterial infection. In some patients with NTM lung disease, bronchiectasis is the result of diseases such as cystic fibrosis, primary ciliary dyskinesia, or alpha$_1$-antitrypsin deficiency, so that the bronchiectasis clearly antedates the MAC disease.[46,82,83] The routine evaluation of underlying causes of bronchiectasis, such as cystic fibrosis and alpha$_1$-antitrypsin deficiency, in patients with nodular/bronchiectatic MAC disease is currently controversial, and no consensus exists concerning routine testing for these possible underlying conditions in all patients with nodular/bronchiectatic MAC disease.

Therapy of MAC Lung Disease. Several aspects of treatment for MAC lung disease are frustrating, difficult to explain, and even counterintuitive. The greatest misunderstanding about treatment regimens for NTM pathogens is the result of the expectation that all NTM infections should respond in a predictable manner to antimicrobial therapy, similar to *M. tuberculosis.* In reality, when treatment regimens are based on in vitro susceptibility testing, the NTM pathogen very often does not respond to antimicrobial agents as predicted from the susceptibility results. The most difficult and frustrating aspect of NTM therapy for many clinicians is the lack of a clear association between the in vitro susceptibility results and the clinical (in vivo) response. For many NTM, including MAC, laboratory cutoffs for "susceptible" and "resistant" do not have a demonstrable clinical correlate and have not been confirmed to be clinically meaningful. Response to treatment of disease caused by MAC correlates only with in vitro susceptibility to macrolides (clarithromycin and azithromycin), and not to other agents.[84–89] Several other NTM species (*M. abscessus, M. simiae, M. malomoense, M. xenopi,* etc.) lack established correlation between in vitro susceptibilities and in vivo responsiveness to any antimicrobial agent. The explanation(s) for the dichotomy between laboratory susceptibility testing results and clinical benefit for many NTM is (are) currently not known. Accordingly, clinicians must use in vitro susceptibility data for many NTM with the awareness that, unlike tuberculosis, the results are an imperfect guide to treatment outcome.

Because the macrolides—clarithromycin and azithromycin—are the only antimicrobial agents for which there is a demonstrated correlation between in vitro susceptibility and in vivo response for MAC lung disease, these agents, partnered with ethambutol, serve as the cornerstones of MAC therapy (Table 35-4). As also shown, this regimen must be reinforced with a rifamycin and, possibly, an injectable aminoglycoside (amikacin or streptomycin), because companion drugs are necessary to prevent the emergence of macrolide-resistant MAC isolates. Macrolides should *never* be used as monotherapy for treatment of MAC disease, either pulmonary or disseminated.[90]

TABLE 35-4. Treatment of Pulmonary Disease due to *M. avium* Complex Infections

Type of Disease	Regimen
Nodular/ bronchiectatic disease	1) clarithromycin 1000 mg tiw or azithromycin 500–600 mg tiw *and* 2) ethambutol 25 mg/kg tiw *and* 3) rifampin 600 mg tiw
Cavitary disease	1) clarithromycin 500–1000 mg/day or azithromycin 250–300 mg/day *and* 2) ethambutol 15 mg/kg daily *and* 3) rifampin 450–600 mg daily *and* 4) consider streptomycin or amikacin 15 mg/kg tiw for first 2–3 months
Advance or previously treated disease	1) clarithromycin 500–1000 mg/day or azithromycin 250–300 mg/day *and* 2) ethambutol 15 mg/kg daily *and* 3) rifabutin 150–300 mg daily or rifampin 450–600 mg daily *and* 4) include streptomycin or amikacin 15 mg/kg tiw for first 2–3 months

tiw, three times per week.
Data from Griffith DE, Aksamit T, Brown-Elliott BA, et al: An official ATS/IDSA statement: Diagnosis, treatment, and prevention of nontuberculous mycobacterial diseases. Am J Respir Crit Care Med 175:367–416, 2007.

There is another difficult-to-explain phenomenon associated with MAC drug therapy. Patients who have failed prior MAC therapy, with or without a macrolide, have lower sputum conversion rates with macrolide-containing treatment regimens, even with macrolide-susceptible MAC isolates, than do patients with no prior therapy.[85,88,91,92] Although the explanation for this observation is also not clear, it is evident that the best chance for treatment success in MAC lung disease is the first treatment effort. Finally, patients who are successfully treated for nodular/bronchiectatic MAC disease can be reinfected by new MAC isolates, sometimes with renewal of progressive disease.[93]

The recommended duration of treatment for MAC pulmonary disease is to continue therapy until 12 months of sputum culture negativity,[5] a goal that requires patients to have sputum collected for mycobacterial culture on a regular basis throughout the course of treatment.

For some patients who are taking clarithromycin, the doses may need to be split (e.g., 500 mg twice daily) because of gastrointestinal intolerance. For patients of low body weight (<50 kg) or older age, the clarithromycin dose for daily regimens may need to be reduced to 500 mg/day or 250 mg twice daily because of gastrointestinal intolerance. Patients receiving clarithromycin and rifabutin should be carefully monitored for rifabutin-

related toxicity, especially hematologic (leukopenia) and ocular (uveitis) toxicity.

Macrolide-resistant MAC lung disease is associated with a poor prognosis.[90] The two major risk factors for macrolide-resistant MAC disease are macrolide monotherapy or treatment with a macrolide and inadequate companion medications. The treatment strategy associated with the most success for macrolide-resistant MAC lung disease includes both the use of a multidrug regimen, including a parenteral aminoglycoside (streptomycin or amikacin), and surgical resection ("debulking") of diseased lung.[90] The optimal drug regimen for treating macrolide-resistant strains is unknown, but some experts recommend ethambutol, rifabutin, an injectable agent, and possibly another oral drug such as an 8-methoxyfluoroquinolone or clofazimine.

Patients whose disease is predominantly localized to one lung and who can tolerate resectional surgery should be considered for surgery under the following conditions: (1) poor response to drug therapy, (2) development of macrolide-resistant MAC disease, or (3) presence of significant disease-related complications, such as hemoptysis. Whenever possible, surgery should be performed by thoracic surgeons who have had considerable experience with resectional lung surgery for mycobacterial disease.[94]

Therapy of Disseminated MAC Disease. Successful treatment of disseminated MAC in persons with AIDS is based on treatment of both the mycobacterial and HIV infections. Clinicians must therefore be aware of the drug-drug interactions between the antimycobacterial and antiretroviral medications. Current guidelines for the use of antimycobacterial drugs with HIV therapies can be found at www.cdc.gov/nchstp/tb/TB_HIV_DRUGS/TOC.htm.

Patients with disseminated MAC disease should be treated with clarithromycin, 1000 mg/day or 500 mg twice daily (or, as an alternative, azithromycin at a dose of 500 mg daily), and ethambutol at a dose of 15 mg/kg daily.[95–97] Rifabutin, if added, should be used at a dose of 300 mg daily, with adjustments for interactions with antiretroviral drugs. As with macrolide-resistant MAC lung disease, patients with disseminated disease from macrolide-resistant strains are far less likely to be successfully treated[84]; clofazimine has been associated with excess mortality and should not be used.[98] Treatment of MAC in patients with AIDS should be considered lifelong, unless immune restoration is achieved by antiretroviral therapy. MAC treatment may be stopped for patients who are asymptomatic, have completed 12 months or more of therapy, and have maintained a $CD4^+$ T-cell count over 100 cells/μL for at least 12 months.[99]

Preventive therapy for disseminated MAC is recommended for all HIV-infected patients with less than 50 $CD4^+$ T-cells/μL.[100] Based on efficacy and ease of use, azithromycin—given as 1200 mg once weekly—is the preferred agent.[101] Clarithromycin is also effective; however, it is considered an alternative agent because it must be given twice daily and the risk of breakthrough with macrolide-resistant strains is higher with daily clarithromycin than with weekly azithromycin. Rifabutin is also effective but should only be used when a macrolide cannot be tolerated. Primary MAC prophylaxis should be discontinued among adult and adolescent patients who have responded to antiretroviral therapy with an increase in $CD4^+$ T-lymphocyte counts to more than 100 cells/μL for more than 3 months. Primary prophylaxis should be reintroduced if the $CD4^+$ T-lymphocyte count decreases to less than 50 to 100 cells/μL.

Therapy of MAC Lymphadenopathy. The treatment of choice for MAC lymphadenopathy, as well as localized lymphadenopathy due to most NTM pathogens, is complete surgical resection of the involved lymph nodes.[65,66,102,103] When complete surgical resection is not possible, due for instance to nerve impingement or encasement by infected nodes, then chemotherapy with MAC treatment regimens similar to those for lung and disseminated disease is necessary.[104]

Mycobacterium kansasii *Pulmonary Disease*

Tap water is the major reservoir for *M. kansasii.*[105–107] *Mycobacterium kansasii* is the second most common cause of NTM lung disease in the United States, but has also been reported in Europe, Asia, and Africa. *Mycobacterium kansasii* lung disease most closely parallels the clinical course of *M. tuberculosis,* including radiographic abnormalities (Fig. 35-5). While most patients with *M. kansasii* lung disease have upper lobe fibrocavitary findings, some patients have been reported with nodular/bronchiectatic radiographic abnormalities. In HIV-infected patients, *M. kansasii* can present with essentially any pattern of radiographic abnormality.[108]

Therapy of *M. kansasii* Pulmonary Disease. The recommended regimen for treating pulmonary *M. kansasii* disease includes daily rifampin (600 mg/day), isoniazid (300 mg/day), and ethambutol (15 mg/kg/day) for a duration that includes 12 months of negative sputum cultures.[5] Limited data suggest that therapy with rifampin, ethambutol, and clarithromycin for *M. kansasii* disease can also be successful,[109] including intermittent therapy.[110] The recommended treatment duration, as with MAC lung disease, is a duration that includes 12 months of sputum mycobacterial culture negativity.

Patients whose *M. kansasii* isolates have become resistant to rifampin as a result of previous therapy have been treated successfully with a regimen that consists of high-dose daily isoniazid (900 mg), high-dose ethambutol (25 mg/kg per day), and sulfamethoxazole (1.0 gm three times per day) combined with several months of streptomycin or amikacin.[111] The excellent in vitro activity of clarithromycin and moxifloxacin against *M. kansasii* suggests that multidrug regimens containing these agents and at least one other agent based on in vitro susceptibilities, such as ethambutol or sulfamethoxazole, are likely to be even more effective for treatment of a patient with rifampin-resistant *M. kansasii* disease.

Therapy of Disseminated *M. kansasii* Disease. The treatment regimen for disseminated disease, as usually observed in patients with AIDS, should be the same as for pulmonary disease.[5] Because of the critically important role of rifamycins in the treatment of *M. kansasii* disease,

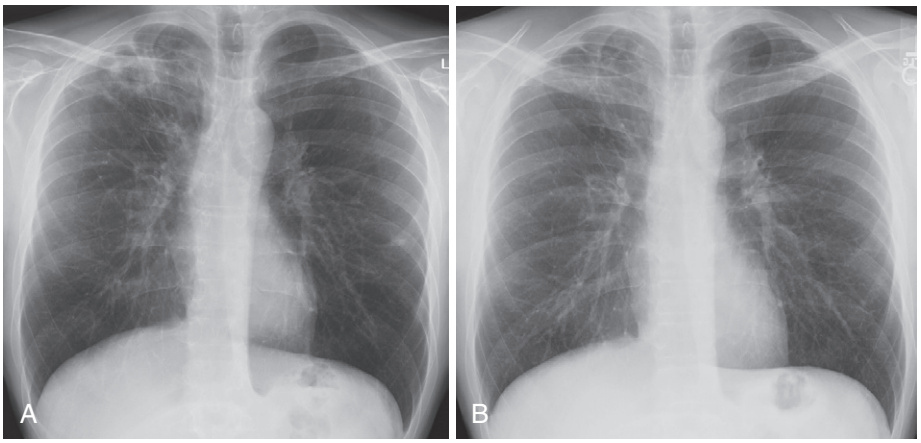

FIGURE 35-5 ■ A 46-year-old male smoker with *M. kansasii* lung disease. The patient presented with cough and weight loss. He was treated as a tuberculosis suspect initially, but his sputum specimen was strongly culture positive for *M. kansasii.* **A,** Chest radiograph showing right upper lobe (RUL) cavitary consolidation. **B,** Chest radiograph with improvement in RUL abnormalities after completing therapy.

it is important to construct *M. kansasii* and antiretroviral treatment regimens that are compatible (see website mentioned in disseminated MAC disease discussion earlier). An option for treating HIV-infected patients who receive an antiretroviral regimen not compatible with rifamycins is to substitute a macrolide or moxifloxacin for the rifamycin. There is no recommended prophylaxis regimen for disseminated *M. kansasii* disease.

Mycobacterium xenopi

Mycobacterium xenopi is a thermophile that survives in hot water systems and natural hot water resevoirs. Its survival in flowing water systems and resistance to common disinfectants enable *M. xenopi* to contaminate laboratory samples and medical devices such as bronchoscopes, thus causing health care–acquired disease (pseudoinfections) and laboratory contamination of specimens. Clusters of hospital isolates have been reported from the United States and Europe.[112] Because of its environmental presence, the differentiation of true clinical infection from pseudoinfection may be difficult but is of paramount importance.

Mycobacterium xenopi is rarely isolated in the United States; however, it is the second most common cause of NTM lung disease in Canada, the United Kingdom, and Europe.[113] Pulmonary *M. xenopi* infections are most common, but extrapulmonary and disseminated infections have been reported. Impaired immunity, either local (preexisting pulmonary disease) or systemic (HIV, immunosuppressive medications) appear to predispose to *M. xenopi* infections. Radiographic findings with *M. xenopi* pulmonary disease are variable but most often include upper lobe cavitary abnormalities compatible with tuberculosis.

In one recent report of therapy for *M. xenopi* infections, overall mortality was high—and mostly unrelated to *M. xenopi* disease—and the response to chemotherapy was not correlated with in vitro susceptibility results.[114] In another recent report from Europe, *M. xenopi* isolates demonstrated favorable in vitro MICs to isoniazid, rifampin, and ethambutol.[113] Even with variable treatment regimens, antimicrobial treatment cured 58% of patients who met American Thoracic Society (ATS) criteria for *M. xenopi* lung disease.[113] Again, there was no correlation between failure or treatment relapse and in vitro susceptibility results. In the most recent published treatment results, a regimen of clarithromycin, rifampin, and ethambutol was compared to ciprofloxacin, rifampin, and ethambutol; treatment success, failure, or relapse did not differ between the two groups.[115] All-cause mortality was again relatively high, and somewhat higher in the ciprofloxacin + rifampin + ethambutol arm. Overall, the optimal pharmacologic management has yet to be determined; however, a regimen consisting of clarithromycin, rifampin, and ethambutol ± isoniazid, administered for a duration of therapy that includes 12 months of sputum culture negativity, seems reasonable. The unusually high overall mortality with this infection is difficult to explain, but may be a reflection of the comorbidities of the patients with *M. xenopi* disease. For whatever reason, it appears to be a consistent observation.

Mycobacterium malmoense

Mycobacterium malmoense is considered the second most serious pathogen after MAC in Northern Europe. The clinical relevance of *M. malmoense* isolates has been described as 70% to 80% in Europe, although clinical isolates in the United States are not nearly as often deemed clinically significant.[116] Patients with *M. malmoense* lung disease frequently have preexisting obstructive lung disease. Not surprisingly, *M. malmoense* lung disease often presents in a manner similar to other cavitary NTM lung disease pathogens. Overall, in vivo response to antimicrobials does not correlate with in vitro susceptibility to antimicrobial agents. In a recent report, clarithromycin, rifampin, and ethambutol were compared to a regimen consisting of ciprofloxacin, rifampin, and ethambutol.[115] Although a more favorable

response to therapy was attained with the macrolide-containing regimen, overall mortality did not differ between the two regimens. The optimal pharmacologic management of *M. malmoense* has yet to be determined.[115–117] Currently, a reasonable regimen for *M. malmoense* might consist of rifampin, ethambutol, and clarithromycin with or without isoniazid for a duration to include 12 months of sputum culture negativity.[116]

Mycobacterium simiae

Recovery of *M. simiae* from clinical specimens has been reported in three geographic regions, Israel, Cuba, and the Southwestern United States, including Texas, Arizona, and New Mexico. The organism is most often isolated as a single positive specimen that is smear negative and not associated with clinical disease. For several clusters of isolates, organisms were also recovered from the local tap water, suggesting it as the likely source.[118,119] A large pseudo-outbreak of *M. simiae* isolates from an urban hospital in Texas has been reported.[120] The source for most of the recovered organisms was a hot water holding area. In most published series, the majority of *M. simiae* isolates have been judged to be not clinically significant.[120,121] In a recent publication, the authors noted, "The available diagnostic criteria are inadequate for the selection of patients for whom drug treatment for true *M. simiae* infection would be beneficial."[121] When *M. simiae* is a significant pathogen, it is most often associated with pulmonary disease or, in immune-compromised hosts, disseminated disease.

As with other NTM, there is no established correlation between in vitro susceptibility of the organism and in vivo clinical response to antimicrobial agents, nor is there an established, predictably reliable treatment regimen for *M. simiae* disease. In a study from Israel,[122] there were no recurrences reported in 102 patients with pulmonary *M. simiae* disease after treatment with rifampin, ethambutol, and clarithromycin given daily for at least 12 months of negative sputum cultures. Some experts suggest using macrolide-based regimens similar to those used for MAC; in addition, other agents such as 8-methoxyfluoroquinolones, sulfamethoxazole, and linezolid may have some activity against this organism.

Mycobacterium szulgai

Mycobacterium szulgai is characterized primarily by cavitary lung disease in patients with underlying chronic lung disease that resembles disease due to *M. tuberculosis.* As with other NTM pathogens, it can also be associated with nodular/bronchiectatic disease. Most respiratory isolates of *M. szulgai* are associated with significant lung disease: 11 of 15 patients (73%) in the Netherlands who grew *M. szulgai* from their sputum met current ATS criteria for disease.[123] In vitro susceptibilities demonstrate susceptibility to rifampin, isoniazid, ethambutol, and clarithromycin. A recent study suggested that regimens containing rifamycin, ethambutol, and clarithromycin with or without a fluoroquinolone for approximately 12 months have almost 100% treatment success.[123] Unlike many other NTM pathogens, the in vitro susceptibilities for *M. szulgai* appear to predict favorable treatment response.

Rapidly Growing Mycobacteria

Rapidly growing mycobacteria (RGM) are distinguished by growth in culture in less than 7 days and comprise over 70 distinct species, 17 of which have been associated with lung disease (see Table 35-1). Because many RGM are not pathogenic in humans, it is important to subclassify organisms within this group to the species level since this affects both treatment and prognosis. Although RGM can produce pulmonary disease, they have a propensity to produce skin and soft tissue infections.

Mycobacterium abscessus

Mycobacterium abscessus is the third most common NTM infection in the United States and causes 80% of infections due to RGM.[38] Most patients with pulmonary disease due to *M. abscessus* are nonsmoking, white women older than 60 years who have no predisposing conditions. The usual clinical presentation is similar that of other NTM pulmonary infections and includes cough and easy fatigability. For most patients with no predisposing conditions, the disease is slowly progressive; however, more fulminant, rapidly progressive disease has been seen in patients with gastroesophageal disorders and cystic fibrosis. The chest radiograph usually shows multilobar, patchy, reticulonodular or mixed reticulonodular-alveolar opacities[38] (Fig. 35-6). HRCT findings include the presence of cylindrical bronchiectasis with multiple small nodules, similar to MAC lung disease.[38,82,124] Cavitation has been reported in 10% to 20% of patients. Death occurred as a consequence of *M. abscessus* in 20% of patients in one report.[38]

Therapy of *M. abscessus* Pulmonary Disease. *Mycobacterium abscessus* is typically resistant in vitro to most of the medications used to treat tuberculosis, and has demonstrated in vitro activity to only a few antimicrobial agents. Cure with medical therapy may be unrealistic for *M. abscessus.* Therapy usually consists of 2 to 4 months of intravenous agents such as imipenem or cefoxitin plus amikacin given daily or three times weekly.[5] Any oral agents that have demonstrated in vitro activity should be included in the treatment regimen. Unfortunately, the macrolides are the only readily available oral agents typically active in vitro against *M. abscessus.* Linezolid, an oxazolidinone, is active against some strains of *M. abscessus,* but is frequently associated with significant hematologic toxicity and peripheral neuropathy.[125,126] Tigecycline has significant in vitro activity against *M. abscessus,* but is available only as an intravenous preparation and is associated with significant nausea and vomiting.

Once the patient has demonstrated a clinical response to therapy, there are several possible choices for continued treatment: (1) stop therapy after 2 to 4 months and follow the patient for signs of progression of disease and, if present, periodically reinstitute treatment; (2) stop the

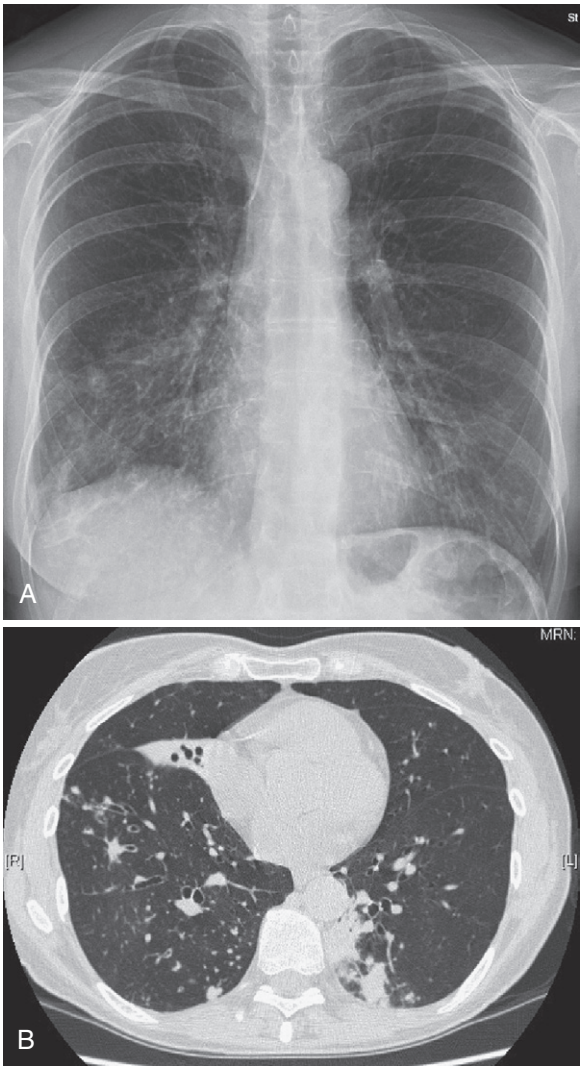

FIGURE 35-6 ■ A 68-year-old nonsmoking female with several-year history of cough, fatigue, and weight loss. Her sputum cultures were consistently positive for *M. abscessus*. **A,** Chest radiograph showing middle and lower lung zone nodular opacities and bronchiectasis. **B,** Chest computed tomography scan showing right middle lobe atelectasis and bronchiectasis with bilateral lower lobe bronchiectasis and nodular opacities. Note the left lower lobe air space opacity in this patient with severe reflux and probable chronic aspiration.

aminoglycoside and continue the cefoxitin or imipenem for a longer period along with an oral agent; and (3) continue an oral agent and institute inhaled amikacin. Unfortunately, none of these choices is evidence-based so, ultimately, treatment decisions will need to be individualized and often some form of therapy will be given periodically on a lifelong basis.

A combination of surgical resection and chemotherapy may increase the chance of cure in patients who have focal lung disease and who can tolerate resection. Patients should be treated with an initial period of antimicrobial drug therapy prior to surgery to lessen the bacillary load.[5] As with MAC lung disease, surgery should be performed by thoracic surgeons experienced in performing this type of surgery.[94]

Therapy of *M. abscessus* Skin, Soft Tissue, and Bone Infections. Serious infections should be treated with a regimen similar to that used for pulmonary disease. Skin and soft tissue infections should be treated for a minimum of 4 months and bone infections for 6 months. Surgery is generally indicated for extensive disease, abscess formation, or when drug therapy is difficult.[5] Foreign bodies such as prosthetic joints, percutaneous catheters, and breast implants should be removed, and the patient treated with a prolonged antimicrobial treatment regimen.

Mycobacterium chelonae

Mycobacterium chelonae is more likely to produce skin, soft tissue, and bone infections than pulmonary disease. Keratitis due to *M. chelonae* has been associated with wearing contact lenses and with ocular surgery such as laser-assisted in situ keratomileusis (LASIK).[127,128] Disseminated disease has been reported in immunecompromised patients and usually presents with characteristic cutaneous lesions.[129] The clinical and radiographic presentation of *M. chelonae* pulmonary disease is similar to that of other rapidly growing mycobacteria.

Isolates of *M. chelonae* are usually susceptible to tobramycin, the macrolides, linezolid, and imipenem.[73,130,131] Other active drugs may include amikacin, clofazimine, doxycycline, and the fluoroquinolones. *Mycobacterium chelonae* isolates are uniformly resistant to cefoxitin. Treatment of *M. chelonae* infections should be based on in vitro susceptibility results. Administration of clarithromycin 500 mg twice daily for 6 months was reported to have a high cure rate in patients with cutaneous lesions associated with disseminated disease.[132] The one patient who relapsed did so with a macrolide-resistant strain. Patients have also responded to linezolid with or without clarithromycin.[133,134] Patients with serious skin, soft tissue, and bone infections should be treated similarly to those with *M. abscessus* disease. For corneal infections, both topical and oral agents are often used, and many patients may require corneal transplants for recovery of vision or cure.

Mycobacterium fortuitum

Mycobacterium fortuitum is responsible for 15% of RGM cases in the United States but is a relatively uncommon cause of lung disease except in patients with disorders associated with chronic aspiration.[38] The clinical and radiographic presentation of patients with pulmonary disease is similar to that of other RGM. Skin, soft tissue, and bone infections are more common than pulmonary disease. Both sporadic and clustered outbreaks of furunculosis due to *M. fortuitum* (and other RGM) have been reported after exposure to contaminated water during pedicures.[135-137]

In contrast to *M. abscessus, M. fortuitum* demonstrates broader in vitro susceptibility to both oral and intravenous antimicrobial drugs, including the newer mac-

rolides, the fluoroquinolones, doxycycline, minocycline, the sulfonamides, and two intravenous drugs, imipenem and cefoxitin.[5] Although most isolates of *M. fortuitum* are susceptible in vitro to the macrolides, these drugs should be used with caution because of the presence of an inducible erythromycin methylase (*erm*) gene.[138]

Mycobacterium fortuitum lung disease should be treated with at least two drugs to which in vitro susceptibility has been demonstrated.[5] As with other NTM lung infections, treatment should be continued for at least 12 months of negative sputum cultures. Skin, soft tissue, and bone infections should be treated similarly to *M. abscessus* infections, although more effective oral agents are usually available.

Hypersensitivity Pneumonitis–Like NTM Pulmonary Disease

Most reports describing the development of a typical pattern of hypersensitivity pneumonitis–like lung disease have been in patients associated with hot-tub exposure, although similar clinical presentations have been associated with other indoor standing water sources and exposures.[28,139,140] In one case report, hypersensitivity-like lung disease was observed in association with an indoor shower.[28] Some investigators have used the phrase "hot-tub lung" to describe the presentation associated with standing water sources. In the cases of exposure to hot tubs, MAC has been the mycobacterial organism isolated from sputum, bronchoalveolar lavage, tissue, and hot-tub water. Furthermore, when assessed by genotyping methods, MAC isolates from both the hot-tub water and the lung specimens have demonstrated identical patterns. Controversy still exists, however, as to whether hot-tub lung is an infectious process, inflammatory process, or combination of processes.

Patients with hypersensitivity pneumonitis–like lung disease tend to be young and without preexisting lung disease. The clinical presentation varies from mild respiratory symptoms to respiratory failure requiring mechanical ventilatory support.[141] Key elements to the diagnosis of MAC hypersensitivity-like lung disease include a compatible clinical history (subacute onset of respiratory symptoms, hot-tub exposure), characteristic radiographic findings, and MAC isolates in sputum, bronchoalveolar lavage, tissue, and hot-tub water (and compatible histopathology when available).

Patient prognosis is generally excellent independent of severity on presentation.[139] The most benefit is gained by simply removing the patient from further antigen exposure. In the case of hot-tub lung, removal from antigen exposure generally involves drainage of hot-tub water and complete avoidance of hot-tub use. Whether continued exposure to ambient environmental MAC organisms can propagate the hypersensitivity pulmonary reaction is uncertain. For selected patients with hypersensitivity pneumonitis–like lung disease, use of systemic corticosteroids may be of benefit and hasten recovery of pulmonary symptoms, gas-exchange abnormalities, and radiographic abnormalities. Likewise, antimycobacterial therapy, with the same medications as for standard pulmonary MAC lung disease, may be required in some patients but for shorter durations of therapy, usually 3 to 6 months. Most patients can be expected to have nearly complete resolution of respiratory symptoms as well as of pulmonary function and radiographic abnormalities.

HEALTH CARE–ASSOCIATED NTM DISEASE AND PREVENTION OF NTM INFECTIONS

NTM are ubiquitous in the environment, so that complete avoidance is difficult if not impossible. The organisms generally have very low virulence for humans compared with *M. tuberculosis,* so NTM disease may be more a problem with host susceptibility than with organism contact. With some notable exceptions previously discussed, the specific susceptibility of an individual patient to NTM infection may be impossible to determine at this point; accordingly, disease prevention remains problematic. The question remains, however, should patients with known vulnerabilities to NTM infection be advised to avoid known environmental sources of NTM? For instance, should vulnerable patients be advised not to take showers, which are known to be associated with aerosolized NTM?[27] Currently the answer is unknown, and prevention of most environmentally acquired NTM infection remains a challenge.

Progress has been made, however, in the prevention of nosocomial NTM infections, which will prove to be the first step in the inevitable subsequent progress that will be made in the prevention of NTM infections as a whole. Transmission of NTM disease in the health care setting has most frequently been linked to tap (municipal) water exposure.[64] While various NTM species (including MAC, *M. kansasii, M. xenopi,* and *M. simiae*) have been isolated from municipal water supplies, *M. fortuitum* and *M. abscessus* have most often been implicated in health care–associated NTM disease. Even with use of potent disinfectants, including organomercurials, chlorine, bromine, 2% formaldehyde, and glutaraldehyde, NTM organisms may persist on equipment or devices after tap water exposure. The inability to eliminate these organisms underscores the importance of avoidance of tap water for preventing health care–associated NTM diseases, such as those following median sternotomy, plastic surgery procedures, liposuction, LASIK, dialysis, and the implantation of long-term central intravenous catheters, tympanostomy tubes, and prosthetic devices such as heart valves, knee and hip joints, lens implants, and metal rod bone stabilizers.[5] Pseudoutbreaks have involved bronchoscopes contaminated with *M. abscessus* and *M. immunogenum.* Documented outbreaks of hygiene-associated *M. fortuitum* and *M. mageritense* furunculosis in association with use of contaminated whirlpool footbaths have been described in nail salons.[137,142]

As a result of the increased understanding of environmental NTM reservoirs and reports linking the use of tap water to health care–associated NTM infections, it is recommended that tap water not be used in preparation of surgical procedures, prosthetics, and intravascular catheters; not be used in cleaning of fiberoptic endoscopes; and not be used to rinse the mouth out before collecting expectorated sputum samples. Moreover, recognition that alternative medicines or unapproved substances for injection may also be at risk of contamination by NTM warrants caution against use of these products as well.

KEY POINTS

- Nontuberculous mycobacteria (NTM) comprise over 140 different species that are ubiquitous in our environment. Members of the *Mycobacterium avium* complex (MAC) are the most common causes of NTM lung disease.
- Infection occurs after exposure to NTM in the environment: human-to-human transmission has not been described.
- Epidemiologic studies suggest that NTM infections are increasing in some areas of the world.
- Risk factors for pulmonary NTM disease include underlying chronic lung diseases such as chronic obstructive pulmonary diseases, cystic fibrosis, alpha$_1$-antitrypsin deficiency, prior tuberculosis, and bronchiectasis.
- Diagnosis of pulmonary NTM infections requires that the patient meet certain clinical, radiographic, and microbiologic criteria.
- The recommended treatment for MAC pulmonary disease is a macrolide, plus ethambutol and a rifamycin, with or without an aminoglycoside administered for at least 12 months of culture negativity.
- The recommended treatment for *Mycobacterium kansasii* pulmonary disease is isoniazid (or macrolide), rifamycin, and ethambutol administered for at least 12 months of culture negativity.
- Treatment of rapidly growing mycobacterial infections should be based on the results of in vitro drug susceptibility testing, but the clinical outcome varies significantly depending on the causative species.

INTRODUCTION

From the standpoint of fungal diseases, North America is unique among the continents because it is the "home" of three of the major endemic mycoses: histoplasmosis, blastomycosis, and coccidioidomycosis. Although histoplasmosis is also found in all the other continents except Antarctica, coccidioidomycosis in South America, and blastomycosis in Africa, only in North America are these illnesses common.

These three fungal diseases share many characteristics. The causative agents are mycelial soil organisms. Illness is acquired by inhaling aerosolized spores. In the infected host, the organisms change their form, a characteristic called "dimorphism." *Histoplasma capsulatum* and *Blastomyces dermatitidis* convert to a yeast

form at 37°C (thermal dimorphism), whereas *Coccidioides immitis* converts in tissue to a spherule that replicates by forming endospores (tissue dimorphism).

The endemic areas are large. Most of the midwest and south-central United States is endemic for both histoplasmosis[1] and blastomycosis,[2] and a large area in the southwest United States and an adjacent area of Mexico are endemic for coccidioidomycosis.[3] All three illnesses occur in normal hosts, although histoplasmosis and coccidioidomycosis are also major opportunistic mycoses in patients with depressed cell-mediated immunity, and especially in patients with acquired immunodeficiency syndrome (AIDS).[4,5] Paracoccidioidomycosis is the major endemic mycosis in South America.[6] The causative organism is also a thermally dimorphic soil organism. Cryptococcosis occurs worldwide. The causative organism is not dimorphic. It is always a yeast form both in nature and in the infected host. The disease is acquired by inhalation, but the organism evokes little inflammatory response in the lung. It has an unusual trophism for the central nervous system (CNS), so most diagnosed cases of cryptococcosis are chronic meningitis rather than pneumonia.

The endemic mycoses and cryptococcosis all share one important feature: inhaled spores cannot be killed by neutrophils either because they resist intracellular killing[7] or, in the case of cryptococcosis, because they escape phagocytosis. Thus, intact cell-mediated immunity is crucial to prevent progressive infection. The result is a high likelihood of benign self-limited infection when cellular immunity is intact and a high likelihood of progressive primary infection when it is not. There is also epidemiologic evidence of relapse after long dormancy (similar to tuberculosis) when T-cell function becomes very depressed. Cryptococcosis, histoplasmosis, and coccidioidomycosis are major T-cell opportunistic infections, as demonstrated by their very aggressive courses in patients with AIDS, in whom T-cell deficiency is most severe. Blastomycosis and paracoccidioidomycosis also exploit T-cell deficiency.

Aspergillosis and mucormycosis occur worldwide; their causative agents are ubiquitous soil organisms that are always mycelial (growing as branching hyphae) both in nature and in infected mammalian tissue. Spores are regularly inhaled, but the fungi have low virulence and almost no ability to invade a normal host. In fact, adequate phagocyte function is sufficient for protection, even without specific cellular immunity. The risk factors for infection include prolonged neutropenia and use of high-dose corticosteroids (which depress phagocyte as well as T-cell function). Patients with human immunodeficiency virus (HIV) infection have no major problem with these organisms unless phagocyte number, phagocyte function, or both are reduced, either by the disease, by comorbid illness, or by the toxicity of various therapies.

Candidiasis is unlike other fungal infections in many ways. *Candida albicans* is not a soil organism and is not acquired by inhalation. Rather, it is part of the normal pharyngeal and gastrointestinal flora of humans. T-cell function is required to prevent mucosal overgrowth, which occurs in mucocutaneous candidiasis and especially with HIV infection. However, normal phagocyte function and intact skin and mucosal barriers are adequate to prevent deep infection, which usually occurs across the bowel wall or through the skin (often aided by intravascular catheters). Pulmonary disease usually results from hematogenous spread to the lung. Primary pulmonary infections, from aspiration of pharyngeal material, are rare.

A variety of other soil organisms rarely causes pulmonary or systemic infections when phagocyte defects are present. They are best thought of as aspergillosis-like infections and are discussed only briefly in this chapter. Sporotrichosis is also caused by a soil fungus. Usually, it is an inoculation disease with lesions of the skin and draining lymphatics. Rarely, sporotrichosis presents as pneumonia, likely following inhalation of aerosolized fungal spores.

In view of their important linkage with immunologic and nonimmunologic defenses, it is possible to classify pulmonary fungal diseases according to the major impairment of host defenses that contributes to their pathogenesis (Table 36-1). The diseases are discussed in this chapter in the order in which they appear in the table. *Pneumocystis jirovecii* (formerly *carinii*) was formerly considered a protozoan but is presently classified as a fungus. *P. jirovecii* pneumonia and the other fungal complications of AIDS and non-AIDS immunosuppressive disorders are discussed in Chapters 80 and 82.

HISTOPLASMOSIS

Histoplasmosis is the illness caused by the thermal dimorphic fungus *H. capsulatum*. The spectrum of disease caused by the fungus ranges from the asymptomatic acquisition of a positive histoplasmin skin test reaction to a rapidly fatal pulmonary or disseminated illness.

TABLE 36-1. Classification of Pulmonary Fungal Diseases According to the Major Impairment of Host Defenses That Contributes to Their Pathogenesis

DEFECTS OF T-CELL FUNCTION

Candidiasis
Pseudoallescheriosis
Other (rare) fungi

History and Epidemiology

The first case of histoplasmosis was recognized by Samuel Darling in Panama in 1906.[8] Darling, a U.S. Army pathologist, performed an autopsy on a man who had died of a progressive systemic infection. Darling identified an organism that resembled *Leishmania donovani* microscopically in the tissue sections. He assumed that the organism was a protozoan, and he named it *Histoplasma capsulatum*. During the next 2 years, Darling found two similar cases, also at autopsy. The name *H. capsulatum*, unfortunate because it implies a protozoan, persists to this date, even though daRocha-Lima[9] correctly surmised as early as 1912 that the organism was actually a fungus. There is no capsule; the lucent areas Darling saw surrounding the organisms probably were due to an artifact of tissue preparation.

In 1926, Riley and Watson,[10] the latter a first-year resident in pathology, reported the next case from Minnesota, also at autopsy, and rekindled awareness of the disease. Histoplasmosis was first diagnosed during life by Dodd and Tompkins,[11] who identified intracellular organisms on the peripheral blood smear of a leukemic child from Tennessee dying of a systemic febrile illness with hepatosplenomegaly and anemia. DeMonbreun[12] successfully isolated the organism using animal inoculation. He proved that the organism was a fungus and demonstrated its thermal dimorphism. For the next few years, scattered similar cases were reported from the central United States, maintaining the general perception that histoplasmosis was a rare and uniformly fatal illness.

About that time, it was recognized that many tuberculin-negative individuals in the central United States had unexplained pulmonary calcifications. A major advance in understanding histoplasmosis came when Christie and Peterson[13] hypothesized that these calcifications might be caused by healed *H. capsulatum* infection. Using the original De-Monbreum isolate, they prepared histoplasmin, a complex skin test antigen. They tested tuberculin-negative persons in Nashville, Tennessee, who had pulmonary calcifications on their chest radiograph: All had positive histoplasmin skin tests. Their findings were quickly confirmed and extended by Palmer[14] of the U.S. Public Health Service. Shortly thereafter, Emmons[15] was able to grow the fungus from the soil in the endemic area, especially soil enriched by bird droppings.

Thus, during a period of only a few years, histoplasmosis, formerly considered rare and uniformly fatal, became recognized as common and almost invariably benign. The natural habitat for the fungus was the soil, and human and animal infections occurred after inhalation of the infecting particle. Extensive skin test surveys suggest that as many as 50 million people in the United States have been infected by *H. capsulatum* and that there are up to 500,000 new infections yearly.[16]

The organism requires organic nitrogen for growth and is frequently isolated from soil heavily contaminated by bird or bat feces.[15,17] In nature, the fungus grows as an aerial mycelium with many small spores on specialized side branches. When a site harboring the fungus is disturbed, an aerosol is formed. Infection often follows exposure because the spores, when inhaled, are almost the perfect size to reach the alveoli.

During the 1950s, many small outbreaks of histoplasmosis were linked to exposure to (usually abandoned) chicken houses. With the shift of the U.S. population from predominantly rural to urban and suburban and the abandonment of household raising of chickens, the epidemiology of histoplasmosis has changed.[18] For decades, most outbreaks have occurred in urban settings, frequently in areas of relatively low endemicity. A large community-wide outbreak in Montreal and two separate outbreaks in Mason City, Iowa, occurred in areas where histoplasmosis had seldom been recognized.[18] All were associated with construction projects that disturbed contaminated soil.[18] The most recent (and largest ever) outbreak occurred in Indianapolis, Indiana,[19] associated with downtown construction of a swimming pool complex. Indianapolis is within the endemic area. The huge number of primary infections during the Indianapolis outbreak suggests that urban dwellers, even in endemic areas, do not regularly become infected with *H. capsulatum*. Thus, they remain susceptible when exposed to aerosolized spores during construction activity.

The source of the fungus has also changed. Small contaminated sites associated with chicken houses have been replaced by large contaminated sites associated with blackbird roosts. Blackbirds (grackles, starlings, red-winged blackbirds, and others) are gregarious and often roost in large aggregations of birds, producing enormous amounts of droppings. Tree-lined river banks are favorite roosting sites. When such sites are disturbed by construction activities, immense numbers of spores can be aerosolized, leading to community-wide outbreaks involving hundreds or thousands of people. Mini-outbreaks also still occur. Cutting up fallen trees for firewood is a more modern cause of histoplasmosis than entering a chicken coop. The chain saw creates an excellent aerosol.

Pathogenesis

The lung is the portal of entry in almost every case.[20] Direct percutaneous inoculation of the spores may occur, but only a few such cases have ever been reported. Also, rarely, the organism can be transmitted by organ transplantation from a donor with unrecognized active histoplasmosis in the donated organ.[21]

When the spores of *H. capsulatum* are inhaled, some elude the nonspecific defenses of the lung. Spores that reach the alveoli convert to the yeast phase and multiply by binary fission. The initial tissue response to the organism is predominantly neutrophilic, followed by an increase in alveolar macrophages.[22] The yeast forms are phagocytosed by the macrophages but are not killed. In fact, they multiply rapidly within the macrophages and spread to hilar lymph nodes and then throughout the body. During this time, metastatic foci of infection develop in many organs, such as the liver and spleen.[23]

When lymphocyte-mediated cellular immunity develops, usually about 2 weeks after the original inhalation, there is an increase in immune lymphocytes in the lung

and other infected organs. These lymphocytes arm macrophages, which improves their ability to control the fungus. In mice, interleukin-12 is an important signal, leading to increased interferon-γ production that confers protection against primary infection.[23–26] Tumor necrosis factor (TNF)-α is also increased and provides additional protective effects.[23–27] Granuloma formation depends on complex cellular interactions between immune lymphocytes and armed macrophages. As the intensity of cellular inflammation increases, necrosis occurs, which is often caseous and at times is indistinguishable from the necrosis seen in tuberculosis.[28] Areas of caseation necrosis occur not only in the lung but also at all distant sites.

Healing of these lesions is accompanied by peripheral fibrosis. Central areas of encapsulated, necrotic material frequently calcify. These calcified foci manifest on chest radiograph as single or multiple calcified nodules or as a classic Ranke complex with peripheral and hilar calcifications. Calcified lesions are often seen in the liver and the spleen.[29]

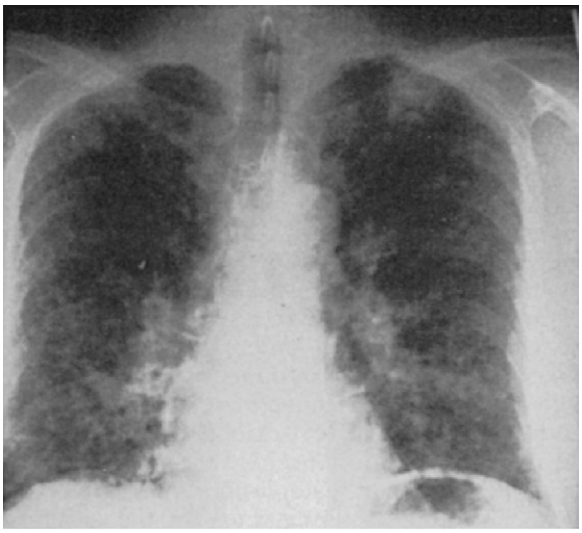

FIGURE 36-1 ■ Chest radiograph shows acute pulmonary histoplasmosis. Note the bilateral opacities and bilateral hilar adenopathy.

Clinical Manifestations

Most normal persons who are infected by the fungus remain asymptomatic. Even when symptoms do occur, they are usually nonspecific; hence, ordinary sporadic, mild infections are seldom diagnosed. Most of what is known about symptomatic primary histoplasmosis comes from the study of outbreaks of the disease. Many of the first reported outbreaks were small, involving only a few individuals. Frequently, the exposure to the fungus took place in a confined place, such as a storm cellar, a chicken house, or a bat cave. In these small outbreaks, symptoms were very common. The severity of illness ranged from mild respiratory illness to overwhelming pneumonia with diffuse nodular opacities and severe gas-exchange abnormalities.[30]

In more recent community-wide outbreaks, exposure to the fungus has been not in enclosed spaces but in open air, where fewer infectious spores are inhaled.[31,32] In these groups, the frequency of symptomatic illness is lower (<50% of infected individuals as determined by skin test conversion). Even when illness is symptomatic, the severity of symptoms is less.

The incubation time of acute histoplasmosis in previously nonimmune individuals ranges between 9 and 17 days. In an open-air outbreak in Minneapolis, Minnesota (low background endemicity), the mean incubation time was 14 days. In that outbreak, the day and the hour of exposure were known, because all patients visited the infectious site for less than 2 hours.

When present, symptoms vary widely from brief periods of malaise to severe, life-threatening illness. In a typical patient, the illness resembles influenza. The onset is abrupt, with fever, chills, and substernal chest discomfort. A harsh, nonproductive cough develops along with headache, arthralgias, and myalgias. Erythema nodusum may occur, drawing attention.

Whether symptomatic or not, normal hosts recover uneventfully from primary pulmonary infection more than 99% of the time.[20] Only rarely, when the infective dose is unusually high, does severe pulmonary illness develop, which may progress rapidly to the acute respiratory distress syndrome, and may lead to death from respiratory insufficiency if not treated promptly.[1]

Even though the portal of entry is the lung, many patients, even those with symptoms, have a normal chest radiograph. When the chest radiograph is abnormal, the characteristic finding is a single area (or occasionally multiple areas) of pneumonitis, usually in better-ventilated lower lung zones. The draining hilar and mediastinal lymph nodes are often enlarged on the ipsilateral side (Fig. 36-1).[1,20] Unfortunately, this parenchymal–hilar node complex may be incomplete, with either component being absent, making the radiographic diagnosis more difficult. Furthermore, these abnormalities on chest radiograph may occur in asymptomatic individuals, causing diagnostic problems when they are discovered accidentally.

Healing of histoplasma pulmonary lesions may be complete, with total resolution of the previously noted pneumonitis. However, in some patients, the lesion contracts into a round nodule concurrent with the pathologic sequence of central necrosis, fibrous encapsulation, and variable calcification (Fig. 36-2). These residual "coin" lesions are common in endemic areas. If the lesions do not calcify, then differentiation from bronchogenic carcinoma is sometimes difficult.[20] Early in the course, they may be metabolically active, even lighting up on positron emission tomography (PET) computed tomography (CT) scans. Later, they have low metabolic activity, are less likely to enhance on contrast CT, and have increased density compared with lung neoplasms. In general, lesions calcify more often and more quickly in children and young adults than in older individuals.

Similarly, healing of caseation necrosis in the hilar and mediastinal lymph nodes may lead to calcifications, often larger than similar calcifications in tuberculosis. Follow-

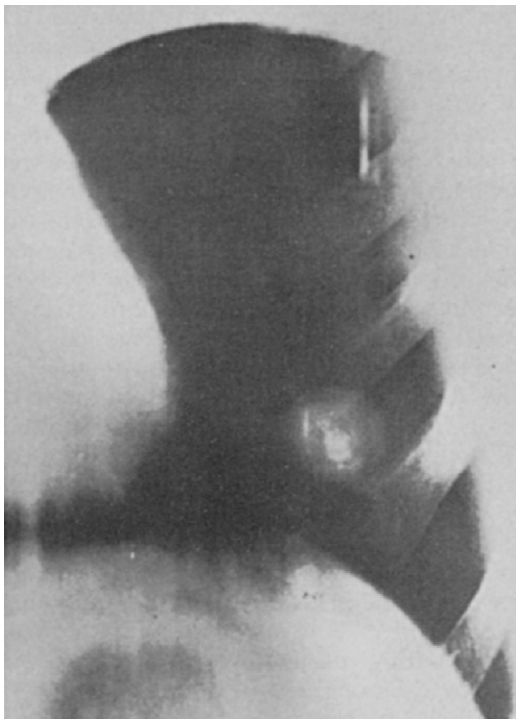

FIGURE 36-2 ■ Tomogram shows dense central calcification as well as concentric circles of laminar calcifications in a "coin" lesion of histoplasmosis.

ing heavy exposure, typical diffuse nodular opacities may develop, which are different from miliary tuberculosis because the individual lesions are larger and not as sharply defined. When healing occurs, the necrotic central areas of all these lesions may calcify, producing characteristic buckshot calcifications throughout the lungs.[20]

Physical examination during acute histoplasmosis is usually negative, except for fever. Hepatosplenomegaly usually implies disseminated disease and is discussed later. However, there are several syndromes associated with acute histoplasmosis that present with striking signs and symptoms. Perhaps the most impressive is the arthralgia–erythema nodosum–erythema multiforme complex. Arthralgias may occur during the acute symptomatic phase of the illness and may be severe enough to interfere with walking and other activities of daily living. Arthralgias usually resolve within a week or so. In several large outbreaks, erythema nodosum and erythema multiforme were noted, usually in patients with arthralgias.[33] These allergic skin manifestations occurred most often in women with normal or mildly abnormal chest radiographs, at the height of the cell-mediated immune response. The overall incidence of erythema nodosum, erythema multiforme, or both, in primary histoplasmosis is less than 1%.

Local Complications

Acute histoplasmosis is usually a benign and self-limited infection in persons with normal immunity. Serious complications occur occasionally and are usually caused by involvement of strategically located structures. Marked enlargement of the paratracheal lymph nodes may compress the trachea or one of the main-stem bronchi, causing an irritative cough, dyspnea, or both. Enlarged mediastinal lymph nodes may impinge on the esophagus (causing dysphagia) or on the superior vena cava (causing edema of the head and upper extremities).[20,34] These complications are encompassed within the term *mediastinal granuloma*. A surgical approach to isolated large nodes may improve symptoms but may not be necessary because the natural history is slow improvement. When surgery is done, the back wall of the resected nodal mass can be left in place to avoid too-aggressive dissection into adjacent vascular structures. Endovascular stenting has been used successfully to relieve superior vena caval obstruction.

Lymph nodes that calcify during healing may also impinge on adjacent structures or may even erode into various tissues. Erosion through the wall of the trachea or bronchi may cause broncholithiasis. Patients present with obstructive pneumonia, with expectoration of stones, or with hemoptysis. Rarely, calcified nodes may create tracheoesophageal fistulas when they erode into both adjacent structures.

Another rare manifestation of histoplasmosis is mediastinal fibrosis, which accompanies the healing of involved mediastinal lymph nodes, entrapping contiguous mediastinal structures. Bronchi may be entrapped, as may branches of pulmonary arteries and veins. In extreme cases, progressive obliteration of pulmonary vessels leads to pulmonary hypertension and death from cor pulmonale. Unfortunately, a surgical approach to diffuse mediastinal fibrosis is risky and not usually helpful, even though the course of illness is progressive. There have been anecdotal reports of endovascular stenting of focally narrowed arteries and pulmonary veins with some symptomatic improvement.[34a]

During the large outbreak of histoplasmosis in Indianapolis, pericarditis was identified as a relatively common complication of primary histoplasmosis, occurring in 45 of 712 patients (6.3%).[35] The pericardial effusions were usually sterile exudates. The pericardial inflammation is probably due to histoplasma involvement of adjacent mediastinal structures rather than to hematogenous spread of the fungus to the pericardium.

Chronic Pulmonary (Cavitary) Histoplasmosis

When primary histoplasmosis occurs in individuals with structurally abnormal lungs, such as heavy smokers with established emphysema, the infection often involves the upper lobes, which are most abnormal. Radiographically, the infection frequently mimics reinfection tuberculosis because bullae in radiographically involved lung may mimic cavitary disease.

Because of the resemblance to tuberculosis, it is not surprising that this form of histoplasmosis was first discovered in tuberculosis sanatoriums.[36] Many patients were chronically ill, and many died quickly, often in part

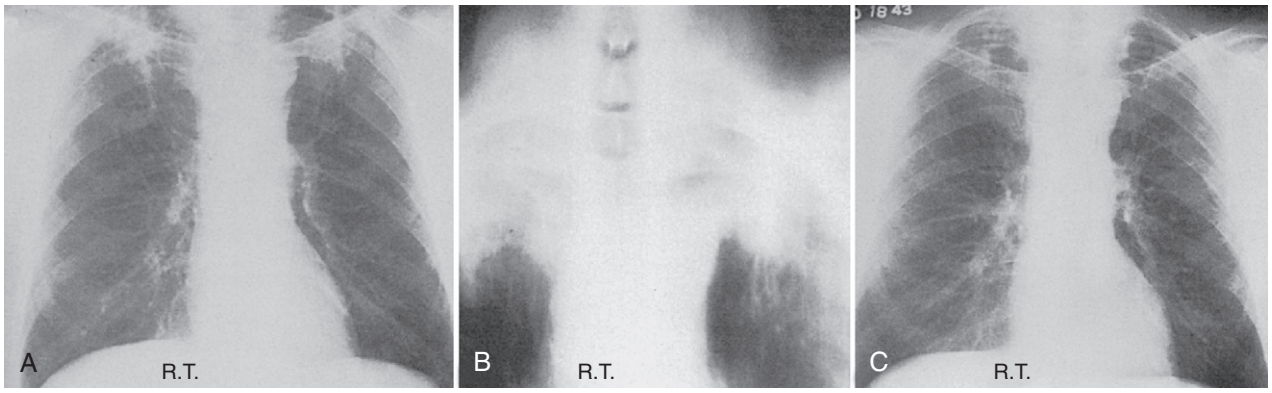

FIGURE 36-3 ■ Acute, self-limited upper lobe histoplasmosis in a 48-year-old cigarette smoker. **A,** The admission chest radiograph shows bilateral apical disease. **B,** The apical tomograms demonstrate multiple small cavities. **C,** The follow-up chest radiograph shows clearing.

from their underlying diseases. This led to the impression, subsequently proved false, that this form of histoplasmosis had a poor prognosis.

Goodwin and colleagues[37] were the first to point out that not all such patients have a progressive, destructive pulmonary infection. Virtually all have underlying chronic obstructive pulmonary disease. The infection smolders in the abnormal lung. Even in this setting, acute histoplasma infection often slowly resolves spontaneously, though more slowly (Fig. 36-3).[37,38] Occasionally, however, infection in these abnormal air spaces persists and progresses, enlarging existing emphysematous spaces and destroying adjacent, more normal pulmonary parenchyma.[37]

Clinically as well as radiographically, the symptoms of this progressive form of upper lobe histoplasmosis mimic those of tuberculosis. Low-grade fever and anorexia with weight loss are common. Most patients develop a productive cough, with variable amounts of mucopurulent sputum. Night sweats also occur but are not as prominent as in tuberculosis. As mentioned, the chest radiographic findings are usually similar to those of reinfection tuberculosis, showing fibrocavitary disease, sometimes with volume loss (Fig. 36-4).

Progressive Disseminated Histoplasmosis

During the early phase of acute histoplasmosis, the fungus gains access to the circulation via the hilar lymph nodes. It is likely that transient self-limited fungemia occurs in most, if not all, patients. Evidence for this comes from postmortem studies in the most highly endemic areas, in which careful search reveals healed, often calcified, granulomas in the spleen in more than 70% of autopsies.[29]

The circulating yeasts are phagocytosed by cells of the reticuloendothelial system. Killing of the fungus does not occur at first, and there is further multiplication intracellularly. With the advent of T-lymphocyte–mediated immunity, fungal replication is checked and granuloma formation begins. If the cell-mediated immune response is poor, the yeast continue to multiply. More macrophages are recruited, which in turn become parasitized and eventually disrupted, perpetuating the cycle.[5] A severe systemic illness develops, which invariably leads to death unless treated promptly and aggressively.

On physical examination, patients are febrile and acutely ill. Hepatosplenomegaly may be present. Laboratory evaluation may show anemia, leukopenia, and thrombocytopenia. In extremely ill patients, disseminated intravascular coagulation may be seen. The chest radiographic findings are variable, ranging from normal to diffusely abnormal (Fig. 36-5).[39] Biopsy material from the bone marrow and other involved tissue shows collections of macrophages full of intracellular yeast (Fig. 36-6) or, in the most severe instances, widespread necrosis with large numbers of organisms lying loose in the extracellular debris with little, if any, evidence of granuloma formation.[40] Virtually all patients with this form of the illness have some degree of T-cell defect. Before the modern era of widespread use of cytotoxic agents and glucocorticoids, many patients had underlying Hodgkin's disease, a well-known example of naturally occurring T-cell immune deficiency.[5,39]

The most severe form of progressive disseminated histoplasmosis (PDH) occurs in patients with AIDS with profound T-cell dysfunction.[41] In fact, most cases of PDH now occur in AIDS patients, and most occur in highly endemic areas.[42,43] Immunosuppressive treatment for malignancy and for organ transplantation is also associated with PDH. Newer biologic therapies including TNF-α blockers for rheumatoid arthritis and other autoimmune disorders have added a new pool of immunosuppressed patients at risk for tuberculosis and for histoplasmosis and other T-cell–opportunistic fungal infections.[43a]

In most instances, exposure of an immunosuppressed person to an infectious aerosol is the antecedent event preceding PDH. In the large outbreak in Indianapolis, most patients who were immunocompromised when they developed primary histoplasmosis progressed to PDH.[43] In particular, patients with AIDS nearly always progressed to PDH.[44]

In other cases, the onset of PDH is temporally related to intense immunosuppression, most commonly from progression of AIDS or therapy with high doses of

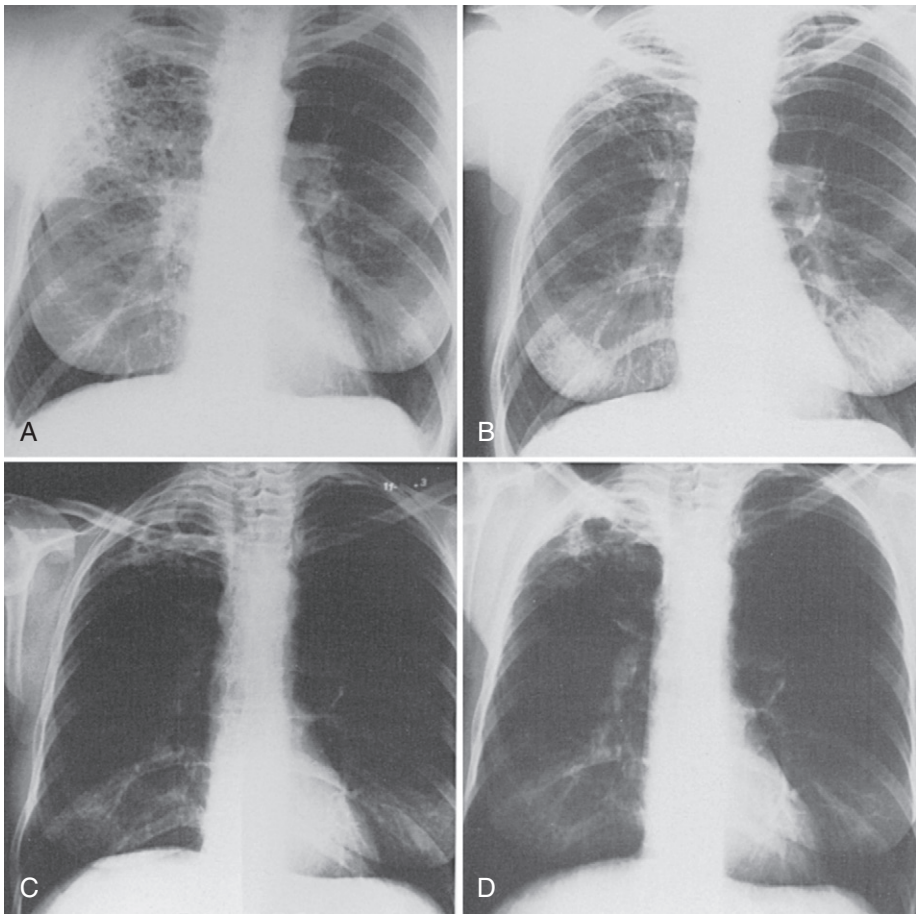

FIGURE 36-4 ■ The evolution of chronic pulmonary histoplasmosis in a smoker. **A,** At the onset of the illness, the chest radiograph shows multiple cavity-like air spaces. **B,** Two and one-half years later, fibrosis has occurred with volume loss of the lobe and retraction of the hilum. **C,** A further 17 months later, the entire right upper lobe appears destroyed. **D,** There are signs of continued activity and a residual cavity at the time of diagnosis. The sputum culture was positive for *Histoplasma capsulatum*.

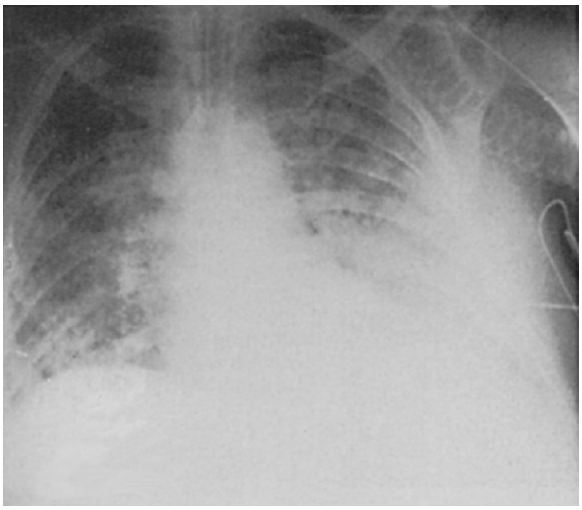

FIGURE 36-5 ■ Admission chest radiograph of a 45-year-old man shows disseminated histoplasmosis. The miliary pattern is clearly seen.

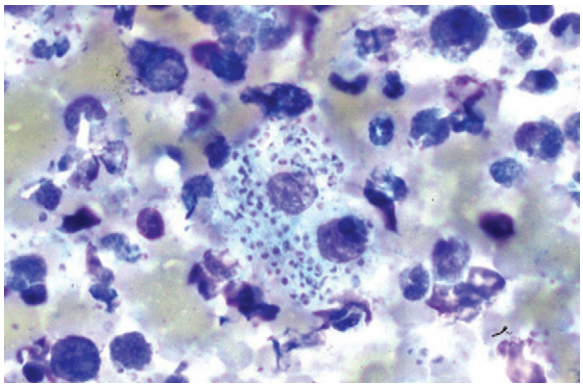

FIGURE 36-6 ■ Photomicrograph of bone marrow biopsy shows abundant small yeast-filling macrophages. There were no well-formed granulomas. (Wright stain; ×450.)

glucocorticoids. In some of these cases, reactivation of dormant histoplasmosis may be the mechanism of infection.[39] Patients with AIDS who develop PDH after long residence in New York City or San Francisco are clear examples of such endogenous reactivation because primary infections are never seen in these cities.

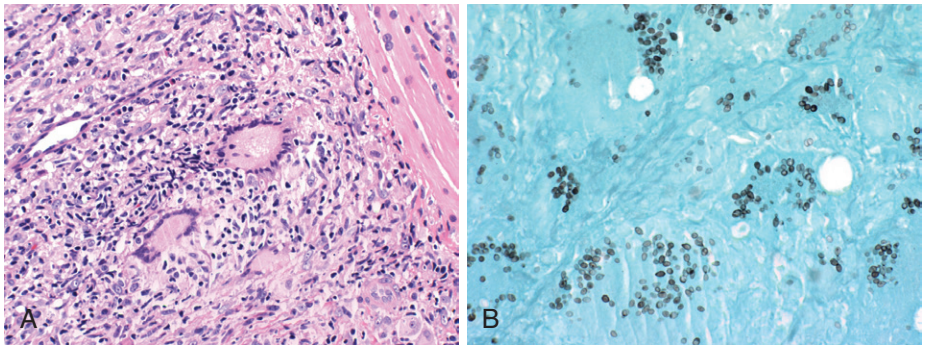

FIGURE 36-7 ■ **A,** Photomicrograph shows a tissue biopsy specimen from a patient with slowly progressing disseminated histoplasmosis. Granulomas are well formed, and no organisms are seen. (Hematoxylin and eosin stain ×450.) **B,** Special stains better demonstrate yeast in tissue sections. (Silver methenamine stain; ×450.)

Some patients with PDH have no major T-cell dysfunction. In fact, when they are tested after recovery from histoplasmosis, T-cell function appears normal. Goodwin and coworkers[5] postulated that these patients have a transient form of T-cell dysfunction, perhaps related to an intercurrent viral infection, which makes them susceptible to PDH. This hypothesis is interesting, but there is little direct evidence to support or reject it.

Some patients with PDH have a smoldering chronic illness. They may have a chronic wasting disease with anorexia, weight loss, and low-grade fever. Mucosal and mucocutaneous junction ulcers may occur in the mouth, oral pharynx, rectum, and glans penis. Adrenal involvement may cause Addison's disease.[45] Biopsy material from involved tissues shows well-formed epithelioid granulomas, and only a diligent search will reveal rare organisms. Demonstration of organisms usually requires special stains (Fig. 36-7). The disease may be systemic or involve only one organ. This more chronic form of PDH generally occurs in patients who are less immunosuppressed than the patients who develop more fulminant PDH.

CNS histoplasmosis is rare and may present as chronic meningitis or intracranial histoplasmoma. Endocarditis can also occur, involving either the aortic or the mitral valves. Vegetations are usually large, and emboli are common. Endocarditis may occur on prosthetic or previously normal valves. Histoplasma involvement of abdominal aortic aneurysms has been reported in a few patients with the chronic form of PDH.[46]

Diagnosis

The "gold standard" of diagnosis is culture of the fungus from biologic material or direct visualization of characteristic 1- to 2-μm yeast within macrophages. Unfortunately, direct examination of sputum is not useful because of the intracellular location within macrophages (uncommon in expectorated sputum) and the small size and nonspecific morphology of the individual yeast forms. (With *B. dermatiditis* and *C. immitis*, discussed later, direct sputum examination is much more important.) Typical histoplasma organisms can often be seen with special stains in other biologic specimens including bone marrow aspirates and tissue biopsies, bronchoalveolar lavage (BAL) fluid, and even in the peripheral blood smear of severely ill patients, most notably those with AIDS.

Mycologic Studies

Unfortunately, sputum cultures are not very useful for diagnosis of acute pulmonary histoplasmosis because the index of suspicion is usually low and the patients seldom have a productive cough. Conversely, patients with chronic cavitary histoplasmosis usually have positive sputum cultures. Specimens obtained from bronchoscopy have a high but poorly defined yield in severe primary histoplasmosis including those with progressive acute respiratory distress syndrome and in PDH in AIDS, when diffuse pulmonary involvement is a common feature.

Bronchoscopy is an important diagnostic tool, especially for PDH. Most studies examining the utility of bronchoscopy for the diagnosis of endemic fungal diseases are retrospective, include all forms of the disease (disseminated or self-limited), and do not distinguish between BAL, washings, cultures, stains, or biopsies. In addition, specific staining procedures are often not described in detail. Recent studies highlight the critical importance of cytologic examination of submitted samples with Papanicolaou staining in addition to the usual preparations (potassium hydroxide [KOH] digestion, periodic acid–Schiff [PAS], and silver stains). Bronchoscopic studies tend to include mainly immunosuppressed patients with diffuse opacities. The most studied population is the AIDS population, which has greatest density of organisms. However, other immunosuppressed groups, including patients receiving intensive cancer chemotherapy, organ transplant recipients, and patients being treated for inflammatory diseases with potent anti-TNF agents, are also at risk.[47]

In highly selected series, the diagnostic yield of bronchoscopy for diagnosis of histoplasmosis in an endemic area is about 60% in patients with radiographic abnormalities and 88% for chronic cavitary histoplasmosis.[48] In an AIDS population in Indianapolis, Indiana, fungal stains performed on BAL fluid provided a rapid diagnosis in

70% of patients; diagnostic yield increased to 89% when culture results (which were not immediately available) were included. In that series, 22% of patients had coinfections or alternative diagnoses that were detected by BAL and would not have been detected if serum histoplasma antigen testing had been the sole diagnostic test.[49] Use of cytologic examination without special fungal staining (silver, PAS) may explain the lower yield of BAL reported in series from nonendemic areas.[50] Although transbronchial biopsy is not mandatory at the time of bronchoscopy and BAL, histopathology does appear to enhance the diagnostic yield.[50] The fungus is difficult to see on standard hematoxylin and eosin stains; special stains (usually a silver stain) are needed. Special stains are particularly important when well-formed granulomas are present because of the paucity of organisms in such cases. This is the "tuberculoid" form of histoplasmosis with paucity of organisms and well-formed granulomas, in contrast to the "lepromatous" form with abundant organisms and little evidence of well-formed granulomas.

In patients with suspected PDH, sampling of the reticuloendothelial system is often effective for diagnosis. Bone marrow biopsy is likely the best and safest method.[40] (Although liver biopsy is also an excellent method to sample the reticuloendothelial system, it is not as safe and is prohibited when there is thrombocytopenia.) In heavily parasitized samples, a direct smear of the bone marrow aspirate, stained with a supravital stain such as Giemsa stain, usually gives a rapid diagnosis. On permanent histologic sections, the fungus is difficult to see on standard slides prepared with hematoxylin and eosin stain. It is best to go directly to special stains, usually one of several modifications of the silver stain. As mentioned, special stains are particularly important when well-formed granulomas are present.

Recently, the role of blood cultures in diagnosis of PDH has expanded. The lysis-centrifugation system increases sensitivity. In AIDS patients with PDH, the density of organisms is higher than in other immunosuppressed patients, and blood cultures are particularly useful, yielding a diagnosis in up to 90% of cases. In fact, in AIDS patients with PDH, typical intracellular organisms can be seen directly on peripheral blood smears (buffy coat preparations) up to 50% of the time. BAL also has a high yield, both by direct smear and by culture in AIDS patients with a high burden of organisms. BAL offers the additional advantage of ready diagnosis of other opportunistic infections that are usually in the differential diagnosis, including *P. jirovecii* pneumonia.

Skin Tests

In highly endemic areas, skin test positivity is practically universal by adulthood. To confound matters, many patients with proven PDH have a negative skin test due either to underlying T-cell deficiency or to the severity of infection. Therefore, a positive skin test never proves current histoplasmosis, and a negative skin test never rules it out. The histoplasmin skin test, however, is valuable as an epidemiologic tool. Skin test conversions are useful in the United States for diagnosing tuberculosis because background skin test positivity is low and because serial skin tests are often performed in individuals with a high chance of acquiring tuberculosis. Neither is true for histoplasmosis. Background positivity is high, and serial studies are almost never performed.

Serologic Studies

Because sputum cultures and skin tests are rarely helpful in the diagnosis of acute histoplasmosis, serologic tests are extremely important.[51] Two standard tests are available for the serodiagnosis of histoplasmosis. The first and most important is the complement fixation (CF) test. The result becomes positive 3 or more weeks after the exposure and remains positive for months or occasionally years in diminishing titer. A fourfold rise in titer or a single determination of 1:32 or higher is suggestive of recent infection. When the clinical picture strongly suggests acute pulmonary histoplasmosis (diffuse nodules 2 weeks after an appropriate exposure, a focal alveolar opacity associated with hilar adenopathy, or isolated unilateral hilar adenopathy), then a titer of 1:8 or higher has strong positive predictive value. Unfortunately, the CF test is negative in about 30% of patients with acute histoplasmosis and in up to 50% of patients with PDH. Patients with chronic pulmonary histoplasmosis frequently have titers of 1:8 or 1:16 that do not rise during the period of observation.

The second test is immunodiffusion testing for precipitating antibodies to the M and H antigens, which produce separate bands (the M band is more common and more important; the H band almost never occurs alone). The test is easy to perform and has more specificity than a low-titer CF test. Regrettably, immunodiffusion fails to identify up to 50% of patients with acute histoplasmosis and usually does not reach maximum positivity for 4 to 6 weeks after exposure.[52]

These serologic tests measure antibodies and are helpful in identifying individual patients with acute histoplasmosis. Their main drawbacks are imperfect sensitivity and lack of timeliness. Several weeks must pass before they become positive. By that time, most patients either have recovered or have required other more invasive methods of diagnosis because of rapidly worsening disease.

Another approach to diagnosis of fungal infections is the use of ultrasensitive assays for fungal antigens. Specificity is very good, but sensitivity is relatively poor in acute histoplasmosis, chronic cavitary histoplasmosis, and even PDH in mildly to moderately immunosuppressed patients. In non-AIDS patients with severe PDH, the sensitivity of urine histoplasma polysaccharide antigen may be about 80%. With severe and especially diffuse pulmonary involvement, the sensitivity of antigen testing on BAL fluid may also be in the 80% range.[53]

The extremely high density of organisms in AIDS patients with PDH makes antigen testing even better in that setting, with almost perfect sensitivity and specificity. In one study, the histoplasma polysaccharide antigen was positive in urine from 70 of 72 patients with

PDH complicating AIDS.[54] Levels of histoplasma polysaccharide antigen in urine and serum also are useful for following the course of treatment and for predicting relapses.[55,56]

Treatment

The overwhelming majority of patients with acute histoplasmosis either are asymptomatic or have rapidly resolving, self-limited disease that requires no treatment. For the rare patient with acute overwhelming pulmonary disease, treatment with amphotericin B is mandatory and may be lifesaving.[57] Treatment with corticosteroids (1–2 mg/kg/day of prednisone in single or divided doses) can be used as adjunctive therapy when there is severe hypoxemia. After clinical improvement, sequential therapy with itraconazole 400 mg/daily is continued for 6 months.

Progressive cavitary upper lobe pulmonary disease can be treated successfully with 400 mg/day of itraconazole.[58] Alternatively, amphotericin B in a total dose of 35 mg/kg may be used over a 12- to 16-week treatment course with excellent results.[59]

Severe cases of PDH in non-AIDS patients are best treated promptly and aggressively with amphotericin B until there is clear clinical improvement. Then the patient is switched to itraconazole (400 mg/day in a single daily dose) to complete a 6-month course of therapy, or 12 months if the patient has moderate immunosuppression such as organ transplantation. Itraconazole can be used from onset for patients with mild to moderate disease.[60] AIDS cases are treated differently from other PDH cases. Relapse is expected if treatment is stopped. All patients require induction therapy to control symptoms and then maintenance therapy. Amphotericin B is used initially for severely ill patients. After clinical response, treatment is changed to itraconazole (400 mg daily for 6 or more months, then 200 mg daily).[61] Lifetime maintenance treatment was recommended in the past but that is changing with more effective antiretroviral therapy. Maintenance therapy can likely be stopped if the immune system recovers to near normal, with CD4 counts above 350. Itraconazole can be used from onset for mild to moderate cases.[62] Other maintenance strategies for those intolerant of itraconazole include weekly amphotericin B infusions or fluconazole at doses of at least 400 mg/day. Ketoconazole therapy is ineffective for maintenance therapy, and fluconazole even at high daily doses (400–800 mg) is less effective than itraconazole.[63]

In a double-blind, randomized trial, liposomal amphotericin B was somewhat more effective than amphotericin B in both time of response and survival, although the differences were not statistically significant.[64] In this study, both forms of amphotericin were used for 14 days before switching to oral itraconazole therapy.

Of the newer antifungal agents, both voriconazole and posaconazole have high activity against histoplasmosis. Voriconazole penetrates better into cerebrospinal fluid. It has been used in CNS disease usually initially in combination with liposomal amphotericin B and then continued as a sequential agent for 12 months. That regimen was first used for treatment failures or relapses but now is often chosen as the first regimen. Posaconazole is very active in animal models and has been used for treatment failures, including CNS disease, in a manner similar to voriconazole. It is unlikely that these agents will ever be studied head to head with itraconazole. The echinocandins are not favorable agents for histoplasmosis.

Amphotericin B, the oral azoles (ketoconazole, fluconazole, itraconazole, and more recently, voriconazole and posaconazole), and the new echinocandins are the current treatment options for most patients with fungal diseases. Treatment is discussed as part of the discussion of each disease, but a brief overview of these agents is presented as background. Recent consensus statements of the Infectious Disease Society of America and the American Thoracic Society discuss treatment issues in greater depth.[65,66]

Amphotericin B

Since its introduction in 1955, the polyene antibiotic amphotericin B has been the mainstay of therapy for most systemic fungal diseases.[67] It is highly effective but has potentially serious side effects. Renal toxicity is most prominent.[68] A dose-dependent reduction of renal function is almost universal. Monitoring renal function at least once a week is mandatory, and reduction of dosage is advisable once the creatinine level reaches 2 mg/dL. Tubular potassium wasting is common, and weekly monitoring of the serum potassium level is advisable to monitor adequacy of potassium supplementation.

Febrile reactions, often with severe chilling, are common. Premedication with 600 mg aspirin and 50 mg diphenhydramine 30 minutes before the start of the infusion and shortening the infusion time to 2 to 3 hours are strategies to reduce the frequency of serious febrile reactions. Pretreatment with intravenous narcotics (meperidine, 50–75 mg) is more effective in preventing amphotericin B reactions, but narcotics should be used only for severe reactions. Usually the reactions, even when initially severe, decrease over the first few weeks of therapy, so narcotic pretreatment can be discontinued.

In stable adult patients, 10 mg amphotericin B can be given on the first day, with daily increments of 10 mg to a dose of 50 mg on the fifth day. If the patient is doing well, 50-mg infusions are given on a Monday-Wednesday-Friday schedule. The package insert recommends a usual dose of 0.5 to 0.7 mg/kg/day, with a maximum daily dose of 1.0 mg/kg. However, to minimize nephrotoxicity, we prefer not to exceed 50 mg as a single daily dose, except in selected patients with invasive aspergillosis. To avoid the problem of diminishing and destroyed peripheral veins, we frequently insert a central venous catheter or a peripherally inserted central catheter. When a patient is critically ill, the early phase of administration of amphotericin B is accelerated. The first infusion contains 20 mg, which is then followed by a further infusion of 30 mg the same day, followed by the daily administration

of 50 mg amphotericin B until the patient is stable. Then the usual Monday-Wednesday-Friday regimen is begun.

The lipid formulations of amphotericin B have less renal toxicity. It is unproved that they have higher efficacy, and their cost is much higher. A review of their safety and efficacy has been published.[69] In a study mentioned previously, amphotericin B was compared with liposomal amphotericin B for initial treatment of PDH complicating AIDS.[64] The observed differences in the two arms were not statistically significant, but liposomal amphotericin B was at least as effective as amphotericin B, with marked reduction in renal toxicity. Infusion-related side effects were slightly but not dramatically reduced. Amphotericin B dosing of 1.0 mg/kg/day or higher almost always causes renal impairment. Diseases requiring amphotericin B dosing at that level, including invasive aspergillosis, should likely be treated with liposomal amphotericin B from onset.

There are differences in the various lipid-based formulations of amphotericin B. In a large study, amphotericin B colloidal dispersion (ABCD) was compared with standard amphotericin B in patients with well-documented aspergillosis. The ABCD also had reduced nephrotoxicity when compared with amphotericin B, but the infusion-related side effects (fever and chilling) with ABCD were more frequent than with the parent compound.[70]

Imidazoles

Ketoconazole, an orally administered imidazole, was the first alternative to amphotericin B for stable patients with mild to moderate cases of histoplasmosis, blastomycosis, and coccidioidomycosis without meningeal involvement.[71] Ketoconazole and the other oral azoles are never indicated for a critically ill patient because they are less potent and have slower onset of positive effect. Ketoconazole is started at 400 mg/day, given once a day before breakfast. If the illness progresses or new lesions appear at the end of 1 month, the daily dose is increased by increments of 200 mg to a total dose of 800 mg/day. There is uncertain added benefit from doses greater than 800 mg/day, although some authorities routinely exceeded that dose, especially in the treatment of coccidioidomycosis.

The main toxicity of ketoconazole is gastrointestinal. Nausea and vomiting are common once the dosage exceeds 400 mg/day. When a higher dose is used, splitting it as equal morning and evening doses frequently allows continued administration of the agent. Gastric acidity is necessary for absorption, and the dosage must be increased to compensate for reduced absorption in achlorhydric patients.[72] Proton pump inhibitors, histamine$_2$ receptor blockers, and even antacids should not be used in patients taking ketoconazole.

Ketoconazole is a potent antitestosterone agent.[73] Decreased libido is common, and aspermia has been noted in some patients. Impotence may force discontinuation. In higher doses, the drug may also block synthesis of cortisol. A single large morning dose has less effect on cortisol secretion than smaller split doses but, as mentioned, may not be tolerated because of nausea and vomiting.

Fluconazole was the second oral azole to become available. The usual dose is 200 to 400 mg/day in a single daily dose. It is well absorbed even without gastric acidity. It has excellent tissue penetration and reaches high levels in cerebrospinal fluid. It is excreted in the urine in high concentrations. For most AIDS patients with cryptococcal meningitis, fluconazole is equally effective compared with standard combined therapy with amphotericin B and 5-flucytosine.[74] Fluconazole is more effective than ketoconazole for candidal esophagitis in patients with AIDS. Fluconazole has also been used with some success for several forms of chronic coccidioidomycosis, including chronic pulmonary infection and meningitis (for primary therapy of mildly symptomatic patients and for long-term maintenance therapy of sicker patients after initial response to amphotericin B). Fluconazole has also become a primary therapy for AIDS patients with disseminated coccidioidomycosis who are stable on presentation, and it is a good maintenance therapy for sicker patients if they improve clinically after an initial course of amphotericin B therapy.

Itraconazole is a potent antifungal agent with a wide range of activity but poor absorption and high protein binding, penetrating poorly into cerebrospinal fluid. The usual dose is 200 to 400 mg/day in a single daily dose. Like ketoconazole, it requires some gastric acidity for maximal absorption. Compared with ketoconazole, it has similar though milder gastrointestinal side effects and a similar but less marked effect on testosterone synthesis. It is the first oral agent with reasonable activity against *Aspergillus* species, and it is useful in solid organ transplant recipients with pulmonary aspergillosis.[75] It is more effective than ketoconazole or fluconazole for treatment of histoplasmosis and blastomycosis.[76]

Itraconazole is very effective for long-term suppression of histoplasmosis in patients with AIDS. Because it is more potent and less toxic than ketoconazole, it has largely replaced that agent for selected cases of histoplasmosis and blastomycosis. It does not replace amphotericin B, which is still necessary for initial treatment of severe infections. Itraconazole has some efficacy for coccidioidomycosis, but is not a major breakthrough for that disease, for which even amphotericin B is marginally effective in some difficult cases. The relative advantages and disadvantages of the various azoles have been reviewed.[77]

V*oriconazole*, a relatively new triazole, combines the potency and wide spectrum of activity of itraconazole and the excellent cerebrospinal fluid and tissue penetration of fluconazole. This agent has excellent bioavailability after oral administration, allowing ready switch from initial intravenous therapy. In adults over 40 kg, a loading dose is recommended for both intravenous therapy (6 mg/kg every 12 hours for two doses) and oral therapy (400 mg by mouth for two doses). After the loading dose, the daily maintenance dose for treatment of aspergillosis is 4 mg/kg every 12 hours. For less serious infections, 3 mg/kg every 12 hours is recommended. For oral use, voriconazole should be taken either 1 hour before or 1

hour after a meal at the dose of 200 mg every 12 hours. For smaller adults, the package insert should be consulted for dosing information.

Rarely, voriconazole can cause severe hepatic injury. The drug should not be used in patients with moderately reduced hepatic function. A common side effect is visual changes, consisting of blurred vision, flashing bright lights, and the appearance of wavy lines. Eye symptoms may occur in as many as half the patients but fortunately resolve upon discontinuing the agent and cause no eye damage.[78]

Another relatively new potent imidazole is posaconazole. Like voriconazole it has wide spectrum of activity, good absorption after oral intake, and good tissue penetration. It has more activity against mucor species than other azoles.

Caspofungin was the first of several echinocandins,[79] a new class of antifungal drugs that inhibits fungal cell wall synthesis by inhibiting 1,3-β-D glucan synthesis. The drug has an excellent safety profile and is well tolerated. It is available only for intravenous administration. Clearance is somewhat reduced in women and in the elderly, but dose adjustment is not necessary. No dosage changes are needed in patients with renal insufficiency, and because it is not removed by hemodialysis, no adjustments are needed in this population either. In the presence of moderate liver disease (Child-Pugh score of 7–9), the dose must be reduced. The standard loading dose is given, but the daily maintenance dose is reduced by about a third. When caspofungin is given with cyclosporin A, caspofungin level is increased by approximately 35%, without any change in cyclosporin A levels. Conversely, when caspofungin is given with tacrolimus, the caspofungin level does not change, but the tacrolimus level is decreased by 20%. More importantly, caspofungin has no pharmacokinetic effect on amphotericin B or itraconazole. The drug is currently approved for the treatment of esophageal and invasive candidiasis and for invasive aspergillosis. Because it has low toxicity and no apparent effect on amphotericin B kinetics, it is being used in combination with liposomal amphotericin B for seriously ill patients with these infections, even in the absence of data from clinical trials.[79] The loading dose of caspofungin is 70 mg, followed by 50 mg daily; in moderate liver disease, the daily dose is 35 mg.

BLASTOMYCOSIS

Blastomycosis is the illness caused by the thermal dimorphic fungus *B. dermatitidis*. The spectrum of disease ranges from the asymptomatic acquisition of delayed, sometimes transient, hypersensitivity to a rapidly progressive and life-threatening respiratory or disseminated illness.

History and Epidemiology

Blastomycosis is the only one of the three common endemic mycoses of North America that was first described on this continent. In 1894, Gilchrist[80] reported the first case in Baltimore, Maryland. He initially thought that the causative agent was a protozoan. This was similar to Darling's later speculation about the cause of histoplasmosis. However, Gilchrist quickly corrected his mistake. With Stokes, he isolated the organism, determined that it was a fungus, and infected a dog with the isolate, successfully fulfilling Koch's postulates.[80,81]

Soon it became apparent that the disease was more common in the central United States than along the eastern seaboard. Although individual cases were reported regularly, there was little increase in knowledge about the disease beyond the description of individual cases. In 1939, Martin and Smith[82] from Duke University reviewed all the available case material and offered an analysis that later proved incorrect. They thought that the purely cutaneous form of the infection was distinct from the pulmonary illness, with a different portal of entry and a different natural history. In 1951, Schwarz and Baum[83] disproved this artificial separation by showing that the cutaneous form of the disease almost always represented distant spread from a pulmonary focus.

The epidemiology of blastomycosis has remained a difficult puzzle. Because of the obvious similarities between histoplasmosis and blastomycosis, investigators attempted to duplicate the kind of experiments that defined the epidemiology of histoplasmosis but with little success. Attempts to isolate *B. dermatitidis* from soil and define its ecologic niche mostly failed. Attempts to develop a sensitive, reproducible, and useful skin test also failed.

Because there is no good skin test, large-scale skin test surveys have not been possible. The exact endemic area for blastomycosis has not been defined with any degree of certainty, but has been deduced only by the location of reported cases.[84] The proposed endemic area includes much of the central, south-central, and southeastern United States, beginning near the Minnesota–North Dakota border and extending eastward and southward. The southeastern limit extends to South Carolina but not to Florida. This area overlaps most of the endemic area of histoplasmosis.[1] However, the northern limit extends much further. Northern Minnesota and northern Wisconsin and also the adjacent Canadian provinces of Ontario and Manitoba are endemic for blastomycosis but are free of histoplasmosis.[85–88]

As mentioned, early attempts to develop a blastomycin skin test failed. Large series of patients with blastomycosis were tested with various skin test antigens, with mixed results. Most patients had a negative blastomycin skin test reaction. Many of the same patients had a positive histoplasmin skin test reaction.[89] These results led to the conclusion that the blastomycin skin test was insensitive and that there was a great deal of cross reactivity between histoplasmin and blastomycin.

An alternative explanation for these results is also possible. Most of the patients who were skin tested in these studies had widely disseminated blastomycosis. Even those with disease limited to the lungs were often severely ill. Under these circumstances, negative blasto-

mycin skin tests would not be surprising. In addition, because virtually all patients were from the endemic area for histoplasmosis, any positive histoplasmin skin test reactions might have reflected previous, unrelated infection with *H. capsulatum*.

Careful investigation of two large point-source outbreaks supports this view. In the 1972 Big Fork, Minnesota, outbreak, 18 of 21 exposed persons had evidence of blastomycosis.[86,90] Big Fork is in northern Minnesota, beyond the endemic area for histoplasmosis. Twelve patients had an abnormal chest radiograph compatible with acute pulmonary blastomycosis. Ten of the 12 had positive blastomycin skin test reactions. An additional 6 patients had a normal chest radiograph but a positive blastomycin skin test. Thus, 16 of the 21 patients at risk had a positive blastomycin skin test reaction. Only 1 of the 21 at-risk individuals had a positive histoplasmin skin test. Surprisingly, when the 16 blastomycin-positive individuals were retested 3 years later, only 5 were still positive.[91] These results suggest that the blastomycin skin test can be quite useful in point-source outbreaks of acute pulmonary blastomycosis, at least when the issue is not confused by high background skin test positivity to histoplasmin. Furthermore, positive blastomycin skin test reactivity might be short-lived (if true, this represents a difference from the other endemic mycoses, for which skin test positivity is more durable).

During the summer of 1984, an even larger point-source outbreak of blastomycosis occurred in Eagle River in northern Wisconsin. Eagle River, like Big Fork, is north of the endemic area for histoplasmosis. A total of 99 individuals were at risk, and 87% of the total demonstrated either a positive blastomycin skin test reaction or a positive lymphocyte transformation to an alkali-soluble and water-soluble *B. dermatitidis* antigen (AWSE), or both. All patients were histoplasmin skin test negative. The investigators recovered the fungus from a beaver lodge, which was the apparent source of the outbreak.[92,93]

When one examines these two outbreaks and other more recent reports, a much clearer picture emerges. Like *H. capsulatum, B. dermatitidis* is a soil-dwelling fungus. Infection occurs by inhalation of airborne spores. Infected individuals develop a positive blastomycin skin test reaction or the in vitro correlate of delayed hypersensitivity. As with histoplasmosis, isolated microfoci of high infectivity exist in a large endemic area. Such foci are likely even more restricted, and it is much harder to culture *B. dermatitidis* from nature. Outbreaks often occur during activities close to recreational waterways[94]; these are most common when soil temperatures have been increasing for several days and when there is rain on the day of exposure. For sporadic cases, residence close to water in a highly endemic area and recent excavation activity are risk factors.[95,96]

Dogs are also susceptible to blastomycosis. Canine blastomycosis is a well-recognized entity in veterinary practice in the endemic areas. The recognition of canine cases in a community should alert physicians that human blastomycosis may be present in their geographic area.[84,97]

Skin test surveys for histoplasmosis and coccidioidomycosis have proved that there are many subclinical and barely clinical infections. Because no skin test surveys for blastomycosis have been possible, most diagnosed patients have had symptomatic infections. Epidemiologic study of two large outbreaks cited suggests that there are subclinical cases of blastomycosis, as does the clinical pattern of patients presenting with distant disease (skin, bone, prostate) without clear history of previous pneumonia. Based on in vitro lymphocyte responses, a study of highly exposed forestry workers also suggests that a sizable minority of such workers, perhaps 30%, have had previous blastomycosis, without a past history of clinically apparent pneumonia.[98] This suggests that there is considerable undiagnosed and self-limited blastomycosis, but that it may not be nearly as large as it is for the other two major endemic mycoses.

Pathogenesis

At ambient temperatures, the fungus grows as an aerial mycelium. When foci of actively growing *Blastomyces* are disturbed, small, 2- to 5-μm, spores become airborne and are infective. These particles may be inhaled by humans or by other mammals disturbing the site. Some spores may escape the nonspecific defenses of the lung and reach the alveoli.

The initial inflammatory response is neutrophilic. As the organism converts to the parasitic yeast form and begins to multiply, large numbers of yeast are seen, surrounded by neutrophils. Then macrophages increase in number. Eventually, as specific cellular immunity develops, there are giant cells and well-formed epithelioid granulomas. Histopathologic examination often shows a mixed pyogenic and granulomatous response, even in chronic cases.[2]

The major mediator of immunity is a specific Th1 T lymphocyte response. Blastomyces yeast produce a specific protein, initially named WI-1, which adheres to the yeast surface and is both an adhesin and a virulence factor. Because of that property, the antigen was renamed the blastomyces adhesion protein or BAD-1. This protein reduces host TNF-α and increases transforming growth factor-β, thus down-regulating the Th1 response[99,100] in addition to promoting adhesion to pulmonary epithelial cells and macrophages. An experimental strain of blastomycosis that does not produce the BAD-1 protein has reduced virulence in animals[101] and may conceivably be a candidate for a live, attenuated vaccine in high-risk groups.

The histopathologic response in cutaneous blastomycosis is striking. The stratified squamous epithelium becomes markedly hyperplastic, with exaggerated downgrowth of the rete pegs. Within these finger-like projections are a number of microabscesses. The same hypertrophic tissue response is seen when the disease involves the oropharynx or the larynx. The histopathologic appearance may superficially resemble carcinoma. The uniformly benign appearance of the individual cells excludes cancer, however, and the characteristic organisms, seen best with special stains, provide a diagnosis.

The initial inflammatory and immune response may confine the infection to the lungs and the hilar lymph nodes. It is likely (but not proved) that self-limited early fungemia does not occur as often as it does in histoplasmosis. However, in some instances, the organism spreads beyond the lung and the hilar nodes. Dissemination is usually to skin, bones, prostate, and meninges but can be seen in any organ.[2,89]

The incubation time for blastomycosis is longer than that for histoplasmosis and more variable. In the Eagle River outbreak, in which time of exposure was short and precisely defined, the median incubation period was 45 days, with a range of 21 to 106 days.[92,93]

Clinical Manifestations

The portal of entry is almost always the lung, except for rare cases of direct inoculation,[102] and the primary illness is a lower respiratory infection. Some patients have an acute illness that resembles bacterial pneumonia, in contrast to acute pulmonary histoplasmosis, which more closely mimics influenza. The onset of symptoms is abrupt, with high fever and chills, followed by cough that rapidly becomes productive of mucopurulent sputum. Pleuritic chest pain may occur.

This acute onset is common in an outbreak setting, but also may be seen in sporadic cases. In fact, blastomycosis must always be considered in the differential diagnosis of severe community-acquired pneumonia, especially if there is disease progression on empirical antibacterial therapy. However, in most sporadic cases, the onset of clinical symptoms is more gradual. The patient presents with a low-grade fever, productive cough, and weight loss.[89,103] Lung cancer and tuberculosis are highest in the differential diagnosis, rather than bacterial pneumonia, depending on the radiographic findings.

Physical examination is sometimes normal usually unremarkable except for fever. Auscultation of the chest in patients who have segmental or lobar opacities may show crackles and focal consolidation; more often, the pulmonary examination is negative. Skin lesions are highly variable in appearance, ranging from subcutaneous nodules and abscesses to papules to ulcers with heaped-up borders mimicking squamous cell cancers. Perhaps the most characteristic lesion has irregular borders and a crusted surface, varying in size from 1 to 10 cm or more (Fig. 36-8). Skin lesions may be single or multiple and may occur in crops of several new lesions daily or every few days if the disease is rapidly disseminating.

Routine laboratory tests are seldom helpful. In cases resembling acute bacterial pneumonia, the white blood cell count is elevated and, frequently, there is a left shift in the granulocyte series.

There is no "characteristic" chest radiographic pattern in blastomycosis.[104] Lesions may vary from single or multiple round densities to segmental or lobar consolidation. Severe pulmonary infections can present with diffuse nodular, interstitial, or even alveolar radiographic changes. The diffuse alveolar opacities can be identical to acute respiratory distress syndrome of diverse cause. Masslike perihilar shadows, especially on the right side, are common and are often misinterpreted as neoplastic. On the lateral chest radiograph, the masslike lesion is usually behind the hilum, in the apical-posterior segment of the lower lobe. Hilar lymph node involvement may occur but is not nearly as common as in histoplasmosis. Cavities may occur during the acute phase of the illness and usually close during successful treatment. Unlike histoplasmosis, calcification due to healed blastomycosis is rare.

FIGURE 36-8 ■ Photograph shows a characteristic large crusted skin lesion above the elbow in a patient with blastomycosis. A punch biopsy of the edge of the lesion revealed characteristic yeast forms on histopathology.

Extrapulmonary spread of the fungus may occur during the acute, symptomatic phase of the illness. In some instances, only the distant lesion (usually skin or bone) is symptomatic. During evaluation, an asymptomatic chest radiographic abnormality is sometimes discovered. Often, however, the pulmonary process has already resolved spontaneously by the time the extrapulmonary focus becomes apparent, and the chest radiograph is normal. These are the patients with the so-called isolated cutaneous form of the disease, which caused so much confusion in the past. Careful history sometimes but not always reveals a preceding self-limited pulmonary illness. Laskey and Sarosi[105] reported patients whose pulmonary blastomycosis was initially symptomatic but resolved spontaneously without being diagnosed. When extrapulmonary blastomycosis occurred (as much as 3 years later), the pulmonary infections were retrospectively proven blastomycotic by review of cytology specimens obtained during the original illnesses.

The skin and the bony skeleton are the most common sites of symptomatic extrapulmonary spread. The prostate gland, meninges, oral pharynx, larynx, and abdominal viscera, including the liver and the adrenal glands, are involved less frequently.[2]

Blastomycosis can present as a progressive infection in patients with T-cell defects, including organ transplant recipients and other patients being treated with glucocorticoids and other immunosuppressive therapy for malignant and nonmalignant disorders.[106] As with histoplasmosis, the disease can often be cured with amphotericin B and/or azoles in patients with intermediate

degrees of immunosuppression. Blastomycosis can also occur in AIDS. Infection is particularly severe, and cure is less likely. Maintenance therapy is required for those patients who do respond to initial treatment. Blastomycosis is much less common in AIDS and other T-cell–deficient conditions than are histoplasmosis and coccidioidomycosis. This is probably because exposure to this fungus while immunosuppressed is less common and perhaps because there is a smaller reservoir of patients with remote healed infection waiting to relapse should T-cell function markedly decline.[107]

Diagnosis

The easiest and most rapid method of diagnosis is examination of expectorated sputum or aspirated pus after 10% KOH digestion.[2] The characteristic large (8- to 20-μm) organism is easily identified. The yeast is single budding, with a broad neck of attachment between the parent and the daughter cells. The wall is thick and is double refractile, and there are multiple nuclei (Fig. 36-9). Other direct fungal stains, including PAS, calcofluor white, and silver stains, are more sensitive. Another sensitive technique for rapid diagnosis of blastomycosis on direct sputum smears is cytologic analysis with the standard Papanicolaou stain. In one study, sputum samples were positive by direct examination in 78% of patients using the Papanicolaou stain compared with only 37% when using a combination of KOH digestion and PAS staining. The direct techniques are probably complementary, and examining multiple sputum samples increases diagnostic yield.[108]

The role of bronchoscopy for diagnosis of pulmonary blastomycosis is not well defined. Bronchoscopy is useful when patients are unable to expectorate adequate sputum, when urgent diagnosis is needed because of rapid pace of the illness, and when the clinical presentation is compatible with malignancy or tuberculosis. In one study, bronchoscopy was diagnostic in 92% of patients when culture results were included in the final analysis; specimens obtained included BAL fluid in 64% and bronchial washings in all.[109] For patients who are acutely ill or have a clinical picture similar to that of acute respiratory distress syndrome, rapid diagnosis is crucial and can be achieved only by direct examination of respiratory secretions or by lung biopsy. If direct sputum smears are negative or not possible, then bronchoscopy should be done urgently, with BAL fluid and bronchial washings sent both for direct fungal stains (some combination of KOH, calcofluor white, silver stain, PAS, and cytology preparation) and for culture.[110] A reasonable combination of direct techniques might include KOH preparation or calcofluor white, a silver stain, and a Papanicolaou stain. The cytology laboratory should be informed whenever there is high clinical suspicion of fungal infection. Fungal organisms can easily be overlooked if the examination is focusing on malignant cells.[111] Cell blocks of concentrated BAL fluid can be done to maximize the yield of the submitted specimens.

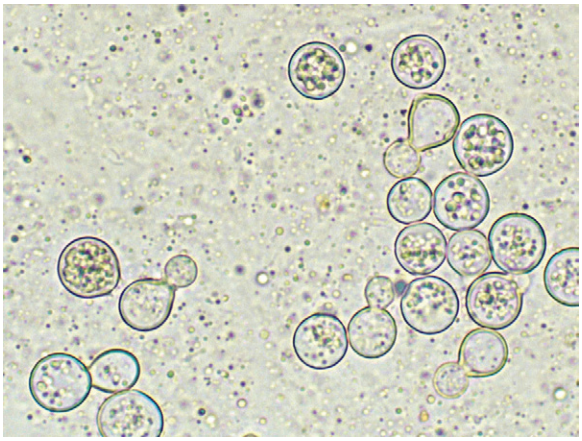

FIGURE 36-9 ■ Micrograph shows *Blastomyces dermatitidis* in fresh sputum after 10% potassium hydroxide digestion. Note the broad neck of attachment, the double refractile cell wall, and the multiple nuclei. (Original magnification ×1000.)

Histopathologic examination of biopsy material is also an excellent way to establish the diagnosis. Standard hematoxylin and eosin stains do not show the fungus, and special stains are required. The PAS stain preserves morphologic detail, but silver stains are more commonly used and likely have better sensitivity. The decision whether or not to perform transbronchial biopsies at the time of initial bronchoscopy will likely depend on contraindications in any given patient that give added risk beyond risk of BAL and on the height of clinical suspicion for malignancy. If infection is much more likely than malignancy, bronchoscopy with BAL can be the initial procedure, reserving transbronchial biopsy for cases with no diagnosis from a safer and easier first procedure. Open lung biopsy may be necessary in selected cases.

Identification of the fungus by culture is not difficult, but it is slower than direct microscopic examination. Growth may occur as early as 5 to 7 days but often takes several weeks. Exoantigen testing can provide positive identification as soon as good growth is established. Formerly, positive identification required conversion of the mycelial culture to the yeast phase of growth, adding 1 or more weeks of delay.

There is no commercially available skin test antigen. Experience during two outbreaks of blastomycosis (described earlier) suggests that skin testing with various antigens may be useful for epidemiologic investigation of outbreaks. In the epidemic in northern Wisconsin, in vitro transformation of antigen-stimulated lymphocytes was an excellent test to identify infected individuals.[112] However, that test is not available for clinical use.

In some cases, the entire clinical picture, including the chest radiograph, suggests cancer rather than infection. Sputum and bronchoscopy specimens are mainly sent for cytologic evaluation, including Papanicolaou stains. Fortunately, the cytology preparations often show the fungus.

Serodiagnosis of blastomycosis remains problematic. The tests (usually immunodiffusion and CF tests to detect antibodies) have lacked sensitivity. Specificity has also been poor due to cross reactions with histoplasmosis, which is a much more common disease. Of course, any

positive test results should focus diagnostic efforts toward proving or disproving blastomycosis. Tests using blastomycin (crude mixture of antigens) and even somewhat purified antigens such as "AWSE (alkali and water soluble extract)" and "antigen A" all have major cross reactivity. It appears that what was described as antigen A was essentially the BAD-1 protein plus a carbohydrate component and that the cross reactivity was largely contained within the carbohydrate portion. It is hoped that better serodiagnostic tests can be developed using specific protein antigens—both tests for host antibodies and tests to identify antigens directly in appropriate biologic specimens. There is one commercially available test for blastomyces antigen in urine and other biologic specimens including cerebrospinal fluid and BAL fluid.[113] It is sensitive in pulmonary and disseminated blastomycosis in selected cases. It is also positive (cross reactions) in more than 95% of selected cases of histoplasmosis. A commercially available histoplasma antigen can also be used diagnostically (in BAL fluid) for suspected blastomycosis cases, because the cross reactivity is so high.[53] It is seldom positive in coccidioidomycosis, other fungal pneumonias, or other pulmonary infections. At present, most cases of blastomycosis are diagnosed in relatively low-tech fashion, by smear, culture, and histopathology on appropriate specimens obtained by astute clinicians. However, major advances in immunodiagnosis may be close.

Treatment

The most severely ill patients with pulmonary blastomycosis require aggressive antifungal treatment, as discussed later. However, there is some controversy as to whether all patients with acute pulmonary blastomycosis require treatment. It is likely that some patients with acute pulmonary blastomycosis would recover without treatment (Fig. 36-10). That was first suggested during the Big Fork, Minnesota, outbreak in 1972. All the patients recovered without specific antifungal therapy.[90] After that experience, 39 carefully selected patients (blastomycosis limited to the lung, acute onset, not severely ill, and already improving when diagnosed) were followed carefully without treatment. All of these patients recovered, and only 1 of the 39 patients followed for up to 20 years had a relapse.[114]

The self-limited nature of some cases of blastomycosis was confirmed during the northern Wisconsin outbreak in the summer of 1984. Klein and associates[92] found 9 "definite" and 39 "probable" cases of acute pulmonary blastomycosis. Of these, 26 were symptomatic and 22 were asymptomatic. Although the 9 patients culturally proved to have the disease were all treated with amphotericin B, the 39 probable patients were not. All probable cases, many with symptoms of pneumonia and abnormal chest radiographs, had complete clinical recovery. Chest radiographs either cleared completely or remained stable. Together these experiences suggest that some highly selected patients with acute pulmonary blastomycosis may safely be followed without treatment.

However, amphotericin B is no longer the only available therapy. There is safe and nontoxic oral therapy with itraconazole. Withholding treatment should be considered only for those patients who present with an acute pneumonia, have relatively mild initial symptoms, and are already improved by the time a specific diagnosis is established—usually by the late return of a positive culture from a respiratory specimen. All patients who are ill at the time of diagnosis should be treated.

Most patients with sporadic pulmonary blastomycosis present with subacute or chronic symptoms (chronic cough, low-grade fever, night sweats, and weight loss) of weeks' to months' duration more closely resembling tuberculosis or lung cancer than acute bacterial pneumonia. All such patients require antifungal therapy to improve their symptoms and prevent progression of disease (Fig. 36-11).

Itraconazole is highly effective for blastomycosis and is the treatment of choice for most patients with pulmonary and nonmeningeal disseminated disease. Oral therapy with 400 mg/day for 6 months successfully treats most patients with mild to moderate pulmonary disease and skin disease. Twelve months' duration of therapy is preferred for bone disease. Amphotericin B to clinical improvement followed by itraconazole in the same manner is preferred for a small minority of severely ill patients, including all patients with diffuse pulmonary involvement and severe gas-exchange abnormalities.

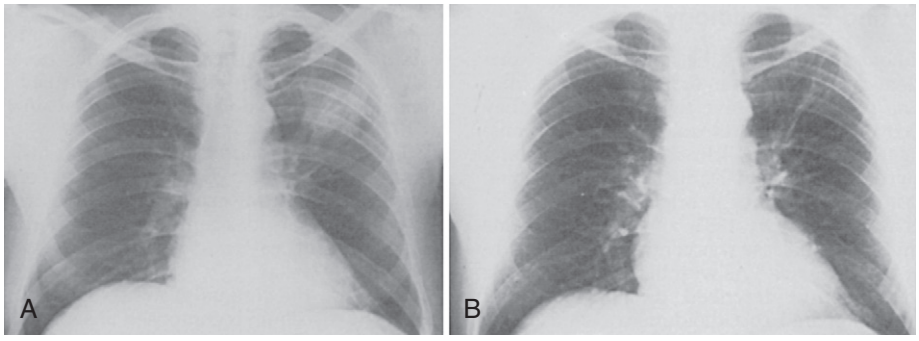

FIGURE 36-10 ■ Chest radiographs show acute self-limited pulmonary blastomycosis. **A,** A chest radiograph taken at the time of diagnosis. Note the left upper zone opacity. **B,** Four months later, the opacity has cleared, leaving a small scar. The patient has remained well for over 4 years.

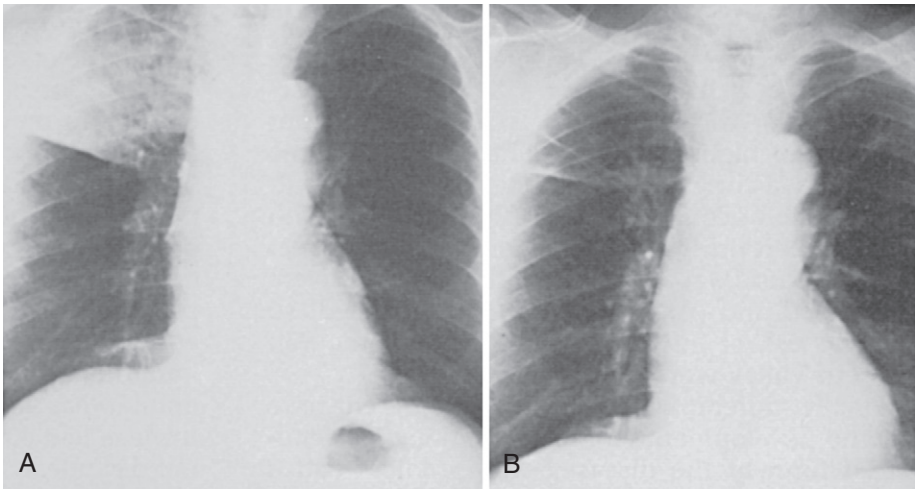

FIGURE 36-11 ■ Chest radiographs show pulmonary blastomycosis successfully treated with ketoconazole. The patient also had a skin lesion. **A,** A chest radiograph taken at the time of diagnosis. Note the right upper lobe alveolar opacity. **B,** After 4 months of ketoconazole treatment, the chest radiograph shows near-complete resolution.

Corticosteroids may have an adjunctive role and may improve gas exchange.[115] Patients with edematous lobar pneumonia (bulging fissures), extremely toxic patients, and patients who are rapidly disseminating should also receive amphotericin B as initial therapy. This general approach is also used for AIDS patients except that lifelong maintenance therapy with itraconazole is needed after induction therapy to prevent relapse (unless immune status returns to nearly normal levels with antiretroviral treatment). Itraconazole is poorly absorbed, although the liquid formulation is somewhat better. The drug has high protein binding and penetrates the CNS poorly.

Meningeal blastomycosis is treated with systemic amphotericin B therapy in standard doses. Liposomal amphotericin B achieves higher brain tissue levels in animals and may be preferred. Fluconazole is overall less potent for blastomycosis than itraconazole but penetrates the CNS much better. High-dose fluconazole (often in combination with liposomal amphotericin B) has been used for CNS blastomycosis.

Because it is better absorbed and has better tissue penetration, voriconazole is theoretically attractive for some forms of blastomycosis, including CNS infections and pulmonary and systemic infections in patients who have poor absorption of itraconazole. There are case reports of use of voriconazole after failure of other regimens, particularly for difficult CNS cases.[113,116,117] Posaconazole has activity against blastomyces in animal models but has not been studied in clinical trials. The echinocandins do not have good activity against blastomyces and, unlike voriconazole, probably should not be used as alternative therapy. Controlled trials comparing itraconazole with newer azoles will likely never be done.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is the illness caused by the tissue-dimorphic fungus *C. immitis* or *Coccidioides posadasii*. Although most infections are mild and self-limited, the spectrum of illness includes life-threatening pulmonary disease and widely disseminated systemic disease with a high mortality rate. Differences from histoplasmosis and blastomycosis include different endemic area, higher frequency of meningeal infections, and poorer therapeutic response to all antifungal agents, including amphotericin B. Similarities to histoplasmosis and blastomycosis include induction of effective cellular immune responses, ability to mimic typical community acquired pneumonia, and formation of residual nodules, worrisome for malignancy, on radiographic imaging.

History and Epidemiology

Coccidioidomycosis, the first discovered of the endemic mycoses, was identified in Argentina in 1892. The investigators thought they had found a new protozoan infection, a mistake later repeated in the initial descriptions of blastomycosis in 1894 and histoplasmosis in 1906. The fungal origin of coccidioidomycosis was proved by 1905, and it soon became apparent that the disease was common in the southwestern United States.[118] As in histoplasmosis, the early reports described dramatic cases of widely disseminated coccidioidomycosis that were always fatal.

Observations by Dickson[119] and Dickson and Gifford[120] enlarged the recognized clinical spectrum of coccidioidomycosis. They demonstrated that primary infection with *C. immitis* was the cause of several acute self-limited syndromes that had been noticed in the San Joaquin Valley in California. These included a nonspecific febrile illness ("valley fever"), an acute polyarthritis ("desert rheumatism"), and erythema nodosum ("the bumps"). They also demonstrated that the primary pulmonary infection was common, was mostly benign, and usually did not disseminate.[119,120]

When World War II broke out, the San Joaquin Valley was chosen for flight training because of the large

number of clear-sky days and the ample space available to construct airfields and supporting facilities. In a series of elegant studies, the epidemiology of coccidioidomycosis was defined, largely through the efforts of C. E. Smith.[120a–120f] All recruits were skin-tested with coccidioidin on arrival. Those with negative skin tests were susceptible to coccidioidomycosis. Many recruits had skin test conversion from negative to positive, without any symptoms. A minority had symptoms with the primary infection. Most had a self-limited febrile respiratory illness, sometimes with polyarthralgias. Less than 1% of infections progressed to dissemination. Recruits with a positive skin test on arrival were protected and did not become ill. The risk of infection was lowest during the wet and cold winter season and highest during late summer, when the weather was driest. New infections correlated with construction activity and were most frequent with construction during the dry months, when a great deal of dust was raised. As the air bases were completed and construction activity decreased, so did the risk of infection. Finally, black soldiers had a higher risk of dissemination than did white soldiers, even though the incidence of primary disease (as judged by skin test conversion) was the same.[121,122]

The endemic area for coccidioidomycosis in North America is the southwestern United States and the contiguous areas of northern Mexico. In the United States, this includes central and southern California and extends eastward to Arizona, New Mexico, and western Texas. In nature, the fungus grows as an aerial mycelium with septate hyphae. Alternating cells form thick-walled, barrel-shaped structures called *arthroconidia*, with empty cells in between. When a natural site harboring the fungus is disturbed, the mature arthrospores easily detach and become airborne, producing an infective aerosol. Strong winds can carry the arthrospores for long distances. A huge wind storm that blew north from the San Joaquin Valley in 1977 caused a major outbreak of coccidioidomycosis in Sacramento, far north of the usual endemic area.[123] Not surprisingly, occupations and activities with exposure to the soil carry the greatest risk for infection, including construction work, farm labor, and working on archeological digs.[124,125] In a recent study, 29% of patients with community-acquired pneumonia had positive serologic tests for coccidioidomycosis, suggesting this infection is a frequent cause of pneumonia in the endemic areas.[126] The overall frequency of coccidioidomycosis has been increasing since the late 1990s, especially in North America.[127]

Pathogenesis

After being inhaled, some arthrospores evade the nonspecific lung defenses and reach the alveoli, where germination begins. The arthrospores develop into spherules, the tissue phase of the fungus. Spherules are large, round, thick-walled structures that vary in diameter between 10 and 80 µm. Reproduction of the fungus occurs within the spherule (Fig. 36-12). The cytoplasm of the spherule undergoes progressive cleavage, forming numerous endospores within the spherule. Once a spherule matures, it bursts and releases the endospores into the surrounding tissues. Each endospore can become a new spherule and thus repeat the process.

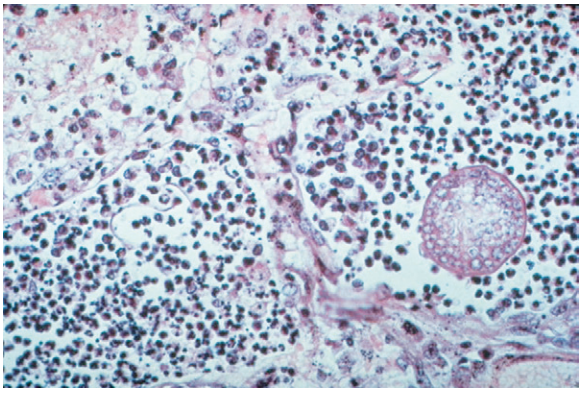

FIGURE 36-12 ■ Photomicrograph shows characteristic giant spherule of coccidioidomycosis in a lung biopsy. (Hematoxylin and eosin stain; original magnification ×450.)

The initial inflammatory response to inhaled arthrospores is neutrophilic. Resident alveolar macrophages also phagocytose the arthrospores and prime specific T lymphocytes, which multiply, recruit more macrophages, and arm the macrophages, engaging specific cell-mediated immunity. Even though many well-formed granulomas are seen, the neutrophilic inflammatory exudate does not disappear. Histopathologically, there is a mixed granulomatous and suppurative reaction with perigranulomatous clusters of B cells and interspersed CD4 T cells.[128] Delayed type hypersensitivity responses to coccidioidin and in vitro T-cell responses to a variety of antigen extracts appear to correlate with long-term immunity.

Clinical Manifestations

Coccidioidal infection can manifest as pulmonary or extrapulmonary disease. Pulmonary coccidioidomycosis makes up 95% of all cases. Most primary infections occur after inhalation and are asymptomatic or relatively mild. The fungus usually remains localized to the lung and hilar lymph nodes. About 60% of individuals with primary pulmonary infection remain totally asymptomatic and can be detected only by skin test conversion. In the remaining 40%, the spectrum of disease ranges from a mild, influenza-like respiratory illness to a severe, life-threatening pneumonia.[129] Dissemination occurs in less than 1% of patients. Hematogenous spread can affect many tissues, including the skin, bones, lymph nodes, visceral organs, and meninges. Meningitis is the most feared clinical syndrome, with a poor prognosis.

Some diagnostic approaches subclassify coccidioidomycosis as "uncomplicated" and "complicated" pulmonary coccidioidomycosis. The latter includes the clinical entities of persistent pneumonia, progressive primary coccidioidomycosis, fibrocavitary coccidioidomycosis, empyema, and acute respiratory distress syndrome.[130] Residual disease with pulmonary nodules, thin-walled cavities, and fibrosis also occurs.

Common symptoms include cough, fever, and pleuritic chest pain. Cough may be nonproductive or may produce small amounts of mucopurulent sputum. Hemoptysis may occur. True rigors are uncommon. Headache, common during the acute phase of the illness, is nonspecific. Severe headache is always worrisome, however, because coccidioidal meningitis often becomes clinically apparent during the early part of the illness. If meningitis is suspected, a lumbar puncture should be performed.

Dermatologic manifestations of coccidioidomycosis include an erythematous macular rash that occurs early during the illness. This finding is frequently misdiagnosed as a drug rash or a heat rash. Erythema nodosum and erythema multiforme are other skin manifestations of primary coccidioidal infection. Together with fever and arthralgias, these skin lesions are part of a variable symptom complex first recognized in the San Joaquin Valley of south-central California and labeled "valley fever."[119,120] The term is now widely applied to symptomatic primary coccidioidal infections irrespective of geographic location. Erythema nodosum, when present, becomes apparent at about the time the coccidioidin skin test turns positive. It is thought to be a good prognostic sign, reflecting hypersensitivity to the fungus. Patients with erythema nodosum characteristically have a severe reaction to coccidioidin skin testing.[131] If skin testing is necessary in these patients, very dilute antigen should be used.

More than 75% of patients with primary coccidioidomycosis have an abnormal chest radiograph. The most common radiographic abnormality is a single area or multiple areas of patchy pneumonitis. The ipsilateral hilar nodes are enlarged in about 25% of patients.[132] Hilar adenopathy may also be seen without recognizable parenchymal disease. Single or multiple pulmonary nodules are also common findings on CT scan, with or without associated pneumonitis. This primary complex usually heals rapidly. In a small fraction of the patients, the parenchymal abnormalities, the hilar abnormalities, or both may persist. The patchy opacities may evolve into spherical coin lesions. They have semisolid centers containing viable organisms. Unlike histoplasmosis, these coin lesions rarely calcify and may mimic malignant pulmonary neoplasms.[133] Unless previous chest radiographs are available to trace the development of these nodules, excision or needle biopsy is the only certain way to exclude a malignancy. In many cases, these nodules are handled clinically much like those of histoplasmosis, with serial imaging to ensure stability. Necrosis in the center of such lesions may produce cavitation. Shelling out of the necrotic material may occur as early as 2 weeks, but characteristically occurs 1 to several months after infection. Most cavities are thin walled and under 4 cm in diameter. Once formed, they may be stable for years. However, many cavities close within 2 years, without specific therapy.

Even though the natural history of coccidioidal cavities is usually benign, several complications may arise. The cavities may become infected with pyogenic organisms, or they may be colonized by *Aspergillus* species, with subsequent formation of a fungus ball. Occasionally, *C. immitis* itself may grow in the mycelial phase in the cavities, producing a coccidioidal fungus ball. Hemoptysis as a late complication is uncommon but can be life-threatening, in contrast to the minimal bleeding that is often seen as the cavity forms. Another complication is rupture of a cavity with development of a pyopneumothorax (Fig. 36-13). This may occur in a patient without previous symptoms. Resection should be considered if cavities are subpleural and progressively enlarging.

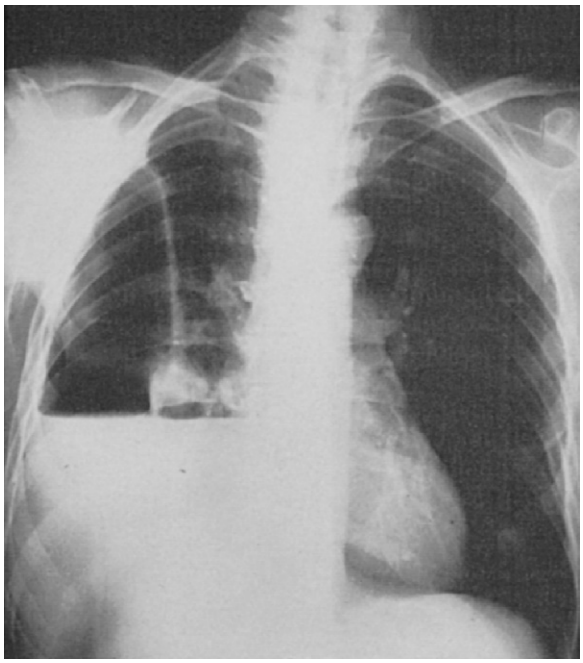

FIGURE 36-13 ■ Chest radiograph shows complications following rupture of a coccidioidomycotic cavity with formation of a bronchopleural fistula with empyema.

Patients receiving corticosteroids, cytotoxic therapy, or immune-modulating therapy such as anti-TNF therapy[134–136] are at risk for severe infection. Patients with persistent pulmonary infection after 6 weeks and those with chronic fibrocavitary pneumonia are at risk for progression and dissemination. Organ transplant recipients and especially patients with AIDS are at high risk for widespread and even fatal disease.[137] The excess risk of coccidioidomycosis in organ transplant recipients in highly endemic areas has led to targeted prophylaxis to prevent reactivation whenever there is a history of coccidioidal infection or positive serologic results on pretransplant screening.[138–141] There are other well-recognized risk factors for dissemination. Race and ethnicity are important. Disseminated coccidioidomycosis is more likely in blacks, Filipinos, and Native Americans than in whites.[121,122] Male gender is also a risk factor, as is diabetes mellitus. The very young and the very old are more likely to have dissemination.[129] There is anecdotal information suggesting that coccidioidomycosis during the third trimester of pregnancy may be a severe illness with rapid dissemination.

Extrapulmonary dissemination from the primary pulmonary focus tends to occur early, usually within a few months after a symptomatic pulmonary infection. However, in some patients, the findings of distant disseminated disease are the first manifestations of coccidioidomycosis, presumably because the preceding pulmonary infection was subclinical and resolved. Dissemination may involve any organ in the body. The skin is one of the most common sites of dissemination[142] and is involved in most patients at some time in the course of the disease. Skin lesions may be single or multiple. Gross appearance is variable, ranging from trivial scaling and induration to large, draining pustules. The clinical course varies from spontaneous healing to rapid ulceration and progression. Subcutaneous abscesses are frequent. They may be the result of sinus tract formation from deep sites of infection, including lymph nodes, bones, and viscera. When such an abscess is incised, thick gelatinous pus is found, laden with spherules.

Involvement of the bones is the next most common manifestation of disseminated coccidioidomycosis, present in up to half of patients.[143] Osteomyelitis may be either the sole evidence of extrapulmonary spread or part of a more widespread dissemination. Vertebral bodies are most commonly involved, followed by tibia, skull, and metatarsal and metacarpal bones, although any bone may be involved. Radiologic studies usually show nonspecific abnormalities. Coccidioidomycotic osteomyelitis of the spine spares the disc space in its early phases, very much like tuberculosis. Paraspinous abscess often accompanies these lesions. Without early and aggressive treatment, there is risk of spinal cord compression. Early bony lesions are frequently asymptomatic. A bone scan for every patient with disseminated coccidioidomycosis is useful to identify such lesions. Diagnosis of coccidioidomycotic joint disease may be difficult because the organism is seldom seen in synovial fluid, and synovial biopsy may be necessary for diagnosis.

Meningitis is the most dreaded complication of coccidioidal dissemination. Between one third and one half of all patients with disseminated disease have meningitis, frequently as the only obvious extrapulmonary site. The onset of meningitis may be subtle, with only mild headache and minimal alteration of mental functions. Involvement of the base of the brain is characteristic. Vasculitis may occur. As the disease progresses, an exudate frequently obstructs the aqueduct of Sylvius and the foramina of the fourth ventricle, producing hydrocephalus.[144] When obstruction occurs, the patient's clinical condition may suddenly worsen, with diminished level of consciousness and the development of papilledema. The cerebrospinal fluid shows characteristics of chronic meningitis: predominantly mononuclear cell pleocytosis, increased protein, and decreased glucose.

When coccidioidomycosis complicates HIV infection, the severity depends on the residual immune competence of the host. With near-normal CD4 lymphocyte counts, coccidioidomycosis is not significantly different from the disease seen in normal hosts. When the CD4 count falls below 200 cells/μL, disseminated disease tends to be severe and rapidly progressive. Patients usually have a high fever, complain of dyspnea, and are hypoxemic; chest radiographs often show diffuse reticulonodular opacities with nodules 5 mm or greater in diameter (Fig. 36-14). These diffuse large nodules are present in less than 1% of non-AIDS patients with disseminated coccidioidomycosis, but in up to 50% of advanced AIDS patients with this condition. Meningeal disease is present in up to 25% of advanced AIDS patients.[145,146]

Diagnosis

Mycologic Studies

Direct examination of sputum and other respiratory specimens (or pus from a nonpulmonary site) may reveal the diagnostic spherules of *Coccidioides*. Direct smears have highest utility in patients who produce copious sputum or have multilobar opacities.[147] Bronchoscopy is often performed in selected cases. In one study, bronchoscopy was diagnostic in 69% of patients, compared

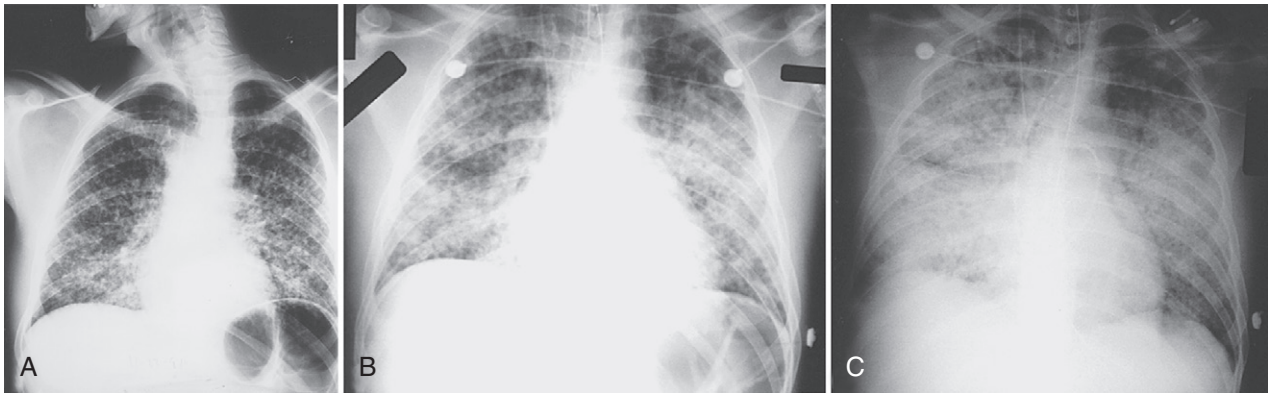

FIGURE 36-14 ■ Serial chest radiographs from a severely immunosuppressed acquired immunodeficiency syndrome patient show disseminated coccidioidomycosis. **A,** Reticulonodular opacities were detected at the time of diagnosis. Treatment with amphotericin B was started on that day. **B,** There was progression over 4 days despite therapy. The patient was then intubated to provide respiratory support. **C,** After further progression over 2 additional days, the patient expired.

with 32% for sputum stains and cultures, when patients with solitary pulmonary nodules on chest radiograph were excluded from analysis.[148] This older study also showed usefulness of a postbronchoscopy sputum examination and equivalent sensitivity for Papanicolaou and silver staining. The airway can be examined at the time of bronchoscopy and may be abnormal, providing clues to the diagnosis.[149]

Bronchoscopy is typically performed in patients who are immunosuppressed and severely ill, especially if they have diffuse opacities on chest radiograph. Multiple infections often coexist, giving additional value to diagnostic bronchoscopy early in the course of illness.[150,151] Bronchial washings and BAL fluid should be sent for cytology, fungal stains, and culture. In a study of an AIDS population in Phoenix, Arizona, the Papanicolaou stain was the most useful direct test (when compared with KOH and calcofluor white) for rapid diagnosis of pulmonary coccidioidomycosis and was even positive in two patients with negative cultures.[152] Histopathologic examination of transbronchial biopsy specimens is extremely helpful. When mature spherules (visible on standard hematoxylin and eosin–stained tissue sections) are seen, the diagnosis is secure. More commonly, only endospores, immature spherules, or spherule fragments are present. Therefore, fungal stains such as a silver stain should always be used in addition to hematoxylin and eosin staining. In one study, transbronchial biopsy yielded a specific tissue diagnosis of coccidioidomycosis in eight of eight patients.[153] Cultural identification of the fungus is not difficult but is hazardous to laboratory personnel. Isolation should be attempted only by experienced laboratories under rigid biohazard protection.

Serologic Studies

Classically, a tube precipitin test for detection of immunoglobulin M (IgM) antibodies is positive in 90% of patients by 1 to 3 weeks (negative only in very mild infections). Because the test usually reverts to negative within 3 months, it is quite specific for recent infection.[3] Currently, an immunodiffusion test for IgM has largely replaced the tube precipitin test. The immunodiffusion test measures the same antibodies, but it is easier to perform. An enzyme immunoassay for IgM is also available and maintains a low false-positive rate, suggesting an isolated positive test should prompt further investigation.[154]

CF antibodies are of the immunoglobulin G (IgG) class and appear later than IgM antibodies. In most symptomatic patients, the CF test is positive by 2 months and remains positive for several months or longer.[155] The test is highly specific but is not sensitive. In the traditional CF test, even titers of 1:2 should raise suspicion of recent exposure and infection. The antigen recognized by IgG antibody (but not by IgM antibody) is known to be a cell wall chitinase. Titers of 1:32 or higher are generally associated with more severe infections, dissemination, and poorer prognosis. A steadily rising titer should raise the suspicion of disseminated coccidioidomycosis and prompt further tests to better define the extent of disease. In addition, titers can be used to follow response to treatment, except in cases of meningitis in which serum antibodies are far less reliable. For suspected meningitis, antibody studies should be done on spinal fluid because they are more sensitive than cerebrospinal fluid cultures. Immunosuppressed individuals may have false-negative serodiagnostic tests. Because immunodiffusion and enzyme immunoassay tests are more widely used than traditional CF, results may not be reported as a dilution or titer. A confirmatory CF test can be considered if it is important to know the actual titer. The enzyme immunoassay has excellent sensitivity and specificity when compared with traditional CF testing.[156]

In 2008, a commercial *antigen* detection assay became available for use on biologic fluids. Although cross reactivity with other endemic mycoses exists and the assay has only modest sensitivity, it provides the more rapid diagnosis in select patients. Although there is great enthusiasm for use of polymerase chain reaction (PCR) on biologic samples, none is yet commercially available.

Skin Tests

Largely through the efforts of C. E. Smith, the role of skin testing in coccidioidomycosis is well defined. There are two skin test antigens: coccidioidin, prepared from the mycelial growth of the fungus, and spherulin, prepared from spherules. Induration is measured at 24 and 48 hours. A positive skin test reaction is 5 mm or more of induration and implies recent or remote infection. Spherulin was initially developed to try to increase sensitivity of skin testing. In epidemiologic studies, it is about 30% more sensitive than coccidioidin.[157] However, for routine clinical evaluation of symptomatic patients, the two skin test antigens are equal.[132] There is less than 10% cross reactivity of both antigens to histoplasmin.[157]

The skin test has been more useful in epidemiologic investigations than in diagnosing individual cases. Up to 50% of patients with disseminated coccidioidomycosis have a negative skin test, and about 10% of patients with coccidioidal pulmonary nodules or cavities have negative tests. Once acquired, the coccidioidin skin test reaction persists for a long time, perhaps even for life in some patients, producing high background levels of reactivity in an endemic area. When the recent skin test status of a given patient is known, conversion from negative to positive does imply recent coccidioidal infection. Currently, no skin test reagent is commercially available in the United States but the coccidioidin skin test may become available again in the near future. The role of skin testing in the contemporary management of this disease is not clear but is likely very limited.

Treatment

Most patients with acute pulmonary coccidioidomycosis require no treatment. Most never come to medical attention because they have minimal or no symptoms. Mildly or even moderately symptomatic patients with primary pulmonary coccidioidomycosis also need no treatment and often are indistinguishable from other

community-acquired pneumonia. Careful clinical and serologic follow-up for 1 to 2 years is necessary to identify illness that either progresses or does not resolve.

Azole therapy is usually the initial regimen of choice. Instances in which amphotericin B deoxycholate or lipid formulations of amphotericin are used include diffuse opacities with hypoxemia, critically ill patients, dissemination to spine and other important sites, and patients failing initial azole therapy. Amphotericin is also used for women in the third trimester of pregnancy. Because dissemination is more likely in immunosuppressed patients, in diabetics, and in certain racial and ethnic groups, it may be prudent to treat patients in high-risk groups during the primary infection, before dissemination takes place. In current practice, many such patients are often given fluconazole for 3 to 6 months; other, less symptomatic, patients with pulmonary coccidioidomycosis receive a shorter duration of therapy. These recommendations are based on expert opinion and observational studies.[158] For persistent pulmonary coccidioidomycosis, including chronic fibrocavitary disease, fluconazole and itraconazole are initial drugs of choice. Amphotericin B can be used for more severe or nonresolving cases.

Disseminated coccidioidomycosis always requires prompt and aggressive treatment. Unfortunately, amphotericin B is not as effective for disseminated coccidioidomycosis as it is for disseminated histoplasmosis or blastomycosis. Currently, mild to moderately ill patients with disseminated disease should be treated with fluconazole or itraconazole first. Amphotericin B preparations should be reserved for severe disease or treatment failure.

Pulmonary nodules caused by coccidioidomycosis usually do not need treatment. Thin-walled cavities are treated only if there are symptoms and positive sputum cultures caused by ongoing growth of fungus within the cavity. Specific antifungal treatment is not needed after uncomplicated surgical resection of nodules or cavities. Treatment of pyopneumothorax from rupture of a subpleural cavity includes chest tube drainage and antifungal therapy (either amphotericin B, fluconazole, or itraconazole). Surgery is indicated for persistent air leak or poor response to antifungal therapy, if the patient is a good surgical candidate.

Ketoconazole was the first therapeutic alternative to amphotericin B for certain patients with mild or moderate nonmeningeal coccidioidomycosis. A daily dose of 400 to 800 mg was used for a minimum of 1 year. Because high-dose ketoconazole has considerable toxicity and limited efficacy, fluconazole and itraconazole are now the azoles of choice for nonmeningeal disseminated coccidioidomycosis. The fluconazole dose should be at least 400 mg/day and 800 mg/day is likely to be better. The itraconazole dose should be 400 to 600 mg/day. Neither is perfect for difficult cases, for which even amphotericin B is often only suppressive. Long-term therapy is often required, extending to years or even indefinitely. Fluconazole has the advantages of better absorption, less gastrointestinal upset, and better penetration of the CNS. One randomized, controlled trial compared oral fluconazole and itraconazole for treatment of nonmeningeal coccidioidomycosis. Soft-tissue dissemination responded best. Overall, itraconazole was somewhat more effective than fluconazole, producing response in 63% of the patients versus 50% response in fluconazole-treated patients ($P = .08$). Among patients with skeletal infections, itraconazole was superior ($P = .05$).[159] Some difficult cases of bone, lymph node, and soft-tissue coccidioidomycosis may be best managed with surgical drainage of the abscesses, a 1000- to 2000-mg course of amphotericin B, and a prolonged course of itraconazole or fluconazole.

As might be expected, the treatment of disseminated coccidioidomycosis in AIDS is particularly difficult. Because of the rapid tempo of the disease, amphotericin B should be considered initially, especially if the patient is severely ill. If the clinical course stabilizes, it is reasonable to switch to fluconazole for long-term suppression. Prognosis is poor. Even with prompt diagnosis and treatment, up to 40% of severely immunosuppressed patients die during the initial hospitalization. Other patients, usually with lesser degrees of immunosuppression, respond well to treatment.[145,146] Select patients with high CD4 counts may be able to stop therapy if infection appears controlled, with close clinical, radiologic, and serologic follow-up. However, if infection is in a vital area, stopping therapy may lead to relapse with serious consequences. Many clinicians continue therapy for years or indefinitely, certainly in patients with AIDS but even in immunocompetent patients with risk factors, as discussed later for meningeal disease.

Meningeal coccidioidomycosis is a major therapeutic challenge. Fluconazole is currently primary therapy for patients with meningitis and as suppressive therapy after initial response. Most patients respond favorably to fluconazole and maintain good clinical function. Dosage is 400 to 800 mg daily or even higher. Therapy should be continued long term, likely indefinitely.[160] Patients may also be treated with intrathecal amphotericin B.[161] Occasionally, severely ill patients are treated with intravenous amphotericin B for initial therapy of the nonmeningeal disease and with fluconazole to control the CNS infection. Amphotericin B is continued to clinical improvement while fluconazole is continued indefinitely. Itraconazole at doses of 400 mg/day or higher has shown benefit in meningeal disease as well.[162] Hydrocephalus, a feared complication of coccidioidal meningitis, requires shunting in almost all cases. CNS vasculitis is sometimes treated with a short course of steroids but there is little evidence to support this.

The potential role of newer antifungals in coccidioidomycosis is uncertain. Posaconazole has shown the most promise in small studies.[163,164] Voriconazole has shown success in case reports.[165] The role of surgery in the management of pulmonary coccidioidomycosis continues to evolve. Pulmonary cavities may be resected when there is a high risk of rupture (large size, subpleural location, size increasing under observation) or when there is major hemoptysis. Extrapulmonary abscesses should be drained or resected whenever possible. Surgery for extrapulmonary foci of infection is often required for optimum control and usually combined with concurrent antifungal therapy.

Although considerable research is aimed at developing a vaccine for coccidiomycosis because it is a common and severe infection in highly endemic areas,[166] there is no immediate prospect for an effective vaccine.

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis is the illness caused by the thermal dimorphic fungus *Paracoccidioides brasiliensis.* The spectrum of illness ranges from asymptomatic skin test conversion to widespread disseminated disease.

Epidemiology

The fungus is endemic in South America, Central America, and southern Mexico.[167,168] Most cases are from Brazil, Columbia, and Venezuela. Unlike histoplasmosis, it is not found in the Caribbean islands. Although it is undoubtedly a soil organism, it has been difficult to isolate from the soil (similar to *B. dermatitidis*). As with other respiratory mycoses, inhalation of the infective spores is the usual method of infection. Most patients with the disease are male agricultural workers in close daily contact with the soil.

Although 13 patients with paracoccidioidomycosis have been reported in the United States, all previously resided in areas of known endemicity and represent endogenous reactivation of remote infection. The United States is not in the endemic area for this fungus.[169]

Pathogenesis

After inhalation of the infective particles, an area of alveolitis occurs. The initial inflammatory exudate contains predominantly neutrophils. Later, macrophages are recruited, and granuloma formation occurs in immunologically intact patients. Cell-mediated immunity is important to limit the infection.[170] The initial episode of pneumonitis tends to be self-limited and may be common in childhood in highly endemic areas, similar to histoplasmosis. Disseminated infection may result from unchecked progression of a primary infection or from late activation of latent infection. Disseminated infection can be fulminant, as in AIDS with markedly diminished T-cell function, or it may be a smoldering subacute to chronic process. The most common sites of distant spread include skin, mucous membranes, lymph nodes, adrenal glands, liver, and spleen.[171]

Clinical Manifestations

In many patients, the primary infection is mild, self-limited, and never diagnosed.[172] In some cases, there are residual pulmonary nodules. Calcifications are rare. In endemic areas, single nodules surgically removed primarily to rule out lung cancer often prove to be paracoccidiodal granulomas. Many of these patients have no history of any symptomatic pneumonia.

Many patients currently diagnosed with paracoccidioidomycosis have pulmonary symptoms at the time of diagnosis. Up to one third of diagnosed patients have only pulmonary disease[173] and may present with nonspecific symptoms of fever, weight loss, and chronic cough. Chest radiographs are variable, with opacities, nodules, cavities, and sometimes impressive intrathoracic lymphadenopathy (even to the point of mimicking lymphoma). The findings on high-resolution CT often show more extensive lymphadenopathy than suspected from plain films.[174] In immunocompromised patients, paracoccidioidomycosis can present as a severe, rapidly progressive pneumonia. Such patients often have high fever and are acutely ill. As with the other endemic mycoses, particularly severe disease including presentation as respiratory distress syndrome has been reported in patients with AIDS.[175]

The majority of patients currently diagnosed with paracoccidioidomycosis have disseminated disease. Skin, mucocutaneous, and cervical lymph node involvement is often obvious and dramatic and causes most patients to seek medical attention quickly. Patients usually present with lesions on the skin or in the oropharynx. Prominent cervical adenopathy is much more common than in the other endemic mycoses. Some patients have concomitant pulmonary disease. In other cases, the lungs are clear when extrapulmonary spread is recognized. Presumably, initial asymptomatic or minimally symptomatic pulmonary lesions have already healed, and disseminated disease presents months or even years later.

The clinical appearance of the oropharyngeal lesions is somewhat characteristic.[176] Ulcers are infiltrated and show multiple hemorrhagic spots. The oral mucosal lesions commonly extend to adjacent skin. Similarly, lesions involving the rectal mucosa often extend to the perianal skin.

Organs of the reticuloendothelial system are frequently involved. Hepatosplenomegaly is common, and lymph nodes may be involved. Cervical adenopathy commonly accompanies mucosal lesions of the mouth and oral pharynx. Necrosis occurs within the nodes, and draining fistulas may extend from infected nodes to the skin. The adrenal glands are often affected with about half of autopsied cases showing involvement. However, clinically significant hypoadrenalism is uncommon. Other sites of dissemination include the kidneys, the male genital tract, and the meninges.

Diagnosis

Direct examination of tissue or sputum after 10% KOH digestion frequently shows the characteristic "pilot wheel" yeast. The organism is large (6–30 μm in diameter) and shows multiple buds circling the parent cell, each with a narrow neck of attachment. Histopathologic examination of biopsy material is also useful. Although the fungus can be seen on sections stained with hematoxylin and eosin, silver stains increase the diagnostic yield.

The fungus is readily cultured from biologic material. It grows slowly, and a positive identification usually takes 3 to 4 weeks. Specimens cultured at room temperature grow as a mycelium. Specimens cultured at 37°C grow in the yeast form.

A skin test is available for the diagnosis of paracoccidioidomycosis. There is some cross reactivity with histoplasmin. The diagnostic accuracy of the skin test is low. Up to 40% of 60% of patients tested have a negative skin test reaction at the time of diagnosis. Skin test reactivity is low because most patients have widely disseminated disease. It is not certain whether the skin test is useful in diagnosing primary pulmonary paracoccidioidomycosis because the sensitivity of the test and the background positivity in endemic areas are not known.

Serologic tests are very useful.[177,178] The CF test for antibodies against a yeast-derived antigen yields a positive result in 80% of cases. Titers of 1:64 or higher are considered diagnostic. A rising CF titer suggests progressive disease or a relapse following initial treatment. Low titers may persist for years, even after successful treatment. An immunodiffusion test is positive in 95% of cases. Cross reactions are rare, and most patients convert to negative after successful treatment. There is now also a direct test for antigen in urine, cerebrospinal fluid, and bronchoalveolar fluid.[179] It has very high specificity, and as with antigen testing in histoplasmosis, it is quite sensitive with severe infection and less helpful in localized or smoldering infection. It is neither fully standardized as yet nor uniformly available.

Treatment

In the past, long courses (often for several years) of sulfadiazine were used successfully for treatment of paracoccidioidomycosis. Two thirds of the patients had a good clinical response. Amphotericin B was used for patients who did not respond to sulfadiazine and for those who relapsed after treatment was stopped. The usual total dose ranged from 1000 to 1500 mg. After a course of amphotericin B, sulfonamide therapy was resumed and continued long term.

Treatment options have expanded with the availability of oral azoles. Ketoconazole is very effective and now, with itraconazole, is one of two preferred treatments.[167,177] A daily dose of 400 mg of ketoconazole usually produces clinical remission in 6 to 8 weeks. Treatment should be continued for a minimum of 12 months with dose reduced to 200 mg/day after the initial phase of therapy. Itraconazole 200 mg/day for 12 months is also highly effective, curing more than 90% of patients. Amphotericin B is used only for critically ill patients and for patients who fail oral azole therapy. Currently, only a small number of patients meet these criteria. Prolonged therapy is required because relapse occurs frequently after shorter courses of therapy. Patients have to be followed clinically and with serial radiographs for several years after completion of therapy.

CRYPTOCOCCOSIS

Cryptococcosis is most commonly caused by the encapsulated yeast *Cryptococcus neoformans*. Recently, disease caused by the closely related *Cryptococcus gattii* has emerged as an important pathogen even in immunocompetent individuals. The spectrum of disease for *C. neoformans* ranges from asymptomatic pulmonary infection in normal hosts to rapidly fatal meningitis in immunosuppressed individuals.

Epidemiology

C. neoformans has been recognized worldwide. Isolation from nature is easy, usually from pigeon or bird droppings. In nature and in the mammalian host, the fungus exists as a yeast form, with an average diameter of 4 to 8 μm. Its distinctive feature is a thick carbohydrate capsule that may be two to three times larger than the yeast itself. It is thought that in nature the yeast dries and loses much of its capsule, allowing it to be aerosolized and inhaled by humans or other mammals.[180] *C. gattii* appears to be endemic to the Pacific northwest and on Vancouver Island.[181]

Pathogenesis

Although newly acquired infection clearly can cause disease, the main mechanism of disseminated infection is due to reactivation during times of immunosuppression. The portal of entry is the lung. Once in the alveoli, the yeast grows and the large capsule quickly appears. Thin-necked, small buds are seen as the yeast multiplies. Alveolar macrophages are the first line of defense in the alveolus. The *C. neoformans* antiphagocytic protein (App1) inhibits a complement-mediated pathway for attachment and ingestion of yeast cells.[182] The polysaccharide capsule also plays an important part in the pathogenesis of cryptococcal infection. Nonencapsulated organisms are readily ingested and destroyed by neutrophils, whereas encapsulated strains resist phagocytosis and killing. The capsule of *C. neoformans* has been shown to interfere with the maturation of dendritic cells in vitro, resulting in diminished fungicidal interferon-γ and T-cell responses.[183] Sophisticated molecular techniques have recently been employed to define novel cryptococcal capsule, growth, and virulence mutations.[184]

Cell-mediated immunity figures prominently in host defense against cryptococci. Before glucocorticoids and cytotoxic agents were in common use, it was recognized that patients with Hodgkin's disease were unusually susceptible to cryptococcal infection. Many presented with fulminant meningitis. The central role of cell-mediated immunity in cryptococcal disease is emphasized by its frequent association with AIDS. Before AIDS, cryptococcal meningitis was uncommon and about half of the patients had immunosuppression. Today, most serious cryptococcal infections occur in AIDS patients.[185] *C. neoformans* antigens, when presented to CD4 T cells, stimulate the production of interleukin-15 and other cytokines, which then activate CD8 T cells. CD8 T cell through production of granulysin, and other mechanisms, is cytotoxic to the fungi.[186] In AIDS, the hallmark CD4 lymphopenia interrupts this cascade.

In patients receiving anti-TNF therapy, fungal infections are increasingly common.[187] In a mouse model of

cryptococcal infection, administration of anti–TNF-α monoclonal antibody on day 0 had no effect on fungal burden in BAL fluid through day 7. However, interleukin-12 and interferon-γ were not induced at day 7 to the same levels seen in controls. This study suggests that anti-TNF therapy neutralizes the type 1 T helper cell arm of defense, which is necessary to prevent fungal dissemination.[188]

Cryptococcal infection in the lung in normal hosts is eventually limited by a granulomatous inflammatory reaction.[189] It is not known whether early systemic spread of the fungus is a routine event, as it is in histoplasmosis, or occurs only in patients with defective cell-mediated immunity. Patients with severe depression of cell-mediated immunity do not form granulomas, and the organism grows unchecked. Large gelatinous masses of cryptococci are sometimes seen in surgical specimens or at autopsy. The fungus is trophic for the CNS, and cryptococcal meningitis is the most common form of extrapulmonary disease.

Clinical Manifestations

Although the lung is the portal of entry, symptomatic cryptococcal pulmonary disease is uncommon. In 1966, Campbell[190] searched the literature and found only 101 instances of cryptococcal disease restricted to the lung. Although the number of reported cases has increased since then, symptomatic pulmonary cryptococcosis is still relatively uncommon.

Fever, malaise, chest pain, and cough occur frequently in symptomatic patients with cryptococcal pulmonary disease. Many patients have no pulmonary symptoms but have changes on routine chest radiographs obtained during evaluation for symptoms of chronic meningitis. This suggests that asymptomatic pulmonary cryptococcosis may be common.[191]

The chest imaging findings are variable. Lesions may be single or multiple and may mimic those of other pulmonary infections and neoplasms. Pleural effusions may be present. The chest radiograph may suggest primary tuberculosis or acute pulmonary histoplasmosis with a small lesion in the periphery of the lung and associated hilar adenopathy. Immunosuppressed patients tend to have more prominent findings including cavitation, confluence of lesions, masses, and other changes.[192] Neurologic imaging can show abnormalities of brain parenchyma, leptomeningitis, or hydrocephalus.[193]

Even though apparently normal persons occasionally develop cryptococcal disease, the illness is most common in patients with AIDS,[194] those with Hodgkin's disease, organ transplant recipients,[195] and patients receiving corticosteroids and other immune-modulating therapies. Although the natural history of pulmonary cryptococcal infection in normal hosts is spontaneous resolution, it is advisable not to dismiss this pathogen as a routine colonizer, but to treat almost all patients who have positive cultures from respiratory specimens.

Meningitis is the most common clinically significant form of cryptococcosis. Patients may present with a subacute illness, consisting of fever, confusion, and headache, or rarely with an acute, fulminant illness with nuchal rigidity, papilledema, and coma. Cranial nerve palsies are common,[196] and there may be symptoms due to hydrocephalus, such as headache and a depressed level of consciousness.[197]

Diagnosis

C. neoformans and some non-*neoformans* species of cryptococci can be recovered from sputum. Non-*neoformans* species can also be recovered from skin. Isolates from the CNS are usually *C. neoformans* and always indicate cryptococcal meningitis. In tissues, the organism appears as yeast of variable size. The unstained capsule looks like a thick "halo" on sections stained with hematoxylin and eosin. The mucicarmine stain shows a bright red carbohydrate capsule. Silver stains commonly used to identify fungi stain the yeast but not the capsule.

The cerebrospinal fluid in cases of meningitis usually shows modest mononuclear cell pleocytosis. The white blood cell count is usually less than 100 cells/μL. The protein level is variably elevated, and the glucose level is variably reduced. The latex particle agglutination test for measurement of cryptococcal antigen is excellent for testing cerebrospinal fluid.[198,199] It is positive in 95% of patients with cryptococcal meningitis. Measurement of cryptococcal antigen in serum is not very sensitive in non-AIDS patients with cryptococcal meningitis and is sometimes negative even in nonmeningeal disseminated cryptococcal disease.[198] The situation is very different when AIDS is present. Virtually all AIDS patients with cryptococcal meningitis have a positive serum test for cryptococcal antigen in addition to a positive cerebrospinal fluid antigen test. In fact, a negative serum cryptococcal antigen test in an AIDS patient virtually excludes cryptococcal meningitis. Occasional false-positive cryptococcal antigen test results in cerebrospinal fluid or, more commonly, in serum result from high-titer rheumatoid factor.[200]

Risk factors for poor outcome of cryptococcal meningitis despite adequate treatment include AIDS, lymphoreticular malignancy, glucocorticoid therapy, high opening pressure on lumbar puncture, a leukocyte count of less than 20 cells/μL in cerebrospinal fluid, positive India ink smear of cerebrospinal fluid, isolation of the fungus from an extraneural site, and high cryptococcal antigen titer in the cerebrospinal fluid.[198] Other sites of cryptococcal disease include the skin, bones, and prostate. Unless there is a primary chancre with a local bubo, implying direct inoculation, all forms of cutaneous cryptococcosis should be assumed to be manifestations of disseminated disease from a deep focus.[201]

Treatment

There is always uncertainty whether to treat a patient when *C. neoformans* is isolated from the sputum. If the patient is a normal host or has chronic bronchitis and has no symptoms and a normal chest radiograph, then careful observation is an option. However, some advocate a course of fluconazole up to 3 to 6 months given low

treatment toxicity profile. If the fungus is isolated from the sputum of an immunocompetent patient with symptomatic pneumonia, a lumbar puncture is recommended. Although the risk of progression to meningitis is low, it is not zero. Many clinicians now treat all diagnosed cases of isolated cryptococcal pneumonia with fluconazole 200 to 400 mg/day for 6 to 12 months.[202] When an immunocompromised patient has pulmonary disease, even if the cerebrospinal fluid is normal, antifungal treatment is mandatory. Options include fluconazole 400 mg daily or amphotericin B (total dose 1000–2000 mg). Choices of therapy for cryptococcal meningitis in non-AIDS patients include fluconazole 400 mg/day for very mild illness with normal mental status and treatment similar to HIV-infected patients when disease is severe.

Cryptococcal meningitis is fatal approximately 50% of the time even with optimal therapy. Treatment of cryptococcal meningitis in AIDS is very different because the disease relapses when treatment is stopped. First, a remission must be induced. Second, lifetime maintenance must be given to prevent relapse. Current evidence suggests that oral fluconazole is the best long-term maintenance therapy.[203] Severely ill patients with abnormal mental status (somnolence, lethargy, obtundation) may have a higher risk of death during initial induction therapy. For the majority of patients with cryptococcal meningitis, an induction regimen of amphotericin B 0.7 to 1 mg/kg/day in combination with flucytosine 100 mg/kg/day for 2 weeks followed by fluconazole 400 mg/day for a minimum of 10 weeks is the regimen of choice provided clinical improvement occurs. Liposomal amphotericin at a dose of 3 to 5 mg/kg/day is probably most appropriate for those intolerant of amphotericin B.[202,204] Evidence suggests itraconazole can be used instead of fluconazole if needed. Voriconazole and posaconazole have been used sparingly thus far, though in vitro susceptibilities suggest they are likely as effective as fluconazole and itraconazole.

Management of elevated intracranial pressure is also important.[205] Patients with initial pressures greater than 20 to 25 cm H_2O should have enough cerebrospinal fluid removed to reduce the pressure by 50%. Lumbar drains may be needed if pressure is very high or repeated lumbar punctures are not effective. Imaging should be performed prior to lumbar puncture to exclude a space-occupying lesion.[202]

Patients with AIDS who receive antiretroviral therapy may experience a paradoxical worsening of their symptoms due to immune reconstitution inflammatory syndrome.[205] Elevated intracranial pressure and formation of CNS cryptococcoma may become manifest with immune reconstitution during antiretroviral therapy and can be treated with adjunctive corticosteroids.

ASPERGILLOSIS

Aspergillosis is an illness caused by any member of the genus *Aspergillus*. The spectrum of human illness is extensive, ranging from allergic reactions to colonization of preexisting pulmonary cavities to invasion and destruction of lung tissue with pyemic spread to brain, skin, and other organs and rapid death.

Epidemiology

Members of the genus *Aspergillus* are ubiquitous in nature. These saprophytic molds exist wherever organic matter is decomposing. More than 100 species have been identified, but over 95% of human illness is caused by *Aspergillus fumigatus*. Other species that occasionally cause human disease are *A. niger, A. terreus, A. flavus*, and *A. nidulans*. The fungi are not dimorphic; they always grow as a mycelium. On the tips of specialized branching hyphae are spore heads that are characteristic for each species.[206] Owing to the ubiquitous nature of *Aspergillus*, everyone has daily contact with their spores, and total avoidance is virtually impossible.

Because the organism causes disease of such wide clinical diversity, a unitary concept of pathogenesis is not possible. Hypersensitivity pneumonitis caused by inhalation of fungal antigens is beyond the scope of this chapter and is dealt with elsewhere (see Chapter 66). Of the remaining clinical forms, five readily distinguishable types emerge: (1) *Tracheobronchial aspergillosis*, often a localized infection of the anastomosis in lung transplant recipients (see Chapter 95); (2) *allergic bronchopulmonary aspergillosis*, which affects patients with asthma (see Chapter 38) and bronchiectasis (see Chapter 42); (3) *mycetomas*, or fungus balls, in which the fungus colonizes existing pulmonary cavities; (4) *chronic necrotizing pulmonary aspergillosis*, in which the fungus locally invades abnormal lung and adjacent pleura; and (5) *invasive aspergillosis*, which occurs in patients with defects in phagocyte number, function, or both. Although other molds can cause similar entities, *Aspergillus* is the best recognized and most well studied pathogen.

Tracheobronchial Aspergillosis

Tracheobronchial aspergillosis has a spectrum of disease ranging from colonization to destructive tracheobronchitis. Although airway involvement is initially localized, untreated tracheobronchial aspergillosis can lead to dissemination. Tracheobronchial aspergillosis has been described almost exclusively in immunosuppressed individuals including patients with far advanced AIDS with extremely low CD4 counts. Patients who have undergone lung transplantation are at highest risk of infection and complications. Often these patients receive antifungal prophylaxis that can interfere with diagnosis. Tracheobronchial aspergillosis with infection of the anastomotic site, particularly in single-lung transplant recipients, has been associated with poor outcome and decreased survival.[207,208] Because clinical symptoms can mimic (and are often associated with) chronic rejection and because tracheobronchial aspergillosis is often isolated to the airway with normal radiographic studies, bronchoscopy is required for diagnosis. Treatment with nebulized amphotericin B is occasionally used in instances of true colonization. However, treatment regimens usually include systemic therapy, with more exten-

sive tracheobronchial aspergillosis being treated the same as invasive aspergillosis (see later).

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis was first described in England in 1952.[209] Its frequency is approximately 5% to 10% of chronically steroid-dependent asthmatics.[210] Patients with cystic fibrosis also have a much higher prevalence [211,212] Although an immunologic reaction to aspergillus antigens is the most important factor leading to allergic bronchopulmonary aspergillosis,[213] the intensity of exposure to the fungus may also be important. In a survey from Chicago, almost 80% of the exacerbations occurred during periods of highest mold counts in the environment.[214]

Pathogenesis

A. fumigatus is the most common organism causing this condition; however, other species of *Aspergillus* and other fungi may cause a similar syndrome, prompting a change in terminology to "allergic bronchopulmonary mycosis." Both immunoglobulin E (IgE) and IgG have been implicated in the intense immunologic response to intrabronchial growth of the fungus.[215] More recently, predisposition to allergic bronchopulmonary aspergillosis was linked to specific polymorphisms in Toll-like recognition receptors.[216] T-cell immunity is an important contributor of inflammation and studies suggest a human leukocyte antigen (HLA)–restricted response.[217] The combination of a lymphocyte and specific IgE response causes cytokine and chemokine accumulation, mast cell degranulation, mediator release, and intense local inflammation, eventually leading to fibrosis or bronchiectasis.

Clinical Manifestations

Patients may be asymptomatic, even if abnormalities are present on radiographs. A symptom complex of fleeting pulmonary opacities, eosinophilia, wheezing, fever, and expectoration of brownish plugs is characteristic of allergic bronchopulmonary aspergillosis. Exacerbations mimic bacterial pneumonia, with pulmonary opacities, mucopurulent or bloody sputum, and fever. Other exacerbations of allergic bronchopulmonary mycosis have prominent wheezing and may appear at first to be exacerbations of ordinary asthma.

Radiographic findings include consolidation, segmental and lobar atelectasis, finger-like shadows from mucous impaction, and tram lines of bronchiectasis. The majority of findings are related to mucoid impaction or abnormal bronchi.[218] High-resolution CT scanning frequently demonstrates central bronchiectasis.[219] Pulmonary function testing varies with disease activity, with obstructive defects being common. Patients may have a combined obstructive and restrictive ventilatory defect. It is hoped but not proved that early treatment prevents development of bronchiectasis or slows progression to fibrosis.

Diagnosis

The diagnosis of allergic bronchopulmonary aspergillosis can be challenging and often is made by a combination of clinical, radiographic, and immunologic findings. Diagnostic criteria for allergic bronchopulmonary aspergillosis include (1) asthma, (2) central bronchiectasis, (3) immediate cutaneous reactivity to *Aspergillus* skin test antigen, (4) serum total IgE concentration greater than 1000 ng/mL, and (5) elevated *Aspergillus*-specific IgG or IgE compared with asthma controls. Those without central bronchiectasis can be diagnosed as allergic bronchopulmonary aspergillosis seropositive.[220] Other classic findings include circulating blood eosinophilia of more than 500 eosinophils/μL, sputum or BAL cultures positive for *Aspergillus*, precipitating antibodies against *Aspergillus* antigen, and history of recurrent pulmonary opacities. Unfortunately, most of these clinical criteria lack specificity because asthmatic persons without bronchopulmonary aspergillosis can have similar findings. Histologic findings often show airway inflammation and a component of bronchocentric granulomatosis.

Treatment

Glucocorticoid therapy hastens recovery from acute exacerbations and may prevent permanent residual damage. Although regimens vary, treatment of active allergic bronchopulmonary aspergillosis typically includes prednisone 0.5 mg/kg daily for 2 weeks followed by 0.5 mg/kg on alternate days for 3 to 6 months.[220] Serial IgE levels should be tested monthly and a doubling may herald an exacerbation. Chest radiographs are obtained 2 months after initiation of therapy and whenever there is an increase in symptoms. At the first hint of an exacerbation, the prednisone dosage should be increased. The role of inhaled corticosteroids is unclear, but they are often used during times of asthma exacerbation. In a double-blind, placebo-controlled trial, itraconazole, 200 mg twice daily for 16 weeks, was beneficial as add-on treatment for those requiring prolonged corticosteroid therapy.[221] Corticosteroids plus itraconazole are now a popular initial choice for patients with this condition. The newer azoles (voriconazole and posaconazole) are likely to be efficacious but only limited reports are available. The role of anti-IgE therapy is not clearly defined but may be most useful in children in order to spare the effects of steroids.[222]

Aspergilloma

Aspergillomas are masses of fungal mycelia that grow in preexisting lung cavities (Fig. 36-15). Although these mycetomas or "fungus balls" can be caused by many different fungi, the vast majority are caused by members of the genus *Aspergillus*. The exact incidence of aspergilloma is uncertain. A large, multicenter study in the United Kingdom evaluated 544 patients with healed tuberculous cavities at least 2.5 cm in diameter, and 11% had radiographic evidence of a fungus ball. Three years

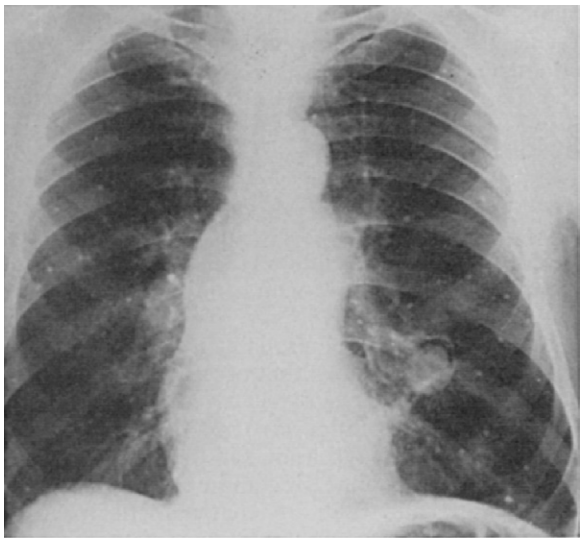

FIGURE 36-15 ■ Chest radiograph shows aspergilloma in an asymptomatic patient. The characteristic air crescent is readily seen. The radiograph also shows the multiple "buckshot" calcification of healed histoplasmosis.

after the original survey, the incidence of aspergillomas had increased to 17%.[223] Patients with residual cavitary disease from tuberculosis, endemic fungal infections, sarcoidosis, bullous emphysema, and fibrotic lung diseases are at risk.

Clinical Manifestations

The natural history of aspergillomas is variable. Most are stable and do not progress under observation. Some increase in size, and a substantial percentage resolve spontaneously. Many fungus balls are asymptomatic and are discovered only during routine radiographic surveillance. Some patients present with hemoptysis, which is the most important clinical feature of this illness. It is estimated that 90% of the patients experience at least one episode of hemoptysis. The magnitude of the hemoptysis ranges from trivial to massive. Hemoptysis has been ascribed to local vascular invasion of the cavity wall by *Aspergillus* organisms, but the source is not always evident. Collateral vessels from the bronchial arteries and from systemic arteries of the chest wall may help supply blood to the inflammatory tissue around the cavity, predisposing to serious bleeding.

Diagnosis

The diagnosis is usually established radiographically. Characteristically, the lung cavities containing the aspergilloma are in the upper lobes (because most residual cavities are due to old tuberculosis and fibrocavitary sarcoidosis) and have thickened walls. The presence of a mobile mass within a cavity is highly suggestive of aspergilloma. The organism can usually be cultured from expectorated sputum. Serologic evaluation is not routinely performed when classic radiographic features are present, but is frequently positive.

Treatment

Aspergillomas usually require no treatment. Although resection of the abnormal lung is curative, many patients have advanced underlying lung disease and cannot tolerate extensive surgery. In one study, 5.7% postoperative mortality was noted.[224] Systemic antifungal therapy for aspergillomas has not been very effective and is not routinely used unless a component of "chronic necrotizing pulmonary aspergillosis" or "chronic cavitary aspergillosis" is also suspected. Patients with aspergillomas who are started on immunosuppressive therapy can have local progression to these semi-invasive forms, necessitating systemic therapy. Bronchial artery embolization under radiographic guidance is often attempted first line to control bleeding in patients with high operative risk.[225] Resection of the lesion will stop the bleeding and cure the patient, if there is adequate pulmonary reserve. Direct (by needle or by percutaneous endobronchial catheter) instillation of amphotericin B or a sclerosing agent into the cavity may also be associated with decreased bleeding and can occasionally be tolerated in patients who are poor candidates for resectional surgery.[226]

Chronic Pulmonary Aspergillosis

Chronic forms of pulmonary aspergillosis requiring systemic antifungal treatment include chronic necrotizing pulmonary aspergillosis and chronic cavitary pulmonary aspergillosis. These entities have been referred to as "semi-invasive aspergillosis" or "complex aspergilloma." They are clearly locally invasive and occur in patients with underlying lung disease.[227,228] Many reported patients with chronic necrotizing pulmonary aspergillosis have had modest degrees of immunosuppression. Chronic cavitary pulmonary aspergillosis is a multicavitary disease that can occur with or without fungus balls and progresses (analogous to chronic cavitary histoplasmosis) over time. This patient population and the allergic bronchopulmonary aspergillosis population may have distinct polymorphisms in Toll-like receptor and surfactant proteins responsible for disease phenotype.[229,230] Most of the symptoms (shortness of breath, cough, sputum production) are due to the underlying lung disease, but slowly advancing tissue destruction from the *Aspergillus* infection worsens the symptoms.

The diagnosis is often suggested by the chest radiograph and CT scan findings, but must be confirmed by culture and sometimes by histopathology. A typical scenario is a patient with chronic obstructive pulmonary disease who develops upper lobe fibrocavitary disease and is initially suspected of having smear-negative tuberculosis. In this setting, repeated cultures that are negative for *Mycobacterium* and *Histoplasma* but are positive for *Aspergillus* cannot be ignored and should prompt therapy for chronic cavitary pulmonary aspergillosis. Chronic cavitary and necrotizing pulmonary aspergillosis frequently respond to oral antifungal therapy with itraconazole or voricoanzole.[228,231] Chronic cavitary forms of the disease often require lifelong suppressive therapy.

Systemic therapy, as is given for invasive aspergillosis, may be needed. Resectional surgery can sometimes be helpful for disease confined to one lobe but is reserved for medically nonresponsive disease because morbidity is high. Pyopneumothorax and aspergillus empyema are known complications.

Invasive Aspergillosis

Myelosuppression is the greatest risk factor for development of invasive pulmonary aspergillosis.[232] Advanced AIDS,[233] organ transplantation, high-dose glucocorticoid therapy, cytotoxic therapy, and treatment with biologics, including anti–TNF antibody therapy[234] are other predisposing factors. Among heart transplant recipients, invasive aspergillosis is the opportunistic infection with the highest attributable mortality. Most cases occur in the first 90 days after transplantation.[235] In one series of lung transplant recipients, 6.2% developed aspergillosis, with invasive pulmonary infection (32% of total infections) and disseminated infection (22% of total infections) predominating. Overall mortality was 52%.[193] Patients with chronic granulomatous disease who have deficient neutrophil oxidative burst are particularly susceptible to *Aspergillus* infection.

Pathogenesis

In vitro studies have shown the critical role of phagocytic cells in host defense against *Aspergillus*. Polymorphonuclear leukocytes are protective against mycelial forms, whereas monocytes are protective against the conidia.[236] Unchecked, the fungus grows into blood vessels, producing multiple areas of hemorrhagic pulmonary infarction distally. Dissemination can then occur. Necrosis and subsequent cavitation can ensue in the distribution of involved blood vessels. Cavitation of these infarcted areas often occurs when the previously suppressed leukocyte count returns toward normal, for example, as a patient with acute leukemia enters remission.[237] Prolonged neutropenia is the most important risk factor for invasive aspergillosis (Fig. 36-16).

Clinical Manifestations

The presentation often mimics that of acute bacterial pneumonia. The typical patient has a hematologic malignancy or has neutropenia due to treatment of malignancy and has been receiving broad-spectrum antibiotics for undiagnosed fever. Nonproductive cough, high fever, and pleuritic chest pain are common features; pleural friction rubs also occur. When dissemination occurs, symptoms at distant sites can predominate.

Diagnosis

Chest imaging is nondiagnostic but certain findings on CT are suggestive of invasive fungal infection. In a recent global comparative aspergillosis study, 94% of patients had one or more nodules and 61% had an associated "halo" sign with an area of lucency surrounding the nodule. Other imaging findings included consolidations (30%), infarct-shaped opacities (27%), cavitary lesions (20%), and air crescent signs (10%). Patients presenting with a halo sign had significantly better responses to treatment than did patients who presented with other imaging findings.[238] The authors concluded that presence of a halo sign in the appropriate clinical setting is sufficient to start antifungal therapy pending final diagnosis. The diagnosis of invasive pulmonary aspergillosis is often difficult and cases are sometimes categorized in the literature as proven, probable, or possible.[239] Sputum cultures may be negative. Even when positive, they are not absolutely diagnostic because the organism frequently colonizes the upper and lower airways. Nevertheless, isolation of *Aspergillus* from sputum of a patient who is at risk is highly suggestive of invasive aspergillosis and should prompt treatment. Cultures may be falsely negative due to antifungal use in prophylactic regimens. Thus, negative cultures do not exclude the diagnosis of invasive aspergillosis. Proof of invasive aspergillosis requires the demonstration of septate hyphae with acute-angle branching in tissue (Fig. 36–17).

The method used to obtain the diagnostic samples depends partly on local circumstances. Transbronchial lung biopsy by fiberoptic bronchoscopy has moderate

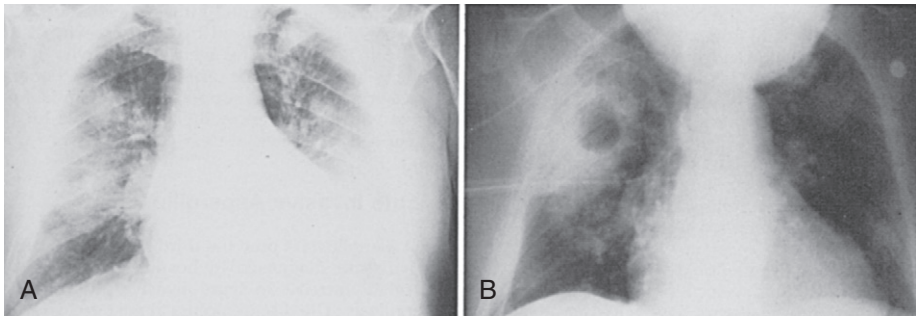

FIGURE 36-16 ■ Chest radiographs show rapidly advancing opacities caused by *Aspergillus fumigatus* in a patient with acute leukemia and fever. **A,** Bilateral nodular densities on day 4 of the fever. **B,** The same densities 2 weeks later. Note the large cavity in the confluent opacity.

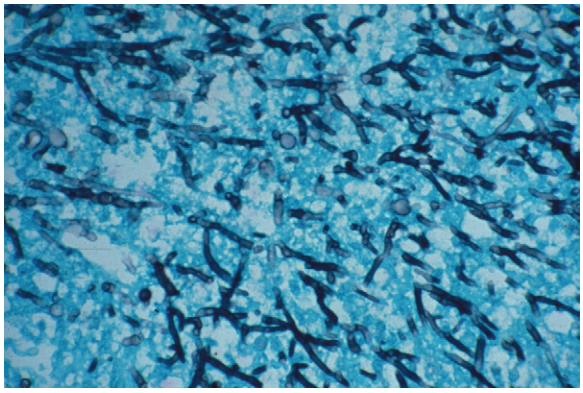

FIGURE 36-17 ■ Micrograph shows typical aspergillus organisms in tissue biopsy (septate, hyphae with finger-like branching at acute angles). (Silver methenamine stain; original magnification ×450.)

sensitivity and is specific when positive. Bronchial washings and BAL have higher (though imperfect) sensitivity and are safer than transbronchial biopsy.[240] Fine-needle aspiration of nodular lesions under CT guidance is often helpful. Some authorities believe that open lung biopsy is the procedure of choice, but it carries risk and is often reserved for situations when definitive diagnosis is elusive and the patient is not improving. Sites of distant spread include skin, brain, kidney, spleen, and other organs. Distant spread to the skin worsens the prognosis but provides a safe, easy site for biopsy to confirm the diagnosis.

Advances in antigen detection assays have significantly enhanced diagnosis of invasive aspergillosis. Studied most in stem cell transplant recipients,[241] galactomannan enzyme immunoassay antigen testing is a noninvasive tool for early diagnosis of aspergillosis in high-risk patients. There are false-positive results in patients receiving intravenous medications manufactured with yeast (i.e., piperacillin/tazobactam, plasmalyte)[242] and cross reactions in patients infected with other fungal pathogens (*Penicillium*, *Histoplasma*). Many studies have been performed in the context of surveillance, with serial testing rather than a single test.[243] Studies are currently ongoing to determine the utility of galactomannan in other patient populations and in biologic fluids including BAL.[244,245] The use of galactomannan testing in the decision to stop or reinstitute therapy is currently investigational. The (1,3)-β-D-glucan assay can detect *Aspergillus* with relatively high sensitivity, but is not specific. PCR-based detection assays are potentially powerful tools in the diagnosis of aspergillosis but, in contrast to antigen detection assays, are not yet standardized or commercially available.

Treatment

Recent guidelines and evidence from controlled trials suggest voriconazole is the treatment of choice for invasive aspergillosis.[246,247] Dosing is 6 mg/kg intravenous loading every 12 hours on day 1, then 4 mg/kg intravenously every 12 hours for the first week, transitioning to 200 mg orally twice daily. Although early reports suggested uniformly poor prognosis for invasive pulmonary aspergillosis, it is now well established that early and aggressive therapy can result in cure of some patients. Better results can be expected when granulocytopenia improves during the course of treatment. Response to therapy requires careful monitoring because many clinical trial end points are reported at 6 to 12 weeks.[248] Weaning of steroids or other immunosuppression is recommended whenever possible. Addition of growth factors (granulocyte-macrophage colony-stimulating factor [GM-CSF] for neutropenia or interferon-γ for chronic granulomatous disease) may be considered on an individual basis.

Amphotericin B is also an effective agent. Many seriously ill immunosuppressed patients have compromised renal function and are receiving potentially nephrotoxic agents such as cyclosporin A. Lipid formulations of amphotericin B permit higher dosing and longer treatment periods, providing the rationale for starting therapy with liposomal amphotericin B from onset of therapy. A recent trial comparing 3 mg/kg/day versus 10 mg/kg/day of liposomal amphotericin B showed equal efficacy but more renal dysfunction with the higher dose in patients being treated for invasive mold infections, primarily aspergillosis.[249] Commonly used dosing for liposomal amphotericin B is 3 to 5 mg/kg/day. Many centers are using combined therapy with voriconazole and liposomal amphotericin B for invasive pulmonary aspergillosis and for disseminated disease with extrapulmonary foci of infection, although clinical trials supporting that approach are not available.

Itraconazole, posaconazole, amphotericin B, if not used in the initial regimen, and echinocandins including caspofungin are alternative treatments for invasive aspergillosis.[250] *A. terreus* is resistant to amphotericin, and treatment with an azole is required.[247] Residual nodules and cavitary lesions can be removed surgically. Surgical removal is especially useful for infection near pericardium or great vessels and in patients who must undergo further episodes of intensive immunosuppression. Precise indications for resection of residual disease are uncertain. An alternative to resection of residual disease is secondary prophylaxis with antifungal therapy to cover all future periods of neutropenia.

ZYGOMYCOSIS

Zygomycosis (also known as mucormycosis or phycomycosis) refers to infection caused by any of several genera of fungi, including *Mucor*, *Rhizopus*, and *Absidia*. The most common manifestations include rhinocerebral zygomycosis in diabetics with ketoacidosis, pulmonary zygomycosis in immunocompromised patients, and local invasion of burned or otherwise denuded skin. These fungi are ubiquitous in nature and, as a rule, are unable to invade normal hosts. They live on decaying organic matter, and everyone has contact with their spores.

Invasion can occur only when normal defenses are altered. Inhibition of polymorphonuclear leukocyte

function by diabetic ketoacidosis,[251] suppression of polymorphonuclear leukocytes and alveolar macrophages by glucocorticoids or cytotoxic agents,[252] and destruction of cutaneous barriers by burns[253] predispose to the usual forms of the disease. Iron overload and treatment with desferoxamine (which acts as siderophore and increases availability of iron to the fungus) also predispose to infection. It is interesting that the incidence of rhinocerebral zygomycosis in diabetics in the United States is declining. One speculation credits wider use of statins, which have in vitro inhibitory activity against mucor species.[254] Conversely, pulmonary zygomycosis in patients with hematologic malignancy seems to be increasing, with reports from cancer centers linking that increase to more widespread use of voriconazole.[255]

The fungus invades blood vessels and causes distal ischemic necrosis.[252] The morphology in tissue is different from aspergillus. The fungus is nonseptate with short stubby side branches at a 90-degree angle. Inflammatory cells are usually polymorphonuclear leukocytes, and granuloma formation is not a feature of the histopathology.

Clinical Manifestations

Rhinocerebral zygomycosis occurs almost exclusively in the setting of diabetic ketoacidosis. High blood glucose levels and low tissue pH favor fungal growth and inhibit polymorphonuclear leukocyte function. Infection usually begins in the nose, with rapid invasion of the palate, sinuses, and orbits and eventual erosion into the cranium. The presence of a black eschar in these areas in a diabetic with ketoacidosis is strongly suggestive of mucormycosis.[251]

Pulmonary zygomycosis is seen almost exclusively in immunocompromised patients, in patients with hematologic malignancy undergoing cytotoxic therapy, and less commonly in organ transplant recipients.[256] The illness begins as an acute pneumonia with fever and cough, followed by signs and symptoms of pulmonary infarction, with pleuritic chest pain and hemoptysis. The chest radiograph usually shows one or multiple wedge-shaped pulmonary opacities extending to the pleura. On CT, the range of findings includes alveolar opacities, masses, nodules, pleural effusions. Reverse halo sign has been reported (central clear area from ischemic area surrounded by a radiographic density), but cavitary lesions with air crescents are much less common than in invasive aspergillosis. There may be systemic spread to multiple other organs, including the skin.[252] The clinical disease is very similar to invasive pulmonary aspergillosis. In one large series, clinical features that favored zygomycosis over aspergillosis included concomitant sinusitis, more than 10 nodules, pleural effusion, and prior treatment with voriconazole.[257]

Diagnosis and Treatment

Because the fungi are ubiquitous in nature, positive cultures must be correlated with the clinical picture. Histopathologic examination of involved tissue that reveals characteristic broad (10–20 μm), nonseptate hyphae, with occasional stubby side branches coming off usually at 90-degree angles is diagnostic. Unlike the hyphae of other fungi, those of mucor and other species may stain better with standard hematoxylin and eosin stains than with silver stains or other special stains usually used for fungal diseases. No serologic test and no skin test are available. Diagnosis often depends on direct identification of characteristic organisms in tissue biopsies. Culture confirmation may be difficult in many cases. Organisms may also be seen directly in sputum and bronchoalveolar fluid samples in patients with pneumonia, sometimes confirmed by culture.

There is no uniformly effective therapy, although amphotericin B has been widely used historically. Best results have been accomplished with the combined use of amphotericin B and aggressive surgical resection. Anecdotal reports describe use of liposomal amphotericin B plus surgical resection (two cases),[258] combination therapy with liposomal amphotericin B and caspofungin,[259] and posaconazole. Posaconazole had surprising efficacy in a salvage study of 91 patients failing or intolerant to standard therapy. There was a clinical response in 60% and 21 had control of their disease.[260] Note that voriconazole and fluconazole have no efficacy. Current approach includes liposomal amphotericin B with posaconazole concomitantly or as a sequential agent after initial response. Surgical resection of localized disease is appropriate for selected patients. Use of an echinocandin as second agent (with liposomal amphotericin B) has also been reported. Further studies may indicate a larger role for posaconazole in initial therapy, especially if an intravenous formulation is developed. Unfortunately, large comparative studies of various regimens are unlikely to be done because of the rarity of disease and the severity of underlying illnesses. The overall mortality and pulmonary zygomycosis in severely immunosuppressed patients remain very high.

CANDIDIASIS

Candidiasis refers to infection caused by members of the genus *Candida*, usually *C. albicans* but occasionally *C. tropicalis* or other species and increasingly the more resistant *C. glabrata*. Systemic candidiasis is a relatively common opportunistic infection, and the lung is frequently involved in widespread hematogenous dissemination. However, primary pulmonary infections in which the mechanism is aspiration of pharyngeal contents are very uncommon.

Candida organisms are ubiquitous in nature and are normal inhabitants of the human mouth and gastrointestinal tract. Thrush in infants and candida vulvovaginitis in young women have long been recognized as common infections in otherwise healthy hosts. Glucocorticoid therapy and broad-spectrum antibiotics also predispose to these conditions. Thrush is also common in persons with HIV infection and serves as a harbinger of progression to full-blown AIDS.[261] When thrush occurs in patients already diagnosed with AIDS, it nearly always

indicates the simultaneous presence of *Candida* esophagitis.[262] Systemic candidiasis is a known complication of neutropenia, parenteral nutrition, and heroin abuse.[263] Different patterns of systemic involvement may be seen with these underlying conditions, but the pulmonary involvement (with multiple hematogenous microabscesses) is usually overshadowed clinically by disease of other organs such as the skin, bones, joints, and eyes.

Pathogenesis

Systemic candidiasis occurs through different portals of entry. The organism may enter the body across injured gastrointestinal mucosa or may cross from the skin into the bloodstream, often aided by an indwelling vascular catheter. Bronchopulmonary candidiasis including pneumonia can result from aspiration from the oropharynx into the lungs but is very uncommon. Most patients with clinically significant candidiasis have not only a portal of entry but impaired host defense mechanisms as well. Normal polymorphonuclear leukocytes are important defenders against *C. albicans*. The role of humoral and cell-mediated immune mechanisms for protection against deep invasion is less clear,[264] although cell-mediated immunity plays a large role in preventing mucosal overgrowth, as seen when AIDS patients get marked mucosal overgrowth, but little tendency to have deep invasion.

Clinical Manifestations

The clinical features of systemic candidiasis depend on the sites of infection, the extent of involvement, and the host immune response. In addition, there is nearly always the confounding presence of underlying disease.

Bronchopulmonary candidiasis can present with cough productive of purulent sputum, dyspnea, and fever. Chest radiographs may show patchy or lobar opacities or be surprisingly normal.[265] The entirely nonspecific manifestations of pulmonary involvement help to explain why pulmonary candidiasis is often not diagnosed until autopsy examination.

Diagnosis

Two factors contribute to the difficulty in diagnosing bronchopulmonary candidiasis during life. First, the presence of *Candida* in cultures or KOH preparations of sputum or even bronchoscopic specimens is virtually impossible to interpret because of frequent oropharyngeal and tracheobronchial colonization, which is nearly universal in patients receiving broad-spectrum antibacterial therapy. Second, there is no satisfactory serologic test despite considerable effort to develop one.[266] The histopathology of *Candida* infection includes yeast that serially buds to form so-called sprout mycelia.

Candidiasis is the only fungal infection in which yeast and pseudohyphae are seen together in tissue sections. Histologic demonstration of tissue invasion is required to prove *Candida* pneumonia.

Treatment

Prevention of systemic candidiasis depends on control of local mucocutaneous sites of infection, control of gastrointestinal overgrowth, and maintenance of healthy barriers (skin and gastrointestinal mucosa) and adequate numbers of functioning phagocytes. Removal of contaminated vascular access lines plus antifungal therapy is usually required to cure *Candida* fungemia. Any positive blood culture is evidence of systemic infection and dictates systemic treatment. Successful treatment of bronchopulmonary and other forms of systemic candidiasis has been reported with several different drug regimens, including amphotericin B (with or without 5-flucytosine), ketoconazole, and fluconazole.

In one study, caspofungin was superior to amphotericin B for treatment of systemic candidiasis. In patients who survived long enough to be evaluable, caspofungin improved the likelihood of eliminating the fungus and had markedly reduced toxicity compared with that of amphotericin B.[267] *C. glabrata* is increasing in frequency, partly due to antibiotic pressure from broad use of fluconazole, to which it is generally resistant. *C. glabrata* is sensitive to caspofungin and other echinocandins.

UNCOMMON PULMONARY FUNGAL INFECTIONS

The number of other fungi that can cause pulmonary disease is increasing, particularly for intensely immunosuppressed patients.

Pulmonary Infections Due to *Scedosporium* (Formerly Pseudallescheriosis, Allescheriosis, Maduromycosis of the Lung)

Human illness caused by *Scedosporium apiospermum* (asexual stage of *Pseudoallescheria boydii*) is uncommon and usually occurs in an altered host.[268,269] The spectrum of illness is similar to that of aspergillosis and includes slowly progressive pulmonary infections in patients with underlying lung disease, intracavitary fungus balls in preexisting cavities,[270] and invasive pulmonary infection.

Epidemiology and Clinical Manifestations

The fungus, a soil saprophyte, is ubiquitous in nature. It may produce a slowly progressive upper lobe cavitary disease, with or without a fungus ball, in minimally abnormal hosts. This illness is similar to chronic necrotizing aspergillosis. In more severely immunocompromised patients, the organism may cause pneumonia with blood vessel invasion and pulmonary infarction, similar to that seen in invasive aspergillosis or pulmonary zygomycosis.

Diagnosis

Cultural recovery of the organism is often hard to interpret because the organism is common in the environment. The histopathologic appearance is identical to that of aspergillosis, with septate hyphae branching at acute angles. Proof of diagnosis usually requires demonstration of aspergillus-like organisms in tissue biopsies or biologic specimens and positive cultures for scedosporum and not for aspergillus.

Treatment

It is important to clearly separate scedosporium infections from aspergillosis in part because amphotericin B is not an effective treatment for scedosporium infections.[271] Voriconazole is probably the treatment of choice and is continued for at least 12 weeks. Miconazole also has activity and was used in the past. There were 24 patients with scedosporium infection included in a large (total of 520 patients) clinical trial of voriconazole for primary and salvage therapy of infections due to aspergillus, scedosporium, and fusarium species.[272] Treatment was successful in 15 of the 24 patients including 6 of 10 with CNS involvement. There are published reports of successful use of voriconazole in small numbers of patients with pulmonary and CNS infections.[273] There likely will not be clinical trials comparing different treatment options because the infection is rare and the patients are difficult to study because of the complexity of the underlying illnesses. This makes it unlikely that there will be a best-treatment strategy that is evidence based.

Pulmonary Sporotrichosis

Even though lymphocutaneous sporotrichosis is far more common than the pulmonary illness, occasional isolated pulmonary disease does occur, probably acquired by inhalation.[274] Recovery of *Sporothrix schenckii* from sputum or bronchoscopic specimens in a compatible clinical setting (chronic radiographic changes, chronic cough, and low-grade fever) is the usual method of diagnosis.

The treatment of sporotrichosis lung disease is not established. Although historically many authorities considered amphotericin B the drug of choice,[275] it was difficult to demonstrate that amphotericin was better than other agents, such as saturated solution of potassium iodide. Ketoconazole has little activity against sporotrichosis.[276] Itraconazole is somewhat more active.[277] Surgical resection of isolated disease, alone or in combination with other treatment, is frequently effective.[278] The disease is rare and its natural history poorly understood, complicating interpretation of treatment results. At present, itraconazole may be a reasonable choice for therapy.

Other Fungi

Many other normally saprophytic fungi can cause pulmonary infection in severely immunocompromised patients. These infections are difficult to diagnose because the causative organisms are frequent contaminants in the laboratory. Proof of infection requires documentation of tissue invasion. These organisms include *Geotrichum*, *Hansenula*, *Penicillium*, *Fusarium*,[279] and many others. These infections occur in the same population of immunosuppressed patients that is susceptible to invasive aspergillosis, but at much lower frequency. Whereas there are many similarities of the mold infections to aspergillosis, there are some differences. For example, fusarium infection has higher frequency of positive blood cultures, higher frequency of peripheral skin lesions, and major resistance to amphotericin B.[273]

Another emerging deep fungal infection is AIDS-related *Penicillium marneffei* (an apparent T-cell opportunist) being reported in AIDS patients in southeastern Asia (see Chapter 80).

KEY POINTS

- Of the endemic mycoses, histoplasmosis, blastomycosis, and coccidioidomycosis are most common in North America and paracoccidioidomycosis is found in South America.
- Histoplasmosis tends to spread to reticuloendothelial organs including lymph nodes, bone marrow, liver, and spleen. Blastomycosis spreads mainly to skin and bones. Coccidioidomycosis spreads to skin and bone, but also to CNS.
- The endemic mycoses and cryptococcosis are T-cell opportunists. They occur in normal hosts and require specific immunity for control of the infection. They exploit T-cell immunodeficiency especially AIDS.
- The endemic mycoses can present as community-acquired pneumonia and must always be considered when a patient has progressive pneumonia despite appropriate antibacterial therapy. Additional diagnostic tests (including bronchoscopy) must be done rather than additional courses of different antibacterial agents largely covering the same pathogens.
- Diagnostic tests include antibody and antigen testing for histoplasmosis and coccidioidomycosis. Organisms causing blastomycosis and coccidioidomycosis have highly

specific morphology (large yeast with single broad-necked bud for blastomycosis and spherule for coccidioidomycosis) that offers specific direct diagnosis in some cases.

- Aspergillus is a ubiquitous soil fungus. Spores can be killed by neutrophils, and the fungus usually cannot invade healthy tissue defended by phagocytes. Aspergillus exploits conditions such as neutropenia, most commonly associated with aggressive treatment of hematologic malignancy and bacterial infections. Of the different forms of disease associated with aspergillus, the invasive form is most lethal.
- For many years, amphotericin B was the major available therapy for deep fungal infections. Now there are other important agents including newer azoles and echinocandins. Treatment is more complex, and guidelines for treatment are regularly updated.

CHAPTER 37

PARASITIC LUNG INFECTIONS

James McCarthy, MD, FRACP • Thomas B. Nutman, MD

INTRODUCTION

PROTOZOAL INFECTIONS
Amebiasis
Malaria
Toxoplasmosis

HELMINTHS
Intestinal Nematode Infections
Tissue-Dwelling Nematodes

INTRODUCTION

Parasites are eukaryotic organisms that require or prefer to live within another organism or host. They are divided into two groups: protozoa, or single-celled organisms, and multicellular helminths. Whereas protozoa are often intracellular in humans, helminths are usually extracellular (the exception is *Trichinella*, which encysts within muscle cells).

Many parasites have complex life cycles, with multiple stages, often requiring multiple host species to complete their life cycle. These host species could be another mammal (e.g., pigs and horses for *Trichinella*), an invertebrate host (snails for *Schistosoma* spp.), or an insect vector such as *Anopheline* mosquitoes for malaria. For most parasitic infections, humans are the definitive hosts in which the adult or sexual stage of the parasite, if there is one, resides. For other parasites, humans are the intermediate hosts or an incidental dead-end host and other species are the definitive host (e.g., *Dirofilaria*, *Toxocara*, *Toxoplasma*).

Infection with these organisms is acquired in a number of different ways: some are ingested and are spread person to person or through fecal-oral or fecal-soil-oral transmission (e.g., *Ascaris*). Others require insect vectors for transmission, passing through intermediate species where they complete part of their life cycles. Some organisms can enter from a contaminated environment by penetrating through the skin (e.g., *Strongyloides*, *Schistosoma*).

Except for *Paragonimus*, the lung fluke, few parasites specifically go to the lungs as their final target organ. The majority that affect the lungs migrate through the lung en route to another organ (e.g., *Strongyloides*, *Ascaris*) or infect the lungs as a secondary site (e.g., amebiasis, toxoplasmosis, echinococcosis). In a few infections, lung pathology is primarily due to a systemic cytokine-mediated inflammatory response (e.g., severe malaria) or to a hypersensitivity response to parasite antigen (e.g., tropical pulmonary eosinophilia [TPE] in filarial infection).

Although some of these organisms have worldwide distribution (e.g., *Ascaris*, *Toxoplasma*), most have narrower geographic distribution. Often, endemic areas are in developing countries with limited resources and access to clean water and sanitation. In industrialized countries, these infections are most commonly encountered in immigrants or returning travelers.

Control programs require resources, a well-developed healthcare infrastructure enabling diagnosis and treatment with appropriate medication, and vector control programs with safe insecticides and molluscides, all of which are difficult in resource poor countries.

Once thought exotic, parasitic diseases are becoming increasingly recognized in industrialized countries because of returning travelers, immigration, and mass movement of people. An awareness of the clinical manifestations and management of these diseases is therefore important for both primary care physicians and specialists. This chapter details the most frequently encountered parasites causing pulmonary pathology. A summary is shown in Table 37-1.

PROTOZOAL INFECTIONS

Amebiasis

Entamoeba histolytica, the causative organism of invasive amebiasis, is a ubiquitous protozoan. The infection usually manifests clinically as dysentery or liver abscess. It is estimated that 40 to 50 million cases of amebiasis

TABLE 37-1. Characteristics of the Most Frequently Encountered Parasites Causing Pulmonary Pathology

Parasite and Disease	Principal Clinical Features of Pulmonary Involvement	Geographic Distribution	Radiologic Appearance	Diagnostic Approach	Treatment
PROTOZOA					
Malaria	ARDS	Widely in tropics	Interstitial infiltrates	Blood film	Antimalarial therapy (see text)
Toxoplasmosis	Interstitial pneumonia	In association with 1st-degree immunosuppressive illness and feline exposure	Interstitial infiltrates	Cytology of BAL fluid Serology	Pyrimethamine-sulfadiazine
Amebiasis	Necrotizing abscess, frequently in contiguity with liver	Widely in tropics	Local abscess	Percutaneous aspiration	Metronidazole, tinidazole
NEMATODES					
Ascaris	Loeffler's syndrome	Widely in tropics	Transient infiltrates	Expectant, stool parasitology	Albendazole Mebendazole
Hookworm	Loeffler's syndrome	Widely in tropics	Transient infiltrates	Expectant, stool parasitology	Albendazole Mebendazole
Strongyloides	Loeffler's syndrome Chronic cough Pneumonia in hyperinfecion	Widely in tropical and subtropical areas	Variable	Stool parasitology Serology	Ivermectin
Lymphatic filariasis	Tropical pulmonary eosinophilia	Tropics, particularly south Asia	Interstitial infiltrates	Circulating antigen test, serology, BAL	DEC Doxycycline
Dirofilariasis	Pulmonary nodule	Widely	Nodule	Exclude other causes of lesion, usually by excision	Nil
Trichinosis	Respiratory distress	Zoonosis	Variable	Muscle biopsy	Albendazole
Visceral larva migrans	Eosinophilic pneumonia	Worldwide	Interstitial infiltrates	Serology	Albendazole
CESTODES					
Echinococcosis	Intrapulmonary fluid-filled cyst	Worldwide (particularly in sheep-raising areas)	Intrapulmonary fluid-filled cyst	Serology Surgical resection	Surgical resection Albendazole
TREMATODES					
Paragonamiasis	Cavitating lung lesion	Southeast Asia, South America, Africa	Cavitating lung lesion	Eggs in sputum or stool, serology	Praziquantel Triclabendazole
Schistosomiasis	Pulmonary hypertension	Asia, South America, Africa	Pulmonary hypertension	Eggs in stool, serology	Praziquantel

ARDS, acute respiratory distress syndrome; BAL, bronchoalveolar lavage; DEC, diethylcarbamazine.

occur each year with 40,000 to 100,000 deaths.[1-3] *Entamoebae* infect people of both genders and all ages. It is more common in developing countries with limited access to adequate sanitation. In these countries, from 1% to 21% of people harbor *E. histolytica*.[4] In the United States, most cases occur among immigrants from endemic areas, travelers, and people living along the Mexican border.

Other risk factors for infection include institutionalization, daycare, mental illness, men who have sex with men, and malnutrition. Chronic alcoholism increases the risk of liver disease, and atrial septal defects may increase the risk of pulmonary disease.[5] Although a study from Mexico found an association with human leukocyte antigen (HLA)-DR 3[6] and susceptibility to invasive disease, another study of amebic liver abscess in Vietnam, found no household clustering.[7] Pleuropulmonary amebiasis is a significant complication of amebic liver abscess and, rarely, of hematogenous spread of the infection.

Transmission

The infective form of *E. histolytica* is the cyst, which is 10 to 16 μm in diameter and has four nuclei when mature. Excystation occurs in the small intestine, where the organisms go through cytoplasmic and nuclear

division, resulting in eight motile uninucleated trophozoites (20–40 μm).[2] The trophozoites then migrate into the large intestine, where they can divide by binary fission into either cysts or trophozoites. Both cysts and trophozoites can be passed into the stool. Cysts passed in the fecal stream are responsible for transmission because their protective wall enables them to survive for days to weeks in the environment. Up to 15 million cysts may be excreted daily by individuals with asymptomatic infection. Trophozoites cannot survive outside of the body's environment.

Demonstration of significant molecular differences between morphologically identical but pathogenic and nonpathogenic strains has resulted in the reclassification of the species into two separate species, the nonpathogenic known as *E. dispar* and the pathogenic as *E. histolytica*.[4] These can also be distinguished on the basis of antigenic differences and can be differentiated by both a fecal antigen test and a polymerase chain reaction (PCR) test.[8] It is estimated that up to 90% of organisms in some areas are the nonpathogenic *E. dispar* species.[9] A new noninvasive species, *E. moshkovskii* has been identified in humans.[10,11]

Transmission usually occurs by a fecal-oral route, especially with contaminated water supplies. It can also occur with fecal exposure through sexual contact, especially among men who have sex with men.[12] In this case, the trophozoites can also be infective. However, many homosexual men previously thought to be infected with *E. histolytica* are actually colonized with *E. dispar*.[4,13,14] Other means of transmission include cockroaches. A study of two species of cockroaches outside a school in Taiwan found *E. histolytica* and *E. dispar* cysts on the cuticles and in the intestinal tract in up to 25% of the roaches.[15]

With interruptions in clean water and sanitation, outbreaks can occur. In Tbilisi, Georgia, invasive amebiasis was rare until July 1998 when a breakdown in water treatment occurred. Between then and September, 177 cases of amebiasis were reported, 52 of which were liver abscesses. Based on serology, from 84,000 to 225,000 people may have been affected.[16]

Pathogenesis

E. histolytica trophozoites adhere to mucosa via the galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin.[5,11] The virulence of *E. histolytica* derives from the parasite's ability to kill and phagocytose host cells.[17] Amebae kill cells by triggering apoptosis. In the intestine, the macroscopic appearance of lesions can resemble inflammatory bowel disease. A wide range of histologic findings has been described. There may be multiple discrete ulcers, areas of mucosal thickening separated by normal colon, diffusely inflamed mucosa, necrosis, and perforation.[5] Unlike other protozoa, tissue invasion is not an obligatory part of the life cycle. In fact, it is a dead end that cannot lead to infection of a new host.

Trophozoites migrate from the intestine to the liver via the portal circulation. When infection becomes established in the liver, it results in areas of hepatic necrosis through obstruction of portal vessels.[18] The average interval between infection and onset of liver abscess is 5 months.[19] Survival within the liver requires substantial changes in the basic aspects of amebic cell metabolism, a process that may involve regulation of heat shock proteins.[19]

A previous amebic liver abscess does not necessarily confer immunity to subsequent infections. Residents in a highly endemic area in Vietnam who had been treated for a liver abscess were actually more likely to get a second amebic infection. Ameba-specific antilectin antibodies do form after invasive disease. Protective immunity in animals can be correlated with the development of an antibody response to a different domain of the same antigen, whereas exacerbation of disease can be linked to the development of antibodies to another domain of the same antigen. Individuals who are colonized with *E. histolytica* but are resistant to invasive disease have a high prevalence of antibodies to the protective epitopes.[20]

Clinical Manifestations

The clinical manifestations of *E. histolytica* infection are protean. Only about 10% of people infected with *E. histolytica* develop disease; others may spontaneously clear asymptomatic infection within a year.[21–23] Intestinal disease can manifest in several different ways: from acute or chronic diarrhea of varied severity to bloody diarrhea (dysentery) and fulminant colitis. Whereas fever rarely occurs with intestinal disease, it is present in most cases of extraintestinal (invasive) disease.[16]

The most common site of extraintestinal infection with *E. histolytica* is the liver, which occurs in 3% to 9% of cases of amebiasis. The most significant complication of hepatic abscess is rupture (in 2%–7%). Abscesses characteristically rupture upward through the diaphragm into the pleural space or the lung parenchyma. An abscess located in the left lobe may rupture into the pericardium, leading to cardiac tamponade with a mortality of 60%. Intraperitoneal rupture can also occur.[18]

Pleuropulmonary Disease

Lung disease occurs in 2% to 7% of those with invasive amebiasis. It is the second most common site of extraintestinal infection after the liver.[5] Owing to the male predominance in amebic liver disease, male gender is associated with lung disease (67% in a series of 501 cases from Mexico).[24] Because most amebic liver abscesses are right-sided, the lower and middle lobes of the right lung are the most affected, but it can affect the left lower lobe or lingula. Right-sided lesions are found in 86% of the cases, left-sided in 13.5%, and bilateral in 1.7%.[5]

Although rare, amebic lung disease can result from inhalation or aspiration.[25] About 14% of lung involvement arises from hematogenous spread from the intestines or liver, but as noted, pulmonary disease most commonly develops by direct extension of a liver abscess through the diaphragm, followed by rupture, either into the pleural space (leading to pleurisy, effusion, or

empyema) or into the lung with development of pulmonary consolidation, lung abscess, or hepatobronchial fistula.[26] Up to 40% of patients with liver abscess develop pulmonary complications. The most common is reactive pleuritis secondary to a contiguous hepatic abscess. These patients may complain of right upper quadrant pain with pleuritic chest pain and may have a pleural rub. Of note, they frequently have normal liver enzymes. The fluid in the pleural space is exudative and sterile. If the abscess extends into the pleural cavity, an amebic empyema can form. Onset of liver abscess can be insidious or acute. It is typically characterized by fever, right upper quadrant and chest pain, and a dry cough. Rupture into the pleural cavity may result in abrupt exacerbation of pain, with rapidly progressive respiratory distress, and shock.[24]

Commonly, the initial pleural irritation of the abscess from below the diaphragm results in pleural scarring, thus preventing extension of the abscess into the pleural space.[27] In this instance, the abscess can extend directly into the lung parenchyma, causing pulmonary consolidation. If invasion into a bronchus occurs, expectoration of blood-stained sputum containing the characteristic anchovy paste–like pus from the amebic abscess may be observed. In a series of more than 2000 patients with amebic liver abscess in South Africa, 146 had thoracic amebiasis; in this series, 47% had hepatobronchial fistula, 29% had pleural effusion and empyema, 14% had lung abscess, and 10% had pulmonary consolidation.[28]

Findings on physical examination in amebic lung disease typically include hepatic enlargement and tenderness, dullness to percussion at the right base with decreased or absent breath sounds, and a pleural rub with occasional crepitation. If the lung disease is chronic, emaciation and clubbing can sometimes be found.

In a series of 75 patients with amebic liver abscess, radiographic abnormalities on chest radiograph were noted in 57% of patients. Presenting symptoms in this group included cough in 16% and chest pain in 19%.[18] Computed tomography (CT) will show the pulmonary lesions and pleural fluid, and loculations. Magnetic resonance imaging (MRI), which is useful in detecting cerebral lesions, is less helpful for identifying lung lesions.[5]

The mortality among patients with amebic lung disease has been reported to range from 5% to 16%.[24,28] Mortality is increased if not diagnosed promptly, which occurs especially in nonendemic areas. Untreated, the mortality of invasive amebiasis[4] and amebic liver abscesses is over 80%.[18]

Diagnosis

Parasitologic examination of stools is frequently negative for the organism (<60%[8]), but antigen tests and PCR diagnosis are more sensitive (>95% and >70%, respectively[8]). A Papanicolaou stain of sputum or bronchoalveolar lavage (BAL) fluid can identify amebas, which appear as 20- to 30-µm oval, cyanophilic erythrophagocytic organisms.[29] In pilot studies of patients with liver abscess, an antigen test demonstrated high sensitivity.[30] Serology is a reliable way of diagnosing invasive amebiasis, especially in patients with extraintestinal disease.[8] Patients infected with *E. histolytica* generally test positive for antiamebic antibodies, whereas those colonized with *E. dispar* do not. The sensitivity of the antibody tests for *E. histolytica* has been reported as 95% for patients with extraintestinal amebiasis, 70% for those with active intestinal infection, and 10% for asymptomatic cyst passers. The specificity is greater than 95%.[31] However, the utility of serology as a diagnostic tool in highly endemic areas is limited because individuals may remain seropositive for years after an infection has been cleared. The prevalence of seropositivity may exceed 25% in some areas. Enzyme assay–based stool antigen detection kits that utilize monoclonal or polyclonal antibodies to identify *E. histolytica* and to differentiate it from *E. dispar* are commercially available.[3,7] PCR techniques are more frequently applied to the diagnosis of amebiasis and are more sensitive and specific than antibody tests.[32] They are of similar sensitivity to antigen-based diagnostic tests.[8]

Hematologic and biochemistry analyses are not usually helpful. Often, in invasive amebiasis, a leukocytosis notably without eosinophilia is observed. Liver function tests with the exception of alkaline phosphatase are often normal.

Radiologic investigation shows elevation of the right hemidiaphragm and hepatomegaly, with pleural effusion in 63% of patients with liver abscess (Fig. 37-1). Basal pulmonary opacities and pleural thickening are often seen. Amebic empyemas rarely are loculated or septated. Ultrasound, CT, and MRI are equally effective at diagnosing amebic liver abscesses, although none is specific. On ultrasound, an amebic abscess appears as a homogenous hypoechoic round or oval lesion.[33] Aspiration of the fluid often reveals odorless pink, red, yellow, or brown "anchovy paste" fluid that may contain trophozoites but is sterile on bacterial culture.[5] It is not unusual for radiographic disease to worsen for a 1- to 2-week period after the start of therapy.[27]

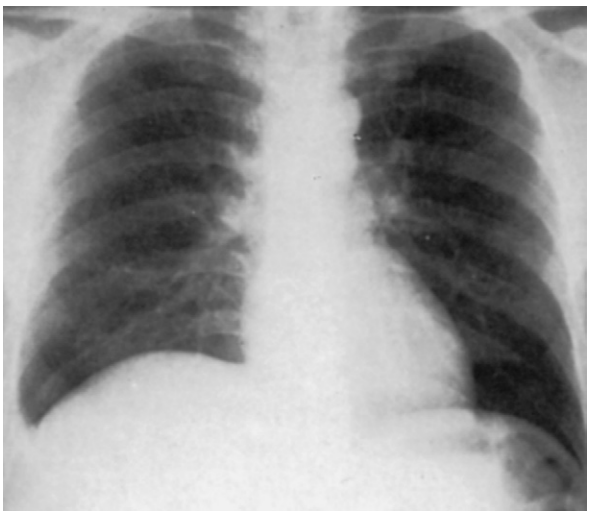

FIGURE 37-1 ■ Chest roentgenogram of a 39-year-old Chinese man with a documented amebic liver abscess shows elevated right hemidiaphragm and a small right pleural effusion.

Treatment

Invasive disease should be treated first with a tissue amebicide, such as metronidazole or tinidazole, followed by a luminal agent to eradicate cysts that are nonsusceptible to these drugs. Metronidazole is given at 500 to 750 mg three times a day orally or intravenously for 10 days. After this, a luminal agent such as paromomycin is given at 25 to 35 mg/kg/day divided in three doses for 7 days or diloxanide furoate, which can be obtained from the Centers for Disease Control and Prevention (CDC) Parasitic Disease Drug Service, is administered at a dose of 500 mg three times daily for 10 days.[10] Noninvasive disease does not require the tissue amebicide.[2] In one small trial, paromomycin was more effective than diloxanide at clearing asymptomatic *E. histolytica* carriage (85% vs. 51%).[2]

Although treatment failures occur and drug resistance can be induced in vitro, resistance has not been documented clinically, but it may be emerging.[34,35] A promising new drug class being investigated is the alkylphosphocholines. One member, miltefosine, has in vivo activity against other protozoa, such as *Leishmania*, and in vitro activity against *Entamoeba*.[34,36] Nitazoxanide and its metabolite tizoxanide have also been shown to be more active than metronidazole against *Entamoeba*. They may also have activity against less susceptible strains.[37] In a group of Mexican children, *E. histolytica/dispar* was found in 10% of children surveyed. After a single course of nitazoxanide, 96% were cured, and this increased to 100% after a second course.[38]

Surgical or noninvasive drainage of amebic abscesses should be reserved for those who have not responded to appropriate medical therapy or for those with abscesses that are at risk of rupture.[10,24] Empyemas should be drained with chest tubes to prevent superinfection and a need for decortication.[24]

Prevention and Control

Prevention of amebiasis depends on improved sanitation, clean water, and safe food in countries where it is prevalent. Efforts to stop transmission include early detection and treatment of infection and disease, health education, and handwashing. *Entamoeba* cysts are resistant to chemical disinfectants including chlorine, but they die if dried, heated, or frozen.[3]

A vaccine that elicits a mucosal response to the parasite may protect against infection and disease and, eventually, help in the eradication of this disease. Several vaccine candidates based on the Gal/GalNAc lectin have demonstrated protective immunity against hepatic amebiasis in animals.[20,39] Bangladeshi children who developed mucosal immunoglobulin A (IgA) antibodies against the lectin had 86% fewer *E. histolytica* infections over a year than those who did not.[40]

Malaria

Malaria is caused by infection with one of four species of the protozoan genus *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. The life cycles of all four species are very similar, with each having an asexual stage, occurring in the human host, and a sexual stage occurring in the female *Anopheles* mosquito.

Malaria occurs worldwide in tropical and subtropical regions. An estimated 3 million deaths occur due to malaria worldwide, 90% of which occur in Africa, mostly in children.[41] In 2000, there were an estimated 350 to 500 million cases of malaria and more than 1 million deaths, most of them occurring in Africa and Asia-Pacific.[41] Up to 5% of African children born in endemic areas will die from malaria. Malaria represents the third largest cause of infectious disease mortality after human immunodeficiency virus (HIV) and tuberculosis, making it the most lethal parasite of humans.

P. falciparum is responsible for the majority of cases of malaria in Africa, and about half of those in endemic areas outside of sub-Saharan Africa. An estimated 70 to 80 million cases annually are due to *P. vivax*, mostly in South and southeast Asia and South America.[42] *P. malariae* and *P. ovale* are less common. *P. ovale*, found in sub-Saharan Africa and southeast Asia, generally causes the mildest form of malaria with the lowest levels of parasitemia.[43]

Malaria is a major cause of fever and illness in travelers to endemic areas, and it is not uncommon to see imported cases in nonendemic areas; moreover, there can be a delay in onset of symptoms in such travelers owing to the interval between the bite of the infected mosquito and release of parasites from the liver.[44] Although malaria cannot be spread from person to person, a few cases of local transmission of malaria have occurred in the nonendemic regions of the world as well as, very rarely, transfusion-transmitted infection.

Transmission

Infected mosquitoes transmit the malaria sporozoites to a new host during a blood meal. The sporozoites travel through the bloodstream to the liver, where they mature into tissue schizonts within hepatocytes. The hepatocytes rupture, releasing thousands of merozoites that reenter the bloodstream and invade red blood cells. There, merozoites mature within the cells, forming rings, trophozoites, and then schizonts, which rupture the cell, releasing more merozoites. Some of these develop into gametocytes, which when taken up by a mosquito during a blood meal, restart the cycle.

The release of parasites from the liver in *P. vivax* and *P. ovale* infection may be delayed due to the propensity of these species to reside in the liver for a considerable time, the so-called hypnozoite stage. Unless specific "radical cure" is given, infection may relapse with the rupture of another infected hepatocyte.

Pathogenesis

P. falciparum is the most virulent species of malaria because it has the ability to parasitize a greater percentage of red blood cells and to sequester in the capillaries and postcapillary venules in many tissues. When *P.*

falciparum parasites infect red blood cells, they cause morphologic changes, including the formation of "knobs" on the surface of the red cells. These make the infected cells more adherent, allowing them to adhere to vascular endothelium, a process that leads to sequestration and obstruction of the microvasculature with resultant tissue ischemia. Sequestration is aided by decreased deformability of the infected red cells and by rosetting (adherence of infected and uninfected cells in clumps). With red blood cell destruction, parasite antigen release, and ischemia due to this sequestration, inflammatory cytokines may mediate at least some of the end-organ damage seen in severe malaria.[45]

The mechanisms mediating lung injury in malaria are poorly understood. In contrast to the frequently observed pattern in severe *P. falciparum* malaria in which splanchnic and cerebral vascular beds are heavily affected by sequestration, high-level sequestration of parasitized red blood cells is seldom observed in pulmonary capillary beds. Autopsy findings of patients who have died with respiratory distress as a feature of severe malaria have demonstrated swelling of the alveolar septa, with marked interstitial edema.[46,46a]

Clinical Manifestations

Malaria usually presents with periodic fever, chills, headache, and malaise. Splenomegaly and anemia are frequent clinical findings. Most cases of malaria are uncomplicated. Infections with *P. malariae*, *P. ovale*, and *P. vivax* are rarely life-threatening. Falciparum malaria can progress rapidly to a fatal disease, involving multiple organs. The World Health Organization's criteria for severe malaria[47] include coma, severe anemia, pulmonary edema, hypoglycemia, hemodynamic collapse, renal failure, bleeding, recurrent seizures, acidosis, or hemoglobinuria. Hyperparasitemia and jaundice have also been added[48] to criteria for severe malaria. The clinical manifestations of severe malaria vary with age. Severe anemia is more common in infancy and early childhood, whereas cerebral malaria occurs more frequently later in childhood. Adults are more likely to develop renal failure, jaundice, and pulmonary edema. However, severe manifestations may occur at any age group.[49]

Falciparum malaria is especially dangerous during pregnancy, representing a major cause of anemia in the pregnant mother, and low birth weight, prematurity, or miscarriage of the infant[50]; the presence of coexisting HIV infection adds greatly to these hazards.[51] The pathogenesis of malaria in pregnancy is largely explained by the ability of *P. falciparum* to express ligands on the surface of the red cell that facilitate sequestration in the placental vascular bed. The severe manifestations of malaria in pregnancy are more likely to occur in women in their first pregnancy than in the second and third trimester and the immediate postpartum period.[52,53] In a recent case report of a fatal case of *P. vivax* infection attributed to respiratory failure, postmortem findings showed changes typical of the Acute Respiratory Distress Syndrome,[46a] again highlighting the potential of *P. vivax* infection to rarely cause lethal pulmonary complications.

Pulmonary Disease

Pulmonary disease in malaria is most commonly a result of infection with *P. falciparum*; but it is increasingly recognized that *P. vivax* can cause pulmonary edema.[54–57] Recent papers report a high frequency of respiratory distress associated with both *P. falciparum* and *P. vivax* in adults and children in endemic areas.[58,59] *P. ovale* is now also recognized to cause pulmonary edema.[43,60] Infection with *P. malariae* has never been associated with pulmonary edema, but has been reported to cause respiratory symptoms. In addition, there has been one reported case of bronchiolitis obliterans following vivax malaria.[61] An Australian study of acute, uncomplicated malaria showed that 4 of 11 patients with *P. falciparum* and 8 of 15 patients with *P. vivax* infection had a cough at the time of diagnosis of malaria. Moreover, subclinical impairment of lung function (small airway obstruction, reduced diffusion capacity) was observed in these patients, both on admission as well as 12 to 20 days later. These abnormalities ultimately resolved in all patients with the successful treatment of their malaria.[56] These findings have also been shown in patients with both falciparum and vivax malaria in endemic areas.[56,62] In another study of Israeli expatriates living in Cameroon, 18% of cases with uncomplicated malaria had a decrease in peak expiratory flow rate while parasitemic.[63]

The most severe form of lung injury in falciparum malaria is a noncardiogenic pulmonary edema with acute respiratory distress syndrome (ARDS). This occurs in less than 1% of infected patients but is associated with a higher mortality. When this manifestation occurs, it often follows the initial treatment after the parasitemia begins to decrease. Patients often have normal pulmonary capillary wedge pressures, and do not respond as well to diuretics as do patients with cardiogenic pulmonary edema.[64] In adults, the pathophysiology likely entails parasite sequestration in pulmonary microvasculature as well as inflammatory response. The causes of respiratory distress in children are less clear, but include acidosis and concurrent pneumonia. The role of pulmonary parasite sequestration and pulmonary inflammation requires further investigation.

Among 188 individuals with malaria admitted to a French intensive care unit, 93 had severe disease, 43% required mechanical ventilation for pulmonary edema; 11% of these patients died. An increased risk of mortality was associated with nonimmune status, coma, pulmonary edema, shock, and metabolic acidosis.[48]

Diagnosis

The standard diagnostic test for malaria is a Giemsa stain of a thick or thin blood smear to identify parasites. Although negative blood smear makes the diagnosis less likely, if the clinical suspicion of malaria is high, blood smears should be repeated every 12 hours for 48 to 72 hours.

Several antigen detection tests are now available and enable a rapid diagnosis of falciparum malaria. They are

based on detection of one of two parasite-specific proteins, the histidine-rich protein 2 (specific for *P. falciparum*) or parasite-lactate dehydrogenase (for either *P. falciparum* or *P. vivax*). Although only one is approved by the U.S. Food and Drug Administration (FDA), field trials have shown good sensitivity (78%–93%) and specificity (92%–98%) for *P. falciparum*.[65-68] PCR diagnosis of malaria species is used for research purposes, but is not widely available.

Treatment

Uncomplicated malaria caused by *P. vivax*, *ovale*, *or malariae* can be treated with chloroquine for 3 days, as can mild falciparum malaria from the few regions where chloroquine-sensitive *P. falciparum* remains (Central America north of the Panama Canal, North Africa, and the Middle East). Therapy of vivax and ovale malaria requires an additional 2-week course of primaquine to eradicate the liver stage of the parasite. Falciparum malaria is almost universally chloroquine-resistant. A range of drug regimens is suitable for treating mild falciparum malaria, including quinine sulfate (650 mg daily for 3 days) plus tetracycline, mefloquine (750 mg followed by 500 mg 12 hours later).[49] Atovaquone-proguanil (Malarone), 4 tablets daily for 3 days in adults, or artemether-lumefantrine (Coartem, Riamet; 20 mg artemether and 120 mg lumefantrine) administered as six consecutive doses (each of four tablets, i.e., 80 mg of artemether and 480 mg of lumefantrine) at 0 and 8 hours on day 1 and twice daily (~8 hr apart) on the following 2 days.[69,70] The treatment of choice for severe malaria is intravenous artesunate administered in four equal doses of 2.4 mg/kg of body weight, with the first dose given on admission, followed by doses at 12 hours and 24 hours, then once on day 3.[71] The drug is available under an Investigational New Drug (IND) from the CDC, by calling the CDC Malaria Hotline (770-488-7788 or 770-488-7100). If the drug cannot be made rapidly available, the second-line agent, quinidine, should be used (see later). Quinine and its D-enatiometer quinidine are alternatives, administered by intravenous infusion as 20 mg salt/kg on admission, then 10 mg/kg every 8 hours. Infusion rate should not exceed 5 mg salt/kg/hr due to cardiotoxicity and ideally should be administered in a monitored environment owing to potential toxicity.

Despite intensive support, severe malaria has a high fatality rate due to end-organ damage. Close monitoring of fluid balance is appropriate to prevent fluid overload and respiratory distress. Early renal replacement therapy is appropriate. Hypoglycemia should be corrected with glucose infusions, and respiratory symptoms with oxygen and, if necessary, intubation and ventilation. Concomitant bacterial infections should be managed with appropriate antibiotic therapy. Transfusion is often necessary for the anemia. Some experts recommend exchange transfusions in patients with a high level of parasitemia. However, no randomized trials have been done that show clear benefit.[72]

Prevention

Prevention of malaria entails several approaches, including decreasing mosquito contact with bed nets, insect repellants, and protective clothing to decreasing transmission from the mosquito (vector control) and susceptibility of the host (antimalarial prophylaxis). Vector control includes extensive use of insecticides and decreasing mosquito breeding areas. Insecticide-impregnated bed nets are an inexpensive and effective method of preventing transmission.[73] They have been shown to decrease parasitemia and anemia, as well as death in children under 5.[74,75] Other less well studied methods for travelers include insecticide-treated clothing and topical insecticides.[76]

Chemoprophylaxis is frequently indicated in nonimmune travelers to endemic areas. Because most *P. falciparum* is now resistant to chloroquine, alternative agents must be given. Agents most commonly used at this time are mefloquine, doxycycline, and atovaquone-proguanil. Mefloquine is given weekly, starting 1 week before travel, and continuing for 4 weeks afterward. It is generally well tolerated, although a significant percentage of people report bizarre dreams and occasionally hallucinations. It should not be given to anyone with a major psychiatric illness or to those with a seizure disorder or disturbance of cardiac rhythm. Atovaquone-proguanil is approved for prophylaxis as a fixed-dose combination pill that is taken daily. Its advantage over mefloquine is that it need be started only 1 to 2 days before travel and continued for just 1 week after return. However, because it is more expensive than mefloquine, it is generally not cost-effective for trips over 2 to 3 weeks duration. Doxycycline is also an effective daily prophylactic agent. Although it is cheaper than atovaquone-proguanil, it cannot be given to pregnant women or small children.

Although vaccines against malaria are being actively developed, most are still in the preclinical phase or early clinical trials. The malaria vaccine candidate that is the most advanced in development is based on the repetitive sequence of four amino acids in the circumsporozoite antigen on the surface of the sporozoite of *P. falciparum*.[77] This vaccine has been subjected to extensive studies involving human volunteers, the results of which indicated a potential protective efficacy of about 40%.[78,79] In a recently completed phase IIb study undertaken in Africa, the vaccine reduced the risk of malaria infection and clinical disease by 65% and 59%, respectively.[80] A phase 3 clinical trial of this vaccine is ongoing.

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular parasite, with humans being incidental hosts. A zoonosis, it can complete its life cycle only within felines, although a wide range of birds and mammals can serve as intermediate hosts.[81] Prior to the HIV epidemic, it was recognized primarily as a cause of congenital infection and of disease in the immunosuppressed. Since the onset of the

HIV epidemic, it has emerged as a common cause of neurologic disease in patients with the acquired immunodeficiency disease syndrome (AIDS). Up to 50% of the world's population are estimated to be infected with *T. gondii*, with great geographic variation.[82]

Transmission

Toxoplasmosis is most frequently acquired by ingestion of cysts measuring 10 × 12 μm. These are excreted in cat feces and sporulate in the environment, where they can remain viable and infective for months. Environmental exposure can occur without direct exposure to a cat, by eating oocysts contaminating raw vegetables or fruits. An alternate, less common mode of transmission is through ingestion in raw or poorly cooked meat of tissue cysts containing thousands of bradyzoites. Tissue cysts are killed by freezing or by exposure to temperatures greater than 60°C.[83] Toxoplasma infection can also be acquired from organ transplantation or congenitally from mother to fetus.

Pathogenesis

Upon entering a host, *T. gondii* must evade host defenses, but can invade any cell in the body, although brain, lymph nodes, heart, and lung are most common. Tachyzoites bind to receptors on the cell surface and are internalized within a vacuole derived from the host plasma membrane, termed the parasitophorous vacuole. Host defense against *Toxoplasma* requires both a functional innate and an adaptive immune system. Typically, *Toxoplasma* infection triggers macrophages to make interleukin (IL)-12, resulting in secretion of interferon-γ (IFN-γ) by $CD4^+$ T cells and natural killer cells. IFN-γ activates macrophage toxoplasmocidal activity, allowing macrophages and monocytes to kill the parasite through oxygen radical formation.[84] IL-10 secretion triggered by the parasite prevents an overexuberant immune response as well as allows the parasite to evade killing by downregulating the immune response.[85] The vast majority of people quickly contain infection, and bradyzoites are confined within tissue cysts.

In the lung, *T. gondii* infection can cause a necrotizing pneumonia with nodule formation, diffuse alveolar damage, and interstitial pneumonitis. Edema develops at the alveolar-capillary interface, accompanied by lymphocyte infiltration.[82] In a French autopsy study of 80 patients who died with AIDS, 44% of the patients had *T. gondii* in their tissues, 5 of whom had evidence of lung disease. Pathologic findings included foci of coagulative necrosis, disseminated microfocal bronchopneumonia, and florid bronchitis with granulocytic infiltrations. Numerous trophozoites were found within the lesions, especially at the margins.[86]

Clinical Manifestations

The vast majority of immunocompetent people who acquire *T. gondii* remain asymptomatic. Ten percent to 20% of infected people develop a painless lymphadenopathy[87]; in an even smaller percentage, a prolonged mononucleosis-like illness occurs, with generalized lymphadenopathy, fevers, and malaise. Rarely, solid organ involvement occurs.

A more fulminant illness can occur among immunosuppressed individuals, either during primary infection or with reactivation of latent infection. Cerebral toxoplasmosis is the most common clinical manifestation among immunocompromised individuals, with necrotizing encephalitis occurring in up to 10% to 40% of AIDS patients not on chemoprophylaxis for toxoplasmosis. Ocular, cardiac, pulmonary, disseminated toxoplasmosis or septic shock can also occur. Extracerebral *Toxoplasma* infection occurs in 1.5% to 2% of AIDS patients, with pulmonary disease occurring in 0.5% of patients.[88]

Pulmonary Disease

AIDS patients with *Toxoplasma* pneumonia present with cough, dyspnea, and fever. As toxoplasmosis is generally seen only in advanced HIV infection with CD4 counts below 100, the majority of AIDS patients who develop toxoplasma pneumonia already have had previous HIV-associated opportunistic infections. The difficulty of defining the contribution of *T. gondii* infection to pneumonitis in a setting where other pathogens such as cytomegalovirus (CMV) and *P. jirovecii* infection are also present is significant, especially where PCR-based diagnosis is employed without quantitation of the infective burden.[89] Nevertheless, the mortality among patients with *Toxoplasma* pneumonia appears to be higher than among patients with extrapulmonary disease, with a median survival of 150 days after diagnosis.[90]

The majority of pulmonary disease is from reactivation of latent disease, although cases of acute primary disease have been reported.[91] In solid organ transplant patients, this is most commonly due to transplantation of a toxoplasma-seropositive lung or heart into a seronegative recipient, resulting in primary pulmonary disease. There is no evidence that specific isolates of *T. gondii* have a predilection to cause pulmonary disease.[91a] Occasionally, in transplant patients, hematogenous spread of the organism can lead to multiple nodules within the lung.[82]

In bone marrow transplant patients, pulmonary toxoplasmosis occurs in 0.28% to 0.45% of patients. Unlike solid organ transplant patients, most of these patients have reactivation, not primary disease. The major risk factors are pretransplantation seropositivity of the recipient, an allogeneic transplant, and graft versus host disease (GVHD) entailing intensification of immunosuppression.[92] Pulmonary disease generally results from dissemination from another site. Most patients developed symptoms within the first 2 months of bone marrow transplantation, at times despite prophylaxis.[93] In a series of 55 cases of disseminated toxoplasmosis after bone marrow transplantation, only 4 patients survived the infection, a mortality rate of 93%.[94]

T. gondii pneumonia can occur in immunocompetent subjects.[95] Apart from the expected features of pneumonia, myalgia, rash, and abnormal liver function tests were

prominent findings. Testing for *T. gondii*–specific IgM antibodies was a sensitive diagnostic approach, as was cytologic examination of BAL fluid for tachyzoites. Full recovery is usual.

Diagnosis

Although serum lactate dehydrogenase may be extremely elevated in toxoplasma pneumonia, it is neither sensitive nor specific. Serology in the appropriate clinical setting can confirm exposure, but is not sufficiently specific. Microscopic examination of lung lavage fluid is the technique of choice for diagnosis of pulmonary toxoplasmosis. Histologic examination of lung biopsy can also identify the organisms. Tachyzoites can be visualized by Giemsa or eosin-methylene blue stains, whereas the cyst forms can be seen on hematoxylin and eosin or silver staining. Immunohistochemical or indirect immunofluorescence staining is also useful for confirmation of the diagnosis, but is not as sensitive.

A range of radiographic patterns have been reported, including interstitial or alveolar opacities, nodules, or a miliary pattern (Fig. 37-2). Pneumonia may be associated with pleural effusions or pneumothorax. In the French study of HIV patients, chest radiographs were abnormal in 53% of patients and 88% of patients with a positive lavage; the remainder were diagnosed on biopsy or autopsy.[88]

PCR techniques are now being explored for early diagnosis of reactivation of toxoplasmosis in bone marrow transplantation patients. This would enable prophylaxis and treatment of positive patients, without exposing others to the potential toxicity of drugs used for prophylaxis.[96] Although PCR has been used in AIDS patients to detect *T. gondii* in brain,[97] lung lavage fluid,[98] and sputum,[99] this technique is not widely used.

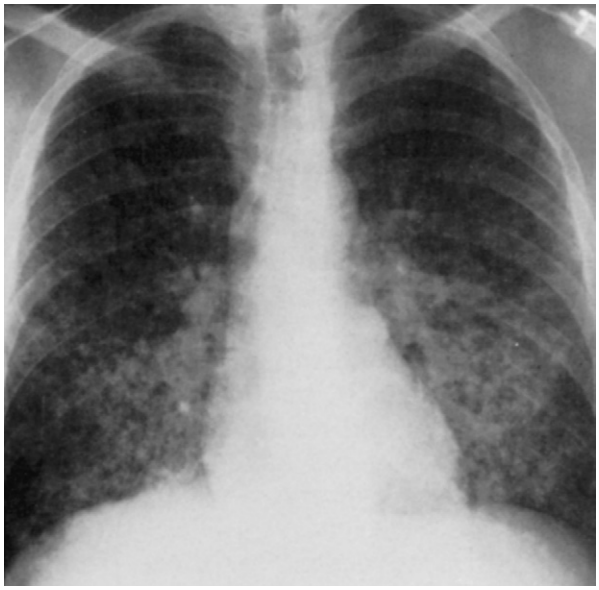

FIGURE 37-2 ■ Chest roentgenogram of a 29-year-old with acquired immunodeficiency syndrome and cerebral and pulmonary toxoplasmosis shows multiple nodular densities throughout both lung fields.

Treatment

Treatment regimens for toxoplasma pneumonia are based on those developed for treatment of cerebral disease. Standard treatment is oral pyrimethamine 50 to 100 mg and folinic acid 10 to 25 mg daily, along with oral sulfadiazine, 1.0 to 1.5 mg every 6 hours. Both drugs act on the parasite's folate pathway. The most common adverse effects are with sulfa drugs, including myelosuppression, rash, hepatotoxicity, and renal impairment. Alternate regimens include pyrimethamine in the just discussed dose, and clindamycin (400–600 mg orally or 600–1200 mg intravenously) every 6 hours. Once an immunosuppressed patient develops toxoplasmosis, lifelong chronic suppressive treatment is necessary unless the immunosuppression can be reversed, for example, by immune reconstitution in HIV infection. Pyrimethamine 25 to 50 mg daily with leucovorin plus sulfadiazine 500 to 1000 mg four times daily is the recommended regimen for suppressive therapy.

Prevention

Prevention of primary infection entails avoiding contact with infected cat feces, washing hands and kitchen utensils that come into contact with raw meat, washing fruits and vegetables well, and cooking all meat thoroughly.

As HIV patients have a significant risk of toxoplasmosis once their CD4 count falls below 200, it is recommended that baseline serology is performed. Trimethoprim-sulfamethoxazole (TMP-SMX), the drug of choice for prophylaxis of *P. jirovecii.* Pneumonia, has additional activity in preventing *T. gondii* infection.[100–102] In sulfa-allergic patients, pyrimethamine or dapsone can also be used. Pyrimethamine-sulfadoxine has also been demonstrated to be effective prophylaxis in *T. gondii*–seropositive bone marrow transplant patients,[103] whereas pyrimethamine given alone has been demonstrated to be effective prophylaxis for heart and heart-lung transplant patients.[104]

HELMINTHS

Intestinal Nematode Infections

Roundworms or nematodes can be classified broadly into those inhabiting the intestine, which are by far the most common, and those infecting deep tissue. Although some of these parasites can be transmitted from human to human, most require some period of maturation in the environment before becoming infectious to the human host. With the exception of *Strongyloides stercoralis*, intestinal nematodes do not multiply within humans; diagnosis is made by finding either eggs or parasites, usually in the stool. It is estimated that there are more than 1 billion cases of ascariasis worldwide. *Strongyloides*, through its autoinfection cycle, can multiply and disseminate widely in an immunocompromised individual (the hyperinfection syndrome).

Although significant pulmonary disease is not a recognized feature of intestinal helminth infections, transient pulmonary symptoms frequently occur during larval migration through the lungs en route to the intestine. Among the intestinal helminths, *Ascaris lumbricoides* (roundworm), *Necator americanus*, or *Ancylostoma duodenale* (hookworm), and *Strongyloides* are the most common helminths whose life cycle entails passage through the lung. The symptoms, typically a transient Loeffler-like syndrome, are characterized by cough, asthma, fever, patchy pulmonary opacities on chest radiographs, and eosinophilia (see Chapter 61).

Ascariasis

A. lumbricoides is the most ubiquitous of the intestinal parasites. Growing to a length of up to 35 cm, it infects more than 1.3 billion people worldwide.[105] Although morbidity and mortality data are difficult to obtain, it is estimated that between 8,000 and 10,000 children die each year from complications of ascariasis, particularly intestinal and biliary obstruction.[106]

Ascariasis is most common in the tropics and subtropics, especially in areas with high rainfall, but its prevalence depends on many factors. It is generally low in developed countries (<1%) and more common in developing countries, ranging from 4% in Mafia Island, Tanzania,[107] to 45% in one study in Vietnam,[108] and 91% in children in northern Pakistan.[109] An estimated 4 million people in the United States are infected.[110] *Ascaris* is still prevalent in the rural areas of the southern United States and is frequently seen in travelers from endemic areas. Some cases may arise from pigs (*Ascaris suum*).[111] Children carry heavier worm burdens than adults, perhaps owing to geophagia or acquired immunity in adults.

Transmission. Humans are the only natural host of *A. lumbricoides*, although the pig species *A. suum* is almost identical except for small differences in morphology and biochemistry. Although individual worms from humans and pigs cannot be differentiated on clinical or morphologic grounds, species-specific genetic markers enable differentiation of host-specific populations.[106,108] The two populations of worms are reproductively isolated.[112] Female worms produce up to 200,000 eggs per day that are shed in the stool. Once in the environment, the embryonated egg matures in moist conditions into a rhabditiform larva within the egg. Infection occurs by ingestion of food or water contaminated with eggs rather than by direct person-to-person contact. Once swallowed, the eggs hatch in the duodenum, where the larvae are released. They burrow through the walls of the intestine and enter the portal circulation, passing through the heart to reach the lungs. In the lungs, they molt twice and then break into the alveoli. They then crawl up the bronchial tree and are swallowed. They then make their way to the small intestine where they mature into adult worms. Eggs are produced after adult worm maturation, a few months after infection. Adult worms feed on intestinal contents and can live for 10 to 24 months in the host. In hyperendemic areas where high worm and egg burdens are prevalent, transmission can even occur by inhaling eggs or swallowing contaminated respiratory secretions.[106,112]

Pathophysiology. The pathophysiology of lung disease due to *Ascaris* is varied. The first effects are attributable to larval migration through pulmonary tissue. The host response to the larva, which results in production of IgE and an eosinophilic inflammatory infiltration, leads to significant pathology. Eosinophils coat the larvae and can envelop them in eosinophilic granulomas. During pulmonary migration, a hypersensitivity reaction can occur, leading to an alveolar serous exudate, with eosinophilic infiltration of the peribronchial tissue and increased mucus production. This can lead to bronchospasm and airway hyperreactivity. On rare occasions, retrograde peristalsis and vomiting can lead to expulsion of fully developed adults from the intestine into the upper airways, leading to upper airway obstruction.[110,113]

On gross examination of ascaris-infected lung tissue, small, consolidated gray patches are seen, especially in the lower lobes. Histologically, interstitial pneumonitis with thickened alveolar walls can be found, as well as bronchiolar infiltration with eosinophils and fibrin. Larvae can occasionally be isolated from airways.[110]

Clinical Manifestations. Most patients with ascariasis are asymptomatic, although nonspecific abdominal symptoms are common. The pulmonary phase occurs while the larvae are passing through the lung. Once they reach the intestine, associated symptoms include nausea, vomiting, vague abdominal pain, and anorexia. The intensity and frequency of symptoms appear to be related to adult worm burden. Complications of ascaris infection are usually associated with ectopic migration of the adult worms into the common bile duct or pancreatic duct resulting in cholangitis, pancreatitis, or liver abscess. Likewise, appendicitis is recognized as is intestinal obstruction in heavy infection leading to perforation with peritonitis.[110]

Heavy worm burdens can cause malnutrition in children, which can lead to stunted growth and neurologic development. Conversely, treatment of intestinal helminths leads to improved growth. Indeed, some studies suggest that deworming may improve learning ability and cognition.[112]

Pulmonary Disease. The classic pulmonary disease in *Ascaris* infection is Loeffler's syndrome, which manifests as transient pulmonary opacities and eosinophilia coinciding with the larval migration through the lungs. Worldwide, ascariasis is the most common cause of transient eosinophilic pulmonary radiographic opacities. In some areas, the pneumonitis occurs at specific times of the year where climatic factors influence transmission.[114]

Symptoms from larval migration through the lungs develop 9 to 12 days after ingestion of the eggs and can last from 2 to 3 weeks. They include a nonproductive cough, burning substernal pain that can be pleuritic, dyspnea, and occasionally mild hemoptysis, crackles, or wheezes.[112] Associated findings include an urticarial rash and low-grade fever. Rarely, an adult worm can

ectopically migrate into the lungs or other viscera and get "lost." For example, adult worms have been found in a tuberculous pyopneumothorax, causing a bronchopleural fistula.[115]

The relationship between helminth infection and asthma and other allergic diseases has led to the postulation of the so-called hygiene hypothesis.[116] Several studies have suggested that intestinal helminth infection decreases the risk of atopy and asthma.[117,118] However, others have found that *Ascaris* and other helminths infections are associated with asthma and that treating the helminths led to better asthma control in asthmatic children.[119–121]

Diagnosis. For the intestinal phase of ascariasis, stool examination for the large, thick-shelled eggs is the most common and reliable diagnostic approach. Because the worms produce so many eggs per day, eggs are relative easy to find in the feces of infected patients. However, because the pulmonary symptoms are due to larval stages, eggs may not be present in the stool during the pulmonary phase if it is the initial infection. Further, ascaris eggs in the stool of a patient with pulmonary symptoms are not necessarily indicative of pulmonary ascariasis, because the patient may not have any larval stages left. Laboratory abnormalities are nonspecific and include blood and sputum eosinophilia that usually appear after the onset of symptoms. The chest radiograph typically shows migratory, transient opacities of varying sizes.

Treatment. Pulmonary ascariasis is a self-limited disease that does not require specific treatment. Thus, anthelmintic treatment probably does not have an effect on larval stages in the lungs.[112] In patients with severe symptoms, corticosteroids can be used to attenuate the inflammatory response. A range of anthelmintics are effective for treatment of ascariasis. Whereas single-dose therapy with albendazole, 400 mg (adults), or mebendazole, 500 mg, dramatically reduces worm burden and egg output, it may not lead to cure.[122] Mebendazole in a dose of 100 mg twice a day for 3 days may be more effective. Alternative treatments are pyrantel pamoate 11 mg/kg (to 1 g maximum) as a single dose or ivermectin (not normally given for the treatment of intestinal helminth infection).[123] Albendazole and mebendazole were both more than 97% effective at eliminating *Ascaris* infection in school children in Zanzibar,[124] although a more recent study showed that albendazole cured infection in only 70% of children in the Philippines.[123] Nitazoxanide, recently approved for use in children in the United States, had a 100% efficacy in curing light to moderate ascariasis in Mexican school children.[38] In patients with intestinal obstruction, piperazine citrate at 75 mg/kg for 2 days narcotizes the worms and helps relieve obstruction prior to treatment with an anthelmintic agent.

Prevention. Transmission of *Ascaris* can be interrupted with improved hygiene, sanitation, cessation of use of human waste as fertilizer, and access to clean water. Education about washing fruits and vegetables and boiling water is also helpful. Mass treatment campaigns of whole populations or targeted to children have been shown to decrease intensity and prevalence of infection and morbidity associated with high worm burdens.[125,126]

Hookworm

Human hookworm disease is caused primarily by either *Ancylostoma duodenale* or *N. americanus*. Together, these two species infect 1.2 billion people and are a major cause of morbidity worldwide.[127] Adult hookworms live in the small intestine and can be identified by the buccal capsule that they use to attach to the small bowel mucosa. The worms feed on blood and tissues from the human host, resulting in iron-deficiency anemia in areas where dietary iron levels are low. Hookworm infection is most common in tropical and subtropical areas. In parts of the world, it is the most common intestinal helminth.

Transmission. Hookworm is generally transmitted by entry of the rhabditiform larvae through the skin, usually of the feet or hands. Once the larvae enter the body, they migrate to the lungs. There, they molt and then crawl up the bronchial tree and are swallowed. In the small intestine, another molt occurs before the worm attaches to the intestinal lumen to feed. Following fertilization, *Necator* begins shedding eggs within 2 months of infection, whereas *Ancylostoma* does so at approximately 38 weeks.[110] Once the eggs are shed in the stool, they hatch, molt into rhabditiform larvae, and crawl to the surface of the soil from which they can infect another host, thus completing the life cycle. Adult worms are small (1 cm long) and cylindrical. Adults can produce up to 7000 eggs/day and can live for up to 8 years.[128]

Pathophysiology. In the lung, migrating larvae may cause alveolar hemorrhage.[110] Bronchoscopy undertaken during the pulmonary migration has revealed airway erythema, with BAL cytology showing a marked eosinophil predominance.[129] The blood loss from the intestine due to hookworm infection can be significant if the burden of infection is heavy. The average daily blood loss is 0.2 mL/adult worm for *Ancylostoma* and 0.03 mL/adult worm for *Necator*.[128] The adult worm changes locations every few hours, leaving behind bleeding, raw mucosa. The consequent anemia can be severe, leading to cardiac decompensation and, rarely, death.

Unlike other helminth infections, hookworm prevalence in communities continues to increase with age, and therefore, the highest prevalence is in older adults and elderly. Protective immunity to hookworm rarely occurs and may require a specific IgE response to hookworm antigens.[127]

Clinical Manifestations. As in ascariasis, the symptoms of hookworm infection depend on the location of the parasite. In the majority of patients, the infection is subclinical. Symptoms are usually related to the burden of infection. Initially, as the parasite enters the skin, a pruritic dermatitis can occur, termed "ground itch." It can be intense in nature, depending on the number of infecting organisms and previous host sensitization. Local pruritus is reported to be more common in *N. americanus* infection than in *A. duodenale* and

generally occurs on the feet where the parasites tend to enter. In an outbreak of hookworm in a cohort of young North Indian men who were heavily infected after playing in a field heavily contaminated with human excrement, the rash lasted for a mean of 6.5 days (but in some continued for up to 30 days). Several days after the pruritus resolved, the pulmonary symptoms started in the majority of patients. These lasted for up to 3 months in this cohort.[130] In five patients experimentally infected with a low numbers of larvae, no appreciable pulmonary symptoms were seen.[129] Transient gastrointestinal symptoms generally follow, manifesting as vague abdominal discomfort, increased flatulence, nausea, vomiting, or severe cramping that can be postprandial in nature. Anemia is the most important consequence of hookworm infection and can cause cognitive and learning problems. Malnutrition and hypoproteinemia can occur from the loss of plasma proteins.[110]

Pulmonary Disease. The migration of the larvae through the lungs may cause a Loeffler syndrome as with ascariasis. Patients may have a mild cough, or the symptoms may be more severe, with associated dyspnea and wheezing. Symptoms generally last about 2 weeks, but in heavy infection, they can last for up to 3 months. The chest radiograph may show transient, migratory opacities, especially in the hilar areas, with spontaneous clearing.[110]

Diagnosis. In intestinal disease, stool examination reveals characteristic hookworm eggs. The diagnosis of pulmonary disease is more difficult, because, as in ascariasis, the pulmonary symptoms occur before patent infection has developed. Definitive diagnosis depends on the isolation of larvae from respiratory secretions or by BAL or from gastric secretions. A history suggestive of exposure, with a characteristic rash followed by pulmonary symptoms several days later, should raise suspicion of hookworm. A retrospective diagnosis can be made if eggs appear in the stool 2 to 3 months later.

Treatment. Anthelmintic drugs are not effective against the larval stages in the lungs, so there is no specific treatment for the pulmonary stage of hookworms. Symptomatic relief of the pulmonary disease associated with hookworm if indicated can be obtained by using bronchodilators or, in rare circumstances, corticosteroids. For intestinal infections, a single dose of albendazole (400 mg) is the recommended therapy for hookworm infection. Mebendazole (100 mg twice daily for 3 days) can also be used. However, both regimens when administered in single dose are less than 100% effective.[122] Community-wide (or targeted mass treatment) campaigns has been shown to decrease the morbidity and cognitive dysfunction associated with intestinal helminths[105] including hookworm. An alternative regimen is pyrantel pamoate 11 mg/kg to a maximum dose of 1 g given as a single dose.

Prevention. Prevention of hookworm infection entails improving sanitation and hygiene. Sewage collection and proper waste disposal and barriers to contaminated areas can decrease transmission. Whereas an effective vaccine for dog hookworm, based on irradiated larvae, was available for a time, indicating that development of a vaccine is possible, the development of a human vaccine appears to be some way off.[127] An intriguing study in Brazil showed that children who had a Bacille Calmette-Guérin (BCG) vaccination scar had a lower prevalence of hookworm infection (by 41%) than those without a BCG scar and intensity of infection even after controlling for possible confounding variables.[131]

Strongyloides

S. stercoralis is rare among intestinal helminths in its ability to complete its life cycle within the human host, which enables a cycle of autoinfection that can persist for decades after initial infection. When host immune surveillance is attenuated by corticosteroids, human T-cell lymphotrophic virus 1 (HTLV-1) infection, malignancy, or certain immunosuppressive drugs, infection can amplify, resulting in disseminated infection leading to a fulminant, overwhelming course with a high mortality rate.[131a] Although epidemiologic estimates are likely to be inaccurate, an estimated 50 to 100 million people are infected worldwide, with between 0.4% to 6% of the population of the southeast United States infected.[132,133] Populations at significantly greater risk for strongyloidiasis include immigrants, travelers from any developing country, veterans who have served in endemic areas, institutionalized persons, and those with achlorhydria.

Transmission. *S. stercoralis* is found throughout the tropical and subtropical world. It is endemic in the southeast United States and in urban centers with large immigrant populations. It is also frequently found in institutionalized populations. Like hookworm, transmission is through contact with soil or water contaminated with feces. Once filariform larvae of the parasite penetrate the skin, they migrate through the venous circulation or lymphatics to the lungs. There, they penetrate the alveolar wall and migrate up the bronchial tree to be swallowed by the host. In the small intestine, larvae molt twice to become adult female worms, which burrow into the wall of the duodenum and jejunum. The parthenogenic female adult parasite begins laying eggs 28 days after infection. These eggs are shed into the lumen of the small bowel and rapidly hatch to become rhabditiform larvae that can either be shed with the feces out into the environment or molt in the bowel into filariform larvae and reinvade the intestinal wall or perianal skin to start the cycle of infection over again. Once in the environment, the rhabditiform larvae can develop either into filariform larvae to await another host to infect or into free-living adult males and females that reproduce sexually. The worms can either continue to exist as free-living organisms or parasitize another person.[134] Human-to-human spread has rarely been reported to occur with sexual contact.

Patients with HTLV-1 infection are more susceptible to infection with *Strongyloides* and to complications of that infection. It has been demonstrated in multiple studies that HTLV-1–positive patients had higher rates of *Strongyloides* infections.[135,136] Also, patients with *Strongyloides* who fail treatment are more likely to have HTLV-1 infection than those who responded to treatment.[137] A

possible explanation for this observation is that HTLV-1 infection skews the immune response toward a Th1 response, with elevation of IFN-γ, and away from a Th2 response characterized by elevation of IL-5 and necessary to control *Strongyloides* infection.[138] Fortunately, this does not seem to be true for HIV-infected individuals, and an increased incidence of disseminated *Strongyloides* has not been seen in areas with high HIV prevalence.[139]

Pathogenesis. The pathology caused by *Strongyloides* infection is largely due to the migration of the worms through tissues and to the immune reaction to them. When the organisms penetrate the skin, a cutaneous eruption can result. Likewise, as the worms migrate through the lungs, a Loeffler-like syndrome can result. If the host immune status is compromised, the autoinfective life cycle can amplify with worms migrating across the intestinal wall, these carrying enteric bacteria with them to multiple sites, resulting in life-threatening sepsis or meningitis.

Extensive alveolar hemorrhage is typically found in patients who succumb to disseminated strongyloidiasis; such hemorrhage is not observed in other organs. In other patients, postmortem histopathologic examination has revealed areas of lung tissue necrosis and neutrophil infiltration with increased congestion. Occasionally, a significant pleural effusion can occur.[140] In most patients with significant pulmonary involvement, larvae and occasionally adult worms and eggs can be identified in BAL fluid or sputum.[141] Other pathologic findings include pulmonary edema and bronchopneumonia. The death of the organisms can cause ARDS.[142] One patient with longstanding obstructive and restrictive lung disease was found on autopsy to have fibrosis of the interlobular septae, within which numerous granulomas were observed with a cellular composition including lymphocytes, plasma cells, histiocytes, giant cells, eosinophils, and neutrophils. In the center of these granulomas, *Strongyloides* larvae were seen.[143]

Clinical Manifestations. Infection with *Strongyloides*, as with other intestinal helminths, is completely asymptomatic in a large proportion of people infected. When symptoms occur, their character depends on the stage of infection and the location of the worms. Upon penetration of the skin by filariform larvae, a characteristic pruritic rash can develop at the site of infection, termed *larva currens*. This can last for up to 3 weeks. This may be followed shortly thereafter by pulmonary symptoms as the worms migrate through the lungs. Abdominal symptoms, characterized by bloating, vague abdominal pain, nausea, and diarrhea, may follow once the parasites reach the intestines. This symptom pattern can recur as autoinfection occurs. Indeed, chronic cough is a recognized feature of occult strongyloidiasis[144] and resolves following curative chemotherapy.[145]

In the hyperinfection syndrome, in addition to symptoms seen in ordinary infections, ileus or intestinal perforation can occur owing to the migration of large numbers of worms across the mucosa and carriage of enteric bacteria into a range of body sites, resulting in pneumonia, sepsis, or meningitis.[134]

Pulmonary Symptoms. In uncomplicated strongyloidiasis, the pulmonary symptoms are predominantly cough, dyspnea, and bronchospasm during the migratory phase, although persistent asthma due to *Strongyloides* infection has also been reported.[146] Patients with chronic lung disease may rarely retain the larvae in the lungs, where they molt into adults and complete their entire life cycle, leading to worsening lung disease, with chronic cough and bronchospasm.[147] In disseminated disease, high worm burdens or the secondary inflammatory response can cause acute respiratory distress or alveolar hemorrhage. Bacterial superinfection of the lungs with enteric pathogens can occur.

In a review of 20 patients in Kentucky admitted with pulmonary *Strongyloides* infection, a recognized risk factor for disseminated disease was present in 18 (90%).[133] These included corticosteroid therapy (65%) and chronic lung disease (45%). Pulmonary symptoms were noted in 95% of the patients, including cough, dyspnea, wheezing, or hemoptysis; 35% had a history of recurrent pneumonia. ARDS developed in 9 (45%) of the patients, 6 of whom subsequently died despite treatment. Gastrointestinal symptoms and eosinophilia were each present in 75% of the patients; 60% of them had secondary bacterial and fungal infection manifesting as pneumonia, lung abscess, or sepsis.

Diagnosis. Making a diagnosis of strongyloidiasis can be challenging. In immunocompetent people, eosinophilia is often present but not universal. In a Spanish study undertaken in a population of farm workers, 26 variables were investigated as predictors of strongyloidiasis.[148] Only eosinophilia was found to be significantly different between *S. stercoralis*–infected and –uninfected workers.[148] However, immunosuppressed individuals often do not have eosinophilia, and eosinopenia is associated with a poor prognosis.[136] The triad of pulmonary disease, gastrointestinal symptoms, and peripheral blood eosinophilia in a person with a history of travel or residence in an endemic area should suggest *Strongyloides* infection. Whereas larvae can often be isolated in stools (eggs are not present), the sensitivity of parasitologic examination of stools is poor, and multiple stools should be examined. Examination of the small bowel fluid by aspirate or string test or tissue by biopsy will often result in identification of larvae or adults. In hyperinfection and dissemination, larvae can be found in other specimens such as sputum, BAL fluid, urine, and cerebrospinal fluid (Fig. 37-3). The organisms can be seen by wet mount or Papanicolaou or Gram stain. Serology is available from CDC and private laboratories. Although the test is highly specific, its sensitivity is less reliable.[149] Concerns that relate to the ability of the test to discriminate between past and present infection likely reflect in part the inability to reliably establish cure. More recent studies in which ivermectin has been used have demonstrated seroreversion.[150] The cross reactivity of the antibody response with other helminth infections is an additional problem.[151]

The migration of larvae through the lungs can cause nodular radiographic changes. The vast majority of patients with pulmonary disease have abnormal chest

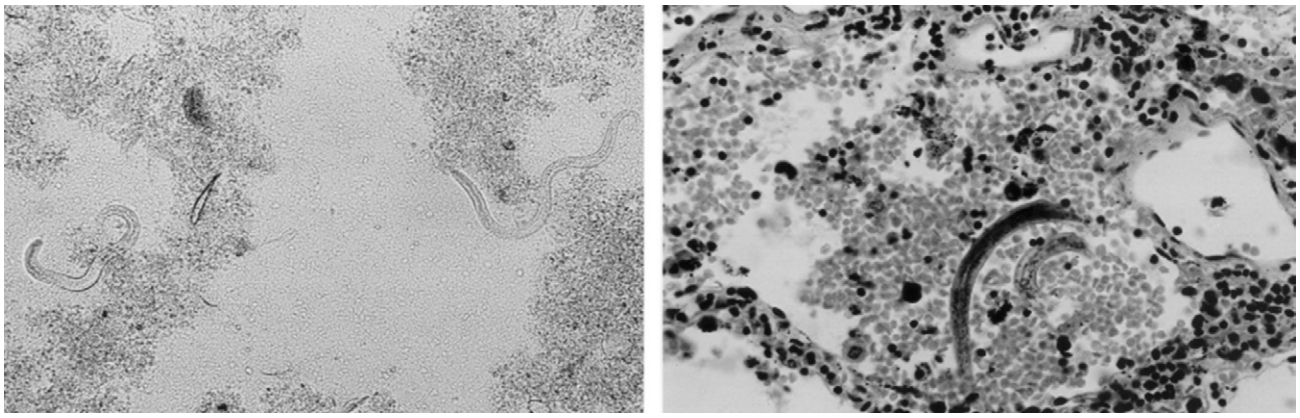

FIGURE 37-3 ■ *Strongyloides stercoralis* larvae identified in sputum (*left*) and in lung specimen taken at autopsy (*right*) in patients with *S. stercoralis* hyperinfection syndrome. (Courtesy of Dr. Franklin A. Neva.)

radiographs. In the Kentucky series,[133] 95% of the patients (18/19) had pulmonary alveolar, interstitial, or both opacities. These progressed to an ARDS pattern in half of the patients. The patient without parenchymal opacities had pulmonary symptoms and bilateral pleural effusions that responded to anthelmintic treatment. Pleural effusions were present in 40% of the patients and lung abscess in 15%.[133]

Treatment. Ivermectin, 200 μg/kg in a single dose and repeated after 1 week if necessary, is the drug of choice for strongyloidiasis. Albendazole, 400 mg daily for 3 days, is a less effective alternative.[145] Patients with disseminated disease or hyperinfection may require treatment for longer periods. There have been case reports of the successful administration of ivermectin per rectum,[152] or the administration of a veterinary preparation of ivermectin by subcutaneous injection,[153] as therapy for patients with ileus or intestinal perforation among whom enteral medications are not tolerated or absorbed. Supportive therapy and treatment of secondary bacterial infection is important. Of note, cyclosporine demonstrates an anti-*Strongyloides* effect,[154] and immunosuppressive therapy with this drug may protect against hyperinfection. It is necessary to treat all patients with strongyloidiasis, even if asymptomatic, because of the risk of later disseminated disease.

Prevention. The prevention of strongyloidiasis entails improving sanitation and hygiene and wearing footwear to prevent skin penetration. To prevent disseminated disease, vigilance in screening and treating asymptomatic and at-risk patients is appropriate. At-risk groups include patients from endemic areas with chronic lung disease, impaired cellular immunity, on corticosteroids, and those with malignancy or HTLV-1 infection. The best approach to identification of patients with occult infection, such as immigrants from endemic areas, has been debated. Screening for peripheral eosinophilia could be an effective approach,[148] but this strategy may miss those most vulnerable to severe disease who often do not have eosinophilia. Others argue that it may be more cost effective to treat all immigrants at risk of intestinal helminth infection with a 5-day course of albendazole without testing them for infection.[155]

Tissue-Dwelling Nematodes

Filarial Infections

Eight species of filarial parasites infect over 150 million people living in tropical and subtropical regions of the world. Adult worms of *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori* inhabit lymphatic vessels and produce lymphatic obstruction with resulting elephantiasis and hydrocele. *Loa loa* adult worms reside in the subcutaneous tissues and cause periodic angioedema. Parasitic stages of *Onchocerca volvulus* migrate in the skin and eye and cause dermatitis and inflammation of the cornea, iris, and retina (river blindness). *Mansonella perstans*, *Mansonella streptocerca*, and *Mansonella ozzardi* occur less commonly. The major pulmonary manifestation of these parasites is TPE, seen in infection with *W. bancrofti* and *B. malayi*. Rarely, pulmonary manifestations occur in infections with *L. loa*,[156,157] but none has been documented in onchocerciasis with the exception of a single report in the English language literature of *O. volvulus* microfilaria found in the lungs and other deep tissues of a Zairian man who died of pulmonary edema after treatment of elephantiasis (lymphatic filariasis) with diethylcarbamazine.[158]

Bancroftian filariasis is found throughout tropical and subtropical regions of Africa, Asia, the Pacific Islands, South America, and the Caribbean. Brugian filariasis is more limited in range, being confined to India and East and southeast Asia. *O. volvulus* is endemic in parts of equatorial Africa, Central and South America, and the Arabian Peninsula. *L. loa* is found in central and west Africa.

Transmission. Filariae have five morphologically and physiologically distinct stages—humans are infected by third-stage larvae deposited on the skin by blood-feeding arthropod vectors. For the agents of lymphatic filariasis, the vectors include *Culex*, *Aedes*, *Anopheles*, and *Mansonia*, whereas *L. loa* is transmitted by *Chrysops* (deer flies) and *O. volvulus* by various blackflies of the *Simulium* genus. After infective larvae penetrate the skin, they molt twice and develop into adults over the course of 6 months to 1 year. Adult worms remain viable for 5 to 20 years depending on the filarial species;

first-stage larvae or microfilariae (250–290 μm in length) are released by fertilized female worms and find their way into the circulation in the lymphatic filariasis, to the skin in loiasis, and to the eye in onchocerciasis.

The microfilariae of *W. bancrofti* and *B. malayi* circulate throughout the bloodstream, with a characteristic periodicity that is coincident with the feeding habits of the mosquitoes that transmit them.[159] The other major blood-borne filarial pathogen, *L. loa*, has a diurnal periodicity, with microfilaremia peaking at midday.

Pathology and Pathogenesis. The usual pathology of the lymphatic filariae is lymphatic dysfunction and obstruction that can lead to lymphedema. In advanced disease, severe, deforming swelling (elephantiasis) can occur, including disabling hydrocele in men with *W. bancrofti* infection.[160] The lymphatic pathology is caused by "nests" of adult worms within afferent lymphatics, usually of the scrotum (in males), and in the axilla, breast, or groin (in females). Ultrasonographic studies have demonstrated that lymphatics containing live worms dilate at a rate of 1.2 mm/person/yr.[161]

In TPE, the pathology appears to be related to increased immune responsiveness to the parasite. In contrast to most patients with lymphatic filariasis, patients with TPE almost never have microfilariae present in the peripheral blood. It is hypothesized that as microfilariae enter the blood, they are opsonized and cleared on first pass through the pulmonary circulation. The clearance of microfilariae leads to an inflammatory process that initially results in recruitment of histiocytes and then eosinophils into the lungs, causing an eosinophilic alveolitis. An increased number of pulmonary eosinophils is significantly associated with decreased forced vital capacity.[162] These eosinophils are activated and have a degranulated morphology.[163]

With time, the eosinophil predominance shifts to one dominated by histiocytes and the resultant chronic alveolitis can lead to fibrosis that can progress to irreversible changes.[164,165] Histologic examination of lung biopsy material early in the disease process reveals microfilariae surrounded by histiocytes. Later, degenerating microfilariae can be seen within eosinophilic granulomas (Fig. 37-4).[166] Although other organs, such as liver, spleen, and lymphatics, can be affected, most of the clinical effects in TPE occurs in the lungs.[167]

Clinical Manifestations. The vast majority of people with lymphatic filarial infection remain asymptomatic or have subclinical pathology, especially if they are natives of an endemic area. Of those with symptomatic infection, most have evidence of lymphatic dysfunction (or obstruction), the initial presentation being fever with acute (retrograde) lymphangitis or adenolymphangitis.

The rare syndrome of TPE has a strong geographic bias, and is more likely to occur in south and southeast

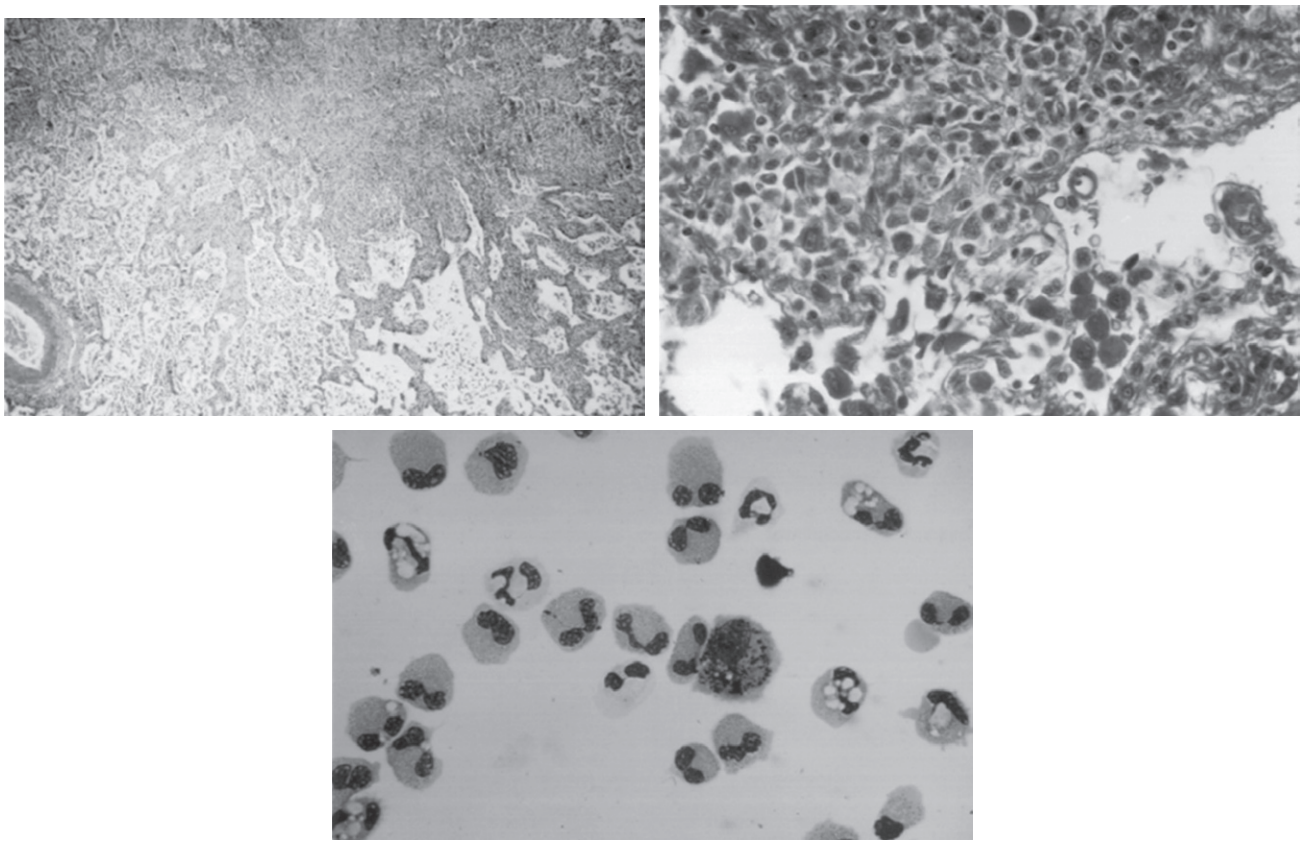

FIGURE 37-4 ■ Pulmonary specimens in tropical pulmonary eosinophilia (TPE). Hematoxylin and eosin–stained section of lung biopsy of patient with proven TPE at low magnification (40×) (*left*) and at higher magnification (160×) (*middle*). *Right,* A Wright-stained specimen from bronchoalveolar lavage from another patient with TPE shows numerous vacuolated and normal bilobed eosinophils.

Asia and Brazil. Males outnumber females by more than 4 to 1,[162,165,168,169] and although people of any age can develop it, it is more likely to occur during the third and fourth decades of life. Although precise incidence figures are not available, it is likely that significantly less than 0.1% of those infected with the lymphatic filarial parasites develop TPE (0.4% of 4282 school children in north India in 1 survey[170]). Whereas naive travelers to an endemic area are more likely to develop symptomatic infection resulting in lymphadenitis and hepatosplenomegaly, with acute lymphedema and eosinophilia,[171] TPE as a manifestation of filarial infection in travelers is rare.

Pulmonary Disease. TPE should be regarded as a systemic syndrome, with the pulmonary component being the most significant. Initially, patients complain of vague systemic symptoms, including low-grade fevers and myalgia. Then, pulmonary symptoms begin, which include cough and wheezing, both of which are worse at night, dyspnea, and occasionally chest pain. These symptoms are often mistaken for asthma, and patients may be incorrectly treated for more common disorders.

In the initial stage, obstructive pulmonary function is characteristic, and later, a restrictive pattern commonly predominates[169] as fibrosis develops.[162,165,172] A decreased diffusion capacity, with hypoxemia occurs in a minority of patients.[168] The pattern of disease progression is variable; symptoms can spontaneously remit and recur, or gradually worsen, with a decrease in the wheezing, but an increase in dyspnea. The condition eventually leads to chronic lung disease with dyspnea and hypoxemia at rest, which in later stages is indistinguishable from any cause of pulmonary fibrosis.[165] Rarely, TPE can present as cor pulmonale.[173]

Of the other common human filarial infections, aberrant migration of *L. loa* microfilariae has been reported to result in lung disease in rare cases.[157,174] A syndrome characterized by loculated eosinophilic pleural effusion has been described.[156]

Diagnosis. The definitive diagnosis of lymphatic filarial infection is made by filtration of peripheral blood to detect microfilariae or by finding adult worms in spermatic cord lymphatics or on biopsy. It is important to draw peripheral blood at a time coincident with the peak frequency of circulating microfilariae from 10 pm to 6 am for nocturnally periodic lymphatic filariae and noon for *L. loa*. A highly sensitive enzyme-linked immunosorbent assay (ELISA) is available to detect an antibody response to lymphatic filarial parasites.[175] This uses crude *B. malayi* adult worm extract as the antigen and is highly sensitive. In addition, a number of antigen tests are available for detection of circulating filarial antigen in bancroftian filariasis,[176] but not brugian filariasis. These include an immunochromatographic card test with greater than 99% specificity and only slightly less sensitivity than the ELISA for the same circulating antigen.

The diagnosis of TPE requires (1) a history of paroxysmal nocturnal dyspnea, (2) radiographic evidence of pulmonary opacities, (3) peripheral blood eosinophilia greater than 3000/μL, (4) elevation of serum IgE levels, (5) high levels of antifilarial antibodies, and (6) a rapid clinical response to antifilarial therapy with diethylcarbamazine . The antifilarial antibody values found in TPE are much higher than those of individuals with active filarial infection with or without microfilaremia. Circulating microfilariae are absent from night blood samples taken from patients with TPE. Examination of BAL of persons with TPE shows an alveolitis with eosinophils constituting more than 50% of the total cells recovered.[163] The eosinophils are activated with a reduction of granules and an increase of vacuoles, indicating the release of eosinophil granule proteins. The differential diagnosis includes other infectious and noninfectious causes of pulmonary disease with eosinophilia, such as other helminth infections, allergic granulomatosis with angiitis (Churg-Strauss), allergic bronchopulmonary aspergillosis, Wegener's granulomatosis, and the idiopathic hypereosinophilic syndrome.

Although chest radiographs of patients with TPE may be normal, the vast majority have small nodular opacities (1–3 mm) in a miliary pattern that can be confused with tuberculosis. Increased bronchovascular markings are often seen (Fig. 37-5).[164,169] Other radiographic patterns include lobar or sublobar consolidation, cavities, or pleural effusions, although these are less common.[177] High-resolution CT provides more detailed information. In a series of 10 patients with TPE, 3 were found on CT to have paratracheal adenopathy and 2 had bronchiectasis.[178] In hypoxic patients, ventilation-perfusion defects and mismatches are often found.[179]

Treatment. The majority of patients with TPE respond quickly to treatment with diethylcarbamazine (6 mg/kg orally daily for 12 days), although a significant

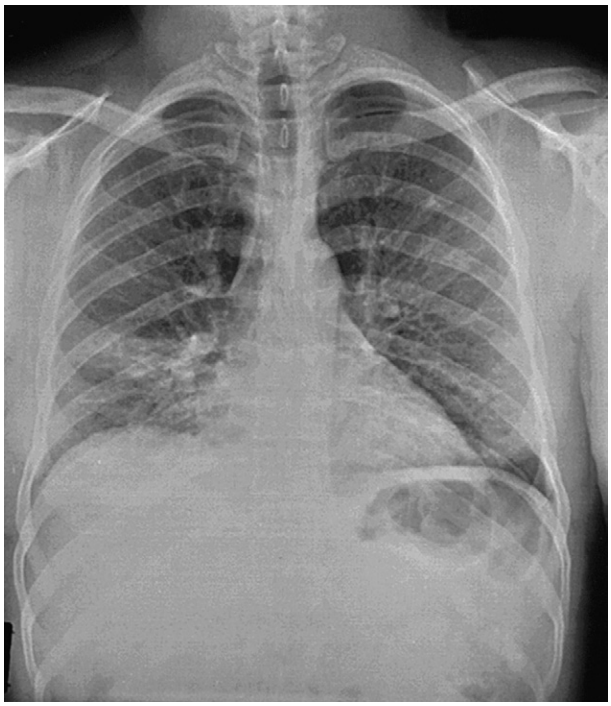

FIGURE 37-5 ■ Chest roentgenogram of a South Indian man with tropical pulmonary eosinophilia shows bilateral diffuse interstitial infiltrates.

percentage (12%–20%) fail to respond or their symptoms recur after treatment. These patients may respond to a course of treatment of longer duration (≤12 mg/kg for 30 days).[180] If, after diethylcarbamazine, patients remain symptomatic, an alternative diagnosis should be excluded. Of note, ivermectin, although effective for treatment of lymphatic filariasis, is not useful for treatment of TPE, probably because it has little effect on adult worms. Data have documented the effectiveness of doxycycline in lymphatic filariasis, through its ability to kill the endosymbiont bacteria *Wolbachia* and thereby lead to permanent damage to adult worms.[181] This indicates that the addition of a 6-week course of doxycycline to diethylcarbamazine is an appropriate, but yet to be proved, supplemental approach to treatment of TPE.

Although symptoms often improve with treatment, and the level of eosinophils and immunoglobulins in BAL fluid quickly decreases,[163] the abnormalities in pulmonary function tests, especially diffusion capacity, do not always return to baseline and can persist for at least 1 month after treatment.[168]

Prevention. Lymphatic filariasis eradication programs based on mass drug administration are ongoing in many of the endemic regions of the world. As these reduce the prevalence of lymphatic filariasis, the incidence of TPE should decrease as well. In the meantime, travelers to endemic areas can take diethylcarbamazine as a prophylactic measure.

Dirofilariasis

Dirofilaria immitis, or the dog heartworm, is an uncommon but well-recognized cause of pulmonary nodules (or "coin lesions") in humans. It is a mosquito-transmitted filarial infection primarily of dogs, with humans being an incidental or dead-end host of this parasite. Whereas most human cases have been reported in the United States, where *Dirofilaria immitis* is found in dogs of all states except Nevada, it has also been reported from many countries including Japan, Brazil, Australia, Italy, and the Netherlands.[182–186] With the increasing use of heartworm prophylaxis for domestic dogs, the incidence of dirofilarial infection in dogs appears to be falling. In the United States, the parasite is concentrated along the Atlantic seaboard and the southeast.

Transmission. The definitive hosts of *D. immitis* (or rarely, *D. repens* in the Old World[184]) are dogs and other carnivores (e.g., cats, wolves, sea lions). Adult worms live within the right ventricle of the animals and release thousands of microfilariae into the bloodstream daily. Mosquitoes of the genera *Anopheles*, *Aedes*, and *Culex* take up the larvae during a blood meal, and the microfilariae develop within the mosquito into infective larvae. When the mosquito bites again, the larvae enter a new host and find their way into the circulatory system where they molt and mature into adults. In humans, the larvae are unable to complete their life cycle and rarely make it through the subcutaneous tissue. If a stray larva is able to enter the circulation, it remains immature despite reaching the heart. Once the larva dies, it is swept into the pulmonary artery, where it embolizes in a distal arteriole.[183]

Pathogenesis. The pathology associated with pulmonary dirofilariasis is related to the infarct caused by the embolization of the parasite and the inflammatory reaction that occurs in response. The infection per se is self-limited.

On pathologic examination, the nodules that are formed are firm, well-circumscribed granulomas, 1 to 3 cm in diameter, grayish-yellow and noncalcified. They have central necrosis with a surrounding wall of fibrous tissue composed of epithelial cells, eosinophils, plasma cells, and lymphocytes, with a few giant cells. Parasite remnants can be found within the granulomas within a pulmonary artery. There may be one or several parasites in one nodule. The surrounding lung tissue and vessels may show evidence of inflammation with surrounding eosinophilic pneumonitis and endarteritis. Although the nodules are commonly subpleural, pleural thickening is present in a minority of cases.[185,186]

Clinical Manifestations and Pulmonary Disease. The majority of patients (54%–59%) with dirofilariasis are asymptomatic.[182,186,187] Nodules are usually incidental findings, most often observed in men in their 50s and 60s. Of those who are symptomatic, the most common symptoms are cough, chest pain, fever, and malaise. Hemoptysis, especially of significant amounts, is extremely uncommon.[186]

Diagnosis. Pulmonary dirofilarial infection usually presents as an incidental finding on a routine chest radiograph obtained for other reasons. The nodules are usually round, solitary (75%),[186] well-circumscribed, and in the periphery of the lower lung fields, most commonly on the right (76%), although they can occur in any lobe. A minority of patients will have multiple nodules, either unilateral or bilateral.[187,188] Pleural effusion can occur, but is rare.[188] CT allows for better definition of nodules, and contrast CT may suggest dirofilariasis if it shows a pulmonary artery entering a density without pleural involvement and speculations.[167]

Unfortunately for such a benign disease, the diagnosis of dirofilariasis is usually not considered or made except by excisional biopsy of the nodule. Because the differential diagnosis includes malignancy, and because people obtaining routine chest radiographs are older adults at higher risk for malignancy, surgery is generally necessary to rule out malignancy. Needle biopsy is usually not successful in making the diagnosis, although in two cases, its successful use in prevention of a more invasive procedure was reported.[189] Finding the parasite embolized within a pulmonary artery establishes the diagnosis. Because the worm can be degenerating, it may be easier to see with silver staining or with specific antibody probes.

Eosinophilia is seen in only a minority of patients (7.5%–10%),[186,187] with the average eosinophil percent only 5%. Serologic tests for *D. immitis*, although available, are not widely used and are rarely clinically useful.

Treatment. No treatment is necessary because there is no active ongoing infection. There is no known complication from this infection.

Prevention. The only ways to prevent this disease in humans are to decrease its prevalence in dogs or to decrease the prevalence of the mosquito vector.

Trichinosis

Trichinosis is a zoonotic infection caused by nematodes belonging to the genus *Trichinella*. *T. spiralis* was the species originally described to be transmitted to humans by domestic pigs. To date, a total of seven species have been reported to infect humans.[190] *Trichinella* spp. are the only nematodes known to occupy an intracellular location in the host and are transmitted only by consumption of contaminated meat. They are found on all continents and climates. The disease is much more common in Europe than in the United States, with 20,000 cases reported in Europe in the 10 years between 1991 and 2000,[190,191] compared with 230 cases reported in the United States in the 5-year interval between 1991 and 1995.[192]

Transmission. *Trichinella* completes its life cycle within a single host. When a person eats undercooked contaminated meat (most often pig, boar, horse, or bear), digestion of the meat in the stomach and intestine releases the encysted larvae. The larvae invade the intestinal wall and live under the columnar epithelium. There, they molt several times to become adults. Fully developed adults form within 5 to 7 days of infection. It is believed that adults only live within a human host for several weeks before they are expelled from the intestine. The adults, however, release larvae that invade the intestinal epithelium and enter the circulation. The larvae travel to muscles, where they invade muscle cells. Once a larva has entered a muscle cell, it molts again into an infective stage and starts to encyst. The infected muscle cell transforms into a "nurse cell," which provides the larva with the nutrients it needs to grow. As time progresses, the larval capsule becomes thicker. In nonhuman mammals, the cycle starts again when another carnivore eats the muscle of the host.

Pathogenesis. The parasite invading the intestinal lumen results in a local influx of eosinophils and mast cells. As the second-generation larvae migrate throughout the body, more eosinophils are recruited into areas where larvae reside, including around the nurse cell. Degeneration of muscle fibers with increased vascularity can be seen. With time, the encysted larvae die within the muscle and calcify.[190,193]

Clinical Manifestations and Pulmonary Disease. The symptoms attributable to trichinosis depend on the infectious burden, the host immune status, and the species of parasite. The incubation period ranges from 6 to 30 days.[190,194,195] As the larvae excyst and invade the intestinal wall, malaise, abdominal pain, fever, nausea, vomiting, and diarrhea, which can be persistent and voluminous, ensue. Although the typical duration of the enteral phase is 2 to 7 days, it can persist for weeks and overlap with the parenteral phase. As the larvae invade muscle cells, more characteristic features develop, which include facial or generalized edema, especially periorbital, remitting fever that lasts for several weeks, myalgia, and muscle weakness. Symptoms can be sufficiently severe to interfere with walking, arms movement, speaking, or breathing. Myocarditis can occur as cardiac muscle cells are infected and can lead to heart failure, arrhythmia, or sudden death. The central nervous system is involved in a minority of patients, with meningoencephalitis the most common manifestation of neurotrichinosis. Although the lungs are rarely directly involved in trichinosis, involvement of the diaphragm and other muscles of respiration can lead to dyspnea and, rarely, respiratory failure.[196,197] Cough and hoarseness can also occur, as can secondary complications such as bronchopneumonia and pulmonary embolism.

Diagnosis. A definitive diagnosis of trichinosis is made by histologic demonstration of larvae in a muscle biopsy. This can be facilitated by enzymatic digestion of the biopsy to locate the larvae. Digestion can only be undertaken once larvae have had time to encyst. Of note, the two *Trichinella* species *T. pseudospiralis* and *T. papuae* do not encyst, and so have to be more carefully isolated. Because of the invasive nature of muscle biopsy, it is not recommended unless the results of other tests are equivocal.[190]

Laboratory tests that are typically abnormal in trichinosis include those associated with muscle damage, an elevated creatinine kinase and lactic dehydrogenase, elevated total white blood cell count and eosinophilia in a majority of patients, and high levels of serum IgE. Serologic identification of *T. spiralis*–specific antibodies is a useful diagnostic test.[198] Molecular methods, including PCR and DNA sequence analysis are useful to speciate the organism if found in muscle and may provide useful epidemiologic information.[199]

Treatment. Controversy exists as to whether treatment alters the course of the infection. In one trial undertaken in Thailand during an outbreak, a faster resolution of symptoms and normalization of laboratory abnormalities was observed among patients who received mebendazole or thiabendazole compared with those treated with placebo.[197] The current recommended treatment for trichinosis is albendazole 400 to 800 mg orally per day (in one or two doses) for 7 to 14 days.[200] However, the optimal duration of treatment has not been reliably established. Because chemotherapy is only effective against larval stages, and only before they have become encysted in the muscle, early administration of treatment is recommended. In patients with significant symptoms secondary to the host reaction, a short course of corticosteroids given concurrently with the anthelmintic drug may be beneficial.

Prevention. The prevention of trichinosis in humans is dependent on its eradication from the food supply. Meat inspection is the first line of defense: meat sold commercially should be inspected prior to release. Such procedures are well established in developed countries, but in countries where oversight of slaughterhouse practices is less robust, infected meat may enter the human food supply.[201] For meat not obtained commercially (e.g., game, wild animals), educating people to freeze it or to adequately cook it (internal temperature of at least

60°C for at least 1 minute) will reduce the incidence of this emerging zoonotic infection.[194]

Visceral Larva Migrans

Visceral larva migrans (or toxocariasis) is a zoonotic infection caused primarily by infection with the dog and cat roundworms (ascarids), *Toxocara canis* and *Toxocara catis*. Other animal species (including other *Toxocara* spp., *Capillaria*, and *A. suum*) may rarely cause the syndrome.[202] An emerging infection in some parts of the world, it is likely an underreported and underrecognized disease owing of the difficulty of diagnosis. Overall seroprevalence in the United States is 2.8%, although this varies by age (6.4% in children), race, socioeconomic status, and region. In some parts of the world, the prevalence is much higher, reaching up to 80% in children in some areas.[203]

Transmission. In their natural hosts, the life cycle of these organisms is like that of *Ascaris* in humans. The adults live in the intestine, where they shed eggs into the stool. The eggs embryonate in moist soil and then are ingested by the next host where they hatch into larvae. The larvae migrate to the lungs via the circulatory system and then molt. The developing larvae travel up the trachea, to the epiglottis, and are swallowed. In the intestine, the larvae molt again into adults. Fertilization of the adult females leads to egg production and recommencement of the cycle.[167] In many species the infection can also be transmitted transplacentally; thus, puppies represent a major sources of eggs.[204] Humans become incidental hosts when they ingest food contaminated with the eggs. Children are at higher risk of ingesting the eggs because they may exhibit pica or geophagia[205] and because they are more likely to eat with soil-contaminated hands. They can also come into contact with infective eggs in contaminated sandboxes or playgrounds.[204] Having had a dog or a cat increases a child's risk of being seropositive for *Toxocara* antibodies, but does not necessary represent infection.[206] When the larvae hatch from the eggs in humans, they penetrate the intestinal mucosa and begin migrating. Because these nematodes are unable to complete their life cycle within humans, larvae can migrate throughout the body for months or years, leading to the clinical features of this infection.[204]

Pathogenesis. The pathology of visceral larva migrans is attributable to hypersensitivity (or inflammatory) responses to the migrating larvae.[204] The damage done and symptoms depend on the organ that is invaded during migration. It is also dependent on the size of the inoculum and the frequency of reinfection.[203]

In experimental animals, within the first 2 weeks of infection, there is an acute inflammatory reaction, with recruitment of eosinophils and neutrophils. One month after infection, an early collagenous capsule covers the larvae and larval tracks. Later, the larvae are encapsulated within eosinophilic granulomas. Larvae typically cannot be identified in most of the granulomas found, suggesting that they have undergone degeneration or else the granuloma has formed around larval antigens.[203] The liver, lungs, central nervous system, and eyes are the organs most commonly affected. In the lungs, *T. canis* induces airway inflammation, increased pulmonary resistance, and decreased compliance**.** Histologically, there is perivascular and peribronchial edema.[167] Protective immunity, if it occurs, is slow to develop,[204] and thus reinfection can occur.[207]

Clinical Manifestations. Most people who are infected with *Toxocara* spp. remain asymptomatic. Symptoms depend on the intensity and frequency of infection, the distribution of larvae in tissues, and the inflammatory response of the host.[203] Two clinical syndromes of infection are well-recognized: visceral larval migrans or ocular larval migrans. The clinical features of visceral larva migrans are related to the organ invaded, most commonly the liver, lung, or other thoracic or abdominal organ. Visceral larva migrans usually affects children younger than 5 years old, although it can affect adults.[208] In a study of children with visceral larva migrans and eosinophilia, 86% had pulmonary symptoms, 80% had fever, and 28% had seizures. On examination, 65% had hepatomegaly; 43% had an abnormal pulmonary examination (wheezes or crackles); 39% were malnourished; and 45% were anemic, although many of these children had concurrent infections with other intestinal helminthes.[202] Rarely, disease can manifest as myocarditis, nephritis, encephalitis, or seizures. Ocular larva migrans usually occurs in older children (average age is 8 yr) and may represent a lower infectious inoculum. In the eye, the granulomatous reaction can impair sight and be confused with retinoblastoma, often necessitating enucleation. Visceral larva migrans and ocular larva migrans rarely occur at the same time or in the same person. So-called covert toxocariasis is thought to be due to long-term subclinical infection. Symptoms are nonspecific. They may include asthma, urticarial rash, arthralgia, adenitis, weakness, dizziness, abdominal pain, anorexia, nausea, vomiting, and sleep and behavioral disturbances.[167,203,204,208]

Pulmonary Symptoms. Between 33% and 86% of people with visceral larva migrans are found to have pulmonary symptoms.[202,203] The most common symptoms are chronic cough, which may be paroxysmal and worse at night, and wheezing. The chest radiograph may be abnormal. Rarely, severe eosinophilic pneumonitis of *Toxocara* has caused respiratory failure.[209,210] Other manifestations include chronic eosinophilic pneumonia that is responsive to albendazole[211] and noncavitating pulmonary nodules with eosinophilia and liver and renal nodules.[212] A Dutch study of children with asthma found a correlation with anti-*Toxocara* antibodies.[206] Seropositive children were also more likely to have an allergic reaction after exposure to animals, and greater allergen-specific IgE, suggesting that *Toxocara* stimulated the production of allergen specific-IgE.[206]

Diagnosis. Diagnosis of human toxocariasis relies on clinical and serodiagnosis. It should be suspected in any child with unexplained fever and eosinophilia, especially if a history of pica and hepatosplenomegaly is also present.[204] Parasitologic diagnosis by detecting *Toxocara* larvae by biopsy is not feasible. In most serodiagnostic tests, excretory-secretory antigens from *T. canis*

second-stage larvae are detected by ELISA.[213,214] Although this test has a reasonable sensitivity (73%) and specificity (92%),[215] cross reactivity with other helminth infections can occur.[214,216–218] Others have reported a higher specificity and sensitivity (92% and 78%, respectively).[203] In areas where the baseline seroprevalence is relatively high, serologic tests may not be as useful.[219]

Patients with visceral larva migrans may have hypergammaglobulinemia, with elevations of total immunoglobulin, IgG, and IgM.[202] Eosinophils and total IgE are greater in seropositive children, regardless of symptoms.[206]

Treatment. Although visceral larva migrans is generally benign, and usually resolves without specific anthelmintic therapy, the recommended treatment is albendazole 10 mg/kg/day in two divided doses for 5 days (for adults, 400 mg twice a day).[204] Corticosteroid therapy may be useful to decrease the inflammatory responses in patients with severe symptoms.

Prevention. Prevention of toxocariasis depends on decreasing exposure to eggs. Covering sandboxes at night, routine deworming of dogs and cats, and decreasing geophagia are all methods to decrease egg shedding and exposure. In some areas, sandboxes have been removed from public playgrounds in order to decrease infection rates.

Pulmonary Capillariasis

The syndrome of pulmonary capillariasis is a very rare event in humans, occurring through zoonotic infection with the nematode parasite *Capillaria aerophila* (synonyms, *Eucoleus aerophilus*, *Thominx aerophilus*).[220,221] It is a nematode that parasitizes the respiratory tree of a variety of carnivorous mammals. Manifestation of accidental infection of humans include cough productive of mucoid or blood-tinged sputum, fever, dyspnea, and eosinophilia. Diagnosis can be made by detecting characteristic eggs in sputum or feces. In a recent case report, the presentation resembled that of bronchial carcinoma.[220] It has been documented in Russia, Ukraine, Morocco, Iran, France, and Serbia.[220] Because a limited number of human infections have been documented, the incubation period is unknown, although some authors believe that it could be similar to the prepatent period in animals (i.e., 25–40 days). Although experience in the treatment of human infection is limited, mebendazole and albendazole have been shown to be effective.[220]

Echinococcosis

Echinococcosis is caused by one of two species of small animal cestodes: *Echinococcus granulosus*, the dog tapeworm, causing cystic hydatid cyst disease, and *E. multilocularis*, the fox tapeworm, causing alveolar hydatid disease. The life cycle requires two hosts for its completion, a canid definitive host and an intermediate host, typically a sheep, goat, kangaroo, or a range of other animals. It has a global distribution, with well-described regions of high prevalence, including in the Mediterranean area, South and Central America, Russia, China, and sub-Saharan Africa.[222,222a] *E. multilocularis*, the fox tapeworm, has a sylvatic life cycle whereby foxes and other carnivores are definitive hosts and the intermediate hosts are rodents and small mammals. Alveolar echinococcosis is endemic in the Northern Hemisphere, particularly at high latitudes in Europe, China, and northern Canada and Alaska. Although *E. granulosus* is more commonly a cause of human disease, *E. multilocularis* is the more pathogenic of the two major species.

Transmission. In the normal life cycle, adult worms live in the intestines of the definitive host and shed millions of eggs with the stool. When an intermediate host ingests an egg, a larva emerges, penetrates the intestinal mucosa, and migrates through the blood or lymphatics to target organs. Larvae usually lodge in the liver or lung (or less commonly, other organs or the body wall), become metacestodes that create vesicles that enlarge over time, eventually forming a mature hydatid cyst. Within the hydatid cyst are multiple brood capsules and protoscolices. When the cyst is ingested by the definitive host, the adult tapeworm develops.[222,223] Humans are incidental intermediate hosts when they ingest eggs from infected dogs through contaminated hands or by consuming contaminated food or water.

Pathology and Pathogenesis. In echinococcosis, the cyst comprises three layers: The inner endocyst is the germinal layer with a nucleated syncytial layer that forms brood capsules and protoscolices. The middle layer, or exocyst, is a carbohydrate-rich acellular hyaline laminated layer that is also parasite-derived and porous to nutrients. The external pericyst is a host-produced fibrous adventitial layer felt to be a by-product of the initial immune response to the cyst. Daughter cysts may form within the larger cyst.[222,223] The interior of an intact cyst contains clear fluid with "hydatid sand": remnants of hooklets, protoscolices, and brood capsules. Cysts expand at a rate of 1 cm per year in the liver, faster (1–5 cm/yr) in the lung.[223,224]

The liver is the organ most commonly affected (in 60% of cases); the lungs are the second most common, affected in 20% to 30% of cases. In pulmonary hydatid disease, the cyst can be anywhere in the lung but has a predilection for the right lobe (54%–63% right vs. 37%–46% left), and for the lower lobes (52%–67.5%) (Fig. 37-6). Children are more likely to have pulmonary disease than adults. Single cysts are most common (72%–83%), with unilateral multiple cysts being found in 10% to 15% of cases and bilateral cysts in 6% to 13%. Among those with pulmonary hydatid disease, the liver may also be involved 10% to 40% of the time.[223,225–229] Cysts can also involve the chest wall as well as the lung parenchyma.[230]

Whereas lesions caused by *E. granulosus* are well circumscribed and defined, *E. multilocularis* lacks the external thick host-derived capsule and proliferates slowly, exhibiting tumor-like behavior, which can invade tissues and metastasize to distant sites. The liver is most commonly affected (97%), but it invades or metastasizes to the lung in about 10% of cases.[231]

With an intact cyst, most of the pathology results from the space-occupying lesion, mechanical compression of nearby structures. Pulmonary tissue surrounding the cyst

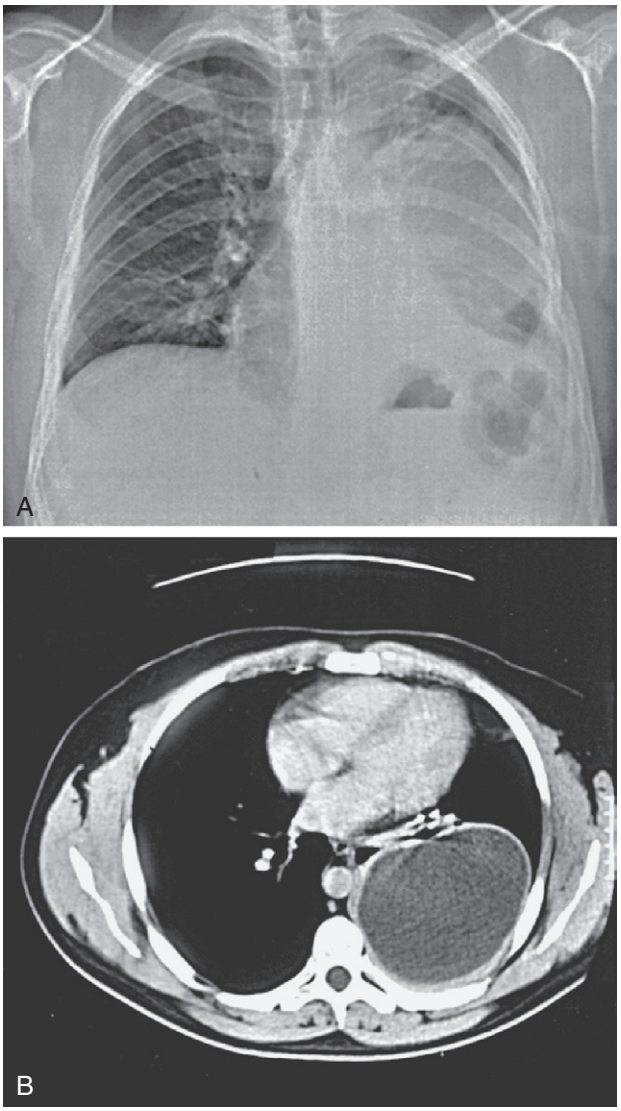

FIGURE 37-6 ■ Chest roentgenogram (**A**) and computed tomography (CT) scan (**B**) of a Peruvian man who had had a left lower lobectomy for hydatid disease and now has a recurrent hydatid cyst in the remaining left lung.

may be normal, be compressed with atelectasis, or have chronic inflammation and fibrosis.[224,225] When a cyst leaks or ruptures, an inflammatory reaction can develop. In its most severe form, it can present as anaphylaxis due to preexisting hypersensitivity to antigens present in cyst contents. If protoscolices are released with cyst rupture, disseminated disease may occur, leading to multiple secondary cysts.

Clinical Manifestations. Infection with *Echinococcus* is generally asymptomatic for months to decades. Cysts are commonly found when compressive symptoms develop, the cyst ruptures, or on routine imaging. For *E. multilocularis*, the latent period is assumed to be at least 5 to 15 years because of the very small numbers of patients younger than 20 years old found to have this form of the disease (2.1% of 559 patients).[231] Symptoms develop through one of one of three pathogenic mechanisms: (1) mechanical pressure or deformation of tissues or nearby vascular structures; (2) rupture or leakage of the cyst; or (3) superinfection. Alveolar echinococcosis causes more severe disease with a greater than 95% mortality among untreated cases within 10 years of diagnosis.[232]

Pulmonary Symptoms. Pulmonary symptoms occur in 67% to 89% of patients with pulmonary cysts. The most commonly reported symptoms are cough, fever, and chest pain.[226,229] Occasionally, hemoptysis can occur, and rarely, bilioptysis, pneumothorax, or pleuritis.[222] With rupture of the cyst into a bronchus, hydatid vomica of cystic contents can occur: clear, salty and peppery fluid with or without hemoptysis. The fluid can be purulent if superinfected. With airway dissemination of the antigenic fluid, respiratory failure or anaphylaxis can occur. One third of diagnosed cases of pulmonary hydatid cyst present following cyst rupture or the development of secondary cyst infection. Cysts can also rupture into pleura; in one study, this occurred in 5% of 400 individuals studied.[225] More rarely, rupture can occur into other mediastinal structures such as the myocardium, which has been reported to occur in 0.5% to 2% of all hydatid cysts.[233] Invasion of the aortic wall causing aortic rupture and pseudoaneurysm formation is very rare and has been described in less than a dozen cases.[234]

Hydatid pulmonary embolism can occur as a result of a hepatic or abdominal cyst rupturing into the hepatic vein, the inferior vena cava, or directly into heart. This event can be acute and fatal or subacute and result in progressive pulmonary hypertension.[235–238]

Diagnosis. The diagnosis of echinococcosis is generally made by clinical history and pathognomic radiologic findings. A history of exposure to dogs, especially in sheep-raising areas, is often, but not always, present for cystic disease. On plain radiograph, if intact, the cyst appears as a homogenous opacity with a well-demarcated margin. In the lung, following bronchial rupture, air can appear in the cyst; with the evacuation of some of the fluid and collapse of the membrane onto the residual fluid, resulting in the well recognized "water lily" sign. With rupture into the pleural cavity, a hydrothorax or a hydropneumothorax can occur.[225] Calcification occurs commonly in hepatic cysts after 5 to 10 years, but it is less common in pulmonary cysts. Alveolar echinococcosis can show radiologic evidence of calcifications within the structure.[223] Ultrasound is the diagnostic modality of choice in abdominal hydatid disease; it is less useful in pulmonary disease. CT better defines cysts than plain chest radiographs, revealing not only their cystic nature but also the density of the fluid within them and their shape. An "inverse crescent sign" appears when air dissects posteriorly separating membranes, without anterior extension; air within the wall of the cyst can create a signet ring appearance.[227]

With MRI, the image depends on whether the cyst is unilocular or multilocular and on the developmental stage of the cyst. In most situations, the capsule is well-defined, with low signal intensity on T2 images (and indistinct in most patients on T1). The daughter cells are, however, better seen on T1-weighted images.

Complicated cysts may not have the characteristic signal of hydatid disease.[239] If a hydatid pulmonary embolism is suspected, the diagnostic techniques of choice are an echocardiogram, a spiral CT, or MRI.[235] Bronchoscopy is not recommended because of the risk of cyst rupture, except if necessary to exclude malignancy.

Serologic tests to evaluate for echinococcosis are available. In a comparison of six different serologic tests (latex agglutination, passive hemagglutination, immunoelectrophoresis, specific IgE, IgM, and IgG ELISA), hydatid antigen-specific IgG was the most sensitive and specific test in pulmonary echinococcosis (83.5% and 99.5%, respectively). The sensitivity of serology increases in patients with multiple cysts, and the test is positive in 96% of patients with both liver and pulmonary cysts.[225,240] Tests based on antigen components of hydatid cyst fluid have not been shown to increase sensitivity or specificity.[241] Serologic tests for alveolar echinococcosis are more sensitive and specific than tests for cystic disease, because they are based on purified species-specific antigens.[222]

Treatment. The recommended treatment for resectable pulmonary hydatid cysts is surgical removal, if possible. Surgery allows for eradication of the parasite, prevention of the complications of rupture, and removal or closure of the cavity. Importantly, medical therapy with adjuvant albendazole therapy should be undertaken before and after surgical resection. It should also be used in the perioperative period to prevent dissemination of viable protoscolices if inadvertent cyst rupture occurs during surgery. Anthelmintic therapy prior to surgery has been shown to decrease the risk of recurrent disease by 3.5 times.[242] The recommended albendazole regimen is 10 to 15 mg/kg/day in two doses at least 4 days prior to surgery and continued for at least 1 month after surgery.[243] In one study, a combination of albendazole and praziquantel (25 mg/kg/day) for 1 month prior to surgical removal of the cysts was more scolicidal than albendazole alone.[244]

Patients who are not operative candidates may benefit from medical therapy; 28% to 45% are reported to be cured and 45% to 51% show improvement after a prolonged course of albendazole, compared with patients not receiving anthelmintic chemotherapy who were reported to show improvement in 15% to 25% with no cure.[245,246] A nonsurgical drainage technique, termed PAIR (puncture, aspiration, injection, and reaspiration), whereby a scolicidal agent typically hypertonic saline is injected into the cavity and then aspirated, has been developed for hepatic cysts. However, PAIR for pulmonary cysts is not recommended.

Treatment of alveolar echinococcosis entails radical surgical excision with wide margins, as would be undertaken for a malignant tumor, if possible. In cases in which complete resection is not possible, prolonged treatment with albendazole, usually for life, is necessary. Because long-term therapy with albendazole can cause significant hematologic toxicity and hepatotoxicity, regular monitoring of blood count and liver function is appropriate.[247] Positron emission tomography may be useful in determining if cysts are metabolically inactive and thus help assess the efficacy of medical treatment.[248] For patients with alveolar echinococcosis that is not responding to albendazole, or where the drug is not tolerated, alternative salvage treatment with nitazoxanide[249] or amphotericin B may be possible.[250]

Prevention. Prevention of hydatid cyst disease involves decreasing the prevalence in the definitive host by deworming dogs, preventing them from eating cysts contaminating intermediate hosts (commonly by preventing farm dogs feeding on offal), and improving hygiene and sanitation in endemic areas. An effective vaccine for dogs has been developed[251] but is not commercially available.

Paragonimiasis

Paragonimiasis is caused by a trematode flatworm of the genus *Paragonimus* and is commonly referred to as the lung fluke. Humans are incidental hosts of this parasite that typically infects other carnivorous animals. Although 43 species of *Paragonimus* are recognized, only 12 have been reported to infect humans of which *P. westermani* is the most prevalent, especially in eastern and southeastern Asia. Paragonimiasis occurs worldwide, the most endemic areas being in Asia, West Africa, and parts of Central and South America.[252] In the United States, most cases are imported and are seen among immigrants and visitors from east and southeast Asian countries where the parasite is endemic.[253] However, infection can be acquired in North America because *P. kellicotti* exists in the midwestern and eastern United States and infects crayfish and a variety of carnivores.[254–256a]

Food preparation practices that lead to ingestion of raw, undercooked, or pickled crabs (crabs soaked in wine, "drunken crabs") or crayfish increase the risk of infection. Infection can also be transmitted by contaminated utensils or raw juice from the infected crustaceans.

Transmission. *Paragonimus* spp. have a complex life cycle involving freshwater snails, crustaceans, and mammals. Humans, when infected, are accidental definitive hosts for the fluke, taking the place of other crustacean-eating mammals. Adult worms live in the definitive host (e.g., canines, felines, otters, boars, skunks) and lay eggs that are shed with feces. In fresh water, the eggs hatch into miracidia that can infect snails. The next life cycle stage, the cerceria, is released from the infected snail; these then infect the next intermediate host, generally crabs or crayfish. Larvae develop within these invertebrates into encysted metacercaria. Humans or other definitive hosts become infected when they ingest infected raw or undercooked crustaceans or infective material contaminating utensils or other food. Once the larvae reach the small intestine, they excyst and penetrate into the peritoneum. They then migrate through the diaphragm and pleura into the lungs. There, worm pairs encyst together near bronchial passages and mature into adult worms that begin egg laying 5 to 6 weeks after infection. When the cysts rupture into a bronchiole, they are expectorated or swallowed and shed with the feces. If they reach fresh water, the cycle starts again. Paratenic animals, carnivores in which the metacercariae do not

develop (e.g., wild boars in Japan), harbor the infection and can serve as vehicles for transmission to humans.[254,257,258]

Pathogenesis. The clinical features of paragonimiasis initially arise through the migration of the worms through the body, causing a hemorrhagic and inflammatory response to the worms and their secreted antigens. As the parasite traverses the pleura, an exudative pleural effusion can form that has an eosinophilic predominance that is likely mediated by IL-5.[259,260] The histologic appearance of lung lesions in the acute phase is that of eosinophilic pneumonitis.[261] Once in the lungs, the parasite encysts and becomes walled off from the immune system. The cyst wall progressively becomes thick and fibrous. Most cysts are connected to, or in communication with, a bronchiole, into which eggs are released. Release of cyst contents or eggs into the lung parenchyma triggers an inflammatory reaction with local bronchopneumonia and granuloma formation. Once the parasite eventually dies, the cyst evolves into a fibrotic scar that may calcify.

Occasionally, the metacercariae can aberrantly migrate to other organs; the central nervous system is the most common extrapulmonary site of disease, and flukes may be present in the central nervous system of 1% to 24% of patients with lung disease.[262] Patients with paragonimiasis typically have high levels of eosinophils in the blood, pleural fluid, and in BAL washings. They also have elevated levels of IL-5 when compared with noninfected persons.[258]

Clinical Features. Paragonimiasis is rarely a serious or fatal infection. Symptoms depend on the location of the worms and their developmental stage. Shortly after infection, patients may complain of diarrhea or abdominal discomfort, although most people are asymptomatic in the initial phase, with symptoms generally commencing 6 to 27 months after infection.[252] Acute symptoms are caused by migration of metacercariae and their encystation. The initial migration of the larvae through the diaphragm and pleura can cause pleuritic chest pain and pneumothoraces. Chronic symptoms are due to the presence of the encysted worms and rupture into the airways. The infection can cause chronic debilitating symptoms that last for years.[263] The clinical manifestations and the amount of extrapulmonary manifestations appear to depend in part on the causative species. A minority of patients have fever, and patients may remain asymptomatic, with the diagnosis made incidentally.[259] Whereas aberrant migration of *Paragonimus* can occur, full maturation into the egg-laying stage cannot occur in tissues other than the lung. Whereas the majority of aberrantly migrating parasites do not cause symptoms, some can cause disease depending on the location. Parasites in the brain can cause headache, dizziness, and visual disturbances. Chronic cerebral paragonimiasis can manifest as seizures, paralysis, or mental impairment.[262] Occasionally, paragonimiasis can manifest with subcutaneous nodules.

Pulmonary Manifestations. Symptoms of paragonimiasis include cough (62%–100% of patients), hemoptysis (61%–95%), and chest pain (38%–94%).[258,263] The hemoptysis is usually rusty or chocolate-colored sputum; hemoptysis with large volumes of fresh blood is unusual. Pleural effusions can form and, if large, can result in dyspnea. Chronic infection is often mistaken for tuberculosis, especially in areas where paragonimiasis is less prevalent. However, in some instances, tuberculosis and paragonimiasis can coexist.[264] The physical examination is usually normal, although crackles may be heard. Rarely, finger clubbing is present.[262]

Diagnosis. A key clue to the diagnosis of paragonimiasis is a history of handling or eating freshwater crabs or crayfish, especially if raw or undercooked. Isolating *Paragonimus* eggs in the sputum or stool makes the diagnosis. Because of the low yield in a single sputum sample, the examination of multiple samples may be necessary to establish the diagnosis. Although the diagnostic yield is greatest from the examination of sputum, parasitologic examination of stool is also useful.[263] The eggs are golden brown and operculated.

Serology, based on an immunoblot assay using crude antigen from whole worm, is available from the CDC. This test is especially useful in patients with ectopic disease in whom eggs are not present in sputum or stool. A skin test using whole worm antigen has been developed but is not generally available. Although less specific than the immunoblot assay, it was reported to be a good screening test in areas where laboratory tests are not readily available.[263] Cytologic and biochemical examination of the pleural fluid reveals an exudate with an eosinophil predominance. It is usually sterile without ova being present. Other laboratory tests are nonspecific. Eosinophilia and an elevated IgE and other inflammatory markers are common.[258]

The radiographic appearance of paragonimiasis may include nodules, pneumothoraces, interstitial opacities, cavities, and ring cysts resembling bronchiectasis (Fig. 37-7).[252,255,261] The chest radiograph can be normal in 10% to 20% of cases.[256] The most common findings are pleural abnormalities. Effusions are seen in 48% to 62% of patients[258,261]; pleural nodules are increasingly recognized on CT scan. Parenchymal consolidation is seen in the majority of patients. Linear streaking is seen in 3% to 41% of chest radiographs of patients with paragonimiasis.[254] These changes can be transient, especially in acute infection when the worms are migrating. The migration tracts of the worms can be seen on CT scan, appearing as linear opacities, whereas cysts can be later seen within parenchymal consolidation, as the inflammation resolves. Ring shadows may represent cysts with attached parasite along the wall.[262] One study in Nigeria of 100 patients noted that most of the lesions are in the midzones, with more in the left lung than in the right.[264]

Treatment. Praziquantel 25 mg/kg/day in three doses for 2 days is now the treatment of choice for paragonimiasis, because it is safer, better tolerated, and more effective than older treatments that included bithionol and niclofolan. A transient increase in eosinophilia immediately after treatment can be seen.[252,254] Three clinical trials, involving a total of 261 subjects in Cameroon and Ecuador, reported the successful treatment of paragonimiasis with triclabendazole.[265,266] The optimal treatment regimen of paragonimiasis with

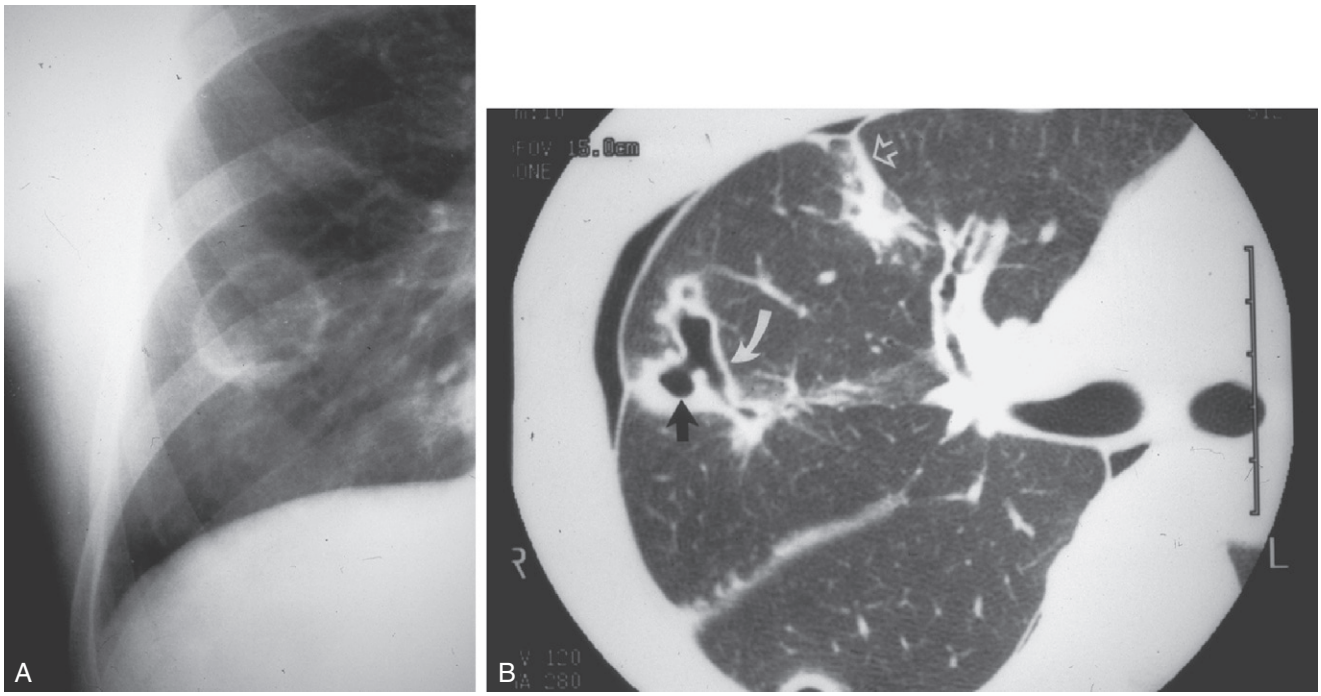

FIGURE 37-7 ■ **A,** Chest roentgenogram of a Korean adult with a large *Paragonimus* cyst in the right lower lung. **B,** CT scan of the chest at the level of the right upper lobe bronchus of a 20-year-old South Korean woman showing an unusually shaped air-filled space (*curved arrow*) and a bandlike opacity abutting the visceral pleura (*open arrow*), indicating worm migration tracks, as well as an air-filled worm cyst (*straight arrow*), a small right-sided pneumothorax, and a second worm cyst in the right lower lobe peripherally (*bottom*). (A and B, From Im J-G, Chang K-H: Paragonimiasis. In Palmer ES, Reeder MM [eds]: The Imaging of Tropical Diseases with Epidemiological, Pathological, and Clinical Correlation, 2nd ed. New York: Springer-Verlag, 2001.)

triclabendazole is 20 mg/kg given in two equal doses. The clinical studies in Ecuador[265,267] demonstrated that triclabendazole is equally effective and well tolerated as praziquantel. Corticosteroids can be used during treatment of cerebral paragonimiasis to decrease the inflammation triggered by the death of parasite. Patients with chronic empyema due to paragonimiasis may also require decortication in addition to anthelmintic treatment.[258]

Prevention. Metacercariae are heat sensitive and are killed by cooking, so the best means of prevention is the thorough cooking of crabs or crayfish before consumption. Handwashing and cleansing of utensils that may have come into contact with raw crustaceans is also an important preventive measure. Irradiation can sterilize the larvae if the consumption of raw crab or crayfish is desired.[254] Given the number of species that can potentially infect humans, it is unlikely that the natural reservoir for this infection will ever become eradicated. Thus, changing food preparation practices is the most feasible means of prevention.

Schistosomiasis

Human schistosomiasis is caused by one of the five species of the trematode (fluke) genus *Schistosoma*. *S. mansoni* is endemic in parts of Africa, the Middle East, South America, and the Caribbean. *S. haematobium* is found in Africa, the Middle East, and in one focus in India, while *S. japonicum* is a zoonosis that is found in China, Indonesia and the Philippines. Less common are *S. intercalatum* (central Africa) and *S. mekongi* (Cambodia and Laos). It is estimated that almost 200 million people in 74 countries are infected with schistosomiasis, with another 650 million at risk for infection. Twenty million people have severe disease.[268–270] Repeated infection is common in endemic areas, with the peak intensity usually occurring in individuals about 15 to 20 years of age.

Transmission. The adult worms reside in abdominal venous plexus in humans (or other definitive mammalian hosts). The favored site for *S. mansoni* is the superior mesenteric veins, for *S. haematobium*, the vesical plexus and veins of the ureters. For *S. japonicum*, the inferior mesenteric veins are preferred. The majority of eggs that are shed pass through the wall of the vessels into the intestinal or bladder lumen, where they are shed in the stool or urine. When eggs reach fresh water, they hatch into swimming miracidia that infect the appropriate snail species (the intermediate host). Within the snail, the parasites multiply over two generations, resulting in the release of many cercariae from a snail infected with one miracidium. Cercariae penetrate the skin of a human host in contaminated fresh water. Once it has penetrated the skin, the tail is lost, and the schistosomulum migrates to the lungs within a week; thence, it goes to the intrahepatic portal veins 2 to 3 weeks later. In the liver, the worms mature into adults and mate. Each pair then migrates to their target venous plexus where they

start producing eggs 1 to 3 months after infection.[269,271] The life span of adult worms is about 5 years, although people have been known to shed eggs for over 30 years after leaving an endemic area.[272]

Pathogenesis.[272a] Acute schistosomiasis otherwise known as Katayama fever, usually occurs in nonimmune persons, with symptoms developing as the worms migrate and mature into adult forms, before eggs are laid. The symptoms are thought to be due to antigen released by the worm: circulating immune complexes are found in the majority of acutely symptomatic patients, but are found only in a minority of chronically infected patients.[273] The level of circulating immune complexes correlates with symptoms and with intensity of infection. With time, the immune response to the parasite is down-modulated, and the symptoms resolve.[271] Lymphocytes from acutely symptomatic patients show high baseline production of tumor necrosis factor-α (TNF-α), IL-6, IL-1, and IFN-γ, suggesting that these proinflammatory cytokines may be responsible for some of the symptoms. In contrast, patients with chronic infection tend to have a predominant production of IL-10, an inhibitory cytokine in response to schistosome egg antigen.[274] In the uncommon circumstance in which lungs are affected during acute disease, eosinophilic pneumonia is the most common finding with a typical eosinophil predominance seen on biopsy or BAL.[275,276]

Once oviposition begins, not all the eggs are excreted from the body. It is the eggs that remain in the tissues that cause most of the chronic disease in schistosomiasis. The host immune system responds to the presence of the egg antigen by forming granulomas around the eggs. The granulomas are characterized by an eosinophilic infiltrate and central necrosis.[277] *S. mansoni* and *S. japonicum* eggs are commonly carried downstream to the liver where the resultant inflammatory response may lead to so-called Symmer's clay pipe stem fibrosis—in which fibrosis develops around the portal vein branches, with intervening normal tissue. As this fibrosis progresses, portal hypertension develops, leading to hepatosplenomegaly.[278]

With the development of significant portal fibrosis and hypertension, portacaval shunts develop, enabling eggs in the mesenteric blood to bypass the liver and lodge instead in pulmonary vessels. As eggs are embolized into the pulmonary vasculature, the local inflammatory response results in a necrotizing vasculitis surrounding the eggs, with eosinophilic infiltration and granuloma formation. Even in vessels that do not contain eggs, a vasculitis can be seen that may be a reaction to circulating antigen. With time, the vessel becomes obstructed and fibrotic, causing an obliterative vasculitis.[279] With the fibrin deposition, focal congestion, endothelial hyperplasia, dilation of the vessels, and a plexiform pattern develop in the vessels, increasing pulmonary resistance and resulting in pulmonary hypertension. Dumbbell-shaped interarterial and perivascular granulomas with local angiogenesis are typically seen on histology.[272] Whereas pulmonary hypertension occurs in 7% to 23% of patients with hepatosplenomegaly due to schistosomiasis, cor pulmonale occurs in less than 5%.[280]

S. mansoni is more commonly a cause of significant chronic pulmonary morbidity than other species. In a study of 78 patients who died of *S. mansoni* infection in Brazil, most had pulmonary findings on autopsy; 45% had only a few scattered granulomas around the remnants of eggs; 9% had many granuloma in alveolar and vascular tissue, but no histologic evidence of pulmonary hypertension.[277] Only 18% had evidence of end-stage lung disease, with diffuse thickening of the intima of the small arteries, edema, and fibrous deposition in the lungs. This group had obstruction of the small arteries with thrombosis and collateral formation; clinical evidence of cor pulmonale was present in 27%.[277]

Clinical Manifestations. The clinical manifestations of schistosomiasis depend on the location and life cycle stage of the parasite. As the cercariae penetrate the skin, a pruritic rash can develop. This "swimmer's itch" can also be caused by nonhuman (usually avian) schistosome species that cannot progress beyond the dermis. With the migration of the schistosomula to the lungs and liver, the acute syndrome known as Katayama fever can develop in a portion of immunologically naive people, usually travelers or immigrants from areas not endemic for *S. japonicum* or *S. mansoni*. This occurs 3 to 8 weeks after infection (average 36 days after exposure). The symptoms of Katayama fever are nonspecific and include fever, accompanied by lethargy, myalgia, chills, and sweats, abdominal pain, and diarrhea. Cough is present in 44% to 80% of people with this syndrome. Clinical examination is generally unremarkable, although a minority has hepato- or splenomegaly, rash, or wheeze.[274,281–283] The hepatomegaly can be tender. The acute disease can be more severe and potentially fatal in *S. japonicum* infection.[274]

Patients with *S. haematobium* infection may develop dysuria or terminal hematuria that first occurs 10 to 12 weeks after infection, once egg laying has begun.[269] Once an infection is established, it can remain subclinical for years, emerging decades later as a consequence of cumulative chronic inflammatory response to the eggs. In *S. mansoni* and *S. japonicum*, the hepatic fibrosis that develops causes hepatomegaly and, ultimately, portal hypertension, resulting in splenomegaly, and varices. Coinfection with hepatitis B or C can accelerate the progression of liver disease. In *S. haematobium* infection, late manifestations of disease include proteinuria, bladder scarring with calcification, and ureteric obstruction, leading to hydronephrosis and obstructive nephropathy. *S. haematobium* infection also increases the risk of squamous cell carcinoma of the bladder.[269]

Pulmonary Symptoms. Respiratory symptoms occur in a significant portion of patients with Katayama fever: 80% of patients in one study had cough, 52% had dyspnea, and 39% had chest pain.[274] In addition to classic Katayama fever, pulmonary symptoms can occur shortly after infection in a proportion of nonimmune people. These symptoms manifest as shortness of breath and a dry cough with occasional urticaria[275] and may present after the acute febrile stage or occur without fever. In such patients, the physical examination is usually normal,

and symptoms and radiographic abnormalities may occur together or independently.[272] Pulmonary function testing in the acute phase is not generally helpful, with a restrictive pattern typically observed. In one study, a decreased forced expiratory volume in 1 second was seen in a majority of patients, whereas a decreased total lung capacity and forced vital capacity were present in a minority; these were reversible with resolution of symptoms. Gas exchange was usually not affected.[284] In another study, reduced maximal voluntary ventilation and vital capacity was observed.[285]

The clinical manifestations of pulmonary hypertension and cor pulmonale due to schistosomiasis are the same as those caused by other etiologies: dyspnea with exertion, fatigue, chest pain, and cough,[272] with typical findings of jugular venous distention, right ventricular heave, and tricuspid and pulmonary regurgitant murmurs.[286] Whereas pulmonary hypertension usually follows portal hypertension in patients with *S. mansoni* infection, people with *S. haematobium* infection can develop pulmonary hypertension in the absence of hepatic fibrosis.

Diagnosis. Acute schistosomiasis is a clinical diagnosis to be suspected in patients with a history of exposure to fresh water in endemic areas, fever, and other characteristic symptoms and eosinophilia and no other cause found. Serology is available through the CDC. Whereas the ELISA test is sensitive and specific, it is not usually positive in acute disease. The average time to seroconversion in two studies was 1.6 months and ranged from 0 to 6 months.[272,281] The development of specific IgM response to somatic antigen (by immunofluorescence) develops earlier, between 26 to 34 days following infection, whereas an IgG to egg antigen becomes positive between 34 and 51 days after infection.[282] Newer specific immunoblot tests can differentiate between infections with different schistosome species and, when used with the ELISA test, can increase sensitivity.[287] The schistosomal ELISA can remain positive for years after treatment, making it less useful in following treatment efficacy or to look for reinfection. Circulating antigen tests enabling detection of current infection have been developed.[287]

Parasitologic diagnosis by identifying eggs in stool or urine is useful in established infection, but is not positive till egg laying begins, usually at least 6 weeks after initial water exposure.[274] Several techniques have been developed to isolate eggs from stool; classically the Kato-Katz thick smear or formalin concentration is used. Quantifying the intensity of infection by the number of eggs per weight or volume of stool or urine is useful.[286] Mean egg counts were found to be significantly associated with the severity of acute symptoms in one study[283] but not in others.[282] In patients who are not shedding eggs, rectal or bladder biopsies can be examined for the presence of eggs.[286]

Eosinophilia and elevated levels of IgE occur in almost all patients with acute schistosomiasis. Mild nonspecific elevation of liver enzymes is often present.[283] In patients with pulmonary symptoms, BAL, although usually not necessary, can reveal eosinophilic alveolitis in the absence of parasites.[276]

On chest radiographs of patients with acute symptoms, nodules with ill-defined borders are seen frequently; on CT, these nodules can have a ground-glass "halo appearance." The radiographic abnormalities may not appear until after treatment has been administered.[275,288] Bronchial thickening and beaded micronodular infiltrates can be seen in patients with interstitial lung disease and is found on CT in a majority of patients with hepatosplenomegaly due to schistosomiasis. The chest radiographic appearance of pulmonary hypertension due to schistosomias does not differ from that of other causes. On CT, vessel thickening is evident.[280] Rarely, a cavitary lesion can mimic tuberculosis.[289]

Treatment. The treatment for infection with *S. mansoni* and *S. haematobium* is praziquantel in a total dose of 40 mg/kg divided into two doses given 12 hours apart, with cure rates of 75% to 100% expected.[286] For *S. japonicum*, a higher total dose of 60 mg/kg given in three doses over 24 hours is required. Taking the drug with cimetidine (an inhibitor of cytochrome P-450) or grapefruit juice can increase drug levels, as can taking the medication with a high-carbohydrate meal.[290,291] Although praziquantel kills the adult worm, it is not active against immature parasites, thus compromising its efficacy in acute disease. In addition, the clinical condition of patients with Katayama fever can occasionally worsen after treatment with praziquantel, perhaps due to release of antigen from dying worms causing increased inflammation.[276,282,292] The acute syndrome is generally self-limited and generally does not require therapy. However, corticosteroid treatment may be used to decrease the inflammatory response to the parasite. Because corticosteroids may decrease the efficacy of praziquantel,[293] it may be prudent to defer praziquantel therapy in acute schistosomiasis until the symptoms have resolved and the worms have matured. Nonviable eggs may be shed for a prolonged period after treatment, so careful examination for viability needs to be done if posttreatment samples are collected to define cure.

Prevention. The prevention of schistosomiasis involves the interruption of the human-snail life cycle. Widespread eradication campaigns are underway in many countries, with mass treatment and application of molluscicides to fresh water to decrease the snail levels. However, because of the large animal reservoirs, this approach may not be effective. Because acute schistosomiasis in developed countries is most commonly seen in returning travelers, pretravel counseling and warnings about freshwater exposure may help decrease the incidence.

Artemether compounds have been shown to be effective in early infection when praziquantel is inactive and have been studied as prophylaxis for schistosomiasis in endemic areas where they seem to have an effect on decreasing the incidence of infection.[294,295] N,N-diethyl-3-methylbenzamide (DEET) and other insecticides have been studied in animal trials and seem to prevent skin penetration by schistosomal cercariae.[296,297] Vaccines are in development,[298] although they have yet to reach large-scale human trials.

KEY POINTS

- Parasites are eukaryotic organisms that live within another organism or host. They may be unicellular protozoa or multicellular helminths. In humans, protozoa usually live intracellularly and helminths usually live extracellularly, except trichinella, which encysts within muscle cells.
- Most parasites have complex life cycles with multiple stages and often multiple host species. Humans may be the definitive or intermediate hosts.
- Infection generally occurs through ingestion, insect vectors, or by penetration through the skin.
- Except for *Paragonimus*, most parasites migrate through the lung en route to another organ or infect the lungs as a secondary site.
- Although the worldwide burden of parasitic infections is enormous, most parasites have ecologic niches; presence in nonendemic areas usually results from travel to endemic areas.
- In most cases, the diagnosis is suspected by identifying an environmental association, compatible symptoms, and eosinophilia. The diagnosis is usually made by detecting antigens or isolating the parasite from the host.

Management of Acute Asthma
Conclusion: Clinician-Patient Partnership

INTRODUCTION

Asthma is one of the oldest known diseases, but it has only been recognized as a major public health problem since the mid 1970s. The prevalence of asthma has increased dramatically and asthma is now recognized as a major cause of disability, medical expense, and preventable death. Asthma has attracted the full spectrum of biomedical investigation, from studies of the prevalence of asthmatic symptoms in different populations to studies of the effects of substitution of single base pairs in genes in animal models of allergic sensitization of the airways. These studies continue to refine the scientific understanding of asthma and suggest new approaches to diagnosis and treatment. The scope and depth of these studies present significant challenges in reviewing the topic of asthma. This chapter combines the perspectives of the authors with a "snapshot" of the body of knowledge, which is expanding at an explosive pace.

DEFINITION

Although asthma is a clearly recognized clinical entity, agreement on a precise definition of asthma has proved elusive. Asthma has been more often described than defined. The earliest feature described was the labored, rapid breathing typical of asthmatic attacks, because the word "asthma" is derived from the ancient Greek word for "panting." As knowledge about asthma has grown, the features described as characteristic of asthma have expanded. Measurement of maximal expiratory flow led to recognition of reversible airflow obstruction as a characteristic feature; measurement of changes in airflow

after inhalation of chemical or physical irritants led to the definition of bronchial hyperresponsiveness. In addition, studies of bronchial biopsies added a description of characteristic pathologic features. This evolution in the understanding of asthma is summarized in the definition offered in the National Heart, Lung, and Blood Institute's 2007 Update on Asthma Pathophysiology and Treatment Guidelines.[1]

Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, including mast cells, eosinophils, T lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in bronchial hyperresponsiveness to a variety of stimuli.

A feature found even more consistently than eosinophilia in bronchial biopsies from patients with asthma is thickening of the lamina reticularis immediately underneath the subepithelial basement membrane, which is considered a hallmark of airway "remodeling," however this feature has not yet been incorporated into consensus definitions of asthma's features.

The consensus conference "definition" of asthma serves well as a description of the major features of asthma but does not hold up as a precise definition. No feature is unique to asthma, and no feature is universal in patients with the condition. For example, all tests of airway caliber may be normal between attacks, even in patients whose attacks are sudden and severe. Bronchial responsiveness may be normal over most of the year in patients with seasonal asthma, and bronchial hyperresponsiveness is often found in people with allergic rhinitis but without asthma. Even the association between eosinophilic bronchial inflammation and asthma is inconstant. Some patients with recurrent episodes of wheezing and dyspnea associated with reversible airflow obstruction and bronchial hyperresponsiveness have no evidence of eosinophilic inflammation on bronchial biopsies. Other patients have eosinophilic inflammation of the bronchial mucosa and chronic cough responsive to treatment with an inhaled corticosteroid but have neither airflow obstruction nor bronchial hyperresponsiveness. Finally, some patients with severe asthma have a predominance of neutrophils, rather than eosinophils, in their bronchial mucosa.

The lack of firm, universally agreed-upon criteria for defining asthma complicates epidemiologic studies of the prevalence of asthma in different populations and of changes in prevalence in the same population over time, but agreement on "working definitions" of asthma has led to many informative studies.

Logically, studies of the genetic basis of asthma should be the most affected by lack of precise diagnostic criteria, but the approach developed by genetic researchers has refined concepts of the disease. Geneticists recognized that asthma is a complex trait, reflecting variations in many genes and their interactions with the environment, so they examined the genetic determinants of well-defined phenotypes rather than those of clinically defined asthma. This approach has clarified the role of genes as determinants of atopy, bronchial responsiveness, and responsiveness to treatment, such as β-agonists. The recognition of asthma as a complex, multifactorial disorder has led to a greater focus on the individual and the varied disturbances in function that contribute to a more or less common clinical expression. Recent advances in science have not necessarily led to a more precise definition of asthma; rather, these advances have made the need for agreement on a definition seem less urgent.

ASTHMA EPIDEMIOLOGY AND RISK FACTORS

Introduction

The epidemiology of asthma is complex and careful epidemiologic studies are essential to enhancing our understanding of a disease that affects millions of people worldwide. The challenges faced when studying asthma epidemiology begin with the lack of a universally accepted definition for the disease. Asthma was defined by the American Thoracic Society in 1962 as a disease characterized by increased hyperresponsiveness of the bronchi and trachea to various stimuli, involving widespread narrowing of the airways that changes in severity either spontaneously or as a result of therapy.[1a,2] In 1975, the World Health Organization (WHO) described asthma as a chronic condition characterized by recurrent bronchospasm resulting from a tendency to develop reversible narrowing of airway lumina in response to stimuli of a level or intensity not causing such narrowing in normal individuals.[2] The emphasis on bronchoconstriction or bronchospasm as the mechanism of asthma is warranted. However, recent advances in research techniques have shown that asthma is a complicated disease that involves both bronchoconstriction and inflammation.

Epidemiologic studies rely on questionnaire assessments of asthma symptoms, physician diagnosis of asthma, and use of asthma medications. Unfortunately, highly sensitive and specific physiologic tests to diagnose asthma are not available. The methacholine challenge test is highly sensitive but not specific. In 1991, the National Institutes of Health (NIH) and National Heart, Lung, and Blood Institute (NHLBI) described asthma as a chronic inflammatory disorder of the airways in which many cells and cellular elements are involved. The chronic inflammation causes an associated increase in airway hyperresponsiveness that leads to recurrent wheezing, breathlessness, chest tightness, and coughing, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible, either spontaneously or with treatment. The NIH updated the asthma diagnosis and treatment guidelines in 2007.[3] Current guidelines emphasize the role of inflammation

in asthma and focus on evidence that the patterns and degrees of inflammation are variable, resulting in phenotypic differences that have important influences on response to therapy.

Prevalence of Asthma

The prevalence of asthma has been increasing worldwide over the past several decades.[4] The etiology of this increase in prevalence is unclear but is likely multifactorial. Factors resulting in increased prevalence rates include obesity and exposure to allergens such as house dust mites, mold, and tobacco smoke. Exposure to environmental triggers results in increased bronchial hyperresponsiveness and asthma. Atopy and allergic rhinitis related to exposure to allergens at an early age likely contribute to the increased incidence of asthma.[5] Obesity has also been increasing in prevalence since the mid 1980s.[6] Although the available studies cannot address the direction of causality, they indicate that there are important relationships between environmental and individual factors that warrant further investigation.

In 2006, the National Health Interview Survey (NHIS) estimated that 16.1 million adults (7.3% of the population) and 6.8 million children (9.4% of the population) in the United States had a diagnosis of asthma.[7] The prevalence of asthma in the United States increased from 3.1% in 1980 to 7.7% in 2005. The prevalence of asthma decreases with increasing age. There are important racial differences in the prevalence and morbidity of asthma. In 2005, Puerto Ricans had an asthma prevalence rate 125% higher than non-Hispanic whites and 80% higher than non-Hispanic blacks. Females had a 40% higher prevalence rate than males; however, boys under the age of 18 years old had a higher prevalence than girls.[4]

The International Study of Asthma and Allergies in Childhood (ISAAC) was performed between June 1996 and November 1997.[5] This is the largest study to document the worldwide prevalence of asthma. The study involved 91 centers in 56 countries and over 6000 subjects. The study enrolled two cohorts of subjects: children aged 6 to 7 years old and 13 to 14 years old. The prevalence of asthma varied widely between countries, ranging from 2.1% to 4.4% in Albania, China, Greece, and Indonesia to 29.1% to 32.2% in Australia, New Zealand, and the United Kingdom. Lower prevalence rates were seen in Asia, Northern Africa, Eastern Europe, and Eastern Mediterranean areas (Fig. 38-1). The prevalence rates in the younger cohort ranged from an average of 4.1% in India, Indonesia, Iran, and Malaysia to 32.1% in Australia, Brazil, New Zealand, and Panama. The results of the ISAAC study indicate that atopy, allergic rhinoconjunctivitis, and atopic eczema are highly correlated with the prevalence and symptoms of asthma. Countries with lower rates of atopy had lower prevalence rates of asthma.

The goal of phase II of the ISAAC study was to further investigate the contribution of atopic sensitization to the large international variation in the prevalence of asthma.[8] This was a cross-sectional study of random samples obtained from 8- to 12-year-old children in 30 centers in 22 countries. The countries covered a wide range of environments including both urban and rural areas. The relationship between atopic sensitization and current wheeze was not significant. However, there was a correlation between wheezing and atopy in countries with higher gross national income (typically in the developed world).[9] Asthma prevalence rates are higher in affluent countries, an effect that is attributed to differential environmental exposures in industrialized countries as compared with developing countries, in which more people live in rural than in urban areas.[10]

ISAAC phase III aimed to identify temporal changes in asthma prevalence rates. The prevalence of asthma symptoms increased in Africa, Latin America, and parts of Asia during the observation period, but the overall prevalence of wheezing decreased in English-speaking countries and Western Europe.[11]

The European Community Respiratory Health Survey (ECRHS)[12] was designed to collect data on asthma prevalence, variation in symptoms, risk factors, and treatment patterns in Europe and several centers outside Europe. In 1996, the ECRHS reported a wide variation in the prevalence of asthma symptoms among countries. The lowest prevalence rates occurred in India and Algeria, whereas the highest prevalence rates occurred in the British Isles, New Zealand, Australia, and the United States.[13] The increased prevalence of asthma has been substantiated by several large epidemiologic studies.[14–18]

Death from asthma was previously thought to be very uncommon; however, asthma-related deaths steadily increased in the United States and worldwide between 1980 and the mid-1990s.[19–21] There was a sharp rise in asthma-related deaths in Australia and New Zealand in the early 1980s. This increased risk of death was attributed to overuse of the β-agonist fenoterol.[22] In 1999, a new diagnostic coding system was initiated, which is thought to have caused the apparent decline in death rates between 1998 and 1999. Although recent death rates have been declining, asthma-related morbidity and mortality continue to be a significant problem. Worldwide, approximately 180,000 deaths are attributable to asthma each year, although considerable regional variation exists.[18]

Approximately 4000 deaths/yr in the United States are attributed to asthma.[23] The recent decline in asthma-related deaths is likely related to the increased use of inhaled corticosteroids, improved access to better medical care, and improved recognition and diagnosis of asthma. Disparities exist in asthma-related morbidity and mortality. In the United States, certain populations have a higher burden of asthma-related morbidity and mortality. Deaths from asthma are rare under the age of 18 years. The Morbidity and Mortality Weekly Report (MMWR)[23] reported a plateau in asthma related deaths between 2001 and 2003. In 2003, 4055 asthma deaths occurred, suggesting a rate of 1.4/10,000 persons. Higher death rates were noted in persons older than age 65 years and in women (death rate 2.3/10,000 compared with 1.8/10,000 in men).[23] Females had a 45% higher risk of dying from asthma than males. Puerto Ricans were the

Worldwide variation in prevalence of symptoms of asthma, allergic rhinoconjunctivitis and atopic eczema. ISAAC. Lancet 351:1225–1232, 1998; with permission.)

most likely to die of asthma, with a death rate 3.6 times higher than non-Hispanic whites. Non-Hispanic blacks had an asthma death rate twice as high as non-Hispanic whites.[24] The disparate rates of death are attributed to variations in severity of disease, socioeconomic factors such as lack of access to quality health care, increased exposure to exacerbating factors in inner city areas, lack of access to medications, and differences in medications prescribed by medical professionals.[20] Health care disparities contribute to the major differences in outcomes in different populations.

Risk Factors

Hygiene Hypothesis

Several large epidemiologic studies have been designed to identify the risk factors that predispose individuals to developing asthma. In 1989, Strachan[25] proposed that exposure to infections early in life results in the development of a predominately T-helper (Th)1-mediated immune response and down-regulation of the Th2-mediated response. The lack of exposure to microbes early in life results in an overactive Th2-mediated response

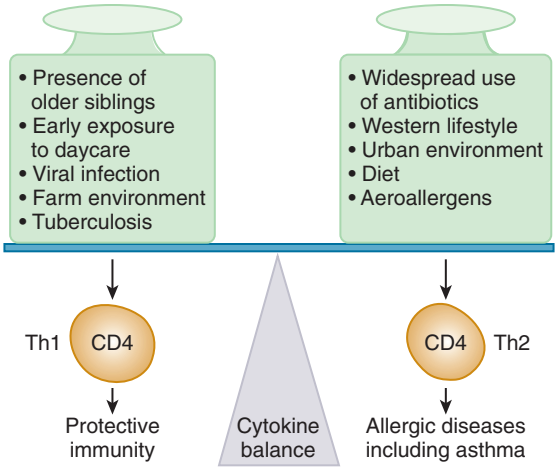

FIGURE 38-2 ■ Determinants of the direction of differentiation of precursor T cells in early life. The concept is that environmental factors in early life can have key influences on the direction of differentiation of precursor T cells. Several factors favor development of a Th1 phenotype, leading to the absence of allergy and asthma.

with increased allergic rhinitis and atopy and an increased risk of developing asthma.[25,26] Modern environments are more likely to be hygienic, with smaller families, increased access to antibiotics, and decreased exposure to bacterial pathogens and microbes, leading to imbalance between the innate and the adaptive immune mechanisms. This maladaptive system increases the risk of developing allergic diseases such as asthma. The presence of a predominantly allergic, Th2-driven milieu results in defective host defense mechanisms that make the host more susceptible to infection (Fig. 38-2).[27] The hygiene hypothesis is supported by data obtained from several subsequent epidemiologic studies involving birth cohorts in the United Kingdom, Europe, and prospective studies worldwide.[28,29] This association appears to be stronger in Europe than in other countries.[10] For instance, the higher incidence of asthma in the inner city is not explained by this hypothesis. Von Mutius[10] concluded that the hygiene hypothesis has led to important discoveries about the etiology of asthma and the interaction between innate and adaptive immune mechanisms, even though it still lacks a unifying etiology. The practical implications of the hygiene hypothesis have not been fully tested.

Infections

The effect of respiratory infections on the incidence of asthma is incompletely understood. Exposure to microbes early in life may be protective against the development of asthma and allergic rhinitis later in life.[25] Respiratory infections, particularly from viral pathogens, are especially common in infancy and childhood. The relationship between infection and the development of atopy and asthma is complex and highly dependent on the type of infection.[30] Exposure to respiratory illness might increase or decrease the incidence of asthma, depending on host factors and the timing, location, and type of microbial exposure.[31,32] Using a birth cohort, Ramsey and coworkers found that having physician-diagnosed croup or having two or more physician-diagnosed ear infections in the first year of life was inversely related to atopy at school age. In contrast, bronchiolitis in the first year of life was associated with increased odds of developing asthma at age 7 years.[30]

Respiratory syncytial virus (RSV) is the most common cause of bronchiolitis and is associated with an increased risk of developing subsequent wheezing or asthma.[31,33–43] Recently, rhinovirus has been recognized as an important risk factor for the development of asthma. Rhinovirus infections are common in childhood and occur in the spring and fall. Rhinovirus is a known cause of bronchiolitis and is the second most common cause of severe bronchiolitis resulting in hospitalizations. Until recently, little was known about the role of moderately severe outpatient lower respiratory tract infections in the development of asthma. Jackson and colleagues[43] performed nasal sinus lavage, culture, and polymerase chain reaction (PCR) for microbial RNA on infants and children with outpatient wheezing illnesses. Viral etiologies were responsible for more than 90% of wheezing illnesses during early childhood. From birth to 3 years of age, wheezing with RSV, rhinovirus, or both resulted in odds ratios of 2.6, 9.8, and 10 for developing asthma by the age of 6 years.[43] Other studies also support the increased risk of developing asthma following rhinovirus infections.[44] Rhinovirus is a very important predictor of asthma if the infection occurs early in life.

Understanding the mechanism by which viruses modify the risk of developing asthma is an area of intense research. In humans, severe viral infections and bronchiolitis result in alterations in both Th1 and Th2 cytokine levels. RSV invades the respiratory epithelium through attachment and fusion proteins. Rhinovirus binds intracellular adhesion molecule (ICAM)-1 and low-density lipoprotein receptors (LDLPRs) on the respiratory epithelium and is internalized with subsequent receptor upregulation. Downstream effects include the induction of inflammatory chemokines and cytokines, including type 1 interferon (IFN), interleukin (IL)-12 and IL-18.[45,46] Additional factors that mediate the effects of acute viral infections in the airways include neuropeptides, growth factors, and leukotrienes.[47,48] The secretion of proinflammatory cytokines causes airway inflammation, whereas growth factors result in airway remodeling, which may eventually increase the risk of wheezing. Although there is substantial knowledge about the mechanisms by which viruses induce acute airway inflammation, little is known about why these changes produce asthma months or years later. Severe respiratory infections may permanently alter the innate immune system, and up-regulation of Th2 cytokines[49] acutely may cause irreversible changes in the airway that lead to increased airway hyperresponsiveness (AHR) and asthma at later times.[48]

Atypical bacterial pathogens are implicated in triggering acute asthma and propagating chronic asthma and airway inflammation.[50] The role of these pathogens in

initiating asthma is poorly defined.[50] Johnston and Martin[50] reported that with few exceptions, the majority of studies support the presence of a relationship between atypical pathogens and chronic stable asthma.[50–55] *Chlamydophila pneumoniae* and *Mycoplasma pneumoniae* are present in the airways of chronic asthmatics and are associated with increased airway inflammation and a more severe asthma phenotype.[56–58] The interaction between pathogens and asthma is not necessarily causative but rather could indicate an increased susceptibility to infections associated with atopy and asthma. Further evidence is required to determine the role of infections in the development of asthma.

Atopy

The incidence of asthma in childhood is strongly and independently associated with hay fever and eczema.[59–61] ISAAC phase I involved 155 centers in 56 countries and focused on the prevalence of asthma, allergic rhinitis, and atopic eczema in two childhood cohorts. This study found wide variations in the prevalence of asthma between countries and in different regions within countries.[5,7] The prevalence rates differed by more than 20-fold between study centers.[5,7,26,60] This variability was likely to be explained by environmental or lifestyle factors.

ISAAC phase II was designed to determine the role of environmental and lifestyle factors on the observed differences in prevalence rates.[8] This study included a smaller cohort of children 9 to 11 years old from 30 study centers in 22 countries and added objective measurements of atopy including skin examination, skin prick tests, bronchial challenge testing, and specific immunoglobulin E (IgE) measurements. Study site selection was based on prevalence rates, and sites with high or low prevalence were included in the second phase of the study.[8] Logistic regression modeling revealed no significant correlation between atopy and wheezing in this cohort of children. Subgroup analysis based on per capita income showed an increase in wheezing associated with atopy and allergy in countries with higher gross national income.[9] The association between maternal or paternal atopy and the occurrence of asthma in children is controversial. Paternal atopy or asthma is not strongly associated with the incidence of asthma in childhood[9]; however, maternal AHR is associated with nonatopic wheezing in children.[62] In contrast, several studies show that a family history of atopy is an important risk factor for atopy in children.[63,64]

The type of allergen and duration of exposure may be important predictors of asthma in childhood and later life. Torrent and associates[65,66] demonstrated that a threshold dose of environmental allergen exposure is required to induce sensitization or asthma, whereas no dose-response relationship existed above this threshold. The determinants of whether one develops allergic rhinitis/atopy, asthma, or both are unclear. The role of early childhood atopy in the development of asthma continues to be an area on ongoing research, and although the data demonstrate a significant link, important questions still remain.

Obesity

The role of obesity in the development of asthma is a new area of investigation. The obesity epidemic has been increasing for the past several decades and there are no signs that the trend will change in the near future. The recent Centers for Disease Control and Prevention (CDC) NHIS survey reported that 30% of adults over the age of 18 years are obese and about 68% of United States adults are either obese or overweight. The incidence of obesity has almost doubled since 1990.[6] The incidence and prevalence of asthma also have increased, and current prevalence data suggest that asthma affects approximately 5% of the U.S. population. Many studies have examined whether the increased prevalence of obesity has resulted in the increasing incidence of asthma. More than 30 cross-sectional and case-control studies of the relationship between obesity and asthma have appeared since the 1990s.[67–71] Almost without exception, these studies report an increased prevalence of asthma in obese and overweight individuals throughout the world. Although such studies do not address the direction of causality, several large epidemiologic studies have found that obese individuals have an increased odds ratio or relative risk of developing asthma (defined as a body mass index [BMI] > 30).[72,73] Obesity is associated with multiple comorbidities, including hypertension, hypercholesterolemia, diabetes mellitus, obstructive sleep apnea, gastroesophageal reflux disease (GERD), and depression.

The biologic basis for the relationship between obesity and asthma has not been established, but several mechanisms have been proposed, including common genetic etiologies, comorbidities, effect of obesity on lung mechanics, and the role of inflammatory mediators secreted by adipose tissue (adipokines). Weiss[74] suggested that obesity and asthma share common etiologies, for example, common effects of fetal programming or common genetics. Obesity may increase the risk of asthma through its effects on other disease processes such as sleep-disordered breathing (SDB) and GERD. The effect of these disease processes on the development of asthma is controversial. In a community-based cohort study of almost 800 children, Sulit and coworkers[75] reported that the association between obesity and asthma was strong even after adjusting for SDB. GERD is associated with increased AHR and wheezing[76–78] as a result of vagal nerve stimulation by acid refluxing into the distal esophagus and microaspiration of acid into the bronchi.[79,80] Treatment of GERD with medications or surgical intervention with Nissen fundoplication improves asthma control and decreases bronchial hyperresponsiveness.[81–85] Whereas GERD and SDB may contribute to the development of bronchial hyperresponsiveness and affect asthma control, these diseases do not entirely account for the association between obesity and asthma.

Recently, there has been interest in the role of adipokines in the development and perpetuation of asthma.[85a]

One link between obesity and asthma may be the effects of adipokines on airway inflammation. Adipose tissue is metabolically active and participates in energy homeostasis. Animal studies of obesity show that adipose tissue secretes biologically active cytokines, including tumor necrosis-α (TNF-α) and IL-6, and adipokines such as leptin, adiponectin, plasminogen activator inhibitor-1 (PAI-1), and resistin.[86] Adiponectin, a potent anti-inflammatory hormone secreted by adipose tissue, is found in low levels in the serum of obese individuals. Adiponectin attenuates allergen-induced airway inflammation and hyperresponsiveness in OVA sensitized and challenged mice.[87] In humans, obesity results in systemic inflammation characterized by elevated serum levels of these adipokines, chemokines, and acute phase proteins.[88] Obesity is associated with increased leptin levels, which may be associated with increased inflammation in the airways of obese asthmatics. Guler and colleagues[89] noted that serum leptin was predictive of asthma in boys, even after adjusting for BMI. Other studies reveal higher leptin levels in asthmatic women as compared with normal women; however, adjusting for serum leptin does not affect the association between BMI and asthma.[90] The relationship between obesity and asthma does not appear to be mediated via leptin in spite the fact that leptin may be an independent predictor of asthma. The effect of obesity on the development of asthma remains incompletely understood, but these early studies are promising and more work in this area is needed.

Genetics

Genetics play a significant role in the development of asthma and allergic diseases and is discussed in greater detail in the "Genetics of Asthma" section. The interplay between genetic predisposition and environmental exposures underlies the development of asthma. Advances in genomics have led to the discovery of several polymorphisms that are important in the development of asthma[91] and the response to therapy. Senthilselvan and associates[92] studied a cohort of 915 nonsmoking students and identified an association between Toll-like receptor 4 (TLR4) polymorphisms and atopy in females. TLR4 polymorphisms reduced the odds of having hay fever by 88%.[92,93] Conversely, Raby and coworkers[94] found no associations between TLR4 polymorphisms and asthma or atopy-related phenotypes. Other polymorphisms of interest in asthma include polymorphisms in IL-4, IL-4 receptor-α, and IL-5 polymorphisms that contribute to susceptibility for bronchial asthma.[95–98] The phenotypic and genetic heterogeneity in asthma poses a challenge to discovering specific genetic mutations that solely increase the risk of asthma.[99]

Tobacco Use and Environmental Exposure

Exposure to environmental tobacco smoke is common and its role in the development of asthma and abnormal lung function in childhood is controversial. There is increasing evidence that both in utero and childhood exposure to tobacco results in detrimental effects on respiratory health. Studies have demonstrated that in utero and early childhood exposure to tobacco leads to an increased risk of abnormal lung function[100,101] and wheezing illnesses in childhood,[102–104] an effect that persists into adulthood.[105] Population-based studies demonstrate that environmental tobacco exposure in childhood also results in an increased risk of asthma.[106,107] These effects of tobacco exposure early in life are thought to be mediated by influences on early immune function, specifically alterations in TLR signaling, which result in an increased susceptibility to microbial infections and a decreased ability to activate regulatory pathways that inhibit allergic responses.[108] The effect of early tobacco exposure on the development of allergic rhinitis and atopy is controversial; however, there is increasing evidence that a strong interaction exists.[109] Gene-environment interactions are important mediators of the effects of in utero exposure on the development of asthma.[110] Polymorphisms of IL-13[111] and β-receptors[102] modify the effect of exposure to tobacco smoke on asthma and wheezing in childhood. Tobacco use is also associated with an increased risk of developing asthma.[112] Polosa and colleagues[113] found that the risk of developing asthma occurs in a dose-response manner in adults with allergic rhinitis. There was an odds ratio of 2.98 (95% confidence interval [CI], 1.81–4.92) of developing asthma in smokers with allergic rhinitis.[113] Environmental smoke exposure in adults results in increased morbidity and poorer asthma control.

Asthma is a complex disease that is the result of the interaction between genetic predisposition, environmental exposures, and responses of the innate and adaptive immune systems. Advances in research have led to the discovery of many possible mechanisms that underlie the development and persistence of asthma. These advances support the conclusion that asthma includes many distinct phenotypes that relate to the underlying pathophysiology and mechanisms of disease. Defining these phenotypes will enhance our ability to tailor therapies and improve outcomes for patients with asthma.

GENETICS OF ASTHMA

Overview

Studies of mono- and dizygotic twins were used initially to estimate the heritability of asthma. These studies showed a higher concordance rate for asthma in monozygotic than in dizygotic twins.[114] Studies showing an increased prevalence of asthma in first-degree relatives[115] lend further support to this hypothesis. Many efforts have been made to study the genetic etiology of asthma in order to better understand its pathogenesis and thereby improve strategies to prevent, diagnose, and treat asthma. Publication of the human genome in 2001 and completion of the International HapMap Project in

2005 produced exponential growth in the field, and over 1 million markers of asthma have been identified. However, asthma is very heterogenous and varies not only in the age of onset, degree of severity, and response to therapy but also in the phenotype, which includes nonspecific AHR, atopy, eosinophilia, and mucus hypersecretion. Moreover, these phenotypes change during life, which further complicates the search to find genetic risk factors for asthma.

Linkage Analysis versus Candidate Gene Approaches

Studies of asthma susceptibility genes have been carried out using two general approaches: linkage analysis and candidate gene association studies. Linkage analysis is a technique used to systematically scan the entire genome of various family members affected by a disease to identify genetic regions associated or "in linkage" with a disease phenotype. Affected family members are hypothesized to share certain alleles located in the identified regions more frequently than would be expected by chance alone. Linkage analysis has been successful in identifying diseases in which the disease penetrance follows simple mendelian genetics but is limited because it has less power than association studies to detect weak genetic effects of loci involved in complex diseases that do not follow mendelian genetics.[116,117] This approach, originally called "reverse genetics," also called positional cloning, does not require a prior hypothesis about which genes cause asthma and has been successful in identifying candidate genes for asthma.[118–121] ADAM 33 was the first gene identified as an asthma susceptibility gene using a positional cloning approach.[120] ADAM 33 belongs to a family of proteins that are membrane-anchored metalloproteases with diverse functions, including the shedding of cell-surface proteins. Increased immunostaining of ADAM33 has been found in the lungs of patients with severe asthma as compared with control subjects or those with mild asthma.[122]

Several studies also have identified linkage between regions of genes and asthma-associated phenotypes, including atopy, AHR, and elevated IgE levels.[123–126] These studies have shown that, although asthma, elevated IgE, and AHR are genetically determined,[127] no single gene controls inheritance of these phenotypes and heritability of the phenotypes is not the same.[128,129]

In contrast to linkage analysis, candidate gene association studies select specific genes based on a biologic theory about their putative role. The gene of interest is chosen because it is believed to influence the expression of a phenotype because of its biologic role or because of its proximity to a region of linkage or association on a specific chromosome. Association studies are thought to be more powerful than linkage studies in detecting alleles that confer modest risk of disease.[116] Furthermore, association studies take advantage of the fact that it is easier to recruit large populations of unrelated individuals than it is to recruit large numbers of family numbers. Furthermore, there is greater statistical power in studying case-control associations than in family-based linkage studies.

To test genes associated with a specific biologic hypothesis, candidate gene studies use case-control or family-based designs. Case-control designs compare allele frequencies between subjects with and without asthma. Case-control designs have been criticized because the recruitment of study populations can create differences in allele frequencies between cases and controls unrelated to disease status and introduce type I error. The family-based design, conversely, avoids issues of population structure and compares the alleles that parents transmit to children with asthma with alleles parents do not transmit. If an allele increases the risk for asthma, it should be more common among the transmitted alleles than the nontransmitted alleles.

More than 100 genes have been associated with asthma phenotypes. However, few reports of associations between asthma and candidate genes have been replicated across studies. In a review of nearly 500 papers on disease association studies, Ober and Hoffjan[130] identified 25 genes that are associated with asthma or atopy in six or more populations and 10 genes that have been associated with asthma or atopy in more than 10 studies (IL-4, IL-13, CD14, adrenergic receptor beta 2 [ADRB2], human leukocyte antigen [HLA]-DRB1, HLA-DQB1, TNF, FCER1B, IL-4Ra, and ADAM 33). These genes in general fall into four broad categories: innate immunity (CD14, HLA-DRB1, HLA-DQB1), Th2 cell signaling (IL-4, IL-13, IL-4Ra), cellular inflammation (TNF, FCEDR1B), and lung development (ADAM 33, ADRB2).

Genome-Wide Association Studies

The completion of the International HapMap Project in 2005 laid the foundation for the next step in investigating genetics in asthma, genome-wide association studies. In genome-wide association studies (GWAS), high-throughput screening of common genetic variations across the genome is used to genotype a single population. This unbiased approach has the potential to identify novel susceptibility genes and pathways not previously identified with asthma. The first GWAS for asthma was published in 2007[131] and revealed an association between a gene on chromosome 17q21 locus and childhood asthma. This finding led to the identification of ORMDL3 as an asthma susceptibility gene. The potential role of this gene in asthma has not yet been defined, and further studies must be performed to determine its effect on susceptibility to asthma. The second GWAS on asthma was reported by Ober and colleagues[132] and showed an association between a promoter variant in the chitinase 3-like 1 gene encoding YKL-40 and asthma, AHR, and decreased lung function. GWAS have also identified the 11p14 locus,[133] 5q23 locus,[134] and chromosome 18[135] as potential regions harboring asthma susceptibility loci that warrant further investigation.

Future Studies

GWAS also have the ability to identify gene-gene interactions and gene-environment interactions. Gene-gene interactions identify whether one gene can modify the effect of another in a biologic pathway. Alone the variant has a modest effect; however, when combined with another genetic variant in the signaling pathway, the variant might amplify the impact on the disease.[97] By analyzing steps in a pathway, discovery of new genes in an unbiased way can occur.

Gene-environment interactions can be used to study the effect that external factors have on influencing phenotypic variance. This approach has shown that the influence of susceptibility genes for common diseases, such as asthma, might not become apparent unless the appropriate exposure to the environmental stimulus occurs. Miller and Ho[136] listed 20 different reports as identifying specific gene-environment interactions with asthma. As an example, linkage of 5q to bronchial hyperresponsiveness was found in asthmatic children exposed to passive smoking, but not in children from non–smoke-exposed families.[137]

The future of GWAS also lies in studying the role of epigenetics in the etiology of asthma and the effect of disease modifiers, such as obesity. Epigenetic modifications are defined as a collection of heritable changes in gene expression that do not directly alter DNA sequences. The most common epigenetic modifications of the human genome are DNA methylation and posttranslational modification of core histone proteins. DNA methylation involves the covalent addition of a methyl group to a cytosine and usually occurs near CpG sites. Methylation of CpG islands can affect gene expression. Posttranslational modification of histones can involve acetylation, methylation, phosphorylation, and ubiquitinylation and can alter transcriptional activity. Both of these epigenetic modifications can be heritable and influence gene expression during growth and development.[138] If environmental exposures such as allergens, antibiotics, air pollution, diet, and tobacco exposure can induce epigenetic regulation in vivo, then epigenetics provides an attractive explanation for environmentally regulated alteration of gene expression. Indeed, evidence from two large prospective clinical studies indicates that prenatal exposure to tobacco smoke is associated with an increased incidence of asthma in young children and adolescents.[139,140] Moreover, data also suggest that exposure to tobacco smoke can increase the risk of asthma across generations.[141] Determining whether genetic or environmentally triggered epigenetic changes occur in the genome will be important in advancing understanding of the pathogenesis of asthma.

The first study to demonstrate genome-wide linkage and association of gene expression traits in tissues other than lymphoblastoid cell lines was published in 2008.[142] Emilsson and associates[142] showed that compared with the 10% correlation found in blood, more than 50% of all gene expression traits in adipose tissue correlated strongly with obesity-related traits. They then used genome-wide linkage and association studies to demonstrate heritability of genetic variations in the two tissues. This approach can be used to determine the effect of disease modifiers on asthma.

GWAS also have the potential to significantly affect medical care in the future by laying the groundwork for personalized medicine. Genetic profiling in subpopulations of asthmatics can be used to determine whether genetic polymorphisms predict response to therapy and adverse effects of therapy. The U.S. Food and Drug Administration (FDA) has approved several genetic tests for cytochrome 2D6 and 2C19 variants as part of its efforts to improve patient safety in the treatment of human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS). Pharmacogenetics is also used in the treatment of childhood leukemia; however, tailored therapies for asthma are still under investigation. To date, the most studied genetic variations in asthma are the β_2-adrenergic receptor polymorphisms. Three loci at amino acid positions 16, 27, and 164 have been found to significantly alter function.[143–145] Genetic association studies and linkage analyses in families have further established the importance of these polymorphisms. Randomized placebo-controlled studies demonstrate that the polymorphism at position 16 may negatively influence response to short acting β_2-agonists.[146] However, the data with regard to the effect of the polymorphism and response to long-acting β-agonists (LABAs) are controversial[147,148] because one small, retrospective study suggested a relationship,[149] whereas two other larger retrospective studies did not.[147,148] Two prospective, genotype-stratified studies are now in progress that should answer this question.

PATHOPHYSIOLOGY OF ASTHMA

Etiology of Asthma

Asthma is a complex inflammatory disease of the airways that involves many different cells (e.g., neutrophils, basophils, eosinophils, mast cells, macrophages, structural cells) and mediators (e.g., cytokines, chemokines, histamine, leukotrienes, reactive oxygen species, and thromboxanes). The concepts about the pathogenesis of asthma have evolved since the mid 1980s, primarily due to new techniques that have linked various asthma phenotypes to genotypic patterns. Based on this work, there is a general consensus that airway inflammation and remodeling are critical components of asthma. Furthermore, environmental exposures throughout life can modulate the expression of asthma susceptibility genes, making asthma a dynamic disease.

Although asthma is multifactorial in origin, inflammation is believed to be the cornerstone of the disease and is thought to result from inappropriate immune responses to a variety of antigens in genetically susceptible individuals. Evidence from patients with asthma and animal models of bronchial hyperreactivity suggests that recruited CD4 lymphocytes orchestrate and implement immune responses and inflammation that contribute to asthma.

Cellular Inflammation and Asthma

CD4 Lymphocytes

Four distinct subsets of CD4 lymphocytes, Th1, Th2, regulatory T cells (T_{Reg}), and T17 cells can differentiate from precursor T cells at the time of antigen presentation and influence cytokine production. The differentiated Th cells are characterized by the specific sets of cytokines they release when stimulated. For many years, it was believed that asthma and other allergic diseases resulted from an imbalance between Th1 and Th2 responses in favor of a Th2 response, promoting an allergic diathesis based on Th2 cell responses. The identification of transcription factors controlling Th1 and Th2 differentiation has provided further support for a predominant role of Th2 cells in the pathogenesis of asthma, because Tbet expression is reduced in the asthmatic lung[150] and GATA 3 is overexpressed.[151,152] However, recent discoveries and an improved understanding of the interaction between Th17 cells and regulatory T cells have shown that the simple Th1/Th2 hypothesis is not sufficient to explain asthma.

Th1 cells drive cell-mediated immune responses and are characterized by the production of IFN-γ, TNF-α, and IL-2 without production of IL-4, IL-5, IL-9, and IL-13. By contrast, Th2 cells mediate humoral responses and are characterized by their secretion of IL-4, IL-5, IL-9, and IL-13 in the absence of IFN-γ and TNF-α. Antigen recognition by naive T cells in the presence of IL-12 favors STAT4 and Tbet activation which promote Th1 cell differentiation. Early IL-4 production favors STAT6 and GATA3 activation, which lead to Th2 cell production. Th17 cells, a newly discovered subset, produce IL-17 and IL-22.[153] These T cells are proinflammatory and have been studied primarily in mice. They express a characteristic transcription factor, retinoic acid orphan nuclear receptor (ROR-γ).[154] In a murine model of allergic asthma, IL-17 was found to be necessary for the induction of allergic asthma. In healthy human subjects with asthma, IL-17 production increases in peripheral blood after allergen challenge. In addition to its proinflammatory role in asthma, Th17 cells also have been detected in other inflammatory autoimmune diseases such as Crohn's disease, rheumatoid arthritis, and multiple sclerosis and have been shown to be important in host defense against bacterial pathogens.[155]

In contrast to Th1, Th2, and Th17 cells, T_{Reg} cells act directly or indirectly to suppress the function of effector T cell responses in allergic asthma. These cells have cytokine profiles that are distinct from Th1 and Th2 cells and appear to control development of autoimmune disease[156] and are able to inhibit development of allergic Th2 responses. Several subsets of T_{Reg} cells have been identified, including natural $CD4^+CD25^+T_{Reg}$ cells, Th3 cells, and inducible type 1 T_{Reg} (TR1) cells.[157] A deficiency in $CD4^+CD25^+T_{Reg}$ cells can result in the development of asthma.[158] These cells originate in the thymus, require expression of the transcription factor FoxP3 for the development of the suppressive function, and do not produce cytokines. Th3 cells produce mainly transforming growth factor-β (TGF-β) and their regulatory function is due to a TGF-β–dependent mechanism. TR1 cells are inducible and secrete high levels of IL-10, IFN-γ, and TGF-β but no IL-4 or IL-2.[159] These cells do not overexpress FoxP3 and appear to be regulated through different pathways.

Epidemiologic studies demonstrate a higher prevalence of asthma in industrialized Western societies than in less technologically advanced societies.[7] These observations are the essence of the "hygiene hypothesis."[160] The hygiene hypothesis proposes that increased hygiene and lack of exposure to environmental antigens, such as animal allergens, may be affecting the immune system by changing the relative balance of the Th1 and Th2 immunologic profile. Early exposures to various triggers that might occur at an increased frequency in a rural setting can tilt the balance to a Th1 dominant response that is protective against the allergic diathesis promoted by Th2 responses. Therefore, in more urban "cleaner" societies where early childhood exposures are less pronounced, a shift toward a Th2 immunologic profile occurs, resulting in a higher incidence of asthma and other allergic diseases.

Eosinophils

Eosinophils are prominent cells in the airways of many patients with asthma. Most asthma phenotypes are associated with increased numbers of eosinophils in blood, bone marrow, and lung, leading to the hypothesis that the eosinophil is a central effector cell in asthma that contributes to ongoing airway inflammation. The secretion of eosinophil peroxidase, leukotrienes, reactive oxygen species/reactive nitrogen species (ROS/RNS) by eosinophils can result in epithelial damage, bronchoconstriction, and mucus hypersecretion. Eosinophils also present antigens and secrete cytokines which can further amplify the Th2 response.[161] Indeed, the number of eosinophils in bronchoalveolar lavage (BAL) and blood correlates with severity of disease in humans with asthma. However, whether the eosinophil is causal in the pathogenesis of asthma or an innocent bystander is still debated. Studies in mice blocking IL-5 either by targeted gene deletion or using anti-IL-5 monoclonal antibodies have produced conflicting results.[162,163] Further studies in humans confirm that pharmacologic inhibition of IL-5 can result in eosinophil depletion, but this does not provide significant improvement in airway function or disease symptoms in asthma.[164] Two published studies[165,166] supported the concept that eosinophils are critical in allergic asthma in mice. In one study, Humbles and coworkers[165] deleted the high-affinity GATA-1 binding site on the GATA-1 promoter, the transcription factor required for differentiation of immature myeloid cells, and found that despite eosinophil depletion, there was no effect on AHR and mucus production. In an entirely different approach, Lee and colleagues[166] used an eosinophil peroxidase promoter to control transgenic expression of diphtheria toxin A chain, to destroy eosinophils, and found that eosinophils were essential for AHR and mucus production. The divergent findings in these two studies are difficult to explain and have been

attributed to background strain variability, controversy about the IL-5 antibody used in the studies, and indirect effects of diphtheria toxin A.[167]

Inflammatory Cytokines and Asthma

Atopic asthmatics have increased expression of Th2 cytokines in airway biopsies and BAL compared with healthy volunteers.[168] Th2 cells regulate allergic inflammation via production of IL-3, IL-4, IL-5, IL-9, IL-10, and IL-13. IL-5 has an essential role in regulating eosinophilic inflammation in asthma and subsequent AHR.[169] IL-9 appears to augment Th2-driven inflammation and be involved in mast cell release, IgE production, and mucus hypersecretion.[170] IL-10 is an anti-inflammatory cytokine and acts to inhibit inflammatory cytokine expression, chemokines, IL-5[171] and granulocyte-macrophage colony-stimulating factor (GM-CSF) production[172] in asthma.

Although all Th2 cytokines contribute to the pathogenesis of asthma, IL-4 and IL-13 are particularly relevant. IL-4 is critical for the synthesis of IgE and is involved in eosinophil recruitment to the airways.[173] Because IL-4 also acts to promote Th2 cell differentiation, it acts at a critical proximal site in the allergic response and is an attractive target for inhibition. This concept is supported by studies in IL-4–deficient mice, which show that IL-4 is essential for the development of allergic symptoms, because allergen-challenged IL-4–deficient mice do not develop an asthma phenotype.[174]

IL-13 has a similar structure to IL-4 and shares a functional receptor, IL-4Rα. A substantial body of evidence supports IL-13 as necessary and sufficient to induce allergic asthma.[175,176] Acute administration of IL-13 to mice recapitulates many of the features of allergic asthma, including AHR, eosinophilia, mucus hypersecretion,[175,176] and subepithelial fibrosis.[177] Genetic evidence in humans further supports a role for IL-13 dysregulation in allergic asthma. Polymorphisms in the promoter region and coding regions of the gene are associated with increased risk of developing asthma.[178,179]

Biochemical Mediators of Asthma

Reactive Oxygen Species

Asthma is characterized by altered airway redox chemistry and increased oxidative stress in the airways.[180] Lung inflammatory cells, including eosinophils, macrophages, and neutrophils, are increased in the asthmatic airway and able to release large quantifies of ROS and RNS.[181] Furthermore, eosinophils, macrophages, and neutrophils isolated from asthmatics produce increased concentrations of ROS compared with normal subjects.[182] Myeloperoxidase and eosinophil peroxidase produced by these granulocytes are increased in BAL and peripheral blood in asthmatics and can produce large amounts of the potent ROS, hydroxyl radical,[182] resulting in epithelial damage and increased AHR in asthmatic individuals. The observation that lung eosinophils in BAL and blood correlate with AHR in asthma provides further support for a proinflammatory role of ROS in asthma. Concurrent with the increased oxidants in asthma, the antioxidant activity in the lower airways is reduced, providing further indirect support for the importance of oxidants in asthma.[183]

Reactive Nitrogen Species

In addition to increased ROS, RNS also may be important in the pathogenesis of asthma. It is well-established that the exhaled breath of asthmatics contains higher concentrations of nitric oxide (NO) than the exhaled breath of normal individuals.[184] NO is produced by nitric oxide synthase (NOS). The three known isoforms of NOS are members of a family of different but related NOS proteins: neuronal NOS (NOS1), immunologic NOS (NOS2), and endothelial NOS (NOS3). NOS1 and NOS3 are constitutively expressed, although they can be regulated.[185] NOS2 was originally described in macrophages and is inducible. All NOS isoforms are expressed in the lung.[186] Whereas NOS1 is found primarily in the neuronal plexus; NOS3 is ubiquitous and expressed in respiratory epithelium, vascular endothelium, and neurons.[187] In contrast, the expression of NOS2 is inducible in respiratory epithelium and macrophages.[187] NO can react with oxygen or ROS to form oxidation products, NO_2^-, NO_3^-, and peroxynitrite,[188] which can induce tissue damage. The concentrations of NO are increased in the exhaled breath of asthmatics, and measurements of expired NO can be used to monitor disease[189] and titrate inhaled corticosteroid therapy.[190] Exhaled NO is a summation of airway NO formation, superoxide anion metabolism, changes in airway pH, and metabolism of S-nitrosoglutathione (GSNO), an endogenous bronchodilator present in the lung. GSNO is deficient in the airways of children with acute asthmatic respiratory failure. Mice deficient in GSNO-reductase (GSNOR), an enzyme that metabolizes GSNO, develop allergic airway inflammation, but do not develop AHR,[191] which suggests that *S*-nitrosothiols may play a critical role in reducing bronchoconstriction in allergic asthma.

Arginase

Recent evidence indicates that arginine metabolism may also contribute to the development of AHR in allergic asthma. Increased arginase activity in allergic asthma was first described in a guinea pig model whereby administration of an arginase inhibitor, *N*-hydroxy-nor-L-arginine (NOHA), reduced AHR and restored NO production.[192] Arginase expression is also increased in BAL cells, inflammatory cells, and airway epithelium obtained from bronchial biopsies of asthmatic subjects.[193] Furthermore, genetic polymorphisms in arginase have been identified, supporting a role for arginase in asthma and atopy in children.[194]

Arachidonic Acid Metabolism

Products of arachidonic acid metabolism are also increased in the exhaled breath of patients with asthma.[195] Cysteinyl leukotrienes and other products of the 5-

lipoxygenase pathway are potent inflammatory mediators implicated in the pathogenesis of asthma. Elevated concentrations of cysteinyl leukotrienes are produced in the airway of asthmatics[196] and have been recovered from the urine of patients with allergen-induced asthma,[197] exercise-induced asthma,[198] and aspirin-induced asthma.[199] Leukotrienes act by binding to receptors on the surface of structural and inflammatory cells. These receptors activate G protein–coupled receptors in the cytoplasm and increase intracellular calcium, resulting in bronchoconstriction and mucus secretion.[200] Inhibitors of the 5-lipoxygenase pathway and cysteinyl leukotriene receptor 1 are used to treat asthmatics who remain symptomatic despite using inhaled corticosteroids.

AIRWAY REMODELING IN ASTHMA

Introduction

Airway remodeling is one of the cardinal pathologic features of chronic asthma and is defined as structural alteration of the airway with characteristic changes in the nature, content, and distribution of airway elements.[201] The degree of remodeling is a function of disease severity over time, because the degree of structural changes on biopsy and imaging studies correlates with the clinical severity of asthma.[202–204] The major pathologic changes include increased deposition of subepithelial collagen, airway smooth muscle (ASM) hyperplasia, proliferation and hyperplasia of goblet cells and submucosal glands, and microvascular changes.[205] These structural changes result in thickening of airway walls and decreased diameter of the airway lumen, which have been observed in pathologic and radiographic studies.[206,207] Ultimately, remodeling contributes to the characteristic physiologic changes of asthma discussed previously, including airflow limitation, AHR, and mucus hypersecretion.

The primary hypothesis about the pathogenesis of airway remodeling is that remodeling is caused by exaggerated airway inflammation in response to environmental stimuli. The experimental support for this hypothesis includes animal data linking allergen-driven Th2 inflammatory responses with extensive airway remodeling in mice.[208,209] For example, overexpression of the Th2 cytokine IL-13 in transgenic mice leads to the characteristic changes of airway remodeling, including increased subepithelial collagen deposition, epithelial hyperplasia, enhanced mucus production, and microvascular changes.[210] Similarly, in an ovalbumin challenge model of allergic asthma, inhibition of leukotriene formation substantially reduced airway remodeling and reduced the expression of Th2 cytokines.[211] Nevertheless, the limited efficacy of anti-inflammatory treatment in preventing remodeling suggests that remodeling may not be entirely due to inflammation. Some evidence suggests that remodeling may occur independently of the recruitment of inflammatory cells.[212] Native airway constituents, including epithelial cells, fibroblasts, and ASM cells, have been shown to produce mediators associated with remodeling in vitro and, to a lesser extent, in vivo.[213,214] The precise relationship between remodeling and inflammation is unclear.

Epithelium

Normal airway epithelium contains ciliated columnar, mucus-secreting goblet, and surfactant-secreting Clara cells that form a highly regulated and impermeable barrier made possible by tight junctions located on the apical surface of the columnar cells.[215,216] The airway epithelium is altered in the airways of mild and severe asthmatics, because epithelial changes have been identified in biopsies of airways of adults and children.[217] Although initial pathologic studies in asthma attributed epithelial abnormalities to bronchoscopy-related injury,[218,219] recent studies have revealed that the airway epithelium is abnormal both in vitro and in vivo. The finding that damaged asthmatic epithelium is associated with up-regulated epidermal growth factor receptors and impaired proliferation suggests a pattern of chronic injury and aberrant repair.[220] This is hypothesized to lead to increased epithelial permeability due to dysfunction of the airway tight junctions[221] and may in part be responsible for the increased susceptibility of asthmatic epithelium to oxidant injury.[222]

A great deal of evidence suggests that the airway epithelium is a central participant in innate and adaptive immune responses.[223] Disruption of the tight junctions allows easy entry of microparticles, allergens, and microbes into the subepithelial space with resultant activation of inflammatory cells, leading to the production of cytokines and chemokines and propagation of inflammation.[215,224] Subsequent production of growth factors is thought to lead to subepithelial fibrosis and airway remodeling. Holgate[225] proposed the concept of the epithelial mesenchymal trophic unit (EMTU) (Fig. 38-3), which is analogous to the "soil" that allows the "seed" of Th2 inflammation to persist. The activated EMTU is hypothesized to propagate Th2 inflammation through interactions with resident airway immune cells via proinflammatory mediators derived from the activated structural cells of the EMTU.[226] The cytokines produced by immune cells are proposed to feed back to the EMTU, contributing to a cycle of persistent chronic inflammation, with propagation of myofibroblasts, proliferation of smooth muscle, and alterations in microvasculature.

Epithelial Basal Lamina

A characteristic feature of asthma in adults and children is the hyalinization and thickening of the basal lamina beneath a normal-appearing epithelial basement membrane.[216] Accompanying this unique change in airway structure is an increased number of myofibroblasts capable of laying down matrix,[227] including increased amounts of type III and V collagens, fibronectin, and tenascin.[228,229] Asthma is not associated with basement membrane thickening but rather subepithelial fibrosis

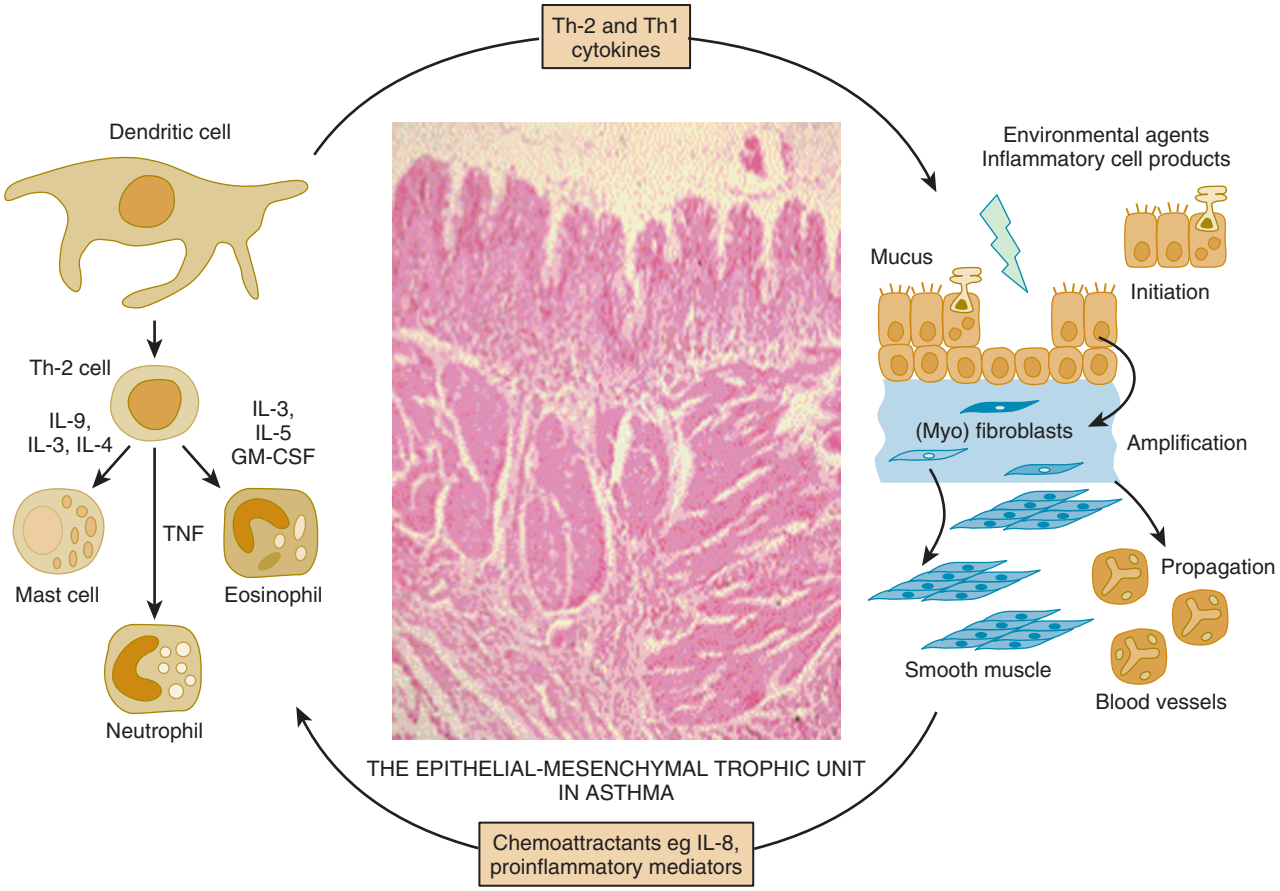

FIGURE 38-3 ■ Schematic representation of the interaction between immune, inflammatory, and structural cells through the epithelial-mesenchymal trophic unit (EMTU) in the pathogenesis of asthma. (Adapted from Holgate ST: The airway epithelium is central to the pathogenesis of asthma. Allergol Int 57:1–10, 2008.)

with deposition of collagen beneath the basement membrane.[230] These changes have been reported in early asthma close to the beginning of the disease, suggesting that the changes in matrix deposition are not the result of chronic inflammation.[216,225,231,232] Both the Tucson Children's Respiratory Study and the Childhood Asthma Management Program demonstrated that reduced lung function can occur early in life and is unabated by conventional therapies.[233,234] The mechanisms involved in remodeling of the basal lamina are unknown. However, murine models of asthma have suggested roles for platelet-derived growth factor (PDGF), TGF-β, and IL-13.[235] TGF-β promotes the differentiation of fibroblasts into myofibroblasts, which form collagen and secrete growth factors.[236] In humans, PDGF has been implicated in airway remodeling by inducing airway fibroblasts to produce collagen and increase matrix formation. The PDGF-BB isoform enhances fibroblast procollagen I formation in subjects with severe asthma as compared to those with mild to moderate asthma.[237,238] Additionally, PDGF and TGF-β have been shown to modulate expression of matrix metalloproteinases and regulation of migratory function of human airway smooth muscle cells.[238a] Further research is required to determine the mechanisms of airway fibrosis and to guide more specific therapy in asthma.

Extracellular Matrix

Extracellular matrix (ECM) is increased in the airway walls of humans with asthma and is seen in experimental models. In ovalbumin challenge models, airway wall collagen, fibronectin, and proteoglycan deposition are increased.[239,240] Loss of elastic fiber content in the small airway adventitial layer has been demonstrated in studies of severe and fatal asthma.[241–243] Airway elastin, the matrix component whose degradation is central to emphysema, is also decreased in biopsy specimens from asthmatic patients.[244–246] These changes appear to be mediated, at least in part, by exposure to Th2 cytokines. For example, IL-5 exposure increases allergen-induced collagen deposition, whereas allergen-challenged IL-5 knockout mice have decreased collagen deposition.[247,248] Mice with a knockout of Tbet, a Th1-specific transcription factor, have profound defects in the production of Th1 cytokines and increased production of Th2 cytokines. As a result, the mice develop a remodeled asthmatic phenotype, with high levels of Th2 cytokines and increased subepithelial collagen deposition. The central role of IL-13 is illustrated by the amelioration of airway remodeling that occurs when IL-13 is neutralized.[249]

TGF-β, derived from eosinophils, macrophages, and other cells, is also strongly implicated in ECM remodeling. Mice treated with anti-TGF-β antibody have decreased ECM deposition,[250] whereas treatment of asthmatics with anti-IL-5 antibody decreases ECM deposition and reduces BAL concentrations of TGF-β.[251] In addition, the gene for TGF-β is up-regulated in allergen-challenged mice[252] and Tbet/IFN-γ–deficient mice have elevated levels of TGF-β.[249]

Changes in the ECM appear to correspond with physiologic changes seen in asthma.[253] Increased submucosal matrix protein deposition, in addition to contributing to luminal narrowing, changes the mechanical properties of the airway wall. Stiffening of the airway wall reduces forces exerted on lung parenchyma, leading to reduced distensibility. There are also data to suggest loss of elastic recoil in asthma, and early data suggest that loss of elastin may play a role.[241,246,254]

Airway Smooth Muscle

Airway smooth muscle (ASM) mass is increased in humans with asthma and experimental animal models. The increased smooth muscle mass in airway walls contributes to airway luminal narrowing by occupying space and increasing the extent of narrowing for each degree of smooth muscle contraction.[255,256] In animal models, increased ASM mass accounts for a significant percentage of AHR[257] and correlates with methacholine sensitivity.[258] In pathologic studies, increased ASM mass in large airways is linked with both severe and fatal asthma.[259,260]

In addition to the effects of increased smooth muscle mass on airway physiology, ASM cells have been shown to play a central role in the molecular events that initiate and propagate airway remodeling. The relationship of smooth muscle to the ECM is complex, with smooth muscle cells elaborating matrix proteins, as well as matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs), possibly via signaling between the ECM and cell surface receptors.[261] Proof of this relationship comes from the ability of ASM cells to secrete ECM proteins in response to asthmatic sera, suggesting autocrine regulation of airway remodeling.[262] Furthermore, ASM obtained from asthmatic airways secretes more ECM protein than nonasthmatic ASM and ECM from asthmatics induces a greater degree of cell proliferation.[262]

The relative contributions of smooth muscle hypertrophy versus hyperplasia in increasing smooth muscle mass is not clear. Data from a Norway rat ovalbumin-challenge model shows that increases in ASM mass are associated with increased DNA synthesis, suggesting smooth muscle hyperplasia.[263] More recent human biopsy data demonstrate that muscle mass increases along with the number of nuclei, providing additional support for the role of hyperplasia in smooth muscle remodeling.[264] However, a second ovalbumin-challenge model showed increased muscle mass without a concomitant increase in the number of smooth muscle cell nuclei.[265] Furthermore, human biopsy studies support hypertrophy as the cause of increased smooth muscle mass in asthma, with greater smooth muscle cellular diameter associated with more severe asthma.[259] Taken together, it seems likely that both hypertrophy and hyperplasia contribute to the increased smooth muscle mass characteristically seen in remodeled airways of patients with asthma.

Asthmatic ASM may be phenotypically different from ASM in nonasthmatic airways, with altered proliferative or contractile capacities. Smooth muscle cells exhibit phenotypic plasticity in vitro, with the ability to switch between a hyperproliferative and a hyperfunctional phenotype, depending on culture conditions. This phenomenon could theoretically explain the variable presence of both ASM hyperplasia and hypertrophy in asthma. To date, gene expression studies addressing this possibility are intriguing but inconclusive.[266]

In addition to alterations in quantity and function, asthmatic ASM appears to have an altered anatomic relationship with inflammatory cells. Data demonstrate that smooth airway infiltration by mast cells is an important feature of asthmatic airway remodeling.[267] Notably, this colocalization of mast cells and ASM is present in a cross section of asthma phenotypes and degrees of severity.[268] Several mast cell products have the potential to adversely affect the growth and function of smooth muscle, and their localization in the smooth muscle may facilitate this interaction. For example, the mast cell–derived mediators histamine, prostaglandin D_2, and the cysteinyl leukotrienes are potent constrictors of airway smooth muscle.[269] Human ASM promotes human lung mast cell (HLMC) survival in vitro, induces rapid HLMC proliferation, and enhances constitutive HLMC degranulation, suggesting a smooth muscle–driven allergen-independent mechanism of chronic mast cell activation.[270]

Goblet Cell Hyperplasia and Mucus Hypersecretion

Goblet cell hyperplasia is a hallmark of the pathology of asthma in mild, moderate, and severe disease. Mucin is secreted by goblet cells in the airway epithelium and mucus glands in the submucosal space. Airway mucus is a viscoelastic gel composed of cells, secreted polypeptides, and cellular debris, which forms a thin film lining the airway surface.[271] Under normal circumstances, airway mucus serves a protective function, trapping foreign debris, bacteria, and viruses, then working in concert with the ciliated epithelium to clear captured material. In asthma, excessive production of mucus contributes to airway obstruction. Secreted mucin levels in induced sputum are higher in patients with lower forced expiratory volume in 1 second (FEV_1) values, indicating that mucus hypersecretion plays an important role in airway obstruction in asthma.[272] Accumulation of intraluminal mucus plays a significant role in fatal or near-fatal asthma, and widespread occlusion of airways by mucus is a common finding in autopsy studies of fatal asthma.[273,274] Mucin is the major protein component of these plugs, which is a high-molecular-weight glycoprotein produced by goblet cells in the epithelium and glands in the submucosa.[275,276] Secreted and oligimerized

mucins have an important role in determining the properties of the extracellular mucus layer.

In patients with asthma, the number of mucus-secreting goblet and submucosal cells in the airway is increased compared with that in normal individuals.[277] Although 19 human mucin genes (MUC) have been described, the major secreted mucus proteins include the gene products MUC5AC and MUC5B. MUC5AC is the predominant gel-forming mucin and is disproportionately increased in asthma.[278] In addition to quantitative differences in mucus gene products in asthma, asthmatic mucus may be functionally different. The increased viscosity seen in asthmatic mucus may be accounted for by variations in oligimerization and by incomplete release of mucins from goblet cells.[279] The latter may lead to "tethering" of luminal mucins to the airway epithelium and increased adherence of mucus to airway walls.[280]

The increase in mucus production seen in asthma may be attributed to increased mucin production, increased exocytosis of previously formed mucus from airway cells, or both. The migration of mucus from preformed granules to the apical surface of epithelial cells is dependent on the presence of myristolated alanine-rich C kinase substrate (MARCKS protein), and activation of the MARCKS protein requires phosphorylation by protein kinase C.[281] The strength of this relationship is bolstered by the observation that protein kinase C is up-regulated together with mucin production after stimulation of airway epithelial cells with neutrophil elastase.[282] Binding of mycoplasma to TLR and subsequent expression of Th2 cytokines has also been shown to lead to increased mucus production in a murine model of asthma, possibly mediated by a nuclear factor-κB (NF-κB) binding site on the MUC5AC promoter.[283] However, TLR2 knockout mice have increased mucus production, possibly due to decreased levels of IFN-γ and subsequently increased TGF-β levels.[284]

Microvascular Changes

Bronchial neovascularization is a recognized feature of airway remodeling, with dilated and tortuous mucosal blood vessels present even in mild asthma.[285] Functionally, the airway microvasculature is more permeable, with leakage of plasma proteins into the extravascular space associated with mucosal edema.[286] Mucosal edema results in airway narrowing, which may have a pronounced effect on airway function.[286]

Vascular endothelial growth factor (VEGF) appears to be a key mediator of the pathogenesis of airway vascular abnormalities in asthma. VEGF levels are increased in the asthmatic airway,[287] with levels of VEGF staining corresponding to increasing bronchial vascularity.[288] A number of different stimuli for VEGF expression are present in asthma. Th2 cytokine exposure prompts the release of VEGF from ASM cells,[289,290] as does increased mechanical strain as seen in symptomatic airway obstruction.[291] Transgenic induction of VEGF in murine airway epithelial cells leads to increased pulmonary angiogenesis and increased expression of Th2 cytokines, suggesting the presence of a feedback loop increasing vascular remodeling.[292]

Physiologic Manifestations of Asthma

Airway Hyperresponsiveness

AHR is a characteristic feature of asthma. Hyperresponsiveness can occur in response to a number of nonspecific environmental irritants, pharmacologic agonists, and inflammatory mediators. In the past, the predominant view was that airway inflammation was the mechanism causing AHR. This concept has been criticized, because a number of studies have shown dissociation between AHR and inflammation,[191,293] highlighting the fact that inflammation alone is insufficient as a mechanism of disease. Evidence suggests that a number of inflammatory Th2 cytokines, CD4 cells, and biochemical mediators contribute to the development of AHR in asthma. Exposure to Th2 cytokines in asthmatic airways can increase the isometric constrictor response of ASM by increasing calcium release from intracellular stores.[294,295] In addition to the airway inflammation, factors contributing to mechanical airway obstruction have also been implicated in the pathogenesis of AHR, including epithelial permeability, smooth muscle hypertrophy, mucus hypersecretion, and airway remodeling.

Epithelial Permeability

The airway epithelium is the source of many of the cytokines and inflammatory mediators contributing to airway inflammation and increased AHR in asthma. The airway epithelium serves several different functions within the lung. The airway epithelium is in a unique position, because it is exposed to the environment and is the primary target of viruses and inhaled agents known to cause or exacerbate asthma. In addition to barrier protection and mucociliary clearance of unwanted pathogens, the epithelium can regulate the response of other lung cells involved in the inflammatory and fibrotic response of the lung to external stimuli.

In asthma, there is evidence that airway epithelial barrier function is impaired and epithelial tight junctions are disrupted. These cells show reduced transepithelial resistance indicating epithelial permeability, which is associated with AHR. Confocal microscopy with antibodies directed at adapter proteins (ZO-1) and tight junction proteins (occludin) support the concept that tight junctions are poorly developed in asthmatic epithelium. In addition to disruption of the tight junctions, epithelial desquamation has been described as a pathologic feature in patients with asthma who die from acute respiratory failure.[296] Furthermore, markers of apoptosis indicating programmed cell death have also been noted in airway tissue of subjects with asthma and correlate with disease severity and chronicity.[222]

Smooth Muscle Hypercontractility

Hypercontractility of ASM is believed to be a key determinant of the development of AHR in asthma. It is still unclear whether contractile force is enhanced in the asthmatic airway, where inflammatory mediators accu-

mulate, or whether smooth muscle is abnormal in asthma. Numerous reports have identified increased ASM mass in fatal and nonfatal asthma. The cellular mechanism of increased ASM mass in asthma represents a balance between smooth muscle hypertrophy and proliferation.[297] Benayoun and associates[259] found that patients with mild asthma had larger smooth muscle cell diameter in their airways than control subjects. The increase in ASM mass correlated with asthma severity, suggesting a causal role for smooth muscle hypertrophy in the development of AHR. Conversely, Woodruff and colleagues[264] found that hyperplasia of smooth muscle occurs in mild to moderate asthma without changes in cell size or gene expression.

Excessive shortening of ASM also can result in excessive narrowing of the airways, and several different mechanisms have been proposed. One proposal suggests that exposure to chronic inflammatory mediators in the local asthmatic environment results in chronic shortening of ASM, so that further shortening occurs during activation.[298] A second proposal suggests that the ECM surrounding ASM alters the ASM phenotype by increasing ASM mass and decreasing its secretory properties.[299] A third scenario suggests that abnormal relaxation of ASM occurs in asthma, which can contribute to increased bronchospasm,[300] whereas a fourth scenario suggests that there is a change in the interdependence between the airway wall and the surrounding lung.[300,300a]

Effects of Treatment on Remodeling

Because of the importance of airway remodeling in the pathogenesis of asthma, efforts have been devoted to reversing airway remodeling. One hypothesis is that treatment of the inflammatory component of asthma may lessen airway remodeling. In a murine model of asthma, administration of corticosteroids in combination with allergen avoidance reduced airway fibrosis and smooth muscle mass.[301] In another study comparing a leukotriene antagonist and a corticosteroid in an allergy-driven mouse model of asthma, the leukotriene inhibitor decreased ASM mass and subepithelial collagen deposition, whereas corticosteroids had no effect on remodeling.[302]

An alternative approach is to mechanically reduce smooth muscle mass in order to improve physiologic function. The application of controlled thermal energy via a radiofrequency catheter in order to reduce smooth muscle mass has been shown to reduce methacholine responsiveness in dogs.[303] Early clinical trials in human subjects have shown beneficial effects on asthma symptoms via reduction in smooth muscle mass, with results that were sustained for 1 year.[304]

With an increased understanding of the molecular mechanisms of asthma pathophysiology and airway remodeling, more focused therapeutic strategies can be explored.[304a] In vitro studies of compounds targeting putative mediators involved in remodeling suggest a promising role for novel agents in the treatment of asthma.[253,305,306] Recent studies highlighting novel genes associated with airway remodeling and asthmatic symptoms suggest new therapeutic avenues targeting the underlying pathogenesis of airway remodeling in asthma.[130]

PHYSIOLOGY

Introduction

As understanding of the pathogenesis of asthma improves and strategies for treatment evolve, it is important to recognize that the link between the pathophysiology and the treatment of asthma is functional, involving variable limitation of air flow. These two cardinal manifestations of asthma, variability of symptoms in response to environmental factors and limitation of air flow, are crucial to making the diagnosis of asthma and distinguishing asthma from other obstructive lung diseases.

Physiology of Airflow Limitation

During asthma exacerbations, diffuse narrowing of the airways results in profound physiologic consequences. This narrowing has been thought to occur disproportionately in the small bronchi,[307] although recent studies suggest a prominent role for large and medium airways.[308] As a result, lung function tests are abnormal, with an increase in airway resistance and a decline in maximal expiratory flow. Airway narrowing also prevents the lungs from completely emptying ("air trapping") due to resistance to expiratory flow and to bronchial closure at higher than normal lung volumes. The breath-to-breath variability of asthmatic obstruction and air trapping led to the concept of dynamic hyperinflation.[309] As a result of dynamic hyperinflation, asthmatics breathe at higher total lung volumes, detectable as increased residual volume.[310] Despite elevated total lung volumes, asthmatics typically have reduced tidal ventilation. Decreasing forced vital capacity (FVC) suggests worsening air trapping, whereas worsening of the FEV_1/FVC ratio indicates increasing airway narrowing.[311]

At high lung volumes, flow limitation due to bronchial narrowing is offset by increased circumferential traction on the bronchial airways due to "tethering" of airways to inflated alveoli.[312] This response may be less effective in asthma, because the altered mechanical properties of the ECM in asthmatic airways reduce the mechanical forces opposing ASM contraction.[313] The net effect is that the work of breathing increases significantly, due in part to decreased lung and chest wall compliance at higher thoracic volumes and in part to the greater effort required to overcome the resistance of narrowed airways. The diaphragm and intercostal muscles are overloaded due to thoracic hyperinflation and mechanically disadvantaged due to suboptimal positioning on their length-tension curves.[314] As a result, accessory muscles of respiration, including the abdominal muscles and sternocleidomastoids, are required.[315] A large proportion of the subjective dyspnea associated with asthma exacerbations has been attributed to respiratory muscle fatigue.[316]

The airway obstruction and closure in asthma is nonuniform, with significant regional variability that may not be completely reflected by decreases in peak flow.[317,318] Although pulmonary blood flow is reduced in areas of alveolar hypoventilation, the magnitude of this response in insufficient to offset more than moderate or severe airflow obstruction. Ventilation-perfusion mismatching leads to a widened alveolar-arterial oxygen difference that tracks with increasing asthma severity; the arterial oxygen tension in acute severe asthma typically falls below 70 mm Hg.[319,320] Arterial carbon dioxide tension initially falls as alveolar ventilation increases, because CO_2 elimination is less impaired than O_2 uptake by ventilation-perfusion mismatching.[321] As respiratory muscles fatigue, carbon dioxide tension increases, so that a normal or elevated P_{CO_2} during an asthma exacerbation suggests impending respiratory failure.[322] Worsening of airflow obstruction or any factor that decreases respiratory drive (such as sedation) can drop alveolar ventilation precipitously; the resultant rise in P_{CO_2} further inhibits respiratory drive and muscle performance and hastens respiratory failure.[323]

Pulmonary Function Testing

Even between asthma exacerbations, pulmonary function testing shows characteristic changes reflecting the reduced flow and air trapping of dynamic hyperinflation. Decreased expiratory flow can be easily and reproducibly detected with a peak flowmeter in ambulatory patients, and peak expiratory flow (PEF) measurement is an accepted method to correlate physiologic function with the clinical severity of asthma. However, peak flow measurements are not standardized and cannot be correlated with other measures of lung function.[324] PEF as a percentage of the predicted value is 10% higher than FEV_1 on average, with a great deal of variability between measurements.[325] PEF measurements tend to underestimate less severe obstruction and overestimate more severe obstruction.[326] Currently, the recommended use of PEF measurement is for the daily monitoring of ambulatory patients. In this situation, the values should be compared with an individual patient's baseline measurement obtained when asymptomatic and well-controlled.[327,328] Evaluation of peak flow measurements obtained during a trial of long- versus short-acting β-agonists suggests that individual peak flow is highly variable and that the variability in PEF has a greater predictive value for asthma exacerbations than the absolute PEF measurement.[329,330]

Spirometry

The best and most standardized test of airflow obstruction is the FEV_1. The FEV_1 has the advantage of being an objective, non–patient-reported measurement of lung function. Improvement in FEV_1 of more than 12% and 200 mL after bronchodilator treatment indicates reversible airflow obstruction and is suggestive, but not diagnostic, of asthma.[331] Prebronchodilator FEV_1 is a strong predictor of decline in asthma control whereas postbronchodilator FEV_1 is a marker of future risk.[332,333] However, accurate measurement requires stopping LABAs for at least 12 hours and short-acting bronchodilators for at least 6 hours. Furthermore, because the FEV_1 may be normal or near-normal between asthma flares, it is a poor marker of response to bronchodilators in mild asthma. The absolute value of the FEV_1 is dependent on FVC and also reflects the small airways. Interpretation of FEV_1 therefore requires simultaneous FVC measurement. In asthma, the relative reduction in FEV_1 is typically greater than the reduction in the FVC. As a result, the FEV_1/FVC ratio in asthma is usually less than 70%. A characteristic flow-volume loop is created with scooping of the expiratory loop consistent with airflow limitation (Fig. 38-4). However, in severe asthma, this ratio may actually increase as profound air trapping increases residual volume and reduces the FVC. This reversible restriction due to air trapping has been reported in asthma.[311,334]

The performance of the forced expiratory maneuver requires inhalation to total lung capacity prior to exhalation. In normal patients, the resultant stretch of intrapulmonary airways causes reflex bronchodilation and a shift

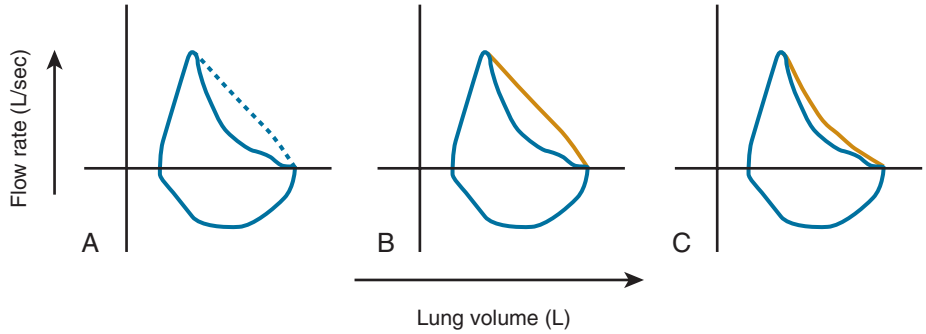

FIGURE 38-4 ■ Flow-volume loops in asthma. **A,** The typical scooped appearance of the flow-volume loop in asthma is shown as the *solid blue line*. The predicted normal flow-volume loop is shown by the *dashed line*. **B,** The scooped appearance of the initial flow-volume loop (*blue line*) may show complete reversal following use of a bronchodilator (*brown line*). **C,** In some cases, the reversal of the scooped appearance following use of a bronchodilator is incomplete (*brown line*). in the pressure-volume curve. This alteration in lung mechanics is generally attributed to a transient decrease in ASM tone.[335] However, some asthmatics have the opposite response, developing bronchoconstriction during deep inspiration. The mechanism of this "spirometry-induced bronchoconstriction" is unknown, but some evidence suggests that it may be partly due to increased inflammation and remodeling of asthmatic airways.[336]

An alternative method for assessing airflow obstruction is to evaluate midexpiratory flow, measured between 25% and 75% of the FVC ($FEF_{25\%-75\%}$). Obtained at lower lung volumes, reductions in the $FEF_{25\%-75\%}$ may be more sensitive for identifying obstruction in small airways.[337] Studies in patients at high risk for asthma based on atopic symptoms have shown that this index is valuable in predicting AHR.[338] Similarly, in childhood asthmatics who have become asymptomatic, the $FEF_{25\%-75\%}$ is a sensitive marker of residual physiologic abnormalities.[339] The clinical utility of the $FEF_{25\%-75\%}$ is limited by the lack of acceptable standardized values. High numbers of false-positive and false-negative results occur when 80% of predicted $FEF_{25\%-75\%}$ is used for classification.[340]

The limitations of the $FEF_{25\%-75\%}$ are in part due to large variation in the duration of FVC maneuvers. To address this issue, measurement of the forced expiratory volume over the first 6 seconds (FEV_6) has been proposed as an alternative to the FVC. The advantages of this maneuver over the FVC include ease of measurement, a more explicit end-of-test definition, and reduced risk of syncope.[341] Data are available suggesting parameters that may be used for disease classification, although the sensitivity and specificity of the FEV_1/FEV_6 in comparison to the FEV_1/FVC ratio remain controversial.[342,343]

Lung Volumes and Diffusing Capacity

As a result of dynamic hyperinflation and consequent air trapping, residual volume, functional residual capacity, and total lung capacity may be elevated in asthma. Exhaled gas dilution measures only the communicating volume of gas and may underestimate these volumes due to regional heterogeneity in the distribution of ventilation.[344] For this reason, body plethysmography is often considered the method of choice for lung volume evaluation in severe asthma. However, because plethysmography measures the total volume of compressible gas within the thorax and abdomen, the inclusion of intra-abdominal gas may lead to overestimation of total lung capacity, particularly in severely obstructed asthmatics.[345]

Single-breath diffusing capacity is a marker of carbon monoxide gas transfer in the lungs and is reduced in most chronic lung diseases because of altered alveolar capillary surface area and/or maldistribution of inspired gas due to airflow obstruction. In asthma, the diffusing capacity is normal or elevated if airflow obstruction is not severe, and this can be useful in distinguishing asthma from other obstructive lung diseases.[346] Elevated diffusing capacity in asthma has been attributed to improved perfusion of well-ventilated upper lung zones and is associated with large lung volumes. The unexpected finding of an increase in diffusing capacity should raise the possibility of undiagnosed asthma, whereas decreased diffusing capacity in a suspected asthmatic is suggestive of an alternate diagnosis or coexisting condition.[347]

Provocative Challenges and Airway Hyperresponsiveness

AHR to environmental stimuli is a hallmark of asthma. Patients suspected of having asthma despite normal lung function testing usually develop bronchoconstriction in response to a provocative stimulus. Direct stimulation, during which a substance known to induce bronchoconstriction via direct action on smooth muscle is inhaled into the airways, is the most widely used method of assessing bronchial hyperresponsiveness. Nebulized methacholine, delivered in doubling concentrations until FEV_1 falls by more than 20%, is the most commonly used agent. The concentration that causes a 20% fall is labeled the PC_{20} (provocative concentration resulting in 20% fall in the FEV_1) and can be used to measure the degree of AHR. A PC_{20} less than 16 mg/mL is consistent with mild AHR, less than 4 mg/mL is consistent with moderate AHR, and less than 1 mg/mL with severe AHR,[348] with lower PC_{20} levels generally corresponding to more severe asthma.[349] Bronchial hyperresponsiveness also has been associated with increased risk of developing persistent asthma and airway remodeling.[350]

Indirect stimuli, such as cold air exposure, exercise, inhalation of hypertonic saline, mannitol, and adenosine monophosphate, may also induce bronchoconstriction. Rather than working directly on smooth muscle, indirect stimuli cause the release of inflammatory mediators from airway cells that then interact with ASM to induce bronchoconstriction. Although the dose response is more difficult to assess with indirect stimuli, the results have direct applicability to daily asthma symptoms. For example, direct challenge of athletes suspected of having exercise-induced bronchospasm is less likely to uncover bronchospasm than indirect challenge using a surrogate for physical activity.[351] There also may be differences between direct and indirect stimuli in the evaluation of response to treatment, with indirect challenge providing a better idea about response to therapy.[352]

MANAGEMENT OF ASTHMA

Introduction

The inherent complexities in evaluating and treating asthma are evident from studies in the 1970s and 1980s documenting a significant number of asthma deaths that were attributable to failure of clinicians to recognize the clinical severity of asthma, leading to inadequate management. For example, a study of asthma deaths in the West Midland and Mersey regions of England in 1979 led to the conclusion that failure to recognize the

severity of asthma delayed treatment, that routine asthma management was unsatisfactory, and that 86% of the deaths might have been preventable.[353] A similar study in 1988 included the observation that a large number of asthmatics admitted to the hospital for observation were discharged with no escalation in the management of their asthma.[354] This ultimately led the NHLBI to convene the first expert panel to develop guidelines for the diagnosis and treatment of asthma, and the resulting recommendations were published in 1991.[355] Other guidelines soon followed, extending the NHLBI's initial recommendations. Subsequent revisions have provided clinicians with a reliable framework for evidence-based management of patients with asthma. These guidelines emphasize maintaining long-term control of symptoms through attention to environmental and social components of asthma and using treatment regimens tailored to the severity of each patient's symptoms. Crucial components of management include initial evaluation of severity and ongoing assessment of control; appropriate pharmacologic therapy to reverse bronchoconstriction and ameliorate inflammation; identification and control of environmental factors that worsen symptoms or trigger exacerbations; and creation of a partnership between the patient and the health care professional to ensure that therapy is tailored to symptoms.

Assessment

Asthma Control

The assessment of patients with asthma involves five essential features: the current degree of control, based on symptoms, reliever medication use, recent exacerbations, and clinical lung function; and the risk of future adverse outcomes. With this in mind, the NHLBI recently updated guidelines, and the Global Initiative for Asthma (GINA) proposed a parallel scheme for asthma control based on expert opinion[328] (Table 38-1). The NHLBI and GINA categorizations represent categorical interval variables with threshold values. For example, the GINA guidelines accept some daytime symptoms (≤2 times/wk) in the definition of "controlled" asthma, whereas nocturnal symptoms move a patient to the "partially controlled" category. The importance of control indices is underscored by the relationship between poor asthma control and substantial degrees of physical impairment and diminished quality of life, even after taking the baseline severity of asthma into account.[356]

Several different validated instruments exist for assessing asthma, including the Asthma Control Questionnaire, Asthma Control Test, Asthma Therapy Assessment Questionnaire, and Asthma Control Scoring System.[357–360] All are useful because they direct history taking, provide

TABLE 38-1. Classification of Asthma Control in Adults and Children Older than 12 Years of Age

Components of Control		CLASSIFICATION OF ASTHMA CONTROL (YOUTHS ≥ 12 YR OF AGE AND ADULTS)		
		Well-Controlled	**Not-Well-Controlled**	**Very Poorly Controlled**
IMPAIRMENT	Symptoms	≤2 days/wk	>2 days/wk	Throughout the day
	Nighttime awakening	≤2 times/mo	1-3 times/wk	≥4 times/wk
	Interference with normal activity	None	Some limitation	Extremely limited
	Short-acting β-agonist use for symptom control (not prevention of EIB)	≤2 days/wk	>2 days/wk	Several times/day
	FEV_1 or peak flow	>80% predicted/personal best	60%–80% predicted/personal best	<60% predicted/personal best
	Validated questionnaires			
	ATAQ	0	1–2	3–4
	ACQ	≤0.75*	≥1.5	N/A
	ACT	≥20	16–19	≤15
RISK	Exacerbations	0-1/yr	≥2/yr†	
		Consider severity and interval since last exacerbation		
	Progressive loss of lung function	Evaluation requires long-term follow-up care		
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk		

*ACQ values of 0.76–1.4 are indeterminate regarding well-controlled asthma.

†(1) The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2–4 wk and by spirometry or peak flow measures. Symptom assessement for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit. (2) At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or intensive care unit admission) indicate poorer disease control. For treatment purposes, patients who had two or more exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.

goals for the management of symptoms, and guide adjustments in treatment.

Lung Function

Lung function testing is an important part of assessing asthma, both for making the initial diagnosis and as a means of evaluating the response to therapy. A recent study from the Genetics in Asthma Network[361] suggested that FEV_1 and FVC are useful components of a standardized scheme for identifying the contribution of genes and environments to disease expression. Further proof of the importance of lung function testing was provided by a recent finding that asthmatic patients with lower FEV_1 values were at significantly higher risk of needing acute care.[362] Although the FEV_1, the FEV_1/FVC ratio, and PEF are useful in the diagnosis and monitoring of asthma, the utility of these measurements in improving the outcome of asthma remains incompletely defined. FEV_1 is an objective measurement of lung function. The prebronchodilator FEV_1 is related to asthma control, whereas postbronchodilator FEV_1 is related to future risk of exacerbations. Accurate measurement requires stopping LABAs for 12 hours and short-acting bronchodilators for 6 hours. Because FEV_1 is often normal or near-normal in mild asthma, FEV_1 may be poorly responsive to bronchodilators in mild asthma.

PEF measurement is a standard method to correlate physiologic function with asthma severity, and has been used as a marker of asthma control in many clinical trials. However, individual peak flow measurements are highly variable and the variability in peak flow has a greater predictive value for future exacerbations than individual PEF measurements themselves.[329,330] The clinical usefulness of peak flow measurements is also limited by patient resistance to home monitoring and difficulty with consistently maintaining peak flow records.

Biomarkers

The presence of sputum eosinophilia provides useful information about the asthma phenotype. Low sputum eosinophil counts predict response to inhaled corticosteroids and decreased risk of exacerbations, whereas elevated sputum eosinophil counts (>10%) put the subject at high risk for future exacerbations.[363,364] A change of 50% in sputum eosinophil counts is considered to be clinically significant, whereas a decline in absolute eosinophil count predicts deterioration when inhaled corticosteroids are withdrawn.[365,366] However, induced sputum eosinophils may be difficult to obtain in clinical practice. Furthermore, the lag between specimen collection and processing may lead to delays in adjusting treatment.

Fractional excretion of nitric oxide (FeNO) has some advantages over counting the number of sputum eosinophils. Measurement of FeNO can be performed rapidly in a primary care setting, requires less technical expertise, and provides real-time objective physiologic data. However, the FeNO in stable, mild asthma after use of inhaled corticosteroids is often in the same range as that in normal, nonasthmatic patients.[367,368] FeNO falls in a dose-dependent manner with steroid use, making FeNO less useful as an ongoing biomarker in patients using steroid therapy.[369,370] A recent trial showed that an FeNO of more than 45 parts/billion excludes well-controlled asthma with a negative predictive value of nearly 90%. High FeNO suggests a severe, steroid-responsive phenotype. A decline in FeNO of more than 40% between visits is a sign of improved control, and low levels of FeNO predicted lower risk of acute exacerbation.[371] Measuring the FeNO during a period of good control can provide a baseline for comparing trends over time when following symptoms and response to treatment. Although the FeNO is a promising biomarker in asthma, the cost/benefit ratio of using FeNO to assess asthma control requires more study.

Treatment

Overview

Pharmacologic therapy for asthma is subdivided into acute, short-term "reliever" medications and chronic "controller" medications. Reliever medications target bronchoconstriction by relaxing ASM. The β-agonists such as inhaled albuterol are the most effective reliever medications. Other reliever medications include methylxanthines (e.g., theophylline) and short-acting anticholinergics such as inhaled ipatropium bromide. The most widely used controller medications are inhaled corticosteroids, which have a localized anti-inflammatory effect. There is overlap in the use and mechanism of action of reliever and controller medications. LABAs, used in conjunction with an inhaled corticosteroid, provide additional control of symptoms. Theophylline, although primarily a bronchodilator, also has a sustained anti-inflammatory effect at low doses, whereas inhaled corticosteroids such as budesonide have been used in the acute treatment of asthma exacerbations.[372,373] The introduction of omalizumab, a specific anti-IgE antibody, provided the first opportunity to treat and control asthma based on specific pathophysiologic characteristics. Tailoring biologic therapy based on pathophysiologic mechanisms in individual patients is an area of active clinical investigation, and additional agents addressing the allergic and nonallergic phenotypes of asthma are under investigation.

Specific Pharmacologic Agents

Current guidelines recommend adjusting therapy in a stepwise fashion to reduce daily symptoms and risk of exacerbations, while minimizing the use of medications.[374,375] The hierarchy of treatment recommendations is based on the available literature about efficacy and safety and provides a prominent role for controller medications at all levels of asthma treatment. In general, the strategy and recommendations in adults and children are similar. However, the increased risk of adverse effects and/or the lack of safety data in pediatric patients for theophylline, omalizumab, and the 5-lipoxygenase inhib-

itor zileuton, lead to their exclusion from current pediatric treatment guidelines.[374]

β_2-Agonists. β_2-Agonists have been used for thousands of years in the form of the ephedrine-containing herbal preparation ma huang.[376] However, it was not until the 1940s, when the nonselective β-agonist isoproterenol was introduced, that β-agonists became the standard of care for treating airway disease. The subsequent development of the β_2-selective agents albuterol and terbutaline, with improved side effect profiles, led to their current role as the cornerstone of asthma therapy.[377]

β_2-Agonist activity is primarily mediated by binding to a specific G-coupled transmembrane receptor found in high abundance on ASM. Receptor binding leads to increased intracellular cyclic adenosine monophosphate (AMP) and relaxation of ASM.[378] Notably, β_2-receptors are also found on other resident airway cells, including airway epithelial cells and circulating immune cells, and binding to these sites may reduce vascular permeability and inflammatory mediator release.[379] One concern raised about the chronic use of β_2-agonists is that of receptor desensitization.[380] As with most signaling receptors, repeated exposure to β_2-agonists can lead to decreased responsiveness of membrane receptors through receptor down-regulation via receptor endocytosis and uncoupling of receptor from downstream transduction pathways. This response appears to be self-limited in ASM.

β_2-Selective agonists are usually administered by aerosol, which maximizes delivery to target tissue (ASM), while minimizing the exposure of nontarget tissues. Both short-acting and long-acting agents are available, and the onset and duration of action are primarily related to lipophilicity.[16] Short-acting agents are used for rescue or emergent treatment, whereas LABAs are used in combination with inhaled corticosteroids for chronic management.

A number of highly selective short-acting β_2-agonists are now available, and all have a rapid onset of action with peak action between 60 and 90 minutes. Because they are inhaled directly into the airways, systemic side effects are minimal, even at high doses. A β_2-agonist preparation containing only the active isomer of albuterol was developed in an attempt to minimize side effects. However, clinical trials have not shown significant differences in outcome or tolerability.[381] Based on current guidelines, these medications should be used to treat symptoms not adequately controlled on a regimen of long-acting agents. Increased frequency of short-acting β_2-agonist use is a sign of inadequate control of symptoms or overreliance on rescue medication. Patients using more than one canister a month or requiring excessive doses of rescue inhalers (defined as >2 doses/wk) should be considered for a step-up in therapy.[374,375]

LABAs have minimal utility for treating acute asthmatic symptoms because of their delayed onset of action. However, in patients with inadequately controlled asthma, they can be added to an inhaled corticosteroid to improve symptoms. Formoterol and salmeterol are the two LABAs available. Formoterol has a shorter onset of action than salmeterol, whereas salmeterol has a longer duration of action. Each has been shown to improve lung function, reduce symptoms, and reduce the frequency of exacerbations.[382]

Adverse events associated with the use of β_2-agonists are primarily due to unwanted activation of β_2-receptors on nonpulmonary tissue. Cardiac stimulation causes tachycardia and arrhythmias, whereas skeletal muscle stimulation causes tremors and hypokalemia. Since the introduction of β-agonists, there has been concern about the clinical implications of receptor desensitization. The short-acting β-agonist fenoterol was implicated in two epidemiologic studies of increased asthma deaths in the 1960s and 1970s[383,384]; later analysis suggested that this might have been due to excessive use, rebound bronchoconstriction due to short duration of action, or tachyphylaxis. After fenoterol was withdrawn, mortality declined,[385] and the safety profile of subsequent short-acting β_2-agonists has been good. Clinical data suggest that "as-needed" versus scheduled short-acting β_2-agonist treatment is associated with improved physiology[386] and fewer, less severe exacerbations.[387]

Adverse events with long-acting β_2-agonists also are of concern, particularly because of their long duration of action. In the Salmeterol Multicenter Asthma Research Trial (SMART),[388] patients were randomized to salmeterol or placebo plus usual care, with approximately 13,000 patients in each arm. There was no significant difference in risk of death in either group, but subgroup analysis identified a small but increased risk of death that was more prominent in African American subjects in the salmeterol arm of the trial. However, the African American patients also had poorer control of symptoms at baseline (with more exacerbations and hospitalizations) and a lower rate of inhaled corticosteroid use than the white patients.[388] Importantly, the use of LABAs with inhaled corticosteroids in the same metered-dose inhaler has been shown to be safe and effective.[389]

Several studies have explored the relationship between polymorphisms in the β_2-receptor and responses to β-agonist therapy. Specifically, the presence of the Arg/Arg mutation at the B16 locus has been associated with lower PEF, FEV_1, symptoms, rescue inhaler use, and increased rate of exacerbations in patients treated with scheduled albuterol as compared with patients who lack the Arg/Arg mutation. All of these symptoms improve when regular albuterol is withdrawn.[146,390,391] Use of LABAs (with and without inhaled corticosteroids) has been shown to worsen physiologic markers of respiratory function in Arg/Arg patients in some studies, although these findings are not consistent.[149,392] Two large randomized trials are currently underway that should shed light on this issue.

Other Bronchodilators. Anticholinergic agents act as bronchodilators via competition with acetylcholine at neuromuscular junctions, thereby blocking transmission of bronchoconstrictor reflexes.[393] The short-acting anticholinergic ipratropium bromide is effective in patients with chronic obstructive pulmonary disease (COPD) but is considered a second-line agent for treating asthma, most likely because cholinergic tone contributes

less to bronchoconstriction in asthma. Although no trials have compared short-acting anticholinergics with short-acting β-agonists, randomized trials studying the addition of anticholinergics to β-agonists do not show any additional benefit in patients with chronic asthma. However, specific asthma phenotypes might be more likely to respond to anticholinergic treatment, including patients with fixed airflow obstruction, advanced age,[394] or longer duration of disease.[395] Furthermore, anticholinergics may be an acceptable alternative for certain subgroups of patients who do not tolerate β-agonist treatment or for patients with the Arg/Arg-16 genotype, although this has not been studied directly.

Tiotropium, a long-acting anticholinergic agent, has been shown to be beneficial for treating the symptoms of COPD. The value of tiotropium in patients with asthma is not clear, but a randomized trial is in progress. Spirometric improvement has been demonstrated in case series of asthmatics who do not have sputum eosinophilia[396] and asthmatics with concomitant COPD.[397] Animal data suggest that tiotropium may have an antiremodeling effect comparable with that of budesonide.[398]

Inhaled Corticosteroids. With recognition of the central role of inflammation in the pathophysiology of asthma, contemporary treatment strategies now emphasize corticosteroids for long-term control of symptoms. Corticosteroids suppress inflammatory responses through a broad influence on signal transduction and gene expression pathways. Corticosteroids bind to a specific cytoplasmic receptor that translocates to the nucleus, where it modulates expression of inflammatory genes through inhibition of histone acetyltransferases and recruitment of histone deacetylases.[399,400] Airway inflammatory cell influx and markers of airway inflammation in asthma are reduced by corticosteroid administration.[401,402]

Systemic corticosteroids have been used in the treatment of asthma since the 1940s and continue to be a cornerstone of the management of acute exacerbations. However, systemically administered corticosteroids are associated with a variety of undesirable side effects. The introduction of inhaled corticosteroids (ICS) in the 1970s ushered in a new era in the treatment of asthma. As with bronchodilators, delivery of drug directly into the lungs through the use of inhaled preparations minimizes systemic toxicity and improves therapeutic benefit.

The use of ICS improves all aspects of asthma control. ICS reduce asthmatic symptoms, improve lung function, decrease airway inflammation, and control AHR.[403,404] A large meta-analysis showed that inhaled corticosteroids reduce asthma exacerbations by 55% as compared with placebo[405] and reduce the risk of hospitalization by 50% as compared with use of as-needed β-agonists alone.[406] Furthermore, risk of death from asthma is reduced in a dose-response manner with the use of ICS.[407] As a result, ICS are considered to be first-line therapy for all patients requiring more than twice-weekly β-agonist use.[375]

The risk of systemic toxicity is diminished but not absent with the use of ICS, particularly at doses less than 400 μg budesonide daily or the equivalent. Data are conflicting about the risk of bone demineralization from ICS; although a small observational study suggested increased risk,[408] a meta-analysis of several randomized controlled trials did not corroborate this finding.[409] The risks of cataract formation[410] and glaucoma[411] are slightly increased, whereas hypothalamic-pituitary axis suppression, gastrointestinal bleeding, and other complications of systemic steroids are not associated with inhaled preparations. The Towards a Revolution in COPD Health (TORCH) trial of the use of inhaled corticosteroids for COPD showed an increased risk of pneumonia, but this has not been demonstrated in patients with asthma.[412] The use of inhaled corticosteroids in the pediatric population has raised concerns about growth suppression. However, available data show only a small and transient decrease in growth trajectory that does not translate into a reduction in adult height.[404,413,414]

Leukotriene Modifiers. Leukotrienes (LTs) are derived from cell membrane arachadonic acid metabolism. LT receptors on ASM and macrophages mediate bronchoconstriction, mucus hypersecretion, and mucosal edema.[415] As a result, the LT pathway is a primary target for the development of novel asthma controller medications. Commercially available leukotriene modifiers (LTMs) work in one of two places in the LT pathway. Zileuton blocks 5-lipoxygenase, the enzyme that converts arachadonic acid to LTA4, which is the first step in LT synthesis. Montelukast, zafirlukast, and pranlukast all inhibit LT receptors, blocking the final step in the LT pathway. All are taken orally as either once-daily or twice-daily doses.

LTMs have a modest bronchodilator effect and may improve asthma symptoms and exacerbation rates.[416] Physiologic benefits have also been seen, with improvements in spirometry and measures of airway inflammation.[417] Whereas the subpopulation of patients with aspirin-sensitive asthma may derive great benefit from LTMs,[418] data also suggest that LTMs are adequate as single agents in mild persistent asthma.[419,420] Although LTMs treat multiple asthma symptoms, they are less efficacious than low-dose ICS. As a result, patients who require ICS for asthma control cannot be safely switched to LTM monotherapy. Therefore, the primary role of LTMs is as an adjunct to ICS, and the addition of LTMs typically leads to a reduction in the corticosteroid dose or an improvement in asthma control.[421,422] Recent data suggest that the substitution of LTMs for ICS in smokers with asthma leads to similar symptomatic benefits, possibly due to impaired therapeutic responses to ICS in this population. However, it is not clear whether this benefit would persist with the addition of LTMs to ICS in patients who smoke cigarettes.[423] Overall, LTMs are less effective than LABAs as adjunctive therapy and do not seem to confer added benefits when added to a regimen that includes an ICS and an LABA.[424,425]

Overall, LTMs are well tolerated. Initial reports suggested a link between LTMs and Churg-Strauss syndrome, but this is now thought more likely to be due to an unmasking of the syndrome by a reduction in corticosteroid dose with the introduction of an LTM.[426] Zileuton is metabolized by the cytochrome P-450 system and has been associated with reports of hepatotoxicity. As a

result, liver function should be monitored during its use. The availability of a sustained-release preparation of zileuton has made it a better option as adjunctive therapy. At present, zileuton is reserved for patients with refractory asthma or who have an asthmatic phenotype suggesting benefit from the use of an LTM.[427]

Phosphodiesterase 4 Inhibitors (Theophylline). Theophylline is a well-established phosphodiesterase inhibitor that has mild anti-inflammatory properties. Because of its narrow therapeutic index, theophylline is not widely used in treating asthma. However, the discovery of additional anti-inflammatory properties, likely mediated by histone deacetylation, has led to a resurgence of interest.[428] Although no longer a first-line therapy, theophylline is currently used in low doses as adjunctive treatment for asthma that is difficult to control with steroids alone.[429] The addition of theophylline to an existing drug regimen for poorly controlled asthma improves markers of control (rescue inhaler use, lung function) to a greater extent than LTMs.[423] Dose-related side effects, such as anorexia, palpitations, dysrhythmias, and seizures, require careful clinical and laboratory monitoring.

Anti-Immunoglobulin E Treatment. The introduction of omalizumab, a monoclonal antibody to IgE, represents a new era of therapy targeted to specific asthma phenotypes. Omalizumab targets the receptor-binding portion of IgE, preventing it from interacting with immune cells to cause degranulation.[430] The addition of omalizumab to ICS in poorly controlled allergic asthmatics is associated with improved asthma control and fewer exacerbations.[431] Omalizumab is generally well tolerated, but rare reports of anaphylaxis have led to recommendations that patients be observed for 2 hours after each of the first three injections to ensure safety.[304] High cost, the requirement for monitoring during treatment, and the need to carefully select patients likely to benefit have limited the use of omalizumab. However, cost analysis suggests that anti-IgE therapy in patients with severe allergic asthma results in a cost-per-quality-adjusted life year that compares favorably with other uses of expensive health care resources.[432]

Nonpharmacologic Treatment

Bronchial thermoplasty is a novel intervention for asthma that is based on the observation that increased ASM mass is a characteristic feature of asthma. During thermoplasty, controlled thermal energy is delivered to the airway wall, resulting in reduction of ASM mass. In patients with moderately severe asthma, thermoplasty been shown to reduce airway responsiveness to an inhaled constrictor and improve lung function.[433] Treatment leads to improvements in symptoms and quality of life and reduction in the use of rescue medication in patients with moderate or severe asthma.[304] However, treatment requires a series of three bronchoscopies, exposing patients to the concomitant procedural risk, and long-term outcome data are lacking. Nevertheless, the specific targeting of ASM in asthma remains an area of investigation.

Additional Management Strategies

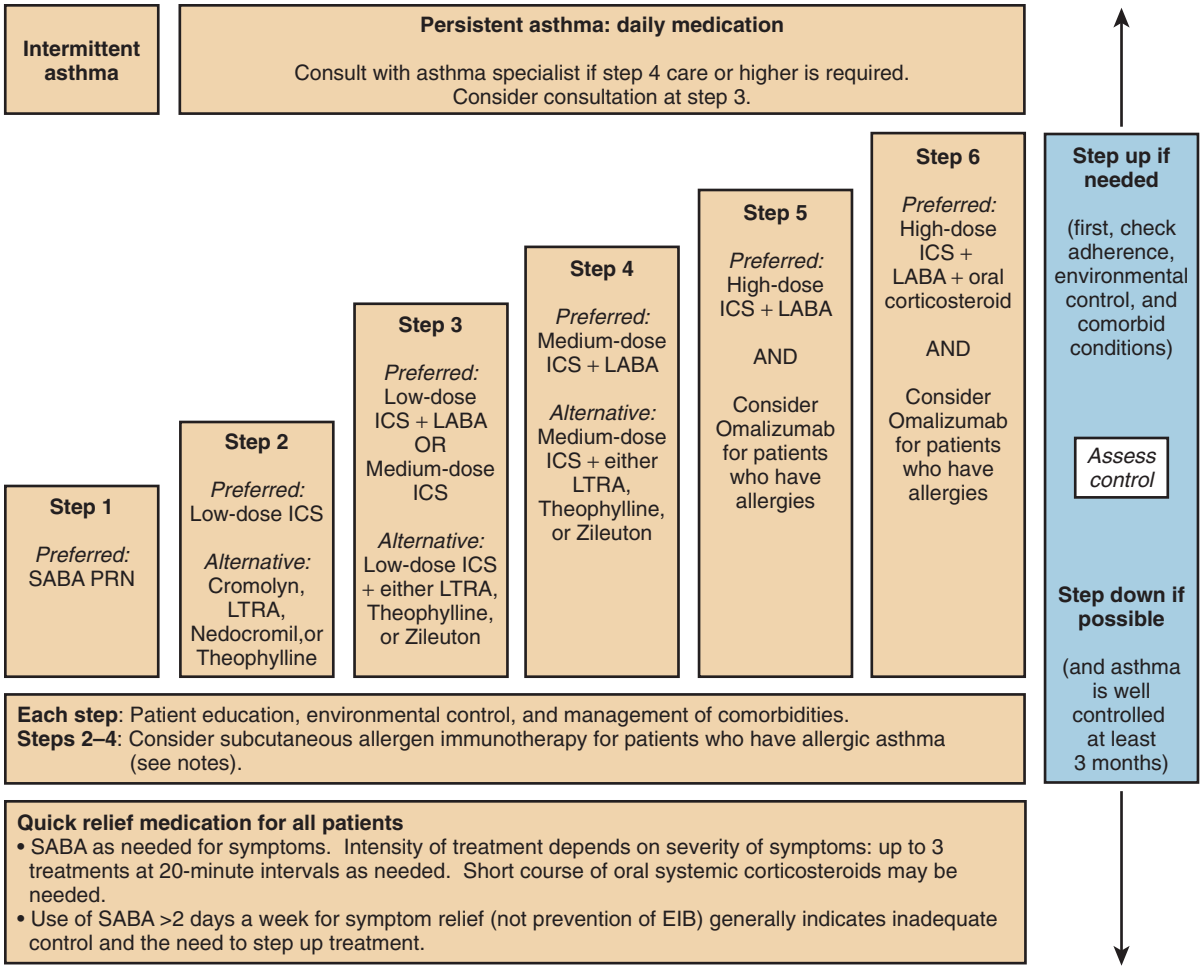
Control of Triggers

Environmental factors have been shown to contribute to the pathogenesis of asthma, including occupational exposures, tobacco smoke, pollutants, respiratory infections, allergen exposures, and comorbid conditions. Cigarette smoking decreases asthma control and reduces the efficacy of corticosteroids. All patients with asthma who smoke cigarettes should be strongly encouraged to quit.[434] Certain comorbid conditions, including GERD and rhinosinusitis, may worsen asthma symptoms and severity. Because treatment of GERD and sinusitis often improves the control of asthma, all difficult-to-treat patients with asthma should be evaluated for these underlying conditions.[435,436]

Reduction of allergen exposure and provision of allergen immunotherapy are common strategies for treating asthma. Allergic asthmatics improve when removed from their domestic environment, but environmental control is often difficult to achieve.[437] The most common allergens include dust mites and cat dander. Whereas avoiding environmental allergens is ideal, most patients do not like the idea of avoiding or giving away their pets. Although overall data are mixed, several studies have shown clinical benefits from dust mite control measures (i.e., impermeable mattress covers, frequent vacuuming, cockroach control).[438,439] For patients with an allergic asthma phenotype, allergen-specific immunotherapy may reduce asthma symptoms and improve bronchial hyperreactivity.[440,441] However, administration must take place under careful conditions owing to the risk of anaphylaxis, and the optimal duration of treatment is not completely clear.

Medication Adjustment Based on Asthma Control

The definition of asthma severity is based on the severity of symptoms at the time of diagnosis. More recent definitions take into account the degree of treatment necessary to maintain control and the frequency of exacerbations. Asthma control, defined as the degree of symptoms present while on appropriate therapy, is more fluid. Depending on the extent of control, a more or less aggressive approach to symptom management may be needed. Recent studies support the importance of focusing on asthma control as a means of reducing exacerbations and morbidity.[441a] Published guidelines provide an up-to-date framework for medication choices when "stepping up" therapy to improve asthma control and "stepping down" therapy when control has been achieved (Fig. 38-5). For patients with mild, intermittent asthma, with symptoms that return to baseline between episodes, as-needed use of a short-acting bronchodilator is usually sufficient to maintain control of symptoms. For patients with chronic asthma (symptoms that occur >2 times/wk, nocturnal symptoms, or symptoms that affect activity), the addition of a controller medication is needed, and an ICS is the initial agent of choice.[404,442,443]



Key: Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy. EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, long-acting inhaled beta$_2$-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta$_2$-agonist.

FIGURE 38-5 ■ Medication recommendations for control of asthma in adults and children older than 12 years of age. (Adapted from the National Heart, Lung, and Blood Institute as a part of the National Institutes of Health and the U.S. Department of Health and Human Services, 2007.)

As mentioned previously, when used properly, ICS ameliorate all asthma symptoms, improve airway physiology, and reduce hospitalizations and asthma mortality. Failure to respond to ICS suggests nonadherence to medications, uncontrolled trigger exposures and/or comorbidities, or a steroid-nonresponsive phenotype. Approximately 30% of asthmatics fall into the last category. These patients typically have less airway inflammation and obtain their maximum response to a low-dose of ICS.[444,445] LTMs are an alternative for patients who do not tolerate ICS and are the preferred agent for patients with concomitant allergic rhinitis.[416,417]

For patients with persistent asthmatic symptoms despite the appropriate use of a controller medication, clinicians have several different options for "stepping-up" therapy. Some guidelines recommend the addition of an LABA to low-dose ICS (often in a combination inhaler) based on a large amount of efficacy data.[446–449] However, because of concerns over the potential side effects of LABAs, the National Asthma Education and Prevention Program (NAEPP) guidelines give the options of increasing the dose of ICS or adding an LABA. This is also the preferred approach for pediatric patients. A third option is the addition of LTMs to low-dose ICS.[422]

If symptoms are still not controlled on one of the regimens just discussed, the next medication added depends on previous medication choices. For patients on increased doses of ICS, the recommended next step is the combination of a moderate- to high-dose ICS with an LABA. However, increasing the ICS dose for a patient already on an ICS/LABA combination is less likely to be effective.[450,451] Other options include the addition of an LTM or sustained-release theophylline to an ICS.[452] If symptoms remain uncontrolled on a full complement of standard medications, options include the addition of systemic corticosteroids or specific anti-IgE therapy for patients with allergic asthma.[431]

Once symptoms are controlled for a protracted period of time, therapy can be stepped down. Strategies for de-

escalation of therapy are determined by a patient's controller regimen. Patients on an ICS alone can be considered for a decrease in dose or dosing interval. Some data suggest that conversion to as-needed combined short-acting β_2-agonists/ICS may be effective with a lower total steroid dose.[453,454] However, an as-needed regimen is not yet part of NHLBI guidelines. Similarly, for patients on a combined ICS/LABA regimen or LTM/ICS regimen, clinicians should focus first on reducing the ICS component.

Management of Acute Asthma

Asthma is a common cause of emergency room visits and hospital admissions. In 2004, asthma accounted for 1.8 million visits to emergency departments, or 64/10,000 people, with 497,000 asthma hospitalizations, or 17/10,000 people.[24] The treatment of acute asthma is based on the cornerstones of chronic asthma therapy but typically requires greater attention to patient monitoring and an escalation in the aggressiveness of asthma care.

Asthma exacerbations are characterized by increased shortness of breath, coughing, and/or chest tightness, and airflow limitation (as measured by decreased peak flow or FEV_1) is a cardinal feature. Increased symptoms typically precede a detectable decrease in air flow,[455] although a subset of patients are at high risk of exacerbations due to poor perception of airflow limitations. In the outpatient setting, increased requirement for rescue inhalers, especially in a patient previously on a stable regimen, suggests an asthma flare.

Patients with asthma exacerbations require prompt evaluation and treatment in order to limit morbidity and mortality. Goals include relief of airflow obstruction and amelioration of respiratory symptoms. Patients with milder symptoms (with peak flow decrease <20%) may be evaluated in an outpatient setting but should be referred to an acute care facility if they fail to respond promptly to aggressive treatment with bronchodilators and systemic glucocorticoids.[374] Conversely, certain patients are at high risk of asthma-related death and should be evaluated in the emergency department as soon as possible when their symptoms worsen. This includes patients with a history of recent exacerbation or previous near-fatal asthma, overutilization of short-acting β_2-agonists or underutilization of ICS, recent oral glucocorticoid use, poor compliance with asthma action plans, or concomitant psychiatric disease.[456]

In the acute care setting, the severity of an asthma exacerbation should be assessed by physical examination, including oximetry and measurement of peak expiratory flow. Use of accessory muscles, ability to complete sentences, and arterial oxygen tension all should be evaluated. Patients require close monitoring during the early stages of treatment, because it may take several hours for symptoms to resolve. Chest radiography is useful if pneumothorax is suspected but does not usually provide clues as to the etiology of an exacerbation. Arterial blood gas measurement typically reflects mild hypoxemia and respiratory alkalosis; the normalization of $PaCO_2$ in the absence of significant symptomatic improvement suggests impending respiratory failure. Anion gap metabolic acidosis may also be present, which is usually due to elevated lactate levels. Patients who fail to respond to albuterol administration within 30 to 60 minutes, with persistent dyspnea and peak flow less than 70% of baseline, require hospital admission.[374]

Key pharmacologic components of treatment include repeated or continuous short-acting bronchodilator administration (via nebulizer or metered-dose inhaler with a spacer) and systemic glucocorticoids.[457] The combination of short-acting β-agonists and ipratropium at the initiation of treatment is associated with physiologic improvements and reduced rate of hospitalization, but the benefits do not persist after hospitalization.[458] Systemic corticosteroids are unequivocally associated with more rapid return to baseline function and are considered the first-line therapy for acute asthma. The initial dosing range for adult hospitalized patients is from 1.5 to 2.0 mg/kg of intravenous methylprednisolone or the equivalent.[459] ICS are typically not used acutely, although some data suggest that the addition of inhaled budesonide to systemic corticosteroids following an emergency department visit leads to improved symptoms and a decreased relapse rate.[460,461] Intravenous magnesium sulfate, usually given as a 2-g bolus, may act as a smooth muscle relaxant and has been shown to reduce hospital admission rates.[462] Supplemental oxygen to keep saturations above 90% helps maintain oxygen delivery to peripheral tissues and minimizes hypoxemic vasoconstriction.

Severe exacerbations of asthma are characterized by persistent reductions in peak expiratory flow of less than 40% predicted with poor response to initial treatment. These patients may demonstrate progressive hypercapnia, fatigue, altered sensorium, and dysrhythmias and are at high risk for respiratory arrest. Low-level noninvasive positive-pressure ventilation without positive end-expiratroy pressure (PEEP) has been shown to reduce the rate of hospitalization and may be considered in alert, cooperative patients who are not in immediate need of intubation.[463] Helium/oxygen mixtures increase flow through the airways and may be a useful adjunct in patients with severe exacerbations that do not respond to initial emergency treatment.[464,465]

Oral intubation and mechanical ventilation are mandatory for patients in respiratory arrest or impending respiratory arrest. Mechanical ventilation in patients with severe asthma exacerbations may be complicated by immediate postintubation worsening of gas exchange and hemodynamic instability due to increased airway and intrathoracic pressures from dynamic lung hyperinflation. Provided that the patient is adequately oxygenated, briefly decreasing the mandatory respiratory rate to allow an extended expiratory phase is often successful. Initial ventilator settings should be focused on minimizing dynamic hyperinflation by using a relatively low minute ventilation (with respiratory rate between 12 and 14/min and tidal volumes in the 6-8 mL/kg range), a high inspiratory flow rate, and minimal to no PEEP.[466] Aggressive sedation should be given to improve comfort and patient-ventilator synchrony. Short-term paralysis may be

necessary in patients for whom ventilator synchrony cannot be achieved with sedation alone. Bronchodilator administration should be continued until airway resistance decreases.

Conclusion: Clinician-Patient Partnership

For chronic asthma, treatment should balance the best symptom control with the lowest possible dosage of medication.[374] Effective management requires that the patients form a partnership with the health care providers in order to ensure an appropriate flow of information, with the patients assuming a major role in the assessment and treatment of their disease. Through collaborative effort, a guided self-management plan can be developed, allowing patients to titrate their own treatment based on changes in symptoms and peak expiratory flow with some degree of independence. The use of such guided self-management reduces asthma morbidity in different patient populations and patient care settings.[467]

Crucial components of self-management plans include education, self-monitoring with symptoms and/or peak flow, regular review, and patient directed self-management using a written action plan. Effective patient education is central to this approach. Better communication by health care providers translates into measurably better outcomes with no additional physician time commitment.[468] Even for patients unable to engage in guided self-management, regular follow-up and medication review is beneficial, because approximately 50% of patients on long-term therapy fail to take medications as directed some of the time.[469]

KEY POINTS

- Asthma is an important cause of disability, death, and economic cost.
- Asthma is increasing in developed countries and appears to be increasing to epidemic proportions in non-Western societies that have adopted features of Western culture.
- On a fundamental level, asthma is a disease of misdirected immunity, with the direction of immune function being influenced by many genes and probably also by airway infections, especially with viruses, but established in the first few years of life. The cells most important in orchestrating this "misdirected" immune response in the airways are dendritic cells and CD4 Th2 lymphocytes.
- The cytokines produced by these lymphocytes, particularly IL-13, alter the function of immunological and structural cells in the airways, either directly through activation of specific receptors on the cells or indirectly through their effects on other cells, such as B lymphocytes, mast cells, eosinophils, and polymorphonuclear leukocytes. Repeated release of these cytokines alters the function and structure of the airways.
- The structural changes, often referred to as "remodeling," are now recognized as potentially irreversible.
- The approach to the diagnosis, assessment, and treatment of asthma has changed in response to the recognition of asthma as a chronic inflammatory disease punctuated by intermittent exacerbations.
- The therapies available are effective in controlling asthma, but their efficacy depends on engaging the patient as a full partner in care.
- Before the most economical and effective approach for preventing asthma can be undertaken, more information is needed about the interplay between individual genotypes and environmental stimuli that are responsible for initiating and perpetuating the disease.
- Until a curative treatment is developed, only the combined use of anti-inflammatory and bronchodilator therapies, coupled with measures to reduce environmental exposures, can reduce the costs of asthma for the individuals affected. Applied widely, these measures can also reduce the consequences and costs for the health care system.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a collection of conditions characterized by persistent expiratory airflow limitation. Although the clinical presentation and course of COPD can vary from individual to individual, there is sufficient overlap that it has been practical to group COPD as a single entity defined on the shared parameter of airflow limitation. The current consensus definition of the Global Initiative for Chronic Obstructive Lung Disease (GOLD) centers on the common feature of altered lung function but recognizes both the systemic nature and the heterogeneity of COPD.

COPD is a preventable and treatable disease with some significant extrapulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles and gases.[1]

The heterogeneity of COPD results from several causes. First, COPD can result from several etiologies,

most importantly cigarette smoke. These exposures can affect the lung by several distinct mechanisms, and it is likely that many genes can modulate individual responses, resulting in marked interindividual differences in susceptibility. Importantly, several anatomic lesions can result in the alveolar walls, in the proximal and distal airways, and in the pulmonary and bronchial vasculature that can cause the airflow limitation and contribute to the clinical features. Finally, as noted in the GOLD definition, COPD is commonly, but variably, associated with disease in other organ systems that can contribute to the clinical features in individual patients. Recognition that COPD is heterogeneous clinically and at a pathophysiologic level has led to new initiatives to categorize and define the subsets of COPD and holds the promise of developing treatments that will be more effective for the individual patient.

HISTORICAL BACKGROUND

Obstructive airway disorders have been known since antiquity. Chronic bronchitis was a major cause of death in Europe following industrialization, but was not well studied until recently, perhaps because then, as now, it is more common among those of lower social economic status.[2] In their detailed review of the history of chronic bronchitis, Fletcher and colleagues[2] attribute the first use of the term to Badham in 1808.[3] Although there were clinical and pathologic studies of chronic bronchitis in the 19th century, including those of Laennec,[4] it was probably the severe London smog of December 5–9, 1952, with the marked increase in acute mortality, which led to increased interest in the condition. The pathologic studies of Reid[5] demonstrating increased mucus gland size led to the development of the "Reid Index" and highlighted the anatomic basis for the clinical syndrome.

Emphysema has also been described for centuries.[6] Enlarged respiratory air spaces on the surface of human lungs was illustrated by Ruysch[7] in 1691. Late in the 18th century, Matthew Baillie provided the earliest illustration[8] and a brief description[9] of emphysema. Laennec,[4] using air-dried inflated lung specimens, also described emphysema. Insightfully, he suggested that the peripheral airways were the primary site of obstruction in emphysema and speculated that loss of elastic recoil was a likely contributor to diminished airflow. In the 1950s, Gough and his coworkers,[10] using sections of whole inflation-fixed lungs mounted on paper, described centriacinar emphysema and distinguished it from panacinar emphysema.

The increasing interest in COPD resulted in several "hypotheses" to explain the pathogenesis of airflow obstruction. The concept espoused by Orie and associates from the Netherlands,[11] which came to be known as the "Dutch hypothesis", was that asthma and airway hyperreactivity could eventually lead to fixed airflow limitation. This was often contrasted with the concept that mucus hypersecretion led to airway remodeling and airflow limitation, a concept proposed by British investigators[2] and, hence, termed the "British hypothesis." In addition, the association of homozygous alpha$_1$ protease inhibitor deficiency with emphysema was discovered by Laurell and Eriksson in Sweden.[12] Together with the description of protease-induced emphysema in animal models,[13] this led to the concept of the "protease-antiprotease hypothesis" of emphysema, which could be termed the "Swedish hypothesis," although this term has never been used. Finally, at about the same time, the American pathologist Averill Liebow[14] suggested that deficient maintenance of lung structure, particularly of alveolar capillaries, could lead to emphysema. This concept—that altered repair mechanisms contribute to the development of COPD—has been termed the "American hypothesis."[15]

Current evidence suggests that the mechanisms proposed by all these "hypotheses" contribute to COPD. The multiplicity of nonexclusive mechanisms, which may be simultaneously present in a given individual, has contributed to the difficulty of clinical subclassification of COPD. Defining the precise mechanisms relevant to individual patients is a key goal of current attempts to define COPD subtypes.

Attempts to subclassify COPD are not new. Pathologic studies delineate inflammation and alteration of airway structures (bronchitis) from destruction of the alveolar wall (emphysema). The concept that altered airway anatomy would lead to heterogeneity of airflow distribution within the lung, resulting in ventilation-perfusion imbalance, hypoxemia, and right heart failure, suggested that bronchitis might be associated with a "blue bloater" clinical phenotype. In contrast, the concept was that emphysema would not cause hypoxia, although there would be decreased airflow, resulting in a "pink puffer" phenotype. These entities are not exclusive, however, and most commonly, individual patients have features of both. The relationship of COPD to asthma, which causes variable airflow limitation and may cause fixed airflow limitation in a subset of individuals, has further confounded clinical classification. To provide a conceptual model to integrate these concepts, Snider and coworkers suggested the "Nonproportional Venn Diagram,"[16] which emphasized the independence of these causes of airflow limitation and the heterogeneity of COPD (Fig. 39-1).

CLINICAL FEATURES OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

History

Cough and dyspnea are the most frequent symptoms reported by patients with COPD. Dyspnea is typically present only with exertion until late in the course of the disease. Cough, therefore, may be the presenting symptom. Either symptom should initiate a diagnostic evaluation that includes spirometry. Most often, however, neither symptom causes the patient to seek medical care until advanced disease is present, and both symptoms should be aggressively sought in routine questioning.

Cough may be very troublesome and can compromise quality of life significantly.[17] In many cases, however, the

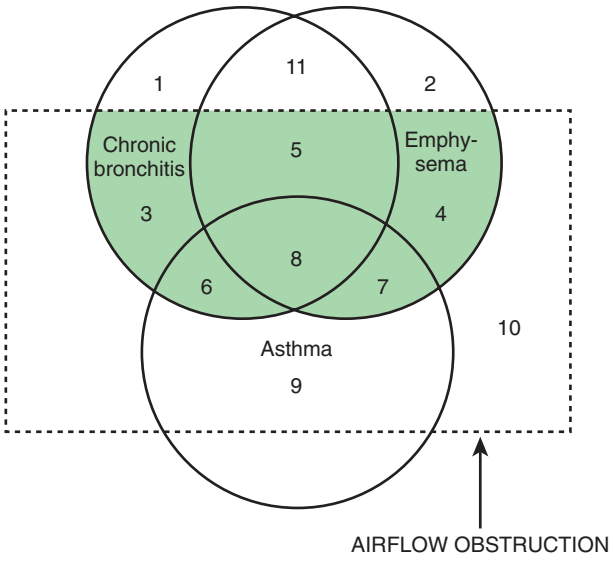

FIGURE 39-1 ■ Schema of subsets of COPD. This non-proportional Venn diagram shows subsets of patients with chronic bronchitis, emphysema, and asthma and their relationship to airflow obstruction (box). The subsets comprising COPD are in green. Subset areas are not proportional to actual relative subset sizes. Asthma is by definition associated with reversible airflow obstruction and those with asthma whose airflow obstruction is completely reversible (subset 9) are not considered to have COPD. Because it is nearly impossible to differentiate patients with asthma with partially reversible airflow obstruction from persons with chronic bronchitis and emphysema who also have partially reversible airflow obstruction, patients with unremitting asthma are classified as having COPD (subsets 6, 7, 8). Chronic bronchitis and emphysema with airflow obstruction are often seen together (subset 5) and some patients may have asthma associated with these two disorders (subset 8). Individuals with asthma exposed to chronic irritation, as from cigarette smoke, may develop chronic productive cough, a feature of chronic bronchitis (subset 6), often called *asthmatic bronchitis*. Persons with chronic bronchitis and/or emphysema without airflow obstruction (subsets 1, 2, and 11) are not classified as having COPD. Patients with airway obstruction due to diseases with known etiology or specific pathology, such as cystic fibrosis or obliterative bronchiolitis (subset 10), are not included in this definition. (From ATS: Standards for the diagnosis and care of patients with COPD. Am J Respir Care Med 152:S77–S121, 1995.)

patient is unaware of cough frequency, and an accurate history may be best obtained from a spouse. A productive cough should not be suppressed and a chronic daily cough is predictive of frequent exacerbations.[18]

Sputum production is insidious in its onset and, in the majority of patients, it is "scanty," defined as less than several tablespoons per day. Sputum production may also relate to smoking status, with current smokers having much more production. The sputum is usually mucoid but becomes purulent during exacerbations. Following smoking cessation, cough and sputum may become transiently more difficult, but symptoms generally improve following smoking cessation.[19]

Hemoptysis complicating chronic bronchitis is the most common cause of hemoptysis in the United States and usually occurs in association with an exacerbation.[20] However, other etiologies of hemoptysis, in particular lung cancer, must be kept in mind in this susceptible population.[21]

Dyspnea, especially with exertion, is usually the presenting symptom and, as the disease progresses, occurs with less and less effort. Dyspnea in COPD patients probably results from dynamic hyperinflation that worsens with increasing respiratory rate (see later). As a result, many patients will avoid dyspnea by avoiding exertion and may become exceedingly sedentary. This may develop insidiously and the patient may have an extremely restricted level of function. As with other chronic diseases, many patients reset their expectations with regard to health, termed "response shift." This frequently results in very few complaints despite patients being very cognizant of their limitations.[17]

Health status, sometimes termed "quality of life," is abnormal in COPD patients. Two instruments have been widely used in research settings, the St. George Respiratory Questionnaire (SGRQ)[22] and the Chronic Respiratory Disease Questionnaire (CRDQ).[23] These measures demonstrate that health status correlates, although poorly, with forced expiratory volume in 1 second (FEV_1) and correlates better with exercise performance,[22] emphasizing the systemic features that can dominate the clinical presentation of COPD. Health status also correlates with survival independently of FEV_1.[24]

Exacerbations, which are characterized by increased cough, sputum, dyspnea, and fatigue, are increasingly frequent as the disease worsens. They generally resolve over a few weeks, but full recovery may take months.[25] Exacerbations may be difficult to distinguish from other acute causes of dypsnea, cough, and/or sputum including pneumonia, congestive heart failure, pulmonary embolism, or pneumothorax without radiologic or laboratory evaluation.

Physical Examination

In many patients with COPD, physical examination reveals little abnormality especially during quiet breathing. Coarse crackles occurring early in inspiration have been associated with obstructive lung disease, although other adventitious sounds may be present. Rhonchi are more prevalent in patients complaining of dyspnea and are usually present during both inspiration and expiration. Wheezing is not a consistent finding and does not relate to the severity of obstruction. The most consistent finding in patients with symptomatic COPD is the prolonged expiratory time, which is best determined by listening over the larynx during a forced expiratory maneuver. Prolongation of the expiratory phase longer than the normal 4 seconds is indicative of significant obstruction. However, the clinical diagnosis of COPD is notoriously poor.[26] Quantification of airflow by spirometry, which is simple and can be done accurately on relatively inexpensive equipment appropriate for the

generalist office,[27] should always be performed when the diagnosis of COPD is considered.[1]

When COPD becomes severe, patients demonstrate more apparent physical signs. These include the barrel-shaped chest, purse-lipped breathing, emaciation, and frequently, inguinal hernias. Patients may be observed sitting forward and leaning on their elbows, or supporting their upper body with extended arms, in a position known as "tripoding." This position stabilizes the shoulder girdle and helps to maximize intrathoracic volume. These are late developments, however, and the diagnosis should be made earlier by spirometry in individuals with relevant histories.

Pulmonary hypertension may develop in patients with COPD and may be worse with exercise.[28] It may be suspected with a loud pulmonary component of the second heart sound and heart sounds may be displaced to the midline due to hyperinflation.

Laboratory Findings

Pulmonary Function Tests

Assessment of lung function (see Chapter 24) is essential to establish a diagnosis and to gauge the severity of COPD. The most important test is spirometry. Measurement of lung volumes and diffusion capacity, which generally requires a specialized laboratory, may also be helpful, particularly in determining whether airflow limitation is due to emphysema or airway disease.

Spirometry. Simple spirometry is the most important test to diagnose and stage COPD. After taking a maximally deep breath, a subject exhales as forcefully as possible, and the volume of air exhaled is measured as a function of time. The FEV_1 is the most important measure. The maximal volume exhaled is the forced vital capacity (FVC). A reduction in FEV_1/FVC ratio is diagnostic of airway obstruction. Because it may take some time for a patient to empty his or her lungs fully, particularly if COPD is present, the forced expiratory volume after 6 seconds, FEV_6, is recommended for use in most office settings.[29] Not only is it easier to perform, but avoiding prolonged exhalation maneuvers reduces the chance of syncope during the test. Because of variability in the FVC (or FEV_6) measure, the FEV_1/FVC ratio can establish a diagnosis of obstruction but is not useful to monitor disease progression.[30] Many other quantitative measures of airflow can be obtained from spirometry, but these usually add little to the FEV_1 and FVC (or FEV_6). Similarly, peak expiratory flow is generally regarded as less useful than the FEV_1. If airflow is abnormal, postbronchodilator testing should be performed. Correction to the normal range suggests a diagnosis of asthma and could exclude COPD. Partial correction, which may vary from day to day in an individual patient,[31] may help to define therapeutic goals.

Lung Volumes. The FVC can be measured spirometrically. Other lung volumes, which include the volume of air remaining in the chest, require specialized testing. The most commonly used method is the body plethysmograph (i.e., "body box") that uses Boyle's law to calculate intrathoracic volumes. In general, the total lung capacity is increased in emphysema because the loss of elastic recoil permits the lungs to expand to a greater maximal volume. The residual volume and the functional residual capacity are also increased. Because the residual volume increases more than the total lung capacity, the vital capacity is decreased. Increases in lung volume with increasing respiratory rate (i.e., dynamic hyperinflation) can be measured but require specialized procedures and are not routinely used in clinical practice. The inspiratory capacity, which is the volume that can be inhaled from end-expiratory lung volume, that is, the volume at which a normal breath starts, has been suggested as a surrogate for the measurement of dynamic hyperinflation. Although it can be readily measured with routine spirometry equipment, standardized procedures for its determination and its use in clinical practice are undefined.

Volume-Pressure Relationship. Compliance of the lungs can be measured with an esophageal balloon. With severe emphysema, compliance of the lungs is increased.[32] Measurement of the volume-pressure curve of the lung is a research procedure not generally used in routine clinical practice.

Diffusing Capacity. The single-breath diffusing capacity is decreased in proportion to the severity of emphysema because of the destruction of the alveoli and the loss of alveolar capillary bed.[32] However, the measurement is not sensitive to low grades of emphysema.[33] It is also reduced in other diseases that destroy the alveolar capillary bed.

Arterial Blood Gases. Arterial blood gases reveal mild or moderate hypoxemia without hypercapnia in the early stages of COPD. In the later stages of the disease, hypoxemia tends to become more severe and may be accompanied by hypercapnia with increased serum bicarbonate levels.[32] Blood gas abnormalities worsen during acute exacerbations and may also worsen during exercise[34] and sleep.[35] Alterations in blood gases largely reflect alteration in ventilation-perfusion relationships. As a result, the relationship between spirometric values, which assess only airflow, and blood gas abnormalities is weak. Hypercapnia is observed with increasing frequency as values of the FEV_1 fall below 1 L. (Acid-base balance is discussed in Chapter 7.)

Imaging

Chest Radiography. Chest radiography can help exclude other pathology in patients with COPD. COPD is a functional diagnosis and, as such, chest radiographs can only suggest this diagnosis. Increased thickness of bronchial walls viewed on end and an increased prominence of lung markings can suggest the diagnosis of chronic bronchitis, but are neither specific nor sensitive. There are two radiographic patterns associated with emphysema, although both are signs of late disease. These are the patterns of pulmonary arterial deficiency and of increased markings. The triad of overinflation, oligemia, and bullae make up the arterial deficiency pattern, which is most often associated with

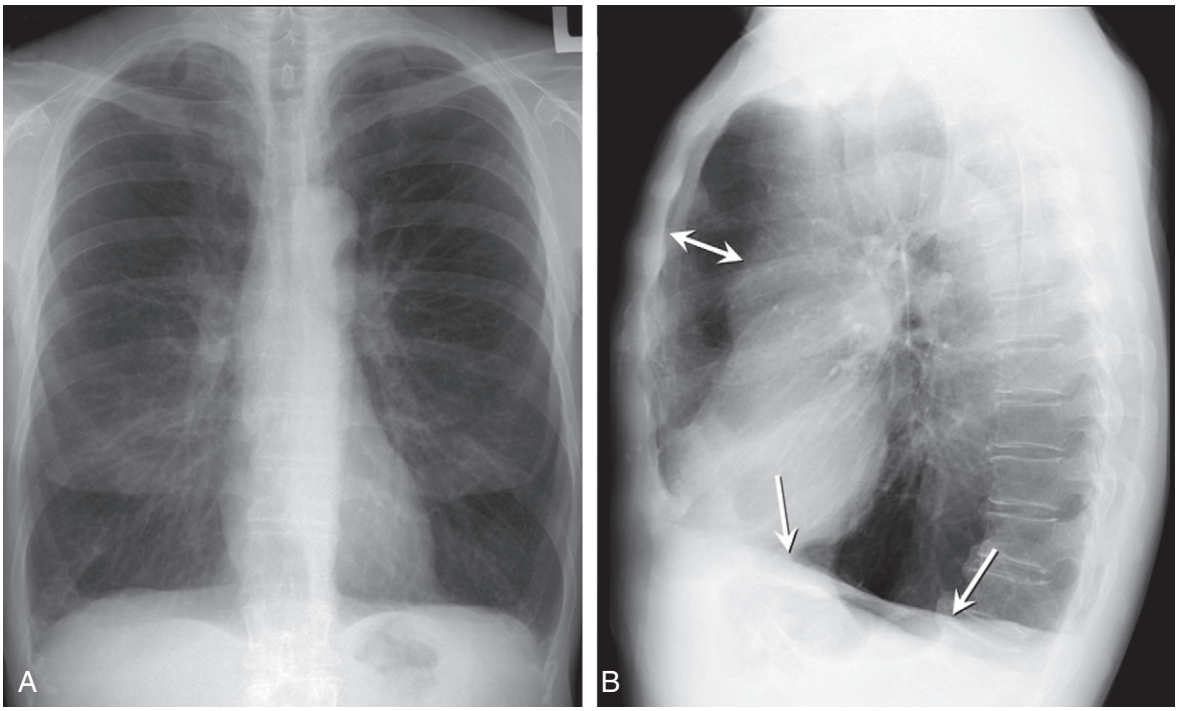

FIGURE 39-2 ■ Frontal (**A**) and lateral (**B**) chest radiograph in a 54-year-old female smoker with centriacinar emphysema. Note the very large lung volumes, with hyperlucency primarily seen in the upper lobes, consistent with a centriacinar emphysema pattern. Flattening of the diaphragms (*arrows*), a prominent retrosternal clear space on the lateral radiograph (*double arrow*), and a small-appearing heart on the frontal radiograph are findings consistent with abnormally increased lung volumes and are typical of advanced emphysema. The upper lobe lucency typical of centriacinar emphysema contrasts with the lower lobe predominant lucency seen in patients with panacinar emphysema (see Fig. 39-13). *See CT scan video of this patient online.* (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

emphysema, and the increased markings pattern, which resembles the "dirty chest" appearance seen in chronic bronchitis. The best evidence of overinflation is flattening of the diaphragms with a concavity of the superior surface of the diaphragm (Fig. 39-2). Another sign is an increase in the width of the retrosternal air space, but this is less sensitive. Clinical correlation is important when overdistention is present on the chest radiograph because these findings may also be seen with severe asthma. However, this sign resolves in asthma with clinical improvement in airflow limitation.

Computed Tomography. In contrast to conventional radiography, computed tomography (CT) has the resolution needed to delineate and quantify subtle findings in the chest and is therefore much more sensitive, particularly in the diagnosis of emphysema (Fig. 39-3). There are several methods to assess COPD using CT. CT density can be used to quantify emphysema, because loss of density is a characteristic feature. This permits estimates of both severity and extent of disease.[36] Analytic methods have been developed that may also distinguish the pattern of emphysema. The ability to distinguish bullae and to determine the location of disease is essential in determining whether individual patients are candidates for surgical therapy[37] (also see later). Several studies suggest that small airways may also be evaluated.[38]

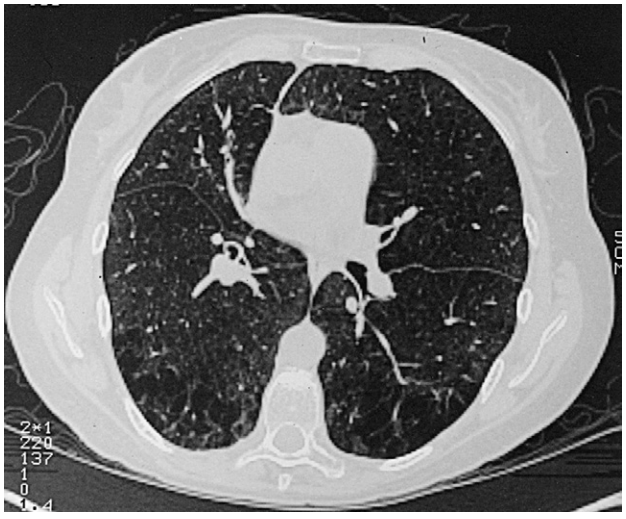

FIGURE 39-3 ■ High-resolution CT scan of the chest of a 65-year-old woman shows enlarged respiratory air spaces posteriorly in both lung fields representing emphysema. The posterior location of the lesions in the upper portions of both lower lobes suggests that the emphysema is centriacinar in type. (Courtesy of Robert Pugatch, MD.)

Laboratory Tests

Biomarkers. Identification of biomarkers, either in peripheral blood or in other body fluids, that reflect specific aspects of COPD is an area of active interest.[39,40] None have yet affected clinical practice.

Erythrocytosis/Anemia. Erythrocytosis may develop in COPD patients. It is generally thought to arise either persistently or intermittently.[41] Anemia may also be a feature of COPD.[42] The presence of a normal hemoglobin should not be used to forgo evaluation of arterial blood gases.

Sputum Examination. In stable bronchitis, sputum is mucoid, and microscopic examination reveals a predominance of macrophages; bacteria are few. During an exacerbation, the sputum often becomes grossly purulent due to an influx of neutrophils. Eosinophils, if present, may indicate a greater likelihood to respond to inhaled glucocorticoid therapy.[43] With an exacerbation, the number of organisms seen on Gram stain usually increases. The pathogens most often cultured from the sputum are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Other oropharyngeal commensal flora such as *Moraxella catarrhalis* can be recovered. Increased numbers of organisms are associated with increased inflammation in stable COPD.[44] Although not always present in exacerbations, increased numbers of bacteria[45] or changes in bacterial strain are associated with exacerbation.[46] Cultures and Gram stains, however, are rarely necessary for institution of antimicrobial therapy unless the patient has sustained an exacerbation during or soon after receiving a course of antibiotic therapy.[47]

COMPLICATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Pneumothorax

Spontaneous pneumothorax in a person with normal lungs produces minor symptoms and disruption of lung function (see Chapter 74). Pneumothorax complicating COPD, however, can precipitate severe dyspnea and acute respiratory failure and may be life threatening. Even a small pneumothorax can cause severe respiratory impairment in COPD patients who have only a marginal pulmonary reserve, and because it is often accompanied by a persistent air leak between the involved lung and the pleural space (bronchopleural fistula), it may be difficult to treat.

Cor Pulmonale

Chronic cor pulmonale is defined as enlargement of the right ventricle (hypertrophy or dilation) due to increased right ventricular afterload from diseases of the lungs or pulmonary circulation (see Chapter 56). Resting mean pulmonary arterial pressures may rise to 30 to 40 mm Hg in patients with advanced COPD as opposed to the normal value of 10 to 18 mm Hg. With exercise, mean pressures may rise as high as 50 to 60 mm Hg or greater. The causes of the pulmonary hypertension in COPD are several.[48,49] Once a common feature in late-stage COPD patients, it is now much less common, perhaps because of the appropriate use of oxygen therapy.

Pathophysiology

Emphysema results in a loss of the pulmonary vascular bed. However, the major cause of increased pulmonary vascular resistance in patients with COPD is vasoconstriction due to alveolar hypoxia. There is subsequent remodeling of the pulmonary vasculature with medial hypertrophy of muscular pulmonary arteries along with the appearance of smooth muscle in normally nonmuscular vessels of the pulmonary circulation. Nocturnal hypoxemia alone, even with noncritical hypoxemia in the awake state, may produce pulmonary hypertension in some patients.[50] Acidemia augments hypoxic vasoconstriction and can play a role in transient rises in pulmonary blood pressure during acute exacerbations of COPD. Increased intrathoracic pressures as a result of airflow limitation with air trapping can also increase pulmonary vascular resistance by compressing pulmonary vessels. Greater viscosity of blood occurring with erythrocytosis secondary to hypoxemia may play a role in the genesis of pulmonary hypertension, although this factor is far less important than hypoxic pulmonary vasoconstriction. Blood volume may be increased in patients with cor pulmonale, in part from impaired sodium and water excretion.[51] This increase in blood volume, along with increases in cardiac output in response to hypoxemia, may contribute to higher mean pulmonary arterial pressure in the presence of a restricted pulmonary vascular bed. Although left ventricular dysfunction is relatively uncommon in patients with cor pulmonale due to COPD, when such dysfunction is present, left ventricular failure and elevated pulmonary venous pressure may also contribute to pulmonary hypertension. In addition, COPD patients are prone to develop chronic pulmonary thromboembolic disease, and embolism should always be considered when the magnitude of pulmonary hypertension is out of proportion to a patient's underlying lung disease and arterial hypoxemia.

The detection of pulmonary hypertension and right ventricular enlargement by noninvasive means can be difficult. The best means is two-dimensional echocardiography, especially with an esophageal transducer, and pulsed Doppler techniques with echocardiography to estimate mean pulmonary arterial pressure.[52–54] Cardiac scintography is rarely required, although cardiac catheterization may be needed to confirm and evaluate pulmonary hypertension.

Successful treatment of cor pulmonale in patients with COPD begins with optimal management of the underlying airflow limitation. Correction of hypoxemia using long-term oxygen therapy is of the greatest importance. Use of pulmonary vasodilators employing a wide range of agents has proved disappointing, with no sustained improvement in hemodynamics or enhanced survival. This remains an active area of research, however, and the availability of newer, more easily administered

agents that may affect vascular remodeling holds promise.

Pneumonia

COPD is generally considered to be an important predisposing condition increasing the risk for pneumonia and for pneumonia of greater severity, although epidemiologic data are limited.[55,56] Pneumonia may also be difficult to distinguish from an acute exacerbation of COPD.[57]

Sleep Abnormalities

A slight decrease in alveolar ventilation with an accompanying modest rise in arterial carbon dioxide pressure (P_{CO_2}) and fall in arterial oxygen pressure (P_{O_2}) is normal during sleep.[58] (Sleep disorders are discussed in detail in Chapter 79.) COPD patients, therefore, may have deterioration in their blood gases at night, even in the absence of sleep apnea. It is not thought appropriate to monitor patients routinely for nocturnal desaturation. However, monitoring nocturnal oximetry could be considered in COPD patients with findings, such as pulmonary hypertension, erythrocytosis or mental status changes, which suggest the presence of intermittent hypoxemia.

Giant Bullae

Bullae occupying one third to one half of one or both hemithoraces may occasionally produce a dramatic chest radiograph. Bullae may become infected and may compromise the function of the remaining lung by filling the chest (Fig. 39-4). There is an increased frequency of carcinoma of the lung with large bullae.[59,60] Tumors may occur in young men with bullae,[60] but occur most frequently in those in the sixth decade of life.[61]

Systemic Manifestations and Comorbidities

It is becoming increasingly clear that COPD is characterized by manifestations outside the lung (Table 39-1). Osteoporosis is also more common in COPD patients and is of clinical significance because it may lead to fractures.[62] Skeletal muscle weakness correlates much better with walking distance in COPD patients than does FEV_1.[63] Walking distance, in turn, is a much better predictor of health status (sometimes termed "quality of life") than is FEV_1.[22] The importance of these features of COPD, which may be independent of airflow limitation, have led to the creation of a multidimensional scoring system, the BODE (body, obstruction, dyspnea, exercise) index (Table 39-2).[64] Interestingly, this index appears to be a much better predictor of mortality than are isolated measures of airflow.

The most common cause of death among COPD patients is coronary artery disease,[65] and reduced lung function has long been recognized as an independent risk factor for cardiac disease.[66] The mechanisms by which COPD increases risk for cardiac disease are not established, but systemic inflammation may play a role in the pathogenesis of atherosclerosis. Hypercoagulability, perhaps due to systemic inflammation, may account for increased risk of deep venous thrombosis and pulmonary embolism in COPD patients. Finally, although controversial, COPD patients may have a higher incidence of depression,[67] which may also result, at least in part, from systemically active inflammatory mediators. These systemic features of COPD are often the major clinical problems faced by patients suffering from this condition.

The mechanisms accounting for the systemic manifestations of COPD are not yet fully defined, but the systemic effects of inflammation have been suggested as the link. Weight loss, for example, may be due, at least in part, to metabolic alterations.[68] Circulating cytokines derived from inflammation in the lung may play a role. Tumor necrosis factor-α (TNF-α), for example, may contribute to the loss of lean body mass and to skeletal muscle dysfunction.[69] Interleukin-6 (IL-6) may account for increased fibrinogen levels and hypercoagulability.[70]

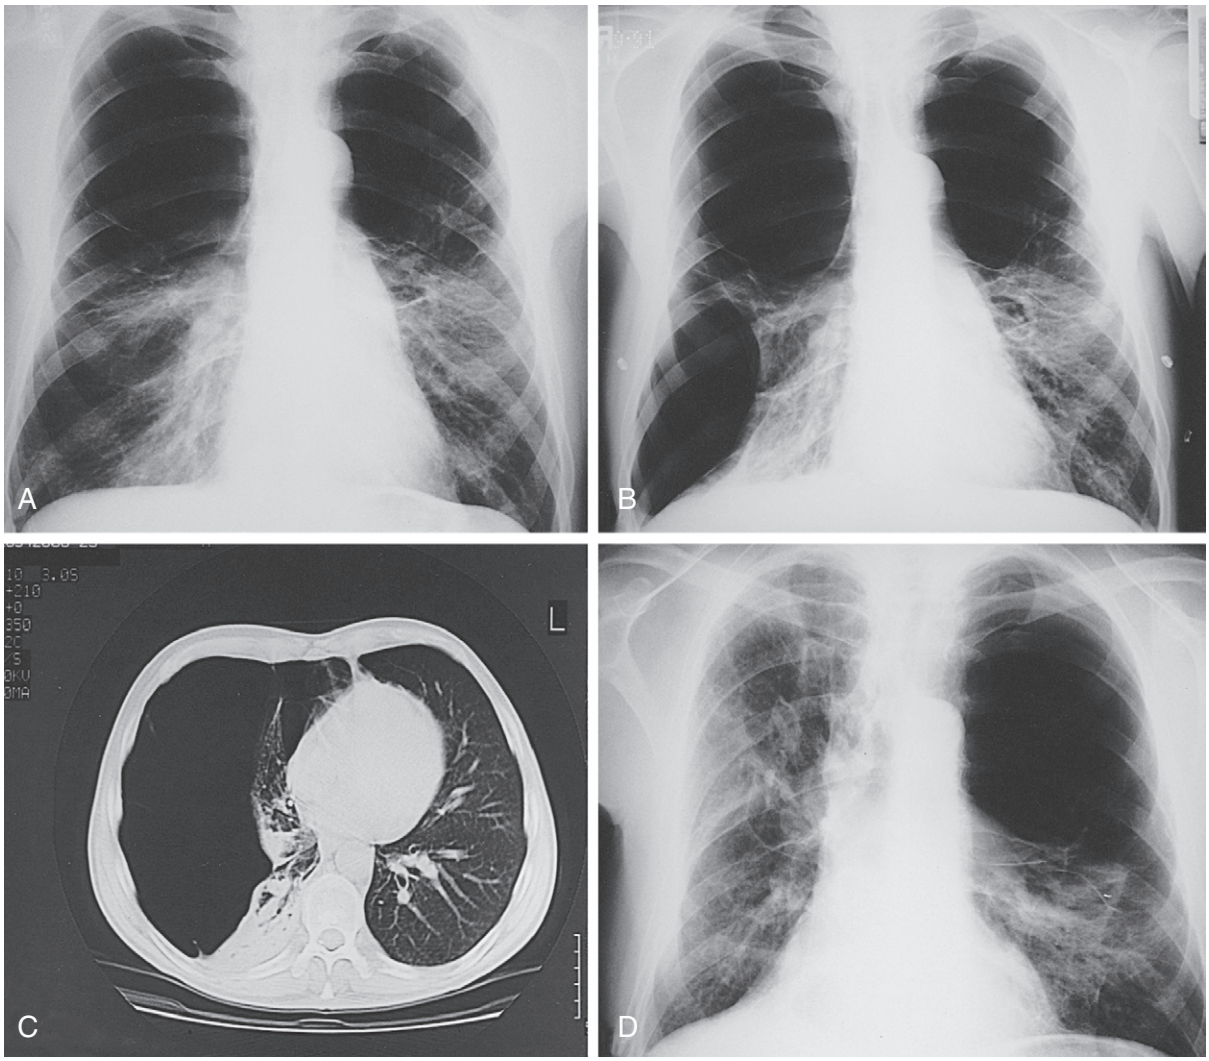

FIGURE 39-4 ■ Radiographs of a 46-year-old man who had smoked an average of 2 packs of cigarettes daily from age 18 years and who presented in the summer of 1991 with dyspnea after walking 20 yards on the level. He was known to have giant bullous lung disease and had had multiple episodes of bronchitis and pneumonia. His serum alpha$_1$-antitrypsin level was normal. Pulmonary function studies revealed an FVC of 2.22 L (44% predicted), FEV_1 1.28 L (34% predicted), FEV_1/FVC 0.58, and diffusing capacity of 9.1 mL/min/mm Hg. Arterial blood gases while breathing air were pH 7.43, P_{CO_2} 38 mm Hg, and P_{O_2} 58 mm Hg. Hematocrit was 51%. Lung perfusion scintiscans showed that virtually all of the perfusion went to the lower half of the left lung. **A,** The chest radiograph of November 14, 1988, reveals giant bullae occupying the upper half of both lung fields with crowding of vascular shadows in the lower lung fields. **B,** In the radiograph of August 9, 1991, an additional giant bulla is seen in the right lower lung field, and a small bulla is noted at the left base. **C,** The CT scan on October 16, 1991 shows atelectasis of the right lower lobe due to compression by giant bullae. The patient stopped smoking. Right thoracotomy with bullectomy was performed on January 14, 1992. **D,** The chest radiograph of February 24, 1992, shows expansion of the right lung with remaining bullae in the left lung. On November 3, 1992, the FVC was 2.81 L, FEV_1 1.80 L, FEV_1/FVC 0.64, and the diffusing capacity was 19.7 mL/min/mm Hg. Arterial blood gases breathing room air were pH 7.43, P_{CO_2} 40 mm Hg, and P_{O_2} 71 mm Hg. The hematocrit was 42%. Dyspnea was markedly diminished, and the patient returned to clerical work.

Renin-angiotensin alterations may contribute to polycythemia.[71] It is likely that cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF) can also contribute. These cytokines may alter both net fluid and salt balance, as well as vascular permeability. Thus, edema and fluid status present in COPD are also likely manifestations of systemic disease as well as of hemodynamic abnormalities.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of chronic airflow limitation relates back to the Venn diagram shown in Figure 39-1. The diagnosis of chronic bronchitis is made on the basis of symptoms, that of asthma is made on the basis of near-complete reversibility spontaneously or with bronchodi-

lators, and that of emphysema on the basis of destruction of alveoli best seen on CT scans of the chest. History and physical examination provide an initial database. Spirometry is essential, because it reveals the defining feature of COPD. The chest radiograph may help to exclude other pulmonary disorders. The single-breath diffusing capacity for carbon dioxide (D_{LCO}) may help determine the presence of emphysema although the CT scan is more sensitive. The CT scan can also show the location of emphysema, which is necessary to identify potential surgical candidates, and can reveal other pathologies.

The most difficult clinical problem is to distinguish asthma from COPD. Spirometry with and without bronchodilators is the most useful test. Improvement in lung function is the characteristic feature of asthma. Improvement into the normal range excludes a diagnosis of COPD. Less useful is the methacholine challenge test, which is usually more severely abnormal in asthma than in COPD. Importantly, as indicated in Figure 39-1, asthma and COPD may coexist. In such a case, compromised lung function may partially correct after bronchodilators. If both asthma and COPD are present, therapeutic goals should target both conditions. For this reason, pulmonary function testing should be used to define the presence or absence of both conditions.

Other Conditions

The most common radiographic presentation of emphysema is that of increased lung volume and vascular shadow attenuation and, therefore, of hyperlucency of involved lung compared with nonemphysematous lung. A number of conditions presenting as unilateral or lobar hyperlucency in the chest radiograph are different from emphysema in pathogenesis and natural history.[72] These conditions may need to be differentiated from unilaterally preponderant emphysema (Table 39-3). Hyperlucency in the chest radiograph may also have a chest wall origin, such as from congenital absence of the pectoralis major muscle or absence of the female breast and pectoral muscles after radical mastectomy.

Unilateral Bronchiolitis Obliterans

In 1953, Swyer and James,[73] and in 1954, Macleod,[74] giving much more detail, described patients with unilateral hyperlucent lungs. Subsequent study showed this entity to be due to patchy bronchitis and bronchiolitis obliterans, sometimes with bronchiectasis and generally with respiratory air space enlargement. This condition is best called *unilateral bronchiolitis obliterans with hyperinflation*, but it is referred to by many other terms in the literature, including *Swyer-James* or *Macleod's syndrome*, *unilateral hyperlucent lung*, and *unilateral emphysema*.[75]

Unilateral bronchiolitis obliterans with hyperinflation is quite rare, with a prevalence of 0.01% in 17,450 survey chest radiographs.[72] The condition is usually asymptomatic and is discovered accidentally by chest radiography. Unilateral bronchiolitis obliterans is believed to originate from a destructive bronchitis and bronchiolitis.

*The list includes examples; all possible conditions are not mentioned.
Modified from Gaensler EA: Unilateral hyperlucent lungs. *In* Simon M, Potchen EJ, LeMay M (eds): Frontiers of Pulmonary Radiology. Orlando, FL: Grune & Stratton, 1969, pp 312–359.

Inhalation of corrosive gases and infections, especially by adenovirus, have been implicated. This usually occurs in childhood, before the full number of alveoli have formed by about age 8, but cases have been documented in adults who were previously normal. Air space enlargement may be due to a reduced number of alveoli (reduced and fixed in number by the insult to the lung during development) which then distend as the thorax grows.

Congenital Hypoplasia

Congenital hypoplasia or absence of a pulmonary artery may also give rise to a small hyperlucent lung[72,75–77]; the amount of hyperlucency varies, depending on the extent

of bronchial artery hyperplasia. Unlike unilateral hyperlucent lung with bronchiolitis obliterans, the affected lung empties at a normal rate.

Atelectasis

Atelectasis of a lobe, especially the left lower lobe, may occasionally lead to impressive hyperlucency of the overdistended upper lobe. The presence of atelectasis and the normal emptying of the overdistended lobe enable easy diagnosis.

Extrinsic compression of a main bronchus by bronchogenic carcinoma with distal air trapping usually presents no diagnostic problem. An intrabronchial neoplasm or postinflammatory stricture of a main bronchus may give trouble in differential diagnosis if hyperlucency of the affected lung results. Emptying of the diseased lung will be delayed and incomplete, with contralateral mediastinal shift on expiration. A localized wheeze may be heard. A CT scan or bronchoscopy is diagnostic.

Congenital Lobar Emphysema

Marked overdistention of a lobe, usually the upper lobe, may give rise to severe respiratory distress in infancy. The condition may also occur later in life and is usually referred to as congenital lobar emphysema. Its cause is unclear. Bronchial cartilage abnormalities and mucosal folds have been identified in some cases.[78] Occasionally, a hyperlucent lung or lobe can be seen as part of bronchial atresia or pulmonary agenesis.[79,80] Both of these conditions are usually manifested in childhood, but bronchial atresia may not become manifest until adulthood. In infancy and childhood, resection is indicated if normal lung tissue is severely compressed resulting in pulmonary insufficiency. Most adults are asymptomatic, and differentiation from unilateral obliterative bronchiolitis may not be possible short of pathologic examination of resected tissue. Such resection is usually not indicated.

EPIDEMIOLOGY

COPD is a major public health problem. Its impact is almost certainly underestimated. It is recognized as the fourth leading cause of death in the United States, accounting for more than 120,000 deaths annually.[81] COPD prevalence and impact have been increasing for several decades, following the epidemic of cigarette smoking in the 20th century, and COPD is projected to be the third leading cause of death by 2020.[82] Mortality may be peaking among men in the United States but, among women, mortality continues to rise and deaths from COPD among women now exceed those among men.[83]

A major goal of the GOLD program is to facilitate the diagnosis and staging of COPD.[1] The key feature necessary to establish the diagnosis of COPD is airflow limitation that is not fully reversible. For diagnosis, a ratio of the FEV_1 to the FVC of less than 0.7 ($FEV_1/FVC < 0.7$) has been used. The FEV_1 can be reliably measured as the disease worsens but, because the FVC may be underestimated, the FEV_1/FVC ratio is only used to establish a diagnosis. The FEV_1, expressed as the percentage of predicted, is used to stage severity.

This classification does not incorporate changes that occur with age. In normals, the FEV_1/FVC ratio may decline with age, resulting in some "overdiagnosis" of mild COPD in the elderly.[84] Because underdiagnosis and undertreatment is a major problem, it was decided to select a simple classification that could be readily used clinically and the ratio was adopted in the GOLD guidelines.

The National Health and Nutrition Examination Survey (NHANES) study, in which lung function was measured in a representative portion of the population, suggests that 24 million people have impaired lung function in the United States.[83] The diagnosis of COPD, however, is extremely inaccurate. It is estimated that 10 million Americans have a diagnosis of COPD. Not only does this reflect tremendous underdiagnosis, but diagnosis in the absence of spirometry is notoriously inaccurate, with more than half of patients misdiagnosed.[26] This inaccuracy of diagnosis is true not only in the United States but also in other population-based studies.[85] This emphasizes the importance of using spirometry to diagnose and stage COPD. Although not recommended for screening of unselected individuals,[86] spirometry should be available in primary care practices to assess those with suggestive symptoms or those at increased risk due to exposures or family history.[86]

The economic impact of COPD in the United States has been estimated to be nearly $40 billion.[87] This includes both direct and indirect costs, and involves a number of assumptions.[88] Nevertheless, these estimates are probably modest. More than half of the direct costs attributable to COPD are attributable to acute exacerbations and are relatively easy to track.[89] COPD patients, however, also have considerably greater total direct healthcare costs than do similarly aged non-COPD patients. The difference in cost is only partially due to direct costs for COPD, indicating that the COPD patient has increased costs for "non-COPD" health problems. This suggests that many of the costs related to COPD may be attributed to associated comorbid conditions.

COPD progresses with age and COPD is more prevalent in elderly populations. In the United States, 15% of the total population aged 55 to 64 will have at least moderate COPD (GOLD stage 2, $FEV_1 < 80\%$ predicted), and this increases to over 25% for those older than 75.[90] There are similar numbers of patients with mild disease (GOLD stage 1, $FEV_1 > 80\%$, FEV_1/FVC ratio < 0.7), although the clinical significance of mild disease in the elderly remains controversial. In two studies designed to determine the prevalence of COPD, standardized spirometric methods were used to estimate the prevalence of COPD in different countries.[91-93] With these spirometric standards, COPD prevalence was found to vary from 2% to 22% (Fig. 39-5).[93] The large variation was only partially explained by variations in age and smoking status, emphasizing the role of other risk factors.

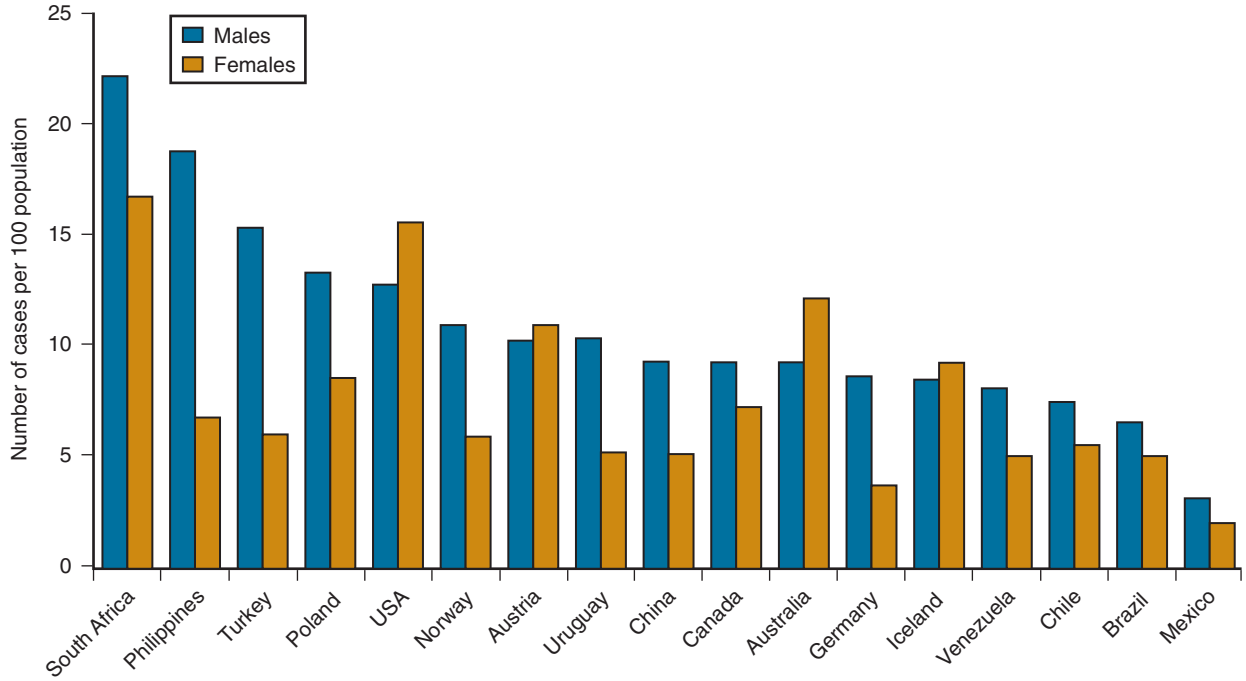

FIGURE 39-5 ■ Prevalence of COPD in different countries. Data were pooled from two multinational epidemiologic studies which used similar methodology. The prevalence of COPD, GOLD stage 2 or higher, is shown on the vertical axis for men (*blue*) and women (*orange*). The sampling sites in the various countries included on the horizontal axis were small and may not be generalizable to the entire population. (Redrawn from Mannino DM, Buist AS: Global burden of COPD: Risk factors, prevalence, and future trends. Lancet 370:765–773, 2007, with permission.)

Risk Factors

Exposure to Toxic Fumes and Gases

Cigarette Smoking. Cigarette smoking is firmly established as the most important risk factor for COPD. Fletcher and colleagues[2] suggested that a minority, perhaps 10% to 15% of smokers, would get clinically significant COPD. This has led to a serious misconception that only 15% of smokers get COPD.[94] In fact, smokers lose lung function in a dose-dependent manner (Fig. 39-6). Thus, the majority of smokers are likely to have reduced lung function, particularly as they age (Fig. 39-7). Even if undiagnosed, this reduced lung function has an adverse prognostic effect. The impact of smoking, therefore, should not be underestimated. Eighty percent of individuals who have COPD and 80% who die from COPD in the United States are smokers.[83] Among these individuals, however, there is variable susceptibility to the effects of cigarette smoke, and other factors also contribute to risk. These other risk factors, which vary greatly among different populations, are estimated to contribute between 27% and 60% of the overall risk for COPD mortality.[93]

Other Exposures

Occupational exposures are also associated with increased risk for accelerated loss of lung function. Whereas the effect of occupational exposures has been stated to be small compared with the effect of cigarette smoking,[95] a recent study attributes nearly 20% of COPD risk to occupational exposures among smokers and more than 30% among nonsmokers.[96] Farming or work in dusty occupations increases the risk of developing chronic bronchitis two- to threefold and, in combination with smoking, the risk increases to sixfold.[97,98] Environmental air pollution, especially due to particulates, may contribute to accelerated decline in lung function,[99] and episodes of increased pollution may contribute to increased mortality.[100] Indoor air pollution, particularly from exposure to smoke generated from the use of biomass fuels, is a major cause of COPD in the developing world.[101] Systemic exposures have also been suggested to play a role. Cadmium is increased in the urine of individuals with COPD[102] and can lead to COPD in animal models. However, because cadmium is present in cigarette smoke, the role of environmental cadmium is not yet defined.

Genetic Susceptibility

COPD most often results from harmful environmental exposures, most importantly, the chronic inhalation of cigarette smoke, in a genetically predisposed individual. Familial aggregation of airflow obstruction has been observed in smokers, suggesting a genetic component. With respect to specific genes, mutations in the serine proteinase inhibitor, alpha$_1$-protease inhibitor (A1PI) (discussed later) represents the only proven genetic abnormality that predisposes to COPD.[12,103] Of note, cigarette smoking markedly accelerates loss of lung function in patients with A1PI deficiency as well.[104]

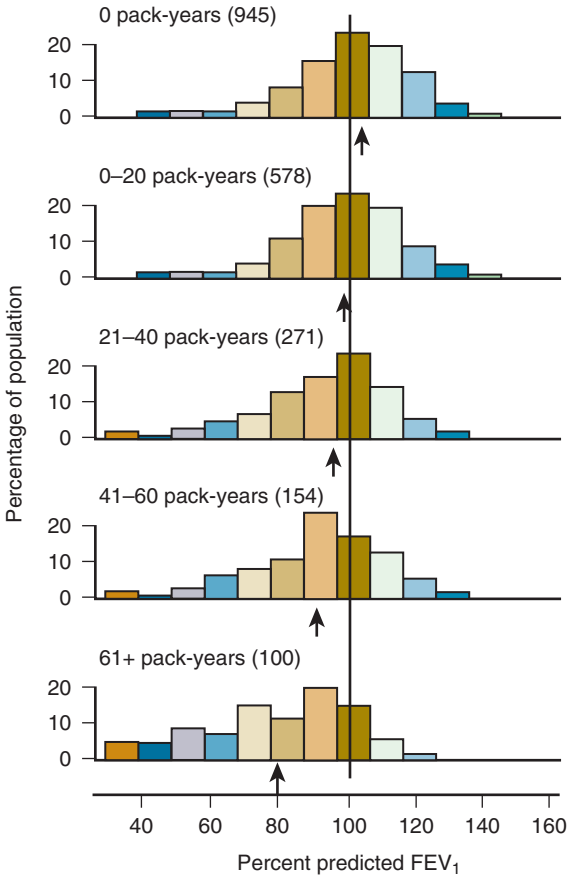

FIGURE 39-6 ■ Distribution of FEV_1 values (as % predicted) in subjects with varying pack-years of smoking. Subjects with "respiratory trouble" before age 16 were excluded. Medians (*arrows*) are shown for each smoking group with numbers of patients in parentheses. (Redrawn from Burrows B, Knudson RJ, Cline MG, Lebowitz MD: Quantitative relationships between cigarette smoking and ventilatory function. Am Rev Respir Dis 115:751–760, 1979.)

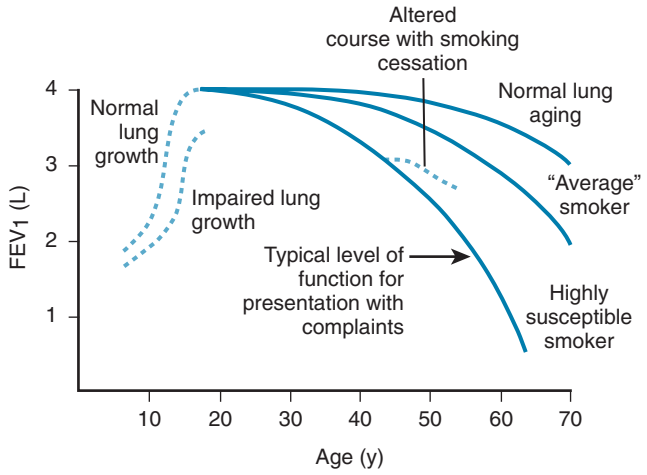

FIGURE 39-7 ■ Natural history of COPD. Lung function increases with growth in childhood and adolescence. Fetal and childhood events can affect lung growth and development, resulting in reduced maximally attained lung function, for convenience shown here as an FEV_1 of 4 liters. Actual predicted values depend on height and gender. After growth is completed, lung function remains constant for some time, the "plateau phase," after which lung function declines at an accelerating rate with age. Smoking reduces the duration of the plateau phase and accelerates the rate of lung function loss. Smoking cessation early in the course of the disease can reduce the rate of lung function loss to that of a nonsmoker. Patients typically present with symptoms when lung function declines below 50% of that in young adulthood but may have limitation much earlier. (See text for details.)

There are probably many other genetic determinants of COPD. Association studies comparing candidate genes in patients with COPD versus control subjects have identified a variety of potential genes. However, these studies are often underpowered and are not adequately controlled. Hence, no gene has been shown unequivocally to be involved in COPD by a candidate gene analysis. Linkage analysis of early-onset COPD families, a more robust method of identifying COPD genes, has identified linkage of airway obstruction to several chromosomal regions.[105] The search is on to narrow these regions to specific genes. The first gene identified by this technique is serpin E2 on chromosome 2.[106] Interestingly, this gene, like A1PI, is a serpin or serine proteinase inhibitor. However, unlike A1PI, serpin E2 is not an elastase inhibitor, suggesting a novel disease pathway. A large genome-wide association study for COPD has recently been launched. This newer technique is complicated but does not require candidate genes to uncover COPD genes throughout the genome.

Early Life Events

Maternal smoking may be a risk factor for the development of COPD, because it has been associated with low birth weight and an increased incidence of respiratory illnesses, including asthma, in children.[107,108] Studies have suggested that both low birth weight and childhood respiratory infections are risk factors for the development of COPD, although these findings are not uniformly reproduced.[108–112] Consistent with the concept that early life events contribute to COPD risk, maximally attained lung function (which is likely related to early lung growth and development) appears related to the risk of development of COPD.[113]

Asthma

As noted previously, the suggestion that asthma can progress to COPD has come to be known as the Dutch hypothesis.[114] Several epidemiologic studies have demonstrated accelerated loss of lung function among asthmatics,[115,116] although it may be that all of the risk is in a subset of asthmatics.[117] Functional changes in both the small airways[118] and the alveolar parenchyma[119] have been reported. Whether airway hyperresponsiveness itself, apart from asthma, is a risk factor remains controversial.[120]

Mucus Hypersecretion

The concept that mucus in the airways could contribute to the development of fixed airflow limitation became known as the "British hypothesis."[2] A classic study of British postal workers was conducted to evaluate this hypothesis, and Fletcher and colleagues[2] concluded that there was no effect of mucus hypersecretion on loss of lung function, after correction for smoking. More recent studies in larger cohorts, however, suggest that mucus hypersecretion does have an effect, though small.[121] Similarly, individuals who experience more frequent acute exacerbations also appear to have a more rapid decline in lung function.[122]

Gender

COPD prevalence shows a gender predominance that is largely related to the demographics of exposure to cigarettes or other inhaled toxins within a population. This accounts for the historically increased prevalence among men. The most recent estimates, however, suggest that COPD is equally prevalent among women in many populations (see Fig. 39-5).[93] Compared to men with COPD, women do appear to have different comorbidities, with a lower prevalence of ischemic heart disease but a higher prevalence of CHF, osteoporosis and diabetes.[123]

Socioeconomic Status

Morbidity and mortality rates have been shown to be inversely related to socioeconomic status, and this relationship has been documented repeatedly in studies over several decades.[93,124,125] A mechanism for this association has not been established. However, it is likely that the relative lack of diagnostic effort and lack of coverage for COPD therapy is, in part, connected to the socioeconomic status of the affected population.

NATURAL HISTORY

Factors that contribute to the natural history of COPD include early life events such as intrauterine lung development and childhood and adolescent lung growth as well as later events such as adult lung exposures. The natural history of COPD, therefore, extends over the entire life span of the individual; in fact, potential effects could precede conception. To date, no longitudinal studies have tracked the entire course of the natural history of COPD. Longitudinal studies have been conducted, but generally for a limited number of years.[126] The classic monograph of Fletcher and colleagues,[2] for example, was a longitudinal study of 8 years. The "natural history" was based on an extrapolation of the collected data. The resulting picture of the natural history of COPD, which is so widely used that a plot of FEV_1 versus age is commonly called a "Fletcher-Peto curve," is also limited by the fact that Fletcher and colleagues did not consider the nonsmoker with COPD. In addition, Fletcher and colleagues were fully aware of the extra-pulmonary features of COPD, but these are not included in the famous curve. Nevertheless, the image of COPD natural history illustrated in the Fletcher-Peto curve helps describe several key clinical issues.

Because COPD develops slowly, the early stages of the illness are often "silent." Exertional dyspnea in COPD patients is believed to result, in large part, from dynamic hyperinflation, which develops with increasing respiratory rate.[127] The COPD patient, therefore, can avoid dyspnea by avoiding tachypnea, which can be achieved by decreasing exercise. As a result, COPD patients become progressively more sedentary. The lack of activity in COPD patients results in severe muscle detraining. Whether skeletal muscle is also abnormal because of the effects of systemic inflammation or systemic vasculopathy is currently debated.[128,129] What is clear is that muscle weakness is a major feature of COPD and often limits exercise more than dyspnea does. This may help explain the observation that health status (sometimes termed "quality of life") is more closely related to exercise performance than to lung function.[130]

Little is known about the natural history of COPD beyond the FEV_1. Several ongoing longitudinal studies, however,[131,132] promise to help define the "Fletcher-Peto curve" by tracking other features of the COPD patient over time. Nevertheless, despite the large gaps in understanding the natural history of COPD, particularly for effects outside the lung and for exposures other than cigarette smoking, a number of important features have been described.

Lung Growth

In the human, the conducting airways are developed by the 16th week of gestation.[133] Gas exchange structures, including respiratory bronchioles and alveoli, develop subsequently. Some alveoli are present at birth, but branching of alveolar wall continues postnatally for several years. Alveolar number does not increase after age 8, and subsequent growth of the lung is due to increase in alveolar size. The airways increase in diameter, but not in number, throughout this later growth process. As a result, maximal lung function is attained in young adulthood. This level of function remains relatively constant for perhaps 10 years and then begins to decline in a slowly accelerating manner.[113] Over 50 years of adult life, a normal individual may lose 1 L of FEV_1, a decline that averages 20 mL/yr, but this decline is not linear and probably accelerates with increasing age.

Cigarette Smoking

Smoking affects this natural history in several ways. First, smoking during the years of lung growth reduces maximally attained lung function.[134] Second, the "plateau phase" is reduced in duration and may be absent.[135] Finally, the rate at which lung function declines is probably increased.[2] Because lung function declines faster with advancing age, this could represent either a shift in the "normal" age-related changes to a younger group or a different pathologic process. As a result of these various

effects, the average smoker loses about 2 L of FEV_1 over 50 years, an average decline of about 40 mL/yr, although there is considerable variation in the rate of lung function decline. How other causative factors affect the natural history of COPD is not defined. Smoking cessation in adulthood can slow the rate of decline among individuals with mild COPD.[136] Whether such benefits can be expected among individuals with more severe disease or in the elderly is unclear,[137] although smoking cessation has many other established benefits.[138]

Decline in lung function, moreover, may not be continuous. Exacerbations, which are characterized by acutely compromised lung function, may not completely resolve and may result in stepwise decrements of lung function.[114] Finally, some individuals may experience a rapid decline in lung function. Starvation, for example, has been reported to cause the accelerated development of emphysema in both animal models and humans.[139]

Individuals who are "rapid decliners" have been observed in prospective studies.[140] Compared to those with a more normal FEV_1, those with a low FEV_1 probably had, and will continue to have, a more rapid rate of decline of FEV_1 and will be more likely to develop COPD, a prediction known as the "horse-racing effect" (analogous to a prediction that, at a given point in the race, the horse in the lead was the fastest, will continue to be the fastest, and is more likely to win)."[141] Interestingly, prospective studies have found that decrease in lung function is more rapid in individuals with less severe COPD.[142,143] Identification of slow and rapid decliners in longitudinal studies such as the Lung Health Study has allowed investigation of biomarkers to distinguish these groups and to define the mechanistic bases for lung function decline.[144,145] Importantly, systemic markers of inflammation have been associated with poorer lung function[146,147] and, in some[148,149] but not all studies,[150] with an increased rate of decline in lung function.

Early Disease

Treatment goals in COPD are largely focused on alleviation of symptoms. Because patients with early disease often have no complaints, the importance of identifying individuals with early disease was not recognized until recently. The 1995 American Thoracic Society (ATS) guidelines, for example, incorrectly suggested that it was not necessary to diagnose such individuals.[151] However, individuals with mild lung function compromise have increased mortality, which is primarily due to acute cardiac events.[65,66] This relationship is true for both smokers and nonsmokers.[152] The link between cardiac events and mild COPD may be systemic inflammation. Identifying a group of individuals with increased cardiac risk, and identifying that they may need treatment to benefit maximally from an exercise training program, has potential clinical benefit.

Advancing Disease

As FEV_1 declines, risk for mortality increases. Cardiac events remain a major cause of death, even when COPD is severe. The relative incidence of death due to respiratory causes, however, increases with increasing severity of lung function compromise. Exacerbations, which increase in frequency as FEV_1 declines, are times at which individuals are at particular risk for death. Mortality is also increased among those who have recovered from an exacerbation. The 2-year mortality rate for patients admitted for acute exacerbation of COPD with CO_2 retention in the SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) trial was 49%.[153] In a retrospective study of a large Canadian database, 1-year mortality of 30% to 40% was observed following hospitalization for COPD exacerbation among individuals over the age of 65, although survival may have been influenced by treatment.[154] However, studies from several centers have shown that some patients with severe obstructive airway disease may survive for many years.[155–158] Thus, it is not possible to predict the course of an individual with a high degree of certainty. Decisions relating to level of care and end-of-life issues, therefore, must be individualized and must be based on many factors in addition to lung function.

PATHOLOGY

Airway Disease—Chronic Bronchitis

Bronchi

A number of morphologic changes in the bronchi have been described in chronic bronchitis.[159] The submucosal glands reveal dilated ducts and hypertrophy and hyperplasia of their glandular elements (Fig. 39-8). The traditional way of measuring glandular enlargement is the Reid index or the ratio of glandular to bronchial wall thickness.[5] Goblet cell frequency is also increased. Patchy areas of squamous metaplasia and dysplasia may replace normal ciliated epithelium.[160] The amount of airway smooth muscle is increased.[161,162] The airway wall contains an infiltrate of inflammatory cells in which monocytes and lymphocytes, especially $CD8^+$ T cells, are prominent.[163,164] BALT (bronchus-associated lymphoid tissue) is also present in late GOLD stages.[165] Whether BALT is related to autoimmune phenomena or is a marker of bacterial colonization is not clear. This inflammation contrasts with the $CD4^+$ Th2 cells that are prominent in asthma.

Neutrophils are more frequently found in the airway lumen[166] and in the glands[167] than in the airway wall. Neutrophil numbers increase with exacerbations. Eosinophils may be present, but are much less common than in asthma,[168] although eosinophils may increase during exacerbations.[169]

Bronchioles

The respiratory bronchioles that represent airways less than 2 mm in diameter are the primary sites of physiologic airway obstruction with narrowing[165,170] (Fig. 39-9). The airway remodeling processes are similar to those in the larger airways involving goblet cell metaplasia with

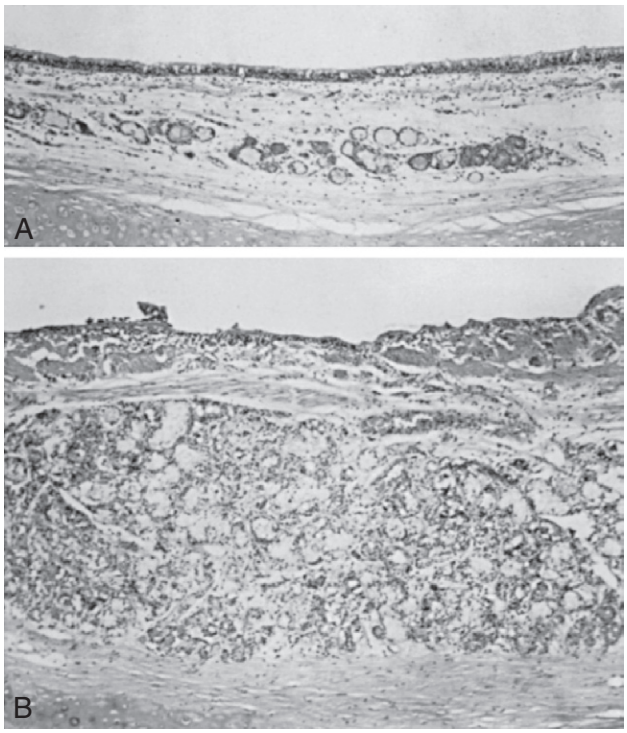

FIGURE 39-8 ■ Photomicrographs show the left main bronchus from a patient without respiratory symptoms (**A**) and from a patient with many years of productive cough and airflow obstruction (**B**). Serous acini (*dark staining*) and mucous acini (*light staining*) constitute the submucosal gland in **A**. The average gland thickness represents about one third the distance between the epithelial basement membrane and the perichondrium. The submucosal gland in **B** is markedly thickened, is made up mostly of mucous acini, and constitutes most of the wall thickness between the epithelial basement membrane and the perichondrium; note also that the epithelium shows desquamation. (From Snider GL [ed]: Clinical Pulmonary Medicine. Boston: Little, Brown, 1981.)

mucus plugging, inflammation, smooth muscle hyperplasia, and fibrosis. Smoking leads to a predominantly mononuclear inflammatory process[170,171] in the small airways and lung parenchyma. Destruction of lung parenchyma may lead to loss of alveolar attachments, predisposing to small airway collapse.[172,173]

Emphysema

Emphysema is characterized by destruction of gas-exchanging air spaces including respiratory bronchioles, alveolar ducts, and alveoli. Cigarette smoking leads to inflammatory cell recruitment, proteolytic injury to the extracellular matrix (ECM), and cell death. Alveolar walls become perforated and later, in the absence of repair, become obliterated with coalescence of small distinct air spaces into abnormal and much larger air spaces.[174]

Pulmonary emphysema, defined as destruction and enlargement of air spaces distal to the terminal bronchiole, may be contrasted with a variety of developmental abnormalities in alveogenesis leading to impaired septation and alveolarization with consequent enlarged air spaces. "Simple air space enlargement," in which there is no destruction or loss of orderly appearance of the lung acinus, also occurs in the contralateral lung following pneumonectomy. Air spaces, particularly alveolar ducts, enlarge with advancing age, resulting in what has been termed "senile emphysema."

Localization of the lesions of mild emphysema in the acinus serves as the basis for classification into several types of emphysema (Table 39-4).[175] The acinus or secondary lung lobule is the unit of lung structure distal to the terminal bronchiole. The acinus is composed of three to five orders of respiratory bronchioles, which have alveoli originating directly from their walls (Fig. 39-10). All of the structures distal to the terminal bronchiole participate in gas exchange and constitute

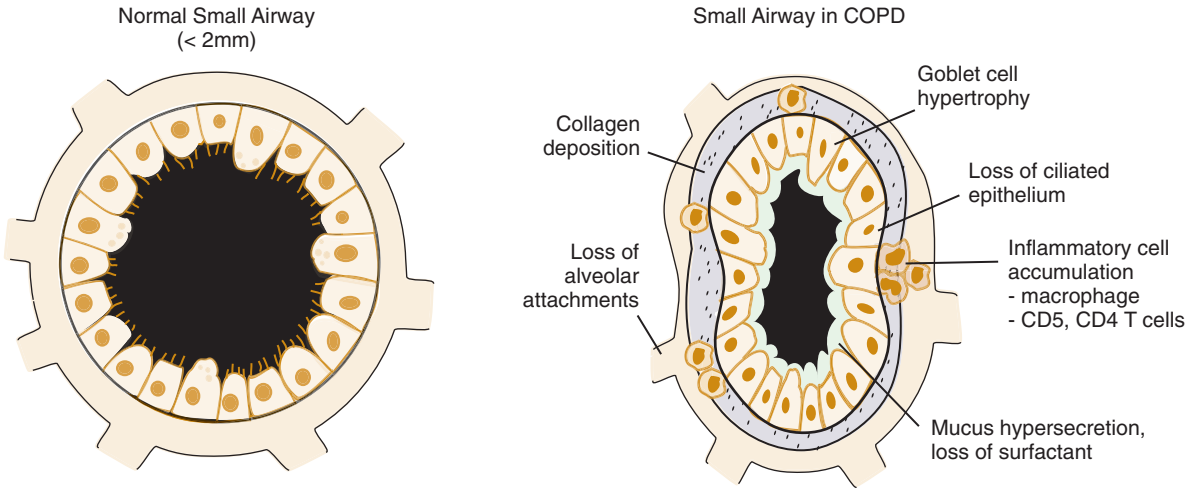

FIGURE 39-9 ■ Small airway obstruction in COPD. In contrast to a normal small airway (*left*), a variety of factors lead to narrowing of the airway lumen in COPD. These changes include mucus hypersecretion, inflammatory cell accumulation, and fibrosis (collagen deposition). Loss of surfactant and loss of alveolar attachments predispose to airway collapse. (Redrawn from Shapiro SD: Evolving concepts in the pathogenesis of chronic obstructive pulmonary disease. Clin Chest Med 21:621–632, 2000.)

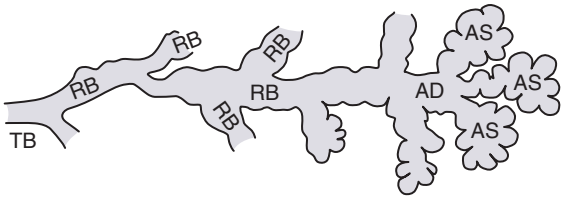

FIGURE 39-10 ■ Normal respiratory air spaces. The terminal bronchiole (TB) leads into several orders of respiratory bronchioles (RB), which in turn open into alveolar ducts (AD) and alveolar sacs (AS). The respiratory air spaces arising from a single terminal bronchiole constitute the secondary lung lobule or acinus. Centriacinar (or centrilobular) emphysema begins in first-order respiratory bronchioles, hence its central localization in the secondary lung lobule. Panacinar (or panlobular) emphysema involves all the respiratory spaces. (Redrawn from Snider GL [ed]: Clinical Pulmonary Medicine. Boston: Little, Brown, 1981.)

the respiratory tissues of the lungs. The description of subtypes of emphysema based on location and distribution has been useful. In most patients, however, the process within the lung will be heterogeneous.

The most important types of emphysema are centriacinar (or centrilobular) and panacinar (or panlobular). The anatomic patterns of emphysema suggest specific pathogenetic mechanisms. The use of CT scans now allows the clinician to more carefully define the type of emphysema and to quantify it better.[176–180]

Proximal Acinar Emphysema

Proximal acinar *emphysema* refers to those types of emphysema that begin in the respiratory bronchioles.[159,181] Scarring and focal dilation of the bronchioles and of the adjacent alveoli result in the development of an enlarged air space or microbulla in the center of the secondary lung lobule. Air space enlargement spreads peripherally from the centriacinar region. This type of emphysema includes focal emphysema and centriacinar emphysema.

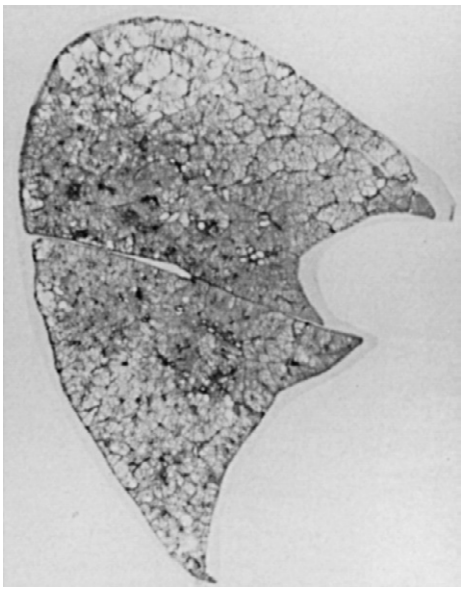

FIGURE 39-11 ■ Centriacinar emphysema is shown. Mounted section of inflation-fixed left lung shows centriacinar emphysema. The disruption of respiratory air spaces is present in the basilar segments of the left lower lobe and lingula but is locally most severe in the apical-posterior segment of the upper lobe and superior segment of lower lobe. (From Snider GL [ed]: Clinical Pulmonary Medicine. Boston: Little, Brown, 1981.)

Focal Emphysema

A form of centriacinar emphysema, occurring in persons who have had heavy exposure to a relatively inert dust such as coal dust,[182] is called *focal emphysema*. Large numbers of pigment-laden macrophages are noted in association with focal emphysema, which is distributed through the lungs.

Centriacinar Emphysema

Centriacinar emphysema is the form of emphysema most frequently associated with prolonged cigarette smoking in persons who have had no unusual dust exposure.[183] This lesion involves the upper and posterior portions of the lungs more than the lower portions (Figs. 39-2 and 39-11).[184,185]

Panacinar Emphysema

The term *panacinar emphysema* refers to dilation of all of the respiratory air spaces of the secondary lung lobule. This form of emphysema may be either focal or diffuse; in the focal form, lesions are more common at the lung bases than at the apices and are often seen in older persons.[165,186] Panacinar emphysema also commonly occurs in the lung bases of smokers in association with centriacinar emphysema in the lung apices. As the disease process becomes more severe, the lesion becomes indistinguishable from centriacinar emphysema.[186,187]

Diffuse panacinar emphysema is the lesion most often associated with A1PI deficiency; the emphysema is

usually more severe at the bases than at the apices. Congenital lobar overinflation or emphysema results in infancy from bronchial atresia, most often in the apicoposterior segmental bronchus of the left upper lobe; available information suggests that the accompanying emphysema is panacinar in type.[79] A group of young (average age about 35 years) intravenous Ritalin (methylphenydate tablet) abusers with severe airflow obstruction and severe panacinar emphysema has been described.[188]

Distal Acinar Emphysema

In contrast to other forms of emphysema that tend to be generalized, *distal acinar emphysema*, which is also known as *paraseptal* or *subpleural emphysema*, is localized along fibrous interlobular septa or beneath the pleura. The remainder of the lung is often spared, so pulmonary function may be normal or nearly so despite the presence of many superficial areas of locally severe emphysema.[79,189] This is the type of emphysema that produces the apical bullae giving rise to simple spontaneous pneumothorax in young persons, as described in Chapter 74.

Air Space Enlargement with Pulmonary Fibrosis

Another type of localized emphysema, *air space enlargement with pulmonary fibrosis*, is commonly seen as an inconsequential lesion adjacent to scars. At times, the air space enlargement may be quite extensive and may be important clinically, arising as a complication of fibrosing diseases such as tuberculosis, silicosis, and sarcoidosis.[159,190] The underlying disease is usually evident radiographically, with extensive linear or nodular shadows evident along with the enlarged air spaces. Air space enlargement with fibrosis is the anatomic lesion underlying emphysema associated with the pulmonary apical cap.[191] Honeycombing or the end-stage of interstitial lung disease is different from air space enlargement with fibrosis. In honeycombing, cystic spaces 0.5 to 2 cm in diameter are located mainly in the periphery of the lung, although they can sometimes be widespread. The spaces have dense fibrous walls and are mostly lined by bronchiolar epithelium.[192] To differentiate air space enlargement due to fibrosis from COPD, definitions of COPD are used to exclude fibrosis. However, this is problematic because scarring, particularly in the small airway subepithelial space, is often a consequence of cigarette smoking and a contributing factor to airflow obstruction in COPD. In addition, collagen accumulates around larger disrupted air spaces. Hence, fibrosis and emphysema might be less distinct than we have previously believed.

Bullae

Bullae are areas of marked focal dilation of respiratory air spaces that may result from coalescence of adjacent areas of emphysema, from locally severe panacinar emphysema, or from a ball-valve effect in the bronchi supplying an emphysematous area.[79,159,183] The bullae may be simple air spaces or may retain the trabeculae of the emphysema that led to them. Most frequently, bullae occur as a part of widespread emphysema. Although locally severe emphysema of any type can give rise to bullae, giant bullae are particularly likely to complicate distal acinar emphysema. In the setting of bullae, the amount of emphysema in adjacent lung without bullae varies. In distal acinar emphysema, the emphysematous changes may be confined to the bullous areas; however, if these bullae become large and compress adjacent lung tissue, they may have important physiologic consequences.

Blebs and Cysts

Blebs are intrapleural collections of air and are, therefore, a form of interstitial emphysema. They may be a complication of interstitial emphysema in the newborn period or a complication of pulmonary barotrauma complicating mechanical ventilation. They may also be a part of the spontaneous pneumomediastinum of adults. Ruptured blebs are a cause of spontaneous pneumothorax.[79,159,183]

Cysts in the lung are air spaces lined by epithelium, which usually have the characteristics of bronchial epithelium.[193,194] They are classically known as intrapulmonary bronchogenic cysts and usually occur near the tracheal bifurcation, but they may be seen more peripherally in the lung parenchyma. Air spaces with fibrous walls, as seen in sarcoidosis and open healed of tuberculous cavities, are sometimes referred to as "cysts." As described previously, they are better referred to as "air space enlargement with fibrosis."

Structure-Function Correlations

The Cause of Airflow Limitation in Chronic Obstructive Pulmonary Disease

The mechanical principles underlying airflow limitation are presented in Chapter 5, and the pulmonary function tests used to evaluate airflow limitation are discussed in Chapter 24. Airflow is not obstructed by bronchial gland enlargement,[195–197] perhaps because the process gives rise to only slight thickening of the mucosa and minimally encroachment of the lumen of the cartilaginous airways. In contrast, airflow is reduced by narrowing of airways due to smooth muscle contraction, narrowing of airways, particularly the small airways, due to peribronchial fibrosis, and destruction of the alveolar wall that results in loss of lung elastic recoil and loss of tethering of small airways, thus permitting small airway collapse during expiration. In a given individual, it may be difficult to distinguish among these mechanisms. Emphysema and bronchiolitis commonly appear together in moderate or severe COPD.

Small airway obstruction has the strongest correlation to airflow obstruction. The internal diameter of respiratory and membranous bronchioles correlates strongly with FEV_1 percent predicted (r = 0.79 and 0.82, respec-

tively).[197,198] The relationship between airflow limitation and bronchiolar pathology persists as airflow limitation and emphysema become moderate in severity, but the strength of the association is less. Airway disease may be a more important determinant of airflow limitation in mild COPD and emphysema more important in severe COPD. This is consistent with autopsy studies that suggest emphysema is the major determinant of airflow limitation.[170,199,200] It also suggests that the various lesions associated with airflow limitation in COPD may have differing natural histories.

Compliance and Lung Volumes in Emphysema

Increased compliance of the lungs was first described in severe emphysema in the 1930's.[201,202] Even in mild emphysema, elastic recoil pressures are consistently decreased.[203] There is increased lung distensibility with an accompanying increase in total lung capacity, functional residual capacity, and residual volume and a decrease in vital capacity. However, the correlations between measures of the whole lung volume-pressure relationship with the pathologic severity of emphysema are relatively weak.[204,205] This may reflect the heterogeneity of emphysema within the lung while the volume-pressure relationship assesses whole-lung function. In addition, the air spaces of centriacinar emphysema may be less compliant than normal lung and much less compliant than the emphysematous lung around them.[204] This may reflect lung destruction that results in maximal expansion of selected areas. These fully expanded regions, paradoxically, are not compliant because they cannot expand further.

Carbon Monoxide Diffusing Capacity

The D_{LCO}—whether measured by the single-breath or steady-state method and whether values are expressed in absolute terms, as percent predicted, as a function of alveolar volume, or as fractional uptake of carbon monoxide—has consistently been a solid functional predictor of the severity of emphysema.[183,190] The correlation coefficients have ranged between 0.60 and 0.87. This relationship probably reflects the loss of internal surface area and of the capillary bed of the lung with emphysema. However, this test is neither a specific nor a sensitive test of mild emphysema. Interestingly, whereas the D_{LCO} increases in normal subjects in the supine or prone position, it fails to increase in COPD patients, possibly due to loss of capillary capacitance or capillary volume.[206]

PATHOGENESIS

Chronic Obstructive Pulmonary Disease

Small Airway Obstruction

Chronic bronchitis refers to symptoms of chronic sputum production. This is mainly a manifestation of large airway disease and is not associated with airflow obstruction. However, small airway obstruction, obstruction of bronchioles less than 2 mm diameter, which is probably caused by similar mechanisms that lead to chronic bronchitis, is a major factor in airflow obstruction in COPD. Our understanding of the pathogenesis of airway disease is much less complete than our understanding of emphysema. This probably relates to the fact that the airways in small animals are less similar to human airways than are the alveoli, hence making small animal modeling of the airway in COPD imperfect.

Whereas cigarette smoke may lead to similar types of injury and inflammation in the airway as in the airspaces, the manifestations are distinct. CT scanning has shown that emphysema and airway abnormalities are fairly independent processes, suggesting distinct pathophysiologic mechanisms, although both lead to airflow obstruction.[179,180] Airway remodeling in patients with COPD leads to physical narrowing of the airway resulting in airway obstruction. As mentioned previously, major remodeling events include goblet cell hyperplasia with excessive mucus production, epithelial dysplasia, smooth muscle hypertrophy, airway fibrosis, and inflammation including BALT in late GOLD stages.

Airway Inflammation

The airways in patients with COPD are characterized by increased numbers of neutrophils, monocytes, and lymphocytes. The numbers of $CD8^+$ T cells and B cells, in particular, grow with increasing severity of COPD.[207] Oxidants and other particulates in cigarette smoke induce epithelial cells and constitutive macrophages to release cytokines and chemokines that activate the innate as well as adaptive immune response. A recent concept is that COPD may in part be an autoimmune disease.[207,208] Infectious agents also activate the immune system during exacerbations.

Goblet Cell Metaplasia

Structural changes, including glandular hyperplasia and increased number of goblet cells, occur in COPD and are responsible for increased mucus production. Neutrophil elastase not only causes elastin destruction in the lung parenchyma but also acts as a potent secretagogue working via cleavage of membrane tethered transforming growth factor-α (TGF-α) that activates the epidermal growth factor receptor (EGFR), leading to expression of the MUC5AC mucin.[209,210] Other factors such as oxidants[211] and matrix metalloproteinases (MMPs)[212] may also induce EGFR-mediated mucus production.

Epithelial Injury, Repair, and Fibrosis

A variety of insults to the airway epithelium may lead to endoplasmic reticulum stress and potentially to cell death.[213] Analogous to skin wound healing, the lung likely can restore epithelial integrity. In the skin, fibroblasts lay down a provisional matrix. Neighboring epithelial cells and perhaps stem cells are rapidly recruited, resulting in cells that proliferate, migrate over the provisional matrix via cell-matrix interactions, and then differentiate. Signals from the epithelium turn off fibroblast

proliferation, resulting in a restored epithelial barrier. This suggests that the repair process involves interactions involving epithelial cells, mediators present within the local milieu, and the local extracellular proteinases and matrix.

Aberrant repair can fail to "turn off" the fibroblast response or lead to epithelial mesenchymal transformation,[214] leading to peribronchial fibrosis that contributes to expiratory airflow limitation.[165,172] In this regard, a general property of fibrotic tissues is contraction. In the skin, this may serve to limit wound size and to maintain structural integrity. In a parenchymal organ, this contraction may lead to tissue distortion. In the airway, this process may be responsible for the airway narrowing that characterizes airflow limitation in mild to moderate COPD. Of note, fibroblasts can contract three-dimensional collagenous matrices, and this process can be modulated by exogenous mediators. Interestingly, epithelial cells can both regulate fibroblast contraction of collagenous matrices[215] and contract the matrices themselves.[216] This suggests that interactions between the epithelium and the mesenchyme in the airway may be important in regulating airway luminal diameter. In asthma models and perhaps also in COPD, abnormal stretch exerted on the epithelium alone may induce release of profibrotic growth factors.[217] MMP-9 produced by activated epithelial cells proteolytically activates TGF-β, further contributing to airway fibrosis.[218]

Exacerbations

Pathogens first encounter innate host defense including mucociliary clearance, the epithelial barrier, constitutive host macrophages, and rapidly accumulating neutrophils. Tobacco smoking impairs macrophage phagocytosis, and airway remodeling interferes with mucociliary clearance, each predisposing to airway colonization and acute infectious bacteria and viruses.[219]

Chronic infections with a variety of pathogens including adenovirus[220] or *Chlamydia*[221] may lead to increased chronic inflammation. A similar role has been suggested for chronic bacterial colonization of the airways. The increased chronic inflammation can potentially predispose both to loss of lung function and to increased risk for acute exacerbation. Finally, acute infections with viruses[222] and bacteria[219] are major causes of acute exacerbations. These exacerbations, moreover, may have adverse effects. Individuals with frequent exacerbations appear to lose lung function at an accelerated rate,[122] and exacerbations result in adverse effects on health status that may persist for months.[25]

Emphysema

The overall scheme (Fig. 39-12) that is emerging for the pathogenesis of emphysema is that cigarette smoke and, less commonly, other toxic particulates lead to inflammation with activation and release of elastases and other matrix-degrading proteinases. Cell death also occurs either as a result of altered ECM attachment or as a direct effect of smoke exposure.[223,224] In the absence of normal cellular and matrix repair, the disrupted air spaces disappear and coalesce, resulting in the air space enlargement that defines emphysema.[225]

Inflammatory Cells

Cigarette smoke leads to recruitment of several inflammatory and immune cell types in the air space.[174,226,227] Neutrophils rapidly accumulate in the lung in response

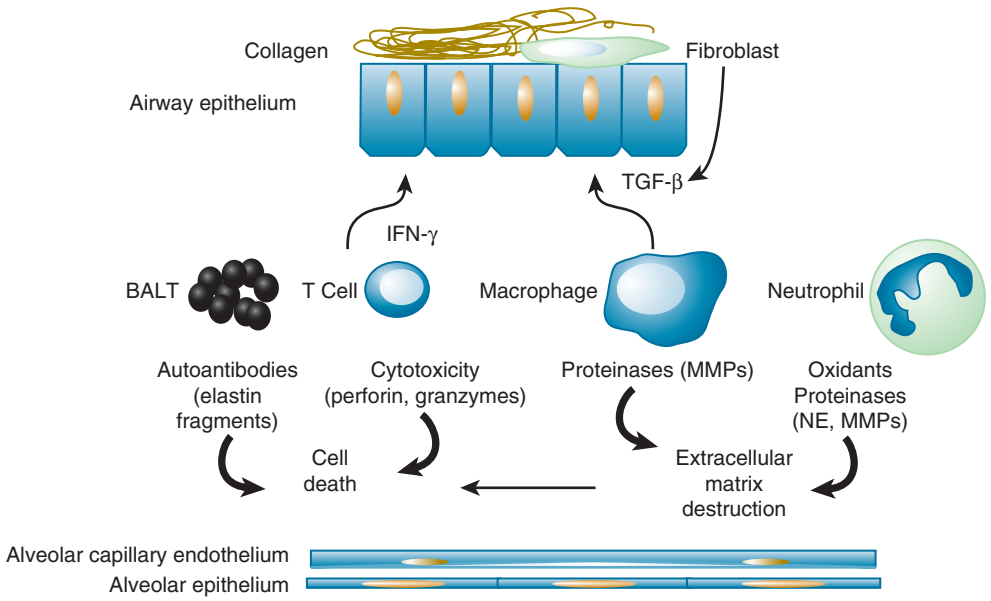

FIGURE 39-12 ■ Alveolar destruction and airway fibrosis in COPD. Loss of an alveolar unit requires destruction of the extracellular matrix by proteinases of macrophage and neutrophil origin, as well as cell death. Proteinases include matrix metalloproteinases (MMPs) and neutrophil elastase (NE). Cell death may occur via oxidant injury, via T-cell cytotoxic products (perforin and granzymes), via autoantibodies produced by bronchus-associated lymphoid tissue (BALT) or via loss of matrix attachment. Fibrosis of airways (and lung parenchyma) is also a feature of COPD. Production of interferon-γ (IFN-γ) by T cells and transforming growth factor-β (TGF-β) by several cell types contributes to accumulation of collagen.

to cigarette smoke. Recruitment occurs via stimulation of epithelial cells and macrophages by cigarette smoke, resulting in release of TNF-α and neutrophil chemokines CXCL1 and CXCL8 (IL-8) operating through the neutrophil receptor CXCR2.[227] Oxidants present in smoke and those generated by the inflammatory cells also promote neutrophilic inflammation.[224,228] Oxidants also play a role in cigarette smoke–induced cell death. Neutrophils contain proteinases that are preformed and stored in granules. Upon neutrophil activation, secondary and tertiary granules containing MMPs, particularly MMP-9, are readily released. Primary or azurophil granules that contain serine proteinases including neutrophil elastase (NE) are not readily released, although a portion of granules translocate to the cell surface upon activation where they are difficult to inhibit.[229] In addition to causing matrix destruction, proteinases from the neutrophil and other cells generate fragments of ECM proteins such as collagen[230] and laminin[231,232] that are also chemotactic for neutrophils, leading to a vicious feedback circle of inflammation and tissue destruction.

COPD is characterized by a gradual, progressive accumulation of macrophages in the lung. Prior to clinical disease, macrophage accumulation is most apparent in respiratory bronchioles, the primary site of centriacinar emphysema.[170] Activation of constitutive macrophages leads to production of both neutrophil chemokine and cytokines, as mentioned previously, as well as production of macrophage chemotactic protein-1 (MCP-1; CCL2), which recruits more monocytes from the peripheral blood, which later differentiate into macrophages.[227] In addition, proteolyzed elastin fragments are chemotactic for macrophages.[233,234] Macrophages have the capacity to produce a variety of MMPs, particularly elastases such as MMP-9 and MMP-12, and thus participate directly in lung destruction. Although macrophage activation promotes inflammation, it should also be recognized that removal of apoptotic cells by macrophages not only limits release of toxic products from dying cells but also results in the production of anti-inflammatory factors and growth factors such as TGF-β and human growth factor (HGF) that may promote tissue repair.[235,236]

Both $CD8^+$ and $CD4^+$ T cells are also increased in airway walls and alveoli of patients with COPD, with $CD8^+$ cells predominant.[164] Airway epithelial cells in smokers with COPD (but not those without COPD) have increased expression of CXCL10 (IP-10), the ligand for CXCR3[237,238] that is expressed on T cells and macrophages. Human studies[238] and animal models[239] show that CXCL10 triggers macrophages, via CXCR3, to produce MMP-12, demonstrating regulation of macrophage proteolysis by $CD8^+$ T cells. Cytotoxic T cells may target epithelial cells and induce cell death, particularly those with (latent) viral infection. Other hematopoietic cells such as dendritic cells, eosinophils, and mast cells have also been observed in COPD, but their roles in the disease process are less well defined.

Recognition of the increased numbers of B cells and lymphoid follicles in the lung has led to the notion of COPD as an autoimmune disease.[207,208] In fact, elastin fragments themselves have been shown to serve as autoantigens.[240] Immunoglobulin G (IgG) autoantibodies with avidity for pulmonary epithelium, and with the potential to mediate cytotoxicity, have also been detected in patients with COPD.[241]

Cigarette smoke both directly and indirectly initiates inflammation, but other factors sustain inflammation later in the disease process in the absence of cigarette smoke. Analysis of end-stage lung tissue obtained from lung volume reduction surgery (LVRS) years after smoking cessation has revealed intense inflammation composed of a variety of cell types.[242] The factors perpetuating inflammation are unknown but could include the presence of pathogens in the airway including colonizing bacteria and latent viral infection with adenovirus.[243,244] Also, as discussed, chemotactic matrix fragments generated by proteinases promote further inflammation.

In summary, multiple inflammatory cell types are present in the lung in response to cigarette smoking and interact to cause COPD. Focus on the innate and adaptive inflammatory-immune network will be required to abrogate inflammation and lung destruction in COPD.

Proteinase-Antiproteinase Hypothesis

Experimental evidence for the role of elastases in emphysema began in 1963 when Laurell and Eriksson[12] reported an association of chronic airflow obstruction and emphysema with deficiency of serum A1PI, the endogenous inhibitor of NE. In 1964, Gross and colleagues[245] intratracheally instilled papain, a plant-derived cysteine proteinase, into experimental animals, resulting in air space enlargement. Together, these observations indicated that emphysema could be induced by proteolytic injury to the lung ECM. These observations formed the basis for the elastase-antielastase hypothesis of emphysema, a concept that persists today.

Elastase-Induced Emphysema. Much of our knowledge of emphysema has come from instillation of elastolytic enzymes into lungs of experimental animals to induce emphysema. Treatment with human NE causes increased air space size and lung volumes,[246–248] but the changes are considerably less severe than those induced by doses of pancreatic elastase with comparable in vitro elastolytic effect. Different susceptibility to these two enzymes may relate to differing accessibility of the enzymes to alveolar elastic tissue,[249] or pancreatic elastase may have a greater ability to activate proteolytic and inflammatory cascades that amplify the initial proteolytic insult.[250]

Emphysema induced by porcine pancreatic elastase (PPE) causes an initial rapid increase in air space size due to direct elastolysis with diminution of lung elastin content at 24 hours followed by rapid restoration of total lung elastin to normal levels.[251] However, the anatomic arrangement of the restored elastic fibers is grossly disordered. The model is also characterized by inflammation with neutrophils and macrophages with subsequent release of endogenous inflammatory mediators including IL-1β and TNF-α with endogenous proteolytic progression of the disease for at least 1 month.[252]

The marked increase in total lung capacity in experimental (and human) emphysema is not likely to arise without disruption of the collagen network of the lungs. There is biochemical evidence of damage and subsequent repair of collagen in experimental elastase-induced emphysema. Elastase-induced emphysema is worse in animals fed diets that prevent lysyl oxidase cross-linking of elastin and collagen.[251] However, not all of the damage is proteolytic. Mechanical forces during breathing are capable of causing failure of the remodeled ECM at loci of stress concentrations and so contribute to the progression of emphysema.[253]

Although elastin is critical to the structural integrity of the lung, and only elastases instilled into the lung cause experimental emphysema, other matrix components such as collagen must also be lost for an alveolar space to enlarge. Thus, a broader concept is the proteinase-antiproteinase hypothesis, which states that the balance between matrix-degrading proteinases and their endogenous inhibitors determines whether the lung is protected or susceptible to proteolytic injury.

Of note, "microenvironmental" localization of proteinases and their inhibitors is an important concept. For example, release of proteinases from a cell in contact with the ECM may block inhibitors from preventing proteolysis.[254] Moreover, proteolytic degradation due to NE released from neutrophil granules takes place by "quantum proteolysis." That is, discrete release of granules results in very high concentrations of their contents at the site of release with decreasing concentrations at increasing distances from the site of release due to diffusion. Inhibition occurs as the concentration decreases with diffusion from the burst.[255] This has significant implications in A1PI deficiency in which inhibitor concentrations are low. Also, when proteinases such as NE and MMP-9 are bound to the surface of the neutrophil, they are resistant to complete inhibition by A1PI[229] and tissue inhibitors of metalloproteinases (TIMPs),[256] respectively. However, synthetic small-molecular-weight inhibitors will fully neutralize cell surface proteolytic activity.

Proteinases and Antiproteinases. There are four classes of proteinases, serine, cysteine, aspartic, and metalloproteinases, that are distinguished by their mechanism of catalysis and endogenous inhibitors.

Serine Proteinases. The serine proteinase NE was first implicated in COPD after the findings that patients deficient in its endogenous inhibitor, A1PI, are at increased risk for emphysema and that instillation of NE caused emphysema in experimental models. NE also plays a role in airway disease. In fact, NE is one of the most potent secretagogues known.[257] In addition, NE is involved in monocyte transvascular migration[258] and, in some instances, mediates neutrophil migration, although probably not simply by creating paths of degraded matrix. Despite intense interest in the development of NE inhibitors over the years, they remain largely untested in terms of their efficacy in COPD.

Mice deficient in NE are protected by two thirds from the development of emphysema in response to cigarette smoke.[258] The role of NE in emphysema is due to a direct effect of NE on elastin as well as to the ability of NE to inactivate TIMPs and mediate monocyte migration into the lung. NE-null mutant mice have also been helpful in defining the major physiologic function of NE, which is one of host defense. NE is a potent bactericidal and fungicidal agent that acts within the neutrophil lysosome.[259,260]

As the name implies, NE is produced mainly by neutrophils, but also to a small degree by monocytes. Two other serine proteinases that are also neutrophil- and monocyte-derived are cathepsin G (CG) and proteinase 3 (PR3). There is some evidence from animal models that PR3, which has some elastolytic capacity, may also be involved in the development of COPD.[261]

Serine proteinases are inhibited by A1PI, as alluded to earlier and discussed in detail later. Inhibition of A1PI ameliorates smoke-induced emphysema in mice.[262] $Alpha_1$-macroglobulin is a large-molecular-weight inhibitor of multiple classes of proteinases that is restricted to the bloodstream. Two smaller-molecular-weight inhibitors include secretory leukoprotease inhibitor (SLPI) and elafin. SLPI is a 12-kDa protein produced by mucus-secreting and epithelial cells in the airway as well as by type 2 pneumocytes. SLPI inhibits NE and CG, but not PR3. Elafin, also produced by airway secretory and epithelial cells, is released as a 12-kDa precursor that is processed to a 6-kDa form that specifically inhibits NE and PR3. These inhibitors are able to inhibit NE bound to substrate, giving them an added dimension that A1PI lacks.

Matrix Metalloproteinases. MMPs represent a family of 24 enzymes that require coordination of zinc at the active site, have overlapping substrate specificity, and are inhibited by TIMPs.[263] Several MMPs degrade elastin and hence are likely to contribute to emphysema including MMP-2, MMP-9 (gelatinase A and B), MMP-7 (matrilysin), and MMP-12 (macrophage elastase). MMP-1, -8, -13 are collagenases, and thus degrade another critical matrix component.

Several MMPs have been associated with human COPD including MMP-1, MMP-9, MT1-MMP, and MMP-12.[264–266] Macrophages have the capacity to produce MMP-1, MMP-3, MMP-7, MMP-9, MMP-12, and MMP-19. MMP-12 has been found in macrophages of smokers[267] and is one of the most highly up-regulated genes both in human smokers and in mouse models of emphysema.[268] MMP-9 has been detected in macrophages of smokers with COPD, to a greater degree than in "healthy" smokers, and has been a prime therapeutic target.[269] MMP-9 and MMP-8 (neutrophil collagenase) are also stored in neutrophil-specific granules. A search for genetic polymorphisms in Caucasians uncovered polymorphisms in the MMP-1 promoter region (the more active promoter had better lung function) and in MMP-12 that together correlated with the rate of lung function decline.[270]

Several animal models have supported roles for MMPs in COPD. Transgenic mice constitutively overexpressing MMP-1 were found to develop air space enlargement.[271] Mice lacking MMP-12 were resistant to long-term cigarette smoke–induced emphysema.[272] Subsequent studies have shown that mice deficient in $\alpha v\beta 6$ develop spontaneous emphysema over time.[273] In the absence of $\alpha v\beta 6$, there is no TGF-β activation. Because TGF-β normally

inhibits MMP-12, αvβ6-deficient mice have 100-fold excess MMP-12 expression over control mice and consequently develop emphysema. Mice that inducibly overexpress IL-13 develop inflammation and expression of MMP-9, MMP-12, and cathepsin S followed by emphysema.[274] This highlights the potential interactions between mediators of asthma and COPD. Of note, mice overexpressing IFN-γ, a Th1 cytokine, also develop cell death, inflammation, and air space enlargement.[274]

Cysteine Proteinases. The cysteine proteinase family includes several highly elastolytic enzymes.[275] Although predominantly intracellular enzymes that work most effectively in an acidic pH, several cysteine proteinases retain significant activity at neutral pH. Moreover, it is possible that cells have the capacity to acidify their immediate extracellular environment.[276] Overall, cathepsins are widely expressed in the lung. Cathepsin L, S, and K are macrophage products. In addition to ECM catalysis, a normal function of cathepsin S is to process antigens in T cells.[277] Cathepsin K is the most potent elastase and collagenase and, hence, might be quite destructive in COPD if present. Cathepsin B is an epithelial cell product that has been shown to have proapoptotic properties.[278]

Cathepsins are inhibited by cystatins, some of which are intracellular whereas others, such as cystatin C, are extracellular. Cystatin C is the most ubiquitous cystatin; it is found in all human tissues and body fluids tested, providing general protection against tissue destruction by intracellular cathepsin enzymes leaking from dying cells. Overall, cathepsins have the potential to contribute to COPD, although they have been less thoroughly studied than other classes of proteinases.

Proteinase Functions in Chronic Obstructive Pulmonary Disease. Cigarette smoke exposure leads to a variety of abnormalities in both the airways and the lung parenchyma that result in the syndrome termed COPD. A variety of proteinases participate in COPD, with their major role being destruction of ECM components, particularly elastin. However, proteinases also regulate inflammation, not only by blazing trails for cells through tissue barriers, but also via both the generation and the degradation of chemokines and cytokines. For example, ADAMs (a disintegrin and metalloproteinase) and select MMPs such as MMP-12 "shed" active TNF-α from the cell surface.[279] Epithelial-derived MMP-7 cleaves IL-8–bound syndecan, generating a chemotactic gradient for neutrophils following bleomycin lung injury.[280] MMPs also limit inflammation via processing of chemokines. For example, MMP-9 was shown to proteolytically process active MCP-3, resulting in maintained chemokine binding to its receptor but without the ability to transmit calcium influx or a chemotactic response.[281]

Within the airways, NE induces mucus secretion, as mentioned previously. This response is mediated by NE-dependent proteolytic activation of EGFR via a TGF-α–dependent mechanism.[209] MMP-9 has been shown to activate TGF-β and mediate airway fibrosis in an animal model of asthma[218] and probably also COPD. Thus, proteinases participate in multiple activities at several anatomic lung sites in the development of COPD.

Cell Death

Alveolar destruction resulting in air space enlargement requires loss of both cells within the alveolar space as well as the ECM components. Traditional theories suggest that the primary event is release of inflammatory cell proteinases resulting in degradation of lung ECM. Because cell viability requires cell-matrix attachment via integrins, loss of matrix disrupts the contact and predisposes to cell death (termed "anoikis"). Experimental models show that noninflammatory cell death can initiate air space enlargement. For example, inhibition of vascular endothelial growth factor receptor (VEGFR) in endothelial cells[223] and epithelial cells[282] of the lung or instillation of active caspase 3 in epithelial cells[283] results in cell death followed by air space enlargement in rodents. Following cell death, presumably, proteinases may be released directly or inflammation initiated that subsequently degrades the ECM. Thus, whereas COPD is characterized by inflammation and proteinase production, these events are not necessarily required for initiation of emphysema in experimental models. Whether these mechanisms play a role in human COPD is unknown; however, it has been shown that increased septal cell apoptosis is associated with reduced lung expression of vascular endothelial growth factor (VEGF) and VEGR receptor-2 in human emphysematous lungs.[284]

Repair

Destruction in emphysema is followed by aberrant repair of alveolar cells and matrix resulting in coalesced and enlarged air spaces with depleted and disordered parenchymal elastic fibers and excessive, abnormally arranged collagen. Whether adult humans can ever reinitiate the process of septation that was responsible for the intricate juxtaposition of matrix, epithelial, and endothelial cells to form functional alveoli during lung development is not clear. It should be noted that, in animal models of COPD, treatment with all-*trans* retinoic acid resulted in limited but significant repair.[285] It has been known for years that following pneumonectomy, there is compensatory lung growth of the remaining lung in humans and animal models.[286,287]

Elastin is the principal component of elastic fibers. Elastic fibers, which possess rubber-like reversible extensibility, come under tension and provide elastic recoil throughout the respiratory cycle. In the lung parenchyma, elastic fibers loop around alveolar ducts, form rings at the mouths of the alveoli, and penetrate as wisps into the alveolar septae where they are concentrated at bends and junctions.

Elastin[288] is secreted as a soluble protein of 60- to 70-kDa called tropoelastin, which is deposited into the extracellular space and aligned on a "scaffold" of microfibrils that consist of fibrillins, microfibril-associated proteins, and latent TGF-β–binding proteins. In the extracellular space, lysyl oxidase modifies lysine residues in tropoelastin monomers, causing them to cross-link and form elastin, a highly insoluble, rubber-like polymer.

The lysine-derived cross-links in elastin are known as desmosines and isodesmosines, which are unique to elastin, and therefore can be used to quantify elastin in tissues and to serve as markers of elastin degradation in body fluids.

Under normal conditions, elastin synthesis in the lung begins in the late neonatal period, peaks during early postnatal development, continues to a much lesser degree through adolescence paralleling lung growth, and stops in adult life.[289] There is evidence that the tropoelastin gene remains transcriptionally active but rapid mRNA degradation prevents expression of the protein.[290] Multiple cell types are responsible for elastin synthesis in the lungs and associated structures. Elastin is resistant to most proteinases and lung elastin normally lasts a human life span, despite virtually absent elastin synthesis in the normal adult lung.[289]

Following elastolytic injury, it is not known whether normal elastic fibers can be properly formed in the lung after the period of growth and development.[291] After an intratracheal injection of elastase into an experimental animal, there is acute depletion of elastin followed by a burst of ECM synthesis so that, over a few weeks, the elastin content of the lungs returns to normal, although the lungs develop emphysema. The newly synthesized elastic fibers appear disorganized, similar to the elastic fibers in human emphysema.[250,251] Less is known about the turnover of other ECM components in human lungs affected by COPD.

Collagen turnover in COPD is complex.[292] Total collagen content in the lung is actually increased in animal models of COPD and humans with COPD.[292] These findings suggest that emphysema is not purely a destructive process but one of aberrant matrix turnover. With loss of an alveolar unit, all local collagen is lost, but this is more than compensated for by excessive collagen deposition around the larger coalesced airspaces. Small airway fibrosis is also prominent in COPD.

Alpha$_1$-Protease Inhibitor Deficiency

Physiologic Role of Alpha$_1$-Protease Inhibitor. A1PI is a serpin or serine proteinase inhibitor that is a prominent protein in the serum. A1PI is also commonly known as alpha$_1$-antitrypsin. The protein is produced mainly in the liver, is found in high concentrations in the bloodstream, and permeates tissues including the lung. A1PI is also an acute phase reactant, with its serum concentration rising during pregnancy, during infections, after severe burns, and in the presence of malignant tumors. Smoking elevates the serum A1PI concentration by about 20%. Serine proteinases whose activities are inhibited by A1PI include pancreatic trypsin, chymotrypsin, NE, and proteases from some microorganisms.[293] However, its main substrate in vivo is believed to be NE.[294]

Genetic Variations. A1PI is a 52-kDa glycoprotein composed of 394 amino acids, and it is coded for by a single gene on chromosome 14. The serum protease inhibitor phenotype (Pi type) is determined by the independent expression of the two parental alleles. The A1PI gene is highly pleomorphic. More than 75 alleles are known, and they have been classified into normal (associated with normal serum levels of normally functioning A1PI), deficient (associated with serum A1PI levels lower than normal), null (associated with undetectable A1PI in the serum), and dysfunctional (A1PI is present in normal amount but does not function normally).[294]

Most variants of A1PI arise because of point mutations that result in a single amino acid substitution. The Z variant results from the substitution of a lysine for a glutamic acid,[295] which changes the charge of the molecule and, therefore, its electrophoretic mobility. The mutant protein can polymerize and the aggregated form can cause cell injury.[296,297] The Z protein is also incompletely glycosylated, which may interfere with the protein's excretion from the liver into body fluids.

The normal M alleles (the alleles are assigned a letter code) are found in about 90% of persons of European descent with normal serum A1PI levels; their phenotype is designated Pi MM. Normal values of serum A1PI are 150 to 350 mg/dL or 20 to 48 μmol. More than 95% of persons in the severely deficient category are homozygous for the Z allele, designated Pi ZZ, and have serum A1PI levels of 2.5 to 7 μmol (mean, 16% normal). Almost all of these persons are whites of northern European descent, because the Z allele is rare in Asians and African Americans. Rarely observed phenotypes that are associated with these low levels of serum A1PI include the following: Pi SZ and persons with nonexpressing alleles; Pi null, found in homozygous form as Pi null-null and found in heterozygous form with a deficient allele as Pi Z null. Persons with phenotype Pi SS have A1PI values ranging from 15 to 33 μmol (mean, 52% of normal). The threshold protective level of 11 μmol (35% of normal) is based on the knowledge that Pi SZ heterozygotes, with serum A1PI values of 8 to 19 μmol (mean, 37% of normal), rarely develop emphysema. Pi MZ heterozygotes have serum A1PI levels that are intermediate between Pi MM normals and Pi ZZ homozygotes (12–35 μmol; mean, 57% of normal). Case-control studies showed increased odds of COPD in Pi MZ individuals, but this finding was not confirmed in cross-sectional studies. Overall, there appears to be a small increase in risk of COPD in all Pi MZ individuals (or a larger risk in a subset of subjects).[298]

Lung Disease in Alpha$_1$-Protease Inhibitor–Deficient Phenotypes. The premature development of severe emphysema is the hallmark of homozygous A1PI deficiency.[299] Symptoms or signs of pulmonary disease rarely develop before age 25 years. The onset of dyspnea occurs at a median age of 40 years in Pi Z smokers and 53 years in nonsmokers.[300] Bronchiectasis has been reported in association with A1PI deficiency.[301] In the 1970s, it was stated that more than half of those with type Pi Z die from pulmonary disease,[299] and this probably remains the case today.

Tobacco smoking and the development of pulmonary disease are strongly associated. Smokers who are type Pi Z have a significantly lower life expectancy than nonsmokers who are type Pi Z. Nonsmokers in the Swedish National Registry did not have reduced life expectancy

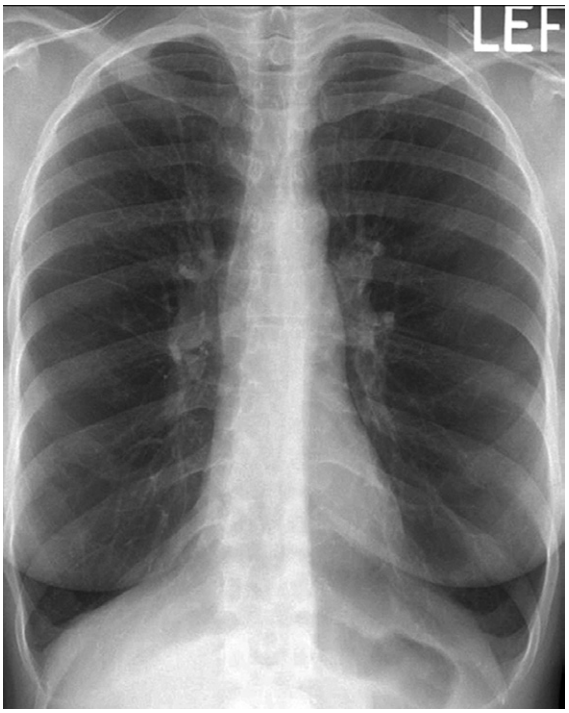

FIGURE 39-13 ■ Frontal chest radiograph in a 51-year-old female with alpha-1-protease inhibitor deficiency presenting for lung transplant evaluation. Note the very large lung volumes with hyperlucency primarily seen in the bases, consistent with panacinar emphysema, as well as flattening of the diaphragms. Contrast the lower lobe lucency in this patient with Figure 39-2, which shows upper lobe hyperlucency in a patient with centriacinar emphysema. *See CT scan video of this patient online.* (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

compared with the general population, but nearly one half of them died of emphysema.[302] Annual decline of FEV_1 is greater than normal in nonsmokers who are type Pi Z, but it is much greater in smokers who are type Pi Z than in nonsmokers.[303]

Severity of lung disease varies markedly[104,304] and indicates the presence of other modifying factors, which remain to be defined. In addition to cigarette smoking, asthma, recurrent respiratory infections, and unidentified genetic factors have been suggested as possible risk factors for chronic airflow limitation.

Radiographically, Pi Z patients characteristically have more definite evidence of emphysema than seen with garden-variety COPD. The finding of basilar emphysema is not constant in Pi Z patients, but when present, it is strongly suggestive of the diagnosis (Fig. 39-13).[305,306] It is common with advanced disease to see hairline arcuate shadows separating markedly radiolucent areas in the lung bases from the less severely involved upper portions of the lungs.

Liver Disease in Alpha$_1$-Protease Inhibitor–Deficient Phenotypes. Homozygous A1PI deficiency is often associated in infancy with hepatomegaly or hepatosplenomegaly and evidence of cholestasis and elevation of hepatocellular enzymes. Some patients with this abnormality may go on to develop cirrhosis. A1PI deficiency is the most common cause of liver transplantation in children. Because the transplanted liver produces normal A1PI, this effectively cures the disorder.[307] Cirrhosis, often with hepatoma, is second in frequency to emphysema as a cause of death in adults.[308]

Liver disease is a result of the Z form of the mutant protein, which forms aggregates in the endoplasmic reticulum.[309] Normally, this leads to the unfolded protein response and autophagy to remove the aberrant proteins but, in a subset of patients with A1PI deficiency, these responses are lacking,[310] leading to hepatic cell injury and potentially to hepatocellular carcinoma.[311]

Diagnosis of Alpha$_1$-Protease Inhibitor Deficiency. The diagnosis of A1PI deficiency is made by measuring the serum A1PI level, followed by Pi typing for confirmation. A1PI should be excluded in patients with premature onset of chronic bronchitis, emphysema, and dyspnea and in nonsmokers presenting with COPD. A predominance of basilar emphysema should raise the possibility of the genetic defect. Some have advocated testing for all new diagnoses of COPD, citing the high prevalence of undiagnosed A1PI-deficient patients, behavioral change (smoking cessation) opportunities, the economic benefits of avoiding further tests, and uncontrolled trials suggesting benefit from augmentation therapy (see later). Others would argue that augmentation therapy has not yet undergone controlled trials, it is not known whether smokers with a diagnosis of A1PI deficiency would stop smoking, and A1PI testing is an added expense. Moreover, there is concern regarding the adverse psychological consequences of the diagnosis to one who is asymptomatic and, importantly, there is a concern for potential genetic discrimination.

Estimates of the frequency of the Pi ZZ phenotype in North America and Europe range from about 1 in 1600 to 1 in 4000,[312] a prevalence approximating that of cystic fibrosis and suggesting that severe A1PI deficiency is among the most common potentially serious genetic conditions. Of note, rigorous attempts to collect all available cases have garnered 10% of estimated cases at most.[312] This suggests that either most subjects who are type Pi Z are asymptomatic or they are masquerading under other diagnoses such as asthma.

Alpha$_1$-Protease Inhibitor Augmentation Therapy. Augmentation therapy with purified human A1PI for patients with severe A1PI deficiency is based on the concept that a deficient protein is being restored to protective levels.[313] Augmentation therapy was approved in the United States as an orphan indication that showed biochemical efficacy. In the 1980s, the ATS published guidelines for augmentation therapy,[314] suggesting that it should be reserved for patients whose serum concentration of A1PI was less than 11 μmol; it is not indicated for patients with cigarette-smoking–related emphysema who have normal or heterozygous phenotypes. It is also not indicated in patients who have liver disease associated with A1PI deficiency unless they also have lung disease. Subsequently, a randomized trial using CT scan as the end point demonstrated some benefit of

treatment.[315] Randomized, controlled trials using lung function are not yet available, but registry data and small prospective trials suggest benefits of treatment for at least some patients.[316,317]

Persons with normal lung function should be monitored but not treated; augmentation therapy should be considered when lung function is abnormal and especially if serial studies show deterioration. The ATS guidelines[314] make the point that it is inappropriate to define a lower limit of lung function or an upper limit of age for administration of augmentation therapy because it is unethical to withhold treatment that may have benefit even in severe end-stage disease. However, it seems reasonable to weigh carefully the advantages and disadvantages of augmentation therapy and to reach a decision jointly with elderly persons or with those with severe lung function impairment (FEV_1 values < 0.8 L). For severely impaired persons, generally younger than age 50, lung transplantation may be a reasonable consideration.

Research continues to explore the benefits of monthly rather than weekly inhaled augmentation therapy, synthetic elastase inhibitors, and recombinant forms of $alpha_1$-antitrypsin. Nevertheless, costly plasma-derived weekly intravenous therapy remains the mainstay.

TREATMENT

Patients with COPD benefit from treatment.[30] Therapeutic goals include (1) prevention of disease progression; (2) relief of symptoms; (3) improvement in exercise tolerance; (4) improvement in health status; (5) prevention and treatment of exacerbations; (6) prevention and treatment of COPD-related complications; and (7) reduction in mortality. These therapeutic goals may be divided into several components: reduction of risk factors; symptomatic management of stable disease; and prevention and management of exacerbations.

General Approach to Therapy

Several consensus staging systems have been developed to rate the severity of COPD. The GOLD guidelines[30] represent a major change in the strategy of disease management (Fig. 39-14). Earlier guidelines, such as the ATS Statement (1995),[151] described symptomatic management after the patient presented to the healthcare system with specific complaints. Because it is now recognized that most patients lose lung function insidiously for many years prior to diagnosis, earlier and more aggressive diagnosis is warranted. Treatment of previously unidentified individuals can help, not only by preventing progression through controlling risk factors but also by improving symptomatic control. In this context, symptomatic improvement in "asymptomatic" individuals can be achieved if improved physiology is combined with an increased level of activity. To achieve optimum results, pharmacotherapy needs to be combined with rehabilitation (See Chapter 94). In addition, treatment of concurrent morbidity is an important component of a comprehensive treatment plan. Depression is frequent among COPD patients and may be more prevalent than expected based on age and morbidity.[318,319] Although psychiatric dysfunction does not directly compromise exercise performance in COPD patients,[320] even subclinical psychiatric disorders are associated with increased morbidity[321] and may compromise participation in an integrated treatment program. Therefore, current guidelines recommend a proactive program of diagnosis and therapy that includes integrated disease management.[30] A general guide to stepwise introduction of treatment modalities based on disease severity has been suggested. It is likely that treatment intensity will need to escalate with time as severity worsens.

Reduction of Risk Factors

Smoking Cessation

Cigarette smoking is the most important risk factor for the development of COPD, and every effort should be made to help the patient stop smoking (see Chapter 40). Cessation early in the development of COPD can stop the accelerated loss of lung function that characterizes COPD.[322] Cessation later in the course of disease may not be as effective because airway inflammation may persist.[323,324] Nevertheless, cessation at any age reduces overall mortality.[325] Smoking should be regarded as a primary disease.[326] Current recommendations are to provide every smoker with the best chance of achieving a remission at each attempt to quit. This requires both the most aggressive behavioral support program appropriate for the patient as well as pharmacologic support. In addition to nicotine replacement therapy, which is available in several formulations, bupropion, varenicline, and two "off-label" medications are currently supported in guidelines: nortryptiline and clonidine.[326]

Other Risk Factors

It is likely that avoidance of exposures to other noxious dusts and fumes that may occur as a result of environmental or occupational exposures may be of benefit in slowing disease progression, but there are no data to support such an approach and no current guidelines. The association of particulate air pollution with increased acute events including mortality[100,327] suggests that a reduction in such exposures may have benefit even late in the disease.

Influenza vaccination can reduce mortality among elderly patients[328,329] and should be given annually to all COPD patients. Although less data support a benefit of the pneumococcal vaccine, its use is also recommended.[30,330]

Development of New Treatments

A variety of novel therapeutics are being explored to address the complex problems of COPD. These include anti-inflammatory agents directed at blocking inflammatory cell recruitment, activation, and the effect of inflam-

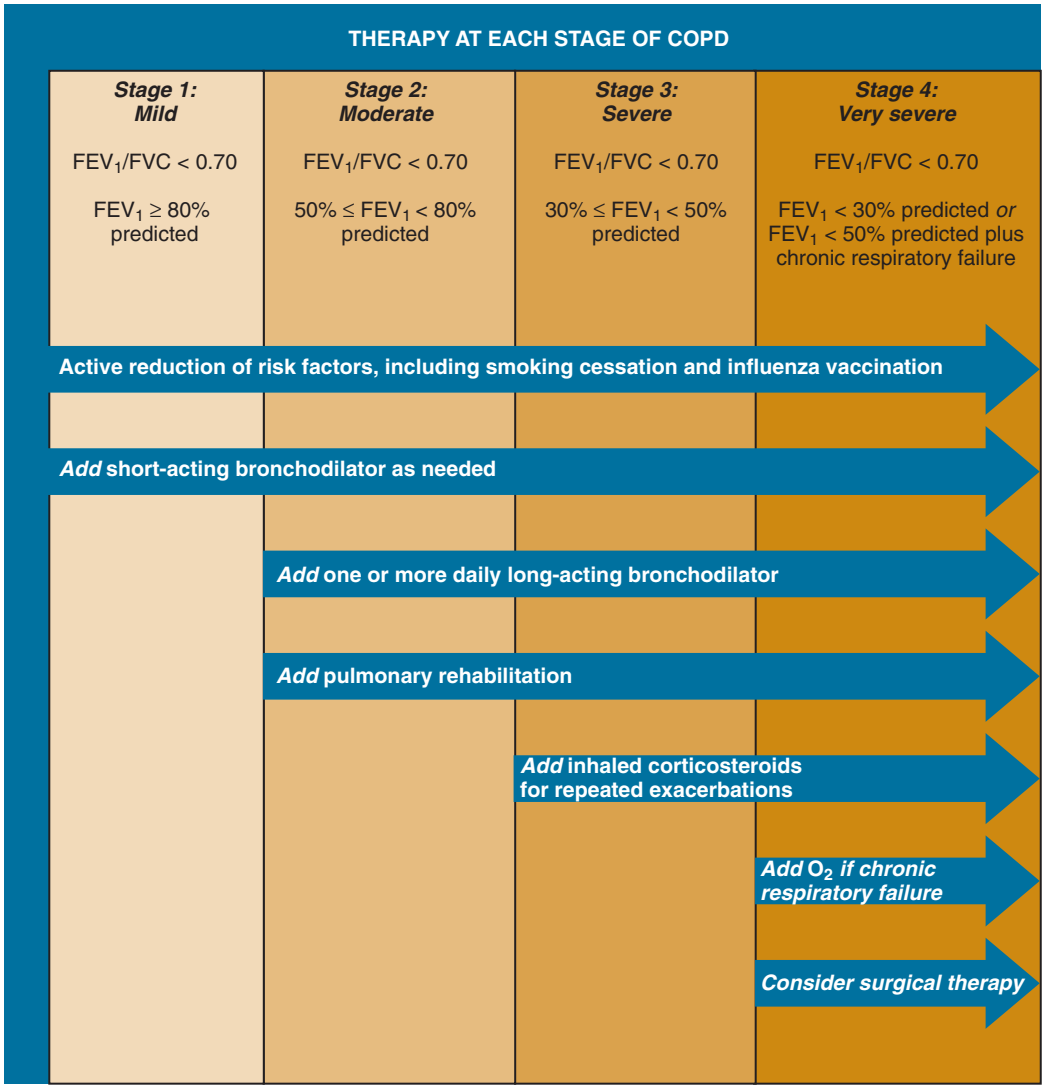

FIGURE 39-14 ■ Step care for COPD patients. The classification and suggested treatments were accessed from the GOLD guidelines. (Redrawn from the Guideline "Global Strategy for Diagnosis, Management, and Prevention of COPD." Updated 12/2009 at http://www.goldcopd.com [accessed 2009].)

matory mediators, as well as treatments that can modify the structural cells of the lung. All studies designed to improve the natural history of COPD face a common problem. Because the disease progresses slowly, a relatively long time is needed to demonstrate a change in the rate of progression.[2] In addition, the changes likely to be observed are small, particularly when compared with the variation in the physiologic measures classically assessed in COPD (e.g., spirometry). As a result, studies of over a thousand subjects for a period of years are needed in order to have adequate statistical power to evaluate changes in the rate of decline of FEV_1.[331] This is a function of the means of assessment and is independent of the intervention. More responsive measures of outcome in COPD are, therefore, urgently needed. A number have been suggested including high-resolution CT, quality of life assessment, and measures of surrogate markers, particularly assessment of inflammation by histology, bronchoalveolar lavage (BAL), induced sputum, markers of elastin turnover, and exhaled air analysis. The hope is that it will be possible to prevent the progression of emphysema in persons who have the beginnings of this disease but are unable to stop smoking.

Pharmacotherapy for Chronic Obstructive Pulmonary Disease

A variety of drugs are frequently prescribed for patients with COPD. The goals of treatment vary and each agent should be assessed in terms of both its efficacy in achieving treatment goals and its associated side effects and risks. The U.S. Food and Drug Adminstration (FDA) recommends five treatment end points be considered for COPD: improvement in airflow obstruction, providing symptom relief, modifying or preventing exacerbations, altering disease progression (including mortality), and modifying lung structure. To date, the primary roles of

pharmacotherapy have been in symptom improvement and in the prevention and treatment of exacerbations.

Symptomatic Therapy

Current symptom-based therapies are primarily directed at reducing airway smooth muscle tone or at reducing inflammation. Because some of the symptoms experienced by COPD patients are due to systemic effects of the disease, treatment directed at extrapulmonary targets may also be of benefit. Finally, effective treatment of the COPD patient requires effective integration of pharmacologic treatment and nonpharmacologic therapy, most importantly pulmonary rehabilitation (see later).

Bronchodilators. In the presence of bronchospasm, as occurs in asthma, bronchodilators can cause marked improvement in airflow. Even normal individuals, however, have some degree of airway smooth muscle tone, and bronchodilators often result in small improvements in airflow that are not clinically meaningful. Some COPD patients have large improvement in airflow following administration of bronchodilators. Most, however, have modest improvements that resemble in magnitude those of normal individuals, which may be due to alterations in resting tone rather than an effect on "bronchospasm." Even these modest improvements, however, may be of benefit for the compromised COPD patient. In addition, improvement in lung volumes, particularly in dynamic hyperinflation, may also occur following bronchodilator treatment. As a result, many patients with COPD will have reduced dyspnea and improved exercise tolerance with bronchodilator therapy, even if improvement in resting spirometry is very modest.[332] Finally, the response of a COPD patient to a bronchodilator can vary from day to day.[333,334] Thus, patients with COPD should always be given a clinical trial of bronchodilators. Both spirometric response and clinical response should be used to gauge effectiveness.

Bronchodilators are often used in COPD both on a chronic basis and also as needed for "rescue."[30] Unlike asthmatic patients who experience dyspnea when acute bronchospasm occurs, patients with COPD most commonly experience dyspnea due to increased respiratory demands, such as occurs with exertion. Rather than treating such episodes with "rescue" medications, it is more appropriate to prevent them, if possible, with maintenance therapy.[335] For such a purpose, long-acting bronchodilators are probably both more convenient and more effective, and their use is recommended. When rescue is needed, a rapidly acting agent is desirable.[30]

β-Agonists. This term refers to the group of medications that bind to the β-adrenergic receptor present on airway smooth muscle, resulting in bronchodilation and improvement in airflow in some patients with COPD. β-Agonists have also been reported to increase ciliary beating frequency and to improve mucus transport[336] and may improve endurance of fatigued respiratory muscles.[337]

Available β-agonists can be divided into "short-acting" and "long-acting" categories. The short-acting agents have a relatively rapid onset of action after inhalation, on the order of 5 to 15 minutes, that persists for 2 to 4 hours. A number of short-acting β-agonist (SABA) compounds are available. The most widely prescribed is albuterol (salbutamol). Recently, the racemer of albuterol has been introduced in hopes of providing equivalent efficacy with fewer side effects (discussed later). The SABAs are available in formulations for inhalation and oral intake. The inhaled route is preferable owing to more favorable ratio of therapeutic effect to undesirable side effects.

Long-acting β-agonists (LABAs) typically have a longer onset of action but produce bronchodilation for up to 12 hours or more. The two agents currently available are formoterol, which has an onset of effect similar to short-acting agents, and salmeterol, which is somewhat slower in onset. Salmeterol has been more extensively studied than formoterol for nonbronchodilator effects.[338] It has been noted to have anti-inflammatory effects, to reduce edema, and to reduce airway epithelial cell injury in model systems.

Mode of Administration. The preferred mode for administering β-agonists is by inhalation using a metered-dose inhaler (MDI) or a dry powder inhaler (DPI). These methods are superior to oral administration in improving FEV_1 and produce fewer side effects.[339] A large number of studies have also convincingly shown that a properly used MDI is as effective as and less expensive than nebulized aqueous solutions of β-agonist for most individuals. The ease of use of DPIs and the lack of necessity for a propellant suggest they will become the standard. However, some patients with COPD may be unable to generate the flow rates needed for effective use of these devices. Nebulizers may be more effective in patients too weak to use an inhaler device, in those with altered mental status,[340] or in those whose inspiratory capacity is too limited to permit effective inhalation[340]; intermittent positive-pressure breathing is not indicated for this purpose.[333]

Treatment Effects.

- Improvement in airflow obstruction. The magnitude of improvement in lung function, as assessed by the FEV_1, in response to inhaled β-agonists is less in COPD than in asthma and, by definition, does not normalize. The proportion of patients who experience a "positive bronchodilator response" as defined by the ATS is 25% to 30% on any given day. More than 50% of patients have a positive response on one or more occasions when tested serially over a 6-month period.[334] Both SABAs and LABAs produce, on average, modest improvements in FEV_1. For salmeterol, reported improvements are 50 to 120 mL, depending on dose in patients who are "poorly reversible," and somewhat higher in those with a greater than 15% improvement in FEV_1 after administration of an SABA.[341]
- Symptom relief. β-Agonists, particularly the LABAs, have been reported to improve symptoms, including those utilizing the St. George's Respiratory Questionnaire (SGRQ). The magnitude of improvement is modest, but significantly better than

placebo. Effects on dyspnea and exercise tolerance are variable, but when a difference was noted, it was in favor of the use of LABAs.[341,342]
- Exacerbation prevention. The LABAs have been reported to reduce exacerbation frequency by 20% to 30%.[341,343]
- Alteration of disease progression. This is usually measured by quantifying the rate of change in FEV_1 over a several-year period. The available data suggest that β-agonists do not change this rate of decline by a clinically meaningful amount.[142]
- Modification of lung structure. There are no human data available to suggest that β-agonists modify lung structure.

Side Effects. Although systemic effects are more common with oral formulations, they may occur with any β-agonist formulation. Tremor, palpitations, anxiety, and insomnia are the most common side effects. Ventricular arrhythmias and hypokalemia may also occur. The heart, in addition to β_1-receptors, also has β_2-receptors, and these probably mediate the cardiac effects of the currently used selective β_2-agonist bronchodilators.[344] Because the systemic side effects are due to drug absorbed from both the lung and that deposited in the pharynx, systemic side effects associated with MDI use may be reduced with a spacer device that reduces oral deposition. DPIs, which generally result in less oral and pharyngeal deposition may be desirable in this situation.

More recently, levalbuterol, the (R)-enantiomer of albuterol, has been marketed based on the observations that it has a shorter half-life than the (S)-enantiomer, is the active constituent that binds to the β-adrenergic receptor and produces bronchodilation. In addition, the (R)-enantiomer may be preferable because the (S)-enantiomer may promote airway inflammation and be associated with some of the systemic side effects. Albuterol is typically available as a racemic mixture of both enantiomers, so levalbuterol was expected to be as efficacious with a more desirable side effect profile. In practice, this is true but the magnitude of the difference in side effects is small and there is some debate as to their clinical relevance.[345] For patients who experience significant tachycardia or tremor while using racemic albuterol, use of levalbuterol may reduce these symptoms.

Owing to reports implicating the LABA salmeterol in an apparent increased rate of death in patients with asthma, there has been concern as to whether this could also be happening in COPD. A recent analysis concluded that this risk is not seen in patients with COPD and that the medications are safe to use.[342]

Many patients with COPD have concurrent cardiac disease and have strong indications for β-blocker therapy. Nonselective β-blockers should be avoided in COPD patients. Use of selective β_1-blockers has been reported to improve survival in patients with cardiac disease and, in meta-analyses, does not adversely affect lung function.[346] Conversely, β-agonist bronchodilators have not been associated with increased cardiac disease in COPD clinical trials that excluded patients with unstable cardiac disease.[347–352] The use of bronchodilators other than β-agonists may be preferred in patients with unstable cardiac disease, if possible, because β-agonists may exacerbate concurrent cardiac disease.[353,354] However, the possibility that other classes of bronchodilators are associated with increased cardiac mortality[355] makes such choices difficult, particularly without an adequate evidence base (see the following section on Anticholinergic Therapy).

Anticholinergics. Anticholinergic bronchodilators have been used in Asia since antiquity and in Western medicine since the early 1800s.[356] Most of these traditional compounds (e.g., atropine) carry a weak ionic charge and thus move easily across the blood-brain barrier; their use is associated with systemic and central nervous system side effects. For use as bronchodilators in COPD, they have been largely replaced by quarternary amines, such as ipratropium and glycopyrrolate, which, having a stronger ionic charge, do not cross the blood-brain barrier and have limited absorption into the circulation. As a result, they have a very high therapeutic ratio (see Chapter 8).

Anticholinergics work as bronchodilators by blocking the action of acetylcholine on M_3 muscarinic receptors, which induce contraction of airway smooth muscle.[357] Tiotropium has a prolonged duration of action because it dissociates from the receptor extremely slowly.[358] When administered chronically, the bronchodilator effect of tiotropium increases with daily dosing and is maximal after 1 week.[359] Because it dissociates from the M_2 receptor faster than from the M_3 receptor, tiotropium demonstrates some receptor selectivity. The clinical significance of M_2-receptor inhibition is undefined. However, M_2 receptors function as feedback inhibitors of acetylcholine release, and these receptors may inhibit bronchoconstriction in COPD patients.[360] M_2 antagonism, therefore, may have untoward effects, and the relative lack of effect of tiotropium on M_2 receptors may be a potential advantage.

Many cells, including airway epithelial cells, express the enzyme choline acetyl transferase,[361] suggesting that non-neuronal cells can produce acetylcholine. In addition, muscarinic receptors are present on many cells in addition to airway smooth muscle cells. In airway smooth muscle cells, acetylcholine stimulates the production of neutrophil chemotactic activity[362] and an anticholinergic could, theoretically, have an anti-inflammatory action. The clinical significance of these findings is unknown.

"Short-acting" agents currently in use include ipratropium and, in some countries, oxitropium which produce bronchodilation in 10 to 15 minutes and last for 4 to 6 hours. The long-acting anticholingergic tiotropium is slower in onset, achieving peak bronchodilator activity after 1 to 2 hours, but has a markedly prolonged duration of action and is used once daily.

Mode of Administration. The preferred mode of administration is by inhalation using an MDI or DPI. Ipratropium is available in several formulations including a nebulized solution. Tiotropium is available only in a DPI. Glycopyrrolate is available as a solution for nebulizer use, although it is not approved by the FDA for this purpose.

Treatment Effects.

- Improvement in airflow obstruction. Anticholinergics produce a modest improvement in FEV_1 of a magnitude similar to that reported for β-agonists.[363,364]
- Symptom relief. Anticholinergics produce modest benefits in symptoms and health-related quality of life (HRQOL) in patients with COPD.[343,363] In clinical trials, tiotropium improves airflow and lung volumes, reduces dyspnea, and improves health status and exercise performance.[359,365-368] The improvement in exercise performance appears to be due to reduction in hyperinflation.[369]
- Exacerbation prevention. Tiotropium and ipratropium in combination with albuterol have been reported to reduce risk of COPD exacerbation. The magnitude of the risk reduction is 20% to 25%.[343,364]
- Alteration of disease progression. A recent prospective trial of tiotropium designed to test the hypothesis that its use would reduce the rate of decline in FEV_1 failed to show a benefit in this measure.[363] There was a trend of decreased mortality in the tiotropium-treated patients that did not reach statistical significance.
- Modification of lung structure. There are no human data available to suggest that anticholinergics modify lung structure.

Side Effects. Local toxicities can occur. For example, if sprayed directly in the eye, anticholinergics can precipitate acute attacks of glaucoma. Some systemic effects can be seen including dry mouth associated with tiotropium and urinary retention.

The report from the Lung Health Study[355] of increased cardiac mortality that did not achieve statistical significance among the subjects randomized to treatment with ipratropium raised concerns about cardiac toxicity related to anticholinergic use. Several subsequent publications have provided additional data related to this issue. Two reports have suggested increased cardiac events in patients using anticholinergic therapy. One is a retrospective database review that found an increased risk of all-cause mortality among a cohort of men prescribed ipratropium for COPD.[370] The second is a meta-analysis of anticholinergic use in COPD, the majority of which was ipratropium, that found an increased risk of cardiovascular death, myocardial infarction, and stroke in patients treated with anticholinergic therapy.[371] These data are in contrast to prospectively collected data in a randomized trial of tiotropium, which showed a significant reduction in the rate of cardiovascular events in patients with tiotropium and did not show any increase in mortality in the tiotropium-treated patients.[363] It is unclear whether these contradictory data reflect differences between tiotropium and ipratropium, the former being more selective for M_1 and M_3 receptors, characteristics of the patient population, confounding by indication, or other factors.

Methylxanthines. Theophylline is the only methylxanthine currently used to treat COPD patients. It has modest bronchodilator activity, but it also has additional effects that may be therapeutic.[372] In this regard, theophylline exerts anti-inflammatory effects,[373] has modest inotropic and diuretic effects, and may augment skeletal muscle strength. Whereas bronchodilator effects are modest,[374,375] subjective responses may be greater than the objective improvements in FEV_1,[376] although several studies have failed to observe such benefits.[377,378] If used, the currently recommended target blood levels are 5 to 10 μg/mL, which often achieve adequate clinical response and provide a greater margin of safety than higher levels. Dose-related adverse effects of theophylline include nausea and vomiting, seizures, and arrhythmias. Its use is also complicated by many drug interactions and, because it is cleared by hepatic metabolism, concurrent morbidity that affects liver function, including congestive heart failure and nonspecific responses to viral infections, can alter theophylline levels.

Combination Therapy with Bronchodilators. It is current practice to begin bronchodilator therapy with a single agent. However, most patients with COPD have modest responses. Combination therapy with a second or third bronchodilator from different classes can result in improved bronchodilator and clinical effect. Data support essentially all possible combinations of bronchodilator classes. Both SABAs and LABAs have been evaluated with both short- and long-acting anticholinergics[379-381] and with theophylline.[374,376] Anticholinergics and theophylline have been evaluated,[382,383] as have all three bronchodilators in combination.[384] Although clinical responses among individual patients may vary, bronchodilator combinations are both rational and encouraged by current guidelines.[30,385] A fixed combination containing the SABA albuterol with the short-acting anticholinergic ipratropium has proved to be widely popular. In clinical trials, its bronchodilator efficacy is superior to that of either agent used alone.[379] Other fixed combinations of inhaled bronchodilators are likely to become available in the future. Their convenience alone is likely to make them popular with patients and physicians.

Choice of Bronchodilators. To date, the use of bronchodilators is for symptom relief and their use is empirical. Any of the bronchodilators may be used, the choice of agent depending on patient and physician preference and on cost.[30,385] For regular use, long-acting agents have advantages of convenience and, probably, efficacy, as discussed previously. When used empirically, it is reasonable to give them a clinical trial in each patient. If little benefit is obtained, it may be reasonable to forgo therapy. However, failure of a patient to respond may be due to several reasons. Poor compliance and ineffective use of the device must be considered. Even if used correctly, however, many patients with COPD may fail to benefit from bronchodilator therapy unless it is integrated into a rehabilitation program (see later and Chapter 94).[386] The reason for this is the severely restricted activity and marked detraining present in many COPD patients. Optimizing physiology of the lung is only one requirement to improve the patient's condition. Even if the patient fails to respond, a repeat clinical trial may be warranted in the future because, with disease progression, responsiveness may increase.

During an acute exacerbation of COPD requiring emergency room treatment, ipratropium appeared to be only equally effective to inhaled β-agonists, with no further benefit from combination therapy,[387,388] and ipratropium did not provide additional improvement when added to an emergency room regimen of inhaled β-agonists and corticosteroids.[388] There is one report, however, that adding ipratropium to β-agonist therapy accelerated the improvement of COPD exacerbations and shortened the duration of emergency room treatment.[389]

Corticosteroids

Inhaled Glucocorticoids. Because inflammation is believed to contribute to the pathogenesis of COPD, it is appealing that anti-inflammatory therapy should alter the disease course. Data supporting this approach, however, are limited.

Treatment Effects.

- Improvement in airflow obstruction. Inhaled glucocorticoids (ICS) cause a modest improvement in airflow. The effect is usually a 50- to 100-mL increase in FEV_1, compared to the 200- to 300-mL benefit achieved with bronchodilators.[390,391] However, glucocorticoids may result in further benefit when added to bronchodilators, and thus, combinations are rational (also see later).[392-394]
- Symptom relief. ICS have been reported to produce modest improvement in symptoms and to slow the deterioration in HRQOL that is seen in untreated COPD. They have not been demonstrated to have a significant effect on exercise capacity.[395]
- Exacerbation prevention. ICS reduce the frequency and severity of exacerbations in COPD.[142,392,393,396] The mechanism for this effect remains to be determined, but it has been observed with both fluticasone and budesonide and, therefore, appears to be a class effect. Current guidelines, therefore, recommend that ICS can be used in patients with COPD experiencing frequent exacerbations,[30] which are more common as FEV_1 declines below 50% predicted. The magnitude of risk reduction is comparable to that seen with LABAs or anticholinergics, approximately 20% to 25%.[343,363]
- Alteration of disease progression. Four large trials evaluated the possibility that inhaled glucocorticoids may affect the rate of decline in FEV_1.[390,391,397,398] None resulted in a statistically significant reduction in the rate at which lung function declines. A number of meta-analyses have been published examining the effect of the regular use of ICS on rate of decline in FEV_1, with the majority concluding that there is no significant effect on this measure.[399-401] With the current evidence base, therefore, ICS are not currently recommended for routine use to prevent lung function decline in COPD.[30,385] Retrospective analyses of several databases have suggested that use of ICS is associated with reduced hospitalization and reduced mortality.[154,402] A prospective trial examining the impact of fluticasone, with or without concomitant salmeterol, reported a reduction in mortality that failed to reach statistical significance ($P = .052$ for combination therapy). In addition to the mortality data, a retrospective analysis of a Veterans Administration pharmacy database demonstrated a reduced incidence in lung cancer among users of ICS.[403]
- Modification of lung structure. There are no currently available data in humans that the use of ICS has any effect on lung structure.

Side Effects. ICS can have adverse effects. Local effects include oral candidiasis (thrush) and dysphonia.[390] Systemic effects include increased bruising[390] and reduced bone density.[398,404] The clinical importance of these effects remains uncertain, however, but appropriate caution and monitoring is essential. In addition, while reducing the frequency of COPD exacerbations, ICS have been associated with an increased incidence of pneumonia.[142]

Selecting Patients for Inhaled Glucocorticoid Therapy. No paradigm exists that effectively predicts which COPD patients benefit from ICS. The 1995 ATS guidelines[16] recommended an oral glucocorticoid challenge but, not only is this inaccurate,[405] the challenge has adverse effects and such an empirical test is no longer recommended.[30] A trial of ICS is more reasonable. Improvements in FEV_1 can occur within weeks, but patients may perceive a symptomatic benefit only after several months.[392,393,406] Because patients with more severe disease, particularly those with FEV_1 less than 50% predicted, are more likely to experience frequent exacerbations, it is this group who have the most to gain from exacerbation prevention. If used for such a goal, however, it is unlikely that the clinician can gauge whether a benefit has occurred in an individual patient because most patients experience only a few exacerbations annually. A reduction of one or two may not be easily recognized. If ICS are started for exacerbation prevention, therapy probably will be continued indefinitely in the absence of side effects.

Combination Glucocorticoid and Long-Acting β-Agonist Inhalers. Potential synergistic interactions between LABAs and ICS have attracted considerable attention, particularly in the treatment of asthma. Fixed combinations of ICS and LABAs have been tested in both asthma and COPD. These trials demonstrate added clinical benefits of the combinations over the individual components.[142,392,393,407] Their use has become popular among patients with COPD. Whether this is due entirely to the convenience of the formulations, to compliance benefits that ensue when an anti-inflammatory drug is added to a bronchodilator, or to synergistic pharmacologic effects is undetermined.

Systemic Glucocorticoids. If at all possible, systemic glucocorticoids should be avoided in the treatment of stable COPD. The regular use of systemic glucocorticoids is associated with increased mortality,[408] although this may be due to the severity of the disease as much as effects of the drug. It is clear, however, that systemic glucocorticoids have major adverse side effects that should be avoided, if possible. A randomized study demonstrated no difference in FEV_1, symptoms, or exacerbation frequency in a cohort of patients on daily glu-

cocorticoids who were randomized to steroid withdrawal in a double-blind, placebo-controlled study design, reinforcing the recommendation to limit parenteral glucocorticoid use to short-term administration for the treatment of exacerbations.[409]

Cromolyn Sodium Nedocromil and Leukotriene Antagonists. There are no data establishing a role for cromolyn, nedocromil, or cysteinyl leukotriene antagonists in treating COPD. Nevertheless, a clinical trial may be undertaken if the patient is properly informed, particularly in patients with evidence of hyperreactive airways.[410]

Thinning and Mobilization of Airway Secretions. Increased mucus production by hypertrophied and hyperplastic airway submucosal glands and goblet cells together with impaired mucociliary clearance and cough are frequent in COPD patients. Cough and sputum production are also the defining features of chronic bronchitis, although airflow limitation can result from other processes. Sputum expectoration in the stable COPD patient may range from only a few milliliters on awakening in the morning to frank bronchorrhea with day-long production of sputum exceeding 100 mL/day.

The most successful means of controlling excessive airway mucous secretion is avoidance of inhaled irritants. Smoking cessation usually reduces sputum expectoration dramatically over several months[19]; the early period of smoking cessation may be associated with more difficult cough and expectoration, especially in the morning. Individuals who complain that their cough worsens upon quitting should be encouraged that this generally resolves. Patients should avoid smoke-filled rooms and stay indoors when air pollution reaches dangerous levels. Air conditioners and electrostatic precipitators can reduce indoor air pollution, but their clinical benefits, if any, are undefined.

A large number of remedies have been proposed and are in use to assist in the control of secretions. None is supported by evidence from rigorous clinical trials.[30] With the lack of evidence, the clinician must individualize patient management. Although, traditionally, patients have been encouraged to drink several glasses of water per day, aggressive hydration in COPD patients has not been shown to improve sputum volume, the physical properties of sputum, or the ease of expectoration.[411] Bland aerosols of water or saline are also of limited value in clearing airway secretions in COPD and such aerosols can precipitate bronchospasm.[412] Some patients expectorate thick secretions more readily after inhaling steam from hot water in a sink.

Mucolytic agents are not recommended for routine use[30] and are not commonly used in the United States, but some agents are widely used elsewhere. *N*-Acetyl cysteine, in particular, is popular in Europe. The agent is an active antioxidant, and this may be its means of action rather than its properties as a mucolytic. Because it can also reverse epithelial metaplasia in an animal model,[413] it continues to attract interest. This agent has been evaluated clinically and was thought to be associated with an improvement in symptoms and in exacerbation frequency.[414] A subsequent prospective, randomized trial failed to show any benefit in patients with COPD, with the possible exception of reducing exacerbations in patients not taking ICS.[415]

Once available in the United States, iodinated glycerol may have had some symptomatic benefits,[416] but has been removed from the marketplace because of toxicity concerns. Saturated solution of potassium iodide (SSKI) may be an alternative. Recombinant human DNAse, currently used for cystic fibrosis, has not proved useful in chronic bronchitis despite initial favorable reports in acute exacerbations of bronchitis.[417]

Expectorants. Therapy with β-agonists and theophylline enhances mucociliary clearance. Bronchorrhea may be controlled by oral corticosteroids[418] and by inhaled indomethacin[419] and atropine.[420] Ipratropium bromide is not used to influence airway mucous production or clearance. The role of oral expectorants in promoting mucous clearance in COPD patients remains controversial; the consensus has been that agents like guaifenesin and glyceryl guaiacolate provide little or no benefit in most patients.[421]

Controlled Coughing. Cough is usually impaired in COPD patients, with frequent uncontrolled coughing inducing fatigue, chest wall pain, and dyspnea. An effective cough is the best means for expelling airway mucus. Controlled cough and the forced expiratory technique, or huffing, have been advocated as safe, useful alternatives.[422] With controlled cough, patients are taught to inspire deeply, hold their breath for a few seconds, and then cough two or three times with their mouth open and without taking another breath. After repeating this sequence several times, patients should rest before beginning the procedure again. Controlled cough is believed to work because the cleansing action of cough in large airways takes place primarily during the first one or two coughs of a cough sequence.[423] The forced expiratory technique consists of one or two forced exhalations without glottic closure, starting at mid lung volume. This is followed by a forced expectoration or a controlled cough at high lung volume to clear mucus from the central airways.

Physical Therapy. It is appropriate to try postural drainage in patients who are major sputum producers (>30 mL/day) and who have difficulty coughing up their secretions. This technique is safe in COPD patients who have negligible changes in lung volumes and arterial oxygen saturation (Sa_{O_2}) after being positioned in up to a 25° head-down tilt for 20 to 30 minutes.[424] An inhaled bronchodilator should be administered 20 to 30 minutes before postural drainage.[425] If difficulty in clearing airway secretions persists, family members can be taught cupped-hand chest wall percussion or the use of an electromechanical percussor. The routine use of postural drainage and chest percussion and vibration in COPD patients is not indicated. Patients who produce only small quantities of sputum, either when stable or during an acute COPD exacerbation, benefit minimally or not at all.[426]

Therapy for Dyspnea

Pharmacologic. Many COPD patients, especially those with severe emphysema, experience intolerable dyspnea,

especially during exertion, which is poorly responsive to standard bronchodilator therapy.

Some patients have been reported to benefit from opioid narcotics, and this can be considered in patients with advanced, not yet terminal, COPD when dyspnea is disabling.[427]

Carotid Body Resection. Of historical interest, bilateral but not unilateral carotid body resection was reported to relieve dyspnea in patients with severe COPD, during both rest and exercise, mainly because of a large fall in respiratory rate, minute ventilation, and therefore, probably dynamic hyperinflation. However, most patients developed worsened hypoxemia and hypercapnia, and death may have been hastened by such surgery.[428]

Long-Term Oxygen Therapy. Two studies, the British Medical Research Council trial[429] evaluating oxygen for 15 hr/day versus no oxygen and the National Institutes of Health (NIH) Nocturnal Oxygen Therapy Trial[430] comparing 12 versus 24 hours of oxygen/day, have firmly established a place for prolonged long-term oxygen therapy in the management of severe COPD. Long-term oxygen therapy extends life in hypoxemic COPD patients; the 24-hour regimen is more beneficial than the 12-hour regimen.[430]

Other benefits of continuous oxygen therapy are a reduction in hematocrit,[430] modest neuropsychological improvement,[431] and some improvement in pulmonary hemodynamics.[432] The dramatic reduction in the prevalence of cor pulmonale has been attributed to routine use of long-term oxygen in hypoxemic COPD patients. Oxygen therapy may also improve dyspnea and the work of breathing by reducing airway resistance[433] and decreasing minute ventilation needs.[434] Home oxygen therapy causes only small increases in arterial P_{CO_2} in patients with hypercapnia[435] and does not result in pulmonary oxygen toxicity.[436] Although patients must be taught the dangers of smoking during oxygen use and some other simple precautions, there is no appreciable increase in fire hazard.[437]

Indications. Long-term oxygen therapy should be prescribed for patients who have a resting arterial P_{O_2} of 55 mm Hg or less while breathing air. For those whose resting arterial P_{O_2} is between 56 and 59 mm Hg, long-term oxygen therapy is indicated if they demonstrate erythrocytosis (hematocrit ≥ 55%) or evidence of cor pulmonale (see Table 39-4). Stable ambulatory patients should meet these criteria after being on an optimal treatment regimen for at least 30 days.[438–440] Patients recovering from a bout of acute respiratory failure may be given ambulatory oxygen treatment even though they have not been observed for sufficiently long periods. They must be reevaluated after approximately 1 month, however, to ascertain that they meet the necessary criteria for long-term oxygen.

Oxygen during Exercise. Patients with an arterial P_{O_2} of 60 mm Hg or higher while breathing room air may develop worsening hypoxemia with exercise. In addition, oxygen therapy has been shown to improve exercise endurance in many studies,[441,442] in part because of greater oxygen transport and improved oxygen utilization by exercising muscles.[443,444] Oxygen has also been found to delay fatigue in exercising ventilatory muscle, as shown by the late appearance of abdominal paradox and a delayed fall in the high-to-low frequency components of the diaphragm electromyogram (a marker of fatigue).[445] Patients participating in exercise training programs benefit from supplemental oxygen, even in the absence of hypoxemia.[446] This has been attributed to a reduced ventilatory rate when breathing oxygen, due to suppression of the carotid body, which results in less dynamic hyperinflation and thus permits a better training effect. However, it makes little sense to perform exercise testing or prescribe oxygen for patients during exercise if they undertake little or no exercise.

Oxygen during Sleep. Patients with COPD typically have a drop in arterial oxygen tension during sleep, particularly those patients with mild resting hypoxemia.[447] This occurs in roughly 50% of patients with daytime resting Sa_{O_2} less than 95%, which represents approximately 5% of the total COPD population.[447] This desaturation is the result of changes in the ventilatory pattern during sleep, particularly during rapid eye movement (REM) sleep, resulting in alveolar hypoventilation, and occurs in the absence of frank sleep apnea.[448] This has prompted concern over the sequelae of recurrent episodes of hypoxemia in this population and has resulted in the recommendation that a clinical trial be performed to determine whether supplemental oxygen produces measurable health benefit.[449] Several smaller studies have failed to show any benefit arising from nocturnal oxygen supplementation in patients with Sa_{O_2} less than 90% for more than 30% of sleep.[450–452] Despite the lack of data supporting its efficacy, many practitioners continue to prescribe supplemental oxygen for patients with nocturnal desaturation.[453]

Modes of Administration

Nasal Cannula. The most frequently used oxygen delivery system at rest is the nasal cannula at a flow rate sufficient to achieve an arterial P_{O_2} of 60 to 75 mm Hg (Sa_{O_2} > 90%). In patients using continuous oxygen, it is common practice to increase the resting oxygen flow rate by 1 L/min during sleep and exercise to prevent falls in arterial P_{O_2} during these periods. For patients who qualify for oxygen only during sleep or exercise, the oxygen flow rate should be set to maintain an Sa_{O_2} of 90% or greater.

Ambulatory Systems. A primary goal of oxygen therapy is to allow all patients to be as active as possible, both in the home and, where appropriate, outside it. Attaining this goal requires prescription of special equipment permitting ambulation. Electrically driven concentrators with a 50-ft length of tubing along with small tanks of compressed oxygen for portable use in a stroller may be used for patients who spend only brief periods outside the home. Nevertheless, concentrators, because of their low equipment and service costs, are often provided to patients who should be using a liquid system. Vendors have been motivated to do this because home oxygen has been reimbursed under a fixed schedule, keyed to the prescribed oxygen flow rate, regardless of the oxygen system used or the needs of the patient.[454]

Liquid oxygen systems with refillable portable units are the most flexible but are also more expensive.[438,454,455] Most recently, several portable concentrators have been introduced, powered by self-contained batteries. Several of these devices are approved for use on commercial airlines, eliminating the need for patients to arrange for supplemental oxygen during airline travel.[456] Battery life and weight remain limitations, but this area of technology is rapidly evolving.

Conserving Devices. Several oxygen-conserving devices are now available that improve the efficiency of oxygen delivery by collecting oxygen flowing during expiration or by providing oxygen flow only during inspiration. These systems result in oxygen savings of 50% or more, thereby prolonging the time of use of ambulatory reservoirs. The types of systems that have gained widest acceptance are a reservoir pendant leading to a two-pronged nasal cannula (Oxymizer; Chad Therapeutics, Inc, Chatsworth, CA) and several demand oxygen delivery systems.[440]

Transtracheal Catheters. Transtracheal catheters are inserted permanently into the trachea. The respiratory dead space is filled with undiluted oxygen flowing from the catheter, thus providing high-concentration oxygen early in inspiration. Several transtracheal catheter systems are available.[457] These systems are invasive and are associated with a wide range of complications including occasional life-threatening tracheal obstruction by mucous balls.[458,459] However, they may correct severe hypoxemia in COPD patients who are refractory to high-flow oxygen by nasal cannula.[460] They can be almost completely concealed by clothing and result in increased compliance by some patients who will not accept the visibility of a nasal cannula.

Commercial Air Travel. The cabins of commercial airliners flying in the stratosphere are pressurized to an altitude between 5000 and 10,000 ft. Accordingly, patients with COPD in these cabins are subject to the added stress of a reduced inspired oxygen partial pressure. The arterial P_{O_2} may fall below 40 mm Hg in some patients with COPD.[461] Fortunately, extensive experience has proved that flying without supplemental oxygen is safe for most subjects with COPD.[462] Hypercapnic COPD patients should employ supplemental oxygen while flying. Normocapnic patients with a sea level arterial P_{O_2} above 68 mm Hg generally have a flight arterial P_{O_2} above 50 mm Hg and do not require supplemental oxygen.[461,463]

In flight desaturation can be measured by a hypoxic challenge,[464] which correlates well within flight saturation.[465] The clinical utility of such testing, however, is uncertain.[1] One hundred percent oxygen at a flow rate of 1 to 3 L/min by nasal cannula should provide a safe arterial P_{O_2}.

To arrange for in-flight oxygen, patients should contact the airline more than 48 hours in advance and be aware that there will be a supplemental charge for oxygen use. The patient's physician may be contacted by the airline for an oxygen prescription as well as for medical clearance to fly.[464] Because some airlines provide only face masks for oxygen delivery, patients should bring their own nasal cannulas. The patient also should know that the airline companies are not responsible for providing oxygen at stopover points or at the final destination.[464] As mentioned previously, several of the recently introduced portable concentrators have been approved by the Federal Aviation Administration (FAA) for use on commercial airliners; participation by carriers is voluntary, so patients should check with the airline on which they plan to travel.[456]

Compact modern respirators can be brought into airplanes by patients, although this usually requires the purchase of an additional seat. However, only gel-cell batteries are approved for air travel. Some airlines provide inverters that convert cabin power to a usable form of electricity for respirators.[466]

Finally, if the patient has major bullous disease, the physician should always warn the patient that ascent to high altitude can precipitate life-threatening pneumothorax. Such a patient should probably not fly.

Pulmonary Rehabilitation

Pulmonary rehabilitation, which attempts to return patients to their highest possible functional capacity, has become an essential component in comprehensive care for patients with severe COPD.[16] (See Chapter 94 for a detailed discussion of rehabilitation.) Numerous studies have confirmed the overall value of a comprehensive rehabilitation program for COPD patients.[467] The benefits are improved independence and quality of life, decreased hospital days, and improved exercise capacity. Lung function, assessed by FEV_1, is not improved. Despite the lack of improvement in airflow, the effects of rehabilitation on health status ("quality of life") are generally much greater than seen with pharmacologic treatments.[468] Whereas all components contribute to patient well-being, exercise training is key.[469]

Exercise conditioning is the single most important aspect of rehabilitation and has been repeatedly shown to improve exercise capacity and endurance in COPD patients, albeit only modestly. Patients should undertake both general exercises and specific muscle training. As with any exercise program, gains in conditioning are lost if the exercise program is stopped. Maintenance of exercise training, therefore, should be a key therapeutic goal in the support of COPD patients. Oxygen during exercise is recommended for patients who both have significant exercise desaturation (<88%) and show improved exercise tolerance while using oxygen.[470] As noted previously, the training benefit of exercise can be optimized if patients are given supplemental oxygen, even in the absence of hypoxemia.[446] It is likely that optimal control of airflow with maximal bronchodilator therapy also improves training. Upper extremity exercises using light weights may improve upper extremity performance and reduce fatigue,[471] perhaps because these muscles participate as accessory muscles of ventilation.[472]

Respiratory muscle training is controversial. The simplest, most reliable method for home use is a pressure-threshold breathing device for endurance training. The

inspiratory pressure needed to achieve training has to be at least 30% of the maximum inspiratory pressure that the patient can generate, and training duration should eventually reach 30 min/day.[473] Such training increases the endurance time that these muscles can tolerate a given load and may improve respiratory muscle strength, diminish dyspnea to the inspired load, and modestly increase walking distance.[474,475] However, up to 50% of patients fail to complete training and, among those who do, the effects abate after several months.[476]

Controlled Breathing

Controlled breathing techniques include pursed-lip breathing and deliberately slow prolonged expiration, which may be coupled with manual upper abdominal compression and the standing bent-forward position, with the outstretched arms and hands supporting the body. The benefits of these methods include control of resting dyspnea, anxiety, and panic attacks.[477] Some patients adopt breathing with pursed lips and the bending-forward posture intuitively during bouts of dyspnea; others adopt them only after instruction. The goal of these methods is to reduce respiratory rate and increase expiratory tidal volume, thereby decreasing air trapping. Pursed-lip breathing may also increase airway pressure and thus prevent dynamic airway collapse[478] and may transiently improve arterial P_{O_2}.[479] The main benefit appears to be a decrease in end-expiratory lung volumes as a result of the prolongation of expiratory time.[480,481] The bending-forward posture improves diaphragmatic function by increasing abdominal pressure, thus placing the diaphragm in a better position for contraction.[482] The overall clinical benefit of these techniques, however, remains to be established.[483]

Nutrition

Patients with advanced COPD and a predominance of emphysema often experience progressive weight loss, with some patients becoming frankly cachectic.[484] Such patients have findings of marked somatic depletion including a significant reduction in triceps skinfold thickness. However, they may show no evidence of protein malnutrition, as indicated by normal serum albumin levels and blood lymphocyte counts. The cause of this excessive weight loss is multifactorial including a 15% to 25% increase in resting energy expenditure,[485,486] perhaps the result of a markedly elevated work of breathing and increases in circulating inflammatory cytokines.[487,488] A higher energy cost of daily activities and a reduced caloric intake relative to need may be other important factors. The main consequence of this excessive weight loss is reduced muscle strength including weakness of both the inspiratory and the expiratory muscles.[489] This depletion has an adverse effect on prognosis[490] and performance.[63]

Improved nutrition can restore respiratory and general muscle strength and endurance, but such improvement is realized only after clear-cut weight gain.[491,492] Unfortunately, this may be difficult to achieve. Use of anabolic androgens can improve muscle strength and may improve body mass,[490,493,494] but there is insufficient evidence to support their routine use either to improve nutrition or facilitate rehabilitation.[30]

Therapy of Respiratory/Ventilatory Failure

Chronic Ventilatory Failure

Intermittent Noninvasive Ventilation. The use of noninvasive mechanical ventilators in an attempt to rest respiratory muscles is based on the concept that, in patients with severe COPD, the respiratory muscles are at the fatigue threshold. Resting the muscles provides time for "recovery" and prevents small increases in respiratory requirements from precipitating fatigue and perhaps acute respiratory failure. A number of small clinical trials have yielded conflicting results. A randomized study comparing 39 patients treated with noninvasive ventilation with 47 untreated patients showed small improvements in P_{CO_2} and in quality of life over 24 months.[495] However, a 12-month study comparing 20 treated and 24 untreated patients failed to show benefits.[496] At present, the routine use of this form of support for COPD patients is not recommended.[30] Whether selected individuals may benefit, as do patients with chest wall deformities and neuromuscular disease, remains to be determined.[497]

Altering Ventilatory Control

Almitrine. Almitrine bismesylate, a peripheral chemoreceptor agonist not currently available in the United States, significantly improves resting room air arterial P_{O_2} in about 80% of stable COPD patients in a dose-dependent fashion; a maximal increase of about 10 to 11 mm Hg is seen after 100 mg of the drug.[498] This increase results mainly from improved ventilation-perfusion relationships because almitrine enhances hypoxic pulmonary vasoconstriction by way of sympathetic efferent pathways.[499] Improvement in arterial blood gases persists during exercise[500] and with sleep.[501] The concern that almitrine might significantly increase pulmonary vascular resistance and pulmonary artery pressures has not been borne out.[502] Its use has been limited because of side effects. However, an intermittent dosing schedule with 100 mg of almitrine daily given for 2 consecutive months followed by a 1-month washout has been suggested to maintain therapeutic efficacy while avoiding complications such as progressive weight loss and peripheral neuropathy.[502] Its routine use in COPD is not recommended.[30]

Analeptic Agents. The benefit of the true analeptic agents in COPD, like acetazolamide, which stimulates respiration by acidifying plasma and cerebrospinal fluid, and medroxyprogesterone acetate, which directly acts on brainstem respiratory neurons, is not established. Acetazolamide does not sustain increased ventilation in most COPD patients with chronic hypercapnia,[503] whereas medroxyprogesterone in a dose of 20 to 40 mg thrice daily may help COPD patients whose resting ventilation is much lower than expected given their lung mechanics. Patients with severe ventilatory limitation

(FEV_1 < 0.5-0.75 L) who are unable to reduce their arterial Pco_2 with voluntary hyperventilation will not respond to this medication.[503] Doxapram has also been used to stimulate ventilation. Clinical benefits are not established for these medications and their use to stimulate ventilation in COPD is not recommended.[30]

Surgical Treatment for Emphysema

Lung Volume Reduction Surgery

Dr. Otto Brantigan pioneered resectional surgery for diffuse emphysema in the late 1950s. A mortality rate of 16% soon caused the procedure to fall out of favor.[504] Advances in technology and in surgical technique resulting from experience with lung transplantation led to a revival of surgical treatments of emphysema. In 1995, Cooper and colleagues presented results of 20 patients who had undergone a resection of between 20% and 30% of each lung via median sternotomy.[505] The improvements in physical measures were remarkable as were functional and quality of life measures. This report generated tremendous interest in the procedure and led eventually to the National Emphysema Treatment Trial (NETT), which attempted to compare surgical and medical treatment in a randomized, controlled study and to evaluate subsets of patients with distinct responses.[506] The first observation made by this study was that individuals with an FEV_1 less than 20% predicted and either homogenous disease or a diffusion capacity of less than 20% predicted were at very high risk for mortality if treated surgically.[507] Cooper and colleagues, however, have reported that selected individuals with heterogenous disease that would be excluded by the NETT criteria may benefit.[508]

In contrast to the group with increased mortality, the NETT study indentified some individuals, specifically those with localized disease and with poor exercise capacity, who experienced a substantial reduction in mortality and improvements in HRQOL and exercise capacity as a result of lung volume reduction surgery (LVRS).[37] In addition, many individuals experienced improvement in lung function, performance, and health status. Although the disease continued to progress, the benefits achieved by surgery persisted for several years following the surgery, confirming earlier trials.[509,510] Although not a goal of the trial, one of the striking observations was the marked benefit of well-designed rehabilitation programs. A large number of questions related to LVRS remain. It is currently available at a limited number of centers and should be considered for patients likely to meet the selection criteria. Much of the current activity in this area centers on attempts to develop less invasive approaches to lung volume reduction, typically performed with a bronchoscopic approach.[511-518]

Lung Transplantation

Transplantation of the lung has proved more difficult than transplantation of other solid organs such as kidney, heart, or liver. It is the only organ in constant communication with the atmosphere, it is prone to infection as well as rejection, and there are special problems related to its preservation before transplantation. Nevertheless, there has been considerable progress in lung transplantation (see Chapter 95). In the years following the initial report by Mal and colleagues,[519] single-lung transplant has become most common procedure of choice when transplantation is performed for emphysema. Single-lung transplantation is an easier operation to perform than double-lung transplantation, cardiac bypass is usually not necessary, and two recipients may receive transplants. More recently, however, data have suggested that bilateral lung transplantation may provide better outcomes and current practice varies from center to center.[520] Available data suggest that lung transplantation offers improved function and HRQOL to patients with advanced COPD, but it is not clear that it offers any survival benefit.[521,522] Worldwide, COPD is the most common reason for lung transplantation, but the number of procedures is limited by the number of available organs. Recent changes in the algorithm for donor organ allocation in the United States are likely to result in a reduction in the proportion of lung transplants done for COPD.[523]

Surgery for Bullous Lung Disease

In the presence of a giant hyperlucent air space in the chest in a patient with compromised lung function, surgical excision may be considered. However, if lung function is not improved by the surgery, the morbidity and mortality of the procedure are high. It is not easy to know when to undertake surgery.

The determinants of the outcome of surgery are the size of the bulla and the impairment of function of the nonbullous lung tissue. Two mechanisms have been invoked for impairment of function by a giant bulla. There may be compression of nonbullous lung by a giant bulla whose internal pressure is high and whose volume does not change during respiration, or there may be impairment of ventilation because of the large amount of space occupied in the thorax by the bulla, with resultant loss of linkage between the chest wall and the nonbullous lung tissue.[20,524] There is little improvement in function after excision when bullae occupy less than one third of the hemithorax and lung function is only minimally impaired. The presence of generalized emphysema is also a predictor of a poor result.

As already noted, surgery in the presence of a low FEV_1, hypercapnia, or cor pulmonale is fraught with danger unless compressed, relatively normal lung can be released by the operation.[525,526] This is best assessed by CT performed, if possible, at both full inspiration and full expiration.[524,527] In general, patients do best who have large bullae occupying at least 30% to 50% of the hemithorax and an FEV_1 of about half the predicted normal value.[20,526] Other physiologic parameters predictive of successful surgery include plethysmographic lung volumes substantially larger than those measured by helium dilution, indicating sequestered gas, and a reasonably well preserved diffusing capacity and normocapnia.[528] The amount of uninvolved lung tissue resected should be kept to a minimum. Follow-up reveals that

resection of giant bullae does not appear to affect the size of other bullae.[526,529]

Acute Exacerbations

The course of COPD is characterized by episodic periods of worsening symptoms, termed *exacerbations*. It has proved difficult to establish a consensus definition of exacerbations, probably because they are heterogeneous and their clinical nature varies with the stage of the disease. The most widely used definitions relate increasing symptoms to increased need to utilize healthcare resources.[530] Although easy to apply, this definition is limited by local variations in health service practice. There are two key approaches to exacerbation management: prevention and acute care.

Prevention

As noted previously, several interventions can reduce exacerbation frequency or severity. ICS have consistently resulted in about a 20% reduction in exacerbation frequency and are recommended in the GOLD guidelines for this purpose.[30] The anticholinergic tiotropium has an effect of similar magnitude.[365,366] Ipratropium may have a modest effect, but conventional doses are not as effective as tiotropium.[366] LABA bronchodilators, used alone, may also reduce exacerbations and salmeterol[348,349] may be more effective than formoterol.[350,352] Influenza vaccination probably reduces the frequency of influenza-associated exacerbations.

Acute Management

As noted previously, acute exacerbations of COPD are events that place patients at increased risk. Comorbidities may complicate the clinical picture. Rib fractures and pneumothorax may occur. Congestive heart failure and pneumonia may be difficult to distinguish from an acute exacerbation because, in severe emphysema, the characteristic radiologic features of these conditions may be masked. Moreover, both conditions may be present with or may complicate an exacerbation. Limited studies suggest deep venous thrombosis and pulmonary embolism are associated with acute exacerbations.[531,532] Exacerbations are associated with acutely worsening health status that may take months to resolve.[25] Interestingly, one prospective study that monitored patient symptoms indicated that nearly half of exacerbations are not reported to healthcare providers.[533] The long-term impact of these exacerbations is not known, but the same study noted that delay in treatment was associated with slower resolution and increased risk of hospitalization for treatment.[533] Mortality is increased, both during the acute exacerbation and in the months following. Tracheal stenosis due to mechanical ventilation can cause deterioration in the postexacerbation period.[534] Current mortality rates of about 10% are reported in hospital, with intensive care unit and non–intensive care unit mortality being similar.[153,535] Mortality of 30% to 40% in the 6 to 12 months following hospitalization for exacerbations with evidence of respiratory failure are also reported,[154,536] but long-term survival is possible, complicating end-of-life decisions. To what extent end-of-life planning affects reported mortality statistics is not known. Based on the currently available evidence, however, aggressive treatment of exacerbations and the associated comorbidities is warranted.

Antibiotics. About one half of acute exacerbations of chronic bronchitis are associated with bacterial infection by pathogens that commonly colonize the respiratory tract: *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*.[537,538] Infected patients generally have larger numbers of bacteria in their sputum than when they are clinically stable.[537,539] Changes in the strain of bacteria have been associated with increased risk for acute exacerbation.[46] The sputum Gram stain provides semiquantitative information on the number of bacteria in the sputum; the culture provides information only on the identity of the organisms[540] and cannot separate colonization from infection. Clinical criteria alone are sufficient to justify a course of antibiotic for a COPD exacerbation in the ambulatory setting. In general, the more symptoms a patient experiences from the triad of dyspnea, cough, and sputum, and the more purulent the sputum, the more likely antibiotics are to be of benefit.[541,542]

A large number of oral antimicrobial agents have been approved for treating acute COPD exacerbations. Treatment is usually empirical and not based on sputum cultures.[47] Because response is generally good even without treatment,[541] a low-cost antibiotic such as trimethoprim-sulfamethoxasole, ampicillin, or a tetracycline is often used for mild exacerbations in relatively uncompromised patients. A 7- to 10-day course is most often prescribed, although 5 days is probably sufficient. Providing patients with a prescription to fill if needed for an increase in symptoms is commonly accepted practice. As baseline disease and exacerbation severity increase, broader-spectrum antibiotics that will be effective against resistant strains of *H. influenzae* and *S. pneumoniae* become increasingly recommended. If systemic symptoms such as fever are prominent, the patient should be regarded as having pneumonia and treated with broad-spectrum antibiotic coverage as recommended.[543]

For the patient with frequent purulent exacerbations, a treatment approach similar to that used for bronchiectasis with the regular use of prophylactic antibiotics may be beneficial. High-resolution CT of such patients may reveal bronchiectasis not apparent on routine chest radiography.[544]

Glucocorticoids. Systemic glucocorticoids have been demonstrated to reduce recovery time and to reduce treatment failures when used to treat acute exacerbations.[545–547] The dose required is not clear, but 30 to 60 mg of prednisone or equivalent appears to be adequate. The duration of treatment is also not established, but 2 weeks of therapy appears sufficient and, in one study, 8 weeks of therapy had no additional benefit.[546] In one recent study, the combination of an antibiotic (doxycycline) and systemic glucocorticoids was more effective than systemic steroids alone.[548]

Bronchodilators. The bronchodilators discussed previously should be used aggressively during an acute exacerbation. It is general practice to use rapidly acting agents and, for very ill patients, to use nebulizers, because many patients may not be able to generate the flows required to use other devices during an exacerbation. Intravenous aminophylline can improve lung function slightly,[549] but its overall clinical benefits remain controversial.[30] It should be used only with caution and blood theophylline levels should be monitored.

Acute Respiratory Failure

Acute respiratory failure in COPD is defined as the development of an arterial P_{CO_2} above 50 mm Hg or an arterial P_{O_2} below 50 mm Hg in association with recent clinical worsening. Most episodes are caused by a superimposed acute chest illness such as an acute exacerbation, but other causes such as pneumothorax, congestive heart failure, pulmonary embolus and metabolic derangements like hypophosphatemia or hypokalemia should be assessed.[550,551] The goals of treatment are primarily maintenance of adequate oxygenation and secondarily prevention of respiratory acidosis, while preventing secondary complications.

Oxygen. Supplemental oxygen should be given to maintain the P_{O_2} above 60 mm Hg and the Sa_{O_2} above 90%.[30] The concentration of oxygen required will vary with the severity of the exacerbation and the underlying disease. Arterial blood gases should be evaluated 30 minutes after initiating oxygen therapy, both to ensure adequate oxygenation and to assess for CO_2 retention, which cannot be determined by pulse oximetry. Rises in arterial P_{CO_2} may occur because of the suppression of hypoxic peripheral chemoreceptor ventilatory drive, the Haldane effect, in which oxygenated hemoglobin transports less carbon dioxide than deoxygenated hemoglobin, and the worsening of ventilation-perfusion matching in the diseased lungs.[552] The hypoxic ventilatory drive is not usually suppressed until the arterial P_{O_2} increases to 60 mm Hg or higher.

Ventilatory Support. A major advance in the treatment of acute exacerbations of COPD has been the implementation of noninvasive positive-pressure ventilation (see Chapter 92). Not only can intubations be avoided, but mortality for severe COPD exacerbations is also substantially reduced.[30,553,554] Several methods have been described including negative-pressure ventilation,[555] as well as nasal,[556] mouthpiece,[557] and face mask[558] intermittent positive-pressure ventilation. A recent randomized trial testing the benefit of a helium-oxygen mixture for use in noninvasive ventilatory support in COPD exacerbations did not show superiority.[559] It is common practice for this form of ventilatory support to be provided in an intensive care unit setting with specially trained staff. There are several contraindications to its use including respiratory arrest, cardiac instability, high aspiration risk, and inability to fit the device securely. If contraindications are present or if noninvasive ventilation is inadequate, patients may require intubation and mechanical ventilatory support (See Chapters 89 and 92).

KEY POINTS

- COPD is very common and its incidence is rising globally.
- COPD is often associated with and worsens outcome of a variety of other cigarette-related diseases such as heart disease and lung cancer.
- COPD is a complex disease caused by an environmental insult, most often cigarette smoke, on a susceptible genetic background.
- COPD is characterized by airflow obstruction that is not fully reversible. Airflow obstruction may be secondary to narrowing of small airways or emphysema (i.e., destruction of alveoli and ECM with consequent decreased elastic recoil).
- Airway narrowing is a result of excess mucus production, airway fibrosis, inflammation, and hypertrophy of structural cells.
- Emphysema is a result of inflammatory proteinases that degrade ECM, combined with cell death and imperfect repair.
- Oxygen therapy is indicated for patients with resting hypoxemia ($Sa_{O_2} < 88\%$) and/or signs of pulmonary hypertension.
- β-Agonists, anticholinergics, and inhaled corticosteroids have all been shown to improve function, reduce symptoms, and reduce exacerbations.
- Pulmonary rehabilitation is an important and underutilized treatment in patients with moderate to advanced COPD.
- Lung volume reduction surgery and lung transplantation offer significant benefits for highly selected patients with advanced COPD.

INTRODUCTION

Cigarette smoking remains the leading cause of preventable premature morbidity and mortality in the United States and in many countries around the world. An average of 435,000 people in the United States die prematurely from tobacco-related disease in a year, which includes one of every three cancers and one in five deaths overall.[1] A lifelong smoker has about a one in three chance of dying prematurely from a complication of smoking.[2]

Smoking is particularly relevant to respiratory medicine, as it is by far the major cause of lung cancer and chronic obstructive pulmonary disease (COPD) in developed countries. Smoking is also a substantial causative factor in respiratory infections, including pneumococcal pneumonia, influenza, and tuberculosis.

EPIDEMIOLOGY OF CIGARETTE SMOKING

Currently, about 43.4 million individuals in the United States are cigarette smokers (19.8% of the adult population), including 22.3% of men and 17.4% of women.[3] People who are poor, are less well educated, and/or have unskilled occupations are more likely to smoke. For example, 33.3% of people with 9 to 11 years of education are smokers, compared with 11.4% of those with a college degree A recent study using a serum biomarker of tobacco use found a prevalence of active smoking of 40% and of active, recent, or heavy secondhand smoke exposure of 55% at San Francisco General Hospital, an urban public hospital that treats primarily the uninsured, disadvantaged minorities, and those with psychiatric and substance abuse problems.[4] The global tobacco disease burden has been reviewed by the World Health Organization in *World Health Report 2002*.[5] Smoking prevalence continues to rise in many low and middle income countries. Disease burden was estimated using disability-adjusted life years (DALYs) lost. In 2000, 8.8% of the global total deaths were attributable to tobacco use, a 45% increase from 1990. If the current levels of smoking remain unchanged, the burden from tobacco consumption is estimated to double by 2020. These figures informed the recently negotiated WHO Framework Convention on Tobacco Control,[6] which aims to reduce both demand and supply of tobacco around the world, through educational, political, and legislative means.

TOXICOLOGY OF CIGARETTE SMOKE

Tobacco smoke is an aerosol of droplets (particulates) containing water, nicotine and other alkaloids, and tar. Tobacco smoke contains several thousand different chemicals, many of which may contribute to human

disease.[7] Major toxic chemicals in the particulate phase of tobacco include nicotine, benzo(a)pyrene and other polycyclic hydrocarbons, *N′*-nitrosonornicotine, β-naphthylamine, polonium-210, nickel, cadmium, arsenic, and lead. The gaseous phase contains carbon monoxide, acetaldehyde, acetone, methanol, nitrogen oxides, hydrogen cyanide, acrolein, ammonia, benzene, formaldehyde, nitrosamines, and vinyl chloride. Tobacco smoke may produce illness by way of systemic absorption of toxins and/or cause local pulmonary injury by oxidant chemicals.

SMOKING-RELATED DISEASES

Tobacco use is a major cause of death from cancer, cardiovascular disease, and pulmonary disease (Table 40-1). Smoking is also a major risk factor for osteoporosis, reproductive disorders, and fire-related and trauma-related injuries.

Cancer

Smoking, the largest preventable cause of cancer (Table 40-2), is responsible for about 30% of cancer deaths.[8] Many chemicals in tobacco smoke may contribute to carcinogenesis as tumor initiators, co-carcinogens, tumor promoters, or complete carcinogens.[9] Binding of tobacco smoke carcinogens to DNA is thought to be a crucial step in cancer induction.[10] Cigarette smoking induces specific patterns of p53 gene mutations that are associated with squamous cell carcinomas of the lung, head, and neck.[11] Lung cancer is the leading cause of cancer deaths in the United States and is predominantly attributable to cigarette smoking. The risk of lung and other cancers is proportional to the number of cigarettes smoked per day and even more strongly to the duration of smoking. In current smokers, the levels of DNA adducts (covalently bound carcinogens) in nontumorous lung tissue or blood mononuclear cells are related to cigarette consumption.[12] Of note, however, in former smokers, DNA adduct levels were inversely associated with age of initiation of smoking. This finding suggests that young smokers are more susceptible to DNA damage and persistence of genetic alterations than are those who begin smoking at an older age, which has substantial implications for the need to prevent adolescent smoking.[13]

Workplace exposure to asbestos or α-radiation (the latter in uranium miners) synergistically increases the risk of lung cancer in cigarette smokers.[14] Alcohol use interacts synergistically with tobacco in causing oral, laryngeal, and esophageal cancer.[15] The mechanism of interaction may involve alcohol solubilizing tobacco carcinogens and/or alcohol-related induction of liver or gastrointestinal enzymes that metabolize and activate tobacco carcinogens. Smoking is associated with 15% of leukemia cases in adults and 20% of colorectal cancers.[16,17]

A detailed description of the epidemiology and the pathogenesis of smoking-induced lung cancer is presented elsewhere in this textbook (see Chapters 45 and 46).

TABLE 40-1. Health Hazards of Tobacco Use (Risks Increased by Smoking)

CANCER (SEE TABLE 40-2)

CARDIOVASCULAR DISEASE
- Sudden death
- Acute myocardial infarction
- Unstable angina
- Stroke
- Peripheral arterial occlusive disease (including thromboangiitis obliterans)
- Aortic aneurysm
- Worsening of congestive heart failure

PULMONARY DISEASE
- Lung cancer
- Chronic bronchitis
- Emphysema
- Asthma
- Increased susceptibility to pneumonia and to pulmonary tuberculosis
- Increased susceptibility to desquamative interstitial pneumonitis
- Increased morbidity from viral respiratory infection

GASTROINTESTINAL DISEASE
- Peptic ulcer
- Esophageal reflux

REPRODUCTIVE DISTURBANCES
- Reduced fertility
- Premature birth
- Lower birth weight
- Spontaneous abortion
- Abruptio placentae
- Premature rupture of membranes
- Increased perinatal mortality

ORAL DISEASE (SMOKELESS TOBACCO)
- Oral cancer
- Leukoplakia
- Gingivitis
- Gingival recession
- Tooth staining

OTHER
- Non–insulin-dependent diabetes mellitus
- Earlier menopause
- Osteoporosis
- Cataract
- Tobacco amblyopia (loss of vision)
- Age-related macular degeneration
- Premature skin wrinkling
- Aggravation of hypothyroidism
- Altered drug metabolism or effects

Chronic Pulmonary Disease

More than 80% of chronic obstructive pulmonary disease in the United States is attributable to cigarette smoking. Cigarette smoking also increases the risk of respiratory infection, including pneumonia, and results in greater disability from viral respiratory tract infections.[18,19] Pul-

TABLE 40-2. Cigarette Smoking and Cancer Risk

Cancer Site	Average Relative Risk
Lung	15.0–30.0
Urinary tract	3.0
Oral cavity	4.0–5.0
Oro- and hypopharynx	4.0–5.0*
Esophagus	1.5–5.0*
Larynx	10.0*
Pancreas	2.0–4.0
Nasal cavity, sinuses, nasopharynx	1.5–2.5
Stomach	1.5–2.0
Liver	1.5–2.5
Kidney	1.5–2.0
Uterine cervix	1.5–2.5
Myeloid leukemia	1.5–2.0

*Synergistic interaction with alcohol use.
Adapted from Vineis P, Alavanja M, Buffler P, et al: Tobacco and cancer: Recent epidemiological evidence. J Natl Cancer Inst 96:99–106, 2004; and International Agency for Research on Cancer: Tobacco smoking and Involuntary smoking. IARC Monographs on the Evaluation of Carcinogenic Risks to Humans. IARC Scientific Publication 83. Lyon: IARC, 2004.

monary disease from smoking includes the overlapping syndromes of chronic bronchitis (cough and mucus secretion), emphysema, and airway obstruction. The lung pathology produced by cigarette smoking includes loss of cilia, mucus gland hyperplasia, increased number of goblet cells in the central airways, inflammation, goblet cell metaplasia, squamous metaplasia, mucus plugging of small airways, destruction of alveoli, and a reduced number of small arteries. The mechanism of injury is complex and seems to include inflammation as well as direct injury by oxidant chemicals, increased activity of elastase (a protein that breaks down elastin and other connective tissue), and decreased antiprotease activity.[20] A genetic deficiency of α_1-antiprotease activity produces a similar imbalance between pulmonary protease and antiprotease activity and is a risk factor for early and severe smoking-induced pulmonary disease.[21]

In addition to the effects of cigarette smoke-induced injury, the delivery of carbon monoxide from cigarette smoke serves to worsen the level of functioning in smokers who have significant COPD. Carbon monoxide binds to hemoglobin, reduces the capacity of hemoglobin to carry oxygen, and impairs oxygen release. Thus, carbon monoxide exposure produces a functional anemia. Carboxyhemoglobin levels are typically 5% to 10% in smokers, compared with 1% or less in nonsmokers. In a normal person, carbon monoxide from cigarette smoke causes few symptoms, but in patients with pulmonary disease, carbon monoxide has the potential to cause significant impairment. Exposure to carbon monoxide at levels less than that derived from cigarette smoking can reduce exercise tolerance in patients with COPD.

Cigarette smoking may contribute to the development of asthma, although this potential link could be confounded by the increased rate of pulmonary infections observed in smokers. A longitudinal study of 5800 individuals taking part in a British national study suggested that regular smoking was associated with asthma in people between the ages of 17 and 33 (odds ratio [OR] = 4.42).[22] The relationship between asthma and smoking was further studied in more than 14,000 Finnish adults, and the prevalence of asthma was higher among male smokers than among male nonsmokers (risk ratio [RR] = 1.73), although no smoking effect was observed for women.[23] Compared with never smokers and ex-smokers, current smokers demonstrate higher asthma severity scores, more frequent asthma symptoms, and more frequent asthma attacks (OR = 2.39).[24] Silverman and coworkers[25] evaluated 1847 emergency room patients presenting with acute asthma and found that 35% of patients were current smokers. Fifty percent of these smoking asthmatics reported that cigarette use worsened their asthma symptoms.

The link between secondhand smoke and asthma would support the hypothesis that bronchial hyperresponsiveness is worsened by tobacco exposure. A study evaluating infants in their first year of life exposed to smoking mothers demonstrated that they were 2.1 times more likely to develop asthma than children of nonsmoking mothers.[26] Likewise, the Swiss Study on Air Pollution and Lung Disease in Adults suggested that secondhand smoke was associated with an increased risk of asthma (OR = 1.39) or reactive airway disease in nonsmoking adults.[27]

Bronchoalveolar lavage fluid in a small cohort of healthy nonasthmatic smokers documented altered macrophage cytokine release, increased cellularity, and an altered cytokine environment.[28] These abnormalities would further suggest a plausible link between smoking and an increased incidence and severity of a chronic lung inflammatory condition such as asthma.

Cigarette smoking has been associated with multiple non-neoplastic pulmonary disorders other than emphysema and chronic bronchitis. These include respiratory bronchiolitis-associated interstitial lung disease, desquamative interstitial pneumonitis (DIP), Langerhans cell histiocytosis, cryptogenic fibrosing alveolitis, and eosinophilic pneumonia.[29] Ninety percent of patients with pulmonary Langerhans cell histiocytosis are smokers. Respiratory bronchiolitis and DIP have similar histopathologic features and are characterized by the accumulation of pigmented macrophages within the alveoli. Respiratory bronchiolitis ("smoker's bronchiolitis") is most often an asymptomatic finding that can persist after smoking cessation.[30] DIP often affects smokers in their fourth or fifth decade of life and the symptoms are more frequent in smokers.[29] Smoking may also have an association with idiopathic pulmonary fibrosis.[31]

Infection

Cigarette smoking is a major risk factor for respiratory tract and other systemic infections.[32] Both active and passive cigarette smoke exposure increases the risk of infection. The mechanisms by which smoking increases risk are multifactorial and include structural and immunologic alterations. As mentioned previously, cigarette

smoking causes structural changes in the respiratory tract. These changes include peribronchiolar inflammation and fibrosis, increased mucosal permeability, impairment of mucociliary clearance, changes in pathogen adherence, and disruption of the respiratory epithelium. A number of components of cigarette smoke, including acrolein, acetaldehyde, formaldehyde, free radicals produced from chemical reactions within the cigarette smoke, and nitric oxide, may contribute to the observed structural alterations in airway epithelial cells.

Immunologic mechanisms include alterations in cellular and humoral immune system function. These include a decreased level of circulating immunoglobulins, a depression of antibody response to certain antigens, a decrease in $CD4^+$ lymphocyte counts, an increase in $CD8^+$ lymphocyte counts, depressed phagocyte activity, and decreased release of proinflammatory cytokines. Many of the immunologic disturbances in smokers resolve within six weeks after smoking cessation, supporting the idea that smoking cessation is highly effective in a relatively short period of time in the prevention of infection.[32]

Cigarette smoking is associated with an increased risk of bacterial and viral infections (Table 40-3). Cigarette smoking is a substantial risk factor for pneumococcal pneumonia, especially in patients with COPD. Smoking is strongly associated with invasive pneumococcal disease in otherwise healthy adults. A population-based case-control study showed that smoking was the strongest independent risk factor for invasive pneumococcal disease among immunocompetent adults.[18] The OR was 4.1 (95% confidence interval [CI], 2.4–7.3) for active smoking and 2.5 (95% CI, 1.2–5.1) for passive smoke exposure in nonsmokers compared with nonexposed nonsmokers. The attributable risk in this population was 51% for cigarette smoking and 17% for passive smoking, and this effect showed a strong dose response. The risk of pneumococcal disease declined to nonsmoker levels 10 years after cessation. Cigarette smoking has also been shown to be associated with a nearly twofold increased risk of community-acquired pneumonia, with 32% of the risk attributable to cigarette smoking.[33]

Cigarette smoking increases the risk of developing viral infections including the common cold, influenza, and varicella and increases their severity. For example, influenza infections are more severe, with more cough, acute and chronic phlegm production, breathlessness, and wheezing in smokers.[19] Influenza infections produce more work-loss days in smokers than in nonsmokers. Influenza vaccination is effective in preventing the disease in smokers, and smoking should be considered to be a high-priority indication for influenza vaccination. The risk of development of varicella pneumonitis in adults is reported to be substantially greater in smokers than in nonsmokers.[34]

Tuberculosis is perhaps the most important smoking-associated infection. Cigarette smoking is a risk factor for tuberculin skin test reactivity, skin test conversion, and for the development of active tuberculosis. Of note is a recent large case-control study from India examining smoking and tuberculosis in men between 35 and 69 years of age. The tuberculosis prevalence risk ratio was 2.9 (95% CI, 2.6–3.3) for ever smokers compared with never smokers, and the prevalence was higher with a higher level of cigarette consumption.[35] The mortality from tuberculosis among men 25 to 69 years old showed a risk ratio of 4.5 (95% CI, 4.0–5.0) and 4.2 (95% CI, 3.7–4.8) for urban and rural residents, respectively. The authors found that the smoking-attributable proportion of deaths from tuberculosis was 61% greater than the proportion of smoking-attributable deaths from vascular disease or cancer. Thus, it is likely that smoking contributes substantially to the worldwide disease burden of tuberculosis.[36]

Of historical interest is the relationship between tuberculosis and the risk of cigarette smoking in the early 20th century. Prior to that time, chewing tobacco was the preferred type of tobacco. Public fears that users of chewing tobacco who spit in public places might be spreading tuberculosis is one of the factors that led to the increase in cigarette sales in the United States. This is nicely described by Kluger as follows: "Chewing tobacco was no longer merely messy but socially disagreeable in more crowded urban America, and its inevitable byproduct, spitting, was now identified as a spreader of tuberculosis and other contagions and thus an official health menace. The leisurely pipe all at once seemed a remnant of a slower-tempo age, and cigar fumes were newly offensive amid thronged city life. The cigarette, by contrast, could be quickly consumed and easily snuffed out on the job as well as to and from work."[37]

TABLE 40-3. Cigarette Smoking and Infection

	Odds Ratio (95% CI)
Tuberculosis	4.5 (4.0–5.0)
Legionnaire's disease	3.5 (2.1–5.8)
HIV infection	3.4 (1.6–7.5)
Periodontal disease	2.8 (1.9–4.1)
Pneumococcal pneumonia	2.6 (1.9–3.5)
Meningococcal disease	2.4 (0.9–6.6)
Influenza	2.4 (1.5–3.8)
Common cold	1.5 (1.1–1.8)

CI, confidence interval; HIV, human immunodeficiency virus.

Cardiovascular Disease

Although not the focus of this textbook, cardiovascular disease is common in patients with respiratory disease. This relates to the facts that both diseases are common and both increase with age and that smoking is a major risk factor for both respiratory disease and cardiovascular disease.

Cigarette smoking accounts for about 20% of cardiovascular deaths in the United States. Risks are increased for coronary artery disease, sudden death, cerebrovascular disease, and peripheral vascular disease, including aortic aneurysm.[38] Cigarette smoking accelerates atherosclerosis and promotes acute ischemic events. The mechanisms of the effects of cigarette smoking are not fully

elucidated but are believed to include: (1) hemodynamic stress (nicotine increases the heart rate and transiently increases blood pressure); (2) endothelial injury and dysfunction (nitric oxide release and resultant vasodilation are impaired); (3) development of an atherogenic lipid profile (smokers have on average higher low density lipoprotein, more oxidized low-density lipoprotein, and lower high-density lipoprotein cholesterol than nonsmokers do); (4) enhanced coagulability; (5) arrhythmogenesis, and (6) relative hypoxemia because of the effects of carbon monoxide.[39] Carbon monoxide reduces the capacity of hemoglobin to carry oxygen and impairs the release of oxygen from hemoglobin to body tissues, both of which combine to result in a state of relative hypoxemia. As a compensation for the reduced oxygen-carrying capacity, polycythemia can develop in smokers, with hematocrits often 50% or more. The polycythemia and the increased fibrinogen levels that are found in cigarette smokers also increase blood viscosity, which adds to the risk of thrombotic events. Cigarette smoking also induces a chronic inflammatory state, as evidenced by increased neutrophil count and increased levels of fibrinogen and C-reactive protein in the blood of smokers. Chronic inflammation is thought to contribute to atherogenesis.

Cigarette smoking acts synergistically with other cardiac risk factors to increase the risk of ischemic heart disease. Although the risk of cardiovascular disease is roughly proportional to cigarette consumption, the risk persists even at low levels of smoking, that is, at one to two cigarettes per day.[40] Cigarette smoking reduces exercise tolerance in patients with angina pectoris and intermittent claudication. Vasospastic angina is more common and the response to vasodilator medication is impaired in patients who smoke. The number of episodes and total duration of ischemic episodes as assessed by ambulatory electrocardiographic monitoring in patients with coronary heart disease are substantially increased by cigarette smoking.[41] The increase in relative risk of coronary heart disease because of cigarette smoking is greatest in young adults who, in the absence of cigarette smoking, would have a relatively low risk.[38] Women who use oral contraceptives and smoke cigarettes have a synergistically increased risk of both myocardial infarction and stroke. Recent data suggest that implementing smoking bans at the community level has an appreciable impact on lowering hospital admission rates for coronary artery disease.[42]

After acute myocardial infarction, the risk of recurrent myocardial infarction is higher and survival is half over the next 12 years in persistent smokers as compared with quitters.[43] Smoking also interferes with revascularization therapy for acute myocardial infarction. After thrombolysis, the reocclusion rate is fourfold higher in smokers who continue than in those who quit.[44] The risk of reocclusion of a coronary artery after angioplasty or occlusion of a bypass graft is increased in smokers.[45] Cigarette smoking is not a risk factor for hypertension per se but does increase the risk of complications, including the development of nephrosclerosis and progression to malignant hypertension.[46] Cigarette smoking has been shown to be a substantial contributor to morbidity and mortality in patients with left ventricular dysfunction. The mortality benefit of stopping smoking in such patients is equal to or greater than the benefit of therapy with angiotension-converting enzyme inhibitors, β-blockers, or spironolactone.[47]

Wound Healing/Postoperative Complications

Cigarette smoking is associated with adverse postoperative events and delayed wound healing. The mechanisms include cutaneous vasoconstriction (reducing skin blood flow), local thrombosis, and reduced oxygen-carrying capacity, all of which can delay wound healing. Impaired clearance of secretions, altered immune function, altered collagen synthesis, as well as the influence of underlying tobacco-related diseases (e.g., COPD and altered cardiovascular function), also contribute to postoperative complications.

The harmful effects of smoking have been shown by preoperative smoking-cessation studies. Moller and colleagues[48] published the results of a randomized, controlled trial of smokers awaiting elective hip or knee surgery at three hospitals in Copenhagen. They compared 56 patients in a smoking-cessation intervention arm (83% stopped or reduced smoking) versus 62 patients in a usual care arm. The overall complication rate was 18% in the intervention arm and 52% in the controls, a highly significant difference. The greatest differences were seen in wound complication rates (5 vs. 31%) and cardiovascular complications (0 vs. 2%), without a significant difference in length of hospital stay.

The harmful effects of smoking are found for a variety of postoperative complications and procedures. A study of 489 adult patients undergoing ambulatory surgery demonstrated a significantly higher rate of respiratory complications (32.8% in smokers vs. 25.9% in nonsmokers) and wound infections (3.6% in smokers vs. 0.6% in nonsmokers, respectively).[49] Causes of major pulmonary events after pneumonectomy for lung surgery were sought in a retrospective analysis of 261 patients.[50] Patients who continued to smoke within 1 month of operation were determined to be at an increased risk of pulmonary events, which were associated with increased postoperative mortality. Cigarette smoking is associated with an increased risk of hepatic artery thrombosis after liver transplantation, and cessation 2 years before transplantation was associated with a decreased risk.[51] Similar data exist regarding renal transplantation and allograft survival in smokers compared with nonsmokers.[52]

The optimal window for smoking-cessation intervention may be at 8 weeks prior to elective surgery, as suggested by data demonstrating that patients who had stopped smoking at least 2 months preoperatively had nearly maximal reduction in postoperative respiratory complications.[53] Data suggest that short-term (2- to 3-week) cessation or reduction in smoking does not substantially alter postoperative wound complications in patients receiving colorectal surgery.[54]

An important issue related to elective surgery is that patients are often highly motivated to quit smoking just

before elective surgery and can benefit from cessation counseling prior to surgery as well as in the hospital and from medication in the postoperative setting. Specific issues related to smoking cessation are discussed later in this chapter.

Other Complications of Cigarette Smoking

Cigarette smoking increases the risk of duodenal and gastric ulcers, delays the rate of ulcer healing, and increases the risk of relapse after ulcer treatment.[55,56] Smoking is also associated with esophageal reflux symptoms. Smoking produces ulcer disease by increasing acid secretion, reducing pancreatic bicarbonate secretion, impairing the gastric mucosal barrier (related to decreased gastric mucosal blood flow and/or inhibition of prostaglandin synthesis), reducing pyloric sphincter tone, and increasing the risk of *Helicobacter pylori* infection.[57]

Cigarette smoking is an independent risk factor for the development of non–insulin-dependent diabetes mellitus, which is a consequence of development of resistance to the effects of insulin.[58] The effects of nicotine seem to contribute at least in part to insulin resistance, and insulin resistance has been described in users of smokeless tobacco, who are not exposed to tobacco combustion products.

Cigarette smoking is a risk factor for osteoporosis in that it reduces the peak bone mass attained in early adulthood and increases the rate of bone loss in later adulthood. Smoking antagonizes the protective effect of estrogen replacement therapy on the risk of osteoporosis in postmenopausal women.[59]

Cigarette smoking is a major cause of reproductive problems and results in approximately 4600 U.S. infant deaths annually. Growth retardation from cigarette smoking has been termed "fetal tobacco syndrome." Cigarette smoking causes reproductive complications by causing placental ischemia mediated by the hypoxic effects of chronic carbon monoxide exposure, endothelial dysfunction, and the general increase in coagulability produced by oxidant chemicals in cigarette smoke.[60]

Other adverse effects of cigarette smoking include premature facial wrinkling, an increased risk of cataracts, olfactory dysfunction, and fire-related injuries. Damage and injuries from fire contribute significantly to the economic costs of tobacco use. Cigarette smoking is associated with an increased incidence of Graves' hyperthyroidism, and particularly of the ophthalmopathy associated with Graves' disease.[61] Smoking reduces the secretion of thyroid hormone in women with subclinical hypothyroidism and increases the severity of clinical symptoms of hypothyroidism in women with subclinical or overt hypothyroidism, the latter effect reflecting antagonism of thyroid hormone action.[61]

Cigarette smoking also potentially interacts with a variety of drugs by accelerating drug metabolism or by antagonizing their pharmacologic effects (Table 40-4). As an example of the clinical consequences of enzyme

TABLE 40-4. Interaction between Cigarette Smoking and Drugs

Drugs	Interaction (Effects Compared with Nonsmokers)	Significance
Antipyrine Caffeine Chlorpromazine Clozapine Desmethyldiazepam Erlotinib Estradiol Estrone Flecainide Fluvoxamine Haloperidol Imipramine Irinotecan Lidocaine Olanzapine Oxazepam Pentazocine Phenacetin Phenylbutazone Propranolol Tacrine Theophylline	Accelerated metabolism	May require higher doses in smokers, reduced doses after quitting. Reduced toxicity with standard doses (e.g., irinotecan)
Oral contraceptives	Enhanced thrombosis, increased risk of stroke and myocardial infarction	Do not prescribe to smokers, especially if >35 yr old
Cimetidine and other H_2 blockers	Lower rate of ulcer healing, higher ulcer recurrence rates	Consider using mucosal protective agents
Propranolol	Less antihypertensive effect, less antianginal efficacy; more effective in reducing mortality after myocardial infarction[61a]	Consider the use of cardioselective β-blockers
Nifedipine (and probably other calcium blockers)	Less antianginal effect	May require higher doses and/or multiple-drug antianginal therapy
Diazepam, chlordiazepoxide (and possibly other sedative-hypnotics)	Less sedation	Smokers may need higher doses
Chlorpromazine (and possibly other neuroleptics)	Less sedation, possibly reduced efficacy	Smokers may need higher doses
Propoxyphene	Reduced analgesia	Smokers may need higher doses

induction from smoking on response to treatment of lung cancer, accelerated metabolism of erlotinib most likely explains the poorer response of smokers versus nonsmokers with non–small cell lung cancer.[62] Smoking is also associated with a decreased risk of hematologic toxicity from irinotecan, a drug widely used for solid tumors, including lung cancer.[63] Smoking accelerates the metabolism of irinotecan to its active metabolite, SN-38, and further accelerates the glucuronidation of SN-38, explaining the reduced toxicity, but also suggesting that smoking could reduce efficacy.

HEALTH HAZARDS OF SECONDHAND SMOKE

Considerable evidence indicates that exposure to secondhand smoke, also known as environmental tobacco smoke, is harmful to the health of nonsmokers (Table 40-5). The U.S. Environmental Protection Agency (EPA) classifies secondhand smoke as a class A carcinogen, which means that it has been shown to cause cancer in humans.[64] Secondhand smoke consists of sidestream smoke that is generated while the cigarette is smoldering and of mainstream smoke that has been exhaled by the smoker. Of the total combustion product from a cigarette, 75% or more enters the air. The constituents of secondhand smoke are qualitatively similar to those of mainstream smoke. However, some toxins, such as ammonia, formaldehyde, 1,3-butadiene and nitrosamines, are present in much higher concentrations in secondhand smoke than in mainstream smoke.

The EPA has estimated that secondhand smoke is responsible for approximately 3000 lung cancer deaths annually in nonsmokers in the United States, is causally associated with 150,000 to 300,000 cases of lower respiratory tract infection in infants and young children up to 18 months of age, and is causally associated with the aggravation of asthma in 200,000 to 1 million children.[58] More recently, the California EPA found that secondhand smoke exposure is also causally associated with asthma induction and aggravation in adults.[65,66] Exposure to secondhand smoke also adversely effects health outcomes in patients with COPD.[67]

TABLE 40-5. Health Hazards of Secondhand Smoke in Nonsmokers

Children	Adults
Hospitalization for respiratory tract infection in first year of life	Lung cancer
Wheezing	Myocardial infarction
Middle ear effusion	Reduced pulmonary function
Asthma	Irritation of eyes, nasal congestion, headache
Sudden infant death syndrome	Cough

An appreciation of the hazards of secondhand smoke for children is important to the physician because it provides a basis for advising parents to quit smoking, for counseling parents who are unable to quit not to smoke in the home or in family vehicles, and for insisting that child care facilities be smoke-free. Although screening for secondhand smoke exposure among adult patients is not yet part of accepted standard of care, all patients presenting with asthma or COPD should be asked about their secondhand smoke exposure and advised to avoid exposure. The known risks of secondhand smoke exposure provide strong support for smoke-free policies in all public places.

NICOTINE ADDICTION

Tobacco use is motivated primarily by the desire for nicotine. *Drug addiction* is defined as compulsive use of a psychoactive substance, the consequences of which are detrimental to the individual or society. Understanding addiction is useful in providing effective smoking-cessation therapy.[68] Nicotine is absorbed rapidly from tobacco smoke into the pulmonary circulation; it then moves quickly to the brain, where it acts on nicotinic cholinergic receptors to produce its gratifying effects, which occur within 10 to 15 seconds after a puff. Smokeless tobacco is absorbed more slowly and results in less intense acute pharmacologic effects. With long-term use of tobacco, physical dependence develops, associated with an increased number of nicotinic cholinergic receptors in the brain.[69] When tobacco is unavailable, even for only a few hours, withdrawal symptoms often occur, including anxiety, irritability, difficulty concentrating, restlessness, hunger, craving for tobacco, disturbed sleep, and in some people, depression.

Addiction to tobacco is multifactorial, including a desire for the direct pharmacologic actions of nicotine, relief of withdrawal symptoms, and learned associations. Smokers report a variety of reasons for smoking, including pleasure, arousal, enhanced vigilance, improved performance, relief of anxiety or depression, reduced hunger, and control of body weight. Environmental cues—such as a meal, a cup of coffee, talking on the phone, an alcoholic beverage, or friends who smoke—often trigger an urge to smoke. Smoking and depression are strongly linked. Smokers are more likely to have a history of major depression than are nonsmokers. Smokers with a history of depression are also likely to be more highly dependent on nicotine and have a lower likelihood of quitting. When they do quit, depression is more apt to be a prominent withdrawal symptom.

Most tobacco use begins in childhood or adolescence.[70] Risk factors for youth smoking include peer and parental influences; behavioral problems (e.g., poor school performance); personality characteristics such as rebelliousness or risk taking, depression, and anxiety; and genetic influences. The adolescent's desire to appear older and more sophisticated, by emulating older role models, is another strong motivator. Environmental influences such as advertising and smoking in movies also

contribute. Although smoking rates among adults have been declining since the 1970s, initiation rates for youth have remained constant since the mid-1980s. Approaches to preventing tobacco addiction in youth include educational activities in schools, aggressive anti-tobacco media campaigns, taxation of tobacco products, changing the social and environmental norms (restricting indoor smoking, educating parents not to smoke around children), and deglamorizing smoking.

Neurobiologic Mechanisms of Addiction

Nicotine binds stereoselectively to nicotinic cholinergic receptors in the brain, autonomic ganglia, the adrenal medulla, and neuromuscular junctions. Most relevant to nicotine addiction are the neuronal nicotinic cholinergic receptors. These are found throughout the brain, with the greatest number of binding sites in the cortex, thalamus, and interpeduncular nucleus, and substantial binding in the amygdala, septum, brain-stem motor nuclei, and locus coeruleus. The nicotinic cholinergic receptor is a ligand-gated ion channel, composed of five subunits. Most brain nicotinic cholinergic receptors are comprised of α- and β-subunits. Usually, there are two α- and three β-subunits, with the α-subunits responsible for ligand binding and the β-subunits mediating other aspects of receptor function.[71] There is much diversity of nicotinic cholinergic receptors with nine α-subunit isoforms (α_2 through α_{10}) and three β-subunit isoforms (β_2 through β_4) identified in brain tissues. Different nicotinic receptors are found in different parts of the brain and have different chemical conductances for sodium and calcium and different sensitivity to different nicotinic agonists. The different nicotinic receptors are believed to mediate different pharmacologic actions of nicotine, perhaps corresponding to the multiple effects of nicotine experienced by human smokers.[72]

Nicotine receptors appear to be located both on cell bodies and at nerve terminals. All nicotine receptors are permeable to calcium ions. Nicotinic receptor activation works, at least in part, by facilitating the release of neurotransmitters, including acetylcholine, norepinephrine, dopamine, serotonin, β-endorphin, gamma-aminobutyric acid (GABA), and others.[73] Nicotine enhances fast excitatory synaptic transmission, which may contribute to learning and memory.[74,75] Nicotine also releases growth hormone, prolactin, vasopressin, and adrenocorticotropic hormone (ACTH). Behavioral rewards from nicotine and perhaps nicotine addiction as well appear to be linked to dopamine release.[76]

The two main dopamine systems in the brain are the mesocorticolimbic and the nigrostriatal systems. The mesocorticolimbic system includes the ventral tegmental area projecting to the nucleus accumbens, the cortex, and limbic regions. The nigrostriatal system connects the substantia nigra to the dorsal striatum. Nicotine causes an increase in burst firing of ventral tegmental area neurons, resulting in release of dopamine in the nucleus accumbens.[76] Dopamine release is potentiated and sustained by nicotine-mediated release of glutamate.[77] Dopamine release in the outer shell of the nucleus accumbens is characteristic of the effects of many addicting drugs (e.g., heroin, cocaine, alcohol) and is thought to be an important site for drug-mediated reinforcement.[78]

Whereas acute exposure to nicotine produces stimulation of dopaminergic neurons in mesolimbic pathways, chronic exposure to nicotine and other drugs of abuse produces other changes in mesolimbic function. Chronic nicotine exposure results in neuroadaptation or the development of tolerance, and the absence of nicotine results in subnormal release of dopamine and other neurotransmitters. Thus, nicotine withdrawal may result in a state of deficient dopamine responses to novel stimuli in general and to a state of malaise and inability to experience pleasure. This has been termed by Koob and LeMoal as "hedonic dysregulation."[79] Hedonic dysregulation may explain craving, and sensitivity to drug effects may explain why even a single slip might easily result in a return to compulsive drug use.

The release of various neurotransmitters discussed previously results in behavioral arousal, sympathetic neural activation, and a number of other effects that are believed to be rewarding.[80] The release of specific neurotransmitters has been speculatively linked to the reported reinforcing effects of nicotine (Fig. 40-1). For example, enhanced release of dopamine and norepinephrine may be associated with pleasure as well as appetite suppression, the latter of which may contribute to lower body weight. Release of acetylcholine may be associated with improved performance on behavioral tasks and improvement of memory. Release of β-endorphin may be associated with reduction of anxiety and tension.

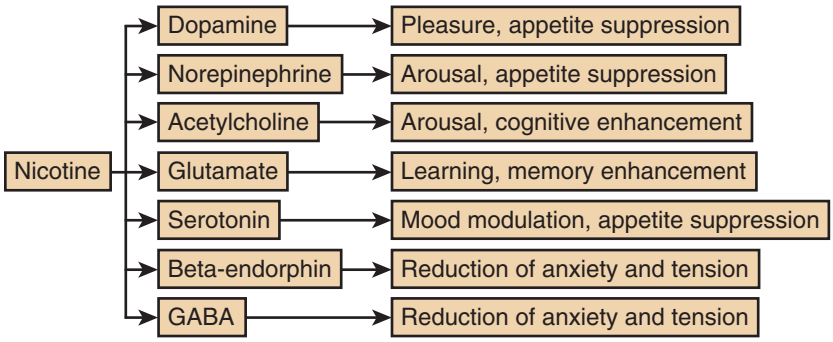

FIGURE 40-1 ■ Neurochemical effects of nicotine.

Although smokers give different explanations for their smoking, most agree that smoking produces arousal, particularly with the first cigarettes of the day, and relaxation, particularly in stressful situations. Consistent with reports of arousal, cigarette smoking or administration of nicotine induces electroencephalographic desynchronization, with an upward shift in the dominant alpha frequency and decreased total alpha and theta power.[81]

Low-Yield Cigarettes

It has been clearly demonstrated that smokers regulate their intake of nicotine. Smokers change the way they puff a cigarette depending on nicotine yield, as determined by a cigarette smoking machine.[82,83] They puff lower-yield cigarettes more frequently or more intensely than higher-yield cigarettes, presumably to obtain more nicotine. Smokers who switch from higher-yield to lower-yield cigarettes consume more nicotine from the lower-yield cigarettes than is predicted by smoking machine tests. Conversely, smokers consume less nicotine than predicted from higher-yield cigarettes. The intake of nicotine, with blood cotinine or nicotine concentrations or urine metabolites used as markers of nicotine intake, has been studied in large groups of people smoking their own chosen brand of cigarettes.[82] In such studies, nicotine intake correlates only weakly with the machine-determined yield. Despite smoking cigarettes with widely differing nicotine yields, smokers demonstrate only small differences in nicotine intake. Correspondingly, the health benefits of switching from higher-yield to lower-yield cigarettes are quite small, if any.[84,85]

The shift over the years from higher- to lower-yield cigarettes may explain the change in the pathology of lung cancer.[86] That is, the percentage of lung cancers that are adenocarcinomas has increased, while the percentage of squamous cell cancers has decreased. The change in tumor type is believed to reflect the higher nitrosamine delivery of lower-yield cigarettes and the increased depth or volume of inhalation of lower-yield cigarettes to compensate for lower level concentrations of nicotine in the smoke.

SMOKING CESSATION

Of cigarette smokers, 70% would like to quit and 46% try to quit each year. Spontaneous quit rates are about 1% per year. Simple physician advice to quit increases the quit rate to 3%. Minimal intervention programs increase quit rates to 5% to 10%, whereas more intensive treatments, including smoking-cessation clinics, can yield quit rates of 25% to 30%.[87]

The main strategies for cessation are behavioral counseling, pharmacologic intervention, or a combination of the two. Many patients try over-the-counter smoking cessation medications prior to discussing smoking with their healthcare providers. The efficacy of over-the-counter medications may be limited by improper use of medications and concomitant untreated issues such as depression, alcoholism, or other factors. Before a therapeutic intervention is attempted, it is important to obtain a history assessing the level of stress, possible exposure to family members or roommates who smoke, or other factors shown to predict relapse.

Guidelines

Evidence-based guidelines for the treatment of tobacco addiction emphasize identifying all tobacco users in a physician's practice and ascertaining each patient's intent with respect to quitting smoking (Fig. 40-2).[88] Identification of tobacco use is facilitated by the implementation of an office-based system so that patients are queried about tobacco use at every visit. Tobacco use

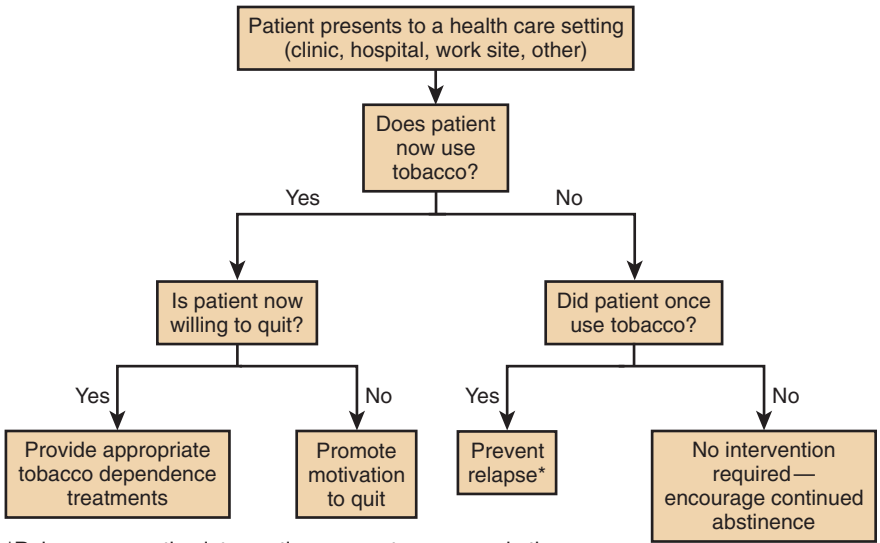

FIGURE 40-2 ■ An algorithm for treating tobacco use.

*Relapse prevention interventions are not necessary in the case of the adult who has not used tobacco for many years.

should be treated as a vital sign by using tobacco status stickers on patients' charts, electronic medical records, or computer reminder systems. The practice of routinely recording a patient's tobacco use status increases the odds ratio for quitting by twofold. Pediatric patients and patients with COPD and asthma should also be asked routinely about their secondhand smoke exposure and counseled to avoid all exposure.

Brief strategies to help a patient quit (the "5 A's") (Table 40-6), which can be implemented in as little as 3 minutes, increase cessation rates significantly. In a meta-analysis of 31 trials, brief physician advice increased quit rates by 70%.[87] Intensive behavioral treatment of tobacco dependence produces higher success rates than brief advice does and is cost-effective. However, these intensive programs are less widely available and may be less acceptable to patients than brief interventions. Nevertheless, clinicians with training in intensive smoking-cessation therapy should be identified as a referral source for smokers who are interested.

The recent Public Health Service guideline[88] recommends that all smokers trying to quit should be offered pharmacotherapy (Table 40-7). In brief, three types of medications have been approved by the U.S. Food and Drug Administration (FDA) for smoking cessation—bupropion, which was originally marketed as an antidepressant drug, nicotine, and varenicline (Table 40-8). Other drugs such as nortriptyline and clonidine have been shown in clinical trials to be effective in aiding smoking cessation but have not been approved by the FDA for this purpose.

Smoking-Cessation Counseling

Counseling smokers about the dangerous effects of tobacco should be routine medical practice and has been

TABLE 40-6. Brief Strategies to Help the Patient Willing to Quit Tobacco Use—The "5 A's"

Strategies for Implementation	Action
Ask—Systematically identify all tobacco users at every visit.	Implement an office-wide system that ensures that, for every patient at every clinic visit, tobacco-use status is queried and documented.
Advise—Strongly urge all tobacco users to quit.	In a clear, strong, and personalized manner, urge every tobacco user to quit.
Assess—Determine willingness to make a quit attempt.	Ask every tobacco user if he or she is willing to make a quit attempt at this time (e.g., within the next 30 days).
Assist—Aid the patient in quitting.	Help the patient with a quit plan.
	Provide practical counseling (problem solving/skills training).
	Provide encouragement and support during treatment.
	Help patient obtain outside social support.
	Recommend the use of approved pharmacotherapy except in special circumstances.
Arrange—Schedule follow-up contact.	Schedule follow-up contact, either in person or via telephone.

Adapted from A clinical practice guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. Am J Prev Med 35:158–176, 2008.

TABLE 40-7. General Clinical Guidelines for Prescribing Pharmacotherapy for Smoking Cessation

- In general, all smokers trying to quit smoking should be offered pharmacotherapy.
- There are seven first-line smoking cessation medications—five types of nicotine replacement therapy, sustained-release bupropion, an antagonist of the nicotinic receptor, and varenicline, a partial agonist of the nicotinic receptor. Varenicline or the combination of nicotine patch plus ad libitum short-acting nicotine products appear to be the most effective. However, the choice of first-line therapy should be governed by patient preference, familiarity of the clinician with the medication, contraindications for specific patients, and prior experience of the patient with specific pharmacotherapies.
- Second-line therapies include clonidine and nortriptyline. These should be reserved for individuals with contraindications to/or failure of response to first-line medications.
- Bupropion and nicotine replacement therapies may delay but not prevent weight gain after smoking cessation. It is recommended that patients start or increase physical activity, but strict dieting is discouraged because this appears to increase the likelihood of relapse to smoking. Patients should be reassured that weight gain after quitting is self-limited and poses much less of a risk to health than smoking.
- Transdermal nicotine (patches), nicotine gum, and bupropion appear to be safe for patients with chronic cardiovascular disease. Other medications are likely to be much safer than smoking in the presence of medical disease, but need further evaluation.
- In those with prolonged withdrawal symptoms or in those who cannot resist smoking without medication, long-term therapy with nicotine replacement medication, bupropion, or varenicline appears to be safe and effective therapy.
- Recent research suggests that combining bupropion with nicotine patches or combining nicotine patches with ad libitum use of nicotine gum or nicotine nasal spray increases abstinence rates compared with the rates produced by a single form of therapy.

TABLE 40-8. Suggestions for the Clinical Use of Pharmacotherapies for Smoking Cessation

Pharmacotherapy	Precautions/ Contraindications	Adverse Effects	Dosage	Duration	Availability
FIRST-LINE					
Bupropion hydrocloride, Sustained release	History of seizure History of eating disorders	Insomnia Dry mouth	150 mg every morning for 3 days then 150 mg twice daily (begin treatment 1–2 wk prequit)	7–12 wk maintenance up to 6 mo	Prescription only
Varenicline	Significant kidney disease Patients on dialysis	Nausea Abnormal or vivid strange dreams Depressed mood and other psychiatric symptoms Trouble sleeping	0.5 mg/day for 3 days, 0.5 mg twice/day for 4 days, then 1 mg twice/day (begin treatment 1 wk prequit)	3–6 mo	Prescription only
Nicotine gum	Temperomandibular joint disorder	Mouth soreness Dyspepsia	if 1–24 cigarettes/day; 2 mg gum (≤24 pieces/day) if ≥25 cigarettes/day; 4 mg gum (≤24 pieces/day)	≤12 wk	OTC only
Nicotine inhaler		Local irritation of mouth and throat	6–16 cartridges/day	≤6 mo	Prescription only
Nicotine nasal spray	Chronic nasal disorders, including rhinitis, polyps, and sinusitis	Nasal irritation Throat burning	8–40 doses/day	3–6 mo	Prescription only
Nicotine patch	Skin diseases, such as atopic or eczematous dermatitis	Local skin reaction Insomnia	21 mg/24 hr 14 mg/24 hr 7 mg/24 hr 15 mg/16 hr	4 wk then 2 wk then 2 wk 8 wk	Prescription and OTC
SECOND-LINE					
Clonidine	Rebound hypertension	Dry mouth Drowsiness Dizziness Sedation	0.15–0.75 mg/day	3–10 wk	Prescription only (oral formulation) Prescription only (patch)
Nortriptyline	Risk of arrhythmias	Sedation Dry mouth	75–100 mg/day	12 wk	Prescription only

OTC, over the counter.
Adapted from A clinical practice guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. Am J Prev Med 35:158–176, 2008.

shown to be an effective method to improve cessation rates. Based on a review of 188 randomized trials, personal advice and encouragement to stop smoking provided by a physician during a routine office visit resulted in an estimated 2% of all smokers stopping and not relapsing over 1 year.[89] Whereas this percentage seems low, it is both cost-effective and important when considering the large population at risk for disease. Specific patient populations may have better results—8% of pregnant smokers, 21% of healthy men at risk for cardiovascular disease, and 36% of survivors of myocardial infarction will stop smoking when receiving advice and encouragement. This high success rate reflects the patient's inherent motivation once challenged by a condition that has been caused or may be aggravated by cigarette smoking.

Group counseling is less cost-effective than brief advice, but may be necessary for smokers who are having a hard time quitting with less intensive therapy. A review of 16 studies comparing group counseling found increased rates of cessation over that of self-help programs (16 studies; OR 1.97) or no intervention (6 studies; OR 2.19).[87] There is no evidence that group counseling is more effective than a similar intensity of individual counseling.

Telephone counseling is also effective in promoting cessation. In a large randomly controlled trial of 1973 intensively counseled callers versus 1309 controls, tele-

phone counseling through the California Quitline nearly doubled abstinence rates.[90] The 12 month self-reported cessation rates for those who made one or more cessation attempts was 23.3% in the treatment group and 18.4% in the control group. Telephone hot lines for smoking cessation are available at no cost in many states across the United States. Thus, the busiest physician can easily refer patients to a hot line for cessation if personal counseling time is not readily available.

Another approach to smoking-cessation counseling that requires no physician resources and allows smokers to be counseled in their homes is the use of web- and computer-based smoking-cessation programs. A number of clinical trials have been conducted on the effectiveness of these interventions, and a meta-analysis of those trials has been recently published.[91] Both web- and computer-based interventions were found to be effective, with a relative risk for smoking cessation of 1.40 (95% CI, 1.13–1.72) and 1.48 (1.25–1.76), respectively.

In-hospital counseling is found to be effective for patients admitted with cardiovascular disease, but is not well studied in other populations. Molyneux and associates[92] evaluated 274 patients in a randomized, controlled trial and found that nicotine replacement therapy given with brief counseling is more effective than counseling alone or usual care. Counseling alone was not more effective than usual care, and differences between all groups disappeared at 12 months. These findings underscore the value of cessation medications when given with even brief advice. Longer physician counseling time and more office visits translate into higher cessation rates, independent of pharmacotherapy.

Pharmacotherapy of Smoking Cessation

Nicotine Replacement Therapy

Currently, three medications have been approved for smoking cessation: nicotine, bupropion, and varenicline. All types of smoking-cessation medications, if used properly, double smoking-cessation rates compared with placebo treatments.[88] Nicotine replacement medications include 2- and 4-mg nicotine polacrilex gum, transdermal nicotine patches, nicotine nasal spray, the nicotine inhaler, and nicotine lozenges. All seem to have comparable efficacy but, in a randomized study, compliance was greatest for the patch, lower for gum, and very low for the spray and the inhaler.[93] A smoker should be instructed to quit smoking entirely before beginning nicotine replacement therapies. Optimal use of nicotine gum includes instructions to chew slowly, to chew 8 to 10 pieces/day for 20 to 30 minutes each, and to continue long enough for the smoker to learn a lifestyle without cigarettes, usually 3 months or longer. Side effects of nicotine gum are primarily local and can include jaw fatigue, sore mouth and throat, upset stomach, and hiccups.

Several different transdermal nicotine preparations are marketed—three deliver 21 or 22 mg over a 24-hour period, and one delivers 15 mg over a period of 16 hours. Most brands have lower-dose patches for tapering. Patches are applied in the morning and removed either the next morning or at bedtime, depending on the patch. Patches intended for 24-hour use can also be removed at bedtime if the patient is experiencing insomnia or disturbing dreams. Full-dose patches are recommended for most smokers for the first 1 to 3 months, followed by one to two tapering doses for 2 to 4 weeks each. Nicotine nasal spray, one spray into each nostril, delivers about 0.5 mg nicotine systemically and can be used every 30 to 60 minutes. Local irritation of the nose commonly produces burning, sneezing, and watery eyes during initial treatment, but tolerance develops to these effects in 1 to 2 days. The nicotine inhaler actually delivers nicotine to the throat and upper airway, from where it is absorbed similarly to nicotine from gum. It is marketed as a cigarette-like plastic device and can be used ad libitum.

Most recently, nicotine lozenges have been marketed over the counter. The lozenges are available in 2- and 4-mg strengths and are to be placed in the buccal cavity where they are slowly absorbed over 30 minutes.[94] Smokers are instructed to choose their dose according to how long after awakening in the morning they smoked their first cigarette (a measure of the level of dependence). Those who smoke within 30 minutes are advised to use the 4-mg lozenge, whereas those who smoke their first cigarette at 30 or more minutes are advised to use the 2-mg lozenges. Use is recommended every 1 to 2 hours.

Nicotine medications seem to be safe in patients with cardiovascular disease and should be offered to them.[95–98] Although smoking-cessation medications are recommended by the manufacturer for relatively short-term use (generally 3–6 mo), the use of these medications for 6 months or longer is safe and may be helpful in smokers who fear relapse without medications.

Bupropion

Bupropion sustained release, a dopamine-norepinephrine reuptake inhibitor that also has nicotinic cholinergic receptor antagonist activity, was originally marketed and is still widely used as an antidepressant. Bupropion was found to aid smoking cessation independent of whether a smoker was depressed or not.[99] Hurt and coworkers[99] demonstrated that with a 300-mg sustained-release dose, 44% of patients quit at 7 weeks versus 19% of controls. This difference was sustained at 12 months (23% vs. 12%). This study also indicated that when smokers quit, they gain less weight while taking bupropion compared with placebo. An additional randomized, placebo-controlled trial demonstrated that the combination of bupropion with a nicotine patch is safe, and that bupropion alone or in combination was as effective or more effective than the patch alone.[100] Bupropion used for 1 year for relapse prevention was demonstrated to be safe and effective and significantly better at promoting cessation (55%) than placebo (42%) (assessed as *point prevalence abstinence*, or no smoking within seven days of assessment).[101] Given its antidepressant properties, bupropion is a logical choice for depressed

smokers but, as mentioned previously, has clear efficacy in smokers without depression as well.

Bupropion is dosed at 150 mg sustained release per day for 7 days prior to stopping smoking, then at 300 mg (two 150-mg sustained-release doses) per day for the next 6 to 12 weeks. Bupropion in excessive doses can cause seizures and should not be used in an individual with a history of seizures or with eating disorders (bulemia or anorexia).

Varenicline

Varenicline, available by prescription only, is a nicotinic receptor partial agonist that selectively binds to $\alpha4\beta2$ nicotinic cholinergic receptors in the brain.[102] This receptor mediates dopamine release and is thought to be the major receptor involved in nicotine addiction. A partial agonist means that the drug both activates the receptor and blocks the effects of other agonists on the receptor. Varenicline activates the $\alpha4\beta2$ nicotinic cholinergic receptor with a maximal effect about 50% that of nicotine and, at the same time, blocks effects of nicotine from tobacco use on the receptor. As a consequence of the receptor stimulation, nicotine withdrawal symptoms are relieved, and as a consequence of receptor blockade, the rewarding effects of smoking are diminished. The latter effect reduces the desire to smoke and, in the case of a lapse, may prevent continued smoking.

In clinical trials, varenicline treatment for 12 weeks has been shown to be more effective than bupropion sustained-release 300 mg and placebo.[103] Abstinence rates from 9 to 52 weeks were 23%, 15%, and 10% for varenicline, bupropion, and placebo, respectively (assessed as *continuous abstinence*, or the absence of any smoking during the study period). Varenicline has also been shown to be effective in preventing relapse over 6 months.[104]

The major side effects of varenicline are nausea, vomiting, and insomnia. A variety of neuropsychiatric side effects including depression, psychosis, and suicide have been reported anecdotally but were not observed in clinical trials. The causal relationship between varenicline and these neuropsychiatric events has not been established because smoking cessation itself can be associated with mood disturbances, including suicidality. In any case, smokers treated with varenicline should be advised about possible neuropsychiatric effects and monitored for such events during treatment.

Varenicline is initiated in a dose of 0.5 mg/day for 3 days, then 0.5 mg twice daily for 4 days, followed by a maintenance dose of 1 mg twice daily. Lower doses may be used if nausea is a problem at higher doses. Because varenicline is eliminated by the kidneys, dose reductions are required in the presence of severe renal disease. The approved duration of treatment is 3 months, with another 3 months optional for prevention of relapse.

Combination Therapy

Combined medications for smoking cessation can be more effective than individual therapies, particularly when combining long-acting medications such as nicotine patch or bupropion with short-acting nicotine replacement therapy used at times of intense urges or cravings to smoke. Only the combination of bupropion and transdermal nicotine has been approved by the FDA. However, a number of studies have looked at various combinations of medications, and there have been no significant safety issues.[101,105–107] Studies comparing different therapies have found that combinations are two to three times more effective than single medications used alone. A stepwise process that incorporates combination therapies after patients have failed single therapies would be logical and would balance the increased costs associated with additional medications with increased benefit.

Motivating Smokers to Quit

The well-known association between cigarette use and lethal diseases such as lung cancer, myocardial infarction, stroke, and COPD is insufficient to motivate many cigarette smokers to quit. This is due to addiction to nicotine, which includes denial and rationalization (which are a part of all drug addictions). As described previously, many smokers depend on nicotine to cope with stressors encountered in daily life. The perceived stress-reducing effect of nicotine is rapid and readily available. In contrast, quitting for many smokers results in a period of intense dysphoria and dysfunction that can easily be avoided by smoking one more cigarette. A telephone-based survey conducted in 1999[108] found that only 29% of smokers felt that they were at greater risk of myocardial infarction, and only 40% felt they were at greater risk for development of cancer compared with nonsmokers. This clearly indicates denial of risk and may explain why many smokers become motivated to quit only when they develop a medical condition later in life. Becoming a nonsmoker requires a profound change of self-image and a discovery of personal coping skills that may not have been used previously.

The physician's role in the motivation process can be substantial. The message to the smoker must be consistent and inspirational. Patients clearly respond to physician advice, and hopelessness can by allayed by describing the many options available for cessation medication and counseling. Smoking cessation is the most important health initiative many patients will ever undertake and is highly cost-effective for the healthcare system. It is difficult to address smoking in patients when three or four medical issues are being managed in addition to smoking cessation. For this reason, a separate return appointment focused solely on smoking cessation is recommended.

Motivating patients to quit needs to be more than steering them away from disease, but also steering them toward greater self-control, self-expression, independence, and positive role modeling. Exercise during trials of smoking cessation may reduce anxiety, tension, and stress but was not found to be an independent predictor of success in a randomized, controlled trial.[109] Walking on a regular basis is a reasonable initial step and in many cases improves self-esteem and investment in health.

Benefits of Quitting

The benefits of quitting smoking are substantial for smokers of any age. A person who quits smoking before age 50 has half the risk of dying in the next 15 years compared with a continuing smoker.[110] Smoking cessation reduces the risks of developing lung cancer, with the risk falling to half that of a continuing smoker by 10 years and one sixth that of a smoker after 15 years' cessation. Quitting smoking in middle age substantially reduces lung cancer risk, with a 50% reduction in risk if a lifelong smoker quits at age 55 compared with age 75.[111] The risk of acute myocardial infarction falls very rapidly after quitting and approaches nonsmoking levels within 1 year of abstinence. Cigarette smoking produces a progressive loss of airway function over time that is characterized by an accelerated loss of forced expiratory volume in 1 second (FEV_1) with increasing age. Loss of FEV_1 due to cigarette smoking cannot be regained by cessation, but the rate of decline slows after smoking cessation and returns to that of nonsmokers.[112] Women who stop smoking during the first 3 to 4 months of pregnancy reduce the risk of having a low-birth-weight infant to that of a woman who has never smoked.

After quitting, smokers gain an average of 5 to 7 pounds, which is perceived by some smokers as undesirable and as a reason not to quit.[113] Smokers tend to be thinner because nicotine increases energy expenditure and suppresses a compensatory increase in food consumption. After they quit smoking, ex-smokers tend to reach the weight expected had they never smoked. On balance, the benefits of quitting far outweigh the risks associated with weight gain, and patients should be counseled accordingly.

Resources for Physicians

Most hospitals have smoking-cessation services available that will enable referral of smokers if deemed necessary. Most states have toll-free quit lines that can be accessed through a national network at 1-800-QUIT-NOW (1-800-784-8669) and that provide smoking-cessation information and counseling and have been shown to be effective.[90] Internet-based programs such as QuitNet (www.quitnet.com) can provide online chat rooms and can give smokers with access to a computer a sense of community with other smokers in a similar position. If patients do not have their own computer, the public library is a smoke-free environment where they can access computers. The American Lung Association (www.lungusa.org) has significant information and a free online program called "Freedom from Smoking" to which patients can be referred (www.ffsonline.org). The Centers for Disease Control and Prevention has information that can be downloaded for adults, youth, and Spanish-speaking patients (www.cdc.gov/Tobacco/). Patients suspected of having underlying depression, anxiety, or other substance abuse disorders may benefit from psychiatric referral to evaluate these conditions known to reduce the likelihood of smoking cessation.[114]

KEY POINTS

- Cigarette smoking is the most important preventable cause of respiratory disease, including lung cancer and COPD, but also of respiratory infections, including pneumococcal pneumonia, influenza, and tuberculosis, as well as for desquamative interstitial pneumonitis and other forms of interstitial lung disease.
- Smoking is a major risk factor for adverse postoperative events, including respiratory infection, cardiovascular events, and delayed wound healing.
- Tobacco use is motivated primarily by a desire for nicotine, a stimulant that acts on specific cholinergic receptors in the brain and leads to changes in brain chemistry and structure.
- Most smokers want to quit smoking but have difficulty doing so because of nicotine addiction. Both behavioral counseling and pharmacotherapy (nicotine replacement therapy, bupropion, and varenicline) enhance quit rates, and the effects of these interventions are generally additive.
- Office practices should identify all smokers, counsel them to quit, and provide guidance and, if necessary, prescriptions for pharmacotherapy.
- Quitting smoking results in tremendous benefits in reducing risks for respiratory cancer as well as for cardiovascular disease risk and in slowing the progression of COPD. Smoking-cessation therapy is far more cost-effective than almost any other preventive medicine intervention.

INTRODUCTION

Cystic fibrosis (CF) is a multisystem disorder affecting children and, increasingly, adults.[1] CF is characterized chiefly by chronic airway obstruction and infection and by exocrine pancreatic insufficiency and gastrointestinal tract dysfunction, with consequent effects on nutrition, growth, and maturation. This condition is the most common life-threatening genetic trait in the white population.[2] Numerous mutations of the cystic fibrosis

transmembrane regulator (CFTR) gene are responsible for the CF syndrome and for variation in its severity. The gene encodes the CFTR protein, which is of the membrane protein class. CFTR functions in many tissues as a kinase regulated Cl^- channel. In some tissues, CFTR also regulates the activity of other ion channels. Typically, mutations in CFTR affect both of these functions.

CF is an important medical problem for a number of reasons. It is the major source of severe chronic lung disease in children and has become an important cause of morbidity and mortality from chronic lung disease in young adults. CF is responsible for most cases of exocrine pancreatic insufficiency in childhood and early adulthood and for many cases of nasal polyposis, pansinusitis, rectal prolapse, nonketotic insulin-dependent hyperglycemia, and biliary cirrhosis in these age groups. Therefore, CF enters into the differential diagnosis of many pediatric and young adult patients. Finally, research advances have produced novel pharmacologic therapies to combat the broad range of manifestations and complications.

Central to CF diagnosis and care is a carefully integrated and closely monitored network of approximately 120 referral centers in the United States, sponsored by the Cystic Fibrosis Foundation. The Foundation also supports a smaller number of multidisciplinary research centers aimed at elucidating the molecular pathophysiology and improving the quality of life for patients with CF. Similar care and research centers are found in Canada and many European countries.

HISTORICAL PERSPECTIVES

CF was first described as a distinct clinical entity in the late 1930s. However, numerous references to infants and children with meconium ileus and characteristic pancreatic and lung diseases are sprinkled throughout the literature as early as 1650. Of interest are references in European folklore to the association of salty skin and early demise.[3] Dorothy Andersen,[4] a pathologist at Babies Hospital in New York City, is usually credited with the first comprehensive description of CF in 1938. She coined the term *cystic fibrosis of the pancreas*. In 1945, Farber[5] suggested that CF is a disease of exocrine glands, characterized largely by failure to clear their mucous secretory product. He introduced the term *mucoviscidosis*, which was used for a number of years. Chronic infection of the lungs was recognized early as a major contributing factor, and antibiotics were first used for the treatment of CF in the 1940s. At the same time, an autosomal recessive inheritance pattern for CF was suggested by Andersen and Hodges.[6] In 1953, di Sant'Agnese and colleagues[7] investigated salt depletion in children with CF during a summertime heat wave and concluded that excessive loss of salt occurred via the sweat. Subsequently, they documented that sodium and chloride levels in sweat are elevated in virtually all (>98%) persons with CF. This observation led to a description by Gibson and Cooke[8] of the pilocarpine iontophoresis method for sweat testing, a method that remains the diagnostic standard to this day. By the late 1950s, CF was reported occasionally in older children and young adults. Soon thereafter, comprehensive and aggressive approaches to the care of patients were instituted in many treatment centers, and these approaches have been credited with the survival into adulthood of a steadily increasing number of patients with CF. Since the 1970s, a markedly refined description of the CF syndrome and the many related complications has emerged.

Several more recent observations have resulted in more comprehensive understanding of CF pathogenesis at a molecular level. In the early 1980s, epithelial physiologists described abnormalities of both sodium and chloride transport by CF respiratory epithelia[9] and chloride impermeability of sweat gland ducts from patients with CF.[10] These observations focused attention on a pathogenetic role for abnormal electrolyte and water movement across CF epithelia. From 1985 to 1987, geneticists, using restriction fragment-length polymorphism analysis, located the CFTR gene on the long arm of chromosome 7.[11–14] Shortly thereafter, the CFTR gene was isolated, cloned, and sequenced,[15] and the major mutation of this gene was characterized.[16] Transfer of a wild-type (normal) gene into CF cells corrected the chloride transport defect.[17,18] The product of the CF gene, the CFTR, was studied and found to be both a Cl^- channel[19–21] and a regulator of other channels.[22,23] Studies of the intracellular maturation of CFTR suggested most mutations led to abnormal folding and mislocation of the protein.[24–26] Detailed studies of (1) the structure of CFTR domains[27] and (2) interactions with other proteins during CFTR's maturation process have provided much new information suitable for novel drug design. Knockout of the CFTR gene in transgenic mice has provided an animal model that possesses several physiologic and clinical similarities to human CF.[28–31] These observations provided a detailed understanding of CFTR structure and function and have laid the groundwork for development of more specific therapeutic interventions, including gene therapy.

EPIDEMIOLOGY

CF is recognized in approximately 1:2500[32] and 1:17,000[33] live births in white and black populations, respectively, in the United States. The range of reported incidence figures worldwide varies from 1:569[34] in a confined Ohio Amish population to 1:90,000 in an Asian population of Hawaii.[35]

Generally, mutations of the CF gene are most prevalent in northern and central Europeans and in persons who derive from these areas. An intermediate incidence is likely, although less well documented, in non-European whites. CF is considered rare in American Indians, Asian populations, and black natives of Africa. It has been suggested that the relatively low frequency in populations living in tropical and semitropical geographic locations is related to adverse consequences in the past from excessive salt loss in heterozygotes as well as homozygotes for the CF gene. In white populations, 2%

to 5% are carriers of a CF gene mutation. These people have no clinical stigmas of CF. Although a number of chemical or physiologic alterations have been described in heterozygotes, these alterations can be identified only on a statistical basis.

GENETIC BASIS

CF is an autosomal recessive trait, resulting from mutations at a single gene locus on the long arm of chromosome 7.[32,36] This locus spans approximately 250 kB of DNA, contains at least 27 exons, and codes for a large protein that has several transmembrane domains, two cytoplasmic nucleotide (adenosine triphosphate [ATP])-binding folds (NBFs), and numerous phosphorylation sites contained a cytoplasmic regulatory (R) domain (Fig. 41-1). The primary and secondary structure of the protein product of the CF gene resembles other membrane proteins that act as pumps, for example, the ATP binding cassette (ABC) transporters.[15]

The predominant *CFTR* mutation is a 3 base pair deletion that eliminates the phenylanine of CFTR at position 508, the so-called ΔF508 mutation.[16] This deletion has been detected in 66% of more than 20,000 CF patient chromosomes analyzed worldwide,[2,32,37,38] but its prevalence varies considerably from population to population (Table 41-1). In general, ΔF508 is more prevalent in Northern than Southern European or Middle Eastern populations.[32] More than 1500 other mutations of the CF gene have been reported, but all at a relatively low frequency. The occurrence of known mutations accounts for only 90% of all CF gene abnormalities.[32,38] CFTR mutations include other deletions, missense mutations, nonsense mutations, frameshift mutations, and introduction of new splice sites.[32,38]

Correlations between genotype and phenotype are beginning to emerge. For example, homozygosity for the ΔF508 mutation almost always confers exocrine pancreatic insufficiency.[33] A severe phenotype, including meconium ileus and liver disease, is strongly associated with the presence of two "severe" (i.e., pancreatic exocrine insufficiency) alleles.[39–41] Regions on human chromosomes 4q35, 8p23, 11q25, and 19q13 have been identi-

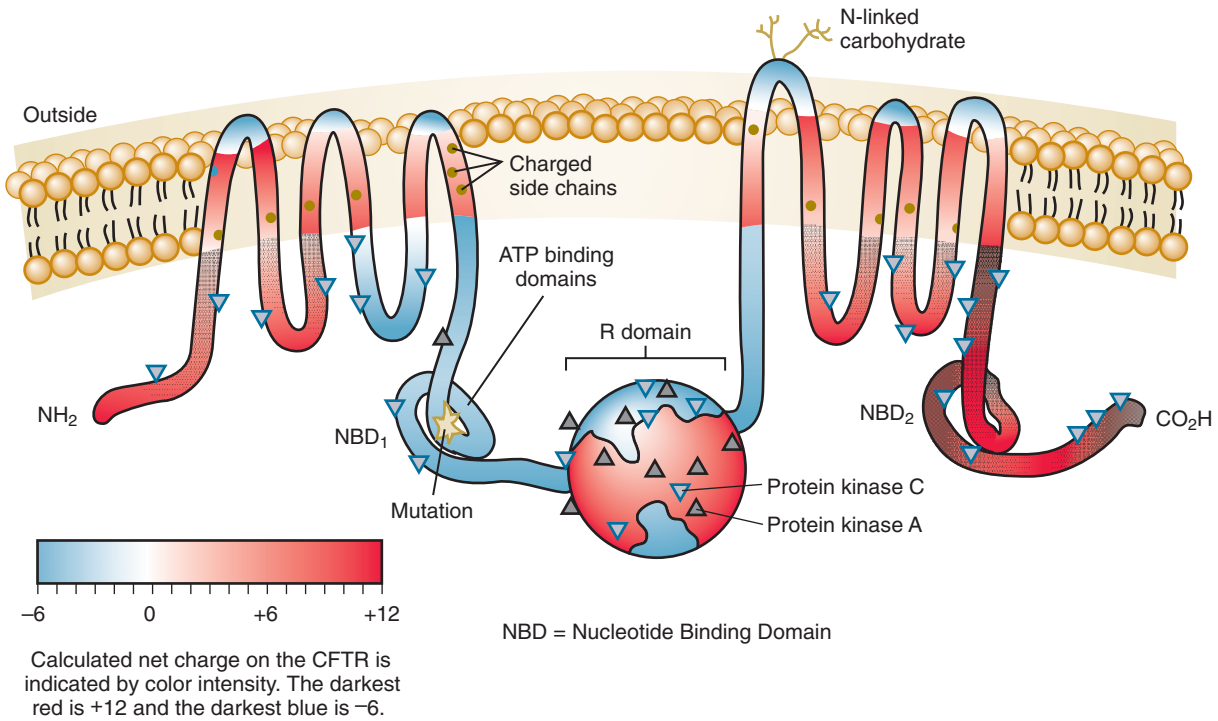

FIGURE 41-1 ■ Proposed structure for the cystic fibrosis transmembrane regulator (CFTR) protein. Two repeat segments each consist of six transmembrane spans followed by a nucleotide-binding domain. The segments are joined by a highly charged region that contains multiple phosphorylation sites, the R domain. Much of the CFTR is intracytoplasmic. Glycosylation occurs on an extracellular loop of the second motif.

fied as modifier loci for meconium ileus.[42,43] Conflicting data exist on whether ΔF508 homozygosity versus other severe alleles is associated with a more severe form of chronic lung disease.[34] Conversely, "mild" mutations with some residual CFTR function and preservation of pancreatic exocrine function have been identified that are associated with normal concentrations of sweat chloride, exocrine pancreatic sufficiency, or both.[44,45] Moreover, variable phenotypes with "mono-organ" disease are also emerging; for example, idiopathic pancreatitis and congenital bilateral absence of the vas deferens are associated with mutations in the CFTR gene.[46–48] In summary, it is now clear that CF is indeed a syndrome, caused by many combinations of mutations at a single gene locus, each of which may confer a slightly different phenotype.[49] The ultimate phenotype of each person with CF is undoubtedly also influenced by genetic background, that is, "modifier genes,"[50–53] as well as postnatal environmental factors.[54]

DNA analysis can now be used to confirm the diagnosis, make prenatal diagnoses, and screen for carrier status in selected cases. For example, probes for 28 of the most common CF mutations in North Carolina provided definitive diagnostic information in less than 90% of persons with CF. Screening for CF carriers using the ΔF508 probe will identify only 50% to 60% of couples at risk of having a CF child.[55]

The high frequency of CF gene mutations in many populations has been ascribed to an unknown heterozygote advantage. Some evidence suggests a reproductive advantage for the carrier state.[56,57] Others have postulated that reduced capacity to generate a secretory diarrhea in response to cholera infection, because of diminished intestinal chloride transport, may have provided an historical survival advantage to heterozygotes.[58–60]

PATHOLOGY

Soon after the original description of the CF syndrome, Farber[5] pointed out the prominent accumulation of mucus in the respiratory and gastrointestinal tracts. Subsequently, mucus stasis has been described in numerous sites, including the conducting airways of the lung,[61] paranasal sinuses, mucus-secreting salivary glands, apocrine sweat glands, small intestine, appendix, pancreas, biliary system, uterine cervix, and wolffian duct structures. However, the eccrine sweat gland, which figures prominently in the pathophysiology of CF, is morphologically normal at all ages. Pathologic changes in the lung, which is the primary site of organ dysfunction, also reflect chronic infection.

Lung Pathology

It is clear that disease of the conducting airways in CF is acquired postnatally. The airways of children with CF who have died within the first days of life display only subtle abnormalities. The earliest macroscopic pathologic lesion is reported to be mucous obstruction of bronchioles.[61] However, the numbers and distribution of mucus-producing goblet cells and the numbers and size of submucosal glands appear to be within normal ranges at birth. A careful morphometric analysis of CF airways early in life demonstrated dilation of submucosal gland acinar and ductal lumens before reaction to chronic infection would be expected.[62] This finding suggests that either hypersecretion or, more likely, failure to clear secretions at an early age accounts for mucus accumulation in bronchial regions, whereas the mucus retention in bronchioles presumably reflects the failure to clear mucus secreted by surface secretory (goblet) cells. Failure to clear secretions from the airway lumens likely initiates infection.

With the progression of lung disease, evidence for bronchiolitis and bronchitis becomes more prominent, the submucosal glands hypertrophy, and goblet cells not only become more numerous but also propagate into the bronchioles. Small airways may be completely obstructed by secretions (Fig. 41-2).[63] Bronchiolectasis and then bronchiectasis are consequences of persistent obstruction-infection cycles. Bronchiectasis had been thought to be manifest in the second decade of life, but now is being detected earlier in life with increased use of computed tomography (CT) scans. Pneumonia, when present, generally assumes a peribronchial pattern.

Detailed pathologic descriptions of lung disease are based on examination of lungs at autopsy or lung transplant and reflect advanced changes.[64–67] Bronchiectatic cysts occupy as much as 50% of the cross-sectional area of the late-stage CF lung.[68] In general, bronchiectasis is more severe in upper than in lower lobes. In addition to dilation of the small airways, bronchioles may be stenotic or even obliterated. The extent of obliterative bronchiolitis appears to be directly correlated with age at death.[65] Autopsied lungs also show extensive overinflation of air spaces. Small amounts of destructive emphysema are seen in many patients, especially those who have lived for 2 or 3 decades.[65] Absence of more extensive alveolar wall destruction can be explained by the confinement of chronic infection to conducting airways. Several patterns of interstitial pneumonia have also been described in autopsied lungs, including usual interstitial pneumonitis, interstitial pneumonitis with organizing pneumonia, and diffuse alveolar damage.[69] Fibrosis is extensive in peribronchiolar and peribronchial regions and may contribute to the restrictive lung function pattern that is superimposed on obstruction in end-stage lung disease.[70] Subpleural cysts often occur on the mediastinal surfaces of the upper lobes and are thought to be related to the frequent occurrence of pneumothorax in patients with advanced lung disease.[71] The bronchial arteries become large and tortuous,[72] contributing to a propensity for hemoptysis in ectatic airways. The pulmonary arteries display varying degrees of change reflecting pulmonary hypertension.

Other Respiratory Tract Pathology

Hypertrophy and hyperplasia of secretory elements, mucus accumulation, and chronic inflammatory changes are also features of the paranasal sinuses and the nasal

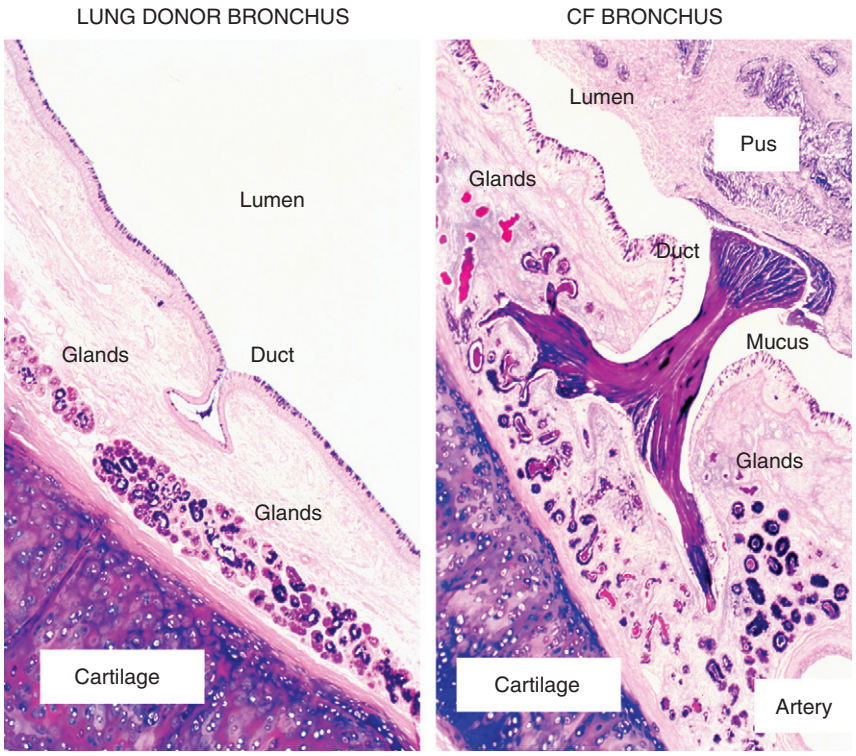

FIGURE 41-2 ■ Large airway pathology. Representative photomicrograph from a lung donor on the left and from an end stage CF lung excised at transplant on the right. In the CF example, note the thinner, less dense appearance of the cartilage, apparent bronchial artery hypertrophy, thickening of the lamina propria with a greater proportion occupied by glands (higher Reid index), a prominent arborized mucus plug in gland ducts, hypertrophic surface epithelium and abundant luminal mucopurulent secretions. Note areas of post-obstructive gland atropy in the end stage CF specimen. (Alcian blue-Periodic acid-Schiffs stain, original magnification ×20.) (Images provided by Dr. Scott H. Randell.)

passages. A common feature of nasal pathology is inflammatory edema of the mucosa with subsequent pedunculation and formation of polyps.[73]

Nonrespiratory Pathologic Features

Most of the nonpulmonary pathology in CF occurs in the gastrointestinal tract and related organs. Striking changes are seen in the exocrine pancreas.[74] Obstruction of ducts by inspissated secretions is an early feature, followed by dilation of secretory ducts and acini and flattening of the epithelium. Loss of acinar cells is widespread, and areas of destruction are replaced by fibrous tissue and fat. Intraluminal calcifications may occur and may be recognized radiographically. Small cysts are common and generally represent dilated ducts. Inflammatory changes are not prominent. The islets of Langerhans are spared until later periods of life. Changes in the islets include disruption by fibrous tissue bands that may provide a barrier between hormone-secreting cells and the vascular spaces.[75] Pathologic changes in the pancreas are used occasionally to make a postmortem diagnosis in atypical or missed cases of CF.

The pancreas is abnormal in almost all patients with CF and is virtually destroyed in approximately 90% of CF patients studied at autopsy. Liver changes are not as frequent or consistent.[76,77] In 25% or more of all autopsies, islands of relatively normal parenchymal cells are divided by fibrotic bands, creating a distinctive multilobular appearance. Microscopically, this focal biliary cirrhosis is characterized by inspissation of secretions within the bile ductules, bile duct proliferation, inflammatory reaction, and a paucity of evidence for bile stasis. Approximately 30% of patients also display fatty infiltration of the liver, which cannot always be ascribed to malnutrition. In approximately 25% of cases, the gallbladder is hypoplastic and contains a gelatinous mucus-like material. Cholelithiasis is an increasingly frequent observation.

Changes in the intestinal tract itself are less prominent.[78] Brunner's glands of the duodenum are hypertrophied, with dilated ducts and acinar lumens filled with mucus. There is little, if any, primary change of the small intestinal tract mucosa. The appendix frequently displays goblet cell hyperplasia of the epithelium and accumulation of secretions within crypts and in the lumen, changes that may be diagnostic of CF. A number of investigators have claimed the ability to diagnose CF by rectal biopsy, based on goblet cell hyperplasia and accumulation of mucus in the crypts.[78a] However, subsequent studies have demonstrated that these findings are not consistent in the rectal mucosa of patients with CF.[79]

Reproductive abnormalities are frequent and characteristic.[80] In a large majority of male patients with CF, the vas deferens, the tail and body of the epididymis, and the seminal vesicles are obliterated by fibrous tissue or are completely absent. Women with CF have mucus-distended uterine cervical glands and plugging of the cervical canal with tenacious mucous secretions. Endocervicitis is a frequent finding.

Non–mucus-secreting glands such as the sweat glands and the parotid salivary glands have a normal gross and histologic appearance. Mucus-secreting salivary glands are usually somewhat enlarged, contain prominent mucus-secreting cells, and display a varied amount of mucus plugging in duct lumens.

PATHOPHYSIOLOGY

Cystic Fibrosis Transmembrane Regulator Protein: Structure, Metabolism, and Function

The CFTR is a single peptide chain that contains 1480 amino acids. The calculated molecular weight is 170 kD, but CFTR migrates in its mature form as an approximately 180-kD glycoprotein due to variable *N*-glycosylation.[32,81] Figure 41-1 demonstrates the domain structure of CFTR, with two repeat motifs, each consisting of six transmembrane-spanning segments followed by a consensus NBF (ATP-binding region). These two segments are linked by a highly charged region, the R (regulatory) domain, that contains multiple phosphorylation sites.[15] The N and C terminii contain important motifs that mediate protein-protein interactions that position CFTR within specialized cellular domains in the apical membrane of epithelia.[82,83] The CFTR structure closely resembles that of a number of other solute transport proteins and places the CF gene product in the ABC super family of proteins.[84] This homology has facilitated the three-dimensional structural modeling of this and other members of the ABC transporter protein family.[27]

CFTR mRNA expression is largely restricted to epithelial cells and is found at moderate levels in human pancreas, salivary glands, sweat glands, intestine, liver (cholangiocytes), and the reproductive tract.[15,81,85] In the lung, CFTR mRNA is expressed in the surface epithelium of the airways and within serous cells of submucosal glands.[86] These sites of CFTR mRNA expression are consistent with locations of tissue dysfunction in patients with CF. Biochemical and immunohistochemical studies describe an apical membrane location for CFTR in predominantly ciliated cells in the lung,[87] although CFTR may also be inserted into the basolateral membrane of sweat ductal epithelia.[88]

Most studies indicate that a central feature of the molecular pathophysiology of CF is that mutated CFTR (e.g., ΔF508) is not normally folded and processed and, hence, does not reach the Golgi or apical plasma membranes (Fig. 41-3).[24,89] The abnormal CFTR ΔF508 trafficking is temperature-sensitive, and some degree of normal processing and delivery of CFTR ΔF508 to the plasma membrane can be detected when temperatures are lowered.[90] Considerable information is emerging on the (1) interactions between different domains of CFTR during folding[27] and (2) the "interactome" of proteins involved in assisting CFTR in this folding process.[91–93]

Most (>80%) of the other identified CFTR mutations also produce a protein that is not normally processed.[94]

Abnormal processing, however, is not characteristic of all CFTR mutations.[94,95] Mutant CFTR may reach the plasma membrane but be refractory to regulatory influences or exhibit conduction abnormalities as a consequence of several types of CFTR gene mutations.[96] The classification of a mutation as one producing a maturational defect versus a regulation/gating defect has become increasingly important, as novel pharmacologic therapies are becoming available that are targeted toward specific CFTR dysfunctions (see later).

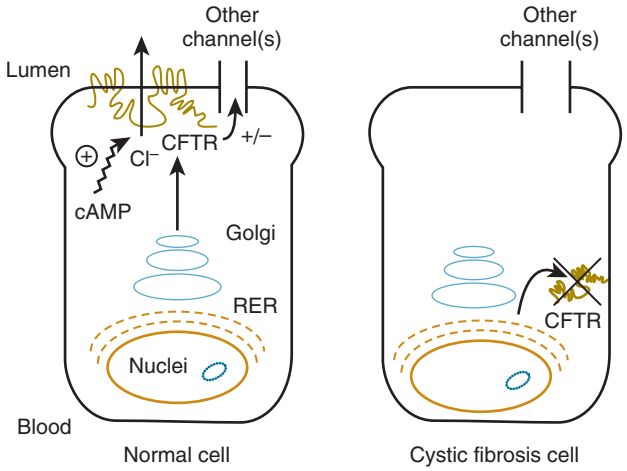

FIGURE 41-3 ■ Schema of biogenesis of CFTR in normal cell (*left*) and ΔF508 CF cell (*right*). In the normal cell, the mature CFTR polypeptide has been synthesized in the rough endoplasmic reticulum (RER), glycosylated in the Golgi, and localized to the apical membrane to function as a cAMP-regulated Cl^- channel and regulator of other channels (e.g., as an inhibitor of the epithelial Na^+ channel). In the CF cell, the ΔF508 CFTR polypeptide has misfolded and been degraded by intracellular proteolytic airways. Hence, it is not positioned in the apical membrane to act as a cAMP-regulated Cl^- channel or to inhibit epithelial Na^+ channel.

The CFTR protein has multiple functions (see Fig. 41-3). It serves as a chloride channel,[20,21] modulates the activity of other plasma membrane channels,[22,23] and perhaps regulates exocytotic and endocytotic events.[97,98] Most of these functions reside at the plasma membrane, although there are unconfirmed data suggesting a role for CFTR in regulating the milieu of intracellular compartments.[99,100] Its chloride channel activity (open probability [P_o]) is regulated through cyclic adenosine monophosphate (cAMP)–dependent kinase, C kinase, and tyrosine kinase pathways.[101–103] Phosphorylation of R-domain serine residues and ATP binding and hydrolysis by the NBFs are necessary and independent steps in the activation of chloride conductance.[104,105]

Abnormal Airway Mucosal Salt and Water Transport

CF is a disease that affects the epithelia lining various organs of the body. Because the native functions of affected epithelia in these organs vary widely, that is, some are salt- but not volume-absorbing (sweat duct), some are volume-absorbing (airways), and others are volume-secreting (pancreas), it is not surprising that the physiologic consequences of mutant CFTR in these epithelia differ widely.

In the lung, airway but not alveolar epithelia are primarily affected. It is not yet clear whether the predominant pathophysiology of CF in the airway occurs in the

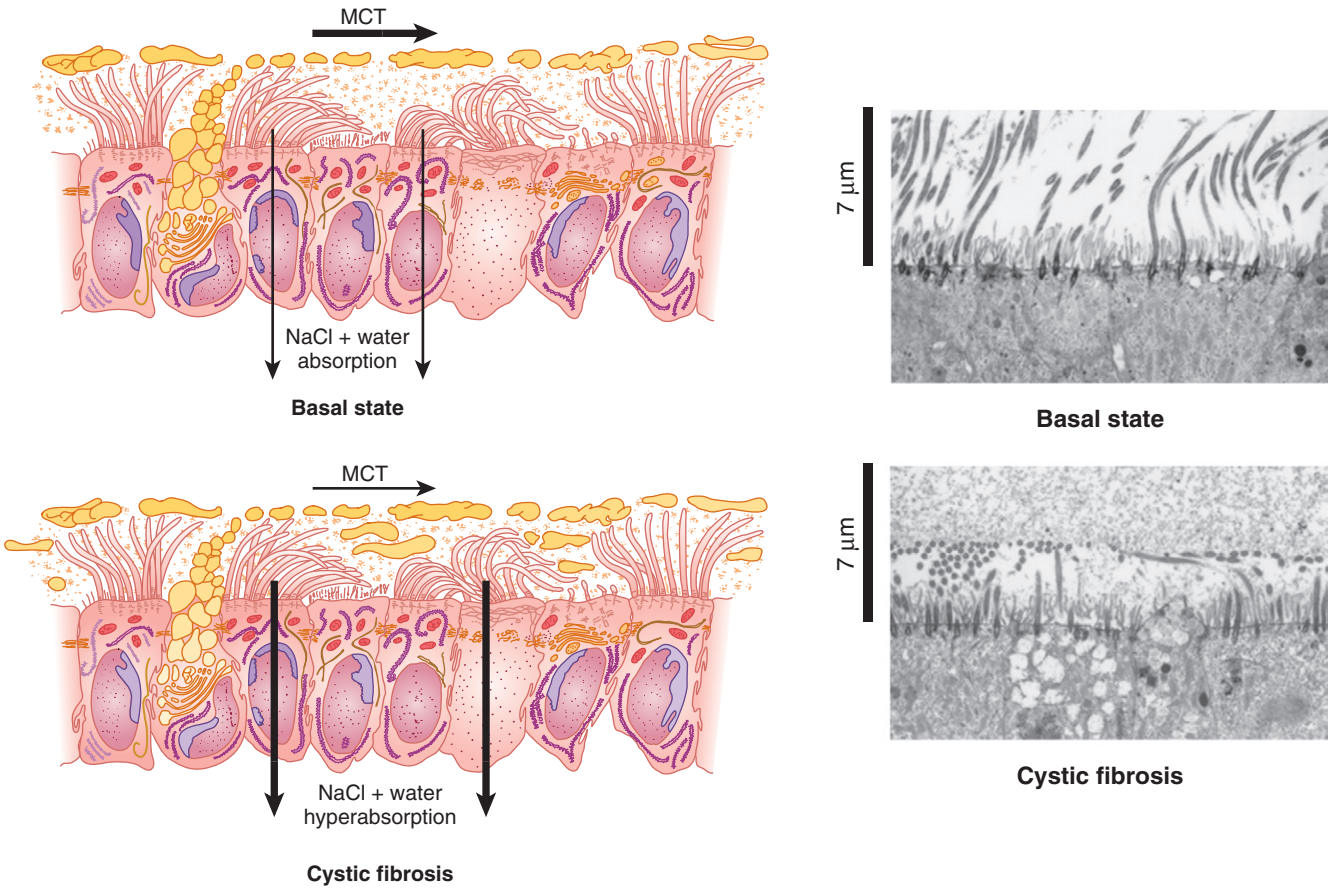

FIGURE 41-4 ■ Schema describing the mucociliary transport (MCT) apparatus in normal and CF airway epithelia. In normal airways (*upper left panel*), the volume and composition of airway surface liquids (granules between cilia) are adjusted so that the extended cilium can transmit energy to the mucous layer that rests on the surface of the periciliary liquid layer. The height (volume) and the composition of this liquid layer are regulated by the superficial epithelial cells. The low-power electron micrograph (*upper right panel*) shows the 7-µm deep periciliary liquid layer on the surface of a cultured normal airway epithelium that exhibits mucus transport.[113] In CF airways (*lower left panel*), hyperabsorption of volume in response to excessive Na^+ transport depletes the height (volume) of the airway surface periciliary layer. It is postulated that this depletion of liquid contributes to slower airway clearance in CF by impacting mucus on cilial shafts and by altering cough clearance properties of mucus. The low-power electron micrograph (*lower right panel*) shows the depleted periciliary layer on the surface of a CF airway epithelial culture that has lost the ability to perform mucus transport.[113] Other composition abnormalities of the periciliary secretory layer also may be important but are as yet unidentified.

superficial epithelium or the glandular elements in the airway wall. The likelihood that the superficial epithelium may be the more important affected epithelium in the lung is suggested by data indicating that the earliest functional manifestation in the CF lung is airflow obstruction in the bronchioles, a region that contains no glands.[106]

A classic premise of CF research has been that abnormalities of chloride and likely sodium transport lead to abnormal regulation of airway surface liquid volume, that is, a depletion of both salt and water (volume) on the CF airway surface (Fig. 41-4). As a result of airway surface liquid volume reduction, mucus concentration and adhesion to cell surfaces occurs, which causes airflow obstruction and ultimately bacterial infection. A second hypothesis linking abnormal sodium and chloride transport to CF pathogenesis focused on differences in salt concentration and activity of antimicrobial factors (e.g., defensins) in CF versus normal airway surface liquid.[107,108] This hypothesis suggested that airway epithelia regulate the ionic concentration, not volume, of airway surface liquid, and sodium chloride concentrations are predicted to be low (<50 mmol/L) in the airway surface liquids of normal individuals and "high" in CF (>100 mmol/L). When salt is low in the airway surface liquid, defensins are active, whereas when salt is high, they are inactive. The result of inactive defensins in CF would be chronic infection. Table 41-2 describes the airway surface liquid composition in normal subjects and CF subjects prior to infection. These data do not support a difference in airway surface liquid sodium chloride composition as central to the initiation of CF lung disease. Further, defensins are found in small quantities in both normal and CF airway surface liquid and are typically bound to mucins.[109]

As discussed in Chapter 8, the role of active ion systems in the pulmonary epithelium can be reviewed on two levels: (1) the requirement of pulmonary epithe-

lium to coordinate intrapulmonary surface liquid volume during "axial" (i.e., surface) flow between different pulmonary regions, such as alveolar and airway surfaces, and (2) the requirement to regulate surface liquid volume in local airway microenvironments to mediate efficient mucus transport. Several studies have increased the level of understanding of how airway epithelia normally regulate airway surface liquid volume under a variety of conditions and how CF airway epithelia fail to do so. For example, confocal microscopy studies of well-differentiated human bronchial epithelial cultures that exhibit rotational mucus transport have revealed normal airway epithelia can autoregulate airway surface liquid volume to maintain sufficient hydration of the periciliary layer and mucus layers for efficient mucus transport.[110–112] Further studies with this system revealed that a failure to regulate volume absorption is a feature of CF airway epithelia, which abolishes mucus transport both by depletion of the 7-μm periciliary liquid layer and by concentration of mucins in the mucus layer.[111,113] The depletion of liquid in the periciliary layer is a "severe" lesion, because it is predicted to reduce the lubricant activities of this layer required for both cilial-dependent and cough-dependent mucus clearance. Consistent with this prediction, the evidence that mucociliary and particularly cough clearance are depressed in CF patients in vivo is mounting.[114,115]

Active Ion Transport Properties of Airway Epithelia

Normal airway epithelia exhibit the capacity to actively absorb Na^+ and actively secrete Cl^- ions. Each of these processes is electrogenic, and they are coordinately regulated, in part by soluble mediators in airway surface liquid.[110–112,116] The relative physiologic role of each process varies depending on the volume of liquid on airway surfaces.

A parameter that describes the overall airway transport activity of airway epithelia is the transepithelial electric potential difference. The transepithelial potential difference can be analyzed simply as the product of the active ion transport rate (short-circuit current [I_{sc}]) and the ionic resistance of the epithelium (R_t). A diagnostic hallmark of CF airway epithelia is a raised potential difference. A series of in vivo ion substitution studies,[9] complemented by in vitro isotopic flux studies of excised tissues,[9,117,118] have revealed that the raised potential difference in CF airway epithelia reflects contributions of both increased ion transport (Na^+ absorption) and increased epithelial resistance (due to decreased cellular Cl^- permeability). Indirect evidence from studies measuring the effects of amiloride, a Na^+ channel blocker, in vivo indicates that the elevated Na^+ absorptive rate rather than the defective Cl^- conductance raised the potential difference of the superficial epithelium of CF airways.

Abnormalities of Superficial Epithelial Cl^- Transport

In vivo potential difference,[9] Ussing flux chamber,[117] and microelectrode studies[119–123] all agree that CF airway epithelial cells exhibit an abnormally low apical membrane conductive Cl^- permeability. Studies utilizing double-barreled Cl^--selective microelectrodes indicate that the basolateral membrane Cl^- conductance and Na^+, K^+, $2Cl^-$ cotransport activities of CF cells are not different from those of normal cells.[121,122,124]

The abnormality in the resting apical membrane Cl^- conductance of airway epithelia reflects the absence of tonic CFTR function at this site. Like other affected epithelia, CF airway epithelia do not respond with Cl^- secretion to agents that raise cellular cAMP (e.g., β-agonists or adenosine), whereas normal airway epithelia do, if the apical membrane Na^+ permeability is blocked.[102,118,125–129] This abnormal response in CF airway epithelia does not reflect dysfunction of adenylyl cyclase or cAMP-dependent protein kinase activities. Rather, CF airway epithelial cells fail to secrete Cl^- due to the absence of CFTR in the apical membrane or to intrinsic defects in mutant CFTR.

Unlike normal airway epithelia, CF epithelia also do not respond with Cl^- secretion to activators of other intracellular kinases. For example, studies with the expressed CFTR protein have indicated that the CFTR Cl^- channel is directly regulated by protein kinase C

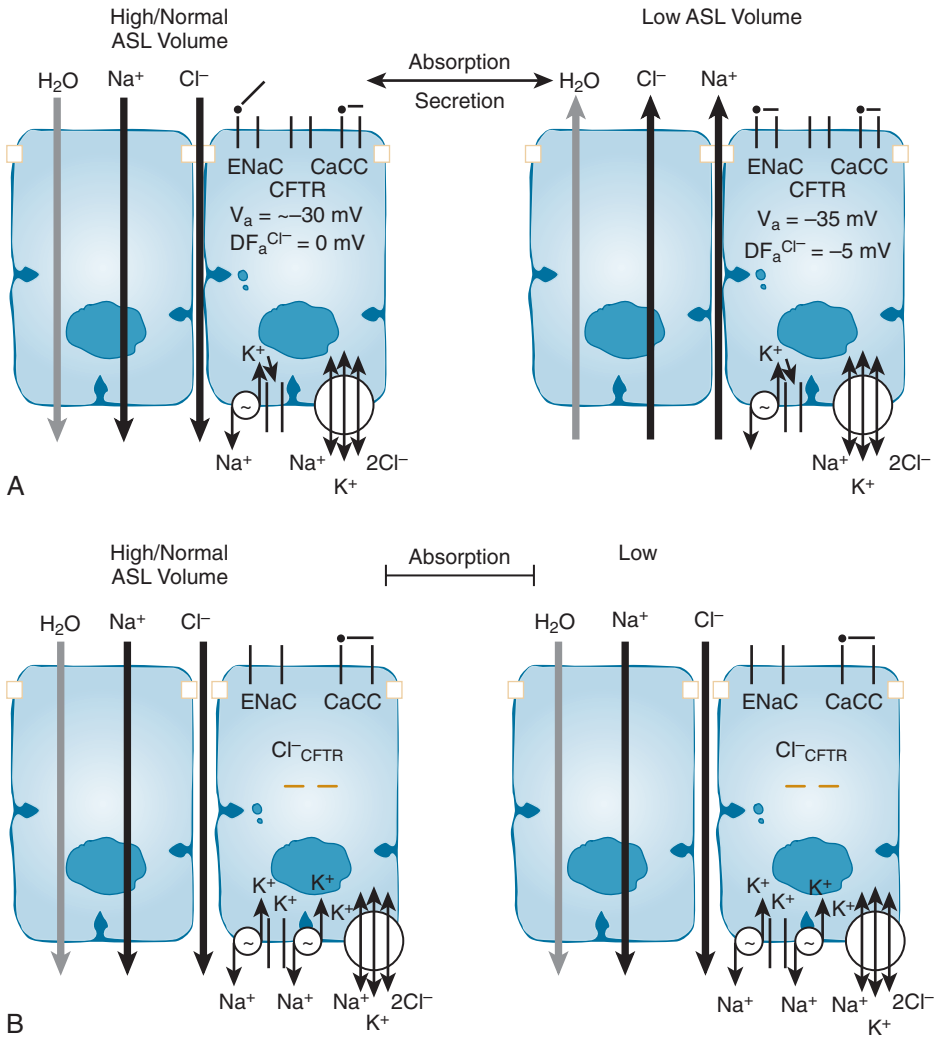

FIGURE 41-5 ■ **A,** Normal human airway epithelia can switch between absorptive and secretory ion transport modes. *Left,* When excess airway surface liquid is present, epithelial Na^+ channel (ENaC)-mediated Na^+ absorption is dominant. Cl^- is projected to be absorbed passively via the paracellular path, reflecting the fact that there is no electrochemical driving force (DF_a^{Cl-}) favoring Cl^- exit from the cell. In contrast, both the negative apical membrane potential (V_a) and low intracellular Na^+ activity (–20 mM) favor Na^+ entry into the cell. Water is absorbed in response to the osmotic gradients generated by combined sodium chloride absorption. *Right,* When airway surface liquid volume is low, the ENaC is inhibited, the apical membrane potential becomes more negative, and a driving force for Cl^- secretion is generated. NaCl and water are secreted. **B,** CF airway epithelia exhibit accelerated airway surface liquid volume absorption under high and normal airway surface liquid volume conditions and cannot switch to a secretory mode during low airway surface liquid volume conditions. *Left,* The routes of raised Na^+, Cl^-, and water absorption and cellular mechanisms for raised Na^+ transport in CF airway epithelia under high or normal airway surface liquid volume conditions. *Right,* The absence of CFTR from the apical membrane eliminates regulation of the ENaC and limits capacity for Cl^- secretion. CaCC, Ca^{2+}-activated Cl^- channel.

phosphorylation.[130] Other studies have shown that CFTR is also regulated by tyrosine kinases and other kinases.[131] The failure of CF airway epithelia to respond to protein kinase C or other kinases reflects absence or dysfunction of the mutated CFTR Cl^- channel itself at the plasma membrane. An area of present research is how CFTR is functionally and physically associated with regulatory kinases and phosphatases in the apical domains of epithelial cells.[132,133]

Recent studies have placed in perspective the function of defective CFTR-mediated Cl^- transport in airway epithelia.[133a–133c] In normal airway epithelia, the maintenance of a normal airway surface liquid volume depends on both the regulation of Na^+ transport rates (see later) and the ability to secrete Cl^- (Fig. 41-5). Specifically, as airway surface liquid layer diminishes to approximately 7 μm, Na^+ absorption is inhibited and CFTR-mediated Cl^- secretion initiated. In CF, the absence of CFTR-dependent Cl^- secretion contributes to the failure to maintain adequate liquid volume on airway surfaces.

CF airway epithelial cells retain the normal capacity to secrete Cl^- in response to elevations in intracellular Ca^{2+}.[134,135] Data derived from studies of cultured monolayers impaled with double-barreled Cl^--selective micro-

electrodes indicate that elevation of intracellular Ca^{2+} with calcium ionophores, such as ionomycin, initiate Cl^- secretion in both CF and normal cells. The Cl^- channel activated by raised Ca^{2+} is molecularly distinct from CFTR, as evidenced by retention of this activity in gene targeted ("CF") mice.[136] This Ca^{2+}-activated Cl^- channel has recently been identified as TMEM16A, a member of an eight transmembrane-spanning family.[137–139] Intense investigations are under way to understand the role of Ca^{2+} regulation of TMEM16A and its relationship to other members of this family.

The observation that Ca^{2+}-regulated Cl^- secretion can be triggered in CF airway epithelia has therapeutic implications. In a search for compounds that interact with receptors on the lumen of airway epithelial cells that regulate intracellular Ca^{2+} levels, it was discovered that the triphosphate nucleotides (ATP, uridine triphosphate [UTP]) were highly effective in initiating Cl^- secretion in CF and normal airway epithelial cells.[140–143] Triphosphate nucleotides increase intracellular Ca^{2+} by interacting with purinoceptors ($P2Y_2$) that via activation of phospholipase C, increase inositol triphosphate (IP_3) levels. In vivo studies found that ATP and UTP were effective Cl^- secretagogues in the nasal mucosa of CF subjects.[142] Indeed, an intriguing finding was that the triphosphate nucleotides were more effective in initiating Cl^- secretion in CF than in normal subjects. These observations have led to the clinical testing of analogues of UTP that, by virtue of being resistant to hydrolysis in CF airways, may have a long duration of action.[144,145]

Abnormalities of Superficial Epithelial Na^+ Transport

Abnormalities in Na^+ transport in CF appear to be confined to epithelia that are involved in volume absorption. Accelerated Na^+ absorption is a feature of the proximal tubule of the kidney,[146,147] jejunum, ileum,[148–150] and airways of CF patients.[118] Interestingly, the mechanisms of Na^+ hyperabsorption may differ in the different affected epithelia. Na^+-coupled solute movements may be the major affected pathways in the intestine, whereas defective regulation of the epithelial Na^+ channel (ENaC) is the major abnormality in the lung.

Studies of freshly excised airway specimens established that the raised potential difference that characterizes CF airway epithelia reflects in part an accelerated basal rate of active Na^+ absorption.[119] These studies also identified a defect in acute regulation of Na^+ transport rates in CF.[119] β-Agonists and other reagents that raise intracellular cAMP paradoxically raise the already accelerated basal rate of Na^+ transport in CF tissues but do not affect Na^+ transport rates in normal tissues.[119]

The principal abnormality in the Na^+ transport path in CF airway epithelia resides in the apical membrane Na^+ conductance.[119] Studies of cultured airway epithelia with double-barreled Na^+ selective microelectrodes show that the apical membrane Na^+ permeability in CF is two- to threefold higher than in normal cells.[151,152] Thus, these studies place a second ion permeability abnormality in the CF apical membrane and strongly suggest that the Na^+ transport abnormality is not secondary to the changes in the electrochemical driving forces for Na^+ entry consequent to absence of an apical membrane Cl^- permeability.

The effects of the CF defect on the regulation of Na^+ transport rates at the single-channel level are still not understood. The available evidence indicates that the fraction of time that the Na^+ channel is capable of conducting ions, the P_o, is approximately threefold greater in CF compared with normal cells.[153–155] This finding suggests that the defect responsible for accelerated Na^+ transport in airway epithelia reflects an absence of the tonic inhibition of epithelial Na^+ channel provided by wild-type CFTR.

A key issue with respect to the Na^+ transport defect relates to its role in pathogenesis of airway infection. As discussed previously, recent laboratory data indicate that both regulation of Na^+ transport rates as a function of the available liquid volume on an airway surface and the capacity to secrete Cl^- are required for airway surface liquid volume homeostasis (see Fig. 41-5). Further, these studies have shown that CF airways fail to normally regulate Na^+ absorption and this defect contributes to abnormally low liquid on CF airway surfaces. For example, in vitro studies of cultured CF bronchial epithelia have shown that in CF, Na^+ hyperabsorption persists despite low airway surface liquid volume and that this defect contributes to periciliary layer depletion and mucus stasis (Fig. 41-6). Further evidence for the role of raised Na^+ absorption in the pathogenesis of CF has emerged from in vivo studies of mice with airway-specific overexpression of ENaC. These mice exhibit raised Na^+ absorption and a lung phenotype that resembles CF (e.g., mucus obstruction, neutrophilic inflammation, and defects in bacterial clearance).[156]

Function of Normal and Cystic Fibrosis Ion Transport under Dynamic Conditions In Vivo

Whereas most standard laboratory assessments of airway epithelial ion transport function are performed under "static" conditions, airway epithelia in vivo are exposed to a variety of respiration-dependent phasic stresses.[157] Studies of airway surface liquid physiology under phasic stress conditions that mimic respiration have revealed key data for understanding airway surface liquid volume homeostasis in vivo. For example, phasic shear stress increases the rate of ATP release from airway epithelia.[111,158–160] The increased rate of ATP release increases airway surface liquid ATP concentrations and, to a lesser extent, adenosine concentrations. In normal airway epithelia, the increased ATP activation of $P2Y_2$ receptors increases inhibition of epithelial Na^+ channel and activation of both CFTR and Ca^{2+}-activated Cl^- channel (TMEM16A), which raise airway surface liquid volume. In CF, shear stress also increases ATP release, which, via ENaC inhibition and Ca^{2+}-activated Cl^- channel activation, increases airway surface liquid sufficiently to

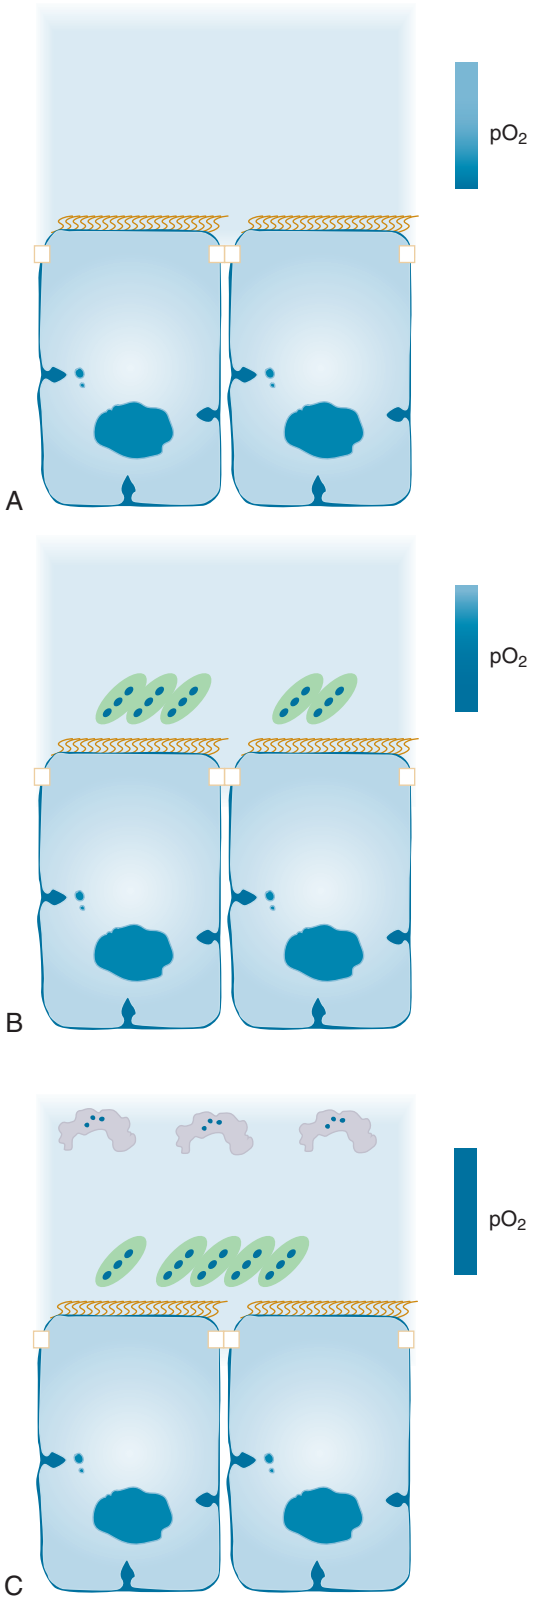

FIGURE 41-6 ■ **A,** Failure of mucus transport, coupled with persistent mucus secretion, with time produces adherent mucus masses or plugs. The raised epithelial oxygen consumption (Q_{O_2}) required to fuel accelerated CF Na^+ absorption generates steep O_2 pressure gradients (*light to dark blue shading in bar*) in thickened mucus masses. **B,** *Pseudomonas aeruginosa* deposited on mucus masses grows and adapts to hypoxic niches within these masses as macrocolonies (biofilms). **C,** The thickened mucus, coupled with macrocolony growth, resists secondary defenses, including neutrophils, setting the stage for chronic infection. The presence of increased macrocolony density and, to a lesser extent, neutrophils renders these mucopurulent masses frankly anaerobic (*blue bar*).

mediate mucus transport.[111,159] This capacity of ATP to partially balance airway surface liquid volume homeostasis under phasic stress conditions in vitro may explain why mucus clearance rates are normal in portions of CF lungs in vivo.[161]

The observation that CF airway epithelia can produce sufficient airway surface liquid with phasic stress to mediate mucus transport raises the question of why CF lungs get infected. Clinical data suggest that CF lung disease is episodic, with intervals of constancy interrupted by acute exacerbations. Further, a substantial fraction of acute exacerbations are triggered by viral infections. Laboratory studies of respiratory syncytial virus (RSV) infection of cultured CF airway epithelia show that RSV can up-regulate extracellular ATPases, under phasic stress conditions. The increased ATPase activity reduces airway liquid ATP concentrations, $P2Y_2$-mediated inhibition of ENaC, and activation of Ca^{2+}-activated Cl^- channel and depletes airway surface liquid volume, which promotes mucus adhesion to airway. The mucostasis associated with viral infection thus could facilitate airway bacterial colonization and growth.

Ion Transport Defects of Glandular Epithelium

In situ hybridization and immunocytochemical studies indicate that lung CFTR is expressed at the highest level in some serous cells in submucosal gland acini and ciliated cells of the ductal epithelium.[87,162]

Unlike the sweat duct, but similar to the parotid duct, nasal glands and ductal epithelium appear to have a similar capacity to secrete volume in CF and normal subjects.[163] However, these studies raised the possibility that submucosal gland ducts could modify the gland secretion to reduce sodium chloride concentrations and make it hypotonic.

In vitro studies indicate that cultured CF bronchial gland acinar cells, unlike the superficial airway epithelium of CF subjects, do not respond to raised intracellular Ca^{2+} with Cl^- secretion, whereas normal glandular cells do.[163a] Thus, the bronchial glands could have a Cl^- transport phenotype that is more similar to gastrointestinal epithelia than the superficial airway epithelium.[150,164,165] Studies of bronchial glands on fresh tissue from lungs removed with transplantation procedures showed that CF airway gland acini, like superficial airway epithelia, do not secrete Cl^- in response to β-agonists, whereas glands from normal subjects do.[164–166] Interestingly, both normal and CF glands secrete Cl^- in response to cholinergic agents, suggesting that Ca^{2+}-regulated Cl^- secretion is preserved. Further, the properties of stimulated CF gland secretions are different from normal, with CF secretions being more viscous and slightly lower pH.[167,168] The relative role of the gland defect in CF airway surface liquid volume depletion is presently unknown, but at a minimum, this deficiency exacerbates the airway surface liquid volume defect generated by the CF superficial epithelium and possibly reduces the secreted load of gland antimicrobial factors onto airway surfaces.

Mucin Macromolecule Secretion in the Cystic Fibrosis Airway

Following Farber's report[5] of mucous obstruction in many exocrine glands, a search was initiated for abnormal macromolecules that might change the physical properties of CF exocrine secretions. Particular emphasis was placed on analysis of mucin glycoproteins, the high-molecular-weight glycoconjugates that are the determinants of the viscoelastic properties of mucus.[169] One of the difficulties in comparing these substances sampled from CF and control airways is that they are susceptible to proteolytic and perhaps other degradative enzymes to which they are exposed in vivo. This problem likely explains the report that CF sputum contains less mucin than normal (i.e., the epitopes used for antibody detection of mucins were selectively degraded in CF mucins).[170] In addition, these glycoproteins display extensive microheterogeneity of carbohydrate constituents and, therefore, are difficult to compare from subject to subject as well as patient group to control group.

Overall, purified mucins from CF patients and control subjects show considerable similarity. Early suggestions that the fucose content of CF glycoproteins was elevated and the sialic acid content decreased appears to reflect the effects of chronic infection and inflammation and not a CF-specific defect.[171] In addition, several investigators have reported that CF mucous glycoproteins from both respiratory and gastrointestinal sources contained increased numbers of sulfated sugars.[172–175] Goblet cells within the bronchial epithelium of patients with CF have an elevated sulfur content,[176] which, if present as sulfate, could reflect increased sulfation of secretory glycoconjugates. However, again, most evidence, including the observation that goblet cells express little or no CFTR, suggests that increased sulfation likely is a reflection of chronic infection rather than a consequence of CFTR mutations.[87,171]

There is also no convincing evidence that CF epithelial cells hypersecrete mucin macromolecules before the onset of airway injury.[177] However, hypersecretion of mucus does occur in response to proteases, oxidative metabolites, and other products of chronic infection and inflammation. This induced hypersecretion, coupled with goblet cell hyperplasia, likely significantly exacerbates the mucus accumulation and obstruction that is initiated by airway liquid volume depletion.[178]

Future research should focus on the behavior of mucins in reduced airway surface liquid volume environments, especially on how mucins are unpackaged from granules and released into a CF-like environment with little water and perhaps more acidic pH.[179] A second key area is to elucidate the nature of the adhesive interactions that occur when a thickened mucus layer comes into contact with cell surface (tethered) mucins in the absence of periciliary layer (see Fig. 41-2). Elucidation of the mechanism of this interaction may lead to therapies to reverse this adhesion and allow clearance of adherent mucus plaques.

Analyses of other macromolecular secretory products from patients with CF have failed to uncover substantial abnormalities. These macromolecules have included α-amylase, ribonuclease, and lysozyme from salivary secretions, and pancreatic enzymes, including chymotrypsin, trypsin, carboxypeptidase, amylase, and lipase.

Pathophysiology of Infection

Failure of the airways to clear mucus normally is likely the primary pathophysiologic event in CF (see Fig. 41-6). Adherent mucus plaques and plugs are the site of the chronic bacterial infection of CF airways.[180] These bacteria are usually found in macrocolonies that appear to represent the biofilm-type of growth characteristic of CF infections. In general, biofilms represent a type of bacterial growth in which bacteria form and become enmeshed in an extensive extracellular matrix. Bacterial cellular physiology may change in this environment and the matrix may provide a barrier to antimicrobial agents and inflammatory cells, thus promoting bacterial persistence. The generation of immobile mucus surfaces thus provides the nidus for the chronic respiratory tract infection that is the major contributor to the loss of lung function and eventual demise of patients with CF.

The chronic infection of the CF lung usually is localized to endobronchial regions and the bacterial species most commonly cultured are *Staphylococcus aureus* and *Pseudomonas aeruginosa*. However, analyses of CF airway secretions with unbiased molecular approaches, including terminal restriction fragment length polymorphism (T-RFLP) and gene chip approaches, suggest a greater diversity of infecting bacteria than heretofore appreciated. Indeed, CF secretions of the typical young adult may contain 12 to 30 distinct bacterial species and many anaerobes.[181–183]

Once established, infection of the CF lung is rarely eradicated. Bacterial infection extending beyond the airways, however, is distinctly uncommon, indicating that local airway, rather than generalized host or pulmonary defense mechanisms, are impaired.

As noted previously, the volume of liquid on CF airway surfaces is severely reduced, which is likely to decrease the function of the periciliary layer and increase the adhesiveness of the mucus layer, leading to a failure of both mucociliary and cough clearance. Mucus stasis, adhesion, and obstruction are likely to be responsible for the lung infections. Mucus clearance reduction is more heterogeneous in the central airways[115] than in the more peripheral airways.[184] Virtually all studies agree that ciliary morphology and beat frequency are normal in CF airway epithelia[185,186] (see Fig. 41-6).

S. aureus and *P. aeruginosa* are infrequent respiratory tract pathogens of children and adults, except in CF. The role played by these organisms in endobronchial infection has prompted suggestions that surface properties of CF airway epithelia are altered in a fashion that promotes their adherence. *S. aureus* does not preferentially adhere to CF airway epithelial cells,[187] and studies of respiratory cell interactions with *P. aeruginosa* also have not demonstrated consistent differences between CF and normal cells.[188,189] In an opposite formulation, studies have suggested that the wild-type CFTR expressed on normal epithelial cells binds *Pseudomonas* and mediates bacterial internalization, which ultimately kills the microorganism. CF cells are reported to fail to perform this function.[190] Although intriguing, there is little pathologic evidence for *Pseudomonas* internalization in normal well-differentiated airway epithelial cells, and this hypothesis does not account for infection in CF patients who express mutant CFTR in the apical membrane (e.g., G551D CFTR).

No difference in bacterial binding to CF versus normal mucins have been detected for *Staphylococcus* or *Pseudomonas*.[187,191,192] Recent biophysical studies suggest that the increase in mucus concentration due to CF airway surface dehydration physically restricts bacterial motility and permeation of *Pseudomonas* quorum-sensing molecules, facilitating biofilm growth.[193]

An important new concept is that the mucus adherent to airway surfaces may be hypoxic or anaerobic (see Fig. 41-6).[192] Prior to infection, the increased O_2 consumption by CF airway epithelia (required to fuel increased Na^+ absorption), coupled with increased diffusion distances for O_2 through mucus plaques, can create relatively hypoxic zones near the epithelial surface. As bacterial densities in CF mucus reach ranges of 10^6 colony-forming units (CFU)/mL, the bacteria consume the remaining O_2 in the environment. Direct measurements of oxygen pressure (P_{O_2}) in vivo with O_2 electrodes have recorded P_{O_2} less than 2 torr in infected CF mucus.[192] This observation has two important consequences.

First, *P. aeruginosa* can adapt to and grow in biofilms in a hypoxic environment, and this environment may exert a subtle pressure that favors *Pseudomonas* acquisition in CF.[194] There are also implications for CF therapy. *P. aeruginosa* sensitivities to antimicrobials change in O_2-depleted versus O_2-rich environments (e.g., macrolides become more effective against *Pseudomonas* in O_2-depleted environments). Thus, clinical testing of *Pseudomonas* isolates for antimicrobial sensitivities may require studies under anaerobic conditions. Because *Pseudomonas* physiology differs under anaerobic than under aerobic conditions,[194] identification of essential genes for anaerobic growth may represent novel therapeutic targets.

Second, the observation that CF mucus may be anaerobic has led to a search for obligate anaerobes in CF airway secretions. Because of the difficulty in culturing many anaerobes, this search has combined specialized culture techniques and molecular approaches for identification and quantitation. Recent reports suggest there may be high concentrations of obligate anaerobes (e.g., *Prevotella* spp., *Veillonella* spp., *Fusobacteria*) in CF secretions.[181] These findings serve to confirm the notion that CF secretions are anaerobic, but the natural history of obligate anaerobe acquisition by the CF patient and their role in pathogenesis (and hence requirement for treatment) are at present unknown.

Once bacterial infection of mucus has occurred, bacteria release products that diffuse to the underlying epithelium and stimulate mucin production[195,196] and

cytokine responses[197] that mediate cell damage. The infection may be worsened after cell damage by bacterial binding to the injured cells.[198]

The immunology of CF has been investigated extensively and little has been found to indicate any deficiency. Although CF subjects tend to have low levels of serum immunoglobulin G (IgG) in the first decade of life, these levels increase dramatically as chronic infection is established.[199] Secretory antibody levels appear to be normal or enhanced.[200] Antibody responses specific for infecting organisms in the respiratory tract are brisk.[201,202] The number of B lymphocytes and plasma cells that differentiate into immunoglobulin-secreting cells are not depressed.[203] T lymphocyte numbers are adequate, and these lymphocytes proliferate in response to nonspecific mitogens.[204] With advancing severity of pulmonary disease, lymphocytes may proliferate less briskly in response to *P. aeruginosa* and other gram-negative organisms.[205] This acquired dysfunction at times can be reversed by intensive antibiotic treatment, but it may contribute to the resistance to antimicrobial therapy in advanced lung disease.

Polymorphonuclear leukocytes and macrophages are plentiful in CF airways and function normally when removed from their usual environment,[206] which suggests that potential phagocytic defects in vivo could reflect infection-induced degradation of opsonins (e.g., IgG and complement) and possibly defective leukocyte migration through thickened, adhesive mucus.[207]

There is an increased inflammatory response in CF.[208,209] Studies from lung lavage fluid from CF neonates indicate that magnitude of the neutrophil response normalized to bacterial counts in lavage fluid is increased in CF as compared with non-CF infants with lung infections.[210] The cytokine interleukin-10 (IL-10), which normally serves to dampen epithelial cell IL-6 and IL-8 responses to luminal bacterial infection, is not produced at normal levels in CF airway epithelia.[211,212] Whether the increased neutrophil influx observed in CF reflects failure to kill bacteria growing in biofilms, failure of an epithelial regulatory mechanism for neutrophil influx, epithelial compensation to a chronic stimulus, or a combination thereof is unknown.

Progressive destruction of airway walls occurs in CF, and proteinases may contribute to this process.[213] Leukocytes and bacteria produce large quantities of elastase that exceed the neutralization capacity of airway antiproteinases. Both leukocyte and bacterial elastases generate C5a nonimmunologically in CF secretions.[214] High levels of this chemotactic factor stimulate further polymorphonuclear leukocyte recruitment, increasing the burden of free elastase in the airway lumen and possibly airway wall. Similarly, a cycle of airway wall destruction may be mediated by polymorphonuclear leukocyte collagen interactions that produce a chemoattractant that reinforces polymorphonuclear migration into airway walls.[215] Ultimately, proteolytic injury to airway walls contributes to their destruction with development of widespread bronchiolectasis and bronchiectasis.[216] The fact that destructive emphysema is not a prominent feature of CF lungs, especially early in the course of lung disease, can be attributed to confinement of infection to endobronchial spaces in mild to moderate lung disease. Other mechanisms of conducting airway tissue injury undoubtedly exist but have not been described in detail.

CLINICAL MANIFESTATIONS

CF presents in many different ways and mimics a number of other clinical entities. Usual presentations include early onset of respiratory tract symptoms, particularly persistent cough and recurrent or refractory chest radiographic changes. Usual gastrointestinal presentations include meconium ileus in approximately 15% of patients and failure to thrive with steatorrhea. A surprising number of people with CF escape detection in the first decade or two of life, often because symptoms are unusual, subtle, or even absent. Patients with "mild" mutations may present in childhood or later in life.[37] A list of unusual presentations is compiled in Table 41-3, and presentations that may be expected at adolescence or early adulthood are highlighted. Recognition of the protean manifestations of CF and a high index of suspicion are required to detect all cases of CF, either in childhood or later in life.

Lower Respiratory Tract Disease

The earliest manifestation of CF lung disease is generally cough. At first, it is intermittent, coinciding with episodes of acute respiratory tract infection and persisting

longer than expected. With time, the cough becomes a daily event. It is often worse at night and especially on arising in the morning. With progression of lung disease, the cough becomes productive and then paroxymal, with associated gagging and emesis. Sputum is usually tenacious, purulent, and often green, reflecting bacterial infection. Hyperinflation of the lungs is noted early in the progression of lung disease. In fact, it is unusual to see CF respiratory tract disease without at least a moderate increase in lung volume. Asthmatic or bronchiolitic-type wheezing is most common during the first 2 years of life but may be encountered at any age. Wheezing may occur with or without evidence of atopy, which is probably not more frequent in patients with CF.[217] Lung sounds are often unremarkable and, often, diminution in the intensity of breath sounds may be the only abnormality noted, correlating with the extent of hyperinflation. Adventitious lung sounds are usually heard first over the upper lobes and often are localized to the right side.

CF patients may have only mild bronchitic symptoms for long periods of time, in some cases for a decade or two, but eventually, these periods of stability are punctuated with exacerbations of symptoms, including increased intensity of cough, tachypnea, shortness of breath, decreased activity and appetite, and weight loss. It has been assumed that these exacerbations are triggered by acute respiratory infections, perhaps of viral or mycoplasmal origin, although studies differ concerning evidence for these infections during periods of increased lung symptoms.[218–223] Environmental factors, including cigarette smoke,[224] also may evoke more respiratory symptoms. Intense antibiotic therapy and assistance with clearance of mucus are usually required to reduce lung symptoms and improve lung function. Exacerbations characteristically occur with increasing frequency. Frank limitation of activity or disability is associated with end-stage lung disease and heralds a sequence of terminal events, including substantial hypoxemia, pulmonary hypertension, cor pulmonale, and death.

Microbiology

The airways of patients with CF are colonized early with bacteria, and once established, infection is rarely, if ever, eradicated. *S. aureus* and *Haemophilus influenzae* are often the first organisms detected.[225] *P. aeruginosa* characteristically is cultured from respiratory secretions months to years later, although this organism is present at diagnosis with increasing frequency. Age at acquisition of *P. aeruginosa* is graphed in Figure 41-7 and is dependent in part on genotype, earlier acquisition occurring in persons homozygous for ΔF508.[34] The possibility of nosocomial acquisition of *P. aeruginosa* has been raised.[226] With progression of lung disease, *P. aeruginosa* is often the only organism recovered from sputum and may be present in several types of colonies, usually with different antibiotic sensitivity patterns. Typically, one of these types is mucoid, due to elaboration of large amounts of alginate. These mucoid organisms are found in microcolonies of pseudomonads embedded and growing in biofilms of alginate.[227] Mucoid properties are thought to inhibit opsonic and nonopsonic phagocytosis, enhance adherence properties, and decrease sensitivity to antibiotics and toxic, reactive intermediates produced by leukocytes.[180,228–230] The recovery of *P. aeruginosa*, particularly the mucoid form, from the lower respiratory tract of a child or young adult with chronic lung symptoms is virtually diagnostic of CF, although it may also occur in patients with primary ciliary dyskinesia.[231]

Recently, other species have been recovered from CF lungs with increasing frequency, including obligate anaerobes.[181] *Burkholderia cepacia* has become prevalent in a few CF care centers and is particularly difficult to treat because it is usually resistant to most antimicrobial drugs. Evidence for patient-to-patient spread is strong and has led to recommendations for stringent infection control measures within CF care settings.[232,233] Colonization has been linked to the rapid demise of a

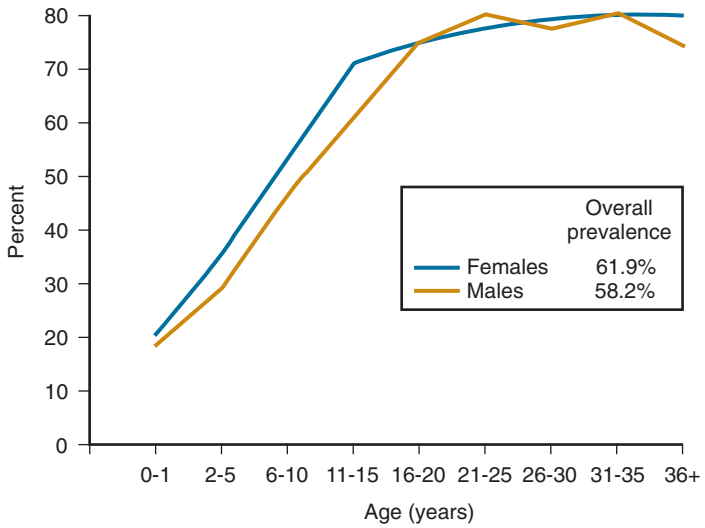

FIGURE 41-7 ■ Prevalence of *P. aeruginosa* infection by age and sex in CF patients enrolled in the U.S. Cystic Fibrosis Foundation Registry, 1991, based on an analysis of 16,417 patients. (Courtesy of Dr. S. FitzSimmons.)

small percentage of patients[234] with what is called the "cepacia syndrome." Molecular analyses have distinguished different genomovars of *B. cepacia*, some of which comprise distinct species.[235-238] Genomovars II (*B. multivorans*) and III (*B. cenocepacia*) have been associated with the cepacia syndrome, and genomovar III includes the highly transmissible strain that may be linked to expression of the cable pilus.[237-239] Occasionally, other gram-negative rods are present in sputum, including mucoid *Escherichia coli*, *Stenotrophomonas maltophilia*, *Alcaligenes xylosoxidans, Klebsiella*, and *Proteus*. Anaerobes have been recovered from CF lung tissue; they may be undetected pathogens and are found in large abscess cavities on rare occasions.[240]

Sputum bacteriology correlates reasonably well with specimens obtained directly from the lower respiratory tract. Oropharyngeal swab cultures that yield *S. aureus* or *P. aeruginosa* are modestly predictive of results from bronchoscopic specimens, but negative pharyngeal cultures do not rule out the presence of these organisms in lower airways.[241] Quantitative bacteriology may be particularly useful for determining the relative contributions of organisms isolated.

A large number of sputum specimens contain yeast and *Aspergillus fumigatus*. Neither organism has been considered a serious pathogen, although the latter causes the symptoms of allergic bronchopulmonary aspergillosis (ABPA) in a small percentage of patients.[242,243] Colonization of lungs with rapidly growing mycobacteria has been documented with increasing frequency. Up to 20% of adult patients in some clinics are colonized by nontuberculous mycobacteria, occasionally prompting treatment with agents directed against these organisms.[244-248] *Mycobacterium tuberculosis* infection has been seen in only very sporadic cases.

Radiology

The earliest radiographic change is usually hyperinflation of the lungs, reflecting obstruction of small airways. The degree of hyperinflation generally increases with age. As bronchitis progresses, peribronchial cuffing becomes increasingly prominent. Mucous impaction in airways may be seen as branching finger-like shadows. Evidence of bronchiectasis, such as enlarged ring shadows and cysts, is common by 5 to 10 years of age. Frequently, peripheral rounded densities are noted during acute exacerbations and may disappear with treatment, leaving residual cysts. Subpleural blebs often become evident during the second decade of life and are most prominent along the mediastinal border. For reasons that remain unexplained, the right upper lobe usually displays the earliest and most severe changes. With advancing disease, the pulmonary artery segments become more prominent. A relatively small and vertical cardiac shadow is typical, but the heart enlarges with onset of cor pulmonale. Hilar adenopathy is rarely prominent. Lobar or segmental atelectasis is uncommon but is most often seen in infants or small children. Chest radiographic scoring systems have been introduced and may be useful for clinical studies and to chart the course of lung injury.[249]

Radiographic improvement with intensive treatment is not readily appreciated because of the fixed nature of airway changes. The most striking improvement often is reduced inflation of the lungs, a change that tends to make the fixed lung markings more prominent.

CT of the chest has not been used routinely for monitoring the course of CF lung changes. The cost is high and resolution for younger patients was initially poor. With the advent of rapid scanning, however, mild bronchiectasis and mucoid impaction can be observed at all ages.[250,251] CT scanning detects these lesions, even when the chest radiograph is nearly normal. The severity of bronchiectasis can be graded in older patients.[252] The indications for CT scanning in place of routine chest radiography are not established. One indication may be the evaluation of a patient considered for lobectomy. Magnetic resonance imaging (MRI) also defines peribronchial thickening, mucoid impaction, and bronchiectasis but has no well-documented advantage over CT scans in these areas of imaging.[253] MRI may be superior for distinguishing hilar adenopathy and prominent pulmonary vessels.[254]

Lung Function

Newborns with CF are thought to have normal lung function. However, within weeks to months, many infants with CF show evidence of increased airway resistance, gas trapping, and diminished flow rates.[255,256] When children reach an age that makes cooperation possible, more complete testing first demonstrates airway obstruction, which presumably occurs in small airways as indicated by reduced maximum midexpiratory flow rates, reduced flows at low lung volumes, and an elevation of the ratio of residual volume to total lung capacity (RV/TLC).[257-259] Other sensitive indicators of lung pathology include an increased alveolar-arterial oxygen gradient, frequency dependence of dynamic compliance, reduced response of flows to a helium-oxygen mixture, elevated slope of phase III of the single-breath nitrogen washout, and an elevated physiologic dead space.[260] Tests that are used most often to follow the course of pulmonary function include spirometry, lung volume measurements, and measures of oxygenation. In general, patients progress from initial reductions in maximum midexpiratory flow rates to reductions in forced expiratory volume in 1 second/forced vital capapcity (FEV_1/FVC) and then to diminished vital capacity and total lung volumes. This progression from peripheral airway obstruction to more generalized obstruction and then to acquisition of a restrictive component is illustrated in Table 41-4.

By the time a diagnosis is made, many children with CF show mild decrements of arterial P_{O_2}. Oxygenation declines slowly throughout life. As a rule, patients who maintain satisfactory oxygenation do well, independent of the extent of the obstructive impairment. When arterial P_{O_2} values dip below 55 mm Hg on a sustained basis, symptomatic pulmonary hypertension should be expected.[261,262] Exaggerated nocturnal desaturation experienced by patients with CF may be a contributing factor to pulmonary hypertension.[263] Hypoxemia gener-

*Values are percent predicted, except those in parentheses, which are simple ratios, and those in brackets, which are millimeters of mercury. Patient A coughs several times a day; the cough is occasionally productive. He shows no restriction of activity. Patient B coughs frequently, expectorates moderately large amounts of mucus, but is able to jog 3 miles daily and is a full-time student in a professional school. Patient C has chronic right heart failure, but is able to work daily as a hair stylist.

FEV_1, forced expiratory volume in 1 second; FRC, functional residual capacity; FVC, forced vital capacity; MMEF, maximal midexpiratory flow; Pa_{O_2}, arterial oxygen pressure; RV, residual volume; TLC, total lung capacity; $\dot{V}max$, maximal consumption.

ally is not accompanied by polycythemia, at least in part due to an expanded plasma volume and in some persons to suppressed erythropoiesis secondary to chronic infection. Elevation of arterial carbon dioxide pressure (P_{CO_2}) generally occurs with FEV_1 volumes less than 30% of those predicted and constitutes an end-stage event for most patients. Less than 50% of patients with FEV_1 less than 30% of predicted, arterial P_{CO_2} greater than 50 mm Hg, or arterial P_{O_2} less than 55 mm live for 24 additional months.[264]

Airway hyperreactivity is a frequent feature of CF lung disease and can be demonstrated by exercise testing, histamine challenge, or response to bronchodilators. Up to 68% of the CF population demonstrates decreased flows after histamine, and flows improve in as many as 40% with aerosolized bronchodilators.[265] In contrast to cross-sectional studies, repeated tests every 1 to 3 months for a year have demonstrated bronchodilator responsiveness at least once in 95% of subjects.[265] Responsiveness is unrelated to the severity of pulmonary disease or indices of atopy, but seems to be more prevalent during winter than during summer months. Responsiveness diminishes with exacerbations of lung disease, but returns as lung function improves over 2 weeks of intensive in-hospital therapy. Several investigators have noted that occasional patients with CF have a paradoxical response to bronchodilators, perhaps due to further loss of tone in bronchiectatic airways. The pathogenesis of bronchial hyperreactivity in CF is unclear.

Exercise tolerance is related to the severity of airway obstruction.[266,267] Most patients with CF maintain adequate oxygen saturation, even with maximal exercise. However, in one study, 12 of 29 patients with an FEV_1 less than 50% of FVC had an arterial oxygen saturation below 90% at peak exercise, compared with no drop for patients with higher FEV_1 values.[268] Persons with CF have higher than expected ventilatory muscle endurance, and this endurance can be further improved with inspiratory muscle training. However, improved inspiratory muscle strength and endurance do not augment exercise performance.[269] Exercise does improve cardiorespiratory fitness, but does not improve standard pulmonary function test results. Varied weight training, however, in one study increased weight and muscle size and in addition reduced RV/TLC by 12%.[270] Another study demonstrated that adults with CF and advanced lung disease improve with exercise, but those with only moderate lung disease decrease end-expiratory lung volumes after graded exercise on a cycle ergometer.[271] Maximum oxygen consumption during exercise appears to be a better predictor of survival than routine pulmonary function testing.[272]

Resting energy expenditure is variably elevated in patients with CF. Although some have claimed that there are genetically determined increases in energy expenditure (e.g., increased ATP hydrolysis) related to certain CFTR mutations,[273] others have found increased work of breathing to be a more plausible explanation.[274]

Upper Respiratory Tract Disease

Virtually all patients with CF have radiographic opacification of the paranasal sinuses[275] and intermittent symptoms of increased upper airway secretions and moderate airflow obstruction.[276] *Nasal polyps* occur in 15% to 20% of patients and are most common toward the end of the first decade and during the second decade of life.[73] Manifestations include severe or complete airflow obstruction, rhinorrhea, and occasionally widening of the bridge of the nose. Despite the presence of radiographic abnormalities, acute or chronic symptoms of *sinusitis* occur in less than 10% of children[277] and approximately 24% of adults.[278,279]

Complications of Respiratory Tract Disease

Lobar and segmental *atelectasis* occurs in about 5% of patients.[280] This complication is most prevalent in the first 5 years of life and thereafter has a diminishing frequency. The right lung is the site of atelectasis in the majority of patients. Many episodes occur in conjunction with an exacerbation of clinical symptoms, but silent atelectasis is common. Occasionally, volume loss is associated with allergic aspergillosis and endobronchial mucous plugs. However, in most instances, a discrete plug is not evident on bronchoscopy.

Pneumothorax is a more frequent complication and is caused by rupture of subpleural blebs. The overall

incidence is about 1%/yr, and increases with age and disease severity, so that about 20% of CF adults will experience at least one pneumothorax.[281] Pneumothorax occurs equally in both sexes and is more frequent in the right chest. A small asymptomatic pneumothorax may be discovered at the time of routine chest radiographic examination. More commonly, patients develop acute onset of shortness of breath, chest pain, or hemoptysis. The incidence of tension pneumothorax is probably higher in patients with CF than in those with less severe or no lung disease, and under these circumstances, the accumulation of pleural air may become a life-threatening event. Simultaneous bilateral pneumothoraces have been described and constitute an urgent situation. Recurrent pneumothoraces are very common.

Hemoptysis is a common event in older CF patients, correlates with clinical and radiologic evidence of bronchiectasis, and is usually due to airway inflammation rather than vigorous activity or trauma to the chest. Blood streaking in the sputum ("minor hemoptysis") is common, whereas massive hemoptysis (>240 mL blood in 24 hr) occurs in approximately 5% of patients.[282] There is a strong correlation between the occurrence of hemoptysis and the exacerbation of lung infection. Any lobe may be involved and localization may be difficult even with emergent bronchoscopy. In the past, the mortality with massive hemoptysis was as high as 10%, but with proper management, it is not much different from the remainder of the CF population.[283]

Allergic bronchopulmonary aspergillosis (ABPA) develops in 1% to 10% of patients at some time in their lives.[284] In one study, more than 50% of patients with CF had precipitating antibodies to *A. fumigatus* in their serum, and this organism can be recovered from the sputum with a similar frequency.[285] New chest radiographic changes, increased cough, respiratory distress, wheezing, and the expectoration of rusty brown plugs of sputum containing many eosinophils suggest this diagnosis. Atelectasis due to plugging of a lobar or segmental bronchus with hyphae-laden mucus may occur. Chronic airway colonization with aspergillus is common, and diagnosis of ABPA requires new clinical findings plus skin hypersensitivity and elevated levels of IgG and IgE antibodies against *A. fumigatus* or other fungi.[242,243]

Pleural effusions and *empyema* are uncommon in patients with CF, but pleuritic symptoms and signs may accompany exacerbations of lung disease. Staphylococcal and pseudomonal empyemas have been described, but respiratory tract infections usually spare the pleural space.[286]

Digital *clubbing* occurs in virtually all patients with CF and is usually present early in the course of symptomatic lung disease. The cause of clubbing is unknown, but its severity generally correlates with the severity of lung disease.[287] *Hypertrophic pulmonary osteoarthropathy* occurs in as many as 15% of older adolescents and adults.[204,288] If radiographic evidence for periostitis is used as the definition, the incidence is 8%. The most common sites are the distal aspects of the tibia, fibula, radius, and ulna. Signs and symptoms include pain, bone tenderness, swelling, and warmth over the involved areas. Effusions in nearby joints may occur. There is often discomfort with ambulation. Hypertrophic pulmonary osteoarthropathy frequently becomes more symptomatic with pulmonary disease exacerbations and tends to subside when control of pulmonary symptoms is achieved. There are rare instances of cutaneous vasculitis due to CF, which causes a self-limited, painless, palpable purpura, typically involving the lower extremities.[288]

Respiratory failure leads to death in greater than 90% of CF patients. *Hypoxemia* often develops during exertion[289] or sleep[290] and progresses over years. Hypercapnia reflects severe airway obstruction and increases with disease severity and acute exacerbations. Hepatic congestion and peripheral edema caused by pulmonary hypertension and cor pulmonale may develop in the last year of life,[291] particularly if hypoxemia is not adequately treated. Occasionally, infections such as RSV or influenza cause acute respiratory failure that is fully reversible.[292]

Gastrointestinal Manifestations

Meconium ileus occurs in at least 15% of newborns with CF and is virtually diagnostic for CF.[78] These infants fail to pass meconium in the first day or two of life, develop abdominal distention, and proceed to bilious emesis. Occasionally, perforation and peritonitis accompanied by shock occurs. Abdominal radiographic images reveal multiple dilated loops of intestine and air-fluid levels. The lower abdomen may take on a granular appearance from accumulated meconium containing small air bubbles. A barium enema demonstrates a small colon, and if contrast material can be refluxed into the ileum, the point of ileal obstruction can be identified. In utero, ileal perforation results in peritoneal and scrotal calcification. Occasionally, obstruction occurs lower in the intestinal tract and causes only delayed passage of meconium. This condition has been termed the *meconium plug syndrome* and is much less specific for CF.[293] Meconium ileus is also a prominent feature of transgenic mice with a disrupted CFTR gene.[28]

Beyond the newborn period, intestinal obstruction may occur for a variety of reasons. About 20% of patients develop obstruction in the terminal ileum associated with voluminous, sticky, incompletely digested intestinal contents as seen with meconium ileus.[39,78,294] With partial obstruction, intermittent abdominal pain may be the only symptom, but complete obstruction is associated with failure to pass stools, abdominal distention, and vomiting. A mobile right lower quadrant mass may be palpable. Obstruction beyond the immediate newborn period is also characteristic of the CF mouse model. Other causes of abdominal pain and obstruction include intussusception, intestinal adhesions from previous abdominal surgery, low-grade appendicitis, which may be associated with partially suppressed antibiotic therapy, and periappendiceal abscess.[295] Nonfilling of the appendix with contrast enema is frequent in patients with CF, even in the absence of appendicitis.[296] Duodenal irritation, caused by failure to buffer gastric acid, may

underlie radiographic changes in this area and recurrent epigastric pain.[297]

Rectal prolapse occurs in nearly 20% of children, but is an infrequent event for adults with CF.[298] In fact, CF is said to be the most common cause of rectal prolapse in the United States. Factors contributing to rectal prolapse include the presence of bulky sticky stools that adhere to rectal mucosa, loss of the perirectal fat that normally supports the rectum, and increased frequency of high intra-abdominal pressure due to paroxysmal coughing. *Pneumatosis coli* has been reported in association with rectal prolapse in an 18-year-old patient with CF.

Pancreatic Disease

Pancreatic exocrine insufficiency is present from birth in the large majority of patients with CF.[299] It has been estimated that only 5% to 10% of patients have significant pancreatic enzyme release. Exocrine pancreatic sufficiency has been associated with several mutations, including 3789 + 10 Kb C to T, R117H, R334W, R347H, R347P, A455E, P574H, and Y563N. Enzyme deficiency results in fat and protein maldigestion, producing a distended abdomen and frequent bulky, greasy, foul-smelling stools. Uncorrected maldigestion results in failure to gain weight and, ultimately, a failure of linear growth. However, poor growth also may be associated with increased expenditure of energy to accomplish the work of breathing, a point that is often overlooked in the assessment of patients who are short or excessively thin.[300] Fat loss in stools may be as high as 50% to 70% of total intake. Nitrogen malabsorption is roughly comparable or perhaps somewhat less severe. In general, carbohydrates are adequately absorbed in CF. Deficient absorption of fat-soluble vitamins occasionally produces symptoms. Symptomatic vitamin A deficiency, initially a prominent part of the CF syndrome, is rare and occurs only in patients who do not take supplementary vitamins or pancreatic enzymes. Increased intracranial pressure, xerophthalmia, and night blindness may result. Vitamin D deficiency, rickets, is rarely seen. However, bone demineralization is common in CF patients.[301-304] Vitamin E deficiency is common in unsupplemented patients but only rarely causes symptoms, including increased red blood cell destruction and neuroaxonal dystrophy.[305] Vitamin K–dependent coagulation factors may also be deficient, resulting in a hemorrhagic diathesis. Although severe hemorrhagic problems occur mostly in young children, associated symptoms such as hemoptysis are occasionally seen in older patients.

It is now recognized that symptoms of pancreatitis are encountered in less than 1% of identified adolescent or adult CF patients and are limited to those who have retained some exocrine pancreatic function.[306] However, recurrent pancreatitis has been reported as associated with mutations in CFTR and is becoming more frequently recognized as a presenting symptom in adults with CF.[47,307,308] Pancreatic calcifications are occasionally seen radiographically but do not seem to correlate with symptomatic pancreatitis.

Hepatobiliary Disease

Focal biliary cirrhosis is characteristic of CF but produces symptoms in less than 5% of CF patients and causes death in about 2%.[40,309] Hepatic abnormalities can present as hepatosplenomegaly or as persistent elevation of hepatic enzymes (particularly alkaline phosphatase). Rarely, patients present with esophageal varices and hemorrhage due to portal hypertension. Fatty liver is more common and may improve with adequate nutrition. Gallbladder disease is common in adults with CF. Ten percent to 30% of patients have dysfunctional gallbladders[310] or gallstones.[311] Common bile duct stenosis secondary to CF is rare.[312]

Genitourinary Tract Abnormalities

More than 99% of male patients with CF have obstructive azoospermia due to obstruction of the vas deferens.[48] Relatively high incidences of inguinal hernia and hydrocele also have been noted. Failure of reproductive function does not become an issue until well into the second decade of life. Semen analysis may be required to identify the 1% of male CF patients who are fertile. The volume of ejaculate is usually one third to one half of normal. There usually is complete absence of spermatozoa, and a number of chemical abnormalities of semen that reflect absence of secretions from the seminal vesicles can be demonstrated.[313]

Female infertility in CF may be as high as 20%.[313] Some women with CF are anovulatory because of chronic lung disease and malnutrition. Another obstacle to conception may be the presence of thick tenacious cervical mucus, which is difficult to dislodge from the os. This mucus is dehydrated and has abnormal electrolyte concentrations, preventing the usual ferning at midcycle and perhaps impeding normal sperm migration.[314] Endocervicitis is commonly noted.

More than 600 pregnancies in CF females have been reported. A longitudinal study of 325 pregnant women with CF demonstrated 258 live births (79%) and 67 therapeutic abortions.[315] Compared with 1142 age- and severity-matched controls, pregnancy in a woman with CF did not have an independent negative effect on pulmonary status or mortality over 2 years.[316] However, it is essential that CF females consider their own health and expected life span in the context of family planning. Women with CF can breast feed successfully.[317]

Sweat Gland Dysfunction

Sweat chloride is elevated in most CF patients due to abnormal sodium chloride reabsorption in the sweat ducts.[318] Excessive loss of salt in the sweat predisposes young children to depletion episodes, especially at times when there is additional salt loss due to vomiting or diarrhea. These children present with lethargy, anorexia, and hypochloremic alkalosis, a presentation that is more common in warm arid zones. Such hypochloremic alkalosis is rare in older children and adults.[319]

TABLE 41-5. Criteria for the Diagnosis of Cystic Fibrosis

PHENOTYPIC CLINICAL FEATURES
Chronic sinopulmonary disease
Chronic cough and sputum production
Persistent infection with characteristic pathogens (*Staphylococcus aureus* and *Pseudomonas aeruginosa*)
Airflow obstruction
Chronic chest radiographic abnormalities
Sinus disease; nasal polyps
Gastrointestinal and nutritional abnormalities
Pancreatic exocrine insufficiency; recurrent pancreatitis
Meconium ileus; DIOS
Obstructive azoospermia in males
LABORATORY EVIDENCE OF CFTR DYSFUNCTION
Elevated sweat Cl^-
Mutation in the CF gene on both alleles
Characteristic bioelectric abnormalities (potential difference) in nasal epithelium in vivo

CF, cystic fibrosis; CFTR, cystic fibrosis transmembrane conductance regulator; DIOS, distal intestinal obstruction syndrome.

Fucosidosis
Malnutrition
Mauriac's syndrome
Familial cholestasis syndrome
Prostaglandin E_1 administration
Hypogammaglobulinemia

DIAGNOSIS

The diagnosis of CF is based on carefully defined clinical criteria and laboratory evidence of CFTR dysfunction, including abnormal sweat Cl^- levels.[318,320] Accepted diagnostic criteria are listed in Table 41-5. Any one of these clinical features, if accompanied by a sweat chloride level greater than 60 mEq/L, is sufficient to make the diagnosis. Characteristic nasal epithelial bioelectric abnormalities can also serve as laboratory evidence of CFTR dysfunction and be used to diagnose CF, when phenotypic clinical features are present.[318,321] Many diagnoses are verified by identifying a mutation in CFTR on both alleles. At this time, however, a substantial number of patients have unidentified mutations. A few persons with sweat chloride values persistently in the diagnostic range but without clinical features of CF or a family history have been identified. As long as they remain symptom-free and mutations of both CFTR genes are not identified, the diagnosis of CF cannot be made. Other clinical entities may be accompanied by elevated sweat chloride concentrations; these are listed in Table 41-6. None of these disorders are easily confused with CF. It is now recognized that a small percentage of persons with CF have sweat values in an intermediate (40–60 mEq/L) or even normal range.[37,322,323]

For the 1% to 2% of patients with compatible clinical features of CF but normal sweat chloride levels, several approaches to the diagnosis are available. Clinical criteria for making the diagnosis of CF in the presence of a normal sweat chloride value were proposed prior to modern diagnostic options.[322] The discovery that bioelectric potential differences across respiratory epithelia are abnormal in patients with CF[9,117,321] offers a more quantitative diagnostic test that has been useful in the evaluation of atypical patients. Also, DNA analysis techniques are now available for detection of CF gene mutations, particularly in clinical variants. For example, a single mutation of the CFTR gene, 3789 + 10 Kb C to T, is associated with many of the suspected patients with CF whose sweat chloride values are in the normal range.[37,44]

Although DNA analysis is becoming a standard of care in CF, the sweat test remains the diagnostic standard. Only one method is recognized by the Cystic Fibrosis Foundation as adequate for the definitive diagnosis of CF. This test involves collection of sweat by pilocarpine iontophoresis, coupled with chemical determination of the chloride concentration.[324,325] The procedure must be carried out in a meticulous fashion to avoid errors that frequently contribute to misleading values. As many as 40% of patients referred to CF centers have been inaccurately diagnosed elsewhere because of false-positive or false-negative sweat test results. In addition to frequent laboratory errors, faulty values can be obtained if the sweat rate is not sufficiently high. At least 50 mg of sweat must be collected in a 30-minute period. Potential pitfalls in interpretation include the presence of hypoproteinemic edema, failure to consider age-related effects, and concurrent administration of corticosteroids. Although using a threshold of 60 mEq/L of chloride in sweat appears to discriminate nearly all adults with CF from those with other lung conditions,[326] normal values of sweat chloride do increase with age, and some investigators insist on documentation of sweat chloride levels in excess of 70 mEq/L for the diagnosis of CF in adults.

Newborn screening for CF is now carried out on all infants in 49 states.[327–329] The test used is an assay of immunoreactive trypsin in dried blood spots collected

on filter paper in the first several days of life. Experience thus far suggests that most newborns with CF may be identified with this test.[330,331] This test has an acceptable rate of false-positive results. Follow-up testing is performed by sweat Cl^- and/or *CFTR* genotyping.[332] Studies of newborns with CF discovered by screening have detected nutritional deficits and infectious/inflammatory lung disease, which suggests that early identification and treatment may be useful to protect against loss of lung function.[333–339] In addition, pharmacologic and gene transfer therapies currently at an experimental stage are theoretically most effective early in life and, if their efficacy is documented, newborn screening will play an important role.

Antenatal diagnosis can now be carried out, especially when the genotype of parents is established. For more than a decade, genetic testing for CF has been offered to couples currently planning a pregnancy,[340] which has necessitated the development of counseling programs.[341,342]

TREATMENT

The primary objectives of CF treatment are to control infection, promote mucus clearance, and improve nutrition.[343] In addition, experience has repeatedly demonstrated that attention to preventive aspects of lung care and psychosocial factors is important. An important concept has emerged from both pathologic and functional (mucus clearance) studies, that is, CF lung disease is heterogeneous.[344] This observation suggests that specific therapies (e.g., CFTR correctors or potentiators or rehydrating agents) may be able to prevent the spread of chronic bacterial infection throughout the CF lung and, hence, truly "arrest" disease progression.

Ambulatory Care

At diagnosis, most patients are introduced to a care program including postural drainage with chest percussion, administration of antibiotics as indicated, and a nutritional regimen including pancreatic enzymes and fat-soluble vitamins. Other therapeutic modalities are prescribed as indicated.

Physical Measures to Promote Airway Clearance

The use of postural drainage with chest percussion to clear mucus is based on the concept that cough clears mucus from large airways but chest vibrations are necessary to move secretions from the small airways where expiratory flow rates are low. The most compelling argument for the use of this therapeutic modality comes from a study of older children with mild to moderate airflow limitation.[345] When patients were receiving chest physical therapy on a regular basis, the only immediate effect documented was an increase in peak expiratory flow rate 30 minutes after therapy. However, after 3 weeks without chest physical therapy, both FVC and flow rates were significantly reduced. The diminution in lung function could be reversed with renewal of regular chest physical therapy. A meta-analysis of 35 studies concluded that standard chest physical therapy increases sputum production and improves FEV_1.[346] Most care centers prescribe this therapy one to four times a day, depending on the severity of illness. A variety of mechanical percussors are available to assist, especially for those patients who do their own therapy. Several studies in the literature suggest that repeated forced expiratory maneuvers,[347] use of positive expiratory pressure,[348] and vigorous exercise[349–351] may substitute for chest physical therapy. The advisability of chest physical therapy for patients who have minimal cough and no apparent sputum production is open to question. Study results are not available to answer this question. Theoretically, chest physical therapy might prevent or delay inspissation of mucus in small airways, which is the earliest lesion. In addition, caregivers have found that many patients who do not receive chest physical therapy on a regular basis are unlikely to initiate this therapy when pulmonary exacerbations arise.

Inhaled Hypertonic Saline for Airway Clearance

Inhaled hypertonic saline (HS) osmotically draws water onto airway surfaces. Indeed, because of the limitation with respect to Cl^- permeability of CF airway epithelia, inhaled salt may remain on CF airway surfaces longer, and hence be osmotically more active, than on normal airway surfaces.[344] Recent data suggest that the rehydrating effect of inhaled HS (7%, four times daily) produces short term (2-wk) effects that restore mucus clearance and improve lung function and quality of life.[161] Further, data from Australia, also using 7% inhaled HS and an identical delivery device (Pari-LC Star), indicated that twice-daily inhalation of HS produced a durable increase in lung function, a substantial reduction in acute exacerbations, a reduction in newly acquired bacterial pathogens, a reduction in days lost from school/work, and an improvement in quality of life.[352] Many centers now consider inhaled HS (7%, twice daily) as a standard of care. However, more data are needed with respect to effectiveness of the wide variety of regimens currently in use (e.g., role of nebulizer type, strength of HS, number of administrations/day).

Aerosolized rhDNase

The lysis of viscous DNA with the recombinant enzyme DNase offers benefit to some patients with purulent airway secretions.[353] When taken once daily, aerosolized DNase reduced relative risk of respiratory exacerbations by 28% and improved FEV_1 approximately 6% above baseline over 6 months. Not all patients had objective improvement in lung function, but symptomatic benefit occurred in many of treated patients without improved lung function. Daily inhalation slows the usual decline

in lung function and decreases the frequency of exacerbations.[354]

Novel Airway Surface Rehydrating Agents

A number of novel agents are being developed to treat CF airways dehydration. For example, as an alternative osmotic agent, inhaled mannitol ("Bronchitol") is being developed as a dry powder inhalation and is currently in phase III clinical testing. There are also novel small molecules in development designed to redirect CF ion transport from absorptive to secretory modes. An extracellular ATPase resistant analogue of UTP, INS37217, is currently completing phase III testing.[145] Like endogenous ATP, INS37217 slows Na^+ absorption and activates Ca^{2+}-activated Cl^- channel-mediated Cl^- secretion in CF airways to rehydrate surfaces. In parallel, long-acting, potent, and safer amiloride derivatives (e.g., GS9411) are being developed for inhalation in an HS vehicle to greatly amplify the hydrating effect of HS. The GS9411/HS combination is currently in phase I testing.

Antibiotics

Lung infection is the major source of morbidity and mortality in CF. Therefore, antibiotics are the mainstay of therapy designed to control progression of disease. In general, antibiotic therapy should be predicated on the presence of symptoms and guided by the identification of organisms from the lower respiratory tract. There is evidence that early and vigorous use of antibiotics produces better results than delaying the administration of antibiotics until symptoms are well developed or advanced.[355] Similarly, *P. aeruginosa* infection has been treated by regularly scheduled courses of intravenous antibiotics.[356] Data justifying these approaches are lacking.

Another principle of antimicrobial therapy in CF is that dosages need to be higher than for non–CF-related chest infections. Both total body clearance and volume of distribution are considerably greater for CF than for other patients.[357] In addition, large doses are needed to achieve therapeutic levels in the infected and mucus- or pus-filled endobronchial space. Sputum levels achieved are highly varied but usually are less than half of the levels measured in serum.[358] Experience also has led many caregivers of CF patients to use longer than usual courses of antibiotics, continuing for at least 2 weeks and, frequently, 3 or 4 weeks.

The choice of antibiotics optimally should be based on the results of sputum culture and sensitivity testing. For patients with nonproductive cough, specimens are best obtained by harvesting secretions with a throat swab placed just above the glottis during repetitive coughing. Nasopharyngeal cultures are not useful as a guide for selection of antibiotics. If *S. aureus* is present or expected, the choice may include a semisynthetic penicillin, a combination of ampicillin and clavulanic acid, a cephalosporin, or clindamycin. Suggested drugs and doses are given in Table 41-7. *Haemophilus* infections are best treated with ampicillin, trimethoprim-sulfamethoxazole, cefuroxime, or cefaclor. In the majority of cases, these antibiotics will eradicate *S. aureus* and *H. influenzae* from the airways on a temporary basis. In older children and adults, tetracyclines may provide useful empirical therapy. Ciprofloxacin appears to control symptoms and reduces numbers of *Pseudomonas* organisms in CF airways, but its usefulness is limited by rapid emergence of resistant organisms.[359]

Because of limited options for treatment of *Pseudomonas* with oral antibiotics, parenteral preparations of aminoglycosides or other antibiotics have been delivered to the lower respiratory tract by aerosol.[360,361] Some studies show clear short-term benefit of aerosolized tobramycin (300 mg in nebulizer) taken twice daily.[362] This treatment, taken in alternate months for three cycles, improved lung function, decreased bacterial burden, and decreased relative risk for hospitalization. The rate of acquired tobramycin resistance was approximately 7% over 24 weeks in the treated group.

Macrolides

Long-term macrolide antibiotics effectively treat diffuse panbronchiolitis and have been tested in CF. Randomized, controlled clinical trials in CF children in the United Kingdom,[363] in adults who were chronically infected with *P. aeruginosa* in Australia,[364] and in chronically *P. aeruginosa*–infected children and adults in the United States[365] demonstrated clinical improvement (better pulmonary function and fewer pulmonary exacerbations) with azithromycin. A sputum acid-fast bacilli (AFB) smear and culture should be obtained prior to initiating chronic macrolide therapy because of the risk that undiagnosed nontuberculous mycobacterial infection could develop macrolide resistance. For patients on chronic macrolide therapy, an AFB smear and culture should be obtained every 6 months.

Bronchodilators

As detailed in the "Clinical manifestations" section, many patients demonstrate bronchial lability, prompting frequent use of bronchodilators,[260] particularly β-adrenoceptor agonists. Although their immediate effectiveness can be documented in the pulmonary function laboratory, overall improvement or long-term benefit has not been established. Indications for the use of bronchodilators include troublesome wheezing and a documented improvement in pulmonary function (e.g., at least a 15% improvement of FEV_1). β-Agonists can be nebulized, administered by metered-dose inhalers, or given orally. Caution should be exercised concerning long-term therapy with these agents because animal studies show that administration of large amounts of β-adrenoceptor agonists cause submucosal gland hypertrophy and presumably a hypersecretory state.[366] Theophylline preparations also may be effective in selected

TABLE 41-7. Antimicrobial Agents Used to Treat Cystic Fibrosis Lung Infection

Route	Organism	Agent	DOSE		Doses/day
			Pediatric (mg/kg/day)	Adult (g/day)	
Oral	*S. aureus*	Dicloxacillin	50–100	2–4	4
		Cefaclor	40	0.75–1.5	3
		Clindamycin	15–25	0.6–1.2	4
		Erythromycin	50	2	4
		Amoxicillin/clavulanate	40	1.5	3
		Azithromycin	—	0.5 day 1, then 0.25 daily for 2–5 days	1
		Linezolid	30	0.6	2–3
	H. influenzae	Amoxicillin	40–60	1.5	3
		Trimethoprim-sulfamethoxazole	20*	0.32–0.64*	2–4
	P. aeruginosa	Ciprofloxacin	—	1.5–2.25	3
		Ofloxacin	—	0.8–1.2	2–3
	Empirical	Tetracycline	50–100	2	3–4
Intravenous	*S. aureus*	Oxacillin	150–200	†	4
		Vancomycin	40	2	2–4
		Linezolid	30	0.6	2–3
	P. aeruginosa	Gentamicin or tobramycin	8–20	†	2–3
		Amikacin	15–30	†	2–3
		Carbenicillin or Ticarcillin	250–500	†	4–6
		Piperacillin, Mezlocillin, or Azlocillin	250–450	†	4–6
		Ticarcillin/clavulanate	250–450	†	4–6
		Imipenem/cilastatin or Meropenem	45–90	4	3–4
	P. aeruginosa and *B. cepacia*	Ceftazidime or Cefepime	150	4–6	3
Aerosol	*P. aeruginosa*	Gentamicin	40–600‡	80–600‡	2–4
		Tobramycin	40–600‡	80–600‡	2–4

*Quantity of trimethoprim.
†Usually dosed by mg/kg/day as with children.
‡Total dose in milligrams.

cases. However, CF patients seem to be less tolerant of theophylline because of frequent gastrointestinal irritation.[367] Ipratropium bromide is at least as effective as β-agonists in CF,[368–370] although distal intestinal obstruction syndrome has been reported coincident with use of this agent.[371] Cromolyn sodium has also been used; a single study failed to demonstrate efficacy.[372]

Corticosteroids

An initial double-blind controlled study of alternate-day oral corticosteroid administration demonstrated better maintenance of pulmonary function and fewer exacerbations of lung disease requiring hospitalization over a 4-year period.[373] A recent Cochrane review of 13 trials of inhaled corticosteroids in patients with cystic fibrosis concluded that there was insufficient evidence to document efficacy and some evidence that they may suppress growth.[373a] Widespread use of oral or inhaled corticosteroids cannot be advocated. They may be used for specific indications such as ABPA.

Anti-inflammatory Therapy with Ibuprofen

A study of high-dose ibuprofen over 4 years indicated that CF patients younger than age 13 years with mild lung disease have remarkable slowing of decline of lung function (eightfold) as compared with placebo control subjects.[374] No effect was documented in patients older than 13 years, even among patients with mildest lung disease. There were few side effects, but most of the patients were taking antacids or H_2-receptor blockers.

Other Respiratory Therapies

Mucolytics, expectorants, and cough suppressants have been used for relief of chest symptoms. In general, cough is an important mucus clearance mechanism for patients with CF and should not be suppressed. Expectorants, which assist in the elimination of airway secretions

during cough, probably do not achieve that objective. Rather than being helpful, long-term administration of iodides to patients with CF has been associated with a high incidence of goiter and hypothyroidism.[375] Mucolytics such as *N*-acetylcysteine are injurious to respiratory epithelium and promote bronchitis when used regularly. Therefore, aerosol inhalation of this substance should be used selectively and only for short periods. Another experimental approach, delivery of elastase inhibitors to airways by aerosol, is the subject of ongoing clinical trials.

Exercise is generally considered beneficial for patients with CF and should be encouraged for all but those with the most severe lung disease and hypoxemia.[376] A 12-week exercise program consisting of three 1-hour sessions a week, during which jogging was used to produce a heart rate averaging 70% to 85% of peak heart rate, has been shown to increase exercise tolerance and cardiorespiratory fitness, probably by increasing respiratory muscle endurance.[270] However, this program did not improve pulmonary function. Most caregivers of patients with CF believe that regular, vigorous exercise promotes a positive self-concept and increases the perception of wellness. In addition to cardiopulmonary conditioning exercises, isometric exercises such as weight lifting may build abdominal and upper body muscle strength and in this way promote deep breathing and effective coughing.

Systemic Agents Designed to Restore Cystic Fibrosis Transmembrane Regulator Function

Two classes of small molecule therapeutics are under development for treatment of CFTR mutant protein. The first class is aimed to improve the maturation of misfolded mutant CFTR (e.g., ΔF508 CFTR). If these drugs are successful, they would have the capacity to move mutant CFTR to the plasma membrane, where residual Cl^- function appears to be adequate to provide therapeutic benefit.[377] A first such compound, VX809, is in phase I testing.

The second class is aimed at mutant CFTRs that have normally folded, and are targeted to the apical membrane, but function poorly. Molecules such as VX770 have been shown to activate, that is, improve the gating, of such mutant CFTR (e.g., G551D). VX770 is currently in phase II clinical testing. Preliminary results suggest benefits on sweat chloride levels, nasal potential difference, and exacerbation frequency.

Gene Transfer Technology

It is technically possible using genetically engineered viral vectors to transfer the wild-type CFTR gene to respiratory epithelial cells in vitro, where it can be expressed at least for days to weeks.[378] Currently, work is ongoing at the laboratory level on adeno-associated virus–, lentiviral-, and paramyxoviral-based vectors for this purpose. When warranted, translation into human studies should be rapid, based on previous experience with preclinical models and human trials.[379,380]

Nutrition

Approximately 90% of patients with CF require mealtime pancreatic enzymes, packaged as granules that are coated with acid-resistant material to promote delivery to the small intestine. Capsules containing 4000 to 24,000 units of lipase are available. Numbers of capsules taken should be adjusted based on weight gain, presence or absence of abdominal cramping, and the character of stools. Dosage should be limited to current guidelines (~2500 lipase units/kg/meal), because a large total daily dose of enzymes has been associated with fibrosing colonopathy.[381–384] Vitamins A and D are supplied by a daily multiple vitamin preparation. Vitamin E, 100 to 200 units daily, is recommended because serum levels are generally low in unsupplemented patients. Vitamin K is given sporadically to treat bleeding complications or to correct prolonged prothrombin times. Other vitamins and trace minerals may be deficient and require supplementation on a selective basis.[300]

Many patients with CF have a higher than normal caloric need because of the increased work of breathing. In general, patients should be encouraged to eat a balanced diet, including at least a moderate amount of fat. When the anorexia of chronic infection supervenes, failure to gain weight or weight loss occurs. Further encouragement to eat high-calorie foods may be helpful. Supplementation with elemental dietary preparations by mouth is unlikely to be sustained over an extended period of time. Some CF care centers administer supplementary elemental feedings nocturnally by nasogastric tube or by percutaneous duodenostomy.[300,385] Although short-term benefits such as increased weight gain can be achieved, long-term beneficial effects on pulmonary function have not been established.

Patients with CF who retain exocrine pancreatic function and maintain good nutrition experience a slower rate of decline of pulmonary function than those with pancreatic dysfunction.[386] This observation has been used as a rationale for emphasizing nutritional interventions. Although this approach may have merit, it is generally more efficacious to maintain good nutrition by preventing progression of lung disease than to maintain good lung function by emphasizing nutritional therapy.

Psychosocial Factors

As with any chronic disease, compliance with therapy and ability to function fully are highly dependent on the patient's attitude. Therefore, approaches that promote a positive self-concept and foster the ability of patients to take control of their medical management, and enable them to participate fully in life events, are likely to promote well-being and perhaps longevity. Medical care that provides continuity and fosters trust may pay large dividends. Personnel who specifically provide psychosocial support are important contributors to CF care teams.[387]

Immunization for Lung Pathogens

Rubeola, pertussis, and influenza infections are particularly injurious to CF lungs and may trigger a downward spiral of lung function. Adequate immunization early in life for pertussis and measles is mandatory. Patients of all ages should be immunized for influenza virus on a yearly basis and the early treatment of influenza A infections may prevent adverse consequences. Other routine vaccines should be administered as for the general population. There is no evidence that administration of pneumococcal vaccine is useful.

Hospital Therapy

Indications for hospitalization and intensive pulmonary therapy include increased cough or wheezing, respiratory distress with decreased activity, weight loss, sustained downward trend in pulmonary function, increasing hypoxemia, or a major pulmonary complication. Hospitalization allows easy administration of intravenous antimicrobial agents to control *Pseudomonas* infections and intensification of all therapies including physical maneuvers to clear airway secretions.

Antibiotics for intravenous administration should be selected on the basis of respiratory tract cultures and susceptibility studies. Two-drug treatment of *Pseudomonas* infection is the rule. A third antibiotic may be added as necessary for control of *S. aureus* or other organisms. Drugs and dosages currently used for intravenous therapy are listed in Table 41-7. A clinical response is often not seen for 4 to 7 days after initiation of therapy. In general, a 2-week course provides good improvement in pulmonary function[388,389] and more sustained benefit than shorter courses. With refractory infection, treatment for 3 weeks or more is not unusual. Some advocate intensive therapy until pulmonary function has returned to a previous baseline or until improvement has reached a plateau. Prolonged courses of antibiotic therapy should include periodic monitoring of respiratory tract organisms and their antibiotic sensitivities, because shifts in either are common.

Aminoglycosides have been the mainstay of anti-*Pseudomonas* therapy for many years. A major advantage is ability to monitor and adjust blood levels. For gentamicin or tobramycin, two to three times a day dosage and achievement of peaks in the range of 10 to 12 μg/mL and troughs less than 2 μg/mL seem to be optimal. Patients should be monitored during aminoglycoside therapy for nephrotoxicity and ototoxicity. An aminoglycoside is usually paired with one of the penicillin derivatives or with ceftazidime.

Patients with CF, particularly those who are in school or holding full-time jobs, may opt to administer intravenous antibiotics at home for all or a portion of the treatment course. This seems to work well in selected cases and may be as effective as hospital treatment.[390,391] For patients requiring frequent courses or long-term home antibiotic therapy, central intravenous catheters have been surgically placed and used for prolonged periods.

One study suggested that the infusion of 500 mg/kg of intravenous immunoglobulin during a course of intravenous antibiotics enhances the pulmonary function response[392]; further studies are needed to confirm these observations.

Interest in bronchial lavage as a therapeutic modality has been tempered by the realization that long-term benefits are unlikely to accrue from this approach and that acute deterioration of lung function is a possible outcome.[393] In fact, there is no evidence that bronchoscopy and lavage, whether it be whole lung, lobar, or segmental, is superior to intensive antibiotic therapy and chest percussion.

Treatment of Lung Complications

Hypercapnic and hypoxemic *respiratory failure* in CF are primarily due to progressive obstructive airway disease with alveolar hypoventilation and ventilation-perfusion mismatching. Treatment of airway infection and inflammation with antibiotics and the airway clearance measures summarized previously is essential. Low-flow oxygen is effective at relieving nocturnal, exertional, and resting hypoxemia and does not usually cause significant hypercapnia.[394] The use of supplemental oxygen in children has been discouraged[395] because nocturnal oxygen did not improve survival or prevent the development of cor pulmonale in one controlled trial.[396] A larger study demonstrated that the development of pulmonary hypertension in adults with CF is strongly correlated with hypoxemia and is associated with increased mortality.[397] Therefore, supplemental oxygen in accordance with the guidelines established for chronic obstructive pulmonary disease[398] is recommended.[399] Diuretics, inotropic agents, and theophylline produce few benefits and are rarely used. Cor pulmonale is a late complication of airway obstruction, and no treatment options beyond those for the primary disease processes are effective.

Ventilatory assistance is effective in CF patients with acute respiratory failure caused by reversible insults[292] but produces few long-term benefits in patients with respiratory failure due to irreversible lung damage caused by CF bronchiectasis.[400] Assisted ventilation using nasal or face masks[401] or endotracheal tubes[402,403] can effectively treat patients awaiting lung transplantation. The airway disease generally progresses, however, and long-term ventilatory support is rarely feasible.

Atelectasis is best treated by vigorous standard therapy, including airway clearance and antibiotics. Corticosteroids may be helpful in the presence of reactive airways or severe airway inflammation. There is no evidence that bronchoscopy and lavage are effective in expanding collapsed segments of lobes.[280] *ABPA* responds to standard doses of systemic corticosteroids.[404] Inhaled steroids[405] and the oral antifungal agent itraconazole[406] may prove to be useful.

Pneumothorax can be observed for spontaneous resolution if small and minimally symptomatic. A pneumothorax more than 20% of the hemithorax volume, compromising ventilation or causing hypotension,

requires tube drainage.[262] Recurrences are very common and may require thoracoscopic talc poudrage or surgical pleural abrasion.[286]

Hemoptysis requires treatment of airway infection and supplemental vitamin K if the prothrombin time is prolonged due to inadequate absorption. Massive hemoptysis may resolve with such conservative therapy and modest cough suppression for 1 to 2 days,[282] but bronchial artery embolization[283,407] provides more definitive control, which usually persists for more than 6 months.

Treatment of Gastrointestinal Complications

Meconium ileus can be relieved in a number of cases with enemas using meglumine diatrizoate (Gastrografin) or other contrast materials, which are refluxed into the terminal ileum under fluoroscopy. If this fails, or if there is evidence of perforation, surgical intervention is required. *Distal intestinal obstruction syndrome* also can be relieved with contrast enemas that reach the terminal ileum. However, this approach has been largely supplanted by intestinal "flushes" with a balanced salt solution; 1 to 2 L rapidly instilled into the stomach is usually effective. Occasionally, surgical intervention is necessary. *Rectal prolapse* usually can be reduced voluntarily by older patients, using abdominal, perineal, and gluteal muscles, but in small children, rectal prolapse must be reduced manually by continuous gentle pressure with the patient in the knee-chest position[298]; sedation may be helpful. Adequate pancreatic enzyme therapy, decreased fat in the diet, and control of pulmonary infection usually prevent recurrences. A few patients may require surgical stabilization of the rectum.

Cirrhosis is generally focal and usually does not require specific therapy. Localization of CFTR to bile ductule cells suggests that abnormal bile secretion may be germane to CF liver disease. Ursodeoxycholic acid (URSO) is effective treatment for primary biliary cirrhosis.[408] Early trials of URSO in CF patients showed improved liver function tests, but the long-term effect on liver function is not known.[409,410] The thresholds for initiating therapy and clinical outcomes are under investigation. Bleeding esophageal varices that complicate cirrhosis often can be managed with banding or sclerotherapy. In the past, significant bleeding has been treated successfully with portal-systemic shunting.[411] Splenorenal anastomoses have been most effective, and hepatic encephalopathy has not been a problem. The transjugular intrahepatic portasystemic shunt procedure[412,413] can relieve portal hypertension and reduce bleeding episodes. Liver failure and ascites are treated as in other patients. Liver transplantation has been successfully performed, with a 2-year survival exceeding 50%.[414,415] Pancreatitis, when it occurs in adolescents or young adults with CF, is treated with standard measures.

Hyperglycemia as a complication of CF can occur at any age, but it is generally a problem of the second and third decades of life.[301] Ketoacidosis is rarely encountered. When blood glucose levels are only intermittently elevated and glycosuria is not present, no treatment is necessary. With the advent of sustained glycosuria, insulin treatment should be instituted. Oral hypoglycemic agents, considered ineffective in the past, may be helpful in selected patients.[416] The development of significant hyperglycemia may not change longevity.[417,418] However, vascular disease affecting the retina and kidneys has been documented in CF patients who have had prolonged hyperglycemia.[419,420] Therefore, careful control of blood sugar levels is desirable. Intensive screening and management regimens have been recommended.[421]

Surgical Therapy

Nasal polypectomy to relieve obstruction is the most common surgical procedure in CF, and most patients get symptomatic improvement.[422] Recurrence of polyps is common,[423] but the incidence of polyposis usually wanes after the second decade. Gallstones are common and symptomatic disease may require elective cholecystectomy in as many as 5% of CF adults.[424] Lobectomy is occasionally indicated for massive hemoptysis that is refractory to bronchial artery embolization. Partial lung resection has been advocated for apparently localized disease and recurrent severe exacerbations.[425] However, the generalized lung disease continues to progress; the limited probability of long-term benefits dictates caution in patient selection.

Transplantation

Lung transplantation has become an accepted therapy for respiratory failure secondary to CF.[426] Heart-lung transplant has been largely replaced by sequential double-lung transplant because of limited organ availability. Patients should be referred when their prognosis is about equal to the waiting time for donor lungs, currently about 2 years after acceptance as a lung transplant candidate. In 2005 in the United States, the allocation of donor lungs was changed to a system that incorporates waiting list and posttransplant survival probabilities based on underlying disease, pulmonary function, and other factors.[427] More than 2300 lung transplants have been performed for CF around the world. The transplanted lungs remain free of CF, but are subject to secondary infection, acute rejection, and chronic rejection (bronchiolitis obliterans syndrome). The 5-year survival is 48%, as good as that of lung transplant recipients with other causes of lung disease. Living lobar transplantation is an effective alternative to conventional cadaveric lung transplants.[428] The lobe donors must have sufficiently large lungs so that their lower lobe will fill the recipient's hemithorax. Survival appears to be similar to that following conventional lung transplantation.

Course of the Disease and Prognosis

CF runs a highly varied course, ranging from death due to complications of meconium ileus in the first days of

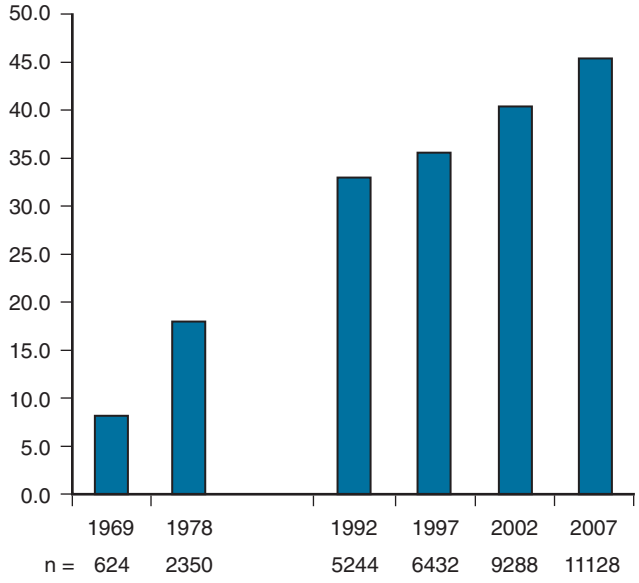

FIGURE 41-8 ■ Percent of CF patients aged 18 or older as shown for 1969 to 2007. (Data from the Patient Registry, Cystic Fibrosis Foundation, Bethesda, MD, courtesy of Dr. S. FitzSimmons.)

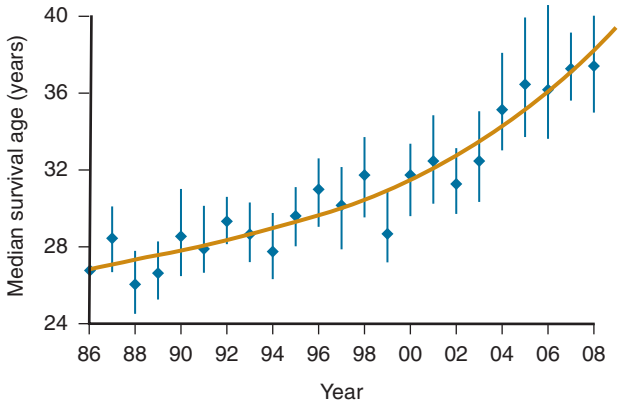

FIGURE 41-9 ■ Median predicted survival age for CF patients in US Cystic Fibrosis centers dating from 1986. (Data from the Patient Registry, Cystic Fibrosis Foundation, Bethesda, MD.)

life or death from severe respiratory tract problems within the first months of life to essentially asymptomatic existence for 10 to 20 years[429] and protracted survival. A few patients with CF do live into the sixth and seventh decades of life.[294] More than 11,100 (45%) of the patients in the U.S. CF registry are 18 years of age or older.[430] The changing age distribution is demonstrated in Figure 41-8.

At most care centers, patients with CF are monitored by general clinical assessment, which often involves the use of a scoring system,[431,432] periodic monitoring of respiratory tract pathogens, periodic chest radiographs, serial pulmonary function testing, and ongoing nutritional assessment. Initial intensive treatment is usually followed by improvement in pulmonary function tests as well as substantial improvement of weight-to-height ratios and accelerated linear growth in children. After initial improvement or stabilization, there is often an extended period of stable lung function that may last 5, 10, or even 15 years. Progressive dysfunction inevitably supervenes. Longitudinal patterns of pulmonary function in older individuals with CF are highly variable.[433,434]

The most recent statistics from the Cystic Fibrosis Foundation indicate that 50% of patients can now be expected to survive beyond age 37 years. These data were generated from all patients under care in Cystic Fibrosis Foundation–sponsored centers in 2007 (Fig. 41-9). Analyses of survival curves over the years have suggested that longevity has increased steadily to the present time. Some of the improvement in survival may have resulted from the diagnosis of milder forms of the disease. However, there is considerable opinion that improved symptomatic therapy has also contributed to better survival.

Multiple factors determine the prognosis for individuals with CF.[432] Data from all U.S. CF centers suggest that survival is better for patients living in northern climates than those living in the South. On average, male patients live 3 years longer than do female patients. The reason for this gender difference is not known, but there is no significant survival difference for CF patients born after 1990.[432] Blacks who survive the first several years of life may have a better prognosis than whites. Age at diagnosis has not emerged as a clear determinant of survival. However, a study of sibling pairs suggests that the younger sibling who is diagnosed before 1 year of age, before the onset of symptoms, usually has better pulmonary function at 7 years of age than does the older sibling diagnosed at an older age because of symptoms.[434]

Several studies suggest that the clinical features present when the patient is first seen make a difference. Patients who initially have only steatorrhea and failure to thrive generally improve remarkably after institution of therapy and do well for extended periods of time.[435] Conversely, patients who have respiratory tract symptoms when first seen usually continue to have respiratory tract problems and have a less favorable prognosis.[436] When the entire CF population is considered, those patients who retain pancreatic exocrine function display a slower progression of pulmonary disease.[33,437] Meconium ileus does not influence longevity if the patient survives the first months of life. Initial claims that CF patients with allergies have improved survival cannot be substantiated. There are many indicators of poor prognosis once airway disease has been established, including colonization with *P. aeruginosa* or *B. cepacia* and occurrence of pulmonary complications such as pneumothorax and massive hemoptysis.[438] Onset of insulin-dependent hyperglycemia is associated with worse lung function, poorer nutrition, and decreased survival compared with those in nondiabetic CF patients.[421,439]

Little is known about the influence of medical care on longevity. Several studies suggest that patients followed at established care centers have a greater median survival than those who receive care in nonspecialized settings.[440] In addition, evidence suggests that center-to-center variation in survival of patients is directly related to the intensity of care rendered in each center, including

frequency of monitoring, antibiotic use, and hospitalization for treatment of pulmonary exacerbations.[355] The U.S. Cystic Fibrosis Foundation now reports center-specific outcomes data on the internet (www.cff.org). It has sponsored a series of quality improvement initiatives to improve care processes and outcomes.[441] This work has already produced pulmonary, nutrition, and survival benefits, and led to the Cystic Fibrosis Foundation's receipt of a 2009 Health Quality Award from the National Committee for Quality Assurance (NCQA).

Finally, psychosocial factors undoubtedly play a prominent role in outcome, although this is difficult to document.[442–444] The role of a supportive family is crucial. Suicide is uncommon. However, it is widely recognized that a substantial number of adolescent and adult patients do not comply fully with therapy regimens because of denial, unresolved dependence-independence issues, and depression. Clearly, attitude and the ability to cope with a fatal illness during maturation and early adulthood do influence outcome.

Even though faced with a life-threatening illness and burdened with staggering demands on time, energy, and financial resources to comply with therapy, most adolescents and young adults cope admirably and are able to achieve a satisfactory quality of life. Successful relationships,[445] advanced education, and a full-time occupation are frequently achieved (Table 41-8), indicating that independent lifestyles and full participation in life events are attainable goals for many patients.

CF 2009.	
Education & Employment	
Data from CFF Patient Registry 2007	
Records of CF Adults (≥18 years) seen in CF Care Centers in 2007 (N = 11,128)	
Highest Education Level	
College graduate	31%
Some college	33%
High school diploma	27%
Less than high school	9%
Current Employment	
Retired	1%
Full-time	37%
Part-time	11%
Student	25%
Homemaker	4%
Unemployed	8%
Disabled	14%

KEY POINTS

- CF is a prevalent autosomal-recessive disease caused by a mutation in a gene encoding for CFTR, an integral membrane protein that regulates a chloride channel and other ion channels in epithelial cells.
- The CFTR defect results in alterations of electrolyte content, intraluminal volume, and diminished clearance of exocrine secretions.
- Lung pathophysiology results from airway obstruction by accumulated mucus and secondary bacterial infection.
- Diagnosis is made by identification of the typical pulmonary or pancreatic manifestations, family history, and documentation of elevated chloride concentrations in sweat or genetic testing.
- Treatment encompasses control of mucus retention and chronic infection in the lungs, replacement of pancreatic enzymes, and nutritional therapy.
- Close monitoring, vigorous attempts to reverse deterioration of lung function and nutritional deficits, and psychosocial support are beneficial.
- The outcome is highly variable, but longevity and quality of life have increased steadily. The median survival now exceeds 31 years.
- New approaches to therapy, including lung transplantation, pharmacologic interventions targeted to epithelial cell pathophysiology, and gene transfer to airway epithelium, offer hope for further advances.

INTRODUCTION

The condition of bronchiectasis (BXSIS) is defined by dilation, or ectasia, of the airways or bronchos. The primary clinical manifestations of BXSIS are recurrent, chronic, or refractory infections. Other significant sequelae include hemoptysis, chronic airflow obstruction, and progressive impairment of breathing. In the preantibiotic era, secondary amyloidosis and embolic brain abscesses were reported as consequences of chronic suppuration in the lungs; such complications are extremely rare now in industrialized nations.

There are many and varied pathways that lead to the development of BXSIS (Table 42-1). Broadly, BXSIS may develop due to an incidental event or episode that does not reflect the patient's intrinsic host defenses. Examples might include a necrotizing pneumonia following aspiration or chronic infection distal to an obstructing bronchial adenoma. Often, however, BXSIS evolves due to conditions that are inherent to the patient's basic genetic constitution. The most common and dramatic example of this is cystic fibrosis (CF). The distinction between these two models is an important element of prognosis and management.

A central issue in understanding the pathogenesis of BXSIS is whether infection is truly the proximate cause of BXSIS or patients develop infections due to an underlying predisposing condition. For example, it has been a commonly held adage that many cases of BXSIS in adults are due to childhood bouts of pertussis or measles.[1] Although this is undoubtedly true in some instances, one might be skeptical of this simple construct, asking why formerly common childhood illnesses resulted in BXSIS in only a small proportion of the patients. The question that should be addressed more thoroughly is whether the individuals were particularly vulnerable to complications; for example, did the pertussis or measles result in excessive damage due to innate susceptibility of the hosts?

CLASSIFICATION

Although there is considerable overlap and coexistence among the various forms of BXSIS, the radiographic patterns and distribution may provide clues to diagnosis, management, and prognosis.[2] Thus, characterizing the morphologic features and distribution of BXSIS is a useful

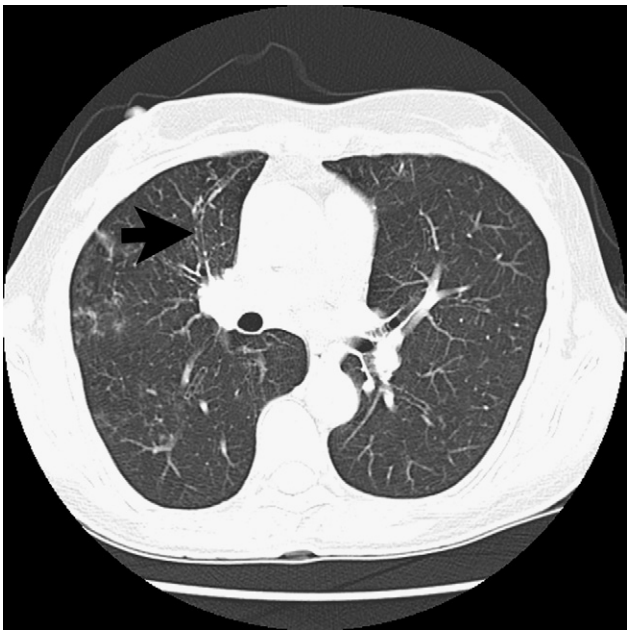

FIGURE 42-1 ■ Cylindrical bronchiectasis (BXSIS). In the anterior segment of the right upper lobe is an extended nontapering airway with moderately thickened and generally regular walls (*arrow*). The patient is a 50-year-old white woman with a slender body habitus and subtle scoliosis but no other identified risk factors for BXSIS. In addition, she had severe varicoid and "honeycomb" BXSIS involving her right middle lobe (see Figs. 42-2 and 42-4).

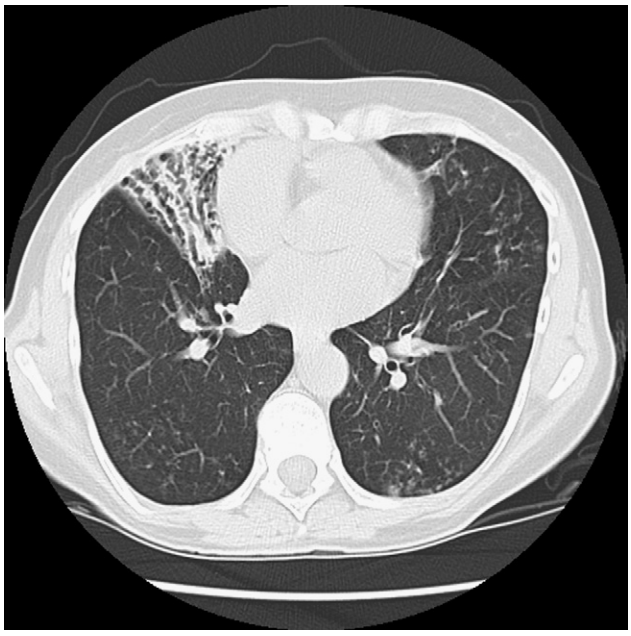

FIGURE 42-2 ■ Varicoid BXSIS. The right middle lobe of this 50-year-old woman is involved with severe atelectasis and dense, side-by-side varicoid BXSIS involving the conducting airways. Distal to this pattern are dramatic honeycomb changes of the terminal air spaces (see Fig. 42-4).

discipline. In this era, BXSIS is primarily identified and described by computed tomography (CT; see later).

Cylindrical BXSIS is described as failure of the involved airways to taper progressively in their distal course. Usually, in this condition, the bronchial walls are smooth or regular (Fig. 42-1). Varicoid BXSIS is an allusion to varicose veins and is marked by irregular dilation, narrowing, and outpouching of the airways (Fig. 42-2). Saccular BXSIS includes focal or cystic distortion of the distal airways; it may be isolated (Fig. 42-3) or may form confluent "honeycomb" patterns (Fig. 42-4).

A traditional clinical distinction within BXSIS has been "wet" versus "dry." Historically, it was observed that some patients with BXSIS had continuous or frequent

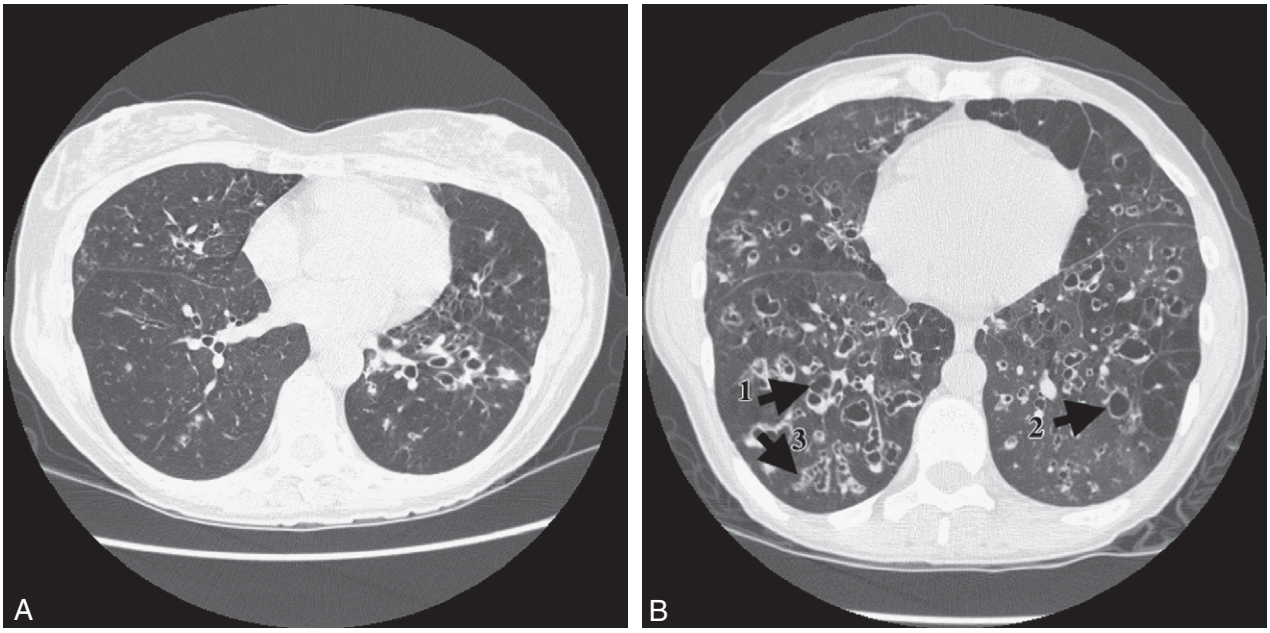

FIGURE 42-3 ■ **A,** Saccular BXSIS. In the left lower lobe of this 52-year-old white woman, there is a clustering of thin-walled dilated airways. Medial to this cluster is a classic "signet ring" consisting of a dilated, thin-walled airway with an accompanying smaller pulmonary artery. **B,** Saccular, cylindrical, and varicoid BXSIS. This 55-year-old woman is alpha$_1$-antitrypsin–deficient with a Pi ZZ phenotype. She has moderately severe chronic obstructive pulmonary disease (COPD) but also suffers advanced BXSIS. In addition to cystic rarefaction of her lung parenchyma, she has features of saccular (*arrow 1*), cylindrical (*arrow 2*), and varicoid (*arrow 3*) BXSIS.

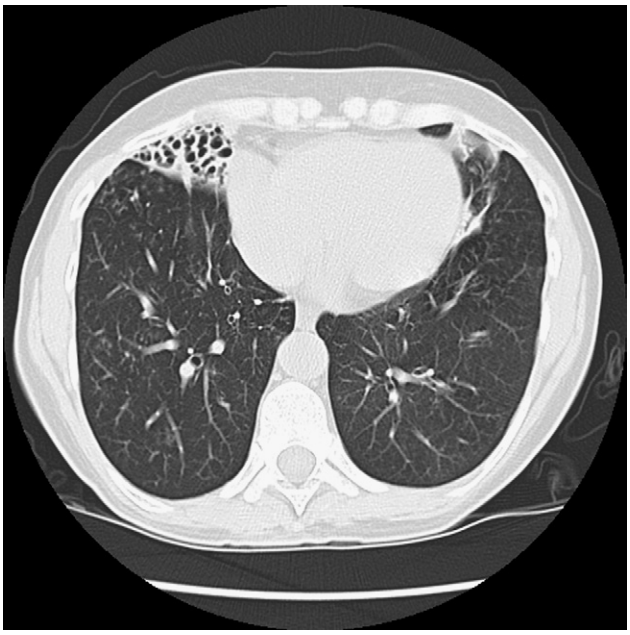

FIGURE 42-4 ■ Honeycomb BXSIS. The inferomedial aspect of the right middle lobe is involved with a coarse cystic process that resembles a honeycomb. Similar changes are often seen in the inferior segment of the lingula. In many cases, such findings are associated with nontuberculous mycobacterial infection; however, in this case, the patient was infected only with gram-negative bacilli including *Pseudomonas aeruginosa* and *Alcaligenes xylosoxidans*.

productive cough that typically yielded copious, often purulent secretions—hence "wet." Others who carried the diagnosis of BXSIS rarely experienced cough, and if they did so, rarely was their cough productive—hence "dry." Independent of etiology, the most frequent patterns associated with wet or dry BXSIS are anatomic localizations. BXSIS involving dependent zones (lower lobes, the right middle lobe, or the lingular segment of the left upper lobe) tends to entail frequent or chronic infections and to be "wet" in nature. By contrast, chronic BXSIS isolated to the upper lobes is less commonly involved with infection and to be "dry" in terms of sputum production. Presumably, this is related in large measure to gravity-driven drainage of the upper zones in contrast to pooling of secretions in the dependent regions.

EPIDEMIOLOGY

There are no systematic data on the incidence or prevalence of BXSIS. Historically, it has been thought that as antibiotics and vaccines were introduced in the 20th century, there has been a declining rate of BXSIS.[3,4] The presumed mechanism was that these modalities lessened the frequency, severity, and duration of lower respiratory tract infections that might result in BXSIS. In this regard, it is suggested that BXSIS remains relatively more common in regions where prompt and effective medical care is not available.[5] However, it should be stressed that there are no careful quantitative studies documenting these trends.

In the United States, there appear to be increasing numbers of BXSIS cases associated with environmental or nontuberculous mycobacteria (NTM).[6,7] Based on serial observations in a cohort now numbering approximately 2000, our group believes that in the majority of cases, the mycobacterial infections both initiate and "drive" the evolution of BXSIS. Of interest, this disorder seems disproportionately to involve women, predominantly slender white women.[8,9] It is not possible to determine whether this is an accurate picture or an artifact of increased awareness and improved diagnostic techniques.

PATHOGENESIS

Various mechanisms operate to produce permanent, pathologic dilation and damage of the airways. In simplest terms, they may be thought of in terms of traction, pulsion, and weakened tensile strength of the airways. In most cases, the pathogenesis becomes inextricably linked with and propelled by the destructive effects of chronic infection.

In normal lungs, airways are held patent by a combination of negative intrapleural pressure (which maintains the lungs in an inflated state) and the cartilaginous rings of the trachea and the large and medium airways. The distending forces of the negative intrapleural pressure are transmitted to the airways by a diffuse system of interstitial tethering. As the lung undergoes fibrotic changes consequent to disorders such as sarcoidosis, interstitial lung disorders, or infections such as tuberculosis, local retractile forces result in fixed dilation of the airways, or "traction" BXSIS.

The prototypic "pulsion" BXSIS occurs with allergic bronchopulmonary aspergillosis (ABPA). In ABPA, there are intense, immunologically mediated reactions to inhaled *Aspergillus* that has lodged in the airways. The proliferating fungi form large mucoid conglomerates that fill and distend the central airways. It is probable that this airway dilation is potentiated by focal damage mediated by inflammatory products that weaken the bronchi.

Weakness of the airways contributing to the development of BXSIS may take many forms. Classic postinfectious BXSIS presumably is mediated in part by chronic damage to the walls of the airways, resulting in secondary loss of structural integrity.[10,11] This is coupled with scarring and loss of volume of the local lung units, leading to regional increases in retractile forces. Examples of primary weakness of the airways contributing to BXSIS includes Mounier-Kuhn syndrome (congenital tracheobronchiomegaly), Williams-Campbell syndrome (absence of cartilaginous rings in the segmental and subsegmental generations of bronchi), Marfan syndrome, or relapsing polychondritis. A case is made later that the apparent propensity of slender women for BXSIS may be based in part on mechanisms analogous to Marfan syndrome.

One particular component of the posited role of "weakened airways" in the pathogenesis of BXSIS that has not received adequate attention is the potential impact of airway collapsibility on the effectiveness of the cough mechanism. Coughing is an essential, primary element of lung defense. An effective cough sends columns of air rushing upward through the bronchial tree at peak speeds measured in the range of 600 mph.[12] To generate these high flow rates, the cartilaginous rings must have the structural integrity to remain patent while the posterior membranous element invaginates into the lumen of the airway to lessen the cross-sectional diameter of the airway and accelerate airflow. While performing bronchoscopy on patients with BXSIS, it is common to observe extraordinary collapsibility of the airways, virtually obstructing the bronchi. It seems likely that such amplified airway compressibility impedes the air-driven propulsion of secretions out of the bronchial tree and helps propagate the chronic or recurring infections that mark most cases of BXSIS.

"VICIOUS CYCLE" AND MICROBIOLOGY

The other major element in the pathogenesis of BXSIS is the destructive effect of chronic airway infections, the vicious cycle theory as described by Cole.[13] Briefly, it is reasoned that once airways are "damaged," they become vulnerable to chronic colonization, which merges into an inflammatory condition; this results in further injury and lessened capacity to resist infection. Analysis of cellular and noncellular constituents in the bronchiectatic airways typically demonstrates intense infiltration by neutrophils as well as mononuclear cells and lymphocytes.[14]

Although there is a burgeoning literature on mechanisms of inflammation and airway damage, the relevance of these findings to the diagnosis and clinical management is not currently apparent and is not addressed in detail in this chapter.

It is apparent that simple colonization and infection of the airways are not sufficient to produce true BXSIS. Sputum from patients with smoking-related chronic bronchitis typically yields organisms such as *Haemophilus influenzae*, *Haemophilus parainfluenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*, a microbial spectrum similar to that seen with BXSIS.[15] In addition, there is heavy cellular traffic and the presence of a variety of inflammatory mediators. However, significant BXSIS does not appear commonly among patients with simple chronic bronchitis. Hence, it is probable that systemic conditions or focal disturbances as noted later are required for the development of classic BXSIS. Notably, however, the appearance in respiratory secretions of *Pseudomonas aeruginosa* on a chronic or recurring basis does pose the risk of deleterious effects on ciliary function and other host defenses.[16] Pseudomonal infections may be of particular importance due to their role in the formation of biofilms (see later). Two reports note worsened lung function[16] and quality of life[17] among BXSIS patients who become infected with *P. aeruginosa*. In a longitudinal study of the microbiology of 89 patients with BXSIS over a 5-year period, 47% were colonized with *H. influenzae*, 12% with *P. aerugi-*

nosa, and 21% had no identifiable pathogen. After 5 years, there was a slight increase in the number of those colonized with *P. aeruginosa*. As expected, those with the mildest disease had no pathogen whereas those with the worst disease were colonized with *P. aeruginosa*.[18]

As previously noted, NTM can colonize bronchiectatic airways as well as cause BXSIS. Based on two recent studies from the United Kingdom, the prevalence of NTM isolated from a heterogeneous group of bronchiectatic patients was approximately 2% to 10%.[19] Furthermore, bronchiectatic patients with NTM infections also have a greater likelihood of having concomitant *Aspergillus* lung disease.[20]

BIOFILMS

Costerton in 1984[21] hypothesized that *P. aeruginosa* in human infections "attaches to solid or tissue surfaces and grows predominantly in biofilms that release mobile swarmer cells into the surrounding fluid phase. These natural and pathogenic biofilms are covered by an exopolysaccharide matrix (glycocalyx) that serves as a barrier against hostile environmental factors such as host defense mechanisms and antibiotics."[21] Since this discovery, there has been clear evidence for the clinical significance of biofilms in promoting chronic infection in the airways of CF patients[22] as well as a variety of other infections.[23] *P. aeruginosa*, among its various attributes, enjoys cilia-driven motility, which appears critical in the aggregation phase of early biofilm formation.[24] Once biofilm formation has commenced, features of growth and gene activation that release virulence factors are influenced by "quorum sensing." Owing to a combination of physicochemical factors that deny access to the microbes by host defense cells and/or antibiotics, infection may persist despite aggressive treatment. In vitro testing indicates that bacteria embedded in biofilms can survive despite exposure to concentrations of antimicrobials that exceed the minimal inhibitory concentration in a suspension culture by 1000-fold.[25] We may anticipate that future understanding and optimal management of patients with chronic BXSIS will entail interventions to modify or interfere with biofilms.[24]

ASSOCIATED DISORDERS AND PREDISPOSITIONS

Lung Injury Due to Acute Infection

In the traditional model of lung injury due to acute infection, patients are deemed to have normal airways and lungs until they experience a specific lower respiratory tract infection that results in irreversible damage to their airways. In the modern era in industrialized nations, most episodes of lower respiratory tract infection—adequately treated—resolve without residual damage eventuating in BXSIS. However, among the older generations who were not protected by readily available antibiotics and vaccines, there are individuals who offer a convincing story of recurring, localized infections following a discrete episode of "pneumonia" in their childhood or early adult years that presumably produced irreversible damage leading to BXSIS.[1]

Specific traditional pathogens to which BXSIS has been ascribed include *Bordetella pertussis*, mucoid strains of *S. pneumoniae*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, adenoviruses, rubeola (measles), and influenza. Chronic granulomatous pathogens commonly related to BXSIS include *Mycobacterium tuberculosis*, *Histoplasma capsulatum*, and NTM such as *Mycobacterium avium* complex (MAC). In addition, mixed infection, including anaerobic mouth flora related to aspiration, may result in extensive damage to the parenchyma ("lung abscesses") with subsequent BXSIS.

Cystic Fibrosis

CF and CF variants are arguably the most common causes of BXSIS in the United States and other industrialized nations of the Western Hemisphere today. Being the most common autosomal recessive disorder among whites (1 in 2000–2500 live births),[26] CF is increasingly prevalent as improved therapies allow those who are afflicted to live longer. At present, there are approximately 30,000 CF patients in the United States with 40% to 45% of them estimated to be over 18 years old or roughly 12,000 to 14,000 adults with CF. In the next decade, it is predicted that about 50% of all CF patients will be adults.[27] The specific manifestations, severity, and rapidity of progression of CF vary highly according to the genotype and other modifying factors. However, the majority of those with childhood-onset CF who survive into their adolescence or early adult years have manifest BXSIS. (See Chapter 41 for details.)

In addition to these "typical" cases in which CF is recognized early in life, among a large series of adult patients seen at the National Jewish Health (NJH) in Denver with BXSIS associated with NTM, 117 of 865 (13.5%) were found to have one or more abnormal alleles of their cystic fibrosis transmembrane regulator (CFTR) gene,[28] well in excess of the anticipated carrier rate of 6% in the general population. In 19 of the NJH patients (2.1% overall), there were two abnormal alleles, and 98 (11.4%) had only one mutation. Of note, the mean age of these patients was 61 years. The clinical importance of these heterozygous mutations may be disputed; however, patients in this cohort had a high frequency of chronic airflow obstruction, sinusitis, difficulties with conception, and coinfection with pathogens typical of CF, including mucoid strains of *P. aeruginosa*—all features compatible with clinical CF. Among another series of patients with BXSIS and/or NTM lung disease, 24 of 50 (48%) had one or more CFTR mutations.[29] Similarly, among a cohort of 63 patients with NTM lung disease studied at the National Institutes of Health (NIH), 36% had mutations in the CFTR gene.[30] Consistent with the assertion that these heterozygous mutations are clinically relevant is a series of 30 patients with clinical features of CF who were reported to have normal CFTR alleles on comprehensive gene sequencing.[31] The authors

concluded that the modifying factors outside the CFTR genome could result in a clinical condition consistent with CF. It is our contention that heterozygous anomalies in the CF gene acts as a predisposing factor for BXSIS.

Based on contemporary understanding of the complex and diverse features of CF, there appear to be two groups in whom BXSIS occurs. The first and obvious group includes those with classic infancy/childhood-onset disease in whom clinical and laboratory data readily confirm the diagnosis of CF. The other group involves those with less severe disease that manifests later in life and for whom diagnostic testing is ambiguous.[32] Sweat chloride testing may or may not be abnormal, and genotyping may demonstrate heterozygous or even normal CFTR alleles. We might include under this rubric persons carrying the label of Young's syndrome (males with BXSIS, sinusitis, and obstructive azoospermia) and males with congenital bilateral absence of the vas deferens,[33] who have not been consistently regarded as having variant CF.

There are a wide variety of genetic factors lying outside the CFTR region that influence the clinical phenotypes of the patients.[34] (See Chapter 41 for additional discussion.)

Disorders of Immunity

Immunologic deficiencies are also associated with the development of BXSIS. Primary diseases that result in immunodeficiency may devolve from mutations that impair B or T lymphocytes and cause abnormal humoral immunity, cellular immunity, or both. Less frequent anomalies may involve natural killer (NK) lymphocytes, neutrophils, or complement proteins. Some specific immune disorders are noted later.

Common variable immunodeficiency (CVID), or acquired hypogammaglobulinemia, is the most frequent syndrome recognized in this group of diseases. Clinically, it is seen equally among males and females, distinguishing it from X-linked agammaglobulinemia (Bruton's disease), which exclusively involves young males. It may occur throughout all age groups, although it is most commonly recognized in early childhood. Although there are normal numbers of circulating B lymphocytes, they fail to differentiate into antibody-producing cells. This results in particular vulnerability to infections with encapsulated bacteria such as *S. pneumoniae*, *H. influenzae*, *S. aureus*, and *P. aeruginosa*. Recurring infections of the airways with these and other organisms frequently result in BXSIS.[35] The diagnosis is established by demonstrating low levels of gamma globulin and failure to produce appropriate antibody responses following vaccination. A variant of the hypogammaglobulinemic disorders is selective deficiency of subclasses of immunoglobulin G (IgG), notably IgG_2 and IgG_4.[36] Because repletion with gamma globulin is so useful in controlling the recurrent infections, pursuit of the diagnosis of deficient antibody production (CVID or Bruton's disease) is strongly indicated. By contrast, selective deficiency of secretory IgA, another cause of recurrent respiratory infections, cannot be controlled by repletion.[37]

Other, less common primary immune disorders that may result in recurrent or refractory respiratory infections leading to bronchiectasis include hyper-IgM or hyper-IgE (Job's) syndrome and thymic hypoplasia resulting in abnormal cellular immunity (DiGeorge syndrome). There are two forms of the hyper-IgE syndrome: an autosomal dominant form caused by mutations in the signal transducer and activator of transcription 3 (STAT-3) gene, resulting in STAT-3 deficiency, and an autosomal recessive form, for which the precise genetic cause is not known.[38] The susceptibility of such individuals with dominant hyper-IgE syndrome to pyogenic bacteria and NTM organisms may be due to impaired production of cytokines secreted by type 1 helper T cells such as interferon-γ, tumor necrosis factor-α, and interleukin-17 (IL-17), cytokines known to be important in controlling such infections.[39] Genetic anomalies that may result in combined humoral and cellular impairment include severe combined immunodeficiency syndrome (SCIDS), "bare lymphocyte" syndrome, Wiskott-Aldrich (an X-linked recessive illness associated with small platelets and eczema), cartilage-hair hypoplasia (associated with short-limbed dwarfism), ataxia-telangiectasia syndrome, and a variety of other rare disorders.

Alpha$_1$-Antitrypsin Anomalies

Various phenotypic abnormalities of alpha$_1$-antitrypsin (AAT) appeared prominently in a recent series of patients seen at the NJH with BXSIS associated with NTM.[40] Previously, there have been reports of the relationship between AAT deficiency and BXSIS.[41,42] However, in the great majority of cases in the NJH series, the patients were not deficient in AAT but had heterozygous phenotypes (mainly MS; to a lesser extent MZ) with normal AAT levels. The prevalence of AAT anomalies in the overall cohort of NJH patients with various NTM infections was 17%[40]; even more striking was the 27% prevalence of AAT anomalies in the patients with rapidly growing mycobacterial disease.[43] Based on various surveys, AAT anomalies would be anticipated in roughly 8% to 9% of the U.S. population.[44] However, the role of heterozygous anomalies of the AAT system in the pathogenesis of lung disease is controversial.[45] The majority of the NJH patients did not have significant chronic obstructive lung dysfunction or grossly visible emphysema on CT scanning. Hence, we postulate that the AAT anomalies render the patients more vulnerable to respiratory tract infections. Inferential evidence in support of this hypothesis includes an informal survey done among emphysema patients being repleted with Prolastin[46]; 74 of the 89 responding patients described a perceptible benefit, and 56 of the 74 identified a reduction in the frequency of infectious exacerbations of their chronic obstructive pulmonary disease. Possibly relevant to the development of BXSIS is the observation that AAT is produced in airway epithelium (as well as the liver) and "Z" AAT may polymerize in the lung and act as a chemoattractant.[47] Direct evidence in support of the effect of AAT on infection includes evidence that aerosolized Prolastin suppresses *P. aeruginosa* lung infection in an

animal model[48] and the observation by Shapiro and colleagues[49] of the inhibitory effects of AAT on replication of the human immunodeficiency virus (HIV) in whole blood. Further support for a role of AAT in direct resistance to infection is the observation in an African population that two polymorphic variants of the AAT haplotype were associated with significantly greater risks of HIV infection when compared with the other nine haplotypes common in sub-Saharan African populations.[50] Chan and coworkers[43] showed that AAT inhibits phagocytosis of *Mycobacterium abscessus* by human macrophages, partially denying the mycobacteria their preferred intracellular milieu. It should be noted that a group from France studied AAT alleles in a large cohort of BXSIS patients and reached a different conclusion.[51] They found the following phenotypes in their patients: MS 11.9%, MZ 3.5%, SS 1.5%, SZ 0.5%, ZZ 0.5%. In this study, the distribution of these phenotypes was not significantly different in their controls, and they inferred that AAT anomalies did not contribute to the risk for BXSIS. In a study of 74 patients with severe AAT deficiency (PiZ phenotype), 70 had bronchiectatic changes on CT scan.[52]

Ciliated Epithelium

Congenital structural and functional disturbances of the ciliated epithelial cells are seen in association with BXSIS as well as with frequent and severe upper respiratory tract problems.[52a,52b] These disorders appear to be an autosomal recessive process, with an estimated frequency between 1 in 12,500 to 1 in 40,000.[53] Primary ciliary dyskinesia (PCD) embraces a heterogeneous group of ultrastructural deficits involving the axoneme or central functional element of the cilia.[54] The normal axoneme is composed of nine paired or doublet microtubules arrayed peripherally around two central, single microtubules; attached to the peripheral doublet microtubules are outer and inner dynein arms as well as radial spokes (Fig. 42-5). The direction in which the cilia beat is determined by the orientation of the two central microtubules. In a local sheet of bronchial ciliated epithelium, the axes of the central microtubules are arrayed within a fairly narrow range, typically deviating 25 degrees or less from each other along the long axis of the airway. A variety of abnormalities have been described, including the complete or partial absence of

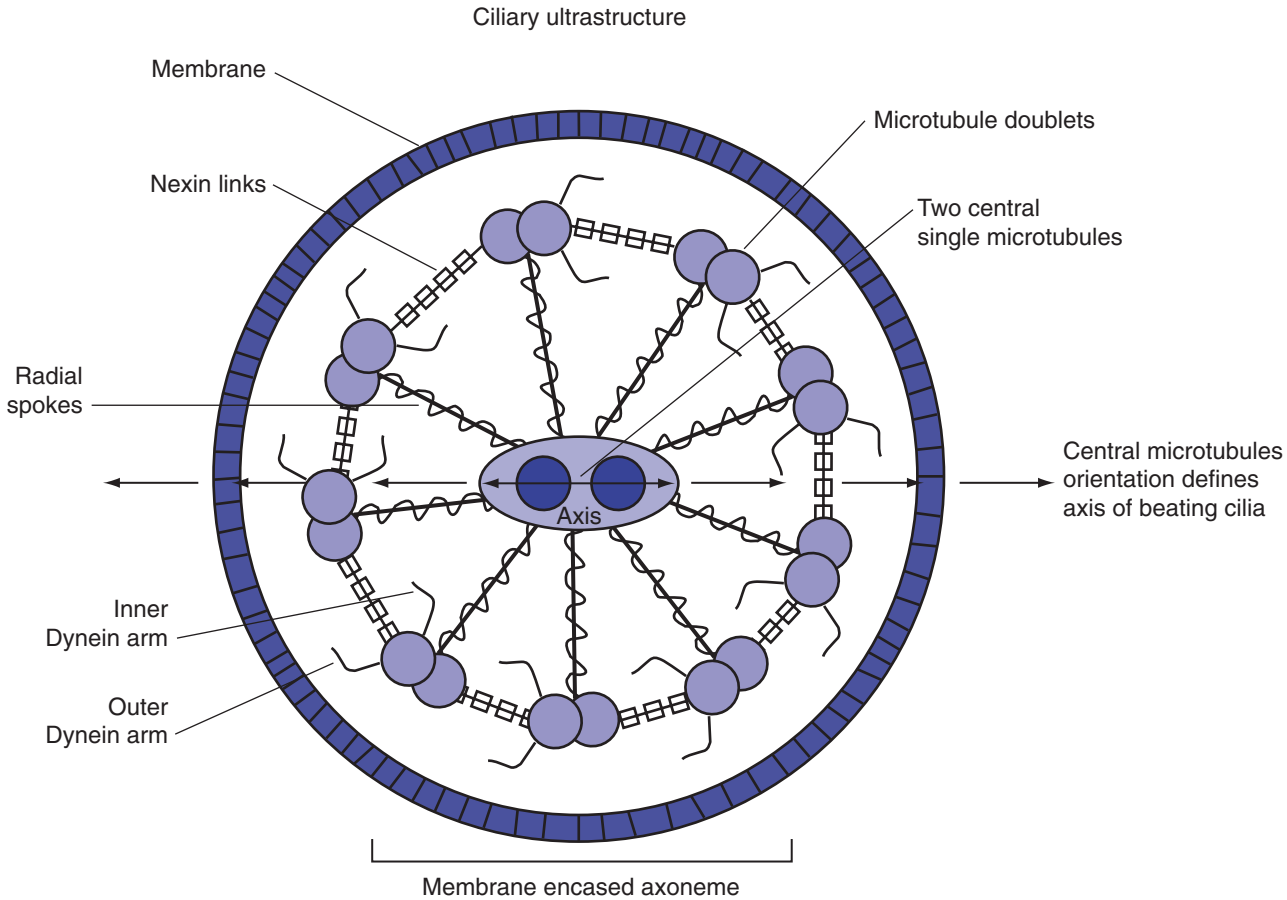

FIGURE 42-5 ■ Ultrastructure of the cilia. The structure and function of cilia are elegant and complex. Each ciliated epithelial cell possesses approximately 200 cilia. The direction of ciliary beating is determined by the orientation of the inner pairs of microtubules. Dysfunction of the ciliary apparatus may involve a variety of structural abnormalities in the cilia or disorganization of the ciliary axes. The cilia beat in a relatively fluidic periciliary medium; above that, adherent by a thin physicochemical junction, is a gelatinous layer of mucus.

outer or inner dynein arms, a lack of radial spokes, disordered microtubule arrangements, ciliary disorientation, and other rare disturbances. Functionally, these disturbances result in reduced or disorganized beating of the ciliated epithelial cells or, in some cases, gross immotility. There may also be inversion of the normal anatomic locations for the organs of the thorax and abdomen, situs inversus universalis or partialis; PCD with situs inversus universalis is known eponymically as Kartagener's syndrome. In the absence of normal ciliary activity, organ orientation appears random, resulting in situs inversus in roughly half of the cases. Evidence in support of this theory includes discordant organ orientation in monozygotic twins with disordered ciliary motility.[55]

The ineffectual beating of the ciliated cells results in stagnation and accumulation of mucus, which classically is associated with early-onset refractory or recurrent infections of the airways including otitis media, mastoiditis, sinusitis, and bronchitis. BXSIS is a common sequelae of PCD, typically involving the dependent zones including the lower lobes, right middle lobe, and/or the lingular segment of the left upper lobe (Fig. 42-6). The defect also involves the flagella of the spermatozoa, resulting usually, although not universally, in male infertility.

Diagnosing PCD is often problematic.[56] Consideration should be given in the setting of early-onset upper and lower respiratory infections (see earlier). Male infertility, although suggestive, is more likely due to Young's syndrome in a North American population. A suggestive feature on high-resolution CT is predominant BXSIS in the lower lobes, with or without right middle lobe or lingular involvement and sparing of the upper lobes (unpublished data). Diffuse, softly marginated flocculent centrilobular opacities in the lower lobes is typical of PCD, reflecting chronic bronchiolitis. Electron microscopic analysis of the ultrastructure of the cilia or clearly documented ciliary dysfunction via high-speed video microscopy are the "gold standard" for diagnosis. However, such testing is complicated by the following factors: (1) chronic infection may denude the airways of ciliated epithelium and (2) chronic infection may damage cilia, resulting in nondiagnostic findings. One report demonstrated that computer-assisted analysis can increase the diagnostic yield significantly over conventional transmission electron microscopy for inner dynein arm disturbances.[57] Direct measurements of ciliary beat frequency or coordination is available only in selected research centers. Among males, dysmotile or immotile spermatozoa may be demonstrated, and ultrastructural analysis of the sperm flagella may confirm the diagnosis. The "saccharine test" has also been employed as an inferential test of ciliary dysfunction. The primary utility of the saccharine test is to exclude PCD by a normal value. An abnormal saccharine test is consistent with, but not diagnostic of, PCD, as individuals with other disorders that result in chronic rhinosinusitis may have denuded their ciliated epithelium or have inflammatory factors that impair ciliary beating. Thus, the test should not be done within a month of an upper respiratory infection.

The latest test for the diagnosis of PCD is nasal nitric oxide (NO) levels.[56] In a large cohort with proven PCD, nasal NO levels were significantly lower than in normals or subjects with CF. Of interest, parents of PCD patients had lower than normal nasal NO levels, intermediate between controls and patients, despite the absence of clinical disease.

Patients with PCD, sinusitis, and BXSIS also have a marked tendency toward colonization and infection with *H. influenzae*.[56] The mechanism(s) for this predilection is unknown. Defective adaptive immunity is a plausible candidate.[34]

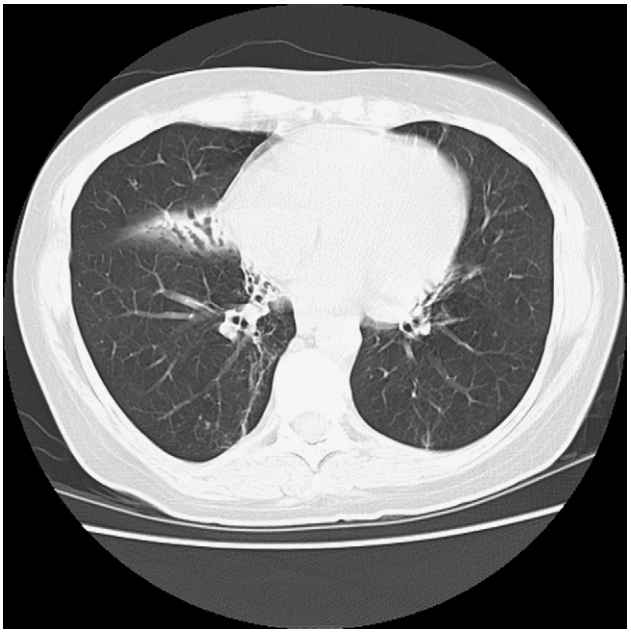

FIGURE 42-6 ■ Dependent-zone BXSIS in primary ciliary dyskinesia (PCD). This 35-year-old white woman has classic PCD. She has atelectasis and saccular BXSIS involving the right middle lobe, the medial basilar segment of the right lower lobe, and the anteromedial aspects of her left lower lobe. She has previously been treated for *Mycobacterium avium* complex (MAC) and now has refractory infections with *P. aeruginosa*.

Bronchial Cartilage

Cartilaginous "C-rings" are present throughout the entire trachea as well as the large and medium-sized airways, typically down to the fourth through sixth generations of the ramifying bronchi. The primary functional role of these structures is to maintain airway patency during expiration including cough. There are two well-described heritable syndromes that involve these cartilaginous structures.

Mounier-Kuhn syndrome, or congenital tracheobronchomegaly, is a rare disorder associated with gross enlargement or dilation of the C-rings in the trachea and segmental bronchi[58] (Fig. 42-7). The underlying defect is atrophy and even absence of elastic fibers and smooth muscle tissues of the large airways.[59] In addition, primary or secondary atrophy of the connective tissue between the rings may result in outpouchings or diverticula, potentially serving as reservoirs for recurrent infections. Distal to the involved airways, bronchial structures gen-

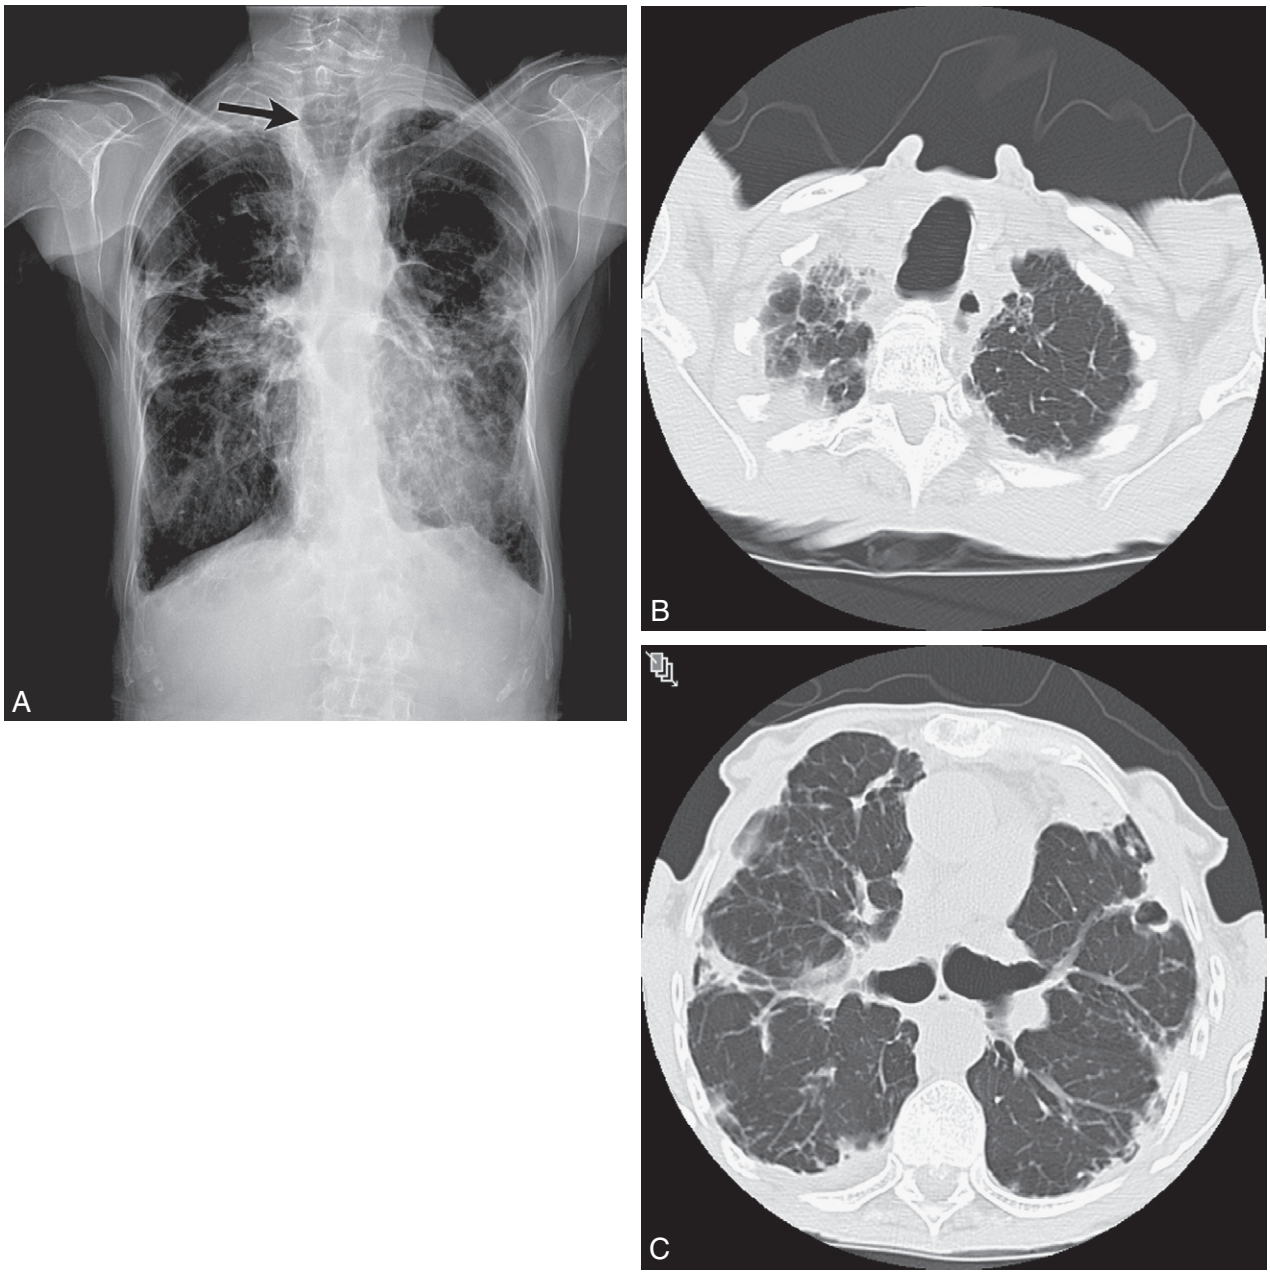

FIGURE 42-7 ■ Congenital tracheobronchomegaly (Mounier-Kuhn syndrome) with BXSIS. This 73-year-old woman has had recurring respiratory infections throughout her adult life, most recently associated with *Mycobacterium avium* complex. **A,** On the posteroanterior view, a massively dilated trachea (*arrow*) is seen. **B,** The dilated trachea with prominent cartilaginous rings is confirmed on a computed tomography (CT) scan. **C,** Not only is the trachea enlarged, but the main-stem bronchi are dilated.

erally appear normal. Clinically, Mounier-Kuhn patients may present in their early years or as late as the fourth decade with recurring lower respiratory infections. In advanced stages, airway collapsibility may result in severe airflow obstruction. The diagnosis is readily made by finding extraordinary dilation of the trachea and central bronchi on CT scans, with airway dimensions 3 standard deviations greater than normal. Special considerations in management include positive end-expiratory pressure support and silicone or metallic stenting. Lung transplantation is an option, although unique issues associated with Mounier-Kuhn syndrome include recurrent infections when tracheal diverticula are present and difficulty with bronchial anastomosis due to discrepancy in the airway diameters between the donor and the recipient lungs.

Williams-Campbell syndrome, or congenital bronchial cartilage deficiency syndrome, is another rare disorder that tends to present early in life with recurring infection and BXSIS.[60] The absence of cartilage from lobar through the first few generations of segmental airways is the typical finding in Williams-Campbell syndrome, although main-stem bronchi may be affected as well. Characteristic findings on CT scan include more extensive periph-

FIGURE 42-8 ■ Williams-Campbell syndrome. This 50-year-old man had a lifelong history of recurring respiratory infections and productive cough. The airways are massively dilated with collections of respiratory secretions pooling in some of the cystic spaces. Notable are the normal dimensions of the main-stem bronchi.

eral BXSIS than would be anticipated by the clinical history and more proximal extension of BXSIS than usual (Fig. 42-8). Inspiratory ballooning and expiratory collapse of the airways on chest CT scan is characteristic of Williams-Campbell syndrome.[61] The degree of peripheral airway distortion suggests that this disorder entails more than simply the absence of proximal cartilage. Patients with Williams-Campbell syndrome are particularly predisposed to proximal bronchomalacia after transplantation due to the combined effects of cartilage deficiency in the main-stem bronchi plus decreased blood supply to the proximal airways due to loss of collateral circulation of the transplanted lung.[62]

Connective Tissue

Among the various formally described heritable disorders of the connective tissues, BXSIS and other structural abnormalities including extensive cystic degeneration of the lungs have been noted most extensively in those with Marfan syndrome.[63,64] In addition to airway and parenchymal abnormalities, persons with Marfan syndrome have various other anomalies, including pectus excavatum, pectus carinatum, scoliosis, straight-back syndrome, and mitral valve prolapse. Two of these conditions, scoliosis and mitral valve prolapse, are found often in patients with two other connective tissue disorders, Ehlers-Danlos syndrome and cutis laxis.

This constellation of findings is mindful of the prototypic female patients we and others are seeing with BXSIS, most commonly in association with NTM. Based on analogy to these heritable disorders, we believe that there may be subtle anomalies or polymorphic variants of connective tissue that predispose to their BXSIS. Phenotypic findings among these patients that are mindful of these connective tissue disorders are various combinations of scoliosis, straight-back syndrome, pectus excavatum or unusually narrowed anteroposterior chest diameter, pectus carinatum, and/or mitral valve prolapse. Among a series of 63 patients reported from the NIH with NTM lung disease, predominantly manifested by BXSIS, careful morphometric studies were performed.[30] Compared with the women in the National Health and Nutrition Examination Survey (NHANES) database, patients with NTM lung disease were found to be significantly taller and more slender. In addition, pectus excavatum, scoliosis, and mitral valve prolapse were found in excess of expected rates. However, the patients did not have dolichostenomelia (a long, narrow frame), hyperdistensible joints, arachnodactyly, or overt aortic root involvement to suggest classic Marfan syndrome.[30] Neither do they have the cutaneous or joint abnormalities typical of Ehlers-Danlos syndrome. Our supposition is that the fundamental "defect" having to do with a propensity for BXSIS is "weakness" of the connective tissue of the bronchial tree. Notable among our patients, as well as other series of females with BXSIS associated with environmental mycobacteria, is bronchiectatic involvement of the right middle lobe and lingular segment of the left upper lobe. Our hypothesis does not identify the "prime factor" in the pathogenesis of the BXSIS: do the airways dilate in response to the high intra-airway pressures generated during coughing that is incidental throughout life, or is there an underlying structural or functional defect that increases the risks for infections that set in motion the coughing and inflammation that lead to BXSIS?

Could slenderness itself—independent of malnutrition or any underlying illness—predispose individuals to mycobacterial infections? One intriguing hypothesis for the increased susceptibility to mycobacterial infections in thin individuals is due to a relative deficiency of leptin, which is normally produced by fat cells. Experimental corroboration for the leptin hypothesis comes from studies showing that leptin-deficient (ob/ob) mice are more susceptible to *M. tuberculosis* and *M. abscessus* lung infections.[65]

In view of the preponderance of females in recent series with BXSIS associated with MAC, two theories have been proposed. "Lady Windermere's syndrome," named after a character in a novel by Oscar Wilde, posits that women—in the effort to be demure or elegant—voluntarily suppress their cough, leading to accumulation of secretions and chronic infections.[66] However, it has been our observation that these patients cough frequently.[67,68] Rather than voluntary suppression, it seems more plausible that their coughing may be ineffectual due to airway collapsibility, which interrupts movement of secretions out of the bronchial tree.

An alternative proposition came from Japan where they, too, have noted a particular female vulnerability to BXSIS with MAC, largely among elderly, postmenopausal women.[69] Tsuyuguchi and associates[69] demonstrated that among female mice, oophorectomy led to higher mycobacterial loads in the lungs and spleen following intravenous challenge with MAC. Furthermore, estrogen

repletion normalized the bacillary burden, and ex vivo macrophages supplemented by estrogens were more competent at limiting mycobacterial growth.

However, neither the putative relationship to connective tissue disorders nor the alleged role of estrogen deficiency can explain the striking disparity of females in recent reports of MAC-related BXSIS. In these series, 80% to 95% of patients described have been women.[6–8] Certainly, this might reflect referral or reporting bias. Furthermore, we cannot exclude the possibility of sex-associated effects on connective tissue strength/integrity or cellular immunity.

An additional remarkable element of the reported cases of MAC-associated BXSIS is the strong preponderance of whites. White females constitute 80% to 95% in recent series, including those compiled in communities/areas with large African American, Hispanic, or other minority populations.[6–8] Again, given the potential for referral, reporting, or ascertainment biases, we cannot be sure of the validity of these observations. However, among the specialists with whom we correspond, this is a strongly held perception. The relatively higher prevalences of CF and AAT anomalies in European-derived populations may partially, but not wholly, explain this apparent imbalance.

Congenital and Developmental Anomalies

Conditions such as sequestration, agenesis, hypoplasia, and atresia may result directly in BXSIS or may predispose to infections that eventuate in this condition. Sequestrations presumably develop due to accessory primordial lung buds, which may be invested within normal lung tissue (intralobar) or external to the normal lungs (extralobar). Sequestrations may or may not connect with the bronchial tree and often derive their blood supply directly from the aorta. Clinically, they most commonly present with recurrent and/or chronic lower respiratory tract infections beginning in the second or third decade of life. Radiographically, they usually appear as irregular, peculiar densities abutting the diaphragm in the posterior basal regions. Unilateral hyperlucent lung (Swyer-James-MacLeod syndrome) is characterized by unilateral bronchiolitis leading to hyperinflation. In some cases, BXSIS is present. The etiology(ies) and pathogenesis of this rare disorder are uncertain but may involve developmental or acquired disturbances of the bronchial tree.

Idiopathic Inflammatory Disorders

There are a wide array of conditions associated with BXSIS that might be included under the rubric of idiopathic inflammatory disorders. They are all systemic illnesses that variably involve the lungs and, in such cases, may or may not result in BXSIS.

Sarcoidosis is by far the most common of these disorders. (See Chapter 59 for a comprehensive review.) Broadly, sarcoidosis may involve the airways by several fundamental mechanisms: diffuse parenchymal scarring resulting in traction and airway distortion, endobronchial granulomatous inflammation including stricture with poststenotic infection, or compression secondary to hypertrophic peribronchial lymphadenopathy.[70]

Rheumatoid arthritis (RA) may entail a variety of pulmonary manifestations. In two early series, BXSIS was seen in 3.2%[71] and 5.2%[72] of referral populations of RA patients. More recently, BXSIS has been described in considerably higher percentages of RA patients undergoing high-resolution CT scanning: 20% to 35%[73]; surely, these studies were skewed by selecting patients with respiratory problems to undergo CT scanning. However, BXSIS was seen in 8% of RA patients without respiratory symptoms.[74] Notably, the majority of the patients in the previously discussed series did not have RA-associated interstitial fibrosis as a presumed cause of the BXSIS. Potential causal mechanisms include increased propensity for infections, either intrinsic to RA or secondary to steroid or cytotoxic therapy. Sjögren's syndrome in association with RA has also been proposed as a risk factor, but the evidence is inconsistent.[73] Clinically, it should be noted that the presence of BXSIS in RA patients was associated with an unfavorable prognosis in one series.[75]

Ankylosing spondylitis has been classically associated with upper lung zone fibrocystic degeneration and ankylotic fusion of the junctions of the ribs and vertebrae, resulting in restricted ventilation. However, in a large series from the Mayo Clinic, pulmonary involvement was described in only 1.2% of the patients.[76] BXSIS independent of apical fibrocystic disease has been seen in a small series from the United Kingdom.[77] Ankylosing spondylitis was reported in association with MAC in an early series from the NJH.[78]

Systemic lupus erythematosus (SLE) may involve an assortment of pulmonary complications, including those intrinsic to SLE and others related iatrogenically (see Chapter 58). BXSIS, as such, was described in 21% of SLE patients studied with high-resolution CT in one series[79]; factors related to BXSIS were not well studied. As with RA, the presence of Sjögren's syndrome may be a comorbid element.

Sjögren's syndrome (SS), keratoconjunctivitis sicca and xerostomia (dry eyes and mouth), may exist in the primary form or in association with other collagen vascular diseases such as RA or SLE. Pulmonary complications of SS include lymphocytic interstitial pneumonia, lymphoma or pseudolymphoma, and/or pulmonary hypertension (see Chapter 58). BXSIS has also been noted.[80–82] It is reasoned that lymphocytic inflammation results in impaired function of mucous glands, in turn resulting in decreased volumes and increased viscosity of mucus. This leads to airway obstruction, poor clearance, and chronic infection. There have not been large surveys employing the CT lung scan in SS patients to quantify the risk for BXSIS. However, we have recently seen several elderly female patients with primary SS in whom BXSIS was prominently involved.

Inflammatory bowel disease (IBD) has been related directly to BXSIS.[83] IBD-associated BXSIS appears to be more common with ulcerative colitis than Crohn's disease.[84] In the majority of cases, the IBD antedates the lung manifestations, but in some cases, the pulmonary

symptoms may herald the IBD. Proposed pathogenic relationships include a cryptogenic infection that incites both airway and intestinal inflammation, common epithelial targets of autoimmunity, or sensitizing agents that are inhaled and/or ingested.

Relapsing polychondritis (RP) is identified essentially as progressive inflammation, weakness, and deformity of cartilaginous structures including the ears, nose, larynx, and tracheobronchial tree, typically associated with nonerosive polyarthritis. In addition, there may be inflammatory and/or functional disturbances of the eyes or the auditory/vestibular components of the ears. Respiratory involvement is a common clinical element of RP and a major cause of mortality. BXSIS in such patients may be due to primary bronchial damage and/or recurrent infection.[85]

Aspiration/Inhalation Accidents

Spillage of foreign matter into the airways may result in BXSIS. There are two fairly distinct scenarios in which such matter might be aspirated into the lungs and cause sufficient damage to result in chronic deformity of the airways. One is the direct spillage of secretions from the oropharynx, infamous for a plethora of microorganisms including microaerophilic and anaerobic bacteria which can produce necrotizing pneumonia. The other is introduction of materials refluxed from the esophagus and/or stomach, which, in addition to the microorganisms noted earlier, contain food particles, hydrochloric acid, biliary or pancreatic secretions, and microbes indigenous to the gut including *Helicobacter pylori*.[86]

Laryngeal protective functions are imperfect, and "microaspiration" occurs frequently. Thus, we might presume that aspiration leading to lower respiratory tract infections involves greater than usual volumes and/or more noxious contents. Also, it is reasonable to posit that once the airways have been damaged, a lesser inoculum can have more substantial clinical effects, a variant of the "vicious circle" theory.

Many factors influence the likelihood/frequency of aspiration. They include (1) depressed sensorium (trauma, alcohol or drug abuse, postictal, general anesthesia); (2) altered brain-stem function (post–cerebrovascular accident, postpolio, primary neurologic diseases such as multiple sclerosis, amyotrophic lateral sclerosis, or syringomyelia); (3) altered laryngeal structure/function (postsurgery, postirradiation); (4) esophageal disorders (dysmotility, obstruction by tumors or strictures, muscular dystrophy, achalasia, tracheoesophageal fistulas, or lower esophageal sphincter (LES) incompetence); and (5) gastric dysfunction (dysmotility or outlet obstruction).

Although all of these elements may contribute to the risk of infection (and BXSIS), it seems likely that gastroesophageal reflux (GER) is the most common factor. Among a cohort of BXSIS patients noted previously from the NIH, approximately three fourths of them had demonstrated abnormalities of esophageal morphology (dilation and thickening), function (dysmotility), anatomy (hiatal herniation), or competence (overt reflux).[87] Indeed, the frequency of esophageal disturbances was so high that one might question whether the esophageal findings were the cause of recurring infections/BXSIS or, in some cases, an effect. In the latter regard, it is important to note that among series of patients with chronic asthma and idiopathic pulmonary fibrosis, the incidence of demonstrated esophageal dysfunction ranged from 80% to 95%.[88,89] It is plausible that labored breathing with wide disparities between intra-abdominal and intrathoracic pressure and/or chronic coughing, which stresses and dilates the diaphragmatic ring, might disrupt the LES and subject the esophagus to distending forces.[90] An additional factor that could contribute to GER is the medications employed for these pulmonary disorders, including anticholinergics, β-agonists, theophylline, and corticosteroids, all of which impair LES function,[91] and broad-spectrum antibiotics which alter gastroesophageal flora.

In any case, clinicians should be alert to the potential of GER/aspiration as a primary or contributing role in the development of BXSIS. For those suspected of disordered deglutition, tailored hypopharyngography employing contrast materials of varying consistency may identify unsuspected aspiration. It is important to note that some patients spill contrast material into their trachea without any awareness or coughing. Such studies may be performed with a speech therapist, who can also aid patients with safer techniques for eating, drinking, and swallowing.

Impaired esophageal motility may be suggested on CT scans of the lungs in which the esophagus is grossly dilated, there is excessive air present along the course of the esophagus, or the walls of the esophagus are thickened. Impaired motility may often be demonstrated on a simple barium swallow. The extent of impaired contractility may be measured by esophageal manometry; this is critical if reconstitution of the LES is contemplated. Demonstrating actual reflux may be problematic. If gross reflux is demonstrated on a routine study, it is sufficient for a presumptive diagnosis. However, if symptoms or other clinical features suggest GER and the upper gastrointestinal series is negative, a 18- to 24-hour pH probe with or without measurement of impedence may both identify and quantify reflux episodes.[88] Recent studies have documented that nonacid reflux may result in chronic cough and even lung injury.[92] Among the implications of these findings is that acid-inhibition measures may not be sufficient to protect the airways. For individuals with evidence of recurrent aspiration, elevation of the head of the bed should be done routinely.

Toxic inhalation or thermal injury may also be associated with BXSIS. Acute and chronic inflammation of the tracheobronchial tree, bronchiolitis, bronchiolitis obliterans, and diffuse alveolar damage may occur after exposure to toxic metal fumes (e.g., aluminum, cadmium, chromium, nickel) or toxic gases (e.g., ammonia, chlorine, phosgene, sulfur dioxide) (see Chapter 68). In severe cases, BXSIS may ensue due to either infectious complications of the exposure, denuding of the ciliated epithelium, or progressive fibrosis. Similarly, chronic airway damage and BXSIS may evolve following thermal or smoke injury.

Postobstructive Disorders

Foreign bodies may be aspirated into the airways in association with infants and children putting foreign objects in their mouths, choking events while eating, trauma, or loss of consciousness including seizures. In some cases, the obstructing object may be radiopaque (teeth, bone, or metal objects), but in most instances, the obstructing material (e.g., peanuts, vegetables) is not discernible by radiographic study. Tumors, benign or malignant, may also result in airway obstruction, poor drainage, recurrent/chronic infection, and BXSIS. The more common tumor types include bronchogenic carcinomas (particularly the squamous cell variety), bronchial adenomas, and papillomas. Extrinsic airway compression due most often to hypertrophic lymphadenitis from granulomatous diseases such as sarcoidosis or infections such as tuberculosis or histoplasmosis may severely narrow or even occlude large airways. In patients with "focal" BXSIS (particularly those with disease limited to only one region, one segment, one lobe, or even one lung), bronchoscopic examination to exclude an obstructing lesion should be performed early if other causes are not evident.

Allergic Bronchopulmonary Aspergillosis

In acute or subacute bronchopulmonary aspergillosis (or other mycoses), ABPA/M, patients develop mucoid plugs in the medium-sized bronchi. The inflammation and distention typically results in thin-walled BXSIS of the central and mid-lung airways (Fig. 42-9). Although ABPA/M typically occurs in the setting of recurrent/refractory (steroid-dependent) asthma, clinicians should be aware that these episodes may also include fever, malaise, pleuritic chest pain, and cough productive of purulent secretions. Such episodes may be confused with pneumonia, acute bronchitis, and/or exacerbations of simple BXSIS, especially if the asthmatic component is absent or minimal. The picture may be particularly obscure if the ABPA/M occurs in individuals with CF, a disorder in which ABPA/M is relatively more common. Features mindful of ABPA/M include characteristic findings on CT scanning, eosinophilia, elevated IgE levels, and dramatic responses to corticosteroids.

The other pathway to BXSIS occurs in the setting of long-standing, inadequately controlled ABPA/M. In such cases, extensive fibrosis and airway distortion may evolve due to uncontrolled inflammation (Fig. 42-10). In these cases, the patients may acquire secondary airway pathogens including *P. aeruginosa* or other gram-negative bacilli as well as NTM. In these "burned-out" cases, the patients may not demonstrate asthma, eosinophilia, or elevated levels of IgE.

Miscellaneous

There are numerous other causes of BXSIS including such diverse entities as HIV infection/acquired immunodeficiency syndrome (AIDS), yellow-nail syndrome, or radiotherapy injury.

Among persons with AIDS, BXSIS has been identified in a significant proportion of those undergoing CT scans, including children.[93,94] Obviously, this is skewed by the selection of those with respiratory problems for scanning. Presumably, the pathogenesis of the BXSIS involves

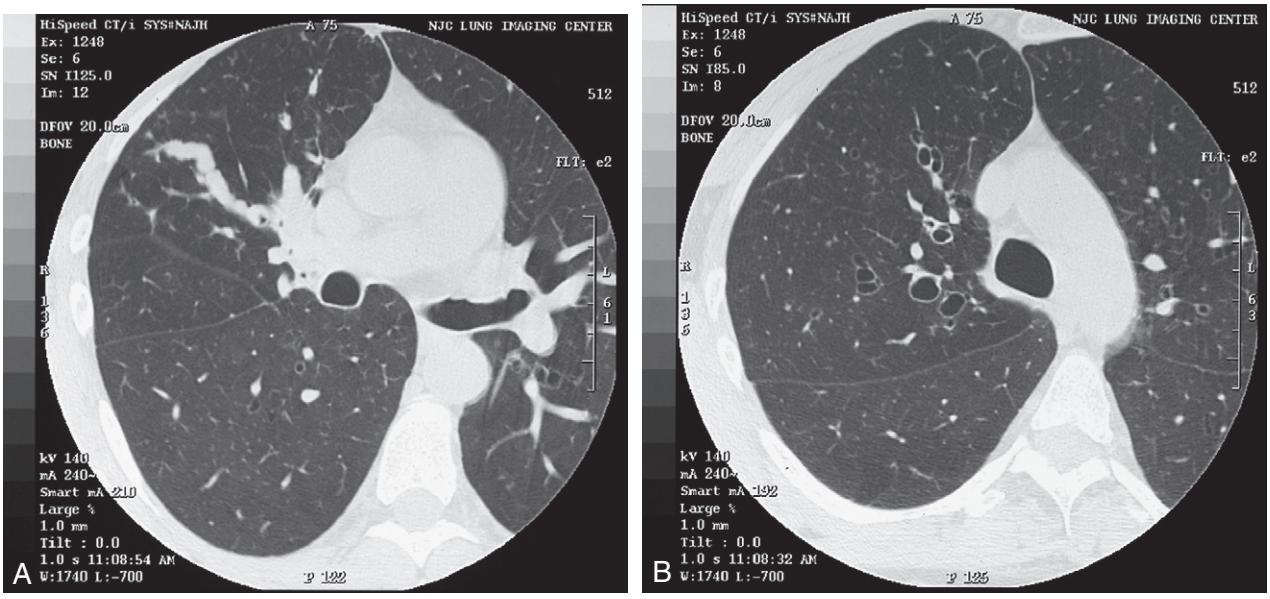

FIGURE 42-9 ■ Allergic bronchopulmonary aspergillosis with mucus-plugging and thin-walled BXSIS. This 44-year-old woman with steroid-dependent asthma reported coughing up gray-green mucus plugs. She had immunoglobulin E (IgE) levels over 1000 IU/mL, 10% to 15% eosinophilia, and precipitins to *Aspergillus fumigatus*. **A,** A classic serpentine mucus plug in the anterior segment of the right upper lobe. **B,** A more cephalad axial CT image of the same patient, showing central thin-walled BXSIS, presumably residual to the more distal mucus plugging.

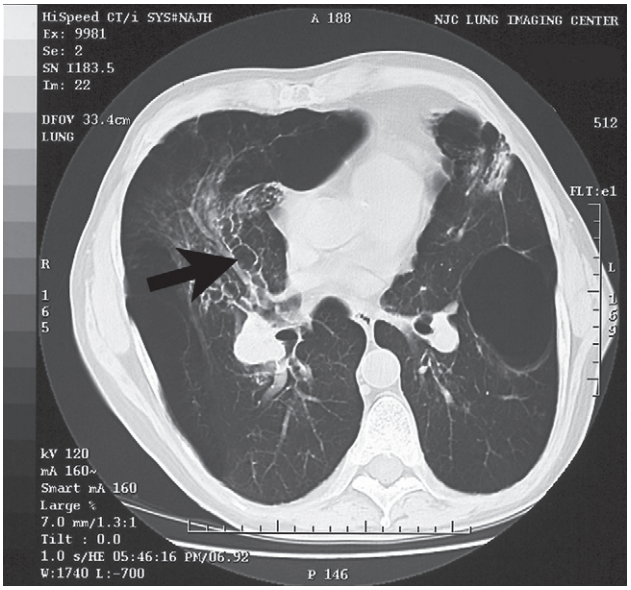

FIGURE 42-10 ■ Late fibrocystic damage from allergic bronchopulmonary aspergillosis (ABPA). The patient is a 70-year-old man with a 30-year history of poorly managed ABPA. CT scan shows residual central thin-walled BXSIS (*arrow*) in addition to fibrotic and cystic damage.

FIGURE 42-11 ■ BXSIS in a field of therapeutic x-irradiation. This 68-year-old woman had been diagnosed with a non–small cell carcinoma of the lung. She received radiotherapy to the right hilar region approximately 18 months previously. Her CT scan shows dense fibrosis and BXSIS in the radiation field. Inferior to this process she had a necrotic, cavitary process associated with *Mycobacterium avium* complex infection.

severe, chronic, and recurrent infections with a variety of opportunistic pathogens. An additional element that has not been fully addressed is the potential impact of oxidative damage associated with infection or other stressors on the AAT system.[95,96] Impairment of AAT function may contribute to the accelerated lung damage, including BXSIS, in persons with AIDS.[97,98]

Yellow-nail syndrome is an uncommon disorder marked by the triad of yellow, thick, dystrophic nails; chronic lymphedema of the face, hands, and lower extremities; and pleural effusions.[99] Females are more often involved than males; the median age of onset is 40 years, with cases ranging from infancy to the seventh decade. The most prominent pulmonary finding is bilateral exudative pleural effusions.[100] Recurrent sinusitis and lower respiratory tract infections are common.[101] BXSIS presumably evolves due to chronic infection. Contributing factors may entail abnormal lymphatic structure, increased vascular permeability, deficient immunoglobulin production, and/or ciliary dysfunction.

Radiation therapy (XRT), typically delivered for carcinoma of the breast or mediastinal tumors including lymphomas, may result in profound damage to the central airways. This reaction is not part of the postirradiation bronchiolitis obliterans syndrome but a distinctive condition marked by focal damage to the cartilage and mucosa of the airways leading to patulous distention and irregularities of the major bronchi in the field of irradiation. In our experience, BXSIS secondary to XRT given for neoplasms has become less common in the recent era when the control of dosage and field has become more refined. In some cases, this condition may be recognized by lung parenchymal scarring in the field of irradiation (Fig. 42-11).

DIAGNOSIS

In the great majority of cases, BXSIS is recognized in the context of chronic or recurring lower respiratory tract infections (deemed to be "bronchitis" or "pneumonia") over many months or years. Some BXSIS patients in whom wheezing is a prominent element may have been identified and treated as "asthmatics" for many years. Occasionally, patients come to attention following an episode of hemoptysis. Less frequently, BXSIS is identified on CT scans done for other considerations.

Although the plain chest radiograph can suggest BXSIS with "tram tracks" (Fig. 42-12) or multiple ring shadows (Fig. 42-13), CT scanning is the current diagnostic study of choice. The finding on the plain lateral chest radiographs of atelectasis of the right middle lobe and/or lingula (Fig. 42-14) is highly suggestive of coexisting BXSIS and should be followed by CT scanning in patients with persistent abnormalities and chronic symptoms.

Once BXSIS has been identified on CT scan, what studies should be performed to help direct management and classify the disease? Certainly, a careful family history may be useful in identifying genetic risk factors; however, the family pattern is rarely specific for a particular disorder unless there is a clear story for CF.

Past medical history and review of systems should focus on the various disorders noted in Table 42-1 and delineated earlier in the discussion of associated disorders and predispositions.

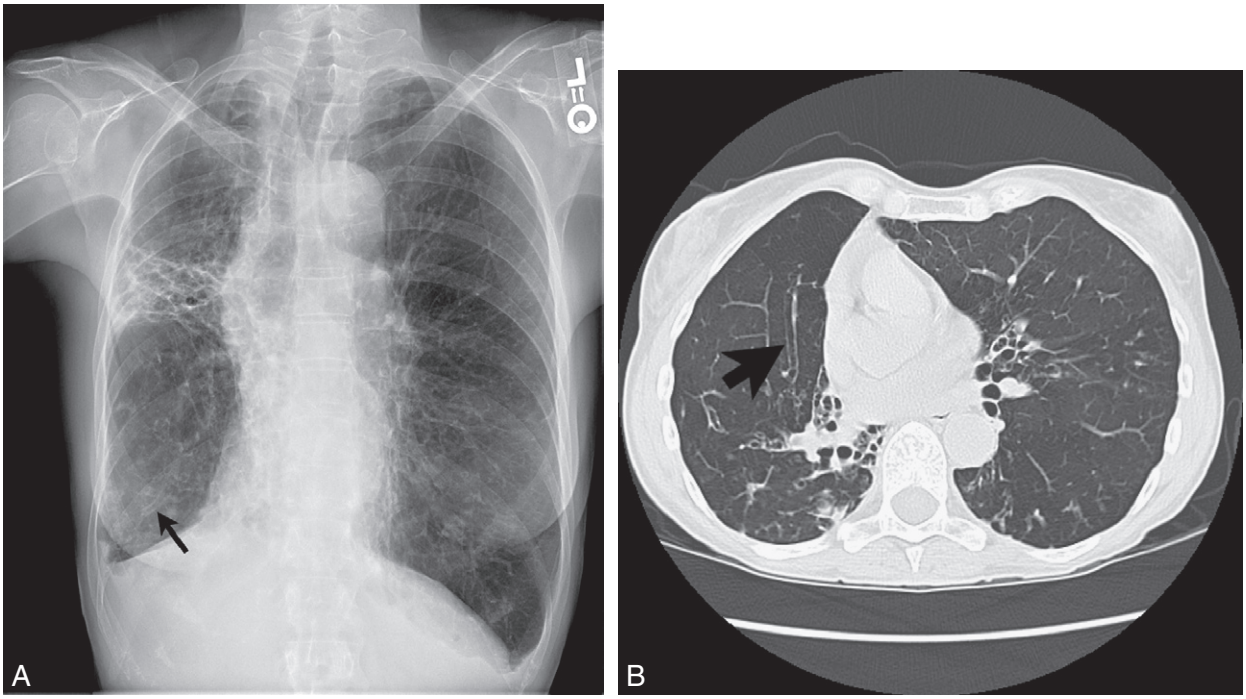

FIGURE 42-12 ■ "Tram tracks" on the routine chest radiograph in BXSIS. **A,** In the right lower lobe are parallel, nontapering shadows, "tram tracks" (*arrow*), representing BXSIS. **B,** The airway is seen as cylindrical BXSIS (*arrow*).

Laboratory testing may variously include the studies noted in Table 42-2. These tests need not all be performed on initial assessment but may be done sequentially, with the more probable disorders being checked initially.

MANAGEMENT

The care of patients with BXSIS typically involves many layers, which may be partitioned into five broad components: airway hygiene, antimicrobial treatment, anti-inflammatory therapy, surgery, and miscellaneous. These modalities are delineated in Table 42-3. Although most patients with BXSIS require various elements of each of these components to enjoy optimal health, there is not a standard formula for treating this disorder. The great majority of recurrently or chronically symptomatic patients benefit from a regular mucus-clearing regimen and periodic antibiotic therapy. For most patients, a pragmatic or "trial-and-error" approach is required to determine individual needs, preferences, and tolerances.

It is important to note that most elements described in this section have not been proved to be efficacious by randomized, controlled clinical trials. Thus, meta-analyses (such as the Cochrane Database of Systematic Reviews) generally cannot confirm the benefits or dysutility of such approaches.[102–109] Perhaps because BXSIS is such a complex mix of varying conditions and/or has been an underappreciated "orphan" disease, a paucity of systematic research has been directed at this very troublesome disorder.

Airway Hygiene and Hyperosmotic Agents

Airway hygiene consists of nonantibiotic therapies directed toward mobilizing and eliminating inflammatory secretions from the tracheobronchial tree and from the paranasal sinuses. Also included under this rubric are steps to prevent/limit aspiration of oropharyngeal or gastroesophageal contents into the airways.

Hypertonic saline, 7% twice or four times daily, has been shown to accelerate mucus clearance, decrease exacerbations, and improve lung function in CF patients.[110] However, its role in non-CF BXSIS remains to be seen. Inhaled dry powder mannitol appears promising in airway clearance in bronchiectatic patients,[111] although more definitive studies are needed.

Antimicrobial Therapy

Antimicrobial therapy historically has been the centerpiece of BXSIS care. However, there is no clear consensus on the major questions in this area including whether treatment should be given on a routine, periodic schedule ("rotating") or an as-needed basis for clinical exacerbations. In a meta-analysis that studied the use of prolonged oral antibiotics for purulent BXSIS, sputum volume/purulence was shown to decrease, but there were no significant beneficial effects in regards to rates of exacerbations, lung function, or death.[112] As well, there are limited data on the preferability of empirical selection of an antimicrobial agent or treatment guided by species identification and in vitro susceptibility testing.

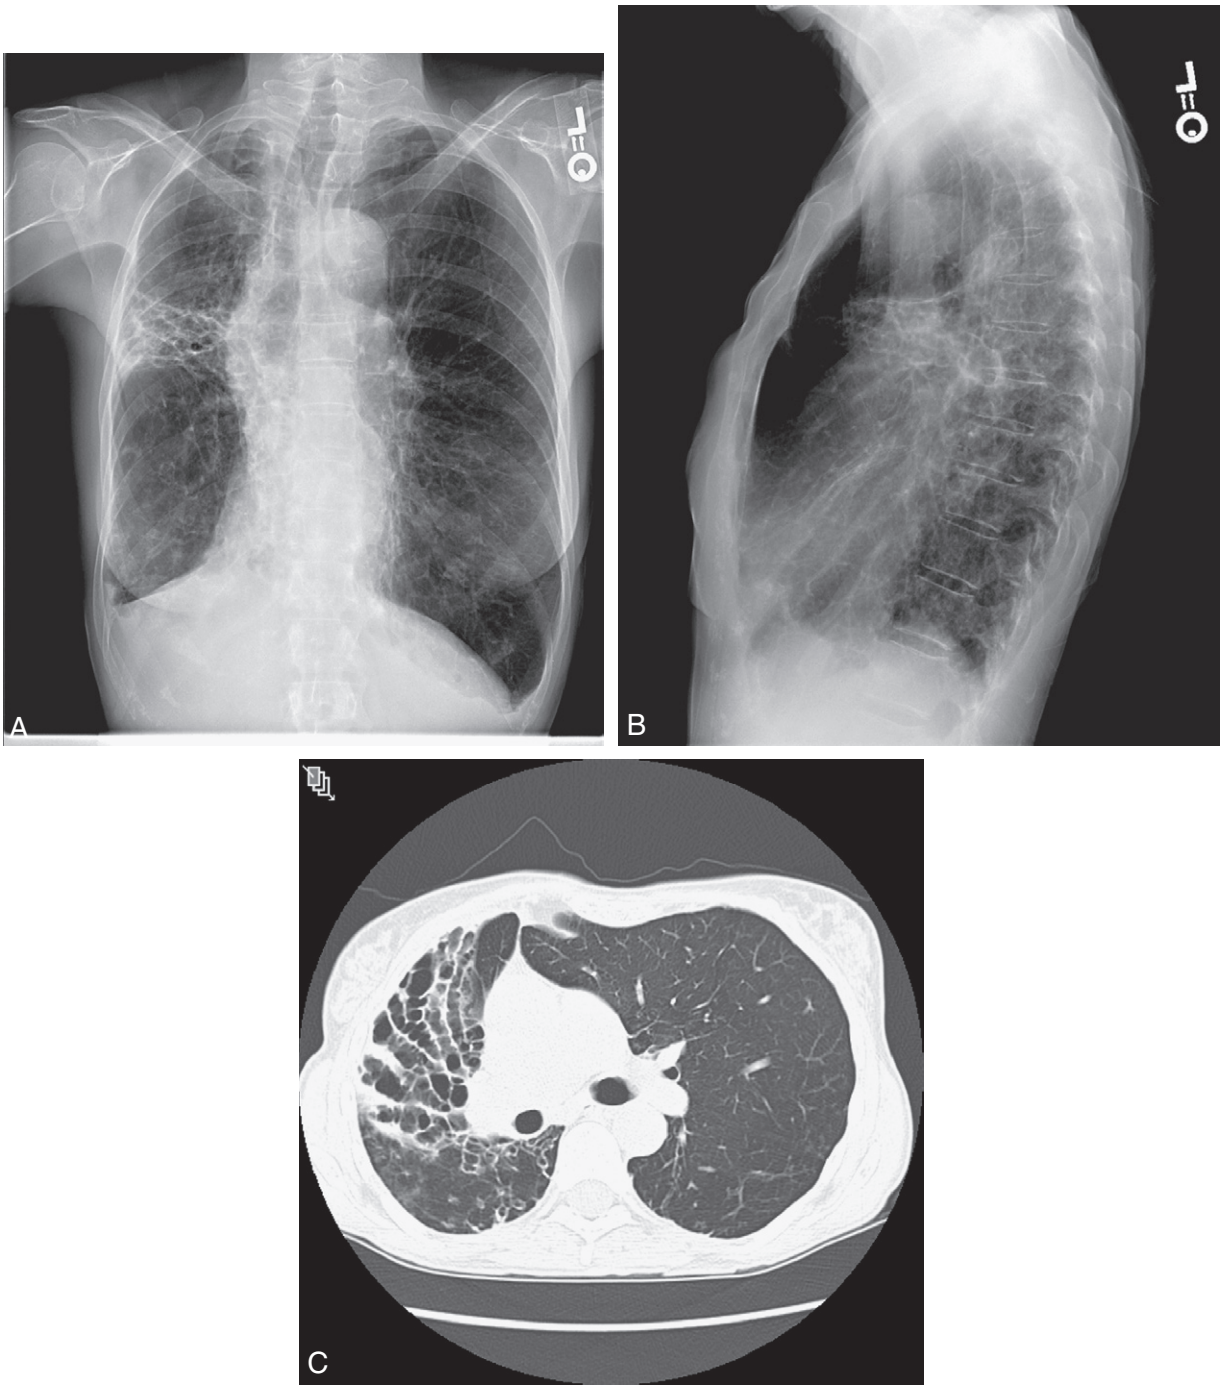

FIGURE 42-13 ■ Multiple ring shadows on the plain chest radiograph in BXSIS. **A,** On the posteroanterior view, thin-walled cystic shadowing is seen in the right mid-lung field. The trachea and mediastinum are shifted to the right, indicating extensive volume loss. **B,** The lateral view confirms the presence of multiple ring shadows in the mid-zone. **C,** CT scan of this 65-year-old white woman indicates severe varicoid BXSIS involving her entire right middle lobe and the anterior segment of the right upper lobe.

Aerosolized antibiotics also appear promising in treating or preventing exacerbations. In patients with CF, inhaled tobramycin twice daily given in alternating months decreased the frequency of exacerbations due to *P. aeruginosa*.[113] Even in patients without CF, inhaled tobramycin was found to be efficacious.[114]

Anti-inflammatory Therapy

The obvious rationale for using the anti-inflammatory agents in BXSIS is that they may reduce the inflammatory cascade, with the goals not only of reducing symptoms but also to limit the progression of disease and decline in lung function. Anti-inflammatory agents that have been examined in BXSIS include the nonsteroidal anti-

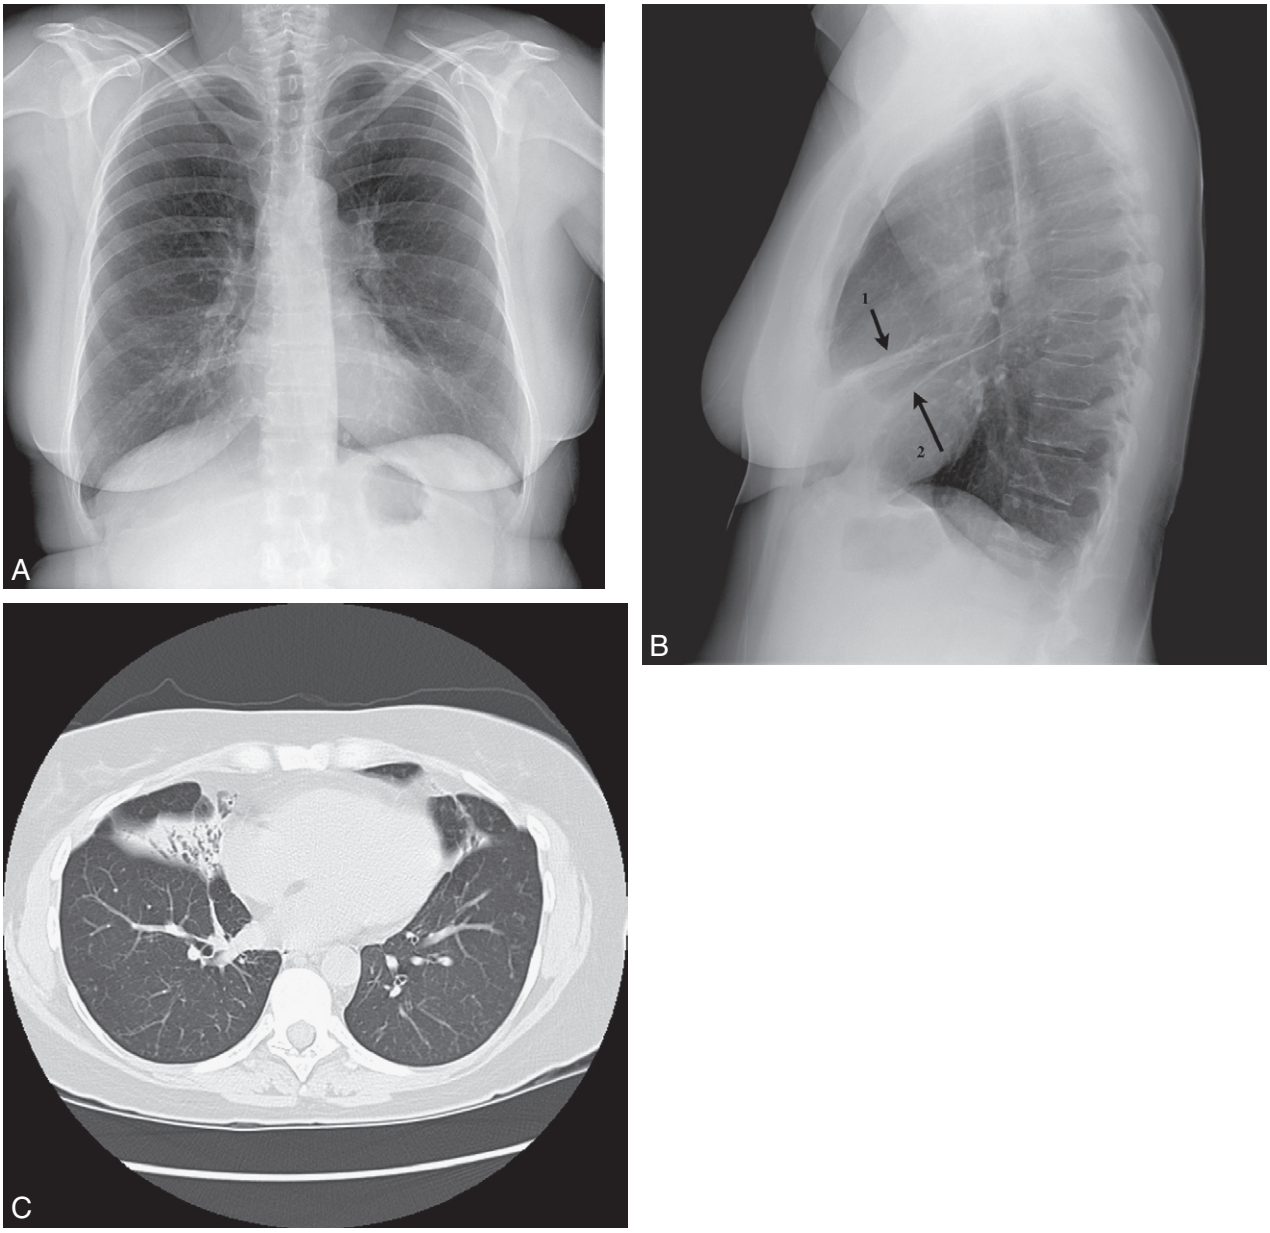

FIGURE 42-14 ■ Atelectasis and BXSIS involving the right middle lobe and lingula on plain chest radiographs and a CT scan. This 60-year-old woman has had recurring "pneumonia" throughout life. **A,** Posteroanterior view shows subtle effacement of the right heart border and cardiophrenic sulcus as well as a hazy opacity at the left heart border. **B,** On the lateral view, there are two oblique densities representing the atelectatic right middle lobe (*arrow 1*) and lingula (*arrow 2*). **C,** CT scan demonstrates BXSIS and atelectasis of the right middle lobe and inferior segment of the lingula.

inflammatory drugs (NSAIDs), inhaled corticosteroids, and intermittent macrolides to exploit their anti-inflammatory and other nonmicrobicidal activities.[114a]

NSAIDs

Because prostaglandins may play a role in augmenting airway secretions, the NSAIDs—by blocking the cyclooxygenase pathway—have been studied in BXSIS. In a double-blind, placebo-controlled study in patients with bronchorrhea due to chronic bronchitis, diffuse panbronchiolitis, and bronchiectasis, inhaled indomethacin significantly decreased the amount of sputum by half as well as the perceived dyspnea.[115] Another mechanism by which indomethacin may help in BXSIS is via inhibition of neutrophil chemotaxis and neutrophil degradation of fibronectin, thereby decreasing airway inflammation and purulence.[116]

In a comprehensive Cochrane Database review of randomized trials of NSAIDs in CF patients, high-dose ibuprofen has been shown to slow the progression of lung disease, especially in children.[117] In contrast, there have been no randomized, controlled trials on the use of NSAIDs in bronchiectatic patients without CF.[118]

TABLE 42-2. Diagnostic Studies for the Classification and Management of Patients with Bronchiectasis

Test	Comments
ROUTINE, UNIVERSAL STUDIES	
Computed tomography lung scan (CTLS)	If bronchiectasis (BXSIS) is suspected, CTLS is the definitive test. Thin-section, high-resolution images may help detect subtle airway dilation before bronchial walls are grossly thickened. Contrast is generally not helpful and may, in fact, compromise the overall resolution of the study. CTLS may also identify esophageal abnormalities.
Pulmonary function tests (PFTs)	For patients with significant BXSIS, comprehensive PFTs, including spirometry, bronchodilator responsiveness, lung volumes, and diffusion capacity, are important studies that aid in management and prognosis. PFTs may also provide useful hints regarding predisposing conditions.
Complete blood count	Anemia may reflect effects of chronic infection or blood loss (consider inflammatory bowel disorders). Leukocytosis may mark severity of infection. Eosinophilia may suggest ABPA/M.
ESR, C-reactive protein	Nonspecific markers of inflammation; very high levels may suggest underlying connective tissue disease or vasculitis.
Routine sputum culture	Antibiotic therapy in BXSIS should generally be directed against specific pathogens and guided by in vitro susceptibility. The presence of mucoid strains of *Pseudomonas aeruginosa* and *Staphylococcus aureus* may raise suspicions for CF. *Stenotrophomonas maltophilia*, *Alcaligenes xylosoxidans*, and *Burkholderia cepacia* are gram-negative bacilli that may prove problematic pathogens in patients with long-standing BXSIS. Isolation of *B. cepacia* and *Helicobacter pylori* require special laboratory techniques.
Mycobacterial sputum culture	Environmental mycobacteria such as *Mycobacterium avium* complex, *M. chelonae*, and *M. abscessus* appear to be increasingly common in contemporary BXSIS. May be commensal but often are pathogenic.
Fungal sputum culture	Especially in patients with an asthmatic component, the presence of *Aspergillus* species (or other molds including Pseudallescheria or penicillium) may suggest etiology.
CT scan of sinuses	Many BXSIS patients also suffer chronic rhinosinusitis. The presence of extensive sinus involvement suggests possible CF, immunoglobulin deficiencies, or ciliary disorders. Also, optimal management often entails aggressive sinus care.
SPECIFIC, DIRECTED STUDIES	
Sweat chloride, CF genotyping, and nasal potential differences	For BXSIS patients with bilateral disease, sinusitis, and no other identified risk factor, mild variants of CF appear to be relatively common (see text and Chapter 41). Sweat chloride is regarded as the primary screening test for CF, but a considerable portion of adults with CF have borderline or normal results. Nasal potential difference may be useful for identifying CF in equivocal cases (see Chapter 41).
$Alpha_1$-antitrypsin (AAT) levels and phenotype	AAT anomalies appear to be a substantial risk factor for BXSIS, especially with white females. Abnormal proteinase inhibitor (Pi) phenotypes, even heterozygous patterns such as MS, appear to confer risk even with normal levels of AAT (see text). Repletion of AAT may enhance resistance to lower respiratory tract infections.
Immunoglobulin (Ig) levels	Deficiencies of IgG or IgA may promote BXSIS; IgG subclass deficiencies may also be a factor. Elevated levels of IgE may suggest ABPA/M or Job's syndrome. Hyper-IgM may be associated, as well, with chronic infections.
Ciliary morphology or function	For individuals with suggestive stories (see text), a nasal ciliated epithelium biopsy with transmission electron microscopy may identify primary ciliary dyskinesia. Other studies including ex vivo ciliary activity, the saccharine test, or spermatozoa analysis may aid in this diagnosis (see text).
Nasal nitric oxide (NNO) levels	Patients with documented PCD have significantly lower levels of NNO than normals or patients with CF.[56] Although not universally available, such testing may prove highly useful in identifying PCD. Paradoxically, exhaled NO levels have been elevated in BXSIS of diverse etiologies[125] except CF.
Barium swallow (BaS)	The BaS may detect disturbed deglutition, esophageal diverticula, obstructing lesions (tumors or strictures), hypomotility, achalasia, hiatal hernias, or lower esophageal sphincter (LES) incompetence with reflux. Note that the absence of reflux on a BaS does not exclude this problem (see pH probe).
pH probe	For patients suspected of gastroesophageal reflux, an 18- to 24-hour study with a transnasal pH probe may identify, quantitate, and characterize reflux. Obviously, medications that inhibit acid production must be stopped before such tests.
Esophageal manometry	For patients being considered for surgical repair of the LES, manometry should be performed to determine that the esophagus generates sufficient pressure to propel food and liquids through the tightened sphincter.
Tailored hypopharyngography (TH)	TH is useful in detecting abnormalities of the initial phase of swallowing, deglutition. Persons particularly prone to problems include those with prior strokes, Parkinson's disease, bulbar disorders including postpolio syndrome, and those with prior laryngeal or pharyngeal surgery. Note that some patients have gross aspiration without clinical manifestations (choking, coughing); this may occur in individuals with none of the above risk factors.
LESS COMMON, EXOTIC STUDIES	
Collagen vascular disease (CVD) serologies	Various CVDs may contribute to the risk for BXSIS, including RA, ankylosing spondylitis, and systemic lupus erythematosus. Thus, for patients with compatible histories or physical findings, assays for rheumatoid factor, HLA-B27, and ANA may provide insight into predisposing conditions. CVD serologies may also suggest the diagnosis of Sjögren syndrome, particularly SSA/Ro and/or SSB/La.
Schirmer's test	For patients with histories suggestive of "sicca syndrome" (dry eyes, dry mouth, oral ulcers), a positive Schirmer test may indicate the presence of either primary or secondary (associated with a CVD) Sjögren's syndrome.

ABPA/M, allergic bronchopulmonary aspergillosis/other mycoses; ANA, antinuclear antibody; CF, cystic fibrosis; ESR, erythrocyte sedimentation rate; HLA, human leukocyte antigen; PCD, primary ciliary dyskinesia; RA, rheumatoid arthritis.

TABLE 42-3. Elements for Management of Patients with Bronchiectasis

Procedure	Comments
AIRWAY HYGIENE	
Tracheobronchial Clearance Techniques	
Mechanical "valve" devices (Flutter, Pep, Acapella, and others)	A variety of these devices exist that are designed to transmit agitating forces to the airways to physically loosen and help propel tenacious secretions out of the bronchial passages. By retarding expiratory flow, they may also stent the airways open. For optimal results, respiratory therapists should assess individual patients' needs and abilities and train them in proper usage.
Postural drainage and chest physiotherapy	For patients with dependent-zone bronchiectasis (BXSIS), positioning in the prone head-down, Trendelenburg, and/or lateral decubitus postures may promote local drainage. This might be optimized by pretreatment with mucus-mobilizing methods (see later) and clapping or vibrating techniques while in these postures.
Therapeutic vest	The pneumatically powered jacket produces high-energy vibrating forces throughout the entire thorax. Of proven utility in CF,[126] the vest may also be useful with BXSIS of other etiologies.
Mucus-Mobilizing Methods	
Inhaled β-agonists (IBAs) and/or anticholinergic bronchodilators (ACBs)	IBAs may accelerate ciliary beat frequency as well as relieve the bronchospasm present in some BXSIS patients. Although the parasympathomimetic ACBs pose a theoretical risk for "drying" secretions, some BXSIS patients tolerate them and enjoy modest benefits not provided by IBAs.[127,128]
Hypertonic saline or mannitol inhalation	Nebulizing hypertonic solutions including saline or mannitol into the airways appears to aid patients in the clearance of tenacious secretions.[129] Hypertonic saline is considerably less expensive than dornase alfa (see later). Mannitol has not yet been approved for use in the United States.
Dornase alfa (Pulmozyme)	This product hydrolyzes neutrophil DNA, which contributes to the viscosity of inflammatory secretions. Of proven utility in CF patients,[130,131] it was not beneficial in BXSIS of differing etiology in one trial.[132] Extended administration in CF patients has been shown to reduce neutrophilic inflammation of the airways.[133] However, we have found it useful in some patients with diagnoses other than CF. It is quite expensive and should be used judiciously.
N-Acetylcysteine (Mucomyst)	Also used primarily in CF patients, it has been generally supplanted by dornase alfa.[126] Its side effects include airway irritation when used in high concentrations. Given orally in Europe, this approach has not been proved efficacious, nor is it approved in the United States.
Anti-inflammatory Airway Management	
Systemic steroids	Mucosal edema and the production of inflammatory secretions may be partially alleviated by corticosteroids. Randomized, controlled trials in young patients with CF have shown improvements in clinical and physiologic parameters with extended courses of alternate-day steroids[134,135] (see Chapter 41 for details). However, there were significant adverse effects, particularly on growth rates in males.[136] Given these and other deleterious effects of long-term systemic steroids, such treatment arguably should be reserved for refractory cases.
Inhaled steroids (ISs)	To avoid some of the complications of systemic steroids, inhaled treatment is a logical approach.[137] Modest evidence of efficacy has been shown in some but not all trials with CF.[119] ISs may also improve the airway hyperreactivity common among BXSIS patients.
Macrolide antibiotics (MLAs)	In addition to their antimicrobial effects, MLAs have demonstrated host defense–modifying activities that include anti-inflammatory effects.[86,140] Azithromycin, an azolide, given over many months has resulted in clinical and physiologic improvement among CF patients infected with *Pseudomonas aeruginosa*.[141–143] These effects must be balanced against the considerable expense and potential for producing drug resistance among bacterial and mycobacterial pathogens common to BXSIS. (Patients should be screened for mycobacterial infections before use.)
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Among young CF patients, long-term administration of ibuprofen has shown some benefits.[144] However, these results may not be generalized, and NSAID therapy should be approached cautiously given the potential side effects and their expense.
Anti-aspiration Measures	
Anti-GER management	Teaching patients to alter their dietary practices (reduced food and liquid intake in the evening), elevated the head of the bed, or most drastically, surgical revision of the LES or hiatal hernia may lessen the risk of recurrent airway soilage.
Improved deglutition	For patients who aspirate on swallowing, changing the consistency of foods or employing maneuvers such as the "chin tuck" may lessen the risk of airway soilage.
Reducing gastric acid	Although lowering gastric acidity with proton-pump inhibitors or H_2-blockers may diminish the symptoms of reflux, it is illogical to think that it should protect against aspiration. Theoretically, lowered acidity of the aspirated matter might result in reduced damage to the lungs; however, it should not be regarded as a lung-protective intervention.
ANTIMICROBIAL THERAPY	
Episodic, targeted antibiotics	Rather than administering "rotating" or "empirical" agents, this approach involves sampling respiratory secretions during clinical exacerbations and employing antimicrobials on the basis of species identification and in vitro susceptibility. Although logically an attractive option, it entails inevitable delays in treatment and may be confounded by the presence of multiple, potential pathogens.

Continued

TABLE 42-3. Elements for Management of Patients with Bronchiectasis—cont'd

Procedure	Comments
Rotating antibiotic therapy	A popular practice, clinicians might treat BXSIS patients with a 1 wk/mo cycle of arbitrarily selected antimicrobials such as, for example, amoxicillin, a fluoroquinolone, and a macrolide. There is some evidence of utility for long-term antibiotic therapy[145]; however, the potential for selecting for drug-resistant strains is a consideration. Imperfect evidence reported in a recent analysis suggests that patients with chronic *P. aeruginosa* infection do better with targeted therapy.[146]
Initial empirical followed by targeted antibiotics	This approach offers the advantage of prompt treatment for an exacerbation, followed by a more narrowly focused regimen based on the results of the initial sputum cultures. To be representative, sputum sampling should be done before initiating empirical antimicrobial therapy.
Role of inhaled antibiotics	The model of inhaled tobramycin in controlling pseudomonal infections in CF patients[147,148] (see Chapter 41) is an attractive model for non-CF BXSIS as well.[149] Certainly, for those patients with chronic or recurrent gram-negative bacillary infections, this approach might be considered. However, our early experience suggests less favorable tolerance of tobramycin in elderly subjects.
Therapy for exotic pathogens	Patients may either acquire secondary infections of preexisting BXSIS or primarily develop BXSIS due to exotic microbes such as environmental mycobacteria or fungi. In such cases, specific therapy may be indicated.
SURGERY	
Resectional surgery	There are no systematic studies of surgical interventions in BXSIS. However, anecdotal observations suggest that extirpation of severely damaged lobes may confer considerable benefit. Disease limited to the right middle lobe or lingula may be particularly amenable.[150–152] Whether such resections should be done through the lateral thoracotomy or VATS approach is unresolved, although our group strongly prefers the former.
Transplantation	For younger patients with BXSIS-associated respiratory insufficiency, the question of transplantation may arise. Based on the model of CF, it is a plausible consideration.
MISCELLANEOUS	
Vaccination vs. *Streptococcus pneumoniae*	Although not specifically proved in BXSIS, this vaccine seems an obvious adjunct.
Vaccination vs. influenza	In addition to vaccination, BXSIS patients should be considered for antiviral therapy if they develop clinical influenza.
Smoking cessation	A priority for all pulmonary patients.
Alpha$_1$-antitrypsin (AAT) repletion	Among COPD patients receiving AAT repletion, there was a perception of reduced frequency of infectious exacerbations (see text). For BXSIS associated with AAT anomalies, repletion might confer protection against recurrent infections.
Oxygen	Patients with BXSIS, especially extensive lower lobe disease, may become hypoxic with exertion or with sleep. Early detection and O_2 supplementation may improve exercise tolerance and physical conditioning. Nocturnal O_2 may lessen pulmonary hypertension and delay the appearance of cor pulmonale.
Methylxanthines (Mx)	Oral Mx (theophylline) theoretically might augment bronchodilation, enhance mucus clearance, and enhance diaphragmatic contractility. However, the side effects, variable pharmacokinetics including interactions with macrolide antibiotics, and GER-promoting effects make Mx a problematic element in most BXSIS patients.
Cromolyn, nedocromil, or leukotriene modifiers	Although these various asthma medications may have some theoretical roles in BXSIS, there have been no studies demonstrating efficacy.

CF, cystic fibrosis; COPD, chronic obstructive pulmonary disease; GER, gastroesophageal reflux; VATS, video-assisted thoracoscopic surgery.

Inhaled Corticosteroids

A review of clinical trials have shown that the use of inhaled corticosteroids in CF did not cause improvement.[119]

Intermittent Macrolide Therapy

Independent of their antimicrobial properties, macrolide antibiotics hold great promise in inhibiting disease activity in BXSIS due to their nonantimicrobial immunomodulatory effects.[120] Intermittent macrolide therapy may help in BXSIS via different mechanisms including decreasing chloride diffusion potential gradient across the airway mucosa (resulting in decreased sputum volume), reducing airway levels of the neutrophil chemotactic factor IL-8, inhibiting both neutrophil and *Pseudomonas* migration, suppressing *Pseudomonas* quorum sensing, and disrupting the established biofilm layer.[121] Clarithromycin but not amoxacillin or cefaclor was shown to significantly reduce sputum production in patients with chronic bronchitis or BXSIS. In a study of a small number of patients with BXSIS[122] randomized to standard care for 6 months followed by the addition of azithromycin given at a dose of 500 mg twice weekly for 6 months or vice versa, azithromycin significantly decreased the incidence of exacerbations and sputum volume compared with standard care.[123] Similar beneficial effects plus improvement in lung function have been shown in various trials using intermittent azithromycin therapy in CF patients chronically infected with *P. aeruginosa* but also in younger CF patients before they have been colonized with *P. aeruginosa*.[124]

Surgery

Surgery remains a controversial issue in the management of BXSIS. No formal systematic studies of the indications and efficacy of resectional surgery have been conducted among patients with BXSIS. Traditional indications for resectional surgery have included chronic disabling infection, recurrent infections of intolerable frequency, or irreversible lung damage distal to a foreign body or benign tumor. Life-threatening hemoptysis may also provoke consideration of surgery, although therapeutic bronchial artery embolization may be the initial treatment of choice. A historical adage has been that surgery does not cure BXSIS. If true, it is likely due to our evolving understanding that most cases of BXSIS are due to innate risk factors that predispose to recurrence. However, surgery is still an appropriate palliative measure in selected cases.

Miscellaneous

Additional measures, such as vaccination against pneumococcal disease or influenza and smoking cessation, are appropriate for all patients. Intuitively, these measures seem particularly important for those with BXSIS; however, no systematic information is available to confirm their usefulness. On the other hand, early recognition of exercise and sleep-related hypoxia has substantially demonstrated benefits in regard to morbidity and mortality.

KEY POINTS

- BXSIS is defined by the presence of permanent dilation of the medium to large bronchi. The main clinical significance of BXSIS is recurrent airway infections by bacterial and fungal organisms resulting in chronic cough, sputum, weight loss, and respiratory compromise.
- Most BXSIS occurs owing to a combination of host susceptibility factors—which may be overt or covert—and the recurrent infections and the largely neutrophilic inflammatory response that perpetuate the airway injury.
- Localized BXSIS is most often due to suboptimally treated bacterial infections. BXSIS due to nontuberculous mycobacteria is increasingly recognized: the two predominant phenotypic presentations are elderly men with upper lobe fibrocavitary disease in a background of emphysema, and postmenopausal women with lingular and right middle lobe BXSIS and nodules.
- BXSIS that is more diffuse is generally due to an underlying host disorder such as cystic fibrosis, primary ciliary dyskinesia, disorders of cartilage as seen with the Mounier-Kuhn and Williams-Campbell syndromes, common variable immune deficiency, and allergic bronchopulmonary aspergillosis.
- BXSIS has also been associated with extrapulmonary disorders such as ulcerative colitis and collagen vascular diseases. Severe fibrotic lung diseases from any cause may also result in a form of BXSIS known as traction BXSIS.
- The linchpins in the management of BXSIS are the timely institution of antimicrobials to treat the culprit pathogens isolated and diligent airway clearance measures to improve symptoms and to decrease the frequency of such infections. Surgical lung resection should also be considered for patients with severe localized disease that are recalcitrant to medical treatment.
- Anti-inflammatory agents such as the NSAIDs and the low-dose intermittent macrolides are promising in helping to alleviate symptoms and reduce the rate of disease progression, but recommendations for their use remain to be defined.

Clinical Disorders

INTRODUCTION

The upper airways—anatomically complicated structures that extend from the airway openings at the nares and lips to the trachea—serve numerous physiologic functions. Their respiratory function includes filtering, conditioning, and conveying air to the lungs. The nasal airway also supports the sense of olfaction; the oral airway, pharynx, and larynx also support deglutition, phonation, and coughing. These processes have been studied extensively. This chapter focuses on the role of the upper airways in breathing and on disorders that affect this function. We also discuss some of the air-conditioning functions of the nasal mucosa because they have a direct impact on the health of the lower airways.

The term *upper airways* includes several anatomically distinct regions (Figs. 43-1 and 43-2). The nose constitutes the upper segment, followed by the nasopharyngeal and oropharyngeal airways, which extend from the nasal choanae and oral cavity to the supraglottic space. The paranasal sinuses drain into the nasal cavities and are attached to the lateral, posterior, and superior aspects of the nose. The larynx divides the upper and lower airways, although some place it in the thoracic inlet.

The major function of the upper airway is to control and coordinate the passage of air, liquids, and food to the appropriate site. This function requires exquisite neural control of numerous muscle groups. The actions of pharyngeal sphincters and glottic adductors enable complete occlusion of the airways at specific sites during deglutition. The action of dilators of several airway segments and the transition from solely nasal to oronasal breathing enable augmentation of airflow during exercise.[1-6] Narrowing and indeed occlusion of the upper airways can result from structural bony or soft tissue abnormalities (either intrinsic or extrinsic to the airway lumen or due to dysregulation of normal physiologic function). Following simple principles of airflow dynamics,[7-10] narrowing in certain parts of the upper airway can result from dynamic collapse of these segments when resistance to flow requires greater inspiratory efforts and hence greater drops in upper airway intraluminal pressure relative to ambient atmospheric pressure. Understanding of the structural and functional characteristics of the upper airway allows one to appreciate its vital and essential connection to the functions of the lower respiratory tract.

THE NOSE

Structure and Function

Air enters the nose through the nasal vestibule, an approximately 1-cm channel in the cartilaginous portion of the nose. At the end of the vestibule lies the nasal valve, the narrowest area of the passages (see Fig. 43-1). Thereafter, the nasal passages become convoluted by the folds of the turbinates. The passage of the nasal vestibule is narrow, and the linear velocity of inhaled air becomes quite high.[11,12] The combination of high linear velocities and the transition from upward to horizontal flow that occurs just beyond the nasal valve favors the deposition of most airborne particles in the anterior nose. Air velocities are lower in the main nasal passages (beyond the

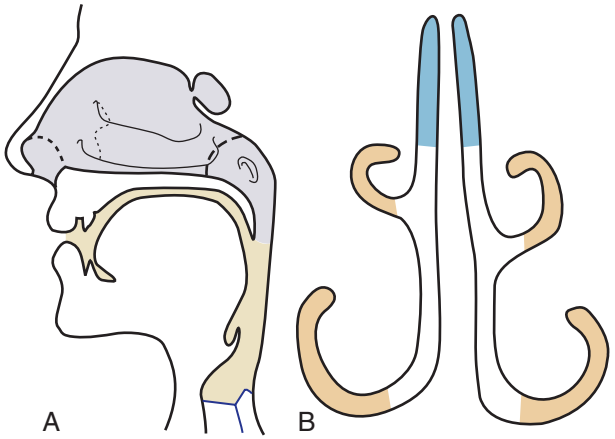

FIGURE 43-1 ■ Upper airways and nasal segments. **A,** Nasal (*gray stripes*) and oropharyngeal (*gold shading*) airways are shown with the nasal septum omitted. The *dashed line on the left* marks the beginning of the nasal valve; the *dotted line* marks the approximate beginning of the ciliated mucosa; the *dashed line on the right* marks the termination of the nasal septum. Note the key position of the soft palate for control of the division between oral and nasal paths for airflow. **B,** This section through the main nasal passage shows the septum and folds of the turbinates. The *blue colored areas* are the olfactory region, through which little inspiratory airflow passes. The *gold colored* areas are meatal spaces, through which there is little airflow. The *clear space* is a region of major inspiratory airflow. (Redrawn from Proctor DF, Anderson I [eds]: The Nose: Upper Airway Physiology and the Atmospheric Environment. Amsterdam: Elsevier Biomedical, 1982.)

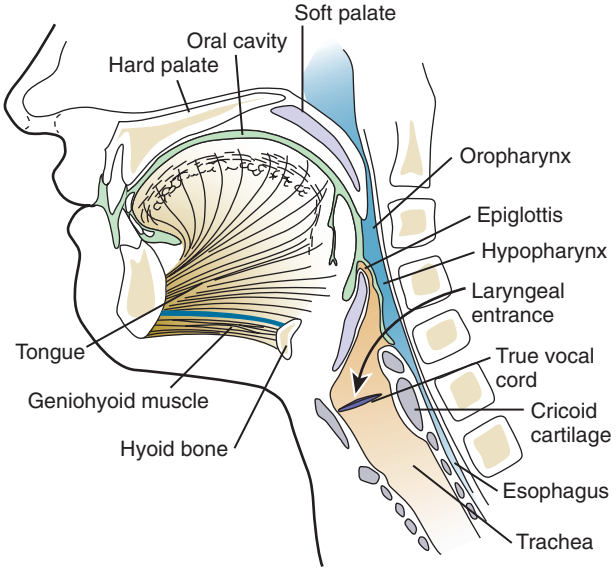

FIGURE 43-2 ■ The major structures that make up the oropharyngeal and laryngeal airway. (Redrawn from Wiegand L, Zwillich CW: Pathogenesis of obstructive sleep apnea: Role of the pharynx. Semin Respir Med 9:540–546, 1988.)

valve) where the cross-sectional area is greater. This reduction in air velocity allows prolonged contact of inspired air with the nasal mucosa, enabling the nose to modify the temperature and water vapor content[13,14] and to remove airborne pathogens and pollutants.[15,16]

Neuromuscular regulation of the skeletal muscles that overlie the cartilaginous portion of the nose (Table 43-1) plays a major role in the control of nasal vestibule patency. Contraction of the transverse part of the alae nasi narrows this segment, whereas activation of the alar part of this muscle and of the depressor septi widens it.[3] When the ventilatory drive is elevated, the pressure difference from the nasal inlet to the pharynx increases as inspiratory effort increases. To avoid collapse of the alar cartilages and limitation of flow during inspiration, a rise in dilator activity at the nasal vestibule is thought to decrease both the resistance and the collapsibility of this nasal segment.[1,8,17] Obstruction in the nasal cavity (which results primarily from vascular engorgement) leads to increases in the resistance downstream to the site of inspiratory airflow limitation in the nasal vestibule.[18] These increases in downstream resistance reduce nasal airflow and increase the driving pressure required to reach maximal flow. Mouth breathing remains the only effective strategy to increase inspiratory flow when elevated nasal resistance occurs.

The specialized functions of the nose are of great importance to the lower airways.[19] A classic example derives from the strong protective effect that nasal breathing has on exercise-induced asthma.[20,21] Nasal functions are attributable to particular anatomic features of the nasal mucosa and are facilitated by the previously described airflow patterns. The nasal mucosa has several key features including numerous submucosal glands and goblet cells in the respiratory epithelium,[22] a dense subepithelial network of fenestrated capillaries,[23] a vascular network of capacitance vessels (venous sinusoids)[24] that rapidly pool blood and engorge mucosal tissue,[25] and an abundance of sensory nerve endings that interdigitate between epithelial cells and act as nonspecialized nociceptors.[26] Production of mucus by seromucous glands and goblet cells provides the trapping material for particles entering the airways with inhaled air. The contents of nasal secretions, which include immunoglobulins (particularly secretory IgA), antibacterial chemicals (lysozyme, lactoferrin), or even antioxidants (uric acid), offer innate and specific immune functions and chemical protection for the lower airways.[27,28] The nasal and particularly the paranasal sinus epithelium are rich in inducible nitric oxide synthase, which confers the ability to produce nitric oxide,[29,30] a substance with antibacterial, antiviral, and smooth muscle–relaxant properties. Rapid passage of blood through the subepithelial capillaries acts as a heat exchanger with tremendous capacity for warming inhaled air. By engorging the tissue, capacitance vessels increase the contact surface with inhaled air and facilitate heat and water exchange. The fenestrae of the subepithelial capillaries are thought to be important in allowing rapid water transportation from the intravascular space to the epithelial layer. Water moves passively through the intraepithelial junctions and effectively humidifies inhaled air. Finally, the nociceptors of the nasal mucosa generate several central reflexes, such as the sneezing reflex, as well as nasonasal reflexes through which the glandular apparatus and the vasculature are activated. Neural reflexes act in concordance to protect the airways.

TABLE 43-1. Muscles Surrounding the Upper Airways

Region	Stabilizing or Widening	May Widen or Narrow	Narrowing or Closing
Nose	Dilator naris	Vascular smooth muscle	Compressor naris
	Alae nasi		
Nasopharynx		Tensor veli palatini	Levator veli palatini
			Palatopharyngeus
Mouth and pharynx	Lateral pterygoid	Salpingopharyngeus	Medial pterygoid
	Genioglossus	Muscles of the lips	Pharyngeal constrictors
	Digastric	Masseter	Pterygopharyngeus
	Mylohyoid	Glossopalatinus	Buccopharyngeus
	Geniohyoid	Omohyoid	Stylopharyngeus
	Stylohyoid	Thyrohyoid	Mylopharyngeus

		Sternothyroid	Chondropharyngeus
			Ceratopharyngeus
			Thyropharyngeus
			Cricopharyngeus
			Styloglossus
			Hyoglossus
Larynx	Cricoarytenoid posterior	Cricothyroid	Aryepiglottic
			Interarytenoid
			Cricoarytenoid lateralis
			Thyroarytenoid
Trachea			Smooth muscle

Allergic and Nonallergic Rhinitis

Nasal symptoms—sneezing, rhinorrhea, congestion, posterior nasal drainage—are familiar manifestations of the common cold, but they represent the basic repertoire of physiologic responses of the nose to a variety of allergic and nonallergic stimuli. In many circumstances of nonallergic rhinitis, the underlying etiology is nonspecific or not known.

Classification and Epidemiology

Allergic rhinitis is classified into episodic, seasonal, and perennial on the basis of the duration of symptoms. Most recently, a classification into intermittent and persistent rhinitis has been proposed.[31] Most patients with nonallergic rhinitis belong to an "unknown etiology" group. This group can be further classified into three conditions: nonallergic hyperplastic (inflammatory) rhinosinusitis; nonallergic, noninflammatory rhinopathy (also referred to as "vasomotor rhinitis"); and nonallergic rhinitis with eosinophilia syndrome (NARES).[32] Other classifications have also been proposed.[33]

Approximately 30% of the population in industrialized countries reports episodic, seasonal, or chronic symptoms of rhinitis in the absence of an upper respiratory infection.[34] An early estimate of the prevalence of allergic rhinitis in the United States of approximately 20%, from the National Health and Nutrition Examination Survey (NHANES) II,[35] has recently been corroborated, which means that about 60 millions Americans are affected.[36] Because of such a high prevalence and because of the many comorbidities from the respiratory tract (sinus disease, otitis media, lower respiratory involvement), the economic burden of allergic rhinitis is high. Previous estimates of the direct costs in the $1–$3 billion range[37,38] rise to $2–$5 billion when indirect costs are included, but additional information is needed to provide a better picture of the current economic burden.[39]

Pathophysiology

Allergic Rhinitis. Allergic rhinitis, very much like allergic asthma, is characterized by mucosal inflammation and hyperresponsiveness.[40] As in asthma, the allergens responsible are inhaled (aeroallergens). Outdoor allergens, such as plant pollens (especially from ragweed, grasses, and weeds) and molds (e.g., *Alternaria*), typically cause seasonal rhinitis, whereas indoor allergens such as house dust mite, cockroach, and pet danders cause perennial symptoms. In subtropical and tropical climates, where seasons are less distinct, the differentiation between seasonal and perennial patterns of disease is of less value.

As in allergic asthma, a basic cellular event is the interaction of antigen (allergen) with the Fab portion of specific IgE antibody molecules anchored on the surface of two types of cell, the mast cell (a stationary tissue cell) and the basophil (a peripheral blood leukocyte). The interaction between antigen and IgE bridges two nearby IgE molecules, leading to activation of the second-messenger pathways that cause the release of preformed inflammatory mediators, such as histamine and tryptase, and the de novo synthesis and release of others, such as

prostaglandin D_2 and sulfidopeptide leukotrienes. These substances cause acute symptoms including intense local pruritus, sneezing, rhinorrhea, and nasal congestion with airflow limitation. Lacrimation is also part of this constellation. In this acute aspect of the clinical manifestation of allergic rhinitis, histamine is probably the most important mediator because it is the only one to generate the entire spectrum of rhinitic symptoms. In the human nasal mucosa, histamine is the most important chemical mediator of allergic rhinitis.[41] Stimulation of H1, H2 and H3 receptors all play a role in generating the full constellation of histamine-induced symptoms.[42] The cysLT1 and cysLT2 leukotriene receptors are also found in the nasal mucosal blood vessels, and sulfidopeptide leukotrienes are known to increase resistance to airflow.[43]

As in the lower airways, exposure of the nasal mucosa to allergen results not only in an acute (early) reaction but also in a late reaction, which is marked by recrudescence of symptoms, especially nasal congestion, a second wave of inflammatory mediator release, and an increase in the numbers of eosinophils, basophils, mononuclear cells, and neutrophils in nasal secretions.[37,44] Although the late-phase reaction has been studied as a laboratory phenomenon, it is thought to be important in the natural history of allergic rhinitis; the most effective treatment modalities, corticosteroids and immunotherapy, strongly suppress this reaction. In general, late reactions occur in the natural setting after exposure to high levels of allergen.

Mucosal biopsies performed 24 hours after nasal provocation demonstrate an inflammatory infiltrate that is mostly lymphocytic, with eosinophils, basophils, and neutrophils found in increased numbers.[45] As in asthma, immunohistochemical staining and in situ hybridization studies reveal that most of the tissue lymphocytes are $CD4^+$ (helper) T cells, primarily of the T-helper type 2–like subclass. This histologic picture is similar to that seen in chronic allergic rhinitis.[46,47] The exact role of the inflammatory infiltrate in the clinical presentation of the disease has not been elucidated. Among the most important consequences of the activation of leukocytes is the production of cytokines and chemokines (chemokines are also produced by resident epithelial and endothelial cells). These substances are thought to orchestrate the perpetuation of inflammation. Certain cytokines, including interleukin-4 (IL-4) and IL-13, intensify the immune/allergic response, whereas others (e.g., IL-5) activate eosinophils, and others (e.g., histamine-releasing factors) can activate inflammatory cells in the absence of direct allergen stimulation.[48]

Two additional phenomena contribute to the clinical presentation of allergic rhinitis. Priming of the nasal mucosa to allergens was described in the 1960s by Connell,[49] who detailed the observation that, with increasing exposure to allergens, the symptoms are progressively accentuated. This explains why, at the beginning of the pollen season, despite the fact that pollen counts rapidly increase, disease severity remains relatively mild. At the end of the season, despite very low pollen counts, patients with allergic rhinitis remain quite symptomatic. The presence of nonspecific nasal hyperresponsiveness explains the clinical observation that a large number of patients with allergic rhinitis specify not only allergens (e.g., pollen, pets) but also various irritants (e.g., strong perfumes; smoke; cold, dry air) as triggers of their nasal symptoms. Both priming to allergen and nasal hyperresponsiveness can be induced in the laboratory setting with allergen provocation. Allergen-induced increased responsiveness to histamine is thought to reflect primarily hyperresponsiveness of the sensorineural apparatus. Neural hyperresponsiveness has been experimentally demonstrated in natural allergic rhinitis whether seasonal or perennial in nature.[50]

Nonallergic Rhinitis. The pathophysiology of the most common nonallergic rhinitis syndromes is obscure. The histologic features of hyperplastic nonallergic rhinosinusitis are similar to those of its allergic counterpart and are characterized by thickened nasal and paranasal sinus mucosa and excessive mucosal inflammation, as discussed later. The cytokine pattern in the inflamed tissues is somewhat different for allergic and nonallergic disease,[51] but similarities exceed the differences. Hence, it is questionable whether the differences are of clinical significance. Also unknown is the etiology of NARES, but the clinical presentation of this syndrome resembles that of allergic rhinitis.[52] It is possible that an as yet unknown allergen is responsible for this illness or that in these patients, allergic sensitization is limited to the local milieu of the nose. In support of the latter hypothesis, investigators in Newcastle, United Kingdom, have produced data indicating that some patients with inflammatory rhinitis and negative skin tests or no serum-specific IgE against common allergens may develop increased nasal airway resistance after intranasal challenges with house dust mite extract.[53] In nonallergic, noninflammatory rhinopathy (vasomotor rhinitis), not only is nasal mucosal inflammation absent but the few functional abnormalities that have been described appear to be limited to the domain of the autonomic nervous system.[54,55] Many studies indicate that patients with this syndrome benefit from treatment with repetitive nasal applications of capsaicin, which results in defunctionalization or down-regulation of mucosal nociceptors.[56,57] It is possible, therefore, that nonallergic, noninflammatory rhinopathy represents a state of sensorineural imbalance.[58] The etiology, however, remains unknown.

More recently, investigators have shown that laryngopharyngeal reflux is associated with increased nasal symptoms, although the mechanism remains incompletely understood.[59]

Management

Allergic Rhinitis. The management of allergic rhinitis is summarized in Figure 43-3. Management involves environmental control aiming at allergen avoidance, pharmacotherapy, and immunotherapy. Because the offending allergens are the same, environmental control for allergic rhinitis is identical to that recommended for the management of allergic asthma. Perhaps, compared with asthma, pollen avoidance may be more beneficial for allergic rhinitis because the size of pollen particles makes them more likely to deposit in the nasal mucosa. Conversely,

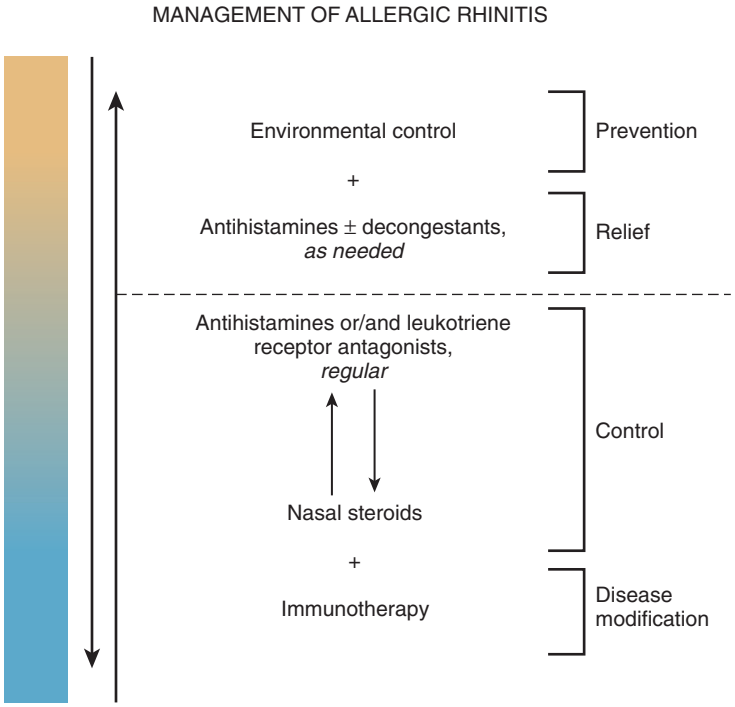

FIGURE 43-3 ■ The management of allergic rhinitis should be based on the severity (*indicated by the increasing darkness of the vertical column*) and the clinical characteristics of the presentation (known environmental exposures, intermittent versus persistent symptoms, predominance of particular symptoms such as sneezing or nasal congestion). In addition, management should be adjusted upward or downward with the goal of optimal control with minimal treatment.

in patients with perennial allergic rhinitis, especially those lacking any evidence of seasonal, pollen-related exacerbations, indoor allergen exposure needs to be targeted as for patients with asthma. A large study has questioned the effectiveness of dust mite control using impermeable bedding covers,[60] but this form of management needs to be evaluated in the context of a more multifaceted strategy involving additional control methods and targeting additional allergens and irritants.

The pharmacologic agents used to treat allergic rhinitis can be separated into two categories: those conferring rapid symptom relief (antihistamines, decongestants, ipratropium bromide) and those controlling the disease on a chronic basis (antihistamines as well as leukotriene receptor antagonists, nasal cromolyn, and nasal glucocorticosteroids). Finally, allergen immunotherapy (allergen vaccines) is widely used as a disease modification strategy.

Antihistamines. Antihistamines are H_1-receptor antagonists.[61] They are effective in reducing pruritus, sneezing, tearing, and rhinorrhea but nasal congestion less so. They can be used on an as-needed basis, although with seasonal disease, they have a better effect if taken either before symptoms develop or continuously. The use of the older compounds (first-generation, or classic, antihistamines) has been limited because of their significant side effects, primarily sedation and systemic anticholinergic activity.[62] Newer agents, first introduced in the early 1980s, are essentially devoid of such adverse effects and can be used with great ease. Also, the newer antihistamines have longer half-lives and active metabolites, which prolong their action. This allows them to be taken once or twice daily, thereby enhancing patient compliance. Currently, four of these agents, cetirizine, desloratadine, fexofenadine, and loratadine, are available in the United States. Additional agents, mizolastine, ebastine, and levocetirizine, are available in many other countries. Azelastine and olopatadine are available in the United States as a nasal spray for topical application. A recent review of the literature supports the current recommendation for nasal antihistamines as first-line treatment for allergic rhinitis.[62a]

Decongestants. Because antihistamines do not have strong clinical potency against nasal congestion, oral and topical decongestants can be used in combination with antihistamines or as single agents.[63] These are α-adrenergic agonists (i.e., vasoconstrictors). The orally available agent pseudephedrine is less potent than the topical ones (oxymetazoline, xylometazoline, phenylephrine) and can cause significant systemic sympathomimetic side effects, including mucosal dryness, insomnia, tachycardia, nervousness, and increased blood pressure. Topical agents are quite potent, but they induce receptor down-regulation and pharmacologic tolerance, which results in a continuously increasing need for dosing and in rebound nasal congestion after discontinuation (rhinitis medicamentosa). Such agents should not be used for more than 4 or 5 consecutive days at a time.

Ipratropium Bromide. Ipratropium bromide, being an antagonist of acetylcholine on muscarinic receptors, can reduce the stimulation of the submucosal nasal glands by cholinergic neural pathways.[64] It is recommended when there is excessive rhinorrhea. This agent has no effects on the other symptoms of allergic rhinitis; therefore, rarely is it sufficient as a single agent to control the disease.

Leukotriene Receptor Antagonists. Montelukast, one of the two leukotriene receptor antagonists currently marketed in the United States, also has approval for the treatment of seasonal allergic rhinitis. Its efficacy

is comparable with that of oral antihistamines,[65] and the spectrum of symptoms it affects is similar. Leukotriene receptor antagonists possess some anti-inflammatory effects. However, antihistamines have a more rapid onset of action and can therefore be used on an "as-needed" basis. Because of the complementarity of histamine and the sulfidopeptide leukotrienes in the pathophysiology of allergic reactions, significant interest has been generated over the efficacy of antihistamine-antileukotriene combinations in allergic rhinitis.[66] Some studies indicate that this combination is as efficacious as nasal glucorticosteroids, whereas others report stronger therapeutic efficacy of steroids.[66a]

Nasal Glucocorticosteroids and Cromolyn. The strategic positioning of nasal glucocorticosteroids and cromolyn in allergic rhinitis is very similar to that in asthma, as are their relative effectiveness and safety profiles. In moderate to severe rhinitis, topical glucocorticosteroids constitute the mainstay of treatment,[67,68] alleviating all symptoms and reducing inflammation and nasal hyperresponsiveness. Continuous use, as opposed to "as needed," results in more effective symptom control. The safety profile is excellent, with the most common side effects being local irritation, dryness, epistaxis, and headaches. In contrast to inhaled steroids, which rather frequently result in oropharyngeal candidiasis, this adverse event is extremely rare with nasal agents. Several studies involving mucosal biopsies have assured us that nasal steroids do not induce mucosal atrophy.[69] There is some systemic bioavailability of these agents, which is associated with some metabolic effects.[70,71] These effects, however, are of far less concern than those of systemically administered glucocorticosteroids. The anti-inflammatory effects of disodium cromoglycate are less than those of nasal steroids and are somewhat limited to mast cell stabilization, although even this property has been questioned. Cromolyn is very well tolerated and can be efficacious in allergic rhinitis so long as it is used on a four times a day or more basis. This results in limited patient acceptability.

Allergen Vaccines (Immunotherapy). The role of immunotherapy in allergic rhinitis is very well established.[72–74] This treatment, during which increasing doses of allergenic extracts are progressively administered subcutaneously once or twice per week until a maintenance dose is reached, alters various aspects of the immune response to allergens, leading to inhibition of many elements of the allergic reaction. Most importantly, it is the only treatment for allergic conditions that can modify the natural history of the disease. For example, some studies suggest that immunotherapy can inhibit the progression of allergic rhinitis to asthma.[75] The indications for immunotherapy include the presence of moderate to severe disease and the lack of effectiveness of conventional medical therapy, intolerance to such therapy, or unavoidable allergen exposure.[76] There are no definitive data determining the optimal duration of treatment, but most specialists recommend 3 to 5 years. The allergens used in immunotherapy are identified on the basis of a thorough diagnostic evaluation with either allergen skin tests or determining the levels of allergen-specific IgE antibodies in the patient's serum. This evaluation has to be complemented by a meticulous exposure history and an assessment of the seasonality of the nasal symptoms so the allergens that are *clinically* relevant are identified. Similar rules apply to the decision regarding the doses of the allergenic extracts to be used. Allergen immunotherapy is a safe form of treatment. Systemic anaphylactic reactions are infrequent and, most of the time, mild and easily manageable. Although very rare, anaphylactic shock can occur, and deaths from immunotherapy have been reported. Therefore, health care providers who administer this treatment should be well trained in the management of anaphylaxis.

Nonallergic Rhinitis. Because of the lack of understanding of the pathophysiology of nonallergic rhinitis syndromes, management of these conditions has not been optimized. In all of these syndromes, symptomatic treatment with antihistamines, decongestants, and ipratropium bromide may provide help so long as the clinical presentation involves sneezing/pruritus, nasal congestion/pressure, and excessive rhinorrhea, respectively. In hyperplastic rhinosinusitis and in NARES, nasal glucocorticosteroid treatment is indicated. The latter syndrome is highly responsive to nasal steroids, whereas a significant number of patients with hyperplastic inflammatory disease do not obtain adequate relief from these agents. Nasal steroids are not indicated in nonallergic, noninflammatory rhinopathy, and symptomatic treatment should be pursued. As mentioned earlier, inactivation of nasal nociceptors with the use of repetitive applications of capsaicin in the nasal mucosa has been suggested for patients with this syndrome.[56,57,77] However, capsaicin therapy has not been approved by regulatory authorities.

THE PARANASAL SINUSES

The paranasal sinuses are four pairs of cavities that are named after the skull bones in which they are located: frontal, ethmoid (anterior and posterior), maxillary, and sphenoid. All sinuses contain air and are lined by a thin layer of respiratory mucosa composed of ciliated, pseudostratified columnar epithelial cells with goblet mucous cells interspersed among the columnar cells.

Structure and Function

The frontal sinuses grow slowly after birth and are barely visible at 1 year of age. After the fourth year, the frontal sinuses begin to enlarge and can usually be demonstrated radiographically in children over 6 years of age. The ostium of these sinuses is located directly posterior to the anterior attachment of the middle nasal turbinate to the lateral nasal wall.

The ethmoid sinuses consist of several air cells, which are present at birth and reach their adult size by age 12. They form a pyramid with the base located posteriorly. The lateral wall of the ethmoid sinuses is the lamina papyracea, which also serves as the paper-thin medial wall of the orbit. The superior boundary separates the ethmoids from the anterior cranial fossa and is composed

by the cribriform plate and the fovea ethmoidalis. The posterior boundary is the anterior wall of the sphenoid sinus. The ethmoidal air cells are divided into an anterior group, which drain into the middle meatus, and a posterior group, which drain into the superior meatus (located inferior to the superior turbinate).

The size of each maxillary sinus is estimated to be 6 to 8 mL at birth, and growth continues into puberty. By adulthood, the maxillary sinus has a capacity of around 15 mL. Its anterior wall is the facial surface of the maxilla, and the posterior wall corresponds to the infratemporal surface of the maxilla. Its roof is the inferior orbital floor and is about twice as wide as its floor. The medial wall of the sinus forms part of the lateral nasal wall and carries the ostium of the sinus, which is located in the infundibulum of the middle meatus. Accessory ostia are present in 25% to 30% of individuals.

At birth, the size of the two sphenoid sinuses is small. By the late teens, most of the sinuses are fully developed. The sphenoid sinuses are frequently asymmetrical. The optic nerve, internal carotid artery, nerve of the pterygoid canal, maxillary nerve, and sphenopalatine ganglion may all appear as impressions indenting the walls of the sphenoid sinuses. The sphenoid sinus drains into the sphenoethmoid recess above the superior turbinate.

Blood is supplied to the paranasal sinuses by the ophthalmic artery (frontals), the maxillary artery (maxillary sinuses), and branches from the internal and external carotids. For several paranasal sinuses, venous blood drains into the cavernous sinus, which is the reason why, in rare cases of sinusitis (particularly in the ethmoids), cavernous sinus thrombosis can occur. Sensory innervation is supplied by the trigeminal nerve. The maxillary sinuses also receive parasympathetic innervation via the preganglionic vidian nerve, which synapses at the sphenopalatine ganglion.

There are many theories as to the function of the paranasal sinuses including imparting additional voice resonance, humidifying and warming inspired air, secreting mucus to keep the nose moist, and providing thermal insulation for the brain. It is also believed that the paranasal sinuses form a collapsible framework to help protect the brain from frontal blunt trauma.

Paranasal Sinus Disease

The most common disease afflicting the paranasal sinuses is sinusitis (i.e., infection/inflammation of the lining mucous membranes and possibly the underlying bone). Sinusitis is often accompanied by rhinitis, thus the term *rhinosinusitis*. Rhinosinusitis ranges from a self-limited acute bacterial infection, most often following a viral upper respiratory infection, to a chronic inflammatory disease. Less common disease entities involving the paranasal sinuses are benign and malignant tumors.

Epidemiology

Recent analysis of the disease burden posed by sinusitis revealed that it was an important cause of emergency room visits and that its health care costs exceeded those of ulcer disease, acute asthma and hay fever.[78] Acute bacterial rhinosinusitis is estimated to complicate up to 2.0% of viral upper respiratory tract infections.[79] This translates into more than 20 million cases of acute bacterial rhinosinusitis in the United States annually. Chronic rhinosinusitis is also very common, with one conservative estimate suggesting that it results in 18 to 22 million U.S. physician office visits annually.[80] The impact on health care expenditure is therefore considerable. Ray and colleagues[81] estimated the 1996 total direct and attributable health care expenditures for the treatment of sinusitis to be $5.8 billion. Several studies have shown that patients with chronic rhinosinusitis have significantly worse overall quality of life compared with the U.S. general population and to patients with various other chronic diseases such as sciatica/back pain, chronic obstructive pulmonary disease (COPD), and angina.

Definitions and Diagnosis

The diagnosis of rhinosinusitis is difficult to make because other nasal diseases, such as allergic rhinitis and viral upper respiratory tract infections, can present with similar clinical symptoms. Yet, misdiagnosing rhinosinusitis leads to erroneous management and might result in prescribing antibiotics that may not be necessary. Most experts agree with the division of rhinosinusitis into acute, acute recurrent, and chronic rhinosinusitis categories based on the duration of illness. Acute rhinosinusitis has an acute onset of symptoms that lasts up to 4 weeks but completely resolves within that timeframe. When symptoms of a viral upper respiratory tract infection last longer than 10 days, worsen after 5 days, or are disproportionate to symptoms seen with a typical upper respiratory tract infection, the diagnosis of acute bacterial rhinosinusitis should be considered. Recurrent acute rhinosinusitis is defined as four or more episodes of acute bacterial rhinosinusitis each year with complete resolution of symptoms between episodes. Last, patients who are symptomatic beyond 12 weeks of medical therapy have chronic rhinosinusitis. Computed tomography (CT) changes 4 weeks or more after an appropriate medical treatment regimen for a single acute episode of acute bacterial rhinosinusitis are also indicative of chronic rhinosinusitis.

An attempt to establish symptom-based definitions for rhinosinusitis was made by the American Academy of Otolaryngology–Head and Neck Surgery in 1997.[82] They divided symptoms that could be associated with rhinosinusitis into major and minor (Table 43-2). However, additional physical findings are now required before the diagnosis can be made. For example, purulent drainage, polyps, and polypoid changes are sufficient to make the diagnosis of chronic rhinosinusitis if the 12-week-duration criterion is met. Mucosal abnormalities of the middle meatus (the narrow passage lateral to the middle turbinate where most sinuses drain) or ethmoidal bulla are also concrete signs of inflammation but usually cannot be confirmed by anterior rhinoscopy, so nasal endoscopy is recommended.

In general, the diagnosis of both acute bacterial and chronic rhinosinusitis is made on the basis of clinical criteria (duration and physical examination). Imaging is helpful in some cases. CT is the preferred radiologic diagnostic examination for visualizing the paranasal sinuses. In acute sinusitis, air-fluid levels are not infrequent, but their absence does not rule out the diagnosis (Fig. 43-4). Unless a compelling diagnostic or treatment dilemma exists, imaging should be performed to rule out residual chronic rhinosinusitis after maximal medical treatment. Plain sinus radiographs lack appropriate sensitivity and specificity and are not recommended as a routine procedure in the diagnosis of rhinosinusitis unless no CT option exists.

In chronic rhinosinusitis, other diagnostic tests may be indicated, such as skin testing or in vitro testing to assess the presence of concomitant allergic rhinitis, immunoglobulin quantitation to rule out immune deficiencies, sweat chloride testing to rule out cystic fibrosis, and nasal biopsy with electron microscopy to rule out immotile cilia syndrome. These procedures may help in the differential diagnosis, which is outlined in Table 43-3.

Allergic fungal rhinosinusitis is a distinctive form of chronic rhinosinusitis. This is usually characterized by nasal polyposis, inspissated greenish secretions with concretions showing a large number of eosinophils (allergic mucin), positive fungal identification by histology or culture, and characteristic CT and magnetic resonance imaging findings.[83] The most commonly isolated fungi are *Bipolaris* and *Aspergillus* species.

TABLE 43-2. Factors Associated with the Diagnosis of Rhinosinusitis

MAJOR FACTORS
Facial pain/pressure*
Nasal obstruction/blockage
Nasal discharge/purulence/discolored postnasal drainage
Hyposmia/anosmia
Purulence in nasal cavity on examination
Fever (acute rhinosinusitis only)
MINOR FACTORS
Headache
Fever (all nonacute)
Halitosis
Fatigue
Dental pain
Cough
Ear pain/pressure/fullness

*Facial pain/pressure alone does not constitute a suggestive history for rhinosinusitis in the absence of another major nasal symptom or sign.
From Lanza DC, Kennedy DW: Adult rhinosinusitis defined. Otolaryngol Head Neck Surg 117:S1–S7, 1997.

Pathophysiology

Acute Rhinosinusitis. Viral rhinosinusitis commonly occurs during a viral upper respiratory tract infection. A study reported by Gwaltney and coworkers in 1994[84] showed that approximately 60% of subjects with a viral upper respiratory tract infection had abnormalities in the ethmoid and maxillary sinuses on CT. These, however, resolve spontaneously with time. Acute bacterial sinusitis occurs mostly as a consequence of viral rhinosinusitis. The most common organisms cultured in cases of acute bacterial rhinosinusitis are listed in Table 43-4.

Chronic Rhinosinusitis. The role of bacteria in chronic rhinosinusitis is less well established. A variety of organisms have been cultured from the paranasal sinuses including α-hemolytic *Streptococcus*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and anaerobes. The relationship between these organisms and clinical disease is not definitive and is confounded by the fact that most of these organisms are cultured at the time of surgery after prolonged antibiotic treatment, thus possibly representing colonization.

There is increasing evidence that chronic rhinosinusitis is an inflammatory mucosal disease with the characteristics of inflammation being very similar to those of

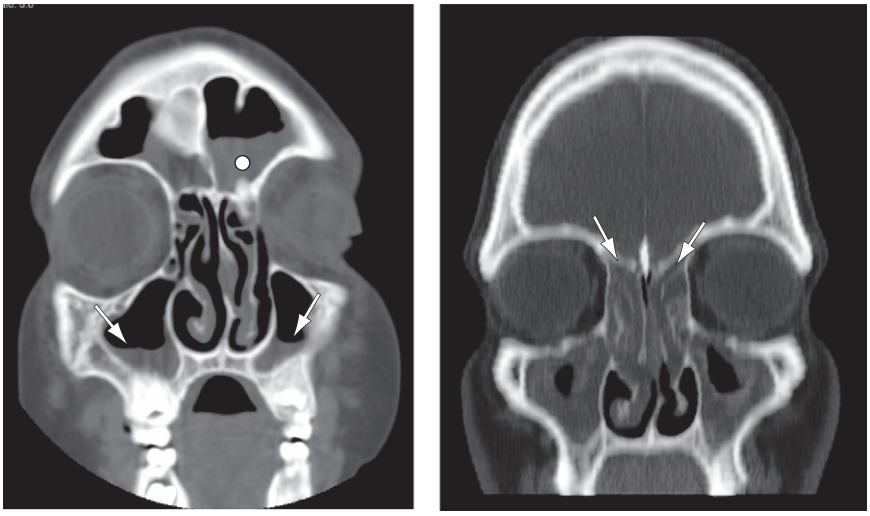

FIGURE 43-4 ■ Paranasal sinus computed tomography. *Left,* An image from a patient with acute rhinosinusitis with air-fluid levels in both maxillary sinuses (*arrows*) and the left frontal sinus (*dot*). *Right,* A scan from a patient with chronic rhinosinusitis and intranasal polyposis. Note the almost complete opacification of both ethmoid (*arrows*) and maxillary sinuses.

TABLE 43-3. Differential Diagnosis of Rhinosinusitis

ALLERGIC RHINITIS
Seasonal
Perennial
Combined seasonal and perennial
Allergic fungal rhinosinusitis

NONALLERGIC RHINITIS
Nonallergic, noninflammatory idiopathic rhinopathy (vasomotor rhinitis)
Nonallergic rhinitis with eosinophilia syndrome (NARES)
Cold dry air–induced rhinitis
Gustatory rhinitis

INFECTIOUS RHINOSINUSITIS
Bacterial
Viral
Fungal
Granulomatous

DRUG-INDUCED RHINITIS
Oral contraceptives
Various antihypertensives and ocular β-blockers
Topical decongestants (rhinitis medicamentosa)
Phosphodiesterase-5 antagonists

MECHANICAL CAUSES OF RHINOSINUSITIS
Septal deviation
Nasal foreign body
Choanal atresia or stenosis
Adenoid hypertrophy
Encephalocele
Glioma
Dermoid

INNATE AND ACQUIRED IMMUNITY DISORDERS
Congenital or acquired immunodeficiencies
Cystic fibrosis
Immotile cilia syndrome

SYSTEMIC INFLAMMATORY DISORDERS
Sarcoidosis
Wegener's granulomatosis
Vasculitis

NEOPLASTIC CAUSES
Benign: polyps, nasopharyngeal angiofibroma, inverting papilloma
Malignant: adenocarcinoma, squamous cell carcinoma, aesthesioneuroblastoma, lymphoma, rhabdomyosarcoma

TABLE 43-4. Microbiology of Acute Rhinosinusitis in Adults

Organism	Range of Prevalence (%)
Streptococcus pneumoniae	20–43
Haemophilus influenzae	22–35
Streptococcus spp.	3–9
Anaerobes	0–9
Moraxella catarrhalis	2–10
Staphylococcus aureus	0–8
Other	4

asthma. Eosinophilic infiltration of the diseased mucosa has been found to be a characteristic feature.[85,86] Driscoll and associates[87] showed an increase in the number of $CD4^+$ T lymphocytes in the sinus tissue of children with chronic rhinosinusitis when compared with adult sphenoid tissue obtained at the time of transsphenoidal hypophysectomy, regardless of allergic status. Two studies by Hamilos and colleagues[51,86] demonstrated a preponderance of proinflammatory cytokines such as IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF) in the tissues of patients with chronic rhinosinusitis with significantly higher levels of the Th2 cytokines IL-4 and IL-5 in patients with chronic rhinosinusitis and allergic rhinitis.

The causes leading to the development of chronic inflammation in the paranasal sinuses are unknown. The possibility of anatomic abnormalities leading to obstruction should be considered, although it would be difficult to explain the simultaneous involvement of several paranasal sinus cavities. In most patients with chronic rhinosinusitis, a generalized airway inflammatory disease is present, and the links between rhinitis, sinusitis, and asthma have been very well established.[88] Allergy to inhalants could potentially explain this inflammatory disease, but no more than 50% of patients with chronic rhinosinusitis cases are atopic.[89] Allergic fungal sinusitis appears to represent a distinct subgroup of chronic rhinosinusitis of atopic etiology. It is thought that its pathophysiology is similar to that of allergic bronchopulmonary aspergillosis (ABPA), but definitive evidence is missing. It has been proposed that, perhaps, chronic rhinosinusitis results from an abnormal host response to naturally colonizing fungus, not necessarily of allergic nature. This hypothesis is currently being tested with the use of nebulized antifungal agents.[90] More recently, investigators have demonstrated that many patients with chronic rhinosinusitis have evidence of significant laryngopharyngeal reflux.[59,91–93] This is particularly evident when one assesses reflux events as evidence of pH excursions less than 5 rather than less than 4.

Immune deficiencies, immotile cilia syndromes, and cystic fibrosis produce generalized airway inflammation with a strong chronic rhinosinusitis component, suggesting that some yet unidentified functional abnormality of the respiratory mucosa, possibly related to the innate immunity, may constitute the predisposing factor for the majority of cases that remain unexplained.

Management

Antimicrobial Therapy.

Acute Rhinosinusitis. When bacterial rhinosinusitis is suspected, it should be treated with a first-line antibiotic, such as amoxicillin, along with an intranasal decongestant, the purpose of which is to decrease nasal edema and facilitate sinus drainage.[94] In areas where resistance is high, if a patient has had an antibiotic within the past 2 months or fails the first-line antibiotic (no improvement within 72 hr), a second-line antibiotic should be given,

such as amoxicillin-clavulanate, high-dose amoxicillin-clavulanate, cefpodoxime, cefuroxime, or a quinolone (levofloxacin, gatifloxacin, or moxifloxacin). Clindamycin is very effective if resistant *S. pneumoniae* is suspected, but it does not provide appropriate coverage against *H. influenzae* or *M. catarrhalis*. Antibiotic therapy should continue for 5 to 7 days after the patient's symptoms resolve, resulting in a typical treatment duration of 10 to 14 days. It is to be kept in mind that some studies show no significant difference in symptom resolution in uncomplicated acute rhinosinusitis when placebo and various antibiotics are compared.[95,96] Thus, many cases of uncomplicated acute disease are probably self-limited and may not need antibiotic treatment. These decisions should be individualized on the basis of the general clinical picture of the patient. For example, patients who are quite ill and present with such symptoms as fever, severe headaches, or eye swelling should be treated aggressively to avoid potential complications, which include subperiosteal orbital abscess or even brain abscess.

Chronic Rhinosinusitis. Despite the doubts as to the role of bacterial infection, antibiotics remain the primary therapy for chronic rhinosinusitis. The choice of antibiotic is essentially the same as for acute rhinosinusitis, except that amoxicillin is not the first choice. If an anaerobe or resistant *S. pneumoniae* is suspected, clindamycin is a reasonable option. In patients in whom a course of empirical therapy fails, there might be an advantage in obtaining a culture to be able to better direct antimicrobial therapy. Although maxillary sinus puncture is the best way to obtain a culture, it is invasive and uncomfortable to the patient. An endoscopically directed middle meatal culture has been shown to correlate reasonably well with cultures of the sinus cavities and is a less invasive alternative.[97] Antibiotic nebulization has been used to treat exacerbations of rhinosinusitis in patients who have had prior surgery, but no controlled studies are available.[98] In unoperated patients, penetration of nebulized antibiotics into the sinus cavities has not been shown.

Adjuvant Therapy. Besides antibiotics, multiple other therapies have been used in the treatment of sinus disease. They include saline irrigations or steam inhalations, topical and systemic decongestants, topical and systemic steroids, and mucoevacuants.

Nasal Saline. The rationale behind the use of saline for the treatment of rhinosinusitis is based on its potential beneficial effects on mucociliary clearance, as well as on the moisturizing effect, which reduces crusting of nasal secretions. Several reports suggest a beneficial effect of variously administered saline preparations (nose drops, nose sprays, nebulization, irrigation) at different concentrations (isotonic, hypertonic) to control symptoms of rhinosinusitis.[9,99]

Uren and coworkers[100] have demonstrated the efficacy of mupirocin in the treatment of chronic rhinosinusitis after surgery with evidence of nasoendoscopically directed *S. aureus*.

Decongestants. Both systemic and topical decongestants are used as adjuncts to antibiotics in the treatment of acute and chronic sinusitis. The rationale behind their use is based on their possible role in improving ostial patency and reducing turbinate swelling and congestion. Controlled studies are lacking to support the clinical efficacy of either systemic or topical decongestants in the treatment of rhinosinusitis. Because of their superior potency compared with systemic agents, topical decongestants may be more useful. As mentioned in the management of rhinitis section, the use of topical decongestants in conjunction with antibiotics for acute rhinosinusitis should be limited to a few days during the acute period.

Mucolytics. High viscosity of mucus is thought to contribute to the pathophysiology of chronic rhinosinusitis. Therefore, expectorants, mucolytics, and mucoregulatory agents are commonly used. Guaifenesin is such an agent. Except for one study showing a reduction in nasal congestion and thinning of postnasal drainage in human immunodeficiency virus (HIV)–positive patients with rhinosinusitis,[101] no controlled studies have demonstrated the efficacy of guaifenesin in the treatment of either acute or chronic rhinosinusitis.

Intranasal Glucocorticosteroids. Several studies treating patients with acute rhinosinusitis or exacerbations of chronic rhinosinusitis with oral antibiotics with or without intranasal corticosteroids have suggested that intranasal corticosteroids are useful adjunctive agents.[102,103] It is not clear, however, whether the use of intranasal steroids reduces the recurrence of acute rhinosinusitis. The speculated mechanism of action of these agents is a reduction in inflammation and a decrease in mucosal edema, facilitating paranasal sinus drainage and accelerating resolution.

The evidence supporting the efficacy of intranasal corticosteroids in the treatment of chronic rhinosinusitis is less convincing than that for acute disease, and both positive and negative results have been reported.[104,105] However, it seems very reasonable to use these agents in subjects with allergic rhinitis, in whom the data on nasal symptoms are convincing.

Sachanandani and associates[106] showed the efficacy and safety of intranasal sinus rinse irrigation using budesonide respules in the treatment of chronic rhinosinusitis.

Systemic Corticosteroids. The use of systemic steroids has not been well studied in rhinosinusitis. Clinical experience, however, suggests that these agents are beneficial. Also, beneficial effects are often seen in the medical treatment of nasal polyps, which are strongly associated with chronic rhinosinusitis. However, continuous treatment with systemic steroids is not advocated. Oral steroids should be utilized in the form of short courses during acute exacerbations or prior to obtaining a CT scan to evaluate residual disease after maximal medical treatment.

Anti-Immunoglobulin E Therapy. Several studies have now shown that omalizumab, a monoclonal antibody that binds human IgE and prevents binding to mast cells and basophils, is efficacious in the treatment of allergic rhinosinusitis,[107] as shown by the example of a patient with persistent and refractory asthma, nasal polyposis and chronic rhinosinusitis who made a striking improvement after treatment with omalizumab.[108]

Surgery. When patients fail maximal medical treatment and have evidence of residual disease in the paranasal sinuses on CT scan, referral for consideration of surgical drainage is appropriate. Surgery might also provide relief to patients with recurrent acute disease who have obstructing anatomic abnormalities such as severe septal deviation, Haller cells (air cells that compromise drainage of the maxillary sinuses), or concha bullosa (a pneumatized middle turbinate that can obstruct the middle meatal drainage path). This is usually performed using functional endoscopic sinus surgery, which can fix the previously discussed abnormalities, can widen sinus drainage sites, and can remove obstructive polyps and hypertrophied mucosa. Symptoms and quality of life scores significantly improve in more than 75% of adults and children who undergo surgery for chronic rhinosinusitis.[109] However, endoscopic sinus surgery, as well as other forms of more aggressive surgery, does not, in most cases, offer a cure for the disease; and recurrence is not uncommon.[110]

THE PHARYNX AND HYPOPHARYNX

Structure and Function

The pharyngeal airway travels from the back of the nasal passages to the supraglottic space (see Fig. 43-2). The nasopharyngeal segment ends at the rim of the soft palate, and the oropharyngeal/hypopharyngeal segments extend beyond this point to the aryepiglottic folds. Several bony structures surround the pharyngeal airway (i.e., the cervical vertebrae, mandible, and hyoid bone). The size and physiologic functions are controlled by the activity of the tongue, the intrinsic muscles in the pharyngeal wall, and the inframandibular and cervical strap muscles.

The nasopharyngeal segment adapts to high inspiratory and expiratory flows, such as during exercise, by changes in palatal and tongue position. The soft tissues and muscles of the oropharynx (see Table 43-1) permit a wide range of changes in its conformation and mechanical properties. Liquids and solids are actively propelled into the esophagus by constriction of extrinsic muscles surrounding the oropharynx, whereas air flows passively through this segment as the genioglossus and strap muscles are activated to maintain airway patency during inspiration. The activity of these muscles can be augmented by several factors, including airflow obstruction, chemical stimuli, pressure, and air flow in the upper airways.[111]

Clinical Disorders

Disorders of concern are listed in Table 43-5. Obstructive sleep apnea is covered in detail in Chapter 79. Obstruction of the extrathoracic airway should be considered when (1) patients present with obvious symptoms and signs of stridor or upper airway compromise; (2) there is chronic cough or sore throat; (3) obstructive airways disease has been suspected and/or diagnosed in the absence of definitive findings consistent with asthma or COPD; or (4) these conditions are present but demonstrate pronounced worsening not controlled with standard medication.

TABLE 43-5. Causes of Pharyngeal Obstruction

Malignant or benign tumors (e.g., papillomas, polyps)
Infection (e.g., croup, epiglottitis, tonsillar abscess)
Edema or hypertrophy (e.g., angioneurotic edema, anaphylactic reactions, postradiation therapy, obstructive sleep apnea)
Trauma (e.g., cricoid fracture, cervical subluxation, precervical hematoma)
Burn injury
Extrinsic compression (e.g., goiter or pregnancy-related thyroid enlargement)
Foreign body
Congenital web (infants)
Sarcoidosis and other granulomatous diseases
Amyloid

Foreign bodies and congenital webs are the most common abnormalities in infants and toddlers, whereas in the older population, tumors (both benign and malignant) and pharyngeal manifestations of systemic diseases such as sarcoidosis or collagen vascular diseases are of greatest concern.

Acute obstruction is commonly caused by infections such as of the supraglottitis. This is commonly due to *S. aureus* and *Streptococcus* species. Adult croup is often viral in etiology rather than bacterial. Retropharyngeal abscesses as well as dental, sublingual, submandibular, and other oral cavity infections are commonly due to *Streptococcus* or oral anaerobic species.

Causes of gradually developing pharyngeal obstruction include pharyngeal stenosis due to prior injury or inflammation and gross enlargement of the tonsils. Children in particular may have tonsil or lingual enlargement due to chronic infections. A combination of enlarged tonsils and adenoids in childhood may result in severe airflow obstruction, particularly during sleep, with pulmonary edema or chronic alveolar hypoventilation, hypoxemia, and cor pulmonale. Fortunately, this syndrome rapidly reverses after tonsillectomy and adenoidectomy.

THE LARYNX

Structure and Function

The larynx, the enlarged upper end of the trachea below the base of the tongue, consists of nine cartilages bound together by an elastic membrane and moved by a series of muscles (Fig. 43-5). The cavity of the larynx contains two sets of folds (also referred to as "cords"): the false vocal folds and the true vocal folds. The slitlike opening to the trachea is called the *glottis*. The larynx has three major physiologic functions: maintenance of a patent

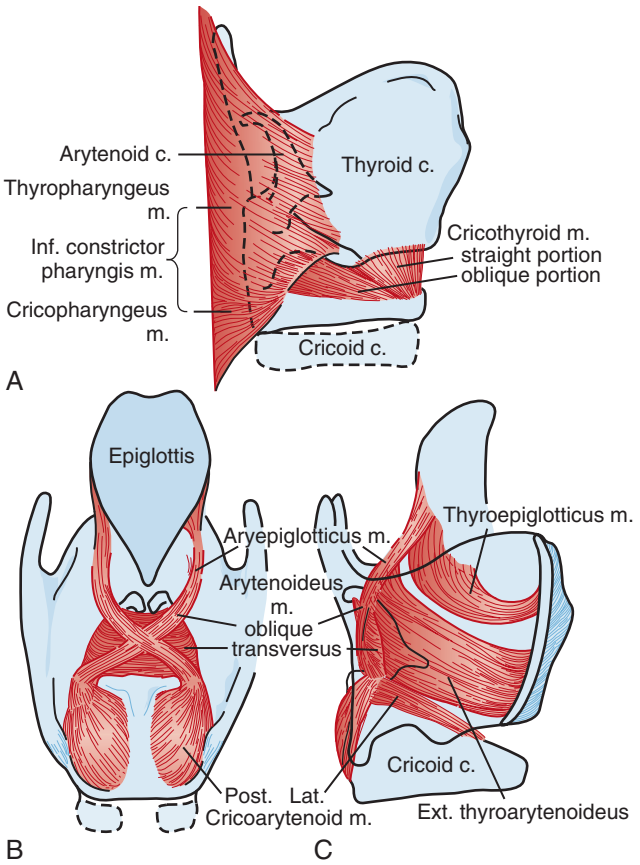

FIGURE 43-5 ■ Muscles of the larynx are shown from the right (**A**), from behind (**B**), and with the right side of the thyroid cartilage cut away (**C**). Note in **A** that the cricothyroid muscle can act to draw the thyroid cartilage toward the cricoid and can draw the thyroid cartilage forward on the sliding cricothyroid joint. (Redrawn from Proctor DF: Physiology of the upper airway. In Fenn WO, Rahn H [eds]: Handbook of Physiology. Washington, DC: American Physiological Society, 1964.)

airway, protection of the airway, and phonation. The laryngeal musculature is involved in the coordination of many important functions, including breathing, swallowing, coughing, phonating, and vomiting. The thyroid and cricoid cartilages provide the major skeletal support. During inspiration, the cross-sectional area between the vocal folds widens and is augmented during deep inspiration.[103] In contrast, the glottis narrows during expiration and may retard expiratory air flow. The movement of glottic structures is controlled by a number of muscles intrinsic to the larynx (Fig. 43-6; see also Table 43-1 and Fig. 43-5).

The caliber of the glottis orifice responds to changes in airflow pressure, temperature, and laryngeal position. In addition, irritant stimuli are capable of stimulating the cough and glottic closure reflexes that are central to protecting the lungs from exogenous noxious agents. The afferent pathway of the glottic closure reflex starts with sensory nerve endings/receptors in the larynx, trachea, and larger airways. The internal branch of the superior laryngeal nerve supplies the supraglottic larynx (epiglottis, aryepiglottic folds, false cords, superior surface of the laryngeal ventricle). The recurrent laryngeal nerve supplies sensory afferents for the glottic and subglottic structures (vocal cords, inferior surface of the laryngeal ventricle, trachea). Nerve impulses are transmitted through the vagus nerve to the nodose (inferior) ganglion and then to the fasciculus solitarius and the nucleus solitarius in the medulla. Major projections then go to the reticular formation, an area in the midbrain important for control of respiration.

The efferent (motor) fibers start in the somatosensory gyrus and pass through the internal capsule, where they partially decussate before joining the somatic motor nucleus (nucleus ambiguous) in the medulla. The nucleus ambiguus receives bilateral cortical input, and the vocal folds function simultaneously. The nucleus ambiguus is

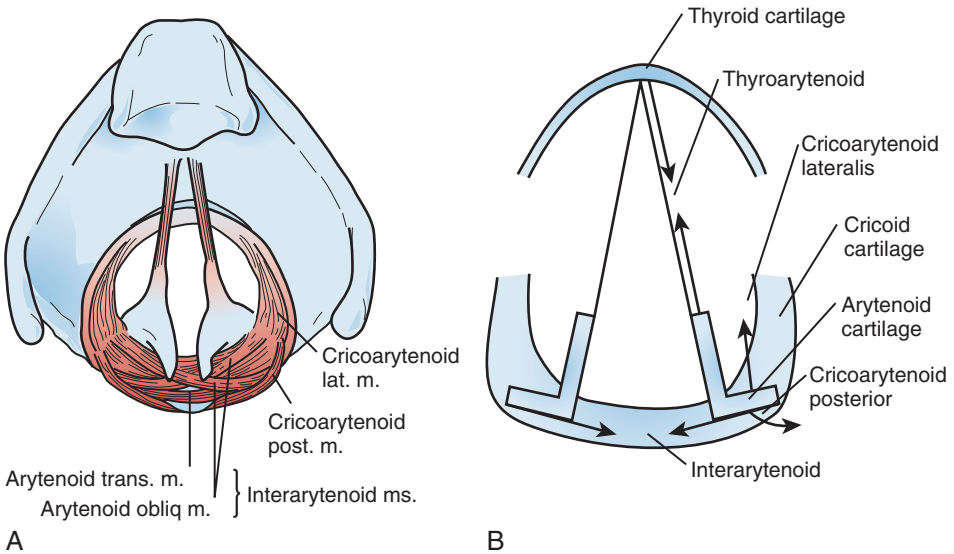

FIGURE 43-6 ■ The muscles involved in opening and closing the glottis. **A,** The cricothyroid muscle is omitted. **B,** The action of these muscles is diagrammed. (B, Redrawn from Proctor DF: Physiology of the upper airway. *In* Fenn WO, Rahn H [eds]: Handbook of Physiology. Washington, DC: American Physiological Society, 1964.)

responsible for the motor innervation of the glossopharyngeal, vagus, and spinal accessory nerves. Important branches of the vagus include the superior laryngeal nerve, which supplies motor innervation to the cricothyroid muscle, and the recurrent laryngeal nerve, which supplies the rest of the motor innervation to the larynx.

The cough and laryngeal closure reflexes are important for protecting the airway during deglutition but also in response to potentially noxious inhaled stimuli. Contraction of the glottic and supraglottic sphincters leads the vocal folds, false folds, and arytenoid cartilages to merge medially and occlude the airway. During swallowing, the larynx elevates under the base of the tongue and pushes the epiglottis out over the airway to act as a shield or roof. The rise in subglottic pressure against a closed glottis is important for the cough reflex but also provides a form of auto-positive end-expiratory pressure (PEEP) by increasing the intra-alveolar pressure. This has been used to advantage by severe asthmatics and those with emphysema to prevent or reduce airway collapse during expiration and thus promote better emptying. This mid to late expiratory closure as a means of creating auto-PEEP should not be regarded as dysfunctional or maladaptive.

Clinical Disorders

Table 43-6 lists acute and chronic causes of laryngeal obstruction. These are frequently associated with problems in the swallowing and phonation functions of the larynx. Acute causes are foreign bodies, accidents (direct, indirect, iatrogenic and noniatrogenic trauma, burns), infectious processes, and angioedema. Slowly developing obstruction has a wider spectrum of etiologies, including tumors and surrounding tissue enlargement, rheumatologic diseases affecting structural aspects of the larynx, and neurologic diseases.

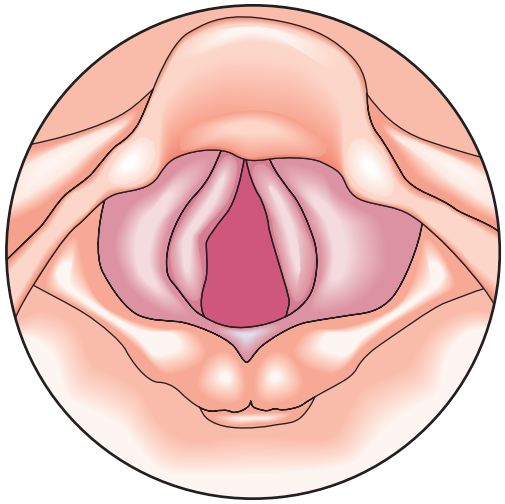
Neuromuscular mechanisms appear to play an important role in the modulation of patency in laryngeal disorders. Laryngeal airway obstruction can result from either decreases in abductor activity or increases in adductor activity (see Table 43-1). Decreased abductor activity accounts for the occurrence of inspiratory airflow obstruction in patients with unilateral and bilateral vocal cord paralysis, most often caused by damage to recurrent laryngeal nerves. When both recurrent laryngeal nerves are injured, the vocal cords move toward the midline (resulting from the action of the still-active cricothyroid muscles). This may go unrecognized because hoarseness may be only slight, and the narrowed airway may still permit limited physical activity for years. Gradually, glottic airflow obstruction increases, and the diagnosis may be made 10 to 20 years later, at which point, surgical intervention is necessary. A past history of a thyroidectomy is frequently elicited in these cases. Unilateral vocal cord paralysis[112] is diagnosed more frequently because for unknown reasons a patient with such a disorder is prone to aspiration and severe laryngospasm during sleep. In a significant percentage of patients, a search for the cause of this condition fails to uncover a specific etiology. The possibility of cervical or mediastinal malignancy or of aortic aneurysm encroaching on one recurrent laryngeal nerve (usually the left) must be considered.[113]

TABLE 43-6. Disorders Associated with Laryngeal Obstruction

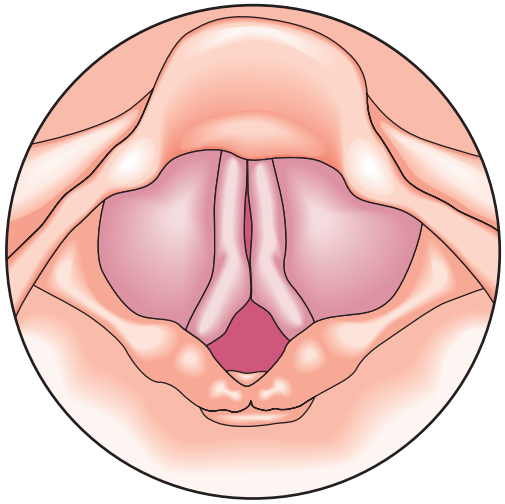
MAY BE ASSOCIATED WITH ACUTE ONSET OF OBSTRUCTION
Foreign bodies
Anesthesia and other states of unconsciousness
Intubation injury
Angioneurotic edema (idiopathic, anaphylactic, C_1-esterase deficiency)
Burn injury
Laryngeal or tracheal trauma
Croup
Epiglottitis
Infections involving surrounding structures
Deep neck infections
Ludwig's angina
Peritonsillar abscess
Retropharyngeal abscess
Malfunction of muscles stabilizing the airways
Syphilitic gumma, tabes dorsalis
USUALLY SLOWLY DEVELOPING OBSTRUCTION
Arthritis cricoarytenoid joint
Enlarged tonsils and adenoids
Esophageal foreign body
Histiocytoma
Laryngeal carcinoma, papilloma, cartilaginous tumors, angioma, cystic hygroma, congenital malformations, polyp, granuloma
Malignant metastases to cervical glands
Neurologic disease
Relapsing polychondritis
Thyroid tumors, malignant and benign
Tracheal cyst, stenosis from cylindroma, tracheomalacia
Vocal cord paralysis

Laryngospasm and Vocal Cord Dysfunction

Disorders in which increases in vocal cord adductor muscle activity lead to laryngeal airflow obstruction include laryngospasm and paradoxical vocal fold adduction or vocal cord dysfunction (VCD). VCD was originally described as paradoxical closure of the vocal folds during inspiration with a characteristic small posterior chink aperture through which patients moved air (Fig. 43-7).[114,115] The etiology and pathophysiology of laryngospasm remain poorly understood. Intubation, certain anesthetics, gastroesophageal reflux disease, and various other etiologies have been implicated.[116–125] As for VCD, it has historically been considered a functional or conversion disorder with terms applied such as "factitious asthma," Munchausen's stridor, or "hysterical asthma." More recently, there has been appreciation for the fact that there can be respiratory symptoms caused by paradoxical adduction of the vocal folds during inspiration and expiration with or without evidence of the posterior



A Normal vocal cords at mid-inspiration



B Vocal cord dysfunction with posterior chinking

FIGURE 43-7 ■ The appearance of the vocal cords during inspiration in a healthy subject (A) and during inspiration in a patient with vocal cord dysfunction (B) show adduction of the vocal cords with the characteristic posterior "chink" opening. (Redrawn from Perkner J, Fennelly K, Balkissoon R, et al: Irritant associated vocal cord dysfunction. J Occup Environ Med 40:136–143, 1998. ©American College of Occupational and Environmental Medicine.)

chink.[126] Morrison and associates[127] have recently introduced the term "irritable larynx syndrome" to encompass individuals with episodic laryngeal dysfunction triggered by irritant exposures with variable clinical manifestations including VCD, cough, muscle tension dysphonia, and globus sensation. Hence, compared with VCD, *irritable larynx syndrome* and *laryngeal dysfunction* are terms that are somewhat more inclusive or descriptive of the phenomenon of upper airway compromise masquerading as asthma. Furthermore, there is a greater appreciation that factors other than psychological problems, such as gastroesophageal reflux and, more specifically, laryngopharyngeal reflux,[127] posterior nasal drainage,[128] neurologic dystonias,[126] or intense irritant exposures,[129] can lead to laryngeal hyperresponsiveness. One may hypothesize that this is simply an accentuation of the normal physiologic reflex known as the glottic closure reflex. One study demonstrated that it was possible to lower the threshold for capsaicin stimulation of laryngeal nociceptor C fibers by pretreatment with halothane anesthetic.[130] Ayres and Gabbott[131] suggested that irritant/inflammatory insults to the region lead to an altered autonomic balance that is perpetuated by repeated local stimuli. Clinically, VCD remains an underrecognized disorder in many cases. Many patients are misdiagnosed as asthmatics for years and develop iatrogenic complications related to steroid therapy, which does not provide significant benefit. This adds to the psychological dimensions of this problem.

Clinical Presentation of Laryngeal Obstruction

The clinical presentation of laryngeal disorders is often ambiguous because breathing difficulties frequently masquerade as swallowing or voice disorders. Conversely, swallowing difficulties that result in failure to clear food particles from the throat may interfere with breathing. Laryngeal obstruction may be noted by the complaint of shortened phrasing and excessively effortful speaking, singing, or both. Conversely, laryngeal complaints often reflect disorders of the pharynx or esophagus such as gastroesophageal reflux disease.[132] Aside from patients being obviously dyspneic, the signs and symptoms of laryngeal obstruction vary according to the cause of the obstruction.

Acute obstruction due to foreign bodies, trauma, or anaphylactic reactions is associated with abrupt onset of throat constriction, panic, and inability to phonate. Cough may be muted or not possible if a foreign body is firmly lodged in the upper trachea such that passage of air is virtually impossible. Salivation may occur. Patients may grab at their throat to identify the point of blockage. Vital signs may show tachycardia and elevated blood pressure or the converse, depending on the degree of hypoxia and/or hypercarbia. Their level of consciousness is affected by the same factors. If the obstruction is almost complete, there may be virtually no audible breath sounds; whereas if the obstruction is partial, laryngeal wheezes (that transmit to the chest and may be mistaken as lower airway wheezing) are best heard directly over the trachea.

Slow-onset laryngeal obstruction may be associated with progressive dyspnea first noted only with exertional activity. Patients may also complain of a chronic dry cough, hemoptysis (rare), sore throat, and/or voice changes. In certain circumstances, patients with space-occupying lesions may also report orthopnea or shortness of breath in relation to positional changes of the neck and consequent compression of the upper airway. There may also be visible evidence of a neck mass such as an obvious goiter or more subtle signs such as asymmetry, bulge, or displacement of the trachea. Individuals with cerebral vascular accidents or central nervous system neoplasms may demonstrate facial asymmetry or cranial nerve deficits.

Evaluation of these patients involves physical examination and various ancillary tests to confirm paradoxical closure of vocal cords and to rule out other disorders or contributory factors. Physical examination may be relatively unremarkable except for direct detection of laryngeal wheezing or stigmata of posterior nasal drainage or gastroesophageal reflux (epigastric tenderness). Skin, neurologic, and musculoskeletal examination is helpful to identify lesions that may explain symptoms as well as signs of rheumatologic or collagen vascular diseases.

Spirometry often provides compelling evidence that an upper airway obstructive process is operative. These patients demonstrate a pattern of extrathoracic airway obstruction on flow-volume loops (truncated inspiratory loop) obtained during an attack (Fig. 43-8). It should be emphasized that these patients may demonstrate flattening in the early segment of the expiratory loop as well. Vlahakis and colleagues[126] reported evidence of an inspiratory flow plateau on the open shutter loop during body plethysmography of a patient with laryngoscopy-confirmed VCD. The utility of this noninvasive measurement requires validation. Radiographic studies are generally not helpful in establishing the diagnosis of VCD but do help to rule out space-occupying lesions that may be due to neoplasm, infection, or chronic inflammatory disease.

Although spirometry can be an extraordinarily useful screening tool for VCD, particularly when the patient is symptomatic, direct visualization of the upper airway is the "gold standard" for making a definitive diagnosis and assessing the nature and severity of the cause of obstruction. Flexible fiberoptic rhinolaryngoscopy is most often sufficient for the evaluation. In the case of an emergent problem involving the upper and possibly the tracheal airway, rigid bronchoscopy may be needed to secure a patent airway. This requires general anesthesia and performance by experienced personnel.

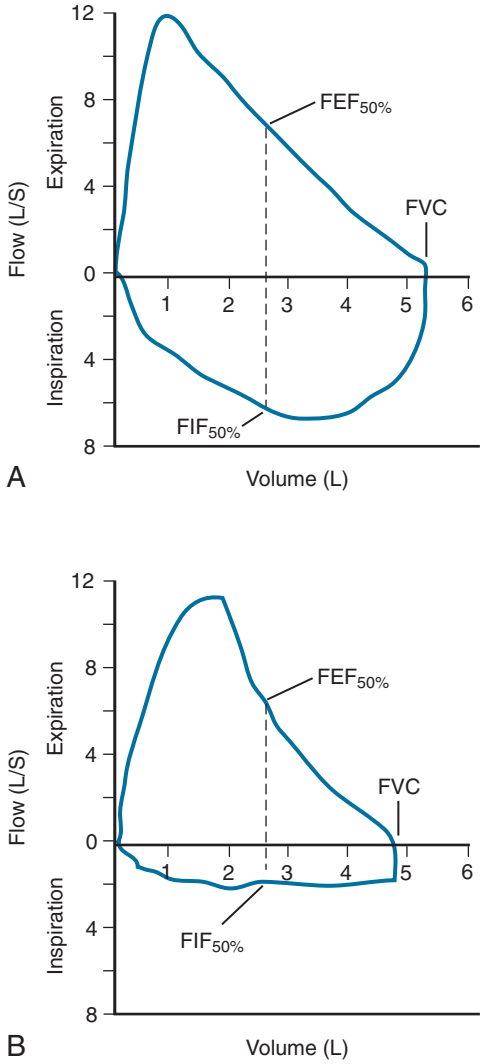


FIGURE 43-8 ■ A, Normal flow volume loop. B, Extrathoracic airflow obstruction with truncation of the inspiratory loop. This is consistent with symptomatic vocal cord dysfunction but may be seen in other laryngeal diseases. FEF_{50}, forced expiratory flow at 50% FVC; FIF_{50}, forced inspiratory flow at 50% FVC; FVC, forced vital capacity. (Redrawn from Perkner J, Fennelly K, Balkissoon R, et al: Irritant associated vocal cord dysfunction. J Occup Environ Med 40:136–143, 1998. ©American College of Occupational and Environmental Medicine.)

Management of Laryngeal Obstruction

Treatment of obstruction of the laryngeal airway is dependent on the etiology. In cases of emergent airway compromise, the key objectives are establishing adequate oxygenation and gas exchange. Ideally, patients are mildly sedated and kept awake if possible. The use of paralytic agents should be avoided, particularly if it is difficult to intubate the patient. The physician should be alerted to evaluate these patients by laryngoscopy during and soon after intubation. In cases in which associated severe tracheal obstruction (e.g., burns, trauma, invasive tumors) is present, one can consider the use of an open ventilating rigid bronchoscope that allows for a secure airway during visualization and ensures adequate oxygenation. Insertion of a rigid bronchoscope also serves the purpose of dilating an acutely narrowing airway. Once the airway is secured, a detailed examination of the upper airway and the tracheobronchial tree can be performed. In cases of massive trauma, patients are intubated for general support; and laryngeal obstruction due to fractures of the laryngeal cartilages, arytenoid cartilage dislocation, hematoma formation, and bilateral vocal cord paralysis can be overlooked or missed and appreciated only after the patient is extubated.

Upper airway obstruction due to laryngeal dysfunction requires the identification of contributing factors (medications, underlying medical problems such as gastroesophageal reflux disease and postnasal drip, psychological factors) and their optimal treatment.[133] Understanding the complex nature of the pathophysiology of VCD and laryngeal dysfunction underscores the need for a multidisciplinary approach.[134]

Speech and language pathologists/therapists specifically trained to address laryngeal dysfunction and to provide instruction in techniques of throat relaxation,

cough suppression, and throat-clearing suppression play a central role in the management and follow-up of VCD.[135] Speech therapists may also be helpful in performing controlled irritant challenges in which individuals are serially exposed to increasing concentrations of a provocative agent and are coached by the therapist during these exposures on how to control their laryngeal response or how to abort an acute attack.

Psychosocial assessment and treatment is key in managing these patients because there is generally some degree (though highly variable) of psychological overlay, either preexisting or as a consequence of developing VCD. Input from psychologists and/or psychiatrists regarding evidence of conversion, panic, anxiety, affective personality, or posttraumatic stress disorder is helpful. In addition, patient education and reassurance are extremely important in managing these patients. Follow-up with supportive counseling and teaching relaxation and/or biofeedback techniques may also be beneficial. Clinicians should discontinue unnecessary medications such as bronchodilators and steroids if coexistent asthma has been ruled out. Treatment for associated gastroesophageal reflux disease and/or rhinosinusitis may reduce symptoms.

Acute severe episodes of laryngeal dysfunction may generally be controlled and managed with sedation and/or heliox (80% helium/20% oxygen).[136] More recent studies have suggested that a simple device that creates resistance during the inspiratory phase can relieve VCD attacks.[137] Topical lidocaine applied to the larynx may also be useful during acute episodes in select patients. In severe cases, superior laryngeal blocks with *Clostridium botulinum* toxin have been attempted with variable success.[138] This treatment has been more successful for muscle tension dysphonia than for VCD.[139] Tracheotomy has been used for some patients with severe VCD refractory to conventional therapy, but it is rarely (if ever) indicated.

KEY POINTS

- As the conduit and indeed the gateway for air destined for the lungs, the upper airway plays a critical role in filtering and conditioning inspired air before it passes to the lower airways.
- Olfaction, allergic responses, nonallergic inflammation, and accentuated laryngeal closure reflexes serve as warning signals and barriers to the entry of noxious or potentially harmful inhalants from reaching the lungs.
- Clinicians who have an appreciation of the important role of the upper airway are better equipped to manage their patients with lower airway disease.

CHAPTER 44

DISORDERS OF THE INTRATHORACIC AIRWAYS

Stephen C. Lazarus, MD

INTRODUCTION

DISORDERS WITH DIFFUSE INVOLVEMENT

Anatomic and Physiologic Features
Epidemiology
Bronchiolitis
Bronchiolitis Obliterans (Obliterative Bronchiolitis)
Bronchiolitis Obliterans and Connective Tissue Diseases
Bronchiolitis Obliterans after Bone Marrow Transplantation
Bronchiolitis Obliterans after Lung or Heart-Lung Transplantation
Bronchiolitis Obliterans with Organizing Pneumonia (Cryptogenic Organizing Pneumonitis)
Treatment of Bronchiolitis Obliterans and Bronchiolitis Obliterans with Organizing Pneumonia
Respiratory Bronchiolitis
Panbronchiolitis
Follicular Bronchiolitis
Bronchopulmonary Dysplasia

LOCALIZED DISORDERS

Neoplasms
Bronchial Compression
Mediastinal Fibrosis (Fibrosing Mediastinitis)
Foreign Bodies
Granulomatous Inflammation
Broncholithiasis
Amyloidosis
Bronchomalacia
Traumatic Injury
Clinical Features
Diagnosis
Treatment
Tracheobronchial Stents

INTRODUCTION

Previous chapters in this section have described the major diseases that affect primarily intrathoracic airways: asthma, bronchitis, cystic fibrosis, and bronchiectasis. There are, in addition, a number of less common entities that involve these airways. Bronchiolitis, bronchiolitis obliterans, and bronchopulmonary dysplasia are diseases of the peripheral airways. In addition, mucus plugging of small airways can occur acutely or chronically in association with a number of diseases. Because of the large cross-sectional area of these peripheral airways, early diagnosis may be difficult. However, the widespread involvement of small bronchi and bronchioles may have major physiologic consequences. Increasing awareness of these diseases has led to an increased frequency of diagnosis. In contrast to these generalized diseases of the peripheral airways, there are also a number of conditions whose effects are localized to more central airways. In this chapter, both the local and the diffuse processes involving intrathoracic airways are discussed. In addition, the use of tracheobronchial stents to treat proximal airway obstruction is described.

DISORDERS WITH DIFFUSE INVOLVEMENT

Anatomic and Physiologic Features

Intrapulmonary airways can be subclassified as bronchi, bronchioles, and gas exchange ducts (see Chapter 1). Although all the conducting airways contain smooth muscle, there are important differences that distinguish bronchi from bronchioles. *Bronchi* contain cartilage, submucosal glands, ciliated epithelial cells, and goblet

cells. Bronchial smooth muscle is innervated by muscarinic output carried in the vagus nerves. Nerve endings responsible for cough ("cough receptors") are found in the large bronchi, mostly at bifurcations. Because of their limited total cross-sectional area, the bronchi are responsible for most of the resistance to airflow in the lung.[1]

In contrast to bronchi, *bronchioles* normally do not contain cartilage, glands, or goblet cells. In many chronic diseases of the airways (e.g., chronic bronchitis, asthma, cystic fibrosis), increased numbers of goblet cells are found in peripheral airways, and they are thought to play significant roles in the pathophysiology of these diseases.[2] Cilia are more sparse in bronchioles than in bronchi, and bronchiolar smooth muscle is not under vagal control. Repeated branching creates a large number of bronchioles arranged in parallel. This results in a large total cross-sectional area, such that bronchioles normally contribute little to total airflow resistance. However, when disease affects large numbers of these peripheral airways, the impact on airway resistance is significant.

Because the walls of the airways are not rigid, their dimensions change with lung volume. The bronchioles are located in the connective tissue structure of the lung, and their walls are relatively thin.[3] Although the contribution of bronchioles to total airflow resistance is small at normal and high lung volumes, they narrow markedly at low lung volumes, and their contribution to resistance increases as residual volume is approached. This increased narrowing explains why normal peripheral bronchioles may close at low lung volumes.[4]

Narrowing of peripheral airways may have profound effects on lung function. For example, local peripheral airway narrowing may decrease ventilation to a diseased area, leading to hypoxemia, but this narrowing may not produce wheezing or striking increases in the total work of breathing. For these reasons, pathologic narrowing of peripheral airways is difficult to detect, and these airways may be considered a "silent zone" of the lung. Despite much effort to design tests to identify obstruction in peripheral airways, no method has been entirely successful (see Chapter 24).

Epidemiology

The frequency of disorders of the peripheral airways is unknown because of the difficulty of localizing abnormalities to these sites. Moreover, because of the continuity between bronchi and bronchioles, it is doubtful whether pure bronchitis or bronchiolitis ever exists. Indeed, some authors prefer to avoid making an anatomic distinction about the site of inflammation and collectively refer to these peripheral airways (<2 mm in diameter) as "small airways."[5] Processes that obstruct small airways may result in severe functional disability.

Bronchiolitis

Bronchiolitis, a cellular and mesenchymal reaction involving bronchioles, is relatively uncommon in adults. Although bronchiolitis may occur in response to various stimuli, identification may be delayed because of the difficulty in detecting this narrowing. Bronchiolitis has been reported after administration of busulfan, gold, or penicillamine.[6] A generalized inflammatory response of the peripheral airways may follow inhalation of a corrosive gas that penetrates deeply into the lungs. Because they are highly soluble, irritants such as sulfur dioxide and ammonia dissolve in the lining fluid of the upper airways, causing damage primarily there. Less soluble gases such as nitrogen dioxide and phosgene pass into peripheral airways where they cause inflammatory changes in bronchioles and alveoli.[7,8] Such toxic fume exposures are a significant industrial and environmental hazard. "Nitrous fumes," for example, may be found in silo gas, jet and missile fuel, metal pickling fumes, and certain fires. Other fumes, such as those associated with food flavoring, have been implicated in the pathogenesis of bronchiolitis.[9,10] (This subject is discussed more fully in Chapter 68.)

After exposure to toxic fumes, three clinical patterns may develop (Fig. 44-1).[7,8] Acutely, patients may develop cough, dyspnea, cyanosis, hemoptysis, hypoxemia, and loss of consciousness. These symptoms and signs may disappear within hours, or they may persist for weeks before they eventually resolve. In patients exposed to higher concentrations, pulmonary edema and severe acute respiratory distress syndrome may develop immediately or following a latent period of 3 to 30 hours. Although most patients recover, death may occur. Finally, some patients develop irreversible airflow obstruction (bronchiolitis obliterans) 2 to 8 weeks after the initial exposure. Typically, this occurs after recovery

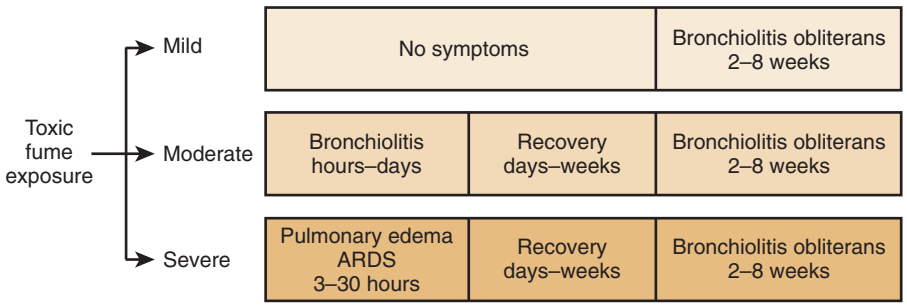

FIGURE 44-1 ■ The severity of bronchiolitis following inhalation of toxic fumes depends in part on the magnitude of the exposure. Most patients will recover from the acute event, although some will develop bronchiolitis obliterans 2–8 wk after the initial insult. ARDS, acute respiratory distress syndrome.

from the acute symptoms of exposure or in patients who had no initial illness; it is characterized by the gradual onset of dyspnea and a nonproductive cough.[7,11] Patients who develop bronchiolitis obliterans after toxic fume inhalation commonly experience progressive deterioration, often leading to death from respiratory failure.

In contrast to adults, in whom it is considered rare, infectious bronchiolitis is a common lower respiratory tract illness in infants and young children. The cause most commonly is a virus, especially respiratory syncytial virus (RSV).[12] In older children and in adults, bronchiolitis has been associated with *Mycoplasma pneumoniae*, *Legionella pneumophilia*, and several viruses including adenovirus, influenza, and parainfluenza.[13–15]

Bronchiolitis in children typically begins as an acute virus-like illness. Within several days, cough, dyspnea, and fever develop. Although wheezing, chest wall retractions, and cyanosis may be seen, respiratory failure is uncommon. Peribronchiolar inflammation with epithelial necrosis and sloughing, when severe, causes airflow obstruction in the peripheral airways of infants, with resulting hyperinflation and severe gas exchange abnormalities.[16] Roentgenograms generally show overinflation of the lungs, and sometimes, nodular shadows appear with areas of focal atelectasis and pneumonia.[15,17,18] Bronchiolitis is usually self-limited, and complete recovery usually occurs within days to weeks. Symptomatic treatment with supplementary oxygen and hydration is usually all that is necessary. Bronchiolitis in infancy has been associated with an increased risk of subsequent wheezing and bronchial hyperreactivity,[19] and non-RSV (e.g., rhinovirus) bronchiolitis may be especially likely to result in wheezing over the next 3 years.[20] However, a direct link to chronic obstructive pulmonary disease has not been shown. Occasionally, bronchiolitis obliterans, bronchiolectasis, and localized emphysema develop as sequelae to bronchiolitis.[12] No role has been proved for bronchodilators, antibiotics, or corticosteroids, although the latter are often used empirically in progressive disease in an attempt to reduce the severity of obliterative bronchiolitis. Elevated levels of cysteinyl leukotrienes have been reported in viral infections,[21,22] and leukotriene modifiers have been shown to reduce respiratory symptoms and wheezing after RSV bronchiolitis in some,[23,24] but not all,[25] studies.

Because of their anatomic features, diseases of peripheral airways are difficult to detect and to differentiate from diseases of large airways. In individual patients, the cause of acute bronchiolitis is often not established, and the disease in patients with progressive bronchiolitis obliterans is frequently classified as "idiopathic." Lung biopsy should be considered in those with chronic progressive disease, and this may require a surgical rather than a transbronchial approach.

Bronchiolitis Obliterans (Obliterative Bronchiolitis)

The term *bronchiolitis obliterans* is commonly used to describe a number of unrelated conditions whose common end point is functional obstruction of bronchioles. Bronchiolitis obliterans was first described by Reynaud in 1835. In 1901, Lange described two young adults who died of rapidly progressive respiratory failure. At autopsy, their lungs revealed fibrous scarring of small airways with polypoid foci of exudate extending into the lumens. Since that time, bronchiolitis obliterans has been described after inhalation of toxic fumes, as a consequence of respiratory infections, in association with connective tissue disorders, and after bone marrow or heart-lung transplantation (Table 44-1). It appears that any damage to the bronchiolar epithelium may lead to excessive proliferation of granulation tissue during the repair phase. The reason this occurs in only a percentage of patients is unknown, but it probably reflects both differences in the magnitude of the provocative stimulus and abnormalities in the responses of host tissue. Bronchiolitis obliterans is classified clinically based upon etiology (see Table 44-1)[26] and histopathologically based on tissue morphology.[27]

TABLE 44-1. Conditions Associated with Bronchiolitis Obliterans

Toxic fume inhalation
Mineral dust exposure
Infection (viral, *Mycoplasma, Legionella*)
Bone marrow transplantation
Lung and heart-lung transplantation
Rheumatoid arthritis
Penicillamine
Systemic lupus erythematosus
Dermatomyositis, polymyositis
Hypersensitivity pneumonitis

Bronchiolitis obliterans characteristically presents with the insidious onset of a nonproductive cough and dyspnea 2 to 8 weeks after an acute respiratory illness or toxic exposure. Physical examination is typically unremarkable but may reveal diffuse expiratory wheezing. Similarly, routine laboratory studies are not helpful. The roentgenographic pattern of bronchiolitis obliterans is variable, and plain chest radiographs are rarely diagnostic. High-resolution computed tomography (HRCT) may show bronchial wall thickening, centrilobular nodules, or diffuse ground-glass opacification, or may on occasion be normal. In some patients, narrowing of small bronchi and bronchioles may result in marked hyperinflation of the distal lung, which is apparent on HRCT as "mosaic perfusion."[18,28] This postobstructive hyperinflation with associated roentgenographic hyperlucency may be generalized or confined to one lung. The unilateral hyperlucent lung syndrome was first described in children by Swyer and James,[29] and a year later, the same abnormality was reported in adults.[30] Currently, it is believed that these forms of hyperinflation with hyperlucency are postobstructive complications of bronchiolitis obliterans.

There are two distinct forms of bronchiolitis obliterans.[27,31,32] "Classic bronchiolitis obliterans," as described

TABLE 44-2. Classification, Prognosis, and Therapy of Bronchiolitis Obliterans

Type	Organizing Pneumonia	Prognosis	Therapy
Toxic fume exposure	Rare	Poor-good	Steroids
Postinfectious	±	Fair-good	Steroids
Connective tissue disease	±	Poor-good	Steroids
Localized	Yes	Good	Resection
Idiopathic	Yes	Fair-good	Steroids

Reproduced with permission from Epler GR, Colby TV: The spectrum of bronchiolitis obliterans. Chest 83:161–162, 1983.

by Lange and currently referred to as *proliferative bronchiolitis*, is characterized by intraluminal polyps of organizing connective tissue. This cellular process with proliferation of fibroblasts is the more common form of bronchiolitis. *Constrictive bronchiolitis*, in contrast, is characterized by partial or complete obstruction of bronchiolar lumens that results from chronic bronchiolar inflammation, concentric submucosal or adventitial scarring, and smooth muscle hypertrophy.[27,31,33] Constrictive bronchiolitis is most commonly seen after inhalation injury. These two forms show little clinical or histopathologic overlap. Histologically, pure bronchiolitis obliterans is rare. When present, there is obliteration of bronchiolar lumens without spread of fibrosis to air spaces or interstitium. Extension of the exudate and granulation tissue into alveoli is referred to as "organizing pneumonia," and the entire process is then known as *bronchiolitis obliterans with organizing pneumonia* (BOOP). Epler and Colby[26] suggested the classification shown in Table 44-2 to describe the histologic effects, prognosis, and response to therapy of different clinical patterns of bronchiolitis obliterans.

Bronchiolitis Obliterans and Connective Tissue Diseases

Bronchiolitis obliterans may occur as an uncommon manifestation of connective tissue or collagen vascular diseases. It has been reported in association with rheumatoid arthritis, where it primarily affects women with long-standing, seropositive rheumatoid arthritis in their fifth or sixth decade of life.[34] The onset and progression of dyspnea and nonproductive cough are rapid, as is the rate of progression of airflow obstruction. The chest roentgenogram usually shows no abnormalities. Unfortunately, no consistent response to corticosteroids has been documented, and the prognosis for these patients generally is poor,[35] although a subset of patients may have a more insidious course.[36] Penicillamine, used to treat rheumatoid arthritis, has been implicated as a potential cause of bronchiolitis obliterans, but confirmation of an etiologic relationship is lacking. Bronchiolitis obliterans has also been reported in systemic lupus erythematosus,[37] polymyositis, and dermatomyositis,[38] and in scleroderma where reflux and chronic microaspiration may play an important role.[39]

Bronchiolitis Obliterans after Bone Marrow Transplantation

Chronic graft-versus-host disease (GVHD) occurs in approximately one third of long-term survivors of allogeneic bone marrow transplantation. Bronchiolitis obliterans occurs in approximately 10% of bone marrow transplant patients who develop chronic GVHD. It is rare after autologous bone marrow transplantation because chronic GVHD does not occur in this setting. Bronchiolitis obliterans is preceded, 2 to 3 months after transplantation, by typical findings of GVHD: mucositis, esophagitis, and skin rash. Four to 6 months later, the patients develop dry, nonproductive cough, and exertional dyspnea that may be severe and rapidly progressive. The physical examination reveals scattered wheezing, and bibasilar crackles are often present. Hypoxemia is common. Of note, the chest roentgenogram usually shows no abnormalities or demonstrates hyperinflation.

Various mechanisms have been proposed to explain bronchiolitis obliterans after bone marrow transplantation.[40] Chronic GVHD and prior methotrexate therapy appear to be risk factors for the development of airflow obstruction.[41] The GVHD may damage small airways directly. Lung epithelial cells can express Ia (class II major histocompatibility complex [MHC]) antigens that may activate T cells from the donor, thus making the airways a target for immunologically mediated injury.[41] Methotrexate, which alone does not cause bronchiolitis obliterans, may act as a "priming" agent in the presence of GVHD, perhaps by inducing antigen expression in the lung. Finally, bronchiolitis obliterans may result from viral infection, and the increased immunosuppression given to treat GVHD may increase the risk of such opportunistic infections. A 25% to 30% incidence of viral infection has been reported in patients with bronchiolitis obliterans after bone marrow transplantation.[42]

Bronchiolitis Obliterans after Lung or Heart-Lung Transplantation

Bronchiolitis obliterans is the major cause of morbidity and mortality of long-term survivors of heart-lung transplantation, developing in 30% to 50% of transplant recipients (see Chapter 81). Although various factors have been suggested as causes of bronchiolitis obliterans after

heart-lung transplantation, including infections, altered mucociliary clearance, altered blood flow secondary to bronchial artery ligation, reaction to immunosuppressive drugs, and loss of the cough reflex with recurrent aspiration, it appears that these entities may act mainly as "cofactors" and that the primary pathogenetic event is chronic transplant rejection.[43,44] By multivariate analysis, human leukocyte antigen (HLA)-A locus mismatch stands out as a significant independent predictor of bronchiolitis obliterans.[45,46] Other factors associated with the development of bronchiolitis obliterans include three or more episodes of acute rejection,[47] primary graft dysfunction (i.e., ischemia-reperfusion injury),[48,49] gastroesophageal reflux disease,[50] and single-lung transplant.[51]

Bronchiolitis obliterans may present several months to several years after lung or heart-lung transplantation. Clinical features include productive cough, dyspnea during exertion, progressive shortness of breath, and irreversible airflow obstruction with moderate reduction of the diffusing capacity. Arterial hypoxemia and hypocapnia are almost always present.

Because bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial biopsy are often used as surveillance for rejection after lung transplantation, this model has provided much information on the immunologic processes involved in the development of bronchiolitis obliterans. Enhanced expression of class II MHC antigens has been found in the epithelium of bronchioles and alveoli of patients with bronchiolitis obliterans after heart-lung transplantation.[52–54] T lymphocytes from the recipient may recognize these donor class II MHC antigens as foreign, resulting in a cascade of lymphocyte activation, proliferation, and differentiation.[55] This concept is supported further by the demonstration of activated T lymphocytes in the cellular infiltrates. Functional testing of BAL cells has been used to monitor patients for the development of bronchiolitis obliterans. Donor-specific activity (primed lymphocyte test, cell-mediated lympholysis) of cells removed from transplanted lung is strongly associated with bronchiolitis obliterans, and alloreactivity of BAL cells may be a significant risk factor for the subsequent development of bronchiolitis obliterans in clinically quiescent patients.[56,57] During rejection, there is marked lymphocytic infiltration of the transplanted organ, and infiltrating cells demonstrate $CD4^+$ and $CD8^+$ phenotypes.[58] A predominant $CD4^+$ cell population, mediating donor-specific class II antigen–directed reactivity, is associated with graft rejection; a predominant $CD8^+$ cell population, mediating donor-specific class I antigen–directed reactivity, is associated with bronchiolitis obliterans.[59] In addition, lung transplant patients with bronchiolitis obliterans have an oligoclonal expansion of $CD4^+$ T cells in peripheral blood.[60] Although the severity of the lymphocytic bronchitis identified on transbronchial biopsies has been identified as a significant risk factor for the development of bronchiolitis obliterans syndrome,[61] this syndrome has also been linked to down-regulation of CD28 on $CD4^+$ T cells.[62]

The role of cofactors such as *Pneumocystis jirovecii* infection or cytomegalovirus (CMV) pneumonia in the initiation of lung allograft rejection and development of bronchiolitis obliterans remains unclear. *Pneumocystis* infection is associated with an increased number and alloreactivity of BAL cells and a higher incidence of chronic rejection leading to bronchiolitis obliterans.[63] It has been suggested that activated T cells, on presentation of antigen by macrophages, proliferate and produce cytokines such as interleukin-2 (IL-2) that lead to an expansion of the number of alloreactive T cells.[63] Similarly, CMV infection may stimulate the release of cytokines such as interferon-γ (IFN-γ), which may lead to the increased expression of MHC antigens on epithelial and endothelial cells.[64–66] Alternatively, CMV may directly stimulate the up-regulation of MHC antigen expression on target cells. Finally, Fujinami and associates[67] described a region of amino acid sequence homology between the immediate-early region of human CMV and the HLA-DR β chain. By "mimicking" the molecular structure of HLAs in the lung, CMV might induce a response directed against the graft (Fig. 44-2). Prophylaxis against CMV with ganciclovir or valganciclovir has been reported to decrease the incidence of bronchiolitis obliterans syndrome.[68]

Bronchiolitis Obliterans with Organizing Pneumonia (Cryptogenic Organizing Pneumonitis)

In 1985, Epler and colleagues[69] described 50 patients whose lung biopsy specimens showed patchy organizing pneumonia in association with bronchiolitis obliterans. They proposed that BOOP was a distinct component of the spectrum of infiltrative lung diseases. Clinically, most patients had a history suggesting a slowly resolving pneumonia spanning weeks or months. The most common symptom on presentation was a persistent, nonproductive cough, and approximately one third of patients reported a flulike illness with fever, sore throat, and malaise. Dyspnea was a prominent feature in half the patients. On physical examination, crackles were present in 68% of patients, and wheezes were rarely present.

Epler and colleagues[69] described an unusual radiographic pattern of bilateral patchy ground-glass densities in 81% of their patients. Other radiographic patterns of BOOP include a miliary nodular pattern resembling miliary tuberculosis, bilateral symmetrical lower lobe interstitial infiltrates, and on rare occasions, a normal chest roentgenogram.[70]

The physiologic abnormalities of BOOP are variable.[35,69] In patients who are symptomatic, arterial hypoxemia is nearly always present. Pulmonary function tests demonstrate a restrictive pattern, with reduction in diffusing capacity in 72% of patients. Airflow obstruction is uncommon in patients who are not smokers.

The histologic pattern identified as BOOP is not specific for a single cause, but rather can occur in association with a large number of pulmonary conditions (Table 44-3). The idiopathic form of BOOP also is known as cryptogenic organizing pneumonitis (COP), and this nomenclature has been recommended by an

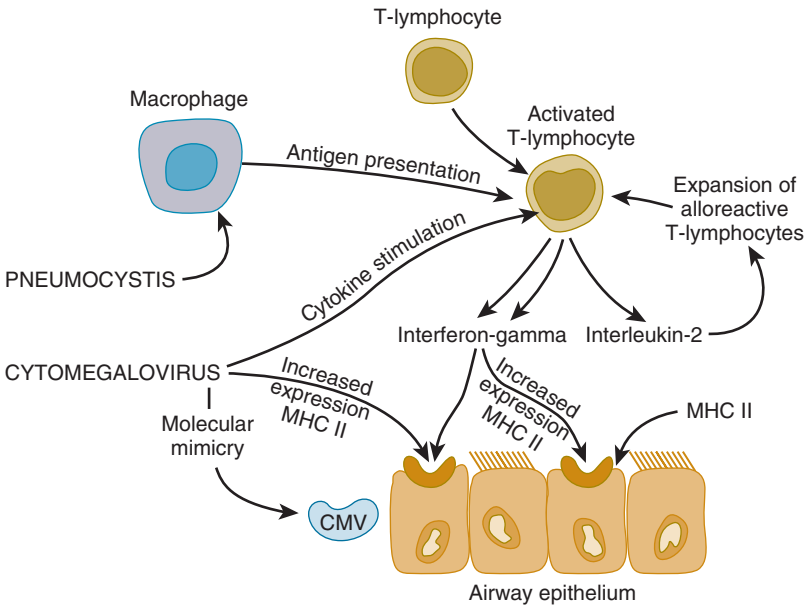

FIGURE 44-2 ■ Schematic diagram shows the potential interactions between infectious and immunologic stimuli that lead to bronchiolitis obliterans following transplantation of lung. Pneumocystis and cytomegalovirus (CMV) may act as "cofactors" to increase numbers of alloreactive T cells and increase expression of class II major histocompatibility complex (MHC) antigens on airway cells.

international committee.[71] These patients have a lymphocytic alveolitis with elevated levels of IFN-γ, IL-12, and IL-18,[72] intraluminal fibrosis that appears to be dependent on IFN-γ,[73] and neovascularization associated with increased levels of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF).[74] Cordier and coworkers[75] described three different clinical profiles. The first group had patchy migratory pneumonic foci. All of these patients recovered completely with corticosteroid therapy but relapsed when therapy was stopped rapidly. In a second group with diffuse interstitial lung disease, approximately half of the patients responded to corticosteroids. A third group had solitary foci of pneumonia that were resected because of concern over carcinoma. These patients recovered without relapse. Other studies have reported similar success with corticosteroid therapy, with an overall response rate of 60% to 70%, and similar rates of recurrence associated with early cessation of corticosteroid therapy.[69,76] Because most patients with BOOP demonstrate complete clinical and physiologic recovery after therapy with corticosteroids, the diagnosis must be confirmed. Usually, this requires an open-lung biopsy to distinguish BOOP from irreversible interstitial lung disease. BOOP should be considered whenever "community-acquired pneumonia" fails to respond to appropriate therapy.

Treatment of Bronchiolitis Obliterans and Bronchiolitis Obliterans with Organizing Pneumonia

Early recognition and therapy of bronchiolitis obliterans is important because treatment is often ineffective when the disease has reached the late, fibrotic stage. Although there is little evidence that smooth muscle contraction plays a significant role, β-adrenergic agonists are usually given in an attempt to provide symptomatic relief. Corticosteroids play an important role and, if administered early, may significantly alter the disease process. This is especially true of bronchiolitis obliterans after exposure to toxic fumes.[8,77,78] Once instituted, corticosteroid therapy should be continued for at least 2 to 3 months, then reduced slowly, to minimize the likelihood of relapse.[75-79] In some patients, it may be necessary to continue low-dose or alternate-day corticosteroid therapy for months or years.

In bronchiolitis obliterans after bone marrow transplantation, the response to therapy has been poor. Generally, by the time severe airflow obstruction has been established, there is minimal if any therapeutic response. Bronchodilators and corticosteroids have not improved airflow in most cases, and the use of immunosuppressive agents to treat chronic GVHD, although occasionally effective,[80,81] has not consistently changed the course of bronchiolitis obliterans.[35] Macrolide antibiotics are sometimes used empirically, but there is little evidence to support this practice.[82] Better prophylaxis against GVHD

and viral infection may reduce the incidence of bronchiolitis obliterans after bone marrow transplantation.

Bronchiolitis obliterans after lung or heart-lung transplantation has been treated by augmenting immunosuppression with high-dose corticosteroids, azathioprine, antithymocyte globulin (ATG), OKT3 monoclonal antibody, tacrolimus (FK506), mycophenolate mofetil, or all of them; the responses have varied. Chronic use of azithromycin has been reported to improve lung function in patients with bronchiolitis obliterans after lung transplantation.[83,84] Patients with prominent BAL neutrophilia are more likely to respond to azithromycin; those who had a rapid pretreatment decline in lung function are not.[85] One study suggests that statin use is associated with decreased rejection and bronchiolitis obliterans after lung transplantation, perhaps by inhibiting expression of MHC class II molecules or by a variety of other antiinflammatory and immunomodulatory effects that have been ascribed to these agents.[86] Furthermore, extracorporeal photophoresis appears to decrease the rate of decline in forced expiratory volume in 1 second (FEV_1) in established bronchiolitis obliterans.[87] If bronchiolitis obliterans is detected early and therapy is initiated immediately, the likelihood of reversal is enhanced.[88] Therapy begun late in the clinical course may stabilize the process or have no effect, although assessing this is difficult because the rate of progression of bronchiolitis obliterans tends to slow spontaneously with time. For patients with progressive bronchiolitis obliterans, retransplantation is an option. In patients who undergo a second lung transplant, the rates of recurrent bronchiolitis obliterans and survival appear to be similar to those of the first transplant.[89,90] The best therapy for bronchiolitis obliterans is primary prevention. Rigorous surveillance for evidence of asymptomatic rejection makes it feasible to prevent the chronic rejection that is thought to lead to bronchiolitis obliterans.

BOOP represents a special situation. Corticosteroid therapy is effective in most cases, and clinical improvement is often dramatic, sometimes occurring within 1 to 2 days of starting therapy.[69,91] In Epler and colleagues' original study,[69] there was complete clinical and physiologic recovery in 65% of patients. Because this lesion is so "steroid-responsive," the diagnosis should be established early so therapy can be initiated before irreversible changes in lung function occur. Corticosteroids should be continued for 1 to 2 months, then tapered slowly (e.g., over 4–6 wk) to prevent relapse. In patients who are not responsive to, or not tolerant of, corticosteroids, cyclophosphamide has been effective.[92,93]

Respiratory Bronchiolitis

Respiratory bronchiolitis (RB) is characterized by the accumulation of pigmented alveolar macrophages in respiratory bronchioles and in the adjacent air spaces. It is a distinct pathologic entity commonly found in cigarette smokers and in patients with mineral dust exposure.[94–96] Previously considered an incidental finding at autopsy, RB currently is thought to be a possible precursor to chronic lung disease in heavy smokers.[94,97] Clinically, RB is often identified radiographically and rarely produces symptoms or physiologic abnormalities. However, in some patients, RB is associated with diffuse pulmonary infiltrates in a disease that resembles idiopathic pulmonary fibrosis. This entity is known as *respiratory bronchiolitis–associated interstitial lung disease* (RB-ILD).[96,98–100] Patients present with subacute cough, dyspnea, and crackles, with diffuse interstitial infiltrates or reticulonodular opacities on chest roentgenogram and pulmonary function tests showing restrictive lung disease with decreased diffusing capacity. HRCT may be useful in differentiating respiratory bronchiolitis from interstitial lung disease, manifesting diffuse or patchy ground-glass densities or fine nodules in the former and peripheral reticular opacities and honeycombing in the latter.[100,101] The duration of symptoms is considerably longer than for BOOP, with patients with RB reporting an average of 37 months of symptoms.[97] Smoking cessation leads to resolution or stabilization of disease in about 30% of patients[102]; some patients develop progressive interstitial fibrosis. Improvement with corticosteroid treatment has been described, but this has not been studied prospectively.[96,98,99]

Panbronchiolitis

Diffuse panbronchiolitis is an obscure inflammatory disease of the respiratory bronchioles and surrounding alveoli. Described originally in Japan, where more than 1000 cases have been identified,[103] it also has been reported in non-Japanese Asians,[104] and in whites in the United States.[105]

Most individuals with diffuse panbronchiolitis are male[103] nonsmokers and almost all have chronic sinusitis. The usual presenting symptoms are cough, dyspnea, and sputum production. The chest radiograph and HRCT are characteristic, showing diffuse small centrilobular nodular opacities and hyperinflation.[101,106] Pulmonary function tests typically reveal progressive airflow obstruction or a mixed obstructive-restrictive pattern, with reduced diffusing capacity of carbon dioxide ($D_{L_{CO}}$).[105] Diffuse panbronchiolitis is associated with recurrent respiratory infections; *Pseudomonas* infection is common late in the disease.[105,107] If untreated, diffuse panbronchiolitis leads to bronchiectasis, respiratory failure, and death. Although the etiology of diffuse panbronchiolitis remains obscure, both genetic and environmental factors are believed to be important.[108–110] HLA-Bw54 is associated with a 13.3-fold increase in risk for diffuse panbronchiolitis.[109] Polymorphisms of the genes for IL-8[110] and MUC5B[111] have been associated with diffuse panbronchiolitis. Airway neutrophilia is a common feature, and chronic treatment with macrolide antibiotics has been shown to be beneficial[112–114] possibly by reducing levels of the neutrophil chemoattractant IL-8.[115,116]

Follicular Bronchiolitis

Follicular bronchiolitis (lymphoid hyperplasia) is characterized by peribronchiolar hyperplastic lymphoid follicles with germinal centers.[117] It has been described with

primary pulmonary lymphoid hyperplasia[118] or as a secondary event in patients with bronchiectasis, collagen vascular diseases (especially rheumatoid arthritis and Sjögren's syndrome), or other infections.[117,119,120] Most patients complain of slowly progressive exertional dyspnea, and centrilobular nodules and ground-glass opacities are seen on HRCT.[118] The natural history of this condition is unknown, and treatment is usually directed at the underlying disease.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) refers to a common, long-term respiratory complication of premature birth. However, as management of prematurity has evolved, so have the histopathologic and clinical descriptions of the disease. BPD was described initially in newborn babies with the infant respiratory distress syndrome (hyaline membrane disease) after prolonged treatment with high concentrations of inspired oxygen and positive-pressure ventilation.[121] Because these two therapeutic modalities are linked so closely in practice, it has not been possible to separate the pathogenetic contributions of each. In all likelihood, both oxygen and positive-pressure play a role. Characteristic histologic features are unusual abnormalities of the bronchioles, including marked metaplasia, obliteration, and cystic changes.[122] The disorder also has been described in adults after acute respiratory distress syndrome.[123] It is possible that this complication occurs more frequently in adults than currently is recognized. The pathologic findings may be misdiagnosed easily as "honeycombing," a nonspecific consequence of many different fibrosing disorders.

The use of antenatal corticosteroids, exogenous surfactant, and improved ventilatory support have resulted in improved survival of more immature infants, and an evolution of what continues to be called "bronchopulmonary dysplasia."[124,125] The "new" BPD is clinically milder and probably reflects developmental arrest in an immature lung rather than barotrauma and oxygen toxicity.[125,126] Histopathology reveals enlarged air spaces with simplified alveolar and alveolar-capillary development. Unlike the original disease, airway abnormalities are uncommon.[125]

LOCALIZED DISORDERS

Many of the specific causes of localized abnormalities of bronchi also underlie abnormalities of the upper airways. Examples are neoplasms, extrinsic compression, granulomatous disease, malacic lesions, and trauma. However, the manifestations, diagnosis, and therapy of localized bronchial disorders are substantially different from similar disorders in the larynx or trachea.

Neoplasms

Because lung cancers are common, any endobronchial mass must be evaluated carefully for possible malignancy. All histopathologic types of primary lung cancer may protrude into a bronchus and narrow or occlude it. Malignant endobronchial tumors often have an irregular, rather than smooth, surface on bronchoscopic examination. Primary malignant tumors of the lung are described in detail in Chapter 47.

Of patients with extrapulmonary malignancies metastatic to the lung, approximately 5% have predominantly endobronchial metastases.[127] The most common primary malignancies are renal cell, colonic, rectal, cervical, and breast carcinomas and malignant melanomas.[128] In most instances, the manifestations of the primary tumor are apparent before the endobronchial metastasis is discovered.[127] Metastatic malignancies of the lung are discussed in detail in Chapter 49.

In patients with lymphomas or leukemia, malignant infiltrations of the bronchial mucosa occur rarely. In Hodgkin's disease or non-Hodgkin's lymphoma, the endobronchial malignant cells may originate in bronchus-associated lymphoid tissue, may invade the bronchial mucosa by direct extension from hilar or peribronchial lymph nodes, or may seed the bronchial mucosa via lymphatic or blood vessels.[129] Leukemic infiltration of bronchial mucosa occurs as a rare, late manifestation of chronic lymphocytic leukemia.[130]

Involvement of the lung occurs in one third to one half of patients with the acquired immunodeficiency syndrome (AIDS) and Kaposi's sarcoma (see Chapter 80). Endobronchial lesions occur frequently, but they rarely cause airway obstruction or hemoptysis. The lesions are usually multiple, bright red or violaceous, and flat when visualized through the bronchoscope. The diagnosis of endobronchial Kaposi's sarcoma is established when a patient with AIDS has widespread extrapulmonary Kaposi's sarcoma and characteristic-appearing endobronchial lesions. Biopsy of the endobronchial lesions is seldom necessary and may be hazardous because of excessive bleeding.[131]

Benign lung tumors frequently originate from cells in the airways, including nerves (schwannomas, neurofibromas, neurolemmomas), smooth muscle (leiomyomas), cartilage (chondromas), blood vessels (hemangiomas), fat cells (lipomas), glands (cystoadenomas, oxyphilic adenomas), and epithelium (papillomas). These tumors often narrow or obstruct bronchi. By bronchoscopic examination, the tumors often are smooth, round, and well localized. Benign tumors of the lung are described in detail in Chapter 50.

Bronchial Compression

When peribronchial lymph nodes are enlarged by carcinoma, lymphoma, or granulomatous infection, narrowing of adjacent bronchi may occur. Although sarcoidosis frequently results in enlarged hilar and mediastinal lymph nodes, bronchial narrowing from compression by lymph nodes in sarcoidosis is rare. In infants with congenital heart defects such as tetralogy of Fallot and transposition of the great vessels with ventricular septal defect, bronchial compression by dilated pulmonary arteries is an occasional complication.

Mediastinal Fibrosis (Fibrosing Mediastinitis)

In patients with pulmonary histoplasmosis or tuberculosis, an interesting and rare complication is mediastinal fibrosis.[132] In such patients, it appears that fungal or bacterial antigens from granulomatous foci in mediastinal lymph nodes stimulate fibrogenesis in surrounding tissue, perhaps because of unusual sensitivity to the antigens.[132] The fibrosis may result in narrowing or occlusion of vital mediastinal structures, and the structures affected depend on the specific lymph nodes involved by the original infection. Mediastinal fibrosis originating from subcarinal or hilar lymph nodes may result in occlusion of main-stem bronchi, pulmonary blood vessels, or the esophagus. Mediastinal fibrosis originating from right paratracheal lymph nodes commonly produces obstruction of the superior vena cava and azygos veins.[132] CT and magnetic resonance imaging (MRI) are useful to diagnose and follow this condition.[133]

Foreign Bodies

Accidental inhalation of foreign bodies is a major cause of death in children, resulting in approximately 2000 deaths annually in the United States. The foreign bodies, which may be seeds, nuts, nails, or a variety of other objects, most frequently lodge in the right main-stem bronchus. Children with aspirated foreign bodies may present with immediate cyanosis, cough, and wheezing or with the delayed onset of pneumonia or bronchiectasis. Suspected aspiration of a foreign body is an indication for immediate bronchoscopic examination of the airways. In the presence of asphyxia, rigid bronchoscopy is appropriate. In most other situations, foreign bodies can be extracted with the flexible bronchoscope, but personnel and equipment for rigid bronchoscopy should be available.

Granulomatous Inflammation

In patients with pulmonary tuberculosis, spillage of infected material into the middle and lower lobes occasionally causes localized endobronchial infection. Endobronchial tuberculosis may present with hemoptysis, bronchorrhea, or localized bronchial obstruction, causing lobar collapse and persistent postobstructive pneumonitis. These findings may develop during active pulmonary infection by tuberculosis or many years after its treatment. The diagnosis is established most readily by fiberoptic bronchoscopy.[134] The typical finding is the presence of localized endobronchial gelatinous granulation tissue. The mucosa may be nodular, red, and ulcerated, and often the diagnosis of bronchogenic neoplasm is suggested until pathologic examination of biopsy material has been carried out.

In patients with pulmonary sarcoidosis, localized endobronchial granulomatous inflammation rarely may lead to stenosis of bronchi.[135] Pulmonary function tests often show airway obstruction, but the common causes of the obstruction are the structural distortion of bronchi and bronchioles that accompanies pulmonary fibrosis,[136] nonspecific bronchial hyperreactivity,[137] or laryngeal sarcoidosis.[138] Only rarely is bronchostenosis present.

Bronchocentric granulomatosis is an uncommon inflammatory lesion defined morphologically by the presence of necrotizing granulomas surrounding bronchi.[139] The entity occurs most commonly in asthmatic patients with allergic bronchopulmonary aspergillosis, and considerable evidence suggests that the granulomatous bronchitis is an immunologic response to endobronchial fungi. Narrowing or obliteration of bronchi may occur because of the inflammatory reaction itself or because of associated mucoid impaction.[139]

Broncholithiasis

Broncholithiasis is defined as the presence of a calcified fragment of tissue within a bronchus.[140] Any disorder that leads to calcification of lung tissue or of lymph nodes may result in broncholithiasis. Most often this occurs when hilar or peribronchial lymph nodes become calcified as a result of granulomatous infections such as histoplasmosis or tuberculosis or, less commonly, from actinomycosis, coccidioidomycosis, cryptococcosis, or silicosis.[140] Necrotizing pneumonias and bronchiectasis may lead to calcification of bronchial cartilage, which can fragment to produce broncholiths. Occasionally, retained foreign bodies may become calcified. Clinical manifestations of broncholithiasis occur when calcified stones erode or break loose into the airways (see later). These stones are composed of 85% to 90% calcium phosphate and 10% to 15% calcium carbonate and, thus, closely resemble the composition of bone.

Amyloidosis

Amyloidosis is defined on the basis of the extracellular deposition of the fibrous protein amyloid. In both the primary and the secondary forms of the disease, these deposits can occur endobronchially, producing obstruction or incidental findings at the time of bronchoscopy.[141] As many as 30% of patients with primary amyloidosis are symptomatic. Pulmonary involvement is usually associated with amyloid of the light (AL) chain variety.[142] The definitive diagnosis of endobronchial amyloidosis requires biopsy and demonstration of amyloid deposits, as defined by their green birefringence when viewed with polarized light after staining with Congo red.[141] Endobronchial amyloid has been treated successfully with neodymium:yttrium-aluminum-garnet (Nd:YAG) laser therapy.[143]

Bronchomalacia

Softening of the bronchial walls may contribute to narrowing of the airways during exhalation in emphysema. Less commonly, bronchomalacia may be found in infants because of inadequate development of bronchial cartilage. These infants generally present with dyspnea, atelectasis, or recurrent pneumonias.

Traumatic Injury

Tears or complete ruptures of main-stem bronchi or the bronchus intermedius are occasional complications of blunt trauma to the chest. The diagnosis should be suspected in any posttraumatic patient with new onset of cough, respiratory distress, subcutaneous and mediastinal emphysema, or pneumothorax. The associated presence of hemoptysis or hemothorax indicates bronchial vascular damage. Occasionally, the development of manifestations of bronchial tears may be delayed days or weeks after the traumatic injury.

Clinical Features

Patients with localized endobronchial lesions generally present with symptomatic, physical, or radiographic manifestations of the lesion itself or of underlying conditions (e.g., malignancy, infection, AIDS, or sarcoidosis). Only the manifestations of the lesions themselves are described in this section.

The most common symptoms of localized endobronchial disease are cough, hemoptysis, wheeze, dyspnea, and fever and chills secondary to postobstructive pneumonia. If an endobronchial lesion only partially obstructs a bronchus, patients may show manifestations of chronic pulmonary infections, such as lung abscess (see Chapter 32) or bronchiectasis (see Chapter 42). A history of recurrent pneumonias in the same segment or lobe of the lung should prompt a careful evaluation for partial bronchial obstruction by an endobronchial lesion. Similarly, for any edentulous elderly patient with a history of a severe anaerobic pulmonary infection, endobronchial obstruction should be considered.

Symptoms of broncholithiasis include cough, hemoptysis, fever associated with purulent sputum, and expectoration of stones. Often, the cough in broncholithiasis is productive of a mixture of gritty, sandy particles and purulent or bloody sputum.

The physical examination in patients with localized endobronchial lesions may reveal fever and tachypnea. When a bronchus is narrowed but not completely obstructed, examination of the chest may reveal a unilateral palpable rhonchus, a prolonged forced inspiratory time on the affected side (the inspiratory "bagpipe" sign),[144] and a localized wheeze during a forced expiratory maneuver. Once the obstruction is complete, there is a loss of breath sounds and vocal fremitus during auscultation over the portion of the lung distal to the obstruction.

In patients with localized endobronchial disease, the chest roentgenogram may show no abnormality. Radiographically apparent lung collapse depends on the completeness of the obstruction and on the extent to which collateral ventilation from adjacent lung is present. In infants, the pores of Kohn, through which collateral ventilation normally occurs, are poorly developed. Hence, the likelihood of complete collapse from localized bronchial disease is great in this age group. Other findings on the plain chest roentgenogram include mediastinal adenopathy with or without calcification, lung abscess, bronchiectasis, or pneumonia. The presence of air bronchograms in a consolidated region of the lung suggests that the bronchus supplying that region is at least partially patent.

Middle lobe syndrome refers to chronic or recurrent radiographic evidence of collapse of the right middle lobe. Originally, it was postulated that the cause was tuberculous adenitis of lymph nodes in the right middle lobe causing bronchial compression.[145] By bronchoscopic examination, however, most of these patients have completely normal right middle lobe bronchi. Therefore, in most instances, the collapse relates to the normal, relatively long length and narrow caliber of the right middle lobe bronchus or to the relatively ineffective collateral ventilation normally present in this lobe.

Diagnosis

In patients with only partial obstruction of a bronchus, comparing roentgenograms obtained at full inspiration with those obtained at full expiration may assist in establishing the diagnosis. Upon inspiration, the negative intrathoracic pressure distends the partially obstructed bronchus, and air enters the distal lung. Upon expiration, the obstruction becomes complete, and air is trapped behind it. The result is a mediastinal shift away from the affected side on expiration. CT scans may identify hyperinflation, compressing lymph nodes, or calcifications in patients with broncholithiasis, or subtle endobronchial abnormalities.[146]

The definitive procedure for diagnosing localized bronchial abnormalities is direct examination of the bronchi via fiberoptic bronchoscopy. In general, any visualized abnormality should be biopsied, and the biopsied materials submitted for histologic examination as well as for culture. If the lesion is friable and bleeds easily during its examination and manipulation, rigid bronchoscopy may be required.

Routine pulmonary function tests in general do not distinguish between localized and widespread bronchial obstruction. In patients with bronchial compression or mediastinal fibrosis, skin tests for histoplasmosis or tuberculosis may be positive.[132] In bronchocentric granulomatosis, peripheral blood eosinophilia and serum precipitins for *Aspergillus* may be present.[139] In endobronchial amyloidosis, immunoelectrophoretic analysis of blood or urine shows evidence of monoclonal gammopathy in 90% of cases.[147]

Treatment

The appropriate therapy for localized lesions of the bronchi depends on the specific underlying cause. Treatment of bronchial neoplasms is described in Chapter 47. In some patients with inoperable, obstructive neoplasms of the trachea, main-stem bronchi, or bronchus intermedius, the use of the Nd:YAG laser, electrocautery, or argon plasma coagulation can provide immediate relief; the therapeutic effects of cryotherapy, brachytherapy, and photodynamic therapy are slower in onset. Bron-

chial obstruction from extrinsic compression or endobronchial granulomatous inflammation may be relieved by medical treatment of the underlying condition (e.g., lymphoma, tuberculosis), but irreversible fibrotic narrowing often requires surgical resection or stenting. There are reports that airway and vascular obstruction due to fibrosing mediastinitis may improve with corticosteroids or with stenting, but prospective trials are lacking. Foreign bodies usually can be removed with specialized wire claws or baskets inserted through a bronchoscope. When they are lodged in central airways, removal of foreign bodies is performed most effectively via a rigid bronchoscope. Broncholithiasis is often self-limited, requiring no further evaluation or treatment. However, if hemoptysis, persistent cough, atelectasis, or infection is present, bronchoscopic visualization is indicated. Stones sometimes can be removed bronchoscopically, and antibiotics should be administered to treat postobstructive infections. Occasionally, surgical intervention is required to manage persistent or recurrent broncholithiasis.[140] In infants with bronchomalacia, effective treatment may require long-term ventilation of the lungs until normal cartilage is formed, which usually occurs by 6 months to 2 years of age. Patients with suspected traumatic bronchial injury should undergo immediate endotracheal intubation and fiberoptic bronchoscopy followed by thoracotomy.

Tracheobronchial Stents

Although prostheses have been utilized to relieve tracheal and bronchial obstruction for many years,[148] recent technical advances have made the procedure easier and more effective. More than 20 types of tracheobronchial stents are now available, in metal, mesh, or silicone rubber; insertion usually can be accomplished by fiberoptic bronchoscopy without general anesthesia. Stents have been used effectively to relieve airway obstruction caused by malignancy, postinflammatory stenosis, and tracheobronchomalacia and to occlude tracheoesophageal fistulas. The success rate is as high as 80% to 90% in selected patients.[149] Fenestrated or mesh stents are more effective for benign lesions than for neoplasms, which tend to grow through the metal mesh. Careful patient selection, choice of the correct stent, and an experienced bronchoscopist are important determinants of success. Virtual bronchoscopy using CT is often useful in planning stent placement.

KEY POINTS

- Because of the large cross-sectional area of the peripheral airways, symptoms and physiologic changes occur late and conditions affecting these airways, including bronchiolitis and mucus plugging, can be difficult to diagnose.
- For bronchiolitis obliterans and especially bronchiolitis obliterans with organizing pneumonia, early diagnosis and treatment can impact prognosis.
- Chronic graft versus host disease is the major risk factor for bronchiolitis obliterans after bone marrow transplantation.
- Bronchiolitis obliterans after lung transplantation reflects chronic graft rejection; infections, gastroesophageal reflux, immunosuppressive drugs, and primary graft dysfunction act as cofactors.
- Diffuse panbronchiolitis responds to treatment with macrolide antibiotics.
- Endotracheal and endobronchial stents are effective for treating obstruction caused by tumors, postinflammatory stenosis, and tracheobronchomalacia.

TRANSLATING LUNG CANCER BIOLOGY TO THE CLINIC
Biomarkers
Molecular Therapeutics

INTRODUCTION

Lung cancer is the number-one cause of cancer-related death in the Western world. Lung cancer remains the leading cause of cancer mortality for both men and women in the United States.[1] Its incidence is highly correlated with cigarette smoking, and about 10% of long-term smokers will eventually be diagnosed with lung cancer. Among the 10% of patients who develop lung cancer without a smoking history, potential environmental or inherited causes of lung cancer are unclear. As large as the clinical challenges patients and physicians face in managing this disease, equally enormous are the challenges in detailing the complex molecular pathogenesis of lung cancer. Major progress has been made, however, and we are beginning to see this knowledge translated into the clinic. In this chapter, we summarize our understanding of how lung epithelial cell injury leads to signaling pathway activation that triggers the uncontrolled proliferation, resistance to apoptosis, metastasis, and escape from immune surveillance seen in lung cancer. Whereas all subtypes of non–small cell lung cancer (NSCLC) have historically been treated the same, stage-for-stage, recent technological advances have allowed a better understanding of the molecular classification of the disease and provided hypotheses for molecular early detection and targeted therapeutic strategies.

The pathogenesis of lung cancer involves the accumulation of multiple molecular abnormalities over a long period of time.[2] Heritable alterations can happen at the level of gene expression through abnormal microRNA expression or methylation, DNA sequence changes, DNA segment amplification, deletion, or whole chromosome gains or losses. These lesions allow cells to escape the normal regulation of cell division, apoptosis, and invasion and/or alter its interaction with the host. The historical focus of much of this research has been to identify and study the role of specific genetic abnormalities in tumor cells related to chromosomal abnormalities, inactivation of specific tumor suppressor genes, the activation of specific oncogenes, the expression of hormone receptors and growth factor production associated with the development of cancer. More recently, the contribution of stromal interactions, angiogenesis, apoptosis, and epigenetic phenomena such as posttransla-

tional modification of critical genes has been the subject of intense research. The completion of the first draft of the human genome sequence[3] and the availability of high-throughput technologies (e.g., microarrays) have also prompted investigators to propose studies to discover molecular alterations of individual tumors with incredible sensitivity and unprecedented scope. Common molecular abnormalities in both pre- and invasive lung cancers are being integrated and hold the promise for potential utility in prevention, early detection, and therapy.

PREDISPOSITION TO LUNG CANCER

Smoking

Tobacco use continues to be a major cause of cancer in the developed world. Tobacco control efforts are leading to a decrease in cancer mortality in some areas of the world, but globally there are still over 1 billion smokers.[4] Over 85% of all lung cancers are attributable to cigarette smoking; however, only a fraction of long-term cigarette smokers develop lung cancer, suggesting a role for variable inherited genetic susceptibility in lung tumorigenesis.

Lung cancer also develops through a multistage process in a background of increasing genomic instability.[5] For example, cytogenetic alterations arise throughout the airways with monoclonal and trisomic clonal patches observed.[6] These changes develop diffusely in the airway following the distribution of cigarette smoke exposure and confirm the "field cancerization" hypothesis.[7] Therefore, elucidating the molecular determinants responsible for the development of lung cancer and identifying intermediate biomarkers associated with malignant progression remain important questions. Cigarette smoking clearly contributes to the accumulation of genetic alterations in lung cancer.[8–10] Tobacco is rich in pulmonary carcinogens and causes many genetic changes by inducing DNA mutation.[11,12] Tobacco-specific nitrosamines also induce DNA methylation.[13] Levels of DNA adducts such as methylated DNA can, in fact, be used as an index of human tobacco exposure. Tobacco also causes methylation of tumor suppressor genes.[14,15] Cigarette smoke has also been shown to induce demethylation of the proto-oncogene synuclein-gamma in lung cancer.[16] Therefore, cigarette smoke could lead to specific patterns of chromatin structure alterations that may promote cancer development. In the future, specific epigenetic alterations induced by cigarette smoking may be useful as markers of lung cancer development.

Chronic exposure to carcinogens initiates a process characterized by genetic abnormalities, phenotypic changes, and overgrowth of clones of genetically altered epithelial cells throughout the lungs.[17] Genomic alterations may form a pattern referred to as a "genomic signature." The signatures found in NSCLC may contain information about their induction by cigarette smoke[18] and may reflect the pathways to cancer development or represent the product of competitive selection of clones.

Genetic Susceptibility and Familial Predisposition

In epidemiologic studies, smoking confers an approximately 14-fold increased risk for lung cancer, and after controlling for tobacco use, a family history of lung cancer accounts for an approximately 2.5-fold increased risk. Here we address susceptibility as it relates to genetic predisposition and familial predisposition separately.

Rare autosomal dominant genes found by segregation analyses may explain susceptibility to early-onset lung cancer, but these results explain a minority of lung cancer cases, including those with a strong family history. Therefore, more common genetic variants or polymorphisms are likely to affect lung cancer risk. Inherited differences in DNA repair capacity in response to tobacco-mediated damage have been incriminated as underlying some of this predisposition. When lymphocytes from lung cancer patients and age-matched controls are exposed to bleomycin, the lymphocytes from lung cancer cases develop more chromatid breaks than the control lymphocytes.[19] A similar assay has been developed using benzo[alpha]pyrene diol-epoxide (BPDE), a reactive substrate that is derived by in vitro processes from benzo[alpha]pyrene, a major carcinogen in tobacco smoke.[20] These results suggest that the DNA repair capacity influences risk for lung cancer. Telomere length has also been inversely associated with lung cancer risk.[21]

In three lung cancer genome-wide association studies (GWAS), polymorphic differences in chromosome 15q25 have been associated with the risk of developing lung cancer.[22–24] Single nucleotide polymorphisms (SNPs), mapped to a region of strong linkage disequilibrium within 15q25.1, contain nicotinic acetylcholine receptor subunit genes. The genetic variants were associated both with nicotine dependence as well as with certain lung cancer phenotypes, including lung cancer developing in younger patients and in patients with lower amounts of smoking; the variants were not associated with lung cancer in nonsmokers or with other smoking-related cancers like renal or bladder.[25] Thus, these genetic variants appear to increase risk both for smoking and for smoking-related lung cancer. Since then, subsequent analyses identified additional variants that influence lung cancer risk,[26] which will require further investigation in a larger sample size. The relative impact of the nicotinic acetylcholine receptor gene variants on the propensity to smoke or on the response to the direct carcinogenic effects of smoke is undergoing validation in large numbers of smokers and nonsmokers.

Familial risks of lung cancer provide another route for uncovering susceptibility genes. In one genome-wide linkage analysis, a genomic locus on chromosome 6q23-25 has now been associated with a familial risk of lung cancer.[27] To date, no tumor suppressor genes inactivated by mutation have been identified in this locus, although the frequent inactivation of multiple candidate tumor suppressor genes within chromosome 6q likely contributes to development of sporadic lung cancer.[28]

Finally, a genome-wide association analysis was conducted to investigate associations between SNPs and the risk of lung cancer in 194 patients with familial lung cancer and 219 cancer-free control subjects.[29] A strong association was found between common sequence variants at 15q24-25.1 and lung cancer. The risk of lung cancer was more than fivefold higher among those subjects who had both a family history of lung cancer and two copies of high-risk alleles in the 15q24-25.1 locus as compared with control subjects.[29] Thus, studies into sporadic and familial cancer risk may identify some of the same genetic predispositions, such as 15q24-25.1, but have the potential to identify novel genetic predispositions.

EARLY EVENTS IN LUNG TUMORIGENESIS

Mucosal Response to Injury, the Emergence of Critical Mutations

Since the late 1970s, somatic mutations have been identified and associated with the development of cancer. These mutations, involving those of tumor suppressor genes or oncogenes, may or may not be critical events in the formation of the cancer. Epidemiologic data support the hypothesis that clones of cells accumulate several key mutations during oncogenesis. Proposed by Loeb,[30] the model of the mutator phenotype, a phenotype in which mutations develop faster than in normal cells, suggests that this propensity for rapid mutation may be required for multistage carcinogenesis and may be acquired by cells early on. This phenotype may also be hereditary.

DNA mutations may arise from a failure to repair DNA damage. In addition to damage and mutations due to environmental carcinogens, spontaneous errors of replication attributed to DNA polymerase occur at a rate of 1/10,000 to 1/100,000 base pairs. These intrinsic mutations may also be an important component underlying genomic instability and eventually tumor development. A recent analysis of 623 genes in 188 lung adenocarcinomas revealed over 1000 somatic mutations, and those in 26 different genes were found to be mutated at significant frequencies.[31] Many of these mutated genes fall into a handful of common signaling pathways. We briefly comment on a few examples of these commonly acquired mutations in *K-ras*, p53, p16, BRaf, and epidermal growth factor receptor (EGFR).

K-ras mutations are the most common mutations found in lung cancer. The mutations are found in 30% of adenocarcinomas of the lung[32] but much less frequently in other subtypes. Mutations in *K-ras* lead to activation of several pathways. Ras proteins activate the RAF/MEK/ERK pathway, which mediates cell growth and cell cycle entry by phosphorylation of transcription factors (such as c-FOS, ELK1, and MYC); phosphorylation of the RSK (ribosomal protein S6 kinase) and MNK (mitogen-activated protein kinase [MAPK]–interacting serine/threonine kinase) family of kinases; and the phosphatidylinositol-3-kinase (PI3K)/protein kinase B (AKT) pathway, which controls cell survival, cell growth, and metabolism.[33] Mutant *K-ras* (most frequently, codon 12 G-T transversions) can transform airway epithelial cells[34] by activating the extracellular signal-regulated kinase (ERK)–MAPK pathway. Because the *K-ras* mutation is found early in alveolar atypical hyperplasia, a presumed precursor lesion to adenocarcinomas, *K-ras* mutation may be an important step in the genesis of this subtype of lung cancer. The fact that mutant ras transgenic mice develop adenocarcinomas of the lung supports this hypothesis.

p53 is a prototype tumor suppressor gene that is the most common genetic lesion in human cancers[35] and is thus well suited for analysis of the mutational spectrum in human cancers. p53 is a potent regulator of cell growth and DNA damage responses and directly regulates the cell cycle via induction of p21. Mutations of p53 are most commonly seen in squamous carcinoma and small cell carcinoma of the lung. Mutations predominantly representing G to T transversions consistent with causation by bulky DNA adducts such as the polycyclic hydrocarbons are frequently found in the lungs of smokers.[8] When mutated, p53 can function as an oncogene. Mutated p53 exhibits a prolonged half-life, and the protein can be found to be overexpressed in about 50% of lung cancers by immunohistochemistry.[36] Although not consistently associated with prognostic significance, there is little doubt that p53 mutations play a key role in tumor development by dysregulation of cell cycle control and apoptosis.

p16, a cyclin-dependent kinase inhibitor, functions as a tumor suppressor gene and critical member of the retinoblastoma (Rb) cell cycle control pathway. It is inactivated in over 40% of NSCLCs. Previous studies have demonstrated that point mutations, deletion or loss of heterozygosity on 9p21, or hypermethylation of the gene provides alternate mechanisms of inactivation in 30% to 50% of NSCLCs. In smokers, the loss of p16 appears to be from different mechanisms than in nonsmokers. In tumors arising in smokers, p16 was lost due to point mutations or homozygous deletions, whereas in tumors from nonsmokers, p16 was lost via promoter hypermethylation.[37] The relationship between the loss of p16 and tobacco points to p16 as another genetic target of cigarette smoke in the pathogenesis of lung cancer.

BRAF is a serine/threonine kinase that belongs to the RAS/RAF/MEK/ERK/MAPK pathway, and is important for transducing mitogenic signals from the cell surface. BRAF mutations were found in thyroid, colorectal, and lung cancer as well as in a majority of malignant melanomas.[38] The percentage of BRAF-mutant lung cancers appears to be less than 5% and to be limited to lung adenocarcinomas.[39] This observation has led to drug discovery programs dedicated to specific targeting of BRAF-dependent tumors. Trials investigating the efficacy of these agents are ongoing in several tumor types.[40] Whether BRAF-mutant lung cancer can be successfully treated with inhibitors targeting downstream pathway members of BRAF remains to be established.

PIK3CA, the gene encoding the catalytic subunit of the class-1a phosphoinositide-(3,4,5)-kinase, is an important component of the AKT antiapoptotic pathway. Mutations in this gene have been found in a large fraction of epithelial cancers.[41] Although the most frequently mutated oncogene in breast cancer, PIK3CA, was found to be mutated in less than 5% of lung cancers. In several functional analyses, these mutations were found to be oncogenic by their ability to activate the AKT survival pathway.[42] Most recently, preclinical studies involving new generation PI3K-kinase inhibitors suggest that tumors carrying these mutations might be exquisitely sensitive to pathway inhibition.[43]

The receptor tyrosine kinase EGFR is mutated in approximately 10% of white and 40% of East Asian patients with NSCLC,[44–46] leading to constitutive activation of this growth factor receptor. These mutations are more common in patients who have never smoked, whose tumors are of lung adenocarcinoma histology, and who are of East Asian ethnicity. Exon resequencing in responders to the tyrosine kinase inhibitors, gefitinib or erlotinib, revealed that most of them had deletion mutations in exon 19 or point mutations in exon 21 of the EGFR kinase domain, but patients not responding to these drugs only rarely had these mutations.[47] Targeting inhibition to this mutant EGFR appeared to be an additional example of successful therapeutic targeting of oncogenically activated tyrosine kinases. Even though dramatic responses are frequently seen in patients with the common EGFR mutations, most patients initially responding to EGFR inhibitors will eventually relapse. These relapses may be explained by additional mutations in EGFR or activation of other growth pathways. In certain cases, resistance has been found to be due to an activating mutation of EGFR at a second site. This mutation, T790M, is analogous to the T315I mutation of the murine leukemia viral oncogene homolog (ABL) that causes acquired resistance in chronic myelogenous leukemia (CML) patients who had initially responded to imatinib.[48,49] An additional mechanism of acquired resistance is the de novo amplification of the MET receptor tyrosine kinase gene.[50] Understanding the sources of acquired resistance may reveal strategies for prevention of resistance.

Because only a minority of lung cancer patients will respond to anti-EGFR therapy, investigators have sought biomarkers of response to EGFR-directed therapy. Mutations in the *K-ras* oncogene constitute a negative predictive marker of response to EGFR-directed therapy.[51] In addition, *K-ras* mutations, male gender, absence of bronchoalveolar carcinoma (BAC) feature, advanced stage, and smoking history were found to be poor prognostic factors for overall survival, whereas EGFR mutation and amplification were not.[52] It is possible that the presence and type of EGFR mutations will indicate which patients will respond to therapy with EGFR inhibitors. Trials selecting patients either on the basis of the EGFR mutations or on clinical characteristics of EGFR mutations (Asian ethnicity, never smokers, adenocarcinoma) have yielded response rates to EGFR inhibition therapy exceeding 70% and led to median overall survival exceeding 20 months.[53–55] However, as mentioned, EGFR mutations are highly prognostic for improved survival independent of therapy and, thus, their use for the selection of therapy is controversial, especially in Western populations.[56] However, there is an increasing sentiment that EGFR (and *K-ras*) mutation testing should become part of the standard pathologic analysis of lung adenocarcinomas.

The efforts to characterize the genomes of major human cancer types[57,58] have revealed that, beyond known cancer-related genes, many additional genes are mutated in individual cancers. However, most of these mutations are found in only a single tumor, suggesting that each tumor contains an individual set of mutations contributing to tumorigenesis. Ding and coworkers[31] found between 0 and 40 mutations in individual lung adenocarcinomas, with an average of 24.3 for those with a mutant PRKDC gene (involved in DNA repair) and 4.7 for those without this mutation. The average number of mutations for different tumors range from 48 in pancreatic cancer to 101 in breast cancer.[59] Interestingly, both of these numbers are higher than that for lung cancer. Ultimately, functional cell biology experiments will be required to establish the individual contributions of these mutations to oncogenic transformation.

Mutagens

Cigarette smoking may account for 85% of lung cancers. Approximately 1 in 10 life-smokers will develop lung cancer, suggesting individual differences in susceptibility,[60,61] Environmental carcinogenesis resulting from tobacco smoke exposure is a complex process that can involve activation of procarcinogens that lead to DNA adduct formation and subsequent failure of DNA repair, which should normally remove these adducts. Studies comparing DNA repair capacity among newly diagnosed lung cancer patients and age-matched controls indicate significant differences between the two groups.[62]

The majority of lung cancers are now diagnosed among ex-smokers.[63] This suggests that the accumulation of molecular damage during cigarette exposure initiates a cascade of events that will lead to cancer even decades after smoking cessation. Risk factors for lung cancer include smoking, including total consumption, age of initiation, and years of smoking; occupational and environmental exposure (asbestos, uranium, radiation), diet (vitamin A, vitamin E, cholesterol), and host (familial aggregation) and genetic factors. Some of the components of cigarette smoke implicated in lung cancer are now recognized. Cigarette smoke is a complex mixture and includes substances that are responsible for DNA adduct formation such as polycyclic aromatic hydrocarbons (PAHs), aromatic amines, and tobacco-specific nitrosamines (NKKs). These form DNA adducts that may escape normal adduct repair mechanisms and result in heritable alterations in DNA sequence. The conversion of G-C base pairs to T-A leads to activation of the *K-ras* oncogene and inactivation of the p53 tumor suppressor gene.[12] The activated form of benzopyrene (BaP) is the diol epoxide BPDE that can cause DNA adducts, leading to point mutations and single-strand chromatid breaks.[64] A major concern is that people who start smoking at

young ages seem to be have greater amounts of permanent DNA alterations than smokers who start smoking later.[9]

The Field Cancerization Effect

Whereas lung cancer may originate from only one or a few airway epithelial cells, it is clear that exposure of the whole airway mucosa to tobacco smoke could cause the entire bronchial tree to be at increased risk of developing lung cancer, leading to the concept of field cancerization (Fig. 45-1). Field cancerization was first proposed in the 1950s[7] and its molecular correlates later confirmed in the airways of human smokers.[65] Field cancerization is also demonstrated by the elevated Ki-67 labeling index in the airways of smokers at more than one site.[66] In addition, evidence has been found in a single smoker with diffuse dysplasia that a single identical point mutation of p53 could be found diffusely in both lungs, but not in the blood or other solid organs, suggesting that a single progenitor bronchial epithelial clone populated the bronchial mucosa. Although the risk of developing lung cancer increases with the presence of such preinvasive lesions, clearly the entire at-risk epithelium does not undergo malignant transformation, and no one has identified the molecular determinants of preinvasive lesions that may predict irreversible progression to lung cancer. Thus, if one considers the total number of bronchial epithelial cells and the proliferation rate of patches of clonal abnormalities, cancer remains a rare event.[67]

The concept of field cancerization has implications for approaching diagnosis, prevention, and treatment of lung cancer. For example, diagnostic information may be contained even in the normal-appearing airway epithelium; in patients with and without lung cancer, changes in the airway field have been found to correlate with the presence of lung cancer elsewhere in the airways or with an elevated risk of transformation.[68,69] Similarly, prevention efforts should be directed to the entire epithelium, which can then also provide biomarkers for effective prevention. Finally, the field cancerization concept has major implications for therapy because one should consider treating the entire field as opposed to limiting treatment efforts to preinvasive lesions that may never develop into lung cancer.[70]

Genomic Instability

Lung cancer develops along a multistage process in a setting of increasing genomic instability. Genomic instability is universally found during accumulation of these genetic abnormalities.[5,30] Genome instability is a fundamental characteristic of cancer initiation and progression. However, our understanding of the onset of instability, the rate of instability, and the mechanisms

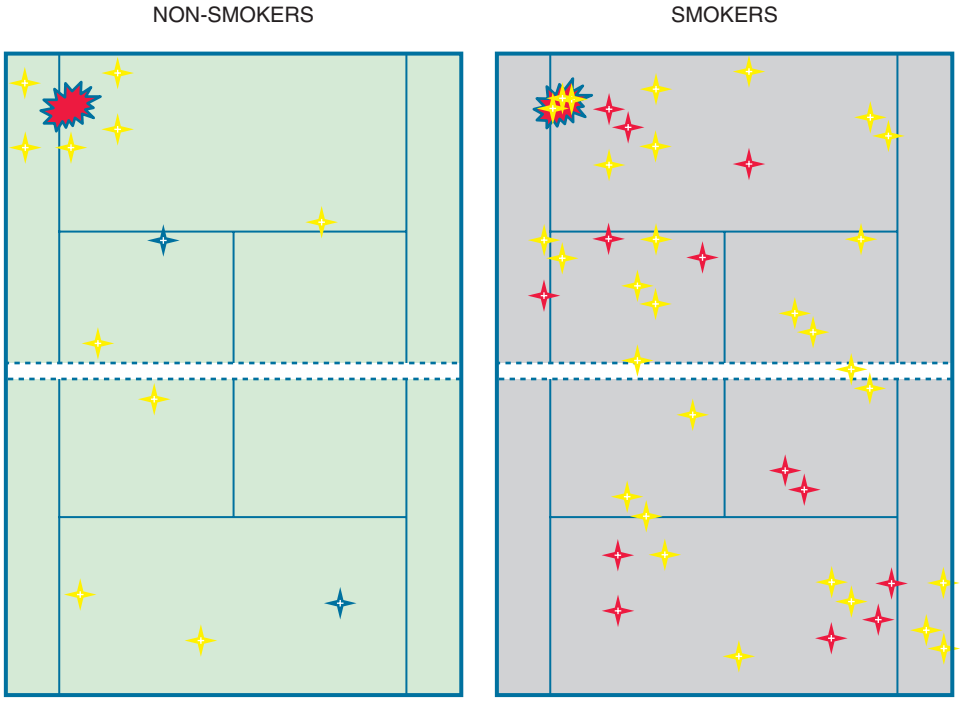

FIGURE 45-1 ■ The different fields of injury in nonsmokers and smokers. The association of lung tumors and genetic mutations differs between nonsmokers and smokers. In this figure, the lung epithelial surface area is displayed as if it were a tennis court, known to be of roughly comparable size. The tumors (*red ovals*) and associated genetic alterations (*red and yellow stars*) are shown as representative for nonsmokers and for smokers. In nonsmokers, lung tumors develop different chromosomal abnormalities (chromosomal segregation and chromatin epigenetic alterations), have a lower number of abnormally expressed genes, and demonstrate a lower mutation rate than that seen in smokers. Other differences, in cancer stem cells or in the inflammatory response to environmental exposures, may also exist between the two groups.

leading to instability is far from complete. We do know that, from initiation to promotion and to the development of an invasive phenotype, a series of molecular changes contribute to a molecular instability that puts the airway epithelium of some smokers at greater risk for lung cancer.

Two main theories of the genomic changes underlying lung tumorigenesis have emerged: the stochastic (random) and the gene-centric (nonrandom) theories. The *stochastic theory* argues that lung cancer arises by genomic aberrations that are stochastic or random in nature.[71] Indeed, in many tumor types, there are relatively few cancer-specific mutations whereas there can be a high degree of subchromosomal aberrations.[72–74] Some of these low-level aberrations have been called noise but may reflect the underlying instability. Nonclonal chromosomal alterations (NCCAs) such as defective mitotic figures, chromosomal fragmentation, or nonrecurrent genomic alterations indicate a dynamic process leading to instability.[71] NCCAs may provide a survival advantage whereas clonal chromosomal alterations at a later stage of progression may confer a growth advantage.

In contrast, the *gene-centric theory* argues that sequential accumulation of epigenetic and genetic aberrations is important for lung cancer development.[75] This gene-centric theory is particularly appealing to explain clonal alterations in genes implicated in tumor cell growth and survival that represent possible targets for the management of cancer.[76] These alterations include single nucleotide point mutations, changes in chromosome copy number (aneuploidy),[6,77] and specific genomic amplifications or deletions.[78–80] These genetic changes are implicated in the pathogenesis of tumor development in part through the activation of oncogenes and inactivation of tumor suppressor genes and are considered the hallmark of cancer.[81] Some genomic signatures seem to persist after tumor development and throughout their progression and their histologic differentiation. The fact that smoking history leads to specific genomic alterations across different tumors also suggests a specific pathogenesis with genomic alteration resulting from a series of dysregulations in DNA repair mechanisms and chromosomal segregation.

The two theories are not necessarily mutually exclusive and both random and nonrandom changes may be important. The progressive accumulation of mutations, loss of apoptotic control and regulation of cell proliferation, and the appearance of an abnormal number of chromosomes (aneuploidy) are associated with worsening dysplasia phenotypes and may reflect underlying dysregulation of mechanisms controlling genomic fidelity. In some lung tumors, mismatch repair deficiency leads to microsatellite instability at the nucleotide sequence level whereas, in other tumors, aneuploidy is the dominant feature.[82] Specific defects in DNA repair may also be present. Polymorphisms in DNA repair genes XPD (codon 312 Asp/Asp vs. Asp/Asn) are associated with impaired efficiency of DNA repair and apoptotic function in lung cancer.[83] Measures of genomic instability parallel rates of loss of heterozygosity[84] and accumulation of other genomic abnormalities.[82] In the airways, progressively more severe and more frequent abnormalities are seen in preinvasive lesions. The progressive accumulation of genomic abnormalities associated with clonal growth among populations of tumor cells is well described. Recent reports use array comparative genomic hybridization (aCGH) to assess genomic instability; in these reports, in addition to numerical chromosome changes, smaller aberrations are found at specific chromosome loci.[85] Clearly, genomic instability itself drives malignant progression and this instability may itself be a target for prevention or therapy of lung cancer.

Role of Inflammation in Lung Tumorigenesis

The tumor cell signaling pathways that trigger the uncontrolled proliferation, resistance to apoptosis, metastasis, and escape from immune surveillance are partially understood. In contrast, how inflammation and its control may participate in lung tumorigenesis remains more poorly understood.

The reason why some smokers develop chronic obstructive pulmonary disease (COPD), some develop lung cancer, and some develop both diseases remains unclear.[86] Cigarette smoke contains high concentrations of oxidants and free radicals (ROS) together with thousands of particles. Local antioxidant and metabolizing enzymes inactivate many toxic species. Nuclear factor-κB (NF-κB) activation and subsequent transactivation of inflammation-related genes appear to play a central role in both COPD and cancer.[87,88] How some smokers remain free of disease while others develop COPD or cancer may be determined by the activation of genes in response to cigarette smoke.[89] Following exposure to the same toxic smoke, individuals appear to progress toward disease along different paths. In those who develop lung cancer, genomic instability develops that causes further chromosomal abnormalities resulting in clonal expansion of cells that have a growth advantage, whereas in those who develop COPD, an intense immune response and further inflammation predominate. The process by which these events diverge is unclear. More likely, heritable genetic polymorphisms that influence susceptibility to DNA or connective tissue damage, efficiency of DNA or connective tissue repair, the intensity of immune responses to constituents of tobacco smoke, intrinsic or acquired genomic instability, or the induction of factors that suppress immune surveillance likely determine the disease pathway taken.

Toll-like receptors (TLRs), which recognize a variety of pathogen-associated molecular patterns, are centrally involved in the initiation of the innate and adaptive immune responses. However, recent evidence shows that functional TLRs are also expressed on a wide variety of tumors, suggesting that TLRs may play important roles in tumor biology, and are being evaluated as therapeutic targets. Activation of tumor cell TLRs not only promotes tumor cell proliferation and resistance to apoptosis but also enhances tumor cell invasion and metastasis by reg-

ulating metalloproteinases and integrins. Moreover, the activation of TLR signaling in tumor cells induces the synthesis of proinflammatory factors and immunosuppressive molecules, which enhances the resistance of tumor cells to cytotoxic lymphocyte attack and leads to immune evasion. Thus, the neoplastic process may usurp TLR signaling pathways to advance cancer progression, which suggests that targeting tumor TLR signaling pathways may open novel therapeutic avenues.

Role of Viruses in Lung Tumorigenesis

Viruses can cause lung cancer in animal models; such viruses, including SV40 large T antigen and polyomavirus (PyV) large and middle T antigens, frequently cause lung cancer in transgenic models. No common respiratory viruses have been conclusively incriminated in the development of human lung cancer, but several have been implicated. Human papillomavirus (HPV), for example, has been associated with lung cancer and, in particular, lung cancer arising in women.[90] Simian virus 40 has been incriminated in the development of mesothelioma[91]; Epstein-Barr virus (EBV) has been suspected to be involved in the development of papillomas, mesotheliomas, and lymphomas of the lung. Some have proposed that the Jaagsiekte sheep retrovirus or a variant may cause BAC in humans as it does in sheep. However, many polymerase chain reaction (PCR)–based assays have attempted to correlate bronchogenic carcinomas with respiratory viruses without success. Recent advances in proteomics may be useful in studying the role of viral infection in airway epithelial cell transformation. The proteomic analysis of tumors may allow the identification of peptide sequences specific to pathogens otherwise unknown in tumorigenesis.

In recent reports, infectious agents associated with diseased human tissues have been discovered by high-throughput sequencing technologies.[92] However, identification of a nucleic acid sequence in a sample does not necessarily implicate an organism in a disease. There may be contamination of tissues, the fragments of nucleic acid do not necessarily mean that the organism itself is present, and viruses (e.g., human herpesvirus and human papillomavirus) may be present and either part of a subclinical infection unrelated to the disease or latent in human tissue but not actively causing the illness.

OTHER MOLECULAR ALTERATIONS DRIVING THE TUMOR PHENOTYPE

Chromosomal Changes

Cancer cells are characterized not only by mutations but also by a series of other chromosomal aberrations including deletions and amplifications.[93–95] Although chromosomal aberrations have been linked to most tumors and are a characteristic of cancer,[81] chromosomal aberrations are recognized as increasingly complicated.[6,96] Many of the observed alterations have been considered consequences instead of causes of lung cancer development. However, there are chromosomal regions with frequent losses found in regions coding for essential tumor suppressor genes and DNA repair genes that may be involved in the pathogenesis of several tumor types.[97]

Genetic alterations in NSCLC have been measured by array comparative genomic hybridization.[79,80,98] Specific areas of amplification and deletion can distinguish squamous from adenocarcinoma of the lung and other subtypes. Among many areas of genomic abnormality, amplification of chromosomal region 3q26-3q29 was the most prevalent abnormality in squamous carcinoma of the lung. These studies confirm and refine previously documented copy number alterations in lung cancer using CGH analysis[78,99] and show particularly common amplified regions on chromosomal arms 1q, 3q, 5p, 8q, 11q, 12p, 17q, and 20q.

Chromosomal abnormalities may have a role in classifying tumors. Attempts have been made to look comprehensively at the genome to identify tumors with common groups of genetic features that might provide biologic or clinical guidance beyond traditional classification by light microscopy. SNP arrays have been developed that are able to analyze loss or gain of genetic material at very high resolution,[80] and cancer genome resequencing efforts are likely to uncover common mutations.[100] From genomic analyses, relatively small differences have been observed between squamous and adenocarcinoma of the lung. The most prevalent differences were described on chromosome 3q and include the p63 gene.[98,101,102] Accumulation of specific chromosomal abnormalities has been correlated with clinical and pathologic data in NSCLC. Chromosomal abnormalities have been correlated with clinical outcome for a variety of cancers,[95] but often, the genes responsible for the observed biology are very difficult to define and are only partly understood.

Chromosomal abnormalities may underlie the progression of cancer. The most common early genetic alterations in NSCLC involve loss of genomic regions of chromosomes 3p and 9p, deletions of the chromosomal arm on 5p, and mutations of p53 and *K-ras*.[103] Loss of chromosomal regions on chromosomes 3p and 9p have been recognized as early events and identified in preinvasive lesions and in the normal-appearing epithelium of smokers.[104,105] In contrast, p53 and *K-ras* mutations have been seen primarily in later stages of preneoplasia or frank invasive lesions.[103] Amplification of large regions on the q arm of chromosome 3 has been characterized in invasive carcinomas[78,79,99,106] and only recently in preinvasive lesions.[101]

Patterns of chromosomal change may be specific to cigarette smoke. In fact, lessons have been learned from the molecular analysis of lung cancers from patients with and without a history of smoking. For example, loss of heterozygosity (LOH), the loss of a chromosome containing a wild-type gene when the gene on the other allele was previously mutated, at chromosome 3p14 was evaluated in smokers and ex-smokers. LOH at this site was found to be more frequent in current smokers (22/25 cases) than in former smokers (5/11 cases), and the high frequency in smokers correlated with a high metaplasia

index.[104,105] This implies that not only are these chromosomal changes frequent in normal-appearing bronchial epithelia but also that cells with these changes may regress after smoking cessation and be replaced by cells without this damage. Patterns of lung cancer alleleic loss have been investigated in detail and new regions of allelic loss have been identified using high-throughput technologies.[84] Interestingly, chromosome losses such as LOH and chromosomal gains are more prevalent at all sites in cancers from smokers than from nonsmokers, indicating a greater chromosomal instability in the cancers from smokers.[10] aCGH has been used to discover specific patterns of genomic alterations found in NSCLC that might be related to smoking history. Smoking-related genomic signatures were identified in NSCLCs and could be predicted with an overall 88% accuracy[18] (Fig. 45-2). Lung tumors arising from current smokers had the greatest number of copy number alterations. The genomic regions most significantly associated with smoking were located within 32 regions and functionally associated with genes controlling the M phase of the cell cycle, the segregation of chromosomes, and the methylation of DNA. Understanding chromosomal abnormalities specific to cigarette smoke exposure may point to the etiology of smoking-induced lung cancer.

Specific translocation is another chromosomal abnormality, but it is much less commonly observed in lung cancer than in hematologic or mesodermal tumors.[107,108] Chromosomal translocations modify gene function through the deregulated expression of cellular proto-oncogenes without altering the structure of the protein product or by generating and expressing a chimeric protein with growth-promoting activities. Unbalanced translocations are also responsible for a large number of LOHs, which is a genetic event known to cause inactivation of tumor suppressor genes.[109] Dang and colleagues[110] identified a chromosome 19-15 balanced translocation associated with overexpression of Notch-3. The authors developed a transgenic mouse model overexpressing Notch-3 causing neonatal mortality with a phenotype suggestive of alveolar cell hyperplasia. These data suggest that Notch-3 overexpression prevents epithelial differentiation and this may play a significant role in promoting oncogenesis in a subset of lung cancers.[111]

Epigenetic Alterations of Gene Expression in Lung Cancer

DNA Adducts

One marker for significant carcinogen exposure is the level of DNA adducts in normal cells. DNA adducts are covalent modifications of the DNA that result from exposure to specific carcinogens. In addition to being markers of carcinogen exposure, it is possible that these adducts may directly alter regulation of transcription of tumor suppressors or oncogenes.[112] The distribution of BPDE adducts along exons of the p53 gene in BPDE-treated HeLa cells and bronchial epithelial cells has been mapped at nucleotide resolution.[8] Cigarette smokers have higher adduct levels than nonsmokers. Because DNA adduct levels in tumor tissue and in blood lymphocytes have been associated with lung cancer[113] and because these levels correlate with daily or lifetime cigarette consumption and do not reverse after smoking cessation,[114] DNA adducts have been proposed as potential biomarkers of risk for lung cancer.

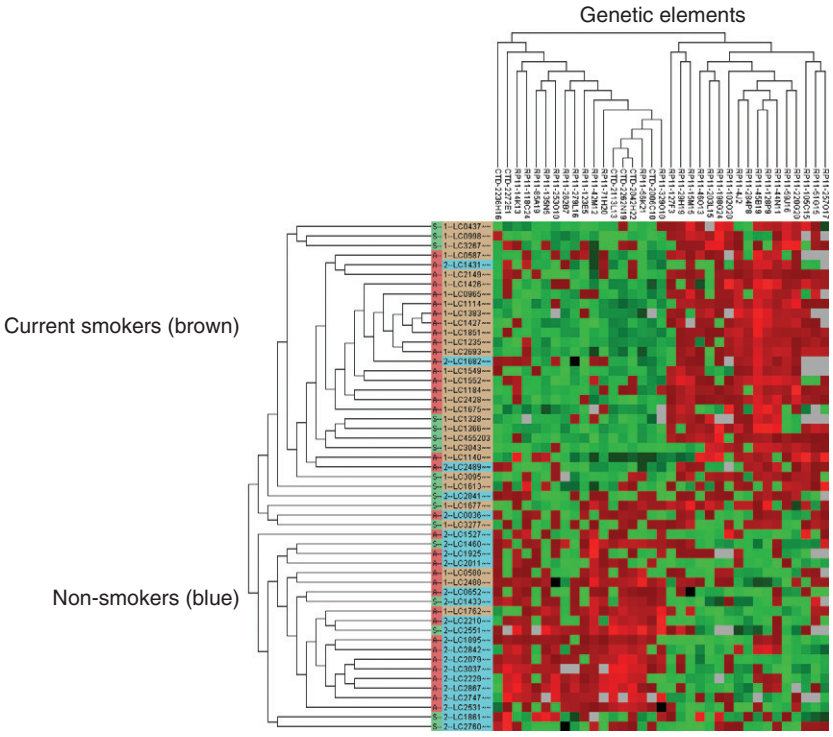

FIGURE 45-2 ■ Smoking-related genomic signatures in non–small cell lung cancer. The genomic signature of lung cancers differs between nonsmokers (N = 23) and smokers (N = 30) and smoking history leaves a specific genomic signature in the DNA of lung tumors. On the y-axis, the current-smokers group is shown in *brown* and the never-smokers or long-term quitters in *blue*. (From Massion PP, Zou Y, Chen H, et al: Smoking-related genomic signatures in non–small cell lung cancer. Am J Respir Crit Care Med 178:1164–1172, 2008.)

In an attempt to identify risk factors associated with the level of DNA adduct accumulation, Wiencke and associates[9] studied DNA adducts in current and former smokers and found that, for current smokers, the most important variable in determining the level of DNA adducts was the number of cigarettes smoked per day. In contrast, they found that for ex-smokers, the most important variable was age at initiation.[9] Mechanisms responsible for the relationship between DNA adduct levels and age of initiation are unknown and the relative contribution of decreased adduct removal by DNA repair or cell turnover or increased adduct formation at younger ages is yet to be determined. Prospective studies are needed to follow current and ex-smokers over time to determine the value of adduct levels in risk assessment.

DNA adducts have been associated with smoking status and with risk of lung cancer. In a matched case-control study nested within the prospective Physicians' Health Study, there was an increased level of DNA adducts in active smokers who later developed lung cancer as compared with smokers who did not develop lung cancer.[115] The level of adducts has also found to be more prevalent among female than male smokers. Women smokers may be at higher risk of developing lung cancer for a given tobacco exposure and women also seem to accumulate aromatic/hydrophobic DNA adducts at a faster rate than men.[116]

DNA Methylation

In contrast to genetic mutations that require two hits to inhibit both alleles, aberrant methylation is a dynamic process over multiple division cycles and may cause increasing degrees of gene function loss by increasing the density of methylation on promoter regions. "CpG islands" the targets of DNA methyltransferase, are associated with the transcription start sites in almost half of human genes.[117] Dense methylation of cytosines within CpG islands can cause heritable gene silencing.[118] Genomic DNA hypomethylation, leading to genomic instability, as well as promoter hypermethylation, leading to inactivation of tumor suppressor genes, have been shown to be common events in human cancers.[119] Gain of methylation in normally unmethylated CpG islands surrounding gene transcription start sites is an increasingly recognized and important means by which gene expression is altered in tumors.[120] The genes affected include over half of the tumor suppressor genes that are known to cause familial cancers. Aberrant methylation can begin early in tumor progression and cause loss of cell cycle control (e.g., p16),[121] loss of mismatch repair function (e.g., MLH1) and loss of cell-cell interaction (e.g., E-cadherin). The exact mechanism by which hypermethylation may cause tumor progression is still unknown. In fact, there is still debate about whether methylation is a result or a cause of gene function loss.[122]

Promoter region hypermethylation has also been proposed as an excellent tumor marker. In lung cancer, methylated loci were found in both tumor and sputum DNA and have been detected in the sputum for up to 3 years before the diagnosis of cancer.[123] Recently, methylation of the promoter region of four genes (TP16, CDH13, RASSFIA, and APC) in patients with stage I NSCLC was shown to be associated with early recurrence.[124]

Histone Acetylation

The association of DNA methylation and histone deacetylation may cause silencing of hypermethylated genes in tumors. During transcription, chromatin unfolds and allows ribosomal access to the DNA. Acetylation of histone tails on the nucleosome is associated with chromatin unfolding and increased regional transcriptional activity. Histone deacetylases (HDACs) modulate chromatin structure by regulating acetylation of core histone proteins. Deacetylation of histones is thus associated with compacting the DNA and repressing transcription. In lung cancer cell lines, for example, deacetylation of histone 3 correlated with refractoriness to retinoic acid, a phenomenon related to RARbeta promoter methylation in a subset of cell lines.[125] Inhibitors of HDACs have already shown to decrease the level of a series of oncoproteins[126] suggesting a potential role as antitumor therapeutic agents.

Expression Arrays

RNA expression patterns may be more relevant than either DNA copy number or epigenetic DNA changes because DNA affects cellular behavior ultimately via proteins translated from the RNA. The microarray technology developed in the mid-1990s offers the hope that a genetic fingerprint of these tumors can be developed associated with clinical features. Beyond the need for better classification of lung cancers, this technical revolution opens a window of understanding to the world of tumor behavior (disease progression, recurrence, response to therapy) as well as to the mechanisms of tumor development. Tumor expression profiles are also influenced by the surrounding nonmalignant cells. The combination of tumor and cell line profiling allows for the study of the regulatory role of both entities.[127]

Expression array data have provided new ways to distinguish and classify tumors. For example, efforts to classify lung cancers based on microarray analysis have revealed subclasses of adenocarcinomas. Selected genes allow the discrimination between primary lung cancer and metastasis of extrapulmonary sites.[128] Studies of expression profiles of adenocarcinomas of the lung using commercially available gene chips[128] or custom arrays[129,130] identified different classes of tumors with some overlap. Four classes of adenocarcinomas were found to have specific prognoses and molecular signatures. These were characterized respectively by their (1) expression of cell cycle or proliferation genes, (2) expression of neuroendocrine markers, (3) expression of markers of alveolar origin, and (4) expression of ornithine decarboxylase or glutathione S-transferase.[128] The neuroendocrine subclass was found to have a clinical outcome significantly worse than the others. These

subclass differences may suggest possible new therapies targeted to these subsets and explain why tumors that superficially seem similar may respond to therapy quite differently. For example, when used to study neuroendocrine tumors, cDNA microarrays found poor correlations between genes expressed in carcinoid and small cell lung cancer (SCLC),[131] tumors that may be morphologically similar but that behave very different clinically.

In sum, since the late 1990s, we have learned that the somatic molecular alterations in cancers yield signatures that can be used for subclassification[128,130] or for predicting patient survival[130,132] risk of recurrence,[133] and response to therapy.[128,134] However, these signatures have not always withstood independent validation.[135]

RNA Regulation by miRNA

Micro-RNA (miRNA) regulates gene transcription and translation.[136,137] In a study analyzing 104 pairs of NSCLC and corresponding normal lung tissues, an expression profile of 43 miRNAs discriminated lung cancers from noncancerous lung tissues.[138] Six miRNAs (hsa-mir-205, hsa-mir-99b, hsa-mir-203, hsa-mir-202, hsa-mir-102, and hsa-mir-204-prec) were differentially expressed in adenocarcinomas when compared with squamous cell carcinomas. Furthermore, high hsa-mir-155 and low hsa-let-7a-2 expression correlated with poor survival in lung adenocarcinomas. In another study of 143 surgically resected NSCLCs, low let-7 expression was also significantly associated with shorter survival whereas overexpression of let-7 in A549 lung adenocarcinoma cell line inhibited lung cancer cell growth in vitro.[139]

Differentially expressed miRNA genes in NSCLC are frequently located in fragile sites of chromosomes highly prone to mutation and/or chromosomal regions with frequent copy number alterations, suggesting that differences in miRNA expression may be induced by genomic alterations. Because greater than 50% of miRNAs are present at cancer-related chromosomal regions, miRNAs are also suspected to play a role as oncogenes or tumor suppressor genes. miRNA expression profiles represent potential markers for lung cancer diagnosis, classification, and prognosis. Methodologic issues related to the reproducibility of the analytical platforms should be resolved soon.

Proteomic Alterations

Changes in DNA and in RNA may not be reflected in changes in protein expression. In fact, recent advances in protein profiling have suggested a poor correlation between gene expression and protein expression. It is now well established that protein activity is often highly regulated by posttranslational modifications such as proteolysis and phosphorylation. Neither protein expression levels nor posttranslational modification can be assessed by genomic or cDNA microarray technologies, prompting interest in evaluation of protein expression, commonly referred to as "proteomics."

Lung cancer has been studied by several proteomic methods including two-dimensional gel electrophoresis, mass spectrometry, and immunohistochemistry to identify biomarkers in tumors[140–142] or in body fluids such as bronchoalveolar lavage (BAL)[143] of patients with or without cancer. Matrix-assisted laser desorption ionization (MALDI) profiling is rapid, high throughput, but detects only the most abundant proteins of relatively low molecular weight and does not enable direct identification when applied to complex proteomes. Two dimensional gel-based analysis suffers problems of interlaboratory reproducibility and throughput. Mass spectrometry has an even lower throughput, but yields confident identification of large numbers of proteins from every cellular compartment.

High-Throughput Profiling Techniques

Matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) is capable of very high throughput in which a sample can be analyzed in seconds and with a higher tolerance for salts, buffers, and other biologic contaminants. Because of these qualities, MALDI MS has been utilized to study proteins/peptides in serum,[144–146] urine,[147] tissue extracts,[148,149] whole cells,[150] and laser-captured microdissected cells.[151] These profiling experiments have been applied to a series of biologic specimens. In one MALDI MS study from our group,[152] hierarchical clustering of data from lung cancers and normal tissues allowed the identification of patterns distinguishing between tumor and normal as well as histologic subgroups.

In general, however, because of a lack of reproducibility between platforms and institutions, proteomic profiling has not yet made a significant impact in clinical medicine. This is in contrast with greater success in the translation of genomic signatures to the clinic.[153,154] Proteomic profiling in biologic fluids or tissue samples is not without challenges. The complexity of the sample composition and the predominance of few abundant proteins in the sample that can mask lower abundant proteins currently limit the utility of this approach.

Molecular Networks, Pathway Analyses

To determine the most informative molecular targets from high-throughput assays, increasingly sophisticated analytic tools are being developed. These analytic tools help define biologic processes, cellular components, or molecular pathways as well as provide gene ontology information about genes of interest; such analytic tools include WebGestalt,[155] Pathway Studio, and Ingenuity. The Kyoto Encyclopedia of Genes and Genomes (KEGG) is a knowledge base for systematic analysis of gene functions in terms of the networks of genes and molecules.[156] Because most pathway and network analysis tools are gene-centric, for tandem mass spectrometry proteomic analyses, a software package called IDPicker has been developed to identify indiscernible protein groups defined by short tryptic peptide sequences. Tools for combining and integrating this multidimensional information at various levels are urgently needed.

TRANSLATING LUNG CANCER BIOLOGY TO THE CLINIC

Biomarkers

Biomarkers are measurable products of tumors that can assist in the diagnosis (identification of cases), prognosis (correlation with outcome independent of interventions), or prediction (associated with outcome after a specific intervention). It is clear that lung cancer outcomes could be improved by high-quality biomarkers addressing each of these categories (Fig. 45-3). Unfortunately, very few candidates have been identified, and even fewer have been validated.

Biomarkers are needed to identify patients at high risk for lung cancer and to identify surrogate end points for response to chemoprevention strategies. The discovery of biomarkers for lung cancer is hampered by the slow onset of lung cancer and the lack of screening tests to identify early disease. The assumption underlying the concept of biomarkers is that certain molecular characteristics of the lesions are highly correlated with specific clinically relevant biologic states. These characteristics include changes in expression levels of genes and proteins and their posttranslational modifications. Detection of cancers at early stages maximizes survival, and identification of blood-borne markers would lead to minimally invasive tests. The best biomarkers are those that are reproducibly measured, that are related to the disease process, and that trigger a clinical decision resulting in improved clinical outcomes (Table 45-1). Despite an intense search for such biomarkers, there are none currently validated for the early diagnosis of lung cancer.[157,158]

Early detection of lung cancer could be aided by biomarkers that are based on the earliest known molecular abnormalities found in lung cancer. Sputum sample analysis for DNA methylation or chromosomal abnormalities by fluorescence in situ hybridization (FISH) may represent approaches suitable for early detection. The analysis of sputum, bronchial biopsies of preinvasive lesions using new detection methods such as fluorescence bronchoscopy,[159] as well as exhaled breath condensate for tumor metabolites may be shown to be efficient ways of assessing high-risk individuals. Early detection by low-dose computed tomography scanning is being evaluated prospectively with the National Lung Cancer Screening Trial in 50,000 smokers. The addition

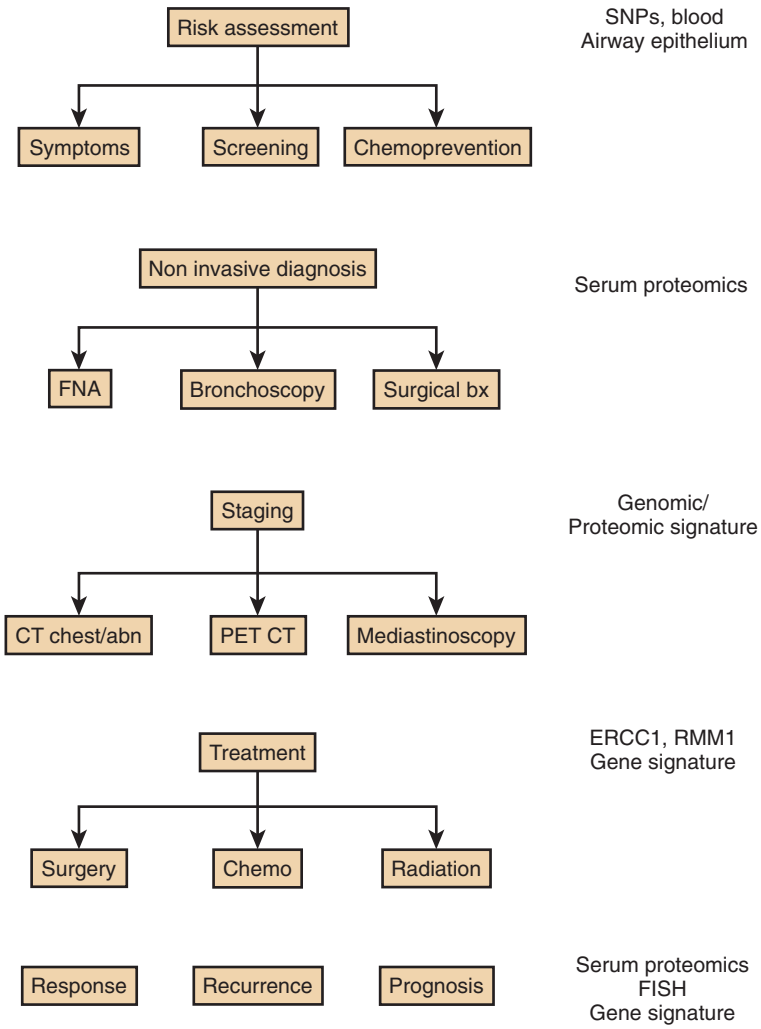

FIGURE 45-3 ■ Future applications envisioned for biomarker-driven personalized management of lung cancer. At each step in the course of the management of lung cancer, important clinical decisions are made. Biomarkers of risk, diagnosis, prognosis, and response to therapy are becoming available and are likely to drive a personalized approach to lung cancer. Examples of such candidate biomarkers are provided in the figure at points in the decision tree where they may affect decision making in the near future.

TABLE 45-1. Characteristics of a Successful Diagnostic Biomarker

Measurable, robust, reproducible, and biologically relevant.
Of proven clinical value *and* triggers a clinical decision.
Clinical community adopts its use and takes advantage of the benefits it affords.
Competitive in terms of cost and insurance reimbursement.

of molecular studies may significantly increase the sensitivity and specificity of this new strategy for early detection.

Prognostic and predictive information may also be provided by biomarkers. Expression array signatures and serum proteomic assays have been discussed previously. Polymorphisms or expression of DNA repair genes (such as ERCC and RRM) have been associated with response to chemotherapy.[160] EGFR gene mutations and copy number alterations are associated with response to EGFR tyrosine kinase inhibitors, and cyclooxygenase-2 (COX-2) expression and urinary prostaglandins have been associated with benefit from COX inhibitors.[161,162] All of these are currently being prospectively tested. For tissue-based predictive and prognostic biomarkers, technical procedures such as tissue processing, use of antibody reagents, and data interpretation need to be developed and standardized. The number of potential cancer-related genes is rapidly growing. Once identified, genes and proteins may be tested in large populations of patients by immunohistochemical or cytogenetic techniques on tissue microarrays.[163] This high-throughput method allows the screening of hundreds of lung cancer samples on a single glass slide and will allow retrospective analysis of material stored with associated clinical outcome. The arrays typically comprise core biopsies 0.6 mm in diameter of different tumors and uninvolved lung from the same individuals retrieved from the pathology archives of various institutions.[164] A firmer understanding of the relationship of relevant protein and genetic markers to clinical and pathologic status could lead to more accurate estimates of the anatomic extent of disease, the risk of recurrence, and the most effective intervention.

Molecular Therapeutics

Many current therapeutic approaches to cancer have been developed to reduce undesirable expression of gene products or otherwise inhibit abnormal protein function: (1) small molecule inhibition of receptor tyrosine kinases, (2) specific antibody approaches (e.g., anti-HER2 or anti-vascular endothelial growth factor [VEGF]), (3) inhibition of p21(ras) farnesylation either by inhibition of farnesyl transferase or by synthesis inhibition of farnesyl moieties, and (4) gene therapy with adenovirus-p53, gene-specific ribozymes, which are able to break down specific RNA sequences, or with antisense oligonucleotides (Table 45-2).

TABLE 45-2. Molecular Targets in Lung Cancer

Characteristics of Cancer	Possible Molecular Targets
Self-sufficient cell growth	EGFR, PI3K, PDGF-R, MAPK
Insensitivity to anti-growth	SMADs, pRb, cyclin-dependent kinases, MYC
Limitless replicative potential	p53, Rb, hTERT, EML4-ALK
Evading apoptosis	*K-ras*, p53, BCL-2, caspases, FAS, TNFR, DR5, IGF/PI3K/AKT, mTOR, *PTEN*, MET, NF-κB
Sustained angiogenesis	VEGF, TGF-β, αvβ3, thrombospondin-1, HIF1α

AKT, protein kinase B; EGFR, epidermal growth factor receptor; EML4-ALK, echinoderm microtubule associated protein like 4-anaplastic lymphomakinase; HIF1α, hypoxia inducible factor 1 alpha; IGF, insulin-like growth factor; MAPK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; NF-κB, nuclear factor-κB; PDGF-R, platelet-derived growth factor receptor; PI3K, phosphatidylinositol-3-kinase; pRb, retinoblastoma protein; *PTEN*, phosphatase and tensin homologue gene; TGF-β, transforming growth factor-β; VEGF, vascular endothelial growth factor.

EGFR Antagonists

One of the most prominent successful molecular therapeutic targets in lung cancer is the EGFR, as described earlier. Interruption of this autocrine pathway with receptor antibodies (extracellular domain of the protein) or tyrosine kinase inhibitors (competition with the kinase adenosine triphosphate [ATP] binding site) can cause tumor regression. Geftinib and erlotinib are potent and specific inhibitors of the tyrosine kinase moiety of EGFR. In clinical trials,[165,166] response rates in heavily pretreated patients with NSCLC varied between 10% and 18%, which may seem low, but it is actually far higher than any standard chemotherapy and represents a major benefit for these low-toxicity oral agents (Fig. 45-4). For patients with activating EGFR mutations in exons 19 or 21, the response rates are as high as 70% to 80%. Studies are proposed to investigate the value of EGFR inhibition with multitargeted inhibitors such as vandetanib (epidermal growth factor [EGF] and VEGF), in combination with chemotherapy or other targeted agents, in earlier stage NSCLC and in lung cancer chemoprevention. Such chemoprevention trials with molecular and morphologic (preinvasive lesions) surrogate end points may suggest reversibility of lesions. However, the rate of spontaneous regression of these preinvasive lesions is, as yet, poorly characterized.

VEGF

Another success story for targeted therapeutics in lung cancer has been the inhibition of the VEGF axis. The addition of bevacizumab, a monoclonal antibody that binds VEGF and inhibits its function, to carboplatin plus paclitaxel prolonged survival in patients with stage IIIB and IV lung cancer.[167] Bevacizumab is now being tested in combination with chemotherapy in the adjuvant treatment of resected lung cancer. In a European trial (AVAIL,

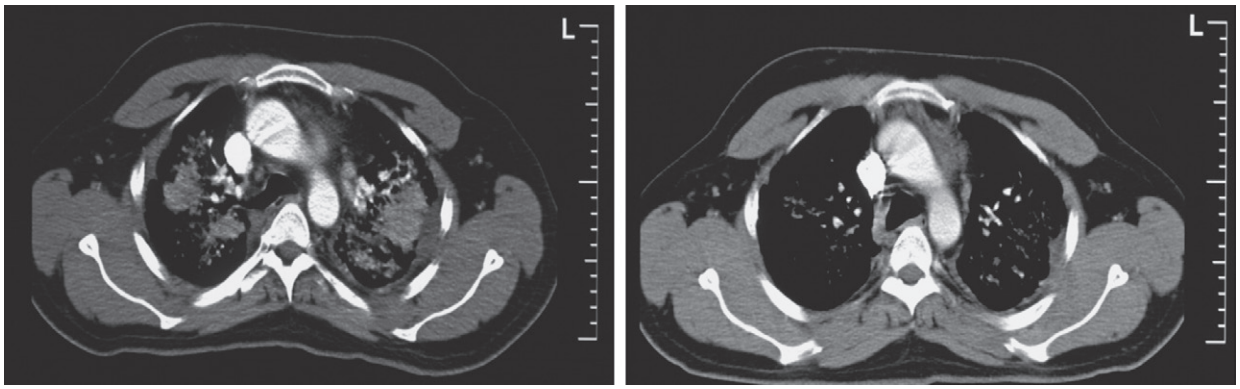

FIGURE 45-4 ■ A response to anti-epidermal growth factor receptor (EGFR)–targeted therapy. Chest computed tomography (CT) scan of a woman with chemotherapy-refractory bronchoalveolar carcinoma shows a dramatic response to gefitinib after 2 months of treatment. This woman was a nonsmoker of Asian ethnicity, a group with a higher frequency of activating EGFR mutations and more frequent responses to EGFR inhibition.

Avastin in Lung Cancer), the combination of bevacizumab with cisplatin plus gemcitabine prolonged progression-free survival, although the duration of follow-up was not sufficient to determine an overall survival benefit.[167a] Tyrosine kinase inhibitors to block the VEGF receptor are also being tested, but have not shown a survival advantage in phase III trials to date.[167b]

p53

Although p53 is a frequently mutated gene in lung cancer, efforts to target this abnormality have not been very successful to date. Several phase I studies have evaluated the safety, biologic effect, and different routes of administration of adenoviral-mediated p53 gene therapy in various tumor types. These studies indicate that introduction of wild-type p53 into tumor cells represents a potentially valuable tool for the therapy of many types of human cancers[168] mainly by causing cell cycle arrest or apoptosis. When injected intratumorally, wt-p53 can be expressed in patients with p53 mutations and 3 of 7 patients showed regression of tumor size.[169] Using the wild-type p53 recombinant adenovirus, the same group of investigators showed in a phase I trial that 16 of 25 patients had stabilization of disease and 2 had partial remissions.[170] One of the major limitations of the intratumoral approach is the inefficient delivery of genes within the tumor mass.

Viruses have been used to facilitate gene entry in vitro into cells (adenovirus-mediated gene transfer) or in vivo into human lung cancer (wild-type p53 delivered by retrovirus)[171] and demonstrated to be administered by bronchoscopy via BAL with repeated dosing.[172] Stabilization of disease and symptomatic improvement may warrant further studies of Ad-p53 or other adenoviruses administered by BAL in patients with BAC.

K-ras: Farnesyl Transferase Inhibitors

K-ras–mutant tumors have so far been refractory to therapeutic targeting. Development of retroviral vectors containing antisense *K-ras* constructs or inhibitors of ras function may reduce proliferation or tumorigenicity. The ras protein is activated by several steps including one critical step in which the activity of farnesyltransferase is necessary to anchor ras to the cell membrane.[173] At the cell membrane, ras relays growth regulatory signals from receptor tyrosine kinases to various pathways of cell signal transduction. Unfortunately, there are some potential barriers to therapeutic blockade of ras. The currently available inhibitors work best with activated *H-ras*, a mutation that is rare in lung cancer compared with the more common *K-ras* activation. Also, the activity of the ras genes does not correlate with antitumor activity. Nonetheless, several farnesyltransferase inhibitors are currently being tested in the clinic, including the inhibitor R115777-Zarnestra, which is being tested in a secondary chemoprevention trial. This trial is essentially based on the efficacy of a similar ras inhibitor on established lung adenomas (considered to be premalignant lesions of the lung) from A/J mice exposed to 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, a tobacco-related carcinogen.[174]

COX-2 Inhibition

COX-2 is an inducible enzyme that catalyzes the production of prostanoids. COX-2 can activate carcinogens in tobacco smoke,[175] and because it correlates with VEGF levels, COX-2 may play a role in angiogenesis. In addition, COX-2 activity may have a role in inhibiting apoptosis and modulating immune responses.[176] While nonsteroidal anti-inflammatory drugs have been shown to reduce the risk of colorectal cancer, no such evidence yet exists in lung cancer. COX-2 overexpression may be a marker of poor prognosis in early stage NSCLC.[177] Certain COX-2 single nucleotide polymorphisms may also correlate with lymph node metastases or with high tumor stage.[178] COX-2 inhibitors are being evaluated in combination therapy for chemoprevention and therapy for lung cancer.

KEY POINTS

- Patients with lung cancer have only a 15% 5-year survival rate and, even though there is a readily identifiable high-risk population of smokers and ex-smokers, there are no generally accepted screening, early detection, or chemoprevention strategies shown to reduce mortality.
- Lung cancer in smokers is preceded by an accumulation of genetic, epigenetic, and posttranslational abnormalities in the entire bronchial epithelium, showing the validity of the field cancerization concept.
- Lung cancer in never-smokers is less well understood. Nonetheless, the risk for either type of cancer (among smokers or nonsmokers) appears to have a hereditary predisposition, as seen, for example, with genetic alterations in the nicotinic acetylcholine receptors.
- Sequencing of hundreds of candidate genes in adenocarcinomas has shown that there are between 0 and 40 lesions in individual lung tumors and that many fall into a handful of previously defined pathways.
- The most common genes altered in lung cancer are *p53* and *K-ras,* for which effective targeted therapies do not yet exist.
- For some genetic lesions, particularly those now seen in EGFR, targeted therapies exist and striking clinical effectiveness can be observed.
- Targeted therapy to inhibit the VEGF angiogenic pathway has shown significant clinical effectiveness when combined with carboplatin plus paclitaxel in adenocarcinoma.

FUTURE DIRECTIONS

INTRODUCTION

Remarkably, at the start of the 20th century, lung cancer was considered a rare disease. However, its epidemic rise across the first decades of that century was soon identified as clinicians began to provide care for increasing numbers of patients with lung cancer and routine vital statistics documented rising mortality. Although tobacco had been widely used throughout the world for centuries, the present pandemic of lung cancer followed the introduction of manufactured cigarettes with addictive properties, which resulted in a new pattern of sustained exposure of the lung to inhaled carcinogens.[1] Epidemiologic research linked smoking to lung cancer in investigations reported from the 1950s forward.[2] Whereas its predominant cause—tobacco smoking—is now well-known, there are other causes of lung cancer as well, some acting in concert with smoking to increase risk synergistically.

This chapter provides a summary of the epidemiologic evidence on lung cancer. It is based primarily on summaries of the evidence prepared by expert committees, and it includes findings of representative and particularly informative studies. Syntheses have been periodically carried out by expert review groups, dating back to reports such as the 1962 report of the Royal College of Physicians[3] and the landmark 1964 Report of the U.S. Surgeon General.[4] The most recent reports include those prepared by the International Agency for Research on Cancer (IARC) in 2004[5] and the 2004 and 2006 reports of the Surgeon General on active and passive smoking, respectively.[6,7]

PATTERNS OF OCCURRENCE

Temporal Trends

Because of the high case-fatality rate of lung cancer, incidence and mortality rates are nearly equivalent, and consequently, routinely collected vital statistics provide a long record of the occurrence of lung cancer. We are at present amidst an epidemic of lung cancer that dates to the mid-20th century (Fig. 46-1).[8,9] The epidemic among women followed that among men, with a sharp rise in rates from the 1960s to the present, making lung cancer the most frequent cause of female cancer mortality in the United States.[10] The epidemic among women not only arose later but also will not peak as high as among men because smoking prevalence crested at substantially lower levels among women than among men.[11–13]

Trends of age-specific lung cancer mortality rates in the United States show differing epidemic patterns in men than in women (Fig. 46-2).[12,14–17] In the older age groups, the rates continue to increase in both sexes, but the rates of increase are decelerating more in men than in women. The rates of lung cancer are now decreasing

in the younger age groups, more for men but also becoming evident in women.[12]

Notable shifts have taken place in the incidence rates of lung cancer by histologic type.[18] After steadily increasing in incidence during the period 1973 to 1987, adenocarcinoma supplanted squamous cell carcinoma as the most frequent form of lung cancer (Table 46-1).[18,19]

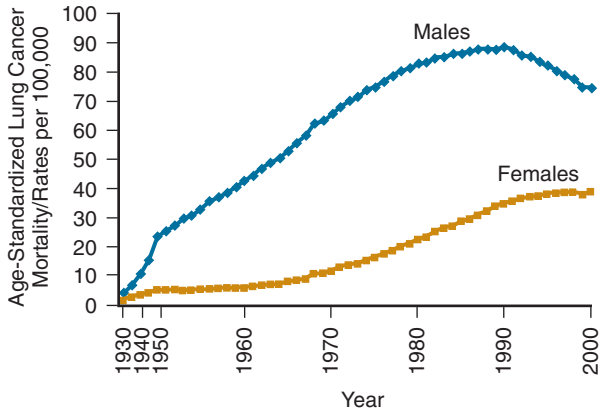

FIGURE 46-1 ■ **Age-standardized lung cancer mortality rates, United States: 1930–2000, age-standardized to 2000 U.S. population.** (Data from Wingo PA, Cardinez CJ, Landis SH, et al: Long-term trends in cancer mortality in the United States, 1930–1998. SEER Stat Database: Mortality 2003. http://seer.cancer.gov/)

Race and Ethnicity

In the United States, whereas lung cancer incidence rates are similar among African American women and white women, rates are about 40% higher among African American men than among white men.[20] A marked reduction in cigarette smoking among African American youths[21] forecasts a possible reversal of this trend. In addition, lung cancer mortality rates among African Americans and non-Hispanic whites are significantly higher than rates among Hispanics, Native Americans, and Asians/Pacific Islanders.[22,23] However, racial differences in historical patterns of cigarette smoking do not fully explain the racial disparities in lung cancer incidence and mortality rates.[24] The high rates in African Americans may be partially due to greater susceptibility of African American smokers to smoking-induced lung carcinogenesis.[25] The higher mortality rates of lung cancer in African Americans compared with white Americans reflect not only their higher incidence rate but also the poorer survival from lung cancer among African Americans compared with white Americans. The 5-year relative survival rate was 13% lower in African Americans than in white Americans during the period 1995 to 2001.[20] This racial gap persisted within each stage at diagnosis category.[20]

Geographic Patterns

Lung cancer is the most commonly diagnosed cancer worldwide,[25,26] but its geographic distribution shows marked regional variation[27]: age-standardized incidence rates vary over a wide range, over fourfold among men and fivefold among women (Fig. 46-3).[28] This marked variation in rates cannot be explained on the basis of diagnostic practices and data quality alone. Lung cancer tends to be most common in developed countries, particularly in North America and Europe, and less common in developing countries, particularly in Africa and South America.[29] However, the lung cancer epidemic is on the rise in the developing world.[30]

Substantial geographic variation in lung cancer mortality rates has also been observed within countries, providing clues about determinants of lung cancer. In the past, rates tended to be highest in urban areas, which led to conjecture that air pollution might be a cause of the lung cancer epidemic.[31] High rates in coastal areas in the United States over the period 1950 to 1969 were linked to asbestos exposure in shipyards.[32] Now, lung cancer mortality rates among white males are highest in the South and lower in the Northeast, likely reflecting patterns of cigarette smoking.[33]

Lung Cancer Occurrence by Histologic Type

Lung cancer manifests itself in multiple histologic types as classified by conventional light microscopy. The four major types include squamous cell carcinoma, adenocarcinoma, large cell carcinoma, and small cell undifferentiated carcinoma; together these four types of lung cancer account for over 90% of lung cancer cases in the United States.[34] These primary bronchogenic carcinomas are composed of a family of epithelial tumors that represent a subset of a larger collection of lung and pleural tumors classified most recently by the World Health Organization (WHO) in 2004.[35] The latest consensus classification,[36] written by the International Association for the Study of Lung Cancer (IASLC) pathology panel, was adopted by the WHO in 1994 to provide consistent criteria for research studies.

Few linkages have been made between particular etiologic agents and the development of a particular histologic type of lung cancer. Cigarette smoking increases risk for all major histologic types.[37-39] The dose-response relationship of increased lung cancer risk according to number of cigarettes smoked varies across the types, being steepest for small cell undifferentiated

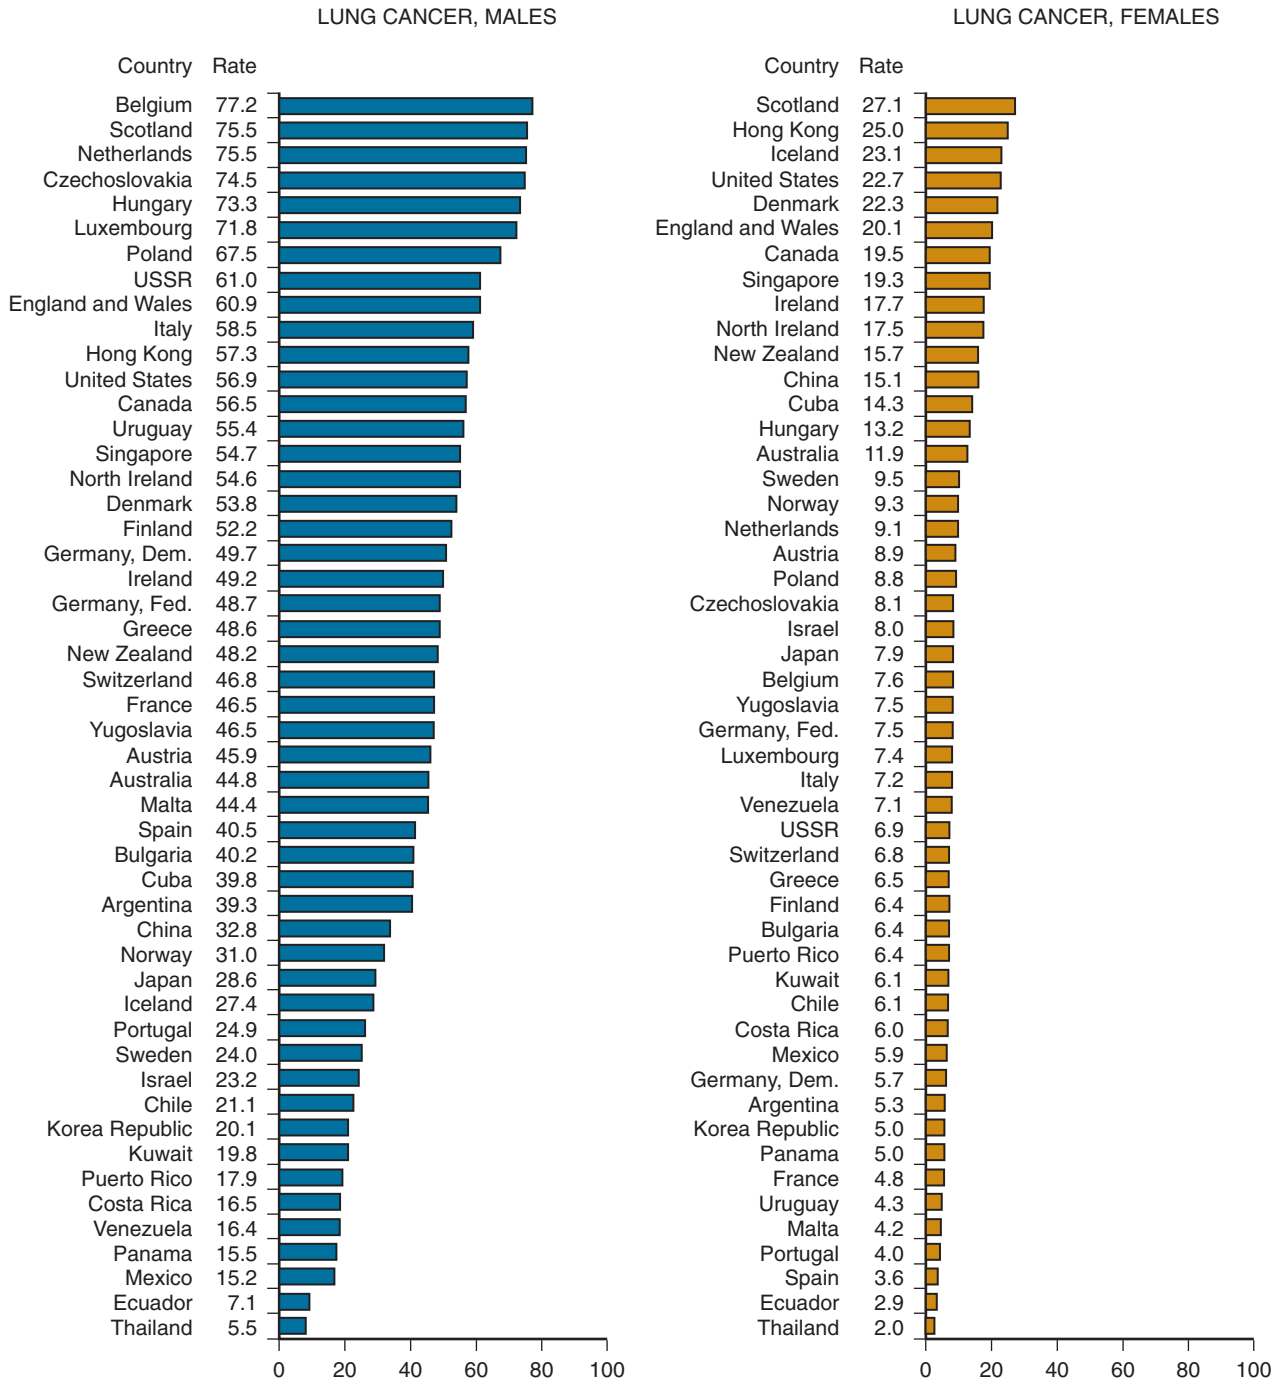

FIGURE 46-3 ■ 1986–1988 Age-adjusted death rates per 100,000 population, male and female. (Data from National Cancer Institute [NCI], Cancer Statistics Branch, and Division of Cancer Prevention and Control: Cancer Rates and Risks. Bethesda, MD: National Institutes of Health, 1996.)

carcinoma.[37-39] A few occupational exposures, such as chloromethyl ethers and radon, have been linked to small cell lung cancer.[34,40]

Since the 1960s, the most commonly diagnosed histologic type of lung cancer has shifted from squamous cell carcinoma to adenocarcinoma. Changing patterns of diagnosis and classification of lung cancers over time could have led to these changes, but most observers have set aside an artifactual change.[34,41,42] For example, even though diagnostic methods have improved, Thun and coworkers[43] analyzed data from the Connecticut Tumor Registry and showed that the rise in adenocarcinoma antedated these diagnostic innovations.

In the United States, during the initial decades of the smoking-caused epidemic of lung cancer, the most frequent type of lung cancer was squamous cell carcinoma, followed by small cell carcinoma. In the 1970s, a shift toward a predominance of adenocarcinoma was

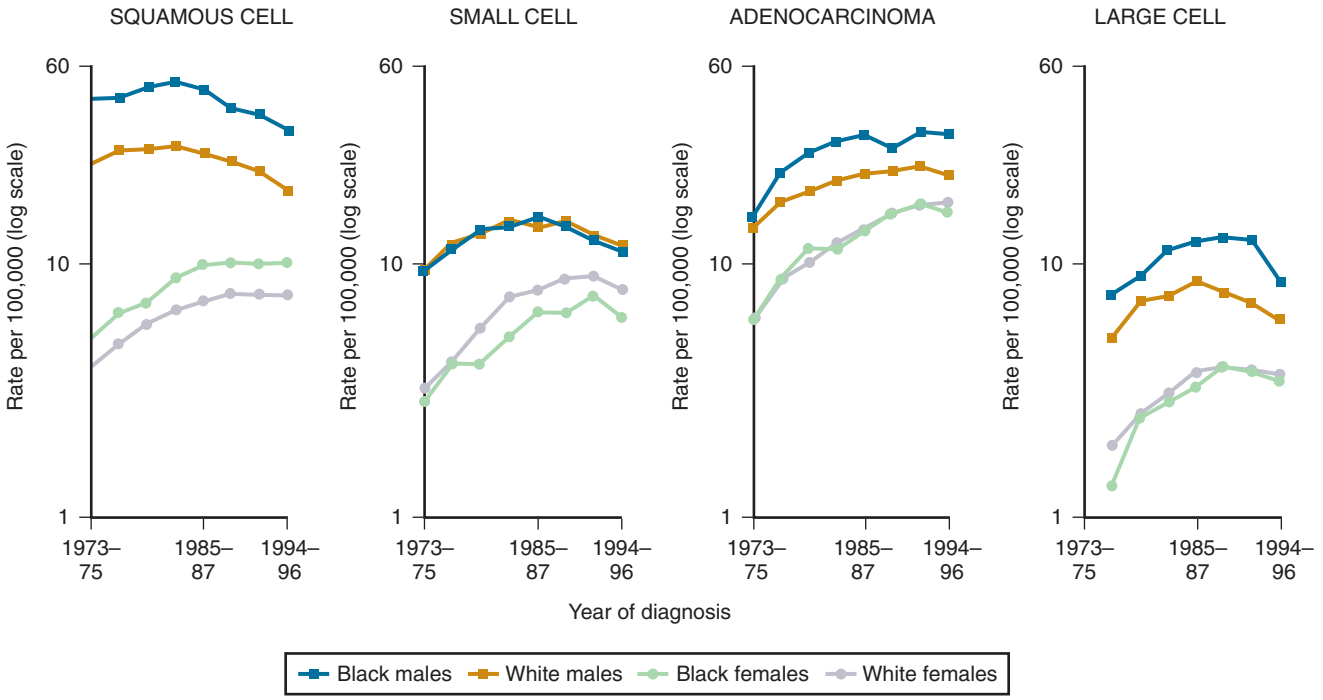

FIGURE 46-4 ■ Cancer of the lung and bronchus: surveillance, epidemiology, and end results (SEER) incidence rates, by histologic type, sex, race, and ethnicity, all ages, 1973–1996. (Data from Wingo PA, Ries LA, Giovino GA, et al: Annual report to the nation on the status of cancer, 1973–1996, with a special section on lung cancer and tobacco smoking. J Natl Cancer Inst 91:675–690, 1999.)

noted,[34,42,44] and with the persistence of this trend, adenocarcinoma is now the most common histologic type.[11,18] In U.S. men, the shift to adenocarcinoma developed in part because, whereas lung cancer incidence and mortality rates began to decline during the 1990s, the decline in lung cancer rates was more rapid for squamous cell and small cell carcinomas than for adenocarcinoma, which is just beginning to show a lower incidence rate (Fig. 46-4).[11] In U.S. women, the increase in lung cancer incidence rates was more pronounced for adenocarcinoma than any other cell type, perhaps because lung cancer rates increased most rapidly among U.S. women during the time period of changing histology.

Similar trends have been noted throughout the globe. Worldwide, adenocarcinoma tends to be the most common cell type seen in female lung cancer patients, accounting for approximately one third of all diagnoses in most regions.[45] In males, squamous cell carcinoma is still the most common cell type in some geographic regions where the lung cancer epidemic has peaked, but trends indicate that the overall percentage of this cell type has fallen over time to 40% or less.

Hypotheses concerning the shift from squamous cell carcinoma to adenocarcinoma have focused on the potential role of changes in the characteristics of cigarettes and consequent changes in the doses and types of carcinogens inhaled.[6,46,47] Puff volume has likely increased over recent decades with the possibility that patterns of deposition in the lung have changed.[46] Nitrate levels in tobacco smoke have also increased due to the rise in the proportion of air-cured tobacco used in manufacturing the blended U.S. cigarette,[46] and the resulting increased production of nitrogen oxides contributes to increased formation of tobacco-specific nitrosamines. An increase in dose of the potent tobacco-specific nitrosamine, NNK, has been postulated as one factor leading to the increase in adenocarcinoma.[48]

When the risks for lung cancers of the different histologic types were compared between participants in the American Cancer Society's Cancer Prevention Study (CPS) I and CPS II, the relative risk associating cigarette smoking with adenocarcinoma of the lung increased markedly in both men and women during the approximately 20-year period between the two studies.[43] These results suggest that the trend of increasing rates of adenocarcinoma is primarily due to changes in cigarette smoking behavior and features of cigarettes.[43]

THE ETIOLOGY OF LUNG CANCER: OVERVIEW

Although the causes of lung cancer are almost exclusively environmental, there is likely substantial individual variation in susceptibility to respiratory carcinogens. For example, only a minority of smokers develop lung cancer. The risk of the disease can be conceptualized as the consequence of the interrelationship between (1) exposure to etiologic (or protective) agents and (2) individual susceptibility to these agents. Given lung cancer's multifactorial etiology, synergistic interactions among risk factors have substantial consequences for lung cancer risk. These interactions have typically been

considered on an agent-by-agent basis, as for example, in studies of the synergistic effect of cigarette smoking on the lung cancer risk from asbestos exposure.[5] Our emerging understanding of cancer genetics indicates the additional relevance of gene-environment interactions.

Given the many risk factors that have been identified for lung cancer, a practical question is the relative contribution of these factors to the overall burden of lung cancer. In the United States, active smoking is estimated to be responsible for about 85% of lung cancer[6]; occupational exposures to carcinogens account for approximately 5% to 10%; radon causes 15% of lung cancer,[40] and outdoor air pollution perhaps 1% to 2%.[49] These known causes may not account for the development of lung cancer in never smokers, an important group for which further epidemiologic research in needed.[49a] The contribution of nutritional factors remains to be determined, but dietary factors have been hypothesized to account for approximately 20% (range, 10%–30%) of the lung cancer burden.[50] Because these attributable risk estimates include joint contributions of risk factors, for example, smoking and occupation, the total percentage can exceed 100%.

ENVIRONMENTAL AND OCCUPATIONAL AGENTS

Smoking

Overview

Cigarette smoking is by far the leading cause of lung cancer, accounting for approximately 80% to 90% of lung cancer cases in the United States[6] and in other countries where cigarette smoking is common.[40] Compared with never smokers, smokers have about a 20-fold increase in lung cancer risk, far higher than the risks for diseases associated with other environmental agents. Cigar and pipe smoking are also established causes of lung cancer.[51] In general, trends of lung cancer occurrence closely reflect patterns of smoking, but rates of occurrence lag smoking rates by about 20 years. According to the Centers for Disease Control and Prevention, in the United States, 156,900 men and women die from smoking-related lung cancer each year.[52] Worldwide, 5.4 million die each year from smoking-related lung cancer.[53]

Quantitative Risks

The risk of lung cancer among cigarette smokers increases with the duration of smoking and the number of cigarettes smoked per day (Table 46-2).[41] In one widely cited analysis, Doll and Peto[54] proposed a quantitative model for lung cancer risk based on data from the cohort study of British physicians. This model predicted a stronger effect from the duration of smoking than from the amount smoked per day. Thus, a tripling of the number of cigarettes smoked per day was estimated to triple the risk whereas a tripling of duration of smoking was estimated to increase the risk 100-fold.[55] These quantitative dimensions of the dose-response relationship between smoking and lung cancer have implications concerning the now widespread smoking among youths. Those starting at younger ages have a greater likelihood of becoming a heavier smoker and remaining a smoker.[56] The exponential effect of duration of smoking on lung cancer risk markedly increases the lifetime risk for those who become regular smokers in childhood.

Smoking Cessation

Cigarette smokers of any age can benefit from quitting smoking. Among those who quit smoking, the likelihood of developing lung cancer decreases when compared with those who continue to smoke[6,57,58] (Table 46-3). As the period of abstinence from smoking cigarettes increases, the risk of lung cancer decreases[57,58] (see Table 46-3). However, even for periods of abstinence of over 40 years, the risk of lung cancer for former smokers remains elevated compared with that for never smokers (see Table 46-3). The benefits derived from smoking cessation also depend on the prior duration of smoking: for a given period of abstinence, the risk decreases with a decrease in the duration of previous smoking.[58]

The Changing Cigarette

The composition and design of cigarettes has changed considerably since the 1950s. The marketplace has shifted from mainly unfiltered cigarettes to predominantly filtered cigarettes and to products that are labeled "light" or "mild." In the mid-1960s, ventilation holes were added to the filter, which dilute the smoke with

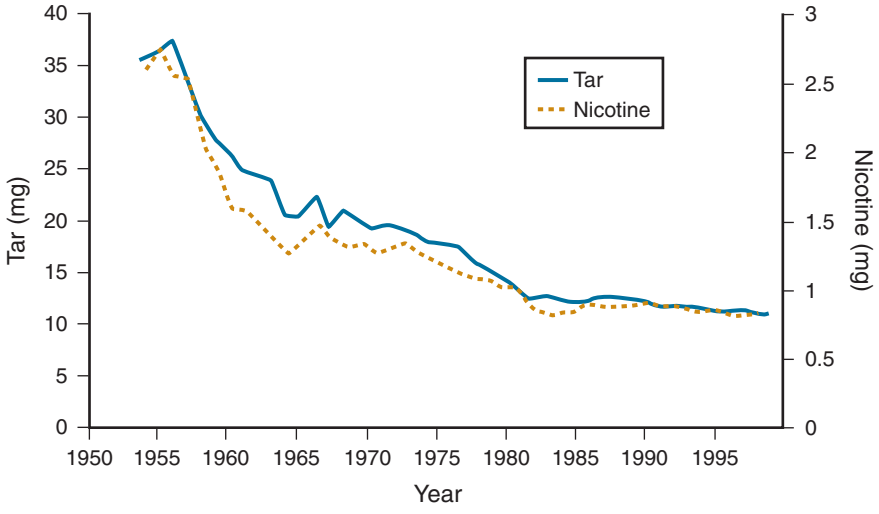

FIGURE 46-5 ■ Tar and nicotine values for U.S. cigarettes as measured using the Federal Trade Commission (FTC) method 1954–1998 and weighted by actual sales to determine the content of tar and nicotine for an average cigarette smoked by the population. (Data from Burns DM, Benowitz NL: Public health implications of changes in cigarette design and marketing. In Burns DM [ed]: Risks Associated with Smoking Cigarettes with Low Machine-Measured Yields of Tar and Nicotine. Bethesda, MD: U.S. Department of Health and Human Services, National Institutes of Health, National Cancer Institute, 2001, pp 1–12.)

air drawn through them. However, whereas these holes effectively decrease the tar measured by the testing machines, smokers can readily block the holes with their fingers, thereby increasing their tar inhalation and exposure to carcinogens. Reconstituted tobacco, essentially reprocessed tobacco leaf wastes, has been used increasingly since the 1960s, and there have been changes to the cigarette paper and additives.[59] These changes in design and content may also have affected carcinogenicity.

A shift toward lowered levels of "tar" and nicotine yields has thus been defined by measurements using a smoking machine according to a standard protocol of the Federal Trade Commission (FTC) (Fig. 46-5).[60] However, the protocol in use is no longer representative of typical smoking patterns.[61] Studies using biomarkers of exposure to tobacco smoke components show little relationship of these levels with levels expected from calculations using the tar or nicotine yield as measured by the FTC's protocol.[47,61,62] The lack of association of tar and nicotine yields with biomarker levels partially reflects compensatory changes in smoking patterns for those switching from higher- to lower-yield products. The compensation includes blocking of the ventilation holes as mentioned previously but also more frequent and deeper puffs and an increase in the number of cigarettes smoked.[61] In a study of smokers in four countries (Brazil, China, Mexico, and Poland), Blackford and associates[62] examined salivary cotinine level in relationship to number of cigarettes smoked per day. The curves describing the increase in cotinine level with number of cigarettes smoked were comparable for smokers of regular and "light" cigarettes. In other words, in each country, the use of "light" cigarettes did not decrease the nicotine intake per cigarette.

If the FTC test protocol was indeed predictive of carcinogen doses delivered to the lung, one would have expected a gradual reduction in smokers' exposures to carcinogens.[63] However, questions remain as to whether the FTC test method is informative with regard to the risks of lung cancer risk or of other smoking-caused diseases.[61] The early studies showed somewhat reduced risk in those switching from nonfilter to filter cigarettes, but subsequent studies showed that declining tar yields,

as measured by a machine, were not followed by lower lung cancer risk.[6]

Useful insights about whether risks have changed have been gained by comparing the risks in the two studies of the American Cancer Society, CPS I (1960–1972) and CPS II (1980–1986).[64,65] If the risk for lung cancer associated with smoking were decreasing over time, the expectation would be that risks for smokers would be less in CPS II than in CPS I. In fact, the opposite was observed; lung cancer mortality increased in male and female smokers in CPS II compared with their male and female counterparts in CPS I.[41] In a separate analysis with similar findings, Doll and colleagues[66] compared the risks of death from lung cancer and other causes during the first and second 20 years of the 40-year follow-up of the British physician cohort. Even though products smoked should have had a substantially lower tar and nicotine yield over time, lung cancer mortality actually increased among smokers in the second 20 years; for the first 20 years (1951–1971), the annual lung cancer mortality rate among current smokers was 264 per 100,000 and, for the second 20 years (1971–1991), it was 314 per 100,000. In the 50-year follow-up,[67] the excess mortality associated with cigarette smoking was less for men born in the 19th century and was greatest for men born in the 1920s, who would have had the lengthiest exposure to the more recent, lower machine-measured yield products.

Several expert panels have reviewed the findings. The Institute of Medicine[68] carried out a comprehensive review on various harm reduction strategies for reducing the disease burden caused by smoking, including lower-yield cigarettes. The Institute of Medicine report concluded that smoking lower yield products has not been shown to benefit the health of smokers.[68] The National Cancer Institute's *Monograph 13: Risks Associated with Smoking Cigarettes with Low Machine-Measured Yields of Tar and Nicotine*[61] concluded that changes in cigarette design and manufacturing over the last 50 years have not benefited public health. Most recently, a Working Group convened by the IARC of the WHO also reached a similar conclusion,[5] as did the 2004 Report of the U.S. Surgeon General.[6]

Passive Smoking

Passive smokers inhale a complex mixture of smoke now widely referred to as environmental tobacco smoke or secondhand smoke. Passive smoking was first considered as a possible risk factor for lung cancer in 1981 when two studies were published that described increased lung cancer risk among never-smoking women who were married to smokers.[69,70] Additional evidence rapidly accrued so that by 1986, two reports, one from the National Research Council[71] and the 1986 Surgeon General's Report,[72] both concluded that passive smoking causally increased risk for lung cancer. Estimates indicate that passive smoking accounts for about 3400 lung cancer deaths per year in the United States.[73]

Since these conclusions were reached, numerous studies have been carried out to characterize further the association of passive smoking with lung cancer, while taking into account some of the limitations of earlier studies, particularly small sample sizes, exposure misclassification, and omission of some potential confounding factors.[74,75] Various panels since 1986 have also concluded that passive smoking increases lung cancer risk, including most recently the IARC,[5] the California Environmental Protection Agency,[73] and once again, the U.S. Surgeon General.[7]

Passive smoking is more weakly associated with lung cancer than is active smoking, as expected given the lower doses of carcinogens received by the nonsmoker compared with the smoker. Marriage to a smoker is associated with about a 20% increase in risk[76] and exposure in the workplace is associated with between a 24% increase in risk up to a twofold increase at the highest levels of exposure.[77] In general, the estimates indicate increased risk associated with exposure, although they are imprecise owing to a small number of cases.[77]

Diet

The possible role of diet in modifying the risk of lung cancer has been the focus of intensive investigation, driven initially by the rationale that specific micronutrients might have anticarcinogenic activity. The most thoroughly investigated dietary factors are also those that at present appear to have the greatest implications for prevention: fruits, vegetables, and specific antioxidant micronutrients that are commonly found in fruits and vegetables.

The results of case-control and prospective cohort studies have tended to show that individuals with high dietary intake of fruits or vegetables have a lower risk of lung cancer than those with low fruit or vegetable intake.[78] To understand better the basis of this protective association, fruits and vegetables have been grouped into classes and also examined individually in relation to lung cancer risk. For example, tomatoes[78] and cruciferous vegetables[78,79] have been associated with a reduced risk of lung cancer in a number of studies. These food-based analyses can help to clarify whether protection arises from the complex mixture that composes fruits and vegetables or from specific biochemical constituents present in particular fruits and vegetables.

Fruits and vegetables are the major dietary source of antioxidant micronutrients. Much of the research on diet and lung cancer has been motivated by the hypothesis that diets high in antioxidant micronutrients may protect against oxidative DNA damage and thereby protect against cancer. For example, this was one of the hypothesized roles for β-carotene,[80] the focus of now-controversial clinical trials. Two different strategies are used to evaluate the relationship of micronutrients to lung cancer risk in observational epidemiologic studies: (1) estimating micronutrient intake from food-frequency questionnaires and (2) measuring serum concentrations of micronutrients. Prospective studies of both dietary intake[81] and prediagnostic blood concentrations[81] suggest that carotenoids are inversely associated with lung cancer risk.

The protective association predicted between β-carotene and lung cancer on the basis of these observational epidemiologic studies was not confirmed in three randomized, double-blind, placebo-controlled chemoprevention trials.[82–84] In fact, two of these studies with participants at high risk for lung cancer (heavy smokers and asbestos-exposed workers) were stopped early because significantly increased risk of lung cancer was observed in the β-carotene group compared with the placebo group.[83,84]

The results of the randomized chemoprevention trials stand in sharp contrast to the considerable observational epidemiologic evidence favoring a protective association. Among the potential explanations for the contradictory findings are that the randomized trials used relatively high doses of β-carotene and that the observational epidemiologic studies may have been flawed by uncontrolled confounding or selection bias.[81] Because of the powerful role of smoking as a cause of lung cancer, disentangling the effects of other lifestyle-related factors, such as diet, from the effect of smoking may be particularly difficult. Further complicating the assessment of protection by dietary factors is the narrow range of likely effects, much smaller than the effect of smoking, and the unavoidable problem of measurement error, that is, the inevitable inaccuracy in estimating usual dietary consumption of particular foods or groups of foods.

Studies of fruits, vegetables, and micronutrients have been the centerpiece of studies of diet and lung cancer, but other factors have also been investigated. For example, the results of a meta-analysis showed alcohol drinking in the highest consumption categories was associated with increased risk of lung cancer.[85] In addition, anthropometric measures have been studied, indicating a tendency for persons with lower body mass index to have increased lung cancer risk relative to heavier persons.[78] However, both alcohol drinking and low body mass index may be difficult to separate from the concomitant effects of smoking. At present, when considering the possible relationships between lung cancer and factors such as alcohol drinking and lower body mass index, residual confounding by cigarette smoking cannot be dismissed as a possible explanation.

Environmental Exposures

Occupational Exposures

Lung cancer has been found to be associated causally with many workplace exposures. Occupational exposures have been estimated by case-control studies to account for 9% to 15% of lung cancer cases.[86] Cigarette smoking also potentiates the effect of some of the known occupational lung carcinogens.[5]

Asbestos

Asbestos, a well-established occupational carcinogen, refers to several forms of fibrous, naturally occurring silicate minerals.[87] The epidemiologic evidence dates to the 1950s, although clinical case series had previously led to the hypothesis that asbestos causes lung cancer. In a retrospective cohort study published in 1955, Doll observed that asbestos textile workers at a factory in the United Kingdom had a 10-fold elevation in lung cancer risk and that the risk was most heavily concentrated during the timeframe before regulations were implemented to limit asbestos dust in factories.[88] A 7-fold excess of lung cancer was subsequently observed among insulation workers in the United States.[89,90] The peak incidence occurred 30 to 35 years after the initial exposure to asbestos.[91] The risk of lung cancer has been noted to increase with increased exposure to asbestos[92] and to be associated with each of the principal commercial forms of asbestos.[93] Whether asbestos acts directly as a carcinogen or indirectly as, for example, by causing chronic inflammation that eventually leads to cancer remains controversial.[94–96] For asbestos, two competing hypotheses have been posed: (1) that asbestos-caused lung cancer occurs as a consequence of asbestosis or (2) that lung cancer risk is dependent on the cumulative dose of asbestos, regardless of the presence of asbestosis, which may be serving as a marker of asbestos dose. The relevant mechanistic and epidemiologic evidence has gaps and the issue has been made even more controversial because of the implications for compensation of lung cancer in asbestos-exposed workers who have smoked.

Asbestos and cigarette smoking are both independent causes of lung cancer, but in combination, they act synergistically to increase the risk of lung cancer. Uncertainty remains as to the precise quantitative characterization of this synergy, reflecting limitations of the available data[5] and lack of understanding of the underlying mechanisms.[97] Nonetheless, the risk of the combined exposure is much higher than would be expected if one merely added the risks together, showing a strong interaction between the two. In fact, the risks are approximately multiplicative. A person who smokes and has been exposed to asbestos has a greater than 50-fold elevated risk of lung cancer compared to a non-smoker with no asbestos exposure, and a much higher risk than a person exposed to cigarette smoke alone (relative risk, 10.9) or exposed to asbestos alone (relative risk, 5.2) (Table 46-4).[98]

Radiation

Epidemiologic studies of populations exposed to high doses of radiation show that lung cancer is causally associated with exposure to ionizing radiation. Two types of radiation, classified by rate of energy transfer to the tissue, are relevant to lung cancer: high–linear energy transfer (LET) radiation (e.g., neutrons and radon) and low-LET radiation (e.g., x-rays and gamma rays). High-LET radiation produces ionization of relatively higher density in tissues than low-LET radiation, so in equivalent doses, more biologic damage is produced by high-LET than low-LET radiation.[99] For both types of radiation, the epidemiologic evidence comes primarily from cohorts exposed at levels substantially greater than those experienced by the general population. Risk assessment methods are then used to estimate risks to the general population.

TABLE 46-4. The Relationship between Cigarette Smoking and Asbestos Exposure on the Risk of Lung Cancer Mortality

	MORTALITY RATES ASBESTOS-EXPOSED		DIFFERENCE IN RATES ASBESTOS-EXPOSED		RATIO OF RATES ASBESTOS-EXPOSED	
Smoking	**No**	**Yes**	**No**	**Yes**	**No**	**Yes**
No	11.3*	58.4	*0*	*47.1*	*1.0*	*5.2*
Yes	122.6	601.6	*111.3*	*590.3*†	*10.9*	*53.2*‡

*Mortality rate per 100,000.
†Difference in rates compared to no smoking/no asbestos exposure; if there were no interaction of asbestos and smoking, the expected rate of lung cancer in those exposed to both would be the sum of each alone (47.1 + 111.3 = 158.2). The actual value of 590.3 greatly exceeds 158.1 providing evidence of strong interaction between smoking and asbestos.
‡Ratio of rates compared to no smoking/no asbestos exposure; the expected value if risks were multiplicative would be the multiple of the rates, 5.2 × 10.9 = 56.1, close to the actual value of 53.2.

High-LET Radiation: Radon. Radon is an inert gas produced naturally from radium in the decay series of uranium. Two of the radon decay products emit alpha particles that can, consequent to high energy and mass, cause damage to the DNA of cells of the respiratory epithelium. Epidemiologic studies of underground miners of uranium and other ores have established exposure to radon daughters as a cause of lung cancer.[40,100] In the underground miners exposed to radon in past centuries, very high lung cancer risks were observed; in the miners in more contemporary workplaces, the observed risks have been much less as exposure concentrations have been better controlled, but still show clear evidence of existing cancer risk.[40] Cigarette smoking and radon decay products synergistically influence lung cancer risk, for example, in a manner that is greater than simply adding the risks of each together.[40]

Radon is of broader societal interest because it is a ubiquitous air pollutant that enters buildings from the underlying soil. On average, indoor exposures to radon for the general population are much less than for occupational groups such as uranium miners; nonetheless, homes have been identified with concentrations as high as in underground uranium mines. Exposure to radon in indoor air is also assumed to cause lung cancer, but the magnitude of the risk is more uncertain because of the assumptions made to estimate the risk, particularly the extrapolation of findings from uranium miners to the generally lower exposures indoors. Concern about radon arises in part from biologic evidence that a single hit to a cell by an alpha particle may cause permanent cellular change, an assumption leading to a non-threshold dose-response relationship.[40] In addition, pooled analyses of case-control studies in the general population show increased risk in association with indoor radon.[101,102]

The assumptions made by the Environmental Protection Agency and the Biological Effects of Ionizing Radiation (BEIR) VI Committee of the National Research Council have led to estimates that approximately 15,000 to 20,000 lung cancer deaths per year in the United States are caused by radon.[103] In the United States, the Environmental Protection Agency has called for testing of all residences and mitigation of those exceeding a guideline value.

Low-LET Radiation: X-Rays and Gamma-Rays. Epidemiologic data relating low-LET radiation to lung cancer stem from three principal populations[104]: the atomic bomb survivors in Japan, patients with diseases such as ankylosing spondylitis or tuberculosis who received multiple radiation treatments, and occupational groups in professions exposed to radiation. The single, high-dose exposure of the atomic bomb survivors was associated with significant lung cancer risk.[105] Regardless of age at the time of the blast, the excess of lung cancer occurred when the survivors reached the older ages when cancer usually occurs.[106] Quantitative risk models are available that describe how risk rises with radiation dose.[104]

Air Pollution

During a typical day, the average adult inhales about 10,000 L of air.[107] Consequently, even the carcinogens present in the air at low concentrations are of concern as a risk factor for lung cancer. Extrapolation of the risks associated with occupational exposures to the lower concentration of carcinogens in polluted ambient air suggests that a small proportion of lung cancer cases could be due to air pollution.[108]

Atmospheric Air Pollution

Carcinogens generated by the combustion of fossil fuels include polycyclic aromatic hydrocarbons and metals such as arsenic, nickel, and chromium (see Cohen and Samet[109] for a recent review). Because these carcinogens are widespread in outdoor air pollution and a large number of urban dwellers are exposed, even a small effect could be of public importance. Descriptive evidence, showing higher lung cancer rates in polluted urban areas, is consistent with a role for air pollution in causing lung cancer.[110] Biomarkers of exposure were addressed in a 2005 review by Vineis and Husgafvel-Pursiainen.[111]

Air pollution has been assessed as a risk factor for lung cancer in epidemiologic studies of both case-control and cohort design.[49,112] The evidence from case-control studies, which are limited in their exposure assessment, has been mixed.[109] Prospective cohort studies[113–115] that

partially address the weaknesses of earlier studies add evidence that air pollution is weakly associated with lung cancer risk. By prospectively studying air pollution levels in relation to risk of lung cancer and by controlling for possible confounders such as age, smoking, and socioeconomic status at the individual level, these newer studies surmount some shortcomings of previous research.[116] In a study of six U.S. cities, the adjusted risk of lung cancer mortality in the city with the highest fine particulate concentration was 1.4 times (95% confidence interval [CI] = 0.8–2.4) higher than in the least polluted city.[117] Using data from the American Cancer Society's Cancer Prevention Study II, for 1982 to 1989, Pope and colleagues[118] observed that, compared with the least polluted areas, residence in areas with high sulfate concentrations was associated with an increased risk of lung cancer (adjusted relative risk = 1.4; 95% CI = 1.1–1.7) after adjustment for occupational exposures and the factors mentioned previously. However, unlike in the Six-Cities study, fine particulate concentration was not associated with lung cancer risk.[118] In a subsequent updating of this report, follow-up was extended to 1998.[115] In this report, the risk of lung cancer associated with a 10 $\mu g/m^3$ increase in fine particles was estimated as 14%. In a study in the Netherlands, traffic exposure variables were weakly associated with lung cancer risk.[113]

Another research approach to evaluate the risk of air pollution has been to investigate populations residing around point sources of pollution, such as factories and smelters.[119,120] Proximity of residence to the pollution source can be used as a proxy for exposure. Areas surrounding nonferrous smelters—which emit arsenic—have been of particular interest, but other industries have also been investigated.

In sum, Doll and Peto,[108] in their 1981 review of the causes of cancer, estimated that perhaps 1% to 2% of lung cancer was related to air pollution. Even in light of recent findings, this remains a reasonable estimate.[110]

Indoor Air Pollution

Indoor air quality has large potential health implications because people spend substantial amounts of time indoors. Indoor air pollution arises from pollutants that enter from the outside as well as those that originate indoors from tobacco smoking, building materials, soil gases, household products, and combustion from heating and cooking.[121] In the more developed countries, two of the most important indoor pollutants that influence lung cancer risk in never smokers are passive smoking[72] and radon.[100] Asbestos exposure may pose a risk to building occupants, but it is estimated to be minimal.[87] In the developing world, the major source of indoor air contamination results from the use of unprocessed solid fuels, notably coal, for cooking and space heating.[122] Mumford and coworkers[123] inferred that smoky coal was a major determinant of the geographic distribution of lung cancer in Xuan Wei, China, a finding corroborated by an animal model.[124] With a subsequent change in fuel source, lung cancer rates were found to decline in this region.[125] Some case-control studies conducted elsewhere in mainland China[126,127] and Taiwan[128] also implicated coal use as a risk factor for lung cancer. A recent risk assessment projected solid fuel use and smoking as preventable causes of most lung cancer cases in China.[129]

HOST FACTORS

Overview

The long-standing interest in genetic susceptibility to lung cancer has recently intensified. Environmental agents, even cigarette smoking, cause lung cancer in only a minority of exposed persons, leading to the hypothesis that susceptibility is inherently determined. Studies showing that a family history of lung cancer predicts increased risk further support a genetic basis for lung cancer susceptibility. This long-postulated hypothesis is now being actively addressed using the approach of molecular epidemiology. Full coverage of this topic is beyond the scope of this chapter; aspects of genetic susceptibility have been reviewed[130] (see also Chapter 45).

In case-control studies, a family history of lung cancer has been shown to be associated with an increased risk of lung cancer; of importance, most of the studies controlled for smoking, which is known to aggregate in families (Table 46-5).[131–143] In a large study in Louisiana, segregation analysis suggested that lung cancer inheritance was consistent with a mendelian codominant autosomal gene determining early onset of disease.[144] Conversely, the largest study of lung cancer in twins reported to date did not provide evidence indicating a genetic basis for susceptibility.[145]

In a genetic epidemiology study of lung cancer in nonsmokers in Detroit, Schwartz, Yang, and colleagues[142,146] explored familial risk for lung cancer. In nonsmokers, Schwartz and associates[142] found an association between risk and a history of lung cancer in a first-degree relative (odds ratio [OR} =1.4; 95% CI 0.8–2.5). The association was much stronger in those aged 40 to 59 years at diagnosis than in older persons, suggesting that genetic factors may be more important at younger ages. This general finding was confirmed by a subsequent, complex segregation analysis of the same data.[146]

Research Findings on the Genetic Basis of Lung Cancer

With application of the new and powerful tools of modern molecular biology, research findings are now characterizing the changes in cells that are caused by exposure to tobacco smoke and providing a framework for understanding the genetic and epigenetic basis of lung cancer risk. A rapidly expanding literature, based both in the laboratory and in the observational approach often referred to as "molecular epidemiology," addresses dosimetry and metabolism of tobacco carcinogens at the cellular and molecular levels, genetic determinants of susceptibility, and patterns of genetic changes in the tissues of smokers and in the cancers that the tissues develop.[48,130,147]

The understanding of the epigenetic changes that may be involved in the causal pathway to lung cancer is

TABLE 46-5. A Summary of Selected Case-Control Studies of Lung Cancer among Persons with a Family History of Lung Cancer Compared with Those with No Family History of Lung Cancer

First Author	Year	Location	Odds Ratio*	Comment
Tokuhata[132]	1963	Buffalo, NY	2.4 (1.1, 5.2)	Adjusted for cigarette smoking, age, sex, generation
Tokuhata[133]	1964	Baltimore	2.6 (1.4, 5.4)	Adjusted for age, sex, generation
Ooi[134]	1986	Ten Louisiana parishes	2.7 (1.7, 4.2)	Adjusted for smoking, sex
Samet[135]	1986	New Mexico	5.3 (2.2, 12.8) [parental]	Adjusted for cigarette smoking, age, sex, ethnicity
Gao[131]	1987	Shanghai, PRC	1.1 (0.6, 2.3) [parental] 3.0 (0.7, 12.5) [sibling]	Adjusted for smoking, age
Tsugane[136]	1987	Tokyo	1.0 (0.3, 3.9)	Smoking and occupational exposure Data collected, but not adjusted for
Horwitz[137]	1988	New Haven, CT	2.3 (0.6, 9.7)	Adjusted for smoking
McDuffie[138]	1991	Saskatchewan, Canada	2.0 (1.2, 3.4)	Smoking and occupational exposure Data collected, but not adjusted for
Osann[139]	1991	Northern California	1.9 (0.7, 5.6)	Adjusted for cigarette smoking education, matched on age and race
Shaw[140]	1991	Gulf Coast of Texas	1.7 (1.2, 2.4) [1 1st-degree relative with cancer] 2.8 (1.2, 6.6) [2 1st-degree relatives with cancer]	Adjusted for cigarette smoking, passive smoking, and number of first-degree relatives
Filho[141]	1995	Sao Paulo, Brazil	3.2 (1.0, 11.1)	Smoking and occupational exposure Data collected, but not adjusted for
Schwartz[142]	1996	Detroit, MI	6.1 (1.1, 33.4)	Adjusted for smoking, occupational and medical history of each family member
Wu[143]	1996	United States, multisite	1.29 (0.9, 1.9)	Adjusted for secondhand smoke exposure
