Disorders falling along the continuum from active granulomatous mediastinitis to pure mediastinal fibrosis have been designated by the following terms: mediastinal adenitis, mediastinal granulomatosis, sclerosing mediastinitis, mediastinal collagenosis, fibrosing mediastinitis, and idiopathic fibroinflammatory lesion of the mediastinum. Conceptually, all these processes may be thought of as variations of a common process (Fig. 77-12).

Pathophysiology and Etiologies

The genesis of granulomatous mediastinitis and mediastinal fibrosis is most easily understood using histoplasmosis or tuberculosis as an example. Infection begins as a primary focus in the lung, which spreads to mediastinal lymph nodes and induces mediastinal adenitis and periadenitis. Eventually, a cluster of caseating lymph nodes breaks down into an irregular mass, heals by fibrous encapsulation, and in some cases, undergoes dense calcification. The thickness of the fibrotic capsule is the main determinant of the clinical picture: when 2

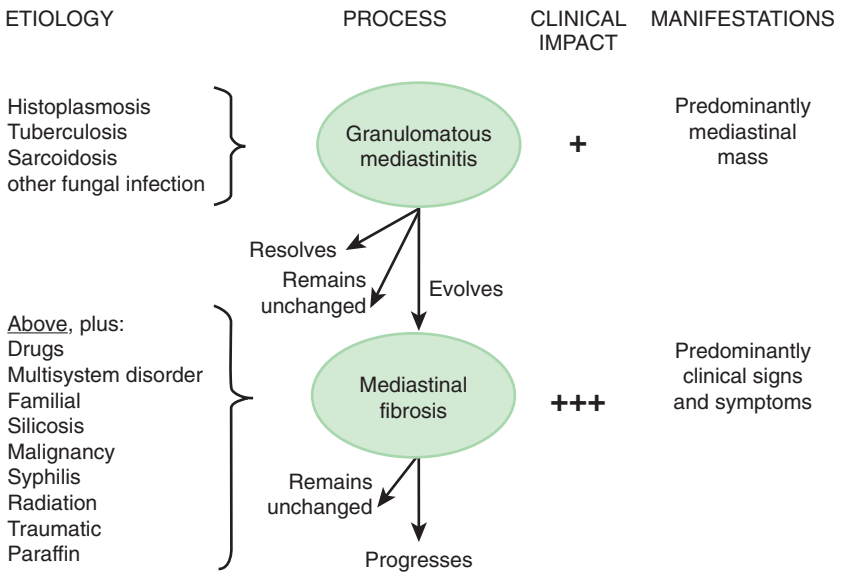

FIGURE 77-12 ■ Pathophysiologic relationships between granulomatous mediastinitis and mediastinal fibrosis.

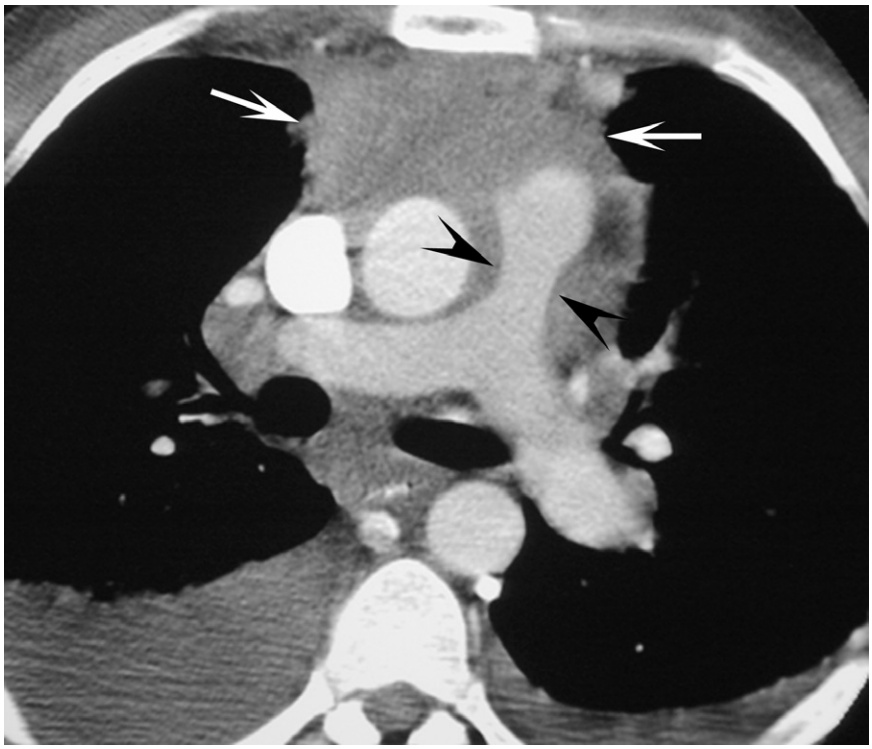

FIGURE 77-13 ■ Axial CT image through the main pulmonary artery shows abnormal soft tissue infiltrating the mediastinum (*arrows*), compressing the main pulmonary artery (*arrowheads*). The presence of mass effect on vessels and bronchi is characteristic of mediastinal fibrosis. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

to 5 mm in thickness, it has little clinical impact, whereas, if the capsule reaches 6 to 9 mm, it can invade or interfere with adjacent tissues.[168,169] This benign localized "healing" process produces physiologically important effects because of the compact nature of the mediastinum and the importance and vulnerability of its structures (Fig. 77-13).

The symptoms and physiologic effects of this process are determined by the location of the involved lymph nodes. Most commonly, the involved lymph nodes are in the right perihilar region, perhaps accounting for the high prevalence of SVC obstruction in chronic mediastinitis. Later, in instances in which the process progresses to generalized fibrosis, the entire upper portion of the mediastinum may be involved.

The mechanism by which inflammation and fibrosis progress in some patients and not in others has been the subject of considerable debate. Goodwin and colleagues[168] postulated that prolonged gradual seepage of some soluble antigen or other substance from the involved lymph nodes causes fibrosis. Other authors reject this theory in favor of an abnormality in collagen organization that when provoked by various stimuli, leads to mediastinal fibrosis.[170] Whether either of these

concepts or some other mechanism is responsible, it is evident that the nature and vigor of the host's response is vitally important.

The development of both mediastinal and retroperitoneal fibrosis in the same patients, and of idiopathic isolated mediastinal fibrosis in others,[171] has led some investigators to postulate an autoimmune mechanism. The finding of mediastinal and retroperitoneal fibrosis, along with other forms of fibrosis in members of the same family, has led to the term *familial multifocal fibrosclerosis*. Fibrosing processes elsewhere in the body that could be related, in at least some cases, to mediastinal fibrosis include retroperitoneal fibrosis, Riedel's thyroiditis, sclerosing cholangitis, orbital pseudotumor, sclerosing cervicitis, ligneous perityphlitis of the cecum, and keloids.[170,172] Others have pointed out dissimilarities between mediastinal and retroperitoneal fibrosis and disagree with this unitary concept.[168]

Most cases of granulomatous mediastinitis are caused by histoplasmosis (especially in North America) or tuberculosis.[166,168,170,173] However, as the disease progresses from active caseous inflammation to largely acellular fibrosis, it becomes more and more difficult to establish the cause with certainty. In 180 cases reviewed by Schowengerdt and coworkers,[166] a definite diagnosis could be established in 33 of 103 examples of "granulomatous mediastinitis" but in only 3 of 77 categorized as "mediastinal fibrosis." Histoplasmosis and tuberculosis together accounted for 83% of the confirmed diagnoses.[166]

Granulomatous infection is the usual cause of mediastinal fibrosis, as diagrammed in Figure 77-12. However, the same histologic and clinical picture can be the ultimate result of other disease processes. Fibrosis associated with use of methysergide, a drug used in the control of severe vascular headache, is perhaps the best known of these. Sarcoidosis accounts for 11% of the cases of granulomatous mediastinitis of known cause in the review by Schowengerdt and coworkers.[166] Other reported noninfectious causes of mediastinal fibrosis include silicosis,[174] paraffin (as a late complication of plombage for tuberculosis), and traumatic mediastinal hematoma.[175] Nodular sclerosing Hodgkin's disease also may masquerade as mediastinal fibrosis,[176] emphasizing the importance of careful review of adequately representative biopsy samples when evaluating a mediastinal mass. Although there are reports of SVC and bronchial obstruction thought to be caused by mediastinal irradiation,[177] radiotherapy as a cause of mediastinal fibrosis must be distinctly unusual in view of its widespread use and the rare documentation of this complication.

Clinical Manifestations

On the continuum from active granulomatous mediastinitis to "burned-out" mediastinal fibrosis, the former tends to be asymptomatic and to be discovered incidentally by chest radiography; the latter tends to cause clinical manifestations.[178] In the largest collection of cases to date, 74% of the patients with granulomatous mediastinitis were asymptomatic, whereas all but 17% with fibrosis presented with symptoms or signs.[166] In 52 patients with mediastinal fibrosis and evidence of histoplasmosis reviewed by Loyd and associates,[167] initial symptoms included cough in 41%, dyspnea in 32%, hemoptysis in 31%, and chest pain in 23%. Clinical manifestations develop either because the fibrotic process invades or compresses mediastinal structures or because a calcified mass erodes into adjacent structures. These manifestations can be grouped into those related to involvement of the airways, the SVC, the esophagus, the major pulmonary vessels, and mediastinal nerves.

Airway Involvement. Clinical manifestations due to involvement of the trachea or major bronchi are common in patients with granulomatous mediastinitis or mediastinal fibrosis. Airway complications including dyspnea, cough, and hemoptysis were the most common clinical manifestations in several series[167,178] and constituted the most common indication for surgical intervention.[178] Any of the main airways may be compromised, but involvement of the right middle lobe is reported as most frequent and is often accompanied by features of the *right middle lobe syndrome*. A rare cause, bronchoesophageal fistula, may be heralded by simultaneous hemoptysis and hematemesis.[179]

Superior Vena Cava Obstruction. SVC obstruction has been the most frequent complication of granulomatous mediastinitis and mediastinal fibrosis in some series.[166,180] Although most patients with SVC obstruction have malignancy, benign causes account for about 3% to 6% of large published series,[181,182] of which most are due to granulomatous mediastinitis or mediastinal fibrosis.[173] SVC obstruction can occur at any stage of granulomatous or fibrotic involvement; in Schowengerdt's and coworkers series,[166] SVC obstruction was present in 77% of symptomatic patients with granulomatous mediastinitis and in 52% of symptomatic patients with mediastinal fibrosis.

The typical presentation is *superior vena cava syndrome*.[183] Because obstruction develops gradually, collateral channels tend to divert much of the venous flow (Fig. 77-14). Therefore, symptoms may be less prominent than might be expected and may improve with time.[173] However, even chronic SVC obstruction can cause serious complications such as hemorrhage from esophageal varices, recurrent upper extremity thrombophlebitis, and postphlebitic syndrome. Less commonly, the inferior vena cava or azygous vein can be involved.[166] Thoracic duct obstruction is rare[166] but can produce chylothorax and its associated clinical manifestations.

Esophageal Involvement. Esophageal involvement can include extrinsic compression, traction diverticulae, disturbances of esophageal motility, or bleeding. Symptoms of dysphagia, chest pain, and eructation can result.[166]

Pulmonary Vascular Involvement. Mediastinal fibrosis can involve major vessels on either side of the heart.[166,168,170] When this occurs, the prognosis can be serious. Progressive obstruction of one or both main pulmonary arteries can result in pulmonary hypertension, cor pulmonale, and refractory right-sided heart

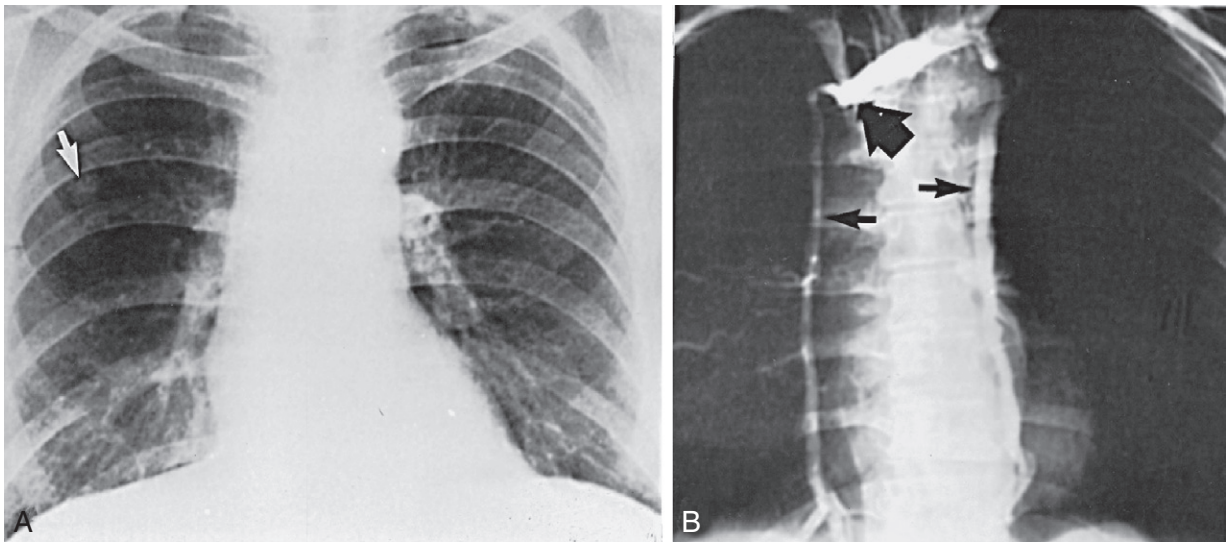

FIGURE 77-14 ■ Mediastinal fibrosis (in this instance from histoplasmosis) with superior vena cava obstruction and extensive collateral circulation. **A,** The standard frontal radiograph shows smooth widening of the superior mediastinum with a peripheral granuloma in the right lung (*arrow*). **B,** Another film taken just after rapid injection of contrast material into an antecubital vein shows complete obstruction of the superior vena cava (*thick arrow*), with filling of the internal mammary veins bilaterally (*thin arrows*). (From Fraser RG, Paré JAP, Paré PD, et al: Diagnosis of Diseases of the Chest [3rd ed, Vol. II]. Philadelphia: WB Saunders, 1989, p 955.)

failure.[184] Stenosis of proximal pulmonary veins can cause a clinical picture similar to that of severe valvular mitral stenosis, with pulmonary venous hypertension and recurrent episodes of hemoptysis. Pulmonary venous hypertension can be unilateral when the veins from only one lung are involved and, thus, may result in unilateral pulmonary edema and fibrosis.

Mediastinal Nerve Involvement. Entrapment or compression of the mediastinal nerves can cause a variety of disorders. Hoarseness can result from involvement of the recurrent laryngeal nerve,[166,170] diaphragmatic paralysis from involvement of one or both phrenic nerves, Horner's syndrome from impingement on autonomic ganglions or nerves, and persistent tachycardia from damage to the vagus nerve.

Diagnosis and Management

In most instances, surgical exploration is necessary to distinguish between benign and malignant causes for SVC syndrome, localized mediastinal mass, or other manifestation of chronic mediastinitis. In occasional cases, radiographs from previous years documenting an unchanged appearance or dense calcification within the mass will permit a confident diagnosis without operation.

Chest radiographs are abnormal in most patients. Granulomatous mediastinitis more often presents as a localized mass, usually in the right paratracheal area, and the later fibrotic state more frequently produces generalized widening of the superior portion of the mediastinum, but these characteristics vary.[170,173] Mass lesions tend to be smooth and lobulated,[173] and contrast studies in cases of SVC obstruction typically show the affected area to be smooth and tapered,[170] in contrast to the more ragged appearances usually seen with cancer. In some cases, the mediastinum is normal in appearance on standard chest radiographs, and venography or CT is necessary to demonstrate the anatomic basis of a clinically evident obstruction.[173]

The role of specific medical therapy for granulomatous mediastinitis or mediastinal fibrosis is unclear.[178] Some evidence suggests that selected cases with active inflammation associated with histoplasmosis may benefit from antifungal therapy,[180,185] but specific indications, if any, for antifungal therapy remain unknown. A similarly conservative approach should be taken to tuberculosis-related mediastinal complications, unless sputum or tissue samples are positive for mycobacteria or convincing clinical evidence of active tuberculosis is present.

The clinical manifestations of this disease appear to be the result of host factors as much as the infection itself. Accordingly, therapy has also been directed at the host inflammatory response. Anecdotal reports of treatment of mediastinal and retroperitoneal fibrosis with corticosteroids have reached opposite conclusions.[186,187] It appears that diffuse forms of fibrosis may be more likely to respond.[188] As in the case of antimicrobial therapy, the appropriate role for anti-inflammatory therapy for granulomatous mediastinitis and mediastinal fibrosis is at present unknown.[189]

At the time of exploration for diagnosis, some surgeons advise removal of as much of the inflammatory or fibrous mass as possible, in order to reduce its bulk and perhaps diminish its later impact on adjacent tissues.[189] Despite the difficulties presented by fibrotic and granulomatous encasement, surgical intervention may be quite successful in these patients.[178] Surgery to bypass an

obstructed vena cava is technically difficult and not always effective, although this may still be considered if bleeding esophageal varices or recurrent upper extremity thrombophlebitis occurs. Endovascular stent placement is another option.[190] Obstruction of major pulmonary vessels is a poor prognostic sign. Therapeutic options are limited, but surgical reconstruction, angiographic dilation and stent placement may be successful in selected cases.[191]

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of David J. Pierson, MD, who wrote this chapter for the first and second editions, and coauthored this chapter with DRP for the third edition. These earlier chapters contain more extensive and historical references.

KEY POINTS

- Pneumomediastinum refers to the presence of air or other gas in the mediastinum.
- The gas that causes pneumomediastinum usually originates from alveolar rupture in the lungs but may arise from the upper respiratory tract or the gastrointestinal tract (especially the esophagus).
- Treatment of pneumomediastinum depends primarily on successful management of the underlying disease process. Rarely, direct intervention is needed to decompress air in the mediastinum.
- Acute mediastinitis is usually a sudden and severe disease that is now most commonly caused by perforation of the esophagus during endoscopic procedures.
- "Spontaneous" rupture of the esophagus during vomiting and descending infections originating in the neck remain important causes of acute mediastinitis, and infectious complications after surgical procedures that incorporate sternotomy incisions are being encountered with increasing frequency.
- All forms of acute mediastinitis are life-threatening and require prompt diagnosis, imaging, surgical drainage, and antimicrobial treatment.
- Chronic mediastinitis results from granulomatous inflammation of the mediastinum and its fibrotic sequelae. Complications include bronchial obstruction, SVC syndrome, esophageal compression, and pulmonary vessel obstruction.
- Management or chronic mediastinitis is aimed at relief of these mechanical complications. The role of anti-inflammatory and antimicrobial therapy is at present unclear.

CHAPTER 78

HYPOVENTILATION AND HYPERVENTILATION SYNDROMES

James Duffin, PhD • Eliot A. Phillipson, MD

INTRODUCTION

THE CONTROL OF BREATHING
Basic Principles
Organization of the Respiratory Control System
Control of Breathing Pattern
Chemoreflex Control of Breathing

HYPOVENTILATION SYNDROMES
General Principles and Diagnostic Approach
Primary Alveolar Hypoventilation

HYPERVENTILATION SYNDROMES
Introduction
Pathogenesis
Physiologic and Clinical Features
Diagnosis
Management

INTRODUCTION

Breathing is regulated by two anatomically distinct but functionally integrated elements referred to as the metabolic (or automatic) and the behavioral (or voluntary) respiratory control systems. The major components are shown in Figure 78-1. The metabolic system is concerned primarily with acid-base balance and blood gas homeostasis. Appropriate to this function, it receives afferent input from peripheral and central chemoreceptors that are sensitive to hydrogen ion concentration ($[H^+]$), P_{CO_2}, and P_{O_2} and from bronchopulmonary mechanoreceptors that are sensitive to the degree of lung stretch and rate of airflow. In contrast, the behavioral control system utilizes the ventilatory apparatus for functions whose primary purpose is not gas exchange, the most notable examples being speaking and singing. Disorders in the control of breathing can arise because of disturbances in either of these two control systems. In broad terms, defects in the behavioral system result in dysphasia, dyspraxia, or alveolar hyperventilation syndromes but do not produce clinically important hypoventilation syndromes. Rather, hypoventilation disorders arise because of either defects in the metabolic control system or defects in the respiratory neuromuscular apparatus, chest wall, lungs, or airways. Such disorders can be acute or chronic. Acute hypoventilation disturbances, which represent life-threatening emergencies, are considered in Chapter 90. This chapter deals with disturbances in respiratory control that result in chronic hypoventilation or chronic hyperventilation syndromes.

THE CONTROL OF BREATHING

Basic Principles

Breathing is responsible for providing sufficient oxygen for metabolism and for eliminating the carbon dioxide produced by metabolism. The respiratory control system accomplishes this goal by adjusting pulmonary ventilation so oxygen uptake in the lungs equals oxygen consumption by the tissues, and carbon dioxide elimination at the lungs equals carbon dioxide production by the tissues (Fig. 78-2). Under these conditions, pulmonary gas exchange matches metabolism, and P_{O_2} and P_{CO_2} remain constant at values satisfying physiologic requirements.

In the case of P_{O_2}, the requirement is relatively simple: it must be kept at a level sufficient to saturate arterial hemoglobin and to provide a pressure gradient that supplies tissue metabolic requirements for oxygen. Because hemoglobin saturation can be achieved over a wide range of P_{O_2} levels, P_{O_2} need not be closely regulated, as

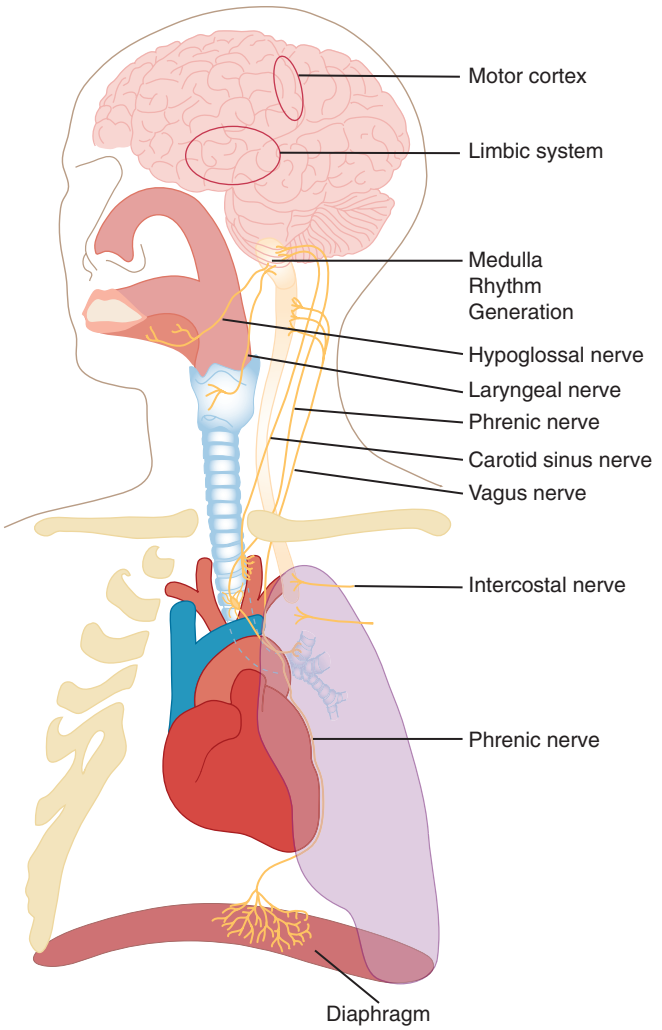

FIGURE 78-1 ■ A cartoon showing the major elements of the central nervous system participating in the metabolic and behavioral respiratory control systems and their anatomic relationships. The automatic respiratory rhythm is generated in the medulla and sent down the spinal cord to motoneurons connecting to the diaphragm via the phrenic nerve and the intercostal muscles via the intercostal nerves. The tongue and upper airway muscles are controlled via the hypoglossal and laryngeal nerves, respectively. The limbic system and motor cortex are the origin of emotional and voluntary control of respiration. Lung receptor signals are fed back to the medullary control center via the vagus nerve, and the carotid sinus nerve conveys the carotid body (peripheral chemoreceptor) drive to breathe.

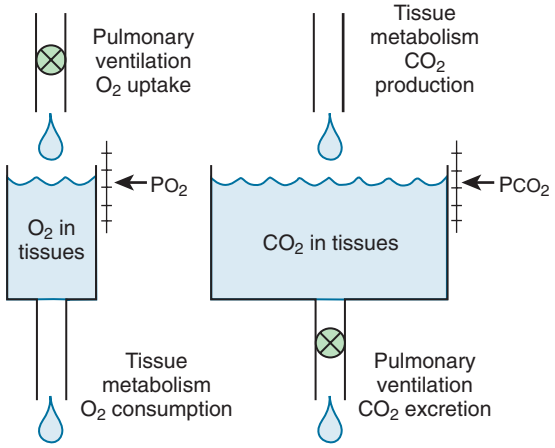

FIGURE 78-2 ■ A conceptual model showing the balance between metabolic requirements for the supply of oxygen and elimination of carbon dioxide, and the pulmonary gas exchange of O_2 and CO_2. Metabolic consumption of O_2 is represented by the drops of O_2 leaving the O_2 storage tank (mostly blood), and CO_2 production in the tissues is represented by the drops of CO_2 entering the CO_2 storage tank (body water). Pulmonary ventilation operates the O_2 inflow tap and the CO_2 outflow tap to control the O_2 uptake and CO_2 elimination represented by the drops. Note the difference in size of the tissue storage compartments of the two gases, as a result of which changes in P_{O_2} stores are fast and changes in P_{CO_2} stores in tissues such as the brain are slow.

long as tissue hypoxia is avoided. In contrast, the requirement for carbon dioxide elimination is less dependent on a pressure gradient because carbon dioxide diffuses much more readily through an aqueous environment than oxygen. However, P_{CO_2} must be controlled at a level that ensures that tissue $[H^+]$ remains within the narrow limits necessary for optimal protein function (normally 40 nM/L).[1] This requirement can be considered as the second goal of the respiratory control system, with renal regulation of ionic concentrations also involved.

Under resting conditions, P_{CO_2} is maintained within a narrow range by a negative feedback regulator involving two sets of chemoreceptors that sense $[H^+]$, one in the brain (central chemoreceptors) and one in the carotid bodies (peripheral chemoreceptors). When these chemoreceptors sense an increase in $[H^+]$, breathing is stimulated. This chemoreflex control system also protects against asphyxia by increasing the sensitivity of the peripheral chemoreceptors to $[H^+]$ under conditions of hypoxia. The regulation of blood gases is discussed in Chapter 4, and acid-base balance is examined in Chapter 7.

During exercise, however, rapid increases in metabolism must be accompanied by rapid changes in ventilation if pulmonary gas exchange is to match metabolism. In this situation, fast neural response mechanisms are activated, including afferent feedback from the exercising muscles and a parallel activation of ventilation with activation of the exercising muscles, termed *central command*.[2]

The two elements involved in matching pulmonary gas exchange to metabolic requirements, the chemoreflex and exercise control systems, collectively constitute the metabolic or automatic control system. However, other physiologic functions also utilize the ventilatory apparatus, notably speaking,[3] singing, and voluntary breath-holding[4] as well as emotions.[5] These activities have impact on the respiratory muscles through the behavioral control system.[6] Breath-holding exemplifies the competition that may exist between the behavioral and metabolic control systems for use of the respiratory

muscles. At the initiation of a breath-hold, voluntary control dominates and breathing is halted; but as the chemoreflex drive to breathe increases progressively, the metabolic control system overrides behavioral control and the breath-hold is terminated. In the process of this competition, the discrepancy between the chemoreflex drives to breathe, on the one hand, and the lack of ventilation, on the other, results in a sensation of dyspnea.[7]

Subsidiary to the metabolic and behavioral systems are other control systems, including those responsible for choice of efficient patterns of breathing in terms of tidal volume and respiratory rate,[8] and for protection of the airways by pulmonary reflexes, such as cough.[9] This hierarchical system of controllers can be put into perspective by examination of the organization of the central respiratory control system.

Organization of the Respiratory Control System

General Organization

Taken together, the demands of the various respiratory control systems vary from moment to moment, and may place conflicting demands on the respiratory muscles, which then act according to set priorities. The site of much of this competition is the respiratory motoneurons in the spinal cord, where the various drives to breathing arrive via separate pathways[6] (Fig. 78-3). The separation of the spinal pathways for behavioral and metabolic control in humans has been deduced from observations of spinal cord injuries that involve only one pathway. For example, some patients are able breathe on command but lack the automatic chemoreflex response to carbon dioxide, whereas others have a response to carbon dioxide but cannot voluntarily influence breathing.[10] Behavioral or voluntary control from the motor cortex arrives via the corticospinal tracts in the dorsolateral spinal cord; metabolic or automatic control from the central controller in the medulla arrives via ventrolateral spinal cord pathways, as do the inputs from hypothalamic, limbic, and reticular formation systems that mediate such behaviors as anxiety hyperventilation, the sudden gasp of a startle, the changes in breathing during sleep, and the response to sensory afferents such as pain.

The metabolic respiratory control system can be viewed as a complex hierarchical control system with multiple feedback loops (Fig. 78-4). The system is centered in the brain stem (medulla), where respiratory rhythm and drives are sent to the respiratory motoneurons in the spinal cord, based on feedback from various afferents. Details of this system are provided in reviews.[11] The afferent inputs to the system include those from the central chemoreceptors within the medulla, the peripheral chemoreceptors in the carotid bodies, and airway and lung receptors. These signals also reach higher areas of the central nervous system such as the pons, where they affect the patterning of breathing,[12] and the cortex, where they may contribute to respiratory sensations

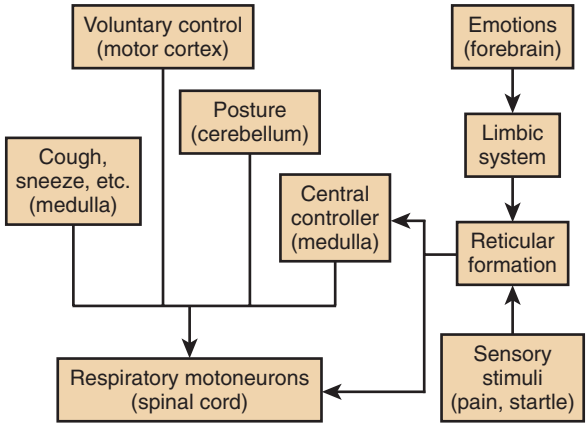

FIGURE 78-3 ■ A general scheme showing various drives to breathing controlling the spinal respiratory motoneurons, with the direct pathways on the left and the indirect pathways on the right. The voluntary control from the motor cortex and the respiratory rhythm from the central controller in the medulla reach the spinal motoneurons via separate spinal pathways, each of which may be damaged to separately disable voluntary and automatic respiratory control of the respiratory muscles. The reticular formation conveys emotional and sensory signals that affect breathing.

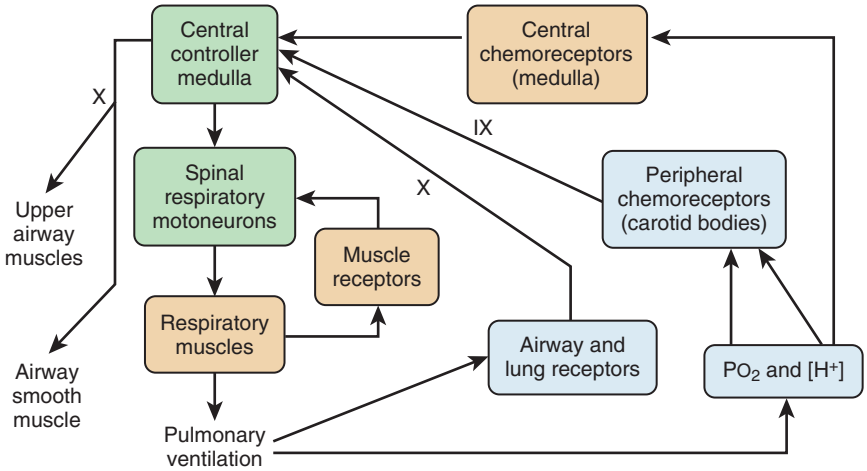

FIGURE 78-4 ■ A schematic diagram of some of the many feedback loops involved in the automatic control of breathing. The central controller rhythmically drives the respiratory muscles via the spinal motoneurons to ventilate the lung and control P_{CO_2}, which controls $[H^+]$ and P_{O_2}. Central and peripheral chemoreceptors feed back information about $[H^+]$ and P_{O_2} to the central controller in the medulla via the glossopharyngeal nerve (IX) (the chemoreflexes). Airway and lung receptors feed back information about irritants and lung volume to the central controller via the vagus nerve (X). Local spinal feedback assists with the control of the complex respiratory musculature.

such as dyspnea, but the pathways involved are mostly unknown. In addition to the medullary feedback loops, there are also local control loops to spinal motoneurons from respiratory muscle receptors, particularly in the intercostal muscles.

Spinal Organization

The spinal organization of respiratory motoneuron control is complex and not fully understood. Four groups of respiratory neurons have been identified in the spinal cord: upper cervical inspiratory neurons in C1-3; phrenic motoneurons and interneurons in C3-5; intercostal motoneurons and interneurons in T1-12; and abdominal motoneurons and interneurons in T6-L3. The interneurons within the motoneuron segments and those more remote in the upper cervical cord probably mediate the segmental and suprasegmental reflex control of the motoneurons.

The upper cervical inspiratory neurons are located bilaterally in longitudinal columns extending caudally from the medulla to mid-C3.[13] These neurons receive a direct drive from the medullary inspiratory neurons, as well as inputs from intercostal afferents. Their axons descend the spinal cord ipsilaterally as far as the upper lumbar segments, and arborize within the phrenic, intercostal, and abdominal motoneuron segments of the spinal cord. As yet, the functional connections of these neurons are undetermined because they do not appear to connect synaptically with spinal respiratory neurons.

The respiratory motoneurons, including the phrenic motoneurons driving the diaphragm, the intercostal motoneurons driving the intercostal muscles, and the abdominal motoneurons driving the abdominal muscles,[14] receive a rhythmic respiratory drive from two sources: the nearby respiratory interneurons in the spinal cord, and the respiratory neurons located in the medulla. These motoneurons produce a ramp of inspiratory nerve activity by an increasing firing frequency and by the recruitment of additional motoneurons. Because some medullary respiratory neurons are the source of the rhythmic drive to the spinal respiratory motor neurons, they are often referred to as respiratory premotor neurons.

Central Organization

The network that generates and transmits respiratory rhythm to the spinal respiratory motoneurons via bulbospinal projections, and to various respiratory muscles of the airway via cranial nerves, lies within the medulla and pons.[15] The medullary respiratory neurons are located in two main groups, longitudinally distributed on either side of the neuraxis, referred to as the ventral respiratory group (VRG) and the dorsal respiratory group (DRG), because of their relative anatomic positions. The groups are located near the obex, the point where the central canal widens into the fourth ventricle (Fig. 78-5). Not shown are the medullary elements sensing [H^+] that constitute the central chemoreceptors[16] that are located close to the ventral surface and elsewhere. These neuron populations have bursting activities that occur in different phases of the respiratory cycle: the most obvious are inspiration and expiration, but the expiratory phase is often divided into two parts, a postinspiratory or early expiratory portion and a late expiratory portion. Within

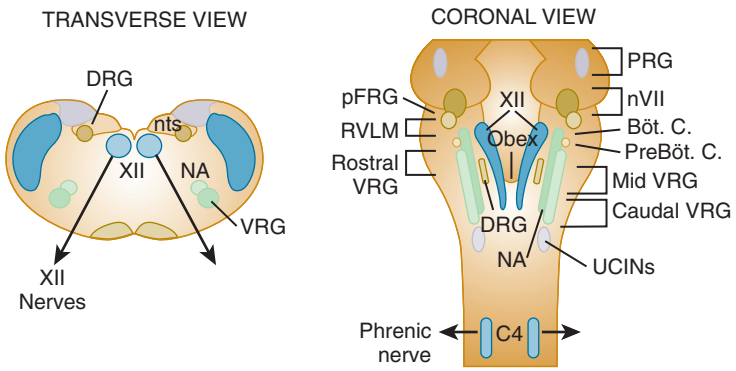

FIGURE 78-5 ■ A schematic diagram of the medulla showing the main groups of respiratory neurons. The coronal view has the cerebellum removed, and the transverse view is at the level of the obex. The two major groups of neurons are the ventral respiratory group (VRG) and the dorsal respiratory group (DRG); the latter is where vagal afferent inputs are processed. The ventral respiratory group (VRG) has been subdivided into a caudal part, where many expiratory premotor neurons are found, and a rostral part, where many premotor inspiratory neurons are found, based on the location of the obex, the point where the central canal surfaces into the fourth ventricle. An intermediate locus about the obex contains both inspiratory and expiratory neurons. Intermingled with these neurons are the cranial motor neurons of the nucleus ambiguous (NA). Caudal to the ventral respiratory group are the mysterious upper cervical inspiratory neurons (UCINs). Above the ventral respiratory group, as a rostral extension of it, lies the Bötzinger complex (Böt C) in the rostroventrolateral medulla (RVLM), containing a variety of neuron types, including cranial motor neurons and a major group of inhibitory expiratory neurons. Immediately rostral, near the facial nucleus (nVII), is the parafacial respiratory group (pFRG) associated with rhythm generation in neonates. Just caudal to the Bötzinger complex is the pre-Bötzinger complex (pre Böt C), whose neurons are also associated with rhythm generation in neonates. Other respiratory neurons involved in rhythm generation are found in the pons (pontine respiratory group, PRG). The hypoglossal motoneurons (XII) controlling the tongue are also shown.

each phase, the pattern of firing frequency may be augmenting, constant, or decrementing.

The caudal VRG contains many expiratory premotor neurons and the rostral VRG contains many premotor inspiratory neurons, whose axons course contralaterally within the medulla before descending the cord to the respiratory motoneurons and interneurons. Caudal to the VRG in the cervical spinal cord lie the upper cervical inspiratory neurons. The DRG includes the respiratory afferent relay neurons of the nucleus tractus solitarius. Pontine respiratory groups include the Kolliker fuse and parabrachial nuclei.[17] Other medullary neurons include the Bötzinger complex, rostral to the VRG, that inhibits medullary inspiratory activity during expiration as well as phrenic motor neurons, and two sites of pacemaker-type cells: the pre-Bötzinger complex (preBötC),[18] located between the Bötzinger complex and the VRG, and the parafacial respiratory group (pFRG), located beside the facial nucleus.[19] The abdominal motoneurons receive excitation from neurons in the pFRG via the caudal VRG premotor neurons.

The VRG also includes the cranial motoneurons of the nucleus ambiguus,[20] which leave the medulla ipsilaterally in the vagus or glossopharyngeal nerves, and innervate several different muscles of the airways.[21] Other cranial neurons include the hypoglossal motoneurons that lie close to the midline and innervate the tongue.[22] These various cranial motoneurons are respiratory in the sense that a component of their activity is related to the respiratory cycle; but they are also involved in other functions, such as speech and swallowing.[23] Because this dual function dictates the requirement for looser respiratory control than the respiratory pump muscles, the hypoglossal motoneurons, for example, are not driven by the same premotor neurons as the diaphragm.[24]

Pontine neurons exchange information with the medulla,[17] but their role as "apneustic" and "pneumotaxic" centers has changed to that involving more complex behaviors. The pons has profound influences on respiratory rhythm generation[25] and is involved in mechanoreceptor and chemoreceptor reflexes.[26] Other aspects include the role of the pons in vocalization,[3] exercise,[27] and nociception[28] and as a source of state-dependent control of respiratory activity, such as the control of airway muscles during sleep.[29]

The Respiratory Rhythm Generator

Current concepts of respiratory rhythm generation remain controversial, with two main theories in contention: the pacemaker hypothesis, and the network hypothesis. Definitive proof for these hypotheses is difficult to establish. Indeed, they have emerged largely from studies based on different experimental preparations (the network hypothesis derives from adult in vivo preparations, and the pacemaker hypothesis from neonatal in vitro preparations) and these differences may account for the different findings. This conflict between hypotheses may be resolved using a new perfused preparation that can be applied to both neonates and adults, the working heart–brain stem preparation.[30] Experiments with this preparation have already demonstrated the importance of synaptic inhibition in normal respiratory rhythm generation.[31]

In neonatal in vitro preparations, pacemaker-like neurons have been identified in two discrete regions in the rostroventrolateral medulla: the preBötC[18] and pFRG.[19] These two pacemaker populations may represent coupled inspiratory and expiratory rhythm generators. However, their interaction is a point of contention. Do the pFRG neurons represent a master rhythm generator that not only sets the expiratory rhythm but also entrains inspiratory bursts, or does the preBötC dominate? Neurons in the pFRG have been shown to excite preBötC neurons, and preBötC neurons have been shown to inhibit pFRG neurons. Perhaps the interaction is cooperative.[32]

Nevertheless, the network hypothesis, which suggests that respiratory rhythm results from the pattern of synaptic interconnections among neurons in a distributed network in the medulla and pons,[33] remains in contention with evidence that, when pacemakers are eliminated, respiratory rhythm continues, and when synaptic inhibition, essential for network rhythm generation, is suppressed, rhythm ceases. Recent experiments have led to the proposal that the generation of respiratory rhythm is organized as a hierarchy of mechanisms.[34] All network models have three basic principles in common. First, mutual inhibition must exist between at least two major groups of neurons of opposite respiratory phase (inspiratory and expiratory). Second, at least one of the neuron types must be self-limiting through an accommodative mechanism whereby the responsiveness of the neuron is decreased by its own activity. Third, a tonic drive to the neurons involved is necessary to produce the oscillation. Figure 78-6 shows proposed connection diagrams for models of two-phase[35,36] and three-phase[37] respiratory rhythm generators.

Control of Breathing Pattern

Two main types of receptors from the lungs and airways provide feedback information to the medullary controller that determines the pattern of breathing; specifically, rapidly adapting irritant receptors, and slowly adapting stretch receptors.[38] The rapidly adapting receptors are found throughout the airway from the nose to the alveoli, and are stimulated by irritants in the inspired air, and by rapid and excessive lung inflation or deflation. These receptors are classified as rapidly adapting because, following stimulation, their activation declines rapidly even if the stimulus persists. Some irritant receptors produce stereotyped patterns of breathing, such as coughing,[39] and all share the property of stimulating inspiration and inducing bronchoconstriction.[21] Stimulation of these receptors during an asthmatic attack exacerbates airway narrowing by producing reflex bronchoconstriction in addition to that produced by the local release of chemical mediators. The pattern of breathing induced by irritant receptor stimulation depends upon their location in the airway: nasal receptors (trigeminal nerves) result in sneezing; epipharyngeal receptors (glossopharyngeal

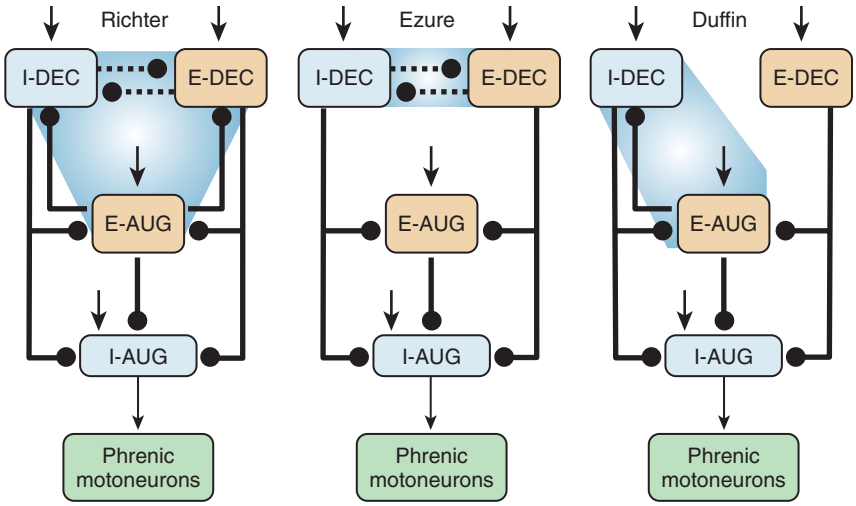

FIGURE 78-6 ■ Three conceptual models[36,37,135] of respiratory rhythm generation based upon inhibitory connections (*shaded area*) between inspiratory (I) and expiratory (E) neurons of the VRG with decrementing (DEC) and augmenting (AUG) patterns of activity. The E-AUG neurons are the Bötzinger complex expiratory neurons, and the E-DEC and I-DEC neurons are accommodating. These neurons control the output of the inspiratory augmenting neurons (I-AUG). The network requires a tonic excitation (*closed circles*) from the chemoreceptors to oscillate. The *dotted lines* indicate theoretical connections, while the *solid lines* indicate known connections.

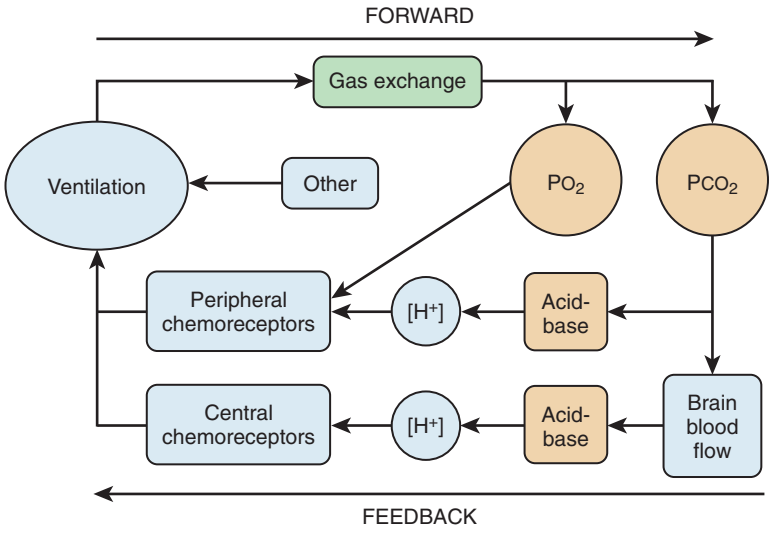

FIGURE 78-7 ■ A schematic diagram of the negative feedback chemoreflex control of breathing. Ventilation controls P_{CO_2} and P_{O_2} via the gas exchange in the lungs (the forward part of the control loop). P_{CO_2} controls brain blood flow, and central and peripheral $[H^+]$ via acid-base relationships. Central and peripheral chemoreceptors drive ventilation according to the levels of P_{O_2} and $[H^+]$ to form a chemoreflex (the feedback part of the control loop). The control system is termed "negative feedback" because an increase in ventilation decreases P_{CO_2}, which in turn decreases the chemoreceptor feedback driving ventilation. Note that "other" drives to breathe, such as wakefulness, behavior, and exercise, also affect ventilation. (Please see the text for more details.)

nerves) result in the aspiration or sniff reflex; laryngeal and tracheal receptors (vagus nerves) result in coughing; tracheal, bronchial, and bronchiolar receptors (vagus nerves) result in Head's paradoxical reflex and the deflation reflex; and juxtapulmonary capillary or J receptors (vagus nerves) result in rapid, shallow breathing.

The stretch receptors, which are located in the main airways of the bronchial tree, respond to lung inflation and produce afferent feedback to the medullary controller through the vagus nerves that is proportional to lung volume.[40] These receptors are responsible for the Hering-Breuer inflation reflex, whereby lung inflation switches respiratory phase from inspiration to expiration. This reflex is very apparent in animals, even at normal lung volumes, so that blockade or section of the vagi results in slow, deep breathing because inspiration continues to larger tidal volumes and longer inspiration times. In humans, however, the inflation reflex is weak, and difficult to demonstrate except at high lung volumes.[41] It is thought that the stretch receptors provide information to the central respiratory controller that enables a judgment to be made of the effectiveness of respiratory muscle activity. Such information may be used for adjustment of the breathing pattern in response to altered loading of the respiratory muscles.[8]

Although the level of ventilation required for metabolic gas exchange can be achieved by several different combinations of tidal volume and respiratory rate, there is a particular combination that will result in minimum work.[42] Stretch receptor information may help to determine this combination. In addition, stretch receptor information may also be sensed consciously, providing information with regard to lung volume and pulmonary ventilation. A discrepancy between the level of ventilation demanded by the central controller (which can also be sensed) and the actual pulmonary ventilation achieved is thought to produce the sensation of dyspnea.[43]

Chemoreflex Control of Breathing

General Organization

The chemoreflex control of breathing is based on a negative feedback loop (Fig. 78-7). When the central and

peripheral chemoreceptors sense an increase in $[H^+]$, breathing is stimulated via a chemoreflex arc that includes the central nervous system, respiratory muscles, and changes in alveolar ventilation, which results in an increased elimination of CO_2 and a fall in P_{CO_2} and $[H^+]$ at the chemoreceptor sites; hence the negative feedback designation of the system. However, in addition to chemoreflex drives to breathing, another tonic drive to breathe also contributes to ventilation, independently of the chemoreflexes and not behavioral in nature. This drive reflects the "state" of the subject, and is referred to as the "waking neural drive," because it is withdrawn during sleep.

The forward part of the loop (see Fig. 78-7) relates the dependence of P_{CO_2} and P_{O_2} on ventilation as the pulmonary gas exchange controls the elimination of CO_2 and uptake of O_2. Therefore, the forward part of the loop can be characterized by the relationships between ventilation and P_{CO_2} and P_{O_2}. Because P_{CO_2} is the major factor controlling the $[H^+]$ sensed by the chemoreceptors, we concentrate on that relationship. The alveolar air equation states that the product of ventilation and alveolar P_{CO_2} is proportional to the amount of carbon dioxide eliminated; hence, in any steady metabolic state, P_{CO_2} depends on carbon dioxide production divided by ventilation. This relationship, when graphed, has the geometric shape of a rectangular hyperbola, and is therefore referred to as the *metabolic hyperbola.* The feedback part of the loop is the increase in pulmonary ventilation in response to stimulation of the chemoreceptors by $[H^+]$ and is referred to as a *chemoreflex.* There are two, central and peripheral, which are defined by the location of their sensors.

Central Chemoreflex

The central chemoreceptors are located in the medulla (near the ventrolateral surface and scattered within the brain tissue) and respond to the $[H^+]$ of their local environment.[44] They are often thought of as CO_2 receptors because central $[H^+]$ is directly dependent on the P_{CO_2} of chemoreceptor tissue. Two factors complicate the physiology of the central chemoreceptors. First, the blood-brain barrier to polar solutes prevents changes in arterial $[H^+]$ from reaching the central environment, whereas carbon dioxide passes freely across the barrier. As a result, central $[H^+]$ may differ from arterial $[H^+]$. The central chemoreceptors are therefore somewhat isolated from arterial acid-base disturbances, except as they involve changes in arterial P_{CO_2}. Indeed, control of central acid-base status to keep central $[H^+]$ at normal values may result in differences in the relation between P_{CO_2} and central $[H^+]$ that produce shifts in the central chemoreflex ventilatory response to CO_2.[1]

Second, because the central chemoreceptors are in brain tissue, they are relatively slow in responding even to changes in P_{CO_2} in arterial blood, so the time constant for the central chemoreceptor response to a change in alveolar P_{CO_2} is about 100 seconds; hence, it takes 5 minutes (three time constants) for the system to respond fully to changes in inspired CO_2. Furthermore, increases in cerebral blood flow in response to increases in arterial P_{CO_2} will affect the relation between arterial P_{CO_2} and central chemoreceptor P_{CO_2}. If cerebral blood flow increases markedly with P_{CO_2}, the difference between central chemoreceptor P_{CO_2} and arterial P_{CO_2} declines as arterial P_{CO_2} increases. Measuring the ventilatory response of the central chemoreflex using a rebreathing technique, which measures only the central chemoreflex ventilatory response, may therefore differ from that using a steady-state technique, which measures both the central chemoreflex ventilatory response and the effect of the cerebral blood flow response.[45] The drive to breathe from the central chemoreceptors increases linearly with $[H^+]$ (or P_{CO_2}) above a chemoreceptor threshold, and the slope of this response is its sensitivity. The central chemoreflex response to any particular P_{CO_2} is therefore determined by both its sensitivity and its threshold (Fig. 78-8A).

Peripheral Chemoreflex

The peripheral chemoreceptors, located in the carotid bodies at the bifurcation of the carotid arteries, "taste" the blood approaching the brain. Signals from the receptors are sent to the respiratory controller in the medulla via the carotid sinus nerve (a branch of the glossopharyngeal or IXth cranial nerve).[46] The peripheral chemoreceptors respond to both the $[H^+]$ and the P_{O_2} of arterial blood, such that, in response to hypoxia, the sensitivity of the chemoreceptor response to $[H^+]$ or P_{CO_2} is increased (see Fig. 78-8B). Thus, the receptors are maximally stimulated by a simultaneous increase in $[H^+]$ and decrease in P_{O_2}—in other words, by asphyxia. Like the central chemoreflex, the drive to breathe from peripheral chemoreceptors increases linearly with $[H^+]$ (or P_{CO_2}) above a chemoreceptor threshold, with the slope of the response representing its sensitivity. Thus, the peripheral chemoreflex response to any particular P_{CO_2} is determined by both its sensitivity and its threshold. However, for the peripheral chemoreceptors, the sensitivity of the response also depends on the P_{O_2}, such that hypoxia increases the P_{CO_2} sensitivity markedly, and hyperoxia decreases it almost to zero.

The peripheral chemoreceptors have traditionally been considered to be primarily hypoxia sensors. Although correct in one sense, this notion is somewhat misleading as it implies an independent drive to breathe associated with hypoxia. Although the peripheral chemoreceptors do sense hypoxia, the only effect of hypoxia acutely (as noted previously) is to increase the sensitivity of the chemoreceptors to $[H^+]$ (or P_{CO_2}). This feature of the peripheral chemoreflex has two important clinical implications: if the P_{O_2} is high, there is little (if any) peripheral chemoreflex response to P_{CO_2}; and if the P_{CO_2} is low (and therefore below the ventilatory recruitment threshold), there is little (if any) peripheral chemoreflex response to hypoxia. However, in the presence of prolonged continuous or intermitted hypoxia, the chemoreflex may undergo modifications.[47]

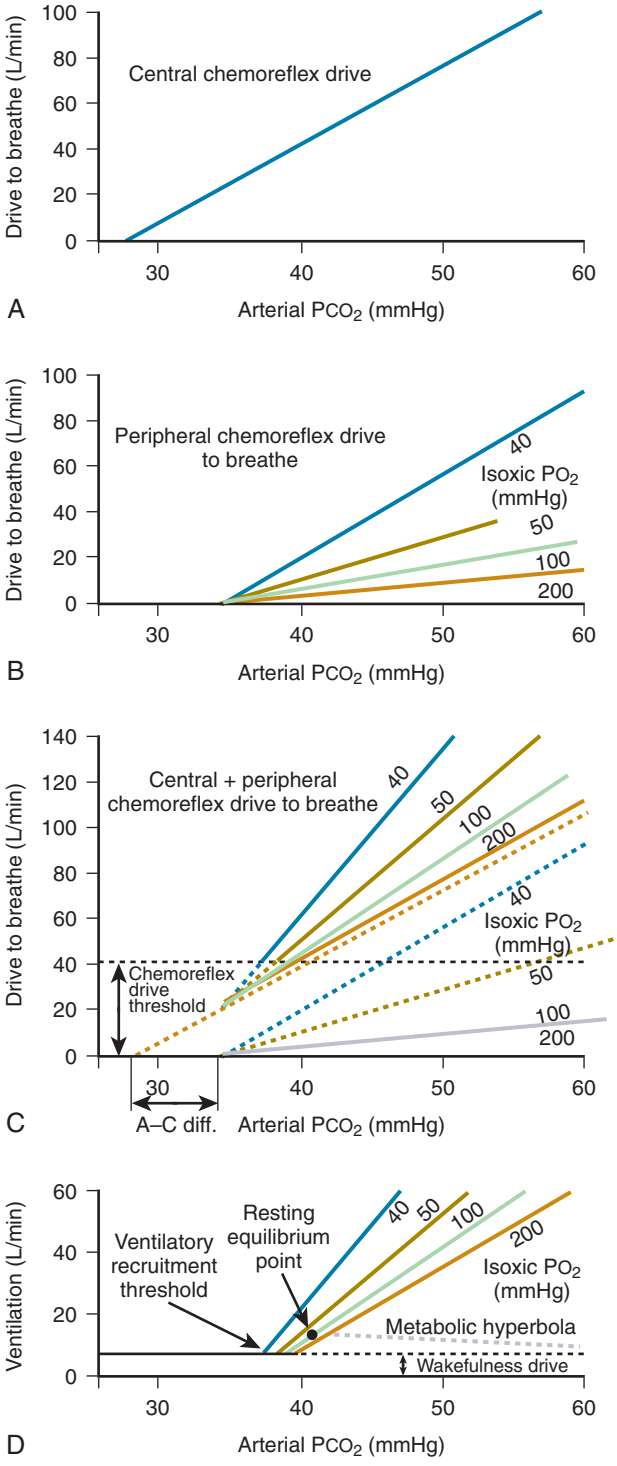

FIGURE 78-8 ■ A graphic solution for the negative feedback chemoreflex control of breathing. **A,** The central chemoreflex contribution to ventilatory drive, which depends entirely on medullary P_{CO_2} (via $[H^+]$). Note that the chemoreceptor threshold P_{CO_2}, when plotted against arterial P_{CO_2}, is less than that for the peripheral chemoreceptors because of the difference between the arterial P_{CO_2} and central chemoreceptor P_{CO_2} (A–C diff.). This arterial-to-central P_{CO_2} difference is affected by cerebral blood flow, itself responsive to changes in arterial P_{CO_2}. **B,** The peripheral chemoreflex contribution to ventilatory drive, which depends on P_{CO_2} (via $[H^+]$) and whose sensitivity varies with P_{O_2}. **C,** The central and peripheral ventilatory drives (*dotted lines*) are added to provide the total chemoreflex drive to breathe but only increase ventilation once a threshold is exceeded (*solid lines*). **D,** Finally, the chemoreflex drive to breathe is added to the wakefulness drive to breathe. The chemoreflex control of ventilation, dependent on both P_{CO_2} and P_{O_2}, is therefore shown as a series of isoxic lines. Below the threshold, ventilation is driven by the waking neural drive (*dotted line*). The intersection of the control lines with the metabolic hyperbola (*dashed line*) defines the equilibrium point of the forward and feedback components of the control system, and the resting ventilation and P_{CO_2}.

Chemoreflex Control System

The central and peripheral chemoreceptor drives to breathe summate to provide the chemoreflex drive to breathe, but do not affect pulmonary ventilation until the total ventilatory drive (neural signals from the chemoreceptors) exceeds a threshold, called the *drive threshold.* Thus, an increase in P_{CO_2} does not increase ventilation until a threshold P_{CO_2} has been exceeded, referred to as the *ventilatory recruitment threshold.* Above the ventilatory recruitment threshold, the ventilatory response to P_{CO_2} is usually linear, with a slope (sensitivity) varying with P_{O_2} (see Fig. 78-8C).[45] When P_{O_2} is high, the ventilatory response to carbon dioxide is due almost entirely to the central chemoreflex. When P_{CO_2} is below the ventilatory recruitment threshold, ventilation is main-

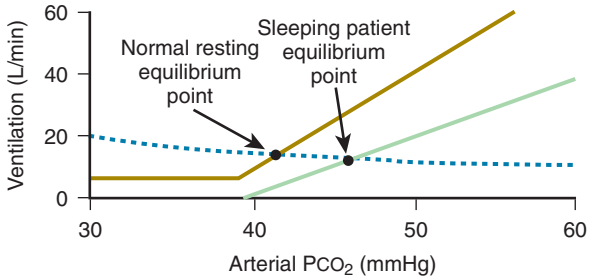

FIGURE 78-9 ■ An illustration of the use of the graphic approach to the chemoreflex control of breathing. The *dashed blue line* shows the metabolic hyperbola, the *brown line* shows the normal waking neural and chemoreflex drives to breathe, and the *pale green line* shows the drive to breathe in a sleeping patient with supplemental oxygen recovering from anesthesia. The intersection of the metabolic hyperbola and the chemoreflex drive shows the resting equilibrium ventilation and arterial P_{CO_2}, and illustrates the large increase in arterial P_{CO_2} for little decrease in ventilation that occurs during sleep.

tained above zero by the waking neural drive (see Fig. 78-8D). However, when this drive is lost during sleep, a P_{CO_2} below the ventilatory recruitment threshold results in apnea (see Chapter 79).

The graphic representation of the chemoreflex control of breathing is useful for predicting ventilation and P_{CO_2} under a variety of conditions. Figure 78-9 shows one example, that of a sleeping patient recovering from anesthesia and breathing supplemental oxygen. In this case the waking neural drive is absent, the peripheral chemoreflex drive is minimal because the P_{O_2} is high, and the central chemoreflex sensitivity is depressed by the anesthesia. As a result, the patient is operating on the flat portion of the metabolic hyperbola, and, under these conditions, a small decrease in ventilation results in a large increase in P_{CO_2}.

Stability

The stability of the chemoreflex control system is governed by the sensitivity or gain of the entire control loop, both forward and feedback portions (see Fig. 78-7). Increases in loop gain are associated with instability.[48] As the anesthetized patient in Figure 78-9 illustrates, moving the equilibrium point to increasing P_{CO_2} increases the ability of ventilation to change P_{CO_2} (i.e., the sensitivity or gain of the forward part of the loop is increased). However, at the same time the chemoreflex sensitivity (the feedback portion of the loop) has decreased in the sleeping patient, so overall the loop gain, which is the combination of the forward and feedback gains, is relatively unchanged.[49] The effect of cerebral blood flow control by arterial P_{CO_2} should also be considered; as P_{CO_2} increases, cerebral blood flow also increases, washing out CO_2 from brain tissue and reducing the stimulus to the central chemoreceptors. A reduction in the sensitivity of cerebral blood flow to arterial P_{CO_2} therefore increases the overall sensitivity of the central chemoreflex response to changes in arterial P_{CO_2}.[50]

HYPOVENTILATION SYNDROMES

General Principles and Diagnostic Approach

Pathogenesis

Alveolar hypoventilation exists when arterial P_{CO_2} increases above the normal range of 37 to 43 mm Hg. In clinically important hypoventilation syndromes, arterial P_{CO_2} is 45 mm Hg or higher and typically ranges from 50 to 70 mm Hg.[51] Numerous disease entities can result in chronic alveolar hypoventilation (Table 78-1), but in all cases the underlying mechanism involves a defect in either the sensors or the integrating neurons of the metabolic (automatic) respiratory control system or in the effector organs of breathing (i.e., the neuromuscular system or the ventilatory apparatus) (Table 78-2).

TABLE 78-1. Classification of Disorders Associated with Chronic Alveolar Hypoventilation

DISORDERS OF CHEMOSENSITIVITY
Carotid body dysfunction, trauma[136]
Prolonged hypoxia[137,138]
Metabolic alkalosis[139]

DISORDERS OF BRAIN-STEM INTEGRATING AND RHYTHM-GENERATING NETWORKS AND BRAIN-STEM MOTOR NEURONS
Bulbar poliomyelitis, encephalitis[140,141]
Infarction[78,142]
Neoplasms[143]
Sarcoidosis[144]
Demyelinating disorders[145]
Chronic drug administration[146]
Primary alveolar hypoventilation syndrome[147–149]

DISORDERS OF SPINAL CORD, PERIPHERAL NERVES, AND RESPIRATORY MUSCLES
Poliomyelitis[77,150,151]
Motor neuron disease[55,60,152,153]
Peripheral neuropathy[154]
Myasthenia gravis[150,155]
Muscular dystrophy[150,155–158]
Chronic myopathy[150,155–157]

DISORDERS OF CHEST WALL STRUCTURE
Obesity-hypoventilation syndrome[104,159–161]
Kyphoscoliosis[162]
Fibrothorax[162]
Post-thoracoplasty[162]
Ankylosing spondylitis[162]

DISORDERS OF LUNGS AND AIRWAYS
Chronic obstructive pulmonary disease (see Chapter 39)
Cystic fibrosis (see Chapter 41)
Laryngeal and tracheal stenosis[163,164] (see Chapter 43)
Obstructive sleep apnea syndrome (see Chapter 79)

TABLE 78-2. Mechanisms Underlying Chronic Alveolar Hypoventilation

Mechanisms Involved	Site or Type of Defect	Major Distinguishing Features
Sensors	Metabolic alkalosis	Alkaline pH
	Peripheral chemoreceptors	Impaired response to hypoxia
	Central chemoreceptors	Impaired response to hyperoxic hypercapnia
Controller	Brain-stem respiratory neurons or networks	Impaired chemoresponses
		Sleep-induced hypoventilation
		Normal ventilatory mechanics
Effectors	Neuromuscular apparatus	Reduced maximal respiratory pressures
	Ventilatory apparatus	Impaired ventilatory mechanics

Defects in the metabolic control system result in hypoventilation because abnormalities in blood gases and cerebral acid-base status are not sensed or, if sensed, do not produce an appropriate change in motor output of the medullary respiratory neurons. Patients with such defects fail to breathe normally in response to metabolic respiratory stimuli, but because the behavioral control system, respiratory motor pathways, and ventilatory apparatus are intact, they are capable of voluntarily driving respiration. As a result, patients with defects in the metabolic control system typically demonstrate normal ventilatory mechanics, but they have impaired responses to metabolic respiratory stimuli and often hypoventilate severely during sleep, when ventilation is critically dependent on the metabolic control system.[52]

As a result of chronic hypoventilation, such patients have a primary respiratory acidosis leading to a secondary increase in extracellular bicarbonate concentration.[53] In contrast, patients with a primary metabolic alkalosis may develop secondary hypoventilation as a compensatory response. This type of hypoventilation represents not a defect in respiratory control but rather an appropriate response of the metabolic control system to a disturbance in acid-base status. It can be said that patients with metabolic alkalosis "shouldn't" breathe, in contrast to those with control defects, who "won't" breathe, and those with mechanical defects, who "can't" breathe. However, the degree of hypoventilation that develops in response to metabolic alkalosis depends on several factors, including associated electrolyte disturbances and the sensitivity of the peripheral chemoreceptors to the accompanying hypoxia.[54] Thus, patients with weak hypoxic responsiveness tend to hypoventilate more than do patients with brisk hypoxic responsiveness.

Chronic hypoventilation resulting from defects in effector elements of the respiratory system (see Table 78-2) represents disturbances of ventilatory motor and mechanical function that do not in themselves mean that the metabolic control system is defective. Because the same effector elements also serve the behavioral control system, such patients are usually unable to breathe normally even when consciously attempting to do so. Hence, such defects are characterized either by reductions in the maximum respiratory pressures that can be generated voluntarily or by impairment of lung volumes and flow rates.[55] In the presence of such neural or mechanical defects, coexisting disturbances in respiratory control are often difficult to identify, because the neuromuscular or mechanical defect may preclude normal responses to chemical respiratory stimuli even when the control system is intact.

Physiologic and Clinical Consequences

Regardless of the underlying cause, the fundamental disturbance in all hypoventilation syndromes is a global reduction in the level of alveolar ventilation, resulting in an increase in alveolar P_{CO_2} and therefore in arterial P_{CO_2}. Because of the inverse relationship between alveolar P_{CO_2} and P_{O_2} defined by the alveolar air equation, the rise in alveolar P_{CO_2} produces an obligatory decrease in alveolar P_{O_2}, resulting in hypoxemia (Fig. 78-10). These disturbances are typically magnified during sleep because of further reductions in alveolar ventilation secondary to a reduction in overall respiratory drive (see Chapter 79).

The primary disturbances produced by alveolar hypoventilation lead to a series of secondary physiologic responses that in turn produce the clinical features of chronic hypoventilation (see Fig. 78-10). These features consist predominantly of hematologic, cardiovascular, and neurologic manifestations. There is considerable debate as to whether the cardiovascular and neurologic features of hypoventilation result from the chronic hypercapnia or from the chronic hypoxemia, but it appears likely that both disturbances play a role. For example, alleviation of hypoxemia alone by the administration of supplemental oxygen reverses the polycythemia and may attenuate the severity of pulmonary hypertension, but supplemental oxygen can also aggravate the degree of hypercapnia and the severity of neurologic complaints.[51]

Laboratory Assessment

The investigation of the patient with chronic alveolar hypoventilation involves the use of a series of laboratory tests that examine one or more components of the respiratory system (Fig. 78-11). Analysis of the pattern of test results usually enables localization of the site of the underlying defect to the metabolic control system, the respiratory neuromuscular system, or the ventilatory apparatus.

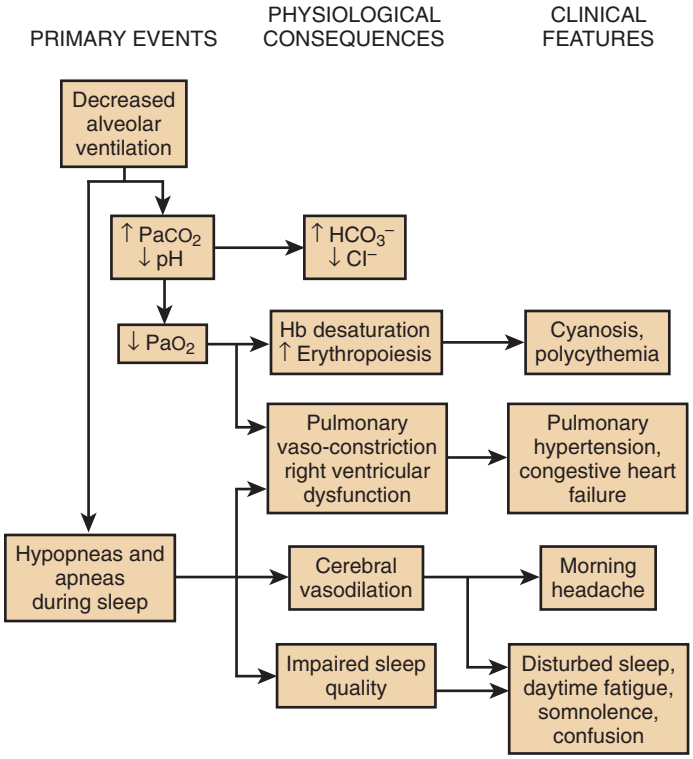

FIGURE 78-10 ■ Schema showing the primary events, physiologic responses, and clinical features resulting from alveolar hypoventilation. $Paco_2$, arterial Pco_2; Pao_2, arterial Po_2.

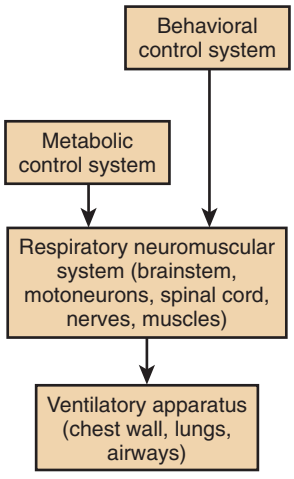

A-a PO2	Resistance and compliance of lungs, chest wall	Volumes, flows	Maximal inspiratory, expiratory pressures	Responses to CO_2, hypoxia		Sleep studies

Normal	Normal	↓	↓	↓	↓	Central apnea, hypopneas
Abnormal	Abnormal	↓	Normal	↓	Normal	Variable

FIGURE 78-11 ■ Pattern of laboratory test results in alveolar hypoventilation syndromes, based on the site of defect. (A-a)Po_2, alveolar-arterial Po_2 difference; EMGdia, diaphragmatic electromyogram; P0.1, pressure generated in first 1/10th second after airway occlusion.

Defects in Metabolic Control. The patient with a defect in the chemoreceptors or medullary integrating and premotor neurons that constitute the metabolic control system typically demonstrates impaired ventilatory responses to hypercapnia, hypoxia, asphyxia, and often exercise.[56] Because central drive is impaired, occlusion pressure responses and diaphragm electromyographic (EMG) responses to chemical stimuli are also diminished, although few systematic measurements have been reported in such patients. Furthermore,

during sleep such patients tend to hypoventilate even more than while awake, as a result of the loss of the stimulatory effect of wakefulness on breathing, and central apneas during sleep may be frequent.[51,57,58] In contrast, in the absence of intrinsic bronchopulmonary or chest wall disease, tests of respiratory system resistance and compliance give normal results and the alveolar-arterial P_{O_2} difference is not widened. Because the behavioral control system and neuromuscular apparatus are intact, such patients can usually hyperventilate voluntarily and can generate normal lung volumes and flow rates.[59] Similarly, tests of respiratory muscle activation and strength yield normal results, including normal maximum inspiratory and expiratory mouth pressures generated against an occluded airway, normal transdiaphragmatic pressure, and normal diaphragmatic EMG responses.

Neuromuscular Defects. Patients with defects in the spinal cord, respiratory nerves, or respiratory muscles resemble patients with disturbances in the control system, in that the former also have impaired ventilatory, occlusion pressure, and EMG responses to chemical respiratory stimuli.[60] In addition, however, patients with neuromuscular disease are unable to generate normal lung volumes (particularly total lung capacity), flow rates (particularly peak flow and maximum voluntary ventilation), and static respiratory pressures.[55]

Ventilatory Apparatus Defects. Patients with intrinsic disease of the lungs, airways, or chest wall demonstrate abnormalities in the values of respiratory resistance or compliance. Because of these abnormalities, values of lung volumes and flow rates are typically abnormal, and ventilatory responses to chemical respiratory stimuli are impaired. In contrast, because the respiratory neuromuscular system is intact in such patients, static tests of respiratory muscle strength and activity, which are not influenced by the resistance or compliance of the respiratory system, usually yield normal results.[61] Thus, maximum inspiratory and expiratory pressures, transdiaphragmatic pressure, and occlusion pressure and diaphragm EMG responses to hypercapnia or hypoxia may be normal.[62,63]

Primary Alveolar Hypoventilation

Primary alveolar hypoventilation is a disorder of unknown origin characterized by chronic hypercapnia and hypoxemia in the absence of identifiable neurologic disease, respiratory muscle weakness, or mechanical ventilatory defects. The disorder is considered to occur from a failure in the metabolic (or automatic) respiratory control system, which results in a diminished central respiratory drive. In most patients, hypoventilation is more severe during sleep, and apneic periods are common. In contrast, because the behavioral respiratory control system is intact, patients with primary alveolar hypoventilation are able to hyperventilate voluntarily and to reduce arterial P_{CO_2} to normal levels.

The clinical syndrome of primary alveolar hypoventilation in its isolated form is a relatively rare disease. However, an element of primary alveolar hypoventilation may play a role in several clinical disorders of the respiratory neuromuscular and ventilatory systems in which the degree of alveolar hypoventilation is out of keeping with the magnitude of underlying neuromuscular or mechanical defect. Such disorders include diseases of the respiratory muscles,[64] the obesity-hypoventilation syndrome,[65] and the "blue bloater" chronic obstructive pulmonary disease syndrome.[63] In these disorders, the impairment of the respiratory muscles or the increased mechanical impedance to breathing may unmask a weakness in central respiratory drive,[66] analogous to the weakness that can be uncovered in some otherwise healthy subjects by the imposition of mechanical ventilatory loads.[67] However, whether the underlying cause of decreased respiratory drive in such patients is the same as in patients with isolated primary alveolar hypoventilation is not known.

Pathogenesis

Primary alveolar hypoventilation is thought to result from a failure of the chemoreceptors or of the medullary neuronal networks that make up the metabolic respiratory control system. As such, it represents a pure disease of the respiratory controller rather than of the respiratory muscles or mechanical ventilatory apparatus. In the majority of patients, this interpretation is based on the clinical and laboratory features of the illness and not on the demonstration of specific lesions in any component of the metabolic control system. In fact, autopsy studies have reported neuropathologic findings in extremely few patients and have found either no abnormalities or only nonspecific lesions in the area of the medullary respiratory neurons.[2] However, studies in both animals and humans indicate an important role for genetic and metabolic factors in the pathogenesis of hypoventilation syndromes,[68] and specific mutations in the *PHOX2B* gene have now been identified in neonates and adults with the disorder.[69] In contrast to primary alveolar hypoventilation, lesions involving the medullary reticular formation have been demonstrated in several patients with central alveolar hypoventilation secondary to known neurologic disease.[70] In some infants who died of sudden infant death syndrome, which may represent a primary alveolar hypoventilation disorder, structural abnormalities of the carotid body chemoreceptors have been demonstrated.[71] Removal of the carotid bodies in experimental animals results in a chronic hypoventilation syndrome that closely resembles the human disorder.[72] However, no studies of carotid body structure have been reported in patients with primary alveolar hypoventilation.

Clinical Features

Primary alveolar hypoventilation occurs in all age groups, including infancy and childhood,[52] but the majority of reported cases in adults have been in men ages 20 to 50 years.[57] Occasional familial cases have been described.[73] In most patients, the development of symptoms is insidious, and the disease is often overlooked because

the patient is typically free of respiratory complaints. In particular, dyspnea is uncommon in this condition, in contrast to other hypoventilation disorders, and the arterial P_{CO_2} may be relatively normal when measured during wakefulness. Often, the diagnosis is first suspected only when the patient develops severe respiratory depression after conventional doses of anesthesia or sedation.

The common presenting complaints of patients with primary alveolar hypoventilation are lethargy, fatigue, daytime somnolence, disturbed sleep, and morning headache (see Fig. 78-10). Cyanosis and secondary polycythemia are also frequent. As the severity of chronic hypoventilation and hypoxemia increases, patients develop clinical evidence of pulmonary hypertension, right ventricular hypertrophy, and, eventually, congestive cardiac failure. The congestive heart failure is due to right ventricular dysfunction and is manifested by elevation of the jugular venous pressure, hepatomegaly, and peripheral edema.

Diagnosis

The key diagnostic findings in primary alveolar hypoventilation are hypercapnia, hypoxemia, and chronic respiratory acidosis in the absence of respiratory muscle weakness or mechanical ventilatory defects (see Fig. 78-11). The degree of blood gas abnormality is often surprising, in that arterial P_{CO_2} levels of 50 to 70 mm Hg and arterial P_{O_2} levels of 40 to 50 mm Hg may be associated with relatively mild symptoms. Typically, patients can voluntarily hyperventilate and reduce the arterial P_{CO_2} to normal or even to hypocapnic levels. As a result, hypercapnia may not be detected in a single arterial blood sample, but the presence of elevated serum bicarbonate should draw attention to the underlying chronic disturbance. The alveolar-arterial P_{O_2} difference is usually normal but may be elevated, presumably because of areas of low ventilation-perfusion matching or microatelectasis, although the mechanism has not been clearly defined.

In addition to normal lung volumes and airflow rates, patients with primary alveolar hypoventilation typically maintain a normal maximum voluntary ventilation and normal maximum inspiratory and expiratory airway pressures (see Fig. 78-11). In contrast, the ventilatory and occlusion pressure responses to hypercapnia are reduced or absent, and the responses to hypoxia are often diminished.[59] In most patients, some hypoxic chemosensitivity persists, in that inhalation of high oxygen concentrations further reduces the level of ventilation.[74] Paradoxically, in a few patients, supplemental oxygen produces an increase in ventilation, which suggests that chronic hypoxia may have contributed to central respiratory depression.[59] In the typical patient, the ventilatory response to exercise is also abnormal, with further increases in arterial P_{CO_2} and decreases in arterial P_{O_2}, in keeping with a failure of metabolic respiratory control. Breath-holding time may be markedly prolonged, without any accompanying sensation of dyspnea.[75]

Patients with primary alveolar hypoventilation are generally able to maintain rhythmic breathing during wakefulness, although at a lower-than-normal level of ventilation, because of the stimulatory effect of brainstem reticular activation on the respiratory neurons.[52,76] During sleep, however, breathing is critically dependent on the metabolic respiratory control system.[76] Hence, such patients are apt to cease rhythmic breathing during sleep. Sleep studies in patients with alveolar hypoventilation usually demonstrate a further deterioration in ventilation, with frequent episodes of central hypopnea or outright apnea followed by arousal or awakening. These sleep-related events presumably account for the clinical complaints of disturbed sleep and morning headache; they contribute to daytime fatigue, lethargy, and somnolence; and they play a role in the development of polycythemia and pulmonary hypertension. Support for this concept is derived from the fact that the daytime symptoms of primary alveolar hypoventilation, as well as the polycythemia and pulmonary hypertension, can be alleviated by improving nocturnal ventilation alone.[59]

Differential Diagnosis

Primary alveolar hypoventilation, in which there is no other identifiable neurologic disease, must be distinguished from central alveolar hypoventilation secondary to underlying neurologic disease (see Table 78-1), although the clinical and laboratory features of the two disorders are often very similar. This distinction requires a careful neurologic history and examination for evidence of other brain-stem or autonomic disturbances. The classic example of chronic alveolar hypoventilation secondary to brain-stem disease is that which follows bulbar poliomyelitis or encephalitis.[77] The disorder has also been reported in association with brain-stem vascular insufficiency or stroke, infections, neoplasms, sarcoidosis, multiple sclerosis, and autonomic insufficiency syndromes.[78] These secondary causes of central alveolar hypoventilation are usually signified by the other features of the underlying disease process and by the fact that the patient may not be able to increase the level of ventilation voluntarily. A form of subacute central alveolar hypoventilation that follows cervical spinal surgery has also been described.[79]

Primary alveolar hypoventilation can be confused with chronic disorders of the respiratory neuromuscular system (see Chapter 87) that are often unrecognized clinically (see Table 78-1). Included in this group of disorders is the postpolio syndrome, a form of chronic respiratory insufficiency that typically develops 20 to 30 years after recovery from poliomyelitis.[77] In addition to the history of polio many years earlier, such patients demonstrate weakness of the respiratory muscles (see Fig. 78-11), and many have developed kyphoscoliosis. Motoneuron disease, an idiopathic degeneration of motoneurons from anterior horn cells to cortex, can manifest as chronic respiratory failure, particularly when the phrenic motoneurons are involved.[80] The disease typically occurs in men ages 50 to 70 years and is distinguished from primary alveolar hypoventilation by the presence of muscle weakness and atrophy, often with fasciculation and spasticity. Laboratory investigation

reveals a pattern of test results typical of respiratory neuromuscular disease (see Fig. 78-11). Furthermore, the abnormalities are progressive, as is the clinical course of the disease; death, from respiratory complications, usually occurs 2 to 5 years after onset of the disease.

Unilateral diaphragmatic paralysis can result from phrenic nerve trauma, inflammation, or neoplastic infiltration, but in most cases the cause is unknown.[81] Patients with unilateral diaphragmatic paralysis are often asymptomatic and do not usually hypoventilate. Bilateral diaphragm weakness or paralysis can result from phrenic neuropathy or from intrinsic diaphragmatic disease, including muscular dystrophies, polymyositis, and acid-maltase deficiency.[82] Bilateral diaphragmatic disease may lead to severe chronic alveolar hypoventilation. Distinguishing features include the presence of orthopnea, paradoxical movement of the abdomen in the supine posture, deterioration in lung volumes and in arterial blood gas values in the supine posture, rapid deterioration in ventilation during a maximum voluntary ventilation maneuver, and reduction of the maximum inspiratory pressures that can be generated against an occluded airway. Transdiaphragmatic pressures, calculated from simultaneous measurement of esophageal and gastric pressures, are reduced or absent, and the EMG response of the diaphragm, recorded by an esophageal electrode, reveals a reduction in diaphragm discharge in response to transcutaneous phrenic nerve stimulation in the neck.[82]

Management

Patients with primary alveolar hypoventilation must be cautioned against the use of sedative medications, which may readily induce acute respiratory failure. Respiratory stimulants may be useful in some patients. Several pharmacologic agents, including methylxanthines and analeptics, have been used to treat patients with primary alveolar hypoventilation (Table 78-3), with variable but generally disappointing results. Long-term administration of progesterone has been beneficial in some patients, particularly those with mechanical ventilatory defects and an element of reduced respiratory drive, such as the obesity-hypoventilation syndrome and hypercapnic obstructive lung disease.[83] Acetazolamide is effective in increasing respiratory drive in patients with primary metabolic alkalosis superimposed on chronic carbon dioxide retention[84] but is not indicated in pure respiratory acidosis. A few patients with primary alveolar hypoventilation have responded favorably to long-term nocturnal oxygen administration, which suggests that cerebral hypoxia during sleep was aggravating the hypoventilation disorder.[59] In the majority of patients, however, supplemental oxygen aggravates the degree of nocturnal hypoventilation and further increases arterial carbon dioxide levels by removing hypoxic ventilatory drive.

In most patients with primary alveolar hypoventilation, neuromuscular disease, or the obesity-hypoventilation syndrome, mechanical ventilatory assistance is required for effective management (see Table 78-3). Noninvasive positive-pressure ventilation, often delivered through a nasal mask, is currently the preferred method of treatment,[85] but diaphragmatic pacing by electrophrenic stimulation can also be very effective.[86] The administration of such treatment only during sleep generally produces dramatic clinical improvement, with alleviation of daytime symptoms; reversal of daytime hypercapnia, polycythemia, and pulmonary hypertension; and prolongation of survival.[85]

HYPERVENTILATION SYNDROMES

Introduction

Hyperventilation refers to an increase in the rate of alveolar ventilation that is excessive for the rate of metabolic carbon dioxide production, resulting in a decrease in arterial P_{CO_2} to below the normal range of 37 to 43 mm Hg. Hyperventilation should be distinguished from tachypnea, an increase in respiratory frequency, and from hyperpnea, an increase in minute volume of ventilation. Neither of these latter conditions derives from nor implies a change in arterial P_{CO_2}. Hyperventilation is often associated with dyspnea, but not all patients with hyperventilation complain of shortness of breath; conversely, patients with dyspnea need not be hyperventilating.

Pathogenesis

Alveolar hyperventilation arises from excessive ventilatory drive that is mediated through either the behavioral or metabolic control systems (Fig. 78-12). Many pathophysiologic conditions and diseases can result in an increase in respiratory drive (Table 78-4). In some cases, the mechanism involved is well understood (e.g., hypoxemic sensitization of the peripheral chemoreceptors); in other cases, several potential mechanisms have been postulated but as yet have not been clearly established (e.g., hyperventilation associated with hepatic failure). Therefore, hyperventilation syndromes are best considered through the use of a clinical rather than mechanistic approach (see Table 78-4).

Hypoxemia

In most clinical settings, hypoxemia is a potent ventilatory stimulus and results in hyperventilation by virtue of

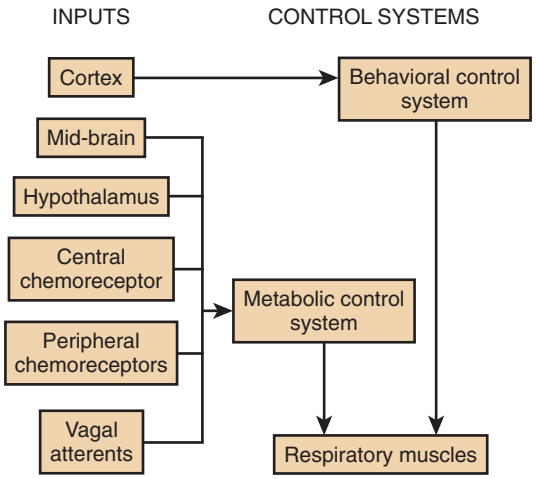

FIGURE 78-12 ■ A schematic diagram showing the main elements of the metabolic and behavioral respiratory control systems that are involved in alveolar hyperventilation. Disorders within sites affecting the metabolic control system include the midbrain, hypothalamus, central and peripheral chemoreceptors, and vagal afferents. The cortex is the site of behavioral control.

its action on the peripheral chemoreceptors (i.e., the carotid bodies). The response of minute volume of ventilation (or alveolar ventilation) to decreases in arterial P_{O_2} is not linear: it is substantially greater when arterial P_{O_2} falls below 60 mm Hg. In contrast, although the oxygen content per se of arterial blood is not the primary hypoxic stimulus of the carotid bodies, the ventilatory response to hypoxemia is relatively linear with regard to decreases in arterial oxygen saturation.[87] However, the magnitude of response is attenuated by reduced levels of arterial P_{CO_2} and increased levels of arterial pH (see "Control of Breathing" section). The hyperventilation associated with hypoxia can be dramatic, particularly in persons with normal ventilatory mechanics. For example, at the summit of Mount Everest, where arterial P_{O_2} was estimated to be 27 mm Hg, alveolar P_{CO_2} was reduced to 7.5 mm Hg.[88] Clinically, however, impaired mechanical properties of the chest wall or lungs often attenuate the degree of alveolar hyperventilation induced by hypoxia. Conversely, in many pulmonary disorders that produce hypoxemia, the associated hypocapnia may not be due to the hypoxia and persists even when the hypoxia is alleviated with supplemental oxygen.[89]

The degree of alveolar hyperventilation induced by hypoxia is highly variable; the variation is determined, at least in part, by genetic factors.[90] In addition, there also appears to be a temporal influence that may, in part, reflect the effects of hypoxia on cerebral blood flow, metabolism, and release of excitatory and inhibitory neuromodulators, all of which secondarily affect breathing.[91] Typically, the ventilatory response to acute hypoxia is initially brisk but then decreases after several minutes,[52] only to increase again after 12 to 24 hours as the longer term process of respiratory acclimatization comes into play.[47] However, sustained hypoxemia of many years' duration, as occurs in long-time residents at high altitudes and in patients with cyanotic congenital heart disease, is associated with considerable attenuation of hypoxic ventilatory drive.[92]

Pulmonary Disorders

One of the most common causes of hyperventilation in patients with pulmonary disease is stimulation of bronchopulmonary receptors that reflexly increase ventilatory drive and, directly or indirectly, contribute to the sensation of dyspnea (see Chapter 28). These receptors, which are sensitive to a variety of mechanical and chemical stimuli, send impulses to the central nervous system through the afferent vagus nerves, resulting in cough, bronchoconstriction, and hyperventilation (see "Control of Breathing" section). Direct evidence implicating these receptors in the alveolar hyperventilation of lung disease is derived largely from animal studies,[93,94] but there are also supportive studies in a few patients who have undergone vagal blockade.[95] Indirect support for this notion is

derived from the fact that administration of supplemental oxygen to patients with hypoxemic interstitial or pulmonary vascular disease does not necessarily abolish the hyperventilation.[96]

Stimulation of chest wall receptors may contribute to the hyperventilation that accompanies asthma, pulmonary fibrosis, and restrictive chest wall disorders.[93] The mechanisms involved have not been clearly established but are thought to include stimulation of respiratory muscle spindles and other chest wall receptors. The same mechanisms may also play a role in the pathogenesis of dyspnea in these disorders.

Cardiovascular Disorders

Patients with congestive heart failure and states of low cardiac output typically hyperventilate at rest, during exercise, and even during sleep.[97–99] The mechanisms involved probably include stimulation of pulmonary vascular and interstitial receptors as a result of pulmonary congestion.[100] In addition, low cardiac output states and hypotension stimulate breathing through the arterial baroreceptors[101] and may also stimulate breathing secondary to "stagnant hypoxia" of the carotid body chemoreceptor cells.

Metabolic Disorders

Alveolar hyperventilation is a well-described compensatory response to metabolic acidosis. Although respiratory compensation is generally effective, physiologic compensation for metabolic acidosis is not complete. For example, in a severe metabolic acidosis that reduces serum bicarbonate concentration ($[HCO_3^-]$) to 8 mEq/L, the uncompensated arterial pH would be 6.92; with hyperventilation to 20 mm Hg (a typical response), pH increases to 7.22. The degree of compensation varies among patients, depending on differences in chemosensitivity and ventilatory mechanics, but in general a decrease in $[HCO_3^-]$ of 1 mEq/L results in a compensatory decrease in arterial P_{CO_2} of about 1 mm Hg.[102] The specific mechanisms involved in the hyperventilation of metabolic acidosis are controversial, but probably include stimulation of both the peripheral and central chemoreceptors.[103] Metabolic acidosis also increases the sensitivity of the peripheral chemoreceptors to hypoxia.

Hyperthyroidism is frequently associated with hyperventilation and increased ventilatory chemoreflexes, both of which return to normal after treatment.[104] Hyperventilation is also a common feature in patients with severe liver disease.[105] Several possible mechanisms have been proposed, including increased blood levels of progesterone, ammonia, and vasoactive intestinal peptide, and increased brain levels of ammonia and glutamine, all of which may stimulate respiration.[91] In addition, patients with severe hepatocellular dysfunction or portal hypertension may develop small pulmonary arteriovenous anastomoses ("spider nevi" of the lungs) or portal-pulmonary venous shunts, resulting in hypoxemia and hyperventilation due to stimulation of the peripheral chemoreceptors.

Neurologic and Psychogenic Disorders

Psychogenic hyperventilation[106] is thought to arise from anxiety or stress, both of which act on the behavioral respiratory control system (see Fig. 78-12). Increasingly recognized in recent years have also been the hyperventilation associated with panic attacks,[107] and an idiopathic form of chronic hyperventilation whose etiology may be distinct from psychogenic hyperventilation.[108] Apart from psychogenic causes, central neurogenic hyperventilation is relatively rare. Indeed, in many patients with intracranial disturbances who are hyperventilating, the immediate cause is either pulmonary edema or hypoxemia.[109] In rare cases, however, disorders of the midbrain and hypothalamus induce hyperventilation.[109–111] In addition, patients with head trauma or intracranial hemorrhage may hyperventilate as a secondary reaction to red blood cell glycolysis and acidosis in the cerebrospinal fluid, and patients with brain-stem infiltration by tumor may hyperventilate, possibly as a result of lactic acidosis produced by the malignant cells.[109,112] In other rare cases, severe cerebrovascular insufficiency or infarction is associated with hyperventilation, possibly by interference with the inhibitory influence normally exerted by cortical structures on the brain-stem respiratory neurons.[113]

Drug-Induced Hyperventilation

Several drugs cause hyperventilation[114] by stimulating the peripheral or central chemoreceptors or by direct action on the brain-stem respiratory neurons (see Table 78-4). The acid-base disturbance resulting from salicylate overdose is biphasic, consisting of an initial primary respiratory alkalosis followed by a metabolic acidosis that induces secondary hyperventilation.[115]

Miscellaneous Causes

Fever and sepsis, even in the absence of hypotension, are commonly associated with hyperventilation, over and above any associated increase in metabolic rate.[116] The mechanisms involved are not clear, but they could include either carotid body or hypothalamic stimulation by increased temperature. Pain is also frequently accompanied by hyperventilation.[117] The mechanisms involved may include adrenergic stimulation of the peripheral and central chemoreceptors.[118] In addition, painful stimuli may act through the behavioral control system. From a practical clinical standpoint, there is often concern that a painful arterial puncture required for blood gas assessment could result in a spuriously low arterial P_{CO_2} and inappropriate diagnosis of hyperventilation. However, there is little difference in arterial P_{CO_2} between samples obtained with and without the use of local anesthetic.[119] Chronic hyperventilation is a normal feature of pregnancy and of the luteal phase of the menstrual cycle. Although hormone-mediated factors may play a role,[120] the relationship involves complex changes in the wakefulness and central chemoreflex drives to breathing and in acid-base balance.[121]

Physiologic and Clinical Features

Respiratory

Because hyperventilation involves an increase in respiratory drive, respiratory muscle effort, and minute volume of ventilation, the most frequent symptom associated with hyperventilation is dyspnea. However, there is considerable discrepancy between the degree of hyperventilation, as assessed by arterial P_{CO_2}, and the degree of dyspnea.

From a physiologic standpoint, hyperventilation is clearly beneficial in patients who are hypoxemic because the alveolar hypocapnia is associated with an increase in alveolar P_{O_2} and with a varied increase in arterial P_{O_2} (dependent on pulmonary ventilation-perfusion inhomogeneities). The relationship among these variables is governed by the alveolar air equation (see Chapter 4). This physiologic consequence of hyperventilation is clinically important in patients with hypoxemic pulmonary disease and in healthy persons at high altitude. Indeed, the successful ascent of Mount Everest without the use of supplemental oxygen was critically dependent on the increase in alveolar and arterial P_{O_2} generated by profound alveolar hyperventilation.[88]

Conversely, alveolar hyperventilation can also have detrimental respiratory effects, including a decrease in or loss of respiratory drive immediately after cessation of the hyperventilation, secondary to the low arterial and cerebral P_{CO_2}. Under these conditions, hypoxemia can develop quickly without an associated return of respiratory drive or a sensation of dyspnea, because of the persisting hypocapnia that reverses at a considerably slower rate. This sequence of events has been implicated in the deaths of healthy underwater divers who, in advance of diving, voluntarily hyperventilate to decrease alveolar P_{CO_2} and increase alveolar oxygen stores, and thereby prolong underwater breath-holding time. A less dramatic but more common clinical problem resulting from hyperventilation during wakefulness is periodic breathing during sleep, with or without associated central sleep apnea. This sequence of events gives rise to the most common type of central sleep apnea syndrome (see Chapter 79).

Blood

Respiratory alkalosis produces a leftward shift in the oxygen-hemoglobin dissociation curve (the Bohr effect), which increases loading of oxygen onto hemoglobin in the lungs but decreases release of oxygen at the tissue level. This change can be beneficial or detrimental, depending on the specific conditions. In general, the detrimental effects of impaired oxygen release at the tissues outweigh the beneficial effects of increased oxygen loading in the lungs, because even under conditions of moderate hypoxemia, hemoglobin is well saturated with oxygen without a leftward shift of the dissociation curve (e.g., at an arterial P_{O_2} of 60 mm Hg, hemoglobin is 90% saturated). However, under conditions of severe hypoxia, as at very high altitudes or in utero, the loading of oxygen onto hemoglobin becomes critical to survival, and therefore a respiratory alkalosis and the resulting leftward shift of the dissociation curve can be beneficial.

Respiratory alkalosis also results in several electrolyte shifts that are clinically important, including hypokalemia, hypophosphatemia, and decreased ionizable calcium.[122] These shifts contribute to many of the clinical features of hyperventilation, including dizziness, peripheral parasthesias, carpopedal spasm, tetany, and muscle weakness.

Cardiovascular and Cerebrovascular

The most important clinical consequences of alveolar hyperventilation are those related to vasoconstriction that is secondary to alkalemia.[123] Severe alkalemia can induce cardiac arrhythmias (possibly related to electrolyte disturbances) and cardiac ischemia, which probably results from both acute coronary vasoconstriction and the increased oxygen affinity of hemoglobin.[123,124] Alkalemia also induces intense cerebrovascular constriction that can result in dizziness, visual impairment, syncope, and seizures.[125] Acutely, every 1 mm Hg decrease in arterial P_{CO_2} reduces cerebral blood flow by 2%,[126] resulting in cerebral hypoxia, as assessed by metabolic, electroencephalographic, and corneoretinal indices and by direct measurements of cerebral P_{O_2}.[127] In patients with sickle cell disease, the degree of cerebral hypoxia may be sufficient to induce red blood cell sickling and cerebral infarction.[128] In general, the severity of cerebral vasoconstriction induced by hyperventilation decreases within hours, as the degree of cerebral alkalosis is attenuated.[125]

Diagnosis

Although hyperventilation may be suspected clinically in the presence of tachypnea or noticeable hyperpnea, the diagnosis can be confirmed only by analysis of arterial blood gases and pH. The key measurements are the arterial P_{CO_2}, a decrease in which indicates the presence of hyperventilation, and the pH, which determines whether the disorder is classified as a primary respiratory alkalosis (increased pH) or a primary metabolic acidosis (decreased pH).[102,129] However, in mixed acid-base disorders, arterial pH may not be alkalemic despite primary alveolar hyperventilation. Measurement of arterial P_{O_2} and calculation of the alveolar-arterial P_{O_2} difference is also helpful, because a widened difference suggests a pulmonary disorder as the underlying cause of the hyperventilation. The finding of a decreased [HCO_3^-] establishes the chronic nature of the disorder. In patients with suspected psychogenic hyperventilation, measurements of minute volume of ventilation and of arterial or transcutaneous P_{CO_2} during sleep can be useful because the hyperventilation may not persist during sleep.

Once the presence of alveolar hyperventilation has been established, the underlying cause can generally be identified on the basis of history, physical examination, and knowledge of coexisting medical disorders (see Table 78-4). Three disorders may not be readily apparent

clinically and frequently give rise to "unexplained hyperventilation": pulmonary vascular disease (particularly chronic or recurrent thromboembolism), psychogenic or anxiety hyperventilation,[106] and idiopathic hyperventilation.[108] However, these disorders can usually be identified and distinguished on the basis of clinical and laboratory features. Hyperventilation secondary to pulmonary vascular disease is invariably accompanied by exertional dyspnea and often by exertional presyncope and clinical signs of pulmonary arterial hypertension. In addition, such patients usually have a widened alveolar-arterial P_{O_2} difference, often have a reduced pulmonary diffusing capacity for carbon monoxide, and usually maintain their hyperventilation during exercise. In contrast, patients with psychogenic hyperventilation typically complain of the need to sigh frequently and of dyspnea at rest and not necessarily during exercise.[130] Symptoms of acute hyperventilation, including parasthesias, carpopedal spasm, and tetany, are frequent, and anxiety is often prominent.[131] Half the patients present with cardiovascular symptoms, including palpitation, tachycardia, and chest pain, and about 25% present with neurologic complaints, including light-headedness, headache, or memory impairment.[125] In contrast to pulmonary vascular disease, in psychogenic hyperventilation the alveolar-arterial P_{O_2} difference and pulmonary function tests yield normal results, and during mild to moderate exercise, the hyperventilation tends to disappear. However, during exercise, heart rate and cardiac output may be high in relation to metabolic rate. In contrast, recent studies have demonstrated that hyperventilation persists during exercise in patients with the idiopathic form of the disorder.[108]

Management

Alveolar hyperventilation can often be managed by appropriate treatment of the underlying cause (see Table 78-4). However, in the few patients in whom alkalemia is thought to be inducing acute cerebral vasoconstriction, cardiac arrhythmias or ischemia, or parasthesias and tetany, inhalation of a low concentration of carbon dioxide can provide relief.

The long-term management of patients with disabling hyperventilation related to anxiety or panic attacks can be problematic. Careful explanation of the basis of the symptoms is helpful and reassures the patient that no serious cardiac or cerebral disorder is present. Such reassurance may be sufficient to allay the patient's anxiety. If not, more intense psychotherapy or medications that relieve anxiety maybe required.[132,133] Some patients have responded well to β-adrenergic antagonists or to an exercise program,[134] and very recently, end-tidal CO_2-guided breathing therapy has been demonstrated to produce long-term reductions in ventilation and in panic disorder severity.[107]

KEY POINTS

- The respiratory chemoreflexes are the primary building block of the metabolic control system.
- The voluntary control of breathing constitutes the behavioral control system.
- The behavioral and metabolic control systems compete for the use of the respiratory muscles.
- Automatic respiratory rhythm is generated in the medulla.
- Alveolar hypoventilation can result from numerous disease entities but is ultimately attributable to defects in the metabolic respiratory control system, the respiratory neuromuscular system, or the ventilatory apparatus. Detailed clinical and laboratory investigations can generally distinguish among these underlying mechanisms and locate the site of the defect.
- In most patients, alveolar hypoventilation is secondary to obstructive airway disease, mechanical chest wall disturbances, neurologic disease affecting the brain stem or spinal cord, or respiratory muscle weakness. In a small percentage of cases, no underlying cause can be found, and such patients are said to have primary alveolar hypoventilation, which is considered to represent a failure of the metabolic respiratory control system.
- Patients with primary alveolar hypoventilation are able to hyperventilate voluntarily, but during sleep, hypoventilation becomes more severe and central apneas are common.
- Management of patients with primary alveolar hypoventilation, as well as those with respiratory neuromuscular disorders, usually involves mechanical ventilatory assistance. Administration of such treatment only during sleep often produces dramatic clinical improvement and alleviates daytime symptoms.
- Hyperventilation can result from several diseases that produce an increase in respiratory drive, including disorders associated with hypoxemia, pulmonary vascular and interstitial

KEY POINTS—CONT'D

disease, congestive heart failure, metabolic acidosis, intracranial disorders, anxiety, and drugs.

- Patients who are hyperventilating may complain of dyspnea, but there is often a considerable discrepancy between the degree of hyperventilation, as assessed by arterial Pco_2, and the degree of dyspnea.
- Hyperventilation may produce important secondary effects on respiratory drive, on the unloading of oxygen from hemoglobin at the tissue level, and on cardiac and cerebral function.
- The underlying cause of hyperventilation can often be identified by the associated clinical features and measurements of arterial blood gases, pH, bicarbonate, and the alveolar-arterial Po_2 difference.
- The disorders that most frequently give rise to "unexplained hyperventilation" are pulmonary vascular disease, anxiety, and idiopathic hyperventilation.
- Treatment of hyperventilation is generally directed at the underlying disorder.

CHAPTER 79

SLEEP-DISORDERED BREATHING

Grace W. Pien, MD • Allan I. Pack, MBChB, PhD

INTRODUCTION

PATHOGENESIS OF OBSTRUCTIVE SLEEP APNEA
Neural Component
Upper Airway Size
Upper Airway Collapsibility
Muscle Factors
Fluid Shift at Night
Different Phenotypes
Arousals

CLINICAL RISK FACTORS FOR OBSTRUCTIVE SLEEP APNEA
Genetics
Upper Airway Anatomic Abnormalities
Obesity
Endocrine Changes

CLINICAL PRESENTATION OF OBSTRUCTIVE SLEEP APNEA
Epidemiology of Obstructive Sleep Apnea
Gender
Age
Ethnicity

DIFFERENTIAL DIAGNOSIS OF EXCESSIVE SLEEPINESS
Insufficient Sleep Syndrome
Restless Legs Syndrome
Narcolepsy

Conclusions

INTRODUCTION

Sleep-disordered breathing is an extremely common problem. The most common form of sleep-disordered breathing is caused by obstruction in the upper airway, and is called *obstructive sleep apnea (OSA)*. Apneas—cessation of breathing—can also occur as a result of temporary loss of neural output to the diaphragm, that is, central apnea. The term "mixed apnea" is also used when the apnea starts as a central event but becomes

TABLE 79-1. Definitions*

EVENTS

Apnea: Cessation of breathing lasting 10 seconds or longer. Obstructive: continued respiratory effort with paradoxical motion of rib cage and abdomen; central: absent respiratory effort.

Hypopnea: Different definitions used. Two alternative definitions are part of the scoring criteria advanced by the American Academy of Sleep Medicine:

1. Score a hypopnea if all of the following are present:
   a. Nasal pressure signal excursions; drop ≥30% of baseline for at least 10 seconds.
   b. There is a ≥4% desaturation from pre-event baseline.
   c. At least 90% of the event's duration must meet the amplitude reduction of criteria for hypopnea.
2. Score a hypopnea if all of the following are present:
   a. Nasal pressure signal excursions; drop ≥50% of baseline for at least 10 seconds.
   b. There is a ≥3% desaturation from pre-event baseline *or* the event is associated with an arousal. (The latter does not require a desaturation.)
   c. At least 90% of the event's duration must meet the amplitude reduction of criteria for hypopnea.

Respiratory Effort–Related Arousal (RERA): Pattern of progressively more negative esophageal pressure terminated by a sudden change in pressure to a less negative level and an arousal; events last 10 seconds or longer.

METRICS OF SEVERITY

Apnea-Hypopnea Index: Average number of apneas plus hypopneas per hour of sleep.

Respiratory Disturbance Index: Average number of apneas plus hypopneas plus RERAs per hour of sleep.

CONSENSUS DEFINITIONS OF SEVERITY

Normal: <5 episodes/hr

Mild sleep apnea: ≥5 and <15 episodes/hr

Moderate sleep apnea: ≥15 and <30 episodes/hr

Severe sleep apnea: ≥30 episodes/hr

CONCEPT OF SLEEP APNEA SYNDROME

Sleep-disordered breathing with complaint of excessive sleepiness.

obstructive later in the same event. Mixed apnea should not be confused with mixed distributions of apnea, that is, where both pure obstructive and pure central apneas occur in the same individual during the same sleep period. Recently, a new term has been introduced—*complex apnea*—which is used when an individual initially has obstructive apneas, but central apneas occur once the individual is treated with nasal continuous positive airway pressure (CPAP).

Fundamental to the identification of these disorders is a description of the breathing events that occur during sleep. In adults, an *apnea* is defined as a cessation of breathing that lasts for more than 10 seconds (for summary of definitions, see Table 79-1). In obstructive apnea, paradoxical motion of the abdomen and rib cage occurs because of continued activation of the diaphragm. This paradoxical motion can be detected by sensors assessing rib cage and abdominal motion. In contrast, in a central apnea, rib cage and abdominal motion ceases. An example of both an obstructive apnea and a central apnea are shown in Figure 79-1 to illustrate this distinction.

Another type of event is a *hypopnea* (see Table 79-1), when respiration declines but does not completely stop. This decline in ventilation can lead to the same consequences as from apneas, for example, a fall in oxygen saturation. As with an apnea, the event is typically terminated by an arousal, that is, brief sudden change in sleep state that can be detected on the electroencephalogram.[1] Whereas, currently, there is one standard definition for apnea, there are a number of different definitions for hypopnea, for example, a greater than 50% reduction in airflow with a 4% fall in oxygen saturation; a discernible fall in airflow with a 3% fall in oxygen saturation, and/or termination of the event by an arousal. The latter definition does not require an oxygen desaturation event to occur. These different definitions of hypopneas lead to some confusion and result in different numbers of events being counted and scored from the same recording in the same subject.[2,3] Moreover, the technology used to assess airflow during sleep studies has changed over the years. Initially, it was based on nasal thermistors, but this has changed to assessment of small changes in nasal pressure with respiration. Nasal pressure is more quantitative, is a more linear signal for airflow than thermistors, and hence, can detect events that are missed by thermistors.[3] The major epidemiologic studies of sleep-disordered breathing that have been performed in the United States—the Wisconsin Sleep Cohort Study,[4] the Sleep Heart Health Study,[5] and the study in Dauphine County in Pennsylvania[6]—were initiated before nasal pressure recordings were available and are based on using thermistors to detect changes in nasal airflow. Hence, one cannot directly compare the number of events that would be identified in current studies with those obtained in these classic epidemiologic studies.

The severity of sleep-disordered breathing is assessed by counting the number of apneas and hypopneas during sleep and then dividing by total sleep time. This gives the event rate—apnea-hypopnea index (AHI), that is, number of apneas plus hypopneas per hour of sleep. By consensus,[7] based on published literature, the following cut-points are used (see Table 79-1): normal AHI < 5 episodes/hr; mild sleep apnea AHI ≥ 5 and < 15 episodes/hr; moderate sleep apnea AHI ≥ 15 and < 30 episodes/hr; and severe sleep apnea AHI ≥ 30 episodes/hr.

Another term that is used is the *upper airway resistance syndrome*. This syndrome was originally described by Guilleminault and associates[8–10] before the introduction of nasal pressure to identify changes in airflow. The original concept was that one might have an event with a progressive increase in upper airway resistance and,

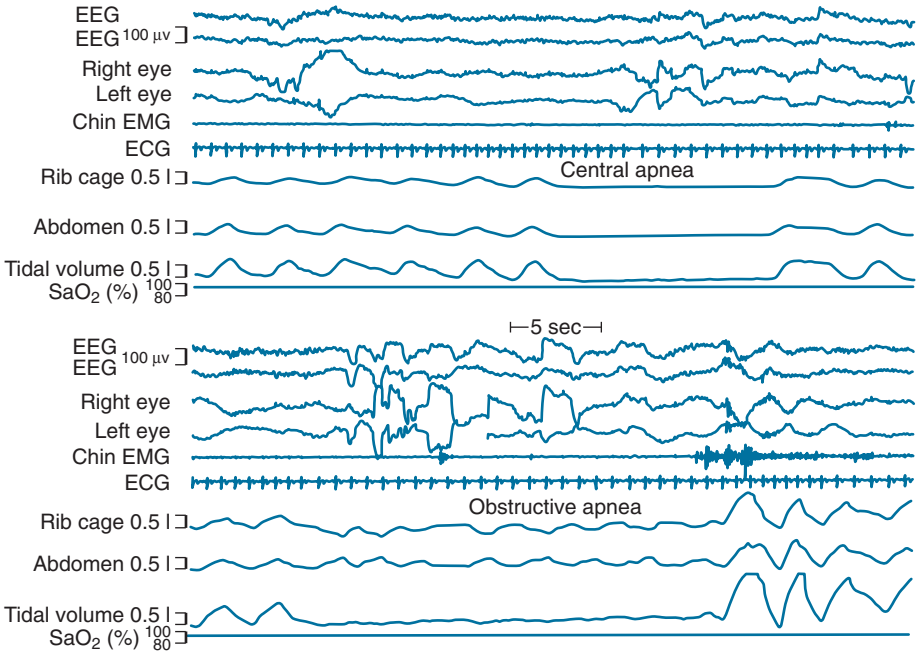

FIGURE 79-1 ■ Recorder tracings during polysomnographic study show distinction between central and obstructive apneas, using a respiratory inductive plethysmograph. *Upper and lower panels* form a continuous record in rapid eye movement sleep. Channels from the top down show the following: electroencephalogram (EEG), right and left eye movements, submental electromyogram (EMG), electrocardiogram (ECG), movements of rib cage and abdomen, tidal volume, and arterial oxygen saturation (SaO_2). Note that during central apnea, the absence of tidal volume excursion was accompanied by absence of rib cage and abdominal movements; during obstructive apnea, paradoxical rib cage and abdominal movements were present. (From Phillipson EA, Bowes G: Sleep disorders. *In* Fishman AP [ed]: Update: Pulmonary Diseases and Disorders. New York: McGraw-Hill, 1982, pp 256–273.)

hence, in snoring that terminated in an arousal. The event did not meet the definition of hypopnea. When the more sensitive nasal pressure measurements were used, some of these upper airway resistance events proved to be hypopneas. Moreover, in a provocative article about the upper airway resistance syndrome, Guilleminault and Chowdhuri[11] altered the concept somewhat. He and his colleague now describe an abnormally sensitive reaction to the normal increase in upper airway resistance that occurs during sleep. This is said to be more common in women and to present with symptoms of fatigue and other somatic symptoms. In a response to this point of view, Douglas[12] proposed that it is premature to consider this a syndrome until treatment benefits have been shown by appropriate interventions. Thus, the concept of the upper airway resistance syndrome remains controversial. Identification of this disorder would require recording esophageal pressure using an indwelling catheter, which most laboratories do not routinely perform. Given the concept, however, the group who developed definitions for all sleep-disordered events and syndromes[7] introduced a new term, the *respiratory effort–related arousal (RERA)*, in order to capture upper airway resistance events (see Table 79-1). Identification of this requires assessment of esophageal pressure. Studies of patients with moderate obstructive sleep-disordered breathing show that this type of event is relatively uncommon and that the vast majority of events are either apneas or hypopneas.[13] Whereas the respiratory disturbance index (RDI) was initially used interchangeably with the AHI, and in some studies still is, the most common use of the term "respiratory disturbance index" denotes the total event rate, that is, apneas plus hypopneas plus RERAs/hr of sleep.

The final aspect of definitions that must be considered before discussing other aspects of sleep-disordered breathing is the use of the term "sleep apnea syndrome." The epidemiologic studies from the Wisconsin Sleep Cohort[4] show that only the minority of subjects with evidence of sleep-disordered breathing actually complain of excessive sleepiness during the daytime. Because excessive sleepiness is such an important clinical consequence of sleep-disordered breathing, the term "sleep apnea syndrome" should be reserved for those patients who not only have abnormal breathing events during sleep of required frequency but also complain of daytime sleepiness. Simple questions can identify patients who are excessively sleepy,[14] and the most commonly used instrument to assess sleepiness is the Epworth Sleepiness Scale.[15-17] This simple questionnaire (Fig. 79-2) has eight questions in which the individual indicates the likelihood of dozing in eight different circumstances (see Fig. 79-2). The total range of the questionnaire is 0 to 24, and studies in several patient populations indicate that a score of more than 10 indicates excessive sleepiness. Although the instrument has been criticized on the grounds that some individuals (e.g., elderly subjects) might not experience the circumstances described in the questionnaire, it identifies robust treatment effects in placebo-controlled treatment trials of OSA.[18] A complete review of the definitions of sleep-disordered breathing syndromes is available.[7]

PATHOGENESIS OF OBSTRUCTIVE SLEEP APNEA

Neural Component

OSA occurs during sleep. Disordered breathing during sleep is the result of sleep-related alterations in neural control of the upper airway. The dimensions of the upper airway are protected by a large group of complex muscles—the upper airway dilator muscles. These muscles, which include the muscles of the soft palate and tongue, have multiple functions in swallowing and speech. With the onset of sleep, neural output to these muscles decline, resulting in an increase in upper airway resistance in all individuals. In addition, this increase in upper airway resistance causes a reduction in ventilation during sleep.

The motoneurons for upper airway dilator muscles receive input from the respiratory pattern generator in the brain stem, so their activity has a respiratory component. However, the fraction of the total drive to these neurons that is respiratory is considerably less than that to phrenic motoneurons (Fig. 79-3). Conversely, the activity of upper airway motoneurons is much more dependent on sleep/awake state than is the activity of the phrenic motoneurons. As a result, obstructive apneas are much more common than central apneas.

The basis for the dependency of upper airway motoneuron activity on sleep/awake state is complex and includes a number of different neuronal systems. During sleep, there is reduced activation of upper airway motoneurons by neuronal systems whose firing declines in non–rapid eye movement (NREM) and particularly rapid eye movement (REM) sleep (serotonin from the raphe, noradrenaline from the locus coeruleus, glutamate from the reticular formation, orexin from the lateral hypothalamus), as well as increased inhibition by glycine (for review, see Horner[19]) (see schematic, Fig. 79-4). Loss of the excitatory inputs, rather than an increase in inhibitory inputs, is the dominant factor for upper airway motoneurons.

The changes in neuronal activation during sleep also affect upper airway reflexes. The upper airway has a negative pressure reflex such that if the airway collapses, there is reflex activation of upper airway dilator muscles.[20] This is lost or attenuated during sleep.[21-23]

These changes in neural control of the upper airway during sleep occur in all individuals—both healthy controls, people who snore, and those with OSA. There is currently no evidence that subjects with sleep apnea have major differences in the sleep-related changes in neural activation, as compared with healthy subjects, although it is difficult to assess this in individual patients. Rather, the upper airway of patients with sleep apnea is much more susceptible to the normal changes in neural control with sleep. Two aspects that make the upper airway of patients with sleep apnea more susceptible are its smaller size, even during wakefulness, and its increased collapsibility.

Upper Airway Size

The upper airway in subjects with sleep apneas is smaller, as shown by studies using different imaging methods (for review, see Ahmed and Schwab[24]) (see example, Fig. 79-5). The reduction in airway size is particularly apparent in the lateral (not anteroposterior) dimension. Airway

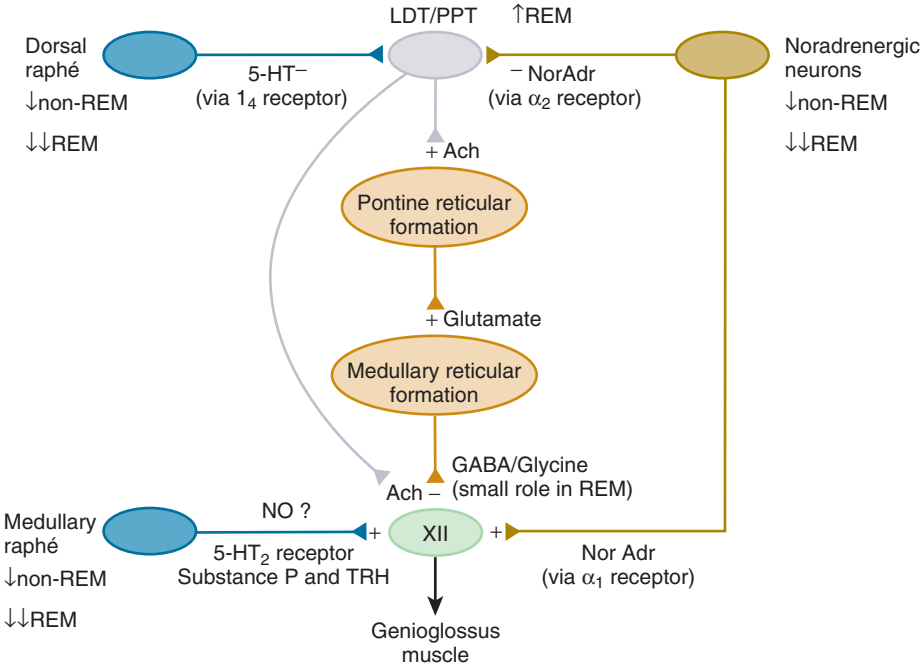

FIGURE 79-4 ■ Schematic shows the neuronal basis for changes in activity of upper airway motoneurons during sleep. 5-HT, serotonin; GABA, γ-aminobutyric acid; LDT/PPT, laterodorsal and pedunculopontine tegmental nuclei; NO, nitric oxide; REM, rapid eye movement; XII, hypoglossal motoneurons. FIGURE 79-5 ■ Axial magnetic resonance imaging (MRI) of upper airway in normal subject (*left panel*) and apneic patient (*right panel*). In the middle of the image is the airway—small dark structure. It is much smaller in the apneics than the normal subject, particularly in the lateral dimension. There is much more subcutaneous fat (*white areas*) in the apneics. (Reproduced from Schwab RJ, Gupta KB, Gefter WB, et al: Upper airway and soft tissue anatomy in normal subjects and patients with sleep-disordered breathing. Significance of the lateral pharyngeal walls. Am J Respir Crit Care Med 152:1673–1689, 1995, with permission.)

size can be compromised by alterations in craniofacial dimensions, for example, small retrognathic mandible, or by increased size of upper airway soft tissues[25] (Fig. 79-6). Total soft tissue, tongue volume, and volume of the lateral walls are all increased in patients with OSA as compared with controls.[26] These differences are heritable and explain part of the genetic basis for OSA.[27]

Upper Airway Collapsibility

Patients with OSA also have a more collapsible airway. The upper airway behaves as a Starling resistor with a critical closing pressure (P_{crit}) at which the airway collapses.[28,29] The P_{crit} can be measured during sleep, and techniques are available to suddenly reduce upper airway

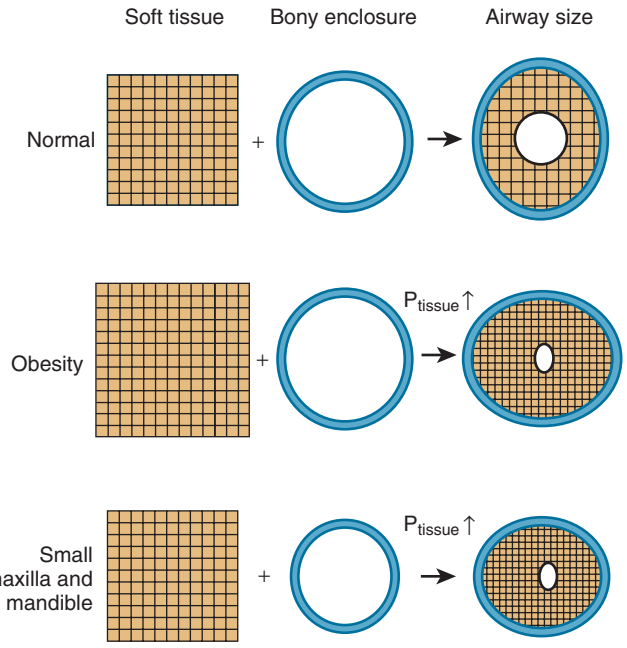

FIGURE 79-6 ■ Schematic shows the different mechanisms that can lead to compromise of upper airway size. The airway is the small open structure in the figures in the right column. The airway can be compromised by obesity that is associated with increased size of soft tissues, including tongue (*middle panel*), or by altered craniofacial dimensions (*bottom panel*). As the schematic shows, the reduction in airway dimensions is particularly in the lateral dimension rather than the anteroposterior. (Reproduced from Watanabe T, Isono S, Tanaka A, et al: Contribution of body habitus and craniofacial characteristics to segmental closing pressures of the passive pharynx in patients with sleep-disordered breathing. Am J Respir Crit Care Med 165:260–265, 2002, with permission.)

motor activity by suddenly altering intraluminal pressure in the upper airway, then measuring the biomechanical collapsibility of the airway. An even more direct method is to evaluate P_{crit} during anesthesia with paralysis, thereby completely eliminating motor activity, as reported by Isono and coworkers[30] (Fig. 79-7). Normal individuals have a negative P_{crit}, which means that significant negative intraluminal pressure is required to collapse the airway. For moderate sleep apnea, P_{crit} is more positive, whereas in severe sleep apnea, P_{crit} is actually positive, that is, these subjects require activation of upper airway dilator muscles to maintain patency of the upper airway. It has been proposed that there is increased activation of upper airway muscles during wakefulness in subjects with sleep apnea, thereby ensuring airway patency.[31]

Muscle Factors

There is also evidence that subjects with sleep apnea have damage to upper airway muscles, thereby creating a vicious circle.[32] This has been called the pharyngeal myopathy of OSA, and has been described in humans as well as in English bulldogs, the only natural animal model of OSA.[33] The concept is that the vibrations produced by snoring, combined with the large surges in intraluminal pressure, produce secondary changes in the muscles as well as the afferent and efferent nerve fibers that innervate the upper airway.[34,35] This concept was originally proposed by Friberg and colleagues[34,36] who coined the term "progressive snorers disease." A study of palatal tissue from patients with sleep apnea showed increased inflammatory cells in muscle and epithelium and increased expression of nerve cell adhesion molecule (NCAM) in muscle fibers,[37] which is seen when muscle fibers are denervated.[38,39] Hence, there is probably some degree of denervation of muscle fibers in the soft palate

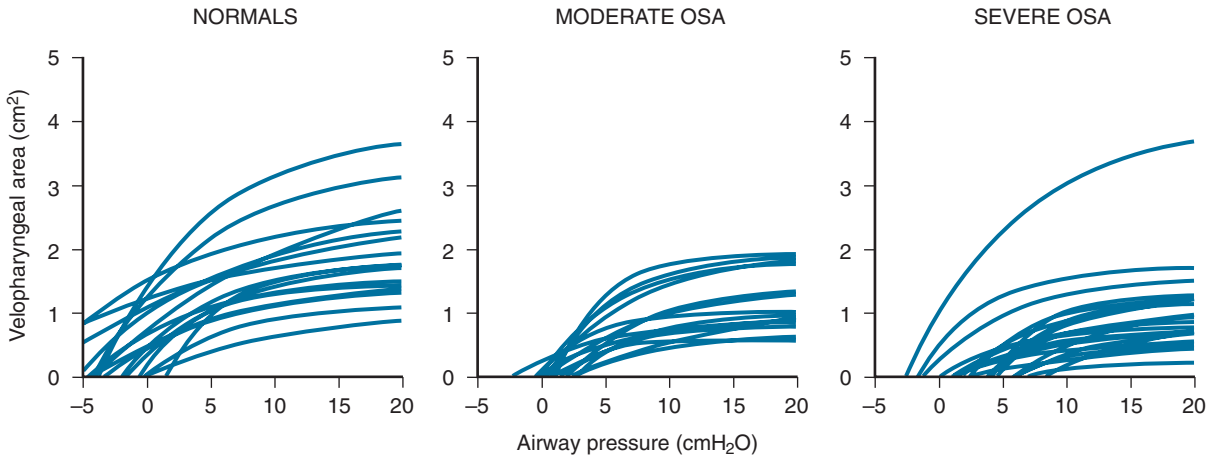

FIGURE 79-7 ■ Plots of velopharyngeal area against intraluminal pressure in a number of normal subjects (*left panel*), those with moderate obstructive sleep apnea (*middle panel*), and those with severe obstructive sleep apnea (*right panel*). In normals, airway area goes to zero at negative intraluminal pressure. In severe apneics, zero airway area occurs at positive pressures. Moderate obstructive sleep apnea subjects are intermediate. (Reproduced from Isono S, Remmers JE, Tanaka A, et al: Anatomy of pharynx in patients with obstructive sleep apnea and in normal subjects. J Appl Physiol 82:1319–1326, 1997, with permission.)

in patients with obstructive apneas. Whether this also occurs in other key muscles like the tongue is unknown. There is also evidence of damage to afferent fibers, with reduction in sensation in the upper airway of patients with sleep apnea.[35,40]

Fluid Shift at Night

An intriguing new concept is that fluid shifts from the legs to the torso, including upper airway structures, during sleep and recumbency play a role in the pathogenesis of OSA.[41–43] Application of pressure to the legs during sleep using antishock trousers, thereby enhancing fluid shift from the legs, increases upper airway dimensions[43] and increases airway collapsability.[42] Moreover, in nonobese subjects, with a body mass index (BMI) less than 30 mg/kg^2, the magnitude of fluid loss from the legs during sleep, as assessed by bioimpedance, is associated with the degree of sleep-disordered breathing.[41] The degree of fluid shift during sleep is associated with sedentary behavior during the day. Thus, particularly in elderly sedentary subjects, fluid accumulation in the legs during the day is likely to be part of the pathogenesis of OSA.

Different Phenotypes

These observations make it likely that specific pathogenetic mechanisms vary in patients with OSA. An additional mechanism is unstable action of the respiratory control system due to a phenomenon called "high loop gain," in which exaggerated neural inputs, for example, from chemoreceptors, produce higher than normal outputs.[44] Techniques to assess loop gain during sleep have been developed.[45] Accumulating evidence suggests that for some patients, a more collapsible upper airway is the major mechanism, whereas for others, high loop gain is more important.[46] Subjects with high loop gain might benefit from oxygen therapy, which reduces chemoreceptor responses and therefore loop gain.[47] However, oxygen is not a good strategy to treat sleep apnea, because it tends to lengthen apneas, further increasing arterial carbon dioxide pressure (Pa_{CO_2}) and reducing pH.

Arousals

The reason that oxygen lengthens apneas is that obstructive apneas are terminated by an arousal, that is, a sudden lightening of sleep state. Arousal is coupled to total ventilatory drive, that is, the magnitude of the neural output to phrenic and motoneurons for other pump muscles,[48,49] which depends in turn on the degree of hypoxia and hypercapnia. The role of arousals in the pathogenesis of OSA has been reviewed by Younes.[50] With arousal, there is a large increase in neural drive to the upper airway motoneurons as a consequence of the sudden change in sleep state. Arousal leads not only to sudden opening of the airway but also to a sudden increase in heart rate and in blood pressure owing to sympathetic activation.[51,52] Thus, arousals are not only beneficial in that they terminate the obstructive events but also potentially detrimental because of the cardiovascular effects.

CLINICAL RISK FACTORS FOR OBSTRUCTIVE SLEEP APNEA

These pathogenetic mechanisms relate directly to the clinical risk factors for OSA, which are summarized in Table 79-2.

Genetics

OSA aggregates in families, as shown in several different populations using relatively unique genealogic approaches: in the United States in the Cleveland Family Study[53]; in Scotland[54]; in Israel[55]; and in Iceland.[56] These studies in different populations have led to similar conclusions. The increased relative risk for having OSA in a first-degree relative of a patient with the disorder is 1.5 to 2.0.[53,56] Thus, obtaining a family history with respect to OSA and a history of snoring should be part of the routine evaluation of patients suspected of having sleep apnea. This genetic influence is mediated in part by obesity, which is a direct risk factor for sleep apnea. The genetic risk for OSA is, however, not due simply to obesity, because obesity-dependent and -independent genetic risks for sleep apnea have been described.[57] Although family aggregation has been demonstrated, genetic variants conferring risk for OSA have not yet been identified (for review, see Riha and associates[58]). Linkage studies have shown modest linkage peaks, but specific gene variants have not been found.[59–61] Association studies using candidate genes such as apolipoprotein E4 (ApoE4) have been performed, and both positive[62] and negative[63] associations have been reported. A genome-wide association study has not yet been conducted. The complexity of sleep-disordered breathing suggests that many different genes will contribute.

Upper Airway Anatomic Abnormalities

As outlined previously, patients with OSA have a smaller upper airway even in wakefulness.[24] Thus, anything that compromises upper airway anatomy is a risk factor for OSA. Sleep apnea is common in individuals with craniofacial disorders such as Treacher Collins and Pierre Robin

TABLE 79-2. Risk Factors for Obstructive Sleep Apnea in Adults

Obesity
Upper airway abnormalities
Craniofacial abnormalities
Endocrine diseases (hypothyroidism, acromegaly)
Postmenopausal status
Family aggregation

syndromes. In individuals who do not have specific craniofacial syndromes, there can be more subtle craniofacial differences such as retroposed mandibles and maxillas or reduced mandibular length. These differences can be quantified by analysis of digital photographs,[64] and the resulting data have some predictive value.[65]

Nasal obstruction is also a risk factor for OSA.[66] With increased nasal resistance, the intraluminal pressure in the pharynx is more negative if the subject has nasal breathing during sleep. This more negative intraluminal pharyngeal pressure facilitates airway collapse when the upper airway dilator muscles lose their tone during sleep.

Soft tissue abnormalities in the upper airway can also be a risk factor for OSA. Enlarged tonsils and adenoids are a major risk factor for OSA in children between the ages of 3 and 5 years (for recent reviews on pediatric sleep apnea, see Gozal and Kheirandish-Gozal[67] and Kheirandish-Gozal and Gozal[68]). Increased tongue size is also a risk factor, as occurs in patients with Down's syndrome, in whom OSA is common.[69] The macroglossia is often relative, that is, the tongue size is increased in relation to the craniofacial structure[70] even though it is not larger in absolute terms than in normal subjects. Occasional patients with upper airway tumors present with OSA.[71,72]

Thus, an important part of the evaluation of patients with OSA is to consider whether they might have upper airway abnormalities. Physicians should have a low threshold for referring patients for a detailed upper airway evaluation by an otolaryngologist, particularly when the reason for the OSA is not obvious.

Obesity

Obesity is the most important single risk factor for OSA in middle-aged adults. The increase in weight that confers risk can be modest, and many patients with OSA are not obese. Obesity has important interactions with other risk factors, such as craniofacial characteristics. The obesity risk was measured in a classic epidemiologic study from the Wisconsin Sleep Cohort.[4] Specifically, a 1 standard deviation in BMI triples the risk of OSA. The distribution of fat is important and patients with sleep apnea have increased neck circumference.[73] This link is so strong that measurement of neck circumference should be part of a routine physical examination.

The effect of obesity is not as marked in elderly subjects[74] so the role of obesity as a risk factor is less important in the elderly than in middle-aged subjects (Fig. 79-8). Several possibilities might underlie this observation: first, subjects with marked obesity are likely to die before becoming elderly; second, other pathophysiologic mechanisms might become increasingly important with age (e.g., the upper airway becomes more collapsible in elderly subjects)[75]; and third, sleep apnea seems to be a slowly progressive disorder that increases in severity with age.[76,77]

The mechanism by which obesity leads to OSA is unknown. Recent attention has focused on the concept that fat is deposited in the tongue, thereby increasing tongue size. Fat deposits in the tongue were originally demonstrated in an autopsy study, with the amount of tongue fat being associated with BMI.[78] Moreover, a polygenetic mouse model of obesity—the New Zealand Obese mouse—has an increased tongue size, as assessed by three-dimensional MRI, and a smaller upper airway than the relevant genetic control mouse.[79] Fat infiltration in the tongue of this mouse was demonstrated.[79] Increased tongue size is a common physical finding in sleep apnea patients with ridging of the tongue by the teeth.[80]

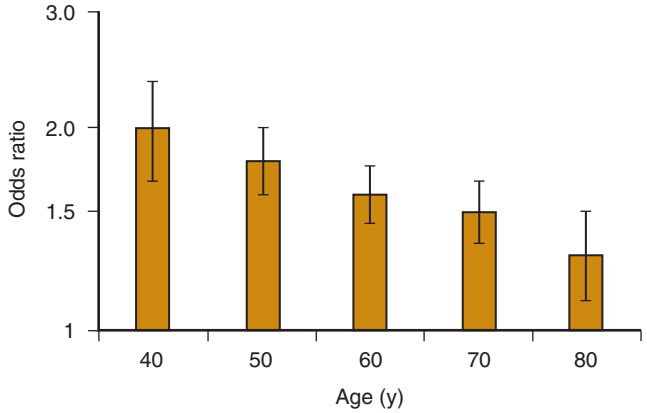

FIGURE 79-8 ■ Odds ratio (y-axis) in logarithmic scale for an apnea-hypopnea index of greater than 15 episodes/hr associated with a body mass increment of 5.3 kg/m^2, adjusted for sex and race. *Error bars* indicate 95% confidence intervals. The role of obesity declines with age. Data are from the Sleep Heart Health Study. (Reproduced from Young T, Shahar E, Nieto FJ, et al: Predictors of sleep-disordered breathing in community-dwelling adults: The Sleep Heart Health Study. Arch Intern Med 162:893–900, 2002, with permission.)

Endocrine Changes

Endocrine abnormalities also increase the risk for OSA. For example, OSA is more common in patients with hypothyroidism[81] and acromegaly.[82] Taking a detailed history, including questions relating to thyroid function, is important. Many practitioners have a low threshold for ordering thyroid function tests, particularly in individuals in whom the etiology of OSA is not obvious.

In females, sex hormones have a protective role. OSA is much less common in premenopausal than in postmenopausal women.[83,84] Moreover, epidemiologic studies show lower rates of OSA in postmenopausal women taking hormone replacement therapy than in those who were not.[83] The mechanism for this protective effect of female sex hormones is unknown. Because of the other adverse consequences of hormone replacement therapy,[85] estrogen is not recommended for postmenopausal women with OSA. Whereas OSA can occur in premenopausal women, the magnitude of the protective effect of female sex hormones is such that the diagnosis of OSA in premenopausal women should always be questioned.

CLINICAL PRESENTATION OF OBSTRUCTIVE SLEEP APNEA

In general, symptoms of OSA can be classified by their occurrence during nighttime (sleep) or daytime (wakefulness). During sleep, the majority of patients with OSA manifest loud, often disruptive snoring: in one study, nearly half of patients reported sleeping in a separate bedroom from their spouse or partner.[86] The bed partners of patients undergoing evaluation for sleep apnea can provide valuable history: in addition to snoring, the bed partner may describe apneic episodes, with periods of silence lasting 10 to 30 seconds or more that are terminated by snorting or choking sounds.[86] Although patients themselves are often unaware of whether they snore, they may perceive awakening with snoring, gasping, or choking or may experience dyspnea upon awakening.[87] Often, patients report awakening with a dry mouth, and some may complain of bruxism.[88] Many individuals with OSA experience nocturia, even in the absence of prostate disease, diuretic use, diabetes mellitus, or other contributory factors.[89,90] Patients with OSA usually describe unrefreshing or restless sleep, even after adequate time in bed for sleep.

The cardinal daytime complaint of patients with OSA is excessive daytime somnolence or fatigue. Individuals undergoing evaluation for OSA should be asked about whether they have experienced drowsiness with driving, because OSA increases the risk for fall-asleep crashes and near-misses.[91,92] Patients who fear driving restrictions (e.g., commercial drivers) may be very reluctant to reveal this history. A minority of patients complain of morning headaches. Because morning headaches can be a symptom of hypercapnia, patients with this complaint warrant additional evaluation for obesity hypoventilation, as described later.[93] Many individuals with OSA notice declines in cognition and performance, especially while performing tasks requiring concentration, cognitive processing, sustained attention, and executive functioning.[94] Patients and their families may also describe personality changes, depressive symptoms, decreased quality of life, and decreased libido.[95–97]

Epidemiology of Obstructive Sleep Apnea

A major community-based population study to document the prevalence of OSA was performed in middle-aged adults in the United States and reported the prevalence of OSA with daytime sleepiness to be between 2% to 4% in men and women between the ages of 30 and 60.[4] Since that time, a number of additional studies using large community samples have been performed in countries as diverse as Australia,[98] the United States,[6,83] China,[99,100] India,[101] Korea,[102] and Spain.[103] These studies are generally consistent in estimating the prevalence of OSA with symptoms to be approximately 3% to 8% in men and 1% to 5% in women.[4,6,83,98–102]

Prevalence estimates for OSA are affected by a number of factors. The characteristics of the population under study, such as the prevalence of obesity and the ethnicity of the population, can affect prevalence because these factors modify the risk for developing OSA. Different diagnostic methods for making the diagnosis of OSA can also cause estimates to vary or introduce bias. For example, methods to detect airflow and the willingness of people to undergo different types of testing vary in different locations. Variability in disease definitions (e.g., hypopnea definition[104,105] or AHI criteria defining OSA[83]) lead to different estimates of disease prevalence, even when studies use similar methods to collect data. The prevalence of sleep-disordered breathing events alone, without daytime symptoms, is considerably higher than the estimates cited above. For example, the Wisconsin Sleep Cohort Study found that 9% of women and 24% of men had an AHI of at least 5 events/hr.[4] In Pennsylvania, a community-based study estimated the prevalence of an AHI of at least 5 events/hr to be 17% in men; when the cutoff was increased to at least 15 events/hr, the prevalence was 7% in men and 2% in women.[83] Investigators in Spain observed that 26% of men and 28% of women had an AHI of at least 5 events/hr.[103]

Gender

Although data from early studies of OSA suggested that it was nearly exclusively a disease of males,[106,107] it is now well established that OSA is also common among women even though the prevalence of OSA is two to threefold higher in men than in women. Among women, several conditions increase the risk for sleep-disordered breathing. During pregnancy, nearly 25% of women have been reported to develop loud, regular snoring by the end of pregnancy[108]; further work is needed to determine the incidence of gestational sleep apnea. Data from several community-based studies show that the risk for OSA is approximately three times higher among postmenopausal women than among premenopausal women.[83,84] The higher prevalence of OSA among postmenopausal women is presumably related to declines in reproductive hormone levels. However, data describing how these hormone levels affect the anatomy and function of the upper airway or the control of breathing and ventilation leading to sleep-disordered breathing remain limited.[109–111] Women with polycystic ovarian syndrome, a common endocrine disorder of premenopausal women that is characterized by androgen excess and obesity, are at markedly increased risk for OSA, even when compared with weight-matched controls.[112,113]

Age

The prevalence of OSA increases with age through midlife, but appears to be relatively constant after the age of 60 to 65.[74] Among a sample of 385 elderly community-dwelling men and women at least 65 years of age, 81% had an AHI of at least 5 events/hr, and 62% had an AHI of at least 10.[114] In a community-based sample of men between 20 and 100 years of age, the odds ratio for

having an AHI of at least 10 events/hr was 6.6 (95% confidence interaval [CI] 2.6–16.7) for men between 65 and 100, as compared with men between 20 and 44 years of age.[6] The odds ratio for women between 65 and 100 years of age in this cohort having an AHI of at least 15 events/hr was 6.8 (95% CI 0.8–25.9) as compared with women 20 to 44 years old.[6,83] The Sleep Heart Health Study observed a plateau effect for the prevalence of OSA, beginning at approximately 60 years of age.[74] However, given the high overall prevalence of sleep-disordered breathing in individuals older than 65 years of age (>50% in several studies[74,103,104]) and conflicting reports regarding the risk for adverse outcomes,[115] controversy exists over the clinical significance of OSA in older people.

Ethnicity

The existing prevalence estimates for OSA are derived largely from white populations. However, a number of studies have been performed to characterize OSA in Asians as well as African Americans. Among other ethnic groups, data regarding the prevalence of OSA are very sparse. In midlife African Americans, the prevalence of OSA is similar to that in whites.[74,116] However, among African Americans younger than 25[116] or older than 65 years of age,[117] the prevalence of OSA appears to be higher as compared with either whites or African Americans in other age groups.

Several studies[99–102] have shown that despite a lower prevalence of obesity among Asians than in whites, the prevalence of OSA is similar in Asian and white population samples. Furthermore, after controlling for age and the extent of obesity, the severity of OSA tends to be higher in Asians than in whites.[118,119] The increased risk for OSA among Asians could be related in part to characteristics of the craniofacial anatomy.[118,120]

Snoring, one of the cardinal symptoms of OSA, is more common among Hispanic populations in the United States than in whites.[121,122] However, studies providing objective measurement of the prevalence of OSA in Hispanics and comparison with whites or other ethnic groups are not available. Studies in these and other ethnic groups are needed to provide a more complete understanding of the worldwide prevalence of OSA.

DIFFERENTIAL DIAGNOSIS OF EXCESSIVE SLEEPINESS

As noted previously, patients with OSA commonly complain of excessive sleepiness, and in managing these patients, it is important to consider the differential diagnosis of excessive sleepiness (Table 79-3).

TABLE 79-3. Differential Diagnosis of Excessive Daytime Sleepiness

Insufficient sleep syndrome
Restless legs syndrome
Narcolepsy
Delayed sleep-phase syndrome
Other medical conditions
Medications with sleepiness as a side effect
Kleine-Levin syndrome

Insufficient Sleep Syndrome

The insufficient sleep syndrome includes individuals who have no specific abnormality in their sleep but simply do not sleep enough. Insufficient sleep is extremely common in American society with about 35% of the population sleeping less than 6 hr/night.[123] For all patients being evaluated for a sleep disorder, a careful history should be taken about their sleep, including the time they go to bed, fall asleep, and wake up in the morning. The method of awakening also should be recorded, including whether they wake up spontaneously or use an alarm clock. Individuals with insufficient sleep will typically use an alarm clock to allow them to terminate their sleep. Insufficient sleep leads to performance impairments as well as metabolic consequences. Specifically, insufficient sleep affects glucose handling.[124] There is also an increase in ghrelin, which stimulates appetite, and a decrease in leptin, which inhibits appetite.[125] Thus, insufficient sleep is a risk factor for obesity.[126] Several excellent reviews about insufficient sleep are available.[127,128]

Restless Legs Syndrome

The restless legs syndrome is another common condition that leads to sleepiness. Patients with this disorder have abnormal sensations in their legs that come on typically in the evening, that is, before sleep, and are exacerbated by inactivity. Because of their time of occurrence and the effect of inactivity, these sensations can make sleep difficult. The symptoms of restless legs syndrome are exacerbated by iron deficiency. Thus, all patients suspected of having restless legs syndrome should have their serum iron and ferritin levels checked, and oral iron should be prescribed for patients who are iron deficient. Whereas restless legs syndrome can occur as a result of other conditions,that is, it is common in patients on renal dialysis and in pregnancy, a primary familial form also exists. Individuals with the familial form of restless legs syndrome typically present before they are 30 years of age.[129] Gene variants associated with restless legs syndrome have been identified in genome-wide association studies.[130,131] Whereas a number of different medications can be used for restless legs syndrome, dopamine agonists such as pramipexole (Mirapex) and ropinirole (Requip) can result in a dramatic reduction in symptoms (reviewed in Earley[132] and Trenkwalder and coworkers[133]).

Narcolepsy

Narcolepsy is another condition that can result in excessive sleepiness. Narcolepsy typically presents in the

second or third decade of life and has four cardinal features, including marked daytime sleepiness, cataplexy, hypnagogic or hypnopomic hallucinations, and sleep paralysis. These features reflect an intense pressure for REM sleep (dream sleep), such that aspects of REM sleep become apparent during wakefulness. Cataplexy is the sudden onset of muscle atonia, as occurs in REM sleep, that is precipitated in wakefulness by emotion. Laughter is the most common trigger. The atonia can be intense, such that the individual might fall to the floor. Hypnagogic or hypnopomic hallucinations are vivid dreams during wakefulness that occur either at sleep onset or at the end of sleep. Individuals with sleep paralysis wake up from sleep unable to move, because they are emerging from REM sleep and the REM-associated atonia has not been switched off. Although particularly common in narcolepsy, this phenomenon also occurs intermittently in otherwise healthy individuals.

Narcolepsy with cataplexy results from destruction of orexin-producing cells in the hypothalamus. These individuals have low levels of orexin in the cerebrospinal fluid.[134] This relationship with orexin deficiency is not found in individuals with other features of narcolepsy who do not have cataplexy.[134] Narcolepsy with cataplexy is associated with a particular human leukocyte antigen (HLA) (HLA DQBI*0602), which is present in about 80% of patients with this condition but is also found in approximately 25% of the general population.[135] The association between a particular HLA and narcolepsy with cataplexy suggests that the disorder may be an autoimmune disorder, with the autoimmune process leading to destruction of orexin-producing cells. Because this HLA is common in the general population, it raises a question about whether the autoimmune process requires an as yet unknown environmental trigger and/or the presence of other gene variants. The latter question has recently been addressed in a genome-wide association study comparing subjects with or without narcolepsy and cataplexy in a cohort in which all subjects (cases and controls) were HLA DQBI*0602–positive. With this design, an association with gene variants of the T-cell receptor alpha locus was identified.[136] Thus, narcolepsy with cataplexy seems to be an autoimmune disorder, and this is the first such disorder in which a role for a particular T-cell receptor gene variant has been identified.

Medications are commonly used to treat narcolepsy. The drug of choice for the excessive sleepiness is modafinil (Provigil), which promotes wakefulness. Occasional patients also require methylphenidate (Ritalin) or dexamphetamine in addition to modafinil to manage their sleepiness. When sleepiness is well managed, cataplexy improves, but in some patients, specific medications must be introduced for managing cataplexy. Tricyclic, monoamine oxidase inhibitor and selective serotonin reuptake inhibitor antidepressants improve cataplexy and γ-hydroxybutyrate (Xyrem) is approved by the U.S. Food and Drug Administration (FDA) for treatment of cataplexy based on the results of a placebo-controlled trial.[137] An excellent review of the management of narcolepsy is available.[138]

Delayed Sleep-Phase Syndrome

Abnormalities also occur in the circadian clock (for review, see Lu and Zee[139]). In such patients, sleep is usually normal, but it takes place at an abnormal time (i.e., it is phase shifted in relation to the light/dark cycle). These phase shifts are likely to be genetic, and heritability of the phase of the internal biologic "clock" has been shown in twin studies. The internal clock has a molecular mechanism, and since the mid 1990s, a great deal has been learned about the molecules involved (for review, see Siepka and colleagues[140]). Although a number of different feedback loops are involved, the core is a negative feedback loop in which clock proteins (three period molecules and two crytochromes) form a complex that is translocated to the nucleus to inhibit their own transcription. The role of genetic changes in producing phase shifts is shown by studies in the familial phase advance syndrome, a mendelian autosomal dominant condition. Patients with this syndrome go to sleep at around 7:30 PM and wake up at 4:00 AM, that is, they are profoundly phase advanced.[141] Two different mutations have been described in these patients—a single base mutation in the period two gene[142] and in casein kinase.[143] The latter enzyme is responsible for phosphorylating the clock proteins, and when phosphorylated, their degradation is accelerated.

Although the familial phase advance syndrome is proof of the concept of genetic variations, it is an uncommon condition. In contrast, the delayed sleep phase syndrome is much more common. Individuals with this abnormality have a marked phase delay. They may not be able to go to sleep until 3:00 AM or later, they sleep until noon, and their sleep is normal. These individuals function normally if they follow the timing of sleep set by their internal clock; however, they are constrained by the need to conform to expectations set by others. Thus, if they need to be at work at 8:00 AM or earlier, they will have inadequate sleep and be continually sleep deprived. This can be particularly troublesome for teenagers with delayed sleep-phase syndrome, because they need to wake up early to go to school. Techniques are available to shift the clock but are not particularly robust. Phase advance of the clock can be produced by melatonin in the evening and bright light in the morning.[144] Both of these interventions can advance the clock by about 1 hour. Thus, part of the management of patients with this disorder is to counsel them about activities and occupations that are compatible with their sleep-onset and -offset times.

Kleine-Levin Syndrome

A rare cause of sleepiness is the Kleine-Levin syndrome (for description of clinical features, see Arnulf and associates[145]). This typically presents in adolescents and individuals with this syndrome have intermittent episodes of intense hypersomnia. These episodes can last for days and the individuals may sleep for 20 hr/day. Associated features include markedly increased appetite during the

episodes and overt sexual behavior. The natural history of the disorder suggests that in later life, these episodes may disappear.

Other Conditions and Medications

Many other conditions can interrupt sleep and result in excessive sleepiness, including pulmonary conditions with nighttime cough, wheeze, and shortness of breath, and gastroesophageal reflux. Chronic pain at night is also a risk factor for sleep interruption and excessive sleepiness and is a prominent risk factor in older subjects complaining of sleepiness.[14]

Many medications also result in sleepiness as a side effect (e.g., antihistamines, some β-blocker drugs).[14] Thus, part of the evaluation of all patients with excessive sleepiness is to check whether their medications have sleepiness as a side effect.

DIAGNOSIS OF OBSTRUCTIVE SLEEP APNEA

The diagnosis of OSA is based on the presence of characteristic clinical symptoms and objective evidence of OSA. A number of patient questionnaires have been created to aid in the stratification of risk for OSA (e.g., Berlin Questionnaire,[146] Multivariable Apnea Prediction Index[87]). These questionnaires are most useful as screening tools in general populations.[147] Several clinical prediction models, which generally incorporate a combination of symptoms and anthropomorphic variables (e.g., BMI, neck circumference), also have been developed.[146–152] These models tend to be relatively sensitive (76%–96%) but not very specific (13%–54%).[153] Thus, there is a continuing need for better tools to objectively document sleep-disordered breathing.

Attended Polysomnography

The "gold standard" for the diagnosis of OSA remains full overnight polysomnography, performed in an attended laboratory setting. Full overnight polysomnography includes monitoring of electroencephalography (EEG), chin and anterior tibialis electromyography (EMG), oronasal airflow and snoring, thoracic and abdominal effort, electrocardiography (ECG), pulse oximetry, and body position. Scoring of sleep stages and arousals from sleep is performed from the EEG and EMG data. Apneas and hypopneas are scored according to the combination of oronasal airflow data, thoracoabdominal effort, and oxyhemoglobin saturation. The AHI, which indicates the severity of sleep-disordered breathing, is calculated based on the number of events per hour of sleep. In general, there is agreement across sleep laboratory facilities about the definition of apneas, that is, complete or near-complete cessation of airflow for at least 10 seconds,[4,105] with obstructive and central events differentiated by the presence or absence of chest and abdominal effort. However, the definition of hypopnea has varied according to the degree of desaturation (if any) that is required to accompany the event, whether arousals without desaturations define events, and whether diminution in airflow alone defines events.[104,105] These variations can lead to substantial disparities in the measured severity of sleep-disordered breathing.[104,105]

In clinical practice, the severity of sleep apnea is determined based on the number of apneas and hypopneas per hour of sleep. Fewer than 5 events/hr is normal, 5 to 15 events/hr represents mild disease, 15 to 30 events/hr defines moderate disease, and greater than 30 events/hr constitutes severe sleep apnea.[7] These definitions are helpful in classifying patients, and disease severity correlates with the likelihood of adverse outcomes (e.g., hypertension, cardiovascular mortality).[5,154] Nevertheless, these definitions fail to capture other significant aspects of OSA, such as the degree of oxyhemoglobin desaturation and nocturnal hypoxemia, or associated sleep disruption.

Unattended Sleep Studies

The increasing demand for evaluating sleep apnea and the relatively high costs associated with full-night attended polysomnography have led to the development of unattended sleep monitoring to evaluate patients for OSA. These studies are usually performed in patients' homes. For many patients, home sleep studies offer greater convenience and more closely replicate their usual night of sleep. The amount of data gathered during portable sleep studies spans a wide range: the most complex monitors can replicate the montage used in the laboratory, whereas other monitors do not monitor sleep and/or use fewer respiratory channels. Portable sleep monitors have been classified into four different types by the American Academy of Sleep Medicine according to the number of channels and types of recording. Attended laboratory polysomnographies are type 1 studies.[155] Type 2 studies are unattended, but generally collect EEG and electro-oculogram (EOG) data to allow sleep to be staged and include respiratory monitoring.[155] Type 3 devices must incorporate at least two airflow and/or respiratory effort channels, as well as oxygen saturation. Type 4 monitors record continuous single or dual bioparameters, typically including oxygen saturation or airflow.

Internationally, the use of portable sleep monitoring varies widely and is likely to be affected by a number of factors, including the availability of laboratory polysomnography and insurance guidelines regarding the reimbursement for portable studies. Even within the United States, substantial regional variation exists. The utility of these studies is likely to be greatest in two situations: for making the diagnosis of OSA in patients with relatively severe disease, because type 3 and 4 monitors, which frequently do not objectively measure sleep, are likely to underestimate the AHI; and for use among patients who may benefit from expedited diagnosis when laboratory polysomnography is not readily available.[156] Unattended monitoring is not recommended for cases in which central sleep apnea is suspected.

CONSEQUENCES OF OBSTRUCTIVE SLEEP APNEA

Pathophysiologic Mechanisms

The consequences of OSA follow from the physiologic changes that occur as a result of the apneic events. The apneic events are terminated by arousals that result in sleep being repetitively interrupted, that is, sleep fragmentation. This not only disturbs the continuity of sleep but also results in patients being "stuck" in the lighter stages of sleep and being deprived of both deep slow-wave sleep (stage N3) and REM sleep.

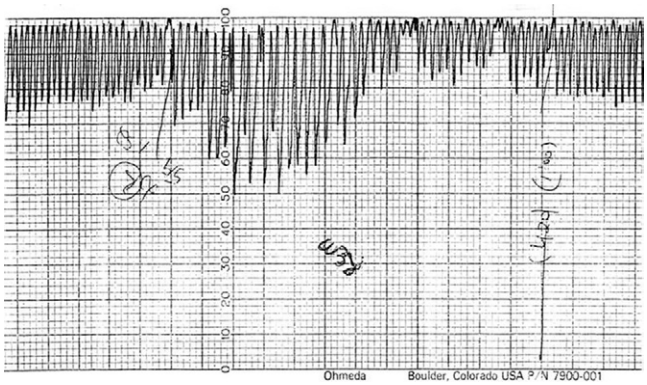

FIGURE 79-9 ■ Example of cyclical falls in oxygen saturation and then recovery in a patient with severe obstructive sleep apnea, as assessed by oximetry. The falls in oxygen in rapid eye movement (REM) sleep (middle of trace) are greater as the apneas were longer. The scale is 0% to 100% oxygen saturation. (Reproduced with permission from Pack AI: Changes in the cardiorespiratory system during sleep. *In* Fishman AP (ed): Fishman's Pulmonary Diseases and Disorders (4th ed). New York: McGraw-Hill, 2008, pp 1689–1695.)

The other major pathogenetic mechanism is the repetitive cyclical deoxygenation/reoxygenation with each event (see example, Fig. 79-9). It has been proposed by Lavie[157] that this is akin to repetitive ischemia/reperfusion with a burst of free radicals being produced with each reoxygenation. In this paradigm, OSA is an oxidative stress disorder, resulting not only in an increase in free radicals but also activation of nuclear factor-κB (NF-κB) with the production of downstream proinflammatory molecules.[158–160] Thus, OSA can lead to elevation of inflammatory biomarkers that are reduced with continuous positive airway pressure (CPAP) therapy.[161–167] However, not all studies agree on this point.[168,169] These pathways activated by OSA are the same pathways that are believed to be activated in obesity, so that both obesity and OSA can lead to overlapping pathogenetic consequences[170] (Fig. 79-10). Because obesity is a major risk factor for OSA, the coexistence of obesity and OSA can augment the pathogenetic consequences. Arnardottir and coworkers[170] have reviewed the molecular consequences of OSA.

Sequelae of Excessive Sleepiness

As described previously, sleep fragmentation and loss of deep NREM as well as REM sleep can lead to excessive sleepiness during the wakeful period. That REM sleep is chronically deprived in some patients with OSA is supported by the observation that when nasal CPAP is instituted for therapy, a dramatic increase in REM sleep occurs in many patients. Such patients report an almost miraculous effect of CPAP and indicate that they have not slept or felt as good for many years.

Excessive sleepiness results in people falling asleep at inappropriate times (e.g., while in conversation) and has a profound effect on quality of life. They can have difficulty coping at work and maintaining social

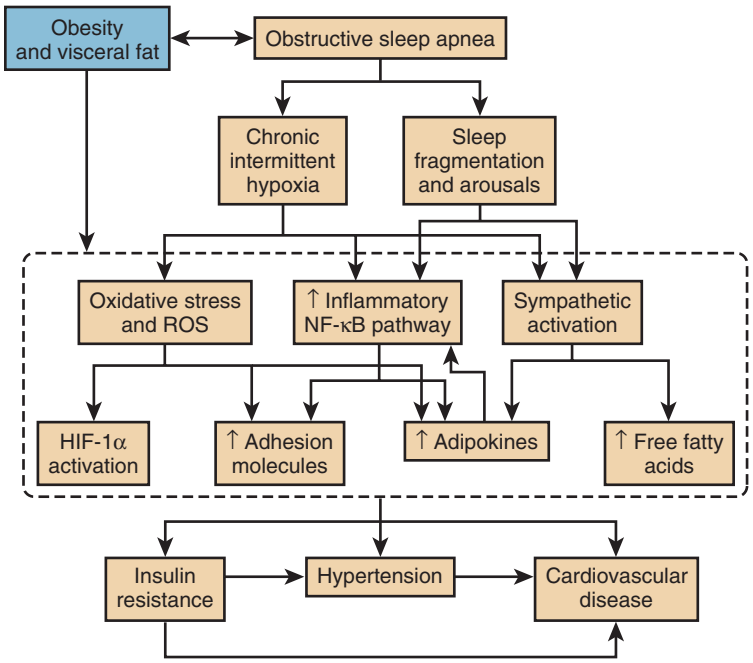

FIGURE 79-10 ■ Schematic illustrates the pathways involved in producing insulin resistance and cardiovascular disease as a result of obesity and obstructive sleep apnea. Both conditions affect the same molecular mechanisms. Because obesity is a risk factor for obstructive sleep apnea, determining the relative roles of these two conditions is challenging. HIF-1α, hypoxia-inducible factor-1α; NF-κB, nuclear factor κB; ROS, reactive oxygen species. (Reproduced from Arnardottir ES, Mackiewicz M, Gislason T, et al: Molecular signatures of obstructive sleep apnea in adults: A review and perspective. Sleep 32:447–470, 2009, with permission.)

relationships. OSA can lead to sexual dysfunction,[171] a finding that is replicated in animal models.[172] The adverse effect of OSA on quality of life and the positive effect of CPAP therapy have been shown in randomized trials.[173] Two specific quality of life instruments have been designed for use in patients with obstructive sleep apnea, and have shown that impaired quality of life improves with CPAP therapy. These include the Functional Outcomes of Sleepiness Questionnaire (FOSQ)[174] and the Sleep Apnea Quality of Life Instrument (SAQLI).[175] A new short form of the FOSQ instrument has been designed.[176]

Many patients with OSA suffer from depression. Epidemiologic studies reveal that the presence of untreated OSA is a risk factor for the development of depression.[97] Thus, symptoms of OSA should be sought in all patients presenting with depression, particularly those who are resistant to drug therapy for depression.

Patients with OSA and daytime somnolence are at significantly increased risk for vehicular accidents. This has been shown in several studies and a meta-analysis has been performed[92] (Fig. 79-11). Patients with untreated OSA have a twofold increase in the relative risk of automobile accidents. Studies show that in patients effectively treated with CPAP, the accident rates return to the same as the rest of the population.[177] This increased crash risk in patients with OSA is challenging to physicians, because if individuals are not treated, there are medicolegal implications. It is important, therefore, for practicing physicians to understand the relevant laws in their own state. Guidelines developed by the American Thoracic Society that were published in 1994[178] are being revised. A helpful discussion of this topic by several leading experts is recommended for the practicing physician.[179]

The increased rate of vehicular crashes is a particular issue for commercial drivers. Commercial drivers are largely male and tend to be more overweight than the general population.[180,181] Two studies, one in Australia[182] and one in the United States,[180,181] have shown a high prevalence of OSA in commercial drivers. Whereas the study in the United States also revealed associated impairment in driving tasks associated with OSA,[181] no data currently show that commercial drivers with OSA have an increased accident risk, because the relevant studies have not been done. Nevertheless, based on data from passenger car studies, an expert panel of the Federal Motor Carrier Safety Administration has recommended screening for OSA in commercial drivers at risk for the disorder as part of their routine medical assessment. These recommendations are published on the Federal Motor Carrier Safety Administration website (http://www.fmcsa.dot.gov/rules-regulations/TOPICS/mep/report/Sleep-MEP-Panel-Recommendations-508.pdf).

Insulin Resistance and Diabetes

Based on the mechanisms described previously, OSA might also lead to insulin resistance, a major risk factor for cardiovascular disease [for review, see Rader[183]]. The conclusion that OSA is an independent risk factor for insulin resistance (i.e., beyond the effects simply of obesity) is supported by association studies in general populations[184] and in a sleep center cohort.[185] Intervention data have also shown that treatment of OSA with CPAP improves insulin resistance,[186] although a second study was negative about this point.[187] Thus, OSA should be considered as part of the metabolic syndrome (Fig. 79-12).

The role of OSA as a risk factor for insulin resistance has led to studies in patients with type 2 diabetes, in whom OSA is extremely common.[188] Approximately 86% have at least mild sleep apnea (AHI > 5 events/hr), whereas 30.5% have moderate apnea and 22.6% severe sleep apnea. Thus, the presence of obesity and type 2 diabetes itself has a high positive predictive value for OSA. These data have led to the expectation that treatment of OSA in type 2 diabetics might improve glucose control, but existing studies conflict.[189,190] A negative study was performed in very obese subjects (mean BMI = 36.8 kg/m^2), raising the possibility that in the very obese, the effects of obesity are so overwhelming that

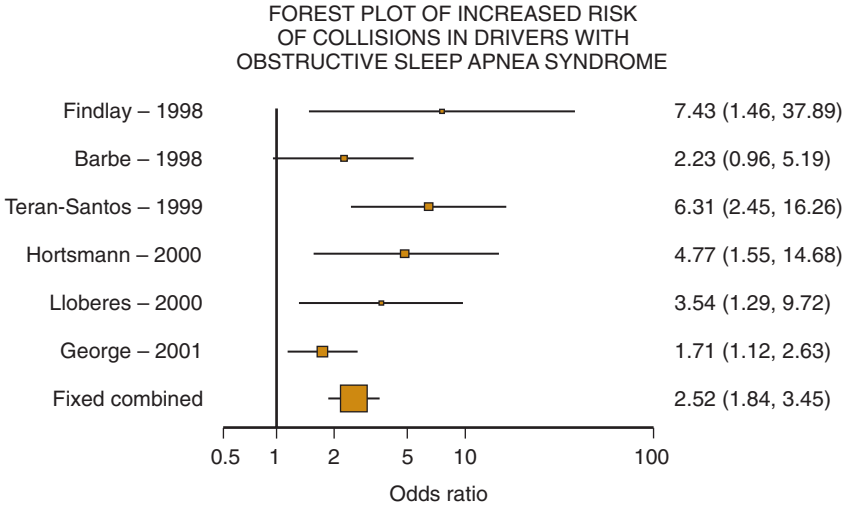

FIGURE 79-11 ■ Results of meta-analysis of studies assessing risk of collisions in drivers with untreated obstructive sleep apnea. The overall increased risk of crashes is slightly more than twofold. The original citations to the original studies are not provided, although the interested reader can obtain this information from the manuscript of Sassani and coworkers. (Reproduced from Sassani A, Findley LJ, Kryger M, et al: Reducing motor-vehicle collisions, costs, and fatalities by treating obstructive sleep apnea syndrome. Sleep 27:453–458, 2004, with permission.)

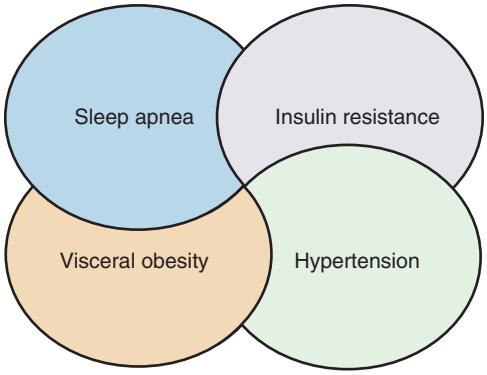

FIGURE 79-12 ■ A new concept of the metabolic syndrome. It includes not only insulin resistance, visceral obesity, and hypertension but also obstructive sleep apnea.

treatment of OSA has no effect. Further studies on this topic are needed.

CARDIOVASCULAR DISEASE

Hypertension

OSA is a risk factor for a number of cardiovascular sequalae [for review, see Pack and Gislason[191]], and the data are most convincing for hypertension. An animal model (dog) in which repetitive obstruction of the airway during sleep produced sustained hypertension during wakefulness, an effect that was reversed when the obstruction was no longer produced.[192] Moreover, when cyclic intermittent hypoxia mimicking that which occurs in OSA was produced in rats, sustained elevations of blood pressure occurred.[193]

Epidemiologic studies also show an independent association of OSA with hypertension after controlling for obesity in cross-sectional studies[5,194] and in the development of hypertension in a longitudinal cohort study.[195]

Randomized intervention studies with CPAP typically using sham CPAP as a placebo (i.e., application of CPAP with very low subtherapeutic pressures) also show improvements in blood pressure[196] (Fig. 79-13). Meta-analysis of these studies reveals that the average effect on blood pressure is small[197] (Fig. 79-14). However, one would not expect to see any improvement in blood pressure in some of these studies, because the inclusion and exclusion criteria excluded subjects with elevated blood pressure or who were on antihypertensive medications.[198] One study that included a large percentage of subjects with hypertension (42%) showed an average fall in mean blood pressure of 10 mm Hg.[199]

These results suggest that OSA might make individuals somewhat resistant to the effects of medical therapy for hypertension. OSA is common in refractory hypertension, defined as persistent hypertension despite treatment with a combination of three drugs.[200,201] Treatment of OSA in such individuals results in reduction of their blood pressure.[200,201] Thus, OSA should be considered in all patients with refractory hypertension.

Arrhythmias

OSA also is associated with cardiac arrhythmias. Whereas the early literature focused on heart block, recent attention has shifted to atrial fibrillation. Atrial fibrillation is more common in individuals with severe OSA than in those without OSA.[202] Patients with untreated OSA whose atrial fibrillation is controlled by cardioversion to sinus rhythm also more frequently relapse into atrial fibrillation.[203] Thus, OSA should be considered in all patients being evaluated for atrial fibrillation.

Cardiovascular Events

OSA has also been associated with cardiovascular events such as myocardial infarction and stroke in cross-sectional studies.[204] More definitive evidence comes from longitudinal follow-up of patients who refused therapy for OSA.[154,205,206] In these studies, there is an increased rate of cardiovascular events and cardiovascular mortality in patients with untreated severe OSA[154] (Fig. 79-15). Conversely, individuals with severe OSA who are treated with CPAP show no elevation of cardiovascular event rates as compared with controls.[154] One study also showed an increase in cardiovascular event rates in patients with moderate OSA.[207]

Whereas these data support the conclusion that treatment of OSA reduces cardiovascular risk, it may also be true that refusal of CPAP is a marker of general nonadherent behavior and that such individuals do not take other medications. Thus, the increased event rate might not be a specific effect of not being treated for OSA, but rather could be a result of poor adherence to health-promoting behaviors. If so, one might anticipate that there would be an association between medication use and CPAP use. One study found this to be true[208] whereas another study did not,[209] so this remains an open question.

Ultimately, there will be a need for randomized intervention studies of OSA treated with well-defined cardiovascular end points. Such a study is currently under way in Sweden[210] and a second much larger multicenter study is being conducted in Australia—the Sleep Apnea Cardiovascular Endpoints Study (SAVE) trial. The need for randomized intervention studies has been reviewed by Pack and Gislason.[191]

Current evidence raises questions about whether individuals with OSA who are not particularly symptomatic, that is, excessively sleepy, should be treated to reduce cardiovascular risk, but definitive data to support this recommendation are not available. CPAP is a safe and effective treatment if the individual can adhere to this therapy. On balance, it is prudent to share the current data with patients and to recommend therapy in such individuals, because they will likely benefit from therapy and there are no major risks. If the individuals cannot tolerate CPAP, more aggressive treatment is not warranted at this time.

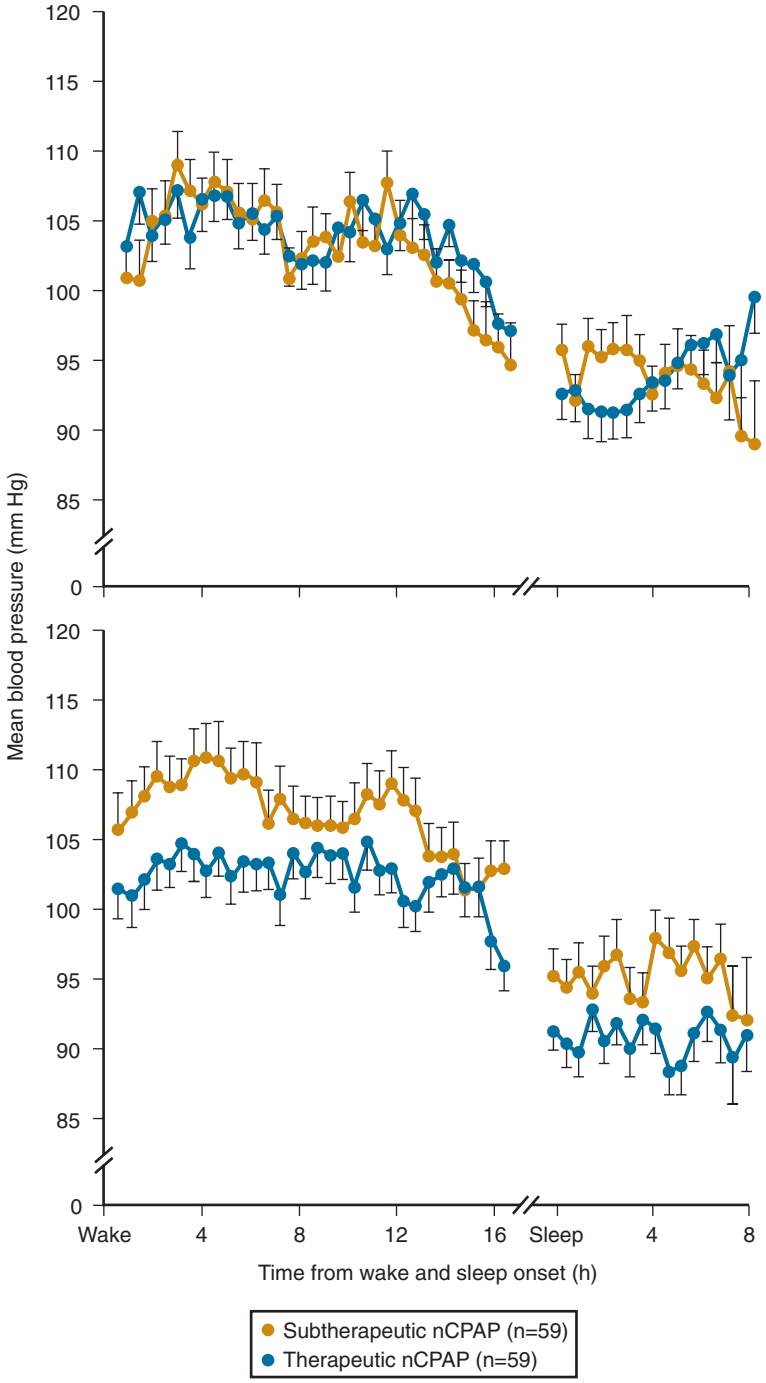

FIGURE 79-13 ■ Twenty-four-hour blood pressure in two groups of subjects with severe obstructive sleep apnea. One group was randomized into active continuous positive airway pressure (CPAP) for 1 month (*blue circles*—therapeutic nasal continuous positive airway pressure [nCPAP]) while the other group used sham CPAP (*brown circles*), that is, CPAP at a very low, ineffective pressure (labeled in the figure as subtherapeutic). Before treatment, the therapeutic group and subtherapeutic group had comparable blood pressures across the day (*top panel*). However, with active CPAP, there was a significant fall in blood pressure in the group on active CPAP but not in the sham group (*bottom panel*). (Reproduced from Pepperell JC, Ramdassingh-Dow S, Crosthwaite N, et al: Ambulatory blood pressure after therapeutic and subtherapeutic nasal continuous positive airway pressure for obstructive sleep apnoea: A randomised parallel trial. Lancet 359:204–210, 2002, with permission.)

ATHEROSCLEROSIS AND MECHANISMS FOR CARDIOVASCULAR EVENTS

OSA might lead to cardiovascular events in a number of ways. First, hypoxic events during sleep might precipitate cardiovascular events. This is believed to have happened to the famous National Football League (NFL) player, Reggie White. NFL players on both the offensive and the defensive lines have a high prevalence of OSA.[211] This hypothesis is supported by sleep studies in individuals who presented with a new myocardial infarction. Individuals with OSA are more likely to have their acute events between the hours of midnight and 6:00 AM as compared with those without OSA.[212]

An alternative hypothesis based on the concept that OSA is an oxidative stress disorder and leads to a proinflammatory state is that OSA can lead to atherosclerosis. For example, C57BL/6 male mice developed aortic atherosclerosis when they were fed a high-fat diet and subjected to cyclic intermittent hypoxia mimicking what occurs in OSA (Fig. 79-16).[213] Neither challenge on its own led to atherosclerosis,[213] suggesting that cyclic intermittent hypoxia and high-fat diet interact to produce

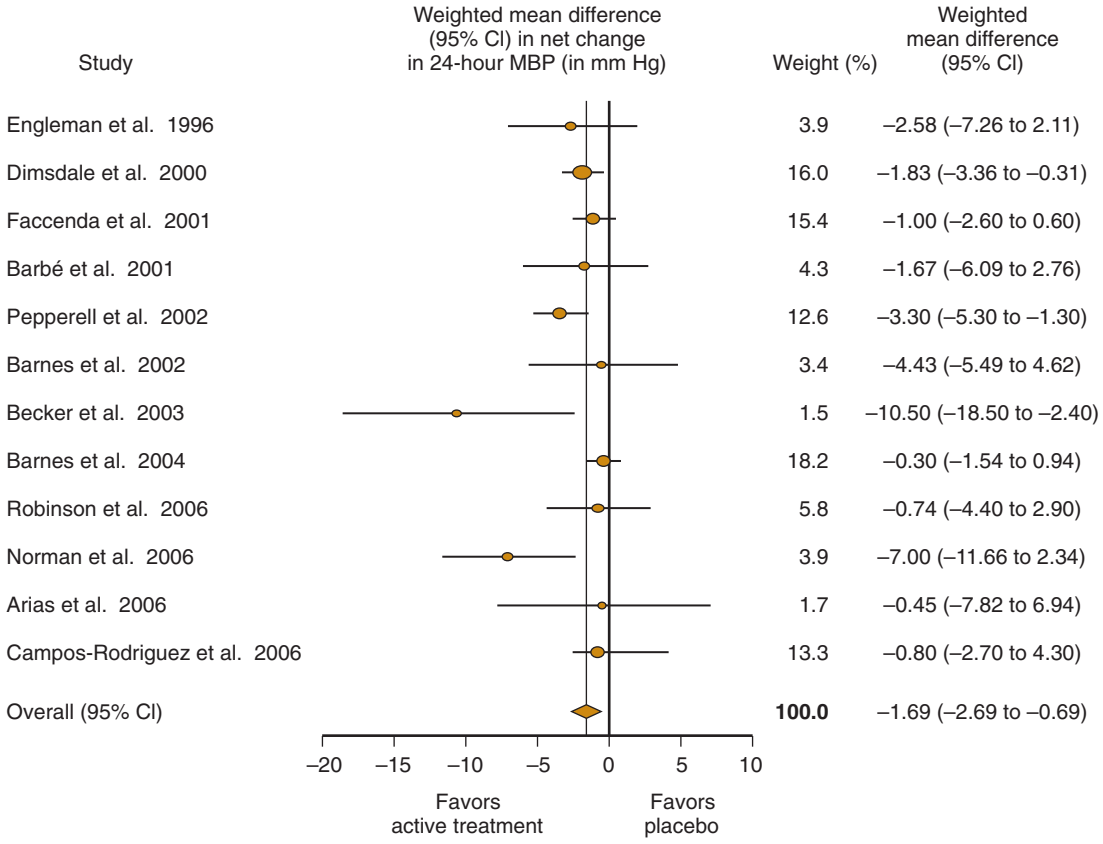

FIGURE 79-14 ■ Results of meta-analysis of effects of CPAP treatment on mean 24-hour blood pressure in patients with obstructive sleep apnea. There is overall a significant, albeit small, effect. Although the test for heterogeneity of results is not significant (P = .07), there was substantial variation between studies in the inclusion/exclusion criteria. One study excluded individuals with hypertension, another with sleepiness. Original articles are not cited but are available in the manuscript of Haentjens and coworkers. (Reproduced from Haentjens P, Van Meerhaeghe A, Moscariello A, et al: The impact of continuous positive airway pressure on blood pressure in patients with obstructive sleep apnea syndrome: Evidence from a meta-analysis of placebo-controlled randomized trials. Arch Intern Med 167:757–764, 2007, with permission.)

atherosclerosis even though the C57BL/6 male mice are relatively resistant to atherosclerosis.[214]

Another interesting hypothesis relates to atherosclerosis specifically in the carotid arteries. It has been proposed that the vibration produced by snoring is transmitted to the carotid artery and produces vessel wall damage. Vibration of rat tails leads to endothelial damage in blood vessels.[215] The time an individual spends snoring during the night in subjects who snore but have few apneas is strongly associated with the presence of plaques in the carotid artery but not the femoral artery.[216] This observation needs to be confirmed in other studies and then tested in intervention studies. If this concept is true, it will fundamentally change medical practice, because treating persistent snoring in individuals without OSA could be very beneficial.

MORTALITY

Not surprisingly, untreated OSA is associated with increased mortality.[217-219] This increased mortality is related to cardiovascular deaths and occurs largely in individuals with severe OSA. Interestingly, the survival curves for patients with severe OSA are identical whether or not patients complain of sleepiness.[217] This adds support for treating nonsomnolent patients with OSA.[220]

The increased mortality associated with sleep apnea is most marked in younger individuals and is not found in those over the age of 65 years.[221] Indeed, it has been argued that in the elderly, the presence of OSA might be protective because it is like ischemic preconditioning and can lead to increased vascular endothelial growth factor (VEGF) and collateral coronary vessels.[222] The evidence for this is not yet sufficient to modify clinical practice and not treat older adults with OSA.

TREATMENT OF OBSTRUCTIVE SLEEP APNEA

Treatment options for OSA generally fall into three categories: positive airway pressure (PAP), oral appliance therapy, and surgery. Among these, PAP is widely

accepted to be the most efficacious option (i.e., it works under ideal conditions, such as in the sleep laboratory), though the effectiveness of PAP therapy (i.e., whether it works in routine clinical care) is poorer, because of variability in the acceptance of and adherence to PAP therapy.

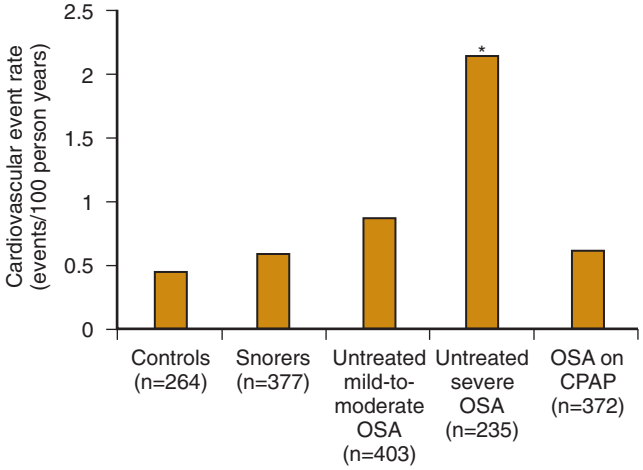

FIGURE 79-15 ■ Cardiovascular event rate over a 10-year period in five cohorts, all matched for age and body mass index (BMI). All subjects are male. Patients with untreated severe obstructive sleep apnea have a marked significant (*) increase in event rate compared with all other groups. Individuals with severe obstructive sleep apnea on CPAP have no increase in event rate. Data are from Marin and colleagues.[154] (Reproduced from Pack AI: Advances in sleep-disordered breathing. Am J Respir Crit Care Med 173:7–15, 2006, with permission.)

Positive Airway Pressure Devices

CPAP is the most commonly prescribed type of PAP therapy, and a number of studies have shown that CPAP is an effective treatment for excessive daytime sleepiness.[223–226] A meta-analysis of randomized, controlled trials for OSA demonstrated that improvements in subjective sleepiness (as measured by the Epworth Sleepiness Scale) were greatest in individuals with severe disease.[227] PAP treatment of individuals with severe OSA has been associated with a reduction in the rate of motor vehicle crashes.[177] Other studies examining the effect of PAP on general and disease-specific quality of life measures have mostly observed improvements with PAP therapy.[198,224,228,229]

CPAP delivers a preset level of pressurized air to the upper airway that prevents airway closure by acting as a "pneumatic splint" and is administered at a constant level throughout both inspiration and expiration. The appropriate level of therapy to eliminate apneas and hypopneas is determined during a CPAP titration study, which is usually performed during monitored overnight polysomnography; successful treatment strategies involving portable sleep monitoring and auto-setting continuous positive airway pressure (auto-PAP) titration have also been developed.[230–232] Treatment algorithms using predictive equations to determine the PAP prescription often require adjustments in pressure based on patient and bed partner report to establish a final treatment pressure.[231,233] The level of pressure needed to eliminate

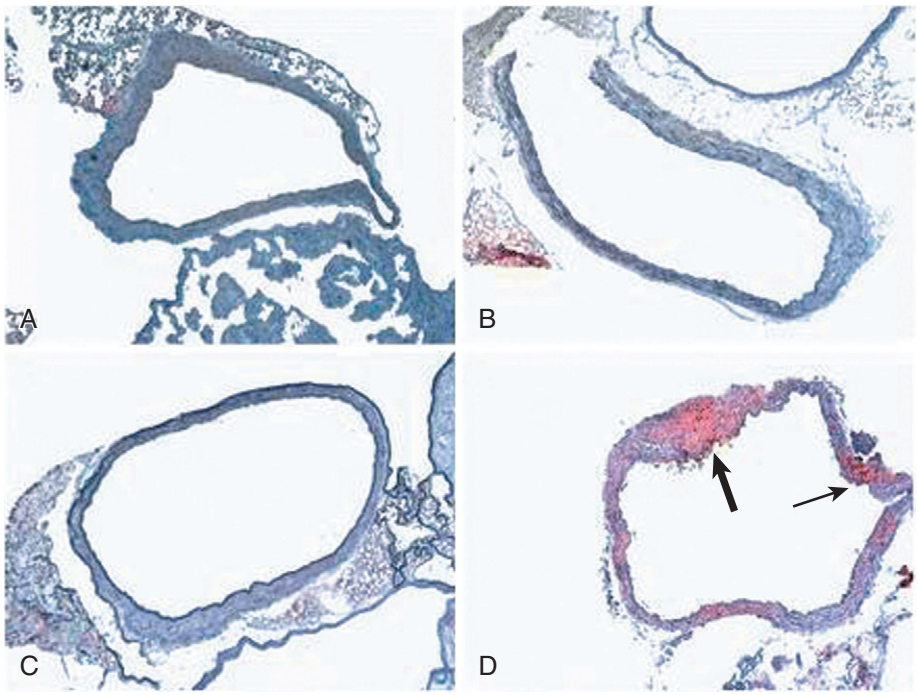

FIGURE 79-16 ■ Aortas of C57BL/6 male mice who received different interventions for 3 months. **A,** Normal diet, no intermittent hypoxia. **B,** Normal diet with cyclical intermittent hypoxia for 8 hr/day. **C,** High-fat diet, no intermittent hypoxia. **D,** High-fat diet and cyclical intermittent hypoxia for 8 hr/day. sleep-disordered breathing events is affected by several factors. Body position during sleep can affect the degree of pressure needed, because the airway is generally more collapsible while the individual is in the supine position. Sleep stage can also affect the degree of pressure required, with higher pressures needed during REM sleep, when REM muscle hypotonia may cause the airway to be more collapsible.[234] Although alcohol and benzodiazepine use might be expected to increase the level of CPAP pressure needed, small studies looking at these factors have failed to show a need for higher pressures.[235–237]

In addition to CPAP therapy, there are several other modalities for delivering PAP, including bilevel positive airway pressure (BPAP), auto-PAP, and auto-setting bilevel positive airway pressure (auto-BPAP). An alternative mode of PAP, adaptive servoventilation (ASV), has been developed for use in patients with central or complex sleep apnea.

BPAP differs from CPAP in that BPAP delivers a higher fixed level of pressure during inspiration and a lower fixed pressure during expiration. For patients who require high levels of CPAP therapy to prevent airway collapse, the lower pressure administered during expiration can make PAP easier to tolerate.[238,239] For patients who require ventilatory support, such as patients with OSA and concomitant obesity hypoventilation or chronic obstructive pulmonary disease (COPD) with respiratory failure, BPAP also provides a pressure gradient for augmenting ventilation.[240,241] A backup respiratory rate is generally not set for patients with OSA receiving BPAP unless central apneas are also present.

Auto-PAP and BPAP devices respond to variations in flow limitation, airflow magnitude, airway impedance, and vibration (snoring) depending on the individual device algorithm.[236,242] These devices vary the level of pressure administered to the patient during each episode of use, allowing the delivery of the lowest pressure that overcomes airflow limitation, between a minimum and a maximum pressure determined by the provider. Auto-setting devices can be used in situations in which patients have difficulty tolerating a fixed, higher level of CPAP or BPAP, especially when sleep-disordered breathing events may be concentrated by sleep stage (e.g., REM-related apnea) or position. Nevertheless, greater adherence to auto-PAP devices than to CPAP has not been consistently demonstrated,[18,242] and adherence to auto-setting BPAP has not been extensively examined. Auto-setting devices can also be used for unattended titrations of PAP: data collected over several days or weeks can be analyzed to provide information about the pressure that is most likely to be effective.[230–232]

A variety of interfaces are available for delivery of PAP, including nasal masks, nasal-oral (full face) masks, nasal inserts ("pillows"), and hybrid nasal-oral masks. A trial of several different masks is sometimes necessary to find a well-fitting mask that is comfortable for the patient. Factors to consider in mask fitting include whether the patient is susceptible to claustrophobia, the use of eyeglasses, the presence of nasal congestion or facial hair, and the shape of the face and nasal bridge. The routine inclusion of a heated humidifier unit in line with the PAP device has been shown in some studies to result in greater adherence to therapy.[243–245]

Recent advances in technology have enabled PAP devices to record sophisticated measurements of adherence to therapy beyond the total number of hours of use. Data regarding the duration and patterns of nightly use, the degree of residual sleep-disordered breathing, and mask leak all create opportunities for augmenting patients' self-report regarding PAP adherence and allow for changes to therapy based on objective data (e.g., by correcting mask leak or by increasing pressure to correct an elevated residual AHI). Because adherence in the first week of PAP use is important in predicting longer-term use,[229,246] adherence monitoring and close follow-up after initiation of PAP should be key components of treatment programs.

Oral Appliance Therapy

Oral appliances for treating OSA are designed to maintain upper airway patency during sleep. Most oral appliances are mandibular advancement devices that advance the position of the lower jaw during sleep.[247] Tongue-retaining devices are less well studied. Mandibular advancement devices vary not only in their design features and material but also in the degree to which they are customized for individual patients. A recent Cochrane review of the effect of oral appliances in the treatment of OSA in adults found that CPAP was more effective in reducing the severity of OSA (i.e., AHI) and sleep disruption and at improving the minimum oxygen saturation during sleep.[248] However, compared with sham oral appliances, active oral appliance use reduces the severity of OSA and improves daytime sleepiness.[248]

Oral appliances are not generally considered first-choice treatment for patients with OSA in whom symptoms and sleep disruption are severe.[249] They are recommended for patients with mild to moderate OSA and those unable or unwilling to use PAP.[249] Overall, the ability of oral appliances to reduce the severity of sleep-disordered breathing to less than 10 events/hr has been estimated to be approximately 50%, and oral appliances reduce the mean AHI by approximately half.[250] The major problem with intraoral devices is that although on average, they produce improvement, there is variation in effectiveness between individuals, and some have no improvement (Fig. 79-17). Thus, sleep studies following treatment are essential to demonstrate the effectiveness of oral devices.

Surgical Treatment of Obstructive Sleep Apnea

The success of surgical treatments for OSA, aside from tracheotomy, is unpredictable and generally less effective than PAP therapy.[251] The objective of the surgical treatments for OSA is to relieve sites of upper airway obstruction within the naso-, oro-, and hypopharynx. A number of procedures have been developed, including

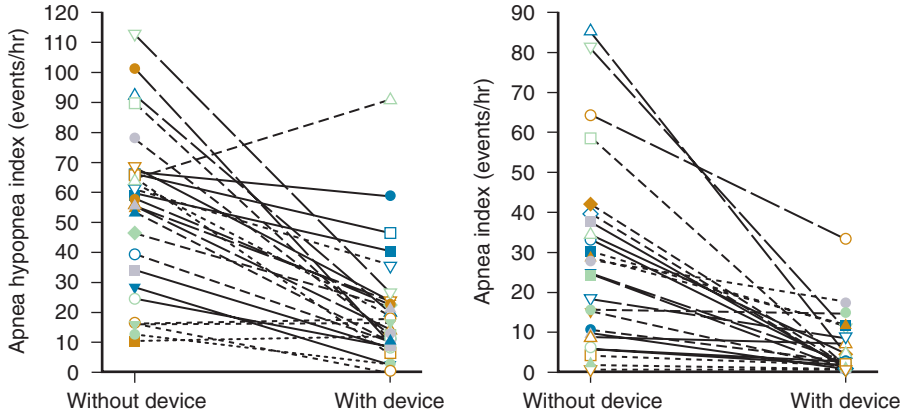

FIGURE 79-17 ■ Effect of an intraoral device on apnea-hypopnea index (*left panel*) and apnea index (*right panel*) in subjects with obstructive sleep apnea. Treatment improved sleep-disordered breathing when assessed across all subjects. In some cases, the improvement is dramatic, but some subjects do not improve and others get worse. (Reproduced from Henke KG, Frantz DE, Kuna ST: An oral elastic mandibular advancement device for obstructive sleep apnea. Am J Respir Crit Care Med 161:420–425, 2000, with permission.)

procedures to reduce soft palate redundancy, such as uvulopalatopharyngoplasty, uvulopalatal flap surgery, and laser-assisted uvulopalatoplasty.[251] Surgeries for nasal and palatal reduction, as well as tongue reduction or tongue advancement surgeries, are referred to as phase 1 surgeries and may be performed in combination or separately from phase 2 surgeries such as maxillomandibular advancement.[251] Although tracheotomy bypasses the upper airway and provides an effective cure for OSA,[252] this procedure is performed only rarely because it is not well accepted by patients. Tonsillectomy and adenoidectomy, a first-line intervention in children, does not reliably improve sleep-disordered breathing in adults.

Only a small number of clinical trials to assess the effectiveness of different surgical techniques for treatment of OSA have been performed.[253] Uvulopalatopharyngoplasty has been reported to reduce the AHI in patients with mild to moderate OSA to less than 50% of baseline or less than 20 events/hr in approximately 40% to 50% of cases. These are less stringent criteria as compared with PAP therapy, in which AHI is reduced to less than 5 events/hr.[254] Because the available evidence does not support widespread use of the surgical therapies, even among patients with mild to moderate OSA,[253,255] surgery should be limited to patients unwilling to consider other forms of treatment or as an adjunctive therapy (e.g., for relief of nasal obstruction to increase tolerance to PAP therapy).[251]

Alternative/Adjunctive Therapies for Obstructive Sleep Apnea

Because of the strong association between obesity and OSA, a major focus of long-term OSA treatment should be on weight loss. Data from two large cohort studies and a number of other studies show that apnea severity changes with changes in weight, although the magnitude of change is greater with weight gain than with weight loss.[76,77,256,257] In the minority of patients with purely positional apnea (usually in the supine position), maintaining alternative sleep postures (e.g., by using a body pillow) is an effective treatment strategy.

A flow diagram outlining an overall approach to treatment of OSA, based on the different modalities of therapy, is shown in Figure 79-18.

CENTRAL SLEEP APNEA

Central sleep apnea is less common than OSA.[258] Central sleep apnea is more complex, however, because a number of different mechanisms are involved. Central sleep apnea can be divided into hypercapnic and hypocapnic types. Hypercapnia occurs in neuromuscular diseases and in association with sleep-related hypoventilation. The apnea in this case is an extreme form of hypoventilation disorders that lead to hypercapnic central sleep apnea. The conditions in which this occurs include brain-stem lesions such as syringomyelia, spinal cord disorders, stroke, muscle disorders such as muscular dystrophy, and Shy-Drager syndrome (dysautonomia).

CONGENITAL HYPOVENTILATION

Chronic congenital hypoventilation is a rare form of hypercapnic central sleep apnea that presents in early childhood and is also known as Ondine's curse. Individuals with this disorder have relatively normal ventilation during wakefulness but a very blunted or absent response to hypercapnia.[259] These subjects hypoventilate when they fall asleep, due to central sleep apnea. During sleep, the ventilatory control system is much more dependent on the chemical drive to breathe when the wakefulness stimulus for respiration is lost.

The genetic basis of this disorder has been identified.[260] The majority of cases have an abnormal number

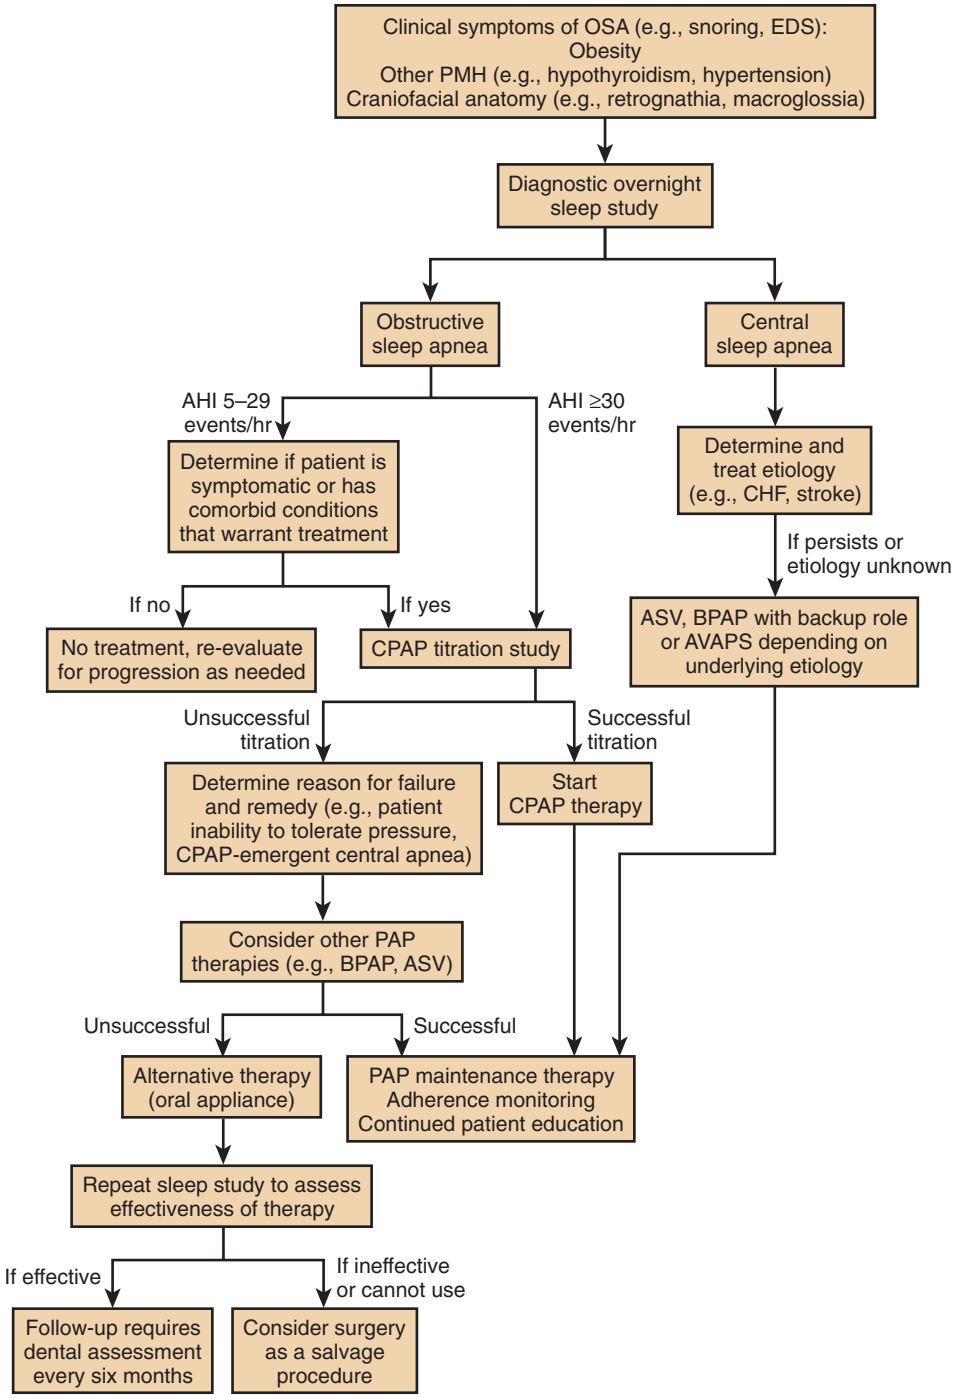

FIGURE 79-18 ■ Flow diagram outlines a treatment algorithm that can be used for diagnosis and management of obstructive sleep apnea. The algorithm has CPAP as a first-line therapy with intraoral devices as a second line. Upper airway surgery is essentially a salvage procedure that can be used to reduce the overall degree of sleep-disordered breathing when other modalities have failed.

of polyalanine repeats in exon 3 of the PHOX2B gene.[260] These mutations usually arise de novo and there is no family history. This gene is a transcription factor involved in development of the autonomic nervous system. Mice with increased polyalanine repeats in the gene have absent responses to hypercapnia, as do human patients, and marked instability of ventilation.[261] In normal individuals, there are usually 20 polyalanine repeats in this location in the gene. In patients with congenital hypoventilation, the number of repeats is typically 25 to 33 repeats. Interestingly, a few patients have been described who presented in adulthood (in their 20s) who had 25 repeats.[262] Other mutations in this gene can also lead to the syndrome.[263] Patients with congenital

hypoventilation also have associated Hirschprung's disease and neural crest tumors. The frequency of these associated conditions is higher in individuals with the rarer mutations of the gene than in those with the more common excess polyalanine repeats.[263]

Patients with congenital hypoventilation can be successfully treated if they are ventilated during the sleep period, because hypoventilation occurs only during sleep. Although this might be achieved by noninvasive ventilation using a face mask, this mode of ventilation is not secure. Therefore, these patients usually are treated by tracheostomy early in life for secure nocturnal ventilation using a positive-pressure ventilator. During the day, the tracheostomy is capped so that individuals can function normally. These patients often live into adulthood and need ongoing management of their nocturnal ventilation and their tracheostomy from physicians who care for adults.

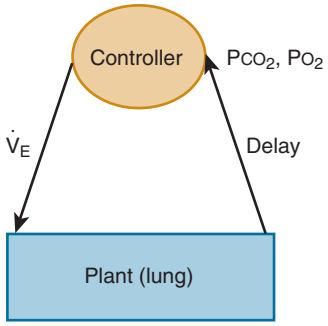

FIGURE 79-19 ■ Overview of control system for ventilatory control. The plant being regulated is the lung. The control variables are carbon dioxide pressure (P_{CO_2}) and oxygen pressure (P_{O_2}), which are served by the central and peripheral chemoreceptors. There is a delay between the plant and the controller. The controller adjusts ventilation ($\dot{V}_E$) in response to the changes in the chemical stimuli.

Hypocapnic Central Sleep Apnea

In contrast to congenital hypoventilation, hypocapnic sleep apnea has a different etiology resulting from alteration in the CO_2 apnea threshold during sleep.[264] During wakefulness, there is a strong drive to breathe that is not coupled to the chemical drive from Pa_{CO_2} and arterial oxygen pressure (Pa_{O_2}). This drive has been termed the "wakefulness stimulus." With the onset of sleep, this drive is lost, and the ventilatory control system becomes almost entirely dependent on the chemical drive to breathe. Thus, if subjects are artificially overventilated during wakefulness, rhythmic respiration is sustained even at low Pa_{CO_2}. In contrast, during sleep, dropping the Pa_{CO_2} by only a few torr below the awake Pa_{CO_2} can result in apnea (i.e., a CO_2-dependent apnea threshold emerges during sleep). Individuals hypoventilate during sleep as a result of the increase in upper airway resistance, so that Pa_{CO_2} rises approximately 2 to 6 torr during sleep. Because of the emergence of the CO_2-dependent apnea threshold during sleep, hypocapnia from any cause is a risk factor for central apnea, because such individuals will be closer to the sleep-related apnea threshold.

Another important concept in the pathogenesis of central apnea of the hypocapnic type is instability of the respiratory control system.[44] Any negative-feedback control system can produce self-sustaining oscillations when the overall response of the control system is high enough and there is a delay between the plant being controlled and the sensors (Fig. 79-19). The responsiveness of the control system is determined by overall loop gain, which is the product of the chemoreceptor response (increase in ventilation for a given increase in Pa_{CO_2} or fall in Pa_{O_2}) and plant gain, which is the change in Pa_{CO_2} for a given change in ventilation. Unstable operation of the respiratory control system results in self-sustaining oscillations in ventilation that are evident as periodic breathing. At the peak of ventilation, Pa_{CO_2} will be driven down to the CO_2-dependent apnea threshold and apnea will ensue.

In this type of apnea, arousals with interruption of sleep can occur but arousals will occur at the peak of ventilation not at the end of the apnea. As described previously, arousal is coupled to total ventilatory output. In unstable ventilation with hypocapnic central apnea, the maximum ventilatory output is at the peak of the ventilatory cycle, at which time an arousal may occur (Fig. 79-20). In contrast, in OSA, the peak ventilatory output to the diaphragm and other pump muscles occurs at the end of the apnea. This difference in the timing of arousals in these two different types of apnea is an important distinguishing feature.

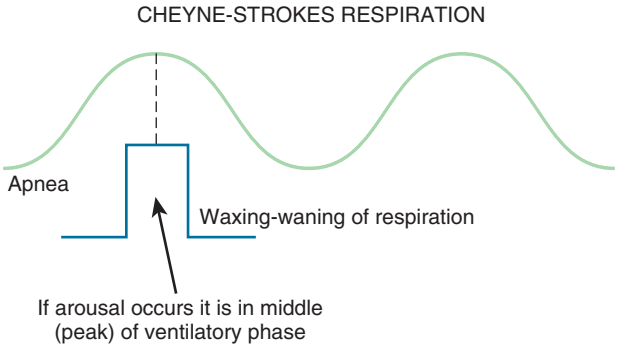

FIGURE 79-20 ■ Schematic shows the waxing and waning of ventilation that occurs in Cheyne-Stokes respiration. As illustrated, when arousal occurs in this type of sleep-disordered breathing, it occurs at the peak of the ventilatory phase, that is, maximal ventilatory output. In obstructive sleep apnea, the maximal ventilatory output occurs at the end of the apnea, and hence, this is when arousals occur. This different timing of the arousal can be helpful in distinguishing the different types of sleep-disordered breathing.

Periodic breathing with hypocapnic central apnea occurs at high altitude and in Cheyne-Stokes respiration. At high altitude, individuals are hypoxic, ventilation is stimulated and Pa_{CO_2} is reduced. The overall chemoreceptor sensitivity and, hence, loop gain are increased. This increase is due to augmentation of input from the peripheral chemoreceptor sensing hypoxia, that is, the

carotid body. Thus, unstable periodic breathing with central apneas can result with the relevant delay being between the lungs and the carotid body. Because this delay is short, the cycle times of these oscillations in ventilation is of the order of 20 seconds. This is the mechanism by which central apneas occur in normal subjects sleeping at high altitude. These apneas result in sleep fragmentation, excessive sleepiness, and other consequences. Central apneas at high altitude can be treated with acetazolamide (Diamox). This seems surprising because acetazolamide produces metabolic acidosis and is a ventilatory stimulant. However, animal studies show that acetazolamide has a different effect on the Pa_{CO_2} during eupnea in wakefulness and the CO_2-dependent apnea threshold.[265] Specifically, it increases the difference between the eupneic Pa_{CO_2} and the apnea threshold, making central apnea less likely.

Cheyne-Stokes Respiration

In contrast to periodic breathing at high altitude, the cycle times of the ventilatory oscillations in Cheyne-Stokes respiration are longer, of the order of 60 to 120 seconds (Fig. 79-21). These are mediated by the central rather than peripheral chemoreceptors, and hence, the relevant delay is between the lungs and the central chemoreceptors. Cheyne-Stokes respiration was originally described in two different independent reports by Irish physicians (Cheyne and Stokes) in the early part of the 19th century.[266,267] Cheyne-Stokes respiration is seen in patients with stroke, encephalopathies, heart failure, and other conditions.[268–270] Cheyne-Stokes respiration has been better studied in patients with heart failure than in patients with stroke.

Early reports from case series suggested that Cheyne-Stokes respiration is extremely common in patients with systolic heart failure.[271,272] Specific risk factors for the presence of Cheyne-Stokes respiration in patients with heart failure include age (risk is higher in those >65 years of age); male gender; presence of atrial fibrillation; and hypocapnia (Pa_{CO_2} < 38 mm Hg).[272] The permissive role of hypocapnia is further shown by studies in which the addition of even small amounts of CO_2 to the inspired air (~1%) profoundly attenuates central apneas in these patients.[273] Although this demonstrates the important role of hypocapnia, this intervention has not been used in large clinical studies.

Cheyne-Stokes respiration in patients with heart failure has a number of adverse consequences, including sleep fragmentation due to arousals resulting in excessive sleepiness and fatigue[274]; higher levels of circulating catecholamines[275]; increased ventricular ectopy[276]; and an increased rate of cardiovascular deaths.[277] Because of these effects, considerable attention has been paid to the question of whether treating Cheyne-Stokes ventilation in patients with heart failure can improve survival.

Different modalities to treat Cheyne-Stokes respiration have been used. Because of the factors involved in pathogenesis, oxygen administration helps to reduce chemoreceptor gain. Oxygen treatment reduces the overall percentage of the night that such subjects have Cheyne-Stokes respiration and the number of central apneas, but it does not completely abolish the abnormalities.[278] Theophylline also has been used,[279] but concerns about increased ventricular ectopy have limited its acceptance.

CPAP has received a great deal of attention in patients with Cheyne-Stokes breathing. This seems unusual because the problem in patients with Cheyne-Stokes respiration is central, rather than obstructive, apneas. Indeed, the mechanism by which CPAP treats Cheyne-Stokes is unknown. In these patients, CPAP is introduced in a different way than it is in OSA. In the latter, CPAP is titrated in the laboratory to eliminate obstructive events. In Cheyne-Stokes respiration, it is introduced at a low pressure, around 5 cm H_2O, and then increased nightly or over a period of days or even weeks depending on the patient's tolerance to the pressure. The CPAP is increased up to the tolerated amount or up

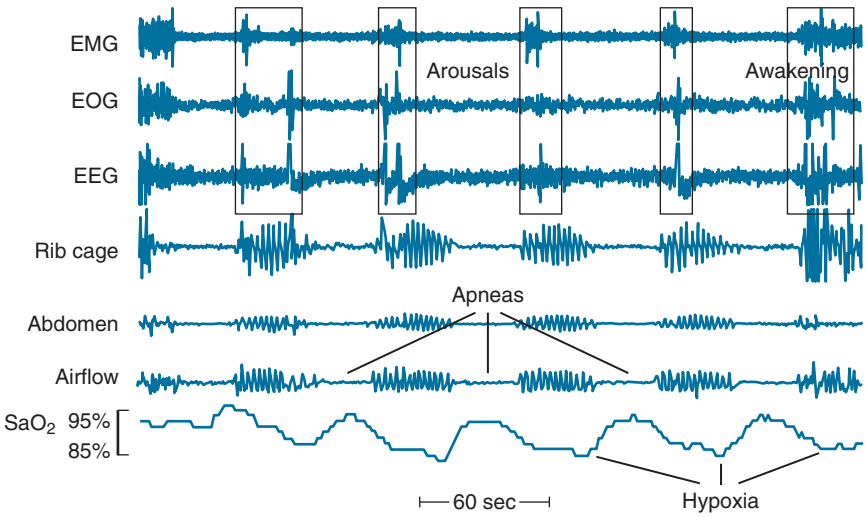

FIGURE 79-21 ■ Example of Cheyne-Stokes respiration. There is waxing and waning of airflow and rib cage and abdominal motion. During the apneas, there is no rib cage and abdominal motion, indicating the lack of respiratory effort, that is, central apnea. Oxygen saturation cycles with these episodes. Arousals occur during the ventilatory phase.

to a maximum of 10 cm H_2O. Early studies showed that CPAP improved ejection fraction[280] and reduced catecholamine levels.[275] In an initial randomized trial of CPAP compared with conservative management, individuals on CPAP had a reduced mortality over a 40-month period.[281]

These small studies led to a larger multicenter trial primarily in Canada—the CANPAP study. In this trial, 130 patients with systolic dysfunction and Cheyne-Stokes respiration were randomized to medical management of their heart failure and 128 were randomized to CPAP therapy.[282] There was no difference in heart transplant free survival (i.e., number living and not needing a heart transplant) between those treated with CPAP and the controls. Indeed, there was a significantly higher mortality in the CPAP treatment group between 12 and 18 months after starting therapy ($P = .02$).

One concern about this trial is that individuals on the CPAP arm were only partially treated. Because of this concern, the investigators performed a post-hoc analysis studying differences in mortality in those subjects who were effectively treated with CPAP.[283] They defined effective treatment as having an AHI less than 15 events/hr on CPAP. When examined in this way, the CPAP group had a markedly improved transplant-free survival as compared with the control group and those using CPAP whose sleep-disordered breathing was not suppressed by CPAP. Because this was an unplanned post-hoc analysis, these data cannot be used as a basis for recommending the use of CPAP therapy in these patients.

A new positive-pressure approach provides improved therapeutic efficacy in these patients. This was initially called auto-CS but is now called an "adaptive servoventilator." The fundamental concept of this approach is that there is a fixed expiratory (E) pressure while the inspiratory (I) pressure is varied on each breath (Fig. 79-22), that is, there is varied pressure support. The algorithm on which the I pressure is adjusted is based on maintaining a target ventilation. Thus, during the hypercapnic phase of the ventilatory cycle, the I pressure is reduced, while during hypoventilation, it is increased. The machine triggers breaths during the apneas. Thus, the device essentially does the converse of Cheyne-Stokes respiration and completely stabilizes ventilation. The E pressure, while fixed for a given subject, can be adjusted for different subjects so that this system can be used to relieve upper airway obstruction. This is of value in patients with Cheyne-Stokes respiration, who for part of the sleep period, might show classic Cheyne-Stokes respiration, while for other parts of the night, they may have obstructive events. The unstable cycling of neural output affects output to the upper airway dilator muscles as well as to the diaphragm. Thus, in these patients, there is a mixed distribution of apneas during the sleep period, with some central and some obstructive. Moreover, the proportion of these different types of apnea varies from night to night.[284] Thus, being able to deal simultaneously with Cheyne-Stokes respiration and obstructive apneas is beneficial in these patients in contrast to CPAP treatment for heart failure. Because of the variable nature of the output of this device, it is effective immediately. It nearly abolishes sleep-disordered breathing events in these patients on the first night of application and is much more effective in this regard than CPAP or BPAP therapy.[285] Improvements in sleepiness in patients with heart failure and Cheyne-Stokes respiration have been demonstrated.[274] A multicenter study evaluating transplant-free survival in heart failure patients with Cheyne-Stokes is in progress. The device can be used for other types of central apnea, and its efficacy in what has been called "complex sleep apnea" has been shown in small studies.[286]

Idiopathic Central Apnea

The idiopathic form of central sleep apnea resembles Cheyne-Stokes breathing, but these patients do not have heart failure and are otherwise normal. They have increased ventilation with hypocapnia during wakefulness and an increased ventilatory response to CO_2.[287] As in Cheyne-Stokes breathing in heart failure, addition of small amounts of CO_2 to the inspired air markedly attenuates the central apneas.[288] This is another example of the importance of the CO_2-dependent apnea threshold that emerges during sleep.

Complex Sleep Apnea

The term "complex sleep-disordered breathing" was initially coined by Thomas and colleagues[289] to describe a range of obstructive and central apnea patterns that included individual events with both central and obstruc-

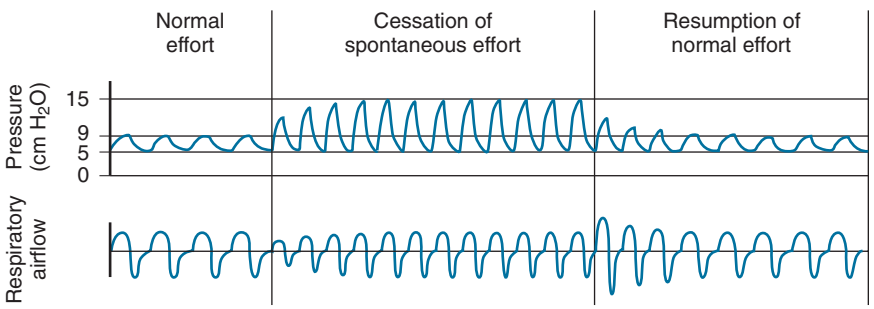

FIGURE 79-22 ■ Schematic shows the mechanism of action of the adaptive servoventilator. The pressure applied by the machine is in the *top panel* and the airflow in the *bottom panel*. The expiratory pressure is fixed on each breath but is titrated to relieve obstruction. The inspiratory (I) pressure is adjusted on each breath to maintain a target ventilation. Thus, in the period when ventilation is maintained, the I pressure is low, whereas it is increased during periods of reduced respiratory effort.

tive characteristics (mixed apneas), flow-limited breaths intermixed with periodic breathing, and variability in the degree of apnea dependent on sleep position, sleep stage, and time of night. These investigators also described a pattern of respiratory instability during sleep that occurred primarily during NREM periods of electroencephalographic cyclic alternating pattern, in which patients had periodic short cycles of obstructive events that responded incompletely to PAP and were minimized during REM sleep.[290]

More recently, the term "complex sleep apnea" has been used to describe central apneas or Cheyne-Stokes breathing that emerges during CPAP treatment of OSA.[291] Approximately 15% of a clinical sample of patients undergoing polysomnography who were characterized initially as having obstructive sleep apnea-hypopnea syndrome (OSAHS) without evidence of heart failure showed either a residual central apnea index of at least 5 events/hr despite elimination of events defining OSAHS or a prominent and disruptive pattern of Cheyne-Stokes respiration. These individuals were more obese than cases diagnosed with central sleep apnea and more likely to be male than patients initially diagnosed with OSA. Their other demographic characteristics and symptoms were generally similar to patients with OSAHS.[291] Additional studies have reported that 5% to 13% of patients treated with CPAP for OSA develop central apneas,[292,293] although it should be noted that a common syndromic definition has not been established.

Since the initial description, there has been debate about whether complex sleep apnea exists as a distinct entity or simply represents a variation in the response to CPAP therapy for OSA. Critics promote paying closer attention to whether the patient might in fact be over- or undertitrated on CPAP therapy, determining whether a mask leak may be causing residual events, scrutinizing whether occult heart failure is present, and examining whether medications (e.g., narcotics) might be contributing factors.[294] Several explanations for the emergence of central apneas with CPAP have been proposed, such as ventilatory control instability, which can induce central apneas as end-tidal CO_2 changes with the application of CPAP. Because men have higher loop gain than women (so that that they require a smaller degree of change in CO_2 to develop central apnea), this greater propensity for ventilatory instability could explain the greater likelihood of men to develop CPAP-emergent sleep apnea.[292] Other theories include an elevated CO_2 ventilatory response in patients with subclinical heart failure that precipitates Cheyne-Stokes respiration when CPAP is applied,[292] changes in CO_2 excretion that lead to central apneas,[295] worsened sleep fragmentation with initial CPAP treatment that leads to central apneas,[294] and a maladaptive response to CPAP therapy in which patients take larger than normal breaths, producing post-hypopnea pauses.[293]

Several approaches have been proposed for treating patients who have central apnea that emerges during CPAP therapy. Two studies have shown that in many patients, central apneas were a transient phenomenon during the CPAP titration night that resolved during further treatment with CPAP.[296,297] However, sample sizes were small, and one of the studies suggested that only half of patients improved with longer-term CPAP treatment.[296,297] Although central apneas may worsen when treated with BPAP alone,[298] BPAP used with a backup rate (i.e., noninvasive ventilation) appears to be an effective treatment for some patients with complex sleep apnea.[286,299]

Adaptive servoventilation (ASV), described earlier, is a relatively new PAP technology for treatment of central sleep apnea, mixed apnea, and periodic breathing that has also been used effectively for patients with the complex sleep apnea pattern.[286,299] In a retrospective, unblinded comparison study of CPAP, BPAP with a backup rate, and ASV for sleep-disordered breathing, ASV lowered the AHI to a greater degree than the other modalities and patients spent more time in REM sleep.[286] A prospective, randomized, crossover trial comparing ASV and BPAP for treatment of CPAP-emergent central apnea also showed that, although both modalities provided effective treatment, ASV was associated with a larger reduction in the AHI.[286]

SLEEP HYPOVENTILATION SYNDROMES

Central apneas can occur in the context of sleep-related hypoventilation syndrome. This syndrome occurs when there is an excessive increase in $PaCO_2$ during sleep. In normal adults, the $PaCO_2$ normally rises between 2 and 7 torr during sleep.[300–302] The diagnostic criteria for this have been defined, and each individual must fulfill criteria A and B.[7]

A. One or more of the following:
   a. Cor pulmonale.
   b. Pulmonary hypertension.
   c. Excessive daytime somnolence that is not better explained by other factors.
   d. Erythrocytosis.
   e. Hypercapnia during wakefulness ($PaCO_2$ > 45 torr).
B. Overnight monitoring demonstrates one or both of the following:
   a. An increase in $PaCO_2$ during sleep > 10 torr from awake supine values.
   b. Oxygen desaturation during sleep not explained by apnea or hypopnea events.

Many risk factors are associated with sleep-related hypoventilation syndromes including morbid obesity (BMI > 35 kg/m^2); chest wall restriction (e.g., kyloscoliosis); neuromuscular disease (e.g., amyotrophic lateral sclerosis); brain-stem or spinal cord lesions; idiopathic central alveolar hypoventilation (as described earlier); obstructive lung disease; or hypothyroidism. These risk factors interact with obesity and obstructive lung disease. Thus, it has been argued that one should consider sleep hypoventilation syndrome as an entity with a number of risk factors rather than as a number of distinct entities.[7] However, the literature typically treats the hypoventilation occurring with different risk factors as a specific entity, for example, obesity-hypoventilation syndrome.

Obesity-Hypoventilation Syndrome

Obesity hypoventilation is relatively common in severely obese subjects but is often not detected.[303] In one series, 31% of severely obese subjects had daytime hypercapnia without other reasons for this (mean $Paco_2$ = 52 torr). Somewhat surprisingly, only 13% of patients with obesity hypoventilation were treated with noninvasive ventilation during sleep.[303] Mortality was higher in the group with obesity hypoventilation than with simple obesity. Thus, obesity-hypoventilation syndrome is an important clinical problem, particularly with the rapid growth in obesity in the U.S. population.

In the majority of patients with obesity-hypoventilation syndrome, OSA with the characteristic symptoms and findings during the sleep study occurs. This is not surprising because obesity is the major risk factor for both conditions. However, about 10% of patients with obesity-hypoventilation syndrome do not have sleep-disordered breathing, and their AHI is less than 5 events/hr.[304–306] Thus, the presence of OSA is not an essential prerequisite for obesity-hypoventilation syndrome.

Although obesity is the major risk factor for the obesity-hypoventilation syndrome, not all obese subjects, including those with morbid obesity, hypoventilate during sleep. The mechanisms for hypoventilation in obesity include the mechanical mass loading effect of obesity, but also alteration in ventilatory control, probably as a result of central leptin resistance. Mice lacking leptin (ob/ob) have hypercapnia and a blunted ventilatory response.[307,308] This is not simply related to their obesity, because these ventilatory changes occur before they become profoundly obese.[307,308]

Certain features should arouse suspicion that obese individuals might have obesity-hypoventilation syndrome including daytime hypoxemia (patients with OSA have normal daytime blood gases); evidence of sustained desaturation on a sleep study, that is, nocturnal hypoxemia not simply related to recurring events; or a bicarbonate level of 27 mEq/L or greater on a routine electrolyte screen. Among patients with OSA (AHI > 5 events/hr) and obesity (BMI ≥ 30 kg/m^2), only 3% of patients with a bicarbonate lower than 27 mEq/L had obesity-hypoventilation syndrome whereas 50% of those with bicarbonate levels greater than 27 mEq/L had obesity-hypoventilation syndrme.[304] All of these findings should trigger an evaluation of blood gases while the patient is awake. Blood gas assessments before and shortly after sleep can document the sleep-related hypoventilation.

Management of these patients requires application of PAP during sleep. CPAP and noninvasive positive-pressure ventilation have been used. There is no standard protocol, but a useful approach has been described in a recent review.[305] The number of prospective randomized studies in this area is very limited.[309,310]

Application of positive pressure in these patients should be done in a setting with experienced technologists. In many patients, CPAP therapy is beneficial, although in about 50% of patients supplemental oxygen needs to be added to CPAP.[305] Whereas combined CPAP and oxygen is sufficient in many patients, some patients require noninvasive ventilation. For the latter, BPAP with a backup rate is typically used. Some of the patients requiring noninvasive ventilation can be identified during the sleep study because they have persistent oxyhemoglobin desaturation even though CPAP has abolished the apneas and hypopneas. Others may only be identified later when a repeat blood gas assessment on therapy shows persistent hypercapnia. No guidelines specify when to switch patients from CPAP to noninvasive ventilation. Because failure of CPAP therapy may take several weeks to be seen, physicians should have a low threshold for using noninvasive ventilation in these patients.[311] Recently, a new ventilatory modality has been used—the average volume-assured pressure support (AVAPS)—which combines pressure-limited and volume-limited modes of ventilation to ensure a more consistent tidal volume. Use of this method has been described in a small series of patients with obesity-hypoventilation syndrome.[310]

Because obesity is the major cause of this condition, these patients should be evaluated for bariatric surgery. Weight loss can be associated with substantial improvements in the degree of sleep-disordered breathing as well as daytime hypercapnia.[312] Patients with obesity-hypoventilation syndrome have an increased risk of complications with bariatric surgery, and untreated sleep apnea is a documented risk factor for death following bariatric surgery.[313] Thus, OSA and hypoventilation need to be well managed before surgery is planned. Indeed, all patients having bariatric surgery should undergo evaluation for sleep-disordered breathing and treatment should be initiated as needed.

Conclusion

In conclusion, a great deal has been learned since the original clinical recognition of OSA in the 1970s. The condition has moved from being considered a rarity, if it existed at all, to being seen as a highly prevalent disorder of major public health significance.[123] The discovery of CPAP by Sullivan and colleagues[314] provided a safe and effective therapy that has transformed the treatment of OSA and helped millions of people. The developing evidence about OSA as an independent risk factor for cardiovascular disease is opening a new chapter in this fascinating area. Despite these important advances, a lot remains to be discovered. Management of patients with sleep-disordered breathing is extremely gratifying because the treatments often result in significant improvement in people's lives.

KEY POINTS

- OSA is a common health problem worldwide, and prevalence increases with age. OSA is two to three times more common among men than women, but the risk rises significantly in women after menopause.
- OSA is associated with daytime somnolence, motor vehicle accidents, hypertension, and cardiovascular mortality and should be considered part of the metabolic syndrome.
- Pathogenetic factors in OSA include small upper airway size, changes in upper airway muscles and nerves, and individual differences in chemoreceptor sensitivity and arousal responses to apneas.
- CPAP is the standard of care in most patients with OSA, but oral appliances and surgical procedures are useful in selected patients.
- Periodic breathing at high altitude and Cheyne-Stokes respiration are forms of hypocapneic central sleep apnea resulting from the dependence of ventilatory control during sleep on the chemical drive to breathe.
- Individuals with obesity-hypoventilation syndrome have an excessive increase in arterial P_{CO_2} during sleep and usually have hypercapnia during wakefulness and a very high BMI. The pathogenetic mechanisms include mechanical mass loading of the chest wall and alterations in ventilatory control.

INTRODUCTION

Since the recognition of the first cases of acquired immunodeficiency syndrome (AIDS) in 1981, our understanding of human immunodeficiency virus (HIV) and its myriad infectious and noninfectious complications has increased enormously. During this period, the prognosis for persons infected by HIV has undergone dramatic change in regions with access to effective combination antiretroviral therapy to suppress HIV replication and strategies to treat and prevent HIV-associated complications. These therapeutic advances have resulted in a dramatic decline in the incidence of new AIDS cases and in the number of AIDS-associated deaths in countries predominantly in North America and Western Europe, where this care is more widely and consistently available.[1] Unfortunately, access to medications is far from universal, a cure for HIV seems unlikely, and an HIV vaccine remains elusive. Therefore, efforts to prevent the spread of new HIV infection, to identify and treat those persons who are already HIV infected, and to slow the progression from HIV to AIDS continue to be worldwide priorities.

The lungs are one of the chief target organs of HIV disease and, accordingly, a major source of morbidity and mortality. The spectrum of pulmonary manifestations is broad, and many infectious and noninfectious complications have been recognized (Table 80-1).[2,3] These complications include diseases that are AIDS defining or HIV associated (such as *Pneumocystis* pneumonia or recurrent bacterial pneumonia), disorders that are not classified as HIV associated but appear to be more common in those with HIV infection (such as lung cancer, pulmonary arterial hypertension, and chronic obstructive pulmonary disease), and conditions whose association with HIV is inconclusive or purely coincidental (such as sarcoidosis). This chapter provides a brief review of the epidemiology of HIV infection and its immunologic abnormalities, followed by a diagnostic approach to the evaluation of pulmonary disease in an HIV-infected patient. Then, the major HIV-associated pulmonary diseases are discussed, with emphasis on clinical features, diagnosis, treatment, and prevention.

TABLE 80-1. Spectrum of Pulmonary Complications

INFECTIONS
Bacteria*
- *Streptococcus pneumoniae*
- *Haemophilus* species
- *Staphylococcus aureus*
- *Pseudomonas aeruginosa*
- Other bacteria

Mycobacteria
- *Mycobacterium tuberculosis*†
- *Mycobacterium avium* complex‡
- *Mycobacterium kansasii*‡
- Other mycobacteria‡

Fungi
- *Pneumocystis jirovecii* (formerly *P. carinii*)§
- *Cryptococcus neoformans*‡
- *Histoplasma capsulatum*‡
- *Coccidioides immitis*‡
- *Aspergillus* species (most often *A. fumigatus*)
- *Blastomyces dermatitidis*
- *Penicillium marneffei*
- Other fungi

Viruses
- Cytomegalovirus§
- Other viruses

Parasites
- *Toxoplasma gondii*¶
- Other parasites

MALIGNANCIES
Kaposi sarcoma§
Non-Hodgkin's lymphoma§
Bronchogenic carcinoma

INTERSTITIAL PNEUMONITIDES
Lymphocytic interstitial pneumonitis¶
Nonspecific interstitial pneumonitis

OTHER
Chronic obstructive pulmonary disease
Asthma
Pulmonary arterial hypertension
Sarcoidosis
Immune reconstitution inflammatory syndrome

*Acquired immunodeficiency syndrome (AIDS)–defining diagnosis in adults and adolescents (>13 years) if recurrent (≥2 episodes in 12 months). Not applicable as AIDS-defining diagnosis in children.
†AIDS-defining diagnosis in adults and adolescents. AIDS-defining diagnosis in children if extrapulmonary or disseminated.

EPIDEMIOLOGY

The AIDS epidemic has had a major impact throughout the world. Since the beginning of the epidemic, 25 million people have died from HIV-related causes.[4] Global estimates at the end of 2007 indicated that 33 million people were living with HIV; during that year, 2.7 million were newly infected and 2.0 million people died due to AIDS.[4] A disproportionate number of all the HIV-infected people in the world live in low- and middle-income countries, especially in sub-Saharan Africa, which has the world's highest prevalence of HIV infection, and which is where approximately 67% of all people with HIV live.[4] In the United States, although the national incidence and prevalence of HIV can only be estimated because of incomplete reporting, the Centers for Disease Control and Prevention (CDC) estimates that there are more than 1 million people living with HIV.[5] As survival has improved for HIV-infected patients after the introduction of combination antiretroviral therapy (ART), more people are living with HIV in the United States than ever before.[6]

In the United States and most developed countries, persons at highest risk for HIV infection are injection drug users (IDUs), men who have sex with men (MSM), and sex workers. Heterosexual contact is a predominant mode of HIV transmission worldwide.[7] In the United States from 2003 through 2006, the main risk for transmission of HIV was MSM (approximately 49% of cases), followed by high-risk heterosexual contact (33%); most of the remaining cases were attributable to IDU.[4] Overall, the proportion of cases with transmission of HIV because of high-risk heterosexual contact has increased over the course of the epidemic. In contrast, rates of perinatal transmission have declined, and the risk of HIV infection from transfusion of blood products is estimated to be as low as 1 in 2 million blood donations with current screening and testing methods.

The gender and racial/ethnic demographics of HIV-infected populations vary worldwide. Globally, women account for approximately 50% of people living with HIV.[4] In the United States, women now comprise an increasing percentage of adult AIDS cases, accounting for about 25% of new cases.[5] Whereas HIV was predominantly seen among non-Hispanic white MSM early in the epidemic, HIV is increasingly affecting minorities. In 2006, 49% of all new HIV/AIDS diagnoses in the United States occurred in blacks, with rates of HIV/AIDS cases of 67.7 per 100,000 in the black population, 25.5 per 100,000 in the Hispanic population, and 8.2 per 100,000 in the white population.[4]

IMMUNOLOGIC ABNORMALITIES

After infection with HIV and without effective ART, HIV-infected persons experience a gradual but inexorable loss of host immunity that has been characterized as a syndrome of immune dysregulation, dysfunction, and deficiency, involving many components of the immune system. HIV is tropic for $CD4^+$ lymphocytes and monocytes.[8] After initial infection, HIV leads to massive depletion of $CD4^+$ lymphocytes of the effector-memory type from mucosal-associated lymphoid tissue.[9] During the chronic phase of untreated HIV infection, generalized immune activation occurs and ultimately, progressive decline in the naïve and memory T-cell pool results in

systemic $CD4^+$ lymphocyte depletion.[9,10] As well as being decreased in number, T cells are also dysfunctional and mount abnormal host responses to T-cell–dependent antigens. In addition, HIV infection is associated with B-cell dysfunction. Abnormal polyclonal activation, hypergammaglobulinemia, and lack of specific antibody responses ensue. This combination of immune dysfunction, dysregulation, and depletion of $CD4^+$ lymphocytes results in a substantially increased risk for infections and other complications over the course of HIV infection. Effective combination ART substantially decreases opportunistic infections and mortality in HIV-infected patients.[1] The chronic immune activation that occurs in the second phase of HIV infection can be decreased by combination ART.[9]

HIV infection also causes alteration in several lines of host defense in the lung and respiratory tract that contribute to an increased risk for pulmonary infections. These include abnormalities in mucociliary function and soluble defense molecules within respiratory secretions.[11] Within the lung parenchyma, innate and adaptive immune responses to pathogens may be impaired.[12] For example, alveolar macrophages, a primary reservoir of HIV within the lung, have been shown to have deficiencies in pathogen recognition. Evidence also suggests that HIV results in chronic stimulation and activation of inflammatory cells within the alveolar space.[11] Furthermore, animal models suggest that HIV-related proteins may disrupt the barrier function of the alveolar epithelium.[11a] The consequences of this persistently increased inflammation on the pathogenesis of chronic lung disease in HIV-infected persons are poorly understood.

DIAGNOSTIC APPROACH

The evaluation of an HIV-infected patient with pulmonary disease is aimed at making a specific diagnosis. Whenever possible, definitive diagnosis is preferred to empirical therapy for a number of reasons. Although each of the HIV-associated pulmonary diseases has characteristic clinical and radiographic features, these features overlap. Occasionally, the presenting features are atypical, or more than one pulmonary disease is present. Without appropriate therapy, HIV-infected patients with pneumonia can progress rapidly to respiratory failure and death. The therapies used to treat HIV-associated pulmonary diseases have substantial toxicities and interactions with other medications that a patient may be receiving for prophylaxis, for a comorbid condition, or as part of combination ART.

The evaluation should begin with the history and physical examination. Laboratory testing should be performed and a chest radiograph obtained from patients with suspected pulmonary disease. Frequently, the results of this evaluation suggest a specific differential diagnosis and management plan. Occasionally, additional studies, including pulmonary function testing, chest computed tomography (CT), high-resolution CT, and gallium-67 (^{67}Ga) scanning, are needed to narrow the differential diagnosis and to refine the management plan.

Owing to their particular importance in the diagnostic evaluation of many patients with known or suspected HIV-related pulmonary disease, the value of $CD4^+$ lymphocyte counts and fiberoptic bronchoscopy are briefly reviewed here. The utility of other diagnostic tests are considered in the discussions of the specific disorders that follow this section.

$CD4^+$ Lymphocyte Count

The $CD4^+$ lymphocyte count is an excellent indicator of an HIV-infected patient's risk of developing a specific opportunistic infection or neoplasm. Many of the HIV-associated pulmonary diseases usually present at or below a characteristic $CD4^+$ lymphocyte count and seldom occur above that count.[13] The exceptions are diseases that can present in persons without HIV infection, such as bacterial pneumonia, tuberculosis, and non-Hodgkin's lymphoma. In HIV-infected persons, these diseases can present at any $CD4^+$ lymphocyte count, although their incidence increases and their characteristic presentation changes as the $CD4^+$ lymphocyte count declines (see subsequent disease discussion).

At $CD4^+$ lymphocyte counts less than 200 cells/μL, bacterial pneumonia is often accompanied by bacteremia, and *Mycobacterium tuberculosis* disease is often extrapulmonary or disseminated. Moreover, below this $CD4^+$ lymphocyte count, *Pneumocystis* and *Cryptococcus neoformans* pneumonia become important considerations, whereas neither typically occurs in a patient with a count significantly higher than 200 cells/μL. At $CD4^+$ lymphocyte counts below 50 to 100 cells/μL, endemic fungi, certain viruses (cytomegalovirus), nontuberculous mycobacteria (*Mycobacterium avium* complex [MAC]), and Kaposi sarcoma become important considerations. Many of these diseases present with extrapulmonary or disseminated manifestations that may dominate the clinical presentation.

The risk of opportunistic infections is best reflected by the current $CD4^+$ lymphocyte count.[14] Primary and secondary *Pneumocystis* prophylaxis can be safely discontinued in patients whose $CD4^+$ lymphocyte counts increase above 200 cells/μL for at least 3 months in response to ART; similar evidence has emerged indicating that it is safe to discontinue primary and secondary prophylaxis against MAC, *C. neoformans,* and *Toxoplasma gondii* when $CD4^+$ lymphocyte counts have been restored to greater than 100 cells/μL (MAC) to 200 cells/μL (*C. neoformans* and *T. gondii*) for at least 3 months for primary prophylaxis and 6 months for secondary prophylaxis.[14]

Fiberoptic Bronchoscopy

Since the beginning of the AIDS epidemic, fiberoptic bronchoscopy has been a cornerstone in the evaluation of HIV-associated pulmonary disease. In general, bronchoscopy should be considered for any known or suspected HIV-infected patient with pulmonary disease whose severity warrants a prompt and accurate diagnosis, for patients with suspected pulmonary Kaposi

sarcoma, for patients with suspected non-Hodgkin's lymphoma (if other diagnostic procedures are thought to be more hazardous or less likely to provide the diagnosis), for patients whose diagnosis remains unknown despite less invasive diagnostic studies (e.g., induced sputum), and for patients whose empirical therapy is failing.

The decision to perform bronchoalveolar lavage (BAL) with or without transbronchial biopsy (TBBX) depends on the suspected diagnosis and on the sensitivities of these procedures for that diagnosis. At the beginning of the AIDS epidemic, both BAL and TBBX were usually performed during the initial bronchoscopy. Studies demonstrated that the yield from these two procedures was complementary in identifying pathogens: The sensitivity of BAL was 86% and that of TBBX 87%; when the two procedures were combined, the sensitivity was 98% for all pathogens and 100% for *Pneumocystis.*[15] Currently, we perform only BAL during the initial bronchoscopy in cases in which *Pneumocystis* pneumonia (PCP) is the suspected pathogen.[16] Our experience is that the sensitivity of BAL fluid examination for *Pneumocystis* is 97% or higher, and, therefore, a negative BAL fluid examination for *Pneumocystis* rules out the diagnosis of PCP in all but the rarest of cases.

In contrast to PCP, TBBX improves the sensitivity of bronchoscopy for diagnosing a number of other important pathogens, including tuberculosis and endemic fungal pneumonias. Furthermore, tissue confirmation from TBBX or another biopsy specimen is mandatory to establish the diagnosis of invasive aspergillosis, cytomegalovirus pneumonia, and pulmonary non-Hodgkin's lymphoma. Therefore, when the clinical and radiographic features suggest one of these diseases, both BAL and TBBX are warranted during the initial bronchoscopy.

Other Invasive Procedures

Other less commonly used invasive procedures include diagnostic thoracenteses, which should be considered for any HIV-infected patient with pleural effusion in whom other studies are nondiagnostic or in whom there is a concern about empyema. Although the addition of pleural biopsy increases the sensitivity of this procedure for tuberculosis, pleural fluid culture alone is often sufficient to establish the diagnosis of bacterial and fungal infections, and pleural fluid cytology can establish the diagnosis of non-Hodgkin's lymphoma. Transthoracic needle aspiration of the lungs can be used to diagnose focal mass lesions and mediastinal adenopathy.[17] Video-assisted thoracoscopy has made a number of important contributions. As a result, open-lung biopsy is only rarely indicated in the evaluation of HIV-associated pulmonary disease, but when used, it establishes a diagnosis in most cases.[18,19]

INFECTIOUS COMPLICATIONS

The lungs are the principal targets of the many infections that lead to an AIDS diagnosis and are often involved in earlier stages of HIV disease as well. In this section, the major pulmonary infectious complications of HIV disease are reviewed according to the category of infectious microorganism that causes them (see Table 80-1).

Bacteria

Early in the AIDS epidemic, bacterial pneumonia accounted for only a small proportion of reported pulmonary diseases. Subsequently, bacterial pneumonia became recognized as a frequent complication of HIV infection and one that often preceded other opportunistic infections. As a result, recurrent bacterial pneumonia (defined as two or more episodes within 12 months) was included as an AIDS-defining illness in the 1993 CDC Expanded Surveillance Case Definition for AIDS.[20]

Prior to the combination ART era, Hirschtick and coworkers in the Pulmonary Complications of HIV Infection Study (PCHIS)[21] confirmed the increased incidence of community-acquired bacterial pneumonia in HIV-infected persons. In this study, there were 5.5 episodes of bacterial pneumonia per 100 person-years in the HIV-infected cohort compared with 0.9 episodes per 100 person-years in the HIV-seronegative control cohort ($P < 0.001$). Bacterial pneumonia was more common in HIV-infected patients than in the HIV-seronegative controls, even in the subset of HIV-infected patients with $CD4^+$ lymphocyte counts above 500 cells/μL ($P < 0.004$). Furthermore, the rate of bacterial pneumonia in the HIV-infected cohort increased as the $CD4^+$ lymphocyte count declined. The rate of bacterial pneumonia was 2.3 episodes per 100 person-years in subjects with a $CD4^+$ lymphocyte count above 500 cells/μL compared to 10.8 episodes per 100 person-years in subjects with a $CD4^+$ lymphocyte count below 200 cells/μL. The incidence of bacterial pneumonia was greater in IDUs (11.1 episodes per 100 person-years) than in either MSM (4.1 episodes per 100 person-years, $P < 0.001$) or female partners of HIV-infected men (3.8 episodes per 100 person-years, $P < 0.003$). Cigarette smoking was also associated with an increased incidence of bacterial pneumonia, especially in HIV-infected subjects with a $CD4^+$ lymphocyte count below 200 cells/μL.

During the combination ART era (1996 to present), the incidence of community-acquired bacterial pneumonia among HIV-infected persons has declined, although it has not declined to as great an extent as opportunistic pneumonias such as PCP.[22] In the CDC-sponsored Adult/Adolescent Spectrum of HIV Disease project, a prospective medical record review of HIV-infected persons of age 13 years or older conducted in 11 U.S. cities, the incidence of recurrent pneumonia declined from 22.0 per 1000 person-years in 1992 to 10.7 per 1000 person-years in 1997.[23] Other studies have reported similar decreases from the use of combination ART in both community-acquired pneumonia[24] and hospital-acquired pneumonia.[25]

Thus, combination ART is clearly associated with a decreased risk for bacterial pneumonia. Antiretroviral regimens that contain an HIV protease inhibitor (PI) may be associated with a further decreased risk of bacterial pneumonia.[24] Another potential reason for decreased

bacterial pneumonia among HIV-infected patients in the current era is the use of trimethoprim-sulfamethoxazole (TMP-SMX) as prophylaxis for PCP.[26]

Yet despite the significant decrease in incidence, bacterial pneumonia remains a common cause of morbidity and is associated with an increased mortality in HIV-infected patients in the combination ART era.[26] One reason for the persistence of bacterial pneumonia despite effective ART is the high prevalence of cigarette smoking in HIV-infected populations.[27] Cigarette smoking is associated with substantially increased rates of pneumonia in multiple studies of HIV-infected patients, at all $CD4^+$ lymphocyte cell counts.[21,26,28] IDU remains a significant risk factor for bacterial pneumonia in the combination ART era. Higher HIV RNA (viral load) may also be associated with increased risk for bacterial pneumonia, independent of $CD4^+$ lymphocyte count.[29] Additionally, impairments in neutrophil number and function can occur in HIV infection, which may be exacerbated by concomitant cigarette smoking and contribute to increased risk for bacterial pneumonia.[11]

Overall, *Streptococcus pneumoniae* and *Haemophilus* species are the most frequently identified bacteria causing community-acquired pneumonia in HIV-infected persons. *Staphylococcus aureus* can be isolated as a cause of community-acquired pneumonia in patients both with and without a history of IDU.[29,30] *Pseudomonas aeruginosa* is also an important cause of bacterial pneumonia in HIV-infected patients. In one study, *S. pneumoniae* and *P. aeruginosa* were the two most common bacteria seen in a series of 111 cases.[30] Although this series included community-acquired as well as hospital-acquired pneumonias, most cases of pneumococcal pneumonia (91%) as well as pseudomonal pneumonia (63%) were community acquired. Other bacteria that are occasionally identified as causes of community-acquired pneumonia in HIV-infected persons include atypical organisms such as *Legionella* species and *Mycoplasma pneumoniae.* Other causes of pneumonia that are less likely in HIV-uninfected persons but should be considered in HIV-infected patients include *Rhodococcus equi* and *Nocardia* species.

The two most common bacterial causes of hospital-acquired pneumonia in HIV-infected persons are *P. aeruginosa* and *S. aureus.* Both of these organisms are more likely to be isolated in patients with lower $CD4^+$ lymphocyte counts.[25,31] Staphylococcal pneumonia is frequently complicated by bacteremia, methicillin resistance, and high mortality.[25] *Streptococcus pneumoniae* and *Klebsiella pneumoniae* are also relatively frequent causes of pneumonia in HIV-infected hospitalized patients.[25]

Streptococcus pneumoniae and Haemophilus Species

Similar to published series of community-acquired bacterial pneumonia in non–HIV-infected populations, *S. pneumoniae* and *Haemophilus* species are the most frequently identified pathogens in people with HIV infection. In several studies, the two organisms have accounted for approximately 50% to 60% of cases combined.[21,31] In studies of bacterial pneumonia in the combination ART era, *S. pneumoniae* and *Haemophilus influenzae* remain two of the most commonly isolated bacterial organisms.[29]

Clinical Features. In HIV-infected persons, the clinical and radiographic features of bacterial pneumonia are similar to those in immunocompetent persons (see discussion in Chapter 32), with a few important exceptions.

$CD4^+$ Lymphocyte Count. Bacterial pneumonia can occur throughout the course of HIV infection and at any $CD4^+$ lymphocyte count. As the $CD4^+$ lymphocyte count declines, however, both the incidence of bacterial pneumonia and the frequency of bacteremia increase. The rate of pneumococcal bacteremia in HIV-infected patients has been estimated to be almost 100 times greater than that in age-matched non–HIV-infected persons.[32] Findings that confer greater risk for bacteremic pneumococcal pneumonia include alcohol abuse, cigarette smoking, recent hospitalization, and presence of comorbid illnesses.[33]

Chest Radiograph. As illustrated in Figure 80-1, the majority of bacterial pneumonias due to *S. pneumoniae* in HIV-infected patients present with segmental, lobar, or multilobar consolidation on chest radiograph.[34] Radiographic findings of pneumococcal pneumonia do not appear to be different among patients on ART compared to those not on ART.[35] Although less common, focal or diffuse alveolar patterns as well as interstitial infiltrates in association with *S. pneumoniae* or *H. influenzae* can also occur.[36,37] Studies suggest that a "classic" presentation with consolidation of anatomic units may be seen more frequently in pneumonias due to *S. pneumoniae* and, to a lesser extent, *Haemophilus* species than in those due to community-acquired *P. aeruginosa.*

Diagnosis. The diagnostic approach to bacterial pneumonia is the same for HIV-infected as for non–HIV-infected persons (see Chapter 32).[14,38] HIV-infected patients continue to be at increased risk for invasive pneumococcal disease in the combination ART era.[39] Definitive diagnosis is possible in the 25% to 80% of HIV-infected patients with pneumococcal pneumonia who present with bacteremia, and in the 5% to 25% of those with *H. influenzae* pneumonia with bacteremia. Thoracentesis should be considered for patients with pleural effusion, especially if the effusion is large or if there is concern about a possible empyema. Efforts to culture the causative bacteria to enable drug susceptibility testing are especially important in communities where drug-resistant bacteria are prevalent.

Pneumococcal urinary antigen testing offers the potential for early, specific diagnosis. In a study of 70 adults with pneumococcal pneumonia, 47 of whom were HIV infected, pneumococcal urinary antigen testing had a sensitivity of 81%, specificity of 98%, positive predictive value of 98%, and negative predictive value of 82%.[40] The test appeared to perform equally well in HIV-infected and HIV-uninfected persons.

Serum procalcitonin and C-reactive protein levels may assist in early differentiation of bacterial community-

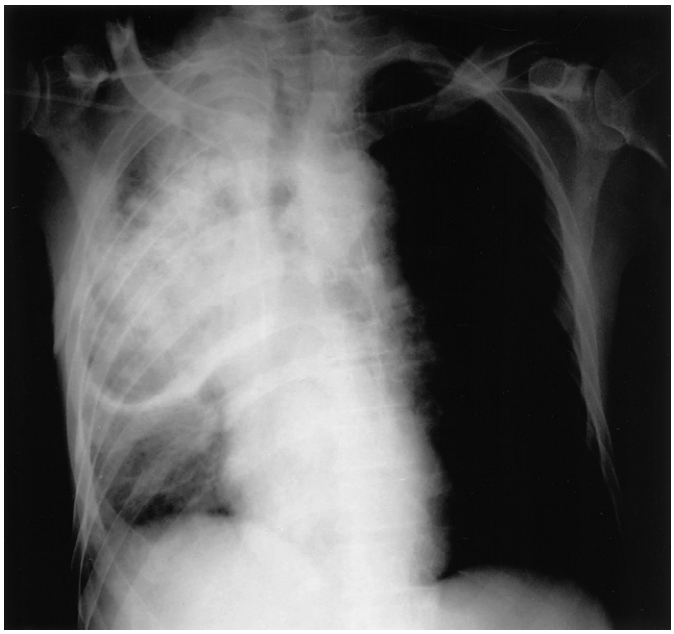

FIGURE 80-1 ■ Posteroanterior chest radiograph of an HIV-seropositive patient showing focal right lung consolidation. Culture of blood and sputum revealed *Streptococcus pneumoniae.* In HIV-infected persons, *S. pneumoniae* is the most frequently identified bacterial pathogen and is often accompanied by bacteremia, especially when the $CD4^+$ lymphocyte count is below 200 cells/μL. (Courtesy of L. Huang.)

acquired pneumonia and pulmonary tuberculosis in HIV-infected patients, as shown by the results of a study from South Africa; procalcitonin and C-reactive protein levels were found to be higher in patients with bacterial pneumonia compared to patients with pulmonary tuberculosis, although overlap occurred between the groups.[41] Because procalcitonin increases in response to microbial toxins and decreases in the presence of viral infections, levels are being used as a biologic marker of community-acquired pneumonia.[42]

Treatment. The principles of the treatment of patients with community-acquired pneumonia are similar for HIV-infected and non–HIV-infected persons.[14,38,43] The choice of antimicrobial agent should be based on a number of factors, such as the results of a sputum Gram stain, the presence of comorbid conditions (e.g., chronic obstructive pulmonary disease, congestive heart failure, alcohol use), the clinical and radiographic presentation, and the severity of the pneumonia. As for non–HIV-infected persons, treatment should be initiated promptly. Initial empirical therapy should include coverage against frequently identified organisms (e.g., *S. pneumoniae* and *Haemophilus* species). Prevailing drug resistance patterns must be considered when the antibiotic is selected. Empirical monotherapy with a macrolide is not advised in HIV-infected patients, particularly if they are already on macrolide prophylaxis for MAC, given increasing pneumococcal resistance rates.[14] Patients on TMP-SMX prophylaxis may be more likely to have penicillin- and TMP-SMX–resistant *S. pneumoniae.*[44] For patients with $CD4^+$ lymphocyte counts less than 100 cells/μL, especially if associated with recent hospitalization, neutropenia, and broad-spectrum antimicrobial use, consideration should be given to including coverage against *P. aeruginosa.*

Prevention. The National Institutes of Health (NIH), the CDC, and the HIV Medical Association of the Infectious Diseases Society of America (HIVMA/IDSA) recommend that the 23-valent polysaccharide pneumococcal vaccine be given to all HIV-infected patients with $CD4^+$ lymphocyte counts above 200 cells/μL and be considered for patients with $CD4^+$ lymphocyte counts below 200 cells/μL.[14] The efficacy of vaccination is believed to be the greatest when the patient's $CD4^+$ lymphocyte count is above 500 cells/μL.[45] Observational studies also suggest, however, that pneumococcal vaccination lowers risk for pneumonia even when $CD4^+$ lymphocyte counts are less than 200 cells/μL.[46] Revaccination can be considered for patients who were initially immunized when their $CD4^+$ lymphocyte count was below 200 cells/μL if their count has increased above 200 cells/μL in response to combination ART. The duration of the protective effect of primary pneumococcal vaccination in HIV-infected persons is unknown; revaccination 5 years after the initial vaccination may be appropriate.[14]

Pseudomonas aeruginosa

In addition to being a cause of nosocomial disease, *P. aeruginosa* is well recognized as a cause of community-acquired bacterial pneumonia in HIV-infected persons, especially those with advanced AIDS. In contrast to non–HIV-infected persons, the classic risk factors for *P. aeruginosa* infection are often absent in HIV-infected patients, and the disease often recurs.[47]

Pseudomonas aeruginosa infection produces a wide spectrum of disease in HIV-infected persons. The two most common presentations are pneumonia and bacteremia. Unlike pneumonia due to *S. pneumoniae* and *Haemophilus* species, however, pneumonia due to *P. aeruginosa* usually occurs at more profound degrees of immunosuppression, and the chest radiograph often reveals cavitary infiltrates. The usual symptoms include fever and cough that is productive, with dyspnea and chest pain seen less frequently.[48]

$CD4^+$ Lymphocyte Count. Most cases of *P. aeruginosa* pneumonia occur in HIV-infected patients with a $CD4^+$ lymphocyte count less than 100 cells/μL, and usually less than 50 cells/μL.[48,49]

Chest Radiograph. Although the chest radiograph may resemble that seen in pneumococcal or *Haemophilus* pneumonias with focal consolidation, a significant proportion of radiographs demonstrate cavitary infiltrates. Schuster and Norris[48] reported that half of 16 HIV-infected patients with *Pseudomonas* pneumonia had cavitary infiltrates on their admission chest radiograph, and another 3 patients (19%) had cavities on subsequent radiographs. Less striking results were noted in a study of 58 HIV-infected patients with *P. aeruginosa* infection in whom 24% of the 25 patients with pneumonia had cavitary infiltrates on chest radiograph.[50]

Other Bacteria

Legionella pneumonia is an infrequent cause of bacterial pneumonia in HIV-infected patients. Blatt and coworkers[51] reported eight cases of *Legionella pneumophila* pneumonia occurring in seven HIV-infected patients; five of the cases were nosocomial. The median $CD4^+$ lymphocyte count was 83 cells/μL (range, 38 to 155 cells/μL). Another series reported 15 cases of *Legionella pneumophila* pneumonia that spanned the combination ART era; 10 of the 15 cases occurred in persons who were receiving ART, and the mean $CD4^+$ lymphocyte count was 348 cells/μL.[52] Five of the 10 also had an undetectable HIV RNA level. The chest radiograph revealed alveolar infiltrates in all 15 cases, with 8 of the 15 having bilateral involvement. Extrapulmonary manifestations (gastrointestinal, $n = 3$; neurologic, $n = 4$) were also seen. Of note, 12 (80%) of the 15 persons developed respiratory failure and 3 died. Although *L. pneumophila* is the most common species identified, other *Legionella* species have also been reported. Rapid diagnosis of *Legionella* pneumonia can be attained with urinary antigen testing. However, cultures and/or serology should still be considered as part of the diagnostic evaluation, as the urinary antigen primarily detects *L. pneumophila* serogroup 1 and can have a lower sensitivity in cases of mild disease.[53] Its performance has also not been prospectively evaluated in HIV-infected patients.

There have been a number of reports of *R. equi* pulmonary disease occurring in HIV-infected persons. A review of over 100 reported cases of *R. equi* infection found that approximately two thirds occurred in HIV-infected persons, with pulmonary disease present in the majority.[54] HIV-infected persons were more likely to have *R. equi* bacteremia or extrapulmonary manifestations, or both, than persons without HIV infection. Most cases present when the $CD4^+$ lymphocyte count is less than 200 cells/μL and usually below 100 cells/μL.[54] In one multicenter series of 67 HIV-infected patients with *R. equi* infection, the mean $CD4^+$ lymphocyte count was 35 cells/μL (range, 1 to 183 cells/μL).[55] The chest radiograph often reveals cavitary lesions that may mimic tuberculosis or nocardiosis, or focal consolidation that may mimic bacterial pneumonia. Sputum, blood, bronchoscopy, and pleural fluid specimens can establish the diagnosis of *R. equi* pneumonia.[55] The optimum treatment regimen and duration have yet to be defined.[54] Combination antimicrobial therapy is generally recommended, and treatment for 6 months is often required; because relapses are common, chronic suppressive therapy is probably indicated.

There have been a handful of reports of *Nocardia* species infection in HIV-infected patients. *Nocardia asteroides* is the most common species identified, and the lung is the most commonly affected site. Most cases present when the $CD4^+$ lymphocyte count is below 200 cells/μL. In one series of 30 HIV-infected patients with nocardiosis, the mean $CD4^+$ lymphocyte count was 109 cells/μL (median 92 cells/μL; range, 12 to 266 cells/μL).[56] The presenting symptoms often mimicked tuberculosis. The chest radiograph usually reveals cavitary lesions or lobar or multilobar infiltrates, especially in the upper lung zones, although reticulonodular infiltrates, solitary masses, and pleural effusions can also be seen.[57] Sputum or bronchoscopy can establish the diagnosis of pulmonary nocardiosis. A modified acid-fast bacilli (AFB) stain may provide an early presumptive diagnosis in the proper clinical setting. Long-term TMP-SMX is the treatment of choice.

Mycobacteria

Early in the AIDS epidemic, mycobacteria were recognized as major sources of HIV-associated morbidity and mortality. Initially, HIV-infected patients were noted to develop disseminated MAC. Subsequently, the relationship between HIV and *M. tuberculosis* and nontuberculous mycobacteria such as *Mycobacterium kansasii* became clearer. Other nontuberculous mycobacteria are also occasionally identified as causes of pneumonia in HIV-infected persons.

Mycobacterium tuberculosis

Tuberculosis is the most prevalent opportunistic infection complicating the HIV epidemic worldwide. Although other pathogens may predominate in individual areas, no other pathogen poses as great a global threat to persons immunocompromised by HIV infection as *M. tuberculosis.* Moreover, unlike most of the HIV-associated opportunistic infections, *M. tuberculosis* is transmissible from person to person, including to those without HIV infection. In fact, it has been found that clusters of transmission of tuberculosis that include at least one HIV-infected person are larger, last longer, and have a shorter time period between successive cases than clusters of solely HIV-negative persons.[58] The disease is also curable and preventable.

The AIDS epidemic has contributed to a veritable explosion of tuberculosis throughout the world, but especially in low-income countries, where it is often the first manifestation of HIV and a leading cause of mortality. The World Health Organization estimated that, in 2007, of the 9.27 million new cases of tuberculosis worldwide, 1.37 million (14% of the total) occurred in

persons with HIV, most of whom lived in sub-Saharan Africa and Southeast Asia; of the 1.78 million total deaths from tuberculosis, 0.46 million (26%) were in HIV-infected persons.[59] Deaths from tuberculosis among HIV-infected people accounted for 23% of the estimated 2 million total HIV deaths in 2007.

The AIDS epidemic has also affected tuberculosis in the United States. Before 1985, the incidence of tuberculosis in the United States regularly declined by 5% to 6% per year. From 1985 through 1992, tuberculosis cases increased by 20%, which resulted in 51,700 additional cases of tuberculosis being reported in excess of that predicted by the annual decline previously noted.[60] Tuberculosis cases have decreased since 1992, with the 2008 incidence being the lowest reported since 1953, when national reporting began; however, the rate of decline has now slowed.[61] The proportion of tuberculosis cases with known HIV infection has also decreased from 15.0% in 2003 to 12.4% in 2006; however, the proportion of cases with HIV discovered at the time of tuberculosis diagnosis has increased from 28.7% in 2005 to 31.7% in 2006.[62]

It remains unclear whether HIV-infected persons are more likely to acquire tuberculous infection after exposure to *M. tuberculosis* than HIV-negative persons. Once an individual becomes infected, however, there is no doubt that HIV infection significantly increases the risk of developing primary tuberculosis as well as progressing from latent tuberculosis infection (LTBI) to active tuberculous disease. Instead of a 5% lifetime risk of "reactivation" disease, the risk among HIV-infected persons with LTBI in the pre–combination ART era has been estimated to be as high as 10% per year.

Multidrug-resistant tuberculosis (MDR-TB), defined as resistance to at least isoniazid and rifampin (also known as rifampicin in many countries), poses a particularly grim prospect for the HIV-infected person. The risk of drug-resistant tuberculosis has been reported to be greater among HIV-infected patients than among others, and drug-resistant tuberculosis appears to be associated with decreased survival.[63] In a multivariate analysis, HIV infection was found to be an independent risk factor for at least isoniazid resistance, for both isoniazid and rifampin resistance, and especially for rifampin monoresistance.[64] A meta-analysis of risk factors for MDR-TB in Europe found that HIV was an independent risk factor (odds ratio = 3.52).[65] In addition, HIV-infected patients treated with intermittent rifabutin-based therapy have been found to have a high risk of acquired rifamycin resistance, particularly if their $CD4^+$ lymphocyte count is less than 100 cells/μL.[66] Factors that lead to acquired drug resistance include an inadequate initial treatment regimen, patient nonadherence with the prescribed regimen, and the addition of a single drug to a failing regimen. Studies using restriction fragment length polymorphism analysis have shown that MDR-TB can also occur as a result of exogenous reinfection from a multidrug-resistant source.[67]

Extensively drug-resistant tuberculosis (XDR-TB), defined as resistance to at least isoniazid and rifampin (i.e., MDR-TB), plus resistance to any fluoroquinolone and to at least one second-line injectable drug, was first reported in 2006.[68] It has been documented in all regions of the world and in HIV-infected persons.[69,69a,69b] It is likely that the true extent of XDR-TB is unknown because many laboratories are unable to perform susceptibility tests, particularly to second-line drugs, and rely only on smear results for diagnosing tuberculosis. A case series of 53 persons with XDR-TB in South Africa found that, of the 44 patients who underwent HIV testing, all were HIV infected; 52 of the 53 patients died, and the median survival was only 16 days.[70] Epidemiologic evidence strongly suggested that the outbreak of XDR-TB was a result of person-to-person transmission, especially in a nosocomial setting.

Clinical Features. Worldwide, tuberculosis is the most common initial manifestation of underlying HIV infection. The clinical and radiographic features of tuberculosis in both HIV-infected and non–HIV-infected persons vary and are fully discussed in Chapter 34. HIV infection is independently associated with an increased risk for extrapulmonary tuberculosis.[71]

$CD4^+$ Lymphocyte Count. Tuberculosis may develop throughout the course of HIV infection, regardless of the $CD4^+$ lymphocyte count, but the incidence increases as the count decreases; tuberculosis is much less common in patients receiving ART but still occurs. The clinical expression of tuberculosis in HIV-infected persons is largely dependent on the degree of host immunosuppression as indicated by the $CD4^+$ lymphocyte count (Table 80-2).[72] HIV-infected persons with relatively early HIV disease typically present with a picture suggestive of reactivation tuberculosis, with disease usually limited to the lungs. In contrast, persons with more advanced HIV disease typically present with a picture reminiscent of primary pulmonary tuberculosis, often with disseminated or extrapulmonary tuberculosis. In a series of 97 HIV-infected patients with tuberculosis, Jones and colleagues[72] reported that extrapulmonary tuberculosis was seen in 30 (70%) of 43 patients with a $CD4^+$ lymphocyte count of 100 cells/μL or fewer, in 10 (50%) of 20 patients with a count between

TABLE 80-2. Manifestations of AIDS-Related Tuberculosis in "Early" and "Late" HIV Infection

Feature	Early Infection	Late Infection
Tuberculin skin test	Positive	Negative
Extrapulmonary	10–15%	More than 50%
Radiographic findings		
Distribution	Upper zones	Lower and middle zones
Cavitation	Common	Uncommon
Adenopathy	Uncommon	Common
Miliary	Uncommon	Common
Pleural effusion	Uncommon	Rare

Adapted from Murray JF: Cursed duet: HIV infection and tuberculosis. Respiration 57:210–220, 1990.

101 and 200 cells/μL, in 7 (44%) of 16 patients with a count between 201 and 300 cells/μL, and in only 5 (28%) of 18 patients with a count above 300 cells/μL. Virtually any extrapulmonary site may be involved; common sites include lymph nodes (usually cervical, supraclavicular, and axillary), bone marrow, genitourinary tract, central nervous system, and liver.[73]

Chest Radiograph. The prevalence of specific chest radiograph features of tuberculosis also depends on the degree of host immunosuppression. Disease occurring early in the course of HIV infection mirrors that encountered in immunocompetent persons: upper lung zone infiltrates, often with cavitation, on chest radiograph. However, tuberculosis occurring later in the course of HIV infection often presents with middle and lower lung zone infiltrates, as illustrated in Figure 80-2; with diffuse infiltrates, including a miliary pattern; or with a normal chest radiograph. As the $CD4^+$ lymphocyte count declines, cavitation becomes less common and intrathoracic adenopathy, as shown in Figure 80-3, becomes more common. Jones and colleagues[72] reported that adenopathy was seen on the radiographs of 20 (34%) of 58 HIV-infected patients with a $CD4^+$ lymphocyte count of 200 cells/μL or fewer compared with 4 (14%) of 29 patients with a $CD4^+$ lymphocyte count above 200 cells/μL ($P = 0.04$). Combination ART also affects the chest radiographic appearance in HIV-infected patients with tuberculosis; in one study of 209 patients, 82% of the patients receiving ART presented with a post-primary pattern of tuberculosis compared to 44% of the patients not receiving ART ($P < 0.001$).[74]

Diagnosis. The diagnostic approach to tuberculosis is the same for HIV-infected as for non–HIV-infected persons (see Chapter 34). Two to three sputum specimens should be examined for AFB and cultured for mycobacteria; a third sputum smear adds little to the diagnosis, but all three specimens, when available, should be cultured for mycobacteria.[74a] In patients with a nonproductive cough or scant secretions, sputum induction should be performed. In addition, the sensitivity of sputum mycobacterial culture for HIV-infected patients with pleural effusions due to tuberculosis has been reported to be as high as 77%, and samples from extrapulmonary sites have a higher sensitivity in those with advanced immunodeficiency.[75]

The "gold standard" diagnostic test for tuberculosis remains the isolation and identification of *M. tuberculosis* by culture or by polymerase chain reaction (PCR). Virtually any specimen can be studied for mycobacteria, including sputum, pleural fluid, urine, cerebrospinal fluid, and BAL fluid; Wang needle, fine-needle, and bone marrow aspirates; and all biopsy specimens. Blood cultures are specific and should be obtained, especially from those persons with a $CD4^+$ lymphocyte count below 200 cells/μL. All cultures positive for *M. tuberculosis* should be submitted for susceptibility testing, as the results are essential in identifying cases of drug resistance and in tailoring definitive treatment.

Treatment. New recommendations for the treatment of tuberculosis are described in Chapter 34. Because tuberculosis is transmissible, persons with suspected tuberculosis should be promptly started on empirical antituberculosis treatment to reduce the risk of transmission. The detection of AFB on smear or in culture, regardless of the source, is an indication for empirical antituberculosis treatment while final identification is awaited. HIV-infected persons with suspected tuberculosis should be started on four antituberculous

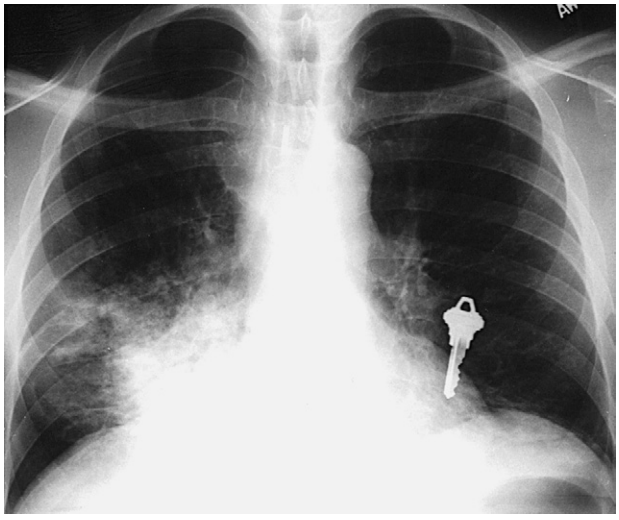

FIGURE 80-2 ■ Posteroanterior chest radiograph of an HIV-seropositive patient showing focal right lung consolidation with air bronchograms. Culture of sputum revealed *Mycobacterium tuberculosis* that was mono-rifampin resistant. Knowledge of the patient's $CD4^+$ lymphocyte count (<50 cells/μL) and understanding that tuberculosis can present with middle to lower lung zone consolidation during "late" HIV infection were instrumental in making the diagnosis of tuberculosis. The key was in the patient's pocket. (Courtesy of L. Huang.)

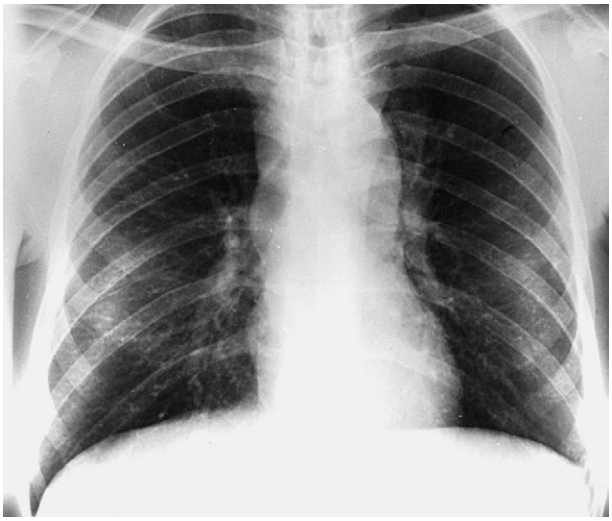

FIGURE 80-3 ■ Posteroanterior chest radiograph of an HIV-seropositive patient showing mediastinal adenopathy. Culture of biopsy material revealed *Mycobacterium tuberculosis.* Among HIV-infected persons, the proportion of cases that present with intrathoracic adenopathy on chest radiograph increases as the $CD4^+$ lymphocyte count decreases. (From Murray JF, Mills J: Pulmonary complications of HIV infection. Am Rev Respir Dis 141:1356–1372, 1582–1598, 1990.)

drugs: isoniazid, rifampin, pyrazinamide, and ethambutol along with pyridoxine.[76] When results of species identification and susceptibility testing become available, drug selection can be tailored as needed. In the United States, the response to therapy and the time to convert sputum cultures from positive to negative appear to be similar in HIV-infected and non–HIV-infected patients.[76] In sub-Saharan Africa, however, the likelihood of death, especially during the first 2 months of therapy, and of relapse following apparently successful treatment is considerably higher in HIV-infected than in non–HIV-infected patients.[77]

HIV-infected patients with tuberculosis are more likely to experience toxicity from antituberculous drugs than are non–HIV-infected persons. One series found that serious adverse events occurred in 40% of HIV-infected patients with tuberculosis compared to 26% of HIV-uninfected persons ($P = 0.008$).[78] HIV-infected patients are frequently receiving a number of additional medications, and it is often difficult to distinguish an adverse drug effect to antituberculous drugs from adverse effects from these other medications. As a result, the first-line antituberculous drugs (especially isoniazid and rifampin) should only be discontinued permanently if there is strong evidence that these medications were the cause.[76]

Moreover, HIV-infected patients who are receiving or who are initiating combination ART at the time that tuberculosis is diagnosed pose a special problem for the treatment of tuberculosis. HIV-infected patients with tuberculosis who begin therapy for both *M. tuberculosis* and HIV infection may develop immune reconstitution inflammatory syndrome (IRIS), a paradoxical reaction presenting as a temporary exacerbation of clinical and radiographic features, which appears to be more common among those starting ART within 6 weeks of initiating antituberculosis therapy and among those with disseminated tuberculosis.[79] However, ART use during tuberculosis treatment has been associated with improved survival and more rapid conversion of sputum smears and culture.[80] Once begun, it is crucial that ART be continued without interruption for maximum, durable results. The optimal timing for initiating combination ART in an HIV-infected patient who is being treated for tuberculosis remains to be defined, but it is generally recommended to wait at least 2 weeks or longer depending on the degree of immunocompromise.[14]

Furthermore, the simultaneous treatment of HIV and *M. tuberculosis* poses additional challenges in terms of drug interactions. Both HIV PIs and non-nucleoside reverse transcriptase inhibitors (NNRTIs) have significant interactions with the rifamycins, principally related to the induction or inhibition (or both) of the hepatic cytochrome P-450 (CYP) enzyme system.[76] Decreased drug levels are associated with the development of resistance by both HIV and *M. tuberculosis,* whereas increased drug levels are correlated with toxicity. Rifabutin is preferred to rifampin in persons receiving PIs as it is a less potent CYP 3A4 inducer than rifampin. Information on the interactions between specific antiretroviral drugs and different rifamycins is constantly being updated and can be found on such websites as the CDC website (http://www.cdc.gov/tb/). Clinicians caring for HIV-infected patients with tuberculosis should consult experts for aid in management prior to initiating tuberculosis or HIV therapy.

Prevention of Exposure. Because tuberculosis can be transmitted from person to person, HIV-infected persons should be advised to avoid settings in which they might be exposed to tuberculosis (i.e., jails, group homes, homeless shelters).[14] In hospitals and health care facilities, all persons with HIV infection and signs or symptoms compatible with tuberculosis should be placed in respiratory isolation until three sputum smears are negative or another disease is diagnosed. Prevention of transmission of drug-resistant tuberculosis is particularly important, both for those with and without HIV infection. In a modeling study, it was shown that mask use and a shift to outpatient therapy could prevent about one third of XDR-TB cases in a highly prevalent area; additional measures such as improved ventilation, rapid drug sensitivity testing, HIV treatment, and tuberculosis isolation facilities were also found to be effective preventive measures, but involuntary detention for XDR-TB treatment was thought to possibly lead to an increase in transmission.[81] Ultraviolet lights are also useful but costly.

Prevention of Disease. HIV-infected persons are at high risk for progressing from LTBI to active tuberculosis. Therefore, HIV-infected persons should be tested for LTBI by either a tuberculin skin test or interferon-γ (IFN-γ) release assay when HIV infection is first identified.[14,82] Repeat testing each year should be considered for persons who have a negative response to either test and who are at risk for exposure to *M. tuberculosis.* In addition, strong consideration should be given to retesting persons who initially had a negative test but subsequently experienced an increase in their $CD4^+$ lymphocyte count due to combination ART.

Several studies document that the risk of LTBI reactivation is virtually eliminated if an HIV-infected person who has been infected with a drug-susceptible organism takes adequate prophylaxis.[14,82] HIV-infected persons with a positive tuberculin skin reaction (5-mm rather than the conventional 10-mm induration), with a history of a positive tuberculin response who have not received prior treatment for LTBI or active tuberculosis, or with a positive IFN-γ release assay should receive isoniazid (daily or twice weekly) plus pyridoxine for 9 months.[14] An alternative treatment for LTBI is rifampin daily for 4 months; if the patient is also receiving ART with a PI or with delavirdine (an NNRTI), expert consultation should be sought. The two-drug regimen of rifampin plus pyrazinamide for 2 months is no longer recommended due to an increased incidence of severe hepatotoxicity and death.[83] At present, the routine use of preventive therapy in anergic or purified protein derivative (PPD)–negative, HIV-infected persons is not generally recommended.[14,82]

HIV-infected persons, including HIV-infected health care workers who have experienced a significant tuberculosis exposure (sufficient to cause PPD conversions in immunocompetent persons), should be offered appropriate chemoprophylaxis. HIV-seropositive persons who have converted their PPD test after exposure to MDR-TB

or anergic HIV-seropositive persons who have experienced a significant contact with MDR-TB should be offered prophylaxis based on the susceptibilities of the MDR-TB case to which they were exposed. Paramount in the management of such patients is the active involvement of an expert in the treatment of drug-resistant tuberculosis.

Mycobacterium avium Complex

As fully discussed in Chapter 35, the *Mycobacterium avium* complex consists of several related *Mycobacterium* species, including *M. avium* and *Mycobacterium intracellulare.* Until 1980, only 24 cases of disseminated MAC had been reported.[83] After the onset of the AIDS epidemic, the number of cases rose dramatically. With the increased use of combination ART, however, the incidence of disseminated MAC has declined since 1996.[1]

The pathogenesis of disseminated MAC is incompletely understood, but it is believed to result from primary acquisition of the microorganism, which is ubiquitous in the environment, rather than reactivation of latent infection.[84] These mycobacteria probably enter the body chiefly through the gastrointestinal tract and occasionally through the lungs.[85] Person-to-person transmission is believed to be unlikely. Nearly all cases of disseminated MAC are caused by *M. avium* serotypes, which suggests that there are important differences in exposure to or virulence of these particular strains.

Clinical Features. Although the lungs are an important potential portal of entry for MAC into the bloodstream, isolated MAC pulmonary disease is rare.[86] The most common clinical presentation of disseminated MAC disease is a febrile, wasting syndrome consisting of fever, night sweats, fatigue, anorexia, and weight loss; other manifestations include abdominal pain and chronic diarrhea, hepatosplenomegaly, lymphadenopathy, progressive anemia, and, rarely, extrabiliary obstructive jaundice.[87]

$CD4^+$ Lymphocyte Count. More than 95% of cases of disseminated MAC occur in HIV-infected patients whose $CD4^+$ lymphocyte count is 50 cells/μL or less.[87] Laboratory abnormalities include anemia, which is often severe, and an elevated alkaline phosphatase level. Other associated factors include a plasma HIV viral level greater than 100,000 copies/mL, history of previous opportunistic infection(s), and previous MAC colonization of the respiratory or gastrointestinal tract.[14]

Chest Radiograph. The chest radiograph is typically normal, even when the organism is cultured from respiratory tract secretions.[85] Focal pneumonia has been reported, but is extremely rare.[86] More frequently seen—but still uncommon—are endobronchial lesions without pneumonia.[88] These endobronchial lesions appear to be submucosal "pearls" that are teeming with AFB on biopsy. Many of the reported cases of isolated pulmonary MAC occurred in patients who received combination ART, thus raising the possibility that this particular manifestation is an example of immune reconstitution. Clinicians should be aware of this possibility when starting patients on ART as it may occur either in patients with diagnosed disease or in those with subclinical infection.

Diagnosis. In HIV-infected patients with MAC, the organism can be cultured from numerous sites, but the most productive sources are blood, bone marrow, liver, or lymph nodes.[81] The sensitivity of blood cultures for disseminated MAC has ranged from 86% to 98% of cases in which disseminated disease was confirmed by autopsy. The diagnosis of disseminated MAC can also be established by cultures from any normally sterile body site. Often, MAC is cultured from respiratory specimens such as sputum or BAL fluid, but this finding may not be indicative of either pulmonary or disseminated disease depending on the clinical situation.[85,89] If patients have abnormal chest radiographs with positive sputum cultures, the diagnostic criteria for nonimmunosuppressed hosts recommended by the American Thoracic Society and the Infectious Disease Society of America (ATS/IDSA), which are listed in Table 35-3, should be applied.[89] The pathologic findings of MAC infection are characteristic, but not definitive; AFB are remarkably abundant and are often packed within foamy macrophages or histiocytes; granulomas are usually absent or poorly formed.

Treatment. Although there are several efficacious treatment regimens, the optimal one for treating disseminated MAC is still debated.[14,89] As emphasized in Chapter 35, the key to any regimen is the inclusion of a macrolide: clarithromycin (500 mg twice daily) is preferred, but azithromycin (500 to 600 mg daily) can be substituted if needed. One of these should be combined with ethambutol (15 mg/kg/day) plus, as recommended by many experts, the addition of rifabutin (300 mg daily), although the principal benefit of rifabutin appears to be in decreasing the risk of macrolide drug resistance among those patients who responded to therapy.[90] As with tuberculosis, the use of rifabutin must be carefully scrutinized with concurrent administration of an NNRTI or a PI. Use of a third or fourth agent can be considered in patients with advanced immunosuppression, high mycobacterial burden, or the inability to use ART.[14] Currently, in the setting of combination ART with increases in the $CD4^+$ lymphocyte count to above 100 cells/μL for at least 6 months—and after a minimum of 12 months of a macrolide-based MAC treatment regimen—most patients have been able to discontinue therapy without relapse.[14]

Prevention. Although MAC can be found in environmental sources such as food and water, there are no specific recommendations regarding exposure avoidance as a prevention strategy. Similarly, although the presence of MAC in a stool or respiratory specimen is predictive of disseminated disease, routine screening of either is not recommended. The NIH, CDC, and HIVMA/IDSA guidelines recommend that MAC prophylaxis be administered to HIV-infected patients with a $CD4^+$ lymphocyte count less than 50 cells/μL and no clinical evidence of disseminated MAC; a number of different MAC prophylaxis regimens are available, including azithromycin (1200 mg weekly or 600 mg twice weekly), clarithromycin (500 mg twice daily), or rifabutin (300 mg daily).[14] If rifabutin is to be used, tuberculosis should first be ruled out. Primary MAC prophylaxis should be

discontinued in persons who have experienced a significant response to ART with an increase in their $CD4^+$ lymphocyte count to greater than 100 cells/μL for at least 3 months.[14]

Mycobacterium kansasii

As documented in Chapter 35, *M. kansasii* has a particular geographic distribution, predominantly in the southern and central United States.[89] Clusters of disease have also been reported in Europe, Asia, and Africa. Prior to the AIDS epidemic, infection and disease due to *M. kansasii* were uncommon; thereafter, a dramatic increase in the incidence associated with HIV infection was observed, even in nonendemic areas. Bloch and associates[91] found a cumulative incidence of *M. kansasii* infection of 2.4 cases per 100,000 HIV-infected adults in three counties in northern California, a rate that is almost five times higher than the national rate. Although *M. kansasii* pulmonary disease can be clinically indistinguishable from tuberculosis,[92] no person-to-person transmission has been documented, and infection is thought to occur from environmental sources.

$CD4^+$ Lymphocyte Count. Similar to tuberculosis in HIV-infected persons, *M. kansasii* pneumonia can occur at any $CD4^+$ lymphocyte count. Most HIV-infected patients with *M. kansasii,* however, have evidence of severe immunosuppression with $CD4^+$ lymphocyte counts below 100 cells/μL.[91-93] In a study from the combination ART era, Canueto-Quintero and colleagues[92] reported a mean $CD4^+$ lymphocyte count of 20 cells/μL among 25 HIV-infected patients with *M. kansasii.* Witzig and coworkers[93] found that 32 (65%) of 49 HIV-infected patients with *M. kansasii* had isolated pulmonary disease (mean $CD4^+$ lymphocyte count, 75 cells/μL), whereas the remainder had disseminated disease (mean $CD4^+$ lymphocyte count, 28 cells/μL).

Chest Radiograph. The chest radiographic findings of *M. kansasii* are varied. The most common radiographic findings resemble tuberculosis and include alveolar infiltrates, diffuse infiltrates, and cavities (see Fig. 35-5); masses, intrathoracic adenopathy, and pleural effusions have also been reported. In a series of 83 HIV-infected patients with *M. kansasii,* the most frequent findings were consolidation (66%) and nodules (42%); abnormalities were most often located in the mid-lung and lower lung zones (89%), and in 10%, the radiographs were normal.[94]

Diagnosis. The diagnosis of *M. kansasii* rests on its isolation and subsequent identification by culture. Pulmonary disease can be diagnosed by all of the techniques used for the diagnosis of tuberculosis. Unlike tuberculosis, however, in which identification of *M. tuberculosis* is diagnostic of disease, the identification of *M. kansasii* can occasionally represent colonization rather than disease.[95] As already mentioned, the ATS/IDSA have defined criteria for the diagnosis of nontuberculous mycobacterial pulmonary disease that includes *M. kansasii,* which can be found in Table 35-3 and in the paper by Griffith and colleagues.[89] In addition, the use of subtyping defined by PCR–restriction enzyme analysis of the *hsp65* gene may help distinguish pathogenic from nonpathogenic isolates.[96]

Treatment. The recommended regimen for treatment of *M. kansasii* pulmonary disease consists of isoniazid (300 mg daily), rifampin (600 mg daily), and ethambutol (15 mg/kg daily).[89] Patients should also receive pyridoxine (50 mg daily) during treatment. Patients who are taking PI or NNRTI therapy for HIV infection should receive rifabutin or clarithromycin in place of rifampin. Pyrazinamide is unacceptable as an alternative drug because all *M. kansasii* isolates are resistant. Patients should receive treatment for a minimum of 12 months after their cultures have converted to negative.

Prevention. There are no recommended prevention strategies for *M. kansasii.*

Other Mycobacteria

MAC and *M. kansasii* account for the great majority of nontuberculous mycobacterial infections complicating HIV disease. Other mycobacteria, however, have been occasionally identified.[87,97] Increased frequency of exposure or specific defects in host defenses might account for the predominance of MAC and to a lesser extent *M. kansasii* in AIDS patients, but the reasons for this striking disparity are unknown.

Fungi

Early in the AIDS epidemic, fungi were recognized as major sources of morbidity and mortality. Despite the overall decline in HIV-associated opportunistic infections in the United States, fungi remain frequent causes of disease. Several fungi can cause pulmonary disease in HIV-infected persons. *Pneumocystis jirovecii,* formerly *P. carinii,* previously classified as a protozoan but currently considered a fungus, remains the most common AIDS-defining opportunistic infection in the United States and Western Europe and is a common cause of HIV-associated pneumonia. *Cryptococcus neoformans,* the most common cause of meningitis in HIV-infected persons, often presents with an associated pneumonia. The endemic fungi *Histoplasma capsulatum, Coccidioides immitis, Penicillium marneffei,* and, to a lesser extent, *Blastomyces dermatitidis* are among the chief causes of HIV-associated disease seen in their particular geographic regions, and all have important pulmonary presentations. Finally, invasive aspergillosis is often a devastating pulmonary disease seen in HIV-infected persons with severe immunosuppression. Further information about fungal pulmonary diseases is provided in Chapter 36.

Pneumocystis jirovecii

PCP (shorthand for *P*neumocystis *p*neumonia) remains the most common AIDS-defining opportunistic infection in the United States, even though its overall incidence has declined substantially.[1] Early in the AIDS epidemic, PCP accounted for nearly two thirds of AIDS-defining

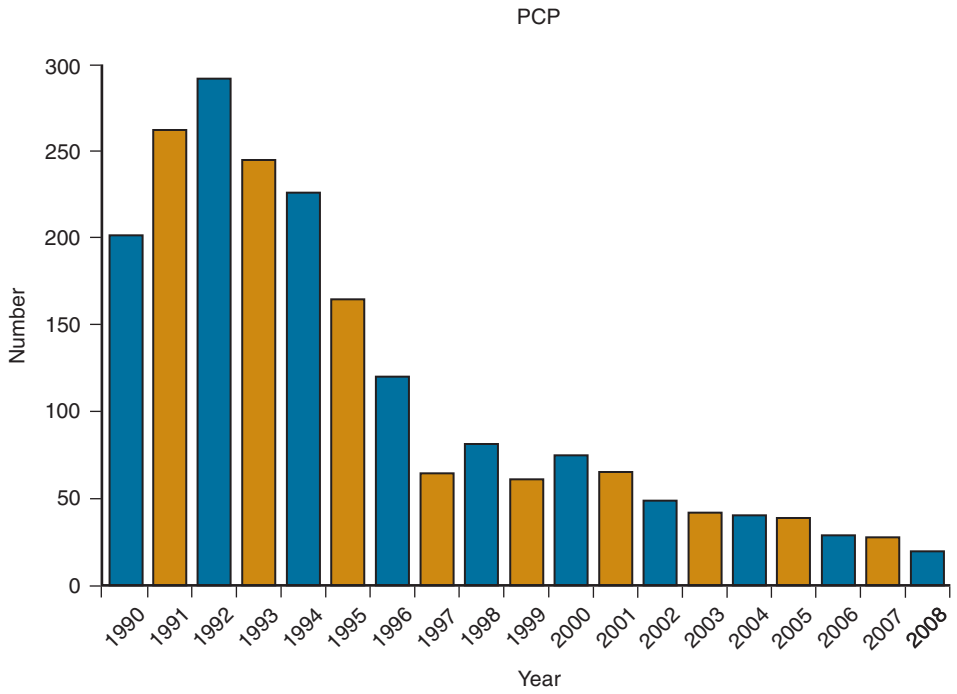

FIGURE 80-4 ■ Annual cases of *Pneumocystis* pneumonia diagnosed at San Francisco General Hospital (1990–2008).

diagnoses, and an additional 15% to 20% of patients developed PCP at some time during their HIV disease. Two factors—the use of combination ART and *Pneumocystis* prophylaxis—have dramatically reduced the overall number of cases (Fig. 80-4). Nevertheless, PCP continues to occur, chiefly among persons who are unaware of their HIV infection, those who fail to seek medical care, and those who fail to adhere to or respond to ART or *Pneumocystis* prophylaxis.[98,99]

History and Epidemiology. First identified early in the 20th century by Chagas, *Pneumocystis* was initially recognized as a human pathogen in the 1940s and 1950s. Despite over a half-century of experience, several gaps in our understanding of this omnipresent organism remain.[99,100] In fact, it was only in 1988 that initial homology studies indicated that *Pneumocystis* was a fungus rather than a protozoan, as previously classified.[101,102] One major obstacle that has impeded further advances has been the inability to reliably culture human *Pneumocystis* in vitro, forcing researchers to rely on animal models for growth and testing. Although mammals are the only known hosts of *Pneumocystis* and a number of mammals are susceptible to infection, *Pneumocystis* has been demonstrated to be species specific.[103] Although *Pneumocystis* can be easily transmitted between mammals of the same species, studies that have attempted to transmit *Pneumocystis* from one species to another have been unsuccessful.[103] In recognition of the host-species specificity of *Pneumocystis,* the *Pneumocystis* that causes *Pneumocystis* pneumonia in humans is now referred to as *P. jirovecii,* in honor of Otto Jirovec, the parasitologist who is credited with first identifying *Pneumocystis* as the cause of pulmonary disease in humans.[104,105]

The precise ecologic niche for *P. jirovecii* and its mode of transmission are unknown.[106,107] The inability to maintain human *Pneumocystis* in culture suggests that *P. jirovecii* may be unable to grow outside of its human host. Given its species specificity, it is doubtful that other mammals are the reservoir for *P. jirovecii.* This host-species specificity also implies coevolution of humans and *P. jirovecii* that, in turn, implies long-term carriage in its human host. It has been shown that infection with *P. jirovecii* is almost ubiquitous. Up to 85% to 100% of the U.S. population have specific antibodies directed against *P. jirovecii* by the age of 3 years.[108,109] Clearly, most of these individuals never develop PCP. In the setting of severe immunosuppression, however—such as typically occurs in untreated HIV infection—PCP can affect significant proportions of people. These studies and others suggest that reactivation of latent infection is a cause of *P. jirovecii* disease among immunocompromised hosts. In addition, outbreaks of newly acquired infection after de novo exposure to persons with PCP have been documented among immunocompromised patients in pediatric wards, cancer clinics or wards, transplantation units, and other confined spaces, which suggests possible person-to-person transmission of *P. jirovecii* and the rapid development of disease. Results of studies that have used molecular tools to detect *Pneumocystis* are consistent with transmission of *P. jirovecii* from patients with PCP to their household and hospital contacts,[110,111] probably via inhalation of a *Pneumocystis*-containing aerosol.

Hughes and colleagues[112,113] demonstrated that immunocompromised axenic rats maintained in germ-free isolators did not develop PCP despite 3 months of immunosuppression with dexamethasone. In a selective

manner, these rats were then exposed to potential sources of *P. carinii,* including air, food, and water. The rats that were exposed to filtered (sterile) air and to regular (unsterile) food and water did not develop PCP. However, rats exposed to room (unsterile) air but maintained on sterile food and water did develop PCP, implying that *P. carinii* is acquired as an airborne disease from de novo infection in the setting of immunocompromise. The duration of exposure necessary for transmission may be short. Soulez and associates[114] housed *Pneumocystis*-free severe combined immunodeficiency (SCID) mice near corticosteroid-treated non-SCID mice and found that a 1-day exposure was sufficient for transmission of *Pneumocystis* to the SCID mice. Transmission of *P. carinii* from PCP-infected SCID mice to other SCID mice via immunocompetent BALB/c mice that were colonized with *P. carinii* has been demonstrated.[115] Taken together, these studies offer a compelling extrapolation that humans are the reservoir for *P. jirovecii,* that person-to-person transmission occurs, and that PCP can result from a recent exposure both to humans with PCP and to humans who are colonized with *P. jirovecii.*[116] If correct, these studies have profound implications as to our current management of persons with PCP.

Risk Factors. Setting aside the question of whether person-to-person transmission of *P. jirovecii* is an important problem, the risk factors for the development of PCP among HIV-infected persons are clear. These risk factors for adults include a $CD4^+$ lymphocyte count less than 200 cells/μL, a history of PCP, and oropharyngeal candidiasis.[117,118]

$CD4^+$ Lymphocyte Count. Approximately 95% of adolescent and adult cases of PCP occur in HIV-infected patients whose $CD4^+$ lymphocyte count is below 200 cells/μL.[118] The Multicenter AIDS Cohort Study found a markedly increased risk for PCP among HIV-infected subjects with a $CD4^+$ lymphocyte count of 200 cells/μL or less at study entry.[117] These subjects had a nearly fivefold greater risk of developing PCP than did subjects who had a $CD4^+$ lymphocyte count higher than 200 cells/μL at study entry. This study also demonstrated that the presence of fever for 2 weeks or more and the development of thrush were independent predictors for PCP. Stansell and colleagues[118] found that the incidence of PCP increased as the $CD4^+$ lymphocyte count declined. Subjects with a $CD4^+$ lymphocyte count between 101 and 200 cells/μL had an incidence of 5.95 cases of PCP per 100 person-years, whereas those with a $CD4^+$ lymphocyte count of 100 cells/μL or less had 11.13 cases per 100 person-years.

Clinical Features. HIV-infected adults, unlike other immunocompromised persons, usually have a prolonged prodromal illness associated with PCP. Kovacs and coworkers[119] found nearly 1 month of symptoms before presentation in most HIV-infected patients with PCP. In this study, the median duration of symptoms in 40 HIV-infected patients was 28 days, which was significantly longer than the median duration of 5 days seen in the 37 patients with other immunosuppressive diseases ($p < 0.0002$). Kales and colleagues[120] reported a median duration of symptoms of 3 weeks in 143 HIV-infected patients with PCP and found that 72 patients (50%) had a duration of symptoms of 2 weeks or longer. This duration of symptoms can often be used to distinguish PCP from pyogenic pneumonia, which typically presents with 3 to 5 days of symptoms.

Classically, PCP presents with fever, a nonproductive cough, and dyspnea on exertion. In one series of 145 HIV-infected patients with PCP, fever was noted in 86%, cough in 91%, and dyspnea in 95% of patients.[120] High fevers, rigors, purulent sputum, and pleuritic chest pain are uncommon and can be used to distinguish PCP from pyogenic pneumonia. In a multivariate analysis, Selwyn and associates[121] found that the presence of purulent sputum was an independent predictor of bacterial pneumonia rather than of PCP or tuberculosis.

Physical examination of the chest may be normal. In the series reported by Kales and colleagues,[120] 78 patients (54%) with PCP had a normal lung examination. When abnormal, the most frequent findings on lung auscultation are inspiratory crackles, which have been reported to be associated with a greater disease severity and an increased mortality.[120]

Numerous studies have shown that the serum lactate dehydrogenase (LDH) level is increased in patients with PCP; however, an elevated serum LDH level does not establish the diagnosis of PCP, nor does a normal serum LDH value rule out the diagnosis. *S*-adenosylmethionine concentration,[122] β-D-glucan,[123] and KL-6[123] have also been reported to be potential diagnostic tools for PCP.

Chest Radiograph. Classically, PCP presents with bilateral, symmetrical reticular or granular opacities as illustrated in Figure 80-5[124]; these opacities typically begin in the perihilar region and extend outward as the disease severity increases. Occasionally, the opacities will be unilateral or asymmetrical. Thin-walled cysts, or pneumatoceles, are seen in 10% to 20% of cases (see Fig. 80-5).[125] Pneumatoceles may be present at the time of diagnosis or may develop during PCP therapy. Pneumatoceles may be single or multiple in number, and small or large in size, and predispose patients to pneumothorax, which is another radiographic presentation of PCP. Usually pneumatoceles resolve, but occasionally they persist despite successful therapy.

Virtually every possible radiographic finding, including focal, lobar, or segmental consolidation, nodules with or without cavitation, and a miliary pattern, can be seen occasionally.[125] Apical or upper lung zone disease that mimics tuberculosis (shown in Fig. 80-6) is typically associated with aerosolized pentamidine prophylaxis, although this presentation can be seen as well in patients taking oral prophylaxis or no preventive therapy. Intrathoracic adenopathy and pleural effusions are rarely due to PCP. These radiographic findings should prompt a search for an alternate or at least a coexisting process such as bacterial pneumonia, tuberculosis, fungal pneumonia, or pulmonary Kaposi sarcoma. PCP may also present with a normal chest radiograph. Published studies report the incidence of a normal radiograph to range from 0% to 39%.[124–126]

Diagnosis. The diagnosis of PCP rests on the microscopic visualization of the characteristic *P. jirovecii* cysts

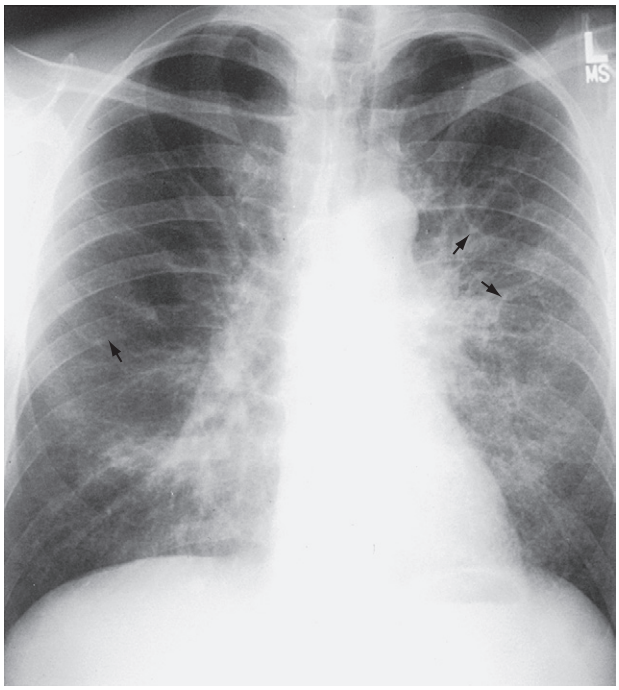

FIGURE 80-5 ■ Posteroanterior chest radiograph of an HIV-seropositive patient with *Pneumocystis* pneumonia showing bilateral, predominantly perihilar, granular opacities and three pneumatoceles (*arrows*). Pneumatoceles may be single or multiple in number, and small or large in size, and may predispose patients to pneumothorax. (Courtesy of L. Huang.)

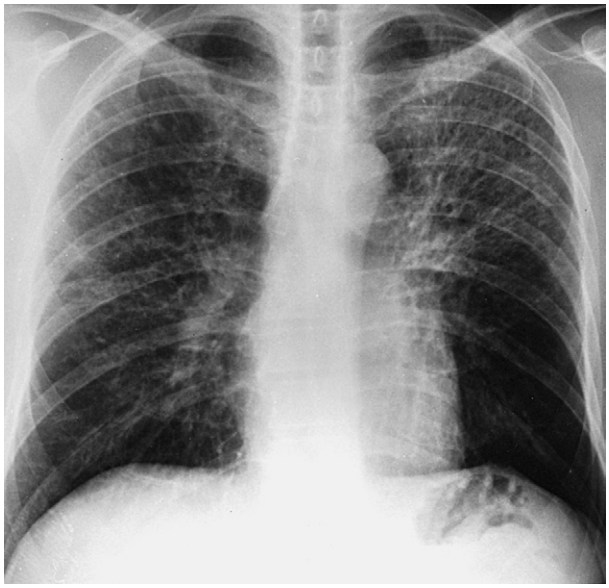

FIGURE 80-6 ■ Posteroanterior chest radiograph of an HIV-seropositive patient who had been receiving aerosolized pentamidine showing reticular infiltration, predominantly of the upper lung zones, secondary to relapsed *Pneumocystis* pneumonia (PCP). This radiographic presentation, however, may also be seen in patients on no PCP prophylaxis. (From Murray JF, Mills J: Pulmonary complications of HIV infection. Am Rev Respir Dis 141:1356–1372, 1582–1598, 1990.)

or trophic forms (or both) on stained respiratory specimens. *Pneumocystis jirovecii* can be detected in expectorated or induced sputum; in pulmonary secretions obtained by nasotracheal suction, BAL, or percutaneous aspiration of the lung parenchyma; and in pulmonary tissue obtained by transbronchial, thoracoscopic, or open-lung biopsy. Of these, sputum induction and BAL are the most widely used. The standard method for detection of *P. jirovecii* has been with cyst wall stains such as methenamine silver and toluidine blue-O or with Giemsa and Diff-Quik, which stain both the intracystic sporozoites and the trophic forms; monoclonal antibodies to *P. jirovecii,* which react with both cysts and trophic forms, are also used.[127] PCR-based techniques have also been employed and have been reported to be more sensitive but also less specific than either of the other methods.[127,128] However, the increased sensitivity of PCR-based assays has allowed for their pairing with noninvasive, rapid (60-second) procedures such as oropharyngeal washing (i.e., gargling) for the diagnosis of PCP. Several studies have reported sensitivities and specificities for PCP of a PCR-based assay using oropharyngeal washing that may permit its clinical use.[129]

A number of studies have examined the impact of PCP prophylaxis on the sensitivity of induced sputum and BAL examination for detecting the organisms.[130–133] Some authors reported a lower sensitivity of diagnostic studies for PCP among patients who were receiving aerosolized pentamidine compared with those having no prophylaxis, whereas others found no difference between the two groups. In patients undergoing bronchoscopy, the yield for *P. jirovecii* may be improved by performing upper lobe lavage or multiple-lobe lavage with or without a more sensitive staining technique (e.g., monoclonal antibodies).[132,133] Our practice is to perform BAL in the most affected lobe visualized on chest radiograph. For patients with diffuse radiographic disease, we usually perform a single lavage in the right middle lobe. For patients with, for example, an upper lung zone predominance on radiograph, however, we often lavage both an upper lobe and the right middle lobe. Despite the widespread use of TMP-SMX and dapsone for PCP prophylaxis, no studies have evaluated whether the yield of diagnostic studies is changed in persons receiving one of these medications. Our clinical experience suggests that, although the severity of chest radiograph abnormalities may be milder in patients receiving prophylaxis than in those receiving no prophylaxis, the high yields from both sputum induction and BAL remain the same.

Treatment. The treatment of choice for patients with mild, moderate, and severe PCP remains TMP-SMX, administered for 21 days. TMP-SMX possesses many benefits, including availability in both an intravenous and an oral form, availability as a single-drug combination, excellent oral bioavailability, and activity against many community-acquired bacteria that may cause concomitant pyogenic infection. The usual dose of TMP is 15 mg/kg/day (range, 15 to 20 mg/kg/day) and that of SMX is 75 mg/kg/day (range, 75 to 100 mg/kg/day), divided into three or four daily doses as described in Table 80-3. Dosing may be intravenous (recommended for patients

TABLE 80-3. Treatment and Prophylaxis Regimens for *Pneumocystis* Pneumonia*

Treatment Regimen	Dose(s), Frequency	Toxicities
Mild PCP† (Arterial P_{O_2} > 70 mm Hg **AND** alveolar-arterial O_2 difference < 35 mm Hg)		
Trimethoprim (TMP)-Sulfamethoxazole (SMX)	15–20 mg/kg (TMP component) daily (q6–8h)	Fever, dermatologic, gastrointestinal, hematologic
Trimethoprim plus	15–20 mg/kg daily (q6–8h)	Dermatologic, gastrointestinal, hematologic
Dapsone	100 mg once daily	
Clindamycin plus	1800 mg daily (q6–8h)	Dermatologic, gastrointestinal, hematologic
Primaquine	30 mg (base) once daily	
Atovaquone	750 mg thrice daily	Dermatologic, gastrointestinal
Moderate-Severe PCP‡ (Arterial $P_{O_2} \leq 70$ mm Hg **OR** alveolar-arterial O_2 difference ≥ 35 mm Hg)		
Trimethoprim (TMP)-Sulfamethoxazole (SMX)	15–20 mg/kg (TMP component) daily (q6–8h)	Fever, dermatologic, gastrointestinal, hematologic
Pentamidine	3–4 mg/kg once daily	Renal, pancreatic
Clindamycin plus	1800–2400 mg (q6–8h)	Dermatologic, gastrointestinal, hematologic
Primaquine	30 mg (base) once daily	

*Recommended duration of therapy = 21 days.
†Oral route is preferred for patients with mild PCP who are treated as outpatients.
‡Intravenous route is preferred (at least until clinical improvement) for patients with moderate-severe PCP. Adjunctive corticosteroids (prednisone 40 mg, PO, twice daily for 5 days, then 40 mg, PO, once daily for 5 days, then 20 mg, PO, once daily for 11 days or potency-equivalent solumedrol, IV) should also be administered.

with moderate or severe PCP) or oral. Unfortunately, adverse effects from TMP-SMX are frequent and include rash, fever, gastrointestinal complaints (nausea, vomiting), elevated liver transaminases, hyperkalemia, and bone marrow suppression, especially anemia and neutropenia. Often these effects develop during the second week of therapy. In a significant proportion of HIV-infected patients, the side effects are ultimately treatment limiting. Rare adverse reactions include Stevens-Johnson syndrome, toxic epidermal necrolysis, and a clinical syndrome resembling septic shock with hypotension, fever, pulmonary infiltrates, and renal and hepatic dysfunction. Studies are conflicting regarding the presence of potential TMP-SMX drug resistance.[134,135]

For patients with an allergy to or intolerance of TMP-SMX, alternative treatment regimens (see Table 80-3) include intravenous pentamidine, clindamycin plus primaquine, trimethoprim plus dapsone, trimetrexate (with or without dapsone), and atovaquone.[14] Similar to tuberculosis, HIV-infected patients with PCP who begin dual therapy for *Pneumocystis* and HIV infection may develop paradoxical reactions, a temporary exacerbation of clinical and radiographic features.[136] The diagnosis of paradoxical reactions is one of exclusion. Patients with paradoxical reactions only rarely require change or discontinuation of anti-*Pneumocystis* or antiretroviral therapies, and symptomatic therapy is recommended.

Corticosteroid Therapy. In 1990, the National Institutes of Health–University of California Expert Panel for Corticosteroids as Adjunctive Therapy for Pneumocystis Pneumonia[137] concluded that adjunctive corticosteroid therapy "can clearly reduce the likelihood of death, respiratory failure, or deterioration of oxygenation in patients with moderate-to-severe pneumocystis pneumonia." The panel recommended that adjunctive corticosteroids be given to adults or adolescents with documented or suspected PCP if they have an arterial P_{O_2} level less than 70 mm Hg or an alveolar-arterial P_{O_2} difference greater than 35 mm Hg. Adjunctive corticosteroids, either oral prednisone or intravenous methylprednisolone, should be started when specific anti-*Pneumocystis* treatment is begun.

Early in the AIDS epidemic, it was realized that acute respiratory failure secondary to PCP, if severe enough to warrant mechanical ventilation, had a mortality rate of 86% or greater.[137] Subsequent reports from individual hospitals confirmed this gloomy prognosis; 39 of 45 patients who were intubated and ventilated for PCP at San Francisco General Hospital from 1981 to 1985 died, a mortality rate of 87%.[138] Although the mortality associated with acute respiratory failure secondary to PCP remains significant (approximately 30% to 50%), encouraging progress has been made.[139,140]

Prevention. The natural reservoir for human *Pneumocystis* remains unknown. Both an environmental and a human reservoir have been suggested.[106,107] Whether PCP results solely from reactivation of latent infection or also from a recent infection is debated; as mentioned, reports of cluster outbreaks of PCP among different immunocompromised populations support the theory that PCP can result from person-to-person transmission. Accordingly, some authorities have argued that HIV-infected and other immunocompromised persons who are at risk for PCP should avoid close contact with any individuals who have PCP. Nevertheless, the current NIH, CDC, and HIVMA/IDSA guidelines for preventing opportunistic infections state that "although certain authorities might recommend that persons who are at risk for PCP not share a hospital room with a patient who has PCP based on animal studies and anecdotal human experience, data are insufficient to support this recommendation as standard practice."[14]

TABLE 80-4. Prevention of *Pneumocystis* Pneumonia

Prevention Regimens	Alternative Dosing	Comments
Trimethoprim-sulfamethoxazole 1 double-strength (DS) tablet daily	1 single-strength tablet daily 1 DS tablet thrice weekly	Also effective prophylaxis against *Toxoplasma gondii* and many bacterial pathogens
Dapsone 100 mg daily		Combine with pyrimethamine and leucovorin in persons who are *T. gondii* immunoglobulin G antibody positive. Consider combining with pyrimethamine and leucovorin when used for secondary prophylaxis
Atovaquone suspension 1500 mg daily, divided into 1–2 doses		Improved bioavailability compared to tablets
Aerosolized pentamidine 300 mg monthly via RespirGard II nebulizer		May be associated with increased risk of extrapulmonary disease

HIV-infected adults or adolescents (including those on ART) who have a $CD4^+$ lymphocyte count less than 200 cells/μL or a history of oropharyngeal candidiasis should receive primary *Pneumocystis* prophylaxis, and persons with prior PCP should receive secondary prophylaxis using one of the regimens shown in Table 80-4.[14] Once started, HIV-infected adults and adolescents should remain on prophylaxis for life, unless their $CD4^+$ lymphocyte counts increase from less than 200 cells/μL to greater than 200 cells/μL for at least 3 months as a result of ART; several studies have demonstrated that primary and secondary PCP prophylaxis can be safely discontinued in the vast majority of these persons.[14] In rare cases, however, PCP has recurred after the discontinuation of secondary PCP prophylaxis, despite an apparent ART-associated immune reconstitution.[141]

TMP-SMX, dapsone, atovaquone suspension, and aerosolized pentamidine are the standard options for PCP prophylaxis.[14] TMP-SMX is the first-line prophylaxis choice, both primary and secondary, against *Pneumocystis.* For those patients intolerant of TMP-SMX, dapsone and atovaquone are both oral drugs that can be used. Many authorities would add pyrimethamine to these drugs for patients with a history of PCP or a $CD4^+$ lymphocyte count less than 100 cells/μL, or both. For patients who are *T. gondii* immunoglobulin G antibody positive, pyrimethamine must be added. Aerosolized pentamidine remains an effective and well-tolerated prophylaxis option. However, caution must be exercised when using this drug for secondary prophylaxis or for a patient with a $CD4^+$ lymphocyte count below 100 cells/μL.

Cryptococcus neoformans

Cryptococcosis is a disease caused by the budding encapsulated yeast *C. neoformans.* It is the only encapsulated fungus that infects humans, both healthy (see Chapter 36) and immunocompromised, and India ink or mucicarmine staining can identify its polysaccharide capsule.[142] Serotyping based on antigenic differences in the polysaccharide capsule demonstrates that serotypes A and D are the most common cause of infection and disease. *Cryptococcus neoformans* infection occurs after inhalation of a yeast-containing aerosol. The yeast is global in distribution and is most commonly isolated from bird excrement, decaying fruit, and soil.

The incidence of cryptococcosis in HIV-infected persons has dramatically declined since the introduction of combination ART. In one population-based surveillance study, the annual incidence of cryptococcosis decreased from 66 per 1000 persons with AIDS in 1992 to 7 per 1000 persons in 2000 in the Atlanta area, and from 24 per 1000 persons with AIDS in 1993 to 2 per 1000 persons in 2000 in the Houston area.[143] Using national surveillance data, a study from France found a 46% decrease in the incidence of cryptococcosis in HIV-infected patients from the pre–combination ART period (1985–1996) to the combination ART period (1997–2001).[144]

Clinical Features. Although the portal of entry is the lung, cryptococcal pulmonary infection is often asymptomatic or minimally symptomatic, and the most commonly encountered manifestation of cryptococcal disease is meningitis.[144–146] In a large series of 106 HIV-infected patients with cryptococcal disease, 89 patients (84%) had meningitis, and only 4 patients (4%) had isolated pneumonia.[145] In a population-based surveillance study that included 1322 HIV-infected patients with cryptococcal disease, only 45 patients (3%) had pulmonary disease in the absence of both fungemia and meningitis.[143] However, autopsy studies suggest that pulmonary disease is underdiagnosed, particularly in settings where diagnostic facilities are limited.[147]

Most cases of pulmonary involvement are discovered serendipitously on routine chest radiograph rather than as a result of specific symptoms or signs. When present, the most frequent respiratory complaints are cough and dyspnea.[145,148] Pleuritic chest pain and productive cough have also been reported,[149] perhaps distinguishing pulmonary cryptococcosis from PCP. Although more rare, cases of acute respiratory failure can occur.[147]

$CD4^+$ Lymphocyte Count. Most cases of cryptococcosis occur in patients with a $CD4^+$ lymphocyte count less than 200 cells/μL, and usually below 100 cells/μL. A study of 1644 patients reported a median $CD4^+$ count of 24 cells/μL with a range of 0 to 480 cells/μL.[144]

Chest Radiograph. Cryptococcal pneumonia most commonly presents with diffuse bilateral interstitial infiltrates.[149,150] In one study, Meyohas and associates[151]

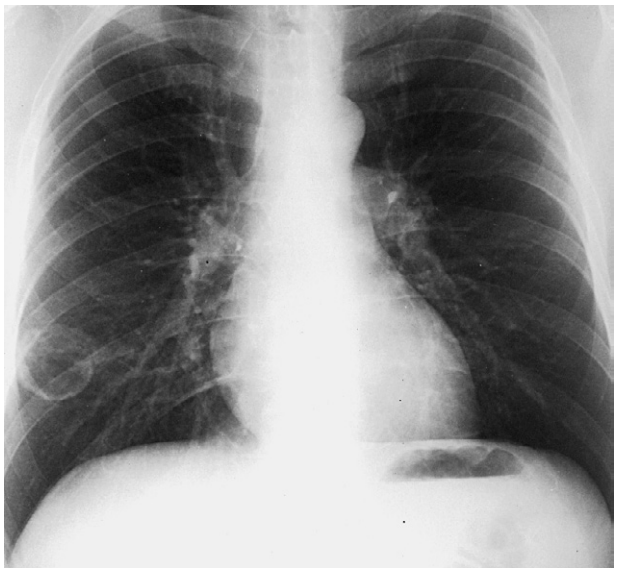

FIGURE 80-7 ■ Posteroanterior chest radiograph of an HIV-seropositive patient showing a solitary cavitary lesion in the right lower lung field. Culture of bronchoalveolar lavage fluid revealed *Cryptococcus neoformans*. In HIV-infected patients, cryptococcal disease can present with a wide range of chest radiographic findings, including a normal chest radiograph. (From Stansell JD: Fungal disease in HIV-infected persons: Cryptococcosis, histoplasmosis, and coccidioidomycosis. J Thorac Imaging 6:28–35, 1991.)

reported interstitial infiltrates in 60 of 92 radiographs (65%); in addition, focal consolidation (13%), nodular opacities (11%), cavitation (11%) (Fig. 80-7), pleural effusion (14%), and hilar adenopathy (27%) were noted. More rarely, radiographic findings include a miliary pattern,[152] solitary pulmonary nodules,[153] pulmonary masses,[154] isolated pleural effusion,[155] and pneumothorax[156] due to *C. neoformans*. Finally, cryptococcal pneumonia may also present with a normal chest radiograph; in the review by Meyohas and associates,[151] for example, normal radiographs were seen in 11% of the 92 cases.

Diagnosis. The diagnosis of cryptococcal infection begins with the cryptococcal antigen (CRAG) test. The test can be performed on serum, cerebrospinal fluid, urine, BAL fluid,[157] or pleural fluid. The serum CRAG test is sensitive and specific for cryptococcemia. A negative serum CRAG test virtually rules out the diagnosis of cryptococcal meningitis but can be seen in cases of isolated pulmonary cryptococcosis. A positive serum CRAG test should prompt an evaluation for disseminated disease, especially meningitis, but it can be seen in the presence of rheumatoid factor or infection with *Trichosporon beigelii*. Blood fungal cultures are specific and should be obtained as part of the diagnostic evaluation. New cutaneous lesions may be signs of dissemination, and their sudden appearance should prompt consideration for biopsy.

The diagnosis of pulmonary cryptococcosis is usually established by culture of sputum or BAL fluid and occasionally of pleural fluid. Biopsy specimens from TBBX and pleural biopsy can also be diagnostic. Batungwanayo and coworkers[149] found that BAL diagnosed 27 of 33 cases (sensitivity 82%) of cryptococcal pneumonia compared with TBBX, which diagnosed 10 of 21 cases (sensitivity 48%). In some cases, cultures are negative, but a BAL or pleural fluid CRAG test can establish the diagnosis.[151] Alternatively, because the treatment is identical, the diagnosis of pneumonia may be inferred in the presence of disseminated cryptococcal disease (e.g., meningitis) and a compatible radiographic presentation. However, caution must be exercised with this approach, because other opportunistic infections such as PCP may be present concurrently and can demonstrate identical radiographic findings.

Treatment. In contrast to cryptococcal meningitis, there are no randomized controlled trials for HIV-infected patients presenting with isolated cryptococcal pneumonia or with concurrent cryptococcal pneumonia and meningitis.[158] Some authorities would treat isolated cryptococcal pneumonia that is mild in severity with fluconazole alone (400 mg daily).[147] However, patients with clinically significant cryptococcal pneumonia should be considered at high risk for early deterioration and should be offered amphotericin B (0.7 mg/kg/day), with or without 5-fluorocytosine.[147] Treatment should be continued until the patient is clinically improved, at which point the patient can be switched to fluconazole (400 mg daily) to complete a 10- to 12-week course. The patient should then be maintained on fluconazole (200 mg daily) for life unless he or she experiences an increase in $CD4^+$ cell counts due to ART. Maintenance therapy can be discontinued in the vast majority of patients who have a $CD4^+$ lymphocyte count greater than 100 to 200 cells/μL for at least 6 months due to ART, who complete their initial 10- to 12-week course for cryptococcosis, and who remain asymptomatic.[14] Similar to tuberculosis and PCP, HIV-infected patients with cryptococcosis who begin dual therapy for *C. neoformans* and HIV infection may develop IRIS.[159] Patients who had cryptococcal meningitis may present with aseptic meningitis and have elevated intracranial pressure. In addition, patients with cryptococcal pneumonia and nodules on chest radiograph may develop cavitation of their nodules or new intrathoracic adenopathy.[159]

Primary Prevention. There are no specific recommendations regarding exposure avoidance or chemoprophylaxis for *C. neoformans*.[14] In addition, routine screening of asymptomatic persons with serum CRAG testing is not recommended.

Histoplasma capsulatum

Histoplasmosis is a disease caused by the dimorphic, soil-dwelling fungus *H. capsulatum*. The fungus is found on all continents except Antarctica, but it is most endemic to North America and the Caribbean basin.[142,160] The heaviest concentration is found in the Mississippi, Ohio, and St. Lawrence River valleys. In these areas, the fungus exists in microfoci related to the enrichment of the soil with bird or bat excrement, which helps to promote sporulation. In the soil, the fungus exists in a mycelial form with characteristic tuberculate

macroconidia. The hyphae also have microconidia that are easily aerosolized when disturbed. Inhalation of these microconidia leads to primary pulmonary infection that is usually clinically silent.

Once deposited in the alveoli, *H. capsulatum* transforms into its yeast (or parasitic) form, and an area of pneumonitis develops. During this period before cell-mediated immunity develops, the organism spreads to regional lymph nodes and to reticuloendothelial organs. Two to 3 weeks after exposure, about 40% of immunocompetent individuals develop a flulike syndrome with fever, chills, myalgias, a nonproductive cough, and chest pain. As emphasized in Chapter 36, 99% of these cases spontaneously resolve with the development of specific cell-mediated immunity. In contrast, progressive disseminated histoplasmosis develops in HIV-infected and other persons lacking cell-mediated immunity. Although most cases of HIV-associated histoplasmosis appear to result from de novo exposure, reactivation disease does occur. These cases account for the histoplasmosis seen in nonendemic areas such as San Francisco or New York.[161]

Clinical Features. Although the portal of entry is the lung, disseminated histoplasmosis most often presents as a febrile wasting illness in HIV-infected persons. In a large series of 72 HIV-infected patients with disseminated histoplasmosis, 69 patients (96%) presented with fever and weight loss; in approximately 10% of cases reviewed, the presentation is dramatic with a sepsis-like syndrome associated with hypotension, respiratory failure, liver and renal failure, and coagulopathy.[162] Prognosis in these patients is poor. Respiratory complaints at presentation, chiefly cough and dyspnea, are found in patients who are likely to have abnormal chest radiographs.[162,163]

$CD4^+$ Lymphocyte Count. Most cases of disseminated histoplasmosis occur in patients with a $CD4^+$ lymphocyte count less than 100 cells/μL and often below 50 cells/μL. Frequent laboratory findings include anemia, leukopenia, thrombocytopenia, and liver function test elevations. Serum LDH and serum ferritin elevations, often pronounced, have also been reported.[160]

Chest Radiograph. Disseminated histoplasmosis will present with a normal chest radiograph in a significant proportion of cases, ranging from approximately 35% to 55%.[150,162,164] In patients with abnormal findings, the most frequent are diffuse, coarse reticular or reticulonodular infiltrates as shown in Figure 80-8. Occasionally, alveolar infiltrates may occur[150]; focal opacities are less common but are seen in 7% to 11% of cases.[163] Hilar and mediastinal adenopathy and calcified granulomata are each found in less than 5% of patients, attesting to the low incidence of reactivation disease.[162]

Diagnosis. The diagnosis of histoplasmosis begins with the histoplasma polysaccharide antigen (HPA) test. The test can be performed on urine, serum, cerebrospinal fluid, or BAL fluid. The sensitivity of the HPA test is greater in urine (95%) than in serum (85%).[14] Although the urine HPA is sensitive in disseminated histoplasmosis, it is often negative in isolated pulmonary disease. With successful therapy HPA values fall, and during relapses HPA values rise (usually by ≥2 HPA units), which are useful features for assessing response to therapy and for evaluating possible relapse.[165] A false-positive HPA test can occur in patients with other disseminated fungal diseases (blastomycosis, paracoccidioidomycosis, and penicilliosis), but it has not been described in patients with coccidioidomycosis, cryptococcosis, aspergillosis, or candidiasis. A persistently positive HPA test indicates continued disease and warrants continued therapy. Definitive diagnosis requires isolation and identification of the fungus by culture. Blood fungal cultures are specific and should be obtained as part of the diagnostic evaluation. Wheat and colleagues[162] reported that fungal blood cultures were positive in 65 of their 72 cases (90%). Occasionally, the peripheral blood smear reveals intracellular yeast. Other potential diagnostic sources include bone marrow, lymph node, and skin. The diagnosis of pulmonary histoplasmosis can be established by direct examination and culture of sputum, BAL fluid, or TBBX.

FIGURE 80-8 ■ Posteroanterior chest radiographic close-up of the left mid-lung of an HIV-seropositive patient showing a medium to coarse reticulonodular pattern characteristic of disseminated fungal disease. (From Stansell JD: Fungal disease in HIV-infected persons: Cryptococcosis, histoplasmosis, and coccidioidomycosis. J Thorac Imaging 6:28–35, 1991.)

Treatment. Either amphotericin B or a lipid formulation of amphotericin B is the treatment of choice for HIV-infected patients with moderate to severe disseminated histoplasmosis, whereas itraconazole is an alternative for patients with mild disease.[14,166] Treatment with amphotericin B should be continued until the patient is clinically improved, at which point the patient can be

switched to twice-daily itraconazole to complete at least a 12-month course.

Primary Prevention. In those areas endemic for *H. capsulatum,* HIV-infected patients, especially if their $CD4^+$ lymphocyte counts are less than 150 cells/μL, should avoid activities that will potentially increase their exposure, including cleaning chicken coops; disturbing native soil beneath bird-roosting sites; cleaning, remodeling, or demolishing old buildings; and exploring caves.[14] Routine serologic testing, even in histoplasmosis-endemic areas, is not recommended. Current NIH, CDC, and HIVMA/IDSA guidelines do not recommend itraconazole for primary *H. capsulatum* prophylaxis, except perhaps in those who have a $CD4^+$ lymphocyte count less than 150 cells/μL, and who are at high-risk due to occupation or who live in hyperendemic regions.[14]

Coccidioides immitis

Coccidioidomycosis is a disease caused by the dimorphic, soil-dwelling fungi *C. immitis* and *Coccidioides posadasii.* As described in Chapter 36, the chief manifestation of coccidioidomycosis is as a mild flulike, often undiagnosed illness, from which most previously healthy people spontaneously recover. Chronic pulmonary disease occurs in roughly 5% of infected persons and disseminated disease in even fewer. By contrast, in HIV-infected persons coccidioidomycosis is an uncommon, but devastating, disseminated disease that is frequently fatal. The fungus is endemic to the semiarid regions of North America, notably the southwestern United States (central California, southern Arizona, southern New Mexico, and west Texas) and also northern Mexico.[142,167] California's southern San Joaquin Valley and southern Arizona are hyperendemic areas.[167] *Coccidioides* is also found in South America, especially central Argentina. In soil, the fungus exists in a mycelial form with characteristic arthrospores. When the soil is disrupted, the few-micrometer diameter arthrospores, which are just the right size for deposition in the distal airways and alveoli after inhalation, become airborne. After deposition in the lungs, the arthrospores transform into spherules that may develop several hundred endospores. Rupture of the spherules allows widespread dissemination of the endospores, which then form additional spherules, replicating the cycle. Although most cases of HIV-associated coccidioidomycosis appear to result from de novo inhalation exposure, reactivation disease does occur.

Clinical Features. The clinical presentation is often nonspecific; fever and chills (68%), night sweats (36%), and weight loss (50%) are common.[168] Although the portal of entry is the lung, coccidioidomycosis often presents with disseminated disease and meningitis. Other frequent sites include the skin, lymph nodes, liver, and skeletal system. In one study, 42% of HIV-infected patients with coccidioidomycosis presented with disseminated disease; overall, 25% of the patients in this series died.[169]

$CD4^+$ Lymphocyte Count. Most cases of disseminated coccidioidomycosis occur in patients with a $CD4^+$ lymphocyte count below 100 cells/μL and often fewer than 50 cells/μL.[168,169] Cerebrospinal fluid examination is warranted in all patients with suspected coccidioidomycosis.

Chest Radiograph. In a series of 91 HIV-infected patients with coccidioidomycosis, diffuse reticulonodular infiltrates (see Fig. 36-14) were seen in 65%; focal opacities were less common but occurred in 14% of cases and consisted of focal infiltrates, single or multiple nodules, and cavities.[168] Pleural effusion and hilar adenopathy were also reported, as well as normal chest radiographs.

Diagnosis. Unlike cryptococcosis and histoplasmosis, there is no specific antigen test available for diagnosing coccidioidomycosis. Thus, definitive diagnosis requires the isolation and identification of the fungus by culture or identification of pathognomonic giant spherules in cytologic or histologic preparations. In cases of suspected coccidioidomycosis, it is critical to alert the microbiology laboratory so that proper precautions can be implemented to prevent laboratory transmission. Serologic tests are useful in the evaluation of suspected coccidioidomycosis. Several studies have found an 80% to 90% sensitivity of complement fixation and tube precipitin tests.[170] False-negative titers usually occurred in the most severely immunocompromised patients with diffuse pulmonary disease; in those with positive tests, the titer appeared to reflect the disease activity and proved useful for monitoring response to therapy.[171]

Direct examination and culture of sputum, BAL fluid, or TBBX can establish the diagnosis of pulmonary coccidioidomycosis in HIV-infected patients. Singh and associates[168] found that sputum culture in 13 of 19 cases (68%) and cytology in 8 of 11 cases (73%) had a high yield. BAL fluid culture diagnosed 29 of 42 cases (69%), and BAL fluid cytology diagnosed 32 of 48 cases (67%); in addition, TBBX culture diagnosed 8 of 10 cases (80%), and biopsy histology diagnosed all 14 cases (100%).

Treatment. Either amphotericin B or a lipid formulation of amphotericin B is the treatment of choice for HIV-infected patients with severe (i.e., diffuse) pulmonary or disseminated coccidioidomycosis.[14,167] Treatment with amphotericin B should be continued until the patient is clinically improved, at which point the patient can be switched to fluconazole or itraconazole. In patients with clinically mild infection, such as focal pneumonia, fluconazole or itraconazole may be used at the outset.[14] In patients with diffuse disease, lifelong suppressive therapy with itraconazole or fluconzaole should be continued after initial treatment is complete. In patients who have had focal coccidioidal pneumonia, and who have had a sustained response to ART with $CD4^+$ lymphocyte counts above 250 cells/μL, therapy may be discontinued after 12 months, but periodic surveillance with chest radiograph and coccidioides serology is recommended.[14]

Primary Prevention. In areas endemic for *C. immitis,* HIV-infected persons should avoid activities that will potentially increase their exposure, such as

visits to construction or other sites where soil is being disturbed. Routine serologic testing is reasonable only in endemic areas; primary prophylaxis for persons living in or traveling to an endemic area is recommended only if serology test results are positive and $CD4^+$ lymphocyte count is below 250 cells/μL.[14]

Aspergillus Species

Species of *Aspergillus* are found worldwide, and exposure is universal. Nevertheless, disease is infrequent unless phagocyte number or function is reduced.[172] Presently, greater than 180 species within the *Aspergillus* genus have been identified. *Aspergillus fumigatus,* however, is the most common disease-causing species, and it accounts for approximately 90% of cases of invasive aspergillosis. Although invasive aspergillosis is a well-documented complication of various immunosuppressive disorders, particularly in patients with hematologic malignancy or organ transplantation, it is an uncommon problem in patients with HIV disease. Risk factors for the development of aspergillosis besides HIV-induced immunosuppression included use of corticosteroids, neutropenia, marijuana, and broad-spectrum antimicrobial drugs.[173] In the combination ART era, the incidence of invasive aspergillosis has further declined. Holding and coworkers[174] reported an aspergillosis incidence of 3.5 cases per 1000 person-years among HIV-infected subjects enrolled in the CDC-led Adult and Adolescent Spectrum of HIV Disease study.

Clinical Features. The entire spectrum of *Aspergillus*-related lung disease (see Chapter 36 for further details) has been observed in HIV-infected persons, from colonization of the respiratory tract or a preexisting cavity, to tracheobronchitis or obstructing bronchial aspergillosis, to invasive aspergillosis, by far the most severe manifestation.[173,175-177] Although most patients with invasive aspergillosis have a $CD4^+$ lymphocyte count lower than 50 cells/μL, the classic risk factors for the disease relate more to phagocyte number and function (as determined by neutropenia and use of corticosteroids or broad-spectrum antibiotics) than to absolute $CD4^+$ lymphocyte counts. Patients with aspergillosis typically present with fever, cough, dyspnea, and occasionally pleuritic chest pain. Hemoptysis is another presenting feature. The chest radiographic abnormalities are variable and include unilateral or bilateral infiltrates, cavitary lesions, nodular and pleural-based densities, and pleural effusions.[178]

Diagnosis. The definitive diagnosis of aspergillosis requires both demonstration of tissue invasion and isolation of the organism by culture. Neither sputum nor BAL is sufficient. Microscopy alone cannot distinguish *Aspergillus* species from *Fusarium* or *Pseudallescheria* species. The results of TBBX are usually negative, but specimens from sputum, BAL fluid, or percutaneous aspirates are often positive on culture. The absence of histologic proof of tissue invasion is always somewhat disquieting, especially in attempting to distinguish invasive disease from possible colonization of damaged airways. Repeated isolation of the fungus in large numbers with a compatible clinical setting makes the diagnosis more tenable.

Galactomannan antigen testing on serum or BAL specimens may be useful in the diagnosis of invasive pulmonary aspergillosis, although its performance has not been prospectively evaluated in HIV-infected patients with suspected aspergillosis. False-positive results can occur in patients who are on concomitant piperacillin-tazobactam or amoxicillin-clavulanate, and cross reactivity can occur with several other fungi.[179]

Treatment. Compared with the fungi previously discussed, there is relatively little experience treating HIV-infected patients with aspergillosis.[172] Voriconazole is the first-line recommended therapy.[14] Alternative agents include amphotericin, capsofungin, and posaconazole. Interactions with ART drugs must be considered. Even with the prompt institution of therapy, the prognosis is poor, undoubtedly in large part because aspergillosis, when it occurs, is nearly always a late complication of advanced HIV disease.

Prevention. Given the ubiquitous nature of *Aspergillus* species, it is impossible to prevent exposure to the organism. However, patients with advanced HIV disease should avoid activities that will potentially increase their exposure, including being near decaying vegetation (e.g., compost) and soil.

Blastomyces dermatitidis

Blastomycosis is a disease caused by the endemic, dimorphic fungus *B. dermatitidis.* Blastomycosis is coendemic with histoplasmosis throughout much of the central United States (see also Chapter 36), but it is much less common than histoplasmosis, and reports of HIV-associated blastomycosis are infrequent.[180,181]

Clinical Features. The largest case series reported 15 cases of HIV-associated blastomycosis; all but one had a $CD4^+$ lymphocyte count less than 200 cells/μL.[180] The authors noted two distinct patterns of disease: one group of patients had disease that was clinically limited to the respiratory system, whereas the other group had disseminated blastomycosis, commonly involving multiple organ systems, including the lungs. Eleven of 15 patients (73%) had abnormal chest radiographs, with diffuse interstitial or miliary disease (55%) being the most common radiographic finding. Definitive diagnosis requires the growth of *B. dermatitidis,* although visualization of the characteristic budding yeast form is strongly suggestive and warrants antifungal therapy while awaiting the results of culture.

Treatment. Intravenous amphotericin B is the treatment of choice for HIV-infected patients with severe disease.[180,181] Treatment with amphotericin B should be continued to a cumulative induction dose of 1.5 to 2.5 g. Patients who have improved can then be switched to oral itraconazole maintenance therapy for life, whereas those without significant improvement should continue taking amphotericin B. With prompt institution of therapy, most patients with disease limited to the lungs responded well; in contrast, patients with disseminated disease did poorly (40% mortality in 30 days).[180]

Penicillium marneffei

Penicilliosis is a disease caused by *P. marneffei,* a dimorphic, soil-dwelling fungus. With expansion of the HIV epidemic into southeastern Asia has come a dramatic increase in cases of penicilliosis.[182,183] *Penicillium marneffei* is endemic in southeastern Asian countries, and, in northern Thailand, it is the third most common opportunistic infection (after tuberculosis and cryptococcosis) in HIV-infected patients with AIDS, accounting for 15% to 20% of all AIDS-related illnesses. Disease is related to soil exposure, especially during the rainy season (May to October), and infection is probably acquired via inhalation.

Clinical Features. Most cases of penicilliosis occur in patients with a $CD4^+$ lymphocyte count less than 100 cells/μL. The clinical presentation is often mistaken for tuberculosis, cryptococcosis, or histoplasmosis. The most common symptoms include fever, weight loss, cough, and generalized papular skin lesions, usually with central umbilication.[184] Symptoms are often present for weeks. In addition to the cutaneous findings, physical examination often reveals peripheral lymphadenopathy and hepatomegaly. Anemia is a prominent laboratory finding.

Diagnosis. *Penicillium marneffei* is most commonly a disseminated disease in HIV-infected patients, and the diagnosis is usually made by blood fungal cultures. Other sites of diagnosis include the skin, lymph nodes, bone marrow, and lungs. In contrast to other *Penicillium* species that cause disease in humans, *P. marneffei* converts to a yeast form in its host, and yeast-laden macrophages can often be seen in peripheral blood, bone marrow aspirates, and touch preparations from tissue biopsies.

Treatment. Amphotericin B, followed by itraconazole, is the standard treatment for *P. marneffei* infection.[14] Mild forms of disease can be treated initially with itraconazole. The duration of amphotericin B treatment is 2 weeks, followed by an additional 10 weeks of itraconazole. This regimen is reported to have a greater than 97% response rate for disseminated *P. marneffei* infection.[185] Without secondary prophylaxis, however, most patients will suffer a relapse within 6 to 12 months. Secondary prophylaxis can be discontinued in patients who are started on ART and have a sustained $CD4^+$ lymphocyte count more than 100 cells/μL for more than 6 months.[14]

Prevention. Itraconazole may be effective as primary prophylaxis against *P. marneffei* for subjects in endemic areas.[186] Given the strong association with soil exposure, especially during the rainy season, HIV-infected patients living in endemic areas should avoid activities that will potentially increase their exposure. Current NIH, CDC, and HIVMA/IDSA guidelines suggest that HIV-infected patients avoid visiting endemic areas if possible.[14]

Candida Species

Despite the high frequency of mucocutaneous candidiasis in HIV-infected patients, pulmonary candidiasis is distinctly uncommon and is rarely diagnosed during life.[187] Because of the small number of documented cases of pulmonary candidiasis, neither the clinical features nor the treatment is well established. However, it is clear that tissue invasion must be demonstrated by biopsy for a convincing diagnosis; the mere identification of the fungus in respiratory secretions by culture alone is insufficient.

Viruses

Many viruses are known to cause pulmonary disease in immunosuppressed persons; however, only cytomegalovirus (CMV) is regarded as an important agent of pulmonary disease in HIV-infected persons. Although clearly the source of significant pathologic conditions in the retina, gastrointestinal tract, and nervous system, the role of CMV in producing pulmonary disease in HIV-infected persons is open to question. Many consider this ubiquitous virus a "passenger" rather than a pathogen in most instances. However, there are also clear instances in which documented pulmonary disease results from CMV.

Cytomegalovirus

Cytomegalovirus, a double-stranded DNA virus in the Herpesvirus family, is fully described in Chapter 31. The risk of exposure to CMV increases with age, and evidence of CMV infection is extremely common in healthy persons. In HIV-infected patients, CMV disease is believed to result chiefly from reactivation of latent infection. However, disease has been documented from de novo infection in recipients of solid organs, bone marrow, and blood (see Chapter 81), which raises the possibility that new infection or superinfection from exogenous sources may also occur in HIV-infected persons.

Clinical Features. Retinitis and gastrointestinal disease are the two most common forms of HIV-associated CMV disease. Cytomegalovirus is a frequent isolate from the BAL fluid of patients with advanced immunosuppression who undergo evaluation for opportunistic infections, notably *Pneumocystis.* Because CMV may be shed in respiratory secretions, its mere presence in BAL fluid cannot be construed as diagnostic of CMV pulmonary disease. When dual pulmonary infection is discovered, treatment directed against the coexisting disease and not against CMV usually results in clinical resolution.[188] However, there are clearly instances when CMV causes pulmonary disease, and the challenge clinicians face is to recognize when these occur.[189,190]

The most common symptoms of CMV pneumonia are cough, dyspnea, and fever. In the study by Salomon and associates,[190] these symptoms were seen in 94%, 94%, and 89%, respectively, of the 18 patients reported. Respiratory symptoms were present for up to 2 weeks in 50% and between 2 and 4 weeks in an additional 44%.

$CD4^+$ Lymphocyte Count. Most cases of CMV disease occur in patients with a $CD4^+$ lymphocyte count less than 50 cells/μL. In one study of 18 patients with biopsy-proven CMV pneumonia, the median $CD4^+$

lymphocyte count was 4 cells/μL.[190] The serum LDH has been reported to be elevated in CMV pneumonia.[190]

Chest Radiograph. The chest radiograph findings of CMV pneumonia vary and include reticular or ground-glass opacities, alveolar infiltrates, and nodules or nodular opacities.[190] Pleural effusions may be seen as well.

Diagnosis. When suspected CMV pulmonary disease occurs in conjunction with other end-organ disease (e.g., retinitis), CMV therapy must be initiated immediately. Treatment of one end-organ CMV disease in fact treats all, although the length of therapy can differ by organ system. The therapeutic dilemma is much greater when only the lungs appear to be afflicted. Patients suspected of having CMV pneumonitis should undergo a careful dilated retinal examination performed by an experienced ophthalmologist, even if there are no ocular complaints. Cytomegalovirus is usually a disseminated disease and commonly involves multiple organ systems in a single host. The only precise criterion for diagnosis of CMV pulmonary disease is the demonstration of widespread specific cytopathic changes in the lungs. Neither culture of BAL fluid[191] nor cytopathic inclusions on TBBX specimens are sufficient to make the diagnosis of CMV pneumonitis.

Treatment. Data for treatment of CMV pneumonia in HIV-infected patients are limited. Intravenous ganciclovir, foscarnet, or cidofovir and valganciclovir are the principal treatment options for CMV retinitis. With these drugs, an initial course of induction therapy is used, and should be continued until clinical improvement occurs; the length of induction therapy for CMV pneumonia, however, is undetermined. Some authorities have recommended a 21-day course for isolated CMV pneumonitis. The usefulness of maintenance therapy in preventing relapse of CMV pneumonitis is unclear.

Prevention. HIV-infected patients who are CMV immunoglobulin G negative should be given CMV-negative blood in the event that a transfusion is necessary. Disease from CMV is best prevented by maintaining $CD4^+$ lymphocyte counts above 100 cells/μL with ART.[14]

Other Viruses

Symptomatic pulmonary viral infection other than CMV is uncommon. Herpes simplex virus, while frequently cultured from BAL fluid, is usually a contaminant from upper airway carriage. Lower respiratory tract involvement is rare in HIV-infected persons (0.2% to 4% of autopsy cases) and appears to be more frequent in other immunosuppressed hosts. Herpes simplex virus pulmonary disease causes a focal pneumonia or a diffuse interstitial pneumonitis.[192] The focal pneumonias appear to result from contiguous spread of herpes simplex virus to the lung parenchyma and are often associated with necrotizing tracheobronchitis, whereas the diffuse interstitial pneumonias appear to be a manifestation of hematogenous herpes simplex virus dissemination.

Varicella-zoster virus is a rare cause of pneumonia in HIV-infected adult patients.[193] Epstein-Barr virus DNA has been identified in lung biopsy specimens of infants and children with lymphocytic interstitial pneumonitis, but the precise role of the virus in this disease is uncertain.[194] Influenza has been isolated from HIV-infected patients.[195] In this small series, neither the clinical presentation of influenza nor the rate of secondary complications appeared to be different from that in healthy persons. Nevertheless, it is generally recommended that all HIV-infected persons be vaccinated annually.[14]

Parasites

Of the classic unicellular and multicellular parasites that afflict otherwise healthy humans (see Chapter 37), several also cause pulmonary disease in HIV-infected hosts. Of these, *T. gondii* is the most frequent.

Toxoplasma gondii

Toxoplasmosis is a zoonosis caused by the intracellular protozoan *T. gondii,* with domestic cats as its definitive host but with an infectious reservoir that encompasses all animals. Transmission to humans occurs when raw or undercooked meat containing *T. gondii* is eaten. Domestic cat feces in litter boxes are an additional source of potential *T. gondii* infection. Vertical transmission can occur from mother to fetus. In HIV-infected patients, the overwhelming majority of cases of toxoplasmosis result from reactivation of chronic, latent infection. Thus, the keys to preventing toxoplasmosis are prevention of exposure for those not yet infected and prophylaxis for those already seropositive. The seroprevalence of *Toxoplasma* antibodies varies. In the United States, the seroprevalence is 10% to 50%, whereas in Western Europe, the seroprevalence may be as high as 90%.

Clinical Features. Central nervous system complications of *T. gondii* are well recognized in HIV disease and include encephalitis as well as focal brain abscess. Pulmonary involvement is uncommon, but can occur in patients with central nervous system or disseminated disease, or can present as isolated pneumonia.[196,197]

$CD4^+$ Lymphocyte Count. Toxoplasmosis presents at the lower range of $CD4^+$ lymphocyte counts. In a large study of 64 patients with pulmonary toxoplasmosis conducted in France, the mean (± standard deviation [SD]) $CD4^+$ lymphocyte count was 40 (±75) cells/μL.[197]

Chest Radiograph. The chest radiograph usually reveals bilateral infiltrates, either fine reticulonodular infiltrates indistinguishable from PCP or a coarse nodular pattern similar to that seen with tuberculosis or fungal pneumonias.[198] Pleural effusions can be seen, and a variety of other radiographic findings have also been described.[199]

Diagnosis. The diagnosis of pulmonary toxoplasmosis is usually established by bronchoscopy and study of BAL fluid. In one review, BAL fluid examination was diagnostic in 16 of 17 immunocompromised patients with pulmonary disease.[199]

Treatment. The treatment for pulmonary toxoplasmosis is identical to that for central nervous system toxoplasmosis. First-line treatment is sulfadiazine plus pyrimethamine with leucovorin to decrease the likelihood of hematologic toxicities associated with

pyrimethamine.[14] The preferred alternative regimen is clindamycin plus pyrimethamine with leucovorin.

Prevention. HIV-infected persons should be tested for *T. gondii* antibodies. Persons who are *Toxoplasma* antibody negative should be instructed to avoid potential sources of infection. Patients should receive primary prophylaxis once their $CD4^+$ lymphocyte count falls below 100 cells/μL.[14] As a practical matter, this is often accomplished when the $CD4^+$ lymphocyte count reaches 200 cells/μL or fewer because the prophylaxis of choice (TMP-SMX) is also the prophylaxis of choice for *Pneumocystis.* For patients who are intolerant of TMP-SMX, dapsone plus pyrimethamine (and leucovorin) or atovaquone plus pyrimethamine (and leucovorin) can be used. Primary and secondary *T. gondii* prophylaxis can be discontinued in HIV-infected persons on ART who have experienced an increase in their $CD4^+$ lymphocyte count to greater than 200 cells/μL for at least 3 to 6 months.[14]

Other Parasites

In general, helminth infections occur infrequently in HIV-infected persons.[200,201] Both pulmonary cryptosporidiosis and pulmonary microsporidiosis in HIV-infected patients with concurrent intestinal disease have been reported.[202] In these cases, aspiration from the gastrointestinal tract appears to be the most probable route of pulmonary infection. Occasionally, patients have presented with disseminated disease, raising the likely possibility of hematogenous spread. The most common respiratory symptoms are cough, dyspnea, and pleuritic chest pain. One review found that these symptoms were present in 77%, 58%, and 33%, respectively, of patients with cryptosporidial pulmonary disease.[202] The diagnosis of *Strongyloides stercoralis* pulmonary disease can be made by either sputum study or bronchoscopy.[203,204] *Strongyloides* hyperinfection syndrome has also been reported in HIV-infected patients,[205] but does not appear to be an important HIV-associated complication, even in countries where the parasite is endemic.[206]

NONINFECTIOUS DISORDERS

The evaluation of respiratory complications usually focuses on the diagnosis of HIV-associated opportunistic infections because of their frequency, the need for prompt therapy, and, in the case of tuberculosis, the concern for transmission to other persons, both HIV infected and non–HIV infected. However, as more people are living with HIV/AIDS and are living longer on effective ART, noninfectious complications and comorbid illnesses among these HIV-positive patients have increased in frequency.[207] In addition to an increased risk for infectious diseases, HIV-infected patients appear to have an increased risk for a number of noninfectious pulmonary diseases, including chronic obstructive pulmonary disease (COPD), lung cancer, and pulmonary arterial hypertension. Increasing age and a high prevalence of cigarette smoking combined with an independent risk from HIV infection itself may all contribute, in particular to increases in COPD and lung cancer. Noninfectious pulmonary diseases that may be encountered in HIV are reviewed here.

Malignancies

Two different HIV-associated malignancies, Kaposi sarcoma and non-Hodgkin's lymphoma, may involve the thorax, including the lung parenchyma, airways, pleura, or hilar or mediastinal lymph nodes. Intrathoracic disease from either neoplasm is usually a manifestation of disease already recognized elsewhere, but occasionally both Kaposi sarcoma and non-Hodgkin's lymphoma may present with isolated pulmonary disease.

Kaposi Sarcoma

The most common HIV-associated malignancy is Kaposi sarcoma, although its incidence has decreased dramatically with combination ART.[208,209] Kaposi sarcoma is an angioproliferative tumor that most commonly presents with mucocutaneous involvement. The lymph nodes, gastrointestinal tract, and lungs can also be involved. Significant advances have been made in our understanding of its pathogenesis, including its association with a human herpesvirus.[210]

The incidence of HIV-associated Kaposi sarcoma has always been significantly higher in MSM than in other HIV risk groups. Approximately 90% to 95% of cases occur in MSM, and it has been estimated that there is a 20,000- to 73,000-fold increased incidence of Kaposi sarcoma in HIV-infected MSM than in the overall population.[211] These observations suggested the presence of a possible sexually transmitted cofactor. In 1994, Chang and colleagues[212] identified DNA fragments present in HIV-associated Kaposi sarcoma specimens but absent in most non-Kaposi specimens. The nucleotide sequence of these fragments demonstrated homology to two known gamma- (lymphotropic) herpesviruses, suggesting that the fragments derived from a novel herpesvirus, subsequently named human herpesvirus 8 (HHV8) or Kaposi sarcoma–associated herpesvirus.[213] Since then, HHV8 has also been found in specimens from non–HIV-infected persons with classic, endemic (African), and transplant-associated Kaposi sarcoma. These and other findings argue for a central role of HHV8 in the pathogenesis of Kaposi sarcoma and provide new avenues for possible treatment of this disease.

Clinical Features. Pulmonary Kaposi sarcoma is detected clinically in approximately one third of patients with known Kaposi sarcoma, with the proportion detected at autopsy approaching 50% to 75%. Most but not all patients with clinically diagnosed pulmonary Kaposi sarcoma have concomitant mucocutaneous disease. Huang and coworkers[214] found that 85% of 168 consecutive patients diagnosed with pulmonary Kaposi sarcoma by bronchoscopy had evidence of mucocutaneous involvement at the time of bronchoscopy. The 15% without mucocutaneous involvement had pulmonary disease that ranged from isolated tracheal lesions to

diffuse endobronchial involvement that was ultimately fatal. A significant proportion of patients with pulmonary Kaposi sarcoma also have concurrent opportunistic infection. For example, in the study by Huang and coworkers,[214] 45 (27%) of the 168 patients with pulmonary Kaposi sarcoma had accompanying opportunistic infection, most frequently PCP. These observations underscore the need to evaluate each patient with Kaposi sarcoma who presents with respiratory symptoms not only for pulmonary Kaposi sarcoma but also for opportunistic infection. Patients with pulmonary Kaposi sarcoma who develop opportunistic infection may also experience a rapid progression of their Kaposi sarcoma that mimics an infectious process.

$CD4^+$ Lymphocyte Count. Pulmonary Kaposi sarcoma presents at the lower range of $CD4^+$ lymphocyte counts. In one study of 168 patients with pulmonary involvement from Kaposi sarcoma, the median $CD4^+$ lymphocyte count was 19 cells/μL; 68% had a $CD4^+$ lymphocyte count below 50 cells/μL, and only 4% had a $CD4^+$ lymphocyte count higher than 200 cells/μL.[214] Patients with Kaposi sarcoma pulmonary involvement appear to have lower $CD4^+$ lymphocyte counts than those without pulmonary involvement.

Chest Radiograph. Pulmonary Kaposi sarcoma characteristically presents with bilateral opacities in a central or perihilar distribution, as shown in Figure 80-9. Typical findings include linear densities, nodules or nodular opacities of varying size, pleural effusions, and intrathoracic adenopathy. Gruden and associates[215] reviewed the chest radiographic presentation of 76 consecutive patients with pulmonary Kaposi sarcoma diagnosed by bronchoscopy whose BAL was negative for infectious organisms. In this study, 95% of the radiographs had peribronchial cuffing and "tram track" opacities, with or without more extensive perihilar coalescent opacities. Small nodules or nodular opacities were seen in 78%, Kerley B lines in 71%, and pleural effusions in 53% of the radiographs. Although these radiographic findings strongly suggest the diagnosis of pulmonary Kaposi sarcoma in HIV-infected MSM, no radiograph is diagnostic for Kaposi sarcoma. Therefore, patients with suspected pulmonary Kaposi sarcoma should have their diagnosis confirmed.

Diagnosis. The diagnosis of pulmonary Kaposi sarcoma is usually established by bronchoscopy. The observation of characteristic endobronchial, red or violaceous, flat or slightly raised lesions is sufficient to diagnose pulmonary involvement (Fig. 80-10). However, the presence of these lesions does not preclude a concurrent infection, nor does their absence in the observable airway preclude more distal disease or parenchymal, pleural, or nodal involvement. Although endobronchial or transbronchial biopsy of the airway or parenchymal abnormalities, respectively, is usually unnecessary, we have occasionally established the diagnosis by TBBX in patients in whom there was a strong clinical suspicion for pulmonary Kaposi sarcoma but who had no endobronchial lesions detected. Patients with cutaneous Kaposi sarcoma who develop new respiratory complaints should undergo thorough evaluation to rule out an opportunistic infection or other process. However, patients in whom there is a strong clinical suspicion for pulmonary Kaposi sarcoma should undergo bronchoscopy as the initial procedure.

Kaposi sarcoma is ^{67}Ga scan negative. In contrast, opportunistic infections and non-Hodgkin's lymphoma are ^{67}Ga avid. Among HIV-associated pulmonary diseases, this unique feature of Kaposi sarcoma has created a

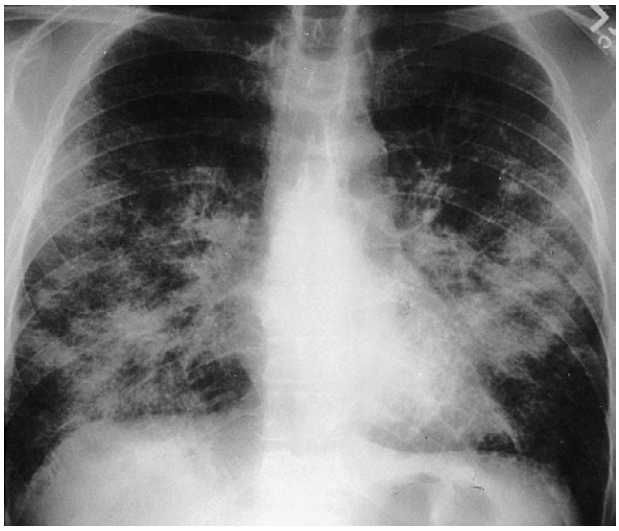

FIGURE 80-9 ■ Posteroanterior chest radiograph of an HIV-seropositive patient with pulmonary Kaposi sarcoma diagnosed by bronchoscopy showing the characteristic bilateral, perihilar distribution of abnormalities consisting of nodules and nodular opacities. Although most HIV-infected patients with pulmonary Kaposi sarcoma will have concomitant mucocutaneous Kaposi sarcoma, approximately 15% will have no evidence of cutaneous or oral involvement. niche for the use of ^{67}Ga scans. In the absence of either a bronchoscopic or tissue diagnosis of pulmonary Kaposi sarcoma, its presence may be inferred by the finding of significant chest radiographic abnormalities and a negative ^{67}Ga scan.

Treatment. Tumors can regress in size and number in response to ART, and therefore all patients with Kaposi sarcoma should receive combination ART if no other contraindications exist.[216] Treatment of systemic disease also includes chemotherapy, with approved agents consisting of doxorubicin, daunorubicin, and paclitaxel; in addition, the antiviral agent cidofovir, although not effective on its own, may have a role as adjunctive therapy.[216] Mortality in patients with Kaposi sarcoma may be related to an increased rate of other malignancies, particularly lymphomas, in this population.[217] Survival in patients with pulmonary Kaposi sarcoma appears substantially worse when compared to patients without pulmonary involvement: 5-year overall survival was reported to be 49% in patients with pulmonary Kaposi sarcoma as compared to 82% in patients without pulmonary involvement ($p < 0.0001$).[218]

Non-Hodgkin's Lymphoma

Almost all HIV-associated non-Hodgkin's lymphomas are of B-cell origin. Most are classified as small, noncleaved Burkitt's, diffuse large cell with centroblastic features, or diffuse large cell with immunoblastic features.[219] Many patients have an advanced stage of disease at the time of presentation. Although initial data concerning non-Hodgkin's lymphoma in the combination ART era did not demonstrate as substantial a decrease in incidence as observed in Kaposi sarcoma, most studies now demonstrate that significant decreases occur in non-Hodgkin's lymphoma as well.[220]

Clinical Features. Most HIV-infected patients with non-Hodgkin's lymphoma present with widely disseminated disease and extranodal involvement.[221] Frequent extranodal sites include the liver, spleen, bone marrow, meninges, gastrointestinal tract, and pericardium. Intrathoracic involvement is seen in a smaller proportion. The reported incidence of intrathoracic disease varies from 0 to 31% of patients at the time of clinical diagnosis and is usually higher at the time of autopsy. Occasionally, the lung is the only site involved.

CD4$^+$ Lymphocyte Count. Non-Hodgkin's lymphoma can present at a wide range of CD4$^+$ lymphocyte counts. The median CD4$^+$ T-lymphocyte count is approximately 100 cells/μL, and 75% of patients have a CD4$^+$ lymphocyte count above 50 cells/μL. In one study of 38 patients with non-Hodgkin's lymphoma, the mean (±SD) CD4$^+$ lymphocyte count was 67 (±65) cells/μL.[222]

Chest Radiograph. The most common chest radiograph parenchymal findings include single (Fig. 80-11) or multiple nodules, nodular opacities or masses, lobar infiltrates, and diffuse interstitial infiltrates.[222] More rarely, cases of endobronchial lesions have been reported.[223] Pleural effusions are the most common radiographic abnormality, occurring in 40% to 70% of cases, and many are bilateral.[222] Bilateral hilar and mediastinal adenopathy can be found in up to 60% of patients. Isolated intrathoracic adenopathy without identifiable extrathoracic nodal involvement is a rare presentation for HIV-associated non-Hodgkin's lymphomas.

Diagnosis. The diagnosis of non-Hodgkin's lymphoma requires demonstration of malignant lymphocytes on cytology or biopsy specimens. Most often the diagnosis is made by needle aspiration or biopsy of an extrathoracic site. Persons who present with isolated intrathoracic involvement should undergo bronchoscopy with Wang needle biopsy, if abnormal nodes are within reach through the bronchoscope, and with TBBX.[222] For lesions outside the sampling distance of the bronchoscope, fluoroscopic or CT-guided fine-needle aspiration should be considered. Other options include mediastinoscopy

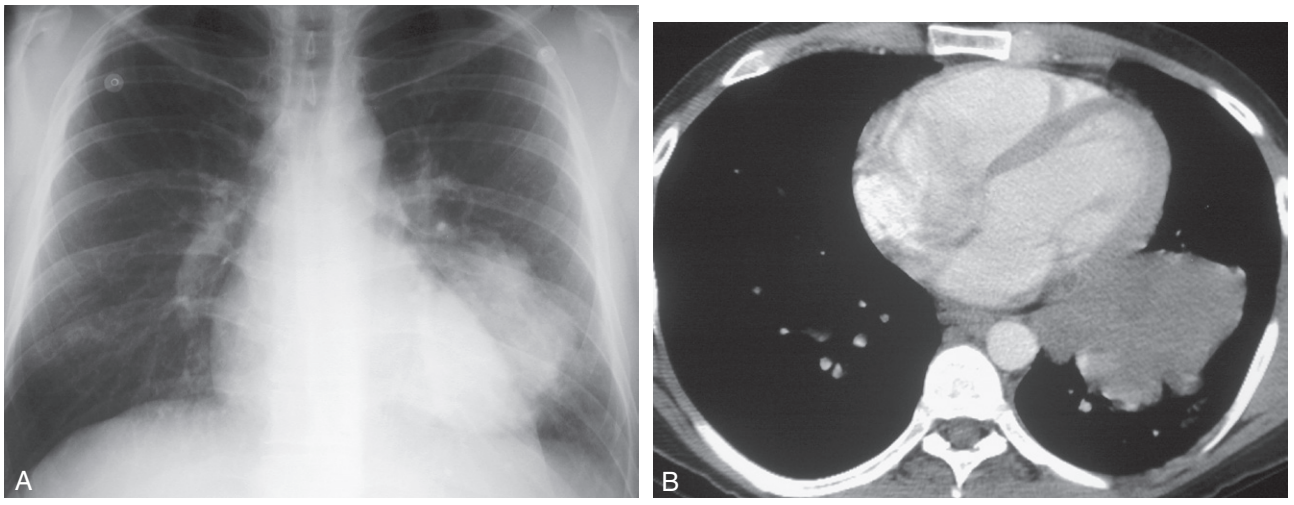

FIGURE 80-11 ■ **A,** Frontal chest radiograph from an AIDS patient with non-Hodgkin's lymphoma showing a large left lower lobe mass. **B,** Axial computed tomogram shows a mass in the left lower lobe without an air bronchogram, suggestive of a neoplasm. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

and open-lung biopsy. For patients with pleural effusions, pleural fluid cytology, biopsy, or both are often diagnostic.[222] Pleural fluid is exudative, lymphocytic predominant, and often with very high levels of LDH.[222] The yield of pleural cytology is significantly higher in HIV-associated pulmonary lymphoma as opposed to HIV-negative cases.[224]

Treatment. Pulmonary involvement in non-Hodgkin's lymphoma is treated as part of systemic disease. Median survival from AIDS-related non-Hodgkin's lymphoma has greatly improved as a result of combining ART with systemic chemotherapy: from 8.3 months to 43.2 months in one analysis.[225] Chemotherapy of non-Hodgkin's lymphoma is frequently complicated by the development of opportunistic infections, particularly PCP, and by the presence of decreased bone marrow reserve. Therefore, *Pneumocystis* prophylaxis should be considered in all cases, regardless of $CD4^+$ lymphocyte count.

Primary Effusion Lymphoma

Classic primary effusion lymphoma is a distinct subtype of non-Hodgkin's lymphoma that presents with isolated effusions in body cavities, including the pleura, pericardium, and peritoneum.[226] The classic form of primary effusion lymphoma presents with lymphomatous effusions that occur in the absence of a discrete nodal or extranodal mass. A rare disease, these tumors are found nearly exclusively in HIV-infected MSM. HIV infection is usually advanced; in one study peripheral $CD4^+$ lymphocyte counts averaged 200 cells/μL.[226] HIV-infected patients with primary pleural effusion lymphoma typically present with symptoms related to the space-occupying nature of the effusion (i.e., dyspnea). Diagnosis is established by pleural fluid histology and identification of HHV8, which can be found in all cases.[227] Primary effusion lymphomas are of a null phenotype, lacking classic B-cell and T-cell markers.[216] Prognosis is poor, with median survival on the order of 6 months. Treatment options include combination ART and systemic chemotherapy. Agents known to have activity against intermediate- and high-grade non-Hodgkin's lymphoma may be used. A handful of cases have noted prolonged survival in patients treated with cidofovir or ganciclovir as adjunctive antiviral therapy.[216]

Multicentric Castleman's Disease

Multicentric Castleman's disease (MCD) is a rare lymphoproliferative disorder of the plasma cell type.[228] MCD can occur in association with Kaposi sarcoma in HIV-infected as well as in HIV-uninfected patients. Most patients with MCD are infected with HHV8, particularly if they are also infected with HIV. Common presenting symptoms and signs of systemic MCD include fever, weakness, generalized lymphadenopathy, anemia, and hypergammaglobulinemia. One series described 12 patients with histologically proven MCD with pulmonary involvement.[229] Symptoms of dyspnea and cough were common in this group; bilateral crackles were frequently described on physical examination. Chest imaging demonstrated reticular (n = 7) and/or nodular (n = 7) interstitial patterns, with mediastinal lymphadenopathy (n = 9) and bilateral pleural effusion (n = 3). In another study, bronchovascular nodularity, consolidation, and mediastinal lymphadenopathy were described on chest CT.[230] HHV8 may be detected on BAL. Diagnosis is based on pathologic evaluation of an involved lymph node or extranodal mass. Involved cells resemble immunoblasts, and are of B-cell lineage.[228] Prognosis is generally poor. Treatment options include systemic chemotherapy as well as monoclonal antibodies against CD20 (rituximab) and interleukin-6 receptor (altizumab); reports of sustained remission have been associated with rituximab therapy.[216] Cases of IRIS, some of them fatal, have been reported in patients with MCD initiated on ART.

Non–Small Cell Lung Cancer

The incidence of lung cancer is greater among HIV-infected persons than among HIV-uninfected persons. Whether this increased incidence is due to HIV infection or to other potential confounders such as increased smoking among HIV-infected populations remains somewhat controversial. Studies that account for potential confounding factors include work by Kirk and colleagues,[231] who analyzed lung cancer deaths in the combination ART era and found that HIV infection was associated with a hazard ratio of 3.6 for lung cancer (95% confidence interval [CI], 1.6 to 7.9), after controlling for smoking status as well as age, sex, and calendar period. Similarly, in a study by Engels and colleagues,[232] HIV infection was associated with a standardized incidence ratio of 2.5 (95% CI, 1.6 to 3.5) for lung cancer, adjusting for estimates of smoking prevalence. The incidence of lung cancer in HIV appears to be increased in the combination ART era, with one study finding an incidence of 0.8 per 10,000 person-years in the precombination ART era compared with 6.7 per 10,000 person-years following ART.[233] Whether this is due to an increased age of patients with HIV or other factors is unclear.

Clinical Features. A number of reports have suggested that bronchogenic carcinoma is increased in frequency, occurs at a younger age, and has a more aggressive course in HIV-infected patients. Most HIV-infected patients who develop bronchogenic carcinoma are cigarette smokers. Although all pathologic types are seen, adenocarcinoma has been the most frequent type reported, similar to that seen in non–HIV-infected patients younger than 40 years of age who develop bronchogenic carcinoma; squamous cell carcinoma is the second most frequently observed pathologic type.[232] HIV-infected patients may be more likely to have advanced-stage disease at presentation, although whether this is due to detection bias is uncertain, and age-matched data do not support this finding.[234] Bronchogenic carcinoma can develop at a wide range of $CD4^+$ lymphocyte counts. In the PCHIS study, the range of $CD4^+$ lymphocyte counts among the patients who developed lung cancer was 127 to 1026 cells/μL.[235] There is no apparent relationship between HIV viral load and use of ART with

lung cancer risk.[231] The characteristic presentation and radiographic finding of bronchogenic carcinoma, as described in Chapter 47, are similar in HIV-infected and HIV-uninfected patients.

Diagnosis and Treatment. The diagnosis and treatment of bronchogenic carcinoma in an HIV-infected patient is similar to that in a non–HIV-infected individual. HIV infection should be considered an important concurrent underlying medical problem, much the same as one would consider underlying cardiopulmonary disease. Overall, mortality in HIV-infected patients with lung cancer appears to be independent of HIV, and median survival in HIV-infected patients with lung cancer is similar to age-matched HIV-uninfected lung cancer patients.[234]

Pulmonary Arterial Hypertension

Since the 1980s, studies have reported an increased frequency of pulmonary arterial hypertension in the HIV-infected population, with a prevalence of approximately 0.5% compared to 1 to 2 cases per million in the non–HIV-infected population.[236] There is some debate about whether this diagnosis has decreased in the era of combination ART, but it still seems to be over-represented in HIV-infected individuals.[237] Data suggest that pulmonary arterial hypertension may be underdiagnosed in this population as screening echocardiograms detected increased pulmonary artery pressures in 35% of HIV-infected subjects compared to 7.7% of non–HIV-infected controls.[238]

Clinical Features

HIV-infected patients are significantly younger, and the proportion with New York Heart Association functional class III or IV significantly lower (50% vs. 75%, $P = 0.01$), than in non–HIV-infected subjects with idiopathic pulmonary arterial hypertension, and 1-year survival is approximately 51%.[239] Intravenous drug use is commonly reported in HIV-infected patients with pulmonary hypertension.[239] In a review of 131 cases of pulmonary hypertension in HIV-infected patients,[240] presenting symptoms and radiographic, pulmonary function, electrocardiographic, echocardiographic, and pathologic findings were similar to those found in non–HIV-related idiopathic pulmonary arterial hypertension (described in Chapter 52).

Treatment

Small studies have reported improved functional and hemodynamic parameters in subjects with HIV and pulmonary arterial hypertension during treatment with epoprostenol and bosentan.[241] Other treatments such as sildenafil and iloprost may also be useful.[242,243] Epoprostenol may be associated with intravascular infections in the HIV population, and high levels of sildenafil can be seen when used in combination with antiretrovirals, particularly ritonavir. Although still controversial, some studies have found a benefit in treating patients with ART or the combination of ART and bosentan.[236,244]

Obstructive Lung Disease

Obstructive lung disease occurs frequently in HIV-infected patients, and a variety of pulmonary function test abnormalities can be seen. The PCHIS researchers performed serial pulmonary function tests in more than 1100 HIV-infected subjects and demonstrated that advanced HIV infection, characterized by a $CD4^+$ lymphocyte count less than 200 cells/μL or HIV-associated symptoms, as well as race, cigarette smoking, and IDU, were associated with reductions in D_{LCO}.[245] A PCHIS multivariate analysis found that both PCP and bacterial pneumonia were independently associated with an accelerated decline in the forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), FEV_1/FVC, and D_{LCO}.[246] Studies have found that significant proportions of HIV-infected subjects self-report wheezing within the past 12 months,[247,247a] and have evidence of airflow obstruction: 33 of 99 persons with AIDS (33%) had decreased forced expiratory flow rates, and 20 of the 33 (61%) experienced a significant response to inhaled bronchodilators.[248]

HIV-infected patients may have asthma that precedes their HIV infection. In one clinic-based study, a history of asthma was reported in 21% and current asthma in 17% of 136 patients attending a primary care clinic for HIV infection.[249] On questioning, 61% of the current asthmatic patients reported subjective worsening of their asthma after becoming HIV infected, but the role of HIV itself is unclear. HIV-infected patients are more likely than non–HIV-infected patients to have bronchial hyperresponsiveness to methacholine.[247] $CD4^+$ lymphocyte counts greater than 200 cells/μL are associated with current asthma in those with HIV infection,[249] and one report has linked use of asthma medication to combination ART use in HIV-infected children, suggesting that immune responses are important.[250]

Obstructive airway disease, chronic bronchitis, and bronchiectasis are well-recognized sequelae of opportunistic infection[251,252]; however, evidence also suggests that HIV infection is associated with an increase in emphysema apart from the effects of opportunistic infections.[253] The impact of combination ART on emphysema and airway obstruction is mostly unknown, but a study of self-report and *International Classification of Diseases,* Ninth Revision, diagnoses of COPD in a cohort of HIV-seropositive and HIV-seronegative veterans found that HIV infection was an independent risk factor for COPD.[254]

Treatment

In general, treatment of asthma and COPD in patients with HIV infection should be similar to that for the non–HIV-infected population (see Chapters 38 and 39). PIs, particularly ritonavir, have been reported to increase systemic levels of inhaled or intranasal fluticasone, leading to Cushing's syndrome or adrenal suppression when the corticosteroids are tapered.[255] The use of high-dose inhaled steroids for COPD in patients with HIV also requires careful monitoring for oral candidiasis and bacterial pneumonia.[256]

Interstitial Pneumonitides

Although opportunistic infection and neoplasia dominate the clinical spectrum of HIV-associated pulmonary diseases, a small number of patients present with signs and symptoms that are attributable to one of the interstitial pneumonitides, lymphocytic interstitial pneumonitis (LIP) or nonspecific interstitial pneumonitis (NSIP).

Lymphocytic Interstitial Pneumonitis

Although described by Carrington and Liebow over 30 years ago, it remains speculative whether LIP is a pathogenically distinct entity or a disorder of multiple causes that all produce a similar pathologic reaction (see also Chapter 57). The facts that LIP occurs with increased frequency in HIV-infected persons (albeit rarely in adults) and is diagnostic of AIDS when it occurs in an HIV-infected child younger than 13 years of age favor the diverse-origin theory.

Clinical Features. The most striking feature of HIV-associated LIP is the effect of age on its incidence. Early in the AIDS epidemic, one third to one half of AIDS-defining diagnoses in HIV-infected children in industrialized countries were due to LIP. In contrast, LIP is rare in adults. We have encountered but a handful of biopsy-proven LIP cases in our experience with several thousand adult AIDS patients at San Francisco General Hospital, and there are only scattered case reports throughout the literature.[257]

The chest radiograph presentation of LIP is nonspecific, as shown in Figure 80-12, and is characterized by bilateral reticulonodular interstitial infiltrates with a middle to lower lung zone predominance.[258] Areas of alveolar opacity believed to result from bronchial compression caused by more severe lymphocytic infiltration may occur but are rare. Hilar or mediastinal adenopathy is occasionally seen. Chest CT scans may reveal small (2- to 4-mm) nodules, often in a peribronchovascular distribution, or diffuse areas of ground-glass opacity.[259]

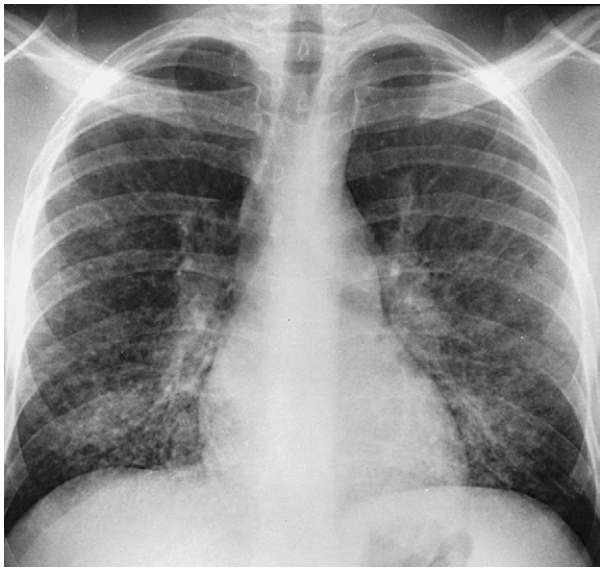

FIGURE 80-12 ■ Posteroanterior chest radiograph of an HIV-seropositive patient showing diffuse reticulonodular infiltration. Biopsy specimen revealed lymphocytic interstitial pneumonitis, a rare disorder in HIV-infected adults that is more frequently seen in HIV-infected children.

Diagnosis and Treatment. The definitive diagnosis of LIP requires histologic confirmation by biopsy. There are so few studies of LIP among HIV-infected adults that neither definitive therapy nor benefit of therapy has been determined. A few cases of LIP that responded to ART alone have been reported.[257,260]

Nonspecific Interstitial Pneumonitis

NSIP is a pulmonary disorder characterized histologically by infiltration of mononuclear cells, predominantly lymphocytes and plasma cells, into the peribronchiolar and perivascular interstitium (see also Chapter 57). NSIP has been reported with various frequencies in HIV-infected patients. Because it is a histologic diagnosis, its incidence depends on the frequency with which biopsy is performed during the diagnostic evaluation.

Clinical Features. The clinical features of NSIP are indistinguishable from those of PCP; however, NSIP may present at $CD4^+$ lymphocyte counts above 200 cells/μL, whereas PCP rarely (≤5%) does. For example, in a series of 67 HIV-infected patients with NSIP, the mean $CD4^+$ lymphocyte count in the patients with NSIP was 492 cells/μL compared with 57 cells/μL for the matched control subjects with PCP.[261] The chest radiographic presentation of NSIP is usually a nonspecific diffuse interstitial pattern, which is also indistinguishable from that of PCP; one study, however, reported that 16 of 36 (44%) patients with HIV-related NSIP had normal radiographs.[262]

Diagnosis and Treatment. The diagnosis of NSIP requires both histologic confirmation and the exclusion of other etiologies. The natural history of HIV-associated NSIP is poorly understood, but it usually resolves or stabilizes without therapy.[261] Observation is all that is required, with the proviso that, if the patient becomes severely ill, repeat bronchoscopy and biopsy are indicated to look for a different, usually infectious, disorder.

Sarcoidosis

Although sarcoidosis would seem an unlikely disorder among patients with HIV, a number of cases of sarcoidosis or sarcoid-like disease have been reported in this population. Many of these cases have been reported during the combination ART era and have correlated the use of ART with the development of sarcoidosis.[263,264] Whether sarcoidosis in HIV represents a manifestation of IRIS is debated. Approximately 75% of HIV-infected patients with sarcoidosis have $CD4^+$ lymphocyte counts above 200 cells/μL.[263]

Both the clinical and radiographic findings of sarcoidosis in HIV-infected patients mirror findings of sarcoidosis in HIV-uninfected patients.[263,264] As described in Chapter 59, granulomatous inflammation of the lungs and other involved organs is characteristic. Stains and cultures of tissue should be obtained and, to diagnose

sarcoid, must be negative for microorganisms (e.g., mycobacteria, fungi). Lymphocytic alveolitis with a high percentage of $CD4^+$ lymphocytes may be encountered.[265] Because no studies have evaluated treatment of sarcoidosis specifically in HIV-infected persons, until further data are available, management should follow guidelines as outlined for HIV-uninfected persons with sarcoidosis.

Immune Reconstitution Inflammatory Syndrome

"Immune reconstitution inflammatory syndrome" describes a paradoxical worsening of clinical status related to recovery of the immune system following a period of immunosuppression, which typically occurs after the initiation of ART in HIV-infected patients. IRIS is thought to occur as a result of reconstitution of the immune system leading to host inflammatory responses to previously recognized or subclinical infections. Immune reconstitution may also result from an inflammatory or immune response to cancer or self antigens, as cases of IRIS have been reported to present with worsening tumor or autoimmune disease.

Numerous different disease processes have been associated with IRIS. These include many infections, sarcoid, autoimmune conditions, and tumors.[266,267] Among infectious triggers, mycobacterial infections—particularly *M. tuberculosis* and MAC—are most frequently encountered. Fungal infections, including PCP and *Cryptococcus,* as well as viral infections, such as CMV, can also be exacerbated by IRIS. The majority of cases of IRIS occur within the first 1 to 3 months following the initiation of ART, although cases may present several months after the initiation of ART.[267] In most studies, IRIS is significantly associated with starting ART in close proximity to treatment for an acute opportunistic infection.[268,269]

In general, ART should be continued in patients who have IRIS, although careful review on a case-by-case basis is required.[14] Nonsteroidal anti-inflammatory agents and corticosteroids can be used to decrease inflammation. Steroids are recommended if the excessive inflammatory response can be particularly harmful, such as in lesions involving the central nervous system or causing airway compromise. Optimal dosage and duration have not been studied, but prednisone or methylprednisolone at approximately 1 mg/kg of body weight, gradually reduced over 1 to 2 weeks, may be used.[14]

KEY POINTS

- HIV infection results in immune dysregulation, dysfunction, and deficiency, with a progressive decline in the circulating $CD4^+$ lymphocyte count, particularly in patients not receiving effective combination antiretroviral therapy (ART). HIV infection also causes alteration in several lines of host defense in the lungs and respiratory tract.
- The peripheral $CD4^+$ lymphocyte count is a key factor that influences the risk for pulmonary complications in HIV-infected persons; the risk of opportunistic infections and HIV-associated malignancies increases progressively as $CD4^+$ lymphocyte counts decrease.
- Worldwide, tuberculosis is the most common infectious lung complication and a major cause of HIV-associated morbidity and mortality. Drug-resistant tuberculosis appears to be increasing in incidence and seems to have a predilection for persons infected with HIV.
- Bacterial pneumonia and *Pneumocystis* pneumonia (PCP) are also common infectious lung complications associated with HIV; noninfectious conditions that may be encountered with increased frequency in patients with HIV include lung cancer, idiopathic pulmonary arterial hypertension, and chronic obstructive pulmonary diseases.
- The differential diagnosis for pulmonary diseases in HIV-infected patients is broad, and the clinical features and radiographic findings of many diseases may overlap significantly. Definitive diagnosis is highly recommended in patients with HIV. When feasible, early bronchoscopy with bronchoalveolar lavage should be performed in patients with pneumonia who do not have an established microbiologic diagnosis.
- In HIV-infected patients recently started on combination ART, immune reconstitution inflammatory syndrome may occur with paradoxical worsening of conditions that include infections (such as tuberculosis, MAC, and PCP), malignancies (such as Kaposi sarcoma), and inflammatory diseases (such as sarcoidosis).

CHAPTER 81

PULMONARY COMPLICATIONS OF STEM CELL AND SOLID ORGAN TRANSPLANTATION

Rodney J. Folz, MD, PhD • Maria Cirino-Marcano, MD

INTRODUCTION

INFECTIOUS COMPLICATIONS
Bacterial Infections
Viral Infections
Fungal Infections

NONINFECTIOUS COMPLICATIONS

EARLY COMPLICATIONS
Pulmonary Edema and Respiratory Failure
Venous Thromboembolic Disease
Diaphragmatic Dysfunction

LATE COMPLICATIONS
Drug Toxicity and Interstitial Lung Disease
Obliterative Bronchiolitis
Pulmonary Metastatic Calcifications
Malignancy
Conclusion

INTRODUCTION

Transplantation of human organs and tissues is an accepted option for otherwise untreatable end-stage diseases of renal, thoracic, gastrointestinal, and hematologic origin. With the development of advanced transplantation techniques and increased organ donation awareness, the number of solid organ transplants has increased dramatically. According to 2009 data from the Organ Procurement and Transplantation Network, over 486,000 solid organ transplants have been performed since 1988 in the United States. Pharmacologic advances for prophylaxis and prevention of rejection have also helped increase patient survival. Because of chronic immunosuppression, these patients are at increased risk of infection and drug toxicity, as well as pulmonary complications from their underlying disease or the transplant itself. For example, the incidence of pulmonary toxicities following hematopoietic stem cell transplantation has been estimated to be anywhere from 2% to 70%, varying with the specific patient population being analyzed, details of the individual therapeutic regimens, and the criteria used to define lung toxicity.[1,1a]

The aim of this chapter is to review the infectious and noninfectious complications of solid and hematologic transplantation as well as the diagnostic and therapeutic options available for this group of patients.

INFECTIOUS COMPLICATIONS

Despite the practice of prophylaxis against opportunistic pathogens in the posttransplantation period and better antibiotics available for resistant organisms, infection after transplantation remains a major concern. Infections in the posttransplantation patient range from common pathogens found in the community (although the severity of disease may be greater), to health care–associated pathogens and opportunistic infections. Signs and symptoms of infection in immunosuppressed individuals may complicate the clinical picture, since fundamental immunologic processes have been altered by these drugs and symptoms of rejection or reactions to medications can mimic an infectious process. For example, fever is a common sign in posttransplantation patients, but its correlation with infection is not as well defined. Chang and colleagues reported that, in liver transplant patients, fever was due to infection in 78% of cases. Of infectious causes for fever, 80% were due to bacterial infections and 20% due to viruses. None of these febrile illnesses were shown to be due to fungi.[2]

Due to direct exposure to the environment, the lung is particularly susceptible to infections. For instance, infection remain the major cause of death in patients with kidney and kidney-pancreas transplants. In a recent study from a single institution following kidney-pancreas transplantation, bacterial pulmonary infection occurred

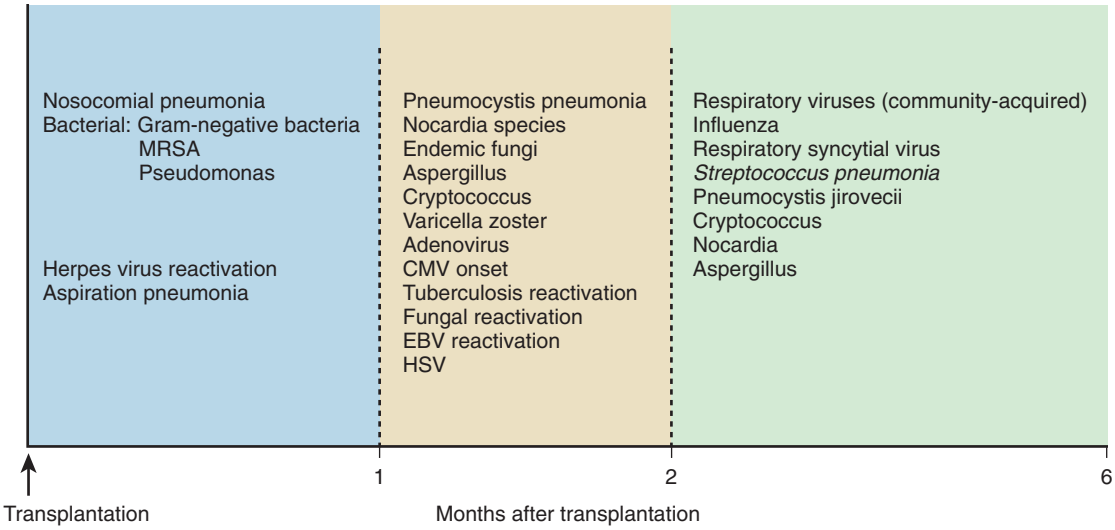

FIGURE 81-1 ■ Timing of infections in the posttransplantation period. CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; MRSA, methicillin-resistant *Staphylococcus aureus*.

in 25% of patients. The pathogens identified were *Pseudomonas aeruginosa, Klebsiella* species, *Staphylococcus warneri,* and *Aerococcus viridans.*[3] Additionally, a recent study from Stanford University evaluated 620 consecutive heart transplant patients with 1073 infectious episodes. Lung infections in this cohort accounted for 28% of all infections. Pulmonary infection was the cause of death for 18% of patients in the early (<30 days) posttransplantation period and 33% of those in the late (>30 days) posttransplantation period.[4]

Infection in posttransplantation patients depends on the degree of immunosuppression as well as individual exposure to the pathogen. In addition, the risk of infection differs in individual patients. There is a higher risk of infection in patients who are taking pulsed-dose corticosteroids as well as with prolonged intubation, wound dehiscence, high risk of rejection, early graft-versus-host disease, latent infection in the recipient or donor, use of plasmapheresis, history of bleeding, or prolonged use of surgical, vascular, or urinary catheters. Numerous risk factors have been identified that may predispose to the development of pulmonary complications following stem cell transplantation (SCT). Many of these risk factors are interrelated. For example, the development of chronic graft-versus-host disease increases the risk for the subsequent development of bronchiolitis obliterans.[5] Additionally, multivariable analysis showed that age greater than 60, pretransplantation FEV_1/FVC less than 80%, respiratory virus infection, and quiescent or progressive-onset chronic graft-versus-host disease were all associated with the development of airflow obstruction.[6] Furthermore, the presence of airflow obstruction significantly and independently demonstrated a 2.3-fold increased risk for mortality following SCT.[6]

The lungs are the most common organs affected by infections in lung and heart transplant patients, the most common cause of infectious death after hematopoietic SCT, and the second most common site of infectious complication in liver transplant patients. Renal transplant patients have the lowest incidence of infections, probably because of the low level of immunosuppression needed. The risk and type of infection depends on the time it is acquired relative to the date of transplantation. In the immediate postoperative period (<30 days), the most common organisms are gram-positive and gram-negative bacteria such as *Staphylococcus aureus* and *P. aeruginosa.* The second time line is from 1 to 6 months after transplantation—a time when intense immunosuppression is given to avoid acute rejection and the patient is once again exposed to the community environment. Opportunistic organisms such as *Aspergillus, Pneumocystis jirovecii,* and cytomegalovirus (CMV) are particularly important. The third stage of the time line is after 6 months of immunosuppression, when the immunosuppressive drug levels are decreased. At this time, opportunistic organisms become less prominent and community-acquired organisms once again become the major cause of pulmonary infection. Figure 81-1 lists the major pathogens for pulmonary infection in the posttransplantation period.

Bacterial Infections

The incidence of bacterial pneumonia is dependent on different factors. Infection following a previous insult or secondary to a latent infection in the donor organ is a particular problem in lung transplantation. For example, infection may occur in patients with a history of latent tuberculosis or fungal disease or recipients with infections from other sites, such as patients with cystic fibrosis colonized with chronic sinus pathogens. Also, insults to the lung during the operative procedure itself may occur, such as superinfection following manipulation of the upper abdomen in liver transplantation.

Bacterial pneumonias are of particular importance in the immediate postoperative phase. Nosocomial organisms are the most common pathogens identified in this period. The incidence of pneumonia depends on the

surgical technique used, site of transplantation (upper abdominal manipulation leads to highest risk of infection),[7] increased transfusion of blood products, increasing age,[8] choice of immunosuppressive therapy,[9] and prolonged intubation.[7]

In general, the most commonly reported organisms are gram-negative organisms, such as *Pseudomonas, Klebsiella, Escherichia, Legionella, Acinetobacter,* and *Stenotrophomonas.* Important nosocomial gram-positive bacteria include *Staphylococcus, Corynebacterium,* and *Enterococcus.* Anaerobic infection appears rare.[7] In a cohort of orthotopic liver transplant recipients, the incidence of bacterial pneumonia was 45%, with gram-negative organisms accounting for 93% of all cases. In this group of patients, *P. aeruginosa* was the most common gram-negative organism.[10] Lung transplant patients who develop bronchiolitis obliterans with bronchiectasis have a higher risk of *P. aeruginosa* infection.[7] In renal transplantation, which is the most common type of solid organ transplantation performed, bacterial infection has been reported to be most commonly associated with *S. aureus, Streptococcus pneumoniae, P. aeruginosa, Acinetobacter* species, *Haemophilus influenzae,* and *Klebsiella pneumoniae.* Lenner and coworkers reported that the most common pulmonary complication following cardiac transplantation was pneumonia (17.0%), followed by bronchitis (9.4%).[9] Of the patients with post–cardiac transplantation pneumonias, the causative pathogens were bacteria in half of the patients. Community pathogens can emerge after the immediate posttransplantation period as well. *Haemophilus influenzae* is the most common isolate, followed by *S. pneumoniae* and *Legionella* species.[7]

The extent to which bacterial bronchopneumonia is present in SCT patients is not known but has been estimated to be 2% by open lung biopsy or greater than 25% when documented at autopsy.[11] Bacterial pathogens can account for over 50% of pulmonary infections and include *P. aeruginosa, S. aureus, Mycobacterium tuberculosis,* atypical mycobacterial infection, *Escherichia coli, Xanthomonas maltophilia, K. pneumoniae, Serratia* species, *Legionella* species, *Enterococcus faecium,* and *Mycoplasma* species.[12,13] In one series, staphylococcal species accounted for 24% and streptococcal species accounted for 13% of all pulmonary organisms isolated.[14] Althought the prevalence of *M. tuberculosis* infection following SCT has been estimated to be about 0.6%, delayed diagnoses due to slow growth of the bacterium can lead to delays in initiating therapy.[15] Particularly in endemic areas, a high index of suspicion should be maintained.

Viral Infections

In a recent study of 152 heart, kidney, and liver transplant recipients, 81 episodes of infection due to respiratory viruses were isolated in 67 patients.[16] Most cases of viral infection were present after 1 year (87%). Only 3% were complicated by pneumonia. No specific risk factors, including gender, age, type of immunosuppression, number of cohabitants, or contact with children, were identified. Heart recipients had more episodes and more complications due to respiratory viral infections compared with liver and kidney recipients.

Cytomegalovirus infection remains the most common etiology for viral illness in solid organ transplant recipients. Most people are infected with CMV early in life. In industrialized countries, the prevalence of CMV seropositivity is approximately 50%. Up to two thirds of transplant recipients have latent CMV infection. Primary infection occurs due to transmission in seronegative recipients, sometimes from the donor, although this is much less common in recent years due to preoperative screening. This form of primary infection is associated with a higher degree of recurrence, higher risk of dissemination, and higher mortality.[17] CMV can also be reactivated from a preoperative seropositive recipient with immunosuppression or by superinfection with a new strain of CMV in a previously seropositive patient in the posttransplantation period.[18] Cytomegalovirus infection causes immediate and delayed complications in this group of patients. Direct effects include a viral syndrome with symptoms such as generalized malaise, fever, and myalgias or a more specific tissue-invading picture with pneumonitis, gastritis, colitis, or hepatitis. These effects are often associated with high viral loads. Indirect effects are caused by a release of cytokines that may lead to allograft injury and rejection. Since a substantial number of CMV infections are asymptomatic, CMV disease can become chronic with low levels of viremia existing for prolonged periods of time that are related to the indirect effects of infection. Antilymphocyte preparations (e.g., OKT3) are clearly associated with an increased risk of CMV disease, as is the use of methylprednisolone.[18a] Cytomegalovirus infection is also associated with an increase in the risk of further complications, including Epstein-Barr virus–associated posttransplantation lymphoproliferative disorder, vasculopathy in heart allograft recipients, and bronchiolitis obliterans syndrome in lung allograft recipients.

Symptoms of CMV pneumonitis range from mild dyspnea to respiratory failure. Signs and symptoms are very similar to rejection. The diagnosis of CMV pneumonitis is usually based on symptoms, diffuse infiltrates on radiologic imaging, and a positive viral culture in bronchoalveolar lavage (BAL) fluid, or cytologic CMV-positive immunostaining. Newer methods for the detection of CMV pneumonitis after lung transplantation makes use of polymerase chain reaction (PCR) analysis of DNA obtained from BAL cells.[19] Most transplantation centers recommend CMV prophylaxis for the first 3 to 6 months after transplantation, using valcyclovir, acyclovir, gancyclovir, or valgancyclovir.

Herpes simplex virus can cause pneumonia in heart-lung transplant and bone marrow transplant recipients. Diagnosis is made by the presence of intracellular inclusion bodies in biopsy or BAL cytology specimens. The clinical picture ranges from normal radiologic findings and dyspnea to failure to wean and acute respiratory distress syndrome (ARDS). Acyclovir is an effective treatment that results in prompt improvement.[20] Varicella-zoster virus has also been reported as a rare cause of pneumonia in transplant recipients. Usually patients will present with the vesicular rash, followed by respiratory

symptoms. Acyclovir is still the treatment of choice. However, the role of human herpesvirus (HHV)6 and HHV7 in transplant patients is not well understood.

Solid organ transplant patients are exposed to the same community-acquired viruses as the rest of the population. Respiratory syncytial virus (RSV) pneumonia can be frequently seen in SCT recipients.[21] McCarthy and associates showed over a 5-year period that 26 (6.3%) of 336 allo-SCT recipients developed RSV pneumonia (19.2% mortality), and this correlated with lower respiratory tract infection and a poor overall outcome.[22]

RSV and adenovirus, among others, can cause significant complications. Lung and heart-lung recipients are most vulnerable to pneumonia. The incidence of respiratory viral infection in immunosuppressed patients has been well described: influenza, parainfluenza 1 and 2, and RSV infections have their peak mostly in the winter months, whereas infections with parainfluenza 3 and adenovirus occur year-round. Viral infections tend to have lower mortality rates, but they may have more long-term consequences. Viral infection predisposes transplant patients to secondary bacterial pneumonias. Superinfection with *S. aureus, Pseudomonas,* and *Acinetobacter* as well as other gram-negative organisms is well documented. Recently influenza and parainfluenza viruses have been reported as an important etiology of respiratory illness in solid organ transplant recipients. In lung transplant patients, the majority of patients with influenza and parainfluenza respiratory viral infection who had transbronchial biopsies had evidence of acute lung allograft rejection.[23] Herpes viruses, influenza A and B, and adenoviruses have also been associated with allograft rejection. RSV has been associated with obliterative bronchiolitis in children and in animal models. Decreases in FEV_1, on the order of 10% to 58%, have also been reported with parainfluenza infections.[24] Respiratory viral infection is usually present after 1 year posttransplantation.[25] In reported cases of parainfluenza infection, serotype 3 is the most common.[24,25]

Prophylaxis for viral infections has greatly improved morbidity and mortality in transplant recipients. Zanamivir and oseltamivir are approved for prophylaxis and treatment of influenza A and B. The Cochrane review has published a meta-analysis of 34 studies (3850 participants) that shows that the antiviral medications gancyclovir, valacyclovir, and acyclovir reduced the risk of CMV disease, all-cause mortality, and bacterial superinfection in heart, kidney, and liver transplant recipients.[26] Maribavir is a new drug that inhibits the *UL97* viral protein kinase of human CMV, causing inhibition of viral encapsidation and nuclear egress of viral particles from cells infected with CMV. This drug is in clinical trials in both SCT and solid organ transplant recipients. Herpes prophylaxis is given in the form of acyclovir once CMV prophylaxis is stopped for latent infection. Currently there are no studies on RSV or adenovirus prophylaxis for adult transplant patients.

Fungal Infections

Fungal infections in the solid organ transplant recipient depend on a number of factors: type of transplant, endemic mycoses in the community, previous colonization, degree of immunosupression, and metabolic abnormalities influencing the immune state (e.g., diabetes, malnutrition). Up to 8% of patients with solid organ transplants will have a pulmonary infection with *Aspergillus* species. Disease of the lung includes invasive pulmonary aspergillosis, tracheobronchitis, sinusitis, and disseminated disease. Lung transplant patients are at particular risk, especially in the anastomosis site. Patients with liver and heart transplants are also commonly at risk, with a lower incidence in pancreas, small bowel, and kidney recipients. Early infection (<6 months posttransplantation) is most common, and there is a high risk of dissemination, particularly to the central nervous system. Cytomegalovirus disease has also been associated with increased risk of invasive aspergillosis. Mortality for *Aspergillus* invasion has been reported to be 50% to 75%, with the higher rates corresponding to invasive disease.

Definitive diagnosis involves histologic evidence of septated hyphae with acute angle branching. Unfortunately, open lung biopsy is not always possible in this group of patients due to poor functional status, thrombocytopenia, and other comorbidities. Recovery of *Aspergillus* from respiratory secretions is not diagnostic, since it is a common colonizer of the respiratory tract, but could suggest the diagnosis along with other clinical criteria. *Aspergillus* can also be identified using PCR with enzyme-linked immuosorbent assay in BAL fluid or tissue samples. In recent years, the determination of galactomannan levels has proven useful in the diagnosis of *Aspergillus*-related disease. Galactomannan is a polysaccharide component of the cell wall of *Aspergillus* and is released during its growth. Serum levels greater than 0.5 ng/dL are suggestive of active aspergillosis. Galactomannan has also been detected in BAL and cerebrospinal fluid. In fact, the diagnostic yield of galactomannan in BAL fluid is higher than that from serum in lung transplant patients. Nevertheless, false positives can occur in patients receiving piperacillin-tazobactam, in the presence of autoreactive antibodies in autoimmune diseases or graft-versus-host disease, in the presence of other fungi, and with translocation of galactomannan antigen present in milk and some cereals across the gut wall. False negatives may occur if antifungal medication is given prior to sample acquisition since it lowers fungal titers.

Pneumocystis jirovecii (previously *Pneumocystis carinii*) is still an important cause of morbidity in immunocompromised patients, though its prominence has decreased due to effective prophylaxis. *Pneumocystis* pneumonitis (PCP) appears to be the result of the surfacing of latent infection during immunosuppression, since there is serologic evidence that many individuals are exposed by age 4.[27–29] Clinical presentation is variable depending on the degree of immunosuppression and neutropenia. Radiologic findings range from normal chest radiographs to bilateral interstitial infiltrates, but other findings may include pulmonary nodules, cystic lesions, and pneumothorax. Diagnosis requires morphologic identification of the *Pneumocystis* organisms in sputum, BAL fluid, or tissue since the organism cannot

be cultured. Sputum samples induced with hypertonic saline or BAL both have a 90% diagnostic yield, and the yield approaches 100% when transbronchial biopsies are added to the BAL samples.

The incidence of infection in recipients of solid organ transplants has been reported to be 2% to 12% in different cohorts. Torres and coworkers reported an incidence of 12% of microbiologically proven PCP in a cohort of patients with orthotopic liver transplantation.[10] In a study in a kidney transplant population, the incidence of PCP was 7% despite 70% of patients receiving prophylaxis with trimethoprim-sulfamethoxazole.[30] Median time between transplantation and PCP diagnosis was approximately 5 months, and the mortality was 35%. The presence of PCP diagnosis has been associated with an increased risk of rejection in both kidney and heart transplant recipients. Invasive infection with CMV seems to augment the virulence of *Pneumocystis*.[30–32]

Most transplantation centers use trimethoprim-sulfamethoxazole prophylaxis to prevent PCP. Low-dose trimethoprim-sulfamethoxazole is usually well tolerated for prophylaxis, although higher levels used for treatment may lead to toxicity, including bone marrow suppression, renal disease, and liver toxicity. Also, cases of Steven-Johnson syndrome have been reported. Alternative agents for prophylaxis against *P. jirovecii* are pentamidine, dapsone, and atovaquone, but they are less effective than trimethoprim-sulfamethoxazole.

Other fungal infections depend on the geographical location of the patient. Endemic mycoses account for approximately 3% of fungal pneumonias in the transplant population in endemic areas. *Histoplasma capsulatum* is prevalent in the Ohio River valley, along the Mississippi River, the St. Lawrence River valley, the eastern half of the United States, and most of Latin America. In immunocompromised patients it may lead to disease ranging from primary infection to disseminated disease. *Blastomyces dermatitidis* is found in the south central and southeastern states, areas along the Mississippi and Ohio River basins, the Great Lakes, and areas of Canada and New York. *Coccidioides immitis* is prevalent in the southwestern part of the United States as well as in Mexico and Central America. The mean time for infection in solid organ transplant patients is within 6 months after transplantation.

NONINFECTIOUS COMPLICATIONS

Due to the degree of immunosuppression, solid organ transplant patients have a higher risk for posttransplantation infection. Nevertheless, there are several factors that can lead to noninfectious complications in this group of patients: toxicity from medications, postsurgical complications, comorbidities, immunologic processes induced by the transplant itself or by previous infections (e.g., CMV), and rejection. Liver transplant patients have a particular predisposition for respiratory complications due to operative manipulation in the upper abdomen and involvement of the diaphragm. Table 81-1 describes the most common complications in the immediate postoperative period. Also, many of these patients have been critically ill prior to the transplantation and have a higher risk of pneumonia.

TABLE 81-1. The Most Common Noninfectious Complications in the Immediate Postoperative Period

Transplantation	Noninfectious Postoperative Complications
Liver	Pulmonary edema/ARDS
	Diaphragmatic dysfunction
	Pleural effusions
Heart	Diaphragmatic dysfunction
	Mediastinitis
	Pleural effusions
	Pulmonary edema
Lung/heart-lung	Reperfusion pulmonary edema
	Primary graft failure
	Bronchial anastomosis dehiscence
	Acute hyperinflation of native lung
	Diaphragmatic dysfunction
Kidney	Pulmonary edema
	Venous thromboembolic disease

ARDS, acute respiratory distress syndrome.

In SCT, the individual components of the conditioning regimen likely play a key role in the development of pulmonary toxicity. In the case of autologous SCT, for example, carmustine (or bischloroethylnitrosourea [BCNU]), one of the chemotherapeutic agents used with autologous bone marrow transplantation, has been shown to cause pulmonary toxicity when used as a single agent or in combination with other agents.[33–38] In fact, a National Heart, Lung, and Blood Institute workshop has suggested that more than 50% of breast cancer patients receiving regimens containing carmustine may develop clinically apparent lung injury.[39] By inhibiting antioxidant enzymes,[40,41] BCNU may deplete epithelial lining fluid glutathione levels,[42–44] resulting in increased oxidative stress. Cyclophosphamide (also used with both autologous and allogeneic SCT regimens) has also been shown to cause lung injury, deplete glutathione stores,[45–47] increase the generation of reactive oxygen species by alveolar macrophages,[48] inhibit prostaglandin E_2 production by macrophages[45] and modulate BAL cell populations.[48] Acrolein, a cyclophosphamide metabolite, can also react directly with glutathione, forming irreversible conjugates.[49] Additionally, cisplatin has been shown to increase the production of superoxide anions[50] and to decrease the activity of lipid peroxide-protecting enzymes, such as catalase, Cu,Zn-superoxide dismutase, glutathione peroxidase, and glutathione-*S*-transferase, in the liver and kidneys of rats.[51] Animal models of lung toxicity following allogeneic SCT generally require the following three components: (1) infusion of alloreactive T cells, (2) total body irradiation, and (3) cyclophosphamide.[52–57] The effects of other chemotherapeutic agents

and radiation on lung pathophysiology are discussed in more depth elsewhere in this text. The following sections review the noninfectious complications in the solid organ transplant population.

EARLY COMPLICATIONS

Pulmonary Edema and Respiratory Failure

Postoperative respiratory failure and ARDS have been well described in the transplantation literature as an early cause of morbidity. Liver transplant patients are at particularly high risk. The incidence of post–liver transplantation pulmonary edema has been reported to be anywhere from 5% to 52%.[8,58] Overall, pulmonary edema in the postoperative period is associated with intraoperative fluid overload, large intravascular fluid shifts, and the use of blood products. Underlying cardiac or renal dysfunction in combination with medications such as antibiotics and immunosupressants are also related to its development. In liver transplant recipients, the most common risk factors for posttransplantation noncardiogenic pulmonary edema include sepsis, pneumonia, gastric aspiration, acute allograft rejection, and multiple transfusions. In an observational study, Yost and colleagues described that transfusion-related acute lung injury was the most likely cause of pulmonary edema in a small group of patients, since there were no other risk factors present and all patients had received blood products immediately prior to its development.[58] In a study of 34 patients, 16 developed pulmonary edema in the postoperative period.[59] There were no differences in the characteristics and hepatic disease severity between the patients who never developed pulmonary edema and the patients who did. However, a greater proportion of Child's class C recipients developed pulmonary edema. Figure 81-2 depicts an orthotopic liver transplant recipient with acute respiratory failure immediately posttransplantation.

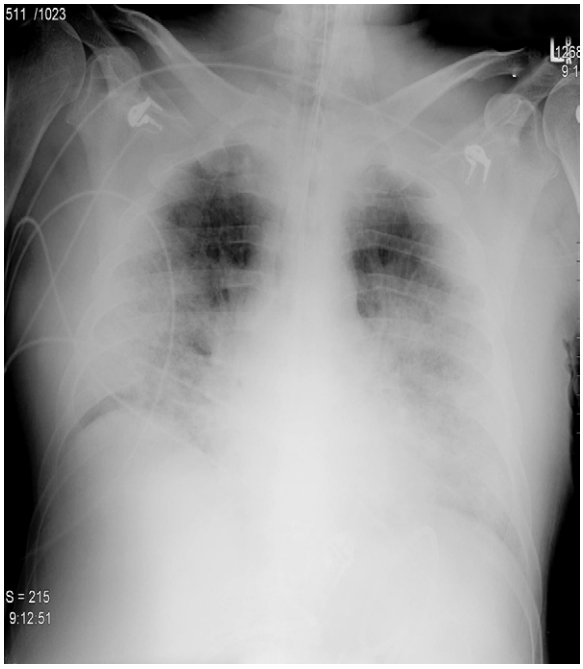

FIGURE 81-2 ■ Pulmonary edema in a 58-year-old man after liver transplantation. The patient developed acute respiratory failure in the postoperative period. Low central venous pressure, hypotension, and a history of multiple transfusions in the absence of other etiologies are suggestive of transfusion-related acute lung injury. An elevated right hemidiaphragm is noted.

Reperfusion syndrome after orthotopic liver transplantation is also associated with an increased risk of pulmonary edema and respiratory failure. It is characterized by hypotension with a decrease in mean arterial pressure of approximately 30%, vasodilation, and pulmonary hypertension. It occurs immediately after restoration of blood flow through the graft. Its pathophysiology is poorly understood but has been attributed to vasoconstriction and intracellular edema resulting in failure of the microcirculation. Alteration of nitric oxide, oxygen-derived free radicals, and endothelin results in prolonging ischemia in certain areas of the liver, resulting in worsening hepatic injury.

Perioperative respiratory failure is less common in the kidney and cardiac transplant population.[60] Orthotopic heart transplantation has a low risk of respiratory failure. Most cases of respiratory failure and ARDS are associated with sepsis. In a recent study, Lenner and associates reported a 4% incidence of respiratory failure in a cohort of 157 cardiac transplant recipients.[9] Allograft rejection, impaired renal function, comorbid cardiac conditions, and uremic cardiomyopathy have been identified as causes for pulmonary edema and respiratory failure in renal transplant patients.[61] Cardiac disease is of particular interest since renal failure patients have an increased risk of cardiac disease, including ischemic cardiomyopathy. In some cases, recipients will have low ejection fractions prior to transplantation. During the postoperative period, fluid overload is fairly common to maintain graft integrity and adequate blood flow. Carlier and coworkers showed that high central venous pressures (up to17 mm Hg) and diastolic pulmonary pressures above 20 mm Hg were associated with improved early graft function.[62] However, this increases the risk of cardiogenic pulmonary edema in kidney recipients.

Respiratory failure immediately after lung transplantation is associated with an increased risk of early mortality and poor 1-year survival. The most common causes for respiratory failure in this population are infections and ischemic reperfusion injury. Ischemic reperfusion syndrome is characterized by alveolar damage, pulmonary infiltrates, noncardiogenic pulmonary edema, and hypoxemia occurring within 72 hours after lung transplantation in the absence of infection or acute rejection. Respiratory failure was documented in 55% of patients undergoing lung transplantation at Temple University.[63] The main etiology for respiratory failure was ischemic reperfusion syndrome, and half of those patients died. Khan and associates reported

their experience at the Cleveland Clinic Foundation, where 57% of patients had reperfusion syndrome after transplantation.[64] Ischemic reperfusion injury appears in a biphasic fashion: initially the ischemic insult results in increases in xanthine oxidase and hypoxanthine; then restoration of blood flow results in increase in oxygen free radicals that appears to worsen cellular damage. Ischemia triggers the activation of macrophages, releasing interleukin (IL)-8, IL-12, and IL-18, tumor necrosis factor-α (TNF-α), and interferon-γ, which in turn activates recipient neutrophils and T lymphocytes, resulting in severe early graft dysfunction and further lung injury.[65–67] Methods for ischemic preconditioning of the harvested organ, such as ischemic hypothermia, the use of preconditioning solutions containing different electrolyte concentrations, attenuating the donor's inflammatory response, and experimental treatments in various animal models, are currently under investigation.

A similar spectrum of noninfectious pulmonary complications affect SCT patients, mainly the idiopathic pneumonia syndrome (IPS). The National Heart, Lung, and Blood Institute convened a workshop in 1991 to review clinical and pathologic features of lung toxicity following hematopoietic SCT, focusing primarily on IPS. IPS is the most severe form of SCT-related lung toxicity and is associated with widespread alveolar injury, respiratory failure, and death.[39,68] Early estimates reported a 35% incidence of IPS in SCT recipients,[69] but in more recent studies, the overall incidence of IPS appears about 10%.[69–73] Mortality can reach 65%.[74–76] While steroids are often used to treat IPS,[77] the efficacy of such treatment has not been proven.[72] The precise pathogenesis of IPS is not yet understood but remains under active investigation. Clark and colleagues showed that proinflammatory cytokine activation may play an important role in the development of lung injury.[78] Analysis of BAL fluid in patient with IPS showed elevated levels of IL-1, IL-2, IL-6, and TNF-α, whereas SCT patients without IPS showed levels of these inflammatory cytokines comparable to those obtained from normal volunteers. The appearance of IPS is delayed by several weeks to months following SCT.[39]

Diffuse alveolar hemorrhage (DAH) has been described in patients receiving autologous and allogeneic stem cells and has been termed *diffuse alveolar hemorrhage* to reflect the finding that sequential BAL aliquots become progressively bloodier and that these later aliquots predominantly sample alveoli.[79–81] DAH is considered to be a syndrome with nonspecific radiologic and clinical presentations. Even though certain infections (bacteria, *Aspergillus,* etc.) can lead to pulmonary hemorrhage,[80] the diagnosis of DAH is reserved for hemorrhage due to noninfectious etiologies.[82]

An increasingly more common, noninfectious, posttransplantation pulmonary complication primarily affecting the airways is best characterized by chronic progressive airflow obstruction otherwise known as bronchiolitis obliterans (BO). BO occurring in SCT patients was originally described in the mid-1980s and was seen exclusively in allo-SCT patients and believed to be a manifestation of graft-versus-host disease of the small airways.[83]

The term *delayed pulmonary toxicity syndrome* (DPTS) is used to describe lung injury following autologous bone marrow transplantation.[84,85] Clinically, DPTS manifests as an acute to subacute onset of progressive exertional dyspnea, shortness of breath, and dry cough, with or without fever and/or hypoxemia. Radiographic changes may or may not be present.[85] Closely following the D_{LCO} is the best way to monitor for its development.[85] The D_{LCO} reaches a nadir level in 15 to 18 weeks following high-dose chemotherapy and SCT.[85] When compared with IPS, DPTS has an overall higher incidence (72%) but lower mortality.[85]

Venous Thromboembolic Disease

Venous thromboembolism (VTE) may be underdiagnosed in the posttransplant population. In a recent report, pulmonary embolism (PE) was identified at autopsy in 34 (27%) of 126 lung- and heart-lung transplant recipients.[86] The prevalence of PE was highest, at 36.4%, in the early group (who died <1 month posttransplantation) compared with 20.0% who died between 1 month and 364 days, versus 23% in the group with greater than 365 days' survival. Kahan and coworkers identified the following risk factors for VTE in lung transplant recipients: gender (women have a higher incidence), longer hospitalization times, and longer ischemic period at the time of transplantation. These all had a higher probability for VTE.[87] In a cohort of 121 lung recipients at New York Presbyterian Hospital, 22% developed VTE despite prophylaxis with subcutaneous heparin.[88] In this group of patients with VTE, 89% presented within their first year posttransplantation.

Renal transplant recipients also have a particularly higher risk for VTE, especially those treated with cyclosporine. It is postulated that this group of patients has impaired fibrinolysis and a hypercoagulable state. The incidence of VTE in renal transplant patients ranges from 0.6% to 25% in some cohorts. Previous studies have linked higher rates of VTE in kidney recipients in association with increased homocysteine levels, CMV infection, D-dimer and prothrombin fragment 1+2 levels, and renal dysfunction.[89–91]

VTE is uncommon after cardiac and hepatic transplantation. In a cohort of 159 heart recipients from Mount Sinai Medical Center, only 2 patients developed VTE: 1 within 6 months posttransplantation and 1 after 6 months.[9] After heart transplantation, VTE may occur in the presence of heparin-induced thrombocytopenia or other hypercoagulable states.

Diaphragmatic Dysfunction

Data on heart and lung transplantation and the incidence of diaphragmatic paralysis are limited. Diaphragmatic dysfunction was present in 12.1% of heart transplant recipients and 7.4% of lung transplant recipients in a study by Dorffner and colleagues.[92] Phrenic nerve injury is in part due to hypothermia and mechanical damage

during surgery. In addition to the transplant procedure, left ventricular assist devices provide cardiovascular support in the pretransplantation period, which allows for 70% survival in patients awaiting an orthotopic heart transplant.[93] Nevertheless, there is up to a 15% incidence of diaphragmatic hernia during explantation depending on the timing for the closure of cannula defects. Persistence of the paralysis may lead to higher risk for pneumonia, respiratory failure, and mortality. Incidence of diaphragmatic paralysis has been reported from 1% to 34%. The difference between the reported incidences may be due to methods used for identification of phrenic nerve damage. In a group of lung transplant patients in Toronto, a retrospective study found 6 patients with documented diaphragmatic paralysis confirmed by imaging in a group of 185 single or sequential single lung transplantations.[94] In a lung recipient cohort, Sheridan and associates reported a 29% incidence of phrenic nerve injury as assessed by phrenic nerve conduction studies and fluoroscopy.[95] Complete diaphragmatic paralysis was present in 89% of those cases, and the highest incidence was after bilateral lung transplantation. The right phrenic nerve was most commonly affected.

The incidence of diaphragmatic paralysis is higher among liver recipients. Injury to the right phrenic nerve is possible because of the close proximity to the diaphragm and inferior vena cava. In a comparison with liver resection, in which the suprahepatic vena cava is not clamped, patients with liver transplantation, in which clamping is performed, have a higher incidence of phrenic nerve crush injury. Gurakar and coworkers found that 44% of patients have diaphragmatic dysfunction after orthotopic liver transplantation.[96] In a prospective study of 48 liver recipients, 38% had diaphragmatic paralysis.[97] Nevertheless, the clinical symptoms range in severity from no symptoms to failure to wean from mechanical ventilation.

LATE COMPLICATIONS

Drug Toxicity and Interstitial Lung Disease

Noncardiogenic pulmonary edema, the pulmonary capillary leak syndrome, and ARDS have been reported in the literature in association with intravenous cyclosporine after liver, kidney, and bone marrow transplantations. Pulmonary capillary leak syndrome is characterized by normal left atrial pressures, low central venous pressures, and pulmonary edema due to extravasation of plasma. These disorders have been reported in both the adult and pediatric transplantation populations.[98,99] There is resolution of the pulmonary symptoms and radiologic findings when the medication is discontinued. This reaction does not commonly occur with oral cyclosporine.

Sirolimus inhibits T-lymphocyte activation and binds to FK binding protein 12, suppressing cytokine-mediated T-cell proliferation. This immunosuppressant, used both for induction and for long-term maintenance, has been recently reported as the etiology for pulmonary toxicity in renal, hepatic, heart, and heart-lung recipients. Exertional dyspnea and dry cough appear to be the most common symptoms, but cases of hemoptysis and biopsy-proven interstitial pneumonitis and cryptogenic organizing pneumonia that resolve after discontinuation or decrease in sirolimus dose have also been described. Radiologic findings include bilateral alveolar patchy infiltrates, ground-glass opacities, and consolidation. In cases of pulmonary toxicity, sirolimus had been started within 6 months after transplantation in 50% of the patients.[100] Sirolimus has also been recently associated with a high rate of bronchial anastomosis dehiscence after lung transplantation, which has prompted a black box warning in the prescribing insert.[101,102] Other immunosuppressive therapies have also been reported to cause long-term pulmonary toxicity. Some relevant interactions are listed in Table 81-2.

TABLE 81-2. Immunosuppressant Therapy and Pulmonary Toxicity

Mycophenolate mofetil (MMF) and mycophenolic acid (MPA)	Pulmonary fibrosis, pulmonary edema, ARDS
Tacrolimus	Cryptogenic organizing pneumonia
OKT3 (muromonab-CD3)	Capillary leakage (pulmonary permeability edema), ARDS
Antithymocyte globulin	Pulmonary edema, pulmonary fibrosis
Azathioprine	Cryptogenic organizing pneumonia, interstitial pneumonitis, alveolar hemorrhage, laryngeal edema, vasculitis
Basiliximab and daclizumab	Capillary leakage (pulmonary permeability edema)
Rituximab	Hypersensitivity pneumonitis, interstitial pneumonitis, pulmonary fibrosis, alveolar hemorrhage

ARDS, acute respiratory distress syndrome.

Obliterative Bronchiolitis

Late allograft dysfunction continues to be an obstacle in solid organ transplantation despite advances in immunosuppressive therapy. Obliterative bronchiolitis appears to be a distinctive pulmonary manifestation of organ rejection. In lung and heart-lung recipients, the transplanted lung contains a large population of macrophages, lymphocytes, and bronchus-associated lymphoid tissue. In allogeneic stem cell transplant the incidence of late onset noninfectious pulmonary complications can be as high as 10–26%.[102a] It is postulated that allorecognition of human leukocyte antigen (HLA) class I peptides will incite sensitization of T cells, leading to the production of anti–HLA class I antibodies. Data suggest that the degree of allorecognition of HLA class I peptides corre-

lates with the development of obliterative bronchiolitis syndrome.[103,104] Proliferation of epithelial cells may also up-regulate growth factors such as transforming growth factor-β.[104] Recruitment of recipient bone marrow–derived circulating fibroblasts has been described after transplantation, as well as increases in fibroblast proliferation factors and platelet-derived growth factor (PDGF). Inhibition of PDGF receptor protein-tyrosine kinase activation prevents these obliterative changes.[105,106] Pathologic findings in BO vary considerably. There are several degrees of luminal obliteration, adventitial and submucosal scarring, bronchiolar inflammation, collagen deposition, and mucoid impaction with or without organizing pneumonia. Fibroblastic proliferation may occur along the airway epithelium and smooth muscle.

Transbronchial lung biopsies are not useful for the diagnosis of obliterative bronchiolitis, due to the small size of the biopsy samples and the patchy distribution of the pathologic changes. Thoracoscopic or open lung biopsies are needed for a definitive diagnosis. Nevertheless, due to the clinical status of these patients, which includes deterioration of pulmonary function and symptoms, patients are not always good surgical candidates to tolerate this procedure. Surveillance bronchoscopy for evaluation of early signs of rejection and to exclude infectious etiologies is valuable in this setting. A recent study from Washington University found a diagnostic yield of 31% for acute rejection during surveillance bronchoscopy in a cohort of 257 lung transplant recipients.[107] An Australian study found an overall 20% yield of acute rejection in 1235 transbronchial biopsies.[108] The differences between diagnostic yields in different centers may be due to immunosuppressive regimens, bronchoscopic surveillance protocols, or clinical bronchoscopy criteria. A detailed discussion on obliterative bronchiolitis syndrome is available in the chapter on lung transplantation (see Chapter 95).

Pulmonary Metastatic Calcifications

Pulmonary calcifications can occur in renal patients due to uremia and parathyroid hormone and calcium imbalance. Rarely, calcifications can progress despite renal transplantation. These calcifications may be diffuse or localized and can lead to restrictive lung disease on rare occasions. There is a predilection for upper lobes and apices. In renal transplant recipients, there may not be a correlation with hypercalcemia.

Malignancy

Malignancy is a well-known complication of prolonged immunosuppression. Transplant-related malignancy affecting the lung includes bronchogenic carcinoma, lymphoma, metastatic calcifications, Kaposi's sarcoma (KS), and posttransplantation lymphoproliferative disorder (PTLD). The risk of malignancy increases with the length of immunosuppression, and the progression of disease is accelerated compared with the general population. The association between lymphocyte-depleting immunosuppressants such as OKT3 and daclizumab and malignancy has been well established. Hibberd and colleagues described the use of polyclonal (antithymocyte globulin) and monoclonal (OKT3) anti–T cell immunosuppressive agents, which increased the risk for non-Hodgkin's lymphoma by 60% in a population of renal transplant patients over a 30-year period.[109] The incidences of vaginal, cervical, and vulvar cancer were also increased; no increased risk was associated with administration of azathioprine, prednisolone, or cyclosporin A. However, other immunosuppressive agents have also been linked to an increased risk of cancer.

The Cincinnati Transplant Tumor Registry has reported a 5% incidence of carcinomas of the lung occurring in transplant recipients.[110] The incidence of bronchogenic carcinoma after solid organ transplantation varies in different studies, mostly because of differences in sample size and because most reports do not take into account age, smoking history, occupational exposure, or other risk factors. Lung cancer developed in 0.28% of a solid organ transplant recipient population of 5400 over a 25-year period at the University of Pennsylvania.[111] The incidence of bronchogenic carcinoma after heart transplantation has been reported to be as high as 4%,[112] with an incidence of 2% in liver recipients[113] and up to 4% in the lung recipient population.[114-116] In solid organ transplantation, KS has been reported in recipients of renal allografts. The Cincinnati Transplant Tumor Registry reported an incidence of 6% at an average of 22 months posttransplantation in this group of patients.[117] An association with herpes simplex infection, and specifically HHV8, has been suggested to play a possible role.[118]

PTLD encompasses a diverse group of altered B-cell monoclonal and polyclonal proliferation disorders associated with immunosuppressed states. Virtually all are associated with Epstein-Barr virus (EBV) infection, although there have been case reports of EBV-seronegative PTLD and T-cell lymphoproliferative disorders. EBV infects B cells, binding to the CD21 receptor, which results in B-cell proliferation. Despite a primary EBV-specific cytotoxic T-lymphocyte response, not all infected B cells are eliminated. Immunosuppressive therapy, which depletes T cells, disrupts the balance of B to T cells, resulting in PTLD. Risk factors for PTLD include seronegativity to EBV prior to transplantation (especially with an EBV-seropositive donor), CMV and hepatitis C infection, high intensity of immunosuppression, and use of T-cell–depleting drugs (such as OKT3), and there is higher risk during the first year after transplantation when the levels of immunosuppressants are higher.[119] The risk of PTLD after solid organ transplantation is approximately 2%, but the organ site also affects the incidence. Patients receiving lung and liver transplants have a risk of PTLD of approximately 3%, and heart recipients 6%, and the risk in renal transplant recipients have been reported as 1%.[120,121] The lower incidence of PTLD for renal transplant recipients may be due to a lower degree of immunosuppression. PTLD responds to decreased immunosuppression and rituximab therapy. Figure 81-3 presents a patient with pulmonary nodules in whom pathology showed PTLD.

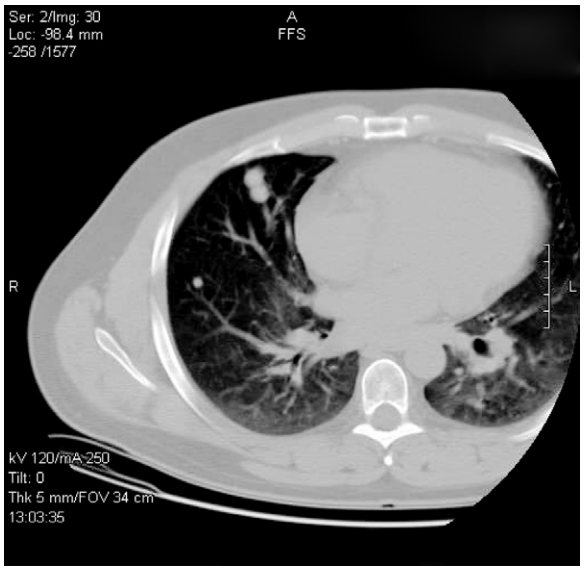

FIGURE 81-3 ■ Posttransplantation lymphoproliferative disorder (PTLD) presenting as pulmonary nodules in a 36-year-old man on chronic immunosuppression. Most pulmonary nodules in a transplant recipient are due to PTLD or invasive aspergillosis.

Conclusion

Pulmonary complications of solid organ transplantation are varied, depending on degree and type of immunosuppression, method of surgery, time from transplantation, previous exposure to CMV or EBV, and early rejection or acute infection in the postoperative period. Few of these complications are unique to one type of transplant. The clinician must have a high level of suspicion since signs and symptoms in the transplant recipient may be attenuated or absent when compared to an immunocompetent patient. Regional exposures must also be considered when infection is suspected.

KEY POINTS

- Pulmonary complications are common following solid organ and hematopoietic stem cell transplant.
- The types of pulmonary complications are related to the time course following transplant.
- Risk factors for the development of pulmonary complications are varied and include degree and duration of immunosuppression, pre-existing lung disease, concomitant medication administration, radiation exposure, perioperative insults and surrounding environmental variables.
- Infectious etiologies must be aggressively assessed and promptly treated.
- Invasive lung sampling is often needed for accurate diagnosis and treatment.
- In some cases, closely following pulmonary function tests can identify and classify early pulmonary disease.
- The use of prophylaxis agents for commonly encountered pathogens is a successful method to reduce the incidence of pulmonary complications in transplant recipients.

CHAPTER 82

PULMONARY COMPLICATIONS OF PRIMARY IMMUNODEFICIENCIES

John M. Routes, MD

INTRODUCTION

DIAGNOSTIC WORKUP
Antibody Deficiencies
Cellular Immunodeficiency
Complement Deficiencies
Phagocyte Deficiencies

DEFICIENCY IN BOTH CELLULAR IMMUNITY AND ANTIBODY PRODUCTION
Severe Combined Immunodeficiencies

ANTIBODY DEFICIENCIES
Immunoglobulin A Deficiency
X-Linked Agammaglobulinemia
Common Variable Immunodeficiency
Specific Antibody Deficiency
Immunoglobulin G Subclass Deficiency
X-Linked Lymphoproliferative Syndrome
Hyper–Immunoglobulin M Syndrome

DEFICIENCIES IN CELLULAR IMMUNITY/COMPLEX IMMUNODEFICIENCIES
DiGeorge Syndrome
Wiskott-Aldrich Syndrome
Ataxia-Telangiectasia
Hyper–Immunoglobulin E Syndrome

PHAGOCYTIC CELL DISORDERS
Phagocytic Defects: Increased Apoptosis of Neutrophils
Decreased Adherence/Chemotaxis
Defects in Oxidative Killing
Disorders of Leukocyte Signaling

DISORDERS IN INNATE IMMMUNITY
IRAK-4 and MyD88 Deficiencies
Complement Deficiencies

INTRODUCTION

Primary immune deficiency disorders (PIDDs) are disorders of the immune system that predispose individuals to infection and frequently malignancy and autoimmunity as well.[1] Most PIDDs are inherited disorders; however, in some PIDDs, such as common variable immunodeficiency (CVID), a family history is often lacking and a genetic cause has yet to be found. Furthermore, in some individuals, somatic mutations, not germline mutations, cause autoimmune lymphoproliferative disease, a disease of immune dysregulation.[2] Thus, we should not limit the diagnosis of PIDD to disorders that are inherited.

Many incorrectly believe that PIDDs are rare and are diagnosed almost exclusively in children. The incidence of immunoglobulin A (IgA) deficiency is approximately 1 in 400 live births, and more serious PIDDs occur in approximately 1 in 2000 individuals.[3] The majority of people affected with PIDD are now adults, not children.[4] Among the patients in the United States receiving intravenous immune globulin (IVIG), 23% are ages 30 to 44 years and 34% are in the 45- to 65-year age group. There are several factors that contribute to the increasing age of patients with PIDD, such as improvements in the treatment with a concomitant increase in survival rates, and the predominance of antibody deficiencies in patients with PIDD.

A diagnostic evaluation for PIDD is a fundamental, but often overlooked issue in the evaluation of patients with pulmonary infections. This oversight may have significant, detrimental consequences for the long-term survival and quality of life of the patient. Numerous studies indicate the importance of the early diagnosis of PIDD in reducing the morbidity and mortality associated with

recurrent infections. For example, early hematopoietic stem cell tranplantation (HSCT) (<3 months of age) results in dramatically improved outcome in infants with severe combined immunodeficiency (SCID).[5] Treatment with high-dose IVIG can prevent many of the infectious sequelae in patients with primary antibody deficiency states.[6] Many routine childhood vaccines use attenuated, live organisms, and the use of such vaccines may lead to disseminated infections in patients with antibody or cellular immunodeficiencies and are contraindicated. Thus, the early diagnosis of PIDD can prevent these life-threatening infections, further supporting the fact that early detection leads to improved outcomes.

The decision to evaluate patients with pulmonary infection for primary immunodeficiencies cannot be made in the context of the pulmonary infection alone; several factors need to be considered (Table 82-1). In general, an evaluation of the immune system is warranted in patients with two or more radiographically documented pneumonias. However, a single infection of the lung with an opportunistic pathogen warrants an evaluation to exclude both primary and secondary immunodeficiencies. A patient with first pneumonia, but with a history of intractable sinus disease or recurrent gastrointestinal infection or with other disorders found more frequently in patients with primary PIDD (e.g., autoimmunity, intractable eczema, unusual facies) should also be evaluated for a PIDD. Approximately 20% of patients with CVID are diagnosed at 50 years of age or later. Therefore, advanced age should not be used to exclude the diagnosis of a PIDD.

There are several clues in the history and clinical presentation of patients with primary immunodeficiencies that suggest the type of immunologic defect present (Table 82-2). The onset of diseases associated with cellular immunodeficiencies usually begins in early infancy. Infections with opportunistic or unusual pathogens, mycobacteria, disseminated viral infections, and severe oral candidiasis may occur. Diarrhea and malabsorption are common and growth is delayed. In contrast, the onset of infections in patients with antibody deficiencies, such as X-linked agammaglobulinemia (XLA), is usually delayed until after 6 months when maternal antibodies are not longer present. Recurrent and severe upper and lower respiratory tract infections are the usual mode of presentation. Complement deficiencies may present in a manner similar to antibody deficiencies or with recurrent *Neisseria* spp. infections. In contrast to patients with cellular immunodeficiencies, growth is usually not delayed in patients with complement or antibody deficiencies.

One common misconception is that opportunistic pathogens are overwhelmingly the cause of most infections in patients with primary immunodeficiencies. In fact, many infections in immunodeficient patients occur with pathogens that are common in the community; however, these infections may be of unusual severity and respond poorly to therapy. For example, recurrent infections with *Streptococcus pneumoniae* occur frequently in patients with several types of PIDD, such as antibody deficiencies, complement deficiencies, Toll-like receptor signaling deficiencies (MyD88, IRAK-4), and mutations in nuclear factor-κB essential modulator.[7] Finally, although this section deals exclusively with primary immunodeficiency disorders, it is essential to exclude secondary immunodeficiencies or other medical conditions (e.g., lymphoproliferative disorders and malignancy, malnutrition, immunosuppressive drugs, protein-losing states, kidney failure, liver failure, heart failure, sickle cell anemia) that predispose patients to recurrent infection.

TABLE 82-1. General Criteria for Immunologic Evaluation

Chronic infections
Recurrent infections
Opportunistic or unusual pathogens
Unusual sites of infections
Incomplete clearing of infection
Poor response to antimicrobial therapy
Associated conditions (unusual facies, tetany, failure to thrive, intractable diarrhea, thrush, intractable eczema, autoimmunity)

TABLE 82-2. Examples of Primary Immunodeficiencies

Type of Immunodeficiency	Example	Mode of Presentation
Antibody	XLA, CVID	Upper and lower respiratory tract infections (encapsulated and atypical bacteria), giardiasis
T cell	DiGeorge syndrome	Abnormal facies, lymphopenia, thrush, recurrent sinopulmonary infections
Combined B cell and T cell	SCID (multiple causes)	Opportunistic infections, thrush, intractable diarrhea, failure to thrive
Cellular/complex	IFN-γ/IL-12/IL-23 axis	Atypical mycobacterial and *Salmonella* infections
Phagocyte	CGD	Recurrent abscesses (*Staphylococcus aureus, Burkholderia cepacia, Aspergillus* spp.)
Complement	C5–C9	Recurrent *Neisseria meningitidis* infections

CGD, chronic granulomatous disease; CVID, common variable immunodeficiency; IFN, interferon; IL, interleukin; SCID, severe combined immunodeficiency; XLA, X-linked agammaglobulinemia.

DIAGNOSTIC WORKUP

There are a number of readily available and inexpensive screening tests that should be used in the evaluation of a patient with a possible immunodeficiency (Table 82-3).[8] Abnormalities found in these screening tests indicate the need for more sophisticated studies in collaboration with a clinical immunologist. The goal in the evaluation of immunodeficient patients should be to define the specific genetic abnormality whenever possible.

Antibody Deficiencies

The quantitative measurement of immunoglobulin G (IgG), IgA, and immunoglobulin M (IgM) is the single best test to screen for primary antibody deficiencies.[9] An abnormality in the level of one or more of these classes of immunoglobulins is present in the majority of patients with primary antibody deficiencies. The pattern of the levels of IgG, IgA, and IgM gives important insight into the likely etiology of the antibody deficiency. For example, frequently clinical immunologists are consulted about the issue of whether a patient on corticosteroids has a primary antibody deficiency. In steroid-induced hypogammaglobulinemia, IgG levels are usually only moderately depressed (usually >400 mg/dL) and the magnitude of reduction reflects the dosage and duration of corticosteroid usage.[10] IgA and IgM levels tend to be preserved. In CVID, IgG levels are usually more profoundly depressed (<400 mg/dL); IgA levels are reduced (<10 mg/dL) in 70% of patients and IgM levels are reduced (<25 mg/dL) in over 80% of patients.[9] Finally, patients with CVID are unable to make antigen-specific antibodies following immunization. In contrast, patients with steroid-induced hypogammaglobulinemia make specific antibodies, although the response may be blunted.[11]

The enumeration of B cells, typically measured by flow cytometry using monoclonal antibodies directed against the CD19 or CD20 surface antigens, may also provide clues to the type of B-cell immunodeficiency present. XLA and autosomal recessive (AR) forms of aggammaglobulinemia usually have severely reduced numbers of B cells. In contrast, the number of B cells in CVID is frequently, but not always, normal. It is important to obtain a careful medication treatment history as novel agents such as rituximab, a chimeric monoclonal antibody directed against CD20, can lead to profound decreases in B-cell numbers for months after treatment.

In assessing response to immunization, it is important to immunize with both a protein and polysaccharide (PS) antigen and to assess the response 4 to 6 weeks postimmunization. The immunologic requirements to make antibodies (e.g., T-cell help, cytokine requirements) in response to immunization with a protein or PS antigen differ. Some patients with normal quantitative immunoglobulins or selective IgA deficiency exhibit a selective inability to make antibody to PS, but not to protein antigens. This immunologic defect results in recurrent sinopulmonary infections and in selected instances may require replacement immunoglobulin therapy.

Protein antigens commonly used to assess specific antibody responses include tetanus and diphtheria toxoids. The *Haemophilus influenzae* type B (Hib) vaccine in present use conjugates the capsular PS (polyribose phosphate) to a protein carrier, thereby making the antibody response thymus-dependent and allowing children under 2 years of age to make specific antibodies to a PS antigen. Therefore, quantitation of antibodies to *H. influenzae* following immunization with the Hib vaccine measures competence of the immune system to make specific antibodies to a protein, not PS antigens. Many adults have not been immunized to Hib, making the Hib vaccine particularly useful in the evaluation of this group of patients.

There are two readily available unconjugated vaccines that can be used to assess antibody responses to PS antigens: the pneumococcal PS and *Neisseria meningitidis* vaccines. Some pneumococcal vaccines are conjugated to a protein carrier and cannot be used to measure a response to the PS antigen (e.g., Prevnar). When using the pneumococcal vaccine, the measurement of antibody responses to several (12 or more)

TABLE 82-3. Screening Tests for Immune Function

Immune Function	Quantitative Assays	Functional Assays
Cellular immunity	CBC with differential*	Cutaneous delayed hypersensitivity
	Flow cytometry	Enzyme assays (ADA, PNP)
	$CD3^+CD4^+$	NK cell cytolysis assay
	$CD3^+CD8^+$	
	$CD16^+CD56^+$	
	FISH for 22q11 and 10p11 deletion	
B cells	Flow cytometry	IgG, IgA, IgM levels
	$CD19^+$ or $CD20^+$	Specific antibody response to immunization
PMN	CBC with differential	Oxidase function (NBT, DHR, chemiluminescence)
	Flow cytometry	Enzyme assays (MPO, G6PD)
	LFA-1 (CD18/CD11a)	Phagocyte function
	CD15	Chemotaxis
Complement	C3, C4	AH_{50} (alternative pathway)
	Specific complement components	CH_{50} (classical pathway)
	Complement split products	

*Preferred initial screening tests are underlined.

ADA, adenosine deaminase; CBC, complete blood count; DHR, dihydrorhodamine; FISH, fluorescence in situ hybridization; G6PD, glucose-6-phosphate dehydrogenase; Ig, immunoglobulin; LFA-1, lymphocyte function antigen 1; MPO, myeloperoxidase; NBT, nitroblue tetrazolium; NK, natural killer; PMN, polymorphonuclear leukocytes; PNP, purine nucleoside phosphorylase.

capsular antigens is indicated. There is considerable controversy about what constitutes a normal response to the pneumococcal vaccine. In the absence of more definitive studies, the only clearly abnormal response to a pneumococcal vaccine in adults is an absent response to all or nearly all capsular antigens measured 3 to 6 weeks after vaccination. Finally, children less than 2 years of age frequently do not make antibody responses to PS antigens. Thus, the use of PS vaccines to diagnose antibody-deficient states in this age group is not indicated.

Cellular Immunodeficiency

Many patients with impaired cellular immunity will have either reduced T-cell numbers or abnormal T-cell function or both (see Table 82-3). Quantitation of T-cell numbers is easily screened by enumeration using flow cytometry. The CD3 antigen measures the total numbers of T cells, whereas CD4 and CD8 antigens are present on the T-helper and T-cytotoxic subsets, respectively. Cutaneous delayed-type hypersensitivity (DTH) is an easily performed test for T-cell function. In the DTH test, a small amount of an antigen is injected into the dermis and a positive reaction is indicated by induration (>2 mm) 48 to 72 hours later at the site of the injection. Antigens such as tetanus toxoid, *Candida,* and *Trichophyton* are frequently used because most individuals will have had a prior immune response to these antigens. However, DTH responses are frequently absent in normal infants, and in vitro assays of T-cell function are indicated in this group of patients.[12] The measurement of natural killer (NK) cell numbers ($CD16^+/CD56^+$) and function is indicated in the evaluation of infants for possible SCID or patients with recurrent, severe herpesvirus infection. The pattern of abnormalities in the numbers of specific lymphocyte subpopulations (T cells, NK cells, B cells) is helpful in identifying the molecular abnormality in infants with SCID (Table 82-4).

Complement Deficiencies

The screening tests for complement deficiency states associated with increased infections are the CH_{50} and AH_{50}, which measure the integrity of the classical and alternative pathways of complement activation, respectively[13] (see Table 82-3). Abnormalities in CH_{50} or AH_{50} could be due to deficiencies in individual components of complement or inappropriate activation and consumption of the complement pathway. Many times these possibilities can be distinguished by the measurement of two or more individual components of the classical or alternative complement pathway and the measurement of complement split products. Complement consumption is indicated by low levels of more than one component of complement and the elevation of complement split products. In contrast, complement deficiency states show depressed levels of individual members of the complement pathway with normal levels of complement split products.

Phagocyte Deficiencies

The initial screening test for phagocytic defect includes a complete blood count, with quantitation of leukocyte number and morphology (see Table 82-3). The dihydrorhodamine (DHR) test has replaced the nitroblue tetrazolium (NBT) test in many centers to diagnose defects in the generation of oxidase activation, such as seen in chronic granulomatous disease (CGD).[14] Advantages to the DHR test include the ease, rapidity, and reproducibility of the test, along with the capacity to readily detect CGD carrier states. Both the NBT and DHR tests measure the ability of phagocytes to generate superoxide free radicals. In the DHR test, phagocytes are loaded with a fluorescent dye (DHR) and activated with phorbol myristate acetate. Activated phagocytes then produce superoxide free radicals that reduce DHR, leading to a change in fluorescence that is quantitated by flow cytometry. Other functional assays for phagocytes include enzyme assays for myeloperoxidase and glucose 6-phosphate dehydrogenase, chemotaxis assays, phagocytic tests, and bactericidal assays. Abnormalities in the adhesion molecules CD18 and CD15 that result in leukocyte adhesion deficiency 1 and leukocyte adhesion deficiency 2, respectively, are detected by flow cytometry.

TABLE 82-4. Common Etiologies of Severe Combined Immunodeficiencies

Form of SCID	Prevalence	T/B/NK*	Inheritance
Common γ chain IL-2 receptor deficiency	45–50%	−/+/−	X-linked
ADA deficiency	15–20%	−/−/−	AR
RAG1/RAG2	10%†	−/−/+	AR
JAK3	5–10%	−/+/−	AR

*Presence (+) or absence (−) of the indicated cell type.
†Total prevalence of patients with mutations in either RAG1 or RAG2 gene.
AR, autosomal recessive.

DEFICIENCY IN BOTH CELLULAR AND ANTIBODY PRODUCTION

Severe Combined Immunodeficiency

SCID is a syndrome that encompasses a variety of molecular defects that result in absent or severely impaired T-cell and B-cell function.[15,16] One commonly used method to classify SCID is based on whether the molecular defects decrease the numbers of T cells only, T cells and B cells, or T cells, B cells, and NK cells (see Table 82-4).

The molecular defects that lead to SCID include mutations that lead to abnormalities in cytokine signaling (e.g., the common γ chain [γc] of the interleukin [IL]-2 receptor; Janus activating kinase 3 [JAK3], IL-7 receptor)

and T-cell receptor signaling (CD45, ZAP-70, CD3γ, CD3ε, CD3ζ); defective T-cell and B-cell receptor gene recombination (*RAG1, RAG2*); defective nucleotide salvage pathway (adenosine deaminase [ADA] deficiency); and defects in the expression of major histocompatibility complex class I or class II molecules. X-linked SCID (γc mutation) is the most common form of SCID, accounting for approximately 50% of all cases. The γc of the IL-2 receptor is utilized by several other cytokine receptors, including the receptors for IL-4, IL-7, IL-11, IL-15, and IL-21. Consequently, the immunodeficiency due to mutation of the γc is due to the combined effects of loss of function in all of these cytokine receptors. Milder or atypical forms of SCID due to gene defects usually associated with classical SCID may also occur. Additionally, there are other gene defects that can lead to diseases of similar severity to SCID such as Wiskott-Aldrich syndrome, DiGeorge syndrome, Ataxia-telangiectasia, X-linked lymphoproliferative disorder, and some forms of hyper-IgM syndrome. For purposes of this chapter, these latter diseases are discussed separately from SCID.

The clinical presentation of SCID is characterized by severe infections most commonly of the respiratory and gastrointestinal tract in early infancy. Infections are caused by common and opportunistic pathogens, and disseminated infections are frequent. Other common manifestations of the syndrome include oral thrush, persistent diarrhea, interstitial pneumonitis, impaired growth, and the absence of lymph nodes. Engraftment of maternal T cells in an infant with SCID can lead to graft-versus-host disease. The prompt treatment of infection, administration of IVIG, and prophylaxis against *Pneumocystis jirovecii* are indicated until HSCT can take place. In the event blood transfusions are needed, only irradiated, cytomegalovirus (CMV)-negative blood should be used. No live virus vaccinations should be given to infants with known or suspected SCID.

Early mortality due to disseminated infections is extremely common in SCID. Therefore, it is incumbent on the physician to make a prompt diagnosis of SCID. The absence of a thymic shadow on chest radiograph in an infant with recurrent infections should prompt further studies to exclude the diagnosis of SCID. In the vast majority of infants with SCID, severe lymphopenia is present (<1500/μl). This important clue to the diagnosis of SCID is frequently overlooked. Lymphocyte enumeration studies quantifying the numbers and subsets of T cells, B cells, and NK cells by flow cytometry and a deficiency in the capacity of T cells to proliferate to mitogens confirms the diagnosis of SCID. Population-based newborn screening of SCID is a promising approach to reduce the mortality in these infants, and the state of Wisconsin began screening all newborns for SCID in 2008.[15,15a,15b]

With the exception of ADA deficiency, HSCT is the preferred treatment for SCID. Early HSCT (<3 months of age) and the use of human leukocyte antigen–identical donors have markedly improved the prognosis of infants with SCID, with long-term survival rates as high as 95%.[16] The administration of polyethylene glycol–ADA is an alternative treatment for SCID due to ADA deficiency. Ten patients with X-linked SCID were immunologically reconstituted by gene therapy.[17] Replication-incompetent retroviruses encoding the γc of the IL-2 receptor were used to transduce autologous $CD34^+$ stem cells, which were then infused into the infants. Retroviral insertion leading to activation of the proto-oncogene LMO-2 resulted in γδ T-cell leukemia in two patients, with an additional leukemia in another patient unrelated to activation of LMO-2.[17,18] More recently, gene therapy used to treat SCID due to ADA deficiency was shown to be safe and efficient.[18a]

ANTIBODY DEFICIENCIES

Immunoglobulin A Deficiency

The prevalence of IgA deficiency varies among different ethnic groups, but the overall prevalence is approximately 1 in 400 live births.[19] The etiology of IgA deficiency remains obscure. Rarely, IgA deficiency may evolve into CVID, and familial occurrences of both IgA deficiency and CVID arise, suggesting a common genetic basis.[20] Medications, in particular anticonvulsants, infrequently cause IgA deficiency or panhypogammaglobulinemia, and immunoglobulins may normalize with elimination of the drug.

There is considerable controversy as to whether IgA deficiency alone predisposes people to infection.[19,21] Most patients with IgA deficiency do not have increased numbers of infection and are often discovered during an evaluation for problems unrelated to infection. However, some patients with IgA deficiency have recurrent infections, predominantly respiratory tract infections.[22] Whether IgG subclass deficiency and/or deficiencies in mannose-binding lectin identify a subgroup of patients with IgA deficiency who are more prone to infection is not clear.[23] Unlike patients with more severe forms of antibody deficiency such as CVID or XLA, replacement therapy with IVIG is not warranted with isolated IgA deficiency. In patients with IgA deficiency and concomitant IgG subclass deficiency who have recurrent and persistent respiratory tract infections, determination of the antibody response following vaccination should be used to ascertain if IVIG therapy is warranted.[24]

Clinical manifestations of IgA deficiency are highly variable. Infectious complications of IgA deficiency include recurrent upper (otitis media, sinusitis) and lower respiratory tract infections.[22] Gastrointestinal tract infections, in particular recurrent giardiasis, may be present. The prevalence of atopic diseases (asthma, allergic rhinitis, eczema) and autoimmune diseases (systemic lupus erythematosus, celiac disease, rheumatoid arthritis) is increased in patients with IgA deficiency.[24] Patients with IgA deficiency may develop IgG anti-IgA antibodies and are at risk to develop anaphylactic reactions following administration of blood or blood products.[25] Although these anaphylactic reactions are rare, blood transfusions using IgA-deficient donors

should be used whenever possible. Extensively washed, packed red blood cells may be used for transfusion in an emergency situation or when an IgA-deficient donor cannot be found.

Serologic studies in IgA deficiency may be subject to false-positive and false-negative results. Due to the presence of heterophile antibodies, which are human antibodies cross reactive to animal proteins, positive serum β-human chorionic gonadotropin pregnancy tests were found in as many as 30% of patients with IgA deficiency.[26] The diagnosis of celiac disease in patients with IgA deficiency is problematic as the most specific serologic assay for celiac disease, IgA anti–tissue transglutaminase, is absent in IgA-deficient patients. Therefore, other assays should be performed in the laboratory assessment of celiac disease in IgA-deficient patients.

X-Linked Agammaglobulinemia

XLA (Bruton's agammaglobulinemia) is a primary antibody deficiency with an estimated prevalence of 1 in 190,000 male live births.[27] Mutations in various locations of the cytoplasmic tyrosine kinase gene Bruton's tyrosine kinase (*Btk*) are responsible for this immunodeficiency.[28] Btk is required for B-cell receptor signaling, playing a key role in the phosphorylation of phospholipase Cγ2, which is necessary for the generation of inositol triphosphate leading to release of calcium from the endoplasmic reticulum. Btk function is essential for the survival and differentiation of immature B cells. Consequently, nearly all patients with XLA have a marked deficiency in B cells (<2% of lymphocytes) and profound panhypogammaglobulinemia. XLA accounts for approximately 85% of inherited forms of agammaglobulinemia due to defects in early B-cell development, with autosomal recessive (AR) forms of antibody deficiency accounting for the remainder.[28] The clinical manifestations of the AR forms of agammaglobulinemia are similar to XLA.

In addition to B cells, Btk is expressed on myeloid cells and platelets but not NK cells or T cells. Consequently, T-cell function is normal in XLA, which contrasts with some other antibody deficiency disorders such as CVID or some forms of the hyper-IgM syndrome in which abnormalities in cellular immunity are frequently present. As many as 25% of patients with XLA present with neutropenia, which may contribute to the severity of infection.[29]

Small or absent tonsils and lymph nodes are the only characteristic physical findings in XLA. The vast majority of patients with XLA have recurrent upper (otitis media; sinusitis) and lower respiratory tract infections, with over 50% of patients having recurrent infections by 1 year of age and nearly all patients symptomatic by age 5. The most common pathogens causing pneumonia are encapsulated bacteria (*S. pneumoniae, H. influenzae, Haemophilus parainfluenzae, Staphylcoccus* spp. and *Pseudomonas* spp.).[27] Respiratory tract infections due to atypical bacteria such as *Mycoplasma pneumoniae* or *Ureaplasma urealyticum* are also frequently encountered. Gastrointestinal tract infections occur in nearly one quarter of patients and are most commonly due to *Giardia lamblia,* although bacteria (*Salmonella* spp., *Shigella* spp., *Campylobacter fetus, Helicobacter pylori*) and viruses (*Rotavirus,* enteroviruses) are also frequently isolated. Disseminated infections that include encephalitis due to infection with enteroviruses, in particular echovirus, were a major cause of mortality in patients with XLA. However, these infections appear to be declining with use of high-dose immunoglobulin replacement therapy.[27]

The pulmonary complications of XLA continue to be a major cause of morbidity and mortality and include bronchiectasis, hypoxemia, and cor pulmonale.[27] Complete pulmonary function tests (if possible) and a high-resolution computed tomography (HRCT) scan of the chest are indicated in the initial evaluation of these patients. High-dose IVIG has been shown to decrease pulmonary infections in these patients, but may not prevent the progression of bronchiectasis. Bronchiectasis, if detected, should be treated with daily pulmonary hygiene (e.g., inhaled β-agonists, chest physiotherapy) and aggressive antimicrobial therapy for intercurrent pulmonary infections. The efficacy of rotating antibiotics or chronic antimicrobial therapy in patients with bronchiectasis is unknown.

IVIG is the most commonly used form of antibody replacement for the treatment of profound antibody deficiencies such as XLA and CVID. Subcutaneous infusion of gamma globulin administered at home is an increasingly used alternative form of therapy and has far fewer infustion-related adverse reactions.[30] Higher doses of IVIG (500 to 600 mg/kg) are superior in preventing infections compared to "conventional" doses of IVIG (100 to 150 mg/kg).[31] Intercurrent sinopulmonary infections should be aggressively treated with appropriate antimicrobial therapy to include coverage of common encapsulated bacteria as well as atypical bacterial pathogens (*Mycoplasma* spp., *Ureaplasma*).[32]

A common mistake in managing patients with profound antibody deficiencies (e.g., XLA, CVID) is the inappropriate use of serologic assays in the diagnosis of infectious disorders. With the exception of IgA and IgG subclass deficiency, patients with antibody deficiency do not make specific antibodies in response to exogenous antigens. Therefore, the use of diagnostic studies to detect specific antibodies against pathogens is unreliable and, if positive, usually reflects antibodies present in the IVIG used to treat such patients. Diagnostic studies that detect microbial antigens or nucleic acids (polymerase chain reaction assays) from the pathogen must be used in place of serologic assays.

Common Variable Immunodeficiency

CVID, also known as acquired hypogammaglobulinemia, is a primary immunodeficiency affecting approximately 1:20,000 to 1:50,000 live births.[33] CVID is a clinical syndrome and represents a family of disorders that exhibit a common phenotype. Although highly variable, the mean onset of symptoms in patients with CVID is in the third decade of life. There remains a considerable

delay between the onset of symptoms and the diagnosis of CVID (>7 to 10 years).[9,34,35] Unlike in XLA, T-cell abnormalities are common in patients with CVID and contribute to the more protean clinical manifestations of this disease.[9] The diagnosis of CVID should be considered in any person with recurrent respiratory tract infections (i.e., two or more confirmed pneumonias) and greater than 2 years of age.

The etiology in the vast majority of cases of CVID is unknown. Recent studies show that mutations in inducible T-cell costimulator (*ICOS*) or CD19 as well as polymorphisms of *TACI* or *Msh5* cause CVID in a small percentage of patients.[36–42] Collectively, mutations or polymorphisms of these genes account for less than 10% to 15% of all cases of CVID. Patients with CVID due to polymorphisms in *TACI,* the most common of the genetic abnormalities occurring in approximately 7% of patients with CVID, are more likely to have autoimmune disease and splenomegaly.[43]

The laboratory evaluation of patients with CVID demonstrates the complex nature of the disease.[9] The definitive diagnosis of CVID requires the demonstration of a low serum level of IgG, low serum level of IgA or IgM, and impaired capacity to make specific antibodies in response to immunization or infection, and the exclusion of other primary or secondary antibody deficiencies. IgG levels are reduced by greater than 2 standard deviations from the mean in all patients. IgA levels are low in nearly all patients and IgM levels are reduced in the majority of patients. B-cell numbers are variable in CVID, and if reduced may indicate a poorer prognosis.[9] B-cell subset analysis by flow cytometry is valuable in predicting risk to develop certain complications of CVID. Low numbers of switched memory B cells ($CD27^+$, IgM^-, IgD^-) in the peripheral blood are frequently found in patients with multisystemic granulomatous disease, which is a risk factor for early mortality. Patients with autoimmune complications frequently have increased numbers of CD21 (lo) B cells in the peripheral blood.[44] T-cell abnormalities occur in approximately 40% of patients and include anergy, T-cell lymphopenia, and poor in vitro proliferative responses to mitogens and antigens.

Nearly all patients present with recurrent upper or lower respiratory tract infections, including bronchitis, sinusitis, otitis media, and pneumonia. Common pathogens include encapsulated (*H. influenzae, S. pneumoniae*) or atypical (*Mycoplasma* spp.) bacteria.[9,32,45] Pulmonary infections with gram-negative rods should also be considered, in particular in patients with longstanding CVID or impaired cellular immunity. Opportunistic infections occur in less than 10% of patients. Patients with CVID appear to be particularly susceptible to infections with atypical bacteria such as *Mycoplasma* spp. and *Ureaplasma* spp., and antimicrobial therapy of respiratory tract infections should be used that is effective against these organisms.[32] Apart from respiratory tract infections, joint and bone infections due to these organisms have also been reported. Gastrointestinal tract infections with pathogens similar to those found in XLA (*Campylobacter jejuni, Salmonella* spp., *G. lamblia*) are also common.[9] The prevalence of hepatitis is increased in CVID, occurring in approximately 12% of patients. The prognosis from hepatitis secondary to infection with hepatitis C is poor and may be rapidly progressive in patients with CVID.

The mortality of CVID due to common infectious pathogens has declined with the increased use of high-dose immunoglobulin replacement.[6] Complications such chronic lung disease, malignancy, and autoimmune disease are now the most common cause of morbidity and mortality. Although patients with CVID are unable to make antibodies to foreign antigens, they exhibit increased propensity to make autoantibodies. Consequently, the prevalence of autoimmune disorders, in particular idiopathic thrombocytopenic purpura (ITP) and autoimmune hemolytic anemia (AHA) is increased.[9,46] Oral corticosteroids, the use of immunomodulatory dosages of IVIG (2 g/kg per month), and rituximab have been used to treat AHA or ITP in patients with CVID.[46]

Patients with CVID are at high risk to develop malignancy. In particular, the prevalence of non-Hodgkin's lymphomas and gastric carcinoma are increased in CVID and are a major cause of morbidity and mortality in this disorder.[47] Careful periodic examination of the lymph nodes and spleen is important, as patients with CVID also frequently have adenopathy and splenomegaly that is nonmalignant in nature. The use of periodic abdominal computed tomography (CT) scans to assess spleen size, and/or the presence of intra-abdominal and retroperitoneal adenopathy, along with upper and lower endoscopic evaluation for gastrointestinal symptoms, may also be useful.

The pulmonary disorders associated with CVID are complex and a major cause of mortality.[44,48–51] Bronchiectasis is the most common pulmonary disorder, occurring in over 20% of patients. Although not consistently found, some investigators report that patients with low serum levels of mannose-binding lectin or low numbers of IgM^+ switched memory B cells with low serum levels of antipneumococcal IgM antibodies may be at risk for increased pulmonary infections and bronchiectasis.[52,53] It is not clear that high-dose gamma globulin replacement therapy can prevent the development of bronchiectasis in patients with CVID.[35] Treatment of bronchiectasis in patients with CVID is similar to the therapy of idiopathic bronchiectasis. Mobilization of pulmonary secretions through the use of medications such as β_2-agonists along with chest physiotherapy is frequently used, although there are few trials that demonstrate the effectiveness of pulmonary hygiene.[54] The early, aggressive treatment of pulmonary infection is indicated in these patients. The efficacy of rotating antimicrobial therapy or thrice-weekly, low-dose azithromycin is also unproven, but individual patients may benefit from such therapy. Diffuse interstitial lung disease (granulomatous lung disease, lymphocytic interstitial pneumonia [LIP], follicular bronchiolitis, bronchiolitis obliterans with organizing pneumonia) occurs in approximately 10% to 25% of patients with CVID and is refractory to IVIG therapy.[44,48–51,55]

There has been considerable controversy regarding the nature and clinical course of granulomatous lung disease in CVID. Some believe that the granulomatous disease in CVID represents a form of sarcoidosis.[56] Common features shared with sarcoidosis include the systemic nature of the disease, frequent presence of mediastinal and hilar adenopathy, and noncaseating granulomas in the lungs and other organs. It now appears likely that this disorder represents a distinct disease entity.[44,51] Unlike sarcoidosis, granulomatous and lymphoproliferative histopathologic patterns (LIP, follicular bronchiolitis, and lymphoid hyperplasia) often appear together, and the term *granulomatous-lymphocytic interstitial lung disease* (GLILD) has been used to characterize this disorder.[51] Other distinguishing features of GLILD in comparison to sarcoidosis include the lack of spontaneous remission of lung disease, poor response to corticosteroid therapy, panhypogammaglobulinemia with low numbers of switched memory B cells, and high prevalence of autoimmune disease, in particular ITP. Patients with granulomatous lung disease and CVID frequently have diffuse adenopathy with splenomegaly and T-cell lymphopenia and are at increased risk to develop non-Hodgkin's lymphoma and of early mortality.[44,51] HRCT of the chest is indicated in the evaluation of patients with GLILD and demonstrates numerous abnormalities, including mediastinal adenopathy and diffuse ground-glass and nodular opacities.[57]

The etiology of GLILD is unknown. In a study of a small cohort of patients, human herpesvirus 8 (HHV8) infection was found in the lung in the majority of patients with GLILD, suggesting that HHV8 infection may underlie the lung and lymphoproliferative disease in a subgroup of patients with GLILD.[58] The overproduction of tumor necrosis factor-α (TNF-α) may also contribute to propagation of granulomatous disease in these patients.[59] Case reports have demonstrated that the use of TNF-α antagonists may lead to regression of granulomatous disease in patients with CVID, lending further support to this hypothesis.[60] Limited anecdotal experience suggests that the GLILD may also respond to low-dose cyclosporine therapy.[61]

The combination of CVID in conjunction with thymoma is known as Good's syndrome.[62] Whether this disorder is unique from CVID or represents another manifestation of the disease is unclear. The thymoma is often not apparent on routine chest radiograph. Autoimmune disorders and opportunistic infections appear to be more common in this group of patients. Resection of the thymoma is recommended, although this will not result in resolution of the immunodeficiency or autoimmunity.[62]

Due to the complexity of the pulmonary disease, periodic chest radiographs, full pulmonary function tests, and HRCT scans of the chest in patients with CVID are indicated. In the diagnostic evaluation of patients with GLILD or other forms of interstitial lung disease, it is essential to obtain sufficient tissue to exclude the diagnosis of lymphoma. Therefore, such patients frequently require an open lung biopsy or mediastinoscopy with lymph node biopsy.

Specific Antibody Deficiency

Specific antibody deficiency (SAD) is a primary antibody deficiency disorder that is characterized by normal levels of IgG, IgA, and IgM but an inability to make specific antibodies, most commonly in response to PS antigens such as Pneumovax.[63,64] Patients with specific antibody deficiency present with recurrent sinopulmonary infections, similar to other forms of hypogammaglobulinemia. The diagnosis of SAD is made by measuring an absence of specific antibody responses following immunization with PS vaccines, most commonly the unconjugated pneumococcal vaccine. Cellular immunity is normal in this disorder. As pointed out earlier in this chapter, considerable controversy exists in regard to what constitutes an "abnormal" response to the pneumococcal vaccine sufficient to make the diagnosis of SAD. Therefore, the prevalence of this disorder is unknown. The initial treatment of SAD is similar to IgA deficiency. However, IVIG is indicated in patients with SAD who fail more conservative treatment.

Immunoglobulin G Subclass Deficiency

IgG subclass deficiency is defined by normal total serum IgG levels with a low level of one or more IgG subclasses. There are four isotypes of IgG in humans, IgG1, IgG2, IgG3, and IgG4. The predominant subclass is IgG1, accounting for over 60% of the total IgG. In some patients evaluated for recurrent sinopulmonary infections, low levels of one of the IgG subclasses are found. However, the significance of IgG subclass abnormality is unclear.[65,66] Some believe that isolated IgG subclass deficiencies predispose patients to recurrent sinopulmonary infections. In contrast, IgG subclass deficiencies, including genetic deletions of IgG subclass loci, are well documented in healthy individuals.[67] Because the clinical significance of isolated IgG subclass deficiencies is unclear, the measurement of IgG subclasses is not warranted in the intial evaluation of patients with recurrent sinopulmonary infections. In patients with an isolated IgG subclass deficiency and recurrent infections, the decision to use IVIG should be based on antibody responses following vaccination.

X-linked Lymphoproliferative Syndrome

X-linked lymphoproliferative syndrome (XLP), or Duncan's disease, is a rare primary immunodeficiency characterized by an extreme sensitivity to infection with Epstein-Barr virus (EBV). Aproximately 80% of XLP (XLP-1) is caused by mutations in the adaptor protein gene *SH2D1A* (also known as *SAP,* the gene for slam-associated protein).[68,69] The SH2D1A adaptor protein affects multiple intracellular signaling pathways in several different lymphocyte subpopulations, including T cells, B cells, and NK cells, a property that leads to the complex immunologic abnormalities seen in these patients. Mutations in the X-linked inhibitor of apoptosis gene (*XIAP*) account for the remainder of patients with XLP (XLP-2), which results in premature apoptosis of

lymphocytes in response to a variety of stimuli.[69] The clinical phenotypes of XLP-1 and XLP-2 are similar with the exception that splenomegaly is frequently the first clinical manifestation of the disease in patients with XLP-2. Patients with XLP have a unique predisposition to infection with EBV, an infection that triggers the immunodeficiency in the vast majority of cases. Approximately 60% of patients with XLP present with overwhelming EBV infection leading to hemophagocytic lymphohistiocytosis. Lymphomas or hypogammaglobulinemia develops following EBV infection in approximately 30% of patients with XLP. Patients may have one or all of the manifestations of the syndrome at the same time. The onset of disease is variable, occurring as early as infancy or well into adulthood. Immunologic abnormalities apart from hypogammaglobulinemia also include markedly reduced NK-cell function and impaired T-cell responses. A deficiency in the numbers of natural killer T cells has been reported to be present in all patients with XLP-1 and XLP-2. The only definitive therapy for XLP is HSCT,[70,71] although IVIG is commonly used in an effort to prevent infections.

Hyper–Immunoglobulin M Syndrome

Hyper-IgM syndrome (HIGM) is a descriptive term that reflects a common laboratory abnormality (high serum IgM level with low serum IgA and IgG levels) that occurs in several otherwise dissimilar types of immunodeficiencies (Table 82-5). Despite the name, high levels of IgM are inconsistently found in all forms of hyper-IgM syndrome.[72,73] Furthermore, many believe that grouping together these distinct immunodeficiencies, some of which are intrinsic B-cell abnormalities, whereas others are complex cellular and humoral immunodeficiencies, leads to diagnostic confusion and is fundamentally flawed. Nevertheless, the classification remains widely used despite the obvious drawbacks. Although we group HIGM under "predominantly antibody deficiencies," only mutations in activation-induced cytodine deaminase (AICD)[74] or uracil nucleotide glycosylase (UNG)[75] result in primary immunodeficiencies that are largely due to antibody deficiency. The other forms of HIGM are complex cellular and humoral immunodeficiencies.

X-Linked Hyper-IgM Syndrome

The classic, X-linked form of HIGM (XHIGM), which accounts for approximately two thirds of cases, is due to a mutation in the CD40 ligand (CD40-L) gene.[72,76] CD40-L is inducibly expressed on activated, CD4 T cells and interacts with CD40, which is expressed on the surface of B cells. The interaction of CD40 on B cells with CD40-L on activated T cells in conjunction with specific cytokines (IL-4) is required for immunoglobulin class switching. Consequently, mutations in CD40-L (or CD40) results in a failure to class switch, leading to defective production of the later immunoglobulin isotypes (IgG, IgA, immunoglobulin E [IgE]). CD40 is also expressed on monocytes and dendritic cells. The lack of CD40-L T-cell interaction with CD40 on monocytes and dendritic cells also contributes to defective cellular immunity.[77] Mutations within the CD40 gene are a rare cause of HIGM with a clinical phenotype similar to that of XHIGM. Low serum levels of IgG are consistently found, and serum levels of IgA are reduced in the majority of patients. However, high serum levels of IgM are an inconsistent finding, occurring in approximately 50% of patients.[72] Antibody responses to immunization show a weak IgM response, without development of IgG- or IgA-specific responses and the absence of immunologic memory. The numbers of switched memory B cells ($CD27^+$, IgD^-, IgM^-) are extremely low. Neutropenia is found in approximately 50% of patients and may respond to treatment with granulocyte colony-stimulating factor (G-CSF).

Patients with XHIGM have recurrent infections beginning early in life. Over half of patients with XHIGM are diagnosed by age 1 and nearly all by age 4. Pneumonia, frequently caused by infection with *P. jirovecii,* is common, occurring in as many as 80% of patients. Sinusitis, otitis media, and other respiratory tract infections occur frequently. Intractable diarrhea, sometimes due to infection with *Cryptosporidium* or more frequently idiopathic, occurs in nearly one third of patients. *Cryptosporidium* infection is also a major cause of sclerosing cholangitis in these patients. Infection of the central nervous system (encephalitis, meningitis), frequently due to infection with echovirus,

TABLE 82-5. Etiologies of Hyper-IgM Syndrome

Mutation	Inheritance	Clinical Phenotype
CD40-L	X-linked	Abnormal cellular immunity, neutropenia in 50%, early onset, recurrent sinopulmonary infections, *Pneumocystis jirovecii* (*carinii*) pneumonia, chronic diarrhea due to *Cryptosporidium* infection, diarrhea, inflammatory bowel disease, autoimmunity
CD40	Autosomal recessive	Similar to CD40-L mutation
NEMO (IKK-γ)	X-linked	Impaired cellular immunity, variable serum levels of IgM or IgA, ectodermal dysplasia (most), recurrent pyogenic infections, viral infections, mycobacterial infections
AICD or UNG	Autosomal recessive	Impaired humoral immunity, normal cellular immunity, later age of onset than other types of hyper-IgM syndrome, increased autoimmunity and lymphadenopathy
Unknown	Variable	Similar to AICD/UNG mutations

AICD, activation-induced cytodine deaminase; AR, autosomal recessive; Ig, immunoglobulin; UNG, uracyl nucleotide glycosylase; see text for other abbreviations.

is a major cause of morbidity and mortality. Treatment of XHIGM includes IVIG, prophylaxis against *P. jirovecii,* G-CSF for neutropenia, and consideration for HSCT.[78]

Mutations of NF-κB Essential Modifier

Hypomorphic mutations within the NF-κB essential modifier (NEMO) gene, an X-linked gene, cause an immunodeficiency characterized by recurrent pyogenic infections, increased susceptibility to mycobacterial infections, and variable B-cell and T-cell abnormalities.[79,80] NEMO, also known as IKK-γ, is part of the IκB kinase (IKK) complex. IKK is responsible for phosphorylating the inhibitor of NF-κB (IκB), thereby releasing NFκB and allowing for its nuclear translocation. The protean immunologic and clinical manifestations due to mutations in NEMO reflect the importance of NF-κB in multiple biologic processes. Approximately 80% of patients with mutations in NEMO have ectodermal dysplasia (abnormal teeth, decreased numbers of sweat glands, fine hair, frontal bossing). The ectodermal dysplasia in these patients is due to the inability of the ectodysplasin A receptor to induce the activation of NF-κB. The susceptibility to mycobacterial infection is likely due to an inability of CD40 ligation to activate the NF-κB pathway, leading to deficient IL-12 production by monocytes and dendritic cells and deficient interferon (IFN)-γ production by T cells and NK cells.[81]

Common immunologic screening tests of immune function may be normal in patients with NEMO deficiency. For example, hypogammaglobulinemia or decreased specific responses to vaccination occur in approximately 60% of patients and high serum level of IgM in only 15% of patients. NK cell function has been reported to be abnormal in all patients with mutations in NEMO and may be a reasonable adjunctive screening test for this disorder.[80,82]

Patients with NEMO mutations have severe infections usually beginning early in life. Common sites of infection include the lung, sinuses, middle ear, skin, and deep tissues (abscesses), blood (septicemia), gastrointestinal tract, and central nervous system. Pyogenic infections are frequently due to *Staphylococcus aureus, S. pneumoniae,* and *H. influenzae* and occur in nearly 90% of patients. Mycobacterial infections (pneumonia, cellulitis, lymphadenitis, osteomylelitis) occur in over 40% of patients and are usually caused by *Mycobacterium avium-intracellulare.* Severe viral infections (encephalitis, gastroenteritis, viremia) occur in approximately 20% of patients. Herpesviruses (herpes simplex virus, CMV) and adenoviruses are the most frequent viral pathogens. Opportunistic infections due to *P. jirovecii* or fungi occur in 10% of patients. Autoimmune disease—in particular, inflammatory colitis—occurs in approximately 20% of patients and can lead to intractable diarrhea. Treatment of patients with NEMO mutation frequently includes replacement gamma globulin and antimicrobial prophylaxis (*Pneumocystis,* mycobacteria). HSCT has had variable success in treating this disorder.[83]

Mutations in AICD or UNG

Mutations in AICD[74] or UNG[75] are causes of AR forms of HIGM. AICD and UNG are essential for class switch recombination.[84] Hence, mutations in AICD or UNG result in high serum levels of IgM, with low serum levels of IgG and IgA. Patients with mutations in either AICD or UNG have a similar clinical phenotype with impaired humoral immunity and intact cellular immunity.[85] Recurrent upper and lower respiratory tract infections and gastrointestinal tract infections frequently occur. Lymphadenapathy is frequent and autoimmunity (AHA and ITP) occurs in approximately 20% of patients.

DEFICIENCIES IN CELLULAR IMMUNITY/ COMPLEX IMMUNODEFICIENCIES

DiGeorge Syndrome

DiGeorge syndrome (DGS), also known as 22q11.2 deletion syndrome or velocardiofacial syndrome, is one of the most common primary immunodeficiencies, occurring in approximately 1 in 3000 live births. The vast majority of patients with DGS have hemizygous deletion of varying degrees in chromosome 22q11.2, with rare cases due to deletion of 10p13. The molecular basis for many of the clinical manifestations of DGS appears to be deletions or mutations in TBX1, a T-box transcription factor important in embryonic development.[86] Background genes also contribute to the phenotype in DGS as patients with identical deletions of 22q11.2 may have a markedly different clinical phenotypes. Patients with DGS exhibit a characteristic facies that includes hypertelorism, saddle nose, shortened philtrum, and low-set ears.[87] Other common features of DGS include hypoplasia of the thymus and parathyroid glands, immunodeficiency, autoimmunity, cardiac abnormalities, velopharyngeal insufficiency, speech delay, developmental delay, and behavioral and psychiatric problems. Nearly 90% of infants diagnosed with DGS in infancy have cardiac abnormalities, and screening for DGS should be considered in any infant with an interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, and anomalous aortic arch (with or without a ventral septal defect).[33,87]

In patients who are not diagnosed in infancy, recurrent infections are common and frequently lead to the diagnosis of DGS.[33] The immunodeficiency associated with DGS is highly variable and correlates with the degree of thymic hypoplasia.[87–89] Patients with "complete DGS," comprising less than 0.5% of the overall numbers of DGS patients, have a profound deficiency of T cells and T-cell function that requires thymic transplantation.[90] In contrast, the majority of patients with DGS are referred to as "partial DGS." Patients with partial DGS generally have a variable, usually non–life-threatening immunodeficiency. Patients with partial DGS may have moderately diminished numbers of T cells, and T-cell defects in these patients are usually mild with relatively normal in vitro and in vivo (delayed-type hypersensitivity

skin tests) assessment of T-cell function. Intact thymic function is essential for deletion of autoreactive T cells. Consequently, patients with DGS have an increased prevalence of autoimmune disorders. Approximately 10% of patients with DGS have autoimmune disease. Juvenile arthritis, AHA, and IPT are the most common autoimmune diseases in DGS. Studies of humoral function have yielded conflicting results. An abnormality in humoral immunity (IgA deficiency, decreased specific antibody production) in one cohort of patients was reported to be as high as 40%.[91] However, most studies show that the need for immunoglobulin therapy is low (<15%) in patients with DGS.

Most patients with DGS tolerate live virus vaccines without complications, but an assessment of humoral and cellular immune function should be performed prior to their administration. Infectious complications of partial DGS usually include recurrent sinopulmonary infections and otitis media. Structural abnormalities of the palate may contribute to recurrent sinus disease in these patients. Opportunistic infections are infrequent in partial DGS, although oral and esophageal thrush is seen. Patients with complete DGS are highly susceptible to infection with opportunistic pathogens, reflecting the much more severe cellular immunodeficiency. Attenuated live virus vaccines should be avoided and irradiated blood and blood products used to avoid graft-versus-host disease.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder characterized by recurrent infections, eczematous skin disease, and thrombocytopenia due to a mutation in the WAS protein (WASp) gene.[92] The function of WASp is complex, but through its interaction with a variety of adaptor molecules and kinases, WASp is involved in the integration of cytoplasmic signaling with the reorganization of the actin cytoskeleton. Consequently, WASp function is critical in the formation of the immunologic synapse, cellular motility, cellular trafficking, and protection against autoimmunity.[93] Mutations in the WASp gene cause four distinct diseases: (1) classic WAS; (2) X-linked thrombocytopenia; (3) intermittent thrombocytopenia; and (4) congenital X-linked neutropenia without other features of WAS.[94] We limit this section to classic WAS.

The laboratory evaluation of patients with WAS usually demonstrates increased levels of serum IgE and IgA with low a level of IgM and normal level of IgG. Despite normal serum IgG levels, impaired antibody responses following immunization to PS antigens is consistently present.[95] Abnormalities in T-cell and NK-cell function occur frequently, resulting in a partial combined immunodeficiency.[96] Decreased platelet counts, platelet function, and platelet size are hallmarks of the disorder and lead to the marked bleeding diathesis.

The clinical expression of WAS includes prolonged bleeding episodes beginning in infancy, recurrent pygogenic infections, autoimmunity, eczematous dermatitis, and an increased prevalence of EBV-related lymphomas. Upper and lower respiratory infections due to encapsulated organisms (*S. pneumoniae* and *H. influenzae*) are common and reflect the inability of patients with WAS to make specific antibody to PS antigens.[95] Pulmonary infections with opportunistic pathogens (*P. jirovecii,* herpesviruses) are also common. Infection and hemorrhage are common causes of death. The treatment of WAS includes aggressive treatment of intercurrent infections and administration of IVIG.[95] The thrombocytopenia usually responds to splenectomy. HSCT is the treatment of choice for WAS, with long-term survival rates over 70%.[93]

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is an AR disorder due to a mutation in the AT gene, which is involved in the repair of DNA breaks.[97,98] The clinical manifestations of AT include neurologic dysfunction (cerebellar ataxia, oculomotor apraxia, delayed motor development), telangiectasias, and immunodeficiency. The mutation in the AT gene with an attendant increased radiosensitivity leads to the increased prevalence of malignancies (lymphomas, epithelial tumors) in this disorder.[97,98] The manifestations of immunodeficiency typically begin in infancy or early childhood and resemble antibody deficiencies. Serum immunoglobulins are usually normal in AT, but hypogammaglobulinemia and defective responses to immunization with pneumococcus vaccine are not infrequent. Elevated levels of carcinoembryonic antigen and alpha-fetoprotein are present in nearly all patients with AT. There is no definitive treatment of AT. Patients with AT should be sent to tertiary referral centers with experience in these disorders to assist in their management.

Hyper–Immunoglobulin E Syndrome

Hyper-IgE syndrome (HIES), also known as Job's syndrome, is a syndrome characterized by recurrent skin and lung infections, severe eczema, and elevated levels of serum IgE. There are two forms of HIES. The more common autosomal dominant (AD) form of HIES is caused by mutations in the transcription factor signal transducer and activator of transcription-3 (STAT-3) and has extra-immunologic features (connective tissue disorders, skeletal abnormalities) not present in the AR form.[99] In addition, the AR form is complicated by a much higher incidence of cutaneous viral infections and neurologic complications and lacks the characteristic facies present in the AD form of HIES.[99,100] Mutations in the kinase Tyk2 may cause the AR form of HIES in a small minority of patients.[101] The remainder of this discussion will focus on the AD form of HIES.

The clinical features of HIES include the onset of moderate to severe eczema and eosinophilic pustular folliculitis in early infancy, skin infections (abscesses), mucocutaneous candidiasis, and recurrrent pneumonias with pneumatoceles. Pneumatoceles are thought to develop as a consequence of disordered healing following primary infection of the lung. Common primary pathogens in HIES syndrome include *S. aureus, S. pneumoniae, H. influenzae,* and *Candida albicans.*

Secondary infection of the pneumatocoeles with *Aspergillus* spp. or *Pseudomonas aeruginosa* often results in invasion of the pulmonary vasculature leading to pulmonary hemorrhage or central nervous system infection, which are major causes of death.[102] The signs and symptoms of serious infection are frequently absent in patients with HIES. Abscesses may develop without signs of external inflammation (cold abscess) or pneumonia may be present with limited clinical symptoms. Therefore, increased vigilance for infection is necessary in the management of patients with HIES.

There are several nonimmunologic features of HIES that aid in the early diagnosis of this disease. Patients with HIES have a characteristic facies (coarse facial features with a protuberant mandible and forehead, hypertelorism, and a broad, fleshy nasal tip), retained primary teeth, severe osteopenia with fractures following minimal trauma, scoliosis, and hyperextendible joints. A recently discovered abnormality in patients with HIES is the proclivity to develop aneurysms, in particular aneurysms of the coronary arteries.[103] The clinical significance of the aneurysms and proper management are unknown at this time.

The diagnosis of HIES cannot be made by routine assays of immunologic function. Typical abnormalities in the laboratory evaluation of patients with HIES include an elevated IgE (>2000 IU/mL) and eosinophilia. These laboratory abnormalities are not pathognomic of HIES and may be present in patients with severe atopic dermatitis. Elevated levels of serum IgE may wane with age, and a normal IgE level does not exclude the diagnosis of HIES.

An understanding of the molecular pathogenesis of HIES was significantly advanced with the discovery that mutations in the STAT-3 gene are the cause of this disorder. The STAT-3 gene codes for a transcription factor that is essential for the biologic activities of numerous cytokines, including IL-6 and IL-10.[104] The absence of the anti-inflammtory effects of IL-10 likely contributes to the dysregulated inflammatory response seen in HIES patients.[105] Interleukin-6 is required for the genesis of $CD4^+$ Th17 cells in humans and, therefore, there is a deficiency of Th17 cells in HIES.[106] Th17 cells are important in the defense against extracellular bacteria and fungi.[107]

The treatment of HIES focuses on the prevention and prompt treatment of infection. Antimicrobial prophylaxis to prevent infection with *S. aureus* is often given. The role of antifungal prophylaxis is unknown. Optimal skin care, including the use of bleach baths, topical corticosteroids, and hydrating measures for eczema, is essential. IVIG or IFN-γ may benefit some patients.[108] As the treatment of HIES is not optimal, other therapies, including HSCT, may be considered in the future.

PHAGOCYTIC CELL DISORDERS

Phagocytic defects can initially be separated by abnormalities intrinsic or extrinsic to the phagocyte. Examples of intrinsic phagocyte defects include defects in adhesion, chemotaxis, signaling, or killing. Alternatively, there are examples of primary immunodeficiencies in which phagocytic cell function is normal, but auxiliary components necessary to optimal phagocytic function are absent. For example, immunoglobulins and complement are necessary for optimal phagocytic function.

There are several indications for evaluation of patients for phagocytic abnormalities, including neutropenia or the lack of neutrophilia with significant infection, infections with unusual or opportunistic pathogens (e.g., fungi such as *Aspergillus or Nocardia;* bacteria such as *Serratia marcescens or Burkholderia cepacia*), unusual sites of infection (e.g., recurrent osteomyelitis, abscesses in the brain, lung, or liver), systemic bacterial infections, recurrent skin or upper or lower respiratory tract infections, and cold abscesses. Apart from infection, patients with phagocytic defects may have ongoing chronic inflammatory responses in the skin (e.g., eczematoid dermatitis) or mucous membranes (e.g., periodontitis, aphthous stomatitis) and disordered inflammatory responses leading to delayed or abnormal wound healing.

Phagocytic Defects: Increased Apoptosis of Neutrophils

Cyclic Neutropenia and Congenital Agranulocytosis (Kostmann's Syndrome)

Cyclic neutropenia is an AD disorder due to a mutation in the gene for neutrophil elastase-2 (ELA2). It is thought that mutations of ELA2 induce premature apoptosis of neutrophil precursors by the induction of the unfolded protein response.[109] In cyclic neutropenia there is a regular, 21-day fluctuation of neutrophils and other blood components (platelets, monocytes, reticulocytes).[109,110] During the periods of neutropenia, patients are predisposed to bacterial infection with pyogenic bacteria and opportunistic pathogens. The diagnosis of cyclic neutropenia should be suspected in the context of cyclic hematopoiesis and neutropenia that coincide with recurrent infections. To document concurrent infection with neutropenia, serial complete blood counts (two to three times/week) for at least 6 weeks should be performed. Most cases of AR congenital agranulocytosis (Kostmann's syndrome) are due to mutations in the gene for HAX1, a mitochondrial protein that is thought to protect myeloid cells against apoptosis.[111]

The clinical manifestations of congenital agranulocytosis typically begin in early infancy with life-threatening infections (cellulitis, meningitis, perirectal abscesses, sepsis).[112] Patients with congenital agranulocytosis have severe neutropenia with an absolute neutrophil count of less than 200/μL. The clinical manifestations of congenital agranulocytosis are more severe than those of cyclic neutropenia. The use of G-CSF is indicated in cyclic neutropenia and congenital agranulocytosis; it will increase neutrophil counts and reduce infection in the vast majority of patients with either disorder.[112] In patients with severe neutropenia unresponsive to G-CSF, HSCT should be performed.[113]

Decreased Adherence/Chemotaxis

Leukocyte Adhesion Deficiency Types I–III

The influx of leukocytes in general and neutrophils in particular to sites of infection is a complex process involving the production and release of neutrophils from the bone marrow, and the activation of neutrophils by chemotactic factors with subsequent adhesion of neutrophils to the endothelium, followed by transmigration of neutrophils through the endothelium of postcapillary venules. The first step in the egress of neutrophils from the circulation to sites of infection is mediated by the rolling (loose) adhesion of neutrophils to endothelium, mediated predominantly by CD15s (sialyl $Lewis_x$) on the neutrophil and its counter-ligands (E-selectin, P-selectin) on the endothelium. The following step in adhesion, which is of higher affinity, is mediated predominantly by the interaction of the integrin leukocyte function–associated antigen (LFA-1; CD11a/CD18) on the leukocyte with its counter-ligand intracellular adhesion molecule-1 on the endothelium. Integrins are composed of two subunits, (α,β), which are non-covalently associated. The common β chain of CD18 associates with CD11a (LFA-1), CD11b (Mac-1 or CR3), CD11c (gp150. 95) and CD11d, which are expressed on a variety of leukocytes. Therefore, mutations in CD18 reduce the expression of CD11a, CD11b, and CD11c, resulting in defects in the endothelial adhesion of all leukocytes. Mutations in CD18 and CD15s lead to the primary immunodeficiencies leukocyte adhesion deficiency type I (LAD-I) and LAD type II (LAD-II), respectively.[114,115] LAD type III (LAD-III) is a neutrophil defect characterized by a failure to activate integrins in response to cytokines and chemokines. A minority of cases of LAD-III are due to mutations in the calcium- and diacylglycerol-regulated guanine nucleotide exchange factor 1 (CalDAG-GEFI), a Rap-1/2 guanine exchange factor.[116]

LAD-I is divided into two broad categories based on whether the deficiency of LFA-1 is severe (<0.5% of normal levels) or moderate (5% to 10% of normal levels).[117] Patients with a complete deficiency in LFA-1 expression often present in the neonatal period with delayed separation of the umbilical cord, omphalitis, and severe infections of the skin, gingiva, gastrointestinal and upper and lower respiratory tracts. Moderate deficiencies of LFA-1 result in a milder phenotype that may contribute to a delay in the diagnosis. Patients with LAD-I exhibit neutrophilia, even in the absence of systemic infection, due to the inability of leukocytes to adhere to the endothelium. The definitive diagnosis of LAD-I deficiency is made by the demonstration of extremely low levels of LFA-1 on neutrophils by flow cytometry. The treatment of LAD-I deficiency includes the aggressive use of antimicrobials in the treatment of infection. HSCT is the only definitive treatment for patients with severe deficiencies of LFA-1.[114,118] Moderate deficiencies of LFA-1 may improve with recombinant IFN-γ therapy and chronic antimicrobial prophylaxis.

LAD-II is an extremely rare disorder characterized by developmental delay, mental retardation, and recurrent infection similar to LAD-I. A mutation in the GDP-fucosyl transporter leads to the absence of CD15s on leukocytes and expression of the Bombay blood phenotype (hh).[119] Oral fucose administration can induce the expression of CD15s, leading to improvement of the central nervous system abnormalities and decreased infection.[120] LAD-III is also a rare disorder characterized by recurrent infections, bleeding tendency, and leukocytosis. Patients with LAD-III and mutations in CalDAG-GEFI also have neurologic abnormalities (developmental delay or mental retardation, seizure disorders). CalDAG-GEFI is expressed in hematopoietic cells and neurons and serves as a Rap-1/2 guanine exchange factor, and is necessary for activation of β_1-, β_2-, and β_3-integrins. The leukocytosis, bleeding tendency, and neurologic manifestations reflect the importance of β-integrins in diverse biologic processes.

Defects in Oxidative Killing

Chronic Granulomatous Disease

CGD is a rare (1 in 1 million live births) immunodeficiency due to mutation in one of the four subunits of the phagocyte NADPH oxidase (PHOX) system. The function of NADPH oxidase is to transfer an electron to molecular oxygen (O_2), leading to the formation of superoxide.[121–123] Approximately two thirds of cases of CGD are X-linked due to a mutation in the g91phox subunit of NADPH oxidase. Mutations of the other subunits of NADPH oxidase (p22, p47, p67) are inherited in an AR pattern and account for the remainder of cases.

The clinical manifestations of CGD usually begin early in life (mean age of onset, 4.4 years) but may not manifest until adulthood. CGD is characterized by recurrent infections with catalase-positive organisms (*Aspergillus* spp., *S. aureus, B. cepacia,* and others). The lungs (pneumonia) and skin are the most common sites of infection, but osteomyelitis, liver abscesses, lymphadenitis, and anorectal infections occur frequently as well.[124] The most common chest CT abnormalities include areas of consolidation and nodular opacities, both associated with either infection or granulomatous inflammation.[125] Invasive aspergillosis is the most common primary cause of death. Autoimmune diseases appear to be increased in CGD, and carriers of X-linked CGD are at increased risk for discoid lupus and photosensitivity.[126] As previously discussed, the diagnosis of CGD is readily made by the use of either the NBT or the DHR test.

Apart from infectious complications, disordered inflammation and wound healing are hallmark manifestations of the disease.[127] Inflammatory granuloma formation may lead to urinary or gastrointestinal tract obstruction. Exuberant granulation tissue leads to disordered wound healing, including wound dehiscence following surgical procedures. The molecular basis for the disordered inflammatory response that is characteristic of CGD is complex. Gene array experiments comparing global gene expression of normal and X-linked CGD neutrophils indicate that CGD neutrophils constitutively

overproduce proinflammatory mediators and exhibit defective neutrophil apoptosis due to the overproduction of the antiapoptotic protein Bcl-xl.[128] Additionally, upon apoptosis, CGD neutrophils do not properly externalize phosphatidylserine. Phosphatidylserine is the ligand for the phosphatidylserine receptor, which is present on macrophages and mediates the efficient clearance of apoptotic cells.[129] Consequently, there is a delay in the removal of apoptotic CGD neutrophils by macrophages.[130] The deficiency in uptake of apoptotic cells may lead to decreased production of anti-inflammatory mediators such as transforming growth factor-β, thereby contributing to the overproduction of inflammatory cytokines.[127] Thus, the increased production of proinflammatory mediators, reduced apoptosis, and delayed clearance of apoptotic neutrophils all likely lead to the disordered inflammatory response in CGD.

The therapy of CGD includes aggressive treatment of infection, including surgical incision and drainage when indicated.[131] The prophylactic administration of trimethoprim-sulfamethoxazole markedly reduces infection, in particular infections caused by *S. aureus.*[132] Prophylactic itraconazole reduces serious fungal infections.[133] Interferon-γ reduces infections and decreases mortality in both X-linked and AR CGD, although the benefits of interferon therapy have been challenged recently.[124,134] Gastrointestinal and urinary tract obstruction due to granuloma formation is treated with systemic corticosteroids.

Disorders of Leukocyte Signaling

Defects in the IFN-γ/IL-12/IL-23 Axis

Th1 type T cells are defined by their capacity to produce high levels of cytokines (IL-2, IFN-γ, TNF-α) that are essential in the generation of a robust cellular immune response. Interferon-γ, which is also produced by NK cells, interacts with a heterodimeric receptor, IFN-γ receptor 1 (IFN-γR1), the ligand binding receptor, and IFN-γ receptor 2 (IFN-γR2), which is required for downstream signaling. Upon ligand binding by IFN-γR1/R2, the Janus activating kinases 1 and 2 (JAK1 and JAK2) are activated, which subsequently phosphorylate the STAT-1 protein in the cytoplasm, leading to homodimerization of STAT-1, translocation to the nucleus, and transcriptional activation of STAT-1–dependent genes. One important biologic function of IFN-γ is to induce the production of IL-12 p70 by dendritic cells and macrophages, which then feeds back in a positive loop to further induce the production of IFN-γ by NK cells and T cells. Interleukin-12 p70 is composed of two disulfide-linked subunits, p35 and p40, the latter of which also associates with the p19 subunit to form IL-23. The IL-12 receptor (IL-12R) is composed of two subunits, IL-12Rβ1 and IL-12Rβ2. Interleukin-12Rβ1 also serves as part of the heterodimeric IL-23 receptor (IL-12Rβ1 and IL-23R). Thus, the IFN-γ/IL-12/IL-23 axis is intrinsically linked due to the biologic functions of IFN-γ and IL-12, the shared cytokine subunit of IL-12 and IL-23 (p40), and the common cytokine receptor subunit of IL-12R and IL-23R (IL-12Rβ1).

Mutations of the genes for IFN-γR1 or IFN-γR2, STAT-1, IL-12 p40, IL-12Rβ1, and NEMO (see earlier discussion) define a group of primary immunodeficiencies known as mendelian susceptibility to mycobacterial disease (MSMD) (Table 82-6).[135,136] Due to the marked hetereogeneity in inheritance, the functional consequences of mutations in these six genes (complete or partial) leads to 13 distinct genetic disorders associated with MSMD. Patients with mutations in one of these six genes are susceptible to infection with *Mycobacteria* and/or *Salmonella,* but are usually resistant to infections with most other pathogens.[135,136] This narrow susceptibility to infection is somewhat surprising based on the importance of Th1 responses in combating infection with a wide variety of pathogens in studies using mice.

AR complete IFN-γR1 deficiency is characterized by the onset of infection with environmental mycobacteria, frequently rapid growers such as *Mycobacterium fortuitum* and *Salmonella,* at an early age (<3 years). The disorder is fatal without HSCT. However, HSCT is frequently not successful in patients with IFN-γR1 deficiency due to preexisting high IFN-γ levels that prevent engraftment. AD partial IFN-γR1 deficiency has a much less severe phenotype, with a mean age of onset at 13 years of age. These patients are susceptibile to infection with environmental mycobacteria and may develop disseminated disease following vaccination with bacille

TABLE 82-6. Etiologies of Mendelian Susceptibility to Mycobacterial Disease (MSMD)

Gene	Inheritance	Defect	Percentage of Patients with MSMD	Treatment
IL12RB1	AR	C	40%	IFN-γ
IFNGR1	AR/AD	C/P	39%	AR-C: HSCT AD-P: IFN-γ
IL12B	AR	C	9%	IFN-γ
STAT1	AD	P	5%	Varies depending on location of mutation
IFNGR2	AR	C/P	4%	AR-C: HSCT AR-P: IFN-γ
NEMO (*IKBKG*)	X-linked	P	3%	HSCT

AD, autosomal dominant; AR, autosomal recessive; C, complete deficiency; HSCT, hematopoietic stem cell transplantation; IFN, interferon; P, partial deficiency.

Calmette-Guérin. Additionally, patients with partial IFN-γR1 deficiency are uniquely predisposed to mycobacterial osteomyelitis, which should trigger an evaluation for this disorder. AR complete IFN-γR2 deficiency and AR partial IFN-γR2 deficiency are rare, and the described phenotype to date is similar to AR complete IFN-γR1 deficiency and AD partial IFN-γR1 deficiency, respectively. The phenotype of patients with a STAT-1 mutation varies depending on the site of the mutation. As previously discussed, STAT-1 homodimers mediate the transcriptional effects of IFN-γ. STAT-1 also forms a heterodimer with STAT-2, which is the transcription factor formed following binding of IFN-α/β with its receptor. Consequently, some patients with mutations in STAT-2 are susceptible to viral infections and mycobacterial disease. AR complete mutations of IL-12 p40, which is the only described immunodeficiency of a cytokine gene to date, result in a markedly increased susceptibility to infection with *Salmonella* in addition to mycobacterial disease. Similarly, AR complete IL-12Rβ1 deficiency, which is the most common cause of MSMD, also results in an increased susceptibility to infection with mycobacteria and *Salmonella.* The clinical phenotype of AR complete IL-12Rβ1 deficiency is milder than complete defects in IFN-γR1 or IFN-γR2 and only a few patients (17%) succumb to disease. Interferon-γ is useful in the treatment of patients with either IL-12Rβ1 deficiency or IL-12 p40 deficiency.

DISORDERS IN INNATE IMMUNITY

IRAK-4 and MyD88 Deficiencies

Toll-like receptors (TLRs) are a family of pattern recognition receptors that are activated following microbial infection, resulting in the activation of innate immune responses. TLRs recognize conserved motifs derived from a variety of pathogenic microorganisms, including bacteria, fungi, and viruses. Upon ligand binding, all members of the TLR family, with the exception of TLR3, use MyD88 as a key adaptor molecule to recruit IL-1 receptor–associated kinases (IRAKs) leading to downstream signaling events resulting in the activation of the transcription factors NF-κB and AP-1. Mutations in either MyD88 or IRAK-4 result in phenotypically similar primary immunodeficiencies. The primary immunodeficiencies caused by mutations in either MyD88 or IRAK-4 are characterized by invasive infections (meningitis, septicemia, liver abscess) predominantly with *S. pneumoniae* (79% of patients) or *S. aureus* (50% of patients).[137,138] Infections with gram-negative rods occur in approximately 25% of patients. No severe infections with viruses, fungi, or parasites were observed, which is surprising based on the broad immunodeficiency found in mice with targeted deletion of MyD88. The onset of invasive infection is early in life (vast majority before age 2) and improves with age. All deaths in patients with IRAK-4 deficiency occurred by age 8. Standard screening tests of immune function are normal. Peripheral blood mononuclear cells exhibited decreased inflammatory cytokine production in response to IL-1 and all TLR agonists except agonists of TLR3. The proper management of patients with MyD88 or IRAK-4 mutations remains to be determined, but prophylactic antibiotics and IVIG may be useful.

Complement Deficiencies

Complement has many important functions that include the modulation of inflammatory responses (e.g., vasodilation, leukocytosis, and chemotaxis), clearance of immune complexes, modulation of the immune response (e.g., enhanced production of antibodies), and microbial elimination (opsonization, neutralization, and microbicidal activity). Complement may also be important in the efficient removal of apoptotic cells, resulting in the presentation of self antigens and the induction of autoimmunity. Deficiencies in components of the complement system are usually manifest by an increased propensity to infection or autoimmunity.[1,139] There are several indications for the evaluation of the complement system, such as a strong family history of autoimmune diseases, recurrent infections caused by encapsulated bacteria, a family history of meningococcal disease, infection caused by unusual types of meningococcus (Y, W-135), age greater than 9 years at the time of meningococcal disease, and recurrent angioedema.

Defects in the early components of complement (C1q, C1s, C2, C4), which are inherited in an autosomal codominant manner, typically lead to an increased prevalence of autoimmune disease (primarily systemic lupus erythematosus). Redundancies in the complement pathway, including the alternative and mannose-binding lectin pathways, may explain why only a minority of patients with early complement deficiencies develops serious bacterial infections. Encapsulated bacteria (*S. pneumoniae, H. influenzae*) are the most common pathogens in people with recurrent infection due to deficiency in early complement components.[13] C2 deficiency is the most common early component deficiency, occurring in 1:10,000 to 1:28,000 live births.

The classical, alternative, and mannose-binding lectin pathways all converge at C3. For this reason, deficiencies in C3 result in more severe infections than deficiencies in other components of complement. Patients with C3 deficiency have an increased prevalence of autoimmune disease and present in a manner similar to those with antibody deficiency.

Deficiencies in the terminal components of the complement pathway (C5 to C9) are inherited in an autosomal codominant manner. Patients with late-component deficiencies are highly predisposed to infection with *N. meningitidis and Neisseria gonorrhoeae.* For reasons that are not clear, meningococcus serogroups W-135 and Y account for the vast majority of meningococcal meningitis infections in patients with late-component complement deficiencies. The prevalence of autoimmune disease is also increased in these patients, but to a much lesser extent than deficiencies in the early components of the complement cascade. Patients with late-component deficiencies usually have the onset of

infection at an older age, and many are asymptomatic well into adolescence.[13]

Deficiencies in components of the alternative pathway (factor D, properdin) are extremely rare and present with increased bacterial infections, including infections with *Neisseria* spp. Properdin deficiency is an X-linked inherited disorder in contrast to the other complement deficiencies (with the exception of hereditary angioneurotic edema), which are inherited in an autosomal codominant manner.

Therapy for complement deficiencies is primarily supportive. Individuals should be vaccinated against common bacterial pathogens associated with complement deficiency (e.g., *S. pneumoniae, H. influenzae, N. meningitidis*). Prophylactic antibiotics may be used in selected situations.

KEY POINTS

- PIDD frequently are not diagnosed in a timely manner, leading to increased morbidity and mortality.
- Patients recurrent upper infections, intractable sinusitis or more than one radiographically documented pneumonia should be evaluated for PIDD.
- Although infection with opportunistic pathogens should always lead to a search for primary or secondary immunodeficienies, common pathogens frequently cause infections in patients with PIDD.
- Advanced age does not exclude the diagnosis of PIDD as there are more adults than children with PIDD.
- Screening tests for most PIDD will frequently be abnormal and should lead to referral to a clinical immunologist for a specific diagnosis.
- The pulmonary complications of PIDD are varied and depend on the nature and severity of the specific disorder.

CHAPTER 83

PULMONARY COMPLICATIONS OF ABDOMINAL DISEASE

Roberto Rodriguez-Roisin, MD • Joan Albert Barberà, MD

INTRODUCTION

GASTROESOPHAGEAL AND GASTROINTESTINAL DISORDERS
Gastroesophageal Reflux
Inflammatory Bowel Disease

HEPATIC DISEASES
Pleural Effusion
Pulmonary Functional Disturbances
Hepatopulmonary Syndrome
Portopulmonary Hypertension
Primary Biliary Cirrhosis
Chronic Active Hepatitis
Sclerosing Cholangitis
Alpha$_1$-Antitrypsin Deficiency

PANCREATITIS
Respiratory Failure
Pleural Effusion

KIDNEY DISEASES
Pulmonary Edema
Pleural Disease
Pulmonary Calcification
Sleep Apnea
Hemodialysis-Induced Hypoxemia

INTRODUCTION

This chapter is devoted to the pulmonary complications of abdominal disease and begins with a discussion of the most relevant esophageal and bowel disorders. Then the lung-liver syndromes and the specific liver disorders associated with particular pulmonary complications are reviewed. Finally, the respiratory consequences of diseases of the pancreas and kidney are described. The objective in each section is the same: to update the most relevant clinical, pathophysiologic, pathogenetic, and therapeutic aspects of the principal abdominal disease states and thereby assist the clinician in diagnosing and managing their sometimes complex and challenging pulmonary complications.

GASTROESOPHAGEAL AND GASTROINTESTINAL DISORDERS

Gastroesophageal Reflux

An international consensus group recently defined gastroesophageal reflux disease—or GERD as it is more commonly known—as follows: "a condition that develops when the reflux of stomach contents causes troublesome symptoms and/or complications."[1] The same group subclassified GERD into "esophageal and extraesophageal syndromes." Among the esophageal syndromes of interest to family physicians and pulmonologists are episodes of chest pain, which may vary from recurrent mild retrosternal "heartburn" to acute crushing substernal distress that is indistinguishable from the pain of angina or even myocardial infarction (see also Chapter 30). Among the extraesophageal syndromes, chronic cough, chronic laryngitis, and refractory asthma have attracted the most attention, but other associations have been made, including bronchitis, bronchiectasis, pulmonary fibrosis, and, most recently, chronic obstructive pulmonary disease (COPD).[2]

GERD is a common condition with a prevalence that varies from 10% to 20% in North America and Western Europe, but that is lower in Asia.[1] A higher prevalence of gastroesophageal reflux than in the general population has been observed in patients with chronic cough and asthma, but the exact contribution of reflux to the patient's symptoms is often difficult to define. For example, Irwin and associates[3] reported that gastroesophageal reflux was clinically silent in 24% of patients with difficult-to-control asthma; by contrast, symptoms

of gastroesophageal reflux were significantly associated with the occurrence of COPD exacerbations.[4]

Pathogenesis

The pathogenesis of respiratory abnormalities associated with gastroesophageal reflux can be divided into three basic mechanisms. First, gross aspiration-linked pulmonary syndromes are usually the result of free esophageal reflux with large-volume retrograde flow. Frequently, there is reduced basal lower esophageal tone and impaired esophageal motility and clearance.[5] These patients may have recurrent aspiration pneumonia, bronchiectasis, or pulmonary infiltrates. Endoscopic examination usually reveals severe anatomic changes, such as visible breaks of the distal esophageal mucosa or Barrett's epithelialization of the mucosa.

A second pathogenic mechanism is related to the microaspiration of gastric contents from the proximal (upper) esophagus. This results from small-volume aspirates that produce an exudative mucosal reaction in the larynx and in the tracheobronchial tree. Respiratory symptoms are less apparent and range from hoarseness or chronic cough to difficult-to-control asthma. Jack and coworkers,[6] using simultaneous tracheal and esophageal pH measurements in asthmatics with gastroesophageal reflux, showed that episodes of reflux that were followed by a fall in intratracheal pH resulted in a marked fall in peak expiratory flow rate, which was several times greater than that observed when reflux was not followed by tracheal aspiration (Fig. 83-1). Accordingly, microaspiration into the bronchial tree not only occurs but also may induce an important increase in airway resistance. Nevertheless, reflux episodes that do not reach the upper sphincter, and hence are without aspiration, may also increase airway resistance.

The third pathogenic mechanism is produced by gastroesophageal reflux activation of a vagal reflex between the distal (lower) esophagus and the tracheobronchial tree. This reflex mechanism can be reproduced by the

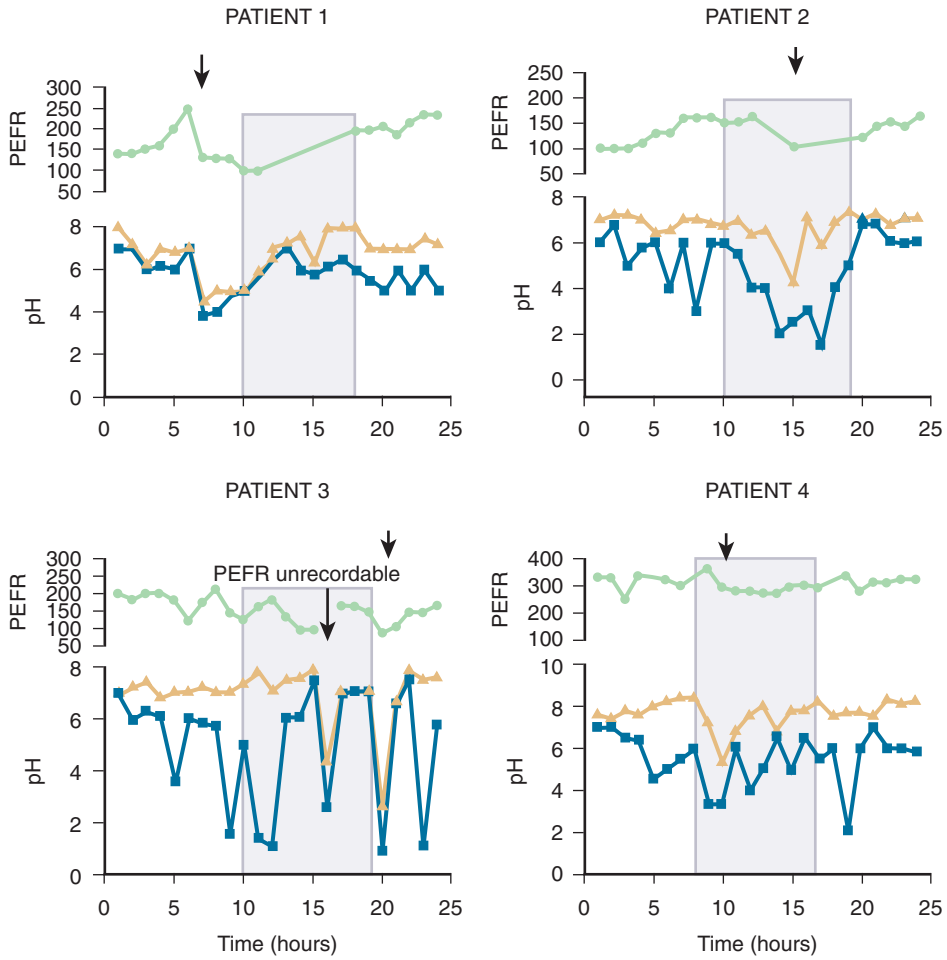

FIGURE 83-1 ■ Graphs showing simultaneous esophageal (*solid blue squares*) and tracheal (*solid beige triangles*) pH measurements in four patients with both gastroesophageal reflux and asthma, along with recordings of peak expiratory flow rate (PEFR, *solid pale-green circles*), over a 24-hour period. There were 37 significant falls in esophageal pH suggestive of gastroesophageal reflux. Five of these episodes were followed by a fall in tracheal pH and were associated with a significant decrease in PEFR (mean change –84 ± 16 L/min), whereas during the remaining 32 episodes of gastroesophageal reflux without tracheal aspiration, the mean change in PEFR was minimal (–8 ± 4 L/min). *Arrows* show representative episodes. (From Jack CI, Calverley PMA, Donnelly RJ, et al: Simultaneous tracheal and oesophageal pH measurements in asthmatic patients with gastro-oesophageal reflux. Thorax 50:201–204, 1995.)

infusion of hydrochloric acid into the esophagus of some,[7] but not all,[8] patients with asthma. Earlier work on the role of gastroesophageal reflux–induced vagally mediated reflexes in expiratory flow rates in experimental models and inpatients with asthma is summarized in the previous edition of this textbook.[9]

The relationship between gastroesophageal reflux and respiratory disorders is further complicated by the fact that physiologic alterations associated with asthma or cough, or with bronchodilator therapy, may themselves promote gastroesophageal reflux. Episodes of bronchospasm and cough are accompanied by an increase in the negative pressure within the thorax, and hence in the esophagus, that may promote reflux. In addition, hyperinflation and "air trapping" may lead to flattening of the diaphragm, allowing the lower esophageal sphincter to be drawn up into the thorax, impairing the antireflux barrier. Bronchodilator therapy may also promote gastroesophageal reflux. Theophylline increases gastric acid secretion and decreases lower esophageal sphincter tone. Indeed, asthmatics with gastroesophageal reflux who receive theophylline show an increase in esophageal acid exposure and reflux symptoms.[10] Specific β-adrenergic agents relax smooth muscle tone throughout the body and thereby may promote gastroesophageal reflux. A decrease in lower esophageal sphincter pressure has been shown with β-adrenergic drugs administered orally or intravenously,[11] but not when these agents were given by inhalation.[12]

Diagnosis

The possibility of associated gastroesophageal reflux should be suspected in patients with refractory chronic cough or difficult-to-treat asthma. Patients should be questioned about symptoms of gastroesophageal reflux, which include heartburn, regurgitation, or dysphagia. However, some patients may complain of atypical symptoms, including substernal chest pain, hoarseness, sore throat, otalgia, hiccups, or even teeth erosion. It is also important to record whether asthma or cough worsens with recumbency, after meals, or during alcohol ingestion. If the clinical history is typical of gastroesophageal reflux, no further diagnostic workup may be necessary and a trial of antacid therapy will confirm that the symptoms are due to acid reflux.

However, gastroesophageal reflux may be clinically silent in a number of patients. If dysphagia is present, a barium radiographic study should be performed in order to rule out esophageal obstruction or obvious motility abnormalities. Until recently, the "gold standard" for diagnosing gastroesophageal reflux was ambulatory esophageal pH monitoring owing to its high sensitivity and specificity. However, demonstration of reflux by pH monitoring shows an association but not always a cause-and-effect relationship.[13] A new method of reflux testing, using a Multichannel Intraluminal Impedance–pH (MII-pH) catheter, adds impedance measurements to those of pH and provides additional informational about the role of nonacid or weakly acid reflux as a cause of atypical symptoms, and is helpful in detecting the importance of ongoing reflux in patients receiving acid suppression therapy.[14]

Treatment

Therapy for gastrointestinal reflux should begin with several changes in lifestyle, such as raising the head of the bed, avoiding meals before bedtime, eating low-fat foods, reducing body weight, and eliminating caffeine and alcohol. Pharmacologic strategies for treating gastroesophageal reflux are now mainly focused on proton pump inhibitors (omeprazole, lansoprazole), which directly inhibit gastric acid secretion.[14a] Treatment with proton pump inhibitors is often started empirically, but they have to be given in sufficient doses to ensure round-the-clock acid suppression and for long periods of time (at least 3 months) to reliably determine effectiveness.[15] If cough or bronchospasm has not improved, testing with the MII-pH catheter should be considered to check the level of acid suppression and to determine if ongoing reflux of non- or weakly acid secretions are related to the patient's symptoms.

Other treatment strategies include prokinetic agents (cisapride, domperidone), which improve esophageal contractility, increase lower esophageal sphincter pressure, and increase gastric emptying, as well as surgical interventions, such as the Nissen/Toupet/Belsey fundoplication and the Hill gastropexy. Total remission of symptoms is unusual no matter what the therapy, which strengthens the conclusion that gastroesophageal reflux plays an aggravating rather than causative role in most patients' extraesophageal symptoms.

Inflammatory Bowel Disease

Extraintestinal complications of inflammatory bowel disease have been described in virtually all organ systems, but—surprisingly—pulmonary disease appears "much less frequently" than manifestations in other organs[16]: "surprisingly" because the gut and lungs share a common embryologic origin, and thus might possess similar vulnerability to immunologically mediated comorbidities. Pulmonary complications occur more commonly with ulcerative colitis than with Crohn's disease; respiratory involvement may occur at any age, and some conditions (e.g., airway disease) appear more often in women than in men.[16] In most cases, respiratory symptoms develop after the diagnosis of inflammatory bowel disease has been made, frequently several years afterward. Nonetheless, in some reports respiratory symptoms antedated or were concomitant with those of the bowel disease.[17]

A recent review of over 400 published cases has confirmed and extended earlier observations.[16] Based on these and newly reported studies, the pulmonary complications of inflammatory bowel disease can be classified as shown in Table 83-1. Most intrinsic (non–drug-related) pulmonary complications involve airways—anywhere from the larynx to the bronchioles—and may take the form of epiglottitis, tracheal stenosis, bronchiectasis, chronic bronchitis, or bronchiolitis. Endoscopic examination shows marked erythema, swelling of

BOOP, bronchiolitis obliterans with organizing pneumonia.

the mucosa, and deformation of the airway lumen. Biopsy specimens have revealed mucosal ulceration, thickening of the basement membrane, and marked infiltration by neutrophils and plasma cells.[16,17] In some cases, the inflammatory process in the subglottic area can take the form of pseudotumoral lesions, with the potential of producing life-threatening acute upper airway obstruction requiring aggressive airway management.[17,18] This panoply of discrete airway pathology has been enriched by the addition of asthma, which proved to be the most common pulmonary comorbidity of both ulcerative colitis and Crohn's disease identified in a large cohort surveyed in Manitoba, Canada.[19] The association between inflammatory bowel disease and asthma supports the belief that patients suffering from one autoimmune condition are more likely than the general population to have a second immune-mediated disorder, which may result from shared susceptibility genes.[20]

Another, major category of pulmonary complications of inflammatory bowel disease is parenchymal (including interstitial) lung diseases, such as bronchiolitis obliterans with organizing pneumonia, sarcoidosis, interstitial fibrosis, and pulmonary infiltrations with eosinophilia. According to Storch and coauthors,[16] drugs, particularly mesalamine, sulfasalazine, and methotrexate, are "the most frequent cause of the pulmonary manifestations of [inflammatory bowel disease]." Although not all reports agree with that assessment, commonly used medications must always be considered in the differential diagnosis of new-onset interstitial lung disease, because the offending drug(s) must be recognized and discontinued to prevent a potentially fatal outcome.

Pulmonary function testing in patients with inflammatory bowel disease, even when asymptomatic and with normal chest radiographs, may reveal a variety of abnormalities. Probably the most common is an obstructive ventilatory defect, but pulmonary restriction is also well described. A reduction in carbon monoxide diffusing capacity (D_{LCO}) during the active phases of inflammatory bowel disease has been reported,[21] which also suggests that subclinical pulmonary parenchymal involvement may be more prevalent than previously suspected. Furthermore, bronchoalveolar lavage examination in patients with Crohn's disease who did not have clinical evidence of pulmonary involvement revealed the presence of a lymphocytic alveolitis, chiefly owing to an increase of CD4-positive T lymphocytes.[21]

Other pulmonary lesions include necrobiotic nodules, corresponding histologically to aggregates of neutrophils with areas of necrosis, which have been reported in a few patients.[17] Serositis affecting the pleura or the pericardium, or both, has been reported in a small number of cases, especially during the periods of increased disease activity. Finally, colobronchial fistulas have been reported in some cases of Crohn's disease, the majority of them presenting with left lower pneumonia.[16] Involvement of the esophagus is rare in Crohn's disease, but four cases of bronchoesophageal fistula associated with esophageal Crohn's disease have been reported.[16] Although conservative management can be attempted, most patients with fistulas will require surgical treatment.

In the majority of patients with pulmonary disorders associated with inflammatory bowel disease, glucocorticosteroids given by inhalation or by mouth usually result in a rapid control of symptoms,[17,22] especially in those patients who do not have severe structural impairment (e.g., bronchiectasis). Lung transplantation has been performed in some cases of severe respiratory compromise.[17]

HEPATIC DISEASES

Pleural Effusion

Between 5% and 10% of patients with cirrhosis of the liver develop pleural effusion, traditionally referred to as *hepatic hydrothorax,* in the absence of a coexisting cardiopulmonary disease. (For further discussion of hepatic hydrothorax, see Chapter 73). Unless the pleural fluid is complicated by infection, hepatic hydrothoraces

are transudates, and are most commonly located in the right hemithorax. Effusions may also be left-sided or bilateral, and are strongly associated with pronounced ascites; rare patients have been reported in whom ascites is almost undetectable. The effusion is usually mild to moderate in size and asymptomatic, but in some cases it can be massive and provoke shortness of breath. The mechanism is related to the presence of anatomic communications (usually small diaphragmatic defects) and to the pressure gradient between the abdominal and pleural cavities that facilitates movement of ascitic fluid into the chest. The presence of pleural fluid disturbs lung mechanics, resulting in decreased lung volumes and pulmonary compliance. Accordingly, pulmonary gas exchange becomes abnormal and leads to moderate hypoxemia and an increased alveolar-arterial P_{O_2} difference ([A − a] P_{O_2}), caused both by a slight right-to-left intrapulmonary shunt through the nonventilated, fluid-compressed lung parenchyma, and by a mild ventilation-perfusion imbalance. Either because of lasting effects of the effusion or because of coexistent hepatopulmonary syndrome (see later), these abnormalities do not easily reverse after thoracentesis.[23]

The clinical management of pleural effusion in the context of liver disease is often difficult. Repeated thoracenteses will have transitory effects only, and thoracostomy tube drainage may result in substantial protein loss. The use of transjugular intrahepatic portosystemic shunting (TIPS) to decrease portal hypertension and, in turn, to reduce the size of both the ascites and hydrothorax, is often beneficial, at least in the short term, but long-term outcome depends on the severity of the underlying liver dysfunction.[24] If the patient is not a candidate for TIPS, other approaches, including video-assisted thoracoscopic surgery to repair diaphragmatic defects and induce a pleurodesis, should also be considered.[25]

Pulmonary Function Disturbances

The most common lung function abnormality in patients with end-stage hepatic disease is a decreased $D_{L_{CO}}$; likewise, both obstructive and restrictive ventilatory defects have been observed.[26] The coexistence of massive ascites can decrease lung compliance, increase pleural pressure, and reduce diaphragmatic motility. Together, these pathophysiologic alterations restrict ventilatory capacity and reduce the efficiency of gas exchange, causing increased (A − a)P_{O_2} values with or without associated hypoxemia.[27]

Hepatopulmonary Syndrome

Severe hypoxemia (arterial P_{O_2} < 60 mm Hg) is uncommon in patients with chronic hepatic disease, and when present in patients without coexisting cardiopulmonary disease, should strongly suggest hepatopulmonary syndrome (HPS). Because patients with advanced liver disorders characteristically hyperventilate and are hypocapnic, measurement of the (A − a)P_{O_2} becomes more sensitive than P_{O_2} alone to detect gas-exchange disturbances in HPS.

TABLE 83-2. Grading of Severity of Hepatopulmonary Syndrome*

Stage	Alveolar-Arterial Oxygen Difference	Partial Pressure of Oxygen
Mild	≥15 mm Hg	≥80 mm Hg
Moderate	≥15 mm Hg	<80 to ≥60 mm Hg
Severe	≥15 mm Hg	<60 to ≥50 mm Hg
Very severe	≥15 mm Hg	<50 (<300 mm Hg [40.0 kPa] on 100% oxygen breathing)

*All with positive contrast-enhanced echocardiography, breathing room air at rest and at sea level; for patients greater than 64 years of age, cut-off values ≥20 mm Hg and <70 mm Hg, respectively, can be recommended.
From Rodriguez-Roisin R, Krowka MJ, Hervé P, et al, for the ERS Task Force Pulmonary-Hepatic Vascular Disorders (PHD) Scientific Committee: Pulmonary-hepatic vascular disorders (PHD). Eur Respir J 24:861–880, 2004.

HPS is rigorously defined as a syndrome characterized by a clinical triad: advanced chronic liver disease; arterial oxygenation defect, which ultimately leads to severe arterial hypoxemia; and widespread pulmonary vascular dilations.[28] The pulmonary gas-exchange disturbance is characterized by arterial oxygen desaturation that may be mild, moderate, severe, or very severe (Table 83-2). There is an increased (A − a)P_{O_2}, commonly associated with hypocapnia and respiratory alkalosis. At sea level, while breathing room air, resting (A − a)P_{O_2} values equal to or above 15 mm Hg can be considered abnormal for most adults; for those older than 64 years, an (A − a)P_{O_2} equal to or above 20 mm Hg can be considered abnormal. HPS is prevalent in most kinds of common chronic liver diseases, such as chronic active hepatitis; it may also occur in other unusual liver disorders (noncirrhotic portal hypertension, alpha$_1$-antitrypsin deficiency, and Budd-Chiari syndrome).[29] At present, there is a special clinical interest in HPS because of its high prevalence (an estimated 20% in some series) among patients with end-stage hepatic disease,[30] its life-threatening nature, the lack of beneficial medical therapy, and its unique improvement or full resolution after liver transplantation in more than 80% of the reported cases.[28]

The most conspicuous pathologic finding is a pronounced vascular dilation of all peripheral branches of the pulmonary vasculature, at both the precapillary and capillary levels of the lung (15 to 150 μm in diameter), near the gas-exchange area in an otherwise intact pulmonary parenchyma.

Pathogenesis

The precise pathogenetic mechanism underlying HPS remains uncertain despite numerous investigations. Whether the mechanism of hemodynamic disturbances is related to failure of metabolism, to insufficient production of one or more circulating vasoactive substances by the injured liver, or to altered clearance of putative vasodilator molecules produced by endothelial cells[31] remains unknown. Circulating humoral vasodilating

substances, such as glucagon and prostacyclin, which may contribute to the development of vascular abnormalities in patients with chronic hepatitis, including a blunted hypoxic pulmonary vasoconstrictor response, have been investigated. However, clear evidence of their involvement in HPS is lacking.

Nitric oxide (NO), a ubiquitous biologic agent considered to be a "fine-tuner" of vascular tone, has been presumed to be a pivotal signaling molecule of potential importance in the pathobiology of HPS.[28,32] Persistent induction of NO synthase (NOS) could account for the hyperkinetic circulatory hallmarks of HPS.[32] Both a constitutive isoform of NOS, expressed in endothelial cells (eNOS, or type III NOS),[33] and the inducible NOS (iNOS, or type II NOS), expressed in target tissues such as human bronchial epithelial cells after exposure to proinflammatory cytokines,[34] have been implicated in experimental models in the pathogenesis of HPS. In keeping with this contention, increased levels of exhaled NO have been observed in patients with advanced hepatic cirrhosis and in those with HPS.[35] However, the results of measurements of exhaled NO after several interventions have been discrepant. For example, administration of methylene blue, which blocks the guanylate cyclase by which NO may mediate vasodilation,[36] or performance of liver transplantation[37] produces significant decrements in exhaled NO. By contrast, N^G-nitro-L-arginine methyl ester (L-NAME) had no effect on gas-exchange abnormalities.[38] In patients with liver cirrhosis, the close correlations between exhaled NO concentration and Child-Pugh score, alkaline phosphatase, bilirubin, aspartate and alanine aminotransferases, and albumin suggest that NO formation in the lung may be triggered by stimulating factors normally inactivated by the liver.[36] Recent work suggests that endothelin-1 and tumor necrosis factor-α can both interact in the development of experimental HPS.[28,39,40] The association between arterial P_{O_2} and carboxyhemoglobin in patients with HPS supports the contention of increased carbon monoxide production in abnormal gas exchange.[41]

Clinically, most patients with HPS are cyanotic, show conspicuous finger clubbing, may complain of shortness of breath and platypnea (increased dyspnea in the upright position relieved by recumbency), and have a hyperkinetic circulation. The majority of patients exhibit the typical clinical and functional stigmata of advanced liver failure, including those of portal hypertension; in a few cases, severe pulmonary abnormalities may antedate those of hepatic dysfunction. The presence of abundant cutaneous spider angiomata has been postulated as a clinical marker of the severity of the systemic and pulmonary circulatory and gas-exchange abnormalities observed in HPS.[42] The more severe the hepatic failure, the greater the severity of HPS, as suggested by the findings of a prospective study in cirrhotic patients: the hypoxemic subpopulation exhibited more severe liver failure and higher Child-Pugh scores and hepatic venous pressure gradients,[43] as well as scores from the Model for End-Stage Liver Disease (MELD).[44] Unlike the situation in hereditary hemorrhagic telangiectasia and other pulmonary arteriovenous malformations (see Chapter 54), hemoptysis and paradoxical emboli are extremely uncommon clinical manifestations of HPS. A single case of brain abscess has been reported.[45] In approximately one third of HPS patients, the syndrome can coexist with other chronic respiratory comorbidities such as COPD or pulmonary fibrosis. Nevertheless, the prevailing clinical and functional pulmonary features in patients with such comorbidities are generally those of HPS.[46]

Diagnosis

The diagnostic criteria for HPS are as follows[28]: presence of liver disease; gas-exchange abnormalities, more specifically an increased $(A - a)P_{O_2}$ (≥15 mm Hg), with or without concomitant arterial hypoxemia (arterial P_{O_2} < 80 mm Hg); and a positive contrast-enhanced echocardiogram or an abnormal intravenous radiolabeled perfusion lung scan, or both. Other additional features that can be useful for further establishing the diagnosis of HPS include decreased $D_{L_{CO}}$, dyspnea with or without platypnea and orthodeoxia (i.e., arterial hypoxemia that worsens by 5% or more or by 4 mm Hg or more when the patient is upright compared to recumbent), and a hyperkinetic circulatory state (high cardiac output and low systemic arterial pressures) with normal or low pulmonary artery pressure (P_{PA}). Although thoracic computed tomography scanning appears to be nonspecific, it may be useful to exclude coexistent respiratory comorbidities.[28]

Two-dimensional contrast-enhanced echocardiography appears to be the most sensitive and accurate noninvasive diagnostic procedure to identify right-to-left shunts of blood by finding microbubbles of air in the left heart cavities within 3 to 6 beats of their visualization in the right-sided chambers[28] (Fig. 83-2). Normally, echogenicity in the left chambers is not detected because the intravenously injected microbubbles (60 to 90 μm in diameter) are trapped in the pulmonary capillaries (<8 to 15 μm in diameter). Contrast-enhanced echocardiography cannot distinguish among the different forms of pulmonary vascular deformities (i.e., precapillary, capillary, and pleural dilations versus direct arteriovenous communications), but it can clearly differentiate them from intracardiac malformations, such as a patent foramen ovale, in which the microbubbles would appear in the left heart almost simultaneously with their appearance in the right. Alternatively, the demonstration of technetium-99m–macroaggregated albumin activity over extrapulmonary organs (e.g., liver, spleen, kidneys, and brain) strongly suggests the presence of right-to-left intrapulmonary shunting, because under normal conditions the albumin macroaggregates (20 to 60 μm in diameter) are trapped in the pulmonary capillary bed.[28]

To date, the exact prevalence of HPS remains unknown, and has ranged between 5% and 32%.[28] Using contrast-enhanced echocardiography as the gold standard tool to identify intrapulmonary vascular dilations, the prevalence of a positive echocardiography test in patients with chronic liver disease is approximately 20%.[30,47] However, the relevance of a positive contrast-enhanced echocardiography result in patients without coexisting

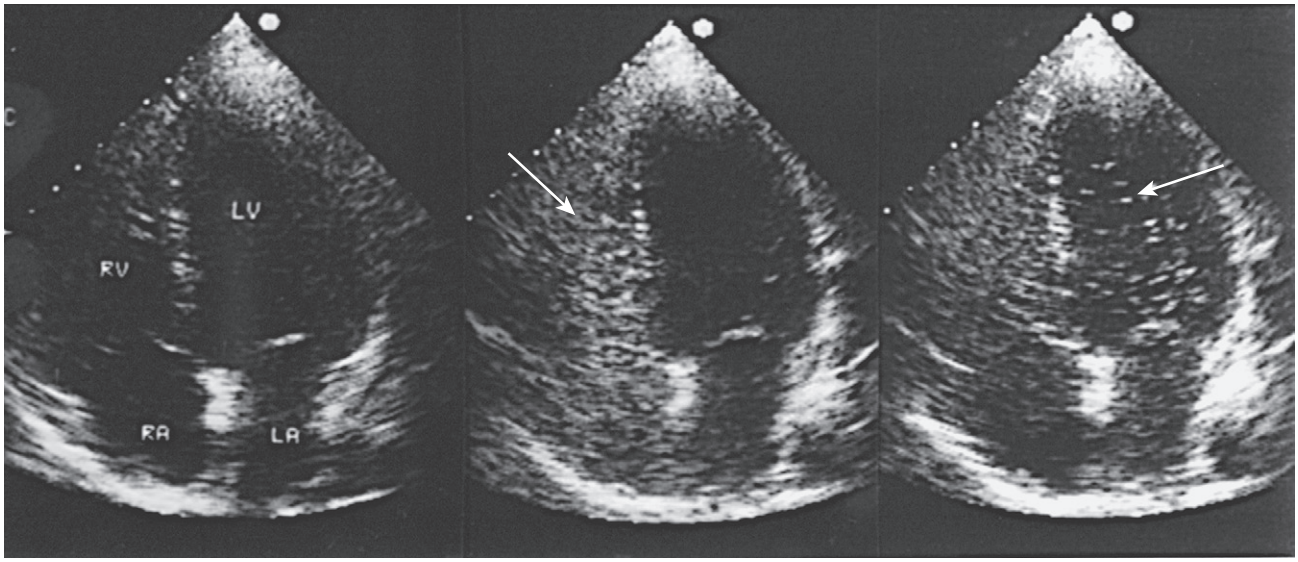

FIGURE 83-2 ■ Contrast-enhanced echocardiograms in a patient with hepatopulmonary syndrome. *Left,* Normal four-chamber view (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle). *Center,* Injected microbubbles appear in the RV (*arrow*). *Right,* Within 5 beats, microbubbles appear in the LV (*arrow*). The demonstration of microbubbles in the left cardiac chambers is highly suggestive of the presence of intrapulmonary vascular dilations, or, alternatively, of anatomic arteriovenous malformations. gas-exchange disturbances, some of whom may have a normal $(A - a)P_{O_2}$, remains unsettled. These patients are considered to have a *forme fruste* of HPS whose natural history is unknown as yet.[47,48]

Systemic hypotension, a normal or low P_{PA} with normal or low pulmonary vascular resistance (PVR) (<1.5 mm Hg/L per minute), an inordinately high cardiac output, and a reduced pulmonary vascular reactivity are the hemodynamic hallmarks of HPS. When the constellation of hypoxemia, normal or low P_{PA}, and finger clubbing is observed in a patient with advanced liver disease, the diagnosis of HPS is likely. Although data describing the natural history of HPS are scant, it appears that HPS patients not undergoing liver transplantation worsen progressively and have an adverse outcome, with median survival of 41 months following diagnosis of HPS.[28] In a recent prospective study, HPS was an independent risk factor for poor prognosis in patients with cirrhosis; those with HPS had a significantly shorter median survival (approximately 11 months) than those without HPS (41 months) even after adjusting for differences in liver disease.[49]

Gas-Exchange Abnormalities

The mechanisms of the gas-exchange abnormalities in patients with HPS have recently been reviewed.[28] When HPS is mild to moderate, the predominant mechanism of hypoxemia is ventilation-perfusion inequality, essentially due to the presence of areas in which ventilation is preserved but perfusion is profoundly increased. In contrast, when HPS is severe, increased intrapulmonary shunt coexists and, along with ventilation-perfusion imbalance, constitutes the primary abnormalities. Collectively, as the severity of the liver dysfunction advances, the greater the systemic and pulmonary dilation, the lower the hypoxic pulmonary vascular response, and the greater the degree of ventilation-perfusion inequalities, including increased intrapulmonary shunt.[28,50] A "diffusion-perfusion defect" has also been postulated to explain an increased diffusion gradient for oxygen in dilated pulmonary capillaries (Fig. 83-3). The contention is that pulmonary vascular dilation causes inadequate diffusion of oxygen to the center of the enlarged capillary. Moreover, the coexistence of a hyperkinetic state and the resulting shorter transit time of red blood cells would exaggerate further this diffusion-induced gas-exchange disturbance.[50a]

Treatment

Many therapeutic agents have been tried in HPS, including bismesylate almitrine, cyclophosphamide, garlic preparation, indomethacin, long-term oxygen therapy, methylene blue, propranolol, prostaglandin, and somatostatin, with disappointing results.[50a] The only successful treatment thus far is liver transplantation. In theory, replacement of the damaged organ should prevent all HPS-induced abnormalities, except for persistent low $D_{L_{CO}}$, whose mechanism remains unclear.[28] As might be expected, the worse the hypoxemia before transplantation, the longer it takes to resolve after surgery.[51] In the largest reported single-institution study thus far, 5-year survival after liver transplantation for HPS was 76%, and did not differ from the rate in patients without HPS who received transplants.[52]

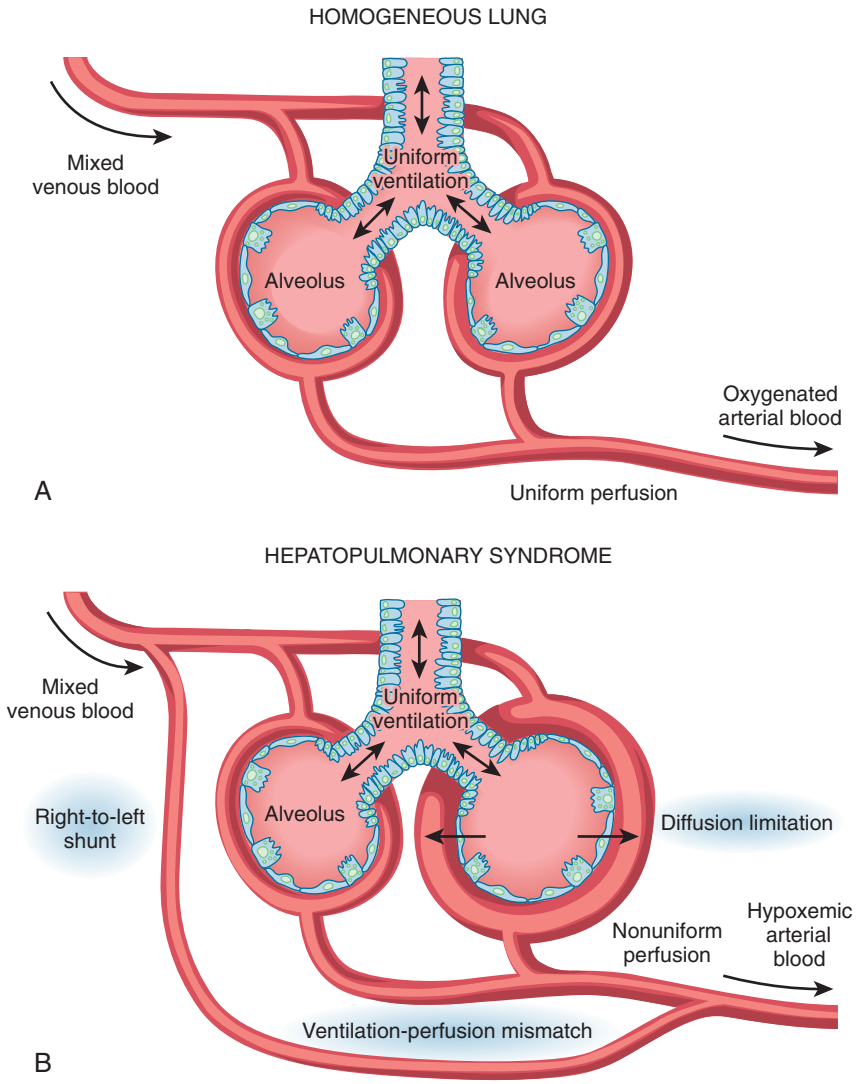

FIGURE 83-3 ■ Mechanisms of arterial hypoxemia in hepatopulmonary syndrome in a two-compartment gas exchange model. **A,** In the homogeneous lung of a healthy individual, with uniform alveolar ventilation and pulmonary blood flow, the capillary ranges between 8 and 15 μm in diameter and oxygen diffuses properly into the capillary while ventilation-perfusion is well balanced. **B,** In hepatopulmonary syndrome, where many capillaries are dilated and blood flow is nonuniform, alveolar ventilation–to–pulmonary perfusion mismatch emerges as the predominant mechanism at any clinical stage, either with or without the presence of intrapulmonary shunt and coexistent with oxygen diffusion limitation into the center of the dilated capillaries (*large arrow*) in the most advanced stages. (From Rodriguez-Roisin R, Krowka MJ. Hepatopulmonary syndrome—a liver-induced lung vascular disorder. N Engl J Med 358:2378–2387, 2008.)

Youth, a good arterial P_{O_2} response to 100% oxygen breathing, and lower presurgical hypoxemia are all factors that seem to predict a favorable response to liver transplantation.[53] Collectively, these elements may indicate a more reactive pulmonary vasculature and less profound intrapulmonary shunt. Recent work indicates that mortality may be higher after liver transplantation in patients with advanced HPS with preoperative arterial P_{O_2} values below 50 mm Hg alone or together with an abnormal (>20%) radionuclide extrapulmonary uptake.[52]

Portopulmonary Hypertension

Pulmonary hypertension (PH) associated with portal hypertension, or portopulmonary hypertension (POPH), is another mysterious pulmonary vascular disorder that appears to be associated with chronic hepatic disease.[53,54] Because both the diagnosis and the outcome of POPH, particularly in relation to the therapeutic benefits of liver transplantation, appear to be substantially different from those of HPS, it is important to highlight the distinctions between the two disorders. According to the European Respiratory Society–European Association for the Study of the Liver, POPH is defined by the following triad of hemodynamic abnormalities in a patient with portal hypertension: (1) a mean P_{PA} exceeding 25 mm Hg at rest; (2) a mean pulmonary artery wedge pressure below 15 mm Hg; and (3) a pulmonary vascular resistance of greater than 240 dynes • sec^{-1} • cm^{-5}.[54]

The results of a recent prospective study of a cohort of 536 patients evaluated for liver transplantation or pulmonary hypertension at seven centers in the United States between 2003 and 2006 documented the presence of POPH in 34 patients: a prevalence of 6%. Furthermore, findings from the cooperative trial established that female gender and associated autoimmune hepatitis conferred increased risk of developing POPH, whereas hepatitis C was associated with decreased risk. There were no major differences between cases and controls in the severity of the underlying liver disease as assessed by various means.[55]

In the classic retrospective postmortem studies, the prevalence of histopathologic evidence of PH in patients

with liver cirrhosis or POPH (or both) ranged between 0.25% and 0.73%[56]; by contrast, PH was detected on histologic examination in only 0.13% of a noncirrhotic population. In a case-control study conducted by the International Primary Hypertension Study Group to investigate the incidence of primary PH, the condition was found in 7.3% of patients with cirrhosis, 3.1% of those with human immunodeficiency virus infection, 2.1% of those with a family history of primary PH, and none of the controls.[57] These and many subsequent observations have documented a causal association between the two conditions, such that POPH has been classified as a category of secondary PH with hemodynamic criteria consistent with the definitions and classification proposed by the Third World Symposium on Pulmonary Artery Hypertension.[58,58a]

From a histopathologic viewpoint, the vascular lesions in POPH are indistinguishable from those identified in primary (idiopathic) PH (see Chapter 52), namely intimal thickening, smooth muscle proliferation, plexogenic pulmonary arteriopathy, and in situ thrombosis,[59] all of which—plus vasoconstriction—contribute to the greatly increased pulmonary vascular resistance.[60] (Of interest, primary PH is also a disease with a female predominance, but generally about a decade younger than in women with POPH.) Chemla and colleagues[61] postulated that the portosystemic shunting of vasoactive agents such as thromboxanes, serotonin, bradykinin, and neuropeptide Y, which are normally metabolized by the healthy liver, may result in pulmonary arterial vasoconstriction; in addition, in primary PH, an attractive alternative pathogenic hypothesis that cannot be ruled out is pulmonary endothelial dysfunction, with decreased production of the endogenous vasodilator NO.

The most common symptom is shortness of breath on exertion; chest pain, syncope, and hemoptysis can also occur.[62] Radiographically, both an enlarged cardiac silhouette and pulmonary artery prominence are noted in from approximately one half to two thirds of patients with hemodynamic confirmation of POPH.[55,62] Overall, maximal airflow rates and lung volumes are within or near normal limits, whereas D_{LCO}, arterial P_{O_2}, and (A – a) P_{O_2} are reduced,[55] although not to the strikingly low levels observed in HPS. Compared with patients with primary PH, the mean P_{PA} is lower in patients with POPH, and cardiac index and mixed venous oxygen saturation are higher.[60]

Transthoracic echocardiography is now routine in patients being considered for liver transplantation because the presence of POPH affects the outcome of surgery; echocardiography should also be performed in other patients with hepatic disease suspected of having PH. Findings such as increased tricuspid peak regurgitant jet velocity, pulmonary valve insufficiency, paradoxical septal motion, right ventricular hypertrophy-dilation, and an increased right ventricular systolic pressure estimate in the setting of portal hypertension suggest, but do not prove, POPH. Right heart catheterization is needed to confirm the diagnosis. A retrospective analysis showed that a screening Doppler echocardiogram with a right ventricular systolic pressure greater than 50 mm Hg identifies essentially all patients who should proceed to right heart catheterization.[54] Until recently, it was believed that median survival in POPH was extremely poor; new information, however, indicates overall survival rates at 1 and 3 years of 88% and 75%, similar to that in patients with idiopathic PH.[58a,59]

Patients with a clinical suspicion of POPH, like all patients with primary PH, should have a pharmacologic vasodilator test to assess the degree of reversibility of the pulmonary vasculature in response to common drugs such as nifedipine, NO, and prostacyclin.[52] A 20% reduction in both P_{PA} and PVR is considered to be a criterion of vascular responsiveness. Although none of the patients with POPH in the series reported by Hervé and colleagues[60] showed a positive vasodilator response, a recent report of 19 patients with POPH revealed that one third were able to reach more favorable hemodynamic status, with better responsiveness to intravenous epoprostenol than to inhaled NO.[63] Vasodilator responsiveness open the possibility of treatment of patients with POPH, with a goal of either preparing patients for liver transplantation by lowering mean P_{PA} below 35 mm Hg, the cutoff for surgery, or improving long-term survival.

Treatment for POPH, however, remains problematic because there are no randomized controlled studies for guidance: available agents include epoprostenol, iloprost, sildenafil, and bosentan.[64] In a recent retrospective study, the safety and efficacy of inhaled iloprost and bosentan were assessed in 31 patients with POPH for up to 3 years; although both agents were safe with regard to liver function, bosentan exhibited significantly superior effects on exercise capacity and hemodynamics, and—of note—had higher survival rates.[65] Prospective trials are clearly needed to provide further guidance.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC), an autoimmune disease, is characterized by a chronic, cholestatic, granulomatous, and destructive process that involves the intrahepatic bile ducts.[66] When severe, these processes result in cholestasis, cirrhosis, and liver failure. The autoimmunologic basis is reflected in the presence of several immunologic alterations, such as depressed T-suppressor cell function, hypergammaglobulinemia, and the presence of antimitochondrial antibodies. Connective tissue diseases such as the sicca complex, Sjögren's syndrome, and scleroderma are frequently associated with PBC,[67,68] which also has a near association ($P = 0.07$) with POPH.[55] Several respiratory abnormalities have been associated with PBC: interstitial lung disorders, such as lymphocytic interstitial pneumonitis and fibrosing alveolitis; subclinical intrapulmonary granulomas that mimic sarcoidosis[69]; increased numbers of $CD4^+$ lymphocytes in the bronchoalveolar lavage fluid; and obstructive airway disease, such as bronchiectasis.[70] Occasionally, the pulmonary manifestations precede the liver involvement.[71] In addition, thoracic wall deformities secondary to osteopenic vertebral complications induced by abnormal vitamin D metabolism related to poor absorption of fat-soluble vitamins can be also observed.[70] A reduced D_{LCO}, with or

without ventilatory defects, is one of the functional hallmarks of the disease, particularly when a connective tissue disorder coexists.[71-73] Furthermore, the clinical, radiographic, and functional respiratory abnormalities in patients with PBC are more likely to be associated with underlying connective tissue disorders than with PBC itself.[73] As with many chronic liver diseases, PBC can be complicated by HPS (discussed previously).

Chronic Active Hepatitis

Chronic active hepatitis, an increasingly frequent liver disease that is characterized by diffuse parenchymal inflammation and hepatic cell necrosis, may be caused by viral hepatitis (most commonly hepatitis C virus), autoimmune disorders, and drug-related liver injury. Pulmonary fibrosis and lymphoid interstitial pneumonitis have been reported but are rare.[72,74] After years of smoldering inflammation, which is often asymptomatic, chronic active hepatitis can lead to cirrhosis and liver failure, which has been associated with HPS.[70] Patients with chronic hepatitis C virus infection and coexistent COPD may demonstrate an accelerated annual decline in FEV_1.[75]

Sclerosing Cholangitis

Sclerosing cholangitis is an unusual disease that results from chronic inflammation affecting both intrahepatic and extrahepatic bile ducts. It has been linked with inflammatory obstructive airway diseases such as bronchiectasis; however, the relationship remains unproven because ulcerative colitis, a frequent clinical accompaniment, has also been associated with the same respiratory complications.[76]

Alpha$_1$-Antitrypsin Deficiency

The discovery that certain patients with COPD had low levels of circulating alpha$_1$-antitrypsin led to the current protease-antiprotease theory of the pathogenesis of pulmonary emphysema (see Chapter 39 for complete discussion). This hereditary disorder is nearly always associated with the homozygous PiZZ phenotype. Genetically predisposed infants often present with hepatomegaly or hepatosplenomegaly and evidence of cholestasis. Most children with alpha$_1$-antitrypsin–induced liver disease recover, but about 15% go on to develop cirrhosis, presumably from toxic effects of the mutant antitrypsin protein retained in the endoplasmic reticulum of hepatocytes[77]; HPS has been reported as a complication of this form of cirrhosis.[78] By far the more common pulmonary complication, COPD is unrelated to the presence of liver disease, occurs in adults, and is characterized by panacinar emphysema and bronchial abnormalities, including bronchiectasis.[70]

PANCREATITIS

Most episodes of acute pancreatitis are mild, but severe injury occurs in about 20% of patients, of whom 15% to 25% will die.[79] Pulmonary complications are frequent and, when present, account for significant mortality. Intrathoracic complications have been implicated as important contributing factors to death from pancreatitis in 22% to 29% of fatal cases.[80] Furthermore, respiratory failure, as defined by an arterial P_{O_2} value lower than 60 mm Hg, is considered one of the major factors adversely affecting survival in acute pancreatitis.[81] Several intrathoracic complications have been linked to acute pancreatitis, including hypoxemia with and without pulmonary infiltrates—basilar atelectasis, pleural effusion, and the pattern of acute respiratory distress syndrome (ARDS)—each of which affects the incidence and outcome of respiratory failure.[82]

Respiratory Failure

Gas-exchange disturbances, ranging from mild hypoxemia to ARDS, may occur during episodes of acute pancreatitis. Arterial hypoxemia (arterial $P_{O_2} < 80$ mm Hg) with a normal chest radiograph is a frequent finding in the early stages of acute pancreatitis.[83] In one study of 116 patients, 69% showed an arterial P_{O_2} lower than 76 mm Hg during the first 48 hours of the episode.[84] Although arterial hypoxemia may be asymptomatic and mild during the initial hours of acute pancreatitis, it should not be dismissed, because these patients are at increased risk for respiratory failure.[82] Ranson and associates[84] reported that 67% of the patients who had an initial arterial P_{O_2} lower than 66 mm Hg developed clinical respiratory symptoms afterward, and 39% of them died. Accordingly, patients who present with hypoxemia during an episode of acute pancreatitis should be closely monitored for worsening respiratory failure.[82]

The mechanisms of arterial hypoxemia with a normal chest radiograph during acute pancreatitis remain poorly understood. Murphy and associates[85] showed that hypoxemia in these patients was caused by an increase in the right-to-left shunt fraction, which improved after recovery in most cases. No changes in expiratory flow rates, lung volumes, or closing capacity were shown, compared with measurements performed after recovery. These authors suggested that hypoxemia in the absence of radiologic abnormalities may be related to changes in pulmonary vascular permeability, similar but milder than that described in ARDS.[85] In a similar group of patients, De Troyer and colleagues[86] measured a transient reduction of $D_{L_{CO}}$ during the episodes of pancreatitis; they suggested that factors released from the injured organ could have increased capillary permeability and impaired $D_{L_{CO}}$. In addition, Greenberg and coworkers[87] demonstrated a reduction in the oxygen affinity of hemoglobin in patients with acute pancreatitis, which was related to the increase in circulating fatty acids.

Because of the normal chest radiograph, arterial hypoxemia may be clinically undetected but profound; therefore, a high index of suspicion should be present for respiratory impairment in patients with acute pancreatitis, and arterial blood gases should be measured

periodically during the initial 48 to 72 hours of hospitalization.[80] When hypoxemia occurs, the patient should receive supplemental oxygen to raise the arterial P_{O_2} to more than 70 mm Hg.[88]

Approximately 15% to 20% of patients with severe acute pancreatitis develop ARDS, the most dangerous of all pulmonary complications, which is associated with a mortality rate of 56%.[89] The incidence of ARDS is higher in patients with hemorrhagic compared with nonhemorrhagic pancreatitis.[90,91] Respiratory symptoms appear 2 to 7 days after the onset of the acute episode. The chest radiograph usually shows signs of pulmonary vascular congestion that progress to bilateral, diffuse infiltrates. Studies of arterial blood gases confirm severe hypoxemia, usually associated with marked hypocapnia. Pathologic findings in these patients reveal evidence of acute lung injury that is indistinguishable from that observed in ARDS attributable to other causes.[90]

The mechanisms of lung injury associated with acute pancreatitis are not completely understood. It is not clear whether the injury results from a direct toxic effect of pancreatic products or is secondary to the release of inflammatory mediators, or both. Several pancreatic products, production of which is markedly increased during acute pancreatitis, have the potential to induce lung injury. Phospholipase A_2 has been extensively studied as a putative mediator, because it binds to pulmonary capillaries and has the ability to induce the enzymatic degradation of the phospholipid components of surfactant, thereby promoting alveolar collapse and increased vascular permeability.[79,82] Free fatty acids, produced from triglyceride degradation by circulating lipase, may induce alveolar edema and hemorrhage.[82] Pancreatic enzymes also have the capability to induce lung injury and cause increased vascular permeability, which has been demonstrated by the radioactive transferring method.[92] In addition to the direct effect of pancreatic products, sequestration of polymorphonuclear neutrophilic leukocytes within the alveolar and interstitial spaces is postulated to play an important role.[79] Moreover, various inflammatory mediators that may be released during pancreatic injury, such as reactive oxygen species,[93] adhesion molecules, platelet-activating factor,[82,94] and many cytokines, possess the potential to produce diffuse lung injury and increase pulmonary vascular permeability.[79,82]

Treatment of pancreatitis-associated lung injury is essentially supportive and does not differ from that for other forms of ARDS (see Chapter 55). Key measures include cardiovascular support and lung protective ventilation.[79] Additional treatment includes suppression of the secretory function of the pancreas by elimination of oral intake, use of nasogastric suction, and inhibition of gastric acid secretion with $histamine_2$ blockers. Studies suggest that octreotide, a potent inhibitor of exocrine pancreatic secretion, may decrease both mortality rates and the incidence of ARDS among patients with severe acute pancreatitis.[95,96] Nevertheless, controlled, randomized trials of the effectiveness of octreotide in the prevention and treatment of pancreatitis-associated ARDS are needed.

Pleural Effusion

Pleural effusions may be associated with both acute and chronic pancreatitis (see also Chapter 73). In acute pancreatitis, pleural effusion is a relatively frequent finding, being present in about 20% of reported patients,[97] but in as high as 50% in one series.[98] In most cases these effusions are of small size; the majority (68%) are left sided, 22% are bilateral, and only 10% are right sided.[82]

Various pathogenic mechanisms have been proposed to explain the development of pleural effusions associated with acute pancreatitis[97]: (1) increased permeability of lymphatics and fluid leak caused by pancreatic enzymes that may diffuse from the peritoneal side to the thoracic side of the diaphragm, (2) impaired lymphatic drainage of pleural exudate caused by obstruction of lymphatic vessels by the high enzymatic content of the pleural fluid, and (3) increased permeability of diaphragmatic capillaries caused by the inflammatory process in the adjacent pancreas.

In patients with pleural effusion associated with acute pancreatitis, symptoms are primarily abdominal (pain, nausea and vomiting); occasionally, respiratory symptoms (pleuritic pain and dyspnea) may also be present. The diagnosis is established by demonstrating an elevated amylase concentration in the pleural fluid, which may be 30 times higher than the concentration in plasma.[79] The pleural fluid usually is an exudate, which is sometimes bloody, and has a high concentration of both protein and lactic acid dehydrogenase; the differential white blood cell count reveals a predominance of polymorphonuclear cells.

Pleural effusions associated with acute pancreatitis usually are self-limited and resolve when the pancreatic inflammation decreases without requiring therapeutic drainage. Therefore, if the pleural effusion does not resolve within 2 weeks after treatment for the pancreatic disease, the possibility of a pancreatic abscess or a pseudocyst should be considered.

Chronic pleural effusions are usually associated with chronic relapsing pancreatitis and pancreatic pseudocyst. In most cases a history of alcohol abuse is present.[99] Chronic effusions are large, may occupy the entire hemithorax, and reaccumulate rapidly after thoracentesis.

The typical mechanism of chronic effusion is a pancreaticopleural fistula, a direct communication between the pancreas and the pleural space. In chronic pancreatitis, the pancreatic duct may rupture because of high internal pressure. Once it is disrupted, pancreatic secretions are able to flow into the retroperitoneum, from which they can enter the mediastinum through the esophageal or aortic hiatuses and then penetrate into the pleural space (Fig. 83-4). Occasionally, a direct communication exists between a pancreatic pseudocyst and the pleural cavity, through the diaphragmatic dome.[99]

Patients with chronic pancreatic effusions usually complain of respiratory symptoms such as chest pain and shortness of breath. Abdominal symptoms may be absent, probably because the pancreaticopleural communication decompresses the pseudocyst.[97] Therefore, the diagnosis of a chronic pancreatic pleural effusion

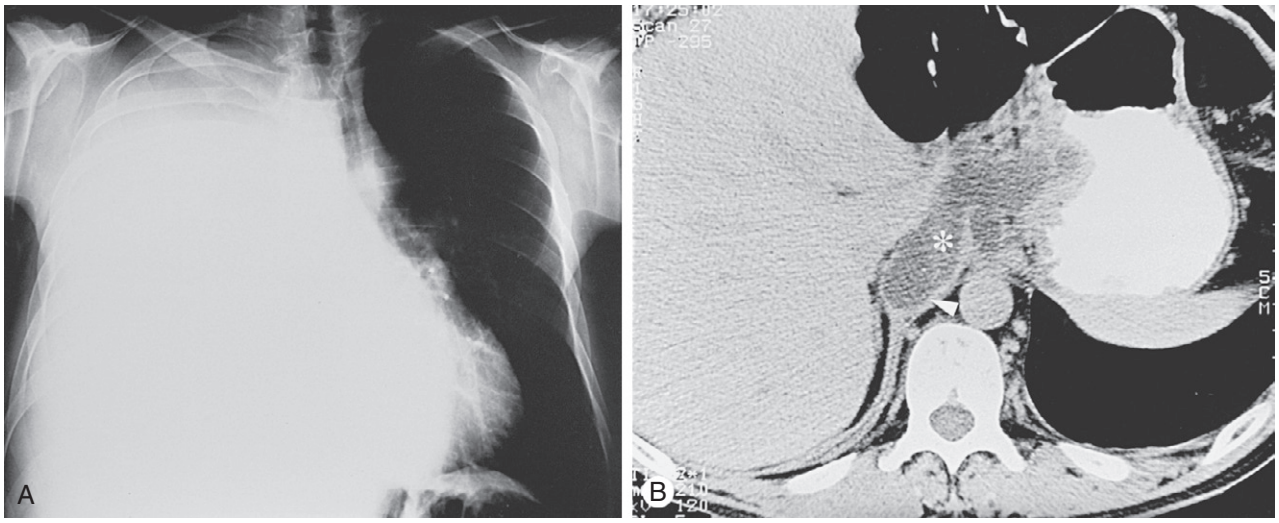

FIGURE 83-4 ■ This massive pleural effusion is associated with a pancreatic pseudocyst. **A,** Chest radiograph demonstrates a massive pleural effusion in the right hemithorax. **B,** Computed tomography scan of the upper abdomen, performed after pleural drainage, shows the cephalad extension of the pseudocyst (*asterisk*) through the right crural insertion (*arrowhead*) and the esophageal hiatus. (Courtesy of Dr. S. Navarro, Hospital Clínic, Universitat de Barcelona, Barcelona.)

should be suspected in any patient with a large pleural effusion who appears to be chronically ill or has a history of pancreatic disease or alcohol abuse.[100] The diagnosis is established by the demonstration of a high concentration of amylase in the pleural fluid. Ultrasonography and computed tomographic scanning of the chest and abdomen usually reveal the presence of a pseudocyst and occasionally may even show the pancreaticopleural fistula[100] (see Fig. 83-4). Endoscopic retrograde cholangiopancreatography provides additional information on ductal structures and may demonstrate passage of contrast material from the pancreatic duct or a pseudocyst into the peritoneal cavity, although visualization of the fistula may be difficult.[99,101] Endoscopic retrograde cholangiopancreatography and computed tomographic scanning together provide complementary information, which is useful especially if the patient has to undergo surgical intervention.

Patients with chronic pancreatic pleural effusions should be treated initially with nasogastric tube placement, no oral intake, parenteral nutrition, and repeated therapeutic thoracenteses. Inhibition of pancreatic secretion with octreotide has been shown to be useful in promoting the closure of pancreaticopleural fistulas in some cases.[102] Nonetheless, if, after 2 to 3 weeks of medical therapy, the pleural fluid continues to accumulate and the patient remains symptomatic, surgery to close the fistula should be considered.

KIDNEY DISEASES

Acute and chronic renal diseases are associated with a variety of respiratory manifestations. Pulmonary edema occurs in both conditions, and pleural disease, pulmonary calcification, and sleep apnea syndrome are fairly common in patients with chronic renal failure. Historically, treatment with hemodialysis caused transient changes in pulmonary gas exchange. These disorders are discussed in this section. Systemic necrotizing vasculitis and diseases associated with autoantibodies, which usually affect both the lung and the kidney, are considered in Chapters 58 and 60.

Pulmonary Edema

Pulmonary edema is common in patients with acute or chronic renal failure. A variety of conditions may favor edema formation: fluid overload, left ventricular failure, hypoalbuminemia, and increased pulmonary microvascular permeability. The relative importance of increased microvascular permeability versus left ventricular failure in the pathogenesis of pulmonary edema in renal failure has been largely a subject of controversy. Autopsy findings showing the presence of protein-rich edema fluid, hyaline membranes, and alveolar hemorrhage[103,104] all pointed to an increased vascular permeability to proteins as the likely mechanism of pulmonary edema formation. The demonstration of an increased protein content in edema fluid sampled directly by endotracheal aspiration reinforced this hypothesis.[105] Furthermore, pulmonary edema has been reported in the absence of volume overload and in the presence of normal intracardiac and pulmonary wedge pressures. However, studies using a double-isotope technique failed to show a significant accumulation of radiolabeled transferrin in patients with renal failure and pulmonary edema.[106] The rate of protein accumulation in patients with renal failure was similar to that in patients with cardiogenic pulmonary edema and in normal volunteers, and significantly lower than in patients with ARDS; these observations suggest that pulmonary edema in most patients with renal failure is probably not related to increased pulmonary vascular permeability to proteins.[106]

Heart failure is believed to play an important role in the development of pulmonary edema associated with chronic renal failure. Cardiac disorders are common in end-stage renal disease, and a variety of factors, including hypertension, diabetes mellitus, anemia, surgical arteriovenous fistulas, and ischemic heart disease, may adversely affect cardiac function.[107,108] Left ventricular dysfunction may be reversible after dialysis or renal transplantation, which suggests that patients with chronic renal failure may have a specific "uremic cardiomyopathy."[107,109,110]

Subclinical lung congestion in patients with chronic renal failure may reduce lung volumes and maximal expiratory flow rates, which usually reverse after hemodialysis.[111–113] In contrast to the findings in patients with left ventricular dysfunction,[114] subclinical pulmonary edema in renal failure is not associated with bronchial hyperresponsiveness, either before or after hemodialysis.[115]

From a clinical standpoint, most instances of pulmonary edema associated with renal failure, both acute and chronic, involve increased intravascular volume from abnormal left ventricular function and fluid overload. Accordingly, its treatment should essentially consist of removal of excess body fluid with dialysis.

Pleural Disease

Approximately 20% to 40% of patients who die from chronic renal failure have fibrinous pleuritis detected at autopsy.[103,116] This fibrinous pleuritis can be manifested as pleuritic chest pain with pleural friction rubs,[117] pleural effusion,[118] or fibrothorax.[119,120]

Pleural effusions were detected in 20% of 257 hospitalized patients receiving long-term hemodialysis; their most common symptom was dyspnea.[121] Other patients may be asymptomatic or they may present with fever, chest pain, or cough. The effusions usually are unilateral and in some cases may be large, occupying more than 50% of the hemithorax. In one study the pleural fluid was transudative in about two thirds of the patients and exudative in the remainder.[121] In patients with exudates, the leukocyte count reveals a predominance of lymphocytes, and the biopsy specimens usually demonstrate chronic fibrinous pleuritis.[122] The pathogenesis of "chronic uremic pleuritis" associated with renal failure is not known, but it is probably related to the effect of retained metabolic toxins.

The effusion usually disappears gradually after several weeks of dialysis. In about 25% of patients, it may persist, progress, or recur. If fibrothorax develops and produces a symptomatic restrictive ventilatory impairment, surgical decortication should be considered.[119,120]

Pulmonary Calcification

Metastatic calcification is a common complication of chronic renal failure that may affect many visceral organs, and is found in 60% to 80% of dialysis patients at autopsy or by bone scintigraphy.[123] Similar diffuse calcifications may occur in other systemic or pulmonary conditions.[124] Pulmonary involvement is common, but it is generally undetectable by ordinary chest films and most patients are asymptomatic.[125] At times, the chest radiograph or computed tomogram may show infiltrates composed of nodular opacities less than 2 mm in diameter that can be diffuse or localized or computed tomogram (see Fig. 85-2). The infiltrates are relatively stable, in contrast to infectious processes. Pulmonary function tests may reveal a restrictive ventilatory defect and/or a reduction in D_{LCO}.

The pathogenesis of pulmonary calcification in patients with chronic renal failure is complex; several factors—in concert—may play a role: (1) the effect of chronic acidosis, which leaches calcium from bones; (2) the effect of intermittent alkalosis, which favors the deposition of calcium salts; (3) the effect of hyperparathyroidism, which causes bone reabsorption and intracellular hypercalcemia; and (4) the effect of low glomerular filtration rate, which causes hyperphosphatemia and a greatly elevated calcium-phosphorus product.[123]

The diagnosis of pulmonary calcification can be confirmed by pulmonary uptake during technetium-99m–diphosphonate scanning (see Fig. 85-3).[126] Treatment is generally unsatisfactory and consists of maintaining adequate dialysis, lowering the calcium-phosphorus product, and treating hyperparathyroidism, when present; renal transplantation may improve or worsen the condition.[123]

Sleep Apnea

Disturbed sleep, including sleep apnea, has long been recognized in patients with end-stage renal disease. (Other causes of sleep apnea, as well as its pathophysiology and treatment, are described in Chapter 79.) The mounting evidence in favor of a high prevalence of sleep apnea in dialysis patients—greater than 50%[127]—has been reinforced by the results of comparisons between patients on standard thrice-weekly hemodialysis and closely matched control subjects from the community-based Sleep Heart Health Study: dialysis patients had a fourfold increase in sleep apnea and episodes of severe nocturnal hypoxemia, after adjusting for comorbid conditions that might have affected outcome.[128]

Various mechanisms have been proposed to explain the high prevalence of sleep apnea in patients with end-stage renal disease undergoing hemodialysis. Perhaps the most persuasive of the pathogenetic speculations involves the importance of fluid overload and its corollary that intermittent hemodialysis fails to reduce "upper airway edema (especially during sleep while supine)," thereby facilitating the presence of airway obstruction.[129] Support for this postulate comes from the increased pharyngeal resistance that accompanies rostral shifts of fluid produced by lower body positive pressure in healthy subjects.[130] Follow-up studies using the same methodology documented an increase in upper airway collapsibility.[131]

Accumulation of uremic toxins might also play a role, independently or in conjunction with fluid overload, in the pathogenesis of sleep disorders. Increasing the frequency and length of nocturnal hemodialysis, which

does not distinguish between the presence of toxins and fluid overload as possible mechanisms, caused a significant decrease in the severity of sleep apnea in all 14 patients in whom it was tried,[132] thus offering a potential, but logistically complicated, solution to an otherwise difficult-to-treat and serious clinical problem.

Standard treatment of obstructive sleep apnea might be beneficial, but experience in patients with end-stage kidney disease is limited.[133] There are anecdotal reports of improvement after renal transplantation,[134] but according to a recent report, only 3 of 18 patients had significant improvement after the procedure.[135]

Hemodialysis-Induced Hypoxemia

Another clinical problem associated with end-stage renal disease and hemodialysis—now largely of historic interest—was the prompt reduction in arterial P_{O_2} of 10 to 15 mm Hg after initiation of dialysis, which reached a nadir after 30 to 60 minutes and persisted for the duration of the procedure.[136–138] The severity of hypoxemia varied according to the type of dialysis membrane and the chemical nature of the dialysate buffer.[139,140] Once-popular explanations for the phenomenon, pulmonary vascular leukostasis and activation of complement, have been excluded. Exposure of blood to certain dialysis membranes activates the alternative complement pathway, and within minutes C3a and C5a are generated, which may induce intrapulmonary sequestration of leukocytes and a fall in circulating leukocytes. Based on the temporal association between the onset of hypoxemia and the transient leukopenia, it was postulated that the decrease in arterial P_{O_2} resulted from ventilation-perfusion mismatching due to leukostasis in small pulmonary vessels.[141] However, studies using the multiple inert gas elimination technique ruled out ventilation-perfusion mismatching as the principal mechanism of hypoxemia,[142–144] even though Romaldini and colleagues[143] showed a tendency for ventilation-perfusion matching to improve during the dialysis procedure, which was most likely explained by a dialysis-induced decrease in extravascular lung water. Furthermore, hypoxemia was observed during dialysis with membranes that do not cause leukopenia.[145]

Currently, the most accepted explanation for the decrease in arterial P_{O_2} during hemodialysis is the hypoventilation associated with the removal of carbon dioxide by the dialysate, which is substantial with acetate buffer but minimal with bicarbonate buffer[146]; in addition, acetate buffer may further reduce respiratory carbon dioxide elimination due to carbon dioxide consumption during acetate metabolism.[147] In one study of patients being hemodialyzed with acetate buffer, minute ventilation dropped from an average of 7.2 L/min to 5.7 L/min within 15 minutes of the start of hemodialysis.[148] The $(A - a)P_{O_2}$ value during hemodialysis actually remains stable despite a significant fall in arterial P_{O_2}.[138,143] An additional consequence of the nonrespiratory carbon dioxide "unloading" was to destabilize resting ventilation, which was manifested by an irregular breathing pattern, with the development of periodicity and sometimes apneas.[148,149]

Currently, the former complications of hypoxia and leukopenia during hemodialysis have been largely eliminated by the use of both synthetic (inert) membranes, which do not activate complement, and dialysates such as bicarbonate, which do not remove carbon dioxide. Supplemental oxygen should still be given during the procedure to patients with coexisting cardiopulmonary diseases.

KEY POINTS

- Gastroesophageal reflux, a common disorder, may cause chest pain, varying from heartburn to myocardial ischemia–like distress, may provoke or exacerbate chronic cough, and may trigger asthma attacks or worsen the underlying condition.
- Inflammatory bowel diseases, ulcerative colitis more so than Crohn's disease, have been associated with a variety of chronic pulmonary diseases, particularly of the airways (asthma, chronic bronchitis, and bronchiectasis), and, less commonly, of the lung parenchyma (interstitial fibrosis and bronchiolitis obliterans with organizing pneumonia) and other sites.
- Between 5% and 10% of patients with cirrhosis of the liver develop pleural effusion(s) (hepatic hydrothorax); as many as 20% of patients with end-stage liver disease develop the hepatopulmonary syndrome, characterized by hypoxemia from marked dilation of pulmonary capillaries; and another 6% of patients develop portopulmonary hypertension (mean Ppa > 25 mm Hg).
- Episodes of severe acute pancreatitis are associated with a high frequency of pulmonary complications, especially hypoxemia, pleural effusions, and acute respiratory distress syndrome, which are major causes of excess morbidity and mortality.
- Diseases of the kidney also are important causes of pulmonary edema, pleural disease, pulmonary calcification, and sleep apnea, some of which may be alleviated by dialysis and/or renal transplantation.

CHAPTER 84

PULMONARY COMPLICATIONS OF HEMATOLOGIC DISEASE

Roberto F. Machado, MD • Mark T. Gladwin, MD

INTRODUCTION

RED BLOOD CELL DISORDERS
Anemia
Polycythemia

HEMOGLOBINOPATHIES
Sickle Cell Disease
Thalassemia
Other Hemoglobin Disorders

WHITE BLOOD CELL DISORDERS
Leukemias
Plasma Cell Disorders

THROMBOSIS AND DISORDERS OF COAGULATION
Inherited Thrombophilia
Coagulopathies and Platelet Disorders

COMPLICATIONS OF TRANSFUSION
Transfusion Associated Acute Lung Injury

INTRODUCTION

Hematologic diseases and their specific therapies can adversely affect several aspects of cardiopulmonary function, by reducing the oxygen-carrying capacity of the blood, by impairing pulmonary vascular function and pulmonary immune defense, and by direct pulmonary parenchymal damage. This chapter reviews the clinical manifestations, epidemiology, pathophysiology, and treatment of pulmonary complications of disorders of the hematologic system.

RED BLOOD CELL DISORDERS

Anemia

Anemia is defined as a reduction in the number of circulating red blood cells. By decreasing oxygen-carrying capacity of the blood, the presence of anemia can impair cardiopulmonary function. However, since multiple compensatory mechanisms exist to adjust to a reduced oxygen-carrying capacity of blood, the signs and symptoms induced by anemia depend on the degree of anemia, the rate at which it evolves, the oxygen demands of the patient, and the presence of chronic cardiopulmonary disease. For instance, in resting adults subjected to acute isovolemic anemia, oxygen delivery can be maintained at hemoglobin concentrations as low as 5 g/dL,[1] a finding that also occurs in individuals with chronic severe anemia.[2,3] As such, anemia, even when severe, rarely causes heart failure or pulmonary edema, and, when it does, it is likely that the high-output failure is superimposed upon some cardiac abnormality. From the hemodynamic standpoint, as hemoglobin level decreases (particularly with hemoglobin values lower than 7 g/dL), cardiac output increases, filling pressures tend to decrease, and systemic and pulmonary vascular resistances decrease. Further, these abnormalities are readily reversible after red blood cell transfusions.[2–4] Finally, in severe cases and especially in patients with cardiopulmonary disease, anemic hypoxia can also occur as a consequence of reduced ability of blood to participate in gas exchange and carry oxygen.

Pulmonary hypertension is an increasingly recognized complication of chronic hereditary and acquired hemolytic anemias. Remarkably, virtually every cause of hemolytic anemia has been associated with pulmonary hypertension (Table 84-1). In contrast, there have been no reports of pulmonary hypertension associated with anemia of chronic disease or iron-deficiency anemia. This suggests that the hemolytic component of anemia is necessary for the development of pulmonary hypertension, which is discussed in detail in the section on hemoglobinopathies.

TABLE 84-1. Hemolytic Disorders Associated with Pulmonary Hypertension

Hemoglobinopathies
Sickle cell disease
Thalassemia intermedia and major
Hb Mainz unstable hemoglobin hemolytic anemia
Red cell membranopathies
Hereditary spherocytosis
Hereditary stomatocytosis
Paroxysmal nocturnal hemoglobinuria
Alloimmune hemolytic anemia
Red cell enzymopathies
Pyruvate kinase deficiency
Glucose-6-phosphate dehydrogenase deficiency
Microangiopathic hemolytic anemia
Thrombotic thrombocytopenic purpura
Hemolytic uremic syndrome
Hemolysis from mechanical heart valves
Left ventricular assist devices and cardiopulmonary bypass procedures
Malaria

Polycythemia

Polycythemia is characterized by an abnormally high hematocrit (>48% and >52% in women and men, respectively), hemoglobin concentration (>16.5 or >18.5 g/dL in women and men, respectively), or red blood cell count. These measurements are dependent upon the plasma volume as well as the red blood cell mass, and, before classifying a patient as having true polycythemia, a decrease in plasma volume as the etiology for these abnormalities must be ruled out. This state of chronically reduced plasma volume with elevated hemoglobin or hematocrit has been called Gaisböck's disease,[5] spurious polycythemia, stress erythrocytosis, apparent polycythemia, and pseudopolycythemia, and has been associated with use of diuretics, alcohol, obesity, hypertension, and renal disease. Patients with elevations in red blood cell mass have absolute polycythemia and are categorized in primary and secondary forms. Primary polycythemia is caused by an acquired or inherited mutation such as in the JAK2 gene,[5a] leading to an abnormality within red blood cell progenitor cells; it includes polycythemia vera and rare familial variants (e.g., activating mutations of the erythropoietin receptor or Chuvash polycythemia). Secondary polycythemia is caused by a circulating factor stimulating erythropoiesis, usually related to the production of erythropoietin as a physiologic response to chronic hypoxia (e.g., chronic hypoxic lung disorders and disorders affecting hemoglobin oxygen affinity), but can also result from erythropoietin-secreting tumors.

Most of the symptoms of polycythemia are related to an increase in blood viscosity, which leads to impairment in systemic and pulmonary blood flow. Thromboembolic events occur in approximately 30% of patients with polycythemia vera and account for 31% of their deaths.[6] Pulmonary nodular lesions secondary to thrombosis, stasis, or infarction have been described in these patients.[7] Late-stage polycythemia vera, which is characterized by myelofibrosis, may cause pulmonary and pleural masses that are related to extramedullary hematopoiesis.[8]

Pulmonary hypertension has been reported in patients with polycythemia and other myeloproliferative disorders.[7,9-12] In a retrospective review, 26 patients (12 with myeloid metaplasia, 5 with essential thrombocythemia, 6 with polycythemia vera, 2 with myelodysplastic syndrome, and 1 with chronic myeloid leukemia) had echocardiographic or hemodynamic evidence of pulmonary hypertension. Interestingly, the median survival after diagnosis of pulmonary hypertension was 18 months and the majority of deaths were related to cardiopulmonary causes, suggesting that the presence of pulmonary hypertension was a direct cause of death.[10] In a cohort of 14 patients with Chuvash polycythemia, the prevalence of pulmonary hypertension (defined as an estimated pulmonary artery systolic pressure ≥ 35 mm Hg) was 36%.[12] The pathogenesis of pulmonary hypertension in these disorders is not well established but can involve hypercoagulability and hyperviscosity leading to in situ thrombosis or chonic thromboembolic disease, as well as hemoglobin-dependent scavenging of endothelium-derived nitric oxide (NO)[13-17] and up-regulation of HIF-1α–mediated pathways, such as endothelin-1.[12]

In patients with polycythemia vera, the mainstay of therapy is phlebotomy and myelosuppression with hydroxyurea, to keep the hematocrit below 45% in men and 42% in women, and antithrombotic therapy with aspirin or anagrelide.[18,19] Treatment of the myeloproliferative disorder has been shown in case series to improve pulmonary hypertension.[9,10] In patients with chronic hypoxic disorders such as chronic obstructive pulmonary disease (COPD) and interstitial lung disease, long-term oxygen therapy should reduce the number of patients who become severely polycythemic. In patients with COPD and severe polycythemia, phlebotomy (to achieve a hematocrit of about 50%) is associated with a decrease in mean pulmonary artery pressure and pulmonary vascular resistance, as well as an improvement in exercise performance.[20] However, the use of phlebotomy should be reserved as adjunctive therapy in the management of the markedly polycythemic and symptomatic patient who remains significantly polycythemic despite appropriate long-term oxygen therapy.

HEMOGLOBINOPATHIES

Sickle Cell Disease

Sickle cell anemia, the most common and most severe form of sickle cell disease, occurs in individuals who are homozygous for a single nucleotide substitution in the β globin gene. This results in the synthesis of hemoglobin S (Hb S), a structural variant that is much less soluble than normal hemoglobin (Hb A) when deoxygenated.[21,22] Deoxygenated Hb S polymerizes and aggregates inside

sickled erythrocytes as they traverse the microcirculation. Rigid, dense, and sickled cells can become entrapped in the microcirculation, a process that is enhanced by their increased propensity to adhere to endothelium. Mechanistic studies in transgenic mice expressing exclusively human Hb S suggest that microvascular occlusion results in ischemia and reperfusion injury, which promotes inflammatory, thrombotic, and oxidant stress.[23–30] In patients with sickle cell disease, vaso-occlusion leads to the frequent episodes of bone pain and acute chest syndrome that complicate sickle cell disease. Furthermore, the membrane of erythrocytes containing intracellular Hb S polymer is constantly exposed to mechanical and oxidant injury as the erythrocytes traverse the microcirculation. Ultimately cumulative membrane damage shortens red cell life span so that sickle cell disease is characterized by a chronic hemolytic anemia. Intravascular hemolysis releases cell-free hemoglobin into the plasma, which scavenges NO and releases red blood cell arginase into the plasma, which catabolizes arginine, the substrate for NO synthesis.[14,31,32] Intravascular hemolysis thus produces a state of endothelial dysfunction, vascular proliferation, and pro-oxidant and proinflammatory stress.[33–35]

It is estimated that around 250,000 children worldwide are born with homozygous sickle cell anemia every year.[36] Approximately 0.15% of African Americans are homozygous for sickle cell disease, and 8% have sickle cell trait. Despite significant improvements in the life expectancy of patients with sickle cell disease, estimates of the median age at death range from 42 to 53 years for men and 48 to 58.5 years for women.[37,38]

Acute and chronic pulmonary complications of sickle cell disease are common but often underappreciated by health care providers. Acute complications include asthma and the acute chest syndrome (ACS), while chronic complications include pulmonary fibrosis, pulmonary hypertension, and cor pulmonale. Pulmonary complications account for a large proportion of deaths among adults with sickle cell disease.[37,39–41] According to the Cooperative Study of Sickle Cell Disease (CSSCD), a prospective multicenter study of 3764 patients, over 20% of adults likely had fatal pulmonary complications of sickle cell disease.[37] Among the 299 patients enrolled in the long-term follow-up study of patients who participated in the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH), pulmonary disease was the most common cause of mortality, accounting for 28% of all deaths.[42]

Acute Chest Syndrome

ACS represents a lung injury syndrome occurring in patients with sickle cell disease and should be considered analogous to the acute respiratory distress syndrome (ARDS). It is clinically defined by the development of a new pulmonary infiltrate in a patient with sickle cell disease, consistent with alveolar consolidation and not atelectasis, involving at least one complete lung segment, that is accompanied by chest pain, fever, tachypnea, wheezing, or cough.[43]

Epidemiology. ACS is the second most common cause of hospitalization in patients with sickle cell disease and the leading cause of admission to an intensive care unit and premature death.[37,40]

ACS can occur in any of the sickle hemoglobinopathies but is more common in individuals with homozygous sickle cell disease (Hb SS). In the CSSCD, there was a 29% incidence of the ACS in 3751 subjects over a 2-year period, representing an attack rate of 12.8 episodes per 100 patient-years for Hb SS disease.[37] The incidence is higher in children than in adults (24.5 events vs. 8.8 events per 100 patient-years). As many as half of ACS episodes occur in association with vaso-occlusive pain crisis, and a sizable proportion of patients will have a painful event within 2 weeks of the diagnosis.[44,45] Since up to 20% of patients admitted with acute vaso-occlusive pain crisis will develop ACS in the first 3 days of hospitalization, physicians must be vigilant for this common and potentially lethal complication.

Laboratory parameters in steady state associated with an increased risk for the development of ACS include an elevated white blood cell count, a higher steady-state hemoglobin level, and a lower steady-state fetal hemoglobin level.[44,45] In children, a number of studies now suggest that asthma is a risk factor for the development of ACS.[46–48] Other clinical events that appear to increase the risk of (or are associated with) the development of ACS include major surgical procedures, acute rib infarcts, avascular necrosis of the hips, pregnancy, use of narcotics, acute anemic events, and previous pulmonary events.[44,45]

During acute hospitalization for vaso-occlusive crisis, the development of ACS is often preceded by an abrupt drop in hemoglobin levels (mean decrease of 0.78 g/dL from steady-state levels) and increases in markers of hemolysis, such as lactate dehydrogenase (LDH). The platelet count also drops preceding ACS, and levels less than 200,000 cells/μL constitute an independent risk factor for ACS severity, associated with increased risk of neurologic complications and mechanical ventilation. In our units, we monitor trends in hemoglobin and platelet counts and pay careful attention to patients with drops in steady-state values.

Pathophysiology. Three major mechanisms appear to be involved in the pathogenesis of ACS: infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction (Table 84-2, Fig. 84-1).

The most common etiology of ACS in both children and adults is infection by a community-acquired pathogen, with an excessive inflammatory lung injury response. More than 80% of adults with sickle cell disease report a history having been admitted to the hospital for "pneumonia."[33] The National Acute Chest Syndrome Study Group analyzed 671 episodes of ACS in 538 patients with sickle cell disease to determine the cause, outcome, and response to therapy, and respiratory samples obtained from sputum and bronchoalveolar lavage were analyzed for viral and bacterial infections.[43] Among the infectious agents identified most were atypical bacteria and viruses (see Table 84-2), including *Chlamydia pneumoniae*

TABLE 84-2. Causes of the Acute Chest Syndrome*

Cause	All Episodes (*N* = 670) and No. of Episodes (%)	AGE AT EPISODE OF ACUTE CHEST SYNDROME		
		0–9 yr (*n* = 329)	10–19 yr (*n* = 188)	≥20 yr (*n* = 153)

(29%), *Mycoplasma pneumoniae* (20%), *Legionella pneumophila* (2%), respiratory syncytial virus (10%), parvovirus (4%), rhinovirus (3%), parainfluenza virus (2%), influenza A virus (2%), cytomegalovirus (2%), Epstein-Barr virus (1%), and herpes simplex virus (1%). Community-acquired encapsulated bacteria were rarely isolated, despite the fact that patients with Hb SS disease rarely have normal splenic function. *Staphylococcus aureus* was isolated in 5% of cases and *Streptococcus pneumonia* in only 4% of cases.

Fat embolization syndrome is the second most common cause of the ACS. It occurs as a complication of vaso-occlusive pain crisis involving multiple bones, which results in bone marrow edema, infarction, and necrosis. As a consequence, bone marrow contents are released into the systemic circulation and are trapped in the pulmonary circulation, producing acute pulmonary hypertension, severe lung inflammation, and hypoxemia (Fig. 84-2).[49-51] Bone marrow fat released into the bloodstream is also converted to free fatty acids by secretory phospholipase A_2, which can also produce direct inflammatory lung injury.[52] Finally, in approximately 20% of patients, direct lung infarction or lung vaso-occlusion is associated with the development of the ACS, with a small percentage of patients actually developing wedge-shaped infarction, sometimes followed by central cavitation.[53]

Clinical Features and Evaluation. The clinical features at presentation are age dependent, which likely reflects the different etiologies of ACS in different age groups, with children having a higher proportion of infectious etiologies in comparison to adults, who tend to have fat embolization as a major etiology. Overall, 80% of patients present with fever, 62% with cough, and approximately 40% have chest pain, tachypnea, dyspnea, and abdominal, arm, leg, rib, or sternal pain.[43] Most adult patients present with severe extremity or chest pain and 24 to 72 hours later develop ACS. Reactive airways disease is observed in 13% of cases of ACS, and is much more common in children.[43]

ACS is associated with signs of systemic inflammation, with mean peak temperatures of 38.9° C and mean white blood cell counts of 23,000 cells/μL^3.[43] As mentioned earlier, while a high steady-state hemoglobin level is a major risk factor for developing ACS, the acute presentation is often associated with a drop in hemoglobin levels (mean decrease of 0.78 g/dL from steady-state levels) and increases in markers of hemolysis. Thrombocytopenia can also occur, and a platelet count less than 200,000 cells/μL appears to be a marker of ACS severity, associated with increased risk of neurologic complications and mechanical ventilation.[43] Secretory phospholipase A_2 levels are elevated early in the course of ACS, even before the development of radiographic changes, and have been used to predict the onset of the syndrome.[54]

The diagnosis of pulmonary fat embolization syndrome relies on the identification of oil-red O–positive lipid accumulations within alveolar macrophages since the clinical manifestations can be indistinguishable from the other causes of ACS (see Fig. 84-1). In a 30-center clinical trial, the National Acute Chest Syndrome Study Group identified fat embolization syndrome in 16% of ACS cases in adults and children based on positive lipid accumulations in alveolar macrophages.[43] Traditionally bronchoscopy has been used as the diagnostic modality of choice for the diagnosis of pulmonary fat embolization syndrome. However, a recent study compared induced

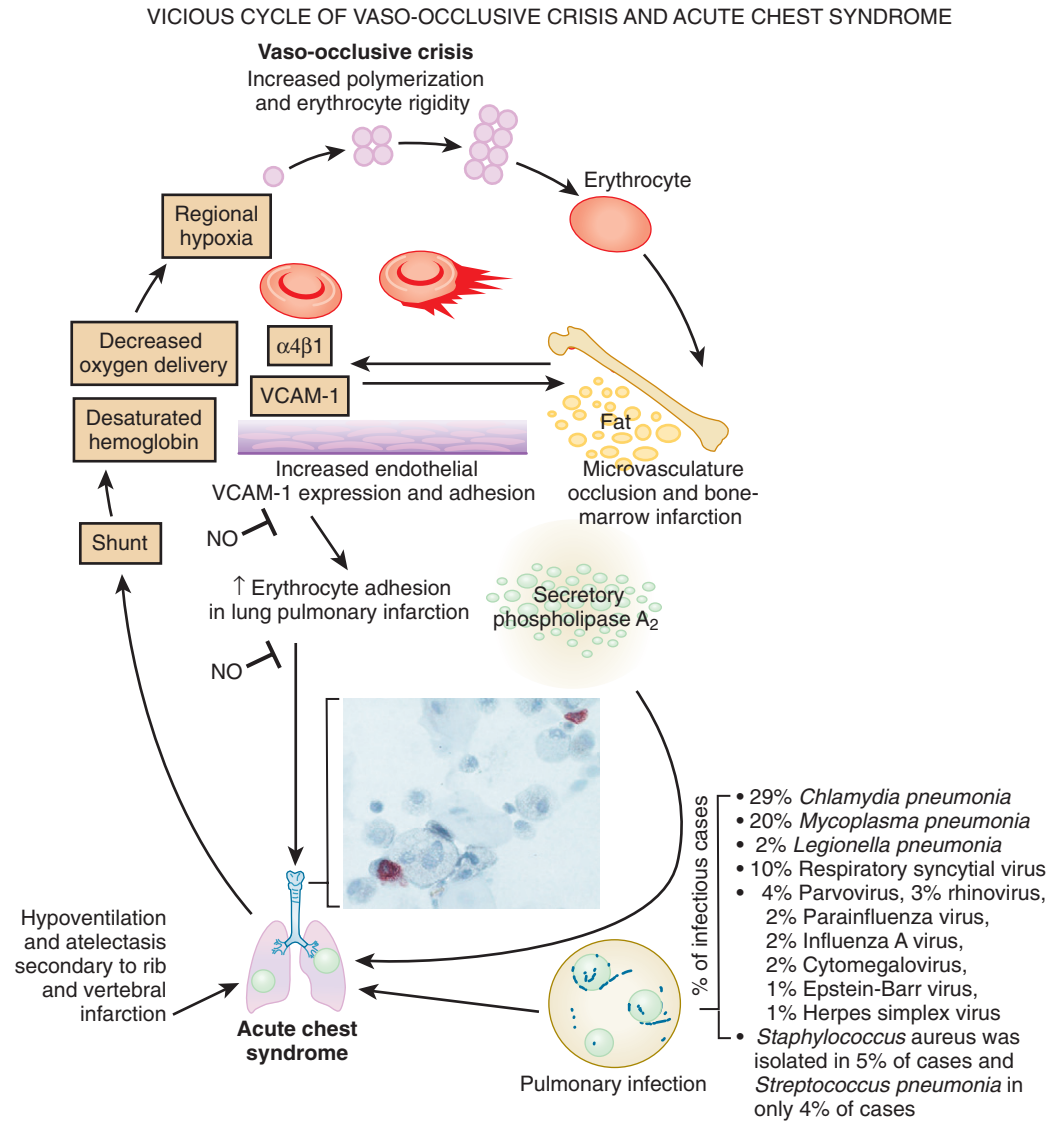

FIGURE 84-1 ■ Pathogenesis of the acute chest syndrome (ACS). Three major triggers are associated with the development of ACS: infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction. Lung injury results in ventilation-perfusion mismatch and hypoxemia, which leads to increased hemoglobin S polymerization, and erythrocyte vaso-occlusion. This worsens bone marrow infarction and pulmonary vaso-occlusion to promote a vicious cycle. Fat embolization can be diagnosed by oil-red O staining of pulmonary alveolar macrophages, revealing the characteristic red lipid inclusions, as shown in panel. Common infectious organisms identified in cases of ACS are listed.

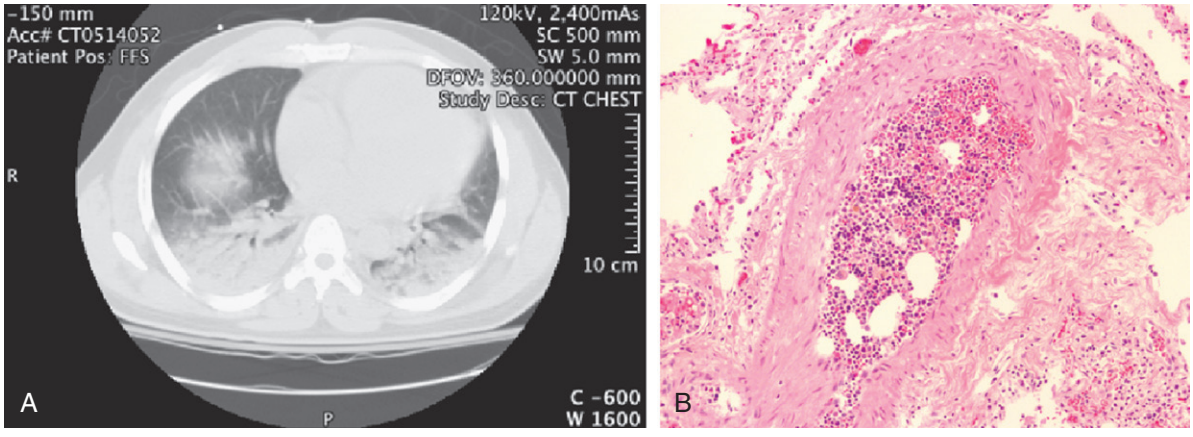

FIGURE 84-2 ■ Fat emoblization in acute chest syndrome. **A,** Chest computed tomography scan of a patient with acute chest syndrome and fat embolization syndrome. **B,** Postmortem examination specimen of a patient who died suddenly during an episode of vaso-occlusive crisis and acute chest syndrome demonstrating bone marrow elements lodged in the small pulmonary artery.

sputum sampling of alveolar macrophages with samples obtained from bronchoalveolar lavage and found a modest but significant correlation between the two measurements ($r = 0.65$).[55]

Some patients manifest evidence of systemic fat embolization, and in this case ACS is part of the spectrum of the systemic fat embolization syndrome, also called the acute multiorgan failure syndrome. This should be suspected in patients presenting with acute multiorgan failure characterized by the development of acute hypoxic respiratory failure, right heart failure, renal and hepatic dysfunction, alterations in mental status, seizures, thrombocytopenia, and coagulopathy.[56,57] In this context, patients with ACS who have lipid-laden macrophages detected in the induced sputum have significantly more extrathoracic pain than those without evidence of fat emboli, more neurologic symptoms, a lower platelet count, and higher transaminase levels.[55] This suggests that the fat embolization syndrome is a major cause of ACS and has a more severe course with systemic complications.

The mean length of hospitalization for ACS is 10.5 days, compared with 3 to 4 days for uncomplicated vaso-occlusive pain crisis. Thirteen percent of all patients with ACS require mechanical ventilation, and the overall mortality is 3% for all patients and 9% for adults. Risk factors for mechanical ventilation and poor outcome include platelet count less than 200,000/μL (likely indicative of the fat embolization syndrome), the number of lobes involved on radiograph, and a self-reported or medical record history of cardiac disease. The latter complication is now thought to represent occult pulmonary hypertension and cor pulmonale. In fact, in a recent study of 84 consecutive hospitalized patients with ACS, 13% of patients manifested right heart failure, and this subgroup had the highest risk for mechanical ventilation and death.[58] These data suggest that pulmonary hypertension and right heart dysfunction represents a major comorbidity during ACS, and that right heart failure should be considered in patients presenting with shock or severe hypoxia. The outcome of patients with severe ACS on mechanical ventilation is better that that of patients with ARDS, with a mortality rate of 19% in contrast to the approximate 30% mortality rate reported in modern ARDS studies.[43]

Treatment. A summary of treatment strategies is outlined in Table 84-3. Since the triggers and risk factors for ACS are well known, clinical surveillance plus aggressive and early therapy of this patient population are likely to improve prognosis. This could be accomplished by close monitoring of patients with vaso-occlusive crisis, a febrile illness, and in the postoperative state. In acutely ill patients, strategies such as aggressive pain management and incentive spirometry can minimize chest wall splinting, with consequent atelectasis and alveolar hypoxia. In fact, the use of incentive spirometry has been shown to decrease the incidence of new pulmonary infiltrates in patients admitted with vaso-occlusive pain affecting the chest wall.[53] Patients with a history of ACS should be treated with hydroxyurea in the outpatient setting as its use has been shown to reduce the risk of developing ACS by approximately 50%.[59,60] A chronic transfusion regimen is also effective in reducing the incidence of ACS.[61]

TABLE 84-3. Treatment of the Acute Chest Syndrome (ACS)

Oxygen therapy to maintain arterial hemoglobin oxygen saturation above 92%
Pain control and incentive spirometry to reduce chest wall splinting and pulmonary atelectasis
Close clinical observation, particularly Po_2/Fio_2 ratio: early diagnosis of worsening respiratory function
Asthma therapy if indicated
Empirical antibiotics
Cover typical and atypical respiratory pathogens.
Consider the regional and seasonal risk of methicillin-resistant *Staphylococcus aureus* and influenza A or B and tailor therapy accordingly.
Transfusion therapy
The main indication for transfusion therapy in ACS is worsening respiratory function.
Simple transfusion is as effective as erythrocytopheresis.
Patients with high initial hemoglobin concentrations (≥9 g/dL), or patients with more severe disease should receive erythrocytopheresis.
Transfused blood should be matched to Rh, C, E, and Kell antigens and obtain transfusion records documenting history of prior alloantibodies.

Given the high prevalence of infectious etiologies for ACS, we recommend the use of empirical antimicrobial therapy in all patients. Considering the high prevalence of atypical bacteria and encapsulated organisms, empirical coverage should include agents effective against these organisms, such as the macrolides or fluoroquinolones. It is also important to consider alternative organisms such as methicillin-resistant *S. aureus* or influenza viruses, especially in patients not responding to therapy or during influenza season.

Although not demonstrated in randomized trials, blood transfusion remains the mainstay of ACS therapy. Acute red cell transfusion increases arterial Po_2 and hemoglobin oxygen saturation and may rapidly resolve the pulmonary event.[43,62] In order to avoid the effects of increasing viscosity and the consequent risk of vaso-occlusion, it is not recommended to increase the hemoglobin level higher than 11 g/dL after simple transfusion. The National Acute Chest Syndrome Study Group found no significant differences in outcomes between patients treated with simple transfusion or a red cell exchange (erythrocytopheresis), suggesting that the former approach is preferred as initial therapy.[43] Patients with high initial hemoglobin concentrations (≥9 g/dL), or patients with more severe disease should receive erythrocytopheresis. However, most patients have a significant decrease in hemoglobin at presentation, allowing for the transfusion of 2 to 4 units of packed red cells over 24 to 48 hours without complication. In order to decrease the risk of delayed hemolytic transfusion reactions related to alloimmunization against minor red

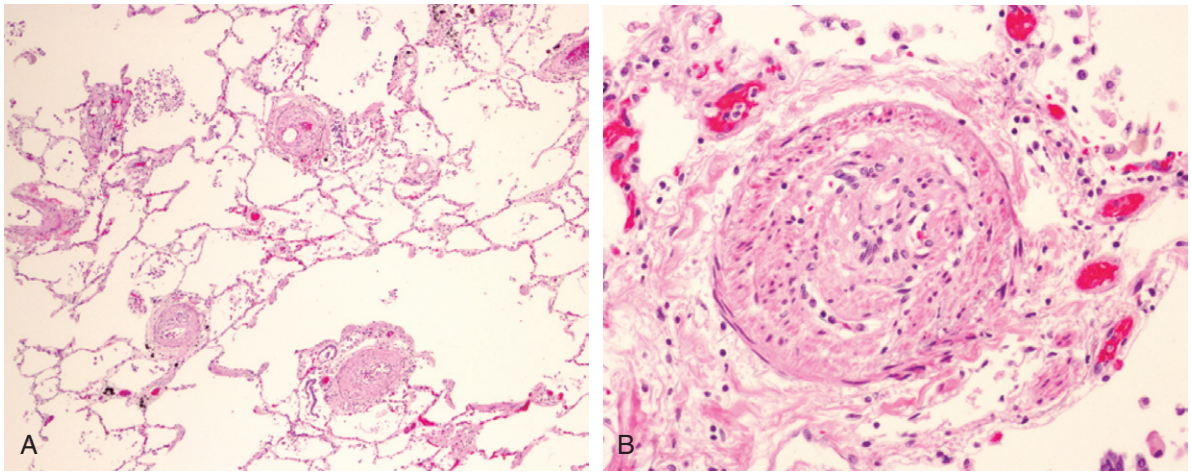

FIGURE 84-3 ■ Pulmonary arteriopathy in sickle cell–related pulmonary hypertension. **A,** Low-power photomicrograph demonstrating pulmonary arterial smooth muscle hypertrophy. (Hematoxylin and eosin stain). **B,** Plexogenic lesion. (Hematoxylin and eosin stain).

blood cell antigens, all transfused blood should be matched to Rh, C, E, and Kell antigens.

Treatment with corticosteroids has been shown to reduce the severity of pain and length of hospitalization, but this therapy is complicated by a high rate of rebound pain and hospitalization.[63,64] Ongoing studies are evaluating strategies to maintain the beneficial effects of corticosteroids while limiting rebound pain and readmission using slow tapering protocols. Inhaled NO has been shown in case studies to improve oxygenation and reduce pulmonary hypertension in mechanically ventilated patients with severe lung injury, and active clinical trials for vaso-occlusive crisis are ongoing.[65-67]

Pulmonary Hypertension

Among the chronic cardiopulmonary complications of sickle cell disease, pulmonary hypertension has emerged as the major threat to the well-being and longevity of patients with sickle cell disease. Sickle cell disease could represent one of the most common causes of pulmonary hypertension. There are 30 million individuals worldwide with sickle cell disease.[68] Given that pulmonary hypertension occurs in 10% to 30% of these patients, there may be as many as 3 to 9 million patients with the disease worldwide.

Epidemiology. Retrospective studies have reported that 20% to 30% of patients with sickle cell disease have pulmonary hypertension.[57,69] In these studies, patients with pulmonary hypertension had a significantly increased mortality rate compared with patients without pulmonary hypertension. Sutton and colleagues reported a 40% mortality rate at 22 months with an odds ratio for death of 7.86 (range, 2.63 to 23.4).[69] Powars and colleagues reported a mean 2.5-year survival in sickle cell patients with chronic lung disease with pulmonary hypertension.[40] Castro and colleagues[70] similarly reported a 50% 2-year mortality rate in patients with sickle cell disease with pulmonary hypertension confirmed by right heart catheterization. In addition, autopsy studies suggest that up to 75% of sickle cell patients have histologic evidence of pulmonary arterial hypertension at the time of death (Fig. 84-3).[71]

These data are now corroborated by three prospective studies.[33,72,73] In the National Institutes of Health pulmonary hypertension echocardiographic screening study, 23% of patients with sickle cell disease had borderline to mild elevations in pulmonary artery systolic pressures (defined by a tricuspid regurgitant jet velocity [TRV] of ≥ 2.5 to 2.9 m/sec, which corresponds to a pulmonary artery systolic pressure of approximately 30 to 39 mm Hg) and 9% had moderately to severely elevated pressures (defined by a TRV ≥ 3.0 m/sec, which corresponds to a pulmonary artery systolic pressure of approximately 40 to 45 mm Hg).[33] Similar rates were found in echocardiographic screening studies performed at two other centers.[72,73] Measurement of N-terminal pro–brain natriuretic peptide (NT-proBNP), a prohormone released by the right and left ventricular myocardium under pressure stress, in stored plasma samples showed that 30% of individuals enrolled in the MSH in 1996 had elevated levels, suggesting the possible presence of pulmonary hypertension.[74] Two centers independently reported the follow-up of adult sickle patients who on initial echocardiographic screening had normal TRVs. After 2 to 3 years of follow-up, 13% to 15% of these patients developed high TRVs, suggesting a pulmonary hypertension incidence of about 4% to 7% per year.[72,75]

Increasing age is associated with an increased risk of pulmonary hypertension. For example, in the National Institutes of Health pulmonary hypertension echocardiographic screening study, patients with pulmonary hypertension were significantly older than patients without pulmonary hypertension (38 ± 19 years for patients with TRV ≥ 3.0 m/sec, 39 ± 12 years for patients with TRV 2.5 to 2.9 m/sec, and 34 ± 10 years for patients with TRV < 2.5 m/sec; $P = 0.02$).[33] An increasing number of studies suggest that pulmonary hypertension is developing in children with sickle cell disease; however, few children have TRV values greater than 3.0 m/sec, and the implications in terms of functional capacity and associated mortality have not been determined.[76-79]

Epidemiologic risk factors associated with pulmonary hypertension include a history of renal or cardiovascular complications, increased systemic systolic blood pressure, elevations in the marker of hemolysis (LDH), elevated alkaline phosphatase, and low transferrin levels.[33,74] In men, a history of priapism was also an independent factor associated with pulmonary hypertension.[33] These data suggest that pulmonary hypertension represents a component of the systemic vasculopathy of sickle cell disease (characterized by systemic hypertension, renal failure, and priapism), and that it is linked to hemolytic rate, iron overload, and cholestatic hepatic dysfunction. Interestingly, the development of pulmonary hypertension was not associated with the number of vaso-occlusive episodes, markers of inflammation, fetal hemoglobin levels, or platelet counts.[33,74] Finally, a high pulmonary artery pressure could also result from the high cardiac output state associated with chronic anemia. However, this hyperdynamic state does not seem to be a major contributor to significant elevations in pulmonary artery pressures as there has been no report of pulmonary hypertension associated with non-hemolytic anemia.

Pulmonary hypertension increases the risk of death for patients with sickle cell disease. In the National Institutes of Health study, compared to patients with TRV less than 2.5 m/sec, the rate ratios for death for TRVs of 2.5 to 2.9 m/sec and greater than 3.0 m/sec were 4.4 (95% confidence interval [CI], 1.6 to 12.2; $P < 0.001$) and 10.6 (95% CI, 3.3 to 33.6; $P < 0.001$), respectively.[33] In support of these findings, De Castro and colleagues found that 6 of 42 patients (14%) with pulmonary hypertension and 2 of 83 patients (2%) without pulmonary hypertension died during a 2-year follow-up period.[73] Similarly, in the study by Ataga and colleagues, 9 of 36 patients with pulmonary hypertension and 1 of 57 patients without pulmonary hypertension died during the 2.5-year follow-up period (relative risk, 9.24 [95% CI, 1.2 to 73.3]).[72]

Pathogenesis. Epidemiologic studies suggest that the central risk factor for the development of pulmonary hypertension in patients with sickle cell disease is the severity of hemolytic anemia (Fig. 84-4).[33,72,73,80] The association between the development of pulmonary hypertension and the intensity of hemolytic anemia has been observed in three prospective screening studies of adult patients with sickle cell disease,[33,72,73] and in an expanding number of pediatric studies.[76–78,81,82] This suggests that hemolysis is related mechanistically to pulmonary hypertension. That relationship is plausible and biologically significant since free hemoglobin inactivates the intrinsic vasodilator NO.[14,32] Hemolysis also releases arginase, which depletes L-arginine, the substrate for NO synthesis.[31] These combined mechanisms result in a state of decreased NO bioavailability and "resistance" to NO-dependent vasodilation.[14]

Hemolysis and decreased NO bioavailability also induce platelet activation,[83] thrombin generation, and tissue factor activation.[84] There is also a correlation between the rate of hemolysis and the levels of procoagulant factors in blood in patients with sickle cell disease.[85–87] Hemolysis is also associated with the formation of red blood cell microvesicles expressing phosphatidylserine, which activates tissue factor.[87,88] These factors all contribute to an increased risk of thrombosis. In addition, sickle cell patients with functional asplenia and thalassemia patients with surgical splenectomy have increased levels of cell-free hemoglobin and red cell microvesicles, providing a potential mechanism for the hypercoagulability associated with both diseases, with possible exacerbation by asplenia.[87] Finally, the accumulation of redox-active heme and iron from lysed red blood cells further contributes to the generation of reactive oxygen species that can exacerbate ischemia-reperfusion injury, thrombosis, and vascular proliferative responses.[89]

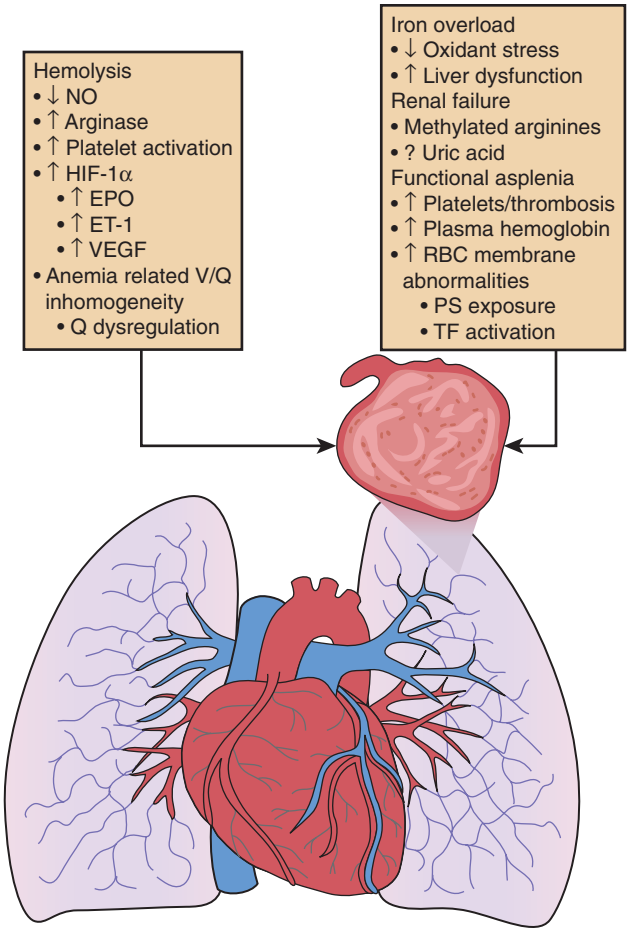

FIGURE 84-4 ■ Multifactorial pathogenesis of pulmonary hypertension in sickle cell disease. EPO, erythropoietin; ET-1, endothelin-1; HIF, hypoxia inducible factor; NO, nitric oxide; PS, phosphatidylserine; Q, cardiac output; TF, tissue factor; VEGF, vascular endothelial growth factor.

Another downstream effect of hemolytic anemia includes increased endothelin-1–mediated vasoconstrictive and proliferative responses. In patients with sickle cell disease, both at steady state and during vaso-occlusive pain crises, plasma endothelin-1 levels are increased.[90] In vitro, sickled erythrocytes increase endothelin-1 production by cultured human endothelial cells. In addition, endothelin receptor A antagonism abolishes the vasoconstrictive effects of media from pulmonary endothelial cells exposed to sickled erythrocytes on aortic rings.[90]

Functional or surgical asplenia could also contribute to the development of pulmonary hypertension in patients with sickle cell disease. Splenectomy has been reported to be a risk factor for the development of pulmonary hypertension,[91] particularly in patients with hemolytic disorders.[92–94] Loss of splenic function may trigger platelet activation, promoting pulmonary microthrombosis and red cell adhesion to the endothelium.[95] The spleen also plays a critical function in the removal of senescent and damaged erythrocytes.[96,97] Following splenectomy, moreover, the rate of intravascular hemolysis increases.[87]

Historically, pulmonary hypertension in patients with sickle cell disease was thought to derive from the repetitive episodes of pulmonary vaso-occlusive crisis and ACS leading to pulmonary fibrosis, vascular obstruction, and chronic hypoxia. However, this association has not been supported by epidemiologic studies, since the number of episodes of vaso-occlusive crisis and ACS is not associated with pulmonary hypertension.[33,74]

Clinical Manifestations and Evaluation. The diagnostic evaluation of patients with sickle cell disease suspected of having pulmonary hypertension should follow the same guidelines established for other causes of pulmonary hypertension.[98,99] Given the high prevalence of pulmonary hypertension in this population and the associated high mortality, we recommend universal noninvasive screening of all adults with Doppler echocardiography or by assessment of steady-state plasma NT-proBNP levels. In patients with sickle cell disease, the echocardiographic estimation of pulmonary artery systolic pressures (where pulmonary artery systolic pressure = $4^{*}TRV^{2}$ + estimate of the right atrial pressure) correlates well with measured pulmonary systolic pressures by right heart catheterization.[33] A TRV greater than or equal to 2.5 m/sec (which corresponds to an estimated pulmonary artery systolic pressure of 35 mm Hg), is approximately 2 standard deviations above normal for individuals less than 40 years of age (normal reference mean is 27.5 ± 4.2 with a 95% CI of 19.3 to 35.5 mm Hg).[100] In addition, even considering that a more traditional echocardiographic definition of pulmonary hypertension would be a TRV greater than or equal to 3.0 m/sec, in patients with sickle cell disease values between 2.5 and 2.9 m/sec are associated with high a risk of death.[33,72,73]

While no prospective data on prevalence and risk of pulmonary hypertension are available for children, we currently recommend that children with hypoxemia, high hemolytic rates (hemoglobin values < 7 g/dL with high LDH values), and/or recurrent ACS be screened. It is important that such screening be performed in the steady state, as pulmonary pressures rise during vaso-occlusive painful crisis.[101]

The diagnosis of pulmonary hypertension in patients with sickle cell disease can be challenging (Fig. 84-5). Exertional dyspnea, the most typical presentation of pulmonary hypertension, is also a cardinal symptom of chronic anemia, and therefore a high index of suspicion for the disease is necessary. Other conditions commonly present in patients with sickle cell disease, such as left ventricular dysfunction, pulmonary fibrosis, and liver cirrhosis, could also present in a similar fashion and could also result in pulmonary hypertension. Patients with pulmonary hypertension tend to be older and have higher systolic arterial blood pressure, lower hemoglobin levels, higher indices of hemolysis (such as high bilirubin or LDH values), lower hemoglobin oxygen saturation, greater degree of renal and liver dysfunction, and a higher number of lifetime red blood cell transfusions.[33] As such, the diagnostic evaluation of these patients should include an aggressive search for other conditions that might contribute to pulmonary hypertension, such as iron overload, chronic liver disease, human immunodeficiency virus (HIV), nocturnal hypoxemia, and thromboembolism. A diagnostic right heart catheterization is essential to confirm the diagnosis and exclude diastolic dysfunction.[98] The 6-minute walk test is a useful surrogate for functional capacity in this patient population even considering the high prevalence of confounding factors such as the presence of avascular necrosis of the hip. Specifically, the 6-minute walk test inversely correlates with the severity of pulmonary hypertension,[102] and pulmonary hypertension–specific therapy improves walk distance.[103]

Most adult patients with sickle cell disease develop abnormal pulmonary function characterized by mild restrictive lung disease (mean total lung capacity values of approximately 79% of predicted), abnormal diffusing capacity, and radiographic signs of mild pulmonary fibrosis,[40,104–108] and the severity of these defects seems to be slightly greater in those patients with pulmonary hypertension.[102] However, in these patients the degree of pulmonary function abnormalities is rarely severe enough to be a major contributor to the etiology of pulmonary hypertension.

A ventilation-perfusion scan is an indispensable component of the evaluation because chronic thromboembolic pulmonary hypertension if amenable to pulmonary endarterectomy is a potential curable cause of pulmonary hypertension that has been reported in patients with chronic hemolytic disorders. In the majority of cases, observed scintigraphic evidence of thromboembolic disease is uncommon, and the most commonly seen abnormality is patchy areas of abnormal perfusion, similar to findings described in other forms of pulmonary hypertension.[102,109] However, chronic thromboembolic pulmonary hypertension occurs in approximately 5% of sickle cell patients with severe pulmonary hypertension,[102] and the disease has been treated surgically with success in two patients with sickle cell disease (Fig. 84-6).[110] As such, patients should undergo imaging studies and, if suggestive of chronic thromboembolic pulmonary hypertension, should undergo more invasive studies (i.e., angiography) to exclude this potentially surgically treatable condition.

Measurement of NT-proBNP levels can be used as a pulmonary hypertension biomarker for diagnosis and risk stratification in patients with sickle cell disease.[74] In a contemporaneous cohort, NT-proBNP levels were higher in patients with sickle cell pulmonary hypertension and correlated directly with the severity of pulmonary arterial hypertension and the degree of functional impairment. An NT-proBNP level of 160 pg/mL or greater

Data from references 3, 70, 102.

had a 78% positive predictive value for the diagnosis of pulmonary hypertension and was an independent predictor of mortality (risk ratio, 5.1; 95% CI, 2.1 to 12.5; $P < 0.001$). In a subset of individuals participating in the MSH patient follow-up study in 1996, 30% of patients had an NT-proBNP level of 160 pg/mL or greater. An NT-proBNP level of 160 pg/mL or greater in the MSH cohort was independently associated with mortality by Cox proportional hazards regression analysis (2.87; 95% CI, 1.2 to 6.6; $P = 0.02$).

In contrast to patients with traditional forms of pulmonary arterial hypertension (e.g., idiopathic, scleroderma associated), who are symptomatic with mean pulmonary artery pressures (mPAPs) in the range of 50 to 60 mm Hg, in patients with sickle cell disease the degree of elevation in mPAPs is mild to moderate, in the range of 30 to 40 mm Hg, with mild elevations in pulmonary vascular resistance. These patients also have coexistent mild elevation in pulmonary capillary wedge pressure, suggesting left heart failure (Table 84-4). Right heart catheterization data show that the hemodynamic etiology of the pulmonary hypertension in these patients is multifactorial: pulmonary arterial hypertension (defined by an mPAP ≥ 25 mm Hg and a wedge pressure ≤ 15 mm Hg) was present in 54% of catheterized patients at the National Institutes of Health, while pulmonary venous hypertension secondary to left heart disease (defined by an mPAP ≥ 25 mm Hg and a wedge pressure > 15 mm Hg) was present in 46%.[102] Further, using echocardiography in a cohort of 141 patients with sickle cell disease, Sachdev and associates[111] found that 47% of patients had pulmonary hypertension, diastolic dysfunction, or both (29% had pulmonary hypertension alone, 11% had diastolic dysfunction and pulmonary hypertension, and 7% had diastolic dysfunction alone). Pulmonary hypertension and diastolic dysfunction were associated with a relative risk of death of 5.1 (95% CI, 2.0 to 13.3) and 4.8 (95% CI, 1.9 to 12.1), respectively, while the relative risk of death when both were present was 12.0 (95% CI, 3.8 to 38.1).[111] These data suggest that both pulmonary hypertension and diastolic dysfunction independently carry additive mortality risk.

Regardless of the hemodynamic etiology, sickle cell disease patients with chronic anemia, who maintain a high compensatory resting cardiac output in order to ensure adequate oxygen delivery, appear to be poorly tolerant of even small additional increases in pulmonary vascular resistance. When compared to age-, gender-, and hemoglobin-matched patients with sickle cell disease without pulmonary hypertension, individuals with pulmonary hypertension and mPAP of 36 mm Hg exhibit lower 6-minute walk distance (435 ± 31 vs. 320 ± 20 meters; $p = 0.002$) and peak oxygen consumption on cardiopulmonary exercise testing (50 ± 3% vs. 41 ± 2% of predicted; $P = 0.02$).[102] Patients with pulmonary arterial hypertension from other etiologies with a higher mPAP (54 mm Hg) also perform better on 6-minute walk testing (398 m) and exercise testing (46% of predicted).[112] In addition, in patients with sickle cell disease, pulmonary artery vascular resistance sharply rises with exercise suggesting that pulmonary vascular disease contributes to functional limitation in these patients.[101] Taken together, these data suggest that, in patients with chronic anemia, mild to moderate pulmonary hypertension has

a severe adverse impact on functional and aerobic exercise capacity.

Treatment. There are limited data on the specific management of patients with sickle cell disease and pulmonary hypertension. Most of the recommendations are based on expert opinion or extrapolated from data derived from other forms of pulmonary hypertension. The general approach should include maximization of sickle cell disease–specific therapy (i.e., treatment of primary hemoglobinopathy), treatment of hypoxia with chronic oxygen therapy, treatment of associated cardiopulmonary conditions (such as iron overload, chronic liver disease, HIV infection, nocturnal hypoxemia, and thromboembolic disorders), and targeted therapy with pulmonary vasodilator/anti-remodeling agents (Fig. 84-7).

Because chronic intravascular hemolysis is a central mechanism in the development of pulmonary hypertension, it is likely that optimizing sickle cell disease therapy would be beneficial through amelioration of the principal mechanism involved in the pathogenesis of pulmonary hypertension. Hydroxyurea has been shown to decrease the incidence of pain episodes and ACS, to reduce the need for transfusions, and to lower overall mortality.[42,59] It is possible that some of the decreases in pulmonary and cardiovascular deaths seen in hydroxyurea-treated patients could be related to an improvement in pulmonary hypertension. However, these considerations have to be balanced with the lack of association between fetal hemoglobin levels and the use of hydroxyurea, and protection against the development of pulmonary hypertension.[33] For patients with creatinine levels less than 1 mg/dL, hydroxyurea is started at a dose of 15 mg/kg/day and titrated up to a maximum of 35 mg/kg/day. Recent detailed treatment guidelines have been published.[60,113] Patients with renal dysfunction tend not to tolerate the myelosuppressant effects of hydroxyurea, and in those cases, we recommend the addition of erythropoietin to the regimen. Long-term transfusion therapy lowers the risk of most complications of the disease, including the risks of pulmonary events and central nervous system vasculopathy,[114-116] and might improve cardiopulmonary function and prevent the progression of pulmonary hypertension.

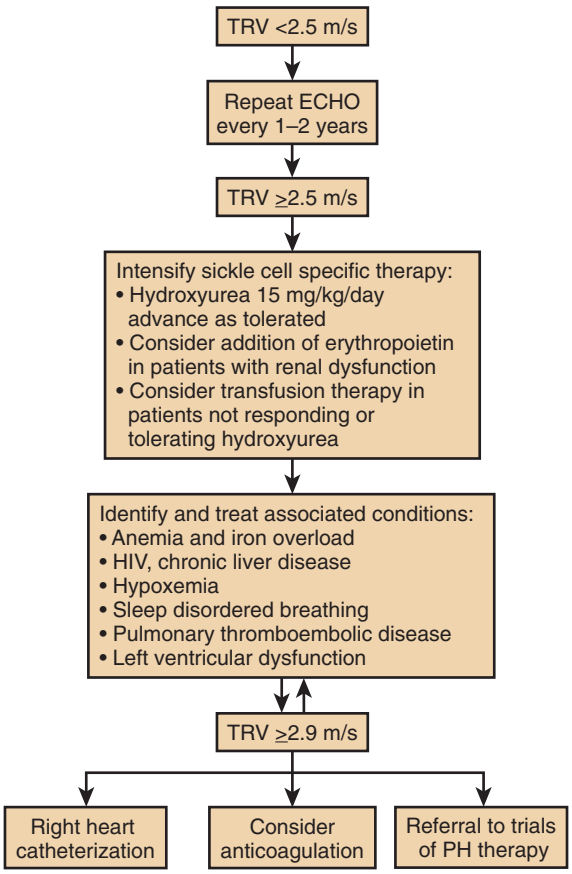

FIGURE 84-7 ■ Treatment algorithm in patients with sickle cell disease and pulmonary hypertension. TRV, tricuspid regurgitation velocity.

The potential benefits of warfarin therapy observed in patients with idiopathic pulmonary arterial hypertension[117] have to be weighed against the risk of hemorrhagic stroke in adults with sickle cell disease or hemorrhage in chronically anemic individuals. We believe that the relatively low risk of hemorrhagic stroke (0.21 events per 100 patient-years[118]) compared with the high risk of death in patients with severe pulmonary hypertension supports anticoagulation in patients with hemodynamic evidence of pulmonary arterial hypertension or chronic thromboembolic pulmonary hypertension and without a specific contraindication.

There are no long-term data on the specific treatment of pulmonary hypertension in sickle cell disease, and the choice of agents is largely empirical and based on the safety profile of the drugs and physician preference. However, there are specific treatment concerns regarding the use of these drugs in patients with hemolytic diseases. The use of prostanoids can produce systemic vasodilation and increases in cardiac output, raising the concern for the potential development of high-output heart failure in anemic patients. In addition, the risk of chronic intravenous-line–related complications such as thrombosis and sepsis is likely higher in patients with sickle cell disease. The main toxicity of endothelin-1 receptor antagonists is hepatocellular injury, which could limit their applicability in patients with sickle cell disease at risk for liver dysfunction (e.g., iron overload, hepatitis C). Another class effect of these agents is a dose-related decrease in hemoglobin levels, usually in the range of 1 g/dL.[112] The main concern related to the use of sildenafil is the potential for the development of priapism in men with sickle cell disease.

Therapeutic interventions that enhance NO effects may be of potential benefit since alterations in NO bioavailability are involved in the pathogenesis of the pulmonary hypertension associated with sickle cell disease. Chronic inhaled NO selectively dilates the pulmonary vasculature, but its use is investigational and expensive and requires a complicated delivery system.[119] L-Arginine (0.1 g/kg three times daily) has been shown to decrease pulmonary artery systolic pressure by 15% in a small study of sickle cell patients[120] and seems promising as

another approach to improving NO bioavailability. Sildenafil functions by inhibiting the metabolism of cyclic guanosine monophosphate, the second messenger that mediates the effects of NO. In a series of seven patients with either thalassemia or sickle thalassemia and severe pulmonary hypertension, treatment with sildenafil from 4 weeks to 48 months resulted in an improvement in TRV, New York Heart Association functional class, and 6-minute walk distance.[121] In another case series, 12 patients with sickle cell disease were treated with sildenafil for a mean of 6 months. Mean pulmonary artery systolic pressure decreased by 9 mm Hg (95% CI, 0.3 to 17; p = 0.047), 6-minute walk distance improved by 78 m (95% CI, 40 to 117; p = 0.003), and mean brain natriuretic peptide decreased by 448 pg/ml (p = 0.002).[103]

The published experience with endothelin antagonists in the treatment of pulmonary hypertension is also very limited. Minniti et al[121a] reported on the use of bosentan and ambrisentan in a cohort of 14 patients with sickle cell disease and pulmonary hypertension documented by heart catheterization. Endothelin antagonist therapy either as monotherapy or in combination with sildenafil was well tolerated and resulted in a modest improvement in six-minute walk distance (baseline 357 ± 22 vs. 398 ± 18 m 6 months post-therapy, $P < 0.05$). There are no published case series of prostanoid therapy in this population.

Two randomized multicenter placebo controlled studies evaluating the role of pulmonary hypertension therapy in patients with sickle cell disease have been conducted. The ASSET-1 and ASSET-2 studies enrolled patients with pulmonary arterial hypertension and pulmonary venous hypertension, respectively who were randomized to bosentan or placebo. After enrollment of 26 subjects the studies were terminated due to slow site activation and patient recruitment. In that limited sample of patients bosentan was well tolerated with no significant differences in serious averse events or laboratory tests between patients receiving study drug or placebo but efficacy endpoints could not be formally analyzed.[121b] Walk-PHaSST (Pulmonary Hypertension and Sickle Cell Disease with Sildenafil Therapy) was a trial evaluating the safety and efficacy of oral sildenafil for the treatment of Doppler defined pulmonary hypertension (tricuspid regurgitant jet velocity ≥2.7 m/s) in adults and children (aged >12 years) with sickle cell disease. After 74 (out of a planned 132) subjects were enrolled the study was discontinued due to a significant increase in hospitalizations due to vaso-occlusive pain crisis in the sildenafil arm. In that study, patients were not required to be on hydroxyurea and/or chronic transfusion therapy for sickle cell disease. Thus, it is uncertain whether these adverse effects could be mitigated by intensification of sickle cell disease specific therapy prior to the initiation of sildenafil treatment.

Chronic Lung Disease

"Sickle cell chronic lung disease" has been used as a wastebasket term to encompass pulmonary fibrosis from recurrent ACS and pulmonary hypertension.[40] Our current understanding of sickle cell chronic lung disease suggests that pulmonary fibrosis is quite mild, and that pulmonary hypertension is a more important cause of chronic pulmonary disease. For this reason, we feel that this older terminology should be replaced with a more specific diagnostic classification.

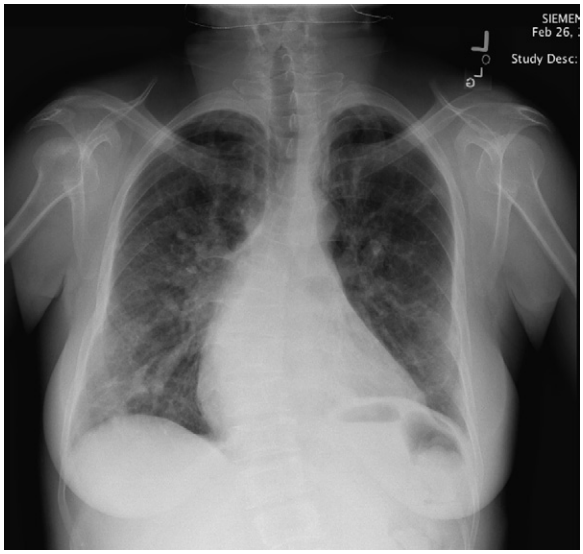

FIGURE 84-8 ■ Pulmonary fibrosis complicating multiple episodes of acute chest syndrome.

In patients with sickle cell disease, repetitive episodes of acute lung injury (ALI) related to ACS can result in parenchymal damage and typically mild restrictive lung disease (Fig. 84-8). In a study of 310 patients with homozygous sickle cell disease, pulmonary function was abnormal in 90% of adult patients; the most common abnormalities included mild restrictive physiology and decreased D_{LCO}.[122] These abnormalities worsen with age and are associated with increases in pulmonary artery pressures.[102,122] In contrast, airway hyperactivity is much more common in children.[123] Data are conflicting on whether children with sickle cell disease have a much higher prevalence of asthma and airway hyperactivity, when compared to ethnically and aged-matched controls.[47,124] It is increasingly apparent that children with a history of asthma appear to have a higher incidence of ACS, cerebral vascular accidents, and need for blood transfusions, arguing for aggressive diagnosis and treatment of asthma in this population.[47,48,125]

Sleep-disordered breathing has been reported in both children and adults with sickle cell disease. In children, sleep-related upper airway obstruction and hypoxemia are the most common disturbances. In an uncontrolled study, adenotonsillectomy led to symptomatic improvement and amelioration of oxygen desaturation.[126,127] Several lines of evidence suggest that nocturnal hypoxemia contributes to the development of neurologic events and vaso-occlusive crisis via mechanisms that could involve up-regulation of several inflammatory endothelial cell adhesion molecules.[128–130]

Thalassemia

Thalassemia refers to a spectrum of diseases characterized by reduced or absent production of one or more α or β globin chains. β-Thalassemia is due to impaired production of β globin chains, which leads to a relative excess of α globin chains.[131] These excess α globin chains are unstable, incapable of forming soluble tetramers on their own, and precipitate within the cell, leading to ineffective erythropoiesis and hemolytic anemia.[131] Thalassemia major, or homozygous β-thalassemia, is a severe disorder due to the inheritance of two β-thalassemia alleles. Starting during the first year of life, patients develop severe and lifelong transfusion-dependent anemia, hepatosplenomegaly, and skeletal deformities due to bone marrow expansion; they are prone to infection and skeletal fractures. β-Thalassemia minor, also called β-thalassemia trait, occurs in heterozygotes who have inherited a single gene leading to reduced β globin chain production. Such patients are asymptomatic, may be only mildly anemic, and are usually discovered when a blood count has been obtained for other reasons. β-Thalassemia intermedia occurs in patients with disease of intermediate severity, such as those who are compound heterozygotes of two thalassemic variants. Such patients may have the skeletal abnormalities and hepatosplenomegaly seen in thalassemia major. However, their hemoglobin concentrations usually range from 5 to 10 g/dL and they usually require transfusions only when they have an intercurrent event, such as an infection, that impairs erythropoiesis. Their clinical symptoms may not be apparent until well after the first year of life. Hemoglobin E, which is the most common hemoglobin variant in the world, is mostly asymptomatic or associated with a mild microcytic anemia in its heterozygous or homozygous states. Because hemoglobin E is synthesized at a reduced rate, it can interact with β-thalassemia to produce a condition called hemoglobin E–thalassemia. About half of these patients are phenotypically similar to patients with thalassemia major and require regular transfusion therapy, with the other half having courses similar to patients with thalassemia intermedia.

Several physiologic abnormalities arise in patients with β-thalassemia, including restrictive and obstructive defects, hyperinflation, abnormal diffusion, and decreases in aerobic exercise capacity.[132–134] However, in the majority of cases, these pulmonary function abnormalities are not associated with clinical symptoms. Several of the clinical complications related to thalassemia are related to complications of therapy such as transfusion-related iron overload, infection, thrombosis, possibly acute deterioration in pulmonary function associated with the use of the iron chelator deferoxamine, and pulmonary hypertension related to splenectomy. In patients who are poorly transfused, extramedullary erythropoiesis can rarely cause pulmonary parenchymal masses and pleural effusions.

Similar to sickle cell disease, pulmonary hypertension is a common complication of thalassemia. Echocardiographic screening studies of patients with thalassemia intermedia suggest that approximately 40% to 50% of patients with thalassemia intermedia[135] and 10% to 75% of patients with thalassemia major have echocardiographic evidence of pulmonary hypertension.[136–138] In spite of its potential complications, chronic transfusion therapy in severe thalassemia has changed the clinical course of the disease and is likely to have a favorable impact in individuals with pulmonary hypertension. This idea is supported by a report that, in well-transfused, iron-chelated patients with thalassaemia major, pulmonary hypertension was completely prevented.[139] A favorable response to sildenafil has been reported in patients with thalassemia major and intermedia.[121,140] To date, however, there are no studies evaluating the specific hemodynamic derangements associated with pulmonary hypertension nor the impact of pulmonary hypertension on survival in this patient population.

Other Hemoglobin Disorders

Hemoglobin gene mutations can result in functional abnormalities in the globin chains that alter gas ligand affinity and alter oxygen uptake and delivery. Remarkably, there are more than 120 human hemoglobin gene mutations that have been associated with abnormal hemoglobin oxygen affinity.[141] Patients with high-affinity hemoglobins usually present with erythrocytosis and are usually asymptomatic, but patients with variants associated with very high oxygen affinity can present with cyanosis or symptoms related to increased red blood cell mass (polycythemia). While patients with low-oxygen-affinity hemoglobin variants are usually asymptomatic, some can present with cyanosis. The initial step in the workup of patients suspected of having a hemoglobinopathy affecting oxygen affinity is to evaluate the red cell oxygen equilibrium curve, where both the oxygen saturation of hemoglobin and partial pressure of oxygen are directly measured to obtain a p50, the partial pressure of oxygen at which hemoglobin is 50% saturated. This approach should obviate the need for unnecessary and potentially invasive diagnostic procedures.

Methemoglobin is a nonfunctional state of hemoglobin in which the irons of heme are oxidized to the ferric (Fe^{3+}) state and are unable to bind oxygen. In addition, the oxygen affinity of any accompanying ferrous hemes in the hemoglobin tetramer are increased such that the oxygen dissociation curve is "left-shifted" and oxygen delivery to the tissues is impaired.[142] Three mechanisms are associated with the development of methemoglobinemia: genetic mutation resulting in abnormal hemoglobin (hemoglobin M), congenital deficiency of methemoglobin reductase enzyme (cytochrome b_5 or cytochrome-b_5 reductase deficiency), and drug/toxin-induced oxidation of hemoglobin. Most individuals with congenital methemoglobinemia are asymptomatic, and their primary complaint is "cyanosis" presenting as a slate-blue color of the skin and mucous membranes.

Cyanosis is clinically detected when the absolute concentration of methemoglobin exceeds 1.5 g/dL, equivalent to approximately 10% methemoglobin.[143] In cases associated with drugs and toxins, the severity of the

methemoglobinemia depends on the dose of the agent and the individual's susceptibility. Methemoglobin levels greater than 35% cause headaches, weakness, and dyspnea; levels greater than 80% are typically incompatible with life.[141] Symptomatic patients should be treated with methylene blue given intravenously at a dose of 1 to 2 mg/kg, which acts as a cofactor for the enzyme NADPH methemoglobin reductase. Electrons are transferred from NADPH to methylene blue, which leads to a reduction of the heme iron, in the form of deoxyhemoglobin.[144] Methylene blue should not be administered to individuals with glucose 6-phosphate dehydrogenase deficiency as it may precipitate hemolysis.[145]

Carbon monoxide (CO) binds to hemoglobin with much greater affinity than oxygen, forming carboxyhemoglobin (COHb). Once CO binds to heme, an allosteric change occurs that diminishes the ability of hemoglobin oxygen binding sites to off-load oxygen to peripheral tissues, resulting in impaired oxygen transport and utilization. As such, CO poisoning is a major cause of morbidity and mortality. The clinical effects of CO poisoning are non-specific and easily confused with other illnesses, such as viral illness, benign headache, and various cardiovascular and neurologic syndromes.[145a] As the severity of exposure increases, patients develop more pronounced symptoms, with oxygen-dependent organs (the brain and the heart) showing the earliest signs of injury. Oxygen therapy improves tissue hypoxia and accelerates elimination of CO. Hyperbaric oxygen therapy should be considered in patients with severe CO poisoning (such as COHb > 25%, evidence of tissue ischemia and loss of consciousness) and may reduce the incidence of the late neurocognitive deficits associated with severe CO intoxication.[145b,145c]

Cyanide binds the ferric ion (Fe3+) of cytochrome oxidase a3, inhibiting this final enzyme in the mitochondrial cytochrome complex preventing oxygen utilization by tissues. A small amount of cyanide can bind to the ferrous (Fe2+) iron of hemoglobin, forming cyanohemoglobin, which is unable to transport oxygen, and further exacerbates tissue hypoxia in patients exposed to cyanide.[145d]

WHITE BLOOD CELL DISORDERS

Leukemias

Although the majority of clinical pulmonary manifestations in patients with leukemia are not related to the disease itself, autopsy studies show that thoracic involvement is common in all leukemia types. Overall, the most common finding is mediastinal and lymph node involvement, but pleural and pulmonary infiltration is found in 20% to 65% of autopsy series.[146-148]

The mediastinum is the most commonly affected intrathoracic site. This is often manifest as a focal mass or generalized mediastinal involvement. Hilar adenopathy occurs in 15% to 25% of patients.[149,150] Pleural effusion, usually unilateral, can occur in up to 25% of cases and presents more frequently in myeloid leukemias.[151] In the majority of cases, the effusion is related to lymphatic obstruction, congestive heart failure, or infections, with only approximately 5% of cases caused by leukemic infiltration.[151]

Clinically significant leukemic pulmonary infiltrates occur in approximately 10% of patients (Fig. 84-9).[146] The usual radiographic pattern of involvement is a bilateral reticular pattern with septal lines resembling interstitial edema or lymphangitic carcinomatosis. Interlobular smooth or nodular septal thickening is the most common high-resolution computed tomography finding, followed by thickening of bronchovascular bundles. Other manifestations include peribronchovascular or random nodules, which can coalesce into masslike consolidation, focal areas of air space disease, and ground-glass opacities.[151-154] The diagnosis of leukemic infiltrates is one of exclusion as most of the pulmonary parenchymal abnormalities in these patients are associated with processes other than the hematologic disease, such as infections, hemorrhage, or pulmonary edema.

Pulmonary leukostasis or hyperleukocytosis is characterized by the distention of small pulmonary vessels by leukemic blast cells. It is most commonly seen in patients with acute leukemias and white blood cell counts greater than 100,000/mm^3 with a predominance of blast cells.[155]

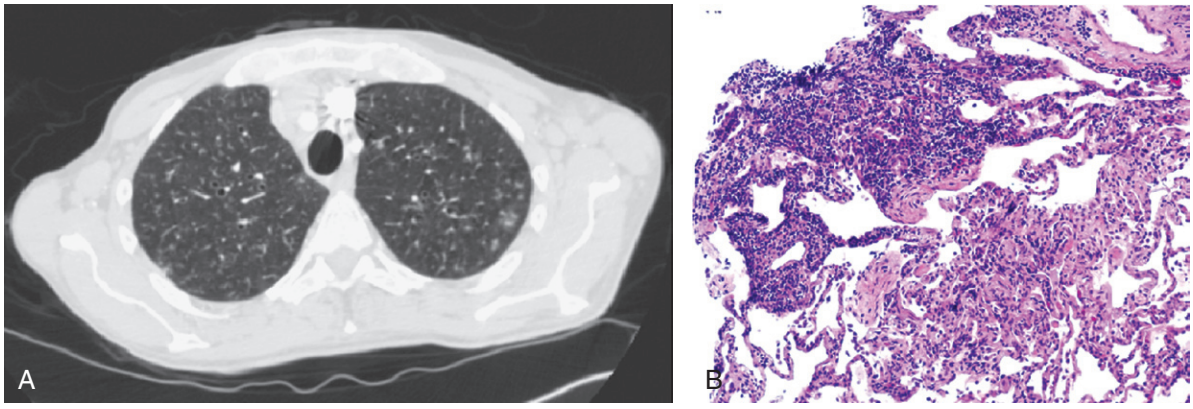

FIGURE 84-9 ■ Leukemic infiltrates in a patient with chronic lymphocytic leukemia. **A,** Diffuse nodular infiltrates. **B,** Transbronchial biopsy specimen demonstrating diffuse infiltration of lung interstitium by leukemic cells. (Hematoxylin and eosin stain).

Clinical and radiographic findings include dyspnea and hypoxia that are associated with a bilateral reticular pattern with septal lines or air space consolidation.[155,156] Symptomatic leukostasis is a medical emergency, and efforts should be made to lower the white blood cell count rapidly. In most patients, rapid cytoreduction can be achieved by chemotherapy, but leukapheresis should be considered in severe cases or in patients who cannot receive chemotherapy immediately. Finally, patients can present with acute spurious hypoxemia caused by an ex vivo decrease in arterial P_{O_2} mediated by the enhanced metabolism of the malignant cells; this process has been referred to as "leukocyte larceny." Pulse oximetry provides an accurate assessment of O_2 saturation in such circumstances.

Leukemic cell lysis pneumopathy occurs in patients with high leukocyte counts undergoing chemotherapy and is part of the spectrum of tumor lysis syndrome. Severe hypoxia and diffuse bilateral infiltrates develop within 48 hours after the initiation of chemotherapy, resembling the clinical and pathologic presentation of ARDS.[157] In patients at intermediate or high risk for the development of tumor lysis syndrome preventive measures such as aggressive intravenous hydration, urine alkalinization in selected patients and the use of agents to decrease uric acid levels such as allopurinol and rasburicase is recommended.[157a] These therapeutic strategies also apply to patients with established tumor lysis syndrome.

Plasma Cell Disorders

Thoracic involvement in multiple myeloma is common, occurring in 46% of patients, with the majority of cases related to neoplastic infiltration of the skeleton.[158] Pleural effusion caused by malignant infiltration has been reported, and for unclear reasons the effusion appears to more frequently involve the left lung.[159] Pulmonary parenchymal or airway involvement is also rare, taking the form of single or multiple masses, diffuse parenchymal infiltrates, or endobronchial lesions.[158] Pulmonary amyloidosis can also occur secondary to systemic amyloid deposition.[160]

Plasmacytoma is a circumscribed proliferation of plasma cells that are not associated with a plasma cell disorder. The vast majority of plasmocytomas involving the respiratory tract occur in the pharynx, followed by the trachea and, much less commonly, the lower airways and the pulmonary parenchyma.[161,162] Pulmonary parenchymal plasmocytomas present as a nodule or mass that is indistinguishable from bronchogenic carcinoma.

THROMBOSIS AND DISORDERS OF COAGULATION

Inherited Thrombophilia

Inherited thrombophilia encompasses the various mutations associated with venous thromboembolism. The most frequent causes of an inherited thombophilia are the factor V Leiden mutation and a prothrombin gene (G20210A) mutation, which together account for 50% to 60% of cases. Mutations in the genes coding for protein S, protein C, and antithrombin account for most of the remaining cases, while dysfibrinogenemias are rare causes of hypercoagulability (Table 84-5). [163,164] Patients with these disorders usually present with recurrent thromboembolism at a young age, typically less than 50 years of age.

It seems evident that several of these disorders are associated with an increased risk of initial and recurrent thromboembolism (see Table 84-5). There is, however, controversy about whether screening of individuals with venous thromboembolism for the presence of these inherited defects is warranted. Expert opinion suggests that evaluation for inherited thrombophilic disorders should be pursued in individuals presenting with idiopathic thrombosis at a young age (≤50 years), a history of recurrent thrombosis, or an unusual site of thrombosis; in those with a first-degree relative with thrombosis at a young age; or in women with thrombotic events during pregnancy or while taking oral contraceptives.[165-167] These recommendations have to be contrasted with the results of epidemiologic studies suggesting that a thrombophilic workup after a

TABLE 84-5. Inherited Thrombophilic Disorders

Disorder	Prevalence in Healthy Individuals (%)	Frequency in Patients with VTE (%)	Relative Risk of First Episode of DVT	Relative Risk of Recurrence
Factor V Leiden (heterozygous)	0.05–4.8	18.8	7	1.4
Factor V Leiden (homozygous)	0.02	1.5	80	n/a
Prothrombin G20210A allele	0.06–2.7	7.1	2.8	1.7
Protein C deficiency	0.2–0.4	3.7	6.5	1.8
Protein S deficiency	0.16–0.21	2.3	5.0	1.0
Antithrombin III deficiency	0.02	1.9	20	2.6

DVT, deep venous thrombosis; VTE, venous thromboembolism.
Adapted from Whitlatch NL, Ortel TL: Thrombophilias: When should we test and how does it help? Semin Respir Crit Care Med 29:25–39, 2008; and Dalen JE: Should patients with venous thromboembolism be screened for thrombophilia? Am J Med 121:458–463, 2008.

first thrombotic event is unlikely to confer clinical benefit.[168–170] The presence of a thrombophilic disorder does not impact the acute management of a thromboembolic event but could have an impact on the duration of chronic anticoagulant therapy.[171] Patients with antithrombin, protein C, or protein S deficiency should be considered for indefinite anticoagulation. Patients with heterozygous factor V Leiden or prothrombin gene mutations generally do not need indefinite anticoagulation but will likely benefit from extended anticoagulant therapy to reduce the risk of recurrence, as shown in other patients with idiopathic thromboembolism.[172,173] Patients with more that one allelic abnormality should be considered for indefinite anticoagulation.

Coagulopathies and Platelet Disorders

Spontaneous pulmonary hemorrhage does not appear to be a common complication of disorders of coagulation such as the hemophilias, von Willebrand's disease, or thrombocytopenia. The risk of bleeding appears to increase in individuals with preexisting pulmonary lesions or in situations in which physical or procedural trauma to the respiratory system occurs. However, episodes of pulmonary hemorrhage, hemomediastinum, and tracheal and pleural hematomas have been described in patients with hemophilias.[174] Radiographic abnormalities such as scarring, fibrosis, pleural thickening, abnormalities in pulmonary vessels, and hyperinflation and cases of pulmonary hypertension have also been described in patients with hemophilia.[141]

COMPLICATIONS OF TRANSFUSION

Transfusion-Associated Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is an ALI syndrome occurring after the transfusion of blood products containing plasma, most commonly whole blood, fresh frozen plasma, platelets, and packed red blood cells. TRALI is currently the leading cause of transfusion-related morbidity and mortality.[175] TRALI is defined as an acute onset hypoxemia (the ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen ≤ 300 mmHg), new chest radiographic opacities, without evidence of elevated left atrial pressure within 6 hours of infusion of a blood product.[176]

Epidemiology

The incidence of TRALI is not well established but appears to be one episode for every 5000 blood component transfusions.[177] This likely underestimates the true incidence of the disease. Recent studies using systematic methods to identify TRALI cases suggest that the incidence can be 5 to 50 times higher than previously thought.[178–181]

TRALI has been reported in all age groups and occurs equally in men and women. A single-center study suggested that patients with hematologic malignancies or cardiovascular disease requiring cardiopulmonary bypass operations are at a higher risk of developing this complication.[178] Administration of fresh frozen plasma, prolonged storage of blood products, and acute underlying conditions such as recent surgery, massive transfusion, cytokine therapy, sepsis, and thrombocytopenia have also been implicated as risk factors for TRALI.[178,180,182–186] Multiparous women are the donors most commonly associated with cases of TRALI, which reflects formation of antibodies related to exposure to paternal leukocyte antigens during pregnancy (see next section on pathogenesis).[177,187,188]

Pathogenesis

Two leading hypotheses have been put forth to explain the mechanisms underlying the pathogenesis of TRALI. One theory involves the transfusion-associated interaction between leukocyte antigens and antibodies causing granulocyte activation and lung injury. An alternative "two hit" hypothesis proposes that active substances accumulate as the blood product is stored and are transferred to a susceptible host, causing granulocyte priming that then secondarily produces lung injury in the setting of systemic inflammation from another insult such as sepsis.

Several lines of evidence support the notion that antileukocyte antibodies are a common cause of TRALI. Antigranulocyte antibodies are found in samples of donors or recipients after clinical episodes of TRALI, and infusion of antigranulocyte antibodies in animals causes a similar form of lung injury.[189,190] There have been three case reports of TRALI occurring in medical studies in which plasma containing strong leukocyte antibodies was infused in healthy volunteers.[191] Antibodies against human leukocyte antigen class I and II antigens and HNA-3a antigens are found in patients with TRALI.[192]

The "two hit" hypothesis is also supported by several studies. The age of transfused blood has been reported as a risk factor for multiorgan failure in trauma patients.[193] The presence of bioactive lipids implicated in the pathogenesis of lung injury, such as lysophosphatidyl choline, is higher in blood products given to patients who develop TRALI.[180,185] CD40 ligand, which induces injury to activated microvascular endothelial cells, accumulates in stored blood products, and significantly higher levels are found in blood products given to patients who develop TRALI.[194]

Clinical Features and Evaluation

Patients typically present with the sudden onset of respiratory distress 1 to 2 hours after the transfusion of blood products. Clinical signs include fever, tachypnea, tachycardia, and occasionally hypotension.[183] Pink frothy secretions with a high albumin content indicative of noncardiogenic pulmonary edema may be observed. Chest radiography classically reveals bilateral alveolar

infiltrates with a normal cardiac silhouette and without pleural effusion. The finding of granulocyte, leukoagglutinating, or lymphotoxic antibodies in the serum from either the donor or recepient supports the diagnosis of TRALI, but these abnormalities do not occur in all patients. The main differential diagnosis in these patients is transfusion-associated circulatory overload, and the differentiation of these two conditions can de difficult. The measurement of brain natriuretic peptide levels has been described as a helpful tool to discriminate these two entities.[195]

Approximately 70% of patients require mechanical ventilation at the time of presentation.[192] Resolution occurs rapidly, within the first 48 hours, and with few exceptions chest radiographs return to normal typically in 4 days. The estimated mortality associated with TRALI is 5%.[192]

Treatment

The management of TRALI is supportive as patients usually improve spontaneously. In patients requiring mechanical ventilation, the management should follow the same approach recommended for patients with ARDS. There is no convincing evidence to support the use of corticosteroids in patients with TRALI. Individuals developing TRALI should not receive further blood products from the implicated donor but do not appear to be at increased risk for recurrent episodes with products from other donors.[196]

KEY POINTS

Hemoglobin Disorders

- Pulmonary hypertension is a common complication of hemolytic disorders.
- Pulmonary complications are a major cause of morbidity and mortality in patients with sickle cell disease.
- Acute chest syndrome (ACS) is the second most common cause of hospitalization in patients with sickle cell disease and the leading cause of admission to an intensive care unit and premature death.
- Patients with ACS frequently develop acute right heart failure (13%).
- Pulmonary hypertension occurs in up to 30% of patients with sickle cell disease and is a major cause of morbidity and mortality in these patients.
- Echocardiography with assessment of TRV and measurements of NT-proBNP levels can be used to identify patients with sickle cell disease at a high risk of death.
- There is emerging evidence that pulmonary hypertension–specific therapy could improve outcomes in patients with sickle cell disease and thalassemia.

White Blood Cell Disorders

- Direct parenchymal involvement by leukemias and plasma cell disorders is uncommon.

Thrombosis and Coagulation Disorders

- There is controversy about whether screening of individuals with venous thromboembolism for the presence of inherited thrombophilic defects is warranted.
- The optimal chronic management of patients with inherited thrombophilia is not well established.
- Spontaneous pulmonary hemorrhage does not appear to be a common complication of disorders of coagulation.

Complications of Transfusion

- Transfusion-related acute lung injury (TRALI) is a leading cause of transfusion-related morbidity and mortality.

ACROMEGALY

INTRODUCTION

Common endocrine disorders may affect the respiratory system in a variety of ways, from an increased risk of specific infections in patients with diabetes to upper airway compression in patients with goiter. Many studies of pulmonary physiology have been done on patients with endocrine disorders, some of which have revealed clinically significant abnormalities. In other studies, however, physiologic abnormalities do not translate into clinical dysfunction, but they help add to our understanding of lung parenchymal growth and development, response to extrathoracic influences, and perhaps even aging. This chapter reviews the effects of various endocrine abnormalities on the pulmonary system.

DIABETES MELLITUS

Diabetes mellitus is the most common of all endocrine disorders, affecting 180 million people worldwide, and the prevalence is expected to rise to 366 million by 2030.[1] Because of the chronic metabolic derangements, many patients with diabetes develop cardiovascular and end-organ dysfunction. The effects of diabetes on the respiratory system are numerous (Table 85-1), but data are mixed with regard to the effect of diabetes on pulmonary function. Some studies have revealed lower than predicted vital capacity,[2,3] total lung capacity,[2] diffusion capacity for carbon monoxide,[2] maximal oxygen uptake,[2] and inspiratory muscle strength.[4] These mild functional abnormalities have been ascribed to premature aging of the lungs in a fashion similar to nonenzymatic protein glycosylation and microangiopathic changes that occur in many affected organs in patients with diabetes.[5] However, other studies showed no significant impairment in total lung capacity,[6-8] and none to only minor decreases in diffusion capacity for carbon monoxide,[6-8] vital capacity,[6,7] pulmonary distensibility,[6] or maximal inspiratory pressure.[9] Results of the Offspring Cohort of the Framington Heart Study[10] found that patients with diabetes had a lower forced vital capacity, with the greatest effect seen in current smokers. There did not seem to be an association between the diagnosis of diabetes and chronic obstructive pulmonary disease, nor did diabetes seem to accelerate chronic obstructive pulmonary disease in smokers. In summary, diabetes mellitus (in the absence of cystic fibrosis) may cause a mild decline in pulmonary function measurements, generally well within 80% of the reference value,[11] but does not appear to cause clinically significant pulmonary impairment, and routine pulmonary function testing in patients with diabetes is not warranted.

The presence of cystic fibrosis–related diabetes has been associated with a higher rate of decline of FEV_1 and forced vital capacity than in cystic fibrosis patients without diabetes.[12] Compared to patients with cystic fibrosis alone, patients with cystic fibrosis–related diabetes had a higher rate of airway colonization with *Pseudomonas,* which might contribute to the accelerated decline in lung function. However, a decline in lung function has been found even in the absence of airway colonization with *Pseudomonas* in females with cystic fibrosis–related diabetes.[13]

From 2006 to 2007, dry powder inhaled insulin was approved in the United States for nonsmoking adults

TABLE 85-1. Pulmonary Complications of Diabetes Mellitus

Pulmonary function abnormalities (typically minor decreases)
↓ Vital capacity
↓ Total lung capacity
↓ Diffusion capacity for carbon monoxide
↓ Carbon monoxide transfer factor
↓ Maximal oxygen uptake
↓ Inspiratory muscle strength
Left ventricular dysfunction
Pleural effusions
Obstructive sleep apnea
Infections
Poorer outcome with:
Community-acquired pneumonia
Legionella pneumonia
Increased risk of:
Aspiration pneumonia
Zygomycetes (mucormycosis) infection
Tuberculosis

with type 1 or type 2 diabetes and without pulmonary disease. Additional inhaled formulations are being developed and will likely be available in the near future. Inhaled insulin improves glycemic control when added to oral agents[14] (though it is not as efficacious as subcutaneous insulin), and has good patient acceptability.[15] The most common pulmonary side effect associated with inhaled insulin is a mild nonproductive cough occuring in 12% to 31%.[14,15] Patients who received inhaled insulin had no change in pulmonary function[14] or a very small decline in FEV_1 over the first weeks to months of therapy.[15,16] Active smoking increases the rate and extent of insulin absorption[17,18]; asthma and chronic obstructive pulmonary disease are associated with unpredictable delivery of the drug. Longer term data on pulmonary function are not yet available.

Cardiovascular factors appear to contribute more than pulmonary factors to impaired physical performance in patients with diabetes. In addition to the increased risk of cardiovascular events in patients with diabetes, there is an increased frequency of heart failure not explained by hypertension or coronary artery disease.[19] Left ventricular systolic and diastolic dysfunction with exercise appears to be more common in patients with insulin-dependent diabetes than in those without diabetes.[20] In addition, when compared with patients with similar degrees of left ventricular dysfunction, exercise limitation and pleural effusions are more common in patients with diabetes.[21] There have been reports of peripheral and pulmonary edema in heart failure patients with diabetes treated with the class of oral hypoglycemic drugs known as the thiazolidinediones[22,23]; the mechanism is likely multifactorial and appears to reverse upon withdrawal of the drug.

Acute respiratory distress syndrome (ARDS) has been reported as a complication of diabetic ketoacidosis.[24] Interestingly, in patients with septic shock, the presence of diabetes has been associated with a lower risk of developing ARDS compared to patients without diabetes, although without a difference in mortality.[25] Diabetes has also been associated with a higher risk of developing idiopathic pulmonary fibrosis.[26]

Newborn babies of diabetic mothers are at increased risk for macrosomia, preterm delivery, and neonatal respiratory distress syndrome[27,28]; infants born to mothers with poor self-care are at the greatest risk.[28] However, with good maternal metabolic control and accurate estimations of gestational age, most pregnant women with diabetes can deliver at or near term with a low rate of respiratory distress syndrome.[29]

Obesity is a risk factor both for type 2 diabetes mellitus and for obstructive sleep apnea. (See Chapter 79 for a full discussion of sleep apnea.) The prevalence of obstructive sleep apnea in patients with type 2 diabetes has been reported to be from 23% to 36%, ranging as high as 70% in patients with type 2 diabetes with a body mass index greater than 35 kg/m^2.[30,31] In addition, obstructive sleep apnea may impose a stress that increases sympathetic output during sleep, which in turn contributes to insulin resistance.[32] Animal models suggest that intermittent hypoxia increases insulin resistance.[33]

Patients with diabetes are at greater risk for some upper and lower airway infections. Patients with diabetes are particularly predisposed to infection with zygomycetes (mucormycosis), a group of infections caused by fungi in the *Mucor, Rhizopus,* and *Cunninghamella* genera. These ubiquitous, saprophytic fungi are found in soil and decaying vegetation. Infection typically occurs during or after an episode of diabetic ketoacidosis, perhaps because the fungi have an enzyme, ketone reductase, that allows them to grow best in an acidic, hyperglycemic environment. Most patients have some underlying predisposition, of which diabetes mellitus is the most important.[33] Five infectious manifestations have been described: rhinocerebral, pulmonary, disseminated, cutaneous, and gastrointestinal. Rhinocerebral infection is the most common form, especially in patients with diabetes. Presentation includes sudden periorbital or paranasal swelling and pain, bloody nasal discharge, and black necrotic nasal mucosa. Characteristic findings on computed tomography (CT) are helpful in suggesting the diagnosis.[34] Treatment requires control of the diabetes, antifungal therapy, and often aggressive surgical debridement. Mortality remains high, especially in patients with intracranial involvement. Pulmonary mucormycosis mimics invasive aspergillosis and occurs mostly in patients with hematologic malignancy, glucocorticoid or deferoxamine therapy, organ transplantation, and diabetes. Inhaled mold spores penetrate bronchiole walls, invade arterioles, and cause thrombosis and ischemia. Patients develop nonspecific cough, fever, and pleuritic chest pain. Hemoptysis occurs in one fourth of cases and can be massive.[35] The most common chest radiographic pattern is consolidation; cavitation occurs in about one third of patients,[36] and adenopathy and pleural effusions may also be present, but are less common. Patients with diabetes appear to have a predilection for endobronchial

disease; however, sputum culture appears to have a very low yield for diagnosis. For specimens obtained at bronchoscopy, histopathologic examination appears to be more sensitive than fungal cultures. Treatment requires antifungal therapy (see Chapter 36) and, if localized, surgical resection. Bronchial stenosis is a potential sequela.

Diabetes mellitus is an independent risk factor for tuberculosis,[37,38] both drug sensitive and multidrug resistant.[38] A recent review of 13 observational studies revealed that diabetes mellitus was associated with an increased risk of tuberculosis (relative risk = 3.11, 95% CI 2.27–4.26)[38a]; an association that was validated in a study of diabetic children in South Africa.[38b] Treatment of latent tuberculosis in patients with diabetes with a positive purified protein derivative test of greater than 10 mm of induration is currently recommended.[39] The radiographic location of tuberculosis in diabetes (i.e., upper or lower lobe predilection) depends on the case series; patients with diabetes and tuberculosis appear to have a higher rate of cavitation.[38,40]

Bacterial pneumonia may or may not be more frequent in patients with diabetes. In a study of over 4000 elderly inhabitants in one township, diabetes mellitus was not an independent risk factor for community-acquired pneumonia.[41] Moreover, diabetes does not appear to be an independent risk factor for either nosocomial pneumonia or ventilator-associated pneumonia.[42] Nonetheless, diabetes may be a risk factor for poorer outcome in those persons who develop pneumonia. In a meta-analysis, diabetes was found to be a risk factor for higher mortality in community-acquired pneumonia.[43] Diabetes also appears to be a risk for higher mortality and bacteremia in patients with pneumococcal pneumonia.[44] Given the high prevalence of and mortality from pneumococcal pneumonia, the demonstrated efficacy of pneumococcal vaccine, and the increasing prevalence of penicillin resistance in pneumococcal strains, pneumococcal vaccination is recommended for virtually all people with diabetes. Diabetes appears to be a risk factor for mortality for critically ill patients with *Legionella* pneumonia.[45] Diabetes may also predispose patients to aspiration pneumonia because of pharyngeal dysfunction and diabetic gastroparesis.[46] Diabetes is a risk factor for chronic oral infections of caries and periodontitis, which may contribute to the increased risk of aspiration pneumonia.[47] There is an increased incidence and mortality of bacterial pneumonia in patients with diabetes during seasonal influenza outbreaks.[48] Consistent with the recommendations of the Advisory Committee on Immunization Practices, influenza vaccination is recommended for patients with diabetes over the age of 6 months.[49] In terms of other viruses, mortality from severe acute respiratory syndrome may be higher in patients with preexisting diabetes.[50]

THYROID DISORDERS

The incidence of multinodular goiter is declining in the United States due the routine use of iodized salt; however, neglected goiters still occur. Because of the thyroid's ability to easily expand anteriorly, bound only by skin, thin muscle, and connective tissue, even large goiters may not cause tracheal impingement. However, some goiters can cause dyspnea, stridor, wheezing, hoarseness, and cough via tracheal deviation (typically if there is unilateral or unequal lobe enlargement) and airway compression.[51–53] Compression or concentric narrowing of the trachea is more common if the goiter extends posteriorly to the trachea (Fig. 85-1). Although goiters typically grow slowly, occasionally patients present with acute respiratory distress requiring urgent intubation or semi-urgent surgery. Some goiters are substernal or intrathoracic, defined as more than 50% of the thyroid below the thoracic inlet. Substernal goiters may cause orthopnea because of increased airflow limitation in the supine position. In these patients, flow-volume loops in

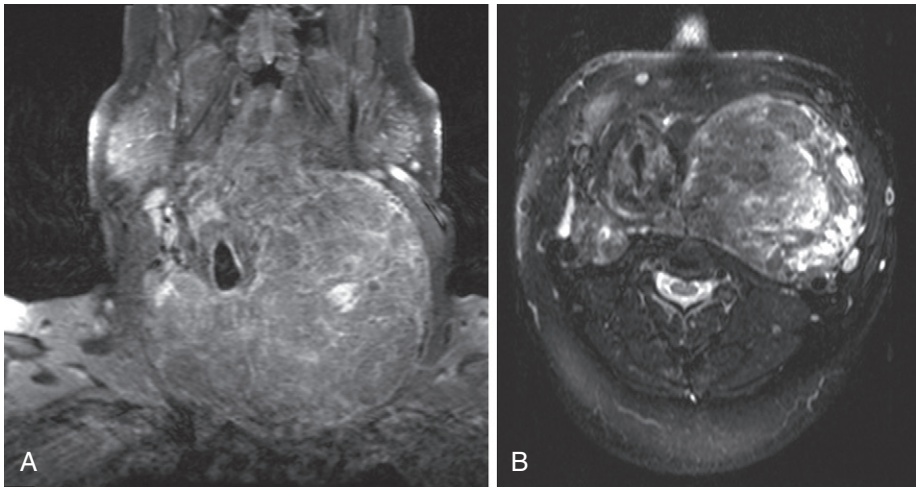

FIGURE 85-1 ■ A massive goiter was found in a 55-year-old man who presented with a change in his voice and increased shortness of breath. Endotracheal intubation required flexible bronchoscopy, followed by uneventful resection of a 900-g multinodular goiter. On coronal **(A)** and axial **(B)** gadolinium-enhanced magnetic resonance images of the neck, tracheal deviation and compression are apparent.

the recumbent position may illustrate upper airway obstruction not demonstrated in upright testing.[53] CT scanning and magnetic resonance imaging generally are the most useful diagnostic imaging studies. CT scanning with iodinated contrast media should generally be avoided because it precludes thyroid nuclear imaging for several weeks and can trigger hyperthyroidism. Surgical resection of substernal goiters is recommended and usually relieves compressive symptoms.[51,54] Postoperative tracheomalacia appears to be rare.[51] Iodine-131 is an alternative therapy for some patients with large goiters who are not surgical candidates because of comorbid illnesses.[55] For patients with baseline tracheal compression, there is often some temporary goiter enlargement from edema and additional airway compromise in the week following ^{131}I treatment. Despite this, with glucocorticoid prophylaxis, most patients do well, and have subsequent goiter shrinkage.[56] Alternatively, bronchoscopic insertion of tracheal stents can relieve large airway obstruction from compressive benign or malignant nonoperable thyroid disease.[57]

Hyperthyroidism

Many patients with hyperthyroidism complain of both resting and exertional dyspnea. Congestive heart failure likely explains some of these complaints,[58] and is the presenting feature in 6% of patients with newly diagnosed hyperthyroidism.[59] Some hyperthyroid patients have decreased vital capacity,[60] decreased respiratory muscle strength,[59–63] and an elevated resting minute ventilation (perhaps due to increased central ventilatory drive) that becomes excessive with exercise.[62] Anaerobic thresholds are typically lower than those of age-matched controls.[62] With treatment, vital capacity and respiratory muscle strength improve,[60,62] although some patients have persistent dyspnea.[61,62]

Patients with coincident asthma and thyrotoxicosis may have worsening of asthma control if β-blocker agents are used to control hyperthyroid manifestations. There may be an association between atopic disease, asthma, and Graves' disease.[64] Approximately 30% of patients with hyperthyroid Graves' disease have an elevation in serum immunoglobin E (IgE) levels, and those with elevated serum IgE are more likely to have a personal or family history of atopy.[65]

Several reports have suggested a link between hyperthyroidism, especially Graves' disease, and pulmonary hypertension in which the pulmonary artery pressures can improve and even normalize with treatment of the hyperthyroidism.[66–68] The explanation for this association is not clear, but may be due to a generalized autoimmune state, a direct influence of thyroid hormone on pulmonary vasculature, changes in metabolism of pulmonary vasculature vasodilators/vasoconstrictors, decreased surfactant production and function, or excess cardiovascular stimulation by the sympathoadrenal system. Interestingly, there may also be an increased prevalence of hypothyroidism in patients with primary pulmonary hypertension.[69] Rarely, mothers with hyperthyroidism from Graves' disease deliver infants with hyperthyroidism via placental passage of maternal thyrotropin receptor-stimulating antibodies. In addition to a variety of infant metabolic and developmental problems, neonatal Graves' disease has been associated with persistent pulmonary hypertension in newborns.[70]

There have been several reports of an increased presence of antinuclear cytoplasmic antibodies and even Wegener's granulomatosis in patients with Graves' disease treated with propylthiouracil.[71,72]

Hypothyroidism

Hypothyroidism has been associated with dyspnea on exertion, alveolar hypoventilation, respiratory failure, obstructive and central sleep apnea, and pleural effusions. Lung volumes are generally normal or mildly decreased in mixed populations of obese and nonobese hypothyroid patients.[73,74] Lung volumes typically, though not uniformly, improve with thyroid replacement and/or weight loss. A reduced diffusion capacity for carbon monoxide can be seen in some hypothyroid, nonobese patients with normal lung volumes and arterial blood gases that improves to near-normal after replacement therapy.[74] Hypothyroidism is associated with overall respiratory muscle weakness as measured by maximal inspiratory and expiratory pressures, and the degree of impairment is linearly related to the degree of pretreatment hypothyroidism.[75] Both obese and nonobese hypothyroid patients may develop diaphragmatic muscle weakness that can range from mild impairment, which limits exercise tolerance, to severe dysfunction, with marked resting dyspnea and chronic hypercarbia.[73] Thyroid replacement therapy can improve respiratory muscle strength. Some nonobese and obese hypothyroid patients have a markedly blunted ventilatory response to hypoxia and hypercapnia,[74,76] which improves often within weeks of initiation of thyroid hormone replacement. This improvement is not associated with changes in spirometric function or maximal voluntary ventilation, thus suggesting a central cause for the abnormal ventilatory response. Respiratory failure from hypothyroidism can occur and may require prolonged mechanical ventilation.[76]

Although up to 25% of patients with hypothyroidism have radiographic evidence of a pleural effusion, most patients also have underlying congestive heart failure (Table 85-2).[77] A small percentage of hypothyroid patients do not have another disease process that would explain the effusion. In these patients, the hypothyroid-related effusions tend to be small, less than one third of the chest cavity; unilateral or bilateral; serous or serosanguineous; and transudates or exudates, although generally noninflammatory.[77] Hypothyroid-related effusions typically resolve with treatment of the hypothyroidism.[77]

Hypothyroidism can predispose patients to sleep apnea,[78–80] possibly from narrowing of the upper airway from mucopolysaccharide and protein deposition in the tongue and oropharynx,[81] from abnormalities in ventilatory control, or from weight gain. In a case series, only 3.1% of patients with obstructive sleep apnea were found to have hypothyroidism[80]; however, 25% of newly diagnosed hypothyroid patients were found to have obstructive sleep apnea. Hypothyroid patients with

FIGURE 85-2 ■ Metastatic calcification occurring in the lungs because of chronic renal failure. A 59-year-old man with end-stage renal disease for 5 years complained of chronic progressive shortness of breath. The serum calcium level was 9.9 mg/dL (normal range, 8.5 to 10.5 mg/dL) and the parathyroid hormone level was 271 pg/mL (normal for the laboratory, 11 to 54 pg/mL). High-resolution computed tomography revealed numerous nodular ground-glass densities in a peribronchial pattern, most prominently in the upper lobes. (Courtesy of Marcia McCowin, MD.)

obstructive sleep apnea have blunted ventilatory responses to hypoxia and hypercapnia; age and body weight were the best predictors of associated obstructive sleep apnea.[80] Some studies have shown improvement in sleep respiratory disturbance index and awake ventilatory response to hypoxia and hypercapnia with thyroid replacement[80,82]; in other studies, however, investigators found less than full improvement or no improvement in sleep apnea with thyroid replacement.[78,83] Central sleep apnea can also occur in hypothyroid patients, and the blunted ventilatory response to hypoxia may improve with thyroid replacement.[78]

Thyroid hormones play an important role in the growth and development of the lung and in the maturation of the lung's surfactant system.[84,85] Transient hypothyroxinemia is common in premature infants, as is respiratory distress syndrome. However, the administration of maternal antenatal thyrotropin-releasing hormone, which increases fetal thyroid hormone levels, did not decrease the frequency or severity of respiratory distress syndrome in premature babies in a large multicenter trial.[86] Treatment of premature infants with thyroxine also did not decrease the incidence of respiratory distress syndrome, the use of surfactant therapy, or the overall developmental outcome at 24 months.[87]

PARATHYROID DISEASES

Hyperparathyroidism, typically secondary hyperparathyroidism in patients with end-stage renal disease, can cause diffuse metastatic calcification in the lungs. Metastatic calcification is the deposition of calcium salts in previously normal tissue; in contrast, dystrophic calcification is the calcification of diseased or abnormal tissue, as in granulomatous processes. Despite dietary phosphate restriction, administration of phosphate binders, and hemodialysis, renal failure patients are at risk for metastatic calcification, especially if the calcium-phosphorus product increases above 70 mg^2/dL^2. Pulmonary metastatic calcific nodules occur predominantly in the alveolar septa and are associated with varying degrees of fibrosis and septal thickening. This phenomenon appears to be quite common; from 60% to 80% of chronic dialysis patients have autopsy or scintigraphic evidence of pulmonary metastatic calcification.[88] Metastatic calcification can also rarely occur in primary hyperparathyroidism.[89] Most patients with end-stage renal disease and metastatic pulmonary calcification are asymptomatic and have normal chest radiographs and pulmonary function; patients with heavy deposition of calcific nodules, however, may complain of dyspnea and nonproductive cough. Pulmonary function tests in patients with extensive metastatic calcification may show ventilatory restriction with hypoxemia and low diffusion capacity for carbon monoxide.[90]

Calcium salts tend to precipitate in alkaline conditions. Indeed, metastatic calcification has a predilection for the apical portions of the lungs, the stomach, and the kidneys—all tissues with a relative alkalinity, because of either carbon dioxide removal or hydrogen ion excretion. Due to the higher ventilation-perfusion ratio and lower carbon dioxide concentration at the lung apex, it is estimated that the pH at the apex is 7.5 compared to a pH of 7.3 at the base.[90,91] Other common sites of deposition include soft tissues and the skin. Radiographically, patients with more extensive calcification typically have numerous nodules about 3 to 10 mm in size, better visualized on CT scans than on plain chest radiographs (Fig. 85-2).[92] In addition to the nodular densities, patchy consolidation and ground-glass attenuation may be seen. The calcific nature of the nodules may not be apparent on plain radiographic or even CT images, perhaps due to the small size of the calcium deposits. However, radionuclide bone scans usually reveal intense uptake in the lungs and other affected organs (Fig. 85-3).[88] Parathyroid-

FIGURE 85-3 ■ Metastatic calcification in the lungs caused by chronic renal failure. This is the same patient as in Figure 85-2. Whole-body bone imaging with technetium-99m-diphosphonate revealed diffuse soft-tissue avidity in both lungs.

ectomy or treatment with vitamin D analogues can decrease the calcium-phosphorus double product, reverse bone scan abnormalities and organ deposition, and presumably improve pulmonary function. Hyperparathyroidism is also associated with calcification in pulmonary arterial and bronchial walls. Of note, about one third of patients with end-stage renal disease on long-term hemodialysis via arteriovenous access have pulmonary hypertension,[93,94] but pulmonary hypertension does not seem to correlate with the presence or severity of pulmonary artery calcification[93,95] or parathyroid hormone levels.[96]

Rarely, enlarged mediastinal parathyroid cysts can cause tracheal compression with stridor or vocal cord impingement and hoarseness, or both. Surgical excision is the treatment of choice.[96]

Hyperparathyroidism is frequently associated with muscle weakness and fatigue. Respiratory muscle function can be affected as well, and postparathyroidectomy improvement in forced vital capacity and FEV_1 values correlates with preoperative serum calcium and preoperative parathyroid hormone values.[97]

ADRENAL DISEASES

Endogenous Cushing's syndrome (i.e., not from glucocorticoid administration) may be caused by pituitary Cushing's disease, by adrenal neoplasia, or by ectopic adrenocorticotropic hormone production from small cell lung cancer or from carcinoids arising from a variety of organs, especially the lung, including the variation of pulmonary carcinoid tumorlets, gastrinoma, pheochromocytoma, or islet cell carcinoma of the pancreas.[98,99,99a] Cortisol levels tend to be much higher with ectopic adrenocorticotropic hormone production and adrenal neoplasia than with pituitary Cushing's disease, and pose a greater risk for infection. Hypercortisolism particularly predisposes patients to mucocutaneous fungal infections and opportunistic pulmonary infections. The most common pulmonary infections are caused by *Cryptococcus, Aspergillus, Nocardia, Pneumocystis,* and *Mycobacterium tuberculosis.*[100-103] *Pneumocystis jirovecii* pneumonia tends to occur in patients with the highest morning cortisol levels.[103] Correction of hypercortisolism is an important adjunct to antimicrobial therapy. Cushing's syndrome is also associated with a hypercoagulable state and fourfold increase in thromboembolic disease.[104,105] The risk may be due to an increase in various coagulation factors.[104] Even in patients without baseline hypercortisolism, cortisol levels increase in stress and extremely elevated cortisol levels at presentation appear to be independent predictors of worse outcome in community-acquired pneumonia.[106,107]

Adrenal insufficiency may be due to either primary adrenal failure (Addison's disease) or secondary adrenal insufficiency. Secondary adrenal insufficiency is most commonly iatrogenic as a result of the withdrawal of exogenous glucocorticoid therapy, or results directly from disease of the hypothalamic-pituitary axis. In industrialized countries, 70% to 80% of cases of Addison's disease are autoimmune in origin; in contrast, in resource-poor countries, tuberculosis remains the most common cause.[108,109] CT scanning can be somewhat helpful in determining the cause of Addison's disease, because tuberculosis and histoplasmosis may cause adrenal calcification.[110] Adrenal insufficiency via the hypothalamic-pituitary axis may be seen in stressed, very-low-birth-weight infants and may render them more susceptible to bronchopulmonary dysplasia.[111]

ACROMEGALY

Acromegaly is a disorder of excess growth hormone secretion in adults, most commonly from a benign pituitary adenoma. Rarely, bronchial carcinoid or small cell lung cancer can produce excess growth hormone–releasing factor, which stimulates excess growth hormone secretion. Clinically, acromegaly is characterized by excessive bone growth, soft-tissue hypertrophy, and coarsening of facial features. These changes appear to be due to high levels of growth hormone and insulin-like growth factor-1, which is secreted in response to growth hormone; the net effect is an increase in somatic growth and metabolic disturbances. Mortality in acromegaly is increased primarily from cardiovascular disease.[112,113]

Patients with acromegaly can develop macroglossia, nasal polyps, oropharyngeal airway narrowing, and vocal cord restriction and edema. In addition, coincidental goiter is not uncommon and can contribute to upper airway narrowing.[112,114] Respiratory manifestations of

acromegaly include sleep apnea, extrathoracic airway obstruction, vocal cord dysfunction, and difficult intubation.[112,114] The prevalence of sleep apnea has been reported as between 20% and 60%.[115,116] Increased rates of obstructive sleep apnea may be due to a narrowed upper airway from osseous enlargement, hypertrophy of tissues in the oropharynx, inspiratory collapse of the hypopharynx, and macroglossia. The circumference of the neck and fingers, but not body mass index, are predictive of the development of sleep apnea in acromegaly.[116] Obstructive sleep apnea may improve with treatment of acromegaly with pituitary ablation[117] or with octreotide, a somatostatin analogue.[115,118] Persistence of obstructive sleep apnea after treatment may be due to irreversible upper airway remodeling. Central sleep apnea is also common. Patients with central sleep apneas and acromegaly have higher growth hormone and insulin-like growth factor-1 levels and higher ventilatory responses to carbon dioxide than acromegalic patients with obstructive sleep apnea.[119] Central sleep apnea in these patients may therefore be due to altered ventilatory control.

Total lung capacity and vital capacity are typically increased in patients with acromegaly compared with controls,[120–125] and appear to correlate with the duration of acromegaly.[122] Possible causes for the increased lung volumes in these patients include hypertrophy or enlargement of individual alveoli, or an increase in the number of alveoli.[120,123,124] Diffusion capacity for carbon monoxide may be within normal limits[120,123] or elevated.[121] Changes in vertebrae and rib morphology contribute to the barrel chest of patients with acromegaly. In addition, with acromegaly, there is a decrease in respiratory muscle force that may contribute to increased dyspnea and fatigue with exercise.[125]

Evidence of a variable extrathoracic airway obstruction on flow-volume loops in seen in 30% to 50% of patients with acromegaly.[122] As noted, intubation may be more difficult in patients with acromegaly because of vocal cord fixation, vocal cord edema, prolapse of an enlarged tongue, and soft-tissue thickening of the oropharynx.[126] Preoperative treatment of patients with somatostatin analogues may decrease soft-tissue swelling and enable easier intubation.[118]

KEY POINTS

- Diabetes mellitus, by far the most common endocrine disorder, is associated with sleep apnea and predisposes to certain fungal and mycobacterial respiratory infections; although the incidence of other bacterial and viral infection is not increased, when they occur in diabetics, mortality is elevated.
- Patients with diabetes should receive pneumococcal and influenza vaccinations.
- Thyroid enlargement may cause upper airway compression; in addition, partly reversible decreases in vital capacity and respiratory muscle strength worsen dyspnea in patients with hyperthyroidism; more commonly, patients with hypothyroidism suffer from dyspnea, alveolar hypoventilation, pleural effusion(s), and, sometimes, respiratory failure.
- Secondary hyperparathyroidism from end-stage renal disease often causes diffuse metastatic pulmonary calcification.
- Endogenous Cushing's syndrome predisposes to a variety of opportunistic infections, whereas acromegaly from excess growth hormone is associated with a high prevalence of sleep apnea, and may lead to upper airway structural disorders.

INTRODUCTION

Both respiratory physiology and the respiratory tract's susceptibility to disease are uniquely altered in gynecologic and obstetric conditions, including normal pregnancy. This chapter summarizes normal physiologic alterations during pregnancy and then considers pathologic diseases and disorders that arise during pregnancy. Airway disorders, infectious diseases, pulmonary vascular and embolic disorders, and acute lung injury are considered in turn. Finally, pleural and parenchymal diseases that arise as a consequence of gynecologic conditions are addressed.

PHYSIOLOGIC ALTERATIONS DURING NORMAL PREGNANCY

Profound alterations of respiratory function and cardiovascular physiology accompany normal pregnancy in healthy women; these conditions contribute to many of the disorders of the lungs that may occur during pregnancy. The adaptive changes during the gravid period are designed to support maternal and fetal well-being during the special stresses of fetal growth and parturition, but they may exacerbate some underlying disorders and confuse interpretation of laboratory and imaging studies used to assess many other common conditions.

Alterations in Respiratory Physiology

Upper airway, particularly nasal, mucosal edema is a common finding in normal pregnancy. About 20% of gravid women complain of rhinitis symptoms, now attributed at least partially to placental growth hormone's effects on mucosal congestion.[1] Animal studies appear to support this attribution. The symptoms begin in the first trimester and persist throughout gestation. Many patients thought to have rhinitis of pregnancy may actually have other or coincident causes of rhinitis.[2] An important implication of nasal mucosal edema in pregnancy is that it predisposes to nosebleeds from nasal intubations, so an oral approach is favored if intubation is required at the time of delivery.

Chest wall configuration is also altered, partially due to a 50% increase in the average costal angle[3] and partially due to an increase in the circumference of the lower chest wall. Diaphragmatic position is elevated 4 to 5 cm, but excursion does not diminish.[3] Muscle strength, as measured by maximum transdiaphragmatic pressure, does not appear to be diminished from its usual mean value of about 95 cm H_2O,[4] allowing reserve for

both the augmented minute ventilation of pregnancy and the stresses of delivery.

Important changes occur in lung function and lung volumes. Because the loss of lung volume resulting from elevation of the diaphragm is only partially offset by the smaller increase in chest wall diameter, functional residual capacity (FRC) is usually diminished by about 18%, or 300 to 500 mL.[5] The FRC diminution is partitioned almost equally between the expiratory reserve volume and the residual volume.[3,5] The loss of FRC at term is made worse by recumbency, when diaphragm elevation is greatest because of the higher intra-abdominal pressure. Increased pulmonary blood volume in pregnancy may also serve to lower the FRC.[6] This reduction in FRC is associated clinically with increased uptake and elimination of inhalational anesthetics and with rapid desaturation during hypopnea, as a result of the loss of the oxygen reservoir function of end-expiratory lung volume. Endotracheal intubation at term is thus substantially more hazardous than in nongravid patients.

Although the FRC is lower, total lung capacity decreases only marginally, and vital capacity does not change.[5] Inspiratory capacity actually increases slightly due to the decrease in FRC, so incentive spirometry is effective in preventing postpartum atelectasis.

Airway function is also largely unchanged during pregnancy.[3] Airway resistance may actually slightly decrease. Routine measurements of air flow, such as the FEV_1 and flow rates at mid-expiratory lung volume (forced expiratory flow between 25% and 75% of FVC, or $FEF_{25-75\%}$) are thus valuable in assessing dyspnea during pregnancy.

The most striking changes are in respiratory drive and minute ventilation. Central drive, as assessed by the inspiratory pressure measured 100 msec after airway occlusion at the onset of inspiration ($P_{0.1}$), has been measured during pregnancy.[4] $P_{0.1}$ is increased by 13 weeks and continues to increase to week 37 of gestation, returning to normal by 24 weeks after delivery. These serial changes in respiratory drive appear to correlate with changes in serum progesterone levels,[4,7] which either stimulate respiration directly or increase the sensitivity of the respiratory center to P_{CO_2}.[4,7] Carbon dioxide production itself increases one third to one half by the last trimester, but this is more than made up for by the greatly augmented minute and alveolar ventilation, so primary respiratory alkalosis with renal bicarbonate wasting as compensation is a normal finding.[8] Arterial blood gas measurements typically show the pH ranging from 7.40 to 7.47, with P_{CO_2} reaching as low as 28 to 32 mm Hg. P_{O_2} rises slightly as a result of the increase in alveolar ventilation.

Most of the increase in minute ventilation is due to a 30% to 35% increase in tidal volume. Respiratory rate is unchanged early and rises only about 10% later in pregnancy. Oxygen consumption increases 20% to 33% in pregnancy, owing to both maternal and fetal metabolic demands. Changes in some of these parameters are shown in Figure 86-1.

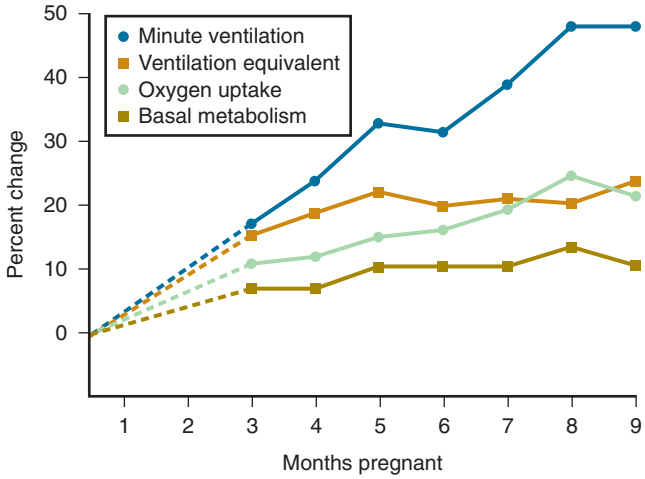

FIGURE 86-1 Changes in minute ventilation, oxygen uptake, basal metabolism, and the ventilatory equivalent for oxygen at monthly intervals throughout pregnancy. (From Prowse CM, Gaensler EA: Respiratory and acid-base changes during pregnancy. Anesthesiology 26:381, 1965.)

Alterations in Cardiovascular Physiology

Adaptive cardiovascular changes are designed to support both maternal and fetal circulations, but contribute to the risk for hydrostatic pulmonary edema, so cardiac disorders during pregnancy often present as respiratory failure. During normal pregnancy, maternal blood volume increases by about 2 L, or 40%.[9,10] Red blood cell mass increases as well, but only by 20% to 30%, accounting for the normal 10% to 12% decrease in hematocrit.[10,11] Plasma oncotic pressure also drops as intravascular volume expands, increasing the risk for pulmonary edema at lower intravascular hydrostatic pressures. During the 24 hours after parturition, oncotic pressure falls further because of blood loss and mobilization of extravascular fluid.

The enlarged intravascular volume of pregnancy is accommodated chiefly by venous capacitance vessels. Central venous pressure and pulmonary capillary occlusion ("wedge") pressure are unchanged, reflecting an increase in left ventricular compliance, as evidenced by the enlarged cardiac silhouette seen on chest radiograph. The increased left ventricular end-diastolic volume results in an augmented stroke volume (ejection fraction is little changed), but systemic vascular resistance (SVR) diminishes.[11,12] These changes account for the 30% to 45% increase in cardiac output reached by 25 to 32 weeks of gestation. After 5 weeks, heart rate increases as well,[13] but less so than stroke volume. The time frame of these changes is depicted in Figure 86-2, which also illustrates the profound effect of vena caval and aortic compression by the gravid uterus when the supine position is assumed.

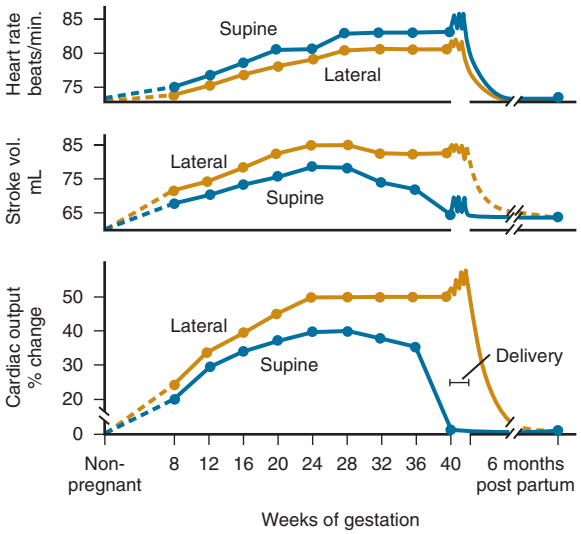

FIGURE 86-2 ■ Changes in maternal heart rate, stroke volume, and output during pregnancy with the gravida in the supine and lateral positions. (From Cheek TG, Gutsche BB: Maternal physiologic alterations during pregnancy. *In* Shnider SM, Levinson G [eds]: Anesthesia for Obstetrics. Baltimore: Williams & Wilkins, 1993, p 8.)

OBSTETRIC DISORDERS AND THE LUNGS

Gravid and newly postpartum patients may acquire disorders and diseases unique to pregnancy but also continue to experience common disorders that occur outside of pregnancy; the natural history or frequency of coexisting disorders is sometimes altered by the gravid state. Even for diseases not altered by pregnancy, management requires special knowledge of the safety of therapies.[14] Specific diseases are considered here with these principles in mind.

Obstructive Airway Disease

Asthma

Asthma affects 4% to 8% of the general population and is the most common pulmonary disorder in pregnancy. The Working Group on Asthma and Pregnancy of the National Asthma Education and Prevention Program (NAEPP) estimated that an almost identical 3.7% to 8.4% of pregnancies are complicated by asthma.[15] Maternal asthma increases the risk of preeclampsia, preterm birth, infants with low birth weight, intrauterine growth restriction or congenital malformations, and perinatal death.[16] The effects of pregnancy on asthma vary with severity, with exacerbations occurring in only an eighth of mild asthmatics, but in over half of those with severe asthma.

Investigations of the interaction of asthma and pregnancy have been of two types: natural history and outcome studies. Studies examining the hormonal milieu have suggested that progesterone might diminish smooth muscle contractility in the lung, as it does in the uterus and the gut. Juniper and colleagues[17] performed serial measurements of bronchial reactivity to methacholine challenge in 16 women before and during pregnancy and found that airway responsiveness improved. Clinical and epidemiologic studies, however, have failed to provide convincing evidence of any consistent change in the natural history of asthma during pregnancy. Turner and coworkers,[18] for example, compiled the results of nine studies of asthma symptoms reported by pregnant women. Among them, 22% reported worsening, 29% reported improvement, and 22% reported no change. Other studies have reported similar figures, with about 23% to 42% worsening, 18% to 36% improving, and 40% to 41% exhibiting no change.[19,20] The differences reported in the natural history probably reflect differences in study populations, smoking history, ethnicity, or other variables.[21]

Fetal and maternal outcome for asthma and pregnancy have also been examined in a variety of studies since 1980. Adverse outcomes, including an increased incidence of preterm labor, low neonatal birth weight, increased perinatal mortality, preeclampsia, vaginal hemorrhage, chronic hypertension, and complicated labor, have been reported.[15,21] A large epidemiologic study from Sweden did confirm an association with perinatal mortality and low birth weight.[22] Nonetheless, adequate therapy tailored to disease severity is associated with good outcomes.[23] Therapy of asthma in pregnancy should be individualized according to severity of disease and frequency of symptoms, as outlined by the NAEPP.[15] Objective measurement of lung volumes and flow should be part of the regimen. Initial office spirometry is recommended, and home peak flow monitoring should be considered for patients taking medication daily. Serial ultrasonography, starting at 32 weeks, and fetal heart rate monitoring may be needed in the third trimester. Patients can supplement this with recordings of fetal activity using "kick counts." For women who have asthma attacks during labor, fetal monitoring is considered essential by the NAEPP.

Environmental control measures are also important to reduce exposure to stimuli that exacerbate the disease.[15,21] Avoidance of cigarette smoke is particularly important. Other specific triggers in individual patients should be identified and controlled, but because of the small risk for anaphylaxis, immunotherapy should be deferred until after delivery.

Therapy should be based on a step approach.[15] Mild intermittent asthma is best managed with albuteral alone, based on safety studies. Asthma that causes more than occasional symptoms should be treated daily with anti-inflammatory therapy, with the preferred choice being inhaled corticosteroids. Budesonide is the best studied and hence preferred. Alternative therapies include cromolyn, sustained-release theophylline, or a leukotriene antagonist.[15] Inhaled short-acting β_2-agonists should be prescribed for symptomatic relief in mild episodic asthma. Although still controversial, long-acting β-agonists should only be used concurrently with long-acting inhaled corticosteroids.[16a] Frequent need for β_2-agonists should prompt institution of, or an increase in, the use of anti-inflammatory agents to treat, rather than to mask,

a deteriorating clinical course. Finally, the addition of rapidly tapered courses of oral corticosteroids should be considered for active symptoms occurring in patients already using inhaled steroids and β-agonists but failing therapy. Daily or alternate-day oral steroid administration at doses up to 2 mg/kg is sometimes required.[15] Extensive practice algorithms have been made available by the NAEPP Working Group on Asthma and Pregnancy.[15]

A large body of literature has examined the topic of possible teratogenicity of agents used in the pharmacotherapy of asthma in pregnancy. In general, the risks of poorly controlled asthma far outweigh the possible hazards of drug therapy. Both animal and human studies of β_2-agonists, administered either by inhalation or systemically, have indicated an acceptable safety profile for the fetus. They are also safe for use during lactation. Nonselective β-agonists, such as epinephrine, carry a risk of uterine vasoconstriction in animal models[24] and are probably best avoided. Acceptable β_2-agonists in pregnancy include metaproterenol, albuterol, pirbuterol, bitolterol, and terbutaline. Because the toxicology and pharmacology of the long-acting β-agonists salmeterol and formoterol are expected to be similar to shorter acting β_2-agonists, these drugs have been recommended in patients with poor control on a combination of inhaled long-acting corticosteroids and short-acting β-agonists.[16a,23] Among long-acting β_2-agonists, there is longer experience with salmeterol in the United States.

Theophylline also has a long history of use during pregnancy and is considered safe, but the therapeutic range in plasma should be lowered to 5 to 12 μg/mL because of diminished protein binding during pregnancy. Theophylline passes freely to the fetus, and newborns occasionally show signs of theophylline toxicity, particularly when maternal blood levels are high. Theophylline is also transmitted to breast milk, with a milk-to-serum ratio of about 0.70; but, in general, less than 1% of the maternal dose is transferred to the infant. Animal studies suggest that the leukotriene inhibitors montelukast and zafirlukast are safe in pregnancy, and they can be continued in patients who have previously responded.[24,25] Zileuton should be avoided, as animal studies have raised questions about its safety in pregnancy.

Animal studies have shown an increased incidence of cleft palate with use of corticosteroids, and limited human data support this association, with an estimated excess risk of 0.2% to 0.3% when used in the first trimester.[15] Systemic corticosteroids have also been reported to cause intrauterine growth retardation, but of a relatively modest degree. Halogenated corticosteroids do not cross the placenta easily, and so fetal and neonatal adrenal suppression is not a major concern with these compounds.[15] Overall, risk-benefit considerations nonetheless favor their use in persistent severe asthma with exacerbations unresponsive to other measures. Among the inhaled steroids, beclomethasone and budesonide are preferred because of their long history of use in pregnancy and the absence of any demonstrated toxicity to the fetus.[24] Table 86-1 summarizes the U.S. Food and Drug Administration (FDA) safety classification for agents useful for the treatment of asthma in pregnancy.

TABLE 86-1. Potential Fetal Risk of Drug Therapy in Pregnancy According to the FDA Classification for Safety in Pregnancy*

Drug	FDA Classification†
ASTHMA THERAPY	
Inhaled Bronchodilators	
Albuterol (salbutamol)	C
Terbutaline	B
Ipratropium	B
Salmeterol	C
Formoterol	B
Inhaled Corticosteroids	
Beclomethasone	C
Budesonide	B
Fluticasone	C
Leukotriene Antagonists	
Zafirlukast	B
Montelukast	B
Zileuton	C
Other Agents for Asthma	
Theophylline	C
Cromolyn	B
Systemic corticosteroids	B
Anticoagulants	
Heparin	C
Low-molecular-weight heparin	B
Warfarin	X
ANTIBIOTICS	
Penicillins	B
Cephalosporins	B
Macrolides	B/C
Quinolones	C
Clindamycin	B
Tetracyclines	D

*Although the Food and Drug Administration (FDA) classification provides an overview of fetal risk, detailed information should be consulted for individual drugs. Classification of individual drugs may change as the literature evolves.

†Class A: Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester, and the possibility of fetal harm seems remote. Class B: Animal studies do not indicate a risk to the fetus, and there are no controlled human studies; *or* animal studies do show an adverse effect on the fetus, but well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus. Class C: Studies in animals have shown the drug to have teratogenic or embryocidal effects, but there are no controlled studies in women; *or* no studies are available in either animals or women. Class D: Positive evidence of human fetal risk exists, but benefits in certain situations (e.g., life-threatening situations or diseases for which safer drugs cannot be used or are ineffective) may make use of the drug acceptable despite its risks. Class X: Studies in animals or humans have demonstrated fetal abnormalities, *or* there is evidence of fetal risk based on human experience, and the risk of the drug clearly outweighs any possible benefit. These drugs are contraindicated in pregnancy.

Labor and delivery can be especially hazardous for asthmatic patients, partly because of the drugs commonly administered. Narcotics other than fentanyl release histamine, which may worsen bronchospasm. Lumbar epidural analgesia is generally preferred, but if general anesthesia is to be used, pretreatment with atropine or glycopyrrolate assists bronchodilation. Ketamine

is the preferred anesthetic, although halogenated anesthetics at low concentrations may provide bronchodilation as well.[15] Preterm labor may be safely treated with nifedipine or magnesium sulfate. Oxytocin is the optimal labor induction agent and is useful for postpartum hemorrhage, but 15-methyl prostaglandin $F_{2\alpha}$, methylergonovine, and ergonovine may cause bronchospasm and should be avoided if possible.

Cystic Fibrosis

Cystic fibrosis (CF), occurring in about 1 in 1500 whites and 1 in 17,000 blacks, is a common genetic disease. With improved therapy, median survival has now increased to 37 years,[26] and as many as 4% of female CF patients between the ages of 17 and 37 may be pregnant at any time.[27] This occurs despite the frequent infertility of women due to delayed sexual development. Pregnancy in CF patients, as might be anticipated, has been associated with adverse fetal and maternal outcomes.[28,29] In a retrospective French study including data from 75 pregnancies between 1980 and 1999, there were 10 premature deliveries, 10 abortions, and 1 maternal death.[30] However, in a large U.S. review of 680 gravid women with CF enrolled in the U.S. Cystic Fibrosis Foundation National Patient Registry, from 1985 to 1997, survival was actually better in the gravid group than in the matched 3327 control patients with CF.[31] Women with CF who became pregnant had higher predicted percentages of FEV_1 and higher weights. Pregnancy was not clearly harmful in any subgroup, after severity adjustment for age, *Pseudomonas aeruginosa* colonization, pancreatic function, and FEV_1. In another case-control study, pregnancy had little effect on patients with stable CF, although poor outcomes were seen in those with severe disease.[32] As might be anticipated, most studies suggest that risk stratifies according to severity of illness.[29,32] Declines in pulmonary function tend to mirror severity-adjusted control subjects, and clearly CF patients require substantially more care and have more visits to physicians when pregnant than when not.[33] Prepregnancy counseling, particularly for women with more severe disease, is essential in limiting excessive maternal and fetal risk.

Infectious Diseases

Bacterial Pneumonia

Pneumonia is a leading cause of maternal and fetal morbidity and mortality.[34-38] Maternal mortality from pneumonia in nonimmunocompromised hosts ranged from 0 to 4% in series published since 1980.[33-35] The reported incidence varies widely, from 1 per 367 to 1 per 2388 deliveries,[34-35] but may not be higher than that in the general population. One report, however, indicated that pneumonia may be increasing in incidence, with human immunodeficiency virus (HIV) infection and chronic disease the major risk factors.[34]

Pregnancy increases the risk for major complications of pneumonia. In the series by Madinger and colleagues,[36] of 25 patients culled from 25,000 deliveries, 40% suffered major complications, including five intubations, two empyemas, one pneumothorax, and one pericardial tamponade. Similarly, in the series by Briggs and associates,[39] 7 of 34 patients required mechanical ventilation, and 2 died. Gestation is also threatened; preterm labor occurs in 4% to 44%.[34-37] The small-for-gestational-age rate is as high as 12%,[34] and intrauterine and neonatal death rates have ranged from 1.9% to 12.0%.[35,36] In all series, underlying chronic illness in the mother has been a powerful predictor of adverse outcome in both fetus and mother.

Pneumonia in pregnancy is most commonly bacterial in origin; the microbiologic spectrum mirrors community-acquired pneumonia, with *Streptococcus pneumoniae* and *Haemophilus influenzae* the most common organisms.[34-36] Other common organisms include *Mycoplasma pneumoniae* and *Chlamydia pneumoniae.* As in other community-acquired pneumonias, the causative agent is identified in only about half the cases. Unfortunately, the diagnosis of pneumonia is frequently delayed because of reluctance to obtain a chest radiograph; a posteroanterior radiograph performed with a grid and a peak voltage of 90 to 120 kV exposes the mother to 5 to 30 mrad but the fetus to 100 times less, or about 300 μrad.[40] A lateral chest radiograph produces greater maternal exposure (150 to 250 mrad) but is usually not required.[40] The hazard to both fetus and mother of delaying the diagnosis greatly exceeds the risk of this very small radiation dose. Antibacterial therapy is similar to treatment in the nonpregnant patient, although tetracyclines, quinolones, clarithromycin, and metronidazole should be avoided if possible.[40] Erythromycin, azithromycin, and β-lactam antibiotics are preferred because of their favorable safety profile (see Table 86-1).

Viral Pneumonia

Viral pneumonia remains a serious concern in pregnancy. In the influenza pandemic of 1918 to 1919, the maternal rate of mortality from pneumonia was as high as 50%. In the more recent epidemic of 1957 to 1958, pregnant women accounted for 10% of fatalities, and about half of the women of childbearing age who died were pregnant.[41] Since the epidemic of 1957 to 1958, the maternal mortality rate from influenza A and B pneumonia has been relatively low but still very much higher than that in the general population. Because of this, the Centers for Disease Control and Prevention (CDC) recommends inactivated influenza vaccine in otherwise healthy women during the second and third trimesters of pregnancy.[42] Although influenza virus does cross the placenta, current opinion holds that it is not likely to be teratogenic to the fetus, despite isolated reports that link influenza with neural tube and other malformations. Amantadine has been used in pregnancy successfully, both as treatment and as prophylaxis, although there have been case reports of cardiovascular defects occurring after first-trimester use; and there is considerable influenza resistance to the drug. The newer neuraminidase inhibitors zanamivir and oseltamivir, given by

inhalation, have an insufficient safety profile for routine use in pregnancy (FDA category C). The chief risk of seasonal influenza in the modern era probably resides in its dreaded complication of superimposed staphylococcal or gram-negative bacillary pneumonia.

In the spring of 2009, a previously unrecognized strain of influenza A (H1N1) virus emerged and quickly spread around the world. Recent reports of clinical experiences with large numbers of hospitalized patients with H1N1 influenza in Australia-New Zealand and throughout the U.S. confirm that pregnancy confers a high risk of serious disease and appreciable mortality.[42a,42b] Early treatment of pregnant women and women up to two weeks postpartum with oseltamivir or zanamavir appears to be beneficial. Pregnant women are also strongly urged to be vaccinated with the monovalent inactivated injectable H1N1 vaccine—not with the live attenuated vaccine.[42c]

Varicella pneumonia, caused by a virus of the DNA herpesvirus group, has also been linked to particularly adverse outcomes during pregnancy. In one review, Haake and coworkers[43] reported a 35% mortality rate in pregnant subjects, compared with 10% in other adults. Data are conflicting, and not all prospective studies have confirmed an increased incidence or mortality in pregnancy.[40] Treatment with acyclovir does appear to reduce mortality in gravid patients and probably should be used as therapy for active disease.[44] Use of varicella-zoster immune globulin (VariZIG) should be considered for susceptible pregnant women who have been exposed to varicella within 96 hours of the exposure. Administration of VariZIG reduces but does not abolish risk for fetal infection or congenital varicella syndrome, and it is effective in preventing complications of varicella in the mother. Patients should be evaluated similarly to other adults and a decision made to administer the immune globulin based on immune status, type of exposure, and health status. The currently licensed attenuated live virus against varicella is contraindicated in pregnancy.

Rubeola viral infection, often complicated by viral and then superimposed bacterial pneumonia, has also been associated with adverse outcomes, including preterm labor, spontaneous abortion, and perinatal mortality.[45] In contrast to rubella (German measles), fetal malformation, however, does not appear to be a consequence of rubeola disease. Nonimmune, exposed pregnant patients can receive passive immunoprophylaxis with immune globulin within 6 days of exposure; the live virus vaccine is contraindicated during pregnancy.

Hantavirus, which usually presents as a hemorrhagic fever and renal syndrome, can be accompanied by pneumonitis and acute respiratory distress syndrome (ARDS). It has been reported to have a similar presentation and course in pregnancy; outcomes of pregnant patients with hantavirus appear similar to those for nonpregnant patients with hantavirus and to those of pregnant patients with other causes of ARDS.[46]

Severe acute respiratory syndrome (SARS), due to a novel coronavirus (HuCoV-SARS), causes pneumonia and ARDS, with respiratory failure occurring in 15% of patients and a mortality rate of 8% to 30%.[47,48] Although data are limited, pregnant women appear to do worse than nonpregnant patients, with four of seven patients requiring ventilatory support in one series.[49] SARS adversely affects pregnancy, with miscarriage, fetal distress, and intrauterine death reported, presumably related to hypoxemia.

Fungal Pneumonias

Fungal pneumonias are uncommon in pregnancy. Although there is no evidence that blastomycosis and histoplasmosis are more severe during pregnancy, it does appear that coccidioidomycosis is more likely to disseminate in pregnancy.[50] In the southwestern United States, about 1 in 5000 pregnancies is complicated by *Coccidioides immitis.*[51] Dissemination is highly probable during the third trimester and has been related both to subtle impairment of cell-mediated immunity and to a stimulatory effect of progesterone and 17-β-estradiols on fungal proliferation. Amphotericin is the accepted therapy for disseminated coccidioidomycosis; azoles administered in the first trimester have been associated with brachial cleft abnormalities and should be only used after delivery.

Tuberculosis

Tuberculosis does not appear to be more common or severe in pregnancy. Classically, it has been said that tuberculosis improves during the latter stages of pregnancy, but then worsens after delivery. Pregnancy does not alter reactivity to tuberculin skin testing and hence the test should be performed in the recommended groups during pregnancy. Interferon-γ-release assays are also an acceptable means of testing for tuberculous infection (see Chapter 34). Asymptomatic patients with positive skin tests should have their chest radiograph deferred until after 16 weeks of gestation. Symptomatic patients with positive skin tests merit chest radiographs regardless of gestational stage. Isoniazid, rifampin, and ethambutol have acceptable safety profiles in pregnancy and are part of the standard treatment regimens advised by the CDC and the American Thoracic Society for pregnant women.[52] There is less collective experience with pyrazinamide, but this drug is recommended for use in pregnancy by the World Health Organization.[52] Worldwide data are accumulating, and pyrazinamide appears to be emerging as a drug that can be considered for treating multidrug-resistant tuberculosis and for HIV-infected women. Streptomycin, by contrast, is clearly associated with congenital deafness and is contraindicated during pregnancy.

Pulmonary Edema and Pulmonary Vascular Disease

Gravid women are at special risk for pulmonary edema for a variety of reasons, including the hypervolemia and high cardiac output of pregnancy, the occasional need for tocolytic drugs that affect the vascular bed, and the unique vascular and endothelial disorders of pregnancy.

Among these effects, it is noteworthy that colloid osmotic pressure diminishes during pregnancy, although the effect on transcapillary pressure gradients is partially offset by a decrease in interstitial fluid colloid osmotic pressure (as explained in Chapter 6).[53] Etiologically, underlying cardiac disease, use of tocolytic drugs, fluid overload, and preeclampsia are the most common causes for acute pulmonary edema in pregnancy.[53]

Hydrostatic (Cardiogenic) Pulmonary Edema

The cardiovascular adaptations to pregnancy have already been summarized. Their effects on underlying cardiac disorders are predictable. Stenotic valvular lesions are particularly poorly tolerated.[54] Of these, mitral stenosis is the most common symptomatic valvular disease in pregnancy and frequently presents with pulmonary edema, not only during gestation but also immediately postpartum, because of the large shifts in intravascular volume associated with delivery. The gradient across a stenotic mitral valve is augmented by the increases in blood volume, cardiac output, and heart rate that occur during gestation and the puerperium. In aortic stenosis, the increase in cardiac output required for pregnancy worsens the gradient across the valve. As a compensatory mechanism, the end-diastolic volume increases, but the low SVR in aortic stenosis impairs diastolic coronary artery filling and can precipitate ischemic syndromes. The reduction in SVR of pregnancy mitigates the consequences of mitral and aortic regurgitation and of the left-to-right intracardiac shunts of endocardial cushion defects, but worsens the consequences of Eisenmenger's syndrome and uncorrected tetralogy of Fallot. Depending on the cardiac disorder, perturbations induced by pregnancy can alter fractional shunts, induce hypoxemia, and precipitate pulmonary edema.

A special problem of pregnancy is peripartum cardiomyopathy, a disorder that occurs in 1 of 1300 to 15,000 deliveries, may present with congestive heart failure, and is associated with a special propensity for pulmonary and systemic embolization during the last month of pregnancy and for up to 5 months thereafter.[55] Standard therapy for heart failure, including β-blockers, diuretics, angiotensin-converting enzyme inhibitors, and blockaders are usually effective, but sometimes implantable defibrillators and even heart transplantation are required.[56]

Tocolysis-Associated Pulmonary Edema

The systemic administration of β_2-sympathomimetic agents to retard premature labor has been associated with a 0 to 4.4% incidence of pulmonary edema.[57] The etiology of this disorder is controversial.[58] One speculation is that it is due to myocardial dysfunction from prolonged sympathetic stimulation, but descriptions of cases in which hemodynamic parameters were measured reported normal pulmonary capillary wedge pressures. The idea that increased vascular permeability may contribute to the syndrome is given weight by its association with maternal infection.[59] Some authors have speculated that the development of the disorder requires a coexisting condition, such as volume overload, sepsis, or preeclampsia.[60] It usually presents after at least 24 hours of β-adrenergic therapy, with relatively acute onset of dyspnea and pulmonary edema seen on chest radiographs (Fig. 86-3). Simple discontinuation of β-adrenergic therapy often results in rapid improvement; whether diuretics need to be given is unresolved, but furosemide is usually administered. Pulmonary edema has complicated tocolysis performed with calcium channel blockers.[61]

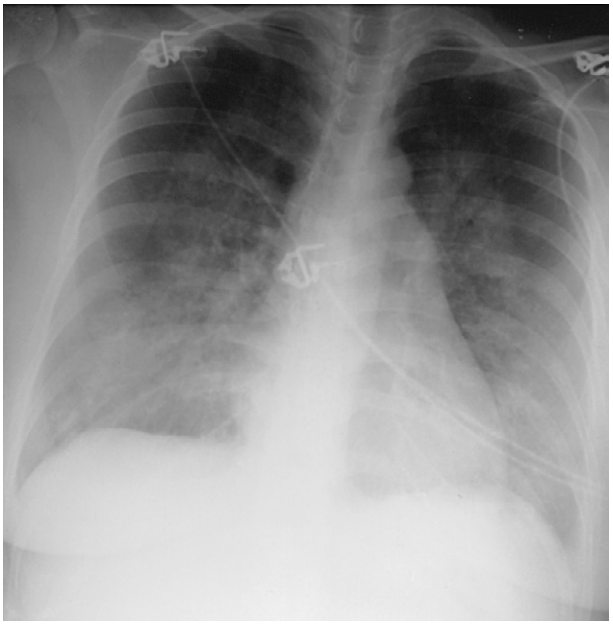

FIGURE 86-3 ■ Tocolysis-associated pulmonary edema in a 38-year-old woman in premature labor.

Pulmonary Edema Associated with Preeclampsia

About 2.9% of patients with preeclampsia or eclampsia develop pulmonary edema.[62] The spectrum of hemodynamic findings associated with pregnancy-induced hypertension and preeclampsia is wide, but, in general, left ventricular preload is normal or low, afterload is high, and cardiac output is normal or low (Fig. 86-4). Systolic and diastolic function may also be impaired.[63] The pulmonary edema commonly first presents in the postpartum period,[62,63] reflecting fluid administration at delivery. Low colloid oncotic pressure and abnormal vascular permeability likely contribute as well. Hemodynamic monitoring of these patients is probably warranted if oliguria complicates the picture.

Pulmonary Embolism

Pulmonary embolism is a leading cause of maternal mortality,[64] accounting for 9% of 95 pregnancy-related deaths in a large health care delivery system in the United States between 2000 and 2006.[64] Even though the risk for venous thromboembolism in pregnant women is about five times as great as in age-matched and sex-matched

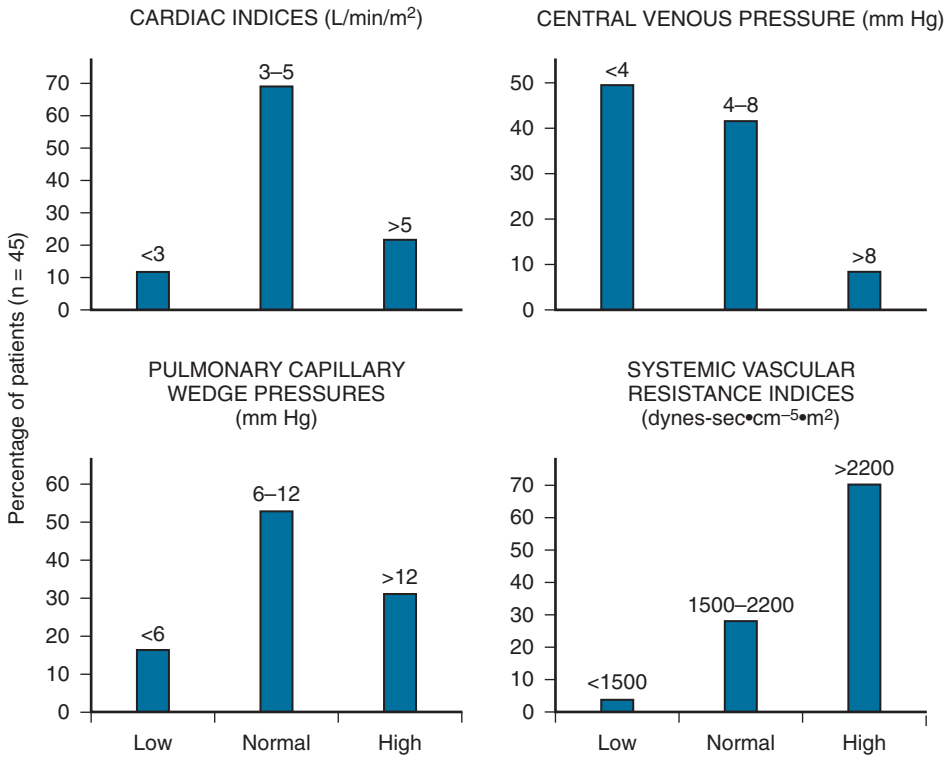

FIGURE 86-4 ■ Spectrum of hemodynamic profiles seen in 45 women with severe pregnancy-induced hypertension, one of the disorders sometimes complicated by pulmonary edema. Pulmonary edema in pregnancy-induced hypertension usually does not reflect simple volume overload. (From Cotton DB, Lee W, Huhta JC, et al: Hemodynamic profile of severe pregnancy-induced hypertension. Am J Obstet Gynecol 158:523–529, 1988.)

nongravid controls, it is still relatively infrequent. A Danish population-based study of 63,000 deliveries found a cumulative incidence of 0.85 in 1000 deliveries from 1984 to 1994.[65] In this study, the incidence of detected venous thromboembolism increased to 1.23 in 1000 deliveries after the introduction of ultrasonography, demonstrating that its reported incidence may depend on the adequacy of diagnostic procedures employed. Other studies have reported rates of 0.5 to 1.3 per 1000, with a lower incidence in younger patients and higher incidence in those over 35 years of age.[66,67]

The risk for thrombosis is increased in pregnancy, partly because of the increase in the coagulation factors, particularly V, VIII, X, and von Willebrand factor antigen, and partly because of a marked fall in protein S.[68] Venous stasis, an important contributor to thrombosis, is caused by uterine compression of the inferior vena cava and the left iliac vein. Local trauma to pelvic veins at the time of delivery probably accounts for the peak incidence of thromboembolism in the postpartum period, especially after cesarean section. Specific risk factors for thromboembolism include previous thromboembolism during pregnancy or while taking oral contraceptives, prolonged bed rest, a complicated or cesarean delivery, age, and inherited coagulation defects. The latter include deficiencies of protein S, protein C, and antithrombin III or the presence of antiphospholipid antibodies, factor V Leiden, and prothrombin G20210A.[66,68] The first two risk factors probably warrant prophylactic subcutaneous heparin administration throughout pregnancy, now more commonly accomplished with low-molecular-weight heparins (LMWHs) due to their safety and decreased risk of heparin-induced osteopenia and thrombocytopenia.

Clinical diagnosis of deep venous thrombosis during pregnancy and the puerperium is exceptionally difficult because of the peripheral edema associated with pregnancy and the asymmetrical compression of the left-sided common iliac vein by the gravid uterus. The initial diagnostic test should be duplex ultrasonography (combined real-time B-mode compression ultrasonography plus Doppler venous ultrasonography). In the patient with high clinical suspicion but a negative test, a repeat examination at 5 to 7 days may be valuable. The "gold standard" for detecting lower extremity thrombosis remains venography, but in pregnancy thrombosis is typically confined to the iliac veins and may be difficult to visualize, even by this technique. When venous thrombosis of the lower extremity is documented, it is usually left-sided, as it was in 58 of 60 cases reported by Ginsberg and colleagues.[69]

The diagnosis of pulmonary embolism in pregnant women is relatively straightforward. Both ventilation-perfusion scanning and pulmonary angiography can be performed during pregnancy in a modified fashion. Estimated fetal radiation exposure for a standard technetium-labeled macroaggregated albumin perfusion scan is about 0.018 cGy (18 mrad),[70] which can be

reduced further by simply halving the dose without greatly impairing resolution. There is no need for the ventilation portion of the study if perfusion is normal. Computed tomographic (CT) angiography is an acceptable imaging modality and is associated with similarly low radiation doses to the fetus.[71] Pulmonary angiography, when performed by the brachial route, exposes the fetus to only about 0.050 cGy (50 mrad).[72] Such levels of exposure are not believed to cause teratogenicity, which is associated with exposure of greater than 5 to 10 cGy (5 to 10 rad). However, an increased incidence of childhood leukemia has been documented with lower fetal radiation exposure, in the range of 1 to 5 cGy (1 to 5 rad). A recent comparison of lung scintigraphy and pulmonary CT-angiography concluded that the former method was more accurate than the latter for diagnosing pulmonary embolism during pregnancy.[72a] Magnetic resonance imaging with gadolinium contrast also has promise because it can image pelvic and lower extremity veins as well as the pulmonary arteries, and it has little contrast-associated toxicity. Its widespread use requires availability of ultrafast scanners and more evaluation of its accuracy.

Embolism in pregnancy is treated with heparin because warfarin crosses the placenta and causes nasal, ophthalmologic, and central nervous system abnormalities. LMWH appears to be safe in pregnancy and, compared to unfractionated heparin, is associated with fewer adverse effects such as thrombocytopenia and osteoporosis.[73,74] A consensus is emerging that LMWH is preferable in pregnancy, but some authors also advocate titrating the dose to achieve anti–factor X levels of 0.5 to 1.24 units/mL 4 hours after injection.[73,74] Weight gain in pregnancy makes formulaic dosing less reliable. Thrombolytic therapy has been used successfully in life-threatening thromboembolism during pregnancy, with a complication rate similar to that in nonpregnant women.[75]

Standard therapy of thromboembolism antepartum encompasses either continuous intravenous unfractionated heparin or LMWH until 24 hours before elective induced or planned surgical delivery. For spontaneous deliveries, because of the risk of epidural hematoma formation with regional anesthesia, LMWH should be switched to unfractionated heparin about 2 weeks prior to the anticipated delivery. If labor begins unexpectedly, reversal of the heparin effect with protamine is advisable. Postpartum, warfarin can be given safely during lactation.

Amniotic Fluid Embolism

Small amounts of amniotic fluid may enter the circulation during uncomplicated pregnancy, but in 7.7 per 100,000 deliveries there is a catastrophic syndrome of amniotic fluid embolism.[76] The onset is usually during labor and delivery or immediately after uterine manipulation, when severe dyspnea, hypoxemia, and then seizures and cardiovascular collapse or arrest occur. If the patient survives the initial insult, disseminated intravascular coagulation and ARDS usually supervene.[77] Risk factors include older maternal age, high parity, cesarean section, low uterine segment laceration, and meconium staining of amniotic fluid.[60] Abruptio placentae is present in 50% of cases, and fetal demise occurs in 40%.[77] The maternal mortality rate has been as high as 86%[78] but has appeared more recently to be as low as 22%[76]; overall, amniotic fluid embolism may account for 14% of all maternal deaths.[64]

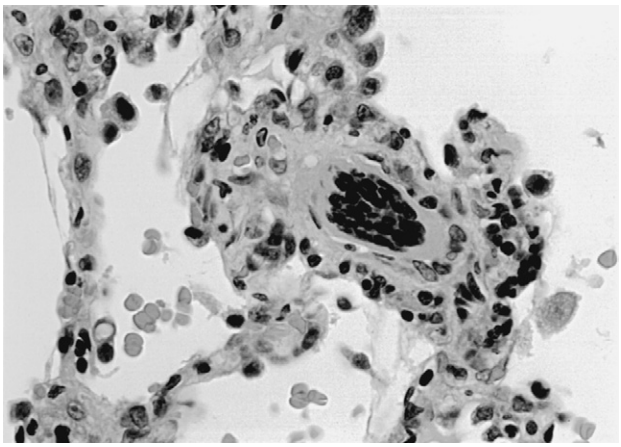

FIGURE 86-5 ■ Small pulmonary vessel filled and distended by fetal squamous cells from a fatal case of amniotic fluid embolism in a 39-year-old woman who succumbed within 4 hours of delivery. (Keratin stain; original magnification ×400.) (Courtesy of Dr. Gerald Berry.)

In a U.S. registry of cases, 78% of the patients with amniotic fluid embolism had ruptured membranes, and several had just undergone intrauterine procedures,[79] clearly implicating traumatic opening of uterine vessels in the pathogenesis. The exact quantity or constituent of the amniotic fluid required to initiate the syndrome is unknown. Pathologically, fetal squamous cells are found in the maternal pulmonary circulation at autopsy (Fig. 86-5), but even in symptom-free patients fetal cells may be recovered from pulmonary artery catheters placed for other reasons.[80] Hemodynamically, the process is often biphasic, with pulmonary hypertension initially followed by left ventricular failure.[81,82] These changes may be caused by leukotrienes and arachidonic acid metabolites, particularly prostaglandin $F_{2\alpha}$, which appear in amniotic fluid during labor. An immunologic basis for some of the changes seems likely because women with male fetuses are more likely to acquire the disorder.[82] Clark and associates[79] seized on the similarities to anaphylaxis and suggested that the disorder be renamed *anaphylactoid syndrome of pregnancy.* A small study did not demonstrate evidence of mast cell degranulation but suggests a role for complement activation.[83]

Radiographically, the patients usually develop bilateral parenchymal infiltrates consistent with pulmonary edema and then acute lung injury. Treatment consists of supportive care for the associated disseminated intravascular coagulation and left ventricular and respiratory failure. If the fetus survives the initial insult and is intrauterine, it should be promptly delivered. In cases of

maternal demise, emergency postmortem or periresuscitative cesarean section is warranted, as in other instances of cardiopulmonary resuscitation in pregnancy.[84]

Arteriovenous Malformations

Pulmonary arteriovenous malformations may expand during pregnancy because of the increase in blood volume and venous distensibility.[85] This increases the likelihood of bleeding, with life-threatening complications occurring in about 1% of pregnant women with hereditary hemorrhagic telangiectasia.[86] Embolization and surgical management have been utilized successfully during pregnancy.

Air Embolism

Occasionally, venous air embolism occurs during pregnancy, presumably through the subplacental venous sinuses.[87] This disorder has been clearly documented during labor and delivery, during cesarean sections and abortions, in patients with placenta previa, and in those engaging in orogenital sex during pregnancy.

Acute Lung Injury in Pregnancy

Aspiration Pneumonitis

Since Mendelson's[88] original report of 66 cases of gastric aspiration in 44,016 deliveries between 1932 and 1945 (an incidence of 0.15%), aspiration has continued to be a major cause of maternal morbidity and mortality. Increased intra-abdominal pressure due to the gravid uterus, the inhibitory effect of progesterone on the tone of the esophageal sphincter, and the assumption of the supine position for delivery all contribute. Eating during or just before labor increases the volume of emesis.[89] Aspiration of gastric contents with pH 2.5 or lower is known to cause chemical pneumonitis and increased permeability edema. Both in Mendelson's original report and today, about two thirds of cases of aspiration occur in the delivery suite. Emergency intubation of the obstetric airway is particularly difficult,[90] and failed intubation in the delivery suite occurs at a rate eight times that in the general surgical population.[91] To reduce the risk for aspiration and to minimize the chance of acid aspiration at intubation, oral administration of histamine$_2$ blockers or sodium citrate before intubation, in conjunction with a formal airway assessment, is desirable. Identified risk factors in intubation include a high Mallampati class, indicating poor visibility of the posterior pharynx, a short neck, protruding maxillary incisors, and a receding mandible.[92]

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome occurs relatively frequently in pregnancy; in one obstetric intensive care unit, it was the leading cause of maternal death during a 6-year period.[93] The three most common nonobstetric causes are pneumonia, sepsis, and aspiration. Common obstetric causes include chorioamnionitis, amniotic fluid embolism, and trophoblastic embolism.[94] Ventilator management is unaltered in pregnancy; the prognosis also appears to be the same, with an anticipated 40% to 75% survival rate.[94,95]

Other Respiratory Diseases in Pregnancy

Obstructive Sleep Apnea

Pregnancy may be complicated by obstructive sleep apnea (OSA), potentially adversely affecting both mother and fetus.[96] In general, apnea and hypopnea are uncommon in pregnancy because of the respiratory stimulatory effect of progesterone. OSA usually occurs in obese patients, precipitated by the airway mucosal edema and vascular congestion that accompany pregnancy. Snoring and OSA are more common in women with preeclampsia.[97] Nocturnal hypoxemia may produce poor fetal growth, although snoring alone is not associated with fetal risk.[98] Treatment with nasal continuous positive airway pressure is safe and effective.

Interstitial Lung Disease

Most cases of interstitial lung disease occur in patients older than those in their childbearing years. When interstitial disease exists in pregnant women, the reduced diffusing capacity may cause difficulty in meeting the increased oxygen consumption requirements of pregnancy. Associated pulmonary hypertension carries significant risks, because cardiac output increases during pregnancy. Few data exist on the management and outcome in these patients, but restrictive lung disease appears reasonably well tolerated in pregnancy.[99] Patients who have a vital capacity of less than 1 L and those who have pulmonary hypertension should consider avoiding pregnancy.[100] Lymphangioleiomyomatosis and systemic lupus erythematosus may worsen as a result of pregnancy.

Pleural Disease

Pleural effusions may accompany obstetric complications such as preeclampsia and choriocarcinoma, but many women with normal pregnancies develop small, asymptomatic pleural effusions in the postpartum period.[101] They occur as a result of the increased blood volume and reduced colloid osmotic pressure that occur in pregnancy, as well as from impaired lymphatic drainage due to the Valsalva maneuver during labor. Moderate-size effusions or the presence of symptoms should prompt a full clinical evaluation. The Valsalva maneuver of labor may also produce spontaneous pneumothorax and pneumomediastinum, particularly in patients with predisposing conditions such as asthma. This diagnosis should be considered in the woman who develops chest discomfort and dyspnea during, or immediately following, delivery.

GYNECOLOGIC DISORDERS AND THE LUNGS

Catamenial Pneumothorax

Lillington and colleagues[102] introduced in 1972 the term *catamenial pneumothorax* to describe the already reported phenomenon of spontaneous pneumothorax occurring within 24 to 72 hours after onset of menses. More than 200 cases have been reported. It appears to account for about 2.8% to 5.6% of spontaneous pneumothoraces in women,[103,104] most often affecting women in the third or fourth decade of life. About 30% to 60% of cases are attributable to thoracic endometriosis, as judged by inspection at thoracotomy[105]; other cases have a more obscure etiology, however, so a number of theories have been advanced. First, during menstruation, the absence of the normal cervical mucus plug permits an open connection between ambient air and the abdominal cavity through the uterus and fallopian tubes. Air can move transdiaphragmatically through right-sided diaphragmatic fenestrations into the pleural space, as it sometimes does during abdominal laparoscopy.[106] This may account for the condition's 90% to 95% right-sided predominance.[107] A second theory is that high levels of prostaglandin $F_{2\alpha}$ during menstruation cause bronchospasm with attendant air trapping and pneumothorax, but wheezing is not a common symptom of this disorder. A third theory is that pleural blebs or bullae are more susceptible to rupture during menstruation because of hormonal changes,[105,107] but visceral pleural leaks are rarely found at surgery (see also Chapter 74 for a full discussion).

For cases of endometriosis-associated pneumothorax, a trial of gonadotropin-releasing hormones is warranted if the phenomenon is repetitive but not life-threatening. Oral contraceptives, other progestational agents, and tubal ligation have also been used with some success. For cases not clearly associated with systemic endometriosis, thoracoscopy during menstruation serves to define the etiology and can be used to achieve pleurodesis.[106]

Endometriosis

Endometriosis probably affects about 10% of women, shows no clear ethnic differences in prevalence, and is most commonly diagnosed at 30 to 34 years of age.[108] Although pelvic pain, dysmenorrhea, and infertility are its predominant manifestations, atypical locations, including diaphragmatic, pleural, and endobronchial sites, have been documented. As described previously, endometriosis can result in recurrent catamenial pneumothorax, which is its most common thoracic presentation. In one review of 110 cases with thoracic endometriosis, catamenial pneumothorax was the presenting symptom in 73% of cases, followed by hemothorax in 14% and hemoptysis in 7%.[108] It also has been associated with right-sided pleural pain, pleuritic effusions, and hemothorax. Inspection at thoracotomy or thoracoscopy typically reveals blue-brown nodules on the pleural surface, sometimes in a "gunshot" distribution.[109] The absence of known pelvic endometriosis is not helpful in making the diagnosis because only 20% to 70% of patients have associated pelvic disease. The diagnosis is suspected on clinical grounds, since neither CT nor endoscopy is specific.[110] Rarely, the implants are found in lung parenchyma, accounting for the catamenial hemoptysis. Most pleural and diaphragmatic disease is thought to arise from transdiaphragmatic spread from retrograde menses, even when abdominal disease is not evident. Massive ascites is sometimes related, although only 27 cases have been reported.[111] Pneumothoraces may be attributed to cyclical sloughing of implants on key surfaces, such as the visceral pleura,[112] or to air trapping from airway involvement or compression.[102] Pulmonary parenchymal disease may be embolic in origin, as it is presumed to be in the central nervous system. The diagnosis can be established only by biopsy showing the characteristic ectopic endometrial glands in involved sites. Medical therapy consists of progestational agents or gonadotropin-releasing hormones; surgical approaches include excision, local laser ablation, or pleurodesis.

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is a rare disorder, with only about 300 reported cases, which afflicts premenopausal women predominantly.[113,114] The most common presenting event is a pneumothorax, occurring in 86.5% of patients in the National Heart, Lung, and Blood Institute registry.[113] It is fundamentally a disorder of smooth muscle proliferation that results in functional obstruction of vessels, lymphatics, and airways. (See Chapter 62 for a complete discussion of LAM.) Involvement of pulmonary vascular structures is responsible for the hemoptysis, whereas lymphatic obstruction accounts for the chylous effusions. Mediastinal and retroperitoneal lymphatic proliferation may be a feature of the disease as well. LAM is also associated with renal angiomyolipomas, another hamartomatous disorder, and with tuberous sclerosis. Conventional therapy has included oophorectomy or progestational agents, mainly medroxyprogesterone acetate. Lung transplantation has been performed in more than 60 patients with this disorder, but it has clearly recurred in some of them. Current research focuses on growth factors and genetic factors that have been implicated in the disease's causation.[115] Particularly intriguing is the identification of lesions on chromosome 16p13 in patients with tuberous sclerosis and LAM or renal angiomyolipomas. Most recently sirolimus, in a trial in patients with angiomyolipomas and tuberous sclerosis complex or LAM, showed ameliorative effects on lung function and volume of angiomyolipomas, presumably by suppressing signaling pathways involved in products of the defective genes.[116]

Trophoblastic Embolization

Trophoblastic embolism is a rare complication of hydatidiform mole. In one series, only 2.6% of 189 patients

with hydatidiform mole had an embolic event, so most episodes of respiratory distress in patients with molar gestations are not caused by embolic events but, rather, by pulmonary edema, anemia, or another complicating event.[117] Embolization, when it does occur, is most common at the time of evacuation of the mole. Chorionic neoplasms that arise during gestation are suggested by a large discrepancy between gestational date and uterine size and should be evaluated by transvaginal ultrasonography.[118] Moles can also arise outside of gestation from the gonads of either sex.

Ovarian Hyperstimulation Syndrome

The use of exogenous gonadotrophins to stimulate ovulation for in vitro fertilization has been associated with pulmonary complications.[119] This ovarian hyperstimulation syndrome usually manifests with ovarian cysts, bilateral pleural effusions, ascites, and intravascular volume depletion. Hypovolemic shock, renal failure, and ARDS may result. Pulmonary embolism may occur due to the hypercoagulable state induced by estrogens associated with intravascular volume depletion. The mechanism of the effusions is unclear but is related to increased permeability due to release of vasoactive mediators, of which vascular endothelial growth factor appears to be the most important.[120] Recent evidence points to mutations in the follicle-stimulating hormone receptor as etiologic in at least some cases.[121] Treatment is supportive and involves maintaining intravascular volume and thoracentesis if required for respiratory distress.

KEY POINTS

- Normal pregnancy is associated with profound alterations in respiratory and cardiovascular physiology, which—although designed for maternal and fetal well-being—may exacerbate underlying cardiopulmonary conditions or cause new ones.
- Major physiologic perturbations found in normal pregnancies include (1) an increase in central drive to breathe, with resulting changes in P_{CO_2} (28 to 32 mm Hg) and pH (7.40 to 7.47); and (2) an increase in both maternal blood volume, of about 2 L (40%), and cardiac output, after 25 to 32 weeks of gestation, of 30% to 45%.
- The most common pulmonary disease to impair outcome in pregnancy is asthma, but the effects of pregnancy on asthma are variable: it worsens, improves, or remains unchanged in roughly one third of afflicted women.
- The risks of poorly controlled asthma for both mother and fetus during pregnancy far outweigh the risks of drug therapy. Some standard drugs are safer than others (see Table 86-1) and should be used whenever possible.
- Cystic fibrosis and infectious pneumonias have all been linked with adverse fetal and maternal outcomes, the risk of which depends largely on the severity of the complicating disorder. Prepregnancy counseling and avoidance of certain antimicrobial drugs (as noted in Table 86-1) are strongly recommended.
- Pulmonary edema may occur during pregnancy in women with underlying heart disease, especially valvular stenosis, or in association with either tocolytic therapy to retard premature labor or preeclampsia. Because the causative mechanisms differ, so does specific therapy.
- Pulmonary embolism is a leading cause of maternal mortality while gravid and immediately afterward. During pregnancy, low-molecular-weight heparins are indicated for both treatment and prevention; warfarin is contraindicated. Ventilation-perfusion imaging and computed tomographic angiography can be used when needed. Magnetic resonance imaging is useful when available.

Data Supporting Noninvasive Positive-Pressure Ventilation in Neuromuscular Disease
Cough Support

INTRODUCTION

Gas exchange between the atmosphere and the human body depends not only on the lungs but also in large part on the function of the "ventilatory pump," which consists of the respiratory control centers located in the brain, the bony rib cage, diaphragm, and intercostal, accessory, and abdominal muscles. A wide variety of neuromuscular disorders can result in dysfunction of the ventilatory pump that in turn can lead to respiratory failure, pneumonia, and even death. Breathing disorders are recognized as the leading cause of mortality in neuromuscular disease,[1] and appropriate interventions can prevent complications and prolong life in individuals with neuromuscular disease affecting the respiratory system.

FUNCTIONAL ANATOMY OF THE RESPIRATORY SYSTEM

The ventilatory pump is designed to bring oxygen into the body to fuel energy generation and remove carbon dioxide as a waste product of cellular metabolism. The system is made up of the cortex of the brain that controls voluntary breathing; the brain stem, which is involved with automatic breathing; the spinal cord and motor neurons that transmit nerve impulses; the respiratory muscles that are the effectors of the system; and a complex system of feedback receptors and nerves that regulate ventilation (Fig. 87-1). The system is remarkably flexible and can precisely maintain CO_2 and acid-base balance despite encountering large variations in metabolic demands that result from the activities of daily living. The following is a discussion of each of the components of this complex network.

Central Nervous System

Voluntary Breathing Controllers

Voluntary breathing is controlled by signals from the cerebral cortex. Centers located within the parietal cortex send volitional signals that initiate inspiration and expiration.[2] These cortical areas project to the motor neurons in the spinal cord via the corticospinal tracts. These tracts are separate pathways from the reticulospinal pathways that connect the central automatic breathing centers to the motor neurons.

Automatic Breathing Controllers

Automatic breathing is controlled by a complex system that includes respiratory centers in the pons and medulla,

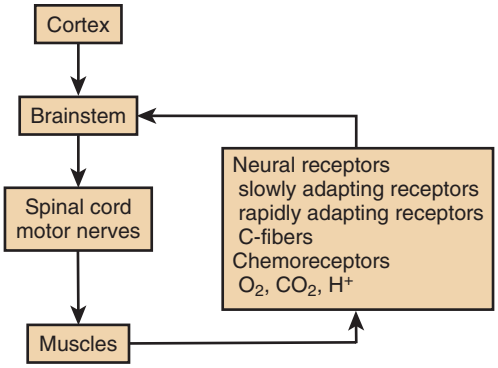

FIGURE 87-1 ■ Neuromechanical respiratory system shows the neuromuscular pathways and feedback control.

nerve tracts in the lower brain stem, the reticulospinal pathways in the spinal cord, and the feedback mechanisms that are both chemical and mechanical in nature. There are thought to be three centers that generate the rhythm and drive to breathe, one located in the pons and two in the medulla. More detailed reviews of this topic are available.[3,4]

Spinal Cord

The spinal cord and motor nerves conduct nerve impulses from the cortex and brain stem to the anterior horn cells of the motor neurons supplying the respiratory muscles. As noted previously, the nerve fiber tracts in the spinal cord responsible for voluntary (corticospinal tract) and automatic (reticulospinal tract) breathing are separate within the spinal cord.[5] The fibers in both of these tracts travel through the spinal cord to synapse with the lower motor neurons.

Peripheral Nervous System

Lower Motor Neurons

The lower motor neuron has its cell body in the spinal cord (anterior horn cell) but exits the spinal cord to become the spinal nerve roots and the nerves that supply the respiratory muscles. When the nerves arrive at the muscle, they divide into branches known as *twigs* that, upon reaching the muscle fiber, further divide into bulbous projections called *boutons* that apply themselves to the muscle membrane at a specialized anatomic junction called the *motor end plate*. These boutons contain acetylcholine, which is the chemical transmitter that serves to excite the muscle to contract. With nerve firing, there is release of acetylcholine at the motor end plate into the cleft between the nerve and the muscle. The acetylcholine binds to receptors on the muscle side of the motor end plate, which results in a *suprathreshold excitatory end plate potential* and depolarization of the muscle membrane.[6] A muscle action potential then results in contraction of the muscle fiber.

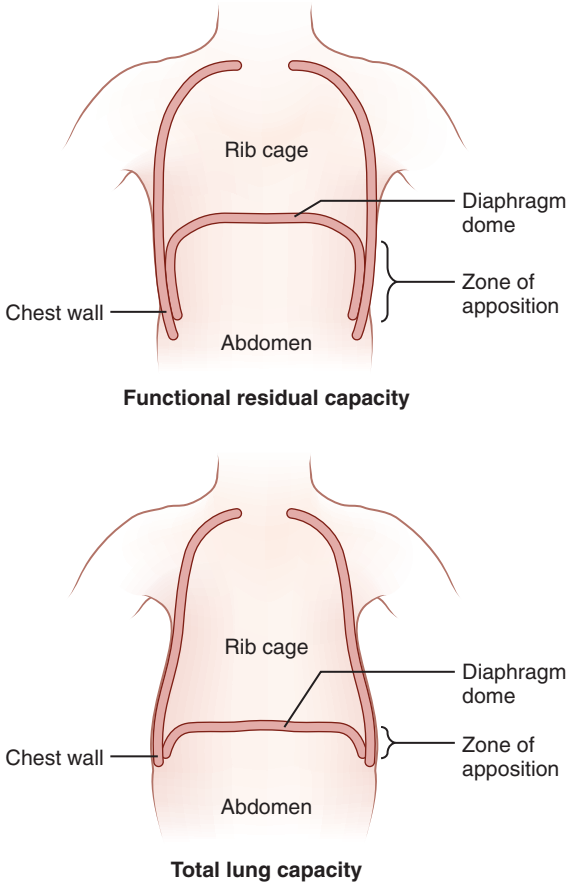

FIGURE 87-2 ■ Diaphragmatic positions at rest (*top*) and at full contraction (*bottom*). At functional residual capacity (FRC; *top*), the diaphragm lies within the chest with a zone of apposition along the chest wall. At total lung capacity (TLC), the contracted diaphragm has displaced abdominal contents and, via the increase in abdominal pressure, has expanded the chest wall outward.

Respiratory Muscles

The respiratory muscles are the mechanical effectors of the breathing system. They are often divided into three major groups: (1) the inspiratory muscles, (2) the expiratory muscles, and (3) the accessory muscles of respiration. The muscles that maintain patency of the upper airway during the respiratory cycle are sometimes also considered muscles of respiration because of their close interaction with the other respiratory muscles.

The diaphragm is the major muscle of inspiration and accounts for approximately 70% of the inhaled tidal volume in the normal individual[7] (Fig. 87-2). Contraction of the diaphragm results in a downward piston motion of the muscle as well as outward and upward movement of the ribs through the *zone of apposition*. The innervation of the diaphragm is via the phrenic nerve that originates from cervical nerve roots three through five. The intercostal muscles are thin sheets of muscular fibers that run between the ribs in the costal spaces.[8] There are two sheets of muscle fibers, the external and internal intercostals. The external intercostals function to expand the

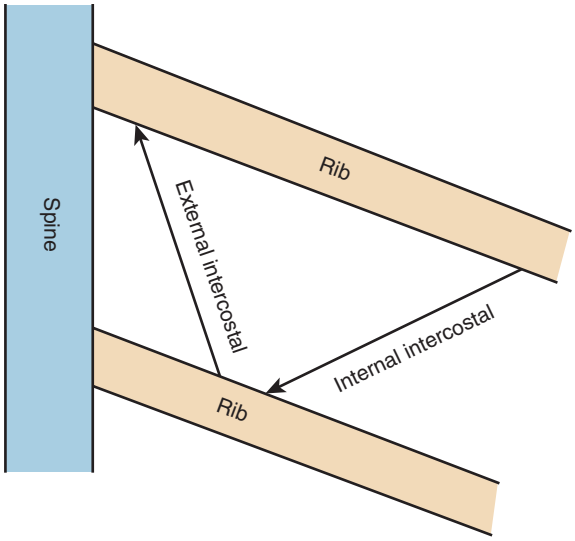

FIGURE 87-3 ■ Actions of the intercostal muscles on the ribs. Contraction of the external intercostals results in an upward and outward movement of the ribs during inhalation. Contraction of the internal intercostals results in a downward and inward movement of the ribs during exhalation.

rib cage during inspiration. The internal intercostals are deeper and function to decrease rib cage size during expiration. The mechanism of action of the intercostal muscles on the ribs is shown in Figure 87-3. The orientation of the muscle fibers with respect to the ribs results in the increase or decrease in the size of the rib cage. Innervation of the intercostals is via the intercostal nerves originating from the thoracic spinal nerve roots.

The abdominal muscles (rectus abdominis, internal oblique, external oblique, and tranversus abdominis) serve a number of functions in respiration that mainly assist expiration but can also function in inspiration. The internal and external obliques and the transversus abdominis result in an inward movement of the abdominal wall that displaces the diaphragm upward into the thoracic cavity and assists exhalation. The rectus abdominis as well as the internal and external obliques pull the lower rib cage caudally and thereby increase pleural pressure and exhalation. The abdominal muscles also may play a minor role in inspiration[9]; if their contraction reduces lung volume below function residual capacity (FRC), abdominal muscles can store elastic recoil energy in the chest wall that then assists expansion of the chest wall during the next inspiration.

The accessory muscles of respiration (sternocleidomastoid, scalenes, trapezii, latissimus dorsi, platysma, and pectoralis major and minor muscles) can expand the rib cage and assist inspiration during situations of increased ventilatory demand such as during exercise or during circumstances in which other inspiratory muscles are impaired as in tetraplegia or chronic obstructive pulmonary disease (COPD). It is now clear that some of them function during minimal exertion and even during quiet tidal breathing.[10]

The muscles of the upper airway are also considered to be muscles of respiration because they maintain patency of the upper airway and allow air to flow into and out of the lungs without interruption.[11] Some of these also participate in protection of the lower airway during swallowing, a key function in the defense of the respiratory system. The upper airway muscles include the abductors of the vocal cords, the palatal elevators, retractors of the tongue, and dilators of the nares. These muscles are innervated by cranial nerves V, VII, and IX-XII. The central control centers for these muscles are the same as those described previously for the more commonly considered ventilatory muscles.

Controller Feedback

The respiratory control mechanisms depend on both neural and chemical receptors found in peripheral and central sites. An excellent discussion of this topic is available.[12] The automatic respiratory centers in the brain stem respond to feedback from these receptors and adjust neural output to the ventilatory and upper airway muscles that expand the chest wall and maintain upper airway patency (see Fig. 87-1).

Neural receptors are present in the upper airway, respiratory muscles, lungs, and pulmonary vessels.[12] Once stimulated, these receptors project signals to the central respiratory controller via the vagus nerve. The respiratory centers then adjust their output to the respiratory muscles to alter ventilation and modulate reflexes such as cough and sneeze. There are several different types of neural receptors. *Muscle spindles* and *slowly adapting pulmonary stretch receptors (SARS)* predominantly respond to changes in lung and thoracic cage volume. As the lung and chest wall inflate, these receptors are stretched and dampen the output from the inspiratory centers in the medulla. These receptors are involved in the "Hering-Breuer" reflex in which inspiration is halted as lung volume increases.[13] *Rapidly acting irritant receptors (RARS)* respond to changes in lung volume, to chemical stimuli such as histamines and prostaglandins, and to noxious stimuli. *C fibers* in the airways and lung are stimulated by chemical stimuli in the local environment. The C fibers likely mediate the hyperventilation that is seen in normoxic circumstances in a number of pulmonary disorders such as asthma, pulmonary embolism, pneumonia, and pulmonary edema.

Chemical receptors or *chemoreceptors* are located both peripherally as well as in the central nervous system.[12] The *peripheral chemoreceptors*, which include the carotid and aortic bodies, are the primary site for sensing low levels of arterial oxygen pressure (Pa_{O_2}) but also respond to a lesser extent to changes in arterial carbon dioxide pressure (Pa_{CO_2}) and pH. They are stimulated when the Pa_{O_2} falls below 75 mm Hg as well as when the Pa_{CO_2} increases and pH decreases. Whereas both receptors stimulate ventilation in hypoxia, the aortic chemoreceptors are more important in infants and the carotid receptors are more important in adults.[14] Once stimulated, the carotid bodies send impulses via cranial nerve IX to the nucleus tractus solitarius (NTS) where neurotransmitters are released that increase

ventilation.[15] Although the control of ventilation during exercise is not completely understood, the predominant stimulus for increased ventilation is thought to arise from the peripheral receptors. It is postulated that additional peripheral receptors exist that are yet to be identified because the hyperventilatory response of exercise cannot be fully accounted for by the carotid bodies.[16] The *central chemoreceptors* are crucial in the adjustments of ventilation to acid-base disturbances and $PaCO_2$. There are four groups of chemosensitive neurons in the brain stem: the locus ceruleus, the NTS, the midline raphe, and the ventrolateral quadrant of the medulla. The central chemoreceptors are responsible for most of the response to carbon dioxide. They respond to increases in $PaCO_2$ by their detection of the fall in pH of the cerebrospinal fluid associated with an increase in cerebrospinal fluid (CSF) $PaCO_2$,[3] which closely follows an increase in serum $PaCO_2$. Of note, it appears that the parasympathetic nervous system is important in the response to CSF pH changes because inhibition of acetylcholine transmission can abolish the central pH response in animals.[15]

DISEASES AFFECTING THE RESPIRATORY SYSTEM

The diseases of the neurorespiratory system can be organized most logically in the framework of functional anatomy. Diseases of the central nervous system known to affect the respiratory system are listed in Table 87-1, and those affecting the peripheral nervous system are shown in Table 87-2.

TABLE 87-1. Diseases of the Central Nervous System Associated with Respiratory Dysfunction

Cerebral Cortex	Brain Stem/Basal Ganglia	Spinal Cord
Stroke	Stroke	Trauma
Neoplasm	Neoplasm	Infarction or hemorrhage
Cerebral degeneration	Poliomyelitis	Demyelinating disease
Seizures	Central alveolar hypoventilation	Disc compression
	Progressive bulbar palsy	Syringomyelia
	Multiple system atrophy	Tumor
	Anoxic encephalopathy	Epidural abscess
	Encephalitis	
	Multiple sclerosis	
	Parkinson's disease	
	Chorea	
	Dyskinesias	

TABLE 87-2. Diseases of the Peripheral Nervous System Associated with Respiratory Dysfunction

Motor Nerves/Anterior Horn Cell	Neuromuscular Junction	Myopathies
Acute idiopathic polyneuropathy (Guillain-Barré syndrome)	Myasthenia gravis	Muscular dystrophies
Motor neuron disease	Lambert-Eaton myasthenic syndrome	Myotonic dystrophy
Amyotrophic lateral sclerosis	Toxins	Poly- and dermatomyositis
Spinal muscular atrophy	Botulism	Glycogen storage diseases
Primary lateral sclerosis	Snake venoms	Pompe disease
Critical illness neuropathy	Scorpion bites	Forbes-Cori disease
Vasculitides	Shellfish	Thick filament myopathy
Toxins (e.g., lithium, arsenic, gold)	Crab poisoning	Mitochondrial myopathy
Metabolic	Drugs	Nemaline body myopathy
Diabetes	Antibiotics	Severe hypokalemia
Porphyria	Neuromuscular junction blockers	Hypophosphatemia
Uremia	Anticholinesterase inhibitors	
Diphtheria	Corticosteroids	
	Lidocaine	
	Quinidine	
	Lithium	
	Antirheumatics	

Central Nervous System Diseases

Cortical and Brain Stem Disorders

Diseases of Voluntary Breathing. The pathways that connect the voluntary respiratory centers of the cortex with spinal motor neurons (corticospinal tracts) can be affected in a number of disorders. Midpontine strokes can damage the corticospinal tracts and cause what is known as the "locked-in syndrome,"[17] a syndrome with total paralysis with the exception of eye movement. Because injury to the reticulospinal tracts causes loss of volitional but not automatic breathing, the response to automatic breathing is preserved.[18] This syndrome is most commonly due to ischemic stroke but can be due to pontine tumor, central pontine myelinolysis, high cervical demyelination, syphilitic arteritis, and head injury. Extrapyramidal disorders such as parkinsonism can also affect voluntary breathing.[19] In these disorders, patients have less ability to alter their breathing pattern voluntarily. They also may demonstrate periodic breathing or a Cheyne-Stokes respiratory pattern.

Diseases of Automatic Breathing. Automatic breathing but not voluntary breathing is classically disrupted in central alveolar hypoventilation, otherwise known as "Ondine's curse,"[20] caused by injury to the automatic respiratory centers in the brain stem. Because automatic triggering controls breathing during sleep, individuals with central hypoventilation develop central sleep apnea. Congenital central alveolar hypoventilation is a rare genetic disorder affecting infants and children, although it has now been described in adults as well.[21] Acquired central alveolar hypoventilation can result from uni- or bilateral medullary infarction, from bulbar poliomyelitis, or from bilateral cervical tractotomy performed to control chronic pain. Although disorders of the neurorespiratory system generally lead to hypoventilation and the need for ventilatory support, diseases of the automatic respiratory centers in the brain stem can also lead to hyperventilation. Hyperventilation may be caused by diseases such as central nervous system infection or tumor[22] or by stimulation of an otherwise normal autonomic respiratory center by fever, sepsis, pain, pregnancy, medications such as progesterone or salicylates, and high altitude. A variety of irregular breathing patterns have also been associated with central nervous system disease including Cheyne-Stokes respiration and ataxic breathing.[23]

Diseases of the Spinal Cord

Spinal Cord Injury. Spinal cord injury (SCI) is most commonly due to traumatic injury caused by motor vehicle accidents, falls, sports accidents, and gunshot wounds. In the United States, there are an estimated 250,000 individuals who have suffered significant SCI; the incidence is approximately 12,000 incident cases per year with 78% of the injuries occurring in males (National Spinal Cord Injury Statistical Center http://www.spinalcord.uab.edu). Respiratory complications including atelectasis, pneumonia, and respiratory failure are the leading cause of morbidity and mortality for individuals with SCI.[24,25] After acute SCI, a number of physiologic changes can affect the respiratory system and predispose to respiratory complications. These aberrations include (1) cough inefficiency due to expiratory muscle weakness, (2) ciliary dysfunction, (3) mucous hypersecretion possibly due to impairment of the peripheral autonomic nervous system, (4) glottic dysfunction or gastric hypomotility increasing the risk of aspiration, and (5) loss of consciousness at the time of the injury increasing the risk of aspiration.[26,27]

Acute respiratory failure immediately after the injury may be due to direct disruption of respiratory muscle innervation (cervical cord injury), aspiration at the scene due to loss of consciousness, pulmonary edema, or other traumatic injuries to the chest or head. Many individuals with SCI are intubated at the scene of the accident or shortly thereafter. Prevention of further respiratory complications is important. Preventive measures include encouragement of deep breathing and cough, frequent changes of position, postural drainage, assisted cough (manual or mechanical), and bronchoscopy when other measures fail. Patients with SCI are at high risk of venous thromboembolism with the greatest risk 3 days to 2 weeks post injury. Prophylaxis for deep venous thrombosis is highly recommended during the initial hospitalization.

The extent of respiratory muscle impairment following SCI will depend mainly on the level and severity of the spinal injury because the function of respiratory muscles innervated below the site of the cord injury is lost. The innervation of the respiratory muscles is shown

TABLE 87-3. Respiratory Muscles and Their Innervation

Muscle Group	Spinal Cord Level	Nerve (s)
INSPIRATORY MUSCLES		
Diaphragm	C3-5	Phrenic
Parasternal intercostals	T1-7	Intercostal

CN, cranial nerve.

in Table 87-3. The overall pattern of pulmonary function abnormality is one of restriction. In the first few months to a year following the initial SCI, there is a significant improvement in lung volumes and maximal inspiratory and expiratory pressures,[28,29] possibly due to resolution of spinal cord edema and/or strengthening of the diaphragm and accessory muscles of inspiration.

In general, the higher the SCI, the more likely that ventilatory assistance will be needed. Treatment of ventilatory failure following SCI can be accomplished by invasive (tracheostomy) or noninvasive (mask or mouthpiece) methods.[30] Many individuals will be ventilated through a tracheostomy tube for some time after their injury; however, transfer to noninvasive means can often be achieved even for those requiring full-time ventilatory support. The choice of invasive versus noninvasive ventilation will be determined by the degree of local expertise with these forms of ventilation as well as by patient preference. For those with high cervical SCI (C1-2) and intact phrenic nerve function, diaphragm pacing is also a possibility. It should be noted that those with diaphragm pacemakers implanted will still need a tracheostomy in place to avoid airway obstruction during sleep owing to the absence of the normal neurologic coordination of diaphragm contraction and upper airway dilation during inspiration. Although traumatic SCI is the major cause of spinal cord pathology, other causes include vascular accidents, demyelinating diseases (multiple sclerosis, transverse myelitis), syringomyelia, tumors, and epidural abscess (see Table 87-1).

Ventilator dependence in patients with SCI is more common with high (cervical) SCI. Because the diaphragm is the major muscle of inspiration (C3-5 spinal nerve roots), those with lesions at C3 and above invariably require ventilatory support and are at the highest risk of respiratory complications.[25,31] Those with injuries between C3 and C5 will vary in their requirements for ventilatory support. Even if they require ventilation initially, these individuals may become independent of ventilatory support eventually.[29,32] The risk of ventilator dependence in this group of patients is greatest for those with injury close to C3 or age older than 50 years.[29] Individuals with lesions below C5 almost always become independent of continuous ventilator support.[27] In contrast to inspiratory muscle function, expiratory muscle function is impaired at all levels of cervical cord injury resulting in expiratory muscle weakness and ineffective cough. Because an effective cough depends in large part on abdominal and intercostal muscle function (spinal nerve roots T1-L1), cervical, thoracic, and even some high lumbar SCI can impair the ability to cough and clear secretions. Therefore, measurement of cough function in these patients is very important.

Other Respiratory Effects of Spinal Cord Injury. For unknown reasons, the frequency of sleep apnea appears to be increased by as much as fourfold in patients with SCI over similar aged normal populations.[33,34] A sleep study should be considered when symptoms of nocturnal hypoventilation such as morning headache, daytime hypersomnolence, or unexplained nocturnal awakenings are present or when daytime hypercarbia ($PaCO_2$ > 45 mm Hg), unexplained cor pulmonale, or forced vital capacity (FVC) less than 50% predicted are present.[35] Bronchial hyperreactivity and bronchial hypersecretion are also present in some individuals following SCI likely due to interference with normal autonomic control of the airways after injury.[36]

Peripheral Nervous System Diseases

Diseases of Motor Nerves or Anterior Horn Cells

Disorders of the motor nerves and the neuromuscular junction (NMJ) can arise acutely as in acute inflammatory polyneuropathy (Guillain-Barré syndrome) or botulinum toxicity or can arise more chronically as in motor neuron disease (e.g., amyotrophic lateral sclerosis [ALS]) or myasthenia gravis (see Table 87-2). The level of motor nerve root involvement will dictate the effects of the disorder on the respiratory system.

Acute Diseases Affecting Motor Nerves

Acute Inflammatory Polyneuropathy. Acute inflammatory polyneuropathy, also referred to as Guillain-Barré syndrome, is a heterogeneous group of diseases that are now thought to be caused by antiglycolipid antibodies.[37] Acute idiopathic demyelinating polyneuropathy (AIDP) is the most common form, making up about 85% to 90% of cases. It is an acute progressive process characterized by symmetrical, ascending muscle weakness progressing over a 2-week period and associated with loss of deep tendon reflexes. It is thought that an antecedent viral infection induces an immune response to viral epitopes that then cross-react with lipid components of the peripheral nerve.[38] The process usually starts in the lower extremities but may start in the arms or the face, head, and neck primarily (Miller-Fisher variant).[39]

AIDP affects the respiratory system by causing (1) weakness of the upper airway muscles, (2) weakness of the inspiratory and expiratory muscles, and (3) secondary complications such as pneumonia or pulmonary embolism.[40] Approximately 25% to 50% of patients develop respiratory insufficiency severe enough to necessitate intubation and mechanical ventilation.[41,42] A number of variables used to predict impending respiratory failure and the need for mechanical ventilatory support have been utilized including FVC, maximal inspiratory pressure (MIP), maximal expiratory pressure (MEP), and nocturnal desaturation. Generally accepted guidelines for intubation and mechanical ventilation include an FVC less than 15 ml/kg, an FVC less than 1 L, a decline in FVC to 50% or less of the normal predicted value for that individual or an MIP of 30 cm H_2O or less.[40] FVC and MIP should be monitored frequently (multiple times per day depending on rapidity of progression). With rapidly progressive disease, the intensive care unit (ICU) is considered the best location for monitoring. Absolute indications for intubation include impaired consciousness, respiratory or cardiac arrest, shock, arrhythmias, blood-gas alterations, or bulbar dysfunction with confirmed aspiration.[40] Noninvasive ventilation is generally not an option for these individuals because

they are at a high risk for aspiration because of bulbar muscle involvement. Successful extubation may be achieved once treatment such as steroids, immune globulin, and plasmapheresis is begun and respiratory muscle strength returns.[43] Until respiratory muscle strength returns, scrupulous supportive ICU care including tracheostomy for prolonged mechanical ventilation is required to prevent complications such as ventilator-associated pneumonia and sepsis.

Poliomyelitis. Poliomyelitis is a viral disease caused by a human enterovirus that caused significant epidemics with frequent respiratory complications in the United States and Western Europe during the 20th century. Owing to improved sanitation and vaccine development, polio is no longer a major public health issue in the developed world. However, in the developing world, acute infections still occur.[44]

In the developed world, the major health issue arising from polio currently is the postpolio syndrome, in which new weakness develops in survivors of the polio epidemics of the mid-20th century.[45,46] The cause of progressive neurologic deterioration in postpolio syndrome is unknown. Theories of pathogenesis suggested include (1) progressive degeneration of reinnervated motor units, (2) persistence of poliovirus in neural tissue, or (3) induction of autoimmunity with subsequent destruction of neural structures.[47,48] The average time to onset from the time of the initial infection is 35 years but ranges from 8 to 71 years. A high percentage of polio survivors, between 20 and 60% of individuals, complain of new muscle weakness.[48] Although the exact incidence of respiratory system involvement in postpolio syndrome is not known, sleep-disordered breathing is common and noninvasive nocturnal ventilation can be highly effective.[49] Fortunately, it appears that frank hypoventilation associated with the postpolio syndrome is unusual.[50]

Chronic Diseases Affecting Motor Nerves. ALS is a progressive neurodegenerative disease with no known cure. The usual clinical presentation is that of an individual with gradually progressive asymmetrical weakness associated with hyperreflexia due to upper motor nerve involvement and muscle fasciculations due to lower motor nerve involvement. Like most neurologic diseases, ALS has no direct effect on the lung; however, it significantly affects the upper airway, chest wall, and diaphragm impairing respiratory muscle function. Indeed, ALS affects all of the major muscle groups of the respiratory system including (1) upper airway muscles leading to abnormal swallowing and inadequate cough, (2) expiratory muscles leading to inadequate cough, and (3) inspiratory muscles leading to inadequate ventilation. Therefore, all patients with ALS are at significant risk of respiratory complications. Respiratory failure, the leading cause of death in this population, has been reported as the initial clinical presentation of ALS.[51] Patients may complain of dyspnea, difficulty managing secretions, or inability to cough effectively. Monitoring pulmonary function in the outpatient setting is crucial. The FVC is the most commonly used measurement and has prognostic significance.[52,53] Attention must be given to glottic and cough function as well.[54] Sleep-disordered breathing is very common in ALS and noninvasive positive-pressure ventilation (NPPV) has been used both at night and, as the disease progresses, during the day to improve quality and duration of life.[55–57] Patients often have difficulty managing secretions owing to swallowing dysfunction. Secretions can be reduced by utilizing anticholinergic agents,[58] by low-dose irradiation of salivary glands,[59] or by injecting the glands with botulinum toxin.[58,60] As ALS progresses, NPPV will cease to be effective and a decision will need to be made concerning the appropriateness of tracheostomy and long-term invasive ventilation. Although tracheostomy can prolong survival substantially,[61] it does not alter the progression of the disease and patients will ultimately become completely paretic. Due to different cultural approaches, rates of invasive ventilation vary substantially among countries.[62]

Spinal muscular atrophy (SMA 1, 2, or 3) is a group of autosomal recessive genetic motor neuron diseases that affect infants and children and is associated with respiratory muscle weakness and breathing failure.[63] Noninvasive ventilation and tracheostomy with mechanical ventilation have both been applied in this disorder.

Neuromuscular Junction Diseases

Myasthenia Gravis. Myasthenia gravis is the most common disease affecting neuromuscular transmission. It is an autoimmune disease characterized by an antibody-mediated immune attack directed at acetylcholine receptors and/or receptor-associated proteins in the postsynaptic membrane of the NMJ. It causes weakness of several muscle groups including the respiratory muscles. The respiratory muscles are particularly susceptible to fatigue during the severe, potentially life-threatening, exacerbations known as *myasthenic crisis*. The clinical considerations during myasthenic crisis are very similar to those for AIDP noted earlier and the indications for intubation are the same.[40] Acute treatment of myasthenic crisis focuses on rapid therapies including intravenous immunoglobulin (IVIG) as well as plasmapheresis and corticosteroid therapy.[64,65] Assiduous attention to respiratory care provides support of the patient, allowing time for therapy of the underlying myasthenia to be effective.

Myasthenia gravis can also occur as a paraneoplastic syndrome in association with thymoma. It has been estimated that approximately 15% of all patients with thymoma will exhibit myasthenia gravis. Removal of the thymoma may result in amelioration of the myasthenia symptoms.

The Lambert-Eaton myasthenic syndrome (LEMS) is a myasthenic syndrome associated with small cell lung cancer that can affect the respiratory muscles in a fashion similar to that of myasthenia gravis. In patients with small cell lung cancer, LEMS may be present in approximately 3% of cases.[66] In patients with LEMS, the small cell lung cancer may also be occult and should be sought for up to 5 years after the diagnosis of LEMS. LEMS is thought to be due to autoantibodies directed against presynaptic voltage-gated calcium channels (VGCCs),[67] thereby interfering with synaptic function. Although

respiratory involvement is often a late finding, frank respiratory failure can be a manifestation of LEMS,[68] and this disorder should be considered in individuals with unexplained neuromuscular weakness. Although LEMS shares a similar pathophysiologic mechanism with myasthenia gravis, the clinical presentation is different and is characterized by (1) an increase in the compound muscle action potential with repetitive nerve stimulation, a feature not seen in myasthenia, (2) more frequent presence of proximal leg weakness, which is worse in the morning, (3) greater autonomic dysfunction, and (4) frequent association with malignancy.[69]

Botulism. Botulism is a neuroparalytic syndrome that is caused by a toxin produced by the gram-positive bacterium *Clostridium botulinum*. It can be acquired by humans in one of five different ways: (1) food-borne botulism, in which there is ingestion of food contaminated with preformed toxin, (2) wound botulism, in which the bacteria growing in the wound produce toxin in vivo, (3) infant botulism, in which there is ingestion of clostridial spores allowing colonization of the host's gastrointestinal tract by the bacteria and production of the toxin in vivo, (4) adult enteric infectious botulism, which is similar to infant botulism, and (5) inhalational botulism, which follows inhalation of aerosolized toxin released in an act a bioterrorism.[70]

C. botulinum produces a number of toxins that can produce paralysis by binding to synaptotagmin I and II receptors that mediate their entry into the nerve cell cytoplasm.[71] Once intracellular, the toxin produces irreversible disruption in stimulation-induced acetylcholine release. The botulinum toxin is one of the most potent toxins known. Recovery from the injury requires regrowth of new synapses, a process than can take 6 months. The clinical syndrome is one of progressive paralysis with early cranial nerve involvement causing blurred vision, dysphagia, dysarthria, and facial weakness. Descending muscle weakness is the usual course and involvement of the upper airway, diaphragm, and intercostal muscles often leads to the requirement for intubation and mechanical ventilation.[72] All patients should be monitored in the ICU and intubation should be undertaken for those who cannot protect their airway or who have a vital capacity of less than 30 % predicted. Botulism antitoxin (IV botulinum immune globulin) is available for use in the United States and is given to infants younger than 1 year of age.[73] For adults, supportive care is the mainstay of therapy. Prolonged hospitalization is common.

Other Neuromuscular Junction Toxins. A number of other toxins can affect the NMJ. The insecticides, organophosphates and carbamates, are potent inhibitors of acetylcholinesterase, leading to high levels of acetylcholine in the NMJ, resulting in parasympathetic and sympathetic overstimulation, skeletal muscle paralysis, and, sometimes, respiratory failure.[74] Several species of tick produce toxins that can inhibit NMJ neurotransmission (tick paralysis) by inhibiting influx of sodium ions and preventing presynaptic terminal axon depolarization and the release of acetylcholine at the nerve terminal.[75] Snake venom from a number of families of snakes produces neurotoxins that can cause paralysis, respiratory failure, and death owing to inhibition of neurotransmission.[76] Finally, a wide range of medications can cause NMJ blockade including D-penicillamine, aminoglycoside antibiotics, fluoroquinolone antibiotics, phenytoin and other anticonvulsants, lithium, β-blockers, glucocorticoids, and magnesium sulfate.[77]

Diseases of the Respiratory Muscles

A large number of disorders both acute and chronic can directly affect the respiratory muscles (see Table 87-2). There are many causes of chronic muscle disease resulting in respiratory muscle dysfunction including genetic muscular dystrophies, myopathies, and myotonias as well as inflammatory myopathies and those associated with systemic diseases.

Duchenne and Becker Muscular Dystrophies. Duchenne and Becker muscular dystrophies are both progressive myopathic disorders caused by mutations of the dystrophin gene on chromosome Xp21.[78] Dystrophins are glycoproteins that coat sarcolemmal, sarcomeric, and cytosolic muscle proteins. In Duchenne dystrophy, dystrophin is absent, whereas, in Becker dystrophy, a milder variant, dystrophin is reduced in quantity or quality. Both disorders are inherited as X-linked recessive traits and are characterized by progressive muscle wasting and weakness,[79] typically of limbs. However, both can involve the respiratory muscles leading to major morbidity and mortality. The diaphragm, however, may be less susceptible than limb muscle because of different gene transcription patterns.[80]

In Duchenne muscular dystrophy, weakness of proximal muscle groups usually manifests itself by age 2 to 3 with respiratory muscle weakness becoming evident later in childhood.[81] In Becker muscular dystrophy, weakness manifests later in childhood and individuals can remain ambulatory often into adult life. Because exercise is limited by limb muscle weakness, affected individuals may not complain of dyspnea on exertion despite involvement of the respiratory muscles. However, severe inspiratory muscle weakness (maximum inspiratory pressure [P_{Imax}] < 50% predicted) will lead to a reduction in lung volumes. This restrictive process can be worsened by other consequences of muscular dystrophy such as scoliosis, kyphosis, or muscle contractures.

The diagnosis is often suspected by noting an elevated serum creatine kinase. However, this finding is not specific for these disorders. Often, a muscle biopsy is obtained to distinguish muscular dystrophies from inflammatory skeletal muscle disorders and other forms of dystrophy. With muscular dystrophy, there is degeneration and regeneration of muscle fibers as well as replacement of muscle by fat and connective tissue. Immunoblots for dystrophin can aid in distinguishing Duchenne from Becker muscular dystrophy. Finally, analysis for deletions in the dystrophin gene may be useful but detection of point mutations of this gene may be difficult.[82] Sisters of individuals with Duchenne or Becker muscular dystrophy should be tested to determine if they are carriers of the disease. Carriers will often

have elevated creatine kinase levels.[83] It is important to identify carriers not only for genetic counseling but also because they may be at higher than average risk of developing cardiomyopathy.

The combination of a restrictive pulmonary deficit and expiratory muscle weakness predisposes these individuals to developing respiratory complications such as atelectasis and pneumonia. Therefore, it is important that these individuals get prompt treatment for bronchitis and pneumonia. In addition, cough-assist devices or assisted cough can be helpful in aiding removal of airway secretions. As the respiratory muscles further weaken and the restriction becomes severe, patients often need nocturnal ventilatory assistance. Nocturnal ventilation is usually initiated if there are symptoms related to nocturnal hypoventilation, right heart failure, or the presence of an elevated $Paco_2$ either at night or during the day. Noninvasive ventilation is a therapeutic intervention that typically can be delivered with a positive-pressure device using an interface such as a nasal mask, nasal-oral mask, or mouthpiece (discussed further later). Although there are no randomized, controlled trials in patients with muscular dystrophy, noninvasive ventilation is likely to improve quality of life, physical activity, and hemodynamics and normalize arterial blood gases.[84,85] Endurance and strength training targeting the inspiratory muscles may slow the progression of the disease in individuals with mild to moderate weakness.[86] If individuals with Duchenne or Becker muscular dystrophy require surgery, they may be at higher risk of respiratory complications.[87] A consensus statement has been published addressing the respiratory and other risks of anesthesia and suggesting methods for avoiding excessive morbidity and mortality.[88]

Other muscular dystrophies such as limb girdle muscular dystrophy (LGMD), fascioscapulohumeral dystrophy (FSHD), and myotonic dystrophy can affect the respiratory muscles but do not generally cause respiratory impairment until later in the course of the disease.

Chronic Inflammatory Myopathies. Dermatomyositis, polymyositis and inclusion body myositis (IBM) are systemic inflammatory diseases of unknown etiology that cause profound skeletal muscle weakness.[89] Dermatomyositis and polymyositis involve proximal muscle groups, whereas IBM may involve both proximal and distal muscle groups. Dermatomyositis can be seen in children and adults, whereas polymyositis and IBM are generally seen only in adults. Inflammatory myopathies can involve the diaphragm, intercostal muscles, and accessory muscles but other peripheral muscle groups are usually more severely affected than the respiratory muscles.[90] Symptoms are due to slowly progressive muscle weakness. IBM is similar to polymyositis except that the onset of symptoms is usually after age 50, it is more commonly seen in men than in women, and characteristic vacuoles are seen in affected muscle. Symptoms related to respiratory muscle weakness usually are not the presenting complaints. However, respiratory muscle weakness can occur in 5% to 10% of the patients with dermatomyositis and polymyositis[90] and may be found in as many as 75% of individuals if respiratory muscle function is carefully evaluated.[91] Interstitial lung disease may occur in up to 70% of patients with dermatomyositis or polymyositis.[92] Individuals diagnosed with dermatomyositis or polymyositis should be evaluated for the presence of restrictive pulmonary disease, which may be due to respiratory muscle weakness as well as to underlying interstitial lung disease. If respiratory muscle weakness is pronounced (P_{Imax} < 30% of predicted), ventilatory failure may ensue.[90] Respiratory muscle weakness can also impair cough, which, in concert with esophageal dysfunction and lymphopenia, can predispose these patients to pneumonia. Occasionally, patients with severe and progressive muscle weakness can develop respiratory failure. However, most cases of dermatomyositis and polymyositis respond to treatment with cortcosteroids whereas IBM is generally resistant to all therapies. As with other diseases, treatment with glucocorticoids and cytotoxic agents increases the risk of opportunistic pulmonary infection with fungi, nocardia, or *Pneumocystis jirovecii*.[93]

Metabolic Myopathies

Glycogen Storage Disease. A number of enzyme deficiencies can lead to disordered glycogen metabolism, resulting in accumulation of glycogen in tissue including skeletal and cardiac muscle. The glycogen storage diseases that are most likely to affect the respiratory system are acid maltase deficiency (type II—Pompe disease) and debranching enzyme deficiency (type III—Forbes-Cori disease). These disorders usually present in childhood, but some, such as Pompe disease, have separate adult-onset forms. In general, glycogen storage disorders are inherited as autosomal recessive conditions.

Acid Maltase Deficiency. Acid maltase deficiency, also known as glycogen storage disease type II or Pompe disease, is due to the deficiency of acid α-glucosidase, an enzyme responsible for the degradation of glycogen polymers to glucose. Deficiency of this enzyme allows accumulation of glycogen within cardiac and skeletal muscle lysosomes, resulting in myopathy. Although typically involving infants, this disease can manifest in adulthood.[94] Complete enzyme deficiency results in cardiorespiratory failure and death, usually in the first year of life.[95] When the onset of weakness occurs after age 1, the disease is less severe and does not involve the heart. Initially, subjects develop symptoms related to muscle weakness; those with a later onset of symptoms have a better prognosis. With respiratory muscle involvement, there may be restrictive ventilatory limitation and, in most severe cases, respiratory failure. Results from trials of enzyme replacement therapy with recombinant acid α-glucosidase are promising, showing potential improvements in motor status, function, and survival.[96]

Other Metabolic Myopathies. Myopathies can be caused by defects of lipid metabolism (carnitine, palmitoyl transferase deficiency) or disorders involving the mitochondria directly.

Disorders of lipid metabolism may be caused by an abnormal carnitine transporter protein ("primary" carnitine deficiency) or a deficiency of carnitine secondary to other metabolic diseases.[97] These disorders usually do not cause respiratory disability but involve other skeletal

muscle groups (arms and legs) and may involve cardiac muscle.

Mitochondrial disorders include those due to deficiencies of enzymes in the mitochondrial respiratory chain complexes and to defects of phosphorylation-respiration coupling. Disorders of mitochondrial metabolism involving complex I, II, III, IV, and V cause multiple respiratory chain defects.[98] The main symptoms of mitochondrial myopathy are muscle weakness and wasting and exercise intolerance. Individuals may exhibit external ophthalmoplegia, ptosis, and hypertrophic or dilated cardiomyopathy. Occasionally, mitochondrial myopathies cause significant respiratory muscle weakness resulting in nocturnal hypoventilation and the need for assisted ventilation. Treatments that focus on bypassing the defective mitochondria include dietary supplements based on dietary substances involved in adenosine triphosphate production such as creatine.[99]

SPECIAL TOPICS

Neuromuscular Disease Related to Critical Illness

Neuromuscular weakness is a very common finding in patients who are in the ICU. More than 25% of patients who are ventilated in the ICU for more than 7 days develop neuromuscular weakness.[100] The possible causes of weakness in the ICU include Guillain-Barré syndrome, rhabdomyolysis, cachectic myopathy, and critical illness neuropathy and myopathy. Weakness in the ICU is most commonly due to the combination of critical illness neuropathy and myopathy now often referred to as "ICU-related weakness" or critical illness polyneuromyopathy. It is now recognized that most individuals will suffer from both neuropathy and myopathy and that the precise cause of the disease process is unknown.

The incidence of critical illness polyneuromyopathy is quite high, with risk estimated in prospective studies at between 33% and 82%.[101–103] The major risk factors for critical illness polyneuromyopathy include sepsis and systemic inflammatory response syndrome (SIRS),[104] treatment with steroids[100] or neuromuscular blocking agents,[105] and hyperglycemia.[102] Other factors that are thought to contribute to this disorder include total parenteral nutrition, aminoglycoside use, catecholamines, hyperosmolality, female gender, longer duration of multiorgan failure, greater illness severity, and renal failure.[106]

The pathophysiologic mechanisms leading to critical illness polyneuromyopathy are not well understood. However, the pathology of the myopathy has been well described and includes two major patterns of disease: (1) type II myocyte atrophy with thick filament (myosin) destruction[107] and (2) widespread myocyte necrosis with intracellular vacuolization and phagocytosis of muscle fibers.[108] The neuropathic changes described by electrophysiologic testing with nerve conduction studies reveal reduced motor and often sensory nerve action potentials and muscle fibrillation suggestive of denervation.[109]

Critical illness polyneuropathy should be distinguished from other neuromuscular diseases. Compared with demyelinating diseases such as Guillain-Barré syndrome, critical illness polyneuromyopathy has normal nerve conduction velocity; compared with rhabdomyolysis, critical illness polyneuromyopathy will have a normal creatine phosphokinase, lack of muscle tenderness, and minimal electromyographic changes; and compared with cachectic myopathy, critical illness polyneuromyopathy is not usually associated with severe malnutrition.[110]

The only intervention thus far shown to reduce the incidence of ICU-acquired neuromuscular disorders is intensive insulin therapy. In one randomized, controlled study, the use of insulin to maintain serum glucose at 80 to 110 mg/dL, compared with a conventional range of 180 to 200 mg/dL, reduced critical illness polyneuropathy in patients in the ICU for at least 1 week by 44%.[111]

Diseases Affecting Diaphragm Function

The diaphragm is the major muscle of inspiration. It is a dome-shaped structure composed of two muscular leaflets attached to a central tendinous dome (see Fig. 87-2). The diaphragm inserts into the bony rib cage along the inner surface of the lower six ribs and costal cartilages anterolaterally and the upper three lumbar vertebral bodies posteriorly. It separates the thorax from the abdomen and, when it contracts, serves to increase the volume of the thorax and inflate the lung by decreasing intrapleural pressure. The diaphragm increases thoracic size in two main ways: by the descent of the diaphragm in a piston-like fashion and by the expansion of the rib cage via an increase in abdominal pressure. Diaphragm weakness or paralysis can involve either one of the diaphragm leaflets (unilateral) or both (bilateral).

Unilateral Diaphragm Paralysis

Unilateral diaphragm paralysis is more common than bilateral diaphragm paralysis. The list of potential causes is similar (Table 87-4). The most frequent causes of unilateral paralysis include phrenic nerve injury related to cardiac or thoracic surgery, herpes zoster, cervical spinal disease, or invasive or compressive tumors.[112] In unilateral diaphragm paralysis, patients may be asymptomatic at rest but have dyspnea with exertion.[113] Orthopnea may be present but is not as common or severe as in bilateral paralysis.

The diagnosis is often suggested by an elevated hemidiaphragm on chest x-ray and confirmed with a fluoroscopic sniff test.[114] In this test, an upward or "paradoxical" movement of the paralyzed hemidiaphragm is seen during a vigorous sniff maneuver performed by the patient. The paradoxical motion is the passive movement of a paralyzed hemidiaphragm in response to the increase in abdominal pressure (and decrease in pleural pressure) created by the contraction of the normal hemidiaphragm. Thus, the unilateral hemidiaphragmatic paralysis can be recognized readily by the different func-

TABLE 87-4. Causes of Diaphragm Weakness and Paralysis

Neuropathic Causes	Myopathic Causes
TRAUMA	**MUSCULAR DYSTROPHIES**
Cardiac surgery with cold cardioplegia	Limb girdle
Blunt trauma	Duchenne and Becker
Spinal cord injury	**METABOLIC MYOPATHIES**
Radiation injury	Hyper- or hypothyroidism
Cervical manipulation	Acid maltase deficiency
Scalene and brachial nerve block	**RHEUMATOLOGIC**
Tumor compression	Systemic lupus erythematosus
Lung cancer	Dermatomyositis
Metastatic mediastinal tumor	Mixed connective disease
METABOLIC	**MISCELLANEOUS**
Diabetes	Amyloidosis
Vitamin deficiency (B_6,B_{12}, folate)	Malnutrition
Hypothyroidism	Idiopathic
INFLAMMATORY NEURITIS	
Idiopathic (neuralgic amyotrophy, Parsonage-Turner)	
Mononeuritis multiplex	
Vasculitis	
Paraneoplastic	
MISCELLANEOUS	
Cervical spondylosis	
Poliomyelitis	
Amyotrophic lateral sclerosis	

tion of the two hemidiaphragms. Ultrasonographic imaging of the diaphragm in the zone of apposition provides an alternate means of diagnosing chronic unilateral diaphragm paralysis by showing a thin diaphragm that fails to thicken with inspiration.[115] There is no specific treatment for this disorder, but recovery following the initial injury is occasionally seen. When disabling symptoms are present and there is significant elevation of the hemidiaphragm on chest radiography, surgical plication of the paralyzed hemidiaphragm to minimize its paradoxical motion has had some success in improving vital capacity and FEV_1, especially in the supine position, and in reducing dyspnea.[116]

Bilateral Diaphragm Paralysis

Bilateral diaphragm paralysis is most often seen in the setting of a disease producing severe generalized muscle weakness. The most common causes are diffuse muscle diseases or motor neuron disease such as ALS.

The symptoms of bilateral paralysis include significant dyspnea with exertion and even at rest, especially when supine. Orthopnea is very common,[117] and dyspnea on immersion in water has been described,[118] probably due to the increases in abdominal pressure and elevation of the diaphragm in either the supine position or after submersion in water. Sleep-disordered breathing with hypoventilation and hypoxemia is common.[119] Pulmonary function is impaired when the vital capacity is reduced and when there are significant drops of vital capacity in the supine position of up to 50%.[120] The P_{Imax} is reduced in most cases. Disability can be quite pronounced. The astute clinician may initially suspect the condition by observing paradoxical breathing in a resting or sleeping supine patient; instead of rising normally due to diaphragmatic contraction, the abdomen may actually fall on inspiration as the negative pleural pressure "sucks" the abdominal contents into the chest.

Interestingly, bilateral diaphragmatic paralysis can be difficult to diagnose. For one thing, there is no normal hemidiaphragm to use for comparison with an abnormal one. Therefore, chest radiography and fluoroscopic sniff testing can yield false negative results. Two-dimensional echocardiography of the movement of the diaphragm dome shares the same limitations as fluoroscopy.[121] Phrenic nerve conduction studies can be useful in diagnosing a neuropathic cause of diaphragmatic paralysis but can have technical limitations.[122] Diaphragm electromyographic measurements may be useful, but technical issues such as "cross-talk" from adjacent muscles, electrode placement, or variable muscle-to-electrode distances due to subcutaneous fat limit its utility. The "gold standard" diagnostic test is measuring transdiaphragmatic pressure using thin balloon-tipped polyethylene catheters placed in the esophagus and stomach (Fig. 87-4A) and showing a lack of ability to generate a transdiaphragmatic pressure[123] (see Fig. 87-4B). B-mode ultrasound of the diaphragm muscle in the zone of apposition showing a lack of thickening on inspiration is a less invasive means of diagnosing bilateral diaphragm paralysis.[124] Bilateral diaphragm paralysis is rarely reversible unless the underlying disease is treatable. However, recovery has been noted in more than 50% of individuals with idiopathic diaphragmatic paralysis or paralysis due to neuralgic amyotrophy (brachial plexus neuritis) with the recovery taking an average of 15 months from the onset of symptoms.[122] The sleep-disordered breathing and orthopnea commonly seen in individuals with diaphragmatic paralysis can be treated with NPPV.[125]

Phrenic nerve pacing is not applicable in most cases of diaphragm paralysis because it requires intact phrenic nerves and normal diaphragmatic motor function. As mentioned previously, in unilateral diaphragm paralysis, hemidiaphragm plication has been used to shorten the paralyzed hemidiaphragm and allow the unaffected hemidiaphragm to contract more effectively.[126]

APPROACH TO RESPIRATORY EVALUATION AND MANAGEMENT OF THE INDIVIDUAL WITH NEUROMUSCULAR DISEASE

Although each neuromuscular disease has a different etiology and natural history as well as potential

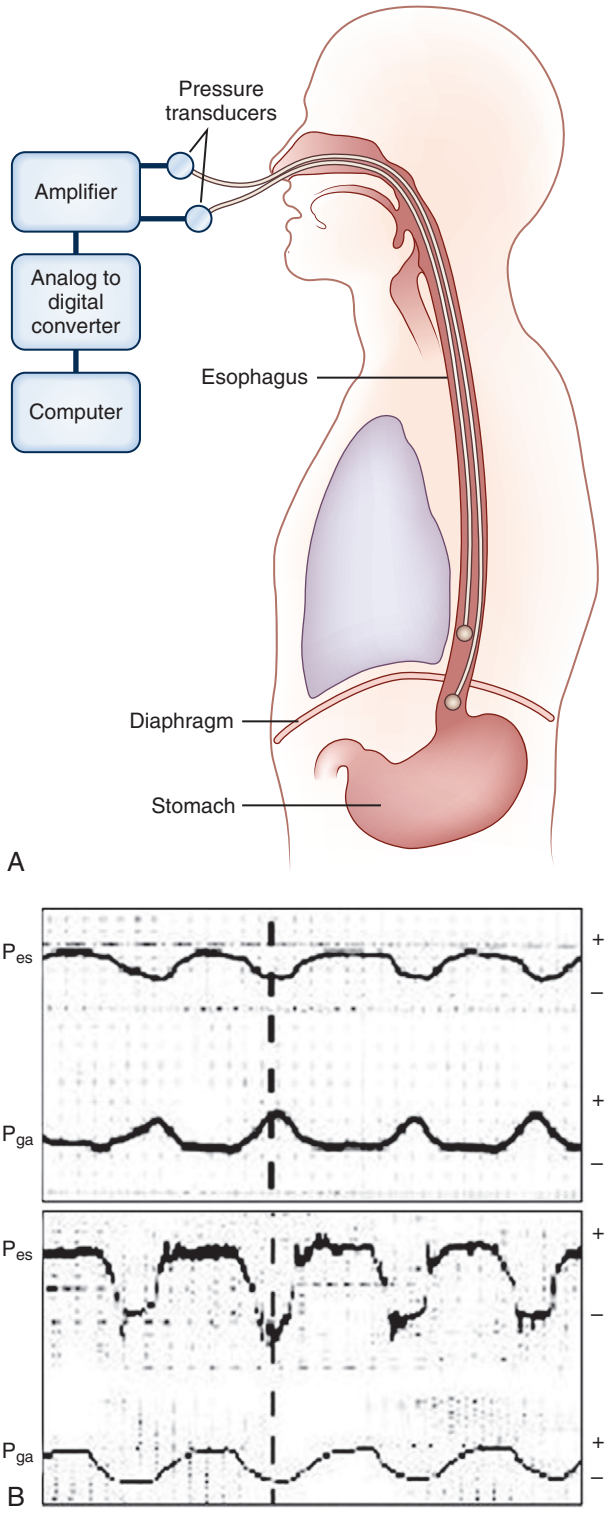

FIGURE 87-4 ■ **A,** Apparatus used to measure transdiaphragmatic pressure. Esophageal and gastric balloons placed through the nose into the esophagus and stomach, respectively, allow measurement of the pressures above and below the diaphragm simultaneously. **B,** *Top,* Normal esophageal (Pes) and gastric (Pga) pressure tracings. Note Pes becomes more negative and Pga more positive during normal inspiration owing to the action of the diaphragm. *Bottom,* Diaphragmatic paralysis where Pes and Pga deflect in the same direction showing no muscular activity of the diaphragm.

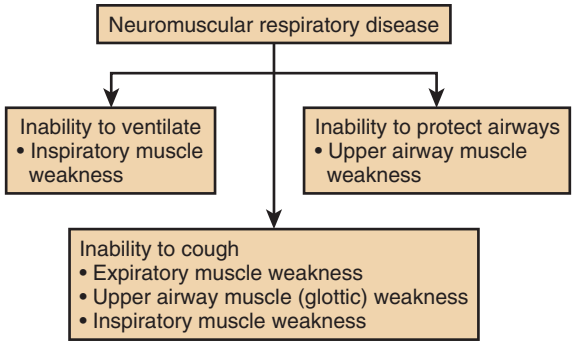

FIGURE 87-5 ■ Clinical effects of weakness or dysfunction of inspiratory, expiratory and upper airway muscles. Neuromuscular conditions lead to respiratory disease mainly via inability to ventilate, to cough, or to protect the upper airway from aspiration.

treatment, the respiratory effects of neuromuscular diseases can be approached in a systematic way that can be applied to any neuromuscular diagnosis. This approach utilizes the fact that the three major muscle groups involved in maintaining ventilation and protecting the airway and lungs are (1) the inspiratory muscles responsible predominantly for ventilation, (2) the expiratory muscles responsible predominantly for cough, and (3) the upper airway muscles responsible for cough, swallowing, and airway protection (Fig. 87-5). For the patient with neuromuscular disease, cough function and airway protection from an intact swallowing mechanism are as important as maintenance of ventilation.[127,128] For patients with Duchenne muscular dystrophy, a consensus committee of the American Thoracic Society[128] has recommended that clinic visits should include evaluation of each of the three areas by eliciting appropriate history, physical examination, and laboratory testing.

Inspiratory function can be tested by measurement of FVC, MIP, and carbon dioxide levels. Carbon dioxide can be measured as Pa_{CO_2}, the traditional measure of adequate ventilation, or as exhaled or end-tidal CO_2 (E_TCO_2), transcutaneous or capillary P_{CO_2}. Arterial blood gas sampling is the most accurate means of assessing alveolar ventilation but can be uncomfortable for the patient. E_TCO_2 measurement in patients without intrinsic lung disease is an easy and accurate method of estimating Pa_{CO_2}.[129] Transcutaneous P_{CO_2} has been successfully measured in children and improving technology may allow more widespread use.[130]

Hypoventilation usually manifests itself by symptoms during sleep. Symptoms consistent with sleep-disordered breathing include more frequent nocturnal awakenings, nocturia, vivid nightmares, night sweats, daytime hypersomnolence, morning headaches, nausea, depression, decreased concentration, and diminished daytime performance. Polysomnography can be used to evaluate sleep in patients with neuromuscular disease, but an overnight stay in a sleep laboratory may be especially difficult for such individuals if they require a personal care attendant, position changes, or help with toileting. Thus, ensuring a high pretest probability prior to order-

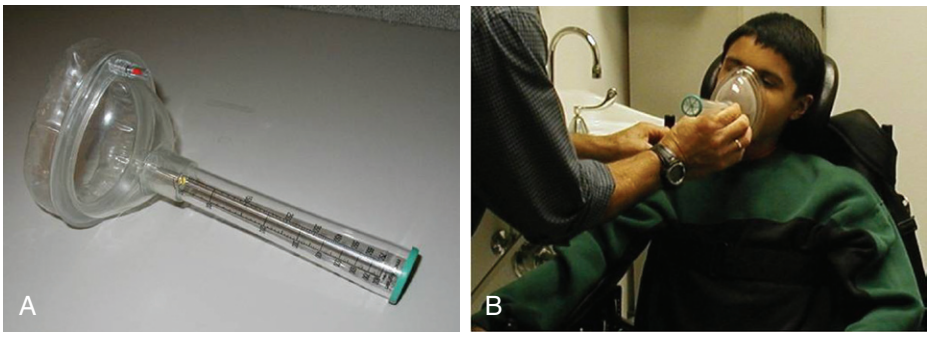

FIGURE 87-6 ■ **A,** Device to measure peak cough flow consists of an asthma peak flowmeter connected to a face mask. **B,** Peak cough flow device being used for measurement in a patient with muscular dystrophy.

ing a sleep study is important. Baseline values of awake $PaCO_2$ 45 or greater or base excess of 4 mEq or greater may correlate with sleep hypoventilation.[131] An unattended sleep study in the home[132] or overnight oximetry and E_TCO_2 monitoring[128] may substitute for a full laboratory polysomnogram; however, the sensitivity and specificity of these portable tests remains to be determined in this population.[132] These studies may serve to screen for those who will benefit from a full polysomnographic study in a sleep laboratory.

Cough insufficiency may be suspected if the patient describes an inability to bring secretions to the mouth for expectoration or if there is a history of frequent respiratory tract infections. Cough function is best assessed by measuring peak cough flow (PCF) rate. This can be easily measured with an asthma peak flowmeter connected to a face mask or mouthpiece (Fig. 87-6). Normal values range from 360 to 960 L/min[133]; a value below 160 L/min may place individuals at high risk for cough insufficiency and ventilator dependence.[127] During a respiratory tract infection, PCF may drop substantially and a PCF below 270 L/min during a healthy period can drop below 160 L/min during infection. Cough assistance is suggested for those with a PCF below 160 L/min.

Patients with neuromuscular diseases such as ALS frequently develop bulbar muscle dysfunction due to motor neuron involvement in the brain stem. Dysfunction of the lips, tongue, and pharyngeal and laryngeal muscles can result in an increased risk of aspiration as well as difficulty with generating adequate glottic closure for effective cough function. Swallowing may be impaired and ingesting adequate nutrition can be challenging for the patient. Choking is common and may even be triggered by aspiration of saliva. Malnutrition or rapid weight loss should signal the clinician to assess the swallowing mechanism.[134] Swallowing may be tested by barium swallow or direct visualization of swallowing endoscopically.[135–137] Referral to a speech and swallowing clinic can be very helpful in diagnosing swallowing and airway protection problems as well as instructing patients and their families in ways to reduce the risk of aspiration.

Ventilatory Support

Ventilatory support for patients with neuromuscular disease has been available for over 60 years[138] (Table 87-5). Some of the first ventilators were known as body ventilators and included devices such as the iron lung, rocking bed, and pneumobelt.[139] With the advent of positive pressure via either invasive (tracheostomy) or noninvasive (face mask) ventilation, these body ventilators are used only very rarely, as in the case of patients who have already been using them for years.

Invasive positive-pressure ventilation utilizing an indwelling tracheostomy has been successfully employed in neuromuscular disease. Benefits of this type of ventilator support include complete control of machine-delivered tidal volume and ease of access to the central airways for suctioning of secretions. In addition, if there is an acute decline in respiratory function, the same method of ventilation can be used for ventilatory support. The development of convenient, portable, positive-pressure generators has made this form of ventilation practical even in the home environment.[140] Invasive positive pressure should be considered in those with (1) coexisting lung disease, (2) copious secretions, (3) poor oropharyngeal muscle strength associated with

ineffective clearing of secretions, (4) uncontrolled seizure disorders that can cause upper airway obstruction, (5) a preference for invasive rather than noninvasive methods, (6) orthopedic or other conditions that interfere with placement of noninvasive devices, and (7) limited access to individuals with expertise in noninvasive techniques.

Unfortunately, invasive long-term positive-pressure ventilation via a tracheostomy has been associated with several complications such as damage to the trachea from the indwelling tracheostomy tube leading to tracheal necrosis, stenosis, hemorrhage, or tracheoesophageal fistulas.[141] However, the development of low-pressure, high-volume cuffed plastic tracheostomy tubes has lowered the incidence of these complications. Tracheostomy tubes can interfere with the normal swallowing mechanism and predispose patients to swallowing problems and food aspiration; they can also increase the risk of airway colonization with bacteria and lower respiratory tract infection. The use of a tracheostomy tube requires supplemental humidification, an additional daily respiratory care task. Finally, social interactions and psychological well-being may be impaired by the inability to speak. However, a number of devices and techniques have been designed to allow speech and communication while a patient has a tracheostomy and is mechanically ventilated. These include one-way valves that allow gas to pass through the vocal cords during exhalation (Passy-Muir valve, Irvine, CA) or channels to direct compressed air through the vocal cords ("Trach Talk" tracheostomy tube, Portex, Keene, NH). Unfortunately, not all individuals can utilize these devices.

NPPV is becoming the preferred method for treatment of patients with neuromuscular respiratory disease. The noninvasive delivery of positive-pressure ventilation was first used during the polio epidemics of the 1950s to allow patients time outside the iron lung. Since the 1980s, there have been considerable refinements in the application of this technique. There are currently three ways in which NPPV may be delivered: (1) via mouthpiece with or without a lipseal, (2) via nasal mask, or (3) via full face mask (Fig. 87-7). Occasionally, more than one method may be used in the same patient, for instance, a mouthpiece may be used during the day and a nasal mask used at night.

The mouthpiece was the first interface to be used with a positive-pressure ventilator. Patients hold the mouthpiece devices between their teeth and often are able to use them while sleeping, especially when lipseal devices are added.[142] Since the late 1990s, nasal interfaces have been developed and used successfully. Initially, nasal masks were designed to deliver continuous positive airway pressure (CPAP) for the treatment of patients with sleep apnea.[143] Currently, they are also used to deliver intermittent positive pressure to patients with neuromuscular disease. Tidal volume is most effectively delivered when there are no leaks around the nasal mask or through the mouth. Patients who experience air leaks may develop oxyhemoglobin desaturation, elevation of $PaCO_2$, and associated symptoms. In this situation, the use of a full oral-facial mask interface may be more appropriate. Utilizing custom-designed appliances also can eliminate leaks via the mouth and may be more comfortable for some patients. Pressure-cycled rather than volume-cycled devices are generally utilized for mask ventilation. With these machines, positive pressure can be delivered at two levels, a higher level during inspiration and a lower level during expiration (bilevel support, BiPAP). The positive-pressure gradient during inspiration results in delivery of a tidal volume to the patient. Exhalation occurs passively and is terminated when the airway pressure returns to the lower expiratory level. Maintenance of a positive expiratory pressure is important for two reasons. First,

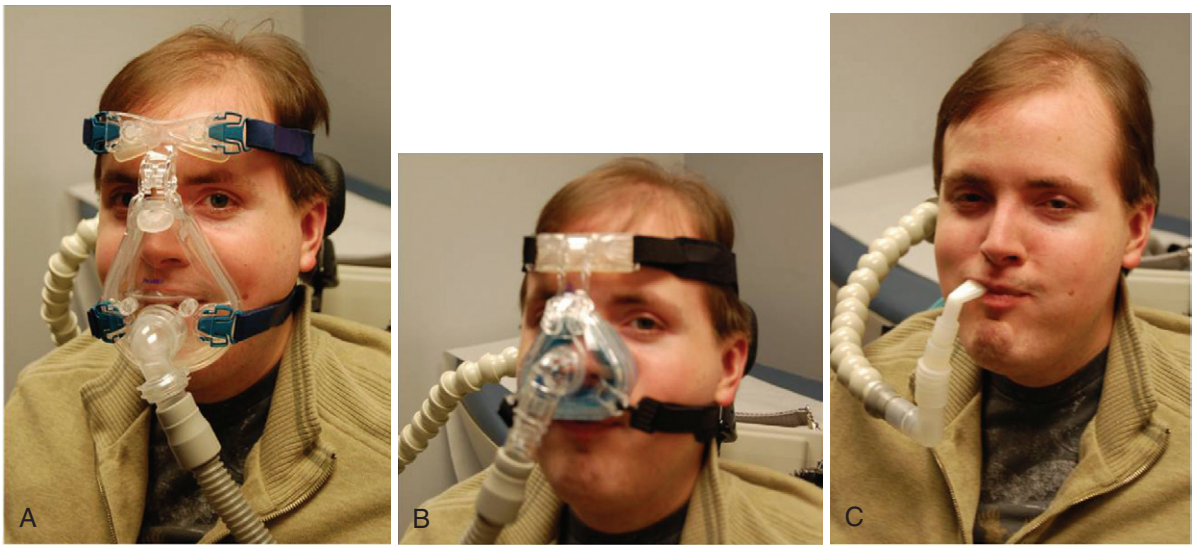

FIGURE 87-7 ■ Different means of delivering noninvasive positive-pressure ventilation. **A,** Full mask. **B,** Nasal mask. **C,** Mouthpiece.

because exhalation valves are not used with bilevel devices, end-expiratory positive airway pressure flushes the ventilator tubing of exhaled CO_2 and prevents rebreathing.[144] Second, because the expiratory pressure is positive and greater than atmospheric, the end-expiratory lung volume is increased, which may be associated with less atelectasis and fewer areas of low ventilation-perfusion or shunt than seen with low end-expiratory lung volumes.

Data Supporting Noninvasive Positive-Pressure Ventilation in Neuromuscular Disease

Nocturnal Ventilatory Support

The use of nocturnal ventilation in patients with neuromuscular disease with sleep disordered breathing has been shown to have a number of benefits, which include (1) reduced $Paco_2$ and increased Pao_2 on and off ventilator, (2) decreased symptoms of sleep-disordered breathing such as morning headache, nocturnal awakenings, vivid nightmares, and night sweats, (3) improved quality of life, and (4) reduced morbidity and most likely reduced mortality. Nocturnal ventilation has become widely accepted, providing ventilatory assistance for patients while sleeping and allowing them to breathe on their own during the day. In one study of patients with late-stage Duchenne muscular dystrophy who had symptoms of ventilatory failure and $Paco_2$ of 60 mm Hg or greater, nocturnal negative-pressure ventilation utilizing cuirass or tank ventilators significantly improved arterial $Paco_2$ values (60.8 mm Hg pretreatment to 45.5 mHg posttreatment) and Pao_2 values (59.3 mm Hg pretreatment and 74.6 mm Hg posttreatment).[145] Since that study, a number of studies have been published using nocturnal ventilation that have supported these findings and an excellent review of these data is available.[146]

The mechanism by which nocturnal ventilation ameliorates daytime symptoms and arterial blood gases in patients with neuromuscular disease is not entirely clear. A number of explanations have been suggested including (1) resting of chronically fatigued respiratory muscles, (2) reversal of mechanical problems associated with neuromuscular disease such as reduced chest wall and lung compliance, and (3) a resetting of the central respiratory control centers with an increase in chemosensitivity to $Paco_2$ during the daytime, thus maintaining blood gas homeostasis.[147–149] In addition to improvement in arterial blood gases, other measures of physiologic function have been shown to improve with intermittent ventilation. Vital capacity increases, right-sided heart failure improves, and there is a reduction in erythrocytosis following nighttime ventilation.[150]

For ethical reasons, the effects of mechanical ventilation on survival have not been studied in a randomized, controlled fashion in patients with neuromuscular disease. In most progressive neuromuscular diseases, once an elevation in $Paco_2$ and a decrease in Pao_2 are noted, cor pulmonale and death are inevitable within a short period of time. It is therefore generally accepted that mechanical ventilation in the home leads to improved survival in most patients.

Full-time Ventilatory Support

For those who require full-time ventilatory support, it is possible to provide NPPV for 24 hours per day.[151–153] As with nocturnal NPPV for neuromuscular disease, there have been no randomized, controlled trials of continuous ventilation. In one cohort study, 24 patients with Duchenne muscular dystrophy using NPPV were compared with 22 patients who received positive-pressure ventilation by tracheostomy.[154] The individuals who used NPPV had significantly fewer hospitalizations and hospital days per year. In another retrospective study by the same group, Duchenne muscular dystrophy patients using a protocol consisting of mouthpiece positive-pressure ventilation and breath stacking plus mechanical insufflation-exsufflation to assist cough (see discussion of "Cough Support," later) had significantly less mortality (3 of 34 patients) than a group that did not have access to the protocol and either received tracheostomy or used NPPV on a near-continuous basis (27 of 31 patients).[155] Further studies of continuous NPPV are needed to assess whether this treatment is truly better than tracheostomy ventilation in a community setting. A consensus statement of the ATS on the respiratory care of patients with Duchenne muscular dystrophy has suggested that NPPV be considered when expertise is available for initiation of appropriate protocols.[156]

Cough Support

Therapeutic interventions aimed at improving cough and airway clearance are equally if not more important than ventilatory support because pneumonia is one of the leading causes of morbidity and mortality in patients with neuromuscular respiratory disease. Normally, the cough reflex is initiated by stimulation of cough receptors in the airways that activate brain stem centers that initiate inhalation, glottic closure, and forceful contraction of expiratory muscles during which intrathoracic gas is compressed under high pressures.[133] The glottis then rapidly opens and an explosive release of gas occurs from the airways through the vocal cords. The high-velocity gas flow causes shearing of secretions away from the airway walls and propels them out of the lung. Adequate cough is essential for airway hygiene. Fortunately, there are a number of ways that an impaired cough can be augmented to maintain pulmonary hygiene without the use of a tracheostomy.

Manually-assisted cough is a method of applying a rapid positive pressure to the abdomen. The increase in abdominal pressure is transmitted to the thorax and expiratory flow ensues, leading to airway clearance and enhanced cough expiratory flow rates. A number of

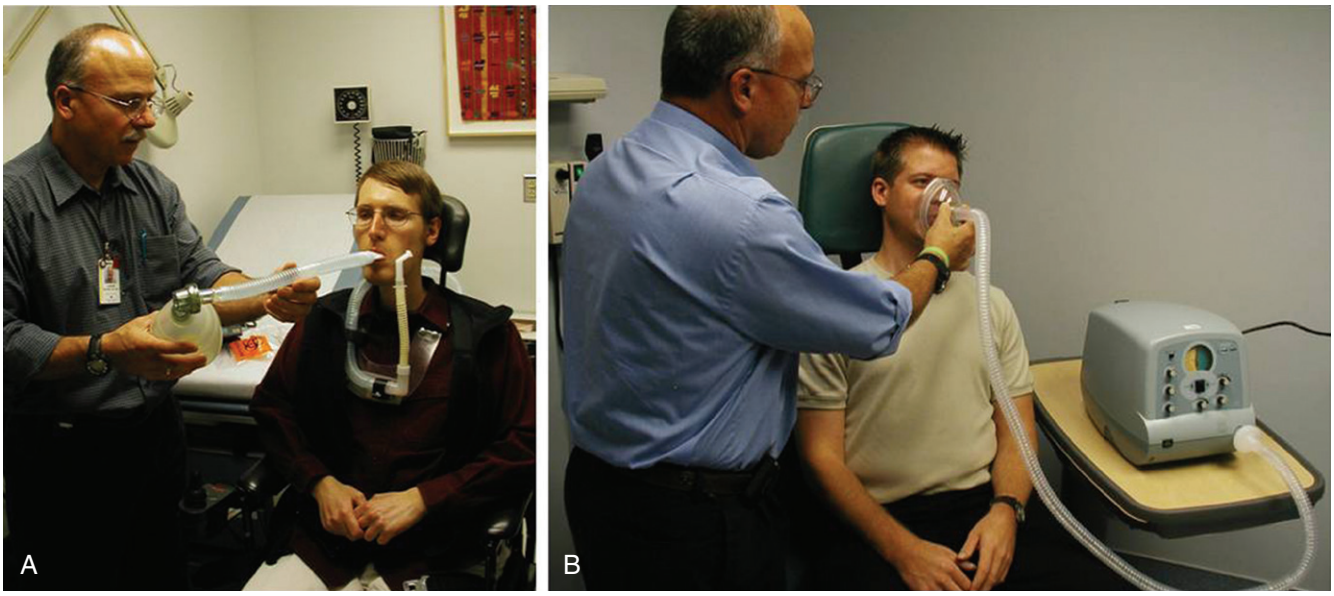

FIGURE 87-8 ■ **A,** Resuscitator bag used to "stack breaths" to increase lung volume and thereby increase cough flow. **B,** Mechanical insufflator-exsufflator being used to assist in secretion removal.

techniques are available for an attendant to apply rapid abdominal thrusts, resulting in effective clearance of secretions.[157] Increasing the volume of air in the respiratory system prior to the assisted cough increases the volume of gas in the lungs for exhalation, optimizes the length-tension relationship of the expiratory muscles so greater intrathoracic pressures can be achieved, and also increases the inward elastic recoil pressure of the respiratory system, which can further increase the expiratory pressures. This maximal achievable inspired volume has been labeled the maximal insufflation capacity or MIC.[158] Inspired lung volume can be increased by patients using breath stacking or glossopharyngeal ("frog breathing") techniques[159] or by use of a resuscitator bag and mouthpiece (Fig. 87-8A). Breath stacking involves taking multiple breaths to increase lung volumes above the single breath volume, holding each successive breath in the lungs using the glottis. Glossopharyngeal breathing is a form of respiration that involves forcing air into the trachea using the tongue and pharyngeal muscles.[159]

A very effective secretion management device, available for over 50 years but only recently used to any great extent, is the mechanical insufflator-exsufflator MI-E or CoughAssist (In-exsufflator, JH Emerson Co., Cambridge, MA) (see Fig. 87-8B). This device consists of an electric motor that can generate positive and negative pressures of up to 50 cm H_2O to insufflate and then rapidly exsufflate the lung. The pressure is applied to the patient's airway via a face mask or mouthpiece; first, a positive pressure of 30 to 50 cm H_2O is applied over a 1- to 3-second period followed immediately by a negative pressure of between 30 and 50 cm H_2O for a short duration. By simulating a cough, this technique moves secretions out of the airway noninvasively without violating airway integrity.[160] Other noninvasive mechanical aids include devices that oscillate the chest wall or airway directly.[161] These have not been well studied in neuromuscular disease patients without tracheostomy and their role in support of secretion management of these disorders is unclear.

The decision to initiate cough assistance is determined by measurement of cough function in the form of PCF. It is recommended that one or more of the previously discussed techniques should be made available to the patient when values of PCF fall below 270 L/min while the patient is well, because this correlates with a value of less than 160 L/min when the patient develops a respiratory tract infection.[127] This drop in cough function with respiratory illness may be due to increased muscle weakness or to the effects of the secretions themselves in reducing expiratory flow.

Treatments for swallowing muscle dysfunction are limited. The risk of aspiration and development of pneumonia in patients with ALS is due primarily to problems with upper airway function and cough. Pharyngeal and laryngeal muscle dysfunction can lead directly to aspiration of oral contents into the lungs. Other than surgical diversion of the airway,[162] no treatment directly aimed at laryngeal and glottic function is available. When patients develop significant dysphagia and aspiration of solids or liquids, many experts recommend placement of a percutaneous endoscopic gastrostomy tube.[163,164]

KEY POINTS

- Respiratory failure is a leading cause of morbidity and mortality in individuals with neuromuscular disease.
- Spinal cord injury is a common traumatic injury worldwide. The degree of respiratory impairment depends on the level of injury in the spinal cord.
- AIDP (Guillain-Barré syndrome) is an ascending paralytic disease thought to be due to antiglycolipid antibodies. Intubation can be life-saving and should be considered when the FVC is 15 mL/kg or less, the FVC is 1 L or less, or the MIP is 30 cm H_2O or less, or there is a lack of upper airway protection.
- Diaphragm paralysis can be unilateral or bilateral. Unilateral disease is most commonly due to injury to the phrenic nerve. Bilateral disease is most commonly due to diffuse muscle or motor neuron disease.
- Respiratory assessment of the individual with neuromuscular respiratory impairment should include evaluation of muscle groups responsible for inspiration, expiration and cough, and airway protection.
- Either noctural or full-time noninvasive ventilation is now commonly used in chronic neuromuscular respiratory disease and likely prolongs survival.
- Neuromuscular weakness is a common occurrence in the ICU and results in increased mortality and hospital length of stay.
- Cough can be aided noninvasively by manual or motorized means and should be considered when the peak cough flow (PCF) rate is less than 270 L/min in a patient without respiratory tract infection and definitely when the PCF rate is less than 160 L/min.

INTRODUCTION

This chapter focuses on diseases of the soft tissue and bony structures of the chest wall. Kyphoscoliosis and ankylosing spondylitis are disorders that involve the spine and its articulations, pectus excavatum involves the sternum, flail chest affects the ribs, and obesity adds to the soft tissues of the rib cage and abdomen. These disorders primarily affect the respiratory system by altering the elasticity of the chest wall, from kyphoscoliosis with the most severe impact on respiratory function to pectus excavatum with the least impact. Pathophysiology of these disorders is discussed in the framework of respiratory mechanics. The most recent developments in treatment are reviewed. Neuromuscular diseases that affect the chest wall are reviewed in Chapter 87.

KYPHOSCOLIOSIS

Diagnosis and Etiology

The term *kyphoscoliosis* is derived from the Greek words *kuphos* and *scolios* ("humpback" and "crooked") and refers to a group of disorders characterized by excessive spinal curvature in the lateral plane (scoliosis) and sagittal plane (kyphosis) as well as rotation of the spinal axis (Fig. 88-1). Scoliosis, which is defined as a lateral curvature greater than 10 degrees,[1] is generally associated with kyphosis and rotation of the spine around its long axis. First described in detail by Hippocrates, kyphoscoliosis is one of the most common abnormalities of the spine, with an estimated prevalence for mild deformity of 1 in 1000 people and that for severe deformity of 1 in 10,000 people in the United States.[1]

Kyphoscoliosis is classified as idiopathic (no known cause), secondary or paralytic (associated with neuromuscular disease), and congenital (associated with vertebral malformation present at birth) (Table 88-1). Idiopathic kyphoscoliosis, the most common form, usually manifests in late childhood or early adolescence and involves females more often than males with a ratio of 4:1. Idiopathic kyphoscoliosis is often seen in multiple members of one family. It is believed to be a multigene condition, with autosomal or sex-linked inheritance with variable phenotypic expression.[2] Recently, a defect in the chromatin-remodeling gene family, CHD7, has been

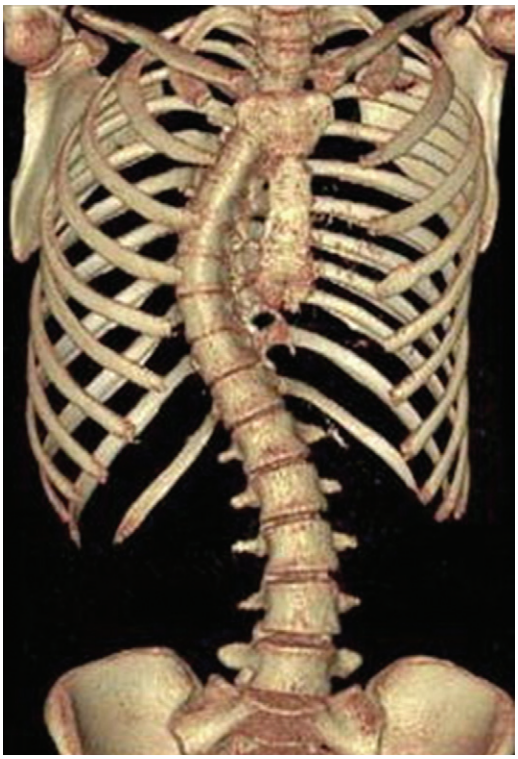

FIGURE 88-1 ■ Spiral computed tomography reconstruction showing the rotation of the spine and rib cage in kyphoscoliosis. (Adapted from Chun EM, Suh SW, Modi HN, et al: The change in ratio of convex and concave lung volume in adolescent idiopathic scoliosis. Eur Spine J 17:224–229, 2008.)

TABLE 88-1. Causes of Kyphoscoliosis

Idiopathic
Multigene disorder, developing by childhood/adolescence
Paralytic or Secondary
Neuromuscular (poliomyelitis, muscular dystrophy, cerebral palsy, Friedreich's ataxia, Charcot-Marie-Tooth disease)
Disorders of Connective Tissue (Marfan's syndrome, Ehlers-Danlos syndrome, Morquio's syndrome)
Vertebral Disease (osteoporosis, osteomalacia, vitamin D–resistant rickets, tuberculous spondylitis, spina bifida)
Post-thoracoplasty
Congenital
Due to spinal/vertebral malformations at birth

associated with idiopathic kyphoscoliosis.[3] The most important sequelae of progressive kyphoscoliosis are back pain, psychosocial problems, and development of respiratory failure.

Severe kyphoscoliosis can be readily diagnosed on physical examination. Typical findings are the dorsal hump, which is due to the angulated ribs and shoulder asymmetry, and hip tilt, which is related to spinal rotation. In children and adolescents with idiopathic kyphoscoliosis, the initial changes may be subtle and require careful inspection such as by Adam's forward bend test. With this test, the examiner observes for thoracic or lumbar region asymmetry while the patient bends forward at the waist until the spine becomes parallel to the floor. In severe kyphoscoliosis complicated by right heart failure, clinical examination may reveal cyanosis, distended neck veins, peripheral edema, and hepatomegaly.

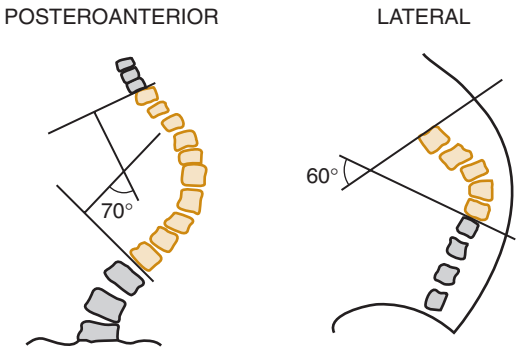

FIGURE 88-2 ■ Drawings of the spine illustrating the lines constructed to measure the Cobb angle of scoliosis and kyphosis. The degree of scoliosis can be assessed on the posteroanterior radiograph (*left*) and the degree of kyphosis on the lateral radiograph (*right*). The angle can be calculated in two ways: either from the intersection of the lines parallel to the vertebra (as shown for kyphosis, on the *right*) or from the intersection of lines perpendicular to these lines (as shown for scoliosis, on the *left*).

The severity of the spinal deformity is assessed by measuring the Cobb angle on a radiograph of the spine.[4] This is the angle formed by the intersection of two lines, one parallel to the top and the other parallel to the bottom vertebrae of the scoliotic or kyphotic curves (Fig. 88-2). The greater the Cobb angle the more severe is the deformity. Angles greater than 100 degrees are usually associated with respiratory symptoms (i.e., dyspnea on exertion) and angles greater than 120 degrees with respiratory failure.[5]

Pathophysiology

Pulmonary Function and Respiratory Mechanics

Kyphoscoliosis can produce the most severe restrictive impairment of all chest wall diseases[6,7] (Table 88-2). Total lung capacity (TLC) and vital capacity (VC) may be reduced to as low as 30% of predicted values; residual volume (RV) may be normal or slightly increased, thus resulting in an elevated RV/TLC.[8] In children with severe deformity, hypoplastic lung may contribute to reduced lung volumes.[9] Restrictive pathophysiology is invariably present when the Cobb angle is greater than 90 degrees. Other factors contributing to the restrictive process include the number of vertebrae involved, curve location, patient's age, presence of kyphosis, degree of spinal rotation, and respiratory muscle strength.[10–12]

Respiratory muscle strength may be normal or reduced in patients with kyphoscoliosis. Individuals with idiopathic kyphoscoliosis and Cobb angles of less than 50 degrees usually have normal respiratory muscle strength,

whereas those with angles greater than 50 degrees may have mild to moderate reductions in maximal inspiratory pressure (PI_{max}) and maximal expiratory pressure (PE_{max})[13] due either to respiratory muscle weakness or to altered chest wall mechanics. In patients with paralytic kyphoscoliosis, profound respiratory muscle weakness may be present and contribute to respiratory failure. Perhaps because of this primary involvement of the respiratory muscles, these patients have a relatively greater restrictive defect for a given degree of spinal deformity than those with idiopathic kyphoscoliosis.[14] Likewise, in congenital kyphoscoliosis, the loss in VC is 15% greater than in patients with idiopathic kyphoscoliosis and a similar Cobb angle, most likely due to associated rib deformities or underlying lung abnormalities.[14]

TABLE 88-2. Representative Values for Pulmonary Function and Respiratory Mechanics in Chest Wall Diseases

	CHEST WALL DISEASE*			
Parameter†	**KS**	**Post-Thor**	**PE**	**AS**
TLC (% predicted)	45	65	90	85
VC (% predicted)	30	50	90	80
RV (% predicted)	95	90	100	100
FEV_1 (% predicted)	40	40	95	80
FEV_1/FVC	80	60	80	75
C_{RS} (% predicted)	50	50	—	70
C_W (% predicted)	30	40	—	60
C_L (% predicted)	60	50	80	80
PI_{max} (cm H_2O)	40	50	90	80
MVV (L/min)	37	37	107	80

*KS, kyphoscoliosis; Post-Thor, post-thoracoplasty; PE, pectus excavatum; AS, ankylosing spondylitis.
†TLC, total lung capacity; VC, vital capacity; RV, residual volume; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; C_{RS}, compliance of respiratory system; C_W, compliance of chest wall; C_L, compliance of lungs; PI_{max}, maximum inspiratory pressure; MVV, maximum voluntary ventilation.
Representative values are from Bergofsky EH: Thoracic deformities. *In* Roussos C (ed): The Thorax. New York: Marcel Dekker, 1995, pp 1915–1949.

Respiratory system compliance is reduced in kyphoscoliosis, primarily due to reduction in chest wall compliance and, to a lesser degree, reduction in lung compliance due to microatelectasis. Cobb angles up to 50 degrees have minimal effect in decreasing respiratory compliance, whereas angles greater than 100 degrees may reduce compliance to levels seen in acute respiratory distress syndrome.[15] The stiff chest wall reduces the resting position of the respiratory system (functional residual capacity [FRC]). These factors result in tidal breathing moving to a flatter, stiffer portion of the respiratory volume-pressure curve. This requires greater inspiratory effort for relatively small tidal breaths, which increases the work and oxygen cost of breathing (Fig. 88-3). The increase in the oxygen cost of breathing may reach values three to five times those measured in healthy individuals and thus place patients at risk for respiratory muscle fatigue.[16]

Exercise Capacity

Adolescents with mild idiopathic kyphoscoliosis usually have normal exercise capacity,[17] whereas those with moderate idiopathic kyphoscoliosis (Cobb angles 25 to 70 degrees) have reduced exercise capacity. In these individuals, exercise limitation may be due to deconditioning rather than ventilatory constraints.[18–20] With severe deformities, ventilatory and cardiovascular factors may each contribute to exercise limitation.[18,19] Supplemental O_2 may improve oxygenation during exercise but usually does not affect walk distance.

Control of Breathing and Sleep-Disordered Breathing

Patients with kyphoscoliosis compensate for the increased elastic loads on the inspiratory muscles by adopting a rapid shallow breathing pattern consisting of low tidal volumes and shortened inspiratory time. Both of these factors correlate with the angle of scoliosis.[21] In the setting of a stiff chest wall, this breathing pattern minimizes the work per breath and the pressure needed to inhale, thereby lowering the risk for respiratory

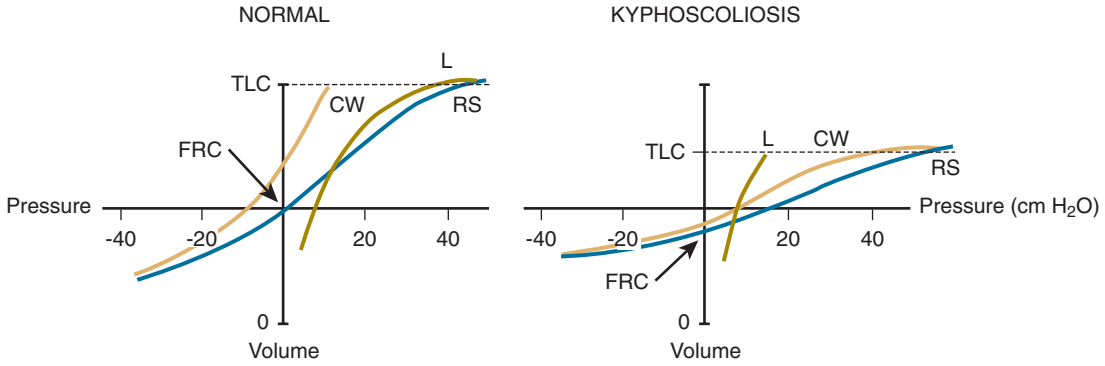

FIGURE 88-3 ■ Schematic illustration of alterations in volume-pressure relationship of the lung (L), chest wall (CW), and respiratory system (RS) in kyphoscoliosis. The chest wall is less compliant, leading to a reduction in functional residual capacity (FRC), and tidal breathing takes place on a flatter portion of the respiratory system volume-pressure curve. TLC, total lung capacity.

muscle fatigue. However, this breathing pattern promotes dead space ventilation and microatelectasis, thus further decreasing lung compliance. Patients also may compensate for the increased elastic load by increasing neural drive to the respiratory muscles. Indirect evidence for this compensatory strategy is the elevated mouth occlusion pressure at 100 msec ($P_{0.1}$) seen during quiet breathing, exercise, or breathing stimulated by hypercapnia. In addition, $P_{0.1}$ correlates positively with the angle of deformity in these patients.[21] This increased neural drive may not be accompanied by increased ventilation as the mechanical limitations imposed by the stiffened chest wall and weak inspiratory muscles limit the augmentation of ventilation when neural drive is increased.

Sleep-related breathing disorders may significantly impact the clinical course and quality of life of patients with kyphoscoliosis.[5] Nocturnal hypoxemia typically predates onset of respiratory failure in these patients.[5,22] Hypoventilation is the most common abnormality during sleep and is related to a reduction in inspiratory muscle activity during rapid-eye-movement sleep. Decreased neural drive to the diaphragm combined with a reduction in chest wall compliance may also contribute to hypoventilation during sleep.[22] However, the magnitude of nocturnal oxyhemoglobin desaturation may not correlate with the angle of deformity, highlighting the importance of overnight oximetry as a screening tool even in patients with moderate spinal deformity.[23] Obstructive sleep apnea may occur with a frequency similar to that seen in the general population and can further aggravate nocturnal hypoventilation.[24] Adverse sequelae of nocturnal hypoxemia and hypercapnia include respiratory muscle dysfunction, persistent hypercapnia and hypoxemia, pulmonary vascular remodeling, pulmonary hypertension, and ultimately cardiorespiratory failure and death.[22] Because sleep-related abnormalities and their effects on cardiorespiratory function are potentially treatable, they should always be evaluated in kyphoscoliosis patients well in advance of development of daytime hypercapnia so that noninvasive ventilation can be instituted early.[5,25]

Clinical Course

Etiology and spinal deformity importantly influence the natural history of kyphoscoliosis.[2] In secondary kyphoscoliosis, progression is largely dependent on underlying disease and age of onset. For example, onset at an early age, rapid curve progression during growth, and progression after skeletal maturity are risk factors for respiratory complications.[26] Congenital kyphoscoliosis may also progress rapidly and compromise respiratory function. In contrast, idiopathic kyphoscoliosis generally has a overall more benign course, with curve progression, cardiopulmonary problems, and psychosocial concerns developing at a variable rate in most untreated patients.[2] Large curves at presentation, skeletal immaturity, and a thoracic, as opposed to a thoracolumbar or lumbar, location of the curve apex are generally considered risk factors for curve progression.[2] In general, the spinal deformity worsens at a rate of about 1 degree per year in individuals with thoracic deformities greater than 50 degrees at skeletal maturity.

In mild idiopathic kyphoscoliosis, the probability of developing respiratory failure with aging is similar to that in a healthy population. However, the risk is higher for patients with moderate or severe deformities. Middle-aged or older patients with severe deformities (i.e., angles around 100 degrees) need to be monitored closely for respiratory complications. The initial symptom is usually dyspnea on exertion, which may then progress to dyspnea at rest. As deformity progresses with aging, respiratory failure may ensue. When cor pulmonary develops, the prognosis is poor and, without therapy, death may occur within 1 year. In addition to chest wall deformity, other factors that contribute to ventilatory failure in these patients are inspiratory muscle weakness, underlying neuromuscular disease, sleep-disordered breathing, and airway compression due to distortion of the lung parenchyma and twisting of airways. These factors should be investigated in individuals with respiratory failure and Cobb angles smaller than 100 degrees.

Treatment

Medical Treatment

General supportive measures include immunizations against influenza and pneumococci, smoking cessation, maintenance of a normal body weight, supplemental oxygen, and treatment of respiratory infections in a timely fashion (instructing patients to call when they first notice a change in sputum characteristics). Physical activity should be encouraged to minimize deconditioning. For chronic respiratory failure, chest physiotherapy, bronchodilators, and diuretics may be needed.

Nocturnal hypoventilation should be treated with noninvasive positive-pressure ventilation, which is typically delivered via a nasal or full-face mask. Pressure or volume preset ventilators can be used with similar efficacy.[5] Indications for instituting noninvasive ventilation include symptoms suggestive of nocturnal hypoventilation or signs of cor pulmonale with either an elevated daytime arterial P_{CO_2} or nocturnal oxygen saturation less than 88% for 5 consecutive minutes[27] (Table 88-3). Supplemental oxygen will be needed if hypoxemia persists despite correction of hypoventilation. Tracheostomy is considered for patients with inability to manage excessive bronchial secretions and for those not responding to or not tolerating noninvasive ventilation.

The benefits of noninvasive ventilation are well documented and include improvements in gas exchange, hemodynamic parameters, sleep architecture, and quality of life[5,25] (Table 88-4). The likely mechanism of improvement in respiratory failure is by increasing ventilatory response to carbon dioxide rather than improving respiratory muscle contractility.[28] Additional benefits of long-term noninvasive ventilation are a reduction in the number and duration of hospitalizations.[5] An increase in survival is also likely, although this evidence is not supported by randomized controlled studies.[29–31] Lung

TABLE 88-3. Indications for Instituting Long-Term Noninvasive Ventilation for Kyphoscoliosis (and Other Chest Wall Diseases)

Symptoms (e.g., fatigue, morning headaches, dyspnea) or *signs* of cor pulmonale and one of the following:
- Daytime arterial $P_{CO_2} \geq 45$ mm Hg
- Nocturnal oxygen saturation < 88% for >5 consecutive minutes
- Progressive neuromuscular disease with $P_{I_{max}} < 60$ cm H_2O or FVC < 50% of predicted

FVC, forced vital capacity; $P_{I_{max}}$, maximal static inspiratory pressure.
Adapted from Consensus Conference: Clinical indications for noninvasive positive pressure ventilation in chronic respiratory failure due to restrictive lung disease, COPD, and nocturnal hypoventilation—a consensus conference report. Chest 116:521–534, 1999.

TABLE 88-4. Benefits of Noninvasive Nocturnal Ventilation in Chest Wall Diseases

- Gas exchange
  - Increased arterial P_{O_2}
  - Decreased arterial P_{CO_2}
- Hemodynamics
  - Decreased pulmonary arterial pressure
  - Improved right ventricular function
- Mechanics
  - Reduced work of breathing
  - Increased maximal static inspiratory pressure ($P_{I_{max}}$)
- Sleep hygiene
  - Normalized sleep patterns
  - Fewer apneic episodes
- Outcome
  - Fewer hospitalizations
  - Improved quality of life
  - Relief of dyspnea
  - Possible increased survival

volumes, respiratory muscle strength, and respiratory endurance are not consistently improved with noninvasive ventilation.

Surgical Treatment

Surgical and nonsurgical (brace) orthopedic treatments have been used in skeletally immature patients with idiopathic kyphoscoliosis in an effort to prevent or correct the spinal deformity. A brace is generally recommended for growing children with angles between 25 and 40 degrees, whereas surgery is indicated for adolescents with an angle greater than 45 degrees.[2] In general, surgery involves fusion of the affected vertebral bodies via the posterior approach and use of modern instrumentation such as rods, wires, hooks, and pedicle screws to support the spine. This technique, which has significantly improved since the initial introduction of Harrington rods, allows for multiplanar correction, stable fixation with less spinal fusion, and no need to use postoperative immobilization with a cast or brace.[2] Immediately following surgery, chest wall and respiratory system compliance may decrease due to rib cage trauma and changes in the chest wall caliber.[32] The long-term benefits of spinal surgery on pulmonary function remain unclear.[33–35] Pulmonary function is more likely to improve in young children and adolescents than in adults. In the absence of randomized controlled studies assessing the efficacy of bracing or surgery, the overall role of surgical management in restoring function to that of nonscoliotic individuals and minimizing the possibility of respiratory failure is not clear.[2]

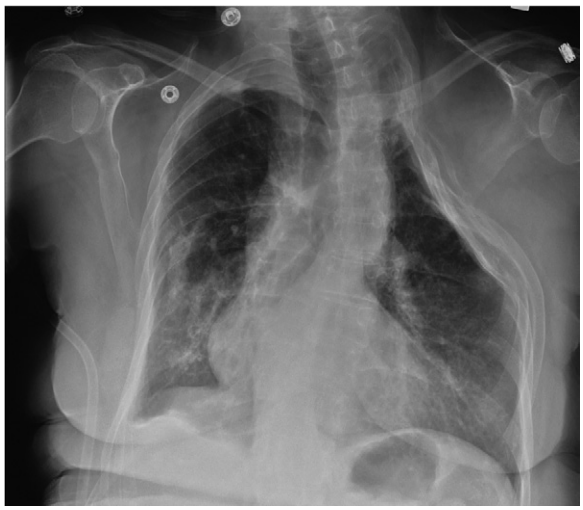

FIGURE 88-4 ■ Frontal chest radiograph in a patient with history of prior *Mycobacterium tuberculosis* infection shows extensive deformity of the left hemithorax consistent with prior thoracoplasty. Scoliosis of the thoracic spine is probably related to the chest wall deformity.

THORACOPLASTY

Thoracoplasty was used frequently in the pre-antibiotic era to treat tuberculosis. The goal of thoracoplasty (Fig. 88-4) was to reduce lung volume by removing ribs, producing rib fractures, resecting the phrenic nerve, or filling the pleural space with foreign material (i.e., ping-pong balls). Severe restrictive impairment usually manifests itself decades following the procedure. Since this procedure was performed in the 1940s and 1950s, very few people are alive today who underwent thoracoplasty,[36,37] but the natural history of this condition is instructive. Symptoms of dyspnea on exertion followed by acute or chronic respiratory failure typically develop after a long asymptomatic phase. Factors such as slowly progressive kyphoscoliosis account, in part, for the delay in the onset of symptoms. The severity of the restrictive defect can be similar to that seen in kyphoscoliosis (see Table 88-2), and is due to reduction in respiratory system compliance, fibrothorax, lung fibrosis related to underlying granulomatous disease, lung resection, phrenic nerve

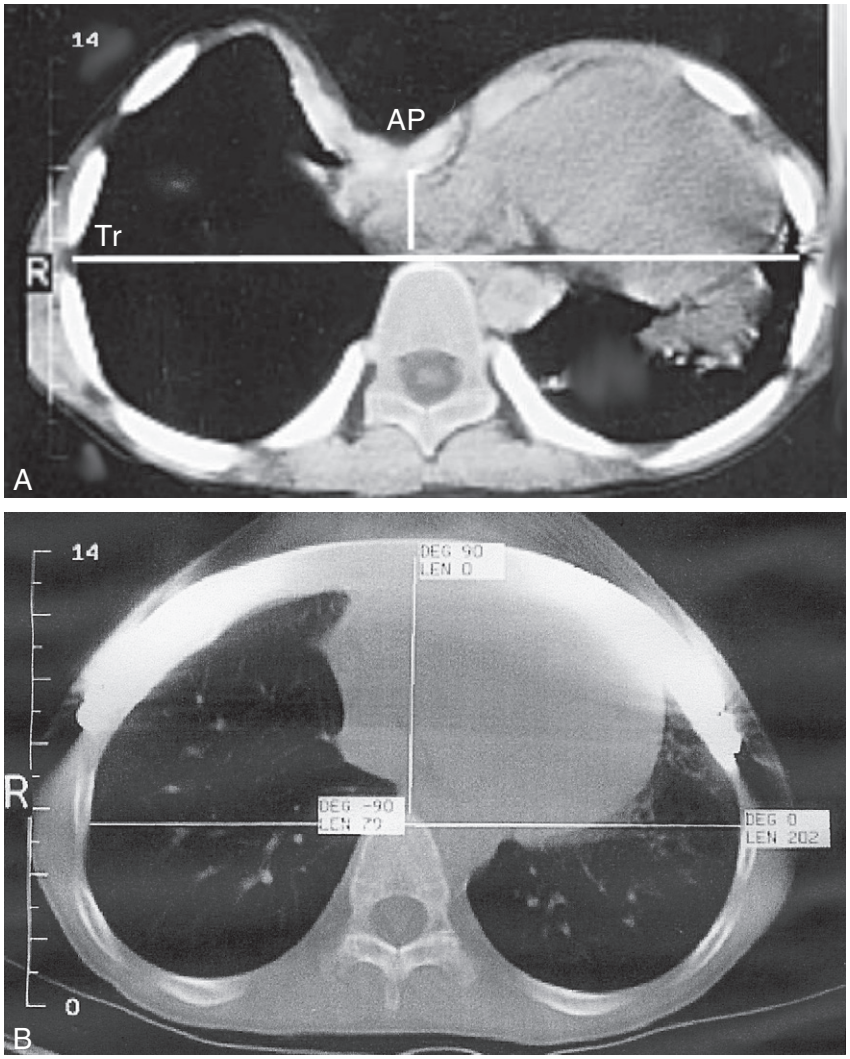

FIGURE 88-5 ■ **A,** Preoperative chest CT scan of a patient with pectus excavatum, demonstrating a severely reduced anteroposterior (AP) diameter relative to the transverse rib cage diameter (Tr) (transverse/AP ratio = 8.6). **B,** Following the minimally invasive Nuss procedure, the AP distance increases and the ratio becomes more normal (transverse/AP ratio = 2.7) (Normal = 2.5).

damage, and scoliosis.[36,37] The substantial elastic loads imposed by the stiff respiratory system lead to an increase in the work of breathing, impaired gas exchange, and ultimately cor pulmonale. As with severe kyphoscoliosis, the treatment consists of oxygen, antibiotics when appropriate, and noninvasive mechanical ventilation. It is important for the clinician to be aware of the natural history of post-thoracoplasty individuals because one may encounter patients with a similar progressive impairment of respiratory function following aggressive surgery on the rib cage to resect tumors or for other reasons such as treatment of unrelenting empyema. Patients undergoing extensive chest wall surgery of any type should have their pulmonary function monitored periodically.

PECTUS EXCAVATUM

Diagnosis and Etiology

Pectus excavatum is a congenital chest wall deformity characterized by excessive depression of the sternum and its adjacent costal cartilages (Fig. 88-5). It is the most common chest wall deformity, occurring in approximately 0.5% to 2% of the population, more frequently in males than in females (ratio of 4:1).[38] Although pectus excavatum may be apparent in infancy, the majority of cases become noticeable at puberty.

Pectus excavatum may result from abnormal cartilage growth that displaces the sternum inward.[38] A genetic predisposition is supported by a large study in which 43% of patients gave a family history of pectus excavatum.[39] Approximately 6% of patients have a connective tissue disorder such as Marfan or Ehlers-Danlos syndrome, and 40% to 60% have scoliosis.[40] Congenital heart disease may coexist in about 2% of cases.[38]

Individuals with pectus excavatum, especially teenagers, often seek medical advice for cosmetic concerns. Dyspnea with activity or exercise intolerance, often out of proportion to any abnormality in cardiopulmonary function, is present in 30% to 70% of patients. There is a considerable range of sternal deformity that is best assessed by computed tomography (CT) measurements

of the ratio of the transverse to anterior-posterior diameter of the rib cage at the level of the deepest sternal depression. A ratio greater than 3.25 (normal 2.5) signifies a pectus deformity that may need correction.

Pathophysiology

Respiratory Mechanics and Exercise Capacity

Most patients with pectus excavatum have normal pulmonary function, although a small percentage of individuals have a mild restrictive deficit.[38,40] Unlike ankylosing spondylitis, the mobility of the rib cage in those with pectus during quiet breathing or mild exercise is not limited.[41] Despite a perception of exercise limitation, cardiopulmonary exercise testing is usually normal. Those with the most severe deformities may exhibit a mild reduction in the maximal work rate and oxygen consumption.[42,43] Although the concept is not widely accepted, right ventricular compression by the depressed sternum may be a mechanism underlying exercise limitation in some individuals.

Treatment

Surgical correction of pectus excavatum is usually considered for patients with a CT index greater than 3.5 in conjunction with symptoms or laboratory evidence of cardiac or pulmonary impairment.[38] Initially, surgical approaches involved resection of costal cartilage combined with sternal osteotomy (Ravitch procedure). Less invasive approaches now entail the substernal placement of a curved metal rod through small incisions on each side of the rib cage; after insertion, the rod is rotated, forcing the sternum outward (Nuss procedure). The bar is removed after 2 years once the sternum is stabilized in its original position.[39] Currently, gradual correction procedures using magnets to pull out the sternum are being tested, and such remodeling approaches may be available in the future.[44] Compared with more invasive procedures, the less invasive Nuss procedure has a lower incidence of complications such as sternal necrosis and infection. With either corrective procedure, improvement of symptoms and function is difficult to predict. In fact, to date, there is no convincing evidence that correction of the deformity improves either cardiopulmonary function or exercise capacity.[45–48]

FLAIL CHEST

Diagnosis and Etiology

Flail chest arises when fractures of adjacent ribs produce a segment of the rib cage that deforms with normal breathing.[49,50] To produce flail chest, double fractures of three or more contiguous ribs or combined sternal and rib fractures are required. This results in an unstable segment of the chest wall that moves paradoxically, inward with inspiration and outward with expiration.

Blunt chest trauma is the most common cause of flail chest in adults. In children, flail chest is infrequent because the chest wall is more compliant; thus, when it does occur, flail chest signifies a much greater degree of trauma.[51] Automobile accidents and falls account for most cases of flail chest, whereas aggressive cardiopulmonary resuscitation and pathologic rib fractures in patients with multiple myeloma or other metastatic rib lesions are less frequent causes. Rarely, flail chest may complicate corrective rib resection or appear in neonatal life due to congenital rib abnormalities.[49,52–55]

The diagnosis of flail chest can be made at the bedside by observing the characteristic paradoxical movement of a segment of the chest wall during spontaneous ventilation. In subtle cases, palpation of the chest wall may aid in appreciating chest wall paradox. Although not highly sensitive, chest radiographs may confirm the presence of multiple rib fractures. A three-dimensional reconstruction of thoracic helical CT or multidetector CT scans,[56] which are often performed to assess the extent of thoracic injuries after blunt chest wall trauma, provides a more sensitive means of identifying rib fractures. However, these more sophisticated techniques are not necessary to confirm the diagnosis of flail chest, which can be made at the bedside by inspecting or palpating the chest wall. In the fully sedated, mechanically ventilated trauma patient, the diagnosis of flail chest may be delayed for days or even weeks and become apparent only after withdrawal of sedation and resumption of spontaneous breathing.[57]

Trauma and Flail Chest

The presence of flail chest following trauma signifies severe thoracic injury and is an independent risk factor for respiratory complications, respiratory failure, and death. Pulmonary complications such as lung contusion, pneumothorax, or hemothorax can occur in up to 60% of patients with flail chest.[51] Flail chest and its associated pain promote atelectasis, impair cough effectiveness, and may lead to respiratory failure. Patients with flail chest are twice as likely to develop respiratory failure and require mechanical ventilation as patients with isolated lung contusion.[51] Overall, mortality from chest wall trauma is high, ranging from 7% to 14%; with concomitant flail chest, the mortality rate increases even further.[51] In a series of over 1000 multiple-trauma patients, overall mortality was 27% while mortality for those with flail chest was 68%.[58] The associated high mortality is in part due to coexistence of other injuries such as fractures of long bones or vertebrae, head trauma, rupture of major vascular structures, or laceration of abdominal organs. Concomitant head injury is a particularly poor prognostic factor in patients with traumatic flail chest.[51] Older age is another poor prognostic factor; in fact, mortality increases by 132% in patients with flail chest for every decade of increase in age above the age of 10 years starting at the second decade and continuing to the eighth decade of life.[59] Of special note, flail chest in a cardiac arrest victim may render manual compressions ineffective by blunting the increase in intrathoracic pressures with compression and thus necessitate internal cardiac massage. Chronic disability related to flail chest may occur in patients who survive the acute injury. Chest tightness, chest pain, or dyspnea on exertion has

been described in as many as half of such patients. However, with operative fixation of the flail segment, these symptoms can improve dramatically.[60,61]

Pathophysiology

Respiratory Mechanics

Flail chest disrupts the anatomic integrity of the chest wall and seriously alters its function. With flail chest, a segment of the chest wall is uncoupled from the forces that promote rib cage expansion, thereby making the flail segment responsive to intrapleural pressure changes. Thus, with inspiration and the decrease in intrapleural pressure, the flail segment moves inward and, during expiration with positive intrapleural pressure, it moves outward. When the normal swings in pleural pressure are amplified by a decrease in lung compliance due to concomitant pulmonary contusion and/or atelectasis, there is greater paradoxical motion of the flail segment. The location of the flail segment may impact the magnitude of disordered chest wall motion. Lateral flail, which is the most common, is generally associated with greater clinical derangement; in contrast, posterior flail has less impact due to splinting provided by the back muscles. However, the patterns of chest wall distortion are not specific to a given location of the flail segment, and the same anatomic location may be associated with different patterns of distortion. For example, paradoxical motion may occur within the rib cage itself or between the rib cage and the abdomen.[62] These disparate patterns include (1) inward displacement of the lateral rib cage as the lower anterior rib cage and abdomen are expanding, (2) inward displacement of the anterior lower rib cage and abdomen as the lateral rib cage is expanding, and (3) inward displacement of the anterior lower rib cage as the lateral rib cage and abdomen are expanding.[62]

Disordered patterns of respiratory muscle recruitment are another factor contributing to motion of the flail segment.[63,64] Normal recruitment patterns may be altered because of severe chest wall pain associated with flail chest. Thus, activation of different respiratory muscles may increase or decrease the degree of rib cage paradox.[65] Clinical observations suggest that the change in the recruitment pattern of the respiratory muscles that follows traumatic flail chest may explain why some cases of flail chest remain unstable following prolonged mechanical ventilation,[66,67] and why lateral flail segments have a higher propensity for dislocation following surgical fixation.[66,67]

Respiratory Failure

Understanding the pathogenesis of respiratory failure in flail chest has markedly evolved over the last 4 decades. The simplistic theory of *pendelluft* (movement of air back and forth between the injured and the uninjured side) has long been abandoned, and recent clinical observations and experimental data suggest that a combination of events, including hypoventilation and flail-induced changes in lung and respiratory muscle function, are key factors. In addition, it has become clear that the effects of the flail segment on respiratory function are complex and that the presence of flail chest alone, without associated pulmonary contusion, has important physiologic sequelae. When present, lung contusion undoubtedly contributes further to the pathogenesis of respiratory failure.

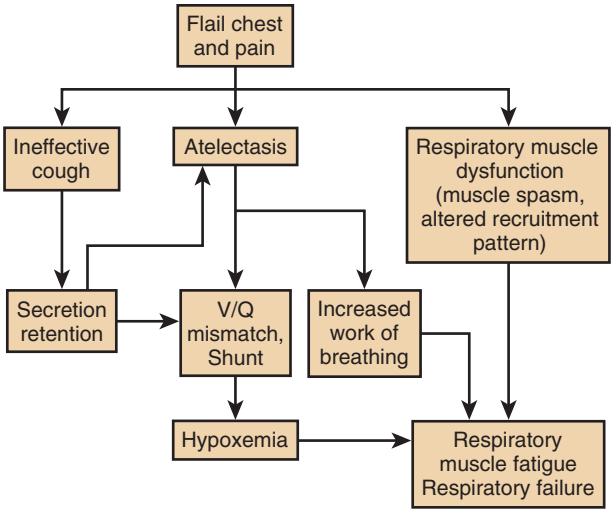

FIGURE 88-6 ■ Factors involved in the pathophysiology of respiratory failure in flail chest.

Both the flail segment and its associated pain contribute to cough impairment, regional atelectasis, intercostal muscle spasm, and alterations in the patterns of respiratory muscle recruitment (Fig. 88-6). In addition to the previously mentioned adverse effects on the lung, the flail segment can impair respiratory muscle performance.[62-65] First, the paradox increases the degree of muscle shortening for a given tidal volume so that, during inspiration, the inspiratory muscles contract at shorter lengths.[62] These effects, combined with the increase in elastic load related to lung contusion and/or atelectasis, reduce respiratory muscle efficiency and increase the work of breathing.[62,68] With the additional effects of hypoxemia, the respiratory muscles are weakened and predisposed to fatigue (see Fig. 88-6).

Pulmonary Function Tests

Reductions in forced vital capacity (FVC) and FRC to as low as 50% of predicted may occur in patients with flail chest. These reductions are related to disordered chest wall motion and, in some patients, to underlying lung contusion. In patients with flail chest without lung contusion treated conservatively, FVC and FRC return to baseline values within 6 months from the acute injury, although mild reductions in pulmonary function may occasionally persist. In contrast, in patients with concomitant lung contusion treated conservatively, reductions in pulmonary function are recorded up to 4 years postinjury, most likely due to fibrosis of the contused area. After operative fixation of flail chest, evidence from controlled[69] and uncontrolled[67] studies showed that the

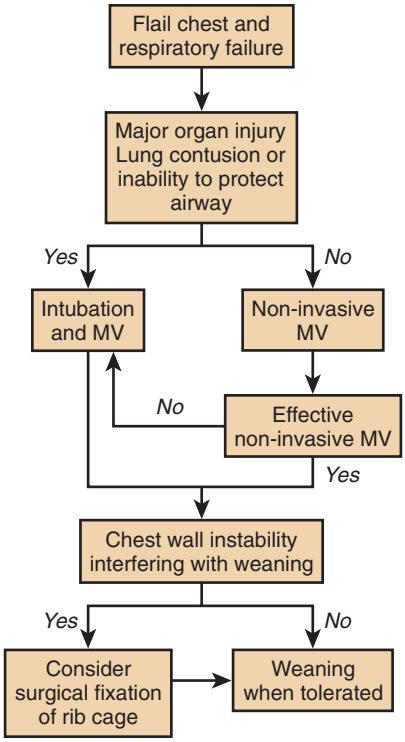

FIGURE 88-7 ■ Algorithm for the management of acute respiratory failure due to flail chest.

impairment in pulmonary function is significantly less than after conservative treatment.

Treatment

General Aspects

The management of flail chest has evolved significantly over the last 2 decades as our understanding of the contribution of the flail segment to respiratory failure continues to be refined. The restoration of anatomic and functional integrity of the chest wall can be achieved with conservative management (with or without mechanical ventilation) or with surgical intervention (Fig. 88-7). However, which modality is best suited for a given patient remains a difficult question to answer.

Nonsurgical Management

Conservative management is based on administration of adequate analgesia, clearing of bronchial secretions, and mechanical ventilatory assistance if needed. Adequate pain relief can be accomplished by oral medications, patient-controlled analgesia pumps, intermittent intercostal nerve blocks, or epidural anesthesia. Control of pain is crucial in averting further atelectasis, arteriovenous shunting, and hypoxemia. Adequate analgesia in combination with supplemental oxygen, effective tracheobronchial toilet, and cautious fluid replacement, often results in successful treatment of flail chest with avoidance of respiratory failure. If respiratory failure ensues, mechanical ventilation is standard treatment. In addition to enhancing gas exchange, positive-pressure ventilation will provide internal pneumatic stabilization of the flail segment. However, mechanical ventilation solely for the purpose of providing stability to the chest wall, as was formerly recommended in the 1960s and 1970s, is no longer recommended due to the increased morbidity and mortality associated with mechanical ventilation. By contrast, noninvasive positive-pressure ventilation may be beneficial to patients with flail chest with less morbidity. When delivered via a nasal or face mask to patients who are spontaneously breathing and able to protect their upper airway, this ventilatory mode in conjunction with patient-controlled analgesia improves gas exchange, allows for early patient mobilization and access for physiotherapy, and significantly reduces morbidity and mortality when compared to mechanically ventilated, intubated patients.[70,71]

If intubation and mechanical ventilation are needed, the choice of ventilator mode may affect the stability of the flail segment. The magnitude of paradoxical motion of the flail segment is related to changes in pleural pressure and is therefore quite sensitive to changes in resistive and elastic loads imposed by the ventilator and its circuit.[62] For example, with the intermittent mandatory ventilation mode, the spontaneous breaths through the added resistance of the circuit may aggravate chest wall distortion. In contrast, high-flow continuous positive airway pressure may reduce chest distortion during inspiration. As a general rule, low-impedance ventilator modes are optimal choices for stabilizing the flail segment and for weaning.[62]

Surgical Management

Surgical fixation of the unstable flail segment has been employed over the last 6 decades to reduce patient ventilator time and the associated ventilator-associated morbidity and mortality. Surgical techniques include mobilization of large chest wall flaps or open thoracotomy and stabilizing the fractured ribs with devices such as medullary wires or nails, Judet struts, or titanium plates. A few controlled studies involving small numbers of patients[69,72] suggested that surgical fixation to restore pulmonary function and chest wall integrity may be superior to conservative management by reducing the length of ventilatory support, duration of intensive care unit stay, infection rate, and incidence of chest wall deformities.

The indications for operative fixation are not fully defined; candidates may be patients with flail chest who are unable to be weaned from mechanical ventilation due to chest wall instability, or those undergoing thoracotomy for concomitant injuries. In addition, patients with persistent pain, with severe chest wall instability, or with progressive decline in pulmonary function could be considered for surgical stabilization.[49,73] Although surgical fixation appears to be a promising therapeutic modality, its benefits and indications need to be clarified by large randomized, well-controlled studies comparing the surgical approach with modern conservative treatment.[73a,73b]

ANKYLOSING SPONDYLITIS

Diagnosis and Etiology

Ankylosing spondylitis (AS) is a chronic progressive inflammatory disease involving primarily the ligamentous structures of the spine and the sacroiliac and large peripheral joints.[74] It usually affects men, with the most common age of onset between 15 and 25 years. The annual incidence is 6.6 per 100,000 white Americans and 3 to 4 times less frequent in black Americans. There is a genetic predisposition for the disease, with nearly 95% of white patients positive for the HLA-B27 antigen.[74]

Compared to other spondyloarthritides, AS exhibits more severe spinal involvement and respiratory complications. The chronic inflammation of the spinal joints and adjacent structures causes fibrosis and ossification of these structures and bony ankylosis of the costovertebral and sternoclavicular joints.[74,75]

Pathophysiology

Respiratory Mechanics

Although the direction of rib cage motion is similar to that in healthy individuals, the magnitude of motion is severely restricted[76] (Fig. 88-8). This limited motion is the hallmark of respiratory dysfunction in AS and is due to stiffening and fusion of the costovertebral and sternoclavicular articulations, to rigidity of the spine, and possibly to intercostal muscle atrophy with advanced disease.[75] Despite a pronounced reduction in rib cage elasticity, lung compliance remains normal except in cases with fibrobullous or interstitial lung disease.[75,77,78] Since the abdomen is compliant and the rib cage is stiff, there is preferential caudal descent of the diaphragm and more expansion of the abdomen than of the rib cage (i.e., the lung expands along the "path of least resistance"). This strategy may minimize the work and energy needed to inflate the lung.[79] Thus, during quiet breathing, exercise, or speech, most of the lung volume change is accomplished by caudal displacement of the diaphragm and expansion of the abdominal wall.[75,79,80] Consequently, transdiaphragmatic pressure increases by 2.4-fold in AS patients at levels of ventilation where healthy individuals increase transdiaphragmatic pressure by 1.4-fold.[75] Greater recruitment of the diaphragm in AS may potentially provide a strength-training stimulus to the diaphragm.

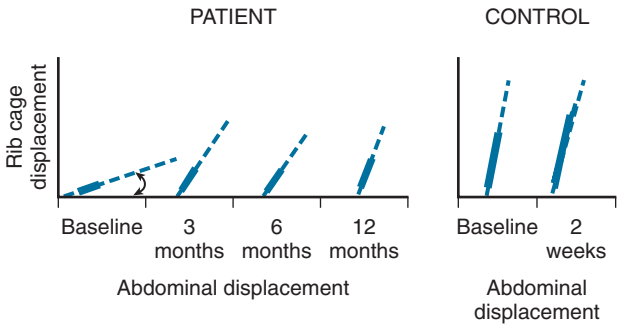

FIGURE 88-8 ■ Representative plots of the rib cage and abdominal displacements during quiet breathing in a seated patient with ankylosing spondylitis, before and at various time points during therapy with anti–TNF-α. Note the diminished contribution of the rib cage to tidal volume at baseline and the progressive increase in the rib cage contribution to breathing with treatment, becoming closer to the normal patterns obtained about 2 weeks apart in a healthy individual (control). (Adapted from Tzelepis GE, Kalliakosta G, Tzioufas AG, et al: Thoracoabdominal motion in ankylosing spondylitis: Association with standardised clinical measures and response to therapy. Ann Rheum Dis 66:966–971, 2009.)

Pulmonary and Respiratory Muscle Function

Despite limited rib cage mobility, there may be only mild decrements in FVC and TLC. The mild restrictive impairment appears to be proportional to disease activity and duration, as well as to the degree of spinal and rib cage immobility.[81,82] The restrictive defect is worsened by concomitant kyphosis, which may occur in advanced disease or be secondary to osteoporosis. Up to 50% of patients with long-standing AS may have some degree of kyphosis.[83] The rigid spine is also susceptible to fracture with minimal trauma. Spinal fractures worsen kyphosis and further impair respiratory function.[84] Cervical spine fractures (typically C6 or C7) can cause tetraplegia and respiratory failure.

The effects of AS on the respiratory muscles are not fully defined. Some, but not all, studies have found that patients with AS have mild reductions in $P_{I_{max}}$ and $P_{E_{max}}$.[82,85,86] Individuals with normal respiratory muscle strength may have impaired respiratory muscle endurance.[86] The mild reductions in strength and endurance may be related to intercostal muscle atrophy secondary to decreased rib cage mobility[75] or to poor coordination of the respiratory muscles during the testing maneuvers.[87]

Gas Exchange and Exercise Capacity

In the majority of patients, arterial P_{O_2} and diffusion capacity are either normal or slightly decreased. The mild impairment in gas exchange is most likely related to the mild reduction in lung volumes.[82] In patients with concomitant fibrobullous disease, gas exchange may be severely compromised. Regional ventilation is usually normal despite the limited expansion of the rib cage.[88]

Exercise capacity may be reduced in patients with AS.[86] The mechanisms underlying this limitation are poorly understood. However, the lack of correlation between the degree of rib cage expansion and maximal oxygen consumption or work rate suggests that exercise is limited by deconditioning rather than ventilation.[86] Others postulate that a decrease in cardiac output related to rib cage stiffness, possibly due to reduced preload from reduced negative swings in intrathoracic pressure, may contribute to exercise limitation.[89,90]

Interstitial Lung Disease

About 1% to 4% of patients with AS, especially men with chronic disease, develop fibrobullous upper lobe

disease.[91–93] The cause of apical fibrobullous disease is unknown. Possible causes include diminished upper lobe ventilation and apical mechanical stress due to thoracic rigidity, as well as recurrent pulmonary infections due to impaired cough. The spectrum of fibrobullous disease ranges from unilateral or bilateral minimal upper lobe interstitial infiltrates to marked fibrosis, honeycombing, and cavitary lesions that may be mistaken for tuberculosis. In a limited number of cases, histologic examination has revealed prominent interstitial fibrosis with hyaline and elastic degeneration of collagen, and absence of granulomas.[92] These patients usually do not have symptoms but are at risk for spontaneous pneumothorax, aspergillosis, or mycobacterial infection. Corticosteroids do not prevent progression of the disease.[93] Because thoracic surgery for fibrobullous disease is complicated by bronchopleural fistula in 50% to 60% of patients, it is recommended only for treatment of major hemoptysis.[93] Another 10% to 20% of patients with AS develop nonapical interstitial lung disease, which can be detected by high-resolution CT scans of the chest.[92]

Treatment

The use of biologic agents has constituted a significant adjunct to standard medical therapy of AS. The tumor necrosis factor-α (TNF-α) antagonists (infliximab, etanercept, and adalimumab) provide significant symptom relief, reduce spinal inflammation, and dramatically improve the quality of life in these patients.[74,94,95] Anti–TNF-α therapy is associated with improvement in respiratory parameters (see Fig. 88-8). Rib cage expansion increases with anti–TNF-α therapy as documented by measurements of maximal rib cage expansion with a tape measure or by measurements of the partitioning of rib cage displacement relative to tidal volume during quiet breathing[79] (see Fig. 88-8). For the standard approach to therapy, exercise continues to be a mainstay.[96] Cardiorespiratory fitness and spinal mobility may be enhanced by instituting exercise and physiotherapy programs.[74,96] Tobacco use should be avoided. Patients should be monitored with baseline chest radiography and spirometry and followed up with repeat studies should respiratory symptoms develop. For patients treated with anti–TNF-α agents, a high index of suspicion for possible reactivation of latent tuberculosis is required. Similarly, specific pulmonary rehabilitation has been tried with varied success. If intubation is required, it should be performed with caution because these patients are at increased risk for spinal cord injury because of involvement of the cricoarytenoid joint.

OBESITY

Diagnosis and Etiology

Obesity has become a major health problem throughout the world, affecting not only adults but also children.[97] In the United States, recent estimates indicate that over half of the population is either overweight or obese.[98] In the year 2000, obesity was responsible for approximately 400,000 deaths, and accounted for about 7% of total health care costs.[99] Body fat usually constitutes 15% to 20% of body mass in healthy men and 25% to 30% in healthy women. In obesity, the body fat content may increase by as much as 500% in women and 800% in men.[100] Along with the fat, fat-free mass also increases in obese individuals, accounting for 15% to 30% of the total weight gain.[101,102] The degree of obesity can be assessed by the body mass index (BMI), which is the ratio of body weight (BW) in kilograms to the square of the height (Ht) in meters (BW/Ht^2). (The BMI can also be calculated as the weight in pounds multiplied by 703 and divided by the square of the height in inches.) Individuals with a BMI between 18.5 and 24.9 kg/m^2 are normal, with a BMI between 25 and 29.9 kg/m^2 are overweight, and those with a BMI greater than 30 kg/m^2 are considered obese. Obesity is severe (morbid) when the BMI is greater than 40 kg/m^2.[97]

The risk of death and likelihood of morbidity becomes greater as BMI increases.[103] In nonsmokers, compared to those with a normal BMI, the overweight have a 20% to 40% higher risk of death and those with a BMI greater than 30 kg/m^2 have a 300% to 400% higher risk of death.[103] Intra-abdominal fat is also an independent risk for cardiovascular disease and mortality.[104] Morbidity is primarily due to cardiovascular and respiratory factors.[105,106]

Dyspnea and exercise intolerance are the most frequent complaints of obese individuals[106]; however, the severity of the respiratory impairment may not correlate with the degree of obesity. For example, even in those with the same BMI, arterial P_{CO_2} may be elevated in some individuals but not in others. The level of arterial P_{CO_2} is used to classify obese individuals as either having simple obesity (SO; individuals who are eucapnic) or obesity hypoventilation syndrome (OHS; individuals who are hypercapnic). In obesity, respiratory symptoms and signs may be due to (1) disordered chest wall mechanics and pulmonary function, (2) alterations in the control of breathing, and/or (3) the presence of inflammatory-mediated effects such as those linking obesity to airway hyper-responsiveness.

Pathophysiology

Pulmonary Function

The most common abnormalities of pulmonary function seen in obesity are reductions in expiratory reserve volume (ERV) and FRC.[107,108] For each unit increase in BMI from 20 to 30 kg/m^2, FRC and ERV decrease approximately 3% and 5%, respectively; thereafter, both FRC and ERV decrease approximately 1%.[107] Consequently, an individual with a BMI of 30 kg/m^2 will have an FRC of approximately 75% of predicted and an ERV of only 47% of predicted.[107] The mechanism underlying the reduction in FRC is the decrease in chest wall compliance related to adipose tissue compressing the rib cage and abdomen, thereby reducing the elastic recoil of the chest wall. Accordingly, the balance between the inward recoil of the lung and the outward recoil of the chest wall resets at a lower lung volume (i.e., a lower FRC). FRC and ERV may be reduced further in patients with OHS.[109]

TABLE 88-5. Representative Values of Respiratory Pathophysiology of Simple Obesity and Obesity Hypoventilation Syndrome

Parameter*	Normal	Simple Obesity	Obesity Hypoventilation
BW (% ideal)	100	200	200
BMI (kg/m^2)	24	45	45
TLC (% predicted)	100	95	80
CRS (L/cm H_2O)	0.10	0.05	0.06
RRS (cm H_2O L^{-1} s^{-1})	1.2	4.0	7.8
Work of ventilation (J/L)	0.43	0.74	1.64
MVV (L/min)	160	130	90
PI_{max} (cm H_2O)	100	95	60

*BW, body weight; BMI, body mass index; TLC, total lung capacity; CRS, compliance of the respiratory system; RRS, respiratory system resistance; J, joule; MVV, maximum ventilatory volume; PI_{max}, maximal static inspiratory pressure.

Adapted from Rochester DF: Obesity and abdominal distention. *In* Roussos C (ed): The Thorax. New York: Marcel Dekker, 1995, pp 1950–1973.

TLC, VC, and RV may be normal or only mildly reduced in those with SO and be significantly reduced (TLC and VC < 80% of predicted) in those with morbid obesity or OHS.[108,110] The more substantial reductions in TLC and VC in these individuals are probably related to weakness of the respiratory muscles.[109] In addition, since pulmonary function is more severely affected in OHS than in SO, factors other than the BMI must be involved (Table 88-5). For example, the distribution of body fat in the upper body (central fat distribution from waist to hips) impairs pulmonary function more than lower body fat distribution (below hips). A waist circumference of 35 inches or more for women and 40 inches or more for men indicates upper body fat distribution.[111]The correlation of respiratory impairment with upper body fat appears to be more apparent in men than in women.[112]

Other tests of pulmonary function such as the FEV_1/FVC ratio, maximal voluntary ventilation, peak inspiratory flow rate, and the ratio of dead space to tidal volume are normal.[109] The single-breath diffusion capacity is usually normal or increased in SO and slightly reduced in OHS.[109]

Respiratory Mechanics

Obesity reduces respiratory system compliance (CRS), primarily by lowering chest wall compliance (CW). In SO, values for CRS and CW are approximately 80% to 90% of normal[109,113] but are further reduced as BMI increases or when changing from the upright to supine position.[114–116] In OHS, CW and CRS are generally less than 45% of normal.[109] The reduced CW is thought to be due to the mass of adipose tissue compressing the rib cage and abdomen. Consequently, breathing occurs at lower lung volumes where the slope of the volume-pressure curve is flatter and a greater pressure is needed for a given volume. In addition, the excess weight on the chest wall imposes a threshold load, that is, a load the inspiratory muscles must overcome before inspiratory flow ensues. This threshold load may account for much of the disordered chest wall mechanics.[113]

Airway and total respiratory system resistance increase as BMI increases.[117] The values for airway and respiratory system resistance are usually double those seen in nonobese individuals.[117–119] Chest wall and total respiratory system resistances are increased more in OHS than in SO.[109] Since airway resistance remains elevated even after normalizing for lung volume (i.e., specific airway conductance is reduced to 50% to 70% of normal), breathing at low lung volumes accounts for part but not all of the change in airway resistance.[109] The normal FEV_1/FVC ratio suggests that the greatest resistance to airflow may be at the level of the small airways and lung tissue itself rather than the large airways. The transition from the upright to supine position may further increase respiratory resistance in severe obesity.[119] The increase in the intra-abdominal pressure when supine also may limit expiratory flow during tidal breathing, resulting in orthopnea in severe obesity.[120] The negative impact of the supine position on respiratory mechanics must be considered when evaluating patients for sleep-related disorders or for general anesthesia.[114]

The work of breathing is increased in both SO and OHS because of the increased forces needed to inflate the lung. Three factors that contribute to the increase in work include increased elastic loads (reductions in CRS and CW), resistive loads (higher airways resistance), and threshold loads (greater force needed to lower alveolar pressure and initiate inspiration). The work of breathing can be up to 60% greater in SO and as much as 250% higher in OHS; the oxygen cost of breathing can be 5-fold greater in SO and 10-fold greater in OHS.[109] The combination of increased work and oxygen costs of breathing may place obese patients at risk for respiratory failure during states of increased ventilatory demands such as an intercurrent illness.[121] To minimize the elastic load during inspiration and optimize the O_2 cost of breathing, obese patients adapt a rapid, shallow breathing pattern. This strategy is more pronounced in OHS than in SO. In subjects with SO, the respiratory rate during quiet breathing is about 40% higher than in normal-weight subjects, with most of the lung volume change during tidal breathing accomplished by rib cage rather than by abdominal displacement.[122] In OHS, however, breathing frequency is 25% higher and tidal volume 25% lower than in SO. The adverse effect of adopting a rapid shallow breathing pattern is increased dead space ventilation, which may contribute to carbon dioxide retention.[121]

Gas Exchange

In individuals with SO, the arterial P_{O_2} is usually normal or slightly reduced.[123,124] However, severely obese patients and those with OHS have hypoxemia and a widened alveolar-arterial oxygen tension gradient.[123,124]

Gas exchange is comparatively worse in obese men than in obese women[124] and more pronounced when assuming the supine position.[119,123–125] The mechanism responsible for hypoxemia is premature airway closure, which promotes ventilation-perfusion mismatch.[124] In OHS, hypoventilation may further contribute to hypoxemia. During exercise, oxygenation may improve due to enhanced ventilation of the lung bases.[125,126] Weight loss, via the resultant increase in FRC and prevention of airway closure during tidal breathing, improves arterial P_{O_2} roughly by 1 mm Hg for every 5 kg reduction in weight.[124] A practical corollary of hypoxemia and the increased metabolic rate in obesity is that, during apnea, the arterial oxygen saturation may fall three times faster in obese individuals than in normal-weight subjects.[127]

Control and Pattern of Breathing

In eucapnic obese individuals, central ventilatory drive is intact. Respiratory drive, as measured by the $P_{0.1}$, ventilatory, and electromyographic (EMG) responses to hypoxia and hypercapnia, is either normal or increased when compared with nonobese subjects.[109,127a] If ventilatory drive is increased, it is considered an appropriate compensatory response to increased elastic and resistive loads placed on the inspiratory muscles. This compensatory increase in ventilatory drive decreases following weight loss.[128,129] In patients with OHS, central ventilatory drive is reduced and the $P_{0.1}$, ventilatory, and EMG responses to hypoxia and hypercapnia are blunted when compared with nonobese subjects.[130,131] In patients with OHS, the ventilatory response to carbon dioxide is reduced by about 65%, but arterial P_{CO_2} can be lowered to a normal level by voluntary hyperventilation.[132] The attenuated ventilatory drive in patients with OHS may be related to a genetic predisposition or to other factors such as chronic hypoxemia, hypercapnia, or sleep apnea. However, the finding that ventilatory drive is intact in first-degree relatives of patients with OHS argues against a genetic abnormality.[133] Alternatively, leptin, a protein produced by adipose tissue that acts in the hypothalamus to decrease appetite and increase metabolic rate, has recently emerged as a possible mediator of the ventilatory response. Serum leptin levels are generally increased in obesity, more so in OHS than in SO,[134] suggesting a central resistance to leptin. Although the precise role of leptin in the pathogenesis of OHS is still evolving, it is believed that development of leptin resistance or relative leptin deficiency may contribute to diminished ventilatory responsiveness and hypercapnia in OHS.[135]

Respiratory Muscle Function and Dyspnea

Obesity may be associated with normal or weakened respiratory muscles. Chronically elevated elastic and resistive loads imposed on the respiratory muscles may help maintain strength in SO,[136,137] whereas deconditioning or other factors related to chronic disease may reduce inspiratory muscle endurance and weaken the inspiratory muscles in OHS.[109,138] In severely obese subjects, especially those with dyspnea or OHS, reductions of diaphragmatic function are often found, especially in the supine position.[137,139] Impaired diaphragmatic function may also be a result of increased intra-abdominal pressure and cephalad displacement of the diaphragm.[140]

Dyspnea, especially with exertion, is a very frequent and disabling symptom in obese individuals. Dyspnea is associated with a greater BMI, airways disease,[136–138] and, in SO, increased ventilatory drive.[129,141] However, other causes such as disordered respiratory mechanics (decreased C_{RS}, increased airway resistance, expiratory flow limitation) or an enhanced perception of dyspnea should be considered.[142,143] Finally, dyspnea may be due to cardiac disease, a frequent comorbid condition.

Exercise Capacity

Individuals with SO generally have near-normal exercise capacity.[126,144,145] Symptom-limited peak oxygen consumption ($\dot{V}_{O_2}$) and ventilatory rate are similar in absolute terms to those of lean individuals.[126] When normalized to fat-free mass, however, the peak $\dot{V}_{O_2}$ is lower in obese than in nonobese individuals.[126,144] For a given rate of external work, obese individuals require a greater $\dot{V}_{O_2}$ and ventilatory rate.[126,145] Likewise, dyspnea ratings at any submaximal work rate appear to be higher in obese individuals, reflecting the relatively higher ventilation and metabolic cost.[126] However, dyspnea scores at any given ventilatory rate or $\dot{V}_{O_2}$ are not higher in obesity, suggesting that respiratory mechanical factors do not significantly contribute to respiratory discomfort.[126] Indeed, during exercise, obese individuals rectify respiratory mechanics with an increase in end-expiratory volume, which serves to optimize operating lung volumes and attenuate expiratory flow limitation.[126]

Treatment

A detailed summary of treatment of obesity is beyond the scope of this chapter. However, to summarize briefly, weight loss is the optimal therapy but is not always attainable, and long-term weight loss maintenance is even more difficult.[146] Guidelines for weight loss treatment emphasize diet, enhanced physical activity, and behavioral therapy as initial treatments in all obese individuals regardless of the severity of obesity. Pharmacotherapy or bariatric surgery should be considered in obese individuals who do not achieve weight control with conventional therapy.[146] Weight loss in obese individuals is associated with improved ERV and FRC; however, there is no strict correlation between the magnitude of weight loss and the degree of improvement of lung volumes. Weight loss also may improve respiratory muscle performance,[147] resting gas exchange,[148] diffusion capacity,[124] dyspnea scores,[129,149,150] sleep apnea,[149] 6-minute walk test,[150] and respiratory drive.[129] Overall, weight reduction appears to be the most effective solution to OHS, with bariatric surgery providing the best option for the various comorbid conditions related to extreme obesity, such as hypertension, hyperlipidemia, and type 2 diabetes.[151,152]

KEY POINTS

Pathophysiology

- Diseases that affect the chest wall, including obesity, primarily affect the respiratory system by reducing chest wall compliance. The degree to which the chest wall stiffens varies with the disease process. Kyphoscoliosis (and individuals with OHS) have the greatest degree of chest wall stiffness, whereas individuals with pectus excavatum or ankylosing spondylitis may have normal chest wall compliance.
- The lung is usually an "innocent bystander" in the sense that it is usually not primarily affected by a pathologic process. As the lung cannot be fully inflated in restrictive chest wall disorders, microatelectesis ensues. Eventually this leads to a reduction in lung compliance and impaired gas exchange.
- Flail chest is the most likely to precipitate acute respiratory failure, whereas kyphoscoliosis and severe obesity are the diseases most likely to lead to chronic ventilatory failure, pulmonary hypertension, and cor pulmonale. Coincident inspiratory muscle weakness in any of these disorders will further worsen restrictive pathophysiology and predispose these individuals to respiratory failure.

Treatment

- Acute respiratory failure may complicate flail chest and can be treated with positive-pressure ventilation. In some patients with flail chest, surgical fixation of the flail segment may reduce the duration of mechanical ventilation.
- Chronic respiratory failure, which can be seen in kyphoscoliosis or with severe obesity, can be successfully managed with nocturnal positive-pressure ventilation. This latter intervention has markedly improved morbidity and mortality in this group of individuals.

INTRODUCTION

Mechanical ventilation is the process of using devices to support the total or partial transport of O_2 and CO_2 between the environment and the pulmonary capillary bed. The desired effect of mechanical ventilation is to maintain adequate levels of P_{O_2} and P_{CO_2} in arterial blood while also unloading the inspiratory muscles. Although negative-pressure chambers or wraps and extracorporeal circuits might fulfill this definition, this discussion focuses on the use of positive airway pressure for respiratory life support.

The use of positive-pressure mechanical ventilation is widespread. In the United States, estimates range from 1 to 3 million patients annually requiring mechanical ventilatory support outside the operating room.[1] Traditionally, this support has been provided in intensive care unit (ICU) settings, but there are clear trends toward expanding the venues to subacute facilities, long-term care facilities, and the home. As the aged population expands and as more aggressive surgical and immunosuppressive therapies are developed, the need for mechanical ventilation in all of these venues is likely to increase.[1] In addition, increasing concerns about widespread outbreaks of respiratory pandemics has led many government agencies to stockpile large numbers of mechanical ventilators that can be quickly mobilized.[1a]

POSITIVE-PRESSURE MECHANICAL VENTILATOR DESIGN FEAURES

Gas Delivery Systems

Positive-Pressure Breath Controller

Most modern ventilators utilize piston/bellows systems or controllers of high-pressure sources to drive gas flow.[2,3] Tidal breaths are generated by this gas flow and can either be controlled entirely by the ventilator or be

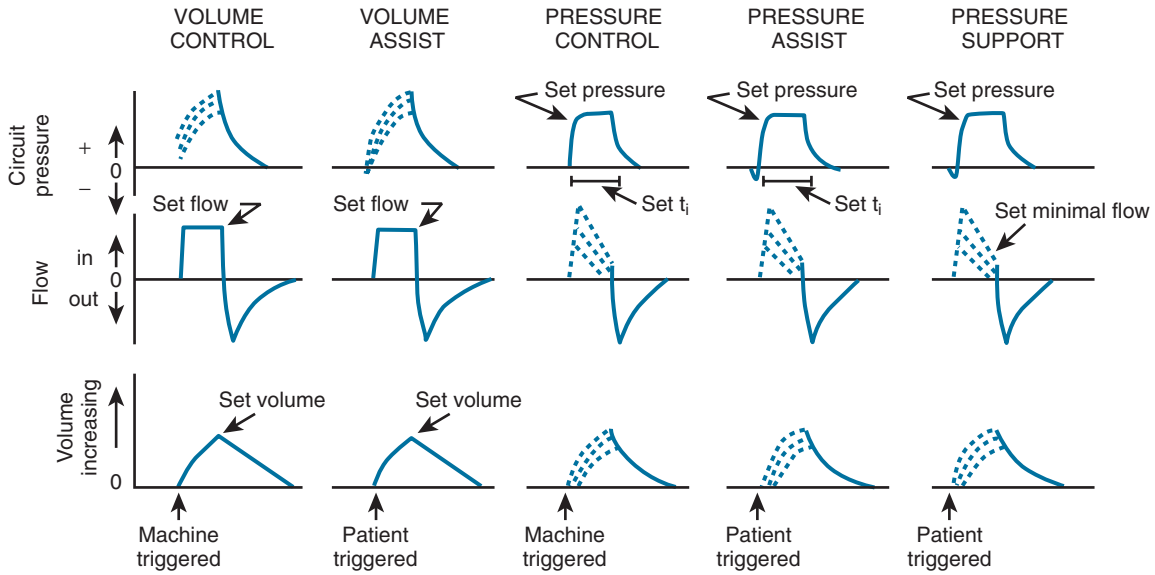

FIGURE 89-1 ■ Circuit pressure, flow, and volume tracings over time depicting the five basic breaths available on most modern mechanical ventilators. Breaths are classified by the variables that determine the trigger (machine time or patient effort), target/limit (set flow or set pressure), and cycle (set volume, set time, or set flow). The *solid lines* represent set or independent responses, and the *dashed lines* represent dependent responses. In all of these breaths, pressure is usually a "backup" cycle variable designed to terminate gas delivery if circuit pressure rises above an alarm limit.

interactive with patient efforts. Pneumatic, electronic, or microprocessor systems provide for various breath types. In general, these can be classified by what initiates the breath (trigger variable), what controls gas delivery during the breath (target or limit variable), and what terminates the breath (cycle variable).[4,5]

These three variables control the delivery of breaths to the patient. Breaths are initiated by a trigger variable, either a change in pressure or flow due to patient effort or a set time. During the breath, gas delivery is controlled to meet a target or limit variable, which is generally either a set flow or a set inspiratory pressure. The breath is then terminated by a cycle variable, which can either be a set volume, a set inspiratory time, or a set flow. A safety high-pressure cycle variable is usually also present as a backup. Figure 89-1 uses this classification scheme to describe the five most common breath types available on the current generation of mechanical ventilators: volume assist (VA), volume control (VC), pressure assist (PA), pressure control (PC), and pressure support (PS).

Mode Controller/Feedback Systems

The availability and delivery logic of different breath types define the "mode" of mechanical ventilatory support.[2,4,5] The mode controller is an electronic, pneumatic, or microprocessor-based system that is designed to provide the proper combination of breaths according to set algorithms and feedback data (conditional variables) (Table 89-1).

The simplest mode is assist-control ventilation (ACV), which can provide either flow-targeted volume-cycled breaths (volume assist-control ventilation [VACV]) or pressure-targeted time-cycled breaths (pressure assist-control ventilation [PACV]). A simple feedback system is employed with ACV that guarantees a set number of positive-pressure breaths. If the patient's underlying respiratory rate exceeds this guarantee, all breaths are patient-triggered breaths (VA or PA breaths). If the patient's respiratory rate is below this guarantee, the ventilator will "make up the difference" with mandatory breaths (VC or PC breaths).

Another relatively simple mode is synchronized intermittent mandatory ventilation (SIMV), which can provide either flow-targeted volume-cycled breaths (volume SIMV) or pressure-targeted time-cycled breaths (pressure SIMV). Like ACV, SIMV guarantees a set minimal number

TABLE 89-1. Breath Types Available on Common Modes of Mechanical Ventilation*

Mode	BREATH TYPES AVAILABLE†					
	VC	VA	PC	PA	PS	Sp
Volume assist-control	X	X				
Pressure assist-control			X	X		
Volume SIMV	X	X			X	X
Pressure SIMV			X	X	X	X
Pressure support					X	

*In addition to the five "basic" breaths depicted in Figure 89-1, this table also includes spontaneous unassisted/unsupported breaths.
†VC, volume control; VA, volume assist; PC, pressure control; PA, pressure assist; PS, pressure support; Sp, spontaneous unassisted.
SIMV, synchronized intermittent mandatory ventilation.

of positive-pressure breaths. Unlike ACV, however, if the patient's respiratory rate exceeds this guarantee, the ventilator will provide assisted breaths up to the set rate and then allow unassisted (SIMV alone) or flow-cycled pressure support breaths (SIMV + PS) thereafter. If the patient's respiratory rate is below the set guarantee, the ventilator will again "make up the difference" with mandatory (controlled) breaths. Note that, although PS breaths are often provided during SIMV, PS breaths can also be provided as a stand-alone mode without any guaranteed breaths (pressure support ventilation). Importantly, many modern systems also have so-called apnea ventilation, which is a backup algorithm (usually a simple volume control mode setting) for safety when modes with either low or no set guaranteed rates are provided and patient respiratory efforts are suddenly reduced or absent.

In recent years, more sophisticated feedback systems have been developed for these basic modes and are now available on many modern devices. These include pressure-regulated volume control (PRVC), volume support (VS), and adaptive support ventilation (ASV).

PRVC is an assist-control, pressure-targeted, time-cycled mode (PACV) that uses tidal volume as a feedback control for continuously adjusting the pressure target.[6] The clinician sets a tidal volume target and the ventilator then automatically sets the inspiratory pressure within a clinician-set range to achieve this goal. VS is a similar feedback design using patient-triggered, pressure-targeted, flow-cycled (PS) breaths. As a patient's respiratory drive exceeds the clinician-set guaranteed rate, some PRVC systems will provide additional patient-triggered time-cycled PRVC breaths while others will provide patient-triggered flow-cycled VS breaths. It is important to note that, with both PRVC and VS breaths, an improvement in respiratory mechanics will result in a lower applied inspiratory pressure while a worsening in respiratory mechanics will result in a higher applied inspiratory pressure. Similarly, increasing respiratory effort by the patient will result in a lower applied inspiratory pressure while decreasing respiratory effort by the patient will result in a higher applied inspiratory pressure.

ASV is also an assist-control, pressure-targeted, time-cycled mode of ventilation (PACV) that utilizes respiratory system mechanics to set the tidal volume-frequency pattern.[7] Using controlled breaths, ASV initially calculates resistance and compliance as well as the expiratory time constant (resistance × compliance). The clinician sets only a desired minute ventilation and a patient weight (for estimating anatomic dead space). ASV then partitions the frequency–tidal volume pattern in such a way as to minimize ventilator work (pressure × volume) and thus conceptually minimizes applied forces to the lung. As respiratory mechanics change, the frequency–tidal volume pattern is automatically adjusted to maintain this "optimal" pattern. ASV behavior when a patient's respiratory drive increases beyond the minute ventilation set by the clinician is complex and involves continually attempting to minimize ventilator work for the higher minute ventilation (see "Patient-Ventilator Interactions" section later).

Subsystems of Mechanical Ventilators

Effort (Demand) Sensors

Current ventilators allow for a number of patient-ventilator interactions.[8,9] Examples include patient-triggered breaths in which the ventilator initiates flow in response to patient demand and pressure-targeted/limited breaths in which the ventilator adjusts flow in response to patient demand (see "Patient-Ventilator Interactions" section later). Patient effort sensors are needed to allow the ventilator to deliver these interactive breaths properly. These sensors are usually either pressure or flow transducers in the ventilatory circuitry and are characterized by their sensitivity (the circuit pressure or flow change necessary to initiate a ventilator response) and their responsiveness (the delay in providing this response).[10]

Gas Blenders

Blenders mix air and O_2 to produce a delivered fractional concentration of O_2 in inspired gas (F_{IO_2}) ranging from 0.21 to 1.0. On newer systems, blenders are also available for other gases such as heliox, nitric oxide (NO), and anesthetic agents.

Humidifiers

With the upper airway bypassed by tracheal intubation, sufficient heat and moisture must be added to the inspired gas mixtures to avert mucosal desiccation. "Active" humidifiers utilize external water sources and electrical power to adjust blended gas mixtures to near body conditions (tracheal temperature of > 35° C, water content of > 40 mg/L).[11] Heated wire circuits help facilitate this by preventing condensation and "rainout" in ventilator tubing. "Passive" humidifiers use simple heat/moisture exchange devices in the ventilator circuit that reutilize heat and moisture trapped from expired gas. These disposable units can usually supply adequate heat and moisture (i.e., greater than 30° to 33° C and greater than 28 to 32 mg/L H_2O) for many patients, particularly those receiving mechanical ventilation for only short periods of time.[11]

Expiratory Pressure Generator

Positive airway pressure can be sustained throughout expiration (positive end-expiratory pressure [PEEP]) to help maintain alveolar patency and improve ventilation-perfusion ($\dot{V}/\dot{Q}$) matching (see "Physiologic Effects of Positive-Pressure Mechanical Ventilation" section later). PEEP is usually applied by regulating pressure in the expiratory valve of the ventilator system but can also be applied by providing a continuous flow of source gas during the expiratory phase. Note that some expiratory valves, even when fully open, have measurable resistance, which may result in inadvertent PEEP.[12] As discussed in more detail below, PEEP can also be generated in alveoli if the expiratory time is inadequate for the lung

to return to its "rest volume" or if significant flow limitation exists. Such inadvertent PEEP is referred to as intrinsic PEEP, or as "auto-PEEP," "occult PEEP," or "air trapping."[13]

Gas Delivery Circuit

The circuit usually consists of flexible tubing that often contains pressure or flow sensors and an exhalation valve. It is important to remember that, because this tubing has measurable compliance (2 to 4 mL/cm H_2O are representative values), high circuit pressures may induce significant amounts of delivered gas to distend the circuitry rather than to enter the patient's lungs.

The Patient–Ventilator Circuit Interface

Positive-pressure ventilation is generally supplied through a tube inserted into the patient's airway (oro- or nasotracheal tube or tracheostomy). These tubes generally have air-filled balloons to provide a proper seal in the airway. An alternative to the tracheal tube is a mask system. Both full-face and nasal masks have been utilized with a variety of ventilatory support systems and modes.[14] Leak around masks, however, can be significant and thus ventilatory support modes using masks must be able to provide adequate volumes and proper inspiratory timing. To this end, special mask ventilators with pressure-targeted and either time-cycled or leak-compensated, flow-cycled capabilities have been developed.[14]

Aerosol Generators

Therapeutic aerosols (e.g., bronchodilators, steroids, vasodilators, antibiotics) can be delivered through the ventilator circuitry.[15] This can be accomplished either by in-line nebulizers or by special adapters designed for metered-dose inhalers. Lung deposition is generally less in an intubated than in a nonintubated patient because the endotracheal tube serves as a significant barrier to aerosol delivery. Higher dosing is thus advisable.

The location of the aerosol generator in the ventilator circuit can affect deposition. The optimal site appears to be in the inspiratory limb several centimeters proximal to the patient "wye" connector.[15] This location allows either nebulized medications or a metered-dose actuation to "charge" the inspiratory limb of the circuit during exhalation. Aerosol particle velocity is slowed and becomes the leading portion of the next inspiration.

Monitors and Graphic Displays

Although electronic and microprocessor-based systems have considerable internal monitoring of electronic and pneumatic function, the three variables generally displayed for clinical use are circuit pressures, flows, and volumes.[16] Alarms can be utilized on all of these monitors.[5,17] Importantly, trending capabilities for up to 72 hours or more are now available on many modern systems. Most modern positive-pressure ventilators also have oxygen sensors in the circuitry to assure that the desired F_{IO_2} is being delivered. In addition, some ventilators may also have analyzers for exhaled CO_2 and inhaled therapeutic gases such as NO or heliox.

PHYSIOLOGIC EFFECTS OF POSITIVE-PRESSURE MECHANICAL VENTILATION

Ventilation and Respiratory System Mechanics

Equation of Motion

The lungs are inflated by mechanical ventilation when pressure and flow are applied at the airway opening. These applied forces interact with respiratory system compliance (both lung and chest wall components), airway resistance, and, to a lesser extent, respiratory system inertance and lung tissue resistance to effect gas flow.[18,19] For simplicity, since inertance and tissue resistance are relatively small, they can be ignored so that the interactions of pressure, flow, and volume with respiratory system mechanics can be expressed by the simplified equation of motion:

$$\text{Driving pressure} = (\text{flow} \times \text{resistance}) + (\text{volume}/\text{system compliance})$$

In the mechanically ventilated patient, this relationship is expressed as:

$$\Delta Pcir = (\dot{V} \times R) + (V_T/C_{RS})$$

where $\Delta Pcir$ is the change in ventilator circuit pressure above baseline (peak pressure minus end-expiratory pressure: Ppeak − PEEP), $\dot{V}$ is the flow into the patient's lungs, R is the resistance of the circuit, artificial airway, and natural airways combined, V_T is the tidal volume, and C_{RS} is the respiratory system compliance.

During an inspiratory hold at end-inspiration (i.e., no-flow conditions: $\dot{V} = 0$), the ventilator circuit pressure "plateaus" at a pressure commonly referred to as the plateau pressure (Pplat). By use of this inspiratory hold, the components of Pcir required for flow and for respiratory system distention can be separated. Specifically, the difference in Pcir during flow and during no-flow (the "peak to plateau difference") allows for a calculation of total inspiratory resistance:

$$R = (Ppeak - Pplat)/\dot{V}$$

Also, when $\dot{V} = 0$ at end-inspiration, Pplat − PEEP allows calculation of the static respiratory system compliance:

$$C_{RS} = V_T/(Pplat - PEEP)$$

Separating chest wall and lung compliance (C_{CW} and C_L, respectively) during a machine-controlled positive-pressure breath requires a measurement of esophageal pressure (Pes) to estimate pleural pressure. With this

measurement, the inspiratory change in Pes (ΔPes) can be used in the following calculations:

$$C_{CW} = V_T/\Delta Pes$$
$$C_L = V_T/(Pplat - PEEP - \Delta Pes)$$

In clinical practice, because C_{CW} is usually quite high and ΔPes is thus quite low, Pplat − PEEP alone is often taken as an approximation of lung-distending pressure. However, in situations in which C_{CW} is reduced (e.g., obesity, anasarca, ascites, or surgical dressings), the stiff chest wall can have significant effect on Pplat and must therefore be considered when using these measurements to assess lung stretch.[20,21]

Flow-Targeted vs Pressure-Targeted Breaths

In considering Figure 89-1, it can be seen that there are two basic approaches to delivering positive-pressure breaths: flow targeting and pressure targeting.[2,4] With flow targeting (breaths 1 and 2 in Fig. 89-1), the clinician sets an inspiratory flow so that circuit pressure is the dependent variable. With pressure targeting (breaths 3 through 5 in Fig. 89-1), the clinician sets an inspiratory pressure target (with either time or flow as the cycling criterion) so that flow and volume are dependent variables (i.e., varying with the lung mechanics and patient effort). With a flow-targeted breath, changes in compliance, resistance, or patient effort will change Pcir (but not flow); in contrast, with a pressure-targeted breath, similar changes in compliance, resistance, or effort will cause a change of tidal volume (but not Pcir) (see dashed lines in Fig. 89-1).

Each strategy has advantages. For flow-targeted breaths, a minimal tidal volume is guaranteed. For pressure-targeted breaths, the rapid initial flow and subsequent adjustable flow of pressure targeting may enhance gas mixing and patient synchrony (see discussions in later "Distribution of Ventilation" and "Patient-Ventilator Interactions" sections).

Pressure-targeted breaths can also be modified with a volume feedback feature described earlier for PRVC and VS breaths to combine the enhanced gas mixing and patient-ventilator synchrony effects of a pressure-targeted breath with a certain volume guarantee. However, it is important to realize that providing a volume guarantee negates the absolute pressure-limiting feature of a clinician-set pressure control level because, with PRVC/VS, worsening respiratory system mechanics will drive applied pressures up. Alternatively, another potential problem with PRVC/VS is that an increase in the patient's demand and tidal volume will drive the pressure level down, a change that may not be appropriate for a patient in respiratory failure.[22]

Intrinsic PEEP and the Ventilatory Pattern

Intrinsic PEEP is the positive end-expiratory pressure that develops within alveoli because of inadequate expiration, either because of inadequate time for expiration or increased airway resistance during expiration (or both). Intrinsic PEEP depends upon three factors: minute ventilation, the expiratory time fraction, and the respiratory system's expiratory time constant (the product of resistance and compliance).[23] With increases in minute ventilation, decreases in the expiratory time fraction, or increases in the expiratory time constant (i.e., with higher R or C_{RS} values), the potential for developing intrinsic PEEP increases.[23]

The development of intrinsic PEEP will have different effects on pressure-targeted compared to flow-targeted ventilation. In flow-targeted ventilation, the constant delivered flow and volume (and thus ΔPcir) in the setting of a rising intrinsic PEEP will increase both the Ppeak and the Pplat. In contrast, in pressure-targeted ventilation, the set Pcir limit coupled with a rising intrinsic PEEP level will decrease ΔPcir and thus the delivered tidal volume (and minute ventilation). Importantly, this may help limit the build-up of intrinsic PEEP.

In the patient without respiratory effort, intrinsic PEEP can be recognized in two ways. First, when an inadequate expiratory time produces intrinsic PEEP, analysis of the flow graphic will show that expiratory flow has not returned to zero before the next breath is given. Second, intrinsic PEEP in alveoli with patent airways can be quantified during an expiratory hold maneuver that permits equilibration of the intrinsic PEEP with Pcir.[11]

In the patient with active respiratory effort, intrinsic PEEP can be assumed to be present if the expiratory flow has not reached zero before the next breath begins. However, the expiratory hold maneuver is impossible to do in an actively breathing patient. As noted in more detail later, in an actively breathing patient, intrinsic PEEP can function as an inspiratory threshold load. This is best quantified by using an esophageal balloon to estimate pleural pressures. With this technique, the change in Pes before a change in Pcir is a reflection of the threshold load imposed by intrinsic PEEP (see "Patient-Ventilator Interactions" section later).

Distribution of Ventilation

A positive-pressure tidal breath must be distributed among the millions of alveolar units in the lung.[24,25] Factors affecting this distribution include regional resistances, compliances, functional residual capacities, and the delivered flow pattern (including inspiratory pause). In general, positive-pressure breaths will tend to distribute more to units with high compliance and low resistance and away from obstructed or stiff units (Fig. 89-2). This creates the potential for regional overdistention of healthier lung units, even in the face of "normal"-sized tidal volumes (see "Ventilator-Induced Lung Injury" below).

The flow pattern may also affect ventilation distribution. For example, when there are obstructive inhomogeneities, slow and constant flows will tend to distribute gas more evenly (although consequent shorter expiratory times may worsen air trapping).[24] In addition, inspiratory pauses can also allow *pendelluft* action to fill slowly filling alveoli (see Fig. 89-2B, High Regional R_{AW}). In contrast, when there is parenchymal lung injury

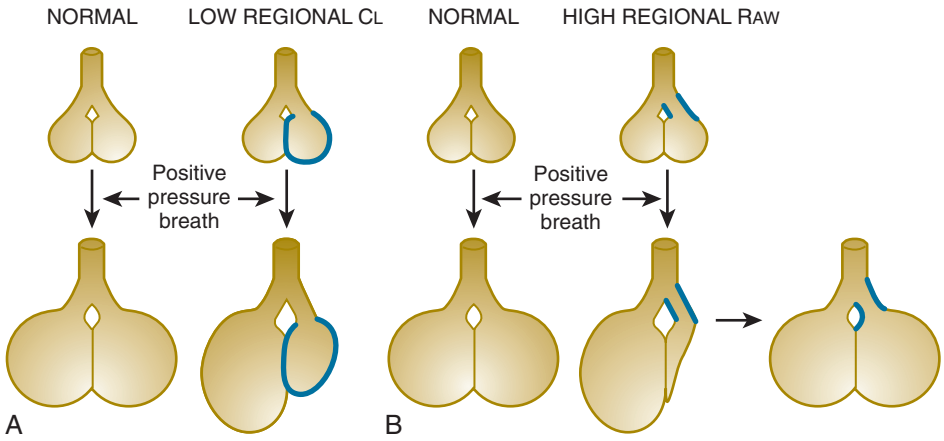

FIGURE 89-2 ■ The distribution of ventilation in lung models with heterogeneous mechanical properties. Models of the lung are shown as two units with homogeneous mechanical properties (normal): (**A**) with abnormal compliance distribution (low regional lung compliance [CL]), and (**B**) abnormal resistance distribution (high regional airway resistance [RAW]). Note that in situations with heterogeneous lung mechanics, positive-pressure breaths are preferentially distributed to "healthier" regions of the lung and can produce regional overdistention—even when a normal-sized tidal volume is delivered. Note that in the obstructed example (high regional RAW), the overdistention may be transitory as gas moves from the low-resistance to the high-resistance unit over time (*pendelluft*). (Redrawn from MacIntyre NR: Mechanical ventilatory support. *In* Dantzker D, MacIntyre NR, Bakow E [eds]: Comprehensive Respiratory Care. Philadelphia: WB Saunders, 1995, p 453.)

without obstructive airway inhomogeneity, initially rapid flows with subsequent deceleration (typically seen in pressure-targeted breaths) may distribute gas more evenly and will pressurize lung units rapidly, producing a higher mean inspiratory alveolar pressure for a given breath volume.[26]

It should be noted that more uniform ventilation distribution does not necessarily mean better $\dot{V}/\dot{Q}$ matching (i.e., more homogeneous ventilation distribution may actually worsen $\dot{V}/\dot{Q}$ matching in a lung with inhomogeneous perfusion). Because of all these considerations, predicting which flow pattern will optimize ventilation-perfusion matching is difficult and often an exercise of empirical trial and error.

Alveolar Recruitment and Gas Exchange

Because of alveolar flooding and collapse, parenchymal lung injury leads to $\dot{V}/\dot{Q}$ mismatching and shunts.[27] In many (but not all) of these disease processes, substantial numbers of collapsed alveoli can be recruited during a positive-pressure ventilatory cycle.[28-31] Additional recruitment can sometimes be provided with the use of formal recruitment maneuvers or prolongation of inspiratory time.[32,33] The application of PEEP is designed to prevent derecruitment during exhalation.

Recruitment Maneuvers

Recruitment maneuvers (RMs) are performed using sustained inflations (e.g., 30 to 40 cm H_2O) for up to 2 minutes.[32] Alternative approaches use transient elevations of the PEEP–tidal volume setting, and single or multiple "sigh breaths" that take the lung briefly to near total lung capacity.[32] Importantly, these transient pressure elevations can sometimes have adverse hemodynamic consequences and, to avoid patient inspiratory or expiratory efforts, the patient may require additional sedation (or even neuromuscular blockade). It also must be pointed out that RMs provide initial alveolar recruitment only—the duration of recruitment depends on an appropriate setting of PEEP to prevent subsequent derecruitment.[32]

Inspiratory Time Prolongations

A positive-pressure breath produces a flow magnitude and a flow profile that, as noted previously, can affect ventilation distribution (and thus $\dot{V}/\dot{Q}$). Prolonging inspiratory time, generally by adding a pause often in conjunction with a rapid decelerating flow (i.e., pressure-targeted breath), has several physiologic effects. First, the longer inflation period may recruit more alveoli.[34,35] Second, increased gas mixing time may improve $\dot{V}/\dot{Q}$ matching in parenchymal lung injury (*pendelufft*).[34,35] Third, the development of intrinsic PEEP from consequently shorter expiratory times can have effects similar to those of applied PEEP (see earlier).[35] It should be noted, however, that the distribution of intrinsic PEEP (most pronounced in lung units with long time constants) may be different from that of applied PEEP and thus, the effects on $\dot{V}/\dot{Q}$ may also be different. Fourth, since these long inspiratory times significantly increase total intrathoracic pressures, cardiac output may be reduced (see "Positive-Pressure Ventilation and Cardiac Function" section later). And finally, inspiratory-to-expiratory ratios that exceed 1:1 (so called inverse-ratio ventilation) are uncomfortable, and patient sedation/paralysis is often required unless a relief mechanism allows spontaneous breathing during the inflation period (see "Airway Pressure Release Ventilation" section later).

Positive End-Expiratory Pressure

PEEP is defined as an elevated transpulmonary pressure at the end of expiration.[28] As noted earlier, PEEP can be produced either by expiratory circuit valves (applied PEEP) or by inadequate expiratory times in lung units with long expiratory time constants (intrinsic PEEP).[18,19,34] Note that expiratory muscle contraction can also raise intrathoracic pressures at end-expiration, but this should not be considered PEEP since it is not a transpulmonary pressure (i.e., alveolar-pleural pressure).

Alveoli prevented from collapsing or "derecruiting" by PEEP provide several potential benefits. First, recruited alveoli improve $\dot{V}/\dot{Q}$ matching and gas exchange throughout the ventilatory cycle.[28] Second, as discussed in more detail later, patent alveoli throughout the ventilatory cycle are not exposed to the risk of injury from the shear stress of repeated opening and closing.[36,37] Third, open alveoli with intact surfactant monolayers improve lung compliance.[38] This is the rationale behind applying PEEP after an RM: recruited alveoli are on the deflation limb of the pressure-volume relationship and thus the pressure required to maintain recruitment is lower than that required for initial recruitment.

PEEP, however, can also be detrimental. Because the tidal breath is delivered on top of the baseline PEEP, end-inspiratory pressures are usually raised by the application of PEEP (although this increase may be less than the actual added PEEP because of improved compliance). This increase must be considered if the lung is at risk for regional overdistention (see "Ventilator-Induced Lung Injury" section later). Moreover, since parenchymal lung injury is often quite heterogeneous, appropriate PEEP in one region may be suboptimal in another and excessive in yet another.[31,39,40] Optimizing PEEP is thus a balance between recruiting the recruitable alveoli in diseased regions without overdistending already recruited alveoli in healthier regions. Another potential detrimental effect of PEEP is that it raises mean intrathoracic pressure, thereby compromising cardiac filling in susceptible patients (see "Positive-Pressure Ventilation and Cardiac Function" section later).

Mechanical Loads

Mechanical loads describe the physical requirements of ventilation with a single value, either the pressure-time product (PTP) or work (W).[18,19] Because mechanical loads correlate with inspiratory muscle oxygen demands,[41–43] the concept of load is useful in considering inspiratory muscle energy requirements during spontaneous or interactive partial ventilatory support (see "Patient-Ventilator Interactions" section later). Moreover, as described in more detail later, load referenced to muscle strength and/or endurance properties (e.g., PTP or W divided by muscle pressure-generating capability) can be used to set levels of partial ventilatory support or predict spontaneous breathing capabilities.[43]

The PTP expresses load as the integral of pressure over time ($PTP = \int P dt$). Work expresses load as the integral of pressure over volume ($W = \int P dV$). Compliance, resistance, and the flow and volume all contribute to the magnitude of the load per breath. During spontaneous breaths, Pcir is zero and integrating Pes over time or volume (referenced to the passive inflation pressure) describes the load borne by the inspiratory muscles to inflate the lungs. During a controlled breath, integrating Pcir over time or volume describes the load borne by the ventilator to inflate the entire respiratory system (lungs and chest wall), whereas integrating Pes over time or volume describes the loads imposed by the chest wall only. During partially supported breaths in which the load is shared between patient and ventilator, the sum of the contributions of patient and ventilator PTP or work should be the same as during a controlled or spontaneous breath of the same volume and flow profile.[44]

Under heavy loading conditions (e.g., the patient with abnormal respiratory system mechanics and thus high pressure requirements), the duration of pressure (i.e., the PTP) correlates better with muscle energetics and fatigue potential than does the volume moved with pressure (i.e., work).[41,42] Indeed, during ventilation requiring high pressures, multiplying PTP by the inspiratory time fraction and referencing this to the maximal pressure that the inspiratory muscles can generate results in the pressure-time index (PTI). Muscle fatigue can be expected if the PTI value exceeds 0.15.[44,45] The concern with high pressure loads in patients receiving partial ventilatory support is one of the rationales for providing ventilator pressure assistance with every spontaneous effort (i.e., pressure-assisted or supported breaths), as opposed to supporting breaths intermittently as in intermittent mandatory ventilation without pressure support (see "Patient-Ventilator Interactions" section later).[46]

Inspiratory muscle overload is one of the major determinants of continuing ventilator dependency and can result either from excessive mechanical loads or from inspiratory muscle dysfunction. Loads can be increased either by disease or by inappropriate ventilatory assistance (see "Patient-Ventilator Interactions" section later). Inspiratory muscle dysfunction can be a result of the systemic inflammatory response syndrome, metabolic disturbances, drugs (e.g., steroids, previous use of neuromuscular blockers), malnutrition, or malpositioning (i.e., diaphragm flattening from lung overinflation).[47] Clinically, inspiratory muscle overload is manifested by rapid, shallow breathing patterns and patient distress. Overt inspiratory muscle fatigue is probably a rare occurrence because clinicians usually intervene under these circumstances to provide ventilatory assistance.

Finally, insufficient loading may also affect inspiratory muscles. Specifically, controlled mechanical ventilation without any patient effort, perhaps for as little as 24 hours, may produce muscle changes similar to disuse atrophy—a condition described as "ventilator-induced diaphragmatic dysfunction" (VIDD).[48–50]

Patient-Ventilator Interactions

Mechanical ventilation modes that permit spontaneous ventilatory activity are termed "interactive" modes

because patients can affect various aspects of the mechanical ventilator's functions. These interactions can range from simple triggering of mechanical breaths to more complex processes affecting delivered flow patterns and breath timing. Interactive modes allow for muscle "exercise," which, when performed at nonfatiguing or physiologic levels, may prevent VIDD and facilitate fatigue recovery.[48-50] In addition, permitting spontaneous patient ventilatory activity and using comfortable interactive modes may reduce the need for the sedation and/or neuromuscular blockers that may otherwise be required to prevent patients from "fighting" positive-pressure ventilation.[51]

Interactive modes can be either synchronous or dyssynchronous with patient efforts. Synchronous interactions mean that the ventilator is sensitive to the initiation, modulation, and termination of a patient's ventilatory effort.[8,9] In the following discussion, synchrony is considered during the three phases of interactive breath delivery: breath triggering, ventilator flow delivery, and breath cycling.

Ventilator Breath Triggering

Interactive mechanical ventilators must sense a spontaneous effort by either an airway pressure drop or airway flow change in order to trigger a mechanical response.[8,9,51a] Even with modern sensors, however, there is unavoidable dyssynchrony in the triggering process. First, a certain level of insensitivity must be incorporated in the sensor to avoid artifacts triggering the ventilator (i.e., "autocycling"). Second, even when the patient effort has been sensed, demand valve systems have a certain inherent delay (up to 100 msec or more) before they physically open and achieve target flow into the airway (system responsiveness). Both of these factors can result in significant "isometric-like" pressure loads on the inspiratory muscles during the triggering process. In addition, in the setting of air trapping and positive end-expiratory pressure (intrinsic PEEP), the elevated alveolar pressure at end-expiration can serve as a significant triggering threshold load on the inspiratory muscles. Under these conditions, judicious use of applied PEEP can equilibrate expiratory pressure throughout the lungs and ventilator circuit to reduce this triggering load.[52,53]

Ventilator-Delivered Flow Pattern

During an interactive breath, inspiratory muscles are contracting[54,55] and the ventilator flow delivery should be adequate to meet one of two goals: (1) reduce the load on the contracting inspiratory muscles to comfortable levels or (2) avoid increasing the loads on contracting inspiratory muscles. Synchronous flow interactions can be defined accordingly.

In general, flow synchrony is best assessed by clinical assessment and by analyzing the graphic representation of circuit pressure over time. Clinical signs of flow dyssynchrony are tachypnea and dyspnea. Synchronous circuit pressure graphic patterns depend upon the clinical goal. With assisted/supported breaths designed to reduce loads, the circuit pressure graph should maintain a convex upward shape indicating that flow is proportional to demand. In contrast, in the setting of providing CPAP only, the circuit pressure graph should be flat. Dyssynchrony (and imposed loading) is said to exist when the circuit pressure graph is literally "sucked downward" below these target patterns (Fig. 89-3).

Breath Cycling

Cycling dyssynchrony can occur in one of two ways. First, if the breath lasts beyond the duration of patient effort, an inadequate expiratory time may develop (along with air trapping) and/or patient expiratory efforts may be required to terminate the breath. This can be a particular concern when using PS breaths in obstructive airway disease—the relatively steady inspiratory flow coupled with the PS flow-cycling algorithm may significantly delay breath termination in patients with severe airway obstruction.[56] Second, if the breath terminates before the patient effort is finished, the patient may be left demanding additional flow without any being delivered. Significant imposed loading and/or double breath triggering may result.

Positive-Pressure Ventilation and Cardiac Function

In addition to affecting ventilation and ventilation distribution, intrathoracic pressure applications from positive-pressure ventilation can also affect cardiovascular function.[57-59] In general, as mean intrathoracic pressure increases, right ventricular filling decreases and cardiac output/pulmonary perfusion consequently decreases. This is the rationale for using volume repletion to maintain cardiac output in the setting of high intrathoracic pressure. Of note is that the effect of reduced cardiac filling on cardiac output may be partially counteracted by the improvement in left ventricular function due to elevated intrathoracic pressures functioning to reduce left ventricular afterload.[60] Importantly, in patients with left heart failure, the reduced cardiac filling and reduced left ventricular afterload effects of elevated intrathoracic pressure may actually improve cardiac function to the point that the removal of intrathoracic pressure may produce weaning failure.[61] An interesting corollary to these concepts is the notion of using high-frequency ventilation timed to ventricular systole to augment cardiac output in patients with severe heart failure.[62]

Intrathoracic pressures can also influence distribution of perfusion. The relationship of alveolar pressures to perfusion pressures in the West model of the three-zone lung helps explain this.[63] Specifically, the supine human lung is generally in a zone 3 (capillary distention) state. As intra-alveolar pressures rise, however, zone 2 and zone 1 (capillary collapse/dead space) regions can appear, creating high $\dot{V}/\dot{Q}$ units. Indeed, increases in dead space can be a consequence of ventilatory strate-

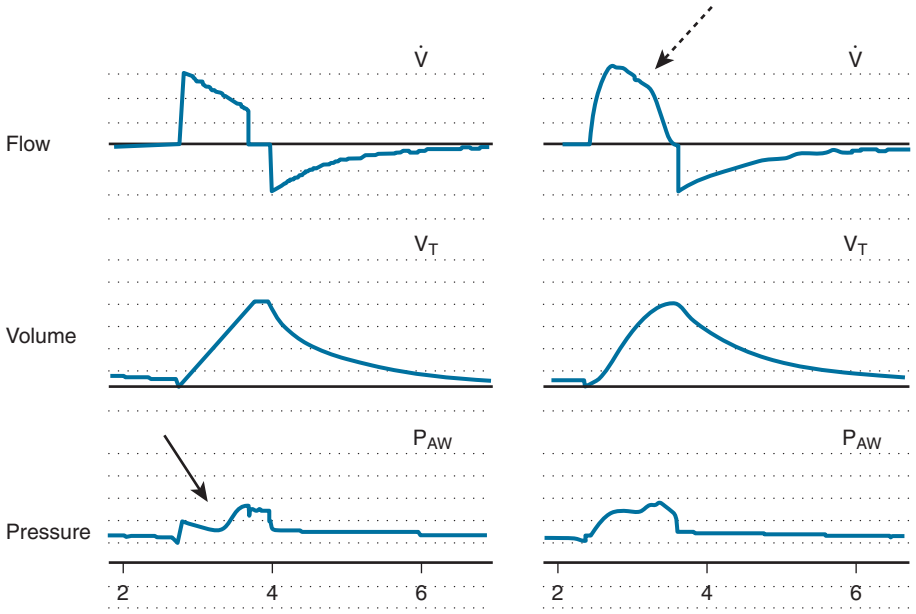

FIGURE 89-3 ■ Flow and pressure pattern differences during dyssynchronous and synchronous breaths in a patient with a vigorous inspiratory effort. Depicted are flow (*upper panel*), volume (*middle panel*), and pressure (*lower panel*) for a dyssynchronous flow-targeted breath (*left*) and a more synchronous pressure-targeted breath (*right*) with matched mean flow, inspiratory time, and tidal volume. Note that, during the flow-targeted breaths (*left*), the fixed flow does not respond to the vigorous inspiratory effort, resulting in the circuit pressure being "sucked" downward (*solid arrow*). In contrast, with the pressure-targeted breath, flow adjusts and increases to meet the inspiratory effort better (*dashed arrow*). (Redrawn from Yang LY, Huang YC, MacIntyre NR: Patient-ventilator synchrony during pressure-targeted versus flow-targeted small tidal volume assisted ventilation. J Crit Care 22:252–257, 2007.)

gies employing high ventilatory pressures as well as with those producing intrinsic PEEP.

Positive-pressure mechanical ventilation can affect other aspects of cardiovascular function. Specifically, dyspnea, anxiety, and discomfort from inadequate ventilatory support can lead to stress-related catechol release with subsequent increases in myocardial oxygen demands and risk of dysrhythmias.[61] In addition, coronary blood vessel oxygen delivery can be compromised by inadequate gas exchange from the lung injury coupled with low mixed venous P_{O_2} due to high oxygen consumption demands by the inspiratory muscles.

COMPLICATIONS OF POSITIVE-PRESSURE MECHANICAL VENTILATION

Ventilator-Induced Lung Injury

The lung can be injured when it is stretched excessively by positive-pressure ventilation. The most well-recognized injury is that of alveolar rupture presenting as extra-alveolar air in the mediastinum (pneumomediastinum), pericardium (pneumopericardium), subcutaneous tissue (subcutaneous emphysema), pleural space (pneumothorax), and vasculature (air emboli).[64] The risk for extra-alveolar air increases as a function of the magnitude and duration of alveolar overdistention. Thus, interactions of respiratory system mechanics and mechanical ventilation strategies (high regional V_T and PEEP—both applied and intrinsic) that produce regions of excessive alveolar stretch for prolonged periods create alveolar units at risk for rupture.

Even without producing extra-alveolar air and rupture, mechanical ventilation can induce a lung injury called ventilator-induced lung injury (VILI). In experimental animals, acute lung injury can be produced by mechanical ventilation strategies that stretch the lungs beyond the normal maximum (transpulmonary distending pressures of 30 to 35 cm H_2O).[65,66] A number of recent clinical trials clearly indicate that ventilator strategies exposing the injured human lung to transpulmonary pressures in excess of 30 to 35 cm H_2O are associated with lung injury.[67–70] Importantly, this injury may be more than simply a consequence of excessive end-inspiratory stretch. Even in the setting of transpulmonary pressures less than 30 cm H_2O, excessive tidal stretch from repetitive cycling of the lung with tidal volumes in excess of 9 mL/kg may contribute to VILI.[67,68] Other ventilatory pattern factors, such as the frequency of stretch[71] or the acceleration/velocity of stretch,[72] may also be involved in the development of VILI. VILI appears to be potentiated by a shear stress phenomenon that occurs when injured alveoli repetitively open and collapse during the ventilatory cycle (i.e., cyclical atelectasis).[36,73,74] Vascular pressure elevations may also contribute to VILI.[75]

VILI likely develops regionally when low-resistance/high-compliance units receive a disproportionately high

regional tidal volume in the setting of high alveolar distending pressures (see Fig. 89-2). This can be appreciated using computed tomography under circumstances when pressures required for recruitment of diseased atelectatic regions simultaneously produce overdistention in already open, less-diseased regions (Fig. 89-4). Regional protection of these healthier lung units is the rationale for using "lung-protective" ventilator strategies that accept less than normal values for pH and P_{O_2} in exchange for lower (and safer) distending pressures (see "Applying Mechanical Ventilatory Support" section later).

VILI is manifest pathologically as diffuse alveolar damage.[36,65,66,76] Moreover, VILI is associated with cytokine release[76,77] and bacterial translocation[78] that are implicated in the systemic inflammatory response with multiorgan dysfunction that results in VILI-associated mortality.

Oxygen Toxicity

Oxygen concentrations approaching 100% are known to cause oxidant injuries in airways and lung parenchyma.[79] Much of the data supporting this concept, however, has come from animals that often have quite different tolerances to oxygen than humans. It is thus not clear what the "safe" oxygen concentration or duration of exposure is in sick humans. Most consensus groups have argued that F_{IO_2} values less than 0.4 are safe for prolonged periods of time and that F_{IO_2} values of greater than 0.80 should be avoided if at all possible.

Patient-Ventilator Interface Complications

The patient-ventilator interface links the patient to the ventilator and includes the ventilator circuitry and the

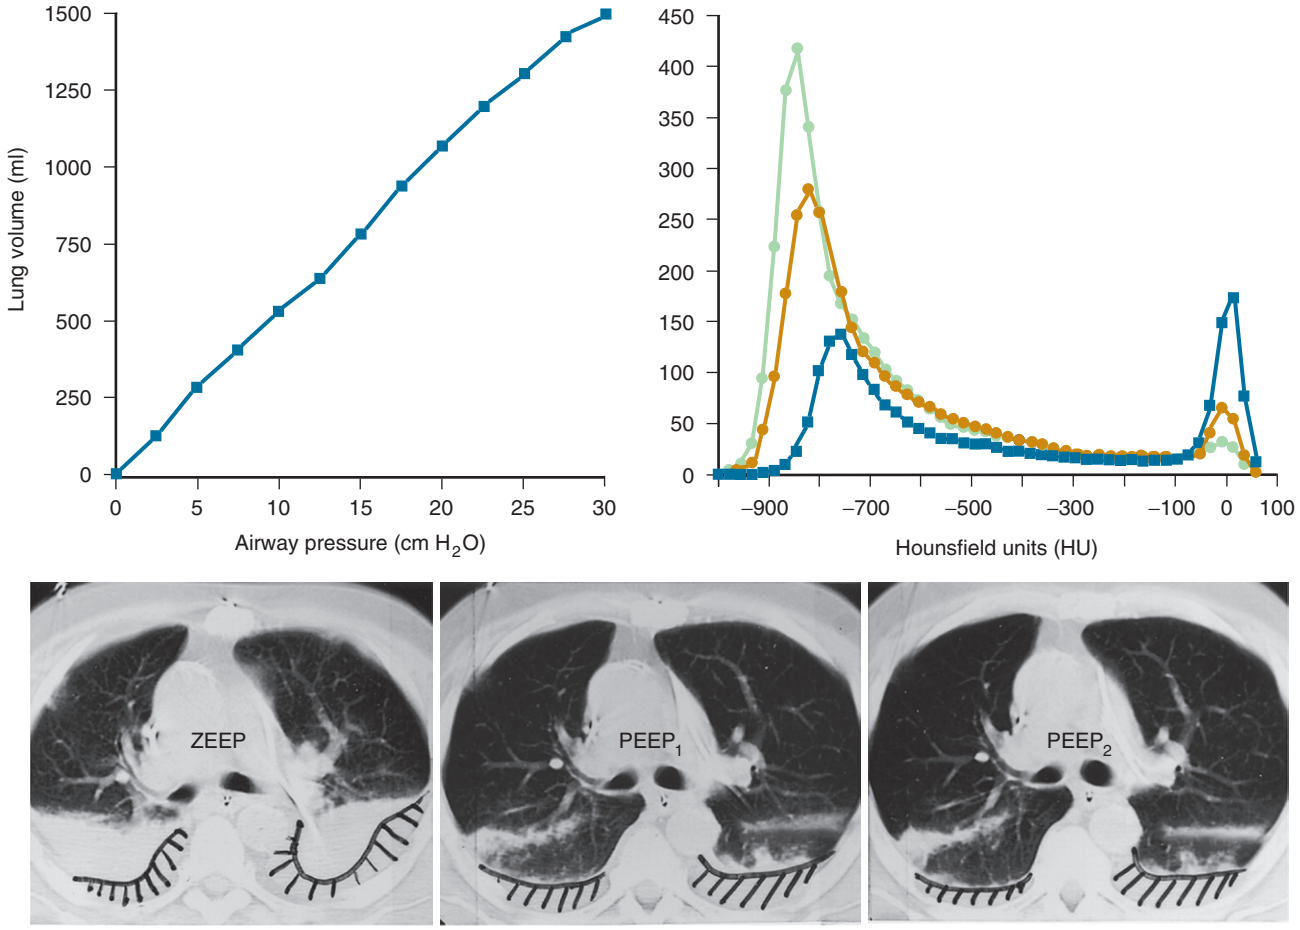

FIGURE 89-4 ■ Effects of positive airway pressure in a lung with heterogeneous injury. The *upper left panel* shows the almost linear pressure-volume relationships as positive airway pressure is applied to the lungs. At the bottom are three representative computed tomographic (CT) lung slices at low, midrange, and maximal airway pressure. In the lung at low airway pressure (ZEEP, *lower left*), note the substantial atelectasis in the dependent lung regions, which is progressively reduced as airway pressure is increased ($PEEP_1$ and $PEEP_2$, in the right two images). The *upper right panel* depicts the distribution of Hounsfield units (HU) in each of these three CT slices, at low pressure (*dark blue squares*), at midrange airway pressure (*brown circles*), and at the highest airway pressure (*light green circles*). Note that, although increasing pressure progressively reduces the number of atelectatic units (those with CT numbers near zero), these same pressures simultaneously increase the number of overdistended lung units elsewhere in the lungs (those with CT numbers less than –900 HU). (From Vieira SR, Puybasset L, Lu Q, et al: A scanographic assessment of pulmonary morphology in acute lung injury. Am J Resp Crit Care Med 159:1612–1623, 1999.)

artificial airway. The most important complications associated with this apparatus are ventilator disconnections (including artificial airway dislodgment). Disconnections have been reported in up to 8% to 13% of ventilated patients[80] and, if left uncorrected, can be fatal. Because circuit pressure and flow can be maintained despite the disconnection of the ventilator from the patient (e.g., if the airway is in the esophagus or if the disconnected circuit remains partially occluded), it is critical that carefully set, redundant (i.e., pressure *and* flow) alarms are present.[5] Other complications of the patient-ventilator interface include obstructions from secretions, circuit leaks, airway injury from inadequate heat/humidity, tracheal injury from the artificial airway, and loss of delivered tidal volume in a compliant circuit.

Pulmonary Infectious Complications

Mechanically ventilated patients are at risk for pulmonary infections for several reasons.[81] First, the natural glottic closure protective mechanism is compromised by an endotracheal tube. This permits continuous seepage of oropharyngeal material into the airways. Second, the endotracheal tube itself impairs the cough reflex and serves as an additional potential portal for pathogens to enter the lungs. This is particularly important if the circuit is contaminated. Third, airway and parenchymal injury from both the underlying disease and management complications make the lung prone to infections. Fourth, the ICU environment with its heavy antibiotic use and presence of very sick patients in close proximity is itself a risk for a variety of infections.

Preventing ventilator-associated pneumonias (VAP) is critical because the development of VAP heavily influences both length of stay and mortality.[81–83a] Handwashing, elevating the head of the bed, and carefully chosen antibiotic regimens for other infections can have important beneficial effects. Management strategies that avoid breaking the integrity of the circuit (i.e., changing the circuit only when visibly contaminated) also appear to be helpful.[82,83] Continuous drainage of subglottic secretions may be another simple way of reducing lung contamination by oropharyngeal material.[82,83] Another concept explored in small trials is the use of aerosolized antibiotics in patients with purulent secretions to reduce the progression of tracheobronchitis to ventilator-associated pneumonia.[84] Finally, it must always be remembered that prompt discontinuation of ventilatory support when clinically appropriate will help minimize the time patients are exposed to infection risks.

APPLYING MECHANICAL VENTILATORY SUPPORT

Mechanical Ventilatory Support Involves Tradeoffs

To provide adequate support while minimizing the risk of VILI, mechanical ventilation goals must involve tradeoffs. Specifically, the need for potentially injurious pressures, volumes, and supplemental O_2 must be weighed against the benefits of supporting gas exchange. To this end, a "re-thinking" of gas exchange goals has taken place over the last decade so that now, pH goals as low as 7.15 to 7.20 and P_{O_2} goals as low as 55 mm Hg are often considered acceptable in order to protect the lung from VILI.[85] Ventilator settings are thus selected to provide at least this level of gas-exchange support while meeting two mechanical goals: (1) provision of enough PEEP to recruit the "recruitable" alveoli and (2) avoidance of a PEEP–tidal volume combination that unnecessarily overdistends lung regions at end-inspiration. These goals embody the concept of a lung-protective mechanical ventilatory strategy. Currently, these principles guide recommendations for the specific management of parenchymal and obstructive lung disease.[86–89]

Considerations in Choosing Ventilator Settings for Different Forms of Respiratory Failure

Parenchymal Lung Injury

Parenchymal lung injury describes disease processes that involve the air spaces and the interstitium of the lung. In general, parenchymal injury stiffens lungs and decreases lung volumes. It is important to realize, however, that, in all but the most diffuse diseases (e.g., diffuse cardiogenic edema), there are often marked regional differences in the degree of inflammation present and thus the degree of mechanical abnormalities that exist. This heterogeneity can have significant impact on the effects of a particular mechanical ventilation strategy. This is because delivered gas will preferentially go to the more normal regions, those with higher compliance and lower resistance, rather than to sicker regions (see Fig. 89-2). A "normal-sized" tidal volume may thus be distributed preferentially to the healthier regions, resulting in a regional overdistention injury.

Parenchymal injury can also affect the airways, especially the bronchioles and alveolar ducts. These narrowed and collapsible small airways can also reduce regional ventilation to injured lung units, leading to regions of air trapping and possibly cyst formation during the healing phase.

Gas-exchange abnormalities in parenchymal lung injury are a consequence of alveolar consolidation, flooding, and/or collapse producing a maldistribution of ventilation and resulting in $\dot{V}/\dot{Q}$ mismatching and shunts. Because $\dot{V}/\dot{Q}$ mismatch and shunt are more of an issue than dead space ($\dot{V}/\dot{Q} = \infty$) in parenchymal lung disease, hypoxemia tends to be more of a clinical problem than CO_2 elevation.

Frequency–tidal volume settings for patients with parenchymal lung injury must focus on limiting end-inspiratory stretch. The benefit of reducing stretch in improving outcome has been suggested by several recent clinical trials[67–70,90] but has been most convincingly demonstrated by the National Institutes of Health (NIH)–sponsored ARDS Network Trial in which a ventilator

TABLE 89-2. The PEEP/F_{IO_2} Combinations Used during the NIH ARDS Network Study*

F_{IO_2}	.30	.40	.40	.50	.50	.60	.70	.70	.70	.80	.90	.90	.90	1.0	1.0	1.0	1.0

*The clinical target is an arterial P_{O_2} of 55 to 80 mm Hg or pulse oximeter oxygen saturation (S_{pO_2}) of 88% to 95%. If the patient is below these target values, move along the table to the right. If the patient is above these targets, move to the left.
Data from NIH ARDS Network: Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. N Engl J Med 342:1301–1308, 2000.

strategy using a VT of 6 mL/kg ideal body weight (IBW) as compared to 12 mL/kg led to a 10% absolute reduction in mortality.[70] Because of this, initial VT settings should start at 6 mL/kg IBW.[90a] Moreover, strong consideration should be given to reducing this setting further if end-inspiratory Pplat, adjusted for any effects of excessive chest wall stiffness, exceeds 30 cm H_2O.[67–70] Increases in VT settings might be considered if there is marked patient discomfort or suboptimal gas exchange *provided that* the subsequent Pplat values do not exceed 30 cm H_2O.[67–70] Respiratory rate settings are then adjusted to control pH. Unlike the case in obstructive diseases, the potential for air trapping in parenchymal lung injury is low if the breathing frequency is less than 35 breaths/min; air trapping may not develop even at frequencies exceeding 50 breaths/min.

The inspiratory time and the I:E ratio in parenchymal injury is set with consideration of several issues. The usual initial I:E ratio setting is 1:2 to 1:4, the normal and the most comfortable setting. The flow graphic should also be assessed to ensure that the expiratory time is adequate to avoid air trapping. An I:E ratio higher than the physiologic range of 1:1 is referred to as inverse-ratio ventilation (IRV). In severe respiratory failure, IRV can be employed as an alternative to increasing PEEP to improve $\dot{V}/\dot{Q}$ matching.[34,35] The beneficial mechanisms involved include longer mixing times, recruitment of slowly filling alveoli, and development of intrinsic PEEP. A variation on IRV is airway pressure release ventilation (APRV).[91–93] APRV incorporates the ability to breathe spontaneously during the long inflation period of a pressure-controlled breath—a feature that may enhance recruitment and gas mixing. APRV is discussed in more detail later.

The PEEP/F_{IO_2} settings are optimized using both mechanical and gas-exchange approaches. Conceptually, in setting the PEEP level in parenchymal lung injury, the mechanical goal is to provide ventilator settings between the upper and lower inflection points on the pressure-volume curve.[94] The most direct mechanical approaches use the static pressure-volume plot to set the PEEP and VT. This traditionally involves multiple VT/Pplat measurements and requires considerable clinician time along with patient sedation or even neuromuscular blockade. A simpler approach is to use a "slow-flow" maneuver, so called because only a single inspiration is required using very small inspiratory flows (e.g., <10 L/min) so that flow-related pressures are minimal. Under these conditions, the single dynamic loop approximates the true static pressure-volume relationship.[95] Another mechanical approach uses step changes in PEEP to determine the PEEP level that gives the best compliance.[96] A simpler mechanical approach analyzes the Pcir profile during a constant-flow breath (stress index) to detect overdistention (late rising profile) or collapse/reopening injury (early rising profile).[97] With all of these approaches, a recruitment maneuver is often used to recruit the maximal number of recruitable alveoli prior to setting the PEEP. F_{IO_2} adjustments are then set as low as clinically acceptable.

PEEP can also be guided by gas-exchange criteria usually involving algorithms designed to provide adequate values for arterial P_{O_2} (e.g., 55 to 80 mm Hg) while minimizing F_{IO_2}. An example would be the NIH ARDS Network PEEP/F_{IO_2} algorithm in Table 89-2.[70] Note that constructing a PEEP/F_{IO_2} algorithm is usually an empirical exercise in balancing pressure, arterial S_{O_2}, and F_{IO_2} and depends upon the clinician's perception of the relative "toxicities" of high thoracic pressures, high F_{IO_2}, and low arterial S_{O_2}. Several recent trials have compared a number of PEEP/F_{IO_2} algorithms in conjunction with low tidal volume/limited Pplat strategies. These studies find that PEEP settings, whether aggressive (i.e., average 13 to 15 cm H_2O) or conservative (i.e., average 7 to 9 cm H_2O), that target adequate, not maximal, arterial P_{O_2} targets have comparable outcomes (see Chapters 90 and 91).[98–100a]

Obstructive Airway Disease

Respiratory failure from airflow obstruction is a direct consequence of increases in airway resistance. This leads to two important pathophysiologic changes. First, the increased pressures required for airflow may overload inspiratory muscles, producing a "ventilatory pump failure" in which spontaneous minute ventilation becomes inadequate for gas exchange. Second, the narrowed airways create regions of lung that cannot properly empty and return to their normal "resting volume," thereby producing intrinsic PEEP. These regions of overinflation create dead space and put inspiratory muscles at a substantial mechanical disadvantage that further worsens muscle function. Overinflated regions may also compress more healthy regions of the lung, impairing $\dot{V}/\dot{Q}$ matching. Regions of air trapping and intrinsic PEEP also function to increase the threshold load the patient must overcome to trigger mechanical breaths, as noted earlier.

The gas-exchange abnormalities in the setting of worsening airflow obstruction are several. First, although

there may be a transient hyperventilation due to dyspnea in the asthmatic patient, the worsening respiratory failure in obstructive lung disease is generally characterized by a falling minute ventilation as inspiratory muscles fatigue in the face of airflow obstruction. The result is termed *hypercapnic respiratory failure.* Second, as noted earlier, regional lung compression and regional hypoventilation produces $\dot{V}/\dot{Q}$ mismatch that results in progressive hypoxemia. Alveolar inflammation and flooding, however, are not characteristic features of respiratory failure due to pure airflow obstruction, and thus shunts are less of an issue than in parenchymal lung injury. Third, overdistended regions of the lung coupled with underlying emphysematous changes in some patients result in capillary loss and increasing dead space. This wasted ventilation further compromises the ability of the inspiratory muscles to supply an adequate ventilation for alveolar gas exchange. These emphysematous regions also have low recoil properties, which can worsen air trapping. Fourth, hypoxemic pulmonary vasoconstriction coupled with chronic pulmonary vascular changes in some airway diseases overload the right ventricle, further decreasing blood flow to the lung and making the dead space worse.

Frequency–tidal volume settings in obstructive diseases are chosen based on many considerations similar to those in parenchymal lung injury. Specifically, tidal volumes should be sufficiently low (e.g, 6 mL/kg IBW) to assure that Pplat values are less than 30 cm H_2O.[67–70] In obstructive diseases, however, clinicians should also be aware that high *peak* airway pressures, even in the presence of acceptable values for Pplat, may transiently subject regions of the lung to periods of overdistention injury (see Fig. 89-2). As with parenchymal lung injury, VT reductions should be considered to meet Pplat goals. VT increases can be considered for comfort or gas exchange *provided that* Pplat values do not exceed 30 cm H_2O.[67–70] The ventilatory rate is used to control pH. Unlike parenchymal disease, however, the elevated airway resistance (and often the low recoil pressures of emphysema) greatly increase the potential for air trapping, a complication that limits the range of breath rates available. Hypoventilation and "permissive hypercapnia" may be an appropriate tradeoff to limit intrinsic PEEP development and overdistention.

The I:E ratio in obstructive lung disease is generally set as low as possible to minimize the development of air trapping. For the same reason, approaches using IRV strategies are almost always contraindicated.

The PEEP/FIO_2 settings assume a different role in obstructive lung disease than in parenchymal lung disease. Because alveolar recruitment is less of an issue and overdistention is more of an issue in obstructive lung injury than in parenchymal lung injury, the strategy in using the PEEP/FIO_2 steps in Table 89-2 should probably be shifted more toward the use of FIO_2 for oxygenation support instead of PEEP. A specific role for PEEP in the obstructed patient arises when intrinsic PEEP serves as an added inspiratory threshold load on the patient attempting to trigger a breath, as described earlier. Under these conditions, judicious application of circuit PEEP (at levels up to 75% to 85% of intrinsic PEEP) can "balance" intrinsic PEEP throughout the ventilator circuitry to reduce this triggering load and facilitate the triggering process.[52,53]

In severe airflow obstruction, the use of the low-density gas helium can help facilitate ventilator settings. Helium is available as 80:20, 70:30, or 60:40 helium : oxygen breathing gas mixtures (heliox) and can both reduce patient inspiratory work and facilitate lung emptying (recall that driving pressure decreases and/or flow increases as gas density decreases).[101] With a helium : oxygen gas mixture, it must be remembered that many flow sensors must be recalibrated to account for the change in gas density.

Finally, it is important to note that it is in the obstructed diseases that noninvasive ventilation has been demonstrated most convincingly to improve outcomes.[102] In setting up noninvasive ventilation, the same principles described previously for invasive mechanical ventilation also apply (see Chapter 92).

Neuromuscular Respiratory Failure

The risk of VILI is generally less in a patient with neuromuscular failure since lung mechanics are often near normal and regional overdistention less likely. More "generous" tidal volumes may thus be used to improve comfort, maintain recruitment, prevent atelectasis, and avoid hypercarbia that may adversely affect central nervous system function. At the same time, however, maximal distending pressures should be kept as low as possible while still being compatible with the other goals noted previously. Certainly Pplat should always be kept well below 30 cm H_2O.[67–70]

Mode selection in neuromuscular disease patients is often determined by patient comfort. As in other patients, the rapid initial flow and the subsequent variable flow provided by pressure-targeted modes is often more synchronous with patient efforts than those provided by volume-targeting modes. Comfort must be weighed against the "reliability" of the patient effort to maintain consistent minute ventilation in the setting of pressure-targeted breaths. Thus, in patients with fluctuating ventilatory drives who may be prone to periods of hypoventilation or atelectasis, volume-targeting offers an advantage. PEEP, even at low levels, is often beneficial at preventing derecruitment (atelectasis) in these patients who are often supine and unable to clear secretions or sigh. Noninvasive ventilation plays an increasingly important role in patients with neuromuscular disease (see Chapter 87).

Recovering Respiratory Failure—The "Weaning" and Discontinuation Process

As respiratory failure stabilizes and begins to reverse, clinical attention shifts to the process of ventilator withdrawal. Unfortunately, a number of large clinical trials have clearly demonstrated that current assessment/management strategies are not optimal, resulting in considerable delay in ventilator withdrawal.[103] Such delay leads to increased length of ICU stay, increased costs, prolonged exposure to circuit pressure, and increased risk

of infection. Attempts to increase withdrawal aggressiveness, however, must be balanced against the risk of premature withdrawal with consequent loss of airway patency, aspiration, and inspiratory muscle fatigue. An evidence-based task force[103] has recommended a two-step process:

1. Consider a patient a candidate for withdrawal *if* (a) the lung injury is stable/resolving, (b) the gas exchange is adequate with low PEEP/F_{IO_2} requirements, (c) hemodynamics are stable without pressors, and (d) the patient has the capability to initiate spontaneous breaths.
2. In these patients, perform a spontaneous breathing trial (using T-piece, CPAP, or pressure support at 5 cm H_2O) for 30 to 120 minutes. Assessments should include the ventilatory pattern, gas exchange, hemodynamics, and comfort. Patients "passing" this trial should be considered for ventilator withdrawal.

In patients passing the spontaneous breathing trial (SBT), separate assessments are required to determine if the artificial airway can be removed. These involve cough strength, suctioning frequency, and, to a certain extent, the ability to follow commands.[103] Cuff leak, however, does not appear to be an important predictor of success except perhaps in the setting of prior upper airway injury. Extubation failures can be expected in 10% to 20% of all extubations. Many of these involve airway protection issues and thus prompt reintubation is indicated. However, in some patients, especially those with chronic obstructive pulmonary disease, an extubation failure caused by increasing inspiratory muscle overload might be managed by noninvasive ventilation.[102]

In patients failing the SBT, a stable and comfortable level of support should be provided until the next SBT.[103] Frequent (e.g., every 2 to 12 hours) support reductions are usually not necessary as they have not been shown to speed up the withdrawal process and only serve to consume resources and expose the patients to muscle overload risks. Repeating assessments for SBTs, however, should be done daily.[103] Importantly, aggressive strategies to reduce sedation can accelerate this process.[104]

To provide comfortable support, modes of partial support are used. By definition, these modes provide some, but not all, of the work of breathing. Ideally, these modes should provide adequate muscle unloading by providing breaths that are initiated promptly in accordance with patient demand. Accordingly, sensitive and responsive triggering systems should be used. Once the breath is initiated, a flow pattern that is synchronous with the patient's ventilatory demands should be provided.

RECENT INNOVATIONS IN MECHANICAL VENTILATORY SUPPORT

Innovative Strategies for "Lung Protection"

There have been several innovations recently introduced that may assist clinicians in reducing ventilator-induced lung injury. Among the more promising are airway pressure release ventilation (APRV), tracheal gas insufflation (TGI), adaptive support ventilation (ASV), and high-frequency ventilation (HFV).

Airway Pressure Release Ventilation

APRV (also known as biphasic ventilation, bilevel ventilation, and bilevel positive airway pressure) is a time-cycled, pressure-targeted form of ventilatory support.[91–93] It is actually a modification of pressure-targeted SIMV that allows spontaneous breathing (with or without PS) during both the inflation and deflation phases. Its differences from pressure-targeted SIMV thus only become evident when the inflation phase is prolonged (producing IRV) and patients breathe during this phase.

The putative advantages of this approach are similar to others with long inspiratory times. Specifically, the long inflation phase recruits more slowly filling alveoli and raises mean airway pressure without increasing applied PEEP (although intrinsic PEEP can develop with short deflation periods). Unlike older IRV strategies that required paralysis, however, the additional spontaneous efforts during inflation may enhance both recruitment and cardiac filling when compared to other controlled forms of support. Although IRV strategies are usually reserved for very severe forms of respiratory failure in which airway pressures and F_{IO_2} levels are approaching potentially injurious levels, the comfort and recruitment potential associated with APRV may prompt consideration of its use in less severe forms of lung injury.

Good gas exchange has been demonstrated with APRV in several small observational clinical trials, often with lower maximal airway pressures than used with control ventilation.[91–93] However, the end-inspiratory lung distention in APRV may not be less than that provided during other forms of support (and, indeed, it could be substantially higher) since spontaneous tidal volumes can occur even while the lung is inflated with the APRV set pressure. In the only randomized study that exists comparing APRV to a true lung-protective strategy, no difference in outcome was found.[93]

Adaptive Support Ventilation

As noted earlier, ASV is an assist-control, pressure-targeted, time-cycled mode of ventilation that automatically sets the frequency–tidal volume pattern according to respiratory system mechanics in order to minimize ventilator work.[7] Conceptually, this minimal ventilator work may translate into minimal stretching forces on the lungs, which may, in turn, reduce VILI. Importantly, the delivered "minimal work" tidal volume with ASV may sometimes be higher than the 6 mL/kg recommended by the ARDS Network trial. In addition, the PEEP settings are not part of the ASV algorithm and must therefore be set by the clinician. ASV has been shown to supply reasonable ventilatory support in a variety of patients with respiratory failure.[105,106] However, outcome studies comparing ASV to conventional lung-protective strategies have not been done.

Tracheal Gas Insufflation

In TGI, fresh gas is insufflated by a catheter placed at the distal end of the endotracheal tube to flush the endotracheal tube free of CO_2 during exhalation.[107] The concept is that the next delivered breath will effectively be free of endotracheal tube CO_2, thereby reducing dead space. This approach has particular appeal when the P_{CO_2} is rising during lung-protective ventilatory strategies. A number of studies have shown that TGI does reduce dead space but also has the potential to increase PEEP.

TGI catheters can deliver fresh gas either continuously or just during exhalation. Continuous delivery is easier to implement, but the exhalation-only approach reduces the potential for excessive end-inspiratory overinflation. TGI catheters can also be designed to deliver gas directly into the lung or in a retrograde fashion back up the endotracheal tube. Direct delivery enhances gas mixing, but retrograde delivery reduces the likelihood of increasing PEEP. At the present time, it is unclear whether TGI can significantly affect outcome and, if so, how best to deliver it. Clearly, however, TGI systems need to have safeguards to protect the lung from inadvertent overdistention.[107]

High-Frequency Ventilation

HFV uses very high breathing frequencies (120 to 900 breaths/min in the adult) coupled with very small tidal volumes (usually less than anatomic dead space and often <1 mL/kg at the alveolar level) to provide gas exchange in the lungs.[108] Gas transport under these seemingly unphysiologic conditions may involve such mechanisms as Taylor dispersion, coaxial flows, and augmented diffusion.[109]

HFV can be supplied by either jets or oscillators. Jets inject high-frequency pulses of gas into the airways. Oscillators literally vibrate a fresh bias flow of gas delivered at the tip of the endotracheal tube. Because of this, oscillatory HFV has sometimes been referred to as "CPAP with a wiggle."

The putative advantages of HFV are twofold. First, the very small alveolar tidal pressure swings minimize cyclical overdistention and derecruitment. Second, a high mean airway pressure can also prevent derecruitment. Interestingly, mean pressures used during HFV are often reported to exceed the 30 to 35 cm H_2O threshold employed during conventional ventilation. This tolerance of a higher mean pressure with HFV may be explained by a better maintained alveolar structure with a slowly applied (albeit vibrating) constant pressure as opposed to cyclical brief tidal pressures.

Clinical experience with HFV has been most extensive in the neonatal and pediatric age groups.[110–112] Experience in the adult population is less because HFV devices have only recently become available to support adequate gas exchange in this setting. Nevertheless, the one randomized trial to date evaluating HFV in severe acute respiratory distress syndrome suggested a trend toward improved survival with HFV.[112]

Automated Weaning Strategies

Over the years, a number of attempts have been made to "automate" the weaning process.[6] An early example is minimum minute ventilation, which adjusted the intermittent mandatory breath rate according to the level of spontaneous ventilation. The concept behind automated weaning was that significant clinician time could be saved and ventilatory support could be reduced in a timely fashion based on simple ventilator measurements.

Volume support (VS, also known by trade names such as "Automatic Pressure Ventilation") is the latest of these strategies with the potential for automatic support reduction.[6] VS is a dual-control breath-to-breath pressure support mode that uses tidal volume as a feedback control for continuously adjusting the pressure support level. All breaths are patient-triggered, pressure-limited, and flow-cycled, but clinicians select a target tidal volume. Depending upon the specific algorithm employed, automatic adjustments in inspiratory pressure are made by the ventilator within a clinician-prescribed range.

Proponents claim that this approach could "automatically" wean a patient by reducing pressure support as patient effort increases and respiratory system mechanics improve. Conversely, pressure support would increase if patient effort diminished or respiratory system mechanics worsened. Similarly, it has also been suggested that VS may be a useful way to maintain a more constant level of partial support in patients with fluctuating levels of effort related to drugs or neurologic conditions. All of these effects have been demonstrated in small studies focused on patients with rapidly recovering respiratory failure.[6]

Unfortunately, the simplicity of VS may introduce problems.[22] For instance, if the volume set by the clinician is excessive for patient demand, a recovering patient may not attempt to take over the work of breathing for that volume and thus weaning may not progress. In addition, if the pressure level increases in an attempt to maintain an inappropriately high set tidal volume in the patient with airflow obstruction, intrinsic PEEP may result. Conversely, if the volume set by the clinician is not adequate for patient demand, a patient may not receive adequate support. Under these conditions, a patient will perform excessive work to maintain a certain tidal volume even as the inspiratory pressure is being reduced.

Although no outcome studies have been performed using VS, there are specific clinical situations in which VS may be useful, as in a patient with fluctuating demand or in the rapidly recovering patient. However, clinicians need to be aware of the behavior of VS under a variety of circumstances to use this mode properly.

ASV, like VS, also has a volume feedback capability on delivered pressure during patient-triggered breaths. However, the ASV feedback control is more complex than VS and incorporates, as noted earlier, a "minimal work" setting for the desired minute ventilation based on respiratory system mechanics. Small clinical studies have demonstrated that ASV can automatically wean ven-

tilatory support safely.[106,113] However, large trials comparing ASV weaning to aggressive daily SBT strategies have not been done.

Other feedback systems controlling pressure support breaths have been touted as being capable of automatic weaning. These feedback systems use end points such as respiratory rate, patient respiratory drive (assessed by measuring inspiratory pressure against a closed circuit 100 msec after effort initiation), and end-tidal CO_2 to adjust ventilator settings.[114] As with other strategies described earlier, these approaches have been demonstrated to reduce pressure support safely in patients during weaning. Again, however, none of these strategies has been compared to aggressive daily SBT strategies in a large trial.

Optimizing Synchrony during Interactive Breaths

Interactive breaths are commonly used during mechanical ventilatory support to improve comfort (and reduce sedation), especially during the recovery phase of respiratory failure. As noted previously, interactive breaths need to be synchronous with patient efforts during all three phases of breath delivery: trigger, flow delivery, and cycle. To this end, a number of recent innovations have been introduced and are reviewed here.[114a]

It must be realized that, while all of these innovations have conceptual appeal and have been shown to perform as designed in both bench testing and small clinical observational trials, patient outcomes, including sedation needs, ventilator days, or patient comfort assessments, often have not been studied. Nevertheless, their straightforward designs, ease of operation, and safety make these innovations appropriate to consider in patients receiving interactive breaths.

Endotracheal Tube Resistance Compensation

The endotracheal tube provides a significant resistance to flow during both inspiration and expiration. During the inspiratory phase, this means that pressure build-up in the airways "lags" behind the pressure build-up in the ventilator circuity. Thus, the "square" wave of pressure in the circuitry provided by a pressure-targeted breath is distorted in the airways to a slower rise of pressure. This may create significant initial flow dyssynchrony in patients with vigorous inspiratory efforts. During expiration, a similar gradient between airway pressures and set circuit PEEP can develop.

One way to address this is to target ventilator pressures to a measured tracheal pressure distal to the endotracheal tube. Unfortunately, readings from intra-airway pressure sensors over prolonged periods are not reliable. Another approach is to account for endotracheal tube resistance mathematically in the ventilator flow delivery pattern.[115] Known by various trade names (e.g., "Automatic Airway Compensation," "Automatic Tube Compensation"), this approach initially provides an inspiratory pressure higher than the set pressure target. As inspiration proceeds, this delivered pressure then tapers to the set inspiratory pressure target. This compensation mechanism also can operate in expiration with an initial expiratory airway pressure below the set PEEP that then rises to the set PEEP. A more square wave pattern of inspiratory and expiratory tracheal pressures is the result.

Applying endotracheal tube resistance compensation is relatively straightforward. Clinicians must input the characteristics of the endotracheal tube. Thereafter, the ventilator provides the appropriate circuit pressure profile during both inspiration and expiration to create the desired square wave pattern in the trachea. Although outcome studies using this compensation approach have not been done, the conceptual appeal should make it a consideration in virtually all patients receiving assisted/supported pressure-targeted breaths—especially those with vigorous inspiratory efforts.

Pressure-Targeted Inspiratory Pressure Slope Adjusters

The original design for pressure-targeted breaths (pressure support and pressure assist-control) had a programmed flow delivery algorithm that attempted to reach the target inspiratory pressure quickly, without causing an uncomfortable overshoot. Newer ventilators, however, allow the clinicians to adjust this pressure rate of rise (slope adjusters), and clinical studies have suggested that slope adjustment could significantly enhance flow synchrony in many patients.[116] Specifically, these studies found that a rapid rate of rise was often desired in a patient with vigorous flow demands, while a much slower rate of rise was often preferable in patients with less vigorous demands.

There are several approaches to setting the slope adjuster. The most direct way is to use the circuit pressure graph and adjust the slope to create a "smooth square wave" appearance to the circuit pressure profile. Studies have also shown that an optimal slope setting correlates with the greatest V_T for a given pressure setting.[116] Patient comfort should always be considered in determining optimal slope settings.

Pressure Support Cycle Adjusters

Cycle dyssynchrony has recently been recognized as a potential problem due to the flow cycling mechanism of pressure support. On earlier machines, a set flow criterion was usually determined by the manufacturer (e.g., 25% to 35% of peak flow). While this set flow was often effective, it could sometimes terminate breaths too early in patients with long inspiratory demands and it could sometimes terminate too late, typically in patients with obstructive airway disease. In this latter situation, air trapping could also be made worse because of the resulting shorter expiratory time.

There are several approaches to improving cycle synchrony with pressure support. One is to switch from pressure support to a pressure assist breath (patient-

triggered, pressure-targeted, time-cycled breath as is usually available on most machines providing pressure ACV if the set rate is turned low or off). This breath provides direct clinician control of inspiratory time and thus of cycling. Another strategy is to adjust the pressure slope setting described previously on pressure support breaths. A very rapid peak initial flow will have a correspondingly high flow cycle variable (and thus short inspiratory time); a very slow peak initial flow will have a correspondingly low flow cycle variable (and thus long inspiratory time).

A newer, more direct approach, however, is to allow adjustments of the flow criteria of the pressure support cycle to assure appropriate synchrony of the cycle with the end of patient effort. As with other adjustments of interactive breaths, airway pressure graphics and assessments of patient comfort should guide adjustments. Proper breath synchrony is characterized by a comfortable patient and no evidence on the circuit pressure graph of continued inspiratory effort after cycling (premature cycling) or of expiratory efforts beginning during the inspiratory phase (delayed cycling). Although no outcome studies have been performed using these cycle adjusters, their physiologic appeal, ease of use, and apparent safety should make them a consideration in virtually every patient receiving pressure support.

Proportional Assist Ventilation

Proportional assist ventilation (PAV) is a novel approach to assisted ventilation in which the clinician sets the "gain" on patient-generated flow and volume.[117,118] In PAV, there is thus no set pressure, flow, or volume. Instead, the sensed patient effort is boosted according to a proportion of the measured work of breathing set by the clinician. The greater the patient effort, the greater the delivered pressure, flow, and volume. This contrasts with volume assist ventilation, where flow and volume are not affected by effort and where, in fact, applied pressure may be "pulled down" by effort. PAV also contrasts with pressure assist/support ventilation, where flow and volume are affected by effort but presure is not.

PAV has been compared to other forms of assisted ventilation and has been found to be comparable in terms of muscle unloading and patient comfort over a range of clinically meaningful settings.[118] Whether PAV improves clinical outcomes remains to be determined.

Neurally Adjusted Ventilatory Assistance

Neurally adjusted ventilatory assistance (NAVA) utilizes a diaphragmatic electromyographic (EMG) signal to trigger and cycle ventilatory assistance. The EMG sensor is positioned in the esophagus at the level of the diaphragm. Triggering of the ventilator breath is thus virtually simultaneous with the onset of phrenic nerve excitation of the inspiratory muscles. Moreover, breath cycling becomes tightly linked to the cessation of inspiratory muscle contraction. Small clinical studies have demonstrated improved trigger and cycle synchrony with NAVA,[119] but data demonstrating improved outcomes (e.g., duration of mechanical ventilation, sedation needs) are lacking. Another concern with NAVA is the expense associated with the EMG sensor.

KEY POINTS

- Positive-pressure breaths are characterized by three variables: the breath trigger, the flow delivery target (pressure or flow), and the cycle criteria.
- The interactions of positive-pressure breaths and respiratory system mechanics are described by the equation of motion: Pressure = (flow × resistance) + (volume/system compliance).
- In lungs with collapsed alveoli, alveolar recruitment is accomplished by a positive-pressure inflation and is maintained by positive end-expiratory pressure.
- Ventilator-induced lung injury can be caused by several mechanisms, including alveolar overdistention and repetitive alveolar collapse/reopening.
- Removing mechanical ventilatory support expeditiously requires regular sedation adjustments and assessments of spontaneous breathing capabilities.

DIAGNOSIS AND EPIDEMIOLOGY

Diagnosis

The acute respiratory distress syndrome (ARDS) is characterized by noncardiogenic pulmonary edema, lung inflammation, hypoxemia, and decreased lung compliance. Unlike some disorders (e.g., coronary artery disease), ARDS is a syndrome reflecting a constellation of clinical and physiologic observations thought to represent a common pathology. In coronary artery disease, narrowing of the coronary vasculature and disruption of an unstable atherosclerotic plaque are known to underpin the symptoms of angina and unstable angina respectively. A diagnostic "gold standard," namely coronary angiography, exists. In contrast, the pathogenesis of ARDS remains elusive and there is no gold standard diagnostic test. The heterogeneity of the clinical conditions associated with ARDS (discussed later) suggests that ARDS is a collection of different diseases that have not yet been separately identified.

The first description of ARDS appeared in a remarkable case series reported in 1967.[1] Ashbaugh and colleagues[1] described 12 patients ranging in age from 11 to 48 years, who presented with respiratory distress, hypoxemic respiratory failure, and patchy bilateral infiltrates on chest radiographs (Fig. 90-1). Most of the cases were preceded by severe trauma or viral infection and the onset of symptoms was relatively rapid, with most patients developing respiratory distress within 48 to 72 hours of the beginning of their illness. Most of the patients required positive-pressure ventilation and had low respiratory system compliance, and some experienced improvement in oxygenation with the application of positive end-expiratory pressure (PEEP). This syndrome was initially termed the *adult* respiratory distress syndrome to distinguish it from the respiratory distress syndrome seen in infants. When it was recognized that it also occurs in children, it was renamed the *acute* respiratory distress syndrome.

The cases described by Ashbaugh and colleagues[1] generated interest and research about ARDS. Unfortunately, the lack of either specific diagnostic criteria or an understanding of the pathogenesis of the disorder made it difficult to identify consistent patient populations in order to compare studies. In 1988, a formalized

and expanded definition of ARDS was proposed that consisted of three parts: (1) the first part described whether the illness was acute or chronic; (2) the second part identified associated risk factors or medical conditions (e.g., sepsis)[2]; (3) in the third part, points were assigned based on the severity of pulmonary dysfunction (the Lung Injury Score [LIS]), as measured by the degree of hypoxemia, the level of PEEP required, the respiratory system compliance, and the degree of radiographic abnormality. An average score was calculated and a final value greater than 2.5 was used to make a diagnosis of ARDS. One advantage of this system was its description of associated medical conditions, which might be pertinent to the etiology of ARDS. Because different etiologies of ARDS might reflect different pathogenetic pathways and perhaps confer different responses to therapy, knowing the cause of ARDS could be important in designing and comparing studies. The 1988 definition, however, made no attempt to exclude cardiogenic pulmonary edema because it was assumed that clinicians would do so automatically.

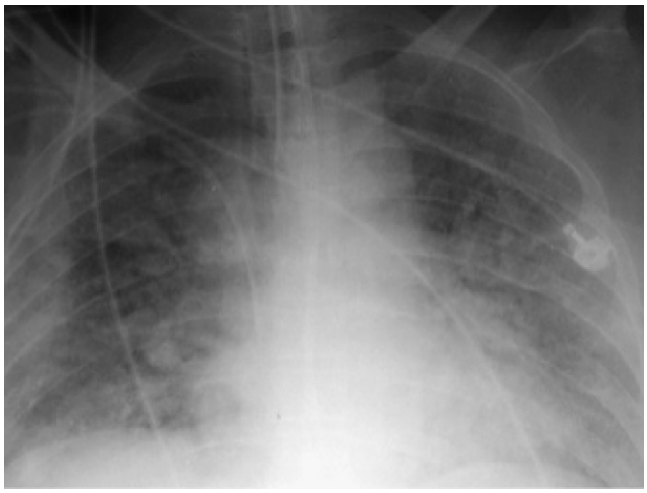

FIGURE 90-1 ■ Frontal radiograph of the chest in a patient with acute respiratory distress syndrome. Note the presence of bilateral infiltrates. (Courtesy of Michael B. Gotway, MD, Department of Radiology, University of California, San Francisco.)

Subsequently, a consensus conference of American and European investigators published their definition of ARDS, which has since been widely adopted[3] (Table 90-1). Aiming for simplicity, ARDS was defined as a syndrome of acute onset, with bilateral infiltrates on chest radiography consistent with pulmonary edema, pulmonary artery (PA) occlusion pressure of 18 mm Hg or less (or absence of clinical evidence of increased left atrial pressure), and hypoxemia as measured by the ratio of the arterial partial pressure of oxygen (Pa_{O_2}) to the fraction of oxygen inspired (F_{IO_2}). Recognizing the spectrum of severity of the disease, the consensus panel recommended that a Pa_{O_2}/F_{IO_2} ratio of 300 or less would define an entity termed *acute lung injury (ALI)*. ARDS was the most severe form of ALI and was diagnosed with Pa_{O_2}/F_{IO_2} of 200 or less.

The simplicity of the definition led to its general acceptance by clinicians and its incorporation into clinical research. However, such a straightforward definition could not take into account the heterogeneity of the disease or the ambiguity of clinical practice. For example, the requirement for bilateral infiltrates on chest radiograph is open to interpretation. One study presented a random series of chest radiographs from intubated hypoxemic patients ($Pa_{O_2}/F_{IO_2} < 300$) to an international group of expert clinicians, the majority of whom had conducted clinical research on ARDS. The clinicians were asked to examine each radiograph and to decide whether it fulfilled the American-European consensus conference (AECC) definition of ARDS (bilateral infiltrates consistent with pulmonary edema). This select group of physicians demonstrated only moderate agreement (κ statistic 0.55) in their classification of the radiographs. When the percentage of radiographs deemed by each physician to be consistent with ARDS was examined, the percentages ranged from a low of 36% to a high of 71%.[4] Another larger study on this issue also found only moderate agreement when two physicians were asked to rate radiographs on the presence or absence of diffuse bilateral infiltrates consistent with ARDS. However, with prior training and discussion, the agreement between an intensivist and a radiologist in the rating of the films was excellent.[5]

The AECC definition has also been criticized for not taking the level of PEEP into consideration. Clinicians

TABLE 90-1. American-European Consensus Conference Criteria for Acute Respiratory Distress Syndrome

	Timing	Oxygenation	Frontal Chest Radiograph	Pulmonary Artery Wedge Pressure
Acute lung injury	Acute	$Pa_{O_2}/F_{IO_2} \leq 300$ mm Hg*	Bilateral infiltrates	≤18 mm Hg if measured, or no clinical evidence of left atrial hypertension
ARDS	Acute	$Pa_{O_2}/F_{IO_2} \leq 200$ mm Hg*	Bilateral infiltrates	≤18 mm Hg if measured, or no clinical evidence of left atrial hypertension

*Regardless of PEEP.

ARDS, acute respiratory distress syndrome; F_{IO_2}, fractional concentration of oxygen in inspired gas; Pa_{O_2}, arterial pressure of oxygen; PEEP, positive end-expiratory pressure.

Adapted from Bernard GR, Artigas A, Brigham KL, et al: The American-European Consensus Conference on ARDS. Definitions, mechanisms, relevant outcomes, and clinical trial coordination. Am J Resp Crit Care Med 149:818–824, 1994.

have long appreciated that applying PEEP can improve oxygenation, an observation that was noted in the first description of ARDS. This implies that the Pa_{O_2}/F_{IO_2} will change as the level of applied PEEP changes; indeed, a patient who initially meets the AECC criteria for ARDS may no longer meet them once PEEP has been increased.[6] It also has been shown that patients who meet the AECC definition for ARDS can be stratified based on their response to standard ventilator settings 24 hours later; many of the patients at that point have a lesser degree of hypoxemia and a significantly lower mortality rate.[7] Thus, the AECC definition, although simple to use, encompasses a very heterogeneous group of patients.

When the LIS and the AECC definitions have been compared, they have been found to identify similar patients with a similar mortality rate.[8,9] In other words, the differences in the definitions of ARDS do not seem to have prognostic importance. This finding is reassuring to clinicians because it suggests that results from studies that used one or the other definition can still be meaningfully compared. Nonetheless, the difficulties with the definition may partly explain some of the negative therapeutic clinical trials in ARDS (see later).

Two additional points should be made about the diagnosis of ARDS. First, physicians have become less likely to insert PA catheters into patients, because of data suggesting that their use does not change outcome.[10,11] Thus, in practice, left atrial hypertension is usually excluded on clinical grounds (i.e., lack of history of heart failure and normal echocardiogram). It is important to note that many patients with ALI/ARDS will have left atrial hypertension during the course of their illness.[12] Second, despite the increasing use of B-type natriuretic peptides as diagnostic tools for acute congestive heart failure, their use in critically ill patients is controversial because of a lack of specificity.[13] The utility of measuring B-type natriuretic peptide as a means of distinguishing ARDS from cardiogenic pulmonary edema remains unclear.[14,15]

Incidence

Because of the multitude of definitions, and the difficulty in making a diagnosis of ARDS or ALI, it is not surprising that determining the incidence of the disease has been challenging. The reported incidence of ARDS has ranged from 75/100,000 population[16] to as low as 1.5/100,000.[17] Many studies did not use the AECC definition and did not include ALI. The incidence of ALI has been estimated to be 78.9 cases/100,000 person-years.[18] One study calculated an incidence of ARDS and ALI of 22 cases/100,000 using data from a large prospective trial of ARDS and the American Hospital Association.[19] One of the methodologic strengths of the study was its inclusion of cases of both ALI and ARDS over a 3-year period, thereby decreasing the effect of seasonal variability. The heterogeneity of the published estimates of incidence probably reflects differences in the methodology of the various studies but may also reflect true variation in different populations. Regional differences in genetic or environmental factors and specific disease associations such as cardiopulmonary bypass or lung transplant may account for some of the regional variability in the incidence of ARDS and ALI.[20]

Risk Factors

Data from a number of studies have shown that sepsis, aspiration of gastric contents, and multiple blood transfusions (>15 units/24 hr in one study) were associated with the highest risk of developing ARDS.[21,22] In particular, almost 40% of patients with sepsis developed ARDS. The presence of more than one presumed risk factor for ARDS increased the incidence of ARDS, although the sample sizes of these subsets were small.[21] In these studies, over a third of patients receiving massive blood transfusion and a quarter of patients with multiple trauma (one or more of pulmonary contusion, multiple fractures, multiple transfusions) developed ARDS.[22]

One of the predisposing factors for ARDS is a history of chronic alcoholism (relative risk [RR] 1.98; 95% confidence interval [CI], 1.32–2.85). This relationship remained significant after adjustment for gender, at-risk diagnosis, and severity of illness. Among those who developed ARDS, patients with a history of alcoholism had a higher mortality rate than those without this history (odds ratio 6.26; 95% CI 2.22–20.38).[23] The mechanisms responsible for this association are not clear, but abnormal concentrations of glutathione in the lung parenchyma, with a shift in antioxidant balance, might be involved.

The same investigators examined whether patients with diabetes might be protected against the development of ARDS, reasoning that hyperglycemia is known to impair neutrophil function, and neutrophils are thought to be central to the pathogenesis of ARDS (see "Etiology and Pathogenesis" section). More than 100 patients admitted to the intensive care unit with septic shock were followed prospectively for the onset of ARDS. Over a 2-year period, diabetes was associated with a significantly decreased risk of ARDS (RR 0.53; 95% CI 0.28–0.98), which persisted after adjustment for the source of sepsis and other potential confounders. Interestingly, there was no difference in mortality between patients with or without diabetes who developed ARDS.[24]

A systematic overview of studies examining potential risk factors for ARDS concluded that the strongest evidence of a causal relationship was for sepsis, trauma, multiple transfusions, aspiration of gastric contents, pulmonary contusion, pneumonia, and smoke inhalation.[25]

The heterogeneity of risk factors for ARDS is remarkable. At the AECC, investigators divided the known risk factors into those thought to cause *direct* lung injury (e.g., pneumonia) and those in which the mechanism of lung injury was thought to be *indirect* (e.g., pancreatitis) (Table 90-2). Whether this conceptually attractive classification scheme (also known as the *pulmonary* vs. *nonpulmonary* risk factor classification) reflects underlying differences in the mechanisms, severity, or outcome of lung injury is still uncertain. For example, one group of investigators has shown that patients with direct pulmonary causes of ARDS had significantly higher lung

TABLE 90-2. Conditions Associated with Acute Respiratory Distress Syndrome, by Possible Mechanisms of Injury

Indirect Injury	Direct Injury
Sepsis	Pneumonia
Major trauma	Aspiration
Multiple blood transfusions	Pulmonary contusion
Pancreatitis	Toxic inhalation
Cardiopulmonary bypass	Near-drowning
Drug overdose	Reperfusion injury (e.g., post lung transplant)
Adverse effect of medication	

elastance than patients with indirect or nonpulmonary causes of ARDS.[26] In addition, increasing PEEP led to improved recruitment of the lung in the nonpulmonary group but to decreased recruitment in patients with ARDS from a pulmonary source. Despite these interesting observations, whether these two groups of patients have different prognoses or different responses to therapy is unclear.[27] This issue is discussed in more detail in the "Long-term Outcomes" section.

ETIOLOGY AND PATHOGENESIS

Overview of Pathophysiology

In the past, ARDS has also been called "noncardiogenic pulmonary edema," a descriptive term that nonetheless reflected what was known about the pathogenesis of the disorder. Unlike congestive heart failure, in which elevated left-sided cardiac pressures cause hydrostatic pulmonary edema, in ARDS, the edema fluid that fills the alveoli is exudative in origin due to increased permeability of the alveolar-capillary barrier, which allows leakage of protein-rich fluid into the airspaces. Alveolar filling leads to decreased respiratory system compliance as well as functional right-to-left shunting and profound hypoxemia. Although arterial carbon dioxide pressure (P_{CO_2}) is generally within the normal range, dead-space ventilation is significantly increased, as demonstrated by elevated minute ventilation. Pulmonary hypertension is also commonly observed in ARDS, and a number of mechanisms have been proposed, including hypoxic vasoconstriction, intravascular fibrin deposition in the pulmonary capillaries, and compression of blood vessels by the positive-pressure ventilation used to treat the disorder. Much of the research about ARDS has focused on determining the basis for the increase in alveolar-capillary permeability.

Pathology

The pathologic features of ARDS have classically been described using three overlapping and sequential stages.[28] In the first or exudative phase of lung injury, the pathologic findings have been termed "diffuse alveolar damage." There are hyaline membranes and protein-rich edema fluid in the alveolar spaces, as well as epithelial disruption and infiltration of the interstitium and air spaces with neutrophils and macrophages. Areas of alveolar hemorrhage also are present. This phase, which is thought to last for 5 to 7 days, is followed in some patients by a proliferative phase. At this point, hyaline membranes are reorganized and areas of fibrosis are visible. Obliteration of pulmonary capillaries and deposition of interstitial and alveolar collagen may be observed, along with a decrease in the number of neutrophils and the extent of pulmonary edema. The initial proliferative phase is followed by a fibrotic phase, emphasizing the appearance of pulmonary fibrosis in the subset of patients with persistent (i.e., >2 wk) ARDS.

More recent evidence suggests that the development of areas of fibrosis probably occurs sooner than previously appreciated. Elevated levels of N-terminal procollagen peptide III, thought to represent collagen synthesis, can be detected in bronchoalveolar lavage fluid of patients with ARDS as early as 24 hours into the course of the illness. In addition, the bronchoalveolar lavage fluid from these patients has been shown to stimulate cultured fibroblasts to proliferate.[29] These and other observations suggest that fibroproliferation begins simultaneously with (rather than after) inflammatory lung injury.[30]

The Alveolar-Capillary Membrane

Because ARDS is a disorder of increased alveolar-capillary permeability, it stands to reason that the pulmonary microvascular endothelium or the alveolar epithelium (or both) must be involved in its pathophysiology. Damage to the alveolar epithelium is thought to be a key event in the increased permeability of the alveolar-capillary membrane in ARDS.[31] In the lung, epithelial cells are normally more resistant than endothelial cells to the injurious effects of circulating endotoxin,[32] and epithelial disruption may, therefore, be conceptualized as an important event in the development of alveolar flooding. The importance of the alveolar epithelium once ARDS has occurred is also clear: type II pneumocytes must differentiate into type I cells to help cover the denuded epithelial surface, whereas both type I and II cells express the Na^+,K^+-ATPase, which is thought to be important in clearance of edema fluid (discussed in some detail later). In addition, injury to type II pneumocytes affects the production and metabolism of surfactant. How the damage to the alveolar-capillary membrane occurs is not known for certain, although neutrophils are suspected to play a role (see later).

Surfactant

Surfactant is a complex mixture of phospholipids and surfactant proteins that reduces alveolar surface tension. Many researchers have described alterations to surfactant lipids and proteins in patients with ARDS. The surfactant of patients with ARDS contains decreased amounts of surfactant-related proteins and decreased dipalmitoyl-

phosphatidylcholine and phosphatidylglyercol. The proportion of large (active) to small (inactive) aggregates of surfactant is diminished due to both decreased production of surfactant and increased conversion of the large to small forms. In addition, plasma proteins that have leaked through the alveolar-capillary barrier may interfere with surfactant function.[33] For example, reduced concentrations of surfactant protein A have been found in patients with ARDS.[34] The impairment in surfactant function observed in ARDS would predispose alveolar units to collapse. In addition, surfactant proteins have been found to have antimicrobial properties,[35,36] but whether the loss of these properties is relevant to the pathogenesis of ARDS is not known. Indeed, despite the abnormalities in surfactant that have been described,[37] the extent to which these alterations contribute to the pathogenesis of ARDS remains controversial. Unlike the *neonatal* respiratory distress syndrome, in which a deficiency of surfactant underlies the pathophysiology of the disease, it is possible that the abnormalities of surfactant in ARDS are the result rather than the cause of altered physiology. Indeed, five large randomized, controlled trials of exogenous surfactant supplementation in ARDS failed to show any improvement in mortality or requirement for mechanical ventilation[33,37a] (see "Therapy" section). Only one trial, using calfactant (a natural surfactant, distinct from previous trials) in pediatric patients with ARDS, has shown any benefit.[38] Whether this is due to the unique surfactant used in this study or to differences between the patients enrolled in this trial and those in the negative trials is not clear.

Neutrophils and Other Inflammatory Mediators

Histologically, one of the hallmarks of ALI/ARDS is the accumulation of neutrophils in the microvasculature of the lung.[39] As key cells in innate immunity, neutrophils generate an array of cytotoxic compounds. These include reactive oxygen species, cationic peptides, eicosanoids, and proteolytic enzymes such as leukocyte elastase. In addition, once activated, neutrophils release growth factors and cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) that enhance inflammatory responses. Given this destructive potential, it has long been theorized that neutrophils may be central to the pathogenesis of ALI[40] (Fig. 90-2), and an abundance of clinical and preclinical data supports this hypothesis. For example, in humans with ARDS following sepsis, bronchoalveolar lavage neutrophilia is associated with a poor prognosis.[41] Neutrophil-depleted mice exposed to hyperoxia develop less lung injury than normal mice.[42] Similarly, in a hamster model of ALI induced by endotoxin inhalation, the administration of a specific inhibitor of neutrophil elastase (NE; even hours after administration of endotoxin) prevented the development of lung injury.[43]

If neutrophils are involved in the pathogenesis of ARDS, some defect in their regulation also might be involved. For example, in an uncomplicated bacterial pneumonia, the pulmonary inflammatory response is limited by counter-regulatory processes that prevent tissue damage. Why this regulation is ineffective or insufficient in ARDS is an unanswered question.[44]

One of the earliest manifestations of ARDS, even before hypoxemia, is a transient leukopenia due to sequestration of neutrophils in the lung microvasculature.[45] On average, the pulmonary capillaries are smaller than neutrophils, so that neutrophils must deform in order to pass through the microvasculature. Activated neutrophils "stiffen" and cannot negotiate narrow capillary segments.[46] Inhibitors of actin polymerization can abrogate this stiffening, implicating a change in the actin cytoskeleton in neutrophil sequestration in the lung.[47] Durable neutrophil sequestration is thought to involve interactions between molecules on the surface of the neutrophil and the lung capillary endothelium. For example, in rabbits, blocking the adhesion molecule L-selectin on the surface of the neutrophil prevented neutrophil sequestration in alveolar capillaries induced by exposure to endotoxin.[48]

After the initial sequestration, neutrophils must translocate (diapedesis) across the alveolar-capillary barrier to enter the alveolar space. The determinants of this seemingly simple movement remain incompletely understood. Integrins on the surface of the neutrophil are thought to mediate emigration of neutrophils from the pulmonary circulation in response to some, but not all, inflammatory stimuli.[49] Proteases secreted by the alveolar epithelium, in concert with regional cytokine production and glycosaminoglycans on the epithelial surface, may act together to form chemotactic gradients that neutrophils follow.[50]

Many studies have focused on the mechanisms of neutrophil activation. Recent work has investigated the interaction between platelets and neutrophils and how mutual activation may contribute to ALI or sepsis.[51] Others have investigated various components of intracellular signal transduction pathways, such as kinases (enzymes that phosphorylate substrates) and transcription factors. For example, one such kinase is the p38 mitogen-activated protein (MAP) kinase, which is activated when cells are stimulated with lipopolysaccharide (LPS).[52] Activation of this kinase stimulates TNF-α production and the release of macrophage inflammatory protein-2 (MIP-2, a CXC chemokine that is a chemotactic factor for neutrophils).[53] Interestingly, inhibition of p38 MAP kinase in mice, even hours after the mice are exposed to aerosolized LPS, attenuates neutrophil chemotaxis and migration from the lung microvasculature into alveoli.[54] Another kinase often discussed in the context of inflammation is phosphatidylinositol 3-kinase (PI3K). This enzyme phosphorylates phosphatidylinositol, a lipid-derived second messenger whose phosphorylated forms have been implicated in many intracellular signaling events. PI3K-γ is preferentially activated in neutrophils exposed to IL-8 or fMLP (a homologue of bacterial-derived chemotactic peptides).[55] Despite exposure to intraperitoneal endotoxin, PI3K-γ knockout mice displayed decreased neutrophil accumulation, cytokine production, and lung injury as compared with control

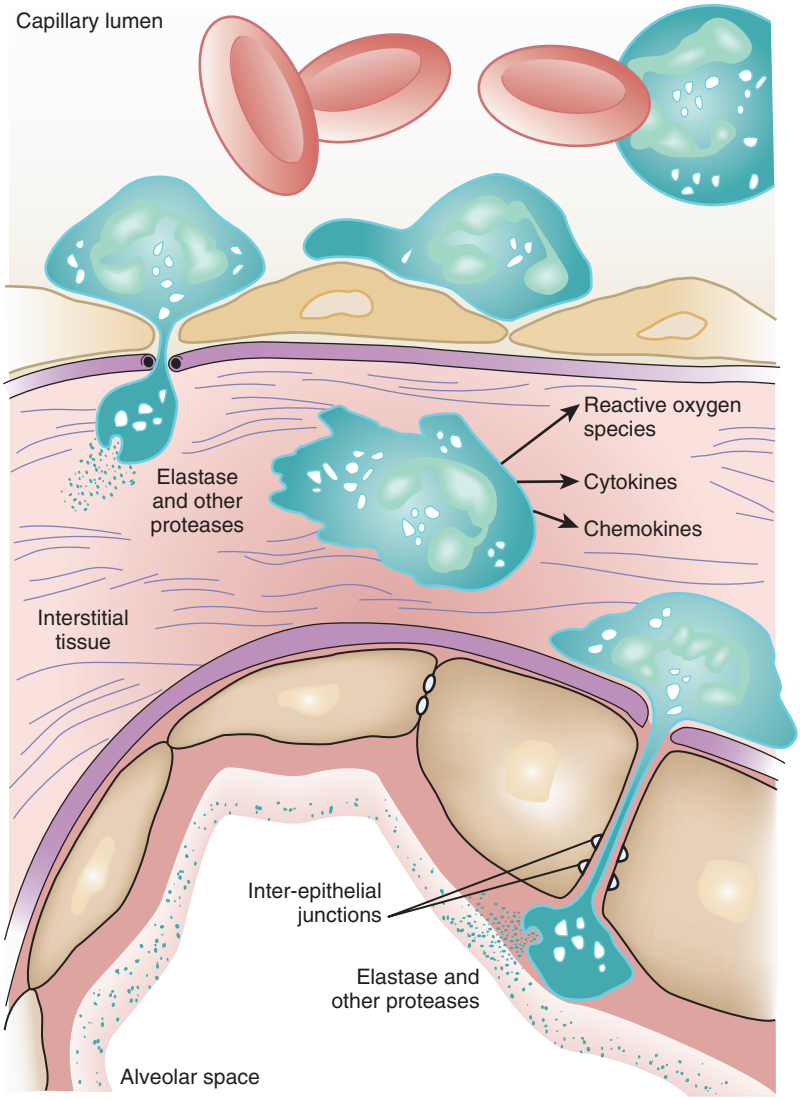

FIGURE 90-2 ■ Role of neutrophils in the pathogenesis of acute lung injury. Activated neutrophils exit the bloodstream and transmigrate across the alveolar-capillary membrane, releasing cytokines, proteases, reactive oxygen species, and other compounds. Although crucial to host defense against pathogens, the compounds secreted or released by the neutrophil have the capacity to damage the tissue of the host. (Adapted from Lee WL, Downey GP: Leukocyte elastase: Physiological functions and role in acute lung injury. A state of the art review. Am J Respir Crit Care Med 164:896–904, 2001.)

mice. The neutrophils in the lungs of the knockout mice also had diminished activation of nuclear factor-κB (NF-κB), an important transcription factor known to mediate the up-regulation of many cytokines and proinflammatory mediators.[56]

Many potential mechanisms might explain how activated neutrophils mediate ALI. In addition to secreting cytokines and growth factors that stimulate local and systemic inflammatory responses, neutrophils generate reactive oxygen species that mediate tissue damage.[57] In animal studies, inhibition of the assembly of nicotinamide adenine dinucleotide phosphate, reduced form (NADPH) oxidase (the major source of reactive oxygen species) by apocynin attenuates sepsis-induced lung injury.[58] The nitric oxide synthase (NOS) pathway has also been implicated in lung injury because knockout mice lacking the gene for inducible NOS developed less severe lung injury than wild-type animals when treated with LPS.[59]

Neutrophils contain proteolytic enzymes that can contribute to ALI. In particular, both NE and metalloproteinases have been extensively studied.[60] Because of its ability to degrade diverse substrates, including growth factors and cytokines, NE may be involved in regulation of inflammatory responses. NE also has been shown to degrade epithelial and endothelial cadherins, proteins that are major components of the adherens junctions that hold cells together. It is possible that elastase-mediated destruction of cadherin junctions between endothelial and/or epithelial cells could promote alveolar flooding.

Although NE might cause tissue damage, it is also important for effective antimicrobial defenses in the lungs. In NE-deficient mice, the administration of intraperitoneal *Klebsiella pneumoniae* caused 100% mortality within 48 hours, as compared with only 50% mortality in normal mice.[61] Interestingly, NE-deficient mice are paradoxically resistant to doses of LPS that are usually lethal. Furthermore, mice that lack both NE and another neutrophil protease (cathepsin G) are protected against alveolar damage induced by endotoxic shock.[62] These apparently contradictory results suggest that NE, although important in a regulated inflammatory response, may nonetheless participate in inflammatory injury in

some situations. Many studies in different species of animals using different experimental models suggest that NE has an important role in the pathogenesis of ALI in animals. Whether it is also important in the development of ALI or ARDS in humans remains unanswered. A clinical trial of a leukocyte elastase inhibitor in ARDS was halted when preliminary analysis suggested lack of efficacy.[63]

Other studies have indicated the importance of metalloproteinases in leukocyte-mediated lung injury. Elevated concentrations of the matrix metalloproteinases gelatinase A and B have been found in the epithelial lining fluid of patients with ARDS.[64] Mice lacking the genes for gelatinase B or stromelysin 1 had less severe injury in an animal model of ALI.[65] Matrilysin (matrix metalloproteinase-7) has been shown to regulate the formation of chemotactic gradients and the transmigration of neutrophils across the alveolar epithelium in a mouse model of ALI.[50] The administration of an inhibitor of elastase and metalloproteinases (chemically modified tetracycline-3) attenuated ALI after cardiopulmonary bypass in pigs.[66]

Despite the emphasis on neutrophils in the causal pathway for ALI, it is important to note that ARDS has been described in patients with profound neutropenia.[67,68] Indeed, it is possible that the neutrophil infiltration observed in some cases of ALI/ARDS is adaptive (i.e., a physiologic response to a primary injury) rather than destructive. At present, however, we believe that the balance of the evidence implicates neutrophils as causative in the development of most cases of ALI. Comparatively little is known about the mechanisms of neutrophil-independent ALI, which should be a major goal of future investigations.

Inflammation and Coagulation

One of the most common precipitants for ARDS is sepsis, and effective therapies for sepsis have the potential to either prevent the onset or improve the outcome of ALI. The current concept of sepsis is of an initial inflammatory state, with up-regulation of inflammatory cytokines such as TNF-α and IL-1β and recruitment and activation of inflammatory cells such as neutrophils, monocyte/macrophages, and lymphocytes. This early stage of inflammation is followed by relatively depressed innate immunity, in which the patient is vulnerable to nosocomial infections.[69] The theory that dysregulation of the inflammatory response is responsible for sepsis has led to a search for agents that would selectively block components of inflammatory pathways. More recent evidence has identified important connections between the molecular cascades that regulate both inflammation and coagulation. For example, TNF-α causes an increase in thrombin and fibrin formation, whereas fibrin fragments themselves are known to attract neutrophils.[70] TNF-α increases tissue factor expression on endothelial cells and inhibits fibrinolysis, both of which favor fibrin formation. Activated protein C (APC), an endogenous anticoagulant, has direct and indirect anti-inflammatory effects, which include decreasing circulating concentrations of IL-6 and attenuating neutrophil activation in sepsis.[71,72] Because sepsis is the most common cause of ARDS and because abnormalities of coagulation are very common in sepsis, investigators have wondered whether altered coagulation is involved in the pathogenesis of ARDS. How this might occur is largely speculative, but intra-alveolar, interstitial, and intravascular fibrin deposition have all been observed in patients with ARDS. Indeed, fibrin is a major component of hyaline membranes. Intra-alveolar fibrin has been postulated to serve as a nidus for fibroblast proliferation and potentially, as ALI resolves, as a stimulus for pulmonary fibrosis. Fibrin might also contribute to ongoing lung injury through its chemotactic properties, and intravascular fibrin deposition, causing intravascular microthrombi, might contribute to the elevated pulmonary vascular pressures observed in ARDS.

Interest in the role of coagulation in the pathogenesis of ARDS has been buttressed in part by observations in animal studies that anticoagulation can attenuate the severity of sepsis-induced lung injury.[73] In addition, a randomized, controlled trial of APC in humans with sepsis showed a significant reduction in mortality.[74] However, a small randomized, controlled trial of APC in patients at risk for ALI was stopped prematurely owing to lack of efficacy.[75]

Other molecular determinants of inflammation continue to be identified. Recent data have implicated transforming growth factor-β (TGF-β) in an animal model of ALI.[76] In one study, TGF-β was postulated to cause increased alveolar epithelial cell permeability by depleting intracellular glutathione levels.[77] Other investigators have attempted to improve the endogenous counterinflammatory response. In one study, the gene for heat shock protein 70 (HSP70) was attached to an adenoviral promoter, and the resultant recombinant construct was instilled into the lungs of rats in which lung injury had been induced by cecal ligation and perforation. Administration of the HSP70 construct increased HSP70 expression specifically in the lungs, and remarkably, this increased expression was associated with a significant reduction in pulmonary edema and inflammation and mortality.[78] Indeed, mice deficient in HSP70 showed increased mortality and lung injury after cecal ligation and perforation.[79] The mechanisms underlying this protective effect of HSP70 are not clear, but may involve suppression of the activity of the proinflammatory transcription factor NF-κB.

Na^+ and Water

Na^+ channels at the apical surface of alveolar epithelial cells mediate intracellular Na^+ uptake from the alveoli. This creates an osmotic gradient, which causes alveolar fluid to follow, thereby allowing for the clearance of pulmonary edema. The Na^+,K^+-ATPases in the basolateral membrane of the epithelial cell exchange intracellular Na^+ for extracellular K^+, maintaining the intracellular sodium concentration low enough for the apical Na^+ reabsorption to continue. This process allows for the net removal of Na^+ and water from the alveolar space and

can be accelerated by catecholamines in experimental preparations.

Dysfunction of either the apical Na^+ channels or the basolateral Na^+,K^+-ATPases (or both) have been postulated to be involved in the pathogenesis of ARDS. For example, it is known that hypoxia decreases epithelial Na^+ reabsorption by impairing the expression of subunits of the epithelial Na^+ channel.[80] Hypoxia also decreases the activity of both the apical Na^+ channel[81] and the Na^+,K^+-ATPase.[82] In an animal model of ALI induced by hemorrhagic shock, the normal upregulation of alveolar fluid reabsorption in response to catecholamines was absent. This defect was attributed to an increase in nitric oxide (NO) in the lung, with a possible effect on β-adrenergic receptor signaling.[83] In a retrospective study of patients with ALI, alveolar fluid clearance was measured. When patients were stratified by their rate of fluid clearance, those with the highest rates had the lowest mortality and the shortest duration of mechanical ventilation.[84] In a model of ventilator-induced lung injury (VILI) in rats, overexpression of the Na^+,K^+-ATPase improved the clearance of lung liquid.[85] Whether alveolar fluid clearance can be manipulated in a clinical setting (e.g., by β-adrenergic agonists) to improve prognosis is the subject of ongoing clinical trials.[86]

Angiopoietins

Angiopoietins are peptides involved in embryonic vascular development. Of the four angiopoietins which have been identified, angiopoietin 1 and angiopoietin 2 (Ang-1 and Ang-2, respectively) are the best studied. Ang-1 is expressed by many cell types whereas Ang-2 is expressed primarily by endothelial cells. Both act on the Tie-2 receptor tyrosine kinase, which is found predominantly on endothelial cells and hematopoietic stem cells.[87] A number of observations have generated interest in the potential role of these proteins in the pathophysiology of ARDS. First, elevated levels of Ang-2 have been found in patients with sepsis and ARDS, and treatment of mice with Ang-2 causes pulmonary vascular leak.[88,89] The effect of Ang-2 in disrupting endothelial cell integrity could be reversed in vitro by Ang-1. Second, overexpression of Ang-1 was protective against both endotoxin-induced shock and ALI in mice.[90] Although the cellular mechanism of these effects is the subject of intense investigation,[91,92] the data to date emphasize the important role for endothelial cells in the development of and recovery from ARDS.

Ventilator-Induced Lung Injury

Although mechanical ventilation for ARDS is often lifesaving, there is abundant preclinical and clinical evidence that it can also be harmful.[93] Whereas it was quickly recognized that excessive airway pressure could lead to *barotrauma* (Fig. 90-3), including pneumothorax, pneumomediastinum, and subcutaneous emphysema, attention has since turned to subtler but more common manifestations of lung injury related to mechanical ventilation. Mechanical ventilation can induce pulmonary edema by causing increases in both epithelial and endothelial permeability.[93] Indeed, investigators noted in 1991 that mechanical ventilation could produce a form of increased-permeability pulmonary edema remarkably similar to ARDS.[94] Now, the accumulated evidence suggests that inappropriate mechanical ventilation strategies may aggravate if not induce ARDS in some patients.[95]

FIGURE 90-3 ■ Barotrauma as a consequence of acute respiratory distress syndrome. Note the presence of a pneumothorax, pneumomediastinum, pneumoperitoneum, and subcutaneous air in this patient receiving positive-pressure ventilation. (Courtesy of Dr. Thomas E. Stewart.)

A major mechanism causing VILI is overdistention of lung units, whereas the absolute airway pressure appears to be less important. Normal rats ventilated with high airway pressure due to a high tidal volume (VT) developed increased permeability, whereas rats ventilated with smaller VTs, but with the same end-inspiratory pressure (obtained by strapping the chest walls of the rats) did not develop increased permeability.[96] Rats were also ventilated with low airway pressure using negative inspiratory pressure (applied at the chest wall) and high VTs. The rats ventilated with high VTs had significantly more edema. In particular, the negative (low)-pressure and high-VT group had the worst edema. These important observations, confirmed in other species,[97] led to the appreciation that a large VT, rather than high airway pressure per se, is an important determinant of ventilator-induced pulmonary edema. The term *volutrauma* was created to recognize this fact.

The repetitive opening and closing of terminal lung units during mechanical ventilation is also detrimental. This injury has been called *atelectrauma*,[98] and the

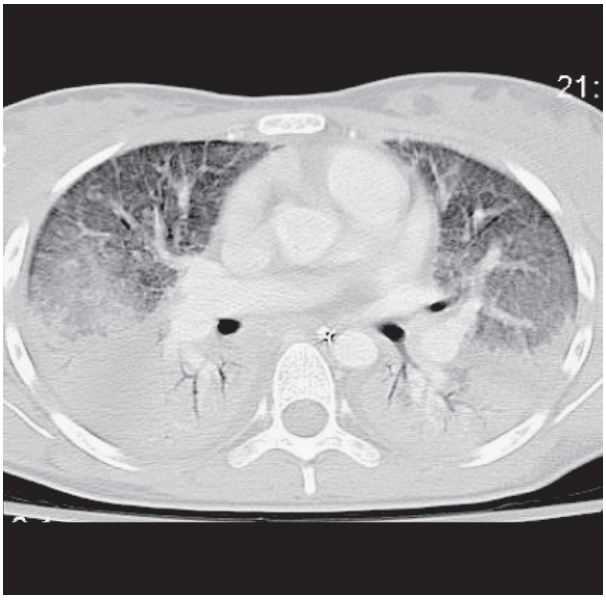

FIGURE 90-4 ■ Section from a computed tomography scan of the chest in a patient with acute respiratory distress syndrome. Note the presence of dense consolidation with air bronchograms in the dependent dorsal lung, with relative sparing of the ventral lung. (Courtesy of Dr. Thomas E. Stewart.)

mechanism is thought to be the high shear stresses generated at the interface of collapsed and aerated tissue when a collapsed airway is reopened.[99] Theoretically, PEEP would be helpful in minimizing this injury by keeping the lung recruited and promoting greater lung homogeneity by maintaining open distal airway and alveolar units.

Patients with ARDS may be especially vulnerable to VILI because of the heterogeneous nature of the pulmonary parenchymal injury. On computed tomography (CT) scans of the lungs, normal-appearing lung and densely consolidated injured lung are both present; consequently, there are marked regional differences in lung compliance[100] (Fig. 90-4). A VT designed to inflate an entire lung would preferentially inflate the normal-appearing areas, leading to overdistention and volutrauma. Similarly, patients with ARDS may be more vulnerable to atelectrauma. Although some evidence suggests that normal lungs can tolerate short periods of cyclic opening and closing of airways during mechanical ventilation,[101] injured lungs would be exposed to much higher shear stresses, which would be expected to be very injurious.[102]

Since the late 1990s, there has been a growing appreciation that VILI not only is a mechanical injury but also reflects an underlying complex cellular and molecular response. The term *biotrauma* has been coined to emphasize this change in thinking.[103] One of the most significant advances made in our understanding of VILI is that mechanical ventilation per se can induce both local and systemic inflammatory responses. In animal studies, it has been shown that ventilation with either zero PEEP or high VTs increases the concentration of inflammatory cytokines in lung lavage fluid. Lungs ventilated with *both* high VTs and zero PEEP had a synergistic elevation in cytokine levels.[104] This inflammatory response to an injurious ventilation strategy also has been shown to extend beyond the lung. In an acid aspiration rat model of lung injury, a ventilatory strategy using high VTs and zero PEEP was associated with an increase in blood levels of various cytokines. This was not observed either in groups ventilated with a small VT or in a group ventilated with the large VT but higher PEEP levels.[105]

Similar observations have been made in patients with ARDS. In one study, patients were randomized to "lung-protective" ventilation, in which the VT was set to avoid overdistention and PEEP was set above the lower inflection point of the pressure-volume curve.[106] Patients in the control group were treated with a strategy that would have been considered conventional ventilation at the time. Whereas bronchoalveolar lavage and plasma cytokine concentrations declined in the lung-protective group, they rose significantly in the control group. Post hoc analyses revealed significantly more ventilator-free days in the lung-protective group than did controls and significant correlations between the development of multisystem organ failure and plasma cytokines. The effect of the ventilator strategy on the development of biotrauma can be remarkably rapid. Stuber and coworkers[107] found an increase in a number of proinflammatory cytokines in the lungs and plasma of patients with ARDS within 1 hour after switching the patients from a protective to a nonprotective ventilatory strategy.

Patients with ARDS often die of the systemic inflammatory response syndrome (SIRS) and multiorgan dysfunction, rather than respiratory failure. Hence, the observation that mechanical ventilation can influence pulmonary and systemic cytokine concentrations is intriguing. Taken together, these findings suggest that mechanical ventilation has the potential not only to injure the lungs but also to cause loss of compartmentalization of the pulmonary inflammatory response. Systemic dissemination of the lung inflammatory response could be associated with the development of SIRS and multisystem organ failure (Fig. 90-5).[108] One study has shown that injurious mechanical ventilation in rabbits causes not only elevated plasma and lung cytokine concentrations but also increased renal epithelial cell apoptosis and renal dysfunction.[109]

Finally, patients with ARDS often require very high F_{IO_2}. The toxic effects of hyperoxia on the lung have been well described,[110] and the histologic appearance mirrors that of human ARDS. Oxygen toxicity is thought to be mediated by the formation of both reactive oxygen and nitrogen species, which damage tissues by a number of different mechanisms,[57] and hyperoxia appears to worsen VILI.[111] Antioxidants have been considered as a potential therapeutic strategy for preventing and treating ARDS, although clinical trials have so far been disappointing (see the section on "Therapy").

Genetic Determinants

To date, little is known about which genes might affect the development or prognosis of ARDS. A small

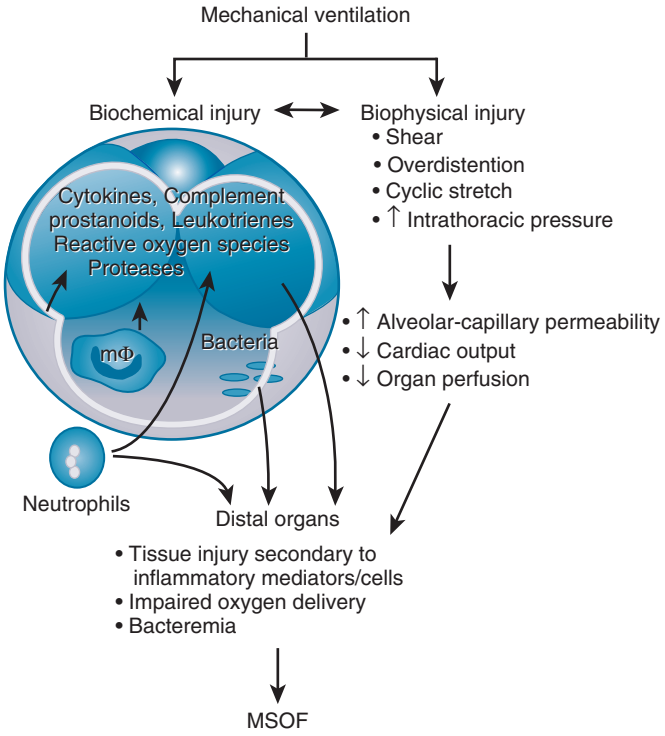

FIGURE 90-5 ■ Potential mechanisms by which mechanical ventilation might cause or contribute to multisystem organ failure (MSOF). mΦ, macrophage. (Redrawn from Slutsky AS, Tremblay LN: Multiple system organ failure: Is mechanical ventilation a contributing factor? Am J Respir Crit Care Med 157:1721–1725, 1998.)

pilot study has reported an association between a polymorphism in the gene for surfactant protein B[112] and ARDS, whereas a larger study described an association between a polymorphism in the angiotensin-converting enzyme[113] and both the incidence and the outcome of ARDS. Subsequent studies have reported conflicting results.[114,115] The heterogeneity of patients with ARDS makes it difficult to identify clinically important genetic associations, except in clearly defined subsets of patients.

MORTALITY AND COMPLICATIONS

Mortality

The mortality rate for ARDS has fallen since the syndrome was first described, with a number of studies describing a decline in the rate from over 60% to about 40% since 1993.[116–118] The reasons for this improvement in survival are not known, although some have attributed it to better supportive care in the intensive care unit and the use of smaller VTs.

Predictors of Poor Prognosis

Despite the prominence of hypoxemia among the clinical manifestations of ARDS, early trials did not find that the severity of hypoxemia early in the course of the illness was a good predictor of subsequent mortality.[119] Pulmonary injury scoring systems like the LIS and the ARDS score have been shown to predict a prolonged (>2 wk) requirement for intubation and ventilation,[120] whereas scoring systems that measure the overall severity of illness, such as the Simplified Acute Physiology Score (SAPS), correlate better with survival.[121] The classic finding is that patients with ARDS do not usually die of refractory hypoxemia, which is paradoxical because hypoxemia is frequently the focus of initial resuscitative efforts. In fact, most patients with fatal ARDS die of sepsis and multiorgan failure.[122,123] The explanation for this apparent paradox is unknown, although it has been hypothesized that injurious mechanical ventilation during the course of ARDS might be involved.[108] As discussed earlier, ventilation using excessive VTs has been shown to cause elevations in pulmonary and systemic cytokine levels and has more recently been linked in an animal model to apoptosis of renal cells and renal dysfunction.[109]

Data from several studies have suggested that the mortality rate from ARDS varies depending on the precipitating factor. The highest risk of death has consistently been reported to occur in sepsis, whereas ARDS following major trauma has a much better prognosis.[124] In addition, it is known that chronic liver disease,[119] older age,[125] chronic alcoholism,[23] and nonpulmonary organ dysfunction[119] are associated with higher mortality from ARDS. Other predictors of death from ARDS have included a history of organ transplantation and human immunodeficiency virus (HIV) infection,[126] whereas another study found higher mortality in men and African Americans than in non–African Americans.[127]

As mentioned earlier, risk factors for ARDS have been classified as being pulmonary or nonpulmonary in origin. Whether this distinction has prognostic importance is still unclear. In one prospective cohort study of patients with ARDS, investigators found a trend toward higher mortality in patients with a pulmonary cause, although the difference was not statistically significant.[128] In contrast, the ARDS Network investigators retrospectively analyzed the data from their large randomized study of low-VT ventilation versus traditional VT ventilation. Although confirming that the mortality rate for ARDS was highest in patients with sepsis and lowest in patients with trauma, there was no difference in mortality, days off the mechanical ventilator, or the development of organ failure between patients with pulmonary and those with nonpulmonary risk factors. In addition, there was no statistically significant evidence that the low-VT strategy was less efficacious in any subgroup.[124] A meta-analysis came to a similar conclusion.[27]

Because hypoxemia is not a reliable predictor of mortality from ARDS, investigators have searched for other lung-specific markers of prognosis. In one prospective study of 179 patients with ARDS, a multiple logistic regression was performed to identify which clinical and physiologic variables predicted mortality.[129] The analysis found that the dead-space fraction (as calculated by the Bohr equation) was elevated in ARDS and was an inde-

pendent predictor of mortality. For every increase of 0.05 in the dead-space fraction, the odds of death from ARDS increased by 45%. The mechanism responsible for this association is not known: it is possible that the extent of pulmonary vascular injury in ARDS may be greater than previously suspected and may account for the increase in dead space.

The development of pulmonary fibrosis is also thought to carry a worse prognosis. Elevated procollagen III levels, which is a marker of collagen synthesis, have been found in the pulmonary edema fluid of patients with ARDS and have been shown to correlate with increased mortality.[130,131] In another study, 22 of 25 consecutive patients with ARDS underwent transbronchial biopsies of the most abnormally appearing areas on the chest radiographs. The mortality rate of patients whose biopsies showed fibrosis, regardless of severity, was significantly higher than the mortality rate of patients whose biopsies showed no fibrosis.[132]

Complications

ARDS is complicated by ventilator-associated pneumonia (VAP) in about 30% to 65% of cases. In this setting, VAP usually occurs more than 5 to 7 days after the onset of mechanical ventilation and is often preceded by colonization of the lower respiratory tract by potential pathogens.[133] The likely organisms include nonfermenting gram-negative rods, methicillin-resistant *Staphylococcus aureus*, and *Enterobacteriaceae*.[134] Although the development of VAP prolongs the duration of mechanical ventilation in ARDS, it does not appear to result in increased mortality.[133,135,136] Making a definitive diagnosis of VAP in patients with ARDS can be challenging because patients with ARDS have bilateral radiographic infiltrates and typically have leukocytosis and fever. If diagnostic techniques such as bronchoalveolar lavage or protected specimen brushes are used, the yield is higher when the lung is sampled bilaterally and when the patient is not receiving antibiotics.[136,137]

Barotrauma is another major complication of ARDS (pneumothorax, pneumomediastinum, subcutaneous emphysema), which occurs because of the effect of positive-pressure ventilation in heterogeneous lung regions with reduced compliance. Because most patients with ARDS are treated in the supine position (rather than erect), diagnosing a pneumothorax requires vigilance. The radiographic appearance of a pneumothorax is different and can be more subtle in the supine patient (e.g., air in the costophrenic angle, the "deep sulcus" sign). Data from a number of prospective studies suggest that the incidence of barotrauma in ARDS is 10% or less.[95,138,139]

THERAPY

Supportive Care

One of the first goals of therapy in ARDS is to treat the underlying cause. In particular, patients with sepsis may respond to aggressive source control, including antibiotics and, when possible, surgical débridement and drainage. In patients with ARDS and sepsis of unknown origin, both the lung and the abdomen should be considered and excluded as foci of infection.[122,123] Additional goals are the prevention of complications and the provision of supportive care (e.g., nutrition, ventilation) to allow the body time to heal. Typically, such treatment should include prophylaxis against gastrointestinal stress ulceration and deep venous thrombosis.

Hemodynamic Management

The optimal approach to hemodynamic management in ARDS has become less controversial. Until recently, it was not clear whether clinicians should try to treat pulmonary edema using diuresis at the risk of causing hypovolemia and renal dysfunction and inducing or aggravating shock.

This issue has been addressed by a large multicenter randomized, controlled trial from the ARDS Network, which consists of investigators at a number of different hospitals in the United States. The investigators randomized 1000 patients with ARDS to one of two strictly protocolized fluid strategies: using the administration of fluids, diuretics, or vasoactive agents, the two protocols targeted either a higher or a lower intravascular pressure for 7 days, as measured by a PA or central venous catheter. Patients randomized to the conservative fluid strategy (targeting a lower intravascular pressure) had significant improvements in oxygenation and more ventilator-free and intensive care unit–free days than the patients in the liberal strategy. Importantly, patients in the conservative arm did not have a higher incidence of dialysis or shock than those in the liberal arm. In addition, the mortality rates in the two arms were similar. Thus, the results of this study suggest that conservative administration of fluids after the initial 24 hours of resuscitation is safe and beneficial for patients with ARDS.

Superficially, this recommendation may seem at odds with the principle of early goal-directed therapy, whereby patients with sepsis are aggressively resuscitated with fluid in accordance with the randomized, controlled trial reported by Rivers and associates.[140] In that study, which did not specifically enroll patients with ARDS or consider ARDS as an outcome, patients with severe sepsis or septic shock who arrived in the emergency department were randomized to 6 to 8 hours of goal-directed therapy versus standard therapy before admission to the intensive care unit. Goal-directed therapy involved protocolized administration of crystalloid, red blood cells, and vasoactive and inotropic agents to achieve a central venous pressure of 8 to 12 mm Hg, a mean arterial pressure of 65 to 90 mm Hg, a central venous oxygen saturation of 70% or higher, and a hematocrit of 30% or higher. In the first 6 hours of the study (but not subsequently), patients in the goal-directed group received significantly more blood and crystalloid than patients in the control group. In addition, more patients in the goal-directed

group received dobutamine. The study found that patients randomized to the goal-directed group had a significantly lower in-hospital mortality rate than those in the control arm. In addition, patients in the goal-directed group were significantly less likely to require mechanical ventilation than patients receiving standard therapy, although the incidence of ARDS was not reported.

The apparently disparate results of these clinical trials are not difficult to reconcile. First, it is important to note that patients in the ARDS Network study were enrolled an average of 24 hours after meeting the criteria for ALI, much later than the 6-hour window in the study by Rivers and associates. In addition, the study protocol of the ARDS Network trial was strictly designed to avoid aggravating or inciting shock or pulmonary edema. An additional caveat is that the ARDS Network study used a very complex algorithm for fluid administration that may not be widely adopted. A simplified protocol has recently been proposed but has not been validated.[141] At present, the best clinical trial evidence suggests that clinicians should manage fluids conservatively, taking care to avoid overdiuresis and hypovolemia.

PA catheters have been used widely in patients with pulmonary edema in order to help establish the diagnosis and guide therapy. However, numerous clinical trials have shown that for most patients, the information from a PA catheter does not improve outcome.[10] PA catheters are no longer recommended for routine monitoring in patients with ARDS.

Which fluid to use in patients with ARDS remains an open question. Starch-based colloids are no longer used in patients with severe sepsis because of evidence from a randomized clinical trial showing a higher incidence of renal failure in patients with severe sepsis who received 10% pentastarch as compared with patients randomized to receive Ringer's lactate.[142] Whether pentastarch has the same detrimental effect in patients with ARDS without severe sepsis is unknown. On a theoretical basis, the use of albumin is appealing because it could increase intravascular oncotic pressure and favor less pulmonary edema formation. A small placebo-controlled study in ARDS demonstrated that a regimen of albumin and furosemide infusions over 5 days caused a substantial and statistically significant improvement in oxygenation accompanied by a decrease in heart rate. However, most of the patients had ARDS following trauma, with fewer than 5% having sepsis. There were no differences in important clinical outcomes (e.g., mortality), although the study was not designed to address these issues.[143] A follow-up study established that the beneficial effect on oxygenation was due to the albumin, not the furosemide.[144] Although a large clinical trial of patients admitted to the intensive care unit has concluded that albumin was as safe as crystalloid,[145] the study did not specifically enroll patients with ARDS and evaluated only short-term outcomes. It is important to remember that as a blood product, the administration of albumin is associated with a small but measurable risk of transmissible diseases. Thus, the role of albumin in the management of patients with ARDS is unclear and the routine use of albumin is not recommended.

Nutrition

Manipulations in diet have been hypothesized to favorably affect the immune system and improve the outcome of inflammatory diseases such as sepsis and ARDS. Dietary strategies have included supplementing enteral feedings with one or more of arginine, glutamine, omega-3 fatty acids, and antioxidants.

One small randomized study examined the effect of a modified enteral feed containing eicosapentaenoic acid, gamma-linolenic acid, and various antioxidants compared with a control enteral feed in patients with ARDS.[146] The authors found that the modified feed improved oxygenation, reduced the number of neutrophils in alveolar lavage fluid, decreased length of stay, and decreased the requirement for mechanical ventilation. A more recent study also found improved oxygenation from modified enteral feeds (containing eicosapentaenoic acid, gamma-linolenic acid, and various antioxidants), although clinically important outcomes were unchanged.[147] Other studies of modified enteral feeds (often called "immunonutrition") have been conducted in less well defined populations of critically ill patients, with conflicting results. A meta-analysis on the topic highlighted the heterogeneity of the studies and suggested that the effect of immunonutrition varied depending on the group of patients being studied.[148] At this point, the role of immunonutrition in the management of ARDS remains unclear.

Pharmacotherapy

Attempts to develop pharmacologic therapies for ARDS have been unsuccessful, with no pharmacotherapies that unequivocally reduce mortality from ARDS, despite randomized, controlled trials of many different therapeutic agents.[149] Despite the heterogeneity of the agents that have been evaluated, three generalizations can be observed:

1. Despite showing effectiveness in in vitro or in animal studies, most potential therapies have failed to reduce mortality or other important clinical outcomes in human clinical trials.
2. A number of agents improve oxygenation but do not affect mortality from ARDS.
3. Post hoc analyses of subsets of patients from a number of studies of various agents suggest benefit, but prospective data are lacking

Corticosteroids

Because of the presumed inflammatory pathophysiology underlying ARDS, a number of trials of high-dose corticosteroids have been performed. In some, the goal was the prevention of ARDS in patients at risk (e.g., with septic shock), whereas in others, steroids were given to patients with established ARDS. The initial regimens included methylprednisolone 30 mg/kg in divided doses

every 6 hours for 1 to 2 days. None of the trials using this treatment regimen showed any benefit from the use of steroids,[150,151] and one showed a higher incidence of infection in patients who were treated with corticosteroids.[152] More recently, the use of steroids has been evaluated later in the course of ARDS, during the fibroproliferative phase. Persistently elevated plasma cytokine concentrations have been shown to correlate with worsened survival from ARDS, prompting some to theorize that late ARDS (>7 days after onset) is characterized by persistent inflammation that might be responsive to treatment with steroids. A small study randomized 24 patients with late ARDS to 2 mg/kg of methylprednisolone (followed by a 32-day taper) or placebo. Patients in the steroid group had lower mortality, improved oxygenation, decreased organ dysfunction, and earlier extubation but also had a higher (but not statistically significant) rate of infection.[153] However, these data have been controversial because of the small sample size and the number of patients who crossed over to the alternate therapy.

A randomized, placebo-controlled trial of 180 patients with ARDS of at least 7 days' duration was subsequently performed by the ARDS Network.[154] Patients were randomized to either placebo or a single dose of 2 mg/kg of methylprednisolone followed by 0.5 mg/kg every 6 hours for 14 days, then every 12 hours for 7 days, then tapering. Although the patients randomized to methylprednisolone had improvements in ventilator-free and shock-free days (during the first 28 days) as well as in oxygenation, there was no difference in the overall 60-day mortality. A subgroup analysis revealed that patients who were treated with steroids beginning more than 14 days after the onset of ARDS had a significantly increased 60- and 180-day mortality rate. The issue of whether to use steroids in late ARDS remains controversial.[155]

Vasodilators

Prostaglandin E_1 (PGE_1) is a vasodilator that has been studied as a potential therapy for ARDS, based largely on its anti-inflammatory properties. In vitro and preclinical studies in animals suggested that PGE_1 given parenterally, especially when administered in a liposome, had the potential to decrease neutrophil activation. Despite promising early data,[156] a large randomized, double-blind, multicenter trial of liposomal PGE_1 found that there was no improvement in survival or in ventilator dependence, even though the drug improved oxygenation.[157]

Prostacyclin (prostaglandin I_2 [PGI_2]) is another vasodilator that when administered by nebulizer, acts on the pulmonary vasculature. Because the aerosolized solution will distribute in the better-ventilated areas of the lung, vasodilation of the branches of the PA that supply these areas will lead to improved ventilation-perfusion matching and improved oxygenation. Although PGI_2 has been used as rescue therapy for refractory hypoxemia and is well tolerated,[158] there are no large randomized studies and no placebo-controlled studies of its use in ARDS.[159,160]

NO is a highly reactive gas formed endogenously by NOS from the amino acid arginine. It stimulates cellular guanylate cyclase, leading to increased cyclic guanosine monophosphate levels. NO acts as a potent vasodilator, and when administered by inhalation, NO causes vasodilation of the pulmonary circulation. NO is rapidly inactivated in the bloodstream by combining with hemoglobin to form methemoglobin, which is usually rapidly metabolized and does not accumulate to levels that are thought to be toxic (i.e., methemoglobin < 5%). Because of this rapid inactivation, inhaled NO is a selective vasodilator in the pulmonary circulation that does not affect the systemic circulation. Like aerosolized PGI_2, NO causes the most vasodilation in the areas of lung that are best ventilated, thereby improving ventilation-perfusion matching.[161] In addition, NO has both anti- and pro-inflammatory properties, although the contributions of these properties to its effects in a clinical setting are unclear.[162] NO also reacts with oxygen and water to form toxic metabolites, such as NO_2 and nitrous and nitric acid, although at concentrations of NO of less than 40 parts per million (ppm), this problem is not usually clinically significant. A soda lime absorber can be placed in the inspiratory limb of the NO circuit in order to remove any NO_2 before the inspired gas reaches the patient.

In a large randomized, double-blind, placebo-controlled study of NO in ARDS, over 170 patients were randomized to different doses of NO (ranging from 1.25 to 80 ppm) or placebo. Although approximately 60% of the patients had a significant improvement in oxygenation within 4 hours of NO administration, there were no differences between the groups in survival or in weaning from mechanical ventilation.[163] In addition, the initial improvement in oxygenation from NO was not sustained over the course of study. There were few adverse effects of NO, and for patients who were treated with less than 40 ppm inhaled NO, the methemoglobin and NO_2 levels were the same as in the placebo group. The results of this study confirmed the findings of other smaller unblinded trials of NO in ARDS,[164,165] and were repeated in a more recent systematic review.[166] In another large randomized but unblinded study of NO in ARDS, a higher proportion of patients in the NO group required renal replacement therapy than in the control group.[167] A recent meta-analysis of trials using NO for ARDS concluded that although NO caused initial improvement in oxygenation, it had no effect on survival and was associated with an increased risk of renal dysfunction.[168] Therefore, NO should not be used routinely in the treatment of patients with ARDS, other than as a "rescue" therapy for life-threatening hypoxemia, despite the lack of evidence for an improvement in survival.

Surfactant

A number of surfactant abnormalities have been described in ARDS (see section on "Etiology and Pathogenesis"). These include an increase in relatively inactive forms, inactivation of surfactant by plasma proteins that

have leaked into the alveolar space, damage to type II epithelial cells (which produce surfactant lipids and proteins), and destruction of surfactant constituents by the inflammatory process.[37] These changes, along with the efficacy of surfactant supplementation in the neonatal respiratory distress syndrome, led to clinical trials of surfactant supplementation in patients with ARDS. Data from animal studies and small case series were promising.[169] In a small randomized trial, patients with ARDS were treated with bovine surfactant administered through an endotracheal catheter. One subgroup of patients showed an improvement in oxygenation and a trend to decreased mortality.[170]

Enthusiasm for surfactant was dampened by the results of a large multicenter randomized, blinded, placebo-controlled trial. In this study, investigators administered an aerosolized synthetic (protein-free) surfactant or saline placebo continuously for up to 5 days to patients with new-onset (<48 hr) ARDS associated with sepsis. There was no physiologic or clinical benefit from the surfactant. Despite its methodologic rigor, the study has been criticized because less than 5% of the administered dose of surfactant was thought to have reached the distal lung. In addition, the lack of surfactant proteins in the synthetic surfactant may have diminished its ability to reduce surface tension.[171] Because of these issues, the role of surfactant supplementation continues to be studied.

In a phase I-II trial, 40 patients with new-onset ARDS were randomized to a surfactant protein C preparation (given up to four times over 24 hr) or to no drug. The surfactant was administered through a catheter placed in the endotracheal tube. The drug had no effect on oxygenation or on ventilator-free days, which were the primary outcomes of the study. The authors reported a significant decrease in IL-6 levels in bronchoalveolar lavage fluid from patients who received the surfactant preparation, although it is unclear whether this was a prespecified end point.[172]

Two phase III trials of the recombinant surfactant protein C–based preparation have been completed. The studies demonstrated that the surfactant improved oxygenation but had no effect on mortality or ventilator-free days. Only one trial, using calfactant (a natural surfactant, distinct from previous trials) in pediatric patients with ARDS, has shown any mortality benefit.[38] Whether this was due to the unique surfactant used in this study or to differences between the patients enrolled in this trial and the negative trials (e.g., adult vs. pediatric) is unknown. Whether surfactant will prove to be useful in well-defined subgroups of patients with ARDS remains an open question.[33,37a]

Antioxidants and Anti-inflammatory Agents Other than Steroids

Oxidative stress is thought to be involved in the pathogenesis of ARDS.[57] In fact, lung injury due to hyperoxia is a commonly used model to study ARDS in animals. Reactive oxygen species form as a by-product of the activation of neutrophils and macrophages; in addition, the requirement for a high F_{IO_2} in many patients with ARDS is likely to predispose to oxidative stress in the lungs. Decreased levels of glutathione, a major endogenous scavenger of reactive oxygen species, have been found in the alveolar fluid of patients with ARDS, including those who have a history of excessive alcohol use. Small clinical trials with *N*-acetylcysteine and procysteine were promising.[173] However, larger clinical trials of antioxidants in ARDS have been disappointing. A multicenter trial of the antioxidant procysteine in ARDS showed no beneficial effect of the drug.[39]

Various agents with potential anti-inflammatory effects have been tested in ARDS. These include ketoconazole, lisofylline, and (in patients with sepsis at risk for ARDS) the nonsteroidal anti-inflammatory drug ibuprofen. In separate, well-conducted, randomized, blinded, controlled trials, none of these agents showed a benefit in patients with ARDS.[174–176] A prospective randomized, controlled trial tested the effect of recombinant platelet-activating factor acetylhydrolase on preventing ARDS in patients with severe sepsis. This trial of over 100 patients showed no reduction in the development of ARDS in patients who received the drug; however, the mortality rate was lower in patients treated with an intermediate dose of the study drug.[177] Other trials of potential anti-inflammatory therapies in sepsis have been disappointing.[69]

Novel Therapies

As discussed earlier in the section on "Etiology and Pathogenesis," alveolar fluid clearance can be augmented by catecholamines. A small trial randomized 40 patients with ALI/ARDS to intravenous salbutamol or placebo for 7 days.[86] Patients receiving salbutamol had a decrease in extravascular lung water but a higher incidence of arrhythmias. A new clinical trial of aerosolized albuterol for ALI/ARDS is being performed by the ARDS Network.[141]

Stem cell therapy for ARDS is being actively explored. Experimental studies have shown beneficial effects in animals treated with endotracheal or intravenous hematopoietic stem cells[178] as well as hematopoietic stem cells transfected with Ang-1.[179]

Discrepancies between Studies in Animals and Humans

Virtually all large-scale clinical trials of pharmacotherapy in patients with ARDS have been negative, despite often promising preclinical studies in animal models of lung injury. There are a number of reasons why positive results in animal studies have not been replicated in human clinical trials. First, in animal studies, the agent being investigated is often administered at the same time or shortly after the lungs are injured (e.g., cecal ligation and perforation followed by administration of the drug within a few hours). In contrast, the onset of lung injury in humans is often much more difficult to define, and experimental therapies are often given hours or days after the diagnosis is made. Thus, agents that might have been effective at preventing or attenuating ARDS may

have be given too late. Second, most "proof of principle" animal studies are of relatively short duration and do not mimic the complicated clinical course of human ARDS. Third, animals in most studies represent a homogeneous group; in contrast, human patients have multiple comorbidities and often have multiple cointerventions. Fourth, the underlying precipitating factor for ARDS, even in carefully selected subgroups of patients, often differs in severity and duration among the study patients, unlike the situation in animals, in which a uniform injury is applied. This heterogeneity makes it challenging to identify agents that may be of only modest clinical benefit. Finally, the current definition of ARDS is imprecise, and as a result, clinical studies might include many patients with different pathophysiology or biology.

Mechanical Ventilation

Introduction

Mechanical ventilation is lifesaving and is the standard therapy for ARDS. Ventilatory management of ARDS has undergone a dramatic change since the early 1990s, in large part due to increased usage of computed tomography (CT) to image the lungs and to advances in our understanding of VILI.

Pressure and Volume Limitation

Mechanical ventilation of patients under anesthesia for surgery traditionally involves large VTs of 10 to 15 mL/kg, with the dual goals of achieving normal arterial oxygenation and arterial pH. A similar approach to ventilating patients with ARDS was followed in the past. This emphasis on achieving normal physiologic parameters in patients with ARDS was understandable at the time: in addition to being characterized by profound hypoxemia and diminished pulmonary compliance, ARDS was thought to involve the lungs diffusely and homogeneously based on chest radiography.[1] A large VT, therefore, appeared to be the best approach to ventilate patients and maintain oxygenation. Subsequently, studies using CT[180] demonstrated that the lungs of many patients with ARDS appear heterogeneous: instead of the diffuse involvement suggested by plain chest radiographs, CT scans often show patchy infiltrates, interspersed with more normal-appearing areas of lung (see Fig. 90-4). The heterogeneous distribution of the injury in ARDS implies that the VT administered to a patient will preferentially inflate the more compliant (or normal) areas of lung. These regions of the lung, exposed to VTs meant for an entire lung, are therefore at risk for overdistention and VILI. As discussed earlier, mechanical ventilation with excessive VTs can cause pulmonary edema due to increased alveolar-capillary permeability, remarkably similar histologically to ARDS.

Despite the clear physiologic rationale and abundant experimental data to support pressure and volume limitation when ventilating patients with ARDS, it was not until the late 1990s that data from randomized clinical trials in humans began to accrue. Between 1998 and 2000, five randomized controlled trials of ventilation strategies in ARDS were published.[95,139,181–183] In all of the trials, patients were randomized either to a strategy involving some degree of VT and pressure limitation or to a "conventional" ventilation strategy with higher VT and pressure limits. Of the five studies, the largest was conducted by the ARDS Network, composed of investigators from hospitals in the United States and supported by the U.S. National Institutes of Health NIH National Heart, Lung, and Blood Institute.[95] This study, which was more than seven times larger than any of the other four studies, randomized 861 patients to lower VTs or traditional VTs. In the traditional group, plateau pressure was also kept below 50 cm H_2O. In the small-volume group, VT was set at 6 mL/kg of predicted body weight and reduced if necessary to maintain plateau pressure between 25 and 30 cm H_2O. Respiratory acidosis was treated aggressively, with the ventilator rate being set at 6 to 35 breaths/min to achieve a pH of 7.3 to 7.45. Bicarbonate infusions were allowed for acidosis that persisted despite a ventilator rate of 35/min. VT was increased for refractory acidemia, until pH was higher than 7.15. Only preset combinations of PEEP and F_{IO_2} were allowed in the two groups, for a target oxygen saturation of 88% to 95%. Patient-ventilator dyssynchrony was reduced by sedating patients when necessary (Table 90-3).

The trial, which originally set out to enroll 1000 patients, was stopped early because an interim analysis showed benefit in the small-VT group. The mortality rate was 39.8% in the traditional group compared with 31.0% in the small-VT group (P = .007). Breathing without assistance at day 28 was also significantly more frequent

TABLE 90-3. Ventilation Protocol Used in the Acute Respiratory Distress Syndrome Network Study

Parameter	Protocol
Mode of ventilation	Volume assist-control
Tidal volume	≤6 mL/kg predicted body weight*
Plateau pressure	≤30 cm H_2O
Frequency	6–35 breaths/min, titrated for pH 7.30–7.45
I:E ratio	1:1 to 1:3
Oxygenation goal	Pa_{O_2} 55–80 mm Hg, or Sp_{O_2} 88%–95%
F_{IO_2}/PEEP (cm H_2O) combinations allowed	0.3/5, 0.4/5, 0.4/8, 0.5/8, 0.5/10, 0.6/10, 0.7/10, 0.7/12, 0.7/14, 0.8/14, 0.9/14, 0.9/16, 0.9/18, 1.0/18, 1.0/20, 1.0/22, 1.0/2
Weaning	By pressure support, required when F_{IO_2}/PEEP ≤ 0.4/8

*See text for formula to calculate predicted body weight.
F_{IO_2}, fractional concentration of oxygen in inspired gas; I:E ratio, ratio of inspired to expired gas; Pa_{O_2}, arterial oxygen pressure; PEEP, positive end-expiratory pressure; Sp_{O_2}, pulse oximetry.
Data from Anonymous: Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. The Acute Respiratory Distress Syndrome Network (comment). N Engl J Med 342:1301–1308, 2000.

in the small-volume group, and the number of ventilator-free days was higher. The number of days without organ failure was also higher in the small-volume arm.

The other study to show a survival benefit was much smaller, involving just over 50 patients.[183] In this study, unlike the ARDS Network study, static inspiratory pressure-volume curves of the total respiratory system were determined in all patients after their condition was stabilized, but before randomization. Patients were randomized to either conventional ventilation or a "protective" ventilation strategy. Conventional ventilation consisted of VTs of 12 mL/kg and PEEP was set according to an algorithm to optimize oxygenation with a F_{IO_2} of 0.6 or lower. There was no stated limit to airway pressures in the control group. Protective ventilation included a VT of 6 mL/kg or lower and peak pressures of less than 40 cm H_2O. Driving pressures (plateau pressure, PEEP) were kept at less than 20 cm H_2O. PEEP was set at 2 cm H_2O above the lower inflection point of the pressure-volume curve (as measured prior to randomization), and the protective ventilation group also underwent "frequent" recruitment maneuvers, in which continuous positive airway pressure of 35 to 40 cm H_2O was applied for 40 seconds. In the protective group, pressure-controlled inverse-ratio ventilation was used if the F_{IO_2} exceeded 0.5.

The study was stopped early because a significant survival difference was detected: 38 % of the protective-ventilation group had died at 28 days compared with 71% in the conventional group ($P < .001$). There was no significant difference in survival to hospital discharge between the two arms, although there was a very strong trend in favor of the protective group. The rate of barotrauma was also significantly different: 7% in the protective ventilation arm versus 42% in the conventional ventilation group.

Unfortunately, multiple confounding factors affect the interpretation of this small trial. Airway pressure was not limited in the control arm, and mean plateau pressure exceeded 35 cm H_2O in those patients. Although the study showed an impressive 33% absolute reduction in 28-day mortality, the mortality rate in the traditional ventilation group was 71%, much higher than in all of the other trials. In addition, the population studied was substantially younger than patients in other trials, with a mean age of about 35 (compared with 50–60 years in the other studies). Finally, the rate of barotrauma in the traditional group, 42%, was approximately four times higher than in other trials.

A key factor in comparing trials is to appreciate that the ARDS Network study used predicted body weight, whereas other studies used ideal body weight or measured body weight. The distinction is worth emphasizing because data from the ARDS Network study showed that measured body weight was approximately 20% higher than predicted body weight. In other words, the VT used in other studies may have been higher than appreciated based on predicted body weight. Predicted body weight in kilograms can be calculated for male patients as 50 + 0.91(height [in cm] − 152.4), and for female patients as 45.5 + 0.91(height [in cm] − 152.4).[95]

The ARDS Network study adopted an aggressive approach to hypercarbia and acidemia, including tachypnea, bicarbonate infusions, and loosening of ventilatory restrictions. As a result, hypercarbia and subsequent low pH in the treatment arm was less marked than in other studies. This too may have contributed to the lower mortality in the lower-VT arm.

Some investigators have proposed that mechanical ventilation in a particular patient should be based on the static inspiratory pressure-volume curve of the patient's respiratory system.[183] In ARDS, such curves often have a sigmoidal shape, with a lower inflection point at low lung volumes and an upper inflection point at high volumes. Initially, it was thought that the lower inflection point represented the pressure at which collapsed lung units reexpand, explaining the abrupt change in compliance. The upper inflection point was felt to represent the pressure at which alveolar overdistention occurs. On this basis, it was proposed that PEEP should be set higher than the pressure of the lower inflection point, and plateau pressure should be kept lower than the upper inflection point. Although conceptually appealing, this interpretation of the static inspiratory pressure-volume curve is likely to be erroneous. Recruitment of the lung is known to continue even above the lower inflection point,[184] and tidal ventilation in patients with ARDS may take place on the expiratory (rather than the inspiratory) limb of the pressure-volume curve.[185] Because of this, setting ventilatory parameters based on the static inspiratory pressure-volume curve remains controversial.[186]

The Role of Positive End-Expiratory Pressure and Recruitment Maneuvers

The first description of ARDS commented on the utility of PEEP in improving oxygenation. From a theoretical standpoint, PEEP may be beneficial in avoiding damage from cyclic opening and closing of terminal lung units (atelectrauma, see "Etiology and Pathogenesis" section) and in allowing for a reduction in VT (and hence volutrauma). In addition, the improvement in oxygenation that often occurs with PEEP may allow for lowering of the F_{IO_2}, decreasing the risk of oxygen toxicity. Conversely, PEEP that is too high can cause excessive end-inspiratory lung volume and volutrauma. PEEP also has the potential to depress cardiac output and blood pressure by raising mean intrathoracic pressures. The optimal level of PEEP to use in patients with ARDS has, therefore, been a source of controversy.[187–189]

Along the same lines, the low VTs and pressures advocated for lung-protective ventilation can lead to progressive derecruitment of the lungs, which can worsen hypoxemia and aggravate atelectrauma. To counteract derecruitment, the use of recruitment maneuvers has been proposed. These maneuvers involve increasing the airway pressure for a defined period of time, although the pressure to be applied and the duration of its application have not been standardized. An example of a recruitment maneuver would be to apply 40 cm of H_2O of continuous positive airway pressure for 40 seconds.

Similar to the problems with setting the level of PEEP, however, it is difficult to predict which patients might benefit from recruitment maneuvers and which might be harmed by overdistension of the lungs. Overdistention of well-perfused lung units could result in diversion of blood to poorly perfused alveoli, with consequent worsening of right-to-left shunt and hypoxemia.[190]

Several randomized, controlled trials have addressed the issue of PEEP and recruitment maneuvers in the management of ARDS. The ARDS Network investigators randomized 549 patients with ALI/ARDS to lower or higher PEEP levels, according to preset combinations of PEEP and F_{IO_2}. The patients in the lower PEEP arm received the PEEP/F_{IO_2} levels used in the original ARDS Network trial of lung-protective ventilation (see earlier). The precise level of PEEP used in the higher arm varied with the F_{IO_2}, but was on average 5 cm of H_2O higher than the control arm (mean of 13–15 over the first 7 days). Recruitment maneuvers were initially used in the higher PEEP group but were discontinued after the first 80 patients because they were not very effective.[191] The study was stopped early due to perceived futility and the mortality rate in both arms was about 25%, significantly lower than had been reported in other trials of ARDS.[192]

A second large trial randomized almost 1000 patients with ALI/ARDS to what was described as an "open-lung" strategy versus the ventilation protocol used in the original ARDS Network trial.[193] The "open-lung" strategy consisted of pressure-control ventilation, recruitment maneuvers, and high PEEP (Pplat < 40) in addition to the low V_Ts used in the control group. On average, on day 1 of the study, PEEP in the open-lung arm was 16 cm H_2O, compared with 10 cm H_2O in the control group. This trial also found no difference in the mortality rates between the two groups (~40%), although the open-lung group had improvements in secondary end points related to hypoxemia.

Finally, a large French trial randomized 767 patients with ALI to PEEP of 5 to 9 cm H_2O or PEEP maximized as long as Pplat was less than 28 to 30.[194] On day 1 of the study, the mean applied PEEP level in the control arm was about 7 cm H_2O, or marginally lower than that of patients in the original ARDS Network trial of lung-protective ventilation, whereas the higher PEEP arm had an average applied PEEP of 15 cm H_2O. The study demonstrated no difference in mortality, but the higher PEEP arm had improved compliance, oxygenation, and a decreased duration of mechanical ventilation and organ failure.[194]

Taken together, the data from these trials suggest that higher levels of PEEP than used in the original ARDS Network trial are safe and improve oxygenation but they do not appear to change mortality. Why these clinical studies are generally negative despite very strong animal data showing the benefits of higher levels of PEEP is puzzling. One possibility is the yin-yang of PEEP. When PEEP recruits lung units, it may be beneficial; but when PEEP leads to greater overdistention of lung units, it may be harmful. In all studies to date, PEEP has been applied to all patients whether or not their lungs are recruitable. As such, one reasonable approach to be tested in future studies of PEEP is to randomize only patients to a high/low PEEP strategy if they have lung regions that are potentially recruitable.[189,195]

The data also suggest that the role of recruitment maneuvers in the management of ARDS is primarily supportive, in that they are unlikely to improve clinically important outcomes. Many studies report a variable and transient improvement in oxygenation after some form of recruitment maneuver,[191] although it is possible that the same degree of recruitment could be achieved by simply raising the level of PEEP.[196,197] Although recruitment maneuvers are generally safe, the patient must be closely monitored for any adverse effects on hemodynamics or oxygenation.

Permissive Hypercapnia and Tracheal Gas Insufflation

The use of lower V_Ts (to avoid VILI) often results in respiratory acidemia, an effect that has been termed "permissive hypercapnia." The theoretical detrimental effects of hypercapnia include myocardial depression, increased pulmonary vascular resistance, and decreased renal blood flow. Perhaps the most clinically important adverse effect of hypercapnia is elevated intracranial pressure from increased cerebral blood flow. However, there are data suggesting that hypercapnia has protective effects, including attenuation of free radical–mediated lung injury and pulmonary inflammation[198,199]; other studies have reported an injurious effect on alveolar epithelial cells.[200] Given the uncertainty about permissive hypercapnia, it is worth remembering that the only large randomized, controlled trial to show a reduction in mortality in ARDS treated respiratory acidosis aggressively. In the absence of other data, following the protocol used in that study seems prudent.

One approach that has been used to decrease high levels of arterial carbon dioxide pressure (P_{aCO_2}) is tracheal gas insufflation (TGI). TGI is a technique whereby a gas flow is introduced via a small catheter placed in the endotracheal tube, with its tip near the carina. TGI has been proposed as an adjunct to permissive hypercapnia, as the insufflated gas improves CO_2 clearance from the anatomic dead space and ventilator tubing. However, the gas flow has the potential to increase alveolar volume and pressure and may increase PEEP.[201] Although many case reports describe the use of TGI,[202] there have been no randomized studies of TGI in patients with ARDS. Because of technical and monitoring issues related to TGI, routine use of TGI in ARDS is not recommended.

Mechanical Ventilation of Patients in the Prone Position (Proning)

Placing patients with ARDS in the prone position was described almost 30 years ago as a means of improving oxygenation. The mechanisms by which this improvement occurs are multiple, but the most important factor is probably the effect that the prone position has on chest wall and lung compliance.[203] In the supine posi-

tion, the most dorsal and caudal regions of lung (along the spine and diaphragm) are the worst affected in many patients with ARDS. Some of this is due to gravity, but the weight of the heart and of the abdominal organs on the lungs also contributes. When a patient is placed in the prone position, the anterior chest wall is fixed (by the bed) and becomes less compliant, thus increasing the proportion of ventilation directed to the dorsal lung. In addition, the volume of lung that is being compressed by the heart due to gravity is substantially decreased. The net result is more homogenous ventilation of the lungs and improved ventilation-perfusion matching. Data from a study in dogs suggest that ventilation in the prone position can attenuate the severity of VILI.[204]

A number of multicenter randomized, controlled trials have now examined the efficacy of ventilating patients with ARDS in the prone position. One study enrolled over 300 patients with ALI or ARDS and randomized them to conventional treatment (supine) or treatment in the prone position for 6 or more hours for 10 days. The study found that oxygenation improved in approximately 70% of prone treatment procedures and that most of the improvement was evident within 1 hour of placing patients in the prone position. However, although oxygenation improved significantly each time the patients were placed in the prone position, there was no difference in mortality between the groups. Retrospective analyses of the quartile of patients with the poorest oxygenation or the highest acuity of illness (or the highest VT) showed a lower mortality rate at 10 days in the patients who had been treated in the prone position, but this difference did not persist beyond discharge from the intensive care unit.[205] The study has been criticized for the relative short duration of the intervention and the fact that most patients spent the majority of the day supine.[206]

A subsequent study randomized over 700 patients with acute hypoxemic respiratory failure to ventilation in the prone or supine position; patients were placed in the prone position an average of 50 hours after intubation for a median of 8 hr/day for a median of 4 days.[207] Patients who were treated in the prone position had improved oxygenation but no improvement in mortality or the duration of mechanical ventilation. These patients also suffered from a higher incidence of complications, including pressure sores, selective intubation, and obstruction of the endotracheal tube. A study of prone positioning in pediatric patients with lung injury (median age 2 yr) was similarly negative,[208] and two recent Spanish trials of prone treatment for adults with ARDS were inconclusive, but suggestive of benefit.[209,210]

Prone ventilation should not be used routinely in all patients with ARDS. It is a reasonable salvage maneuver for a patient at imminent risk of death from hypoxemia, because multiple studies have demonstrated that it can increase oxygenation. A more difficult question is how to manage patients who have severe ($PaO_2/FiO_2 < 100$), but not life-threatening, hypoxemia. Evidence from 4 trials[205,207,209,210a] (admittedly post hoc and each statistically insignificant) suggests a reduction in mortality in such patients.[210b] This, along with a biologically plausible mechanism-less oxygen toxicity attributable to lower FiO_2 during prone positioning, which is likely to be more important at higher FiO_2 levels (i.e., in patients with severe hypoxemia), suggests that prone ventilation is a reasonable treatment option for these patients. However, given the potential complications of proning, it should ideally be performed only in centers that have expertise with this modality.

Volume-Control versus Pressure-Control Ventilation

The volume- and pressure-limited protocol in the ARDS Network study used volume-assist control as the mode of ventilation. The Lung Open Ventilation study showed that pressure-control ventilation could be used with equivalent outcomes.[193] Other studies that have examined this issue have also found little difference in physiologic parameters or outcome between the two modes of ventilation.[211,212]

High-Frequency Jet Ventilation and High-Frequency Oscillation

In high-frequency jet ventilation (HFJV), a small-gauge catheter is used to introduce gas under high pressure into the endotracheal tube. The high velocity of the gas entrains additional oxygen and humidified air from side ports in the system. This form of mechanical ventilation achieves a VT of 2 to 5 mL/kg and involves frequencies of 100 to 200 breaths/min.[213] Exhalation is passive, requiring recoil of the lungs and chest wall. There is little evidence that HFJV is superior to conventional mechanical ventilation for ARDS. A randomized trial of over 300 oncology patients compared conventional ventilation (using volume-cycled ventilation) to HFJV. The end points of the study were physiologic and differed between the two groups of patients, making it difficult to interpret the data. Nonetheless, the authors found no significant difference in any clinically important outcome.[214]

In high-frequency oscillation (HFO), lung recruitment is maintained using a constant mean airway pressure, generated by an inspiratory bias flow and limitation of gas outflow from the circuit. Ventilation is achieved through rapid (e.g., 5 Hz) regular oscillations of a piston or diaphragm. The push-and-pull action of the piston causes oscillations in pressure in the endotracheal tube and proximal airways, creating peak and trough pressures around the set mean airway pressure. The VTs achieved through HFO are small, on the order of 1 to 5 mL/kg. In theory, HFO seems ideally suited for avoiding VILI; atelectrauma is minimized because of the relatively high mean airway pressure, which along with small VTs, limits derecruitment of the lung, and volutrauma is minimized because the small VTs limit end-inspiratory stretch.[215] Recruitment maneuvers (e.g., application of continuous positive airway pressure for ~30–40 sec) should be applied after each time the patient is disconnected from the ventilator (e.g., open suctioning), because loss of pressure from the circuit during

disconnection will lead to portions of the lung becoming atelectatic (derecruited).

In the first of two randomized trials of HFO in adults, 148 patients with ARDS were randomized to conventional ventilation using the pressure-control mode or to HFO.[216] The specific ventilatory parameters for both the conventional group and the HFO group were adjusted to achieve adequate oxygenation at a minimum F_{IO_2} (i.e., 88% at $F_{IO_2} \leq 0.60$) as well as an arterial pH > 7.15. As the study was begun before the publication of the ARDS Network trial on V_T limitation, the conventional ventilation arm of this study targeted V_Ts of 6 to 10 mL/kg. The trial was not powered to detect a mortality difference, and there was no significant difference in 30- or 90-day mortality or in any other outcome. The authors performed a retrospective analysis of predictors of mortality and discovered that being on conventional ventilation for more than 5 days correlated with a poor outcome.

A smaller study enrolled patients with ARDS an average of 2 days after intubation and randomized them to HFO versus ventilation using a conventional ventilator (V_T 8–9 mL/kg predicted body weight, peak inspiratory pressure < 40 cm H_2O). The study was stopped prematurely after enrolling only 37 patients and there was no difference in outcome between the two groups.[217]

In summary, although the physiologic rationale for using HFO in ARDS seems sound, the lack of data showing any clinically important advantage has limited its general acceptance.

Inverse-Ratio Ventilation

The normal ratio of inspiration to expiration (I:E) ranges from 1:2 to 1:4, varying with the respiratory rate. Inverse-ratio ventilation (IRV) refers to a mode of ventilation in which the duration of inspiration is extended to yield an I:E ratio greater than 1. Clinicians found that IRV could improve oxygenation (by decreasing right-to-left shunt) in ARDS while allowing lower peak inspiratory and end-expiratory airway pressures. However, the mechanism of the improvement in oxygenation is likely due to the increase in mean airway pressure due to the longer inspiratory time or as I:E is increased due to the generation of auto-PEEP because of the shortened time available for expiration. This latter mechanism would lead to an increase in end-expiratory alveolar volume. IRV causes an increase in mean airway pressure relative to conventional ventilation, even though peak airway pressure is lower. The same reduction in right-to-left shunt can be achieved using a normal I:E ratio by increasing the applied (extrinsic) PEEP alone. For the same reduction in shunt, the mean airway pressure is elevated more by IRV than by simply raising the PEEP. Because of concerns about volutrauma, the fact that IRV increases mean airway pressure (and hence mean alveolar volume) relative to extrinsic PEEP makes it less attractive. In addition, IRV is uncomfortable for patients and often requires the administration of sedatives and neuromuscular blocking agents. For these reasons, IRV is not usually used in the management of ARDS.[218]

Liquid Ventilation

Liquid ventilation relies on the oxygen- and carbon dioxide–carrying capacity of organic liquids such as perfluorocarbons. Perfluorocarbons are modified hydrocarbons in which hydrogen atoms are replaced with fluorine, generating inert liquids that are nontoxic and minimally absorbed through the respiratory epithelium. The most widely studied perfluorocarbon, perflubron (perfluorooctylbromide), can dissolve about 17 times more O_2 than saline solution and almost four times more CO_2.[219] Total liquid ventilation is a technique in which the lungs are completely filled with liquid and an extracorporeal exchanger is used to add O_2 and remove CO_2 from the liquid. Partial liquid ventilation, which is much easier to use clinically, involves partially filling the lungs with liquid and then using a traditional ventilator to deliver gas V_Ts.[220]

The theoretical benefits of liquid ventilation stem largely from improved lung recruitment, due to the lower surface tension of the perfluorocarbons and because the liquid tends to distribute to the dependent regions of the lung. Deposition of liquid with low surface tension in these areas may enhance alveolar recruitment. In addition, the weight of the liquid is thought to cause diversion of pulmonary blood flow to the nondependent (better-ventilated) areas, improving ventilation-perfusion matching. Clearance of secretions (due to their displacement by the liquid) is also improved. Anti-inflammatory effects of perflubron have been described, although the clinical relevance of these effects is not well understood.

Two randomized, controlled trials of partial liquid ventilation in adults with ARDS have been published.[221] The first randomized 90 patients with ARDS to partial liquid ventilation with perflubron or to conventional mechanical ventilation. Other than very general guidelines (such as target arterial oxygen saturation [Sa_{O_2}] > 90%), neither of the two ventilation strategies was protocolized. In addition, the inclusion and exclusion criteria were modified slightly during the course of the study. There was no significant difference in the number of ventilator-free days (the primary outcome measure) or in any other predefined outcome. More patients in the liquid ventilation arm experienced hypoxia, bradycardia, and respiratory acidosis, although the increase in the incidence of these adverse events was not statistically significant.

More recently, a multicenter randomized trial of partial liquid ventilation with perfluorocarbon compared with conventional mechanical ventilation (V_T 10 mL/kg) enrolled over 300 patients with ARDS.[222] The study found a trend toward higher mortality in the groups receiving perfluorocarbon, in addition to a higher incidence of barotrauma, hypoxia, and hypotension.[222] Based on these data, partial liquid ventilation cannot be recommended for patients with ARDS.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO), also referred to as extracorporeal life support (ECLS) or

extracorporeal lung assist (ELA), refers to the process by which the patient's blood is circulated to an external machine that provides oxygenation and/or carbon dioxide removal.[223] In theory, ECMO could be used to oxygenate patients with ARDS while minimizing VILI and oxygen toxicity and allowing the lungs time to heal. There are many case reports of ECMO being used in ARDS,[223a] and it is used routinely in neonates with severe respiratory failure. A randomized, controlled trial of ECMO in ARDS was published in 1979 and did not show any benefit.[224] However, the mortality rate in that study was approximately 90% in both the ECMO and the control arms. Subsequently, a variant of ECMO dedicated to carbon dioxide removal (extracorporeal carbon dioxide removal, or $ECCO_2R$) was developed and showed promise in a case series when compared with a historical control group.[225] This was followed by a randomized, controlled trial using pressure-controlled IRV and $ECCO_2R$ in ARDS, but this trial failed to find any improvement in survival.[226] This study illustrates the importance of using concurrent controls when assessing a novel therapy.

Patients on ECMO have a high rate of bleeding; in the most recent randomized trial, patients randomized to the device were transfused an average of 1.7 L of blood/day. Because of its cost and the lack of evidence to support its use, ECMO is not recommended in the management of most patients with ARDS.

Summary

The modern approach to mechanical ventilation of patients with ARDS is based on two facts: first, the pathogenetic injury in ARDS affects the lungs heterogeneously; and second, that mechanical ventilation itself can cause ALI. Thus, until new data emerge, the lung-protective ventilatory strategy adopted by the ARDS Network[95] is the standard of care for patients with ARDS. Plateau pressure should be maintained lower than 30 cm H_2O, and V_T should be limited to 6 mL/kg predicted body weight as much as possible. Further study will be required to determine whether intermediate V_Ts (6 mL/kg < V_T < 10 mL/kg), which might be easier to implement, are as safe in ARDS.

The optimal level of PEEP in ARDS remains unclear, although randomized trials indicate that using higher PEEP levels than the original ARDS Network study is safe and may improve oxygenation. Higher levels of PEEP are useful in order to prevent atelectrauma, reduce F_{IO_2}, and prevent hyperoxic lung injury, as long as the patient's hemodynamic status is stable. The lowest possible F_{IO_2} should be used that maintains Sa_{O_2} above 90%, with an empirical target F_{IO_2} of less than 0.6. Although prone positioning of patients with ARDS may transiently improve oxygenation, it does not improve survival. Finally, despite the theoretical appeal of HFO, no survival benefit has yet been demonstrated.

LONG-TERM OUTCOMES

Despite the profound derangement in oxygenation and respiratory system compliance that is characteristic of ARDS, it is remarkable that patients who survive often have near-normal pulmonary function tests 6 to 12 months later. Lung volumes and flows are generally slightly reduced or normal at 6 to 12 months, whereas the diffusion capacity sometimes remains slightly reduced.[227,228] Follow-up chest radiographs are usually normal, with a minority showing subtle abnormalities including pleural thickening or small cysts.[228]

Despite this impressive physiologic and radiologic recovery, patients who survive ARDS continue to have important functional limitations and a decreased health-related quality of life for at least 2 years after their illness.[229] This reduction in quality of life seems attributable to ARDS or to its management or complications, because in one parallel cohort study, patients with ARDS were matched to patients with sepsis or trauma with an equivalent severity of illness. The ARDS survivors continued to report significant decrements in health-related quality of life, particularly as related to physical function and pulmonary symptoms.[230] This reduced quality of life (in areas reflecting physical function) has been correlated with the presence of persistent abnormalities in pulmonary function tests.[227] In other patients, a persistent reduction in functional capacity (as measured by a 6-minute walk test) has been ascribed to persistent muscle weakness and wasting.[228] A multivariate analysis in that study found that lack of systemic corticosteroid administration, absence of illness acquired in the intensive care unit, and rapid resolution of lung injury and multiorgan dysfunction were associated with better functional status after hospital discharge. Patients who ultimately survive an episode of ARDS do not appear to have an increased mortality compared with other intensive care unit survivors who were similarly ill.[231]

Psychological problems have been described in survivors of ARDS. In a retrospective case-control study, survivors of ARDS were found to have significantly more signs and symptoms of posttraumatic stress disorder (PTSD) than patients who had undergone maxillofacial (and presumably elective) surgery; they also had more signs and symptoms of PTSD than soldiers who had served for prolonged periods of time in Bosnia.[232] Persistent cognitive impairment has also been observed in survivors of ARDS for as long as 1 year after hospital discharge.[233] Most patients in that study had impairments in one or more parameters, including memory, concentration, attention, or mental processing speed. Interestingly, these abnormalities were correlated with the degree and duration of hypoxemia that the patients experienced.

KEY POINTS

- ARDS is a syndrome defined by acute hypoxemia, bilateral infiltrates on chest radiograph, and the absence of left atrial hypertension.
- ARDS has been associated with diseases that directly involve the lungs (e.g., pneumonia) and also with diseases that do not obviously involve the lungs (e.g., pancreatitis).
- The pathogenesis of ARDS is not clear, but increased permeability of the alveolar-capillary membrane due to neutrophilic infiltration of the lungs is thought to be an important factor.
- ARDS is a syndrome, not a specific diagnosis; clinicians must, therefore, look for the cause in order to institute specific therapy.
- The mortality rate for ARDS has fallen since the 1980s and is now about 40%.
- Mechanical ventilation is lifesaving but, when inappropriately applied, can induce or aggravate lung injury.
- Most deaths in patients with ARDS are from multiorgan failure rather than hypoxia per se.
- No pharmacologic therapies have been shown to improve survival in ARDS; thus, management consists of treating the underlying cause, lung-protective ventilation, conservative management of fluids, and excellent supportive care.
- Many survivors of ARDS suffer from a reduced quality of life and cognitive impairment.

CLINICAL APPROACH

INTRODUCTION

The main goal of cardiopulmonary function is to deliver an adequate amount of oxygen (O_2) to meet the metabolic requirements of the peripheral tissues. Proper oxygenation of tissues depends on two factors: (1) the amount of O_2 delivery (Do_2), and (2) the rate of O_2 consumption ($\dot{V}o_2$) in the tissues. Do_2 is proportional to the arterial content of O_2 and the cardiac output (Do_2 = arterial O_2 content × cardiac output). $\dot{V}o_2$ is expressed by the following equation:

$$\dot{V}o_2 = 1.34 \times [Hb] \times (\text{arterial } O_2 \text{ saturation} - \text{venous } O_2 \text{ saturation}) \times \text{cardiac output}$$

This equation highlights the importance of mixed or central venous blood O_2 saturation as a parameter to monitor cardiopulmonary function. An impairment in any of these factors will result in a lack of tissue oxygenation or hypoxia, which when severe is life-threatening.

Among all the potential pathophysiologic alterations causing hypoxia, this chapter focuses on *hypoxemic respiratory failure*, defined as the impairment of respiratory function characterized by the presence of hypoxemia, diagnosed by reduced partial pressure of oxygen in arterial blood (Pao_2). Normally, Pao_2 ranges between 85 and 100 mm Hg, but the Pao_2 declines progressively during life, reaching values of 85 mm Hg at sea level by the age of 60. It is important to note that Pao_2 does not measure the entire content of oxygen in the arterial blood, but rather the partial pressure of the dissolved fraction of O_2, which drives its binding to proteins in blood, particularly hemoglobin (Hb), which has the highest ability to bind O_2 (1.34 mL O_2/1 g Hb). The Pao_2 determines the percentage of Hb saturated with O_2, according to the oxyhemoglobin dissociation curve (Fig. 91-1). Therefore, the actual oxygen content in the blood depends on the solubility of oxygen gas in the plasma and on the Hb concentration, according to the following equation:

$$O_2 \text{ content} = 1.34 \times [Hb] \times O_2 \text{ saturation} + 0.0031 \times Pao_2$$

DIAGNOSIS

Hypoxemic respiratory failure is diagnosed when there is a clinically significant decrease in Pao_2. Most commonly, the critical threshold of Pao_2 is considered to be 60 mm Hg, which is an anchor point in the oxyhemoglobin dissociation curve. This means that when the Pao_2 is less than 60 mm Hg, the saturation of hemoglobin with oxygen begins to fall rapidly with further decreases in Pao_2. Conversely, when the Pao_2 is above 60 mm Hg, the slope of the saturation curve is almost flat, implying that further increases in Pao_2 will result in small gains in oxygen saturation (see Fig. 91-1). It is important to recall that the oxyhemoglobin dissociation curve can be shifted horizontally by changes in temperature, partial pressure of carbon dioxide ($Paco_2$), concentration of H^+ ion, and red blood cell 2,3-diphosphoglycerate (DPG). In particular, the curve is shifted to the right when there is an increase in temperature, $Paco_2$, H^+ concentration, or DPG concentration, favoring the unloading of oxygen to the peripheral tissues, which is advantageous during muscle exercise, respiratory distress, or prolonged hypoxia.

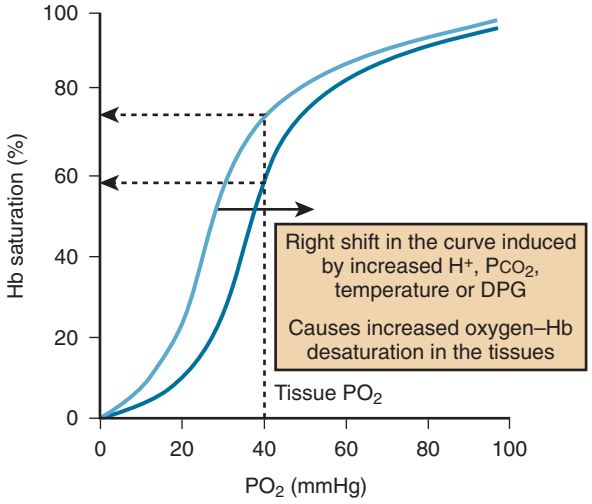

FIGURE 91-1 ■ Oxygen-hemoglobin dissociation curve shows the affinity-binding of oxygen to hemoglobin based on the partial pressure of oxygen (P_{O_2}) under normal conditions (*light blue line*) and during conditions of increased H^+ concentration, carbon dioxide pressure (P_{CO_2}), temperature, and/or DPG (2,3-diphosphoglycerate) (*dark blue line*). Note that at a P_{O_2} of less than 60 mm Hg, the oxygen saturation of hemoglobin begins to fall with increasing rapidity.

The measurement of P_{aO_2} is performed by arterial blood gas analysis (ABG), which also yields direct measurement of O_2 saturation of Hb, P_{aCO_2}, and pH and requires the puncture of an artery or the insertion of an indwelling arterial catheter to allow periodic sampling of arterial blood. Although crucial for the diagnosis and management of hypoxemic diseases, continuous monitoring of P_{aO_2} is not currently feasible, as would be ideal for the management of critically ill patients. The degree of hypoxemia is not specific for disease states because similar values of P_{aO_2} characterize patients with a broad spectrum of severity of illness, revealing that the definition of hypoxemia using arterial blood measurements is simplistic and suggesting that a more detailed pathophysiologic classification of hypoxemia would be useful.

Although measurement of P_{aO_2} remains the most commonly used technique to identify hypoxemia, other modes of monitoring oxygenation are also used to assist in the management and diagnosis of hypoxemic respiratory failure.

Pulse oximetry allows the continuous pulsatile monitoring of Hb O_2 saturation as the percentage of oxyhemoglobin, which is calculated based on the absorption of two wavelengths of light by Hb using a noninvasive probe applied to a perfused cutaneous area (usually a finger). One wavelength reflects oxyhemoglobin, and the other reflects deoxyhemoglobin, Arterial O_2 saturation is a very useful parameter, and values of 92% or greater represent adequate oxygenation; however, a specifically defined threshold to diagnose tissue hypoxia has not been identified.[1]

Another useful parameter to monitor oxygenation is the *alveolar-arterial P_{O_2} difference (A – a)P_{O_2}*, which is defined as the difference between the partial pressure of O_2 in the alveoli (P_{AO_2}) and the partial pressure of O_2 dissolved in the plasma of arterial blood ($P_{AO_2} - P_{aO_2}$). The (A – a)P_{O_2} gradient is normally less than 10 mm Hg; however, the range of normality changes with age and can be estimated as follows:

$$(A - a)\ \text{gradient} = 2.5 + 0.21 \times \text{age (in yr)}$$

The P_{AO_2} is calculated using the alveolar gas equation:

$$P_{AO_2} = F_{IO_2} \times [\text{Patm} - P_{H_2O}] - [P_{ACO_2} \div R] + F$$

where F_{IO_2} is the fraction of inspired O_2 (21% at room air), Patm is the atmospheric pressure (760 mm Hg at sea level, decreasing progressively with increasing altitude), P_{H_2O} is the partial pressure of saturated vapor (47 mm Hg at 37°C), P_{ACO_2} is the partial pressure of carbon dioxide in the alveoli (assumed to be equal to the partial pressure of CO_2 in the arterial blood [P_{aCO_2}] given the high diffusion coefficient of CO_2), R is the respiratory quotient (~0.8), and finally, F is a correction factor that is usually ignored. Clinically, it is worth noting that the (A – a)P_{O_2} difference increases with increasing F_{IO_2}, because oxygen support is often administered to patients suffering from hypoxemic respiratory failure.

Another parameter using similar information to that of the (A – a)P_{O_2} difference, is the A – a oxygen ratio, which is calculated by dividing the P_{aO_2} by the P_{AO_2} and normally exceeds a value of 0.77. However, this analysis of oxygenation is rarely used compared with the (A – a)P_{O_2} difference, which is in wide clinical use.

An additionally important measure of oxygenation is the P_{aO_2}/F_{IO_2} ratio, normally ranging between 300 and 500. In clinical practice, this index is routinely used to monitor the severity of noncardiogenic hypoxemic respiratory failure. Following the guidelines of the American European Consensus Conference, in the presence of bilateral lung infiltrates and hypoxemia from noncardiogenic origin, a P_{aO_2}/F_{IO_2} ratio less than 300 mm Hg indicates acute lung injury (ALI) and below 200 mm Hg indicates acute respiratory distress syndrome (ARDS). Like the (A – a)P_{O_2} difference, the P_{aO_2}/F_{IO_2} ratio is affected by alterations in the F_{IO_2}.

In particular clinical settings, such as pediatric departments, oxygenation is commonly monitored using the oxygenation index (OI), which is calculated using the following equation:

$$\text{OI} = \frac{\text{Mean airway pressure} \times F_{IO_2} \times 100}{P_{aO_2}}$$

where increasing values of OI indicated a worsening of oxygenation. The OI could be considered a more robust index than the P_{aO_2}/F_{IO_2} ratio, because it takes into consideration the mean airway pressure, thus providing a better pathophysiologic assessment of impaired lung function.

CLASSIFICATION

A classification of hypoxemia is helpful in order to allow a systematic approach to managing patients with hypoxemia. Various classifications of hypoxemic respiratory

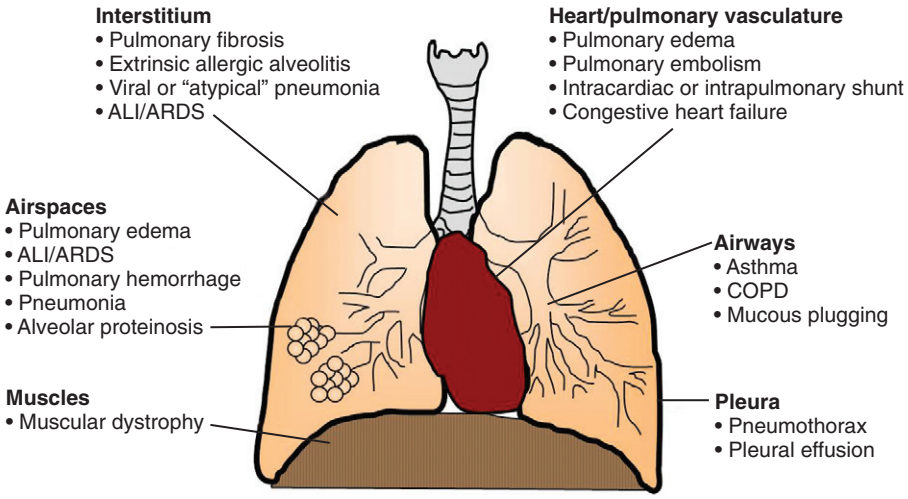

FIGURE 91-2 ■ Anatomic classification of hypoxemic respiratory failure displays examples of possible diagnoses based on structural dysfunction. This is not an exhaustive list and is meant for illustrative purposes only.

failure have been used that highlight important clinical aspects of the hypoxemia.

Time of Onset

The first classification uses time as the main parameter to define hypoxemic respiratory failure as acute or chronic. *Acute hypoxemia* occurs over a period of hours to days, and *chronic hypoxemia* occurs over a period of weeks to months. These two categories of hypoxemia, acute and chronic, are also characterized by differences in diagnostic approach, therapeutic strategy, and pathophysiologic mechanisms (considering the physiologic adaptations to hypoxemia that develop over time). Thus, acute and chronic hypoxemia reflect two different disease processes.

Underlying Etiology

Hypoxemic respiratory failure can also be classified based on its underlying cause; however, there is such a large number of possible diseases inducing hypoxemia that it is difficult to list them in a comprehensive classification. Several multicentered international studies have reported the most frequent causes of acute hypoxemic respiratory failure. In particular, in two large prospective studies of patients with acute hypoxemic respiratory failure requiring mechanical ventilation, the most common cause of hypoxemia aside from cardiogenic pulmonary edema was pneumonia, followed by sepsis, aspiration, trauma, and multiple transfusions.[2,3] Furthermore, in a randomized clinical trial investigating the use of noninvasive mechanical ventilation during severe hypoxemic respiratory failure, the leading underlying etiologies in order of frequency, were pneumonia, cardiogenic pulmonary edema, thoracic trauma, ARDS, acute severe asthma, postoperative respiratory failure, and interstitial pneumonitis.[4] For a further detailed discussion of many of the specific causes of hypoxemic respiratory failure (e.g., pneumonia), the reader is referred to Chapters 55, 57, and 92.

Anatomic Dysfunction

A third method used to classify hypoxemic respiratory failure is the identification of the anatomic structure primarily affected by the disease causing the drop in Pa_{O_2}. Dysfunction in many different areas of the chest—including diseases of the alveoli, interstitium, bronchi, airways, pleura, pulmonary vasculature, heart, and muscles—can induce hypoxia (Fig. 91-2). Furthermore, damage to the respiratory muscles and to specific areas of the central nervous system can also induce hypoxemia; however, these anatomic dysfunctions are usually characterized by an elevation in Pa_{CO_2}. Each of these anatomic areas can be targeted by different diseases. For example, alveoli can be filled with exudates, transudates, blood, inflammatory cells and proteins, hyaline membranes, fibrin, fibroblasts, and tumor cells, each one corresponding to different acute or chronic diseases, such as pneumonia, cardiogenic pulmonary edema, ALI, alveolar hemorrhage, cancer, idiopathic pulmonary fibrosis, cryptogenic organizing pneumonia, and pulmonary alveolar proteinosis.

Pathophysiologic Mechanisms

Finally, hypoxemic respiratory failure can be classified according to the pathophysiologic mechanisms leading to hypoxemia. This classification is particularly important because the identification of the pathophysiologic cause often allows the physician to administer a more appropriate treatment. However, understanding the pathophysiologic mechanism is not always helpful in making a specific diagnosis, which is crucial for determining prognosis, so this information must be used in combination with the parameters discussed previously.

MECHANISMS OF HYPOXEMIC RESPIRATORY FAILURE

There are five pathophysiologic mechanisms of hypoxemia: (1) decreased inspired oxygen pressure (P_{IO_2}) or fraction, (2) hypoventilation, (3) impaired diffusion, (4) shunt, and (5) ventilation-perfusion (V/Q) mismatch.[5]

Decreased Inspired Oxygen Pressure

The P_{IO_2} depends on the F_{IO_2} multiplied by the difference between the Patm and the pressure of saturated vapor (P_{H_2O}):

$$P_{IO_2} = F_{IO_2} \times (Patm - P_{H_2O})$$

As mentioned previously, the F_{IO_2} at room air is 0.21 and can decrease only in rare circumstances, such as the saturation of a closed environment with toxic fumes, where the inspired gas mixture contains a lower oxygen fraction.

Therefore, according to the equation, a naturally occurring lower P_{IO_2} can be observed only in conditions of low Patm. Patm progressively declines as altitude increases, going from 760 mm Hg at sea level to 253 mm Hg at the summit of Mount Everest (8848 m [29,029 ft]). Hence, P_{IO_2} ranges from 150 mm Hg at sea level ((0.21 × (760 mm Hg − 47 mm Hg)) to 43 mm Hg on top of Mount Everest (0.21 × (253 mm Hg − 47 mm Hg)) (Fig. 91-3).[5a]

According to the alveolar gas equation (see earlier), a reduction in P_{IO_2} results in a decrease in P_{AO_2}, which consequently reduces the driving pressure for oxygen through the alveolar-capillary membrane, inducing respiratory hypoxemia.

Hypoventilation

Hypoventilation is the condition defined by the reduction of alveolar ventilation ($\dot{V}_A$), which is a determinant of P_{ACO_2} ($PACO_2 = K \times \dot{V}CO_2/\dot{V}A$, where K is a constant and $\dot{V}CO_2$ is the rate of production of CO_2, and depends on the metabolic rate). According to the alveolar gas equation:

$$P_{AO_2} = F_{IO_2} \times [Patm - P_{H_2O}] - [P_{ACO_2} \div R] + F$$

if the respiratory exchange ratio (R, normally = 0.8) remains constant, any increase in P_{ACO_2} results in a reduction of P_{AO_2}, which can lead, in severe cases of hypercapnia, to hypoxemia. For example, if the $PaCO_2$ is increased to 80 mm Hg, the resulting P_{AO_2} on room air (at sea level) would be decreased to 50 mm Hg. This form of hypoxemia, exclusively due to hypoventilation, is readily recognizable because it is characterized by a normal (A − a)P_{O_2} difference, and a high $PaCO_2$, and is easily corrected by increasing the F_{IO_2} or reducing the P_{ACO_2} by increasing alveolar ventilation (e.g., with mechanical ventilation).

The reduction of alveolar ventilation leading to an increase in $PaCO_2$ is the result of an imbalance between the function of the respiratory pump and the load applied to the respiratory system. The respiratory pump encompasses all of the neuromuscular structures from the central nervous system to the respiratory muscles, including the motor-neuron and the neuromuscular junction, responsible for the expansion of the chest during inspiration. The respiratory load can be subclassified as the resistive load (due to the resistance of the airways), elastic load (due to the compliance of the lungs and chest wall), and the CO_2 production load, determined by the metabolic demands of peripheral tissue, which

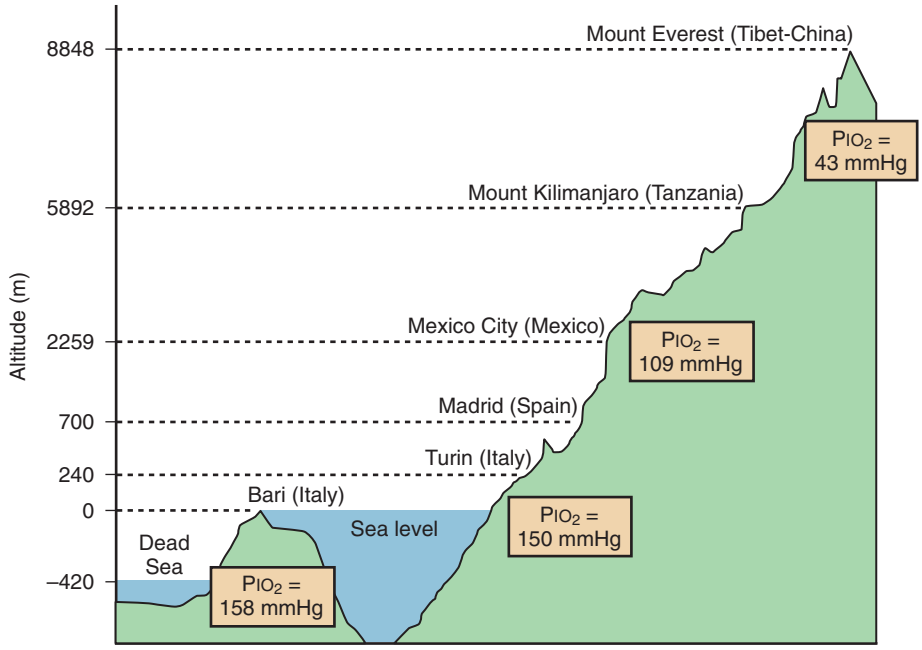

FIGURE 91-3 ■ Altitude effects on the pressure of inspired oxygen (P_{IO_2}), which geographically can range from 43 mm Hg at the summit of Mount Everest to 158 mm Hg at the Dead Sea. Most major world cities are located near sea level, where the P_{IO_2} is 150 mm Hg.

can increase dramatically during exercise, sepsis, trauma, and other factors.

Impaired Diffusion

Alveolar oxygen must diffuse through the alveolar-endothelial membranes in order to dissolve in the bloodstream and bind to Hb in red blood cells. Under normal conditions, complete oxygenation of blood in the pulmonary capillaries requires only 0.25 second, which is only a third of the total time in which the blood remains in contact with the alveolar-endothelial membrane (Fig. 91-4). Consequently, the relatively long alveolar capillary transit time can compensate for any impairment in oxygen diffusion. Thickening of the blood-gas barrier occurs in several diseases such as diffuse interstitial fibrosis, idiopathic pulmonary fibrosis, cryptogenic organizing pneumonia, asbestosis exposure, ARDS. Nevertheless, owing to this reserve of diffusion time, hypoxemia due solely to impaired diffusion is rarely observed in resting conditions, even during disease states. Impairment in oxygen diffusion through the blood-gas barrier can become clinically significant during exercise or other circumstances causing increased cardiac output, which induces a faster transition of the red cells through the alveolar capillaries. Therefore, rises in cardiac output will increase the flow through the pulmonary capillaries, thereby significantly reducing the time available for oxygen diffusion, which, if combined with an impaired diffusion rate, can lead to the development of hypoxemic respiratory failure because of a diffusion limitation (see Fig. 91-4).

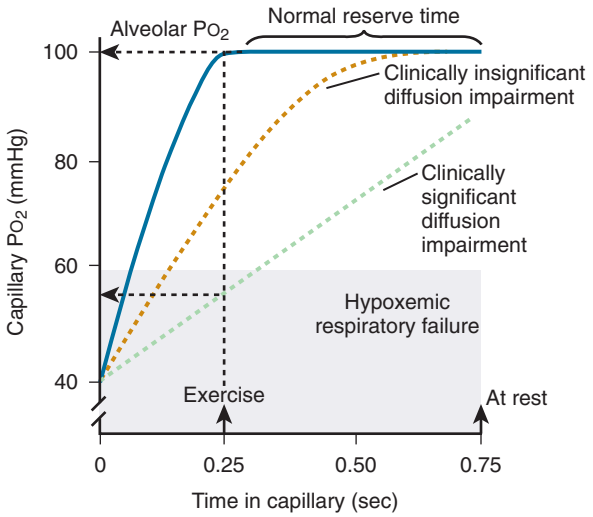

FIGURE 91-4 ■ Oxygen diffusion at the alveolar-capillary barrier requires only a third of the available time to obtain complete equilibration under normal resting conditions (*blue line*). Small impairments in diffusion (*dashed brown line*) use the available "reserve time," maintaining capillary oxygenation of greater than 60 mm Hg, so this impairment will be clinically insignificant. Larger diffusion impairments (*dashed pale line*) may prevent complete oxygenation, which during exercise when blood flow is increased may become clinically significant, leading to hypoxemic respiratory failure.

Shunt

Shunt is defined as the passage of venous blood into the arterial circulation without passing ventilated alveoli and, consequently, not becoming oxygenated. It is more accurate to define this mechanism as "right-to-left shunt," because the communication between the venous and the arterial circulation can cause hypoxemia only if the direction of the shunted blood flow is right to left.

Hypoxemic respiratory failure can be caused by intrapulmonary or extrapulmonary shunts. Examples of diseases with intrapulmonary shunts are pulmonary arteriovenous malformations, hepatopulmonary syndrome, and diseases characterized by alveolar consolidation or collapse (e.g., pneumonia, atelectasis). This latter condition of alveolar consolidation or collapse can also be viewed as an extreme *V/Q mismatch*, defined by areas of the lung that are unventilated but still perfused (discussed later). An interesting clinical example of intrapulmonary shunt is hepatopulmonary syndrome, which is cause by a regional dilation of pulmonary capillaries at the bases of the lungs. In this condition, the shunt increases when the patient is in the upright position, leading to hypoxemia. Because perfusion is redistributed toward the apex of the lung when the patient is placed in the supine position, this positioning will allow progressive reduction of shunt, thereby lessening the hypoxemia.

Extrapulmonary shunts are caused by the presence of intracardiac communication between the ventricles or the atria, due to atrial or ventricular septal defects, or by patency of the ductus arteriosus.

The presence of hypoxemia caused by shunt is characterized by the failure of Pa_{O_2} to rise despite inhalation of pure oxygen (100%).

The shunt fraction can be estimated by the following equation:

$$\dot{Q}s/\dot{Q}T = (Cc'_{O_2} - Ca_{O_2}) \div (Cc'_{O_2} - C\bar{v}_{O_2})$$

where, $\dot{Q}s$ is the shunt flow, $\dot{Q}T$ is the total blood flow, Cc'_{O_2} is the end-capillary O_2 content, calculated from the P_{AO_2}, Ca_{O_2} is the arterial O_2 content and $C\bar{v}_{O_2}$ is the mixed venous O_2 content, measured from the venous blood sampled through the pulmonary artery catheter.

Ventilation-Perfusion Mismatch

To become fully oxygenated and allow the total removal of CO_2, all the blood perfusing the lungs needs to be in contact with ventilated alveolar units. Ideally, the V/Q ratio should be equal to 1. Physiologically, in the upright position, the perfusion of the lungs changes anatomically, increasing from the apex to the base, due to either gravitational or anatomic considerations. Likewise, the ventilation is greater at the base of the lung, as opposed to the apical regions. However, from apex to base, the perfusion increases more rapidly than that of ventilation, resulting in a progressive decrease of V/Q ratio. The overall V/Q ratio of the lungs is normally around 0.8. This mild difference of the real V/Q from the ideal value of 1 is responsible for a physiologically appreciable $(A-a)P_{O_2}$ difference.

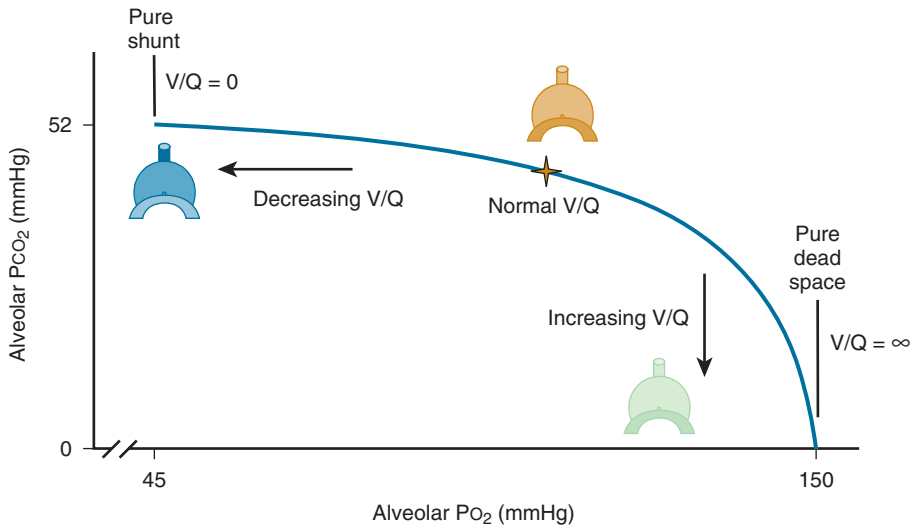

FIGURE 91-5 ■ Ventilation-perfusion (V/Q) ratio displays the normal balance (*star*) between alveolar ventilation and vascular perfusion allowing for proper oxygenation. When ventilation is reduced, the V/Q ratio decreases, in the most extreme case resulting in pure shunt, where V/Q = 0. When perfusion is reduced, the V/Q ratio increases, in the most extreme case resulting in pure dead space, where V/Q = infinite (∞).

V/Q varies broadly between pathophysiologic extremes. On one side, there are alveolar units with no ventilation but normal perfusion, resulting in a V/Q ratio of 0. This phenomenon is referred to as right-to-left shunt, as discussed previously. In these alveolar units, the oxygen content is similar to that of the mixed venous blood and the CO_2 is elevated. At the other extreme, some alveolar units are fully ventilated but not perfused, resulting in an infinite V/Q ratio. This area of ventilation is called "dead space," in which the alveolar oxygen content is similar to that of the inspired gas mixture and the CO_2 is almost absent (Fig. 91-5).

Between these two extremes, any alteration of V/Q matching can lead to severe impairments in gas exchange with clinically significant hypoxemia, hypercapnia, or a combination of both. In the majority of respiratory failure cases, V/Q mismatch is the cause of hypoxemia and can be identified by an increased $(A - a)P_{O_2}$ difference and exclusion of the other four mechanisms of hypoxemia. Moreover, arterial oxygenation can normally be improved by adding supplemental O_2 to the mixture of inspired gas, which increases P_{AO_2} in poorly ventilated alveolar units.

Overall, among all five pathophysiologic mechanisms causing hypoxemia, shunt and V/Q mismatch are the most relevant from a clinical perspective. In fact, reduction of P_{IO_2} and impaired diffusion are rarely significant, and hypoventilation-induced hypoxemia can be easily corrected with minimal increments of F_{IO_2}. However, in clinical practice, more than one mechanism often contributes at the same time to the development of hypoxemia. It is important to stress that adequate cardiac output is necessary to avoid hypoxemia, because a reduced cardiac output is associated with lung perfusion impairment and consequent inequality of the V/Q ratio. Moreover, a low cardiac output is associated with a significant reduction in mixed venous oxygen saturation, which can thereby cause other mechanisms of hypoxemia (i.e., impaired diffusion), which under normal conditions are clinically insignificant, to contribute to the development of hypoxemia.

CLINICAL APPROACH

Hypoxemic respiratory failure can present with diverse signs and symptoms, depending on the time of occurrence (acute or chronic), the responsible pathophysiologic mechanism, the underlying etiology, and confounding comorbidities. For example, patients with hypoxemia can be tachypneic and tachycardiac or have a very low respiratory rate, as is seen in severe hypercapnia caused by hypoventilation. Hypoxic patients can have signs of severe respiratory distress, in cases of acute causes of hypoxemia, or appear completely comfortable, as is sometimes seen in patients with chronic obstructive pulmonary disease. Therefore, a systematic, clinical approach is very useful to identify a specific diagnosis from a large number of possible alternatives and to accelerate the initiation of proper treatment, which is urgently needed in cases of acute hypoxemic respiratory failure (Fig. 91-6).

The ABC evaluation (airway, breathing, and circulation) should be performed in every case. Supplemental oxygen should be given and intravenous access should be obtained. Patients with severe hypoxemic respiratory failure should be referred immediately to facilities that have the ability to continuously monitor vital signs, arterial oxygen saturation, blood pressure, and the electrocardiogram. Details of the presenting illness and the past medical history should be obtained rapidly in order to differentiate acute and chronic forms of hypoxemia and to identify the possible cause of hypoxemia and the important comorbidities that the patient might have. In

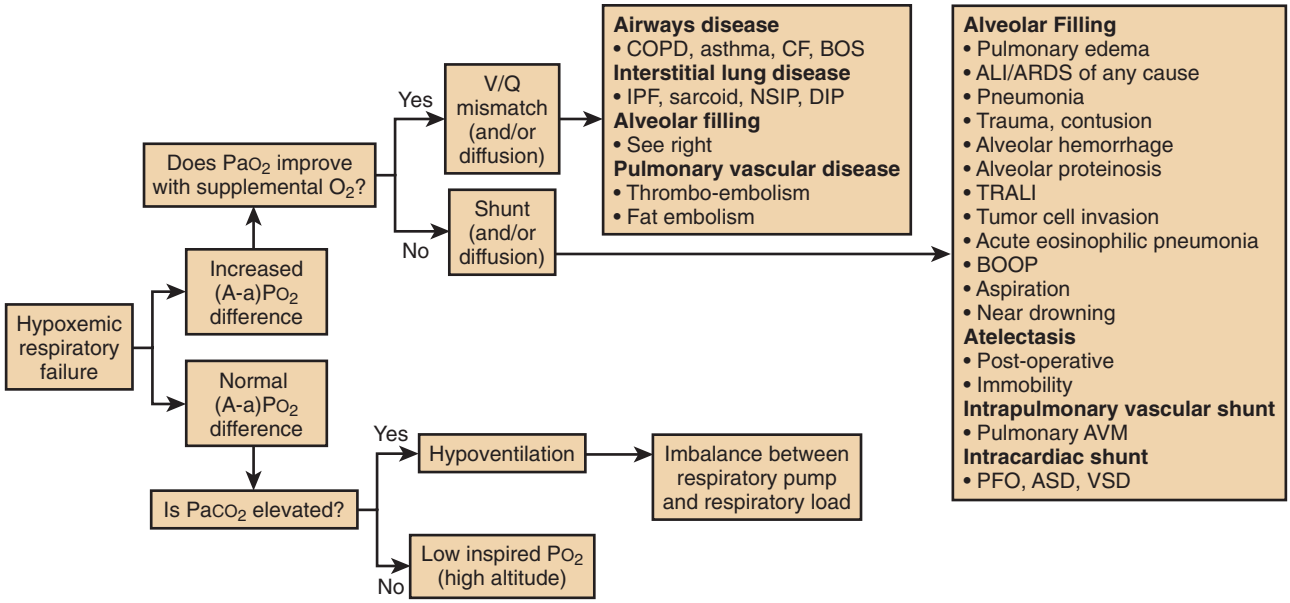

FIGURE 91-6 ■ Patient diagnostic algorithm shows a general approach to treating patients with hypoxemic respiratory failure based on the (A – a)P_{O_2} difference, Pa_{CO_2}, and/or response to supplemental oxygen. This is by no means an exhaustive list. In addition, it should be noted that multiple mechanisms can contribute simultaneously, thereby complicating the diagnostic process.

cases of acute hypoxemic respiratory failure, cardiac dysfunction, pulmonary infection or aspiration, venous thromboembolism, obstructive lung diseases, pneumothorax, hemothorax, and pulmonary contusion must be considered and excluded as the most frequent causes. An accurate physical examination of the respiratory and cardiac system is still necessary and sometimes sufficient to distinguish the different etiologic possibilities. In particular, the recognition on physical examination of congestive heart failure, a focal area of pulmonary consolidation, or a possible pneumothorax can expedite the diagnostic approach by excluding a large number of diseases and hasten the appropriate therapy. Therapy of patients with acute or severe hypoxemic respiratory failure must be initiated at the same time the diagnostic evaluation is under way in order to prevent delays in treatment.

Every patient with hypoxemic respiratory failure should be investigated with a chest radiograph, an electrocardiogram, routine blood work, and ABG. Other useful diagnostic tools include echocardiography, computed tomography angiography of the chest, ultrasound of the chest, bronchoscopy, and scintigraphy.

In particular, the values of arterial Pa_{O_2} and Pa_{CO_2} are essential to discriminate among the five mechanisms leading to hypoxemia. In fact, excluding a reduction in P_{IO_2} usually related to a stay at altitude, the measurement of Pa_{O_2} and Pa_{CO_2} allows calculation of the (A – a)P_{O_2} difference, which is normal (<10 mm Hg) in cases of hypoventilation as an isolated cause of hypoxemia and increased in cases of impaired diffusion, shunt, and V/Q mismatch. However, impaired diffusion is rarely a cause of clinically significant hypoxemia. Therefore, the differential diagnosis usually involves distinguishing V/Q mismatch and shunt, which can be identified by the response to 100% oxygen, because treatment with 100% supplemental O_2 does not improve the Pa_{O_2} when shunt is the primary cause of hypoxemia, but causes a significant increase in Pa_{O_2} when V/Q mismatch is present.

The treatment of hypoxemia has the immediate goal of increasing the Pa_{O_2}, in order to provide adequate oxygen delivery to the cells throughout the body. Therefore, in the management of patients with hypoxemic respiratory failure, it is also important to optimize the Hb concentration and cardiac output because each contributes significantly to the delivery of oxygen to peripheral tissues.

The most common strategies used to improve a patient's Pa_{O_2} rely on the administration of oxygen with positive pressure by means of either noninvasive or invasive mechanical ventilation. The historic "gold standard" for the treatment of hypoxemic respiratory failure is invasive mechanical ventilation, using various modalities of mechanical ventilation to provide adequate respiratory support to hypoxemic patients.[6] In particular, there is a large body of literature focused on improving mechanical ventilation in patients with the most severe forms of hypoxemia, including ARDS and its milder form, ALI[7] (see Chapter 90).

Another way to deliver supplemental oxygen with positive pressure is through the use of noninvasive ventilation, which can be dispensed through different types of interfaces, such as the helmet, nasal mask, and facial masks with different shapes to accommodate different facial features. Noninvasive ventilation is currently recommended by international guidelines as the first choice for the treatment of hypoxemic respiratory failure due to cardiogenic pulmonary edema or exacerbation of chronic obstructive pulmonary disease.[8] Moreover, there is evidence showing that noninvasive ventilation is also

effective in the treatment of postoperative hypoxemic respiratory failure in patients who have undergone abdominal surgery.[9] Furthermore, there are several studies of the administration of noninvasive ventilation to patients with hypoxemic respiratory failure of noncardiac origin, but these are not conclusive.[4,10,11]

In cases of severe hypoxemic respiratory failure that are refractory to all conventional treatments, there remain additional therapeutic options, such as prone positioning of the patient, administration of inhaled nitric oxide, use of high-frequency oscillatory ventilation, and extracorporeal membrane oxygenation.[12-14] However, these are still considered as rescue therapies because these therapies have not been shown to improve overall outcome, even though they often improve oxygenation.

ACKNOWLEDGMENTS

We acknowledge the contribution of Dr. Warren L. Lee and Dr. Arthur S. Slutsky to this chapter in previous editions.

KEY POINTS

- Hypoxemic respiratory failure is diagnosed when Pa_{O_2} is less than 60 mm Hg.
- There are several methods of measuring oxygenation that can be used when evaluating hypoxemia.
- Classification of hypoxemic respiratory failure, based on time of onset, underlying etiology, anatomic dysfunction, and/or pathophysiologic mechanism, can assist in diagnosis and management of hypoxemia.
- There are five pathophysiologic mechanisms leading to hypoxemia: decreased P_{IO_2}, hypoventilation, impaired diffusion, right-to-left shunt, and V/Q mismatch.
- The measurement of Pa_{O_2}, Pa_{CO_2}, $(A - a)P_{O_2}$ difference, and the response to supplemental oxygen are crucial steps in the diagnostic approach to hypoxemic respiratory failure.
- Low cardiac output associated with reduced mixed venous oxygen saturation can contribute to the development of hypoxemia,
- Owing to the large number of diseases that can induce hypoxemic respiratory failure, a systematic clinical approach is needed when evaluating and treating patients.

INTRODUCTION

Respiratory failure exists when the respiratory system cannot maintain gas exchange, causing dysfunction in other organs or threatening life. Such impairment can affect primarily oxygenation, manifested by hypoxemia, or ventilation, manifested by hypercapnia and respiratory acidosis. This chapter deals with this latter circumstance, commonly called *ventilatory failure*.

Carbon dioxide (CO_2) tension in the arterial blood (Pa_{CO_2}) is a function of alveolar ventilation ($\dot{V}_A$) and CO_2 production ($\dot{V}_{CO_2}$), according to the following relationship.

$$Pa_{CO_2} = \left(\dot{V}_{CO_2} \times k\right) / \dot{V}_A \quad (1)$$

Total minute ventilation is the sum of both $\dot{V}_A$ and dead space ventilation. Either a decrease in total minute ventilation or an increase in dead-space ventilation can thus decrease $\dot{V}_A$. Any decrease in $\dot{V}_A$, or increase in $\dot{V}_{CO_2}$ relative to $\dot{V}_A$, results in an increase in Pa_{CO_2}. Because bicarbonate retention by the kidney in response to hypercapnia occurs slowly, a sudden increase in Pa_{CO_2} will not be buffered readily by bicarbonate and thus will abruptly lower arterial pH. Ventilatory failure exists whenever Pa_{CO_2} is substantially elevated, and acute ventilatory failure is present when the change from the patient's baseline state develops rapidly enough to produce a clinically important drop in arterial pH. Because patients with severe chronic obstructive pulmonary disease (COPD), chronic neuromuscular disease, and other disorders may already have hypercapnia at baseline, the presence of acute ventilatory failure is determined not so much by the Pa_{CO_2} value as by the presence of acidemia, typically to an arterial pH of less than 7.30. The presence of acute ventilatory failure cannot be determined accurately by physical examination, pulse oximetry, exhaled CO_2, or other noninvasive tests. Thus, making the diagnosis requires arterial blood gas analysis.[1]

PATHOPHYSIOLOGY OF ACUTE VENTILATORY FAILURE

Alveolar ventilation becomes inadequate in relation to CO_2 production either because of a failure of the patient's

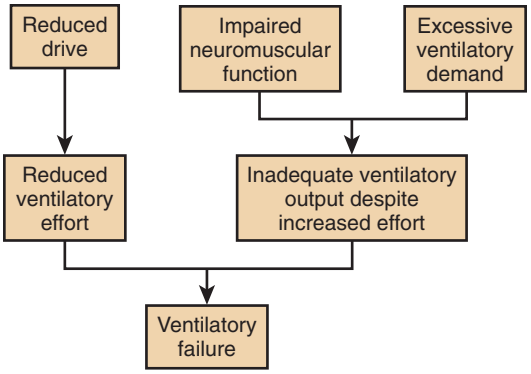

FIGURE 92-1 ■ The physiologic mechanisms of acute ventilatory failure.

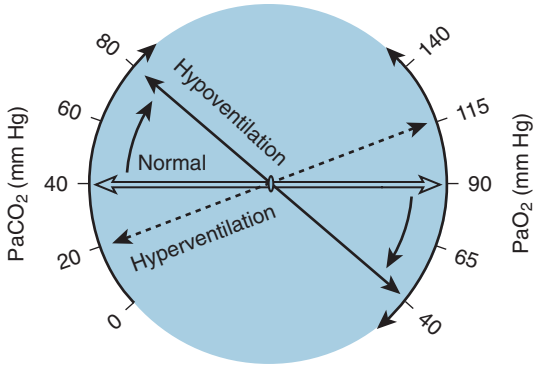

FIGURE 92-2 ■ The relationship between arterial oxygen pressure (Pa_{O_2}) and arterial carbon dioxide pressure (Pa_{CO_2}) as ventilation increases or decreases, assuming that the alveolar-arterial oxygen pressure (A – a)P_{O_2} difference does not change and the respiratory exchange ratio is 0.8. (Redrawn from Pierson DJ, Kacmarek RM [eds]: Foundations of Respiratory Care. New York: Churchill Livingstone, 1992, p 298.)

ventilatory capability (pump failure) or because of a failure of the ventilatory effort (drive failure)[2,3] (Fig. 92-1). These two mechanisms are distinct in their clinical presentations. Patients with acute failure of the ventilatory pump are dyspneic and tachypneic with other signs of distress and sympathetic nervous system activation, whereas patients with failure of ventilatory drive are not short of breath and typically demonstrate bradypnea or apnea.

Although acute ventilatory failure is primarily a disorder of alveolar ventilation, hypoxemia is also usually present. Alveolar hypoventilation causes a proportional fall in alveolar oxygen pressure ($P_{A_{O_2}}$), according to the alveolar gas equation.

$$P_{A_{O_2}} = P_{I_{O_2}} - (Pa_{CO_2}/R) \quad (2)$$

where Pa_{CO_2} can be assumed to be nearly the same as alveolar carbon dioxide pressure ($P_{A_{CO_2}}$), $P_{I_{O_2}}$ is the inspired P_{O_2} (i.e., the inspired oxygen fraction multiplied by the difference of barometric pressure and 47 [water vapor pressure at body temperature]), and R is the respiratory exchange ratio. This relationship explains the fall in Pa_{O_2} that accompanies alveolar hypoventilation, as shown in Figure 92-2.[2] Calculating Pa_{O_2} using Equation 2 permits determination of the alveolar-arterial oxygen pressure difference [(A – a)P_{O_2}] (commonly but imprecisely called the "A – a gradient" and more precisely called the "A – a oxygen tension difference"). This calculation distinguishes between pure hypoventilation as an explanation for hypoxemia (in which case [(A – a)P_{O_2}] is normal) and the presence of other mechanisms such as low ventilation-perfusion (V/Q) ratios and right-to-left shunt (in which case (A – a)P_{O_2} is increased).

Finally, hypercapnia can be a feature of hypoxemic respiratory failure if the derangement in gas exchange is sufficiently severe. Both right-to-left shunt and low V/Q ratios are present in the acute respiratory distress syndrome (ARDS) and can increase dead space–to–tidal volume ratios (V_D/V_T) as determined by the Bohr equation,[4] thus impairing CO_2 elimination and contributing to hypercapnia.

Table 92-1 classifies the typical clinical presentations of acute ventilatory failure according to the site or type of defect and the physiologic mechanism or category of disorder responsible. Not every listed example is discussed in this chapter.

More than one mechanism may coexist in a given patient, producing a life-threatening condition even when the individual processes are only moderate in severity. For example, in decompensated obesity-hypoventilation syndrome, a patient whose underlying respiratory drive is reduced and whose obesity poses an increased elastic load on the ventilatory pump may develop acute-on-chronic ventilatory failure in the presence of a relatively modest increase in the work of breathing from the additional restrictive effects of cardiomegaly and pleural effusions.

ACUTE VENTILATORY FAILURE DUE TO INSUFFICIENT VENTILATORY DRIVE

Pharmacologic Causes

Depression of the drive to breathe by drugs is by far the most common circumstance of this form of acute ventilatory failure and, it may be argued, the only one in which it is the primary mechanism. In the conditions discussed later, and even in acute drug overdose, an inability to protect the airway and the increased work of breathing usually play a major role in the genesis of acute respiratory acidosis. The opioids are the most potent depressors of both hypoxic and hypercapnic ventilatory drive, but any sedative, hypnotic, or anxiolytic agent causes respiratory depression if administered in sufficient quantity.[5]

Respiratory depression resolves as the drug is cleared from the body or is pharmacologically antagonized, as signaled by the return of spontaneous breathing efforts. Because the central nervous system effects of some agents may wax and wane due to the enterohepatic circulation, lipid storage, or other mechanisms, patients should be observed until it is clear that the ventilatory drive has been reestablished before they are weaned

TABLE 92-1. Clinical Classification of Ventilatory Failure

Site or Type of Defect	Mechanism or Category	Clinical Examples
Ventilatory drive	Pharmacologic	Drug overdose (opioids, sedatives, alcohol); general anesthesia
	Congenital	Primary alveolar ventilation (Ondine's curse)
	Acquired	Cerebrovascular accident; neoplasm; carotid body resection
	Combination	Obesity-hypoventilation syndrome; myxedema
Neural transmission to ventilatory muscles	Cervical spinal cord injury	Trauma; tumor; vascular accident
	Demyelinating peripheral neuropathy	Guillain-Barré syndrome
	Anterior horn cell disease	Poliomyelitis; amyotrophic lateral sclerosis
	Phrenic nerve lesion	Trauma; cardiac surgery; neoplasm; idiopathic
Ventilatory muscles	Pharmacologic	Neuromuscular blocking agents
	Primary muscle disorder	Muscular dystrophy; polymyositis; dermatomyositis
	Disorders of the neuromuscular junction	Myasthenia gravis; botulism; tetanus; tick paralysis
	Electrolyte and metabolic disturbances	Hypophosphatemia; hypokalemia; hypomagnesemia; myxedema
Chest wall	Decreased mobility	Kyphoscoliosis; traumatic asphyxia; tight casts or bandages; severe obesity; ankylosing spondylitis; flail chest
Pleural disorders	Extrapulmonary restriction	Pneumothorax; pleural effusion; pleural thickening or malignancy
Airway obstruction	Upper airway obstruction	Epiglottitis; foreign body; tumor; vocal cord paralysis; tracheomalacia
	Lower airway obstruction	COPD; acute severe asthma
Increased dead-space ventilation	Very high V/Q	COPD
	Very low V/Q; right-to-left shunt	Severe ARDS
	Generalized pulmonary hypoperfusion	Hypovolemic or cardiogenic shock; during CPR; pulmonary hyperinflation (excessive applied PEEP; intrinsic PEEP)
	Localized pulmonary hypoperfusion	Pulmonary thromboembolism*; venous air embolism
Increased CO_2 production*	Inflammation; hypermetabolism	Fever; sepsis; burns; severe trauma
	Muscle activity	Shivering; tetany; seizures; malignant hyperthermia
	Excessive caloric intake	Increased overall caloric intake (especially carbohydrate calories)
Exogenous CO_2 inhalation	Increased inspired P_{CO_2}	Laboratory or industrial accident; therapeutic use; rebreathing

*In the absence of ability to compensate with increased overall ventilation.
ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; CPR, cardiopulmonary resuscitation; PEEP, positive end-expiratory pressure; P_{CO_2}, carbon dioxide pressure; V/Q, ventilation-perfusion ratio.

from ventilatory support. In the case of drug overdoses and other poisoning, identifying the specific agent or agents involved and the use of any specific therapies available, such as antidotes or dialysis, is important to expedite the weaning process from ventilatory support.[5]

Patients who fail to wean from mechanical ventilation because of inadequate drive from depressant drugs breathe slowly or not at all when ventilatory support is briefly discontinued. The much more common reason for difficulty weaning after drug overdose is that other mechanisms (e.g., aspiration pneumonia or sepsis) intervene. In these circumstances, with a return of respiratory drive, patients become tachypneic and manifest signs of respiratory distress when ventilatory support is discontinued.[6]

Congenital or Acquired Central Hypoventilation

Decreased ventilatory drive is a frequent contributor to the development of chronic ventilatory insufficiency, but it is typically not the sole mechanism for acute ventilatory failure, except for those patients presenting with drug-induced suppression. When patients with underlying abnormalities of ventilatory drive develop respiratory infections, congestive heart failure, or other acute illness, they are more likely than individuals without such defects to develop acute ventilatory failure.

The obesity-hypoventilation syndrome, discussed in Chapter 88, is characterized by blunted responses to hypoxia and hypercapnia[7] and is one disorder in which patients may first present in acute ventilatory failure. Typically, such patients have a history of recent weight gain and are found to be markedly fluid-overloaded, with features of cor pulmonale. The increased work of breathing from decreased chest wall compliance, cardiomegaly, and often large pleural effusions, as well as worsening hypoxemia, all contribute to respiratory muscle fatigue and the development of severe hypercapnia and respiratory acidosis. Hypoventilation is more common among hospitalized patients with severe obesity than has previously been appreciated.[8] As the

prevalence of obesity increases, ventilatory failure from decompensation of the obesity-hypoventilation syndrome is likely to be encountered more frequently.

Disorders in addition to the obesity-hypoventilation syndrome that may be associated with diminished hypoxic or hypercapnic ventilatory drive include myxedema,[9] the Prader-Willi syndrome,[10] and hypogonadism treated with exogenous testosterone.[11] These disorders may contribute to the development of acute ventilatory failure in susceptible individuals.

Acute stroke is another setting in which disordered ventilatory drive may contribute to acute ventilatory failure. The prognosis of patients with strokes who require intubation and mechanical ventilation is poor.[12] Outcomes in patients with ischemic and hemorrhagic strokes were equally poor in one study.[12] Other reports have found an especially unfavorable prognosis after basilar artery occlusion.[13] However, acute ventilatory failure in the setting of acute stroke does not preclude survival; in one series of 124 patients with hemispheric stroke requiring mechanical ventilation, one third of the patients were alive after 1 year.[14] Although impaired ventilatory drive may contribute to acute ventilatory failure following acute stroke, other processes, especially the inability to protect the lower airway and adequately clear respiratory tract secretions, are usually present.[12,15]

Principles of Management

Because the underlying physiologic defect is inadequate drive for ventilation with a presumably normal ventilatory pump, management focuses on restoring normal alveolar ventilation. Although noninvasive positive-pressure ventilation (NPPV) is being applied in an increasing number of clinical settings to augment alveolar ventilation, its utility lies mainly in maintaining respiration in patients with failure of the ventilatory pump, whereas endotracheal intubation is generally necessary following acute failure of respiratory drive. This is not only because restoration of alveolar ventilation can be attained more rapidly and reliably with invasive mechanical ventilation but also because the concomitant problems with airway protection and secretion clearance in most patients with acute depression of ventilatory drive are relative contraindications to NPPV.

Because of the patient's impaired ventilatory drive, a ventilator mode should initially be chosen that provides full support, such as volume-targeted assist-control ventilation. In the absence of acute lung injury or severe airflow obstruction, ventilator settings should be chosen to aim for values for arterial pH and P_{ACO_2} in the normal range, and supplemental oxygen should be supplied (with positive end-expiratory pressure [PEEP] if necessary) to maintain normal arterial P_{AO_2}. Unless there are serious coexisting pulmonary conditions, weaning should be carried out as soon as there is evidence that ventilatory drive is restored (see Chapter 89). Extubation is probably safe if the patient has a spontaneous cough, does not require frequent suctioning, and is judged able to protect the airway, even if alertness remains impaired.[16]

ACUTE VENTILATORY FAILURE DUE TO NEUROMUSCULAR IMPAIRMENT

Cervical Spinal Cord Injury

Injury to the upper cervical spinal cord may interrupt transmission of the stimulus to breathe from the respiratory centers in the brain stem to the diaphragm and other ventilatory muscles. Because the phrenic nerve roots that supply the diaphragm arise from spinal segments C3 to C5, patients with acute injury at this level or above usually require mechanical ventilation. Patients with C1–2 spinal injury levels are permanently ventilator-dependent, whereas those with C3–4 injuries may eventually achieve at least partial ventilator-independence. Lesions below C4 are usually compatible with unassisted ventilation unless there are complicating processes such as intrinsic lung disease or impaired mental status (see also Chapter 87).

Adverse physiologic effects of cervical spinal cord injury in the initial days or weeks include loss of lung volumes and inability to take deep breaths (which predispose to atelectasis), inability to cough normally (which predisposes to the development of pneumonia and complicates its management), and impaired hypoxic pulmonary vasoconstriction (which predisposes to severe and often refractory hypoxemia when atelectasis or pneumonia occurs). Although it is accurate to say that the short-term prognosis is generally related to the level of the injury,[16a] retrospective studies have shown that both mortality[17] and intensive care unit (ICU) length of stay[16a] for patients with cervical spinal cord injury are more strongly influenced by the development of pneumonia and other respiratory complications than by the specific cord injury level.

Although there are reports of initial management of patients with high cervical spinal cord injury with NPPV,[18] great expertise is required to avoid aspiration and other complications; in most centers, invasive ventilatory support is preferable, at least initially. Phrenic nerve pacing,[19,20] thereby permitting extubation or decannulation from tracheostomy, has also been reported in the later period following injury. The eventual ability to wean from ventilatory support and undergo decannulation from tracheostomy are major determinants not only of survival but also of quality of life for patients with cervical spinal cord injury.[16a,17]

Injury or Disease Affecting the Phrenic Nerve

Although loss of diaphragm function as a cause for ventilatory failure is often due to spinal cord injury, paralysis of the diaphragm leading to ventilatory failure may also result from phrenic nerve injury or disease. The most common setting is phrenic nerve injury following cardiac surgery, which is almost always unilateral and likely due to either cold cardioplegia or physical injury during internal mammary artery harvesting. The presentation ranges

from an incidentally discovered radiographic abnormality without clinical impact (most common) to ventilatory failure requiring long-term mechanical ventilation.[20,21]

As first outlined by Diehl and associates,[22] post–cardiac surgery phrenic nerve injury can be a severe problem. They retrospectively evaluated 13 patients encountered during a 2-year period who could not be weaned from ventilatory support for several weeks after cardiac surgery and were found to have severely impaired respiratory muscle function. Clinically relevant diaphragmatic dysfunction was estimated to be 0.5% when no topical cooling was used and 2.1% when iced slush with no insulation pad was added for myocardial protection.[22]

Bilateral diaphragmatic paralysis can present unassociated with trauma or surgical manipulation. In some patients, no systemic disease or specific cause could be found.[23] One case of bilateral diaphragm paralysis complicating von Recklinghausen's neurofibromatosis has been reported.[24] Isolated ventilatory muscle weakness can also be the initial manifestation of generalized neuromuscular disorders such as myasthenia gravis[25] and amyotrophic lateral sclerosis (ALS).[26]

Neuromuscular Disease

The most common cause of acute paralysis and neuromuscular ventilatory failure presenting to acute care hospitals is Guillain-Barré syndrome,[27] in which one third of patients may develop acute ventilatory failure.[28–30] Therapy with plasma exchange and immune globulins has improved the outlook for patients who develop Guillain-Barré syndrome, although 3% to 8% die, and 5% to 10% of individuals who survive remain seriously disabled.[27,31] Theoretically, death should be preventable in most if not all patients with this disease, because mortality is primarily from potentially avoidable respiratory complications (see also the discussion in Chapter 87). It remains unclear whether the need for mechanical ventilation can be predicted prior to the onset of frank ventilatory failure in this condition.[32]

Myasthenia gravis is a relatively infrequent cause of acute ventilatory failure. Investigators at one large regional neuromuscular disease center reported 18 patients with 24 episodes of ventilatory failure requiring mechanical ventilation during a 9-year period.[33] Acute ventilatory failure usually occurs in patients with an established diagnosis of myasthenia gravis, although isolated ventilatory muscle weakness requiring mechanical ventilation has been reported as the initial manifestation of the disorder.[25]

ALS and other motor neuron diseases may demonstrate progressive weakness of the bulbar and ventilatory muscles that is variable both in presentation and in the rate of progression.[34,35] Typically, ventilatory muscle weakness develops in patients in whom the diagnosis of ALS is already well established.[34–38] Repeated assessment can usually detect the onset of ventilatory muscle dysfunction during outpatient management.[37,38] However, dyspnea or even acute ventilatory failure can be the initial clinical manifestation of motor neuron disease.[39,40] Elective initiation of noninvasive ventilation is becoming more common in patients with gradually progressive ventilatory insufficiency.[37,38] Its successful use has also been reported in acute ventilatory failure complicating ALS,[41] although bulbar weakness and a high risk of aspiration make invasive mechanical ventilation a safer choice for such patients, at least initially. With appropriate counseling and management, only a small proportion of patients with ALS receive invasive mechanical ventilation, and presentation with acute ventilatory failure should be an unusual occurrence.[42]

Botulism remains an important cause of acute ventilatory failure worldwide, although only about 25 cases of food-borne illness and 3 cases of wound botulism have been reported annually in the United States since the 1970s.[43] A high proportion of patients with both forms of botulism develop clinically important respiratory muscle weakness. In one food-borne outbreak, 81% of patients developed pulmonary involvement, and 11 of 34 patients required mechanical ventilation for acute ventilatory failure.[44]

Because it is infrequent and does not occur in outbreaks, wound botulism poses a challenge in both diagnosis and appropriate early management. Historically associated with dirty traumatic wounds, especially those sustained in rural areas, wound botulism has also been encountered in recent years as a complication of injecting "black tar" heroin.[45,46] In a series of 20 consecutive patients with black tar heroin–associated wound botulism,[45] acute ventilatory failure developed in 15 (75%) and was more frequent in those patients in whom the administration of antitoxin or antibiotics was delayed beyond 12 hours of initial presentation. Ventilatory failure in wound botulism may be prolonged. Twelve of 15 patients with black tar heroin–associated botulism needed ventilatory support for more than 30 days.[45] Recovery may likewise be prolonged, with residual ventilatory muscle weakness detectable as long as 2 years after presentation.[47]

Dermatomyositis may also cause respiratory muscle weakness severe enough to cause acute ventilatory failure,[48,49] although not as an initial manifestation in the absence of other typical symptoms and signs of this condition. In these reported cases, ventilatory function recovered as the disease was brought under control with immunosuppressive therapy.

Neuromuscular Weakness Associated with Critical Illness

Neuromuscular dysfunction associated with critical illness commonly contributes to the subsequent inability to wean such patients from mechanical ventilation.[50] Several forms of critical illness–associated neuromuscular dysfunction are recognized.

Prolonged Neuromuscular Blockade

Neuromuscular blocking drugs are sometimes administered to ventilated patients, in conjunction with

sedation, to facilitate mechanical ventilation, to reduce oxygen consumption, or to control intracranial pressure. The clinical kinetics of these agents have been determined mainly in the context of short-term general anesthesia, and their effects on ventilatory muscle function in critically ill patients are much more variable. Most neuromuscular blocking drugs are cleared more slowly in the presence of hepatic—and especially renal—insufficiency. This is particularly true for pancuronium and vecuronium, and the effects of these drugs can last days or even weeks in the presence of renal failure.[51] Because they are metabolized in plasma and thus do not depend on renal or hepatic function for clearance, atracurium and cisatracurium are not associated with prolonged muscle weakness as a result of delayed clearance.[50]

Train-of-four stimulation can be used to monitor the depth of neuromuscular blockade, avoiding excessive paralysis and reducing the quantity of drug used as well as the recovery time of neuromuscular function in critically ill patients.[52] Although these benefits may not be seen when atracurium and cisatracurium are used,[53] train-of-four testing is sufficiently simple and inexpensive to perform that many experts believe it should be employed routinely.[54] Minimizing the use of neuromuscular blocking drugs in ventilator management and using train-of-four stimulation to monitor the degree of muscle relaxation as well as daily interruptions of paralysis can prevent unsuspected prolonged paralysis.[55]

Intensive Care Unit–Acquired Weakness

Unexpected, acute weakness and prolonged ventilatory failure was first reported in patients with status asthmaticus treated with corticosteroids and neuromuscular blocking drugs.[56,57] Subsequently, a similar syndrome has been recognized in other groups of ICU patients, especially those with sepsis and systemic inflammation, even without corticosteroid administration or therapeutic paralysis.[50] Both muscle and nerve abnormalities can predominate, leading to a confusing array of diagnostic terms, such as "critical illness myopathy," "critical illness polyneuropathy," "postparalytic myopathy," "ICU-acquired paresis," "acute quadriplegic myopathy," and the preferred term, "ICU-acquired weakness." The pathophysiology of ICU-acquired neuromuscular dysfunction is poorly understood, but may involve elements of disuse and active muscle catabolism sparked by systemic inflammation. Electromyography reveals reduced compound muscle action potential upon motor nerve stimulation (with normal conduction velocity); increased action potential duration; and spontaneous electrical activity on muscle needle recording (e.g., fibrillation potentials; positive sharp waves).[58] Biopsy findings may include primary axonal degeneration, type II muscle fiber atrophy, thick filament (myosin) loss, and (occasionally) necrotizing myopathy.

One quarter to one half of all patients who require more than 7 days of ICU care and the majority of patients who develop the systemic inflammatory response syndrome can be shown by neurophysiologic testing to have ICU-acquired weakness.[50] These neurophysiologic abnormalities arise early, accumulate during the course of illness, and usually affect both nerves and muscles.[59] Prospective studies have shown that about one third of critically ill patients exhibit weakness on clinical evaluation.[50,60] The typical patient exhibits symmetrical extremity weakness in which proximal function is more impaired than distal and the facial muscles are spared. Clinically, this disorder can produce severe neuromuscular weakness, often affects the respiratory muscles, and may prolong the need for ventilatory support.[60,61] This syndrome should be suspected in patients who are weak (Medical Research Council [MRC] score < 48[60]) in the context of critical illness, have the typical clinical examination, and in whom no better alternative cause for weakness can be identified. Handgrip strength may serve as a simple test to identify ICU-acquired weakness.[62] Nerve conduction studies, electromyography, and muscle biopsy generally are not necessary, but their role in diagnosis remains an area of active investigation. The prognosis for recovery of strength is variable, with many patients improving rapidly over days to weeks while others remain weak for many months or longer. The incidence of ICU-acquired weakness can be reduced by intensive insulin therapy,[61,63,64] avoiding neuromuscular blocking drugs and corticosteroids where possible, and possibly by physical therapy.[64a] Because ICU-acquired weakness is so strongly associated with severity of illness, length of ICU stay, and the presence of multiple organ system dysfunction, prevention focuses on scrupulous attention to good general ICU care and avoidance of sepsis.[50]

Ventilator-Induced Diaphragmatic Dysfunction

Many critically ill patients develop muscle weakness that impedes functional recovery and is associated with prolonged mechanical ventilation. Some component of this represents ICU-acquired weakness,[65] but mechanical ventilation itself (without systemic inflammation) is sufficient to weaken respiratory muscles.[66-68] The lack of neural stimulation or associated contraction plays a role in the evolution of weakness because measures to keep muscles contracting can ameliorate weakness. The diaphragm, the muscle most responsible for sustaining the work of breathing, may be even more sensitive than other skeletal muscles to the effects of critical illness. In animal models, the diaphragm weakens during the first 1 to 3 days of mechanical ventilation. Using phrenic nerve stimulation, one study demonstrated a reduction in maximal transdiaphragmatic pressure in a group of ventilated patients in comparison to findings in normal volunteers.[69] As in studies of peripheral skeletal muscle, stimulating the diaphragm to contract serves to attenuate greatly the loss of strength.[70] This raises the possibility that partial rather than full ventilatory support may serve to maintain diaphragmatic strength, potentially reducing time on the ventilator.[70]

Assessment of Need for Mechanical Ventilation in Neuromuscular Weakness

Respiratory muscle weakness should be considered when there is obvious peripheral muscle weakness, but neuromuscular abnormalities may not always be evident. Respiratory muscle weakness may also be suspected when dyspnea is out of proportion to radiographic and respiratory mechanical abnormalities seen during mechanical ventilation. Further confirmation can be gained by measuring the maximal inspiratory pressure or, in some instances, by performing ultrasound examination of the diaphragms.

Early clinical indicators of the need for mechanical ventilation in patients with neuromuscular weakness remain controversial. In addition to subjective assessments of symptoms of dyspnea and of respiratory distress, objective assessments of vital capacity and maximum inspiratory pressure have generally been used to evaluate ventilatory muscle capability. In one retrospective study, 60 patients with Guillain-Barré syndrome who required intubation and ventilation were compared with 54 similar patients who did not. Clinical evidence of rapid disease progression, development of bulbar weakness, bilateral facial weakness, and dysautonomia were highly correlated with the need for intubation and mechanical ventilation.[29] Other findings associated with intubation were a vital capacity of less than 20 mL/kg, a maximum inspiratory pressure that failed to reach −30 cm H_2O, a maximum expiratory pressure of less than 40 cm H_2O, or a decrease in one or more of these functions by at least 30% of the initial value.[29] However, without prospective randomized studies, the predictive value of these thresholds cannot be confirmed.

A prospective study of electromyography in 60 patients with Guillain-Barré syndrome, in which the managing clinicians were unaware of the test results, showed that electrophysiologic evidence of demyelination was highly correlated with the need for intubation and mechanical ventilation.[71] In another study of patients with Guillain-Barré syndrome, 44 patients who required mechanical ventilation were more likely to have cranial nerve involvement and immunoglobulin G (IgG) anti-GQ1b antibodies than were 87 patients who did not require ventilation.[72]

For patients with myasthenia gravis, not all studies have found bedside tests of pulmonary function to be predictive of the need for intubation and mechanical ventilation.[73] Nonetheless, most authors recommend serial assessments such as vital capacity in patients hospitalized with acute neuromuscular disease in order to detect as early as possible the need for ventilatory assistance.[74] Although the optimal means for monitoring respiratory muscle function remain uncertain, it is clear that intubation and mechanical ventilation should be undertaken prior to the development of severe respiratory acidosis or respiratory arrest. For this reason, patients with acute neuromuscular disease who show signs of pulmonary compromise should be monitored in an ICU. Although the rate of progression may fluctuate, serial measurements of vital capacity and maximal inspiratory pressure along with repeated physical examinations focusing on bulbar function and ability to cough are advisable to avoid emergent intubations (Fig. 92-3).[75]

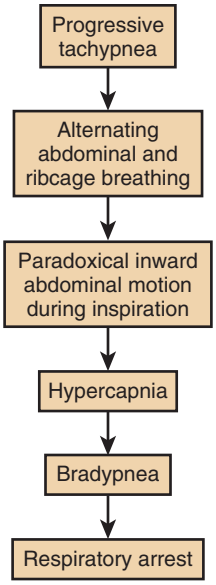

FIGURE 92-3 ■ The sequence leading to respiratory arrest with failure of the ventilatory pump. Individual patients proceed through the steps shown at variable rates and may skip one or more stages. However, except for sudden events affecting the central nervous system or the administration of paralyzing drugs, respiratory arrest does not occur abruptly without preceding physical manifestations. (Adapted in part from Cohen CA, Zagelbaum G, Gross D, et al: Clinical manifestations of inspiratory muscle fatigue. Am J Med 73:308–316, 1982.)

Principles of Ventilator Management

Patients with acute ventilatory failure due to neuromuscular disease usually have normal underlying lung function. Because atelectasis is especially common for these patients,[76,77] it has been common practice in the past to use larger than usual tidal volumes, typically 12 to 15 mL/kg or more. Anecdotally, many patients with neuromuscular disease seem less dyspneic with large tidal volumes, although this has not been subjected to prospective evaluation. As a result of the use of large tidal volumes, such patients commonly manifest respiratory alkalosis. A reasonable alternative is to use more typical tidal volumes (~6 mL/kg), faster rates, and 5 to 10 cm H_2O PEEP to prevent atelectasis while avoiding respiratory alkalosis. Patients incapable of breathing unassisted should be ventilated in a manner that makes them comfortable; there is no convincing evidence that "exercising" their respiratory muscles speeds recovery. Also, no evidence supports the use of weaning approaches other than those currently recommended for other patients with acute ventilatory failure,[78] although, prior to extubation,

special attention should be paid to the patient's ability to protect the airway and clear secretions once the patient can breathe unassisted.

ACUTE VENTILATORY FAILURE DUE TO THORACIC OR LUNG RESTRICTIVE MECHANISMS

Many restrictive diseases of the lungs or chest wall progress insidiously over months or years. Critical illness may represent the natural history of the underlying condition but may also signal an acutely superimposed, potentially reversible crisis such as infection, pneumothorax, or thromboembolism.

Chest Wall and Pleural Disease

Thoracic restriction and ventilatory muscle dysfunction due to severe kyphoscoliosis typically leads to gradually progressive ventilatory insufficiency, and patients can present with acute or acute-on-chronic ventilatory failure and require intensive care. Physiologic studies have shown that both lung and chest wall mechanics are impaired during acute respiratory failure in patients with kyphoscoliosis.[79] Primary disease of the pleura, such as asbestos-related diffuse pleural thickening or postinflammatory fibrothorax, could potentially present in similar fashion; but dyspnea and hyperventilation are more common with these diseases, and respiratory acidosis develops late in the course of the disorder unless ventilatory drive is depressed or there is concomitant lung involvement. Pleural effusion or pneumothorax can likewise precipitate acute ventilatory failure but usually in the presence of underlying obstructive or restrictive pulmonary disease. Obesity-hypoventilation syndrome with decompensated cor pulmonale, discussed earlier, is another example of acute-on-chronic ventilatory failure involving pulmonary restriction. The fact that most severely obese individuals do not have hypercapnia or develop acute ventilatory failure emphasizes the fact that this phenomenon is multifactorial.

Long-term noninvasive ventilation appears to be beneficial in selected patients with kyphoscoliosis and other chest wall diseases,[80] and has been reported to be successful in acute-on-chronic ventilatory failure[81,82] as well as in obesity-hypoventilation.[83] However, patients with acute ventilatory failure due to restrictive mechanisms may require intubation during the acute phase of their illness because noninvasive ventilation may be a less effective option in restrictive than in obstructive lung disease. For example, patients with restrictive disease may need higher inflation pressures due to increased chest wall elasticity; the lower volumes and superimposed neuromuscular weakness in restrictive disease may limit expiratory flow and cough efficiency leading to retained secretions. In a recent study of patients with chest trauma complicated by persistent hypoxemia, NPPV reduced the need for intubation and shortened the hospital stay.[84]

Parenchymal Lung Disease

Idiopathic pulmonary fibrosis and other pulmonary parenchymal restrictive diseases are usually associated with hyperventilation rather than hypoventilation. However, acute ventilatory failure can occur in the late stages of these conditions, either as a manifestation of the primary disease process[85,86] or, more often, in conjunction with pneumonia, surgery, or other intercurrent illness.[87-89] Physiologic assessment has demonstrated markedly increased lung stiffness and resistance in patients with end-stage idiopathic pulmonary fibrosis requiring mechanical ventilation,[89] explaining the development of hypercapnia and acute ventilatory failure in such individuals.

Several series have documented the poor prognosis of patients who present with acute respiratory failure in the setting of advanced interstitial fibrosis.[86,88,89] In one retrospective report of 14 consecutive patients with idiopathic pulmonary fibrosis admitted to the ICU with acute respiratory failure, all 14 died despite aggressive ventilatory support.[87] In a second report, of 23 similar patients, 22 patients died, the single survivor received a lung transplant shortly after admission.[88] In a third series of 19 patients with pulmonary fibrosis who received mechanical ventilation mostly for acute respiratory failure complicating the underlying disease, 13 died.[89] Outcomes appear equally poor regardless of whether ventilation is invasive or noninvasive.[90]

Principles of Ventilator Management

During NPPV of patients with restrictive disease, the need for higher airway pressures than are used for COPD, and thus the difficulty in achieving a seal at the interface and in avoiding gastric insufflation, lowers the likelihood of success. Furthermore, considering that a superimposed confounder such as a respiratory infection often precipitates the acute bout of respiratory failure, accompanied by increased work of breathing and secretion retention, invasive ventilatory support (as with volume-targeted assist-control ventilation) is usually required. The best way to ventilate patients with acute respiratory failure in the setting of underlying restrictive thoracic or lung disease has not been determined by clinical trials. The potential for hemodynamic compromise, barotrauma, and ventilator-induced lung injury with the use of high pressures and the physiologic similarity to ARDS in patients with deteriorating pulmonary fibrosis make it reasonable to apply similar lung-protective ventilator strategies and management targets (see Chapter 89). Low tidal volumes (e.g., 6 mL/kg predicted body weight) should be applied, attempting to keep the end-inspiratory plateau pressure at less than 30 cm H_2O if possible. Patients with restrictive lung disease typically breathe rapidly and shallowly, so tachypnea may not be avoidable during the weaning process and should not be used

as the sole reason for delaying extubation if gas exchange and other assessments are acceptable.

ACUTE VENTILATORY FAILURE DUE TO AIRWAY OBSTRUCTION

Upper Airway Obstruction

Upper airway obstruction is an occasional cause of acute ventilatory failure. The onset can be precipitous, as with occlusion of the glottis by an aspirated foreign body (i.e., "café coronary") or a swollen and edematous epiglottis due to acute epiglottitis.[91] The onset can also be insidious, occurring over months, as with a tracheal tumor. The severity and length of narrowing and air flow determine the resistance and thereby the additional work of breathing imposed by the obstruction. Gradually progressive upper airway narrowing may be well tolerated, at least during breathing at rest, until a critical limit is reached, often when the airway diameter drops to the range of 5 to 6 mm.

The location and variability of the narrowing are also important in determining the clinical manifestations. Extrathoracic variable upper airway narrowing affects mainly inspiratory flow because the negative intraluminal pressure exacerbates the narrowing during inspiration. During expiration, the positive intraluminal pressure tends to push variable extrathoracic obstructions open. Vocal cord paralysis is an excellent example of a variable extrathoracic upper airway obstruction, producing stridor and severe airway obstruction during inspiration but no significant obstruction during expiration. The opposite pertains to variable intrathoracic obstructions, with narrowing becoming less severe during inspiration as pressure gradients favor airway widening. During expiration, the airways narrow and the severity of the obstruction worsens. Tracheomalacia can cause variable intrathoracic airway obstruction. Fixed obstructions affect both inspiration and expiration regardless of their location.

Pathophysiologically, upper airway obstruction causes ventilatory failure by increasing airway resistance to the point at which respiratory muscles can no longer maintain minute volume at a level adequate to maintain CO_2 homeostasis. Negative-pressure pulmonary edema can contribute to the gas-exchange impairment.[92] Conceptually, the therapeutic aim is to relieve the obstruction. This may be achieved by removal of a foreign body, laser therapy of an endotracheal tumor, placement of a stent in an area of tracheomalacia or stenosis, or tracheostomy to bypass an area of obstruction. Inhalation of heliox, continuous positive airway pressure (CPAP), or noninvasive ventilation can be useful to reduce the work of breathing and avoid intubation in patients who have reversible causes of their upper airway obstruction, such as postextubation stridor, or who are awaiting tracheostomy or surgical repair of an obstruction. However, these temporizing measures require close monitoring with the recognition that the patient can deteriorate abruptly.

Chronic Obstructive Pulmonary Disease

COPD is the fourth leading cause of death among adults aged 65 to 84 in the United States and poses enormous costs to the U.S. health care system. Exacerbation of COPD is the most common cause of acute ventilatory failure in the U.S. adult population. Although COPD exacerbations are most commonly infectious in etiology, either viral or bacterial, a number of other etiologies should be considered when patients with COPD have respiratory deterioration, including acute pneumonia, congestive heart failure, pulmonary embolism, pneumothorax, or environmental exposure.

Pathophysiology

Exacerbations of COPD lead to acute ventilatory failure in perhaps one third of patients admitted to an acute care hospital for exacerbation. Those with severe COPD (stage 2 or 3, forced expiratory volume in 1 second [FEV_1] < 50%) are at the highest risk. Severe COPD places the respiratory muscles at a mechanical disadvantage.[93] As depicted in Figure 92-4 for a patient with emphysema, hyperinflation flattens the diaphragm, increasing its radius of curvature. According to Laplace's law, this increases muscle tension and the impedance to blood flow. Even at residual volume, the diaphragm remains flat with a relatively short sarcomere length, and inspiratory-force generation is compromised by the diaphragm's inability to reach a sufficient length on its length-tension curve. Also, because of the horizontal orientation of the diaphragm and the loss of the zone of apposition between the diaphragm and the chest wall, the force vector on the lower rib cage becomes inward rather than cephalad, so lower rib cage motion during inspiration becomes paradoxical, moving inward on inspiration instead of outward, a movement referred to as the "Hoover sign." Accessory muscles are recruited to maintain ventilation at the hyperinflated lung volumes, contributing to the already increased oxygen cost of breathing. Finally, incomplete emptying leading to positive pressure in alveoli at end-expiration (intrinsic or auto-PEEP) poses an inspiratory threshold load requiring that the inspiratory muscles work to reduce this pressure to subatmospheric levels in order to initiate airflow for the next inspiration.

During an exacerbation of COPD, this precarious situation becomes potentially catastrophic. Usually related to a combination of swelling, secretions, and bronchospasm caused by acute inflammation, the airway resistance increases adding to the work of breathing. As depicted in Figure 92-5, patients with severe COPD often reach a limitation to expiratory flow, even during resting breathing, and a small increase in airway resistance lowers airflow further at any given lung volume. The patient's only workable strategy, if airflow is to be maintained, is to breathe at even higher lung volumes, a futile compensatory response that adds further to the work of breathing. Patients adopt a rapid, shallow breathing pattern, thus shortening the time for expiration and aggravating intrinsic PEEP. The diaphragm flattens more and

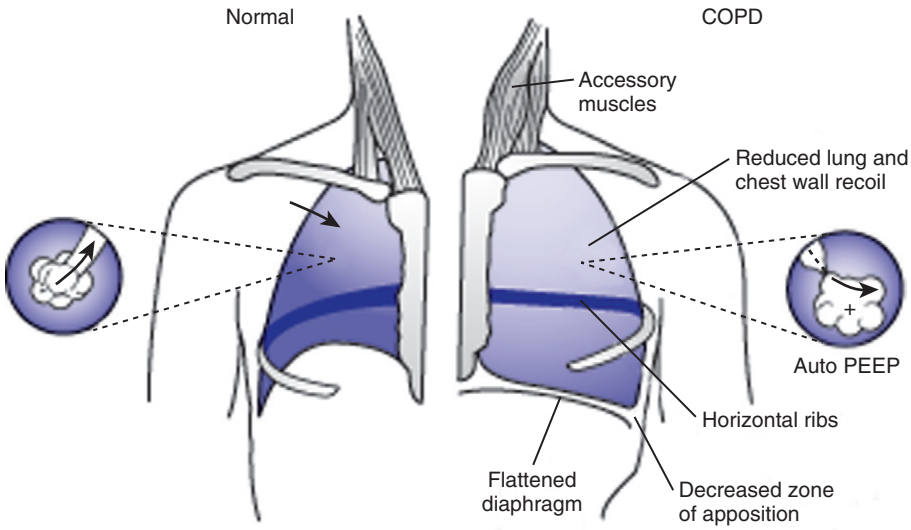

FIGURE 92-4 ■ Schema depicting the chest wall configuration at functional residual capacity of a normal individual (left hemithorax) and a patient with severe chronic obstructive pulmonary disease (COPD; right hemithorax). The COPD patient has a flattened diaphragm, which increases its radius of curvature and increases the tension for a given pressure. The COPD patient's ribs are horizontal, and the zone of apposition between the diaphragm and chest wall is reduced, greatly reducing the diaphragm's efficiency in expanding the chest wall. Also, intrinsic positive end-expiratory pressure (Auto PEEP) poses an inspiratory load, adding further to the inspiratory work. Exhalation is slowed by airway collapse and the loss of elastic recoil. (Redrawn from Hill NS: Current concepts in mechanical ventilation for chronic obstructive pulmonary disease. Semin Respir Crit Care Med 20:375–395, 1999.)

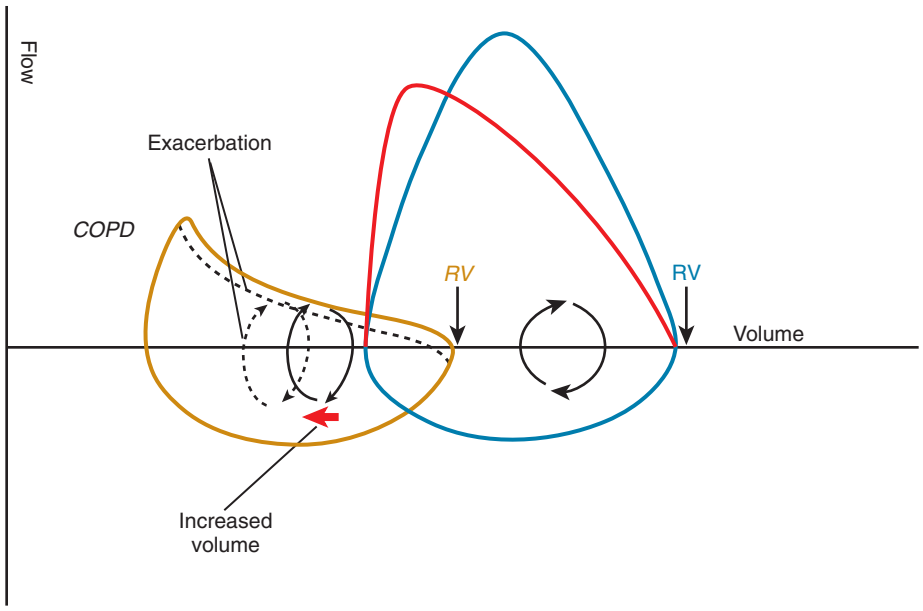

FIGURE 92-5 ■ The flow-volume loops are shown for a patient with a normal lung (*blue line on right*) and one with COPD (*brown line on left*) along with their respective tidal volume loops (*inner black loops with arrows*). Note that the expiratory flow during tidal breathing in the COPD patient reaches maximal expiratory flow. During an exacerbation (*interrupted lines*), expiratory flow drops; because the flow during tidal breathing is already maximal, the only mechanism available for maintaining flow is to increase lung volume during tidal breathing (leftward shift of tidal breathing loop, shown by *thick red arrow*). Although this strategy maintains expiratory flow, it increases the work of breathing and oxygen consumption, predisposing to inspiratory muscle fatigue and eventual respiratory failure. (Redrawn from Hill NS: Current concepts in mechanical ventilation for chronic obstructive pulmonary disease. Semin Respir Crit Care Med 20:375–393, 1999.)

develops increased tension, augmenting impedance to blood flow. The resulting limitation in the supply of substrate to the muscle is aggravated by progressive hypoxemia, caused by worsening hypoventilation and V/Q imbalance related to secretion retention. Thus, as the demand for breathing increases, the capacity to supply the increased work of breathing becomes further compromised. Despite the worsening alveolar hypoventilation, the drive to breathe is increased and the diaphragm becomes fatigued, characterized by reduced muscular performance despite a steady or increased neural drive. A vicious circle ensues, leading inexorably to worsening respiratory muscle fatigue, ventilatory failure, and death unless therapeutic interventions interrupt the cycle.

Clinical Assessment

Patients with exacerbations of COPD must be carefully evaluated to identify those at risk of developing respiratory failure and to exclude other causes of respiratory failure. Historical and physical features are very useful. Although Borg's or visual analogue scales help gauge the level of dyspnea in clinical studies, a subjective assessment that dyspnea is worse than baseline and of at least moderate severity places the patient at risk for respiratory failure. Physical findings seen with severe exacerbations include tachypnea, accessory muscle use, abdominal paradox, Hoover's sign (inspiratory inward motion of the lower, lateral rib cage), cyanosis, and mental status alterations.

In addition to a sputum examination for purulence, a white blood cell count, an electrocardiogram, a chest radiograph, and arterial blood gases should be obtained to assess the severity of an exacerbation. The widespread use of continuous pulse oximetry has decreased, but not eliminated, the need for arterial blood gases. Arterial blood gases provide a rapid assessment of arterial P_{CO_2} and pH, information that is critical when deciding to place patients in critical care units or to initiate mechanical ventilation and in assessing response to therapy. During severe exacerbations, chronic CO_2 retainers develop acute-on-chronic hypercapnia, manifested by a drop in pH indicative of retained CO_2 uncompensated by bicarbonate, an important indicator requiring measurement of arterial blood gases.

Medical Therapy

When patients with severe exacerbations come to medical attention, they are promptly begun on medical therapy, such as bronchodilators, corticosteroids, and antibiotics. Additional therapies include diuretics and nitrates if congestive heart failure is thought to be contributing and anticoagulation if pulmonary embolism is considered a risk. Oxygen supplementation is routine but must be administered with caution in patients with CO_2 retention. Overzealous oxygen supplementation in such patients has long been known to aggravate CO_2 retention, by either blunting the hypoxic ventilatory drive, increasing physiologic dead space (perhaps due to oxygen-induced bronchodilation in poorly perfused lung regions), or both. Because hypoxemia in COPD patients is usually due mainly to the hypoventilation and is easily reversed, initial supplementation with nasal oxygen at 2 L/min is often adequate. In patients with severe exacerbations, arterial blood gases should be repeated periodically to assess the effect of oxygen supplementation on arterial P_{CO_2}.

Noninvasive Mechanical Ventilation

Medical therapy alone is often effective and is the therapy of choice for mild COPD exacerbations. However, when exacerbations are more severe or medical therapy fails, manifested by persisting or worsening tachypnea and dyspnea as well as CO_2 retention, respiratory muscles may begin to fatigue, requiring ventilatory assistance. In the past, patients who failed medical therapy were endotracheally intubated and mechanically ventilated; if they declined intubation, they were kept comfortable and usually died. Invasive mechanical ventilation was successful in the majority of cases, but hospital mortality rates were substantial, averaging 30% in several studies.[94] Complications of invasive mechanical ventilation were common, including upper airway trauma, pneumothorax, and nosocomial infection, contributing to patient mortality.[95]

In the early 1990s, noninvasive positive-pressure ventilation (NPPV) began to be used increasingly to treat COPD exacerbations. Consisting of a mask (or interface) that conducts pressurized air into the lungs from a positive-pressure ventilator, NPPV has appeal for the therapy of COPD exacerbations because it is an effective way of providing partial ventilatory assistance.[96] It also avoids airway invasion and many of the complications of invasive mechanical ventilation, such as upper airway trauma, nosocomial infection, and prolonged intubation.[95]

NPPV has the potential to reverse the vicious circle leading to respiratory failure in patients with severe exacerbations of COPD. CPAP reduces the work of breathing during COPD exacerbations by counterbalancing the effects of intrinsic PEEP, effectively reducing or even eliminating the inspiratory threshold load.[97] Pressure support also reduces the work of breathing in COPD patients, assisting each breath by increasing airway pressure during inspiration.[97] However, when CPAP and pressure support are combined, NPPV reduces the transdiaphragmatic pressure more than either CPAP or pressure support alone.[97] Thereby, NPPV has the potential to serve as a "crutch," reducing the work of breathing and halting the progression of respiratory muscle fatigue while medical therapies are given time to work.

Acute Exacerbations. NPPV is effective in treating acute respiratory failure due to COPD exacerbations. Starting with Brochard and coworkers[96] using historically matched controls and subsequent randomized, controlled trials,[98–100] a number of benefits have been attributed to NPPV in these patients. These include more rapid improvements in arterial P_{CO_2},[98] heart and respiratory rates, and dyspnea scores[98–100] within the first hour in noninvasively-treated patients compared with rand-

omized conventionally-treated controls. Encephalopathy scores also improve more rapidly,[100] intubation rates drop precipitously (from roughly 75% in controls to 25% in NPPV-treated patients),[98,99] and the mortality rate is lowered (from 30% in controls to ~10% with NPPV).[99] In addition, complication rates and hospital lengths of stay fall significantly compared with those of controls.[98–100]

In the largest study thus far reported,[100] 236 patients with exacerbations of COPD were randomized to receive NPPV or standard therapy administered by nurses in general medical respiratory wards at 14 medical centers in England. Intubation and mortality rates were significantly lower in the NPPV group than in controls (15% vs. 27%, $P = .02$, and 10% vs. 20%, $P = .05$, respectively), and the study confirmed the earlier findings of more rapid improvements in arterial pH, respiratory rate, and breathlessness in the NPPV group compared with the control group. Notably, the mortality benefit was not apparent in patients with pH less than 7.30. The authors speculated that these sicker patients might have fared better had they been monitored in an ICU. In the only study with negative findings,[101] NPPV failed to lower intubation or mortality rates or hospital lengths of stay in patients admitted consecutively to the hospital with COPD exacerbations, but it is notable that no intubations or mortality occurred in the control group. This suggests that patients with relatively mild COPD exacerbations are not likely to benefit from NPPV, implying that NPPV should be applied to selected patients who have a demonstrable need for ventilatory assistance.

Several meta-analyses have combined the results of the previous studies.[102,103] These concluded that NPPV is effective in avoiding intubation (relative risk 0.42 and absolute risk reduction 28%, respectively), reducing mortality (relative risk 0.41 and absolute risk reduction 10%, respectively), and shortening hospital length of stay (by ~4 days). Based on this evidence, the authors of these meta-analyses, reviews, and consensus groups[102–106] have advised that NPPV should be used early in the course of COPD exacerbations.

Chronic Obstructive Pulmonary Disease Complicated by Pneumonia. Pneumonia has been associated with a poor outcome in patients treated with NPPV.[107] However, in one trial of patients with "severe community-acquired pneumonia," defined as patients with severe hypoxemia ($PaO_2/FIO_2 < 200$) and respiratory distress (respiratory rate > 35/min), randomized to NPPV or to standard oxygen therapy, NPPV reduced the need for intubation (21% vs. 50%, $P = .03$), shortened the ICU length of stay (1.8 vs. 6.0 days, $P = .04$), and lowered the mortality rate among the COPD subgroup of patients determined 2 months after hospital discharge (11% vs. 63%).[108] Thus, although the presence of pneumonia is a risk factor for poorer outcome with NPPV, these patients can still benefit from NPPV. Moreover, a COPD exacerbation complicated by pneumonia is an appropriate indication for NPPV.

Postoperative Patients. A randomized trial of NPPV in post–lung resection patients with acute respiratory insufficiency showed significant reductions in the need for intubation, ICU length of stay, and mortality rate compared with conventionally-treated controls.[109] Although only a portion of these patients had COPD, accumulating evidence now supports the use of NPPV in selected postoperative (including COPD) patients to maintain improved gas exchange and avoid reintubation and its attendant complications. Noninvasive positive-pressure techniques (CPAP or NPPV) are also being used prophylactically to reduce secretion problems, atelectasis, and hypoxemia after some high-risk operations such as thoracoabdominal[110] and major abdominal[111] surgery.

To Facilitate Extubation. NPPV has been used to facilitate early extubation after bouts of acute respiratory failure in patients who fail to meet standard extubation criteria, with the aim of shortening the duration and thereby avoiding the complications of invasive mechanical ventilation. One randomized controlled trial of 56 COPD patients who had been intubated for 48 hours and failed a T-piece trial[112] found that, compared with controls left intubated, the early extubation/NPPV group had a higher overall weaning rate after 60 days (88% vs. 68%), a shorter duration of mechanical ventilation (10.2 vs. 16.6 days), a briefer stay in the ICU (15 vs. 24 days), and an improved 60-day survival (92% vs. 72%) (all $P < .05$). A more recent randomized, controlled trial in patients with "persistent weaning failure" (failure of spontaneous weaning trials on 3 consecutive days) showed that the early extubation/NPPV group had significant reductions in ICU and hospital days, a lower incidence of nosocomial pneumonia (from 59% to 24%, $P < .05$), diminished hospital and 90-day mortality (odds ratio 3.5), and fewer complications.[113] Thus, these randomized, controlled studies have yielded results supporting early extubation to NPPV. However, if early extubation is contemplated, it should be reserved for carefully selected intubated COPD patients. Patients should be on 15 cm H_2O or less of pressure support, able to sustain 5 to 10 minutes of unassisted breathing, have an adequate cough without excessive secretions, be easy to intubate, and have few if any comorbidities.

Extubation Failure. NPPV can be used in an attempt to avoid reintubation in patients who fail extubation. Extubation fails after 5% to 20% of planned[114] and 40% to 50% of unplanned[115] extubations and extubation failure has been associated with a mortality of 43% compared with only 12% in those who succeed after extubation.[114] In a historically controlled study of 30 COPD patients with extubation failure,[116] NPPV lowered the reintubation rate (20% vs. 67%, $P < .05$) and ICU length of stay. In a subsequent randomized trial of patients at high risk for extubation failure and who developed respiratory distress within 48 hours of extubation, however, NPPV did not reduce the need for intubation, duration of mechanical ventilation, length of hospital stay, or mortality.[117] However, COPD patients were excluded from this study after the first year because of ethical concerns. In an international randomized trial of 221 patients with risk factors for extubation failure, those randomized to NPPV showed an unexpected increase in mortality rate compared with the standard treatment group, most likely related to a longer delay before proceeding with reintubation.[118] Notably, only 10% of patients in this

study had COPD and 25% of controls were crossed over to NPPV when they further deteriorated and met criteria for reintubation. These crossover patients had reintubation rates of only 25%, half that of the intention-to-treat NPPV group. This led to the speculation that results would have been favorable if more patients with COPD had been enrolled and NPPV had been reserved for patients with frank extubation failure but good candidates for NPPV, similar to the crossover group. This speculation has been borne out by two subsequent randomized, controlled trials, one showing drastic reductions in respiratory failure, need for reintubation, and mortality in a subgroup of hypercapnic patients[119] and the other demonstrating that patients at "high risk" for postextubation failure had better outcomes when treated with NPPV.[120,120a] Thus, the best current recommendation is to use NPPV selectively in patients with extubation failure, mainly for COPD or other hypercapnic patients, but to avoid delays in needed intubation should NPPV fail.

Do-Not-Intubate Patients. The use of NPPV to treat respiratory failure in patients who have declined intubation accounted for 10% of acute applications in one survey.[121] This application has been controversial, with some arguing that there is little to lose because it may reverse the acute deterioration or, at least, provide relief of dyspnea and a few extra hours to finalize affairs.[122] Others have argued that this merely prolongs the dying process, consumes resources inappropriately, and may add to discomfort or counter patients' wishes about avoiding life-prolonging measures.[123] In prospective observational studies of 113[121]and 131[124] "do-not-intubate" (DNI) patients treated with NPPV, survival to hospital discharge was greater than 50% for COPD and congestive heart failure patients, whereas it was lower (14%–25%) for those with a diagnosis of hypoxemic respiratory failure (pneumonia) or advanced cancer. Thus, NPPV can be used to treat respiratory failure for DNI patients with acutely reversible processes such as COPD exacerbations or acute cardiogenic pulmonary edema. Alternatively, it can be used to palliate DNI patients, by alleviating dyspnea or providing temporary support. The patient or the family should be informed that NPPV is being used as a form of life support that may be uncomfortable and can be removed at any time.

Heliox Combined with Noninvasive Ventilation. By virtue of its lower density compared with nitrogen, helium can be combined with oxygen to lower the airway resistance attributable to turbulent flow. The oxygen concentration can be increased to 40% in the helium-oxygen mixture but not higher without losing the density advantage of the added helium. Heliox has been combined with NPPV to treat patients with COPD exacerbations, with beneficial physiologic responses including reduced airway resistance and more rapid improvements in gas exchange.[125] However, a randomized, prospective trial on patients with COPD in respiratory failure found that the addition of heliox to NPPV offered no significant advantages over NPPV alone in terms of intubation or mortality rates or hospital lengths of stay.[126]

TABLE 92-2. Predictors of Success for Noninvasive Positive-Pressure Ventilation in the Acute Setting

ABLE TO COOPERATIVE
Synchronous breathing with NPPV
Good neurologic status
Better "compliance"*
ABLE TO PROTECT AIRWAY
Low volume of secretions
Minimal air leaking
Dentate (dentition corresponds with minimal air leak)
NOT TOO ACUTELY ILL
No pneumonia
Low APACHE score
Initial arterial P_{CO_2} < 92 mm Hg
Initial pH > 7.10
GOOD INITIAL RESPONSE TO NPPV (WITHIN FIRST HR OR TWO)
Improvement in pH
Reduction in respiratory rate
Reduction in arterial P_{CO_2}
Improved level of consciousness

*"Compliance" refers to the clinician's assessment of the patient's acceptance of the technique.

Crit Care Med 22:1253–1261, 1994.

Patient Selection. Selection of appropriate patients is key to the successful application of NPPV. The selection process takes into account a number of factors, including the patient's clinical characteristics and risk of failure on NPPV. Ultimately, it becomes a clinical judgment depending largely on physician experience. Predictors of success of NPPV have been identified[107,127] (Table 92-2) and include a better neurologic status (and hence more cooperativeness), ability to protect the airway, and no more than moderate acid-base or gas-exchange derangement. Several studies have also found that improvements in pH, Pa_{CO_2}, and level of consciousness within the first hour or two of NPPV initiation are strong predictors of success.[107,127] These studies indicate that there is a "window of opportunity" when initiating NPPV that opens when patients need ventilatory assistance but closes if they progress too far and become severely acidemic. Thus, early initiation of NPPV is recommended so patients have time to adapt and respiratory crises can be averted. Conversely, NPPV begun too early might be unhelpful and wasteful of resources if treated patients would have done well without any ventilatory assistance. For this reason, selection guidelines suggest first establishing the need for ventilatory assistance according to clinical and blood gas criteria (indicating that the

TABLE 92-3. Selection Criteria for Noninvasive Positive-Pressure Ventilation in Acute Exacerbations of Chronic Obstructive Pulmonary Disease

ESTABLISH NEED FOR VENTILATORY ASSISTANCE
Moderate to severe respiratory distress
Tachypnea (RR > 24 breaths/min)
Accessory muscle use or abdominal paradox
Blood gas derangement
pH < 7.35, arterial P_{CO_2} > 45 mm Hg *or*
Arterial P_{O_2}/F_{IO_2} > 200
EXCLUDE PATIENTS WITH CONTRAINDICATIONS TO NPPV
Respiratory arrest
Medically unstable (septic or cardiogenic shock, uncontrolled upper gastrointestinal bleeding, acute myocardial infarction with planned intervention, uncontrolled arrhythmias)
Unable to protect airway
Excessive secretions
Uncooperative or agitated
Unable to fit mask
Recent upper airway or upper gastrointestinal surgery

window of opportunity has opened) and excluding patients in whom NPPV is contraindicated or likely to fail (indicating that the window of opportunity has closed) (Table 92-3).[128]

Practical Application of NPPV. A thorough discussion of the application of NPPV is beyond the scope of this chapter, and the reader is referred elsewhere for a more complete description.[105,129] The following sections focus on aspects relevant to applications in COPD patients with acute respiratory failure.

Mask Selection. The full face (oronasal) mask is usually the preferred initial mask choice for the acute setting because it avoids the leaking of air through the mouth that can be significant with nose masks.[130] Nasal masks, however, may be more comfortable for long-term applications,[131] so transitioning from a full face mask to a nasal mask should be contemplated after the first few days if NPPV is to be continued. Masks should fit optimally; a mask that is too small is uncomfortable, and one that is too large may require excessive tightening of the straps to minimize air leakage, predisposing to ulceration over the nose. Within each mask category (nasal and oronasal), many types of masks are now available. Practitioners should have a current knowledge of available masks in order to maximize the likelihood of success.

Ventilator Selection. In the acute setting, both "critical care" and "bilevel" ventilators (portable pressure-limited devices designed especially for the administration of NPPV) have been used with similar success rates. A bilevel device designed for use in the acute care setting that includes an oxygen blender and displays waveforms has gained popularity. In addition, many ventilators designed primarily for invasive mechanical ventilation now offer noninvasive modes that are programmed to improve leak compensation, silence "nuisance" alarms that are triggered by air leaks, and permit limitation of inspiratory time to enhance patient-ventilator synchrony.[132] The capabilities of these modes differ considerably between one another, however, and may require additional adjustment in the face of mask leaks.[133]

Ventilator Initiation. To begin NPPV, the properly sized mask is placed on the patient's face and attached to the ventilator. Patients often feel more comfortable if they can hold the mask themselves. Pressure-limited modes may be better tolerated than volume-limited.[134] Initial ventilator pressures are usually low, to enhance patient comfort and acceptance, but adjusted upward as tolerated to provide adequate ventilatory assistance. Typical initial settings on pressure-limited ventilators are 8 to 12 cm H_2O for inspiratory pressures (IPAP) and 4 to 5 cm H_2O for expiratory pressures (EPAP or PEEP), with subsequent adjustments as needed to alleviate respiratory distress (inspiratory pressure ≤ 20 cm H_2O) or to counterbalance intrinsic PEEP or treat hypoxemia (expiratory pressure ≤ 8 cm H_2O). The difference between IPAP and EPAP is the level of pressure support and should be adequate to alleviate inspiratory effort while avoiding excessive discomfort.

Coaching is usually necessary to enhance synchrony between the patient and the ventilator. Some ventilators permit adjustments in airflow to enhance synchrony, such as the "rise time," which determines the time to reach the target IPAP, and the adjustable inspiratory time. These may be helpful in optimizing comfort in COPD patients who tend to prefer relatively high inspiratory flows[135] (and hence short rise times, often 0.1 sec) and short inspiratory times (often < 1 sec) to avoid prolongation of delivered IPAP during expiration.

Oxygenation and Humidification. Most patients with COPD exacerbations do not have severe oxygenation defects and can be managed successfully with bilevel ventilators lacking oxygen blenders. With these ventilators, oxygen is administered at rates up to 15 L/min into ports in the mask or via a T-connector at the proximal end of the ventilator tubing, adjusted to maintain the desired level of oxygenation (usually to an arterial oxygen saturation [Sa_{O_2}] > 90%–92%). Because F_{IO_2} using this arrangement cannot exceed 45% to 50%, ventilators with oxygen blenders are necessary when the oxygen defect is more severe, such as may occur when COPD is complicated by pneumonia. Humidification should be used routinely because it may reduce the work of breathing and enhance comfort and tolerance during NPPV.[136,137]

Adaptation and Monitoring. The first few hours are critical in achieving successful adaptation. Coaching and encouragement are usually required to assist patients in synchronizing with the ventilator and reducing their breathing effort. Instructions such as "try to take slow deep breaths" and "let the machine breathe for you" may be helpful. Also, judicious administration of low doses of sedatives may enhance patient acceptance.

TABLE 92-4. Monitoring Noninvasive Positive-Pressure Ventilation in Chronic Obstructive Pulmonary Disease

ACUTE SETTING
Patient comfort
Mask fit and leak
Patient-ventilator synchrony
Sternocleidomastoid muscle activity
Vital signs (heart and respiratory rate; systemic blood pressure)
Continuous oximetry (until stabilized)
Occasional blood gases (initial and after 30–120 min, then as clinically indicated)
CHRONIC SETTING
Patient comfort
Mask fit and leak
Hours of use
Problems with adaptation (e.g., nasal congestion, dryness, gastric insufflation, conjunctival irritation, inability to sleep)
Symptoms (e.g., dyspnea, fatigue, morning headache, hypersomnolence)
Gas exchange (daytime, nocturnal oximetry, blood gases periodically to assess arterial P_{CO_2})
Polysomnography (if symptoms of sleep disturbance persist or nocturnal desaturation persists without clear explanation)

P_{CO_2}, partial pressure of carbon dioxide.

TABLE 92-5. Indications for Invasive Mechanical Ventilation in Chronic Obstructive Pulmonary Disease

Severe dyspnea with the use of accessory muscles and paradoxical abdominal motion
Respiratory frequency > 35 breaths/min
Life-threatening hypoxemia (arterial P_{O_2} < 40 mm Hg or arterial P_{O_2}/F_{IO_2} < 200)
Severe acidosis (pH < 7.25) and hypercapnia (arterial P_{CO_2} > 60 mm Hg)
Respiratory arrest
Somnolence; impaired mental status
Cardiovascular complications (hypotension; shock; heart failure)
Other complications (metabolic abnormalities; sepsis; pneumonia; pulmonary embolism; barotrauma; massive pleural effusion)
Failure of noninvasive positive-pressure ventilation

F_{IO_2}, fractional concentration of oxygen in inspired gas; NPPV, noninvasive positive-pressure ventilation; P_{CO_2}, partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen.

From Pauwels RA, Buist AS, Calverley PM, et al: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease: NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) workshop summary. Am J Respir Crit Care Med 163:1256–1276, 2001.

Close bedside monitoring is essential until the patient's respiratory status stabilizes. Although NPPV can easily be administered on general medical wards, the acuteness of the patient's illness and need for close monitoring should dictate the site of administration. Acutely ill patients should be treated in an ICU or step-down unit until their condition stabilizes, regardless of whether they are treated with invasive ventilation or noninvasive ventilation. As shown in Table 92-4, patient comfort and tolerance are key initial goals. In COPD patients, a drop in respiratory rate and reduction in sternocleidomastoid muscle activity are important salutary signs that should be apparent early. They are usually accompanied by good patient-ventilator synchrony, and upward adjustments in IPAP may enhance these effects. Sa_{O_2} is monitored continuously, and blood gases are obtained as is clinically indicated, usually at least once during the first hour or two.

Commonly Encountered Problems and Possible Remedies. Noninvasive ventilation is safe and well-tolerated in most properly selected patients. The most commonly encountered problems in COPD patients are similar to those in other patients and are related to the mask, air pressure, or airflow (see Table 92-4). Patients often complain of mask discomfort, which can be alleviated by minimizing strap tension or by trying different mask sizes or types. Patients may be anxious and experience difficulty synchronizing their breathing efforts with the ventilator. Adjustments in ventilator settings (increasing or lowering IPAP or titrating EPAP to counterbalance intrinsic PEEP) and judicious use of sedation often improve synchrony.

Excessive air pressure leading to sinus or ear pain is another common complaint, alleviated by lowering the pressure temporarily and then gradually raising it again as tolerance improves. Other commonly encountered problems include erythema, pain, or ulceration on the bridge of the nose related to pressure from the mask seal. Minimizing strap tension, using artificial skin, or switching to alternative masks such as nasal "pillows" can alleviate this problem. Gastric insufflation occurs frequently but is usually not severe, probably because inflation pressures are low.

Air leaking through the mouth (with nasal masks) or around the mask (with all interfaces) is inevitable during NPPV. Nasal and oronasal masks, particularly if too large, may leak air onto the eyes causing conjunctival irritation. Refitting or reseating the mask usually addresses this problem. Pressure-limited devices compensate for air leaks by maintaining inspiratory airflow during leaking but, during nasal ventilation, patients should keep their mouths shut, try chin straps to assist in mouth closure or, failing these measures, try an oronasal mask.

Invasive Mechanical Ventilation

Indications and Patient Selection. The increasing use of NPPV has reduced the need for invasive mechanical ventilation. However, there remain patients who are too ill and are not candidates for NPPV upon arrival to the hospital or who fail a trial of NPPV. Indications for the use of invasive mechanical ventilation for COPD are listed in Table 92-5.

Invasive mechanical ventilation in COPD must be administered with caution to minimize the risk of complications. Excessive tidal volumes and rates must be

avoided, and the urge to normalize $PaCO_2$ must be repressed in an effort to minimize intrinsic PEEP and excessive hyperinflation. Excessive respiratory rates reduce the respiratory cycle, shorten expiratory time, and prevent complete exhalation. This problem is aggravated by large tidal volumes. The consequence is air trapping and the potential for the adverse consequences of intrinsic PEEP. With intrinsic PEEP, increased intrathoracic pressure reduces venous return and lowers cardiac output. Patients with severe intrinsic PEEP may be hypotensive with low cardiac output and elevated pulmonary artery wedge pressure due to transmission of the intrathoracic pressure. In their clinical presentation, they may therefore mimic those with cardiac shock. Temporary disconnection from the ventilator can differentiate hemodynamic compromise due to intrinsic PEEP from true cardiogenic shock because the release of intrathoracic pressure permits rapid resolution of the former but not the latter. Intrinsic PEEP may also cause patient-ventilator asynchrony related to missed triggering due to the delay before the patient can lower the inspiratory threshold load.

Recommended Ventilator Settings. Volume-limited or pressure-limited modes can be used, but volume-limited assist-control is the most frequent choice initially and provides control over the tidal volume, which is important in avoiding dynamic hyperinflation. A small tidal volume (e.g., 5–7 mL/kg predicted body weight) should be used. Care should be taken to avoid overventilation and alkalemia. The need for sedation varies among patients, although muscle relaxants are seldom necessary. The backup respiratory rate for COPD patients receiving invasive mechanical ventilation should be set between 10 and 14/min. Given an inspiratory time of 1 second, if the respiratory rate is 20/min, the expiratory time is only 2 seconds; at a respiratory rate of 15/min, expiratory time increases to 3 seconds. Thus, relatively small changes in rate can effect large changes in expiratory time. Another way to increase expiratory time is to shorten the inspiratory time by increasing the inspiratory flow rate. However, this strategy is not as fruitful because substantial increases in flow rate result in only minor decreases in inspiratory time. For example, if the inspiratory time is 1 second and inspiratory flow is 60 L/min, an increase in the inspiratory flow rate to 100 L/min decreases the inspiratory time to 0.6 second (if tidal volume is held constant); thus, expiratory time increases only from 2.0 to 2.4 seconds. Furthermore, rapid flow rates may increase the spontaneous respiratory rate[138] as well as respiratory distress. COPD patients prefer flow rates in the 60 L/min range and tend to sense faster or slower rates as less comfortable.[135]

Weaning Chronic Obstructive Pulmonary Disease Patients from Invasive Mechanical Ventilation. Minimizing the duration of mechanical ventilation is desirable to minimize potential complications such as ventilator-associated pneumonia. When patients no longer require high levels of oxygen ($SaO_2 > 89\%$ on $FIO_2 \leq 40\%$), are hemodynamically stable and not excessively sedated, spontaneous breathing trials should be initiated. Pairing the spontaneous breathing trial with a daily interruption of sedation speeds liberation from the ventilator, reduces hospital and ICU length of stay, and lowers mortality.[139] If the patient can comfortably tolerate a trial of 30 to 120 minutes without excessive tachypnea, hemodynamic instability, or oxygen desaturation, extubation should be undertaken so long as the patient has an adequate cough without excessive airway secretions. If the patient fails to meet extubation criteria but is otherwise a good candidate for noninvasive ventilation, extubation to NPPV should be considered with the caveats discussed earlier.

Asthma

Acute ventilatory failure due to acute asthma should be unusual if patients adhere to a medical regimen including corticosteroid inhalers, monitor their peak flows, and alter their medical regimen (with the addition of enteral steroids) when peak flows begin to drop. Unfortunately, some patients are not treated with optimal regimens, some do not adhere to the regimen, and some have severe exacerbations even with optimal regimens, so acute ventilatory failure in asthmatics remains a problem. Studies on near-fatal asthma have identified several risk factors for exacerbation including poor access to health care, substance abuse, nonadherence with therapy, underuse of corticosteroids, and underestimation of the severity of attacks.[140]

Medical Management of Acute Asthma

Patients presenting with severe asthma should be promptly treated with systemic as well as inhaled corticosteroids and bronchodilators. Rapidly acting β_2-agonists are administered by inhalation, although no optimal route of administration or dose has been established. Metered-dose inhalers with spacers or nebulizers may be used, usually every 20 minutes for the first hour. Some centers use continuous nebulization for severe acute asthma. Magnesium, either intravenous or inhaled, has been administered, with some evidence to suggest that it aids aggressive β_2-agonist therapy, especially in the most severely ill asthmatics.[141]

Mixtures of helium and oxygen have been used since the 1930s to lower resistance to flow related to turbulence in the airways of asthma patients, just as in COPD patients. Several randomized, controlled trials of heliox have been performed with patients with acute asthma, but the results are inconclusive. Two demonstrated more rapid improvements in dyspnea and airflow with heliox than with oxygen alone,[142,143] but another showed no improvement in airflow rates (although dyspnea was reduced more by heliox).[144] The study showing little or no improvement with heliox enrolled less severely obstructed patients than the favorable studies, but a subgroup analysis of sicker patients in the negative study showed no benefit in that subgroup either. A Cochrane analysis concluded that there is no defined role for heliox in treating severe acute asthma,[145] but many centers use it when patients are not responding promptly to standard therapy.

Ventilatory Management

Assessment of Ventilatory Status. In patients with acute asthma exacerbations, frank ventilatory failure is unusual. Signs of severe respiratory distress, such as excessive use of accessory muscles, extreme tachypnea, or abdominal paradox, warrant the initiation of ventilatory assistance. Arterial blood gases showing normocapnia in a patient with severe respiratory distress should also cause alarm because patients reach a "crossover" point as they fail, when they can no longer sustain hyperventilation but have not become sufficiently fatigued to retain CO_2. These patients should be monitored closely so that noninvasive ventilatory aids can be initiated promptly in order to avert the need for invasive ventilation with its attendant potential complications.

Continuous Positive Airway Pressure. CPAP alone may ameliorate respiratory distress in asthmatics by stenting airways open, reducing atelectasis, and offsetting intrinsic PEEP. However, the unequal distribution of airways resistance in asthma, in contrast to the more simultaneous closure of airways in COPD, creates areas with very different expiratory time constants. In this setting, CPAP can promote overdistention of some lung regions. Thus, caution should be exercised when applying CPAP to these patients, at least at levels exceeding 5 cm H_2O and CPAP should be reduced to 5 cm H_2O or less if there is no further amelioration of respiratory distress at higher levels.

Noninvasive Ventilation. Despite the success of noninvasive ventilation in COPD exacerbations, its role in treating asthma exacerbations has not been clearly defined. An early cohort study observed substantial improvements in blood gases ($PaCO_2$ dropping from 65 to 52 mm Hg in the first 2 hours) among 17 patients treated with NPPV, only 2 of whom required intubation.[146]

In the one randomized trial on acute asthma that yielded favorable results,[147] patients treated with NPPV had significantly greater improvements in FEV_1 in the first hour compared with sham-treated patients (53.5% vs. 28.5%), and the need for hospitalization was significantly reduced. These results are encouraging, suggesting that the positive pressure might exert a bronchodilator effect; however, the results are not conclusive, because there was no evidence for reduced need for intubation or mortality. Nonetheless, a trial of noninvasive ventilation seems reasonable when patients fail to respond promptly to initial bronchodilator therapy, particularly if they manifest signs of respiratory muscle fatigue including a respiratory rate of more than 30 breaths/min, accessory muscle use, abdominal paradox, normocapnia in patients with respiratory distress, hypercapnia, or hypoxemia.

Invasive Mechanical Ventilation. Invasive mechanical ventilation in patients with acute ventilatory failure due to asthma should be used as a last resort but is necessary when patents present with coma or delirium or with hemodynamic instability. Another clear indication is failure of medical therapy that may include NPPV. Of patients admitted to the ICU with acute severe asthma, about one third have been reported to require invasive mechanical ventilation,[140,148] however, the proportion of patients who require intubation when its avoidance is a specific goal of therapy has not been determined. Invasive mechanical ventilation is best avoided because of the frequency and severity of the potential complications, but, if needed, intubation and ventilation should be initiated before a respiratory arrest, an emergent situation that heightens the risk of complications. Complications of mechanical ventilation in asthmatics include barotrauma such as pneumothorax and pneumomediastinum, reported in 6.5% of patients in one series,[149] the need for sedation and paralysis, which should be avoided because of the risk of postparalysis myopathy, ventilator-associated pneumonia, and mortality rates in the 5% to 10% range.[150]

If invasive mechanical ventilation is necessary, great care must be exercised to minimize the risk of complications, using an approach similar to that used for COPD patients. Excessive respiratory rates and tidal volumes should be avoided, with the ultimate goal of keeping plateau pressures under 30 to 35 cm H_2O. "Permissive hypercapnia,"[151] first described in invasively ventilated asthma patients,[152] remains a sensible approach in severely obstructed patients. In permissive hypercapnia, plateau pressures are maintained in the safe range as the first priority while allowing the CO_2 to rise, in some reports up to 70 to 100 mm Hg. Using this strategy, the major risks of positive-pressure ventilation can be minimized while providing time for the medical therapy to take effect. Bicarbonate or other buffers such as trishydroxymethyl aminomethane (THAM) can be administered if the pH drops too low but this is probably not necessary and may not even be effective in raising the pH, a situation also described in patients with acute lung injury.[153] Because of the variability of resistance between airways, some of which may be entirely obstructed, measurement of intrinsic PEEP using the expiratory hold technique may underestimate the severity of regional hyperinflation.[154] When ventilation remains difficult, even with use of lung-protective ventilation and permissive hypercapnia, the addition of heliox to the ventilator circuit may help (although heliox may alter ventilator performance and not all ventilators can accommodate heliox). As a last resort, extreme measures such as general anesthesia with bronchodilator anesthetics (e.g., halothane)[155] or induced hypothermia may be helpful. Anecdotally, *N*-acetylcysteine may be helpful in treating severe acute asthma with excessive mucus plugging, although no properly designed trials have tested efficacy, and worsening of bronchospasm is a potential side effect.

ACUTE VENTILATORY FAILURE DUE TO VASCULAR IMPAIRMENT

An increase in physiologic dead space by disorders affecting the pulmonary vasculature reduces alveolar ventilation in relation to overall minute ventilation. Although hypercapnia might be expected in such a cir-

cumstance, it is typically prevented by a modest increase in overall ventilation. Thus, acute ventilatory failure is seldom seen in primary pulmonary vascular disease. In pulmonary thromboembolism, for example, hypercapnia is unusual. Hypercapnia following pulmonary embolism can be seen, however, in patients with a comorbid condition such as severe COPD or a depression of the ventilatory drive by drugs that impair the function of the ventilatory pump. Indeed, acute respiratory acidosis, with or without concomitant worsening in oxygenation, may be the initial manifestation of pulmonary thromboembolism in a patient on controlled mechanical ventilation or with a high cervical spinal cord injury or pharmacologic paralysis who cannot increase minute ventilation.

Another rare circumstance in which acute ventilatory failure may develop as a result of a disorder of the pulmonary circulation is venous air embolism, in which hypercapnia and a marked discrepancy between arterial and end-tidal exhaled CO_2 levels may be observed.[156] Hypercapnia may also complicate the acute chest syndrome in patients with sickle cell disease; one series documented respiratory acidosis in 42% of patients who developed this syndrome.[157]

KEY POINTS

- Respiratory failure is the consequence of inadequate alveolar ventilation, generally due to poor central drive, neuromuscular disease, or profound mechanical derangement of lungs or chest wall.
- Respiratory muscle weakness may either precipitate ICU admission, as in Guillain-Barré syndrome, or result from other critical illness, as in ICU-acquired weakness; measuring the maximal inspiratory pressure or visualizing the diaphragm with a bedside ultrasound can be used to identify weakness.
- Noninvasive positive-pressure ventilation (NPPV) is especially useful in exacerbations of COPD, but may also play a role in other forms of acute respiratory failure, such as in facilitating extubation of those who fail a trial of spontaneous breathing or in avoiding reintubation in those who fail extubation.
- Invasive mechanical ventilation can generally be accomplished using tidal volumes of roughly 6 mL/kg, which limits the risk of ventilator-induced lung injury in those with parenchymal lung disease and minimizes the circulatory compromise that can complicate restrictive chest wall conditions.
- When initiating NPPV, there is a "window of opportunity" that opens when patients need ventilatory assistance but closes if they progress too far and become severely acidemic. Improvements in pH, arterial P_{CO_2}, and level of consciousness within the first hour or two of NPPV initiation are strong predictors of success.
- In patients with respiratory failure due to asthma or COPD, attempts to normalize arterial P_{CO_2} generally lead to dynamic hyperinflation, thereby risking hypotension and pneumothorax; instead, to minimize the risk of barotrauma, "permissive hypercapnia" is used to limit minute ventilation and maintain airway pressures in a safe range while allowing the arterial P_{CO_2} to rise.

IMPROVING THE QUALITY OF CARE AT THE END OF LIFE

INTRODUCTION

Patients with acute, chronic, and acute-on-chronic respiratory failure often suffer from symptoms such as pain and dyspnea, and they manifest a high mortality. These patients may be aggressively treated when they, their families, and their physicians believe that the patients' health and quality of life can be restored. Nevertheless, treatment goals at the end of life generally should be more palliative than restorative. In keeping with this approach, therapies such as mechanical ventilation, which can reverse respiratory failure in patients with acute decompensation, may be forgone for the terminally ill. When clinically appropriate, the withholding and withdrawal of life-sustaining therapy is supported by ethical and legal principles. These principles, along with the process of medical decision making and the desirable components of end-of-life care, are discussed in detail in this chapter.

THE BURDEN OF RESPIRATORY FAILURE

Respiratory failure is characterized by inadequate ventilation, inadequate oxygenation, or both (see Chapter 89). These inadequacies are reflected in increased systemic

arterial P_{CO_2}, decreased systemic arterial P_{O_2}, or a combination of the two. Acute respiratory failure may be caused by conditions such as pneumonia and the acute respiratory distress syndrome (ARDS). Chronic respiratory failure may be due to chronic obstructive pulmonary disease (COPD), lung cancer, and other disorders. Many patients are healthy and feel well before they develop acute respiratory failure. In contrast, most patients with chronic respiratory failure experience progressively more severe symptoms as their pulmonary function declines.[1,2] Their downhill course often is punctuated by acute exacerbations (acute-on-chronic respiratory failure) caused either by worsening of their primary disorder or by superimposed secondary illnesses such as pneumonia.[3]

Respiratory failure and the diseases responsible for it are a major cause of death throughout the world. For example, of the 2,337,256 people who were known to have died during 1998 in the United States, 154,972 (6.6%) did so because of malignant neoplasms of the lungs, trachea, bronchi, or pleura. Another 117,966 people (5.1%) died because of COPD and related conditions, and 64,144 (2.7%) died because of pneumonia or influenza. These data from the Division of Vital Statistics of the Department of Health and Human Services were derived from death certificates containing *International Classification of Diseases*, 9th Revision (ICD-9) codes for the underlying cause of death.[4] Deaths attributable to ARDS are more difficult to identify because a specific ICD-9 code is lacking for this condition, and death due to ARDS may be attributed to pneumonia or other disorders. Nevertheless, ARDS probably accounts for approximately 75,000 deaths in the United States each year.[5]

Respiratory failure and the diseases that cause it are associated with considerable morbidity as well as mortality. This association was demonstrated by the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT).[6] The SUPPORT study was based on a large cohort of hospitalized adult patients with at least one of nine conditions, including pneumonia, ARDS, COPD, and stage III or stage IV non–small cell lung cancer. Many SUPPORT patients with acute respiratory failure due to pneumonia or ARDS had normal physiologic function and enjoyed a good quality of life before hospitalization. Yet they had an in-hospital death rate of 26% and a 6-month mortality rate of 47%. Dying patients who were in an intensive care unit (ICU) spent an average of 9 days on a mechanical ventilator, most with severe pain and confusion, according to their families.[7] Of the ventilated patients who survived hospitalization and lived to 6 months, 29% rated their quality of life as only fair or poor.[8]

Regarding the impact of chronic respiratory failure on morbidity and mortality, SUPPORT demonstrated that an exacerbation of COPD among patients with an arterial P_{CO_2} of 50 mm Hg or more on hospital admission was associated with an in-hospital death rate of 11% and a 6-month mortality rate of 33%.[9] The families of patients who died in the hospital reported that their relatives generally experienced intense pain and dyspnea. Most of the patients who survived hospitalization were dyspneic for the rest of their lives, and their quality of life generally was poor. Of SUPPORT patients with advanced non–small cell lung cancer, 16% died during hospitalization, and an additional 42% did so in the following year. Suffering was commonplace among lung cancer patients during death in the hospital; those patients who were discharged demonstrated a progressive loss of function and an increase in symptoms as death approached.[10]

PREDICTING THE OUTCOME OF RESPIRATORY FAILURE

The prevalence of diseases that cause respiratory failure, coupled with the morbidity and mortality they cause, has prompted clinicians and investigators alike to seek prognostic information about patients with these disorders. Some of this prognostic information has been derived from single- or multi-institutional studies of specific conditions such as COPD,[11] *Pneumocystis jirovecii* pneumonia in patients with the acquired immunodeficiency syndrome (AIDS),[12] and ARDS.[13] Other information has come from studies of certain age groups, such as the elderly,[14] or from studies of interventions, such as mechanical ventilation.[15] These studies in turn have been used to develop tools to predict not only patient outcome but also the need for admission to the ICU for diseases such as pneumonia.[16]

Additional information has been obtained from the use of prognostic scoring systems based largely on physiologic variables such as arterial P_{CO_2} and P_{O_2} recorded on hospital admission or on other occasions. Although many of these systems were developed specifically for patients in ICUs, where physiologic variables are routinely measured, they also have been applied to patients elsewhere. Perhaps the best known prognostic scoring system is the Acute Physiology and Chronic Health Evaluation (APACHE), which has gone through four iterations.[17–20] The prognostic system developed for SUPPORT is similar to APACHE. It was based on patient diagnosis, age, number of days in the hospital before study entry, presence of cancer, neurologic function, and 11 physiologic variables recorded on day 3 of study entry.[21]

Prognosis based on the experience of individual clinicians or institutions is necessarily limited; despite wide use, such prognostication has never been subjected to rigorous evaluation. Although prognostication based on broader investigations of specific diseases should be more accurate, the changing outcome from *P. jirovecii* pneumonia,[22] ARDS,[23] and other conditions over time limits the use of these investigations in predicting outcome unless they are frequently updated. Furthermore, the tools based on these studies that may be used to determine the need for intensive care for pneumonia and other diseases have limited predictive value, presumably in part because the outcome from these conditions has changed over time.

Physiologically-based prognostic scoring systems have been shown to be as accurate—or inaccurate—as clinical assessment by physicians and nurses.[24] They have

demonstrated good calibration in that the overall hospital mortality predicted by the systems is comparable with that actually observed in research studies. Nevertheless, the systems have not discriminated well between individual survivors and nonsurvivors. For example, recommended prediction criteria were not effective in identifying a SUPPORT population with a survival prognosis of 6 months or less, limiting their use in determining which patients might generally meet hospice eligibility requirements.[25] Furthermore, when derived on the day before actual death, the median predicted likelihood of survival for 2 months among patients using the SUPPORT prognostic system was 17%, and when derived 1 week before actual death, the predicted likelihood was 51%, indicating how poorly the system could predict death shortly before it occurred.[26]

Prognostic scoring systems have contributed greatly to our understanding of the general outcomes of patients with respiratory failure and other conditions. Furthermore, the calibration and discriminatory power of the systems may improve as more studies of the systems are performed and more patients are entered into their databases. Yet, at present, the systems are imperfect in predicting outcome in individual patients. For the foreseeable future, therefore, the use of prognostic scoring systems should continue to be adjunctive in that they provide information to help in medical decision making but cannot be used by themselves to decide who is destined to die despite intensive care.

TREATMENT GOALS AT THE END OF LIFE

The limitations of prognostication are unfortunate because patients' and their families' predictions of prognosis largely determine their treatment preferences, just as physicians often base their recommendations to patients and families on their own prognostic estimates. Presumably because their quality of life was good and their deaths were not anticipated prior to becoming ill, SUPPORT patients with acute respiratory failure due to pneumonia and ARDS and their families and physicians generally preferred life-sustaining therapies until death appeared imminent.[7] In contrast, hospitalized SUPPORT patients with advanced COPD and lung cancer usually preferred care that was focused on their comfort rather than on extending their lives.[27] These preferences were related primarily to the patients' perceptions of how far advanced their underlying conditions were. For example, hospitalized patients with lung cancer who thought they were going to live at least 6 months were more likely to favor life-sustaining treatment over comfort care than patients who thought they had at least a 10% chance of dying within the next 6 months.[28]

The SUPPORT data suggest that as patients with respiratory failure become more symptomatic and perceive that death is near, they, their families, and their physicians become interested less in therapies that improve physiologic function and prolong life than in those that ease suffering and provide a peaceful and dignified death. Of course, these treatment goals are neither distinctly different nor mutually exclusive: life support and symptom relief often are sought simultaneously. Nevertheless, inside and outside the ICU, the emphasis often changes from restorative to palliative care among patients at the end of life. This change was described as "the transition from cure to comfort" in the title of the first published textbook on end-of-life care in the ICU.[29]

The term *end-of-life care* is meant to encompass two processes. One, the withholding and withdrawal of life support, represents the tapering of life-sustaining interventions such as pulmonary rehabilitation in the outpatient setting and mechanical ventilation in the ICU.[30–33] The other, the administration of palliative treatment, applies, among other things, to improving patient comfort through the giving of sedatives and analgesics. Combining these two processes signifies that end-of-life care involves more than removing something—in this case, life-saving treatments—from patients. It also means giving something to them: proper medical decision making; thoughtful communication; an appreciation of their needs and those of their families, physicians, and other caregivers; the use of an appropriate setting for death; and the management of pain, dyspnea, and other symptoms. This comprehensive and compassionate approach is what is meant by the expression "intensive caring at the end of life."[34]

WHERE AND HOW DEATH OCCURS

In less developed countries, most patients with respiratory failure who die do so at home largely because they have limited access to hospitals and other institutional settings. In the United States and other developed nations, however, death increasingly occurs outside the home. For example, of the large cohort of hospitalized patients in SUPPORT, 47% died within 6 months of study enrollment, and 55% of these deaths occurred during the enrollment hospitalization. Of the patients who survived the enrollment hospitalization, 46% died during hospitalization later that year, and only a minority died in a nursing home or hospice, let alone at home.[35] Similarly, in one investigation of all the deaths recorded in six states during 1999, 38% occurred in hospitals and 22% occurred following ICU admission.[36] Using these data to project national estimates, the investigators concluded that 540,000—fully one fifth—of all patients who die in the United States do so in ICUs each year.

Many factors account for the high prevalence of in-hospital and in-ICU deaths in the United States and, presumably, other developed countries. Among them are the availability of these facilities and of the physicians who admit patients to them and the fact that fewer elderly persons still reside with their families. In the United States, patients must be determined to have fewer than 6 months to live to qualify for hospice placement, but it is difficult to predict with accuracy which patients have such a limited life expectancy. Most patients want to live as long as possible unless life is a burden to them

and their families, and most physicians want to use all the means at their disposal to prolong life. Given these factors and the limits of prognostication, it is understandable that many patients with respiratory failure die in hospitals and ICUs, not in hospices or at home.

When ICUs were first developed during the 1950s and 1960s in the United States and Europe, patients who died in them did so despite full support, including attempted cardiopulmonary resuscitation (CPR). The wishes of patients and their surrogates regarding such support rarely were solicited, and do-not-attempt-resuscitation (DNAR) orders were rarely written for the patients because most hospitals felt obligated to perform CPR on everyone. Indeed, a host of potentially restorative treatments were automatically provided with little concern about their effectiveness or desirability. This approach was based on the belief, held by both health professionals and the public, that technologies should be used to preserve life whenever possible regardless of the human and economic costs.[37]

In recent years, however, the "technologic imperative" has been challenged, just as the expenses of the ICU have been scrutinized.[38] CPR has been shown to be ineffective in hospitalized patients.[39] Similarly, SUPPORT[6] has demonstrated that many seriously ill patients never leave the hospital alive or do so only after prolonged pain and suffering. Patients have been found not to prefer attempted restorative therapy in all instances, and courts in the United States have declared that these patients have a "right to die."[40] The ethical, legal, and economic consensus that has resulted from these developments has been reflected in a series of statements from professional societies[41,42] on the appropriateness of forgoing life-sustaining therapies at the end of life. As a result, although hospitalized patients once died despite attempted restorative treatment, they are more likely to die today during the withholding and withdrawal of life support and the administration of palliative care, especially in the ICU.[32,33]

TABLE 93-1. Ethical (Worldwide) and Legal (United States) Principles for Withholding and Withdrawing Life-Sustaining Therapy

ETHICAL PRINCIPLES
Beneficence
Nonmaleficence
Autonomy
Justice
LEGAL PRINCIPLES: RIGHT OF INFORMED CONSENT AND REFUSAL
Exercised by Patients with Decision-Making Capacity
Exercised by Family Members for Incapacitated Patients
As authorized under proxy directives
Using a substituted-judgment standard (facilitated by instructional directives)
Using a best-interests standard
Exercised by a Court-Appointed Conservator
Using a substituted-judgment standard (facilitated by instructional directives)
Using a best-interests standard
Exercised by Physicians, Often after Ethics Committee Review
Using a substituted-judgment standard (facilitated by instructional directives) (legal justification in a few states)
Using a best-interests standard (no legal justification)

ETHICAL AND LEGAL JUSTIFICATION FOR END-OF-LIFE CARE

Justification for Withholding and Withdrawing Life-Sustaining Therapy

The withholding and withdrawal of life support is justified by four ethical principles[43] (Table 93-1). The first principle is *beneficence*: the physicians' obligation to do good for patients. Relieving pain and suffering, rather than sustaining life at all costs, may be beneficent in certain situations. The second principle is *nonmaleficence*: the physicians' obligation to avoid harm. Life-sustaining interventions may be painful and incapable of sustaining life, and limiting such interventions may reduce harm in some patients. The third principle is *autonomy*: respect for the patients' right of self-determination. Patient autonomy is reinforced when patients are allowed to refuse unwanted life-sustaining therapies. The fourth principle is *justice*: the fair allocation of medical resources. Justice may be served if life support is withdrawn from one patient with a poor prognosis to help another patient with a better prognosis during a mass casualty occurrence or in an influenza pandemic.[44]

In the United States, the withholding and withdrawal of life-sustaining therapies is justified legally by the principles of informed consent and refusal, which have strong roots in common law.[45] The right of adults who are capable of making medical decisions either to consent to or to refuse treatment was first established in *Schloendorff v. Society of New York Hospitals* in 1914.[46] In this case, the Court of Appeal of New York declared that "Every being of adult years and sound mind has the right to determine what should be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages, except in cases of emergency when the patient is unconscious or when it is necessary to operate before consent can be obtained."

The right of adults with decision-making capacity to refuse treatment was furthered in cases such *as Bartling v. Superior Court*[47] and *Bouvia v. Superior Court*[48] in California. In the first of these cases, the Court of Appeals allowed a man with advanced COPD to have a mechanical ventilator removed against the wishes of his physicians and of the hospital. In the second, the appeals court ordered a hospital to stop force-feeding a quadriplegic woman against her will even though she might

die in the process. Most states have dealt with similar cases, and the principle that adults with capacity can refuse unwanted therapies is now widely accepted.

As SUPPORT[6] and other studies have shown, because of their illness and sedation, many critically ill patients cannot make medical decisions. In this circumstance, family members and other surrogates, if available, may consent to or refuse treatment for them. Parents have a long-standing right, indeed an obligation, to speak for their dependent children. The legal right of surrogates to act for incapacitated adult patients was established in *In re Quinlan*[49] in which the Supreme Court of New Jersey allowed the parents of a vegetative patient to refuse mechanical ventilation for their daughter through the mechanism of surrogate decision making. Through this mechanism, family members also were allowed to make life-determining decisions for their adult relative in *Barber v. Superior Court*[50] in California. In this case, the court determined that not only mechanical ventilation but also nutrition and hydration—indeed, any therapy that was not clearly benefiting the patient—could be forgone.

The U.S. Supreme Court dealt with the issue of surrogate decision making in the case of *Cruzan v. Director, Missouri Department of Health*.[51] In this case, a family argued that it was unconstitutional for a chronic care facility in Missouri to deny their request to remove a feeding tube from their vegetative adult daughter. The facility argued that the daughter had not specified her wishes not to be fed artificially in advance of incapacity. In its *Cruzan* decision, the Supreme Court allowed Missouri and other states to require "clear and convincing evidence" of patients' prior wishes before care was forgone for them. Nevertheless, it did not demand this requirement of other states, and it accepted the argument that the right of adult patients with decision-making capacity to refuse any and all therapies was protected under the Constitution.

Substituted judgment, through which surrogates know patients' wishes and can articulate them, is the highest standard under which surrogates may make medical decisions for incapacitated patients. Nevertheless, surrogates also may consider the patients' best interests. One delineation of a best-interests standard is that of the New Jersey Supreme Court relative to *In re Conroy*.[52] In this case, a nephew asked that a feeding tube be withdrawn from his elderly aunt, who had not declared her wishes before becoming demented, on the grounds that forgoing nutrition and hydration was in her best interest. The court would allow the best-interests standard in this case only because the burdens of the patient's life with treatment outweighed the benefits of continuing life, and because the recurring, unavoidable pain of life with treatment was such that administering therapies such as nutrition and hydration was inhumane. These requirements were imposed because the court considered the best-interest standard less compelling than the substituted-judgment standard.

Another legal perspective on the standards of substituted judgment and best interests came in the case of *Wendland v. Wendland*.[53] This case involved a middle-aged man who was conscious but hemiplegic, uncommunicative, and unable to feed himself after a motor vehicle accident. After his feeding tube repeatedly became dislodged, his wife, who was his conservator, refused to authorize its reinsertion. In support of her decision, she cited her husband's statements prior to his accident that he would not want to live in a severely debilitated condition. At this point, his mother went to court to block the plan not to reinsert the feeding tube, and it was reinserted. Mr. Wendland subsequently died, but the California Supreme Court deliberated on the issue of whether a conservator could withhold or withdraw life support from a patient who was conscious but incapable of articulating his current wishes. The Court ultimately ruled that feedings could be discontinued only if there was clear and convincing evidence that "the patient wished to refuse life-sustaining treatment or that to withhold such treatment would have been in his best interest," which was not thought to be true of Mr. Wendland. The decision in his case suggests that the courts are unlikely to allow surrogates to limit treatment in patients who are neither terminally ill nor severely neurologically impaired on the basis of a best-interests standard unless the patients have specified what they would want done in such a situation or unless their best interests can be objectively defined.[54]

Legal guidelines are less clear when incapacitated patients lack family members or other surrogates. Some states (e.g., Hawaii, Connecticut) allow physicians to make decisions for such patients based on wishes expressed to the physicians when the patients had decision-making capacity. However, no state explicitly allows physicians to make decisions based on a best-interests standard. Be that as it may, some physicians do make decisions to withhold or withdraw life-sustaining therapy from incapacitated patients, usually after consultation with their colleagues or with a hospital ethics committee, on the basis of best interests, as documented in a study from seven U.S. medical centers.[55] Other physicians ask the probate court to appoint conservators or other advocates for the patients, presumably under the unproven assumption that such advocates can determine what is in the patients' interests better than physicians can.

The U.S. Congress supported patient autonomy and the substituted-judgment standard by passing the Patient Self-Determination Act. This statute mandates that patients admitted to medical facilities be asked whether they have advance directives and that they be assisted in drawing up directives if they do not already have them.[56] Advance directives are of two types: instructional directives that state what patients want done in a given situation (e.g., living wills) and proxy directives that appoint surrogates to make decisions for them in these situations (e.g., the durable power of attorney for health care). SUPPORT has shown that most hospitalized patients have not filled out advance directives, that physicians are often unaware of the directives when they have been filled out, and that the directives have little impact on decision making or the use of hospital resources.[57] Nevertheless, advance directives have the potential for

reinforcing patient autonomy, even though this potential has not been realized.[58]

Before leaving the subject of justification for withholding and withdrawing life support, it is important to mention that decisions regarding this process are different for brain-dead patients than they are in patients who have lesser degrees of neurologic impairment. In the United States, death is defined as the total and irreversible loss either of cardiopulmonary function or of the function of the entire brain.[59] The determination of death by whole-brain criteria requires the demonstration of coma, indicating the loss of cerebral hemispheric function, and the documentation of absent corneal, oculovestibular, and ventilatory reflexes, indicating loss of function of the brain stem. Absence of ventilatory reflexes is demonstrated by an abnormal apnea test in which intubated, nonparalyzed patients removed from mechanical ventilation and given oxygen fail to initiate respiratory muscle efforts despite an increase of their arterial P_{CO_2} to at least 60 mm Hg.

Life-sustaining therapy usually can be forgone without a formal declaration of brain death. Conversely, some surrogates may insist that therapy be continued until patients die, in which case determining death by whole-brain criteria may be desirable. That said, the only patients in whom brain death must be determined are those who seem to be dead and whose organs will be transplanted after life support is withheld or withdrawn. Regarding the latter patients, one might argue that withdrawing life support from someone who is dead is an oxymoron. Because of this argument, and because brain-dead patients usually receive mechanical ventilation and other interventions only until their organs can be harvested, "life support" for them can be likened to "organ support."

The ethical and legal justification for removing therapies from brain-dead patients is not just that the therapies generally are unwanted by patients and surrogates in this situation but also that the patients are dead and cannot benefit from them. Inasmuch as the patients are dead, physicians have no obligation to treat them, and they do not need to obtain consent from surrogates before withholding or withdrawing treatment. Nevertheless, consent is required for organ retrieval and transplantation. Furthermore, the families of brain-dead patients frequently do not understand the concept of brain death and consider the patients to be alive because their chests rise and fall as the ventilator cycles and a tracing of their cardiac rhythms is displayed on the bedside monitor. Families also may reject the concept of brain death for religious reasons.

Motivated by consideration for such families and by a desire to gain their consent for organ donation, many physicians are appropriately nonconfrontational in addressing the issue of brain death. They take time to explain what death means in a biologic and legal sense, how brain death is determined, and how valuable transplantation can be for organ recipients as well as for the families of patients who serve as organ donors and even for the patients themselves. This approach generally is helpful to families, regardless of whether they ultimately approve transplantation. It also is useful in maintaining emotional equilibrium during a difficult time for all parties in the ICU.[60]

Medical Futility

Although the ethical principle of autonomy and the legal principles of informed consent and refusal are the most compelling justifications for withholding and withdrawing life support, the concept of futility also has been used as a justification. This concept is invoked on the relatively rare occasions when patients or their surrogates request interventions (particularly those that are costly, scarce, or both) that physicians object to because they believe the patients cannot benefit from them. Some treatments, such as brain transplantation for patients who are brain-dead, are physiologically futile in that they cannot be accomplished. Other treatments, such as the administration of vasopressors to raise blood pressure, can succeed physiologically, but some physicians may consider them medically futile because they cannot prolong life indefinitely or improve its quality in patients whose life expectancy is short and whose quality of life is poor.

One group of investigators[61] sought to define medical futility as an intervention that has been useless in the last 100 cases or that "merely preserves unconsciousness and cannot end dependence on intensive medical care." In a similar vein, the American Thoracic Society[42] argued that "a life-sustaining intervention may be withheld or withdrawn from a patient without the consent of the patient or surrogate if the intervention is judged to be futile. A life-sustaining intervention is futile if reasoning and experience indicate that the intervention would be highly unlikely to result in a meaningful survival for that patient. Here, meaningful survival specifically refers to a quality or duration of survival that would have value to that patient as an individual. Survival in a state with permanent lack of consciousness (i.e., completely lacking cognitive and sentient capacity) may be generally regarded as having no value for such a patient."

Despite what has been called the "futility movement," a broad concept of futility has never achieved consensus within the medical community in the United States or elsewhere, and the American Thoracic Society position has not gained broad support.[62] A contrary position has been advanced by the Society of Critical Care Medicine,[63] which holds that "Treatments should be defined as futile only when they will not accomplish their intended goal. Treatments that are extremely unlikely to be beneficial, are extremely costly, or are of uncertain benefit may be considered inappropriate and hence inadvisable, but should not be labeled futile. Futile treatments constitute a small fraction of medical care. Thus, employing the concept of futile care in medical decision-making will not primarily contribute to a reduction in resource use."

In some ways, the development of prognostic scoring systems can be seen as an attempt to predict which patients cannot benefit from therapies with very low efficacy, especially those that are expensive, and thereby provide a rationale for denying such therapies to them.[64] Yet most patients and families are quite willing to forgo

such therapies even when physicians are not, as indicated by SUPPORT.[8] Furthermore, a study of the theoretical implementation of a strict futility guideline for over 4000 SUPPORT patients demonstrated that only minimal cost savings could be realized by not treating patients who were predicted to have a 1% or less 2-month survival.[65] Nearly 75% of the savings in hospital days would have resulted from stopping treatment for 12 patients, one half of whom were under 51 years of age and 1 of whom lived 10 months when treatment was continued.

The emphasis on cost savings in the aforementioned study speaks to the fact that arguments about futility often have economic overtones. At one time, it appeared that American society could transition from a "rule of rescue," in which large sums of money were spent on therapies providing only marginal benefit, to a "rule of reason," in which this money could be used for primary and preventive care.[66] Yet health care reform failed in the United States, and managed care became identified as a tool for increasing corporate profits by denying medical services.[67] Arguments based on futility seem to provide a rationale for forgoing treatment on the grounds that it is not worthwhile, apart from the matter of cost. Yet these arguments conceal value-laden assumptions, and they obscure the underlying issue of rationing.[68] American physicians lack a social mandate to perform such rationing, a fact that is overlooked when they invoke futility.

Thus, the greatest problem with medical futility is not how it is defined but who defines it.[69] In this regard, the debate over futility pits physicians, who believe that their training and experience enables them to know what therapies are truly useful and cost-effective, against patients and families, who feel entitled to such therapies regardless of whether they pay for them directly. Physicians certainly are able to identify physiologic futility, and they are not legally or ethically required to perform procedures they consider nonbeneficial and below professional standards. Benefit, however, seems often to be in the eyes of the beholder: although physicians may regard mere prolongation of life as undesirable in certain circumstances, patients and families may consider it valuable. When these persons want treatments that physicians consider futile in more than a physiologic sense, which party should decide?

The American Medical Association Council on Ethical and Judicial Affairs has stated that, "Since definitions of futile care are value laden, universal consensus on futile care is unlikely to be achieved."[70] At the same time, the Council has recommended a process-based approach to futility determinations whereby patients or families who insisted on therapies that physicians considered futile would be required to undergo a dispute resolution process. Central to this process would be mediation by a hospital ethics committee. If resolution was not reached through mediation, the patients would be transferred to another institution or care would be terminated if transfer were impossible. So-called futility policies based on this model have been developed in Houston, Texas, and other cities.[71]

Based on the Houston experience, the State of Texas adopted a law providing an extrajudicial due process mechanism for resolving medical futility disputes. A survey[72] of Texas hospitals' experience with this law indicates that a minority of the hospitals had used the due process mechanism and that life-sustaining treatment was discontinued against patients' or surrogates' wishes in only a small number of cases. Furthermore, the constitutionality of the Texas statute has not been determined at the appellate or U.S. Supreme Court level. As a result, the implications of the Texas statute for that state and for the rest of the United States are unclear.

To date, legal cases such as *In re Helen Wanglie*[73] and *In the Matter of Baby K*[74] suggest that judges are unwilling to allow physicians to withhold or withdraw support from patients when the physicians ask to do so and the patients or families object. In the first of these cases, a court in Minneapolis refused to replace a husband who was seeking continued life support for his wife, life support which her physicians considered nonbeneficial, with another conservator who might allow support to be forgone. In the second, a Virginia court required that physicians repeatedly resuscitate an anencephalic infant at the request of its mother but against their own wishes, reasoning that to do otherwise would violate the Emergency Medical Treatment and Active Labor Act.

In contrast, the case of *Gilgunn v. Massachusetts General Hospital*[75] indicates that physicians are likely to obtain legal results more to their liking when they refuse to provide care they consider futile and defend their decisions in court as consistent with professional standards. In this case, a jury in Boston exonerated physicians at Massachusetts General Hospital for removing a patient from life support and writing a DNAR order for her over the objections of her daughter. The patient's husband and other children did not protest the physicians' actions, and the jury apparently believed that the physicians acted within the standard of care. This case does not set legal precedent because a written judgment was not rendered. Nevertheless, the jury decision in *Gilgunn* suggests some public support for the concept of futility.

How the debate over futility will be resolved is uncertain. Because patient autonomy is so widely accepted in the United States, because national health insurance does not exist there, and because patients and families are suspicious of managed care organizations, it seems unlikely that American physicians will soon be granted a mandate to restrict services on the basis of futility. This is not the case in other countries, however, where resources are limited, national health insurance exists, and physicians implicitly and explicitly are allowed to ration care.[76] Whether physicians will continue to exercise this and other prerogatives if American-style patient autonomy becomes more prevalent in their countries remains to be seen.

Justification for Administering Palliative Care

One reason that the concept of futility remains unresolved in the United States is that the Supreme Court has

not dealt with this issue. Nevertheless, the Court has provided ethical and legal justification for the administration of palliative care at the end of life, as in the cases of *Washington v. Glucksberg*[77] and *Vacco v. Quill*.[78] These cases dealt with the constitutionality of laws prohibiting physician-assisted suicide in the states of Washington and New York. In *Glucksberg*, the Court decided that terminally ill patients do not have a liberty interest in committing suicide or in receiving a physician's assistance in committing suicide because of both the long tradition of prohibiting suicide in the United States and the states' legitimate interest in continuing to make suicide illegal. In *Vacco*, it distinguished between assisted suicide and withholding and withdrawal of life support. "Everyone, regardless of physical condition, is entitled, if competent, to refuse lifesaving medical treatment; no one is permitted to assist a suicide," the Court wrote. "When a patient refuses life-sustaining medical treatment, he dies from an underlying fatal disease or pathology; but if a patient ingests lethal medicine prescribed by a physician, he is killed by that medication."

In *Glucksberg* and *Vacco*, five justices reasoned that Washington and New York could prohibit assisted suicide because these states had no barriers that prevented patients from receiving medications to relieve pain and suffering. However, as Justice Breyer wrote, "Were state laws to prevent the provision of palliative care, including the administration of drugs as needed to avoid pain at the end of life, an action against such law might be called for by the Supreme Court." Through this and other statements, a majority of the justices suggested that being free of pain while dying was a liberty interest protected under the Constitution.[79]

The Supreme Court distinguished assisted suicide from palliative care in *Glucksberg* and *Vacco* by accepting the ethical principle of double effect. Under this rule, acts such as giving sedatives and analgesics that lead to morally good effects, such as the relief of suffering, are permissible even if they produce morally bad effects, such as the hastening of death, provided that only the good effect is intended. The morally bad effect may be foreseen in that physicians are aware of its possibility and even its likelihood, but they may not wish that it occur. The bad effect also may not be a means to the good effect, and the good effect must outweigh the bad one; that is, risking death is reasonable in palliating a terminally ill patient only if there are no less risky ways of relieving suffering.[80]

The Supreme Court's approval of palliative care included sanctioning the practice of *terminal sedation*, in which patients are rendered unconscious while life-sustaining therapies, including nutrition and hydration, are withdrawn. Under *Vacco*, a state may allow terminal sedation if it is "based on informed consent and the double effect. Just as a state may prohibit assisted suicide while permitting patients to refuse unwanted lifesaving treatment, it may permit palliative care related to that refusal, which may have the foreseen but unintended 'double effect' of hastening the patient's death."

Some have argued that the rule of double effect has many shortcomings as an ethical guideline, in particular because it overlooks the complexity of human intention.[81] Such complexity was demonstrated in a study of the administration of sedatives and analgesics during the withholding and withdrawal of life support in two ICUs.[82] In this study, physicians indicated that they ordered these agents primarily to decrease pain, anxiety, and dyspnea—but also to hasten death—in 39% of critically ill patients. In another investigation, 16% of a sample of ICU nurses reported that they had engaged in assisted suicide or euthanasia while trying to relieve patient suffering, often without physicians' knowledge.[83]

Just as some physicians and nurses have mixed motives in caring for dying patients, so do some family members want to ease suffering and hasten death simultaneously in their relatives. That such motivation is widespread presumably accounts for the fact that few physicians who are suspected of participating in assisted suicide or euthanasia have been punished through the criminal justice system in the United States.[84] In general, physicians and other caregivers are unlikely to be prosecuted or even criticized if they act compassionately in administering sedatives and analgesics to dying patients and do so with informed consent.

The Supreme Court did not judge the laws prohibiting physician-assisted suicide in Washington and New York to be unconstitutional in *Glucksberg* and *Vacco*. Nevertheless, it also did not prevent other states from permitting physician-assisted suicide if they chose to do so. Physician-assisted suicide was legalized in Oregon in 1997 under that state's Death with Dignity Act. Experience over the subsequent 2 years indicated that few patients requested lethal medications, that physicians granted few requests, and that palliative interventions led some, but not all, patients to change their minds about assisted suicide.[85] By and large, the decision to request and use a prescription for lethal medication stemmed from patients' concern about loss of autonomy or control of bodily functions, not from fear of intractable pain or financial loss.[86]

Although the Death with Dignity Act has not been abused, the U.S. Congress and the Bush administration have tried to overturn it. In 1999, Congress considered a so-called Pain Relief Promotion Act, which would have amended the federal Controlled Substance Act, a law designed to prevent drug abuse and drug trafficking within the United States. This amendment "to promote pain relief and palliative care without permitting assisted suicide and euthanasia" would have interfered with Oregon's law had it not died in Congress. In 2001, Attorney General John Ashcroft ruled that the Death with Dignity Act violated the Controlled Substance Act and authorized the Drug Enforcement Administration to take action against Oregon physicians who prescribe lethal medications. This directive was blocked, however, by a U.S. District Court judge. As a result, physician-assisted suicide remains legal in Oregon. The U.S. Supreme Court may ultimately decide the fate of that state's Death with Dignity Act.[87]

Physician-assisted suicide (in which physicians prescribe potentially lethal medications that patients themselves can take) and euthanasia (in which physicians

actually administer the medications) are practiced in several European countries.[88] Although none of these countries has legalized the practices, physicians in the Netherlands have not been punished for performing them since 1991, when a national study revealed that assisted suicide and euthanasia were being performed.[89] Instead, Dutch physicians are required to report all cases in which they administered or supplied drugs with the explicit intent of hastening death. Patient requests for assisted suicide or euthanasia rose from 8900 in 1990 to 9700 in 1995 and remained stable at 9700 in 2001, according to one study.[90] Assisted suicide was listed as the cause of death on only 0.2% of all death certificates in the Netherlands during the same years. In 1990, 64% of Dutch physicians thought that patients have a right to decide about their own life or death; the percentage of physicians was the same in 1995 but fell to 56% in 2001. These data suggest that, in the Netherlands as in Oregon, the demand for assisted suicide has not increased; in fact, over time, Dutch physicians appear to have grown more reluctant in their attitude toward this practice. How common assisted suicide will become in other European countries and how their laws will deal with these practices are unclear.

MEDICAL DECISION MAKING AT THE END OF LIFE

Two Models of the Physician-Patient Relationship

Medical decisions may be made by physicians, patients, their families, or other surrogates alone or in combination. How decisions are actually made depends in large part on the model of the physician-patient relationship that is used. Perhaps the oldest model is *paternalistic*; this model also has been called *parental* or *priestly*. According to it, physicians using superior knowledge and experience act as guardians in defining what their patients' interests are and then serving these interests as they see fit, with little or no input from the patients themselves.[91] With pediatric patients, the families' input similarly might not be sought or might be disregarded. The paternalistic model overlooks patient autonomy and is supported primarily by the ethical principles of beneficence and nonmaleficence: acting to benefit patients and to avoid harm.

Another model of the physician-patient relationship is the *deliberative* one. Under this model, physicians help patients define their best interests, provide treatment alternatives through which the interests can be served, and assist the patients in deciding which alternative is best. With pediatric patients, families decide what the patients' interests are and how best to serve them with the physicians' assistance. This process is more than the mere passing of information: a moral deliberation, based on a mutual understanding of patients' wishes and values, is pursued. Physicians functioning under the deliberative model serve as teachers, not guardians as they do under the paternalistic model.[91] The deliberative model is a model of shared decision making. It is supported primarily by the ethical principle of autonomy: respect for the patients' right of self-determination.

The paternalistic model is particularly well suited to decision making in emergency situations wherein time is of the essence, patients may be unable to communicate, and their consent for treatment is considered to be implied because most of them presumably would want to be treated in emergencies. The deliberative model is best suited for situations in which physicians, patients, and families have ample time to discuss alternatives, extensive communication is possible, and consent can be informed. Consent can be informed only if patients or their surrogates are competent to make decisions, are provided with information relevant to their situation, can ask questions, and can act voluntarily.[92]

The paternalistic model once dominated medical decision making at the end of life in the United States. In fact, the early cases such as *Bartling*, *Bouvia*, and *Quinlan* were brought because physicians and hospitals were unwilling to let patients or surrogates refuse therapy. The deliberative model is more widely used today because the ethical principle of autonomy and the legal principles of informed consent and refusal are more widely accepted. Nevertheless, paternalism is implicit when physicians argue that therapies they consider futile should be withheld or withdrawn. It is ironic that some physicians today demand that patients and families forgo treatment that other physicians once insisted they accept.

Medical decision making and the attitudes that underlie it vary from country to country. Although the deliberative model is gaining popularity in France, the paternalistic model still is employed at the end of life in ICUs there. Physicians are granted decision-making prerogatives in these ICUs that are not permitted for their American counterparts. Furthermore, French families have no legal right to make decisions for patients who cannot make decisions for themselves.[93] In response to a questionnaire distributed to members of the European Society of Intensive Care Medicine, only 49% of physician respondents included patients and families in end-of-life decisions, and physicians differed in implementing the decisions.[94] The paternalistic model also is prevalent in Hong Kong, where people fear that acknowledging impending death is like casting a curse, physicians and families commonly make decisions for patients, and there is no legislation regarding patient autonomy or the status of advanced directives.[95]

Variations in attitudes also exist within a given country depending on its ethnic and cultural composition. For example, in one study in the United States, Korean Americans and Mexican Americans were significantly less likely than European Americans and African Americans to believe that a patient should be told the diagnosis of metastatic cancer or that the patient should make the decision about the use of life-sustaining therapy.[96] In another study, African Americans were more likely than European Americans to want to be kept alive on life support.[97] Interviews of these African Americans subjects documented a deep distrust of the health care

system and a fear that access to health care was based on one's ability to pay.

Importance of Physician, Patient, and Family Communication

Of course, American families would not need to be so involved in medical decision making in the ICU setting if physicians facilitated such decision making when the patients' diseases were not far advanced and they could speak for themselves.[98] Yet SUPPORT[6] and other studies have shown that physicians and patients rarely discuss end-of-life issues in advance of the patients' deterioration, even when patients reside in nursing homes. A study of patients with severe COPD enrolled in pulmonary rehabilitation revealed that almost all had health concerns, the most common of which was fear of increasing dyspnea.[99] Although many of the patients had concerns about being intubated, a minority had completed an advance directive describing their choices in regard to that intervention. Furthermore, although the patients generally wanted discussions with their physicians, only 19% had such discussions, only 15% had discussed life support, and only 14% thought that their physicians understood their end-of-life wishes.

Why patients with chronic and terminal diseases do not discuss end-of-life care with their physicians has been the subject of several investigations. In the study of patients with COPD enrolled in pulmonary rehabilitation, those patients who had not had discussions identified their own procrastination and the fact that their physicians had not brought up the topic as the most important reasons.[99] When these patients participated in an end-of-life educational intervention as part of their rehabilitation, they were more likely to have such discussions subsequently with their physicians and to complete durable powers of attorney for health care.

In another study of patients with advanced AIDS, structured interviews of the patients and their physicians were used to identify barriers to communication.[100] Patients who had not had discussions with their physicians about end-of-life care most frequently agreed that, "I don't like talking about getting very sick" and "I would rather concentrate on staying alive than talking about death." Physicians who did not initiate discussions most often agreed that, "There is too little time during our appointments to discuss everything we should" and "I worry that discussing end-of-life with [patient name] will take away his or her hope." Many physicians in this study acknowledged that they felt uncomfortable discussing end-of-life issues, suggesting that their own discomfort was as important as the lack of time for discussions in inhibiting communication.

Limited communication between physicians and patients was also reported in SUPPORT.[6] Furthermore, SUPPORT disclosed that communication was frequently inadequate between physicians and the families of critically ill patients. This finding was corroborated by a study from an ICU in France in which half the families of critically ill patients reported the same inadequacy.[101] A follow-up investigation from that and other ICUs in France indicated that family satisfaction with their relatives' care was due in part to their being of French descent and having a language and cultural values similar to those of the ICU caregivers.[102] Family satisfaction also related to information provided by hospital physicians, a patient-to-nurse ratio of 3:1 or less, knowledge of the specific role of each caregiver, help from the family's own physician, sufficient time spent giving information, and an absence of perceived contradictions in information provided by caregivers. Distribution of a family information leaflet in the ICUs improved family understanding of how the units functioned and increased their satisfaction with the care given therein.[103]

The importance of good communication also has been highlighted in a study of the quality of end-of-life care assessed through the responses of family members to a quality of death and dying (QODD) questionnaire after their relatives had died in and outside of hospitals.[104] In this study, higher QODD scores, which reflected a better quality of care at the end of life, were associated with death at home, death in the location the patient wanted, lower symptom burden, and better ratings of symptom treatment. Although the presence of an advance directive was not associated with a higher QODD score, higher scores were associated with communication about treatment preferences, compliance with treatment preferences, and family satisfaction regarding communication with the health care team.

In a study from one U.S. hospital, families were interviewed about their experiences in the ICU and the decision-making process for withholding or withdrawing life support.[105] They reported a high incidence of conflicts, the vast majority of which were between themselves and physicians. The conflicts most often involved problems in communication or perceived unprofessional behavior, such as disregarding the primary caregiver in treatment decisions. These families identified pastoral care and prior discussion of treatment preferences as sources of psychological support. They appreciated lenient visiting hours and the availability of family conference rooms. Most of the families singled out attending physicians as the preferred source of information and reassurance. In this regard, a study from another institution demonstrated that intensive communication achieved through regular family meetings led by attending physicians increased family satisfaction and also decreased ICU length of stay among patients who died.[106] Still another study indicated that allowing family members more opportunity to speak during conferences may increase their satisfaction.[107]

Another investigation looked at priorities and problems in end-of-life care identified by parents of children who had died after withdrawal of life support in three pediatric ICUs.[108] In response to a parental perspectives questionnaire, these parents placed highest priorities on their children's quality of life, likelihood of improvement, and their perceptions of their children's pain when considering withdrawal of support. Twenty percent of parents disagreed that their children were comfortable in their final days, a finding that echoed the SUPPORT study involving adult patients.[6] Fifty-five

percent of parents felt that they had little to no control during their children's final days, and nearly one fourth reported that, if able to do so, they would have made decisions differently. At the same time, the parents generally reported that ICU nurses and physicians were available and helpful to them, and many also had access to their community pediatricians.

Successful conflict resolution at the end of life is a process of negotiation between physicians and patients and families.[109] This process varies depending on whether the paternalistic or deliberative model of decision making is used, which in turn depends on the cultural context. In the United States, the process involves educating patients and families about likely prognoses, deferring to requests for seemingly benign treatments, convincing patients or families to forgo potentially harmful interventions, and occasionally refusing requests for therapy that physicians consider nonbeneficial.[110] Proper negotiation requires cross-cultural understanding and the use of communication skills, particularly that of listening to patients and families.[111,111a] Ethics committee consultations appear to be useful in resolving conflicts about treatments said to be futile and also are associated with reductions in ICU hospital days and life-sustaining therapy among patients who ultimately fail to survive until discharge from the hospital.[112] Whether such consultations also increase family satisfaction with the dying process of their loved ones is unclear.

UNDERSTANDING WHAT PHYSICIANS, PATIENTS, AND FAMILIES NEED AT THE END OF LIFE

End-of-life care could be optimized if the needs of the parties involved in the dying process were better understood. In this regard, a survey of seriously ill patients, recently bereaved families, physicians, and other caregivers revealed that decisions about treatment preferences, knowing what to expect about one's physical condition, and preparation for death were important to all four groups at the end of life.[113] Other important needs were sharing time with family and friends; being kept clean; being free of pain, anxiety, and dyspnea; and being treated as a "whole person." Patients, but not physicians, also rated as important being mentally aware, coming to peace with God, not being a burden to their families, being able to help others, praying, having funeral arrangements planned, and gaining a sense of completion in life (Table 93-2).

The needs of families have also been assessed in several studies using a survey tool called the Critical Care Family Needs Inventory. In an overview of recommendations for end-of-life care in the ICU, the Ethics Committee of the Society of Critical Care Medicine[114] combined these studies to determine what these needs are. Overall, family needs include being with the dying patient, being helpful to that patient, being informed of the dying patient's changing condition, understanding what is being done to the patient and why, being assured of the patient's comfort, being comforted, having an opportunity to express emotions, being assured that the family's decisions were right, finding meaning in the patient's death, and having personal needs attended to during the dying process.

TABLE 93-2. Factors Considered Important by Patients at the End of Life

Being kept clean
Naming a decision-maker
Having a nurse with whom one feels comfortable
Knowing what to expect about one's physical condition
Having someone who will listen
Maintaining one's dignity
Trusting one's physician
Having financial affairs in order
Being free of pain
Maintaining a sense of humor
Saying goodbye to important people
Being free of shortness of breath
Being free of anxiety
Having a physician with whom one can discuss fears

From Steinhauser KE, Christakis NA, Clipp EC, et al: Factors considered important at the end of life by patients, family, physicians, and other care providers. JAMA 284:2476–2482, 2000.

Unfortunately, the needs of physicians and others who care for dying patients have not been well addressed. Nevertheless, at a minimum, all caregivers probably need to feel comfortable during the dying process, to gain experience from it, to feel supported by their colleagues and by their institutions, and to have opportunities for bereavement themselves. Nurses, respiratory therapists, social workers, and clergy who work alongside physicians want to know that the physicians respect them, provide them with adequate information, take their opinions into account, and engage in proper decision-making practices at the end of life.[115]

PROVIDING APPROPRIATE SETTINGS FOR DYING PATIENTS

Under the deliberative model of the physician-patient relationship, physicians are obligated to help patients understand their conditions, explore their therapeutic options, and decide what is best for them. Essential to this relationship is preparing patients for death when appropriate. Such preparation should include consideration of whether the patients' interests are best served by hospital and ICU admission when death is imminent, assuming that the imminence of death can be identified. Many patients, especially those with COPD and other chronic diseases that allow time for advance planning as death approaches, decide to die in a hospice or at home if given the opportunity.

Terminal patients who prefer a trial of attempted restorative treatment in the hospital or undergo it

because their wishes are not known should at least die in an environment that is comfortable for them and their families when the trial fails. A private room with enough space to accommodate visitors might be such an environment. Visiting hours should be relaxed, if necessary, to allow families and friends to spend as much time as they wish with dying patients. Some hospitals have separate palliative care units for this purpose. Others offer palliative care teams or services that consult throughout the hospital.[116,117]

EMOTIONAL AND SPIRITUAL SUPPORT

Reviews of end-of-life care in and outside the ICU have emphasized the importance of providing emotional and spiritual support to dying patients and their families.[118] Physicians contribute to this support, of course, and their regular communications and presence at the bedside are greatly appreciated. Nurses, social workers, clergy, and other members of the health care team deliver most of the support, however. Occasionally, patients or their families request that friends, caregivers, and religious persons from outside a particular institution provide consultations or participate in bedside rituals or observances. These should be allowed, if not encouraged, unless they interfere with patient care.

End-of-life care may extend after death in that physicians, nurses, and others who have helped the patients' families when the patients were alive have much to offer them thereafter. Advising on the disposition of bodies, reporting the results of autopsy studies, coordinating burials and funeral services, and attending funerals are among the professional responsibilities of caregivers that are greatly appreciated by families. These responsibilities can be assumed by independent bereavement follow-up services, which have been described at one hospital.[119] Alternatively, caregivers who have established personal relationships with families in the ICU and other settings may maintain them after the patients' death.

Physicians, nurses, and other caregivers have their own emotional and spiritual needs, of course, and caring for dying patients and their families exacts an appreciable toll on them. Because of this, caregivers themselves should have opportunities to grieve. Conferences scheduled after patients die provide both an opportunity for bereavement and a mechanism for evaluating the processes of withholding and withdrawal of life support and of administering palliative care to them. Such evaluation may lead to improvements in these processes for future patients.

SYMPTOM MANAGEMENT

Why Symptoms May Be Poorly Managed

Management of pain and other symptoms is a traditional role and responsibility of the medical profession. Nevertheless, patients too frequently die with pain and other symptoms. Nearly 50% of SUPPORT patients or their surrogates interviewed after study enrollment reported that the patients experienced pain during hospitalization.[120] Nearly 15% reported extremely or moderately severe pain occurring at least half the time, and many of those patients with pain were dissatisfied with its control. Uncontrolled pain was most common among patients with more dependence on others in activities of daily living and who had more comorbid conditions, more anxiety, more depression, and a poor quality of life.[120]

That pain and other symptoms are poorly managed in some patients probably is due in large part to the strong emphasis restorative care places on the diagnosis and treatment of diseases rather than on the relief of symptoms. Palliative care reverses this emphasis and, when properly applied, should help increase patient comfort at the end of life. Nevertheless, the transition from restorative to palliative care is far from seamless for many patients. In this regard, it is difficult for patients and their families to know when to stop requesting treatment, just as it is for physicians and other caregivers to stop recommending life-sustaining therapies.

Pain and other symptoms may also be poorly managed because they are subjective experiences that are not easily assessed by objective methods. Pain and sedation scales have been developed to quantify the levels of pain and anxiety among patients who can self-report. Nevertheless, some patients cannot adequately communicate these sensations, either because they cannot find the words or because they are intubated and sedated. To detect pain in these patients, physicians and other caregivers must attend to patient grimacing and other admittedly nonspecific manifestations of pain, including tachycardia and hypertension. Although bispectral analysis of the electroencephalogram has been used to assess the level of sedation in ICU patients, the correlation of this technique with sedation scales and, most important, the subjective experiences of patients is unclear.[121]

Another reason that symptoms are poorly managed at the end of life is that patients differ in their desire to have symptoms relieved. Some patients value symptom relief highly and would prefer to be rendered unconscious rather than to experience pain, anxiety, or dyspnea, especially at the end of life. Others, however, would be willing to tolerate these symptoms or have them mitigated only slightly in order to stay awake. Dying patients may find it difficult to titrate sedatives and analgesics to their desired level of consciousness, although they should be encouraged to do so. Physicians and caregivers may find it even more difficult to achieve the ideal level of sedation and analgesia for patients who cannot communicate or administer drugs to themselves.

Finally, symptoms may be inadequately managed because physicians and other caregivers feel uncomfortable about giving high doses of sedatives, analgesics, and other mood-altering agents. In some instances, this discomfort stems from a reluctance to cause drug addiction in dying patients, a concern irrelevant to the patients' condition. Other discomfort results from awareness that the agents may hasten death by depressing not only consciousness but also respiratory and cardiovascular

function. That the U.S. Supreme Court has justified the administration of sedatives and analgesics under the principle of the double effect should help put caregivers at ease. Although one third of physicians in one study who ordered these agents to dying adult patients did so in part to hasten death,[82] virtually all the physicians in a comparable study[122] conducted in a pediatric ICU viewed hastening death only as an "acceptable, unintended side effect."

Management of Pain

Pain can be managed indirectly by nonpharmacologic means. For example, placing patients in a quiet environment where friends and family can visit may diminish the sense of pain, as may the proper treatment of anxiety and depression. Although respiratory depression due to drugs or underlying disease usually is undesirable in patients with COPD, the encephalopathy that results from the hypercapnia and hypoxia may be tolerated, if not favored, in terminal patients because it attenuates pain. Similarly, patients who forgo nutrition and hydration at the end of life may develop a euphoria that has been attributed to the release of endogenous opioids or the analgesic effects of ketosis.

A direct approach to pain control generally centers on the use of opioids, and morphine is the opioid most commonly used. In addition to causing analgesia, morphine induces some degree of sedation, respiratory depression, constipation, urinary retention, nausea, and euphoria. It also produces vasodilation, which may cause hypotension, in part through the release of histamine. Fentanyl, a synthetic opioid that is approximately 100 times more potent than morphine, does not release histamine and, therefore, causes less hypotension. Hydromorphone, a semisynthetic morphine derivative, is more sedating than morphine and produces little euphoria.[123]

Morphine, fentanyl, and hydromorphone can be administered orally, subcutaneously, rectally, or intravenously. Opioids usually are given by the intravenous route to ICU patients, including those who are dying. These agents may be administered to inpatients and outpatients alike through the technique of patient-controlled analgesia. Long-acting oral preparations of morphine and hydromorphone are available for outpatients. Fentanyl can be administered orally in the form of a lollipop. It can also be given by the transcutaneous route, which makes this agent particularly suitable for patients who have difficulty with oral medications.

Opioids ideally should be administered in anticipation of pain and not after its occurrence. The optimal doses of these drugs given for pain relief are unknown and certainly vary among patients. Nevertheless, opioids generally should be started in relatively low doses if respiratory depression and other side effects are to be avoided and titrated upward until their analgesic effect is realized. In reports of critically ill patients undergoing the withholding and withdrawal of life support in both adult and pediatric ICUs, opioids were used in doses sufficient to achieve pain relief that caregivers considered adequate.[82] In dying patients, the use of opioids should not be limited by some arbitrary amount but by the balance between analgesia and any undesirable side effects.

Management of Anxiety

As in the case of pain, anxiety and its physical manifestation agitation can be managed nonpharmacologically. If drugs are required, benzodiazepines and propofol are preferred. Benzodiazepines cause anterograde amnesia in addition to anxiolysis, and they exert a synergistic sedating effect with opioids. Benzodiazepines also cause hypotension and cardiac depression, especially when administered quickly and in high doses. Lorazepam, an intermediate-acting agent, can be given by the oral, intramuscular, or intravenous route; when given intravenously, it can be done so by bolus or by constant infusion. Midazolam, which is short-acting, usually is administered intravenously by constant infusion, although boluses may be required when therapy is initiated.[124]

Propofol is an intravenous general anesthetic agent with sedating, amnestic, and anxiolytic properties when administered in subanesthetic doses. In such doses, propofol is similar to midazolam in that it usually is given by constant infusion after bolus injection. The drugs also are comparable in the sedation they produce, although propofol has a greater propensity to cause hypotension.[124] Neither propofol nor midazolam is appropriate for the management of anxiety in outpatients and, in hospitals, their continuous use may be restricted to the ICU.

Management of Delirium

Delirium may be confused with anxiety because it too can cause agitation. The confusion is clinically important both because the conditions are treated pharmacologically with different drugs and because the drugs used to treat anxiety can exacerbate delirium.[117] Delirious patients should be helped to obtain regular sleep, should be oriented regularly to their environment, and should avoid benzodiazepines, which cloud consciousness. Haloperidol, a butyrophenone neuroleptic agent, is widely used to treat delirium in critically ill patients. It may be given orally, rectally, intramuscularly, or intravenously. Haloperidol may cause QT prolongation on the electrocardiogram and should be used cautiously with other agents that have a similar effect. Haloperidol also can cause rigidity, restlessness, and other dyskinesias.

Management of Dyspnea

Dyspnea should be understood and managed according to its underlying pathophysiology, especially in its earlier stages[3,125] (see Chapter 28). For example, patients with moderate to severe COPD may benefit from oral bronchodilators that decrease airflow resistance, inhaled corticosteroids that decrease airway inflammation, and lung volume reduction surgery that decreases hyperinflation. These patients also may become less dyspneic through exercise training and the emotional support available through pulmonary rehabilitation programs.[126] At the same time, patients with lung cancer may feel less breath-

less after drainage of malignant pleural effusions or placement of stents to overcome airway obstruction.

In patients with far advanced lung disease, attention to pathophysiologic mechanisms is less important, and treatment is more palliative than restorative. Bronchodilators may not reduce breathlessness in such patients; corticosteroids may cause more unwanted side effects than symptom relief; lung reduction surgery may prove fatal. Patients with COPD who are dying, at home or in hospice, do not benefit from exercise training and may be too breathless to attend pulmonary rehabilitation programs; these patients should be encouraged to use wheelchairs and to rest. In most terminal cancer patients, malignant effusions and airway obstruction should not be diagnosed or treated.[3]

Patients with chronic respiratory failure of whatever cause should receive supplemental oxygen, which has been shown to both increase survival and decrease breathlessness.[127] In the United States, Medicare reimbursement for long-term oxygen therapy is based on physiologic criteria (e.g., $Pa_{O_2} \leq 55$ mm Hg while breathing room air), not symptomatology. Despite this fact, many patients use oxygen primarily to relieve dyspnea, and hospice patients do not have to meet physiologic criteria to receive reimbursement. Supplemental oxygen usually is started in low doses (e.g., 1–3 L/min) and titrated to effect. The results of titration are difficult to predict inasmuch as neither the flow rate nor the route of administration of oxygen determines its impact on breathlessness.[3] Furthermore, air may relieve dyspnea as well as oxygen does in patients with advanced malignancy.[128] In addition, breathless patients frequently are relieved by exposure to fresh air in the outdoors or during automobile rides with the windows down. Those who are bedridden may benefit from using fans to blow air over their faces.[3]

Opioids such as oral morphine have been demonstrated to increase exercise tolerance acutely and to alleviate dyspnea in occasional patients with COPD.[129] Nevertheless, the long-term administration of sustained-release morphine has not been shown to be superior to placebo in reducing breathlessness in such patients, most of whom reported nausea, constipation, and other adverse effects.[130] Although many patients become tolerant to these adverse effects over time, opioids probably should be used only on a trial or as-needed basis for patients with recalcitrant dyspnea who do not respond to oxygen or air. However, because their analgesic properties are undisputed, these agents may be particularly useful in patients who have pain in addition to breathlessness, such as those with lung cancer.[3] Although the use of morphine and other opioids to relieve dyspnea in patients with ARDS and other causes of acute respiratory failure is widespread and seems reasonable, this practice is not supported by research studies.

Benzodiazepines such as alprazolam have been shown to reduce dyspnea in some patients with COPD.[131] Yet these agents also may cause drowsiness, uncoordination, and dysphoria; and they probably should be used only in outpatients whose dyspnea is not relieved by oxygen and opioids.[3] As is true of opioids, benzodiazepines and propofol are commonly used to reduce dyspnea, in addition to anxiety, among patients with acute respiratory failure, particularly those receiving mechanical ventilation. Again, this practice appears reasonable, especially if the patients are not experiencing unwanted side effects. Nevertheless, benefits of treating dyspnea with sedatives in ICU patients have not been demonstrated scientifically.

Management of Nausea and Vomiting

Nausea and vomiting may result from systemic illnesses such as diabetes, renal failure, hypercalcemia, adrenal insufficiency, and viral infections. These symptoms also may be caused by central nervous system disorders, including cerebral metastases and other conditions that increase intracranial pressure; primary gastrointestinal diseases such as gastric outlet obstruction; and a variety of drugs, including theophylline, phenytoin, opioids, antibiotics, and chemotherapeutic agents. Nausea and vomiting may remit with treatment of the disorder or discontinuing use of the drugs that cause them. Because eating can increase nausea, patients may benefit by being placed on a nothing-by-mouth status or undergoing gastric decompression. Clear liquid diets may be administered to patients as tolerated. Supplemental oxygen has been shown to reduce the incidence of postoperative nausea and vomiting.[132]

Patients with nausea and vomiting who do not respond to more conservative measures may be candidates for prophylactic or therapeutic antiemetic therapy, which can be given orally, intramuscularly, intravenously, or in suppository form. Among the older antiemetics are dexamethasone and other corticosteroids; butyrophenones such as haloperidol and droperidol; chlorpromazine, promethazine, prochlorperazine, and other phenothiazines; and muscarinic receptor antagonists such as scopolamine, which is particularly helpful in patients with vestibular symptoms. Of these agents, dexamethasone, droperidol, and promethazine are the most widely used.

Newer antiemetics include the serotonin receptor antagonists ondansetron, dolastron, granisetron, and tropisetron. These drugs have been tested primarily in the postoperative period and among patients who have received chemotherapy or radiation therapy. Because of their expense, they probably should be used only after other agents are found to be unsuccessful in preventing or relieving symptoms.[133] Cannabinoids, administered either orally or through smoking the *Cannabis sativa* (marijuana) plant, are as effective as older antiemetic agents such as chlorpromazine, prochlorperazine, and metaclopramide in reducing nausea and vomiting caused by chemotherapy. Nevertheless, although some patients welcome the sedation and euphoria they experience with cannabinoids, others complain of dizziness and dysphoria.[134]

Management of Hunger and Thirst

People eat food and drink fluids to relieve hunger and thirst and to sustain metabolic processes. Food and fluids

are administered to hospitalized patients under the assumption that they are staples of life and components of routine medical and nursing care. Under this assumption, some have argued that refusal of nutrition and hydration is tantamount to suicide and that food and fluids should be administered to all patients other than those who reject them because of intolerable pain and suffering in the last moments of life.[135] Others have noted that voluntary forgoing of nutrition and hydration by terminal patients represents only a refusal of unwanted treatment that is ethically and legally justified.[136] Still others have argued that force-feeding violates patient autonomy and that voluntary "terminal dehydration" on the part of patients offers substantial advantages over physician-assisted suicide with respect to self-determination, access, and professional integrity.[137]

Of course, patients may desire food and fluids until they die; alternatively, they may choose not to eat or drink. In fact, one study has documented that in Oregon, where physician-assisted suicide is allowed, many hospice patients forgo eating and drinking, perhaps as an alternative to assisted suicide.[138] As was the case in this study, another investigation conducted in a comfort care unit demonstrated that most cancer patients either never experienced hunger and thirst or did so only initially during their terminal illnesses.[139] In the few patients who were symptomatic, hunger, thirst, and dry mouth usually could be alleviated with small amounts of food and fluids or by the application of ice chips or lubrication to the lips. Similar measures can be used in other settings, including the ICU.

WITHHOLDING AND WITHDRAWAL OF LIFE-SUSTAINING THERAPY

What Therapies Are Withheld and Withdrawn

Life-sustaining therapies are withheld and withdrawn in many settings. Nevertheless, most of the studies of this process have been conducted in ICUs. These studies, from pediatric and adult ICUs around the world, reveal that, although any and all interventions may be withheld or withdrawn, variation exists in the type, number, and sequence of interventions forgone.[31,32,140] In one investigation in an adult ICU in the United States, an average of five separate interventions were forgone per patient.[141] CPR, intubation and mechanical ventilation, and dialysis generally were the first interventions withheld; thereafter, vasopressors, transfusions, intravenous fluids, parenteral nutrition, antibiotics, and tube feedings were either withheld or withdrawn. Decisions regarding withdrawing therapy occurred later than decisions regarding withholding it. Whereas a decision not to intubate a patient was made early for patients not already on ventilators, once patients were on ventilators, decisions to withdraw ventilatory support were generally made late, after several other interventions were first forgone.

Another study in which physicians were surveyed about the withdrawal process indicated distinct preferences about the form of support withdrawn.[142] From most likely to least likely, the order was blood products, dialysis, vasopressors, parenteral nutrition, antibiotics, mechanical ventilation, tube feedings, and intravenous fluids. Four biases in decision making also were identified. Physicians preferred to withdraw therapies supporting organs that failed for natural, rather than iatrogenic, reasons and therapies that were instituted only recently. They also preferred to withdraw therapies resulting in an immediate, rather than a delayed, death and to withdraw therapies resulting in a delayed death only when faced with diagnostic uncertainty.

Withholding and Withdrawal of Intubation and Mechanical Ventilation

Intubation and mechanical ventilation are often used in patients with acute, chronic, or acute-on-chronic respiratory failure and are among the therapies most commonly withheld or withdrawn. As noted earlier, some patients with advanced COPD and other causes of chronic respiratory failure have concerns about intubation and mechanical ventilation and decide against these therapies in advance of decompensation. Nevertheless, other patients with chronic respiratory failure request intubation and mechanical ventilation or are intubated and ventilated—either in the field, in the emergency department, or in the ICU—without having decided on their wishes or having communicated them. Similarly, patients with acute respiratory failure often end up on ventilators because their conditions are assumed to be reversible. When they and their counterparts with chronic respiratory failure do not improve, intubation and mechanical ventilation may be withdrawn. One study revealed that the strongest determinants of withdrawal of mechanical ventilation in critically ill patients were the physicians' perception that the patients preferred not to use life support, the physicians' prediction of a low likelihood of survival in the ICU and a high likelihood of poor cognitive function, and the use of inotropes or vasopressors.[143]

How intubation and mechanical ventilation are withdrawn varies among institutions. One approach is rapid extubation: the patient is given analgesics and sedatives, and both the endotracheal (or tracheotomy) tube and the ventilator are removed. Patients then are given either supplemental oxygen or, more commonly, room air to breathe. Rapid extubation is direct and, in the pediatric setting, it offers the potential advantage of allowing parents to hold their infants without being encumbered by the ventilator or its tubing. A potential disadvantage is that patients may appear distressed due to upper airway obstruction after the tube is removed.

A second process, called *terminal weaning*, involves decreasing the inspired oxygen fraction, the ventilator rate, the level of positive end-expiratory pressure, or some combination of these variables before the ventilator

is removed. Patients are given drugs during this process, and they most often die before extubation. First described in 1983, this technique was developed in order to avoid abruptly discontinuing treatment in such a way that "might be interpreted with intent to kill" and might make patients and their families uncomfortable.[144] The first part of this rationale is not relevant today because the differences between terminal weaning and euthanasia have been delineated by the U.S. Supreme Court. Nevertheless, terminal weaning still may cause less discomfort than rapid extubation by preventing upper airway obstruction.

The relative advantages and disadvantages of rapid extubation and terminal weaning have been debated. They have not been compared scientifically, although one study of what was called "rapid terminal weaning" demonstrated that patients could be kept comfortable during the procedure with relatively low doses of opioids and benzodiazepines.[145] A survey of critical care physicians indicated that 15% of respondents almost never withdrew intubation and mechanical ventilation from dying patients.[146] Of physicians who did, 13% preferred rapid extubation, 33% preferred terminal weaning, and the remainder used both methods. Reasons for preferring rapid extubation included the directness of the action, family perceptions, and patient comfort. Reasons for preferring terminal weaning included patient comfort, family perceptions, and the belief that terminal weaning was less abrupt.

When intubation and mechanical ventilation are withdrawn, most patients with respiratory failure die from their underlying diseases. Nevertheless, some survive, and their survival should not be prevented by drugs that hasten death. At the same time, even patients who are too sick to survive should not receive drugs that interfere with observing tachypnea and other signs that may signal the need for symptom relief. For these reasons, although sedatives and analgesics may be given to relieve suffering, neuromuscular blocking agents should not be introduced to patients while intubation and mechanical ventilation are withdrawn. Furthermore, if the patients are already receiving them, a common situation with infants, these agents should be continued only if two requirements are met. First, death is expected to be both rapid and certain after removal of the endotracheal tube, the ventilator, or both. Second, the burdens to patients and families of waiting for neuromuscular blockade to diminish to a reversible level exceed the benefits of allowing better assessment of the patients' comfort and possible interaction with their families.

IMPROVING THE QUALITY OF CARE AT THE END OF LIFE

Palliative care is a robust, well-recognized discipline, and it is extensively practiced in the outpatient setting. Yet end-of-life care has been incorporated into inpatient practice only recently, as patients in developed countries increasingly die in hospitals and in ICUs. Despite its fledgling status, however, inpatient end-of-life care is rapidly being improved upon as more physicians and other caregivers participate in it. Such improvement and participation were stimulated in large part by publication of the SUPPORT study[6] and the articles drawn from the SUPPORT database, many of which are cited in this chapter. For the most part, these publications documented the deficiencies of care at the end of life for hospitalized patients with respiratory failure and other critical illnesses.

In response to SUPPORT and its spin-offs have come a number of articles recommending possible improvements in end-of-life care; again, many of these articles are referred to in this chapter. Also referenced are an international consensus conference on challenges in end-of-life care in the ICU[147] and the first textbook on end-of-life care in the ICU.[29] Publication of this textbook was accompanied by release of a research agenda that outlines some of the questions about end-of-life care that must be answered before such care can be improved.[148] One strategy noted in the agenda is the need for structural changes, such as the expansion of family waiting areas, and for procedural changes, such as the development of clinical guidelines for palliative care. Pursuing this strategy has led to the articulation of end-of-life care domains and quality indicators[149] (Table 93-3), a content analysis of forms and other materials documenting end-of-life care in ICUs, and the creation of standardized comfort care orders for the withdrawal of life-sustaining therapies.[150,151] In the future, tools such as these will be used to assess and improve the quality of care at the end of life in ICUs.

TABLE 93-3. Seven Domains of End-of-Life Care

Patient- and family-centered decision-making
Communication
Continuity of care
Emotional and practical support
Symptom management and comfort care
Spiritual support
Emotional and organizational support for staff

KEY POINTS

- End-of-life care is a combination of palliative treatment and withholding and withdrawal of life-sustaining therapy provided to patients who are terminally ill, including those with acute, chronic, and acute-on-chronic respiratory failure.
- End-of-life care is justified by the ethical principles of beneficence, nonmaleficence, autonomy, and justice and by the legal right of informed patients to consent to or refuse any or all therapy, including that which sustains life.
- The legal right of consent or refusal may be exercised by patients themselves or by their family members and legally appointed surrogates through substituted-judgment and best-interests standards. It also may be exercised by the patients' physicians using the same standards, although little legal support exists for this practice.
- End-of-life care is enhanced by a shared model of medical decision making and by intensive communication among patients, family members, and caregivers. Such care should attend to the needs of patients, families, and caregivers alike.
- The components of end-of-life care include providing appropriate settings for dying patients; supplying emotional and spiritual support; managing such symptoms as pain, anxiety, delirium, dyspnea, nausea and vomiting, and hunger and thirst; and removing unwanted therapies.

INTRODUCTION

Patients with advanced chronic respiratory disease frequently have distressing symptoms, limitations in exercise ability, and reductions in health and functional status that persist despite optimal pharmacologic management. Pulmonary rehabilitation complements standard medical therapy and can provide additional, clinically meaningful benefit in these areas. Indeed, pulmonary rehabilitation has become the standard of care for patients who are motivated to participate in such programs. As is described in this chapter, patients can improve their exercise and functional capacity, decrease their dyspnea, improve their health status, and (perhaps) reduce their risk of premature morbidity and mortality. Pulmonary rehabilitation is now accepted as a standard of care for patients with chronic obstructive pulmonary disease (COPD), and it has been incorporated into international guidelines for this disease.[1,2] Although pulmonary rehabilitation was designed and is applied primarily to symptomatic patients who are limited due to the burden of COPD, the same fundamental principles appear applicable to other chronic respiratory disease states leading to disability.

DEFINITION AND GOALS

The American Thoracic Society and European Respiratory Society define pulmonary rehabilitation as "an evidence-based, multidisciplinary, and comprehensive intervention for patients with chronic respiratory diseases who are symptomatic and often have decreased daily life activities. Integrated into the individualized treatment of the patient, pulmonary rehabilitation is designed to reduce symptoms, optimize functional status, increase participation, and reduce health care costs through stabilizing or reversing systemic manifestations of the disease."[1] As this definition indicates, there is now a strong evidence base demonstrating the effectiveness of pulmonary rehabilitation, and it should be considered in the general care of the individual with chronic respiratory disease.

Pulmonary rehabilitation and exercise training have been erroneously considered to be equivalent. Although exercise training is a necessary component of pulmonary rehabilitation, other interventions are also necessarily provided in this comprehensive management. Pulmonary rehabilitation programs generally include patient assessment, exercise training, education (especially

involving collaborative self-management strategies), nutritional intervention, psychosocial support, as well as discussion of advance directives. Activity promotion in the home and community settings is becoming recognized as an essential component in pulmonary rehabilitation. Smoking cessation, breathing retraining, chest physical therapy, oxygen therapy, and adjunctive therapies are also given to selected individuals.

It may appear paradoxical that pulmonary rehabilitation does not have a significant, direct effect on pulmonary function, yet it provides the greatest improvements in dyspnea, exercise tolerance, and health status of any therapy for COPD. Emerging data suggest that it may also be beneficial for other chronic respiratory diseases. This apparent paradox is explained by that fact that COPD can be considered as a systemic disease,[3] and comorbidity (such as decreased oxidative capacity of the muscles of ambulation, physical deconditioning, fear of dyspnea-producing activities, improper pacing) contributes to the symptoms and disability of patients. Patients with other chronic respiratory diseases also frequently have this comorbidity. The 6-minute walk distance, which reflects the systemic nature of the disease, is therefore a stronger predictor of survival in COPD patients than measurements of airflow limitation such as the forced expiratory volume in 1 second (FEV_1).[4] Similarly, mid-thigh cross-sectional area[5] and mid-arm cross-sectional area,[6] measures of muscle mass depletion, are better predictors of survival than lung function.

Pulmonary rehabilitation is effective in reducing the negative impact of some of this comorbidity. For example, exercise tolerance in COPD is limited by multiple factors, including increased resistive work of breathing (due to breathing through narrowed airways), increased elastic work of breathing (due to static and dynamic hyperinflation), and abnormalities in the muscles of ambulation (leading to lactate production and fatigue at low exercise intensities). Pulmonary rehabilitation exercise training leads to a decreased ventilatory requirement at a given level of exercise due in part to physiologic changes in the leg muscles. This decrease in ventilatory requirement allows the patient to breathe at a lower respiratory rate during exercise, thereby reducing the effects of dynamic hyperinflation. In addition, recent evidence suggests that dynamic hyperinflation decreases cardiac function and may also decrease exercise tolerance by this mechanism.[7] Thus, pulmonary rehabilitation exercise training leads to increased exercise capacity by its direct effects on the leg muscles that reduce the ventilatory requirement and its direct effects on dynamic hyperinflation[8] and cardiac output[7]—despite the fact there is no measurable change in FEV_1.

Comprehensive pulmonary rehabilitation requires contributions from different health care professionals. Physicians, nurses, nurse practitioners, physical therapists, respiratory therapists, nutritionists, or occupational therapists may be involved in a particular program, depending on availability and resources. A physician medical director and a professional pulmonary rehabilitation coordinator are necessary for program certification in the United States. The goals of pulmonary rehabilitation are to reduce symptoms, improve functional status, and reduce health care costs.[1]

HISTORY

Pulmonary rehabilitation and its components have been recognized by clinicians as an effective intervention since at least the middle of the 20th century.[9,10] However, since the mid 1990s, it has risen to prominence as a state-of-the-art, scientifically proven intervention for individuals with chronic lung disease. Its current importance as a therapeutic option is underscored by four events.

- Its incorporation as the "best therapy" to which lung volume reduction surgery was compared in the National Emphysema Treatment Trial (NETT).[11]
- A Cochrane report demonstrating the effectiveness of pulmonary rehabilitation in their meta-analyses.[12]
- Its endorsement by the Global Initiative for Obstructive Lung disease (GOLD), and its prominent position in their current treatment algorithm for COPD.[13]
- Its acceptance as an approved medical benefit in the United States under the Centers for Medicare and Medicaid Services (CMS) beginning in January 2010.[14]

Over time, what was considered a form of therapy reserved only for patients with the most severe impairment is now recommended for all patients with symptoms that limit their performance and a moderate severity of disease. Prior to 1991, much of the literature supporting pulmonary rehabilitation consisted of descriptions of comprehensive pulmonary rehabilitation and presentations of uncontrolled, preintervention-postintervention studies showing its effectiveness primarily in reducing hospital utilization.[15,16] However, in 1991 Casaburi and colleagues[17] reported on a study of 19 COPD patients who were randomized to either higher or lower levels of exercise training on a cycle ergometer. Training was 5 days per week for a total of 8 weeks. The patients who trained at lower levels exercised longer, so the total amount of work was roughly equivalent in the two groups. Both levels of training led to significant physiologic benefits manifested by reduced lactic acidosis and ventilatory requirement at the same work rate. However, those who trained at higher intensity had more physiologic benefit than those who trained at lower intensity. Prior to this study, many believed that patients with advanced COPD, often being ventilatory-limited during exercise, could not derive true physiologic benefit from this type of intervention. This was the first randomized, controlled trial to demonstrate that a training effect could result from exercise training, the cornerstone of pulmonary rehabilitation.

In 1994, Goldstein and associates[18] reported a prospective, randomized, controlled trial of pulmonary rehabilitation. Eighty-nine patients with COPD were ran-

domized to either pulmonary rehabilitation, initially given in an inpatient setting, or conventional medical care. The group that participated in pulmonary rehabilitation had significantly greater increases in the 6-minute walk distance, submaximal cycle endurance time, and health status compared with the group given standard medical care. This was the first of several randomized, controlled trials of pulmonary rehabilitation that established the effectiveness of pulmonary rehabilitation as a treatment option for chronic lung disease.

That same year, Reardon and coworkers[19] reported on 20 COPD patients who were randomized either to comprehensive outpatient pulmonary rehabilitation or to a waiting period during which they were given conventional medical care. Rehabilitation led to significant improvements in exertional dyspnea, measured by incremental treadmill exercise testing and by questionnaire-rated dyspnea with daily activities. Exertional dyspnea was probably reduced at levels of exercise common to activities of daily living, underscoring its clinical meaningfulness. This was the first study to demonstrate the effectiveness of pulmonary rehabilitation on dyspnea, the most important symptom in advanced lung disease. Subsequent studies by O'Donnell and colleagues[20,21] showed that the reduction in postexercise training dyspnea was associated with decreased ventilatory demand, probably due to physiologic changes in the leg muscles.

In 1996, Ries and associates[22] reported on 119 patients with COPD who were randomized either to comprehensive outpatient pulmonary rehabilitation with exercise training or to education alone. Compared with education alone, rehabilitation led to significant relief of dyspnea, maximal exercise capacity, exercise endurance, and self-efficacy for walking. "Self-efficacy" refers to the patient's confidence in successfully managing respiratory symptoms associated with an activity. Positive results declined over time, approaching those of the control group by 18 to 24 months. This was the first large randomized, controlled study showing the effectiveness of outpatient pulmonary rehabilitation on multiple outcomes. The decline in gains made over time underscored the importance of strategies to improve long-term adherence with rehabilitation.

In 1996, Maltais and coworkers[23] reported on 11 patients with COPD who were evaluated before and after 36 sessions of high-intensity endurance training. In addition to the expected physiologic training effect including reduced exercise-induced lactic acidosis, exercise training led to increased levels of oxidative enzymes in muscle biopsy specimens. Of additional importance, the improvement in biochemical markers correlated with reduced lactic acid production during exercise. Along with other work, this study shows that exercise training improves skeletal muscle oxidative capacity in COPD patients and that this improvement has clinical value.

In 2000, Griffiths and colleagues[24] presented data on 200 patients with chronic lung disease who were randomized to either 6 weeks of multidisciplinary pulmonary rehabilitation or standard medical management. In addition to showing substantial improvements in exercise performance and health-related quality of life, the pulmonary rehabilitation intervention led to fewer days in the hospital and fewer primary care home visits in the 1-year follow-up period. Thus, this large randomized trial demonstrated a substantial reduction in health care utilization following pulmonary rehabilitation, confirming conclusions from earlier noncontrolled studies. A subsequent study from this group[25] provided evidence supporting the cost-effectiveness of pulmonary rehabilitation.

Bourbeau and associates[26] demonstrated in 2003 that a self-management program in the home led to fewer hospital admissions and other health utilization variables and improvement in health status. Self-management skills are prominent components of comprehensive pulmonary rehabilitation. This study provides scientific evidence supporting this educational component of comprehensive pulmonary rehabilitation.

In 2005, Casaburi and coworkers[27] showed that increasing bronchodilation in patients with COPD led to enhanced outcomes when they participated in pulmonary rehabilitation. Patients with optimized lung function could exercise at higher intensities and achieve greater increases in exercise capacity. Thus, not only does pulmonary rehabilitation add to the positive outcomes from pharmacologic therapy, pharmacologic therapy also adds to the benefits from pulmonary rehabilitation.

In 2007, joint guidelines from the American College of Chest Physicians (ACCP) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR)[28] summarized the current evidence base underlying pulmonary rehabilitation. The document cited very strong evidence supporting the effectiveness of pulmonary rehabilitation on improvements in dyspnea and quality of life. There was also substantial evidence supporting its effectiveness in health care utilization and psychological outcomes. Longer-term pulmonary rehabilitation, maintenance strategies following pulmonary rehabilitation, and the incorporation of education and strength training were also supported by new evidence.

Pulmonary rehabilitation is the most effective therapy available for increasing the exercise capacity of patients with chronic respiratory disease. However, its effectiveness in promoting increased activity in the home and community setting was not proved until fairly recently. Increased physical activity is an important outcome because patients with COPD are often very sedentary,[29] and lower levels of physical activity are associated with poorer long-term outcomes.[30] In 2008, Walker and colleagues[31] demonstrated that directly measured activity (from activity monitors) was indeed increased following 8 weeks of pulmonary rehabilitation. This study corroborates results from two other studies that also demonstrated this positive effect.[32,33] These studies, therefore, provide strong support for the idea that the increased exercise capacity attained in the pulmonary rehabilitation center is translated into increased activity in other settings.

RATIONALE

Pulmonary rehabilitation has a minimal, if any, effect on the abnormal lung function or respiratory physiology of individuals with chronic lung disease. Despite this, it usually results in clinically meaningful improvement in multiple outcome areas of considerable importance to the patient, including a reduction in exertional dyspnea and dyspnea associated with daily activities, improvement in exercise performance and in health status, and reduction in health care utilization. The apparent paradox is explained by the fact that a considerable portion of the dyspnea and the health status limitations from chronic lung disease results from extrapulmonary effects of the disease, which do respond to treatment. Some of the associated systemic manifestations of chronic lung disease include nutritional depletion,[34,35] a decrease in lower extremity muscle mass and peripheral muscle weakness and fatigability,[36,37] alterations in peripheral muscle fiber type,[38] and a reduction in peripheral muscle oxidative enzymes.[39] In addition, poor pacing techniques, maladaptive coping skills, and fear of dyspnea-producing activities result in a vicious circle of further deconditioning and debilitation. Pulmonary rehabilitation is effective in interrupting this cycle.

INDICATIONS

Pulmonary rehabilitation is indicated for individuals with chronic respiratory disease who have persistent symptoms or disability despite standard medical therapy. Figure 94-1 represents the course of patients with lung function limitation over time and the role of pulmonary rehabilitation. Figure 94-2 represents the relative roles of medical therapy and pulmonary rehabilitation during disease progression. Although all individuals with chronic respiratory disease are eligible for consideration for pulmonary rehabilitation, to date COPD is the most common disease for which patients are referred, often for one or more of the following symptoms or conditions[40]:

1. Severe dyspnea and/or fatigue.
2. Decreased exercise ability.
3. Interference with performing activities of daily living.
4. Impaired health status.
5. Decreased occupational performance.
6. Nutritional depletion.
7. Increased medical resource utilization.

It should be noted that persistent symptoms and/or limitation in these clinical areas—not just the specific physiologic impairment of the lungs (such as a low FEV_1 or hypoxemia)—dictate the need for this intervention. Furthermore, symptoms, exercise performance, functional status, and health status correlate relatively poorly with pulmonary function abnormalities. Because of this, there are no specific threshold pulmonary function inclusion criteria for pulmonary rehabilitation.

Often the referral to pulmonary rehabilitation has been reserved for advanced lung disease. Although patients in this category can still benefit from the intervention,[41] referral at an earlier stage would allow more emphasis on preventive strategies such as smoking cessation and would permit exercise training at higher levels of intensity.

Traditionally, pulmonary rehabilitation has dealt primarily with COPD, whereas its effectiveness for other pulmonary conditions has received less attention.[42] Nonetheless, patients with chronic asthma and airways remodeling, bronchiectasis, cystic fibrosis, chest wall disease, or interstitial lung disease may be appropriate candidates.[42a] Pulmonary rehabilitation is the standard of care before and after lung transplantation and lung volume reduction surgery. Based on these accepted indications, pulmonary rehabilitation should also be useful to recondition patients for other major surgical procedures.

There are two primary exclusion criteria for pulmonary rehabilitation:

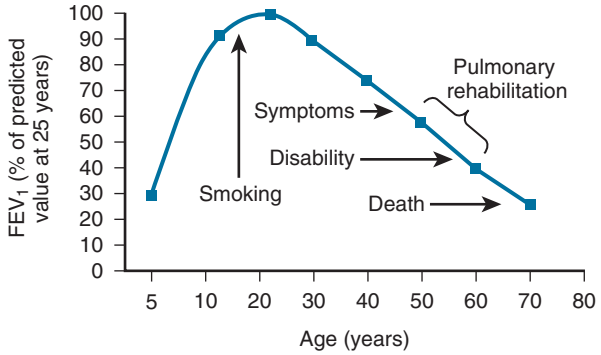

FIGURE 94-1 ■ Change in forced expiratory volume in 1 second (FEV_1) over time in persons susceptible to the effect of cigarette smoking and who develop chronic obstructive pulmonary disease (COPD). The progressive decline results in functional limitation, poor health status, and eventual death. Pulmonary rehabilitation has a role once persistent symptoms or disabilities develop and for as long as patients benefit.

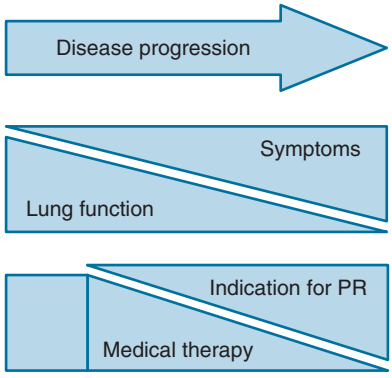

FIGURE 94-2 ■ Indication for pulmonary rehabilitation in disease progression. Pulmonary rehabilitation is an appropriate therapy in the course of respiratory disease when, after usual medical therapy, physiologic impairment is associated with significant symptoms and functional status limitation.

1. An associated condition that might interfere with the rehabilitative process. Examples include disabling arthritis and severe neurologic, cognitive, or psychiatric disease.
2. A comorbid condition that might place the patient at undue risk during exercise training. Examples include severe pulmonary hypertension or unstable cardiovascular disease.

It should be noted that many patients with pulmonary hypertension have safely (and successfully) participated in pulmonary rehabilitation programs, often while awaiting lung transplantation. The exercise training component has to be modified in this situation and patients require close monitoring. In addition, poor motivation is a relative contraindication to pulmonary rehabilitation. However, the level of motivation might change during therapy, especially if patients perceive demonstrable benefit from the sessions.

SMOKING CESSATION

Cigarette smoking is the cause of COPD in over 90% of affected patients. Furthermore, there is no doubt that smoking cessation is the single most important therapy that can retard the progression of airflow limitation and positively influence survival. The various pharmacologic and behavior modification techniques that are available to assist persons to stop smoking are reviewed in Chapter 40. Although controversy still exists, active cigarette smokers are reasonable candidates for pulmonary rehabilitation provided smoking cessation interventions become an important component of the process. Indeed, frequent contact and reinforcement during the rehabilitation program can influence a patient to adopt a proactive role in cessation.

COMPONENTS OF A COMPREHENSIVE PULMONARY REHABILITATION PROGRAM

Exercise Training

Exercise training, including upper and lower extremity endurance training and strength training, is an essential component of comprehensive pulmonary rehabilitation. This follows the current knowledge that the peripheral muscles in patients with chronic lung disease not only are wasted but also appear to have alterations in fiber-type distribution and decreased metabolic capacity. Exercise training improves endurance, increases the level of functioning, aids in performance of activities of daily living, helps reduce systemic blood pressure, improves lipid profiles, tends to counteract depression, reduces anxiety associated with dyspnea-producing activities, and facilitates sleep.

Exercise training for individuals with chronic lung disease, similar to that in healthy individuals, is based on general principles of intensity (higher levels of training produce more results), specificity (only those muscles trained show an effect), and reversibility (cessation of regular exercise training leads to loss of training effect).[43]

Ventilatory or gas-exchange limitations are common in advanced chronic lung disease and limit the intensity of exercise training. However, exercise capacity in many patients is also limited by peripheral muscle and cardiovascular deconditioning, with an early onset of anaerobic metabolism and the production of lactic acidosis during exercise. Peripheral muscle dysfunction is responsive to the exercise training intervention. Many respiratory patients are capable of exercising for prolonged periods of time at levels close to capacity,[44] and the higher level of exercise training results in greater improvement in exercise performance.[34] The demonstrated reduction in ventilation and lactate levels at identical submaximal work rates[17] following high-intensity exercise training strongly suggests that a training effect is attainable in many patients with advanced lung disease. A dose-related increase in oxidative enzymes in the peripheral muscles accompanies these physiologic adaptations to training.[39] A reduction in lactic acid production has been demonstrated to be associated with improvement in oxidative capacity of the peripheral muscles.[45]

Most pulmonary rehabilitation programs emphasize endurance training of the lower extremities, often advocating sustained exercise for about 20 to 30 minutes two to five times a week. This may include exercise on a stationary cycle ergometer or motorized treadmill, climbing stairs, or walking on a flat surface such as a corridor or auditorium. Training is usually performed at levels at or greater than 50% or 60% of the maximal work rate. For those unable to maintain this intensity for the recommended duration, interval training, consisting of 2 to 3 minutes of high-intensity training (60%-80% maximal exercise capacity) alternating with equal periods of rest, has similar results with less dyspnea.[46,47] Optimization of bronchodilator therapy is desirable because it will allow patients to exercise at higher intensities. Similarly, supplemental oxygen therapy for hypoxemic patients, in addition to increasing safety, will allow patients to train at higher work rates. Oxygen supplementation may even promote exercise training at higher intensities in nonhypoxemic COPD patients,[48] but further studies will be needed before this can be endorsed. If patients cannot achieve high work rates during exercise training, lower work rates have also been demonstrated to produce positive outcomes.[49]

Although the strength of the upper extremity muscles is relatively preserved compared with that of the lower extremities in COPD,[50] the former are very important to many activities of daily living. The use of upper extremity muscles is often associated with considerable dyspnea, probably because the arm muscles are also accessory muscles of respiration. Endurance training of the upper extremities is thus an important component of pulmonary rehabilitation. Its effectiveness has recently been demonstrated in a randomized clinical trial.[50a] Training can be accomplished using supported arm exercises, such as with arm ergometry, or unsupported arm exercises, such as by lifting free weights or dowels or by stretching elastic bands.[51]

Because peripheral muscle weakness and/or atrophy contributes to exercise limitation in patients with lung disease,[52] strength training is a rational component of exercise training during pulmonary rehabilitation.[53] Training in weight-lifting exercises alone, involving the upper and lower extremities, increases muscle strength and endurance performance on a cycle ergometer.[54] In the current practice of pulmonary rehabilitation, strength training is usually added to standard aerobic training. This combination increases muscle strength and mass, but its additive effect on health status has not been proved.[55]

The total duration of exercise training in pulmonary rehabilitation should reflect the patient's underlying respiratory disease, his or her level of physical and cardiovascular conditioning, and the progress made during the exercise training sessions. The Global Initiative for Obstructive Lung Disease (GOLD) guidelines[13] report that the optimum length of exercise training has not been determined in randomized, controlled trials, but suggests there is evidence that programs of longer duration provide greater benefit. Ideally, the optimal length of an exercise training program should depend on whether the patient continues to progress toward goals. However, in reality, the program length is generally set by resources, reimbursement, and continued patient motivation. Longer programs may provide more sustained benefits in outcomes.[56]

Exercise training is typically given in the pulmonary rehabilitation facility under supervision. Generally, this is supplemented with patient-specific instructions for additional exercise training at home or in the community. Early incorporation of home exercise into the routine of daily life may promote long-term adherence with the exercise prescription. Carrying this concept one step further, a recent randomized trial has demonstrated that after 4 weeks of standardized education, 8-weeks of exercise training *in the home* was as effective in its primary outcome as 8 weeks of supervised training in the pulmonary rehabilitation center.[57] The primary outcome in this study was questionnaire-rated dyspnea at 1 year following rehabilitation. Similar improvements were noted in exercise capacity, although the mean changes in the 6-minute walk distance were well below the established minimum clinically important difference of 54 m. Of importance, there were no significant differences in adverse events in the two groups, and the treating physicians and the study steering committee did not identify any serious adverse events attributable to the exercise training. It remains to be determined whether this home exercise approach to pulmonary rehabilitation will become a practical alternative to the traditional approach.

Education

Education is an important component of pulmonary rehabilitation programs, and its incorporation alongside exercise training provides a good setting to promote the health behavior change necessary to optimize disease control. Educational needs are determined as part of the initial patient assessment and then are reassessed over the course of the program. Education provides the patient and family important information on the disease process, its comorbidity, and its treatment. This information encourages active participation in health care, thereby promoting adherence to therapy and important self-management skills.[58,59] Education also helps the patient and family find ways to cope with chronic illness and its comorbidities.[60] Some standard educational topics are listed in Table 94-1. In pulmonary rehabilitation, education is usually provided both in small-group settings and in a one-to-one format.

The educational process includes the promotion of a healthy lifestyle, the incorporation of adaptive techniques (such as self-pacing) into the home setting, and the promotion of long-term adherence with the postrehabilitative instructions. Self-management education is an essential component of pulmonary rehabilitation. It emphasizes "learning through doing," enhances patient self-confidence, and encourages a "take charge" attitude (in collaboration with the health care providers) toward managing the disease.[14] Some strategies in collaborative self-management include interventions for smoking cessation, encouragement of regular exercise at home, incorporation of increased levels of physical activity into the home setting, and early recognition and treatment of respiratory exacerbations. The development of a patient-specific, collaborative self-management plan for COPD exacerbations is an important goal of pulmonary rehabilitation; this includes education about the symptoms and signs associated with exacerbations to foster early recognition followed by the implementation of an action plan, which often includes using filled prescriptions for a short course of systemic steroids and an antibiotic. Ongoing collaboration among

the patient and the medical team members is the key to effective self-management. Advance directive discussions are also an important component of pulmonary rehabilitation.[61]

Because education is a component of virtually all pulmonary rehabilitation programs, there are few studies evaluating its individual contribution to the overall effectiveness of the comprehensive program. However, self-management strategies applied to the home setting have been shown to be effective in improving health status and reducing utilization of medical resources.[26]

Psychosocial Training and Support

Psychosocial problems, such as anxiety, depression, deficiencies with coping, and decreased self-efficacy, contribute to the burden of advanced respiratory disease.[62] Psychosocial and behavioral interventions vary widely among comprehensive pulmonary rehabilitation programs but often involve educational sessions or support groups, focusing on areas such as coping strategies or stress management techniques. Techniques of progressive muscle relaxation, stress reduction, and panic control may reduce not only anxiety but dyspnea as well.[63] Educational efforts may also improve coping skills. Participation by family members or friends in pulmonary rehabilitation support groups is encouraged. Informal discussions of the common symptoms and concerns of patients with chronic lung disease may provide emotional support to patients and their families. Because of these interventions, it should come as no surprise that a randomized clinical trial has demonstrated that comprehensive pulmonary rehabilitation can decrease psychosocial morbidity in patients with severe COPD even when no specific psychological intervention is provided.[64] Individuals with substantial psychiatric disease should, of course, be referred for appropriate professional care outside the program.

Nutritional Support

Nutritional depletion, including decreased weight and abnormalities in body composition such as decreased lean body mass, is present in 20% to 35% of patients with stable COPD.[65,66] Depletions in lean body mass undoubtedly contribute to the morbidity of patients with chronic respiratory disease by leading to decreased respiratory muscle strength,[67] handgrip strength,[68] exercise tolerance,[69,70] and health status.[71] Nutritional depletion and alteration in body composition are also significant predictors of the mortality of COPD, independent of FEV_1.[5,6,72] Because of this, nutritional intervention is a recommended component of comprehensive pulmonary rehabilitation.

However, the benefit from simple nutritional supplementation to underweight patients with chronic lung disease has not been substantial, with one meta-analysis of nutritional intervention for COPD reporting only a 1.65-kg increase in weight following intervention.[73] In view of these disappointing results with calorie supplementation alone, consideration is being given to hormonal supplementation with anabolic steroids.[74] This has led to increases in weight, lean body mass, respiratory muscle strength, and arm and thigh muscle circumference.[75] In addition, one study has demonstrated that the combination of testosterone and weight training in men with COPD and low testosterone levels leads to greater increases in muscle mass and strength than either alone.[76] Whether these preliminary findings in this select group can be applied with safety and efficacy to a more generalized population remains unknown. The Joint ACCP/AACVPR Guidelines on Pulmonary Rehabilitation[2] do not recommend routine use of anabolic steroids for COPD patients.

Breathing Training, Inspiratory Muscle Training, and Chest Physical Therapy

These modalities have been part of pulmonary rehabilitation over the years, but conclusive evidence supporting their effectiveness in pulmonary rehabilitation is for the most part lacking. Breathing training is aimed at controlling the respiratory rate and breathing pattern, with a goal of decreasing air trapping. *Pursed-lip breathing* takes place when the patient inhales through the nose and exhales over 4 and 6 seconds through lips pursed in a whistling/kissing position. This technique facilitates the recruitment of abdominal muscles during exhalation and has a favorable effect on the breathing pattern, thereby increasing tidal volume and reducing end-expiratory lung volumes. The result is less hypoxemia, decreased oxygen cost of breathing, and decreased dyspnea. In selected patients, pursed-lip breathing has also been shown to reduce the oxygen cost of breathing.[77] Patients with COPD can usually be readily trained in pursed-lip breathing; in fact, they often spontaneously adopt this breathing pattern when dyspneic. *Breathing while bending forward* has been shown to decrease dyspnea in some patients with severe COPD, both at rest and during exercise. Similar improvements can be achieved by breathing in the supine and Trendelenberg positions. The best explanation for the reduction in dyspnea is that the increased abdominal pressure caused by bending over stretches the diaphragm, moving it into a better contracting position and leading to improved diaphragmatic function. *Diaphragmatic breathing* has not been shown to be beneficial; in fact, this technique may actually *decrease* breathing efficiency.[77]

The rationale behind inspiratory muscle training (IMT) is that COPD patients have weak inspiratory muscles and that training them may improve outcomes. The Joint ACCP/AACVPR Evidence-Based Clinical Practice Guidelines reviewed the relatively numerous studies on IMT and concluded that this treatment does increase inspiratory muscle strength, increases exercise performance, and decreases dyspnea. Their recommendation is to consider IMT in selected COPD patients with decreased inspiratory muscle strength and breathlessness despite optimal medical therapy.[2]

Chest physical therapy is used in an attempt to remove airway secretions. The techniques include postural drainage, chest percussion and vibration, and directed cough. Postural drainage uses gravity to help drain the individual lung segments. Chest percussion should be performed with care in patients with osteoporosis or bone problems. Cough would be an effective technique for removing excess mucus from the larger airways; unfortunately, patients with COPD have impaired cough mechanisms (maximum expiratory flow is reduced, ciliary beat is impaired), and the mucus itself has altered viscoelastic properties. Because spasms of coughing may lead to dyspnea, fatigue, and worsened obstruction, directed cough might be helpful by enhancing the beneficial effect and preventing the untoward ones. With directed coughs, patients are instructed to inhale deeply, hold their breath for a few seconds and then cough two or three times with the mouth open. They are also instructed to compress the upper abdomen to assist in the cough. These techniques are probably useful in selected patients with difficulty mobilizing secretions.

Vaccination

The causes of exacerbations of COPD are poorly understood and are probably multifactorial; both influenza virus and *Streptococcus pneumoniae* may play a role; and there is no doubt that when either of these infections occurs, patients with chronic lung disease are at increased risk for serious complications, including death.[78] One of the national health objectives in the United States for the year 2000 was to increase influenza and pneumococcal vaccination levels to higher than 60% among persons at high risk for complications and for everyone 65 years of age or older.[79] As stated, this includes all patients with COPD and other forms of chronic lung disease, regardless of age. Because the influenza vaccine is type-specific and serotypes are constantly changing, vaccination must be repeated every year, preferably at the beginning of the season in the fall. In contrast, the pneumococcal vaccine is polyvalent and its benefits should last a lifetime.[80] One of the responsibilities of a rehabilitation program is to educate enrollees about the importance of vaccination against influenza and pneumococcal infections and to ensure that it is carried out and (for influenza) repeated annually.

Oxygen Assessment and Therapy

Background

Although not in itself a unique component of pulmonary rehabilitation, testing for oxygen needs and/or adjusting the oxygen to achieve its full benefits is part of all rehabilitation programs. Two landmark studies clearly showed improved survival in patients with COPD and hypoxemia (arterial oxygen pressure Pa_{O_2} < 55 mm Hg) who breathed supplementary oxygen at night compared with those who received no oxygen; there was even better survival in those who breathed oxygen for longer periods through the aid of an ambulatory delivery system.[81,82] Contemporary guidelines for prescribing home oxygen for patients with COPD, based in part on these trials, are shown in Table 94-2. The chief criterion is a significant level of hypoxemia, defined as a Pa_{O_2} of 55 mm Hg or less for 3 weeks or more when the patient is in a clinically stable state (i.e., has been free from exacerbation of bronchitis, heart failure, or other intercurrent complications). Additional criteria were also used in the North American multicenter trial to enroll stable patients with COPD whose Pa_{O_2} values were between 55 and 59 mm Hg.[81] They included evidence of pulmonary hypertension as judged by radiographic abnormalities (an enlarged pulmonary outflow tract); electrocardiographic findings of elevated right-sided intracardiac pressures (*P* waves in standard leads II, III, and aVF > 2-mm amplitude); clinical evidence of cor pulmonale with heart failure; or secondary polycythemia from chronic hypoxemia. Patients with COPD who have echocardiographic evidence of right ventricular hypertrophy and/or pulmonary hypertension also qualify.

TABLE 94-2. Guidelines for Prescribing Home Oxygen for Advanced Chronic Obstructive Pulmonary Disease

PATIENT SELECTION CRITERIA
Accepted Indications
Resting Pa_{O_2} consistently 55 mm Hg or less, *or* consistently 55–59 mm Hg plus cor pulmonale clinically diagnosed and/or hematocrit > 55%
Stable course of disease on optimum medical therapy
Arterial blood gas determinations while breathing room air at rest for a minimum of 20 min
Patients with substantial nocturnal hypoxemia (i.e., Pa_{O_2} < 55 mm Hg on multiple occasions, *or* patients with hematocrit > 55%, *or* clinical evidence of pulmonary hypertension)
Possible Indications
Normoxic patients in whom less dyspnea and substantially increased exercise capability is demonstrated with oxygen
Supplementation during exercise training
OXYGEN DOSE
Continuous flow by double or single nasal cannulas (see text) or by demand system with demonstration of adequate oxygen saturation
Lowest liter flow to raise Pa_{O_2} to 60–65 mm Hg or oxygen saturation to 90%–94%
Increase baseline liter flow by 1 L/min during exercise and sleep. Consider higher flows if patient traveling by air

Pa_{O_2}, arterial oxygen pressure.

Dosage

The therapeutic goal of administering supplementary oxygen is to raise Pa_{O_2} to the range of 60 to 65 mm Hg or, alternatively, to reach an oxygen saturation of 90% to 94%. The results of the Nocturnal Oxygen Therapy Trial

(NOTT)[81] established the fact that the great majority of patients with advanced COPD and hypoxemia achieve this goal with oxygen delivered by nasal cannula at 1 to 2 L/min. Less than 10% of the patients require 3 L/min or more while at rest. Additional results obtained during the conduct of the trial indicate that additional oxygen of 1 L/min was required during the stress of exercise and while sleeping; those extra needs are undoubtedly caused by the increased metabolic demands of exercise and the modest degree of hypoventilation and/or worsening of gas exchange that occurs during sleep.

Thus, if the baseline flow of oxygen is 2 L/min with patients at rest, the flow rate should be turned up to 3 L/min when they are exercising or sleeping. Periodic monitoring of oxygenation is essential to determine who should receive supplementary oxygen in the first place; moreover, in those who are being treated, monitoring is used to evaluate whether therapeutic goals are being met or exceeded. Two techniques are available: arterial puncture with direct measurement of Pa_{O_2} and pulse oximetry to quantify oxygen saturation. The latter is being increasingly used given the convenience and improved accuracy of the newer oximeters.

Delivery Systems

The oxygen delivery systems available for home use are as follows: compressed gas in high-pressure cylinders; liquid gas in lightweight canisters; and stationary oxygen concentrators. Large compressed gas cylinders are fixed in place, but patients can move short distances while using long (50-ft) tubing; smaller cylinders can be attached to wheelchairs or installed in automobiles to allow journeys out of the home. Ambulatory patients are best served with a small portable, liquid system, which is the only practicable way to deliver oxygen to someone who is working or active. Liquid gas–containing canisters are constantly being improved to reduce weight and to increase duration of use. Because the goal of pulmonary rehabilitation is to restore the patients' functional capacity to its optimal level and exercise is a fundamental part of pulmonary rehabilitation, every effort must be made to provide hypoxemic patients with portable devices that help achieve these goals.

Oxygen as an Adjunct to Pulmonary Rehabilitation Exercise Training

In addition to life-prolonging effects, supplemental oxygen therapy increases exercise capacity in hypoxemic[83] and even nonhypoxemic[84] COPD patients. Part of this beneficial effect is probably mediated through a reduction in carotid body respiratory drive, resulting in a lower respiratory rate and, consequently, less dynamic hyperinflation. Because supplemental oxygen increases exercise capacity in COPD patients, it may enhance outcomes in pulmonary rehabilitation by allowing patients to exercise and train at higher intensities. Oxygen therapy for individuals with exercise-induced hypoxemia is a standard of care in the United States, but the role of oxygen therapy for nonhypoxemic patients as a potential exercise-enhancer is not well-established. To date, a few clinical trials have demonstrated that supplemental oxygen (or oxygen plus helium) during pulmonary rehabilitation exercise training in nonhypoxemic patients with COPD may allow for exercise training at higher intensities and greater short-term improvement from the intervention.[85,85a] Further research is needed in this area.

Long-term Adherence

Although the short-term effects of pulmonary rehabilitation in multiple outcome areas are firmly established, the long-term effectiveness of this therapy is often disappointing. In controlled trials of pulmonary rehabilitation, gains in exercise performance and health status obtained after 6 to 8 weeks of therapy essentially disappear by 18 to 24 months.[22] However, it seems illogical to expect that a therapy that is only applied for 6 to 8 weeks could substantially modify the natural course of the disease. In all likelihood, two factors are mainly responsible for this drop-off in effectiveness: (1) exacerbations of underlying lung disease, leading to prolonged symptoms and reassuming a more sedentary lifestyle and (2) a gradual decline in adherence with the postrehabilitation exercise prescription. With these factors in mind, the pulmonary rehabilitation program must include strategies to promote long-term adherence. One approach is to incorporate the principles of pulmonary rehabilitation, including exercise training, more actively into the home setting. This is supported by studies of home-based programs, which suggest that gains made in this setting may be longer lasting[86] than those of hospital-based programs. Promoting regular walking seems to help prolong effectiveness in some outcome areas.[87] Although regularly scheduled repeated pulmonary rehabilitation sessions do not give additional prolonged benefit,[88] giving a "booster shot" of pulmonary rehabilitation following an exacerbation, by emphasizing short periods of supervised exercise training to return the patient to baseline performance, appears to be a reasonable intervention in selected cases. Longer-duration pulmonary rehabilitation seems to confer longer-lasting effectiveness.[56]

Pulmonary Rehabilitation and the Integrated Care of the Respiratory Patient

The American Thoracic Society/European Respiratory Society (ATS/ERS) guidelines define pulmonary rehabilitation as "a spectrum of intervention strategies integrated into the lifelong management of patients with chronic respiratory disease and involves a dynamic, active collaboration among the patient, family and healthcare providers."[1] Depending on the specific needs of the individual patient, this care might include smoking-cessation counseling and therapy, activity promotion, education on a healthy lifestyle, vaccinations, the incorporation of regular exercise training into the individual's lifestyle, optimization of pharmacology, an exacerbation

prevention strategy, a collaborative management plan for the early recognition and treatment of exacerbations, and discussion of advance directives. These interventions can be conveniently bundled into a comprehensive outpatient or inpatient pulmonary rehabilitation program administered by a multidisciplinary staff. However, if pulmonary rehabilitation is not available or feasible for a particular patient, the onus of this patient-centered comprehensive management rests on the health care provider. Unfortunately, our current acute care health model is poorly suited for this type of management. Another approach—which has not yet been implemented to any significant degree—is the concept of *integrated care*.[14] Integrated care, as it applies to individuals with respiratory disease, has been described as "a system-wide, multidisciplinary, collaborative approach that is individualized to the specific needs of the patient. This approach stresses comprehensive assessment, self-management education, agreement on an individually-tailored care plan, and communication among health care professionals, patients, and families/caregivers."[14] An integrated care approach would be particularly useful during COPD exacerbations, when there is an abrupt deterioration in the patient's condition and a far greater likelihood of increased health care utilization. Some data suggest that an integrated care approach in this setting reduces health care costs.[89]

Promoting Physical Activity in the Patient with Chronic Respiratory Disease

Daily activity energy expenditure is an important predictor of mortality in healthy community-dwelling older adults,[90] and patients with COPD are more sedentary than age-matched healthy individuals.[91] Hypoxemic COPD patients are generally very sedentary and, disappointingly, supplemental oxygen is not particularly effective in reversing this maladaptive behavior.[91a] Because decreased physical activity in COPD patients appears to be related to increased health care utilization and mortality,[92,93] an important goal of pulmonary rehabilitation is to promote increased physical activity in the home and community settings. Although pulmonary rehabilitation unequivocally increases exercise capacity, it is less clear whether the increase in exercise capacity is translated into increased physical activity outside the pulmonary rehabilitation environment: "*can do*" versus "*do do*" (R.Casaburi, personal communication). Clinical trials incorporating direct measurements of physical activity using motion detectors (accelerometers worn at the waist or on the leg) have demonstrated that pulmonary rehabilitation does indeed increase physical activity.[31–33]

PROGRAM ORGANIZATION

The pulmonary rehabilitation program needs a coordinator to organize the various components into a functioning unit. The coordinator develops the integrated program and monitors its progress and function. The program should have resources available to teach and supervise respiratory therapy (oxygen, use of inhalers, nebulizers), physical therapy (breathing techniques, chest physical therapy, postural drainage), exercise conditioning (upper and lower extremities), and activities of daily living (work simplification, energy conservation). Also desirable are services to evaluate and advise on nutritional, psychological, and vocational needs.

Whether to have an inpatient or an outpatient program depends on the methods of reimbursement, patient population, available personnel, and institutional policy. The ideal system is one that provides an in-hospital component for patients who may benefit from the program while recovering from acute exacerbations and an outpatient component (including home therapy) that could complete the program started in the hospital. This program ensures good continuity of care.

OUTCOME ASSESSMENT

Outcome assessment can be defined as the assessment of the "consequences" of an intervention. As stated earlier, pulmonary rehabilitation does not affect the degree of respiratory impairment as measured by tests of physiologic pulmonary function. However, exercise training in rehabilitation increases the content of oxidative enzymes in the trained muscles, accompanied by a beneficial delay in the generation of lactate (a marker of muscle performance). This results in improved exercise performance and reduced dyspnea, and it may be responsible, at least in part, for improved functional capacity. Therefore, even though pulmonary rehabilitation does not change the impairment of lung function, it ameliorates the disability and handicap of the patient.

Outcome assessment for pulmonary rehabilitation encompasses three areas: (1) a generalized audit of the effectiveness of the global pulmonary rehabilitation program and its components; (2) evaluation of individual patient response to the intervention; and (3) assessment of the effect of pulmonary rehabilitation on society, especially with respect to its effect on health care utilization and its cost-effectiveness. Some commonly used outcome measures are listed in Table 94-3.

Evaluating the effectiveness of the pulmonary rehabilitation program is important in continuous quality assessment. Testing can be made in several areas, especially in the measurements of dyspnea, exercise performance, and health status. Dyspnea evaluation falls into two categories: measurement of exertional dyspnea during standardized exercise testing and measurement of breathlessness by questionnaire. Exertional dyspnea is usually rated using a Borg scale[94] or a visual analogue scale. Measurement of dyspnea by questionnaire usually assesses the dyspnea associated with daily activities or the way in which exertional dyspnea limits activities.[95]

Exercise performance can be measured in the laboratory using protocols involving incremental treadmill or stationary bicycle exercise. However, field tests of exercise performance, such as the 6-minute walk test

TABLE 94-3. Examples of Outcome Assessment for Pulmonary Rehabilitation

Measurement	Scales/Tests
Exertional dyspnea	Borg scale or visual analogue scale during exercise testing
Dyspnea with daily activities	Modified Medical Research Council (MRC) questionnaire Baseline and Transitional Dyspnea Indexes (BDI/TDI) San Diego Shortness of Breath Questionnaire
Functional exercise capacity	Six-minute walk test Incremental and endurance shuttle walk tests
Laboratory measures of exercise performance	Incremental cardiopulmonary exercise testing Endurance testing at constant work rate
Health status	Chronic Respiratory Disease Questionnaire (CRQ) St. George's Respiratory Questionnaire (SGRQ) Medical Outcomes Study Short Form-36 (SF-36)
Functional performance	Pulmonary Functional Status Scale (PFSS) Pulmonary Function Status and Dyspnea Questionnaire (PFSDQ)
Nutritional status/body composition	Body mass index (BMI) Body composition using bioelectrical impedance or dual-energy x-ray absorption (DEXA)
Psychological variables	Measurement of anxiety and depression using the Hospital Anxiety and Depression (HAD) questionnaire

or the shuttle walk test, are more commonly performed. The 6-minute test is easy to perform, relates well to functional status, and is responsive to the pulmonary rehabilitation intervention. As stated earlier, the 6-minute walk test is a better predictor of mortality in patients with COPD than is lung function. For the shuttle walk test,[96] the patient is instructed to walk around a 10-m course at gradually increasing speeds. Speed is determined by an auditory beeping signal that sets the pace. The test is terminated when the patient cannot complete the course in time, usually because of breathlessness. Total distance traveled is the variable assessed.

Health status is often assessed using respiratory-specific questionnaires, such as the Chronic Respiratory Disease Questionnaire (CRQ)[97] or the St. George's Respiratory Questionnaire (SGRQ).[98] Some pulmonary rehabilitation programs may also use a generic instrument, such as the Medical Outcomes Study Short Form-36 (SF-36),[99] to complement information from the respiratory-specific questionnaires. Assessment in the areas of nutrition/body composition, educational goal achievement, and psychosocial variables (e.g., anxiety, depression, coping skills) is also possible.

In the evaluation of the response to therapy of an individual patient, exercise tests such as the timed walk, a questionnaire assessment of dyspnea, or measurements of functional status or health status may provide some useful information. However, to date, these outcome measures, which have become routine for program assessment, have not been extensively validated for *individual* patient assessment. Traditional one-on-one clinical assessment remains necessary for the individual patient. Outcome assessment in health care utilization or cost-effectiveness generally requires participation of several centers in a multicenter study to accrue the necessary number of subjects for this type of analysis.

RECENT ADJUNCTS

Several adjuncts may prove to be beneficial in patients with severe disability from chronic respiratory disease. Noninvasive positive-pressure ventilation (NPPV), through its effect in helping unload the respiratory muscles, may improve breathlessness in COPD.[100,101] The use of proportional assist ventilation in pulmonary rehabilitation in patients without hypercapnia had no appreciable added benefits in mild COPD.[102] However, in patients with more severe lung disease, this form of therapy allowed the patient to exercise at a higher intensity, resulting in the achievement of a greater maximum exercise capacity.[103] The Joint ACCP/AACVPR Evidence-Based Clinical Practice Guidelines stated that NPPV does confer a postrehabilitation benefit in *selected* patients.[2] Similarly, the application of electrical stimulation combined with active limb mobilization in COPD patients on mechanical ventilation or with severe disability improves muscle strength and provides other benefits.[104–106] Finally, the inhalation of less-dense, oxygen-enhanced gas mixtures, such as 72% helium–28% oxygen, can improve exercise performance in patients with severe COPD.[107] These techniques remain experimental and therefore appropriate topics for research.

KEY POINTS

- Pulmonary rehabilitation is a multidisciplinary, patient-centered approach to the treatment of patients with chronic respiratory disease.
- Although pulmonary rehabilitation has no direct effect on lung function, it nonetheless produces substantial improvements in dyspnea, exercise performance, and quality of life. It also reduces health care utilization.
- Pulmonary rehabilitation works through decreasing the effect of comorbidity that is frequently present in patients with chronic respiratory disease.
- Whereas most patients referred for pulmonary rehabilitation have COPD, this therapy should be beneficial for patients with other respiratory diseases.
- Important components of pulmonary rehabilitation include education, exercise training, nutritional therapy, and psychosocial support.
- Exercise training is the cornerstone of pulmonary rehabilitation; high-intensity, low-intensity, and strength training are all utilized.
- Developing collaborative self-management strategies, especially involving the early detection and treatment of COPD exacerbations, is an important educational component of pulmonary rehabilitation.
- Pulmonary rehabilitation should be considered part of the integrated care of the patient with COPD and other chronic respiratory diseases.
- Physical activity promotion in the home and community setting is an important goal of pulmonary rehabilitation.
- Optimization of pharmacologic therapy and supplemental oxygen (when indicated) may allow the patient to exercise at higher intensity and thereby achieve greater increases in exercise performance.

CHAPTER 95

LUNG TRANSPLANTATION

Robert M. Kotloff, MD

INTRODUCTION

INDICATIONS AND CANDIDATE SELECTION

TIMING OF REFERRAL AND LISTING

ALLOCATION SYSTEM

DONOR SELECTION AND MANAGEMENT

AVAILABLE SURGICAL TECHNIQUES

Heart-Lung Transplantation
Single-Lung Transplantation
Bilateral-Lung Transplantation
Living Donor Bilobar Transplantation

ROUTINE POSTTRANSPLANTATION MANAGEMENT

OUTCOMES

Survival
Pulmonary Function
Exercise Capacity
Hemodynamics
Quality of Life

COMPLICATIONS

Primary Graft Dysfunction
Airway Complications
Phrenic Nerve Injury
Native Lung Hyperinflation
Infection
Rejection
Posttransplantation Lymphoproliferative Disorder
Lung Cancer
Recurrence of Primary Disease

RETRANSPLANTATION

FUTURE DIRECTIONS

INTRODUCTION

Human lung transplantation was first attempted in 1963, but it was not until nearly 2 decades later that extended survival was achieved. Further refinements in patient selection, surgical technique, immunosuppression, and postoperative care have since facilitated the successful application of lung transplantation to a wide variety of advanced disorders of the airways, lung parenchyma, and pulmonary vasculature. The field has realized dramatic growth, with over 28,000 procedures performed worldwide to date and approximately 2500 procedures now performed annually.[1] Nonetheless, serious problems persist that limit the utility of this procedure. The donor pool remains insufficient to meet the demands of the many desperately ill patients awaiting transplantation. Immunosuppressive therapy is associated with a number of troubling side effects, most notably a significant risk of infection and malignancy. Despite the use of immunosuppressive agents, rejection occurs frequently and continually threatens organ function. Though lung transplantation offers the prospect of improved functional status and quality of life, long-term survival remains an elusive goal, with only half of recipients living beyond 5 years. In order to optimize outcomes in the face of these shortcomings, judicious selection of candidates is essential and care of recipients must be rendered in a meticulous and vigilant fashion by clinicians familiar with the hazards of posttransplant life.

INDICATIONS AND CANDIDATE SELECTION

Lung transplantation is a therapeutic option for a broad spectrum of chronic debilitating pulmonary disorders of the airways, parenchyma, and vasculature. Chronic obstructive pulmonary disease (COPD) represents the leading indication for lung transplantation and together with alpha$_1$-antitrypsin deficiency accounts for over 40% of all procedures performed worldwide.[1] Other leading indications include idiopathic pulmonary fibrosis (IPF) (21% of cases) and cystic fibrosis (CF; 16% of cases). Once a common indication for transplantation, idio-

pathic pulmonary arterial hypertension now accounts for less than 4% of procedures, reflecting major advances in the medical management of these patients. Transplantation of patients with lung involvement due to collagen vascular disease (e.g., scleroderma) remains controversial owing to concerns that extrapulmonary manifestations of the systemic disease could compromise the posttransplant course. Nonetheless, short-term functional outcomes and survival following transplantation are comparable with those of other patient populations and most centers are willing to offer transplantation to carefully selected patients without significant extrapulmonary organ dysfunction.[2] In contrast, lung transplantation for bronchioalveolar carcinoma, a subtype of lung cancer that tends to remain localized to the lung parenchyma, has largely been abandoned due to an unacceptably high rate of cancer recurrence.[3]

The scarcity of organs and the somewhat inferior outcomes achieved with recipients of advanced age have prompted many lung transplant programs to establish an upper age limit of 60 to 65 years. Notably, however, there has been a steady increase in the percentage of recipients exceeding this traditional age cutoff; in 2008, 35% of transplant recipients were 60 years or older and 9% were over the age of 65.[1] Candidates should be functionally disabled (New York Heart Association class III or IV) but, ideally, still ambulatory. Many programs screen for and exclude profoundly debilitated patients by requiring a minimum distance on a standard 6-minute walk test, commonly set at 600 ft.[4] The presence of significant renal, hepatic, or left ventricular dysfunction precludes isolated lung transplantation, but multiorgan transplantation can be considered in highly select patients. Other absolute contraindications include recent malignancy (other than nonmelanoma skin cancer); active infection with the human immunodeficiency virus, hepatitis B virus, or hepatitis C virus with histologic evidence of significant liver damage; active or recent cigarette smoking, drug abuse, or alcohol abuse; severe psychiatric illness; and extremes of weight.[5] The risk posed by other chronic medical conditions such as diabetes mellitus, osteoporosis, gastroesophageal reflux, and coronary artery disease must be assessed individually based on severity of disease, presence of end-organ damage, and ease of control with standard therapies. Among CF candidates, colonization with *Burkholderia cepacia* complex, in particular genomovar III (also known as *Burkholderia cenocepacia*), is considered a strong contraindication by the majority of centers, owing to the demonstrated propensity of this organism to cause lethal posttransplant infections.[6,7] In contrast, the presence of pan-resistant *Pseudomonas aeruginosa* in this patient population is associated with acceptable outcomes and should not be viewed as a contraindication.[8] Transplantation of patients on mechanical ventilation is associated with an increased risk of death within the first year and is generally restricted to patients early in the course of respiratory failure prior to onset of profound debility or intercurrent complications of critical illness. Prior thoracic surgery and pleurodesis render the native lung more difficult to explant and increase the risk of intraoperative bleeding, particularly when cardiopulmonary bypass is required, but do not contraindicate transplantation in most instances. Pleural thickening associated with aspergillomas similarly complicates anatomic dissection and explantation of the native lung and carries the additional risk of soiling the pleural space with fungal organisms. Defining the degree of pleural reaction that contraindicates transplantation is a judgment call influenced by the experience and aggressiveness of the transplant surgeon.

TIMING OF REFERRAL AND LISTING

Listing for transplantation is considered at a time when the lung disease limits basic activities of daily living and is deemed to pose a high risk of death in the short term. Disease-specific guidelines for timely referral and listing of patients, based on available predictive indices, have recently been updated (Table 95-1).[5] The imprecise nature of these predictive indices can make decisions about transplant listing problematic for all but the most severely ill patients. The patient's perception of an unacceptably poor quality of life is an important additional factor to consider but should not serve as the sole justification for listing of a patient whose disease is not deemed to be at an advanced and potentially life-threatening stage.

ALLOCATION SYSTEM

Methods governing allocation of organs vary between different countries but typically employ a time-based or need-based ranking of candidates on the waiting list, or some combination of the two systems. Examination of the systems that have been operative in the United States permits an appreciation of the advantages and limitations of both approaches. From 1990 to 2005, lung allocation in the United States prioritized candidates on the basis of the amount of time they had accrued on the waiting list, without regard to severity of illness. Based on a simple and objective parameter, this system was easily understood but was ultimately called into question because it failed to accommodate those patients with a more rapidly progressive course who often could not survive the prolonged waiting times.[9] In response to the perceived inequities of the time-based system, and under mandate of the federal government, a new system was implemented in May of 2005 that allocates lungs on the basis of both medical urgency (i.e., risk of death without a transplant) and "net transplant benefit" (i.e., the extent to which transplantation will extend survival). By incorporating this latter concept, the system attempts to avoid the pitfall of preferentially allocating the limited donor organ pool to critically ill patients with an unacceptably high posttransplantation mortality rate.

The new model, derived from an analysis of the comprehensive United Network of Organ Sharing (UNOS) national database, identifies 10 factors independently predictive of 1-year survival on the waiting list and 7

TABLE 95-1. Disease-Specific Guidelines for Listing for Lung Transplantation

CHRONIC OBSTRUCTIVE PULMONARY DISEASE
- BODE index of 7-10 **or** at least one of the following:
- History of hospitalization for exacerbation associated with acute hypercapnia (P_{CO_2} > 50 mm Hg)
- Pulmonary hypertension or cor pulmonale, or both, despite oxygen therapy
- FEV_1 < 20% and either DL_{CO} < 20% or homogenous distribution of emphysema

IDIOPATHIC PULMONARY FIBROSIS
- Histologic or radiographic evidence of UIP **and** any of the following:
- A DL_{CO} < 39% predicted.
- A ≥ 10% decrement in FVC during 6 months of follow-up
- A decrease in pulse oximetry < 88% during a 6MWT
- Honeycombing on HRCT (fibrosis score > 2)

CYSTIC FIBROSIS
- FEV_1 < 30%of predicted, or rapidly declining lung function if FEV_1 > 30% (females and patients < 18 yr of age have a poorer prognosis; consider earlier listing) **and/or** any of the following:
- Increasing oxygen requirements
- Hypercapnia
- Pulmonary hypertension

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION
- Persistent NYHA class III or IV on maximal medical therapy
- Low (350-m) or declining 6MWT
- Failing therapy with intravenous epoprostenol or equivalent
- Cardiac index < 2 L/min/m^2
- Right atrial pressure > 15 mm Hg

SARCOIDOSIS
- NYHA functional class III or IV **and** any of the following:
- Hypoxemia at rest
- Pulmonary hypertension
- Elevated right atrial pressure > 15 mm Hg

BODE, [b]ody mass index, airflow [o]bstruction, [d]yspnea, [e]xercise capacity; DL_{CO}, diffusing capacity for carbon dioxide; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; HRCT, high-resolution computed tomography; 6MWT, 6-minute walk test; NYHA, New York Heart Association; P_{CO_2}, pressure of carbon dioxide; UIP, usual interstitial pneumonia.

Modified from Orens JB, Estenne M, Arcasoy S, et al: International guidelines for the selection of lung transplant candidates: 2006 update. J Heart Lung Transplant 25:745–755, 2006.

TABLE 95-2. Standard Lung Donor Criteria

- Age < 55 yr
- Clear chest radiograph
- Pa_{O_2} > 300 mm Hg on F_{IO_2} 1.0, PEEP 5 cm H_2O
- Cigarette smoking history < 20 pack-years
- Absence of significant chest trauma
- No evidence of aspiration or sepsis
- No prior thoracic surgery on side of harvest
- Absence of organisms on sputum Gram stain
- Absence of purulent secretions and gastric contents at bronchoscopy
- Negative for HIV antibody, hepatitis B surface antigen, and hepatitis C antibody
- No active or recent history of malignancy (excluding localized squamous or basal cell skin cancer, localized cervical cancer, and primary brain tumors with low metastatic potential and in the absence or invasive procedures to the brain and skull)
- No history of significant chronic lung disease

F_{IO_2}, fractional concentration of oxygen in inspired gas; HIV, human immunodeficiency virus; Pa_{O_2}, arterial oxygen pressure; PEEP, positive end-expiratory pressure.

factors predictive of 1-year survival following transplantation.[10] For each patient, these factors are utilized to calculate a lung allocation score (LAS). Patients who demonstrate a large net difference in survival (predicted posttransplant—pretransplant survival) in conjunction with a high degree of medical urgency (low predicted pretransplant survival) receive the highest LAS.

An analysis of data from the 2008 Organ Procurement and Transplantation Network (OPTN)/Scientific Registry of Transplant Recipients (SRTR) Annual Report sheds light on the impact of the new LAS system in the initial 2 years since it was implemented.[11] Because there is no longer an incentive to place patients on the active waiting list simply to accrue time (many of whom were ultimately deactivated rather than transplanted), the number of actively listed patients has fallen to approximately one half of the previous level. Median waiting time, which had ranged from 2 to 3 years under the time-based allocation system, has decreased to roughly 4 months, and one quarter of patients are waiting less than 35 days. By prioritizing patients with more rapidly progressive diseases, the LAS system has led to an increase in the percentage of transplants performed for IPF and a commensurate decline in the percentage performed for COPD. Importantly, there has been a significant reduction in the annual death rate of patients on the waiting list, one of the stated objectives of the new system. Notably, preferential transplantation of sicker patients has not resulted in an increase in early mortality following transplantation. Further experience will be required to determine the impact of the new system on long-term outcomes following transplantation. Of concern is the fact that the IPF population, the group receiving the highest priority under the LAS system, has the poorest long-term outcomes, with a median survival of only 4.1 years.[1]

DONOR SELECTION AND MANAGEMENT

In addition to meeting strict criteria for declaration of brain death, cadaveric lung donors are selected on the basis of established guidelines (Table 95-2).[12] Lungs are a particularly fragile organ in the brain-dead patient and are frequently compromised by volume overload, contusion, aspiration of gastric contents, or pneumonia as well as by extensive prior smoking. As a result, the vast major-

ity of donors fail to meet standard criteria for organ donation, leading to a historical recovery rate of only 15% from cadaveric organ donors deemed able to donate other organs. There is mounting evidence that these standard criteria may in fact be too stringent, leading to unnecessary wastage of suitable lungs. In one study, 29 pairs of lungs that had been rejected for transplantation were assessed for the magnitude of extravascular water content, intactness of alveolar fluid clearance capacity, and presence of pneumonia or emphysema.[13] Twelve pairs (41%) were found to have minimal or no abnormalities and thus to be potentially suitable for use. Additional evidence comes from published reports documenting that outcomes with use of "extended criteria" donors are similar to those achieved with use of donors meeting standard criteria.[14–18] Use of modified donor management protocols to optimize lung function through judicious fluid management and lung recruitment maneuvers has also been shown to enhance lung harvest rates.[19] This has been put into practice at a national level through the Organ Donation Breakthrough Collaborative, an initiative to increase the number of organ donors through increased consent for donation and through optimization and standardization of donor management practices. As a combined result of this initiative and liberalization of lung donor selection criteria, there has been a recent 20% increase in the number of lung transplants performed annually in the United States.[11]

Despite increases in the number of organs harvested, the demand for organs continues to outstrip supply, prompting a search for alternatives to the brain-dead donor pool. One emerging source is the non–heart beating or "donation after cardiac death (DCD)" donor who has experienced either an out-of-hospital (i.e., uncontrolled) arrest or a planned withdrawal of life-support in the operating room. Approximately 40 lung transplant procedures utilizing DCD donors were performed in the United States as of 2007, and centers in Spain and Australia have reported small numbers as well.[20,21] Preliminary data suggest that short-term outcomes approximate those associated with use of traditional brain-dead donors.

Once a donor has been identified, matching with potential recipients is based on size and ABO blood group compatibility. Prospective human leukocyte antigen (HLA) matching is not performed. However, potential candidates identified through standard pretransplant screening as having preformed circulating antibodies to foreign HLA antigens require either prospective donor-recipient lymphocytotoxic cross-matching or avoidance of donors with specific incompatible antigens.[22]

AVAILABLE SURGICAL TECHNIQUES

Four surgical techniques are currently utilized to varying degrees: heart-lung, single-lung, bilateral-sequential, and living donor bilobar transplantation. The choice of procedure is dictated by such factors as the underlying disease, age of the patient, survival and functional advantages, and center-specific preferences.

Heart-Lung Transplantation

Heart-lung transplantation was the first procedure to be successfully performed, but it has largely been supplanted by techniques to replace the lungs alone. Currently, fewer than 100 procedures are performed worldwide on an annual basis. Indications are largely restricted to Eisenmenger's syndrome with surgically irreparable cardiac lesions and to advanced lung disease with concurrent severe left ventricular dysfunction or extensive coronary artery disease. In the past, the presence of profound right ventricular dysfunction in the setting of severe pulmonary hypertension was deemed to be an indication for heart-lung transplantation. However, subsequent experience with isolated lung transplantation has demonstrated the remarkable ability of the right ventricle to recover once pulmonary artery pressures have normalized. The small number of patients requiring heart-lung transplantation in the United States face potentially protracted waiting times due to the preferential allocation of hearts to status 1A cardiac transplant candidates.

Single-Lung Transplantation

Single-lung transplantation was, until recently, the most commonly performed procedure. Traditionally, a standard posterolateral thoracotomy was utilized, but some surgeons now employ a less invasive anterior axillary muscle–sparing approach in select cases. Three anastomoses are executed—main-stem bronchus, pulmonary artery, and left atrium (incorporating the two pulmonary veins). Major advantages of the procedure are its technical ease and its efficient use of the limited donor pool, permitting two recipients to benefit from a single donor. Single-lung transplantation is an acceptable procedure for patients with pulmonary fibrosis and COPD, though in the latter setting, progressive native lung hyperinflation may occasionally complicate perioperative ventilator management.[23] Single-lung transplantation also has been performed successfully in carefully selected patients with severe pulmonary hypertension. However, concerns about exaggerated reperfusion pulmonary edema in an allograft that must bear the burden of nearly the entire cardiac output have prompted the vast majority of centers to abandon this approach in favor of the bilateral procedure. Because of infectious concerns, single-lung transplantation is contraindicated in patients with suppurative lung disorders such as CF.

Bilateral-Lung Transplantation

Bilateral sequential lung transplantation involves the performance of two single-lung transplant procedures in succession during a single operative session. Surgical approaches include transverse thoracosternotomy ("clamshell") incision, bilateral anterolateral thoracotomies (sparing the sternum), and median sternotomy. In the absence of severe pulmonary hypertension, cardiopulmonary bypass can often be avoided by sustaining

the patient on the contralateral lung during implantation of each allograft. The principal indications for this procedure are CF, other forms of bronchiectasis, and severe primary and secondary forms of pulmonary hypertension. In addition, many programs now advocate its use for patients with COPD, arguing that it offers functional and survival advantages over single-lung transplantation.[24–27] Although it is also being employed with increasing frequency in treatment of fibrotic lung disorders, the justification for this is less clear.[28,29] As a result of these trends, bilateral-lung transplantation now accounts for two thirds of all procedures performed worldwide.[1]

Living Donor Bilobar Transplantation

Living donor bilateral-lobar transplantation was developed chiefly to serve the needs of candidates with far-advanced or deteriorating status that would not allow them to tolerate a protracted wait for a cadaveric donor. The procedure involves transplantation of lower lobes from each of two living, blood group–compatible donors. In order to ensure that the lobes will adequately fill the hemithoraces, it is preferable to employ donors who are taller than the recipient. Patients with CF are particularly well suited as a target population because, even as adults, they tend to be of small stature. Intermediate-term functional outcomes and survival among recipients are similar to those achieved with cadaveric transplantation.[30,31] Concerns about excessive risk to the donor have thus far proved to be unfounded. In the two largest series published to date involving a combined total of 315 donors, there were no deaths or episodes of postoperative respiratory failure, and only 9 donors (2.9%) experienced complications of sufficient magnitude to warrant surgical reexploration.[32,33] Donation of a lobe results in an average decrement in vital capacity of 17%, a degree of loss that should be of little functional significance in an otherwise normal individual.[34] Despite the apparent low risk posed to the donor, living donor transplantation has not gained widespread acceptance, accounting for only 3.5% of annual transplant volume at its peak.[35] Its use has been further undermined by the new UNOS allocation system that expedites transplantation of more severely ill candidates.

ROUTINE POSTTRANSPLANTATION MANAGEMENT

Care of the lung transplant recipient requires close surveillance to ensure that the allograft is functioning properly, that immunosuppressive medications are properly administered and tolerated, and that complications are detected early and treated expeditiously. Most centers require patients to return frequently for office visits, blood tests, and chest radiographs during the initial 2 to 3 months following transplantation and to participate in an intensive pulmonary rehabilitation program during this time. Analogous to home glucose monitoring of the diabetic patient, lung transplant recipients chart their pulmonary function on a daily basis with a handheld microspirometer and are instructed to contact the transplant center if a sustained fall of greater than 10% in the forced expiratory volume in 1 second (FEV_1) or forced vital capacity is documented.

Many transplant programs employ frequent surveillance bronchoscopies and transbronchial lung biopsies within the first posttransplant year as a means of monitoring the allograft. Such an approach has been demonstrated to detect low-grade rejection or subclinical cytomegalovirus (CMV) pneumonitis in up to 30% of asymptomatic, clinically stable patients.[36] However, it has yet to be determined whether treatment of clinically silent disease has a beneficial impact on long-term graft function.

Immunosuppressive therapy is initiated immediately at the time of transplantation and is maintained lifelong. No consensus currently exists on the role of induction therapy with lymphocyte/thymocyte-depleting globulin preparations or interleukin-2 (IL-2) receptor antagonists (basiliximab and daclizumab), and only half of all centers currently employ this strategy. The lack of consensus reflects insufficient and conflicting data on the ability of these agents to reduce the incidence of acute and chronic rejection specifically in the lung transplant population.[37] Maintenance therapy consists of a calcineurin-inhibitor (cyclosporine or tacrolimus), purine synthesis inhibitor (azathioprine or mycophenolate), and prednisone. Sirolimus (also known as rapamycin), an inhibitor of IL-2–stimulated T-cell proliferation, is the newest immunosuppressive agent to be introduced into clinical practice. Its role in maintenance immunosuppression has yet to be established. Lacking inherent nephrotoxicity, sirolimus has been successfully substituted for calcineurin-inhibitors in patients with renal insufficiency, leading to recovery of renal function without undue risk of rejection.[38,39] Sirolimus impairs wound healing and has been associated with life-threatening bronchial anastomotic dehiscence when used immediately following transplantation.[40] As a result, the drug should never be initiated until complete healing of the bronchial anastomosis has been documented.

Individuals providing care to transplant recipients must be familiar with the administration, side effects, and drug interactions of these immunosuppressive agents (Table 95-3). Although serving as the cornerstone of therapy, the use of calcineurin inhibitors is particularly problematic. When administered orally, the bioavailability of these agents is poor and unpredictable, necessitating frequent monitoring of blood levels to ensure appropriate dosing. These drugs are metabolized via the hepatic cytochrome P-450 system and blood levels are influenced by the concurrent administration of other drugs that affect this enzymatic pathway. Adverse effects of these agents, as well as of the other drugs commonly utilized, are legion and contribute significantly to the morbidity associated with transplantation.

Management of medical comorbidities is an essential component of the care of the lung transplant recipient. Common medical issues that emerge in this population include osteoporosis, hypertension, renal insufficiency, coronary artery disease, diabetes mellitus, and hyperlipidemia.[41] Treatment of these conditions is similar to that of the general population.

TABLE 95-3. Commonly Used Immunosuppressive Medications

Medication (Class)	Dosing*	Adverse Effects	Drug Interactions
Cyclosporine and tacrolimus (calcineurin inhibitors)	Cyclosporine: dosed to achieve a whole blood trough level of 250–350 ng/ml (first year), then 200–300 ng/mL† Tacrolimus: dosed to achieve a whole blood trough level of 10–12 ng/mL (first year), then 6–8 ng/ml)	Nephrotoxicity Hypertension Neurotoxicity (tremor, seizures, white matter disease, headache) Hyperkalemia, hypomagnesemia Hyperuricemia/gout Hemolytic-uremic syndrome Gastroparesis Hyperglycemia Hirsutism, gingival hyperplasia (cyclosporine)	**INCREASED BLOOD LEVELS** Macrolide antibiotics (except azithromycin) Azole antifungals Diltiazem, verapamil Grapefruit juice **DECREASED BLOOD LEVELS** Phenobarbitol Phenytoin Rifampin
Sirolimus (mTOR inhibitor)	Dosed to achieve a whole blood trough level of 6–12 ng/mL	Thrombocytopenia Anemia Hyperlipidemia Peripheral edema Rash Impaired wound healing Interstitial pneumonitis	Same as calcineurin inhibitors
Azathioprine (purine synthesis inhibitor)	2 mg/kg/d	Leukopenia Macrocytic anemia Thrombocytopenia Hepatotoxicity Pancreatitis Hypersensitivity reaction (fever, hypotension, rash)	Synergistic bone marrow suppression when administered with allopurinol
Mycophenolate mofetil (purine synthesis inhibitor)	1000–1500 mg bid	Diarrhea Leukopenia Anemia	Concurrent use of cyclosporine may decrease serum concentrations of mycophenolate by limiting biliary secretion/enterohepatic recycling
Prednisone (corticosteroid)	0.5 mg/kg/d for 6–12 wk, then tapered to 0.15 mg/kg/d	Hyperglycemia Hypertension Hyperlipidemia Weight gain Osteoporosis Avascular necrosis Myopathy Mood changes, insomnia Cataracts	No significant interactions
Polyclonal antilymphocyte or antithymocyte globulin	Dose depends on specific preparation used	Leukopenia Thrombocytopenia Anaphylaxis Serum sickness "Cytokine release syndrome"—fever, hypotension	No significant interactions
Basiliximab and daclizumab (monoclonal IL-2 receptor antagonists)	Basiliximab: 20 mg IV on dayS 1 and 4 Daclizumab: 1 mg/kg every 2 wk for 5 doses	Hypersensitivity reactions (rare)	No significant interactions

*Dosing is based on the protocol used at the University of Pennsylvania Medical Center; dosing may vary between transplant centers.
†Measured by high-performance liquid chromatography assay.
IL-2, interleukin-2.

OUTCOMES

Survival

Current 1-, 5- and 10-year survival rates documented in the Registry of the International Society for Heart and Lung Transplantation (ISHLT) are 79%, 52%, and 29%, respectively.[1] Although 1-year survival approximates that achieved following heart and liver transplantation, 5-year survival remains considerably below the 75% rate associated with these other procedures. Modest gains have been made in survival rates associated with lung trans-

plantation since the early 1990s, principally due to improvements in perioperative outcomes. There are disease-specific differences in survival that likely reflect the degree of technical difficulty in performing the transplant, the average age of the particular patient population, and the extent of accompanying comorbidities. In descending order, median survival is 7 years for CF, 6.1 years for alpha$_1$-antitrypsin deficiency, 5.6 years for idiopathic pulmonary arterial hypertension, 5.1 years for COPD, and 4.3 years for IPF.[1] The preferential use of bilateral- over single-lung transplantation favorably affects long-term survival in patients with COPD, but data are conflicting on whether this holds true for recipients with IPF.[1,24,27–29]

Mortality is highest during the first year, with primary graft dysfunction and infection representing the most common causes of death. Factors portending an increased risk of early death include ventilator-dependence or inotropic support of the recipient prior to transplantation, an underlying diagnosis of pulmonary fibrosis or idiopathic pulmonary arterial hypertension, elevated bilirubin, and advanced recipient or donor age.[1] Beyond the first year, attrition slows to an annual rate of approximately 5% to 10%. Most late deaths are attributable to the development of bronchiolitis obliterans, the lethal effects of which are due to both progressive respiratory failure and to an increased susceptibility to infection.

Whether lung transplantation truly extends survival compared with the natural history of the underlying disease remains a matter of some debate. In the absence of randomized trials, this question has been approached by comparing observed posttransplant survival to survival of wait-list patients or by simulating survival with and without transplantation by statistical modeling; both of these approaches suffer from significant methodologic shortcomings. In the case of IPF, a disease with an extremely poor short-term prognosis, studies have suggested that lung transplantation does confer a survival advantage.[9,42] This has been more difficult to demonstrate for COPD, which typically follows a protracted course even in the advanced stages, and available studies have yielded conflicting results.[9,43,44]

A complex statistical model analyzing survival benefit for the COPD population has recently been published.[27] Although it employs many of the same variables as the UNOS LAS system, this model differs in two important ways—it takes into account the type of transplant performed and it carries the predicted survival curves with and without transplantation well beyond the first year. The model suggests that approximately 50% of COPD patients undergoing single-lung transplantation and two thirds of those undergoing bilateral transplantation would derive benefit. Survival benefit is heavily influenced by FEV_1 as well as a number of other functional and physiologic parameters. As an example, nearly 80% of patients with an FEV_1 less than 16% but only 11% of those with an FEV_1 greater than 25% are predicted to gain at least a year of life with bilateral transplantation. Notably, survival benefit is often not apparent until several years after transplantation and would, therefore, not be detected by the LAS model. A calculator that generates an estimate of survival benefit for an individual patient with a particular set of parameters is available at the following web site—http://www.copdtransplant.fr/

Using similar statistical modeling in the CF population, it has been suggested that only those patients with a predicted 5-year survival without transplantation of less than 50% and without *B. cepacia* and CF-arthropathy are likely to demonstrate enhanced survival with transplantation.[45] An extremely controversial and unsettling prediction of this model is that lung transplantation rarely improves survival in CF patients younger than 18 years old.[45,46]

Pulmonary Function

The peak effect of lung transplantation on pulmonary function parameters is usually not realized until 3 to 6 months following the procedure, at which time the adverse impact of such factors as postoperative pain, weakness, altered chest wall mechanics, and ischemia-reperfusion lung injury has dissipated. Complete normalization of pulmonary function is the anticipated result of bilateral-lung transplantation. Following single-lung transplantation for COPD, the FEV_1 increases severalfold to a level of approximately 50% to 60% of the predicted normal value. Similarly, single-lung transplantation for pulmonary fibrosis results in marked but incomplete improvement in lung volumes, with persistence of a restrictive pattern.

Transplantation also leads to correction of gas-exchange abnormalities. Oxygenation improves rapidly, permitting the majority of patients to be weaned off of supplemental oxygen within the first week. Hypercapnia may take longer to resolve, due to lingering abnormalities in the ventilatory response to CO_2.[47]

Exercise Capacity

Exercise tolerance improves sufficiently to permit the majority of transplant recipients to achieve functional independence and resume an active lifestyle. Although free of limitations with usual activity, transplant recipients with normal allograft function demonstrate a characteristic reduction in peak exercise performance as assessed by cardiopulmonary exercise testing. Specifically, patients typically achieve a maximum oxygen consumption at peak exercise of only 40% to 60% of predicted.[48] Suboptimal exercise performance persists in subjects tested as late as 1 to 2 years following transplantation. Despite the greater magnitude of improvement in pulmonary function experienced by bilateral transplant recipients, there is no significant difference in peak exercise performance between this group and those who receive only one lung.[49]

Characteristically, breathing reserve, oxygen saturation, and heart rate reserve remain normal during exercise while anaerobic threshold is reduced, a pattern most consistent with skeletal muscle dysfunction. Factors possibly contributing to this include chronic deconditioning, steroid myopathy, and calcineurin

inhibitor–induced impairment in muscle mitochondrial respiration.[48,50]

Hemodynamics

When performed in patients with pulmonary hypertension, both single- and bilateral-lung transplantation lead to immediate and sustained normalization of pulmonary arterial pressure and enhanced cardiac output.[51] In response to a decrease in afterload, right ventricular geometry and performance gradually normalize in the majority of patients.[52,53] A threshold of right ventricular dysfunction, below which recovery will not occur, has yet to be defined.

Quality of Life

After successful lung transplantation, quality of life measures improve markedly across most domains, achieving levels approximating that of the general population.[54–58] Nonetheless, several important limitations have been observed. Although improved from pretransplant status, impairments in psychological functioning—including increased levels of depression and anxiety, and poor perception of body image—persist.[54,55] In addition, troubling side effects from immunosuppressive medications adversely affect quality of life.[55,58] Finally, the development of bronchiolitis obliterans syndrome (BOS) is associated with a significant deterioration in quality of life measures.[57]

Despite improvements in performance status and quality of life, fewer than half of lung transplant recipients return to the workforce.[59,60] Factors cited by recipients as barriers to employment include employer bias against hiring an individual with a chronic medical condition, the potential loss of disability income or medical benefits, side effects of medications, concerns about risk of infection in the workplace, and prioritization of recreational activities over work as a posttransplantation goal.

COMPLICATIONS

Primary Graft Dysfunction

Primary graft dysfunction (PGD) is a term applied to the development within 72 hours of transplantation of radiographic opacities in the allograft(s) associated with impaired oxygenation, in the absence of identifiable insults such as volume overload, pneumonia, rejection, atelectasis, or pulmonary venous outflow obstruction.[61] PGD is presumed to be a consequence of ischemia-reperfusion injury, but inflammatory events associated with donor brain death, surgical trauma, and lymphatic disruption may be contributing factors. Supporting the concept of PGD as a form of acute, nonimmunologic lung injury, histologic examination of lung tissue from affected patients reveals a prevailing pattern of diffuse alveolar damage.[61] A grading system proposed by a working group of the ISHLT classifies the severity of PGD based on the arterial oxygen pressure–to–fractional concentration of oxygen in inspired gas (Pao_2/Fio_2) ratio (Table 95-4).[62] In most cases, the process is mild and transient, but in approximately 10% to 20% of cases, injury is sufficiently severe to cause life-threatening hypoxemia (PGD grade 3) and a clinical course analogous to the acute respiratory distress syndrome.

TABLE 95-4. Grading System for Primary Graft Dysfunction

Grade	Pao_2/Fio_2	Radiographic Evidence of Pulmonary Edema
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

Pao_2/Fio_2, ratio of arterial oxygen pressure to fractional concentration of oxygen in inspired gas.
From Christie JD, Carby M, Bag R, et al: Report of the ISHLT Working Group on Primary Lung Graft Dysfunction Part II: Definition. A consensus statement of the International Society for Heart and Lung Transplantation. J Heart Lung Transplant 24:1454–1459, 2005.

A number of risk factors for development of PGD have been identified, but their applicability in clinical practice is limited by the absence of corroborative studies in some cases and by frankly conflicting studies in others. Identified donor-related risk factors include female gender, African American race, older age, and low donor Pao_2/Fio_2 ratio.[63–65] An elevated level of IL-8 in bronchoalveolar lavage (BAL) fluid recovered from the donor has been associated with the development of severe PGD, supporting the notion that inflammatory events preceding organ harvest may play a role.[66] Recipient risk factors include an underlying diagnosis of idiopathic pulmonary arterial hypertension[63] as well as the more generic presence of elevated pulmonary artery pressures.[63] Intuitively, one would anticipate an association between graft ischemic time and PGD, but this has not been consistently demonstrated.[63,67,68] Rather than a linear relationship, ischemic time may become a factor only when it exceeds a certain threshold, suggested by one study as occurring beyond 6 hours.[68]

Treatment of severe PGD is supportive, relying on conventional mechanical ventilation utilizing low tidal volume strategies, as well as on such adjunct measures as independent lung ventilation and extracorporeal life support for select patients who otherwise cannot be stabilized.[69,70] The use of nitric oxide in patients with established graft injury has been associated with sustained reduction in pulmonary artery pressures and improvement in oxygenation.[71] However, the prophylactic administration of nitric oxide to all recipients at the time of reperfusion does not reduce the incidence of severe PGD.[72] Results of emergent retransplantation in this setting have been poor.[73,74]

With an associated perioperative mortality rate of 30% to 40%, severe PGD is a leading cause of early deaths among transplant recipients.[75,76] The risk of death remains

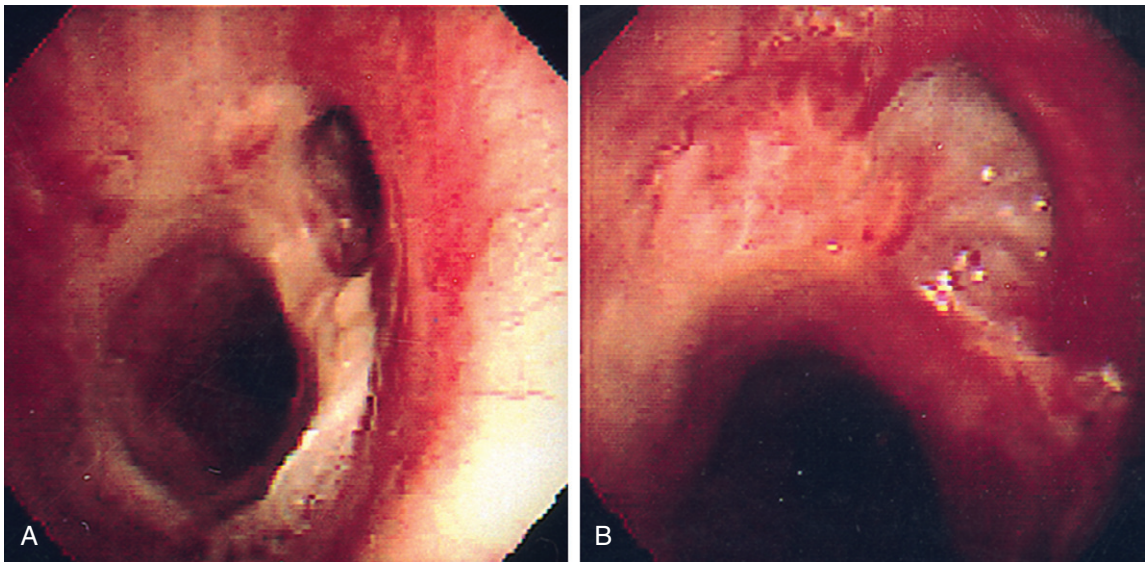

FIGURE 95-1 ■ Bronchial anastomotic dehiscence. **A,** Bronchoscopic view immediately distal to the main carina demonstrates partial dehiscence of the right bronchial anastomosis at the 1 o'clock position. **B,** Repeat view several weeks later demonstrates near-complete healing of the dehiscence with expectant management only.

excessive even beyond the first year, suggesting that PGD has lingering adverse consequences well after resolution of the acute event. Recovery among survivors is often protracted and incomplete, though attainment of normal lung function and exercise tolerance is possible.[77] There appears to be an increased risk of BOS following development of PGD, but data are conflicting on whether the increased risk spans all grades of PGD or is seen exclusively following the most severe grade.[78,79]

Airway Complications

During implantation of the allograft, no attempt is routinely made to reestablish the bronchial arterial circulation. As a consequence, the donor bronchus is precariously dependent upon retrograde blood flow through low-pressure pulmonary venous to bronchial vascular collaterals, placing the airway at risk for ischemic injury. Rarely, this may result in bronchial anastomotic dehiscence, which, when extensive, can lead to mediastinitis, pneumothorax, hemorrhage, and death. Treatment of this life-threatening complication previously required risky and often unsuccessful surgical intervention to buttress the anastomosis. More recently, success has been reported with temporary placement of a bare metal airway stent across the dehiscence in order to provide a scaffolding upon which granulation tissue can form.[80] For lesser degrees of dehiscence, conservative management with reduction in corticosteroid dosing and chest tube evacuation of associated pneumothorax will often lead to successful healing (Fig. 95-1).

Ischemic injury to the airway more commonly manifests as necrosis of the anastomotic cartilage and as patchy areas of bronchial mucosal ulceration and pseudomembranes. These devitalized areas in turn place the patient at increased risk for fungal superinfection of the airway (see later).

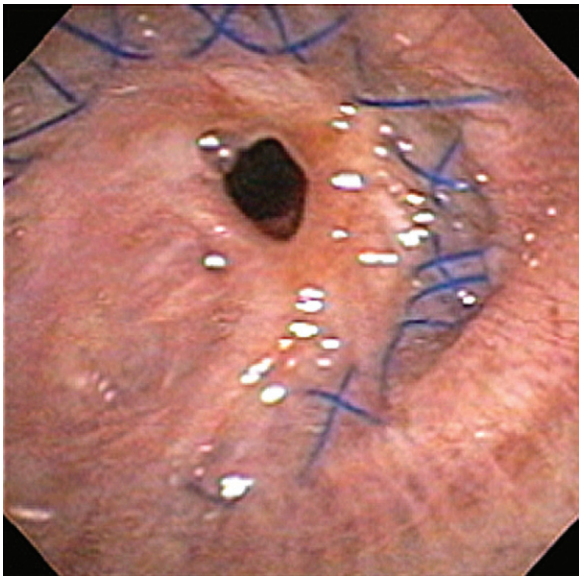

FIGURE 95-2 ■ Bronchial anastomotic stricture. Bronchoscopic view of a left main-stem bronchial anastomosis demonstrates marked narrowing of the lumen due to formation of a fibrous web. The true outer margin of the bronchus is outlined by the suture material.

The most common airway complication currently encountered is bronchial anastomotic stenosis, with a reported frequency of 12% to 24% in contemporary series.[81,82] Narrowing can be due to excessive granulation tissue, fibrotic stricture (Fig. 95-2), or bronchomalacia (the latter two mechanisms likely a sequela of prior ischemic injury). Occasionally, fibrotic strictures can extend beyond the anastomosis, leading to narrowing of the bronchus intermedius or lobar bronchi. Anastomotic narrowing typically develops within several weeks to

months following transplantation. Clues to its presence include focal wheezing on the involved side, recurrent bouts of pneumonia or purulent bronchitis, and suboptimal pulmonary function studies demonstrating airflow obstruction and truncation of the flow-volume loop. Bronchoscopy both confirms the diagnosis and permits therapeutic interventions including balloon dilation, laser débridement, endobronchial brachytherapy, and stent placement.[81,83] Although these measures are often successful in the short term, recurrent stenosis is common, necessitating repeated interventions and leading to compromised functional outcomes and excess mortality.[84]

Phrenic Nerve Injury

Phrenic nerve injury following lung transplantation can result from intraoperative traction, use of an iced slurry to cool the allograft in the chest cavity prior to reperfusion, or transection of the nerve in the setting of extensive fibrous adhesions and difficult hilar dissection. Depending in part on whether screening is restricted to clinically suspected cases or more broadly to all recipients, the reported incidence of phrenic nerve injury ranges from 3% to 30%.[85–88] Important albeit nonspecific clues to the presence of phrenic nerve injury include difficulty in weaning from mechanical ventilation, persistent hypercapnia, orthopnea, and radiographic evidence of persistent elevation of the diaphragm and associated basilar atelectasis. Phrenic nerve injury has been associated with increases in ventilator days, tracheostomy rates, and intensive care unit length of stay.[86] Achievement of a normal functional outcome is ultimately possible for those with reversible injury, but recovery in some cases may be protracted or incomplete. For severely impaired patients, nocturnal noninvasive ventilatory support and diaphragmatic plication have been successfully employed.[89,90]

Native Lung Hyperinflation

Acute hyperinflation of the native lung leading to respiratory and hemodynamic compromise in the immediate postoperative period has been reported in 15% to 30% of emphysema patients undergoing single-lung transplantation.[23,91] Although risk factors remain poorly defined, the combination of positive-pressure ventilation and significant allograft edema serves to magnify the compliance differential between the two lungs and may predispose to this complication. Acute hyperinflation can be rapidly addressed by initiation of independent lung ventilation, ventilating the native lung with a low respiratory rate and prolonged expiratory time to facilitate complete emptying. Beyond the perioperative period, some single-lung transplant recipients with underlying emphysema demonstrate exaggerated or progressive native lung hyperinflation that more insidiously compromises the function of the allograft. In this setting, surgical volume reduction of the native lung can result in significant functional improvement.[92]

Infection

Infection rates among lung transplant recipients are severalfold higher than among recipients of other solid organs. The greater risk is likely related to the unique exposure of the lung allograft to microorganisms via inhalation and aspiration and to the higher level of immunosuppression maintained in these patients. A comprehensive discussion of infectious complications is beyond the scope of this chapter; only the most common pathogens are discussed.

Bacteria

Bacterial infections of the lower respiratory tract account for the majority of infectious complications and have a bimodal temporal distribution.[93,94] Bacterial pneumonia is most frequently encountered within the first month posttransplantation. In addition to the immunosuppressed status of the recipient, factors that predispose to early bacterial pneumonia include the need for prolonged mechanical ventilatory support, blunted cough due to postoperative pain and weakness, disruption of lymphatics, and ischemic injury to the bronchial mucosa with resultant impairment in mucociliary clearance. Although passive transfer of occult infection with the transplanted organ is an additional concern, the presence of organisms on Gram stain of donor bronchial washings is not predictive of subsequent pneumonia in the recipient.[95] Bacterial infections, in the form of purulent bronchitis, bronchiectasis, and pneumonia, reemerge as a late complication among patients who develop BOS. Gram-negative pathogens, in particular *P. aeruginosa*, are most frequently isolated in association with both early and late infectious events.[93,94]

Cytomegalovirus

CMV is the most common viral pathogen encountered following lung transplantation, though in the era of effective prophylaxis, its incidence and impact have diminished considerably.[94] Infection can occur by transfer of virus with the allograft or transfused blood products or by reactivation of latent virus remotely acquired by the recipient. Seronegative recipients who acquire organs from seropositive donors are at greatest risk for developing infection, and these primary infections tend to be the most severe.

CMV infection typically emerges 1 to 3 months following transplantation, though onset is commonly delayed in patients receiving antiviral prophylaxis. Infection is often subclinical, evidenced only by silent viremia or shedding of virus in the respiratory tract. Clinical disease may present as a mononucleosis-like syndrome of fever, malaise, and leukopenia ("CMV syndrome") or as organ-specific invasion of the lung, gastrointestinal tract, central nervous system, or retina. Detection of virus in peripheral blood by either the pp65 antigenemia assay or polymerase chain reaction techniques establishes a diagnosis of CMV infection but does not necessarily reflect events at the tissue level. A diagnosis of

CMV pneumonia, the most common manifestation of invasive disease in the lung transplant recipient, is unequivocally established only by demonstration of characteristic viral cytopathic changes on lung biopsy or on cytologic specimens obtained by BAL, but the sensitivity of these findings is relatively low. Caution must be exercised in interpretation of a positive rapid shell viral culture of BAL specimens, because shedding of virus into the respiratory tract can occur in the absence of tissue invasion.

Standard treatment of CMV syndrome and tissue-invasive disease consists of a 2- to 3-week course of intravenous ganciclovir at a dose of 5 mg/kg twice daily, adjusted for renal insufficiency. Monitoring of peripheral blood viral load should be performed weekly to confirm response to therapy. Treatment should be continued until at least 1 week after an undetectable viral load is documented.[96] Some experts advocate the addition of CMV hyperimmune globulin in treatment of severe disease, but evidence supporting this practice is scant. Although treatment is effective, relapse rates of up to 60% in primary infection and 20% in seropositive recipients have been reported.[97] Initiation of oral valganciclovir as secondary prophylaxis after completion of definitive treatment is a common practice, but its impact on relapse rates is uncertain.

In an attempt to minimize the adverse impact of CMV infection on the posttransplantation course, emphasis has shifted to preventive strategies. Numerous prospective, randomized trials have documented the efficacy of antiviral prophylaxis in delaying the onset and reducing the incidence and severity of CMV infection.[98] Ganciclovir, administered orally or intravenously, has historically been the drug most commonly employed for this purpose. In current practice, oral valganciclovir has emerged as an attractive alternative, owing to its excellent bioavailability after oral administration, once-daily prophylactic dosing requirement, and demonstrated efficacy.[99] Universal prophylaxis of all donor-seropositive/recipient-seronegative patients is recommended because the risk of CMV disease is high.[96] Because the risk of disease is significantly lower in seropositive recipients (independent of donor status), it has been argued that universal prophylaxis of this group leads to overtreatment, increasing costs and unduly exposing patients to the risk of drug toxicity. In this population, preemptive strategies targeting antiviral therapy exclusively to patients demonstrating a rising viral load in peripheral blood have been advocated, but many programs still adhere to a universal prophylaxis strategy.[100]

Emergence of ganciclovir-resistant strains of CMV has been reported in 5% to 15% of lung transplant recipients with CMV infection.[101,102] Risk factors that have been identified include donor-positive/recipient-negative CMV status, use of potent immunosuppressive agents such as antilymphocyte antibodies and daclizumab, increased number of CMV episodes, and prolonged exposure to ganciclovir.[103,104] Foscarnet, administered alone or in combination with ganciclovir, is the agent of choice for treatment of ganciclovir-resistant disease.[102] The drug is potentially nephrotoxic, and careful monitoring of renal function is essential. Although treatment is often successful, the presence of ganciclovir-resistant disease is associated with decreased survival in lung transplant recipients.[104,105]

Aspergillus

Aspergillus species are by far the most frequently encountered fungal organisms in the lung transplant population. As a ubiquitous organism acquired by inhalation, *Aspergillus* colonizes the airways of approximately one quarter of transplant recipients.[106] Airway colonization itself does not appear to pose a major risk of subsequent progression to invasive disease.[106] Whether this is due to the inherently benign nature of colonization or to the common practice of initiating fungal prophylaxis when colonization is detected is unclear.

Aspergillus infection of the bronchial tree occurs in approximately 5% of lung transplant recipients.[106] In most cases, infection is localized to the bronchial anastomosis, where devitalized cartilage and foreign suture material create a nurturing environment. Less commonly, infection may present as a more diffuse ulcerative bronchitis with formation of pseudomembranes, typically following in the wake of a severe ischemic injury to the bronchial mucosa. Clustered within the first 6 months posttransplantation, these airway infections are usually asymptomatic and detected only by surveillance bronchoscopy. Although usually responsive to oral azoles or to inhaled or intravenous amphotericin, airway infections have rarely progressed to invasive pneumonia or have resulted in fatal erosion into the adjacent pulmonary artery.[106,107] An increased risk of subsequent bronchial stenosis or bronchomalacia has also been reported, but it is unclear whether this is a consequence of the infection or of an underlying ischemic injury to the bronchus that predisposed to infection.[108,109]

Invasive aspergillosis, a highly lethal form of infection, occurs in 5% of lung transplant recipients, most commonly within the first year.[106] It nearly always involves the lung but dissemination to distant sites, particularly the brain, occurs in a minority of patients. Symptoms are nonspecific and include fever, cough, pleuritic chest pain, and hemoptysis. Radiographically, pulmonary aspergillosis may appear as single or multiple nodular or cavitary opacities or as alveolar consolidation (Fig. 95-3). The "halo sign"—a rim of ground-glass attenuation surrounding a central nodular opacity—is a suggestive but uncommon finding on chest computed tomography (CT) scans.

Diagnosis of invasive pulmonary aspergillosis can be problematic. As discussed previously, many lung transplant recipients are colonized with *Aspergillus*, making it difficult to interpret the significance of positive fungal stains and cultures derived from BAL specimens. Conversely, the sensitivity of bronchoscopic studies has been reported in the range of only 45% to 62% in solid organ transplant recipients with invasive disease.[110] Measurement of galactomannon levels in serum or BAL fluid has been touted as a useful test for establishing a diagnosis of invasive disease in certain patient

populations, but performance characteristics in the lung transplant population are not sufficiently robust to endorse its use at the present time.[111,112] In the context of compatible clinical and radiographic features and/or demonstration of *Aspergillus* in respiratory secretions by culture or cytology, the clinician must exercise judgment in deciding whether to initiate an empirical trial of antifungal therapy or pursue more definitive proof by means of transthoracic needle biopsy or surgical lung biopsy.

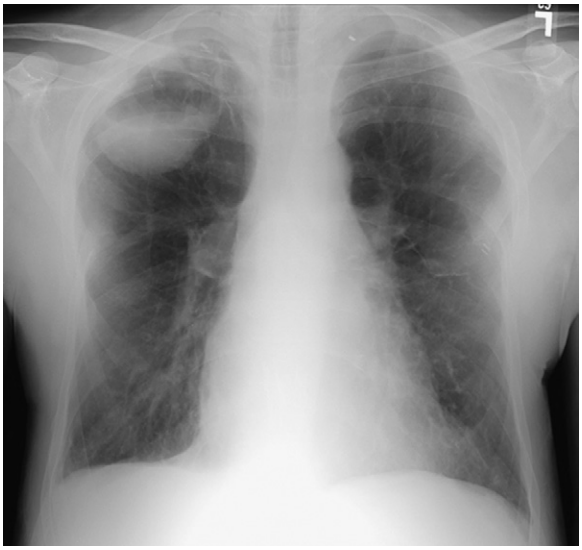

FIGURE 95-3 ■ Invasive aspergillosis. Bilateral lung transplant recipient with a large right upper lobe cavity containing an air-fluid level. Transthoracic needle biopsy demonstrated fungal elements morphologically consistent with *Aspergillus* species. The patient failed to respond to antifungal therapy and surgical resection was required for definitive cure.

Amphotericin B was traditionally the mainstay of therapy for invasive aspergillosis. More recently, however, the triazole voriconazole has been shown to have superior efficacy and less toxicity than amphotericin B and has emerged as the treatment of choice.[113] Voriconazole is a potent inhibitor of the cytochrome P-450 hepatic enzyme system and can lead to dangerously high blood levels of concurrently administered calcineurin inhibitors and sirolimus if appropriate adjustments in the dosing of these agents are not made. The echinocandins (e.g., caspofungin) represent a third class of agents that have been successfully employed in the treatment of invasive aspergillosis.[114] Despite the availability of antifungal therapy, mortality rates in the range of 60% to 80% have been reported.[106,115] The therapeutic role of surgical resection remains uncertain, but surgery has been advocated in cases of localized infection refractory to medical therapy.[116,117]

Rejection

Despite the use of potent immunosuppressive agents, allograft rejection remains a pervasive problem. Features of the various forms of rejection are summarized in Table 95-5 and elaborated upon later.

TABLE 95-5. Features of Allograft Rejection

Feature	Hyperacute Rejection	Acute Rejection	Chronic Rejection
Onset after transplant	Minutes to hours	Days to months	Beyond first year
Risk Factors	Recipient preformed antibodies to donor HLA antigens	Uncertain	Acute rejection, lymphocytic bronchiolitis, community respiratory viruses, primary graft dysfunction, silent aspiration
Histology	Marked interstitial neutrophilic infiltrate, alveolar edema, and platelet and fibrin thrombi in small arterioles	Perivascular lymphocytic infiltrates	Bronchiolar submucosal inflammation and fibrosis; luminal obliteration
Signs and symptoms	Copious production of pink, frothy edema fluid; severe hypoxemia; hypotension	Low-grade fever, dyspnea, cough, impaired oxygenation, leukocytosis	Dyspnea, chronic cough, recurrent bouts of purulent bronchitis
Chest radiograph	Dense consolidation of allograft	Alveolar or interstitial opacities, pleural effusions	Clear lung fields (may show hyperinflation)
High-resolution CT	Not applicable	Ground-glass or alveolar opacities, interlobular septal thickening	Tree-in-bud opacities, bronchiectasis, air trapping
Pulmonary function testing	Not applicable	Proportional decline in FEV_1 and FVC	Disproportionate decline in FEV_1 with worsening obstructive pattern
Yield of transbronchial biopsy	Not applicable	High	Low
Treatment	Plasmapheresis, cyclophosphamide, mechanical ventilation	High-dose corticosteroids	Uncertain: azithromycin is a popular but unproven option
Outcome	High mortality rate	Favorable response to treatment	Poor response to treatment; progressive allograft dysfunction

CT, computed tomography; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; HLA, human leukocyte antigen.

Hyperacute Rejection

Hyperacute rejection is a rare but highly lethal complication mediated by preformed antibodies of recipient origin directed against HLA antigens contained on donor tissue. The pulmonary microvascular endothelium is the principal target, leading to complement- and neutrophil-mediated damage and widespread deposition of platelet/fibrin thrombi.[118] Hyperacute rejection becomes clinically manifest within minutes to hours of establishing perfusion to the freshly implanted lung. The allograft appears dusky, mottled, and grossly edematous on direct inspection and densely opacified on chest x-ray. Reflecting the severity of pulmonary edema, copious amounts of pink, frothy edema fluid often are produced by the allograft and must be frequently suctioned from the endotracheal tube. Profound graft dysfunction and hemodyamic instability ensue. Four of the five cases reported in the literature resulted in death.[119] The one surviving patient was successfully managed with a combination of plasmapheresis, antithymocyte globulin, and cyclophosphamide.[120] Routine screening of all lung transplant candidates for preformed anti-HLA antibodies and either avoidance of donors with the targeted antigens or prospective cross-matching prior to transplantation have proved to be highly effective in minimizing the risk of hyperacute rejection.

Acute Rejection

Frequent surveillance of the allograft by transbronchial biopsy has demonstrated that most transplant recipients experience at least one episode of acute cellular rejection in the first year.[36] Beyond this initial period, the incidence of acute rejection declines considerably. Risk factors for development of acute rejection remain poorly defined. Data are conflicting on whether the degree of HLA discordance between donor and recipient represents a risk factor.[36,121,122] Polymorphisms in Toll-like receptor 4 that down-regulate recipient innate immune responsiveness are associated with a lower incidence of acute rejection.[121]

Episodes of acute rejection may be clinically silent in up to 40% of cases.[36] When present, clinical manifestations are nonspecific and include malaise, low-grade fever, dyspnea, cough, and leukocytosis. Radiographic opacities, a decline in arterial oxygenation at rest or with exercise, and an abrupt fall of greater than 10% in spirometric values are important clues to the possible presence of rejection, but similar findings accompany bouts of infection.

Reliance on clinical and radiographic criteria alone runs the risk of misdiagnosis and needless augmentation of immunosuppression. Transbronchial lung biopsy has emerged as the "gold standard" for diagnosis of acute rejection. The procedure is safe, can be performed in serial fashion over time, and has a high sensitivity and specificity. The histologic hallmark of acute rejection is the presence of perivascular lymphocytic infiltrates that in more severe cases, spill over into the adjacent interstitium and alveolar airspaces. Lymphocytic bronchiolitis may accompany the parenchymal involvement or may be an independent feature. A histologic classification system has been universally adopted to grade the severity of acute cellular rejection (Table 95-6).[123]

TABLE 95-6. Histologic Grading System for Acute Cellular Rejection

Grade	Description
0 (none)	Normal pulmonary parenchyma
1 (minimal)	Scattered, infrequent perivascular mononuclear infiltrates
2 (mild)	Frequent perivascular mononuclear infiltrates surrounding venules and arterioles; readily recognizable at low magnification
3 (moderate)	Easily recognizable cuffing of venules and arterioles by dense perivascular mononuclear cell infiltrates, with extension of the inflammatory cell infiltrate into perivascular and peribronchiolar alveolar septa and air spaces
4 (severe)	Diffuse perivascular, interstitial, and air space infiltrates of mononuclear cells with prominent alveolar pneumocyte damage and endothelialitis

From Stewart S, Fishbein MC, Snell GI, et al: Revision of the 1996 working formulation for the standardization of nomenclature in the diagnosis of lung rejection. J Heart Lung Transplant 26:1229–1242, 2007.

Conventional treatment of acute rejection consists of a 3-day pulse of intravenous solumedrol at a daily dose of 15 mg/kg. In most cases, this results in rapid improvement in symptoms, pulmonary function, and radiographic abnormalities, but follow-up biopsies show histologic evidence of persistent rejection in 30% of patients with prior mild (A2) acute rejection and 44% of patients with prior moderate (A3) acute rejection.[124] Asymptomatic and functionally stable patients with minimal (A1) rejection have typically been observed without treatment, but data demonstrating progression to a higher grade of acute rejection in one quarter of cases and an increased risk of developing BOS have challenged this approach.[125] A variety of modalities have been employed for refractory or recurrent acute rejection including antilymphocyte antibody preparations and photopheresis.

Chronic Rejection (Bronchiolitis Obliterans Syndrome)

Chronic rejection, in the form of bronchiolitis obliterans, develops in approximately half of recipients by 5 years and represents the major impediment to long-term graft and patient survival. Bronchiolitis obliterans is a fibroproliferative process characterized by submucosal inflammation and fibrosis of the bronchiolar walls, ultimately leading to complete obliteration of the airway lumen. The functional consequence of this process is progressive and largely irreversible airflow obstruction. Because the characteristic histology is difficult to demonstrate by transbronchial lung biopsy, the clinical

schema of "bronchiolitis obliterans syndrome" (BOS) was developed, employing the FEV_1 as an easily obtained diagnostic surrogate for histology (Table 95-7).[126] As originally conceived, BOS was defined as an otherwise unexplained and sustained fall in FEV_1 by at least 20% from posttransplant baseline. Concern that this definition might delay diagnosis beyond a stage amenable to treatment prompted the more recent introduction of a BOS 0-potential (BOS 0-p) stage, defined as a decline in FEV_1 by 10% to 19% or in mean forced expiratory flow between 25% and 75% of the forced vital capacity ($FEF_{25\%-75\%}$) by at least 25%. The FEV_1 criterion for BOS 0-p has proved to be a reasonable predictor of patients at risk for progression to more advanced BOS, with a positive predictive value of 60% for progression within 1 year and 80% for progression within 4 years.[127,128] The positive predictive value of the FEV_1 criterion is lower in single-lung transplant recipients with native lung emphysema, likely because of the confounding impact of native lung hyperinflation on lung function.[128] Notably, the $FEF_{25\%-75\%}$ criterion suffers from a low positive predictive value in all recipient populations and is of questionable clinical utility.[127,128]

TABLE 95-7. Grading System for Bronchiolitis Obliterans Syndrome

Stage	Spirometric Criteria
0	FEV_1 > 90% of baseline and $FEF_{25\%-75\%}$ > 75% of baseline
0-potential	FEV_1 81%–90% of baseline and/or $FEF_{25\%-75\%}$ ≤ 75% of baseline
1	FEV_1 66%–80% of baseline
2	FEV_1 51%–65% of baseline
3	FEV_1 ≤ 50% of baseline

$FEF_{25\%-75\%}$, mean forced expiratory flow between 25% and 75% of forced vital capacity; FEV_1, forced expiratory volume in 1 second.
From Estenne M, Maurer JR, Boehler A, et al: Bronchiolitis obliterans syndrome 2001: An update of the diagnostic criteria. J Heart Lung Transplant 21:297–310, 2002.

Acute rejection and lymphocytic bronchiolitis have been consistently identified as major risk factors for development of BOS, supporting the view that BOS is a consequence of alloimmune injury.[129,130] Whereas the risk of BOS appears to correlate with the severity and frequency of these immunologic insults, even minimal (A1) acute rejection is associated with an increased risk.[125,131] Nonimmune factors may also be important in initiating or perpetuating injury but have been more variably substantiated. These factors include CMV infection, community respiratory viral infections, a synergistic interaction between older donor age and prolonged ischemic times, primary graft dysfunction, and gastroesophageal reflux with occult aspiration.[78,130,132,133]

The decline in FEV_1 that heralds the onset of BOS may be either insidious or abrupt, the latter more commonly seen in patients who develop this complication within the first 3 years.[134] Dyspnea, weight loss, cough, and recurrent bouts of purulent tracheobronchitis, with recovery of *P. aeruginosa* from sputum cultures, are characteristic clinical features. Although chest radiographs are usually unremarkable, high-resolution CT commonly reveals air trapping, tree-in-bud opacities, and/or bronchiectasis (Fig. 95-4). Progressive airflow obstruction is the rule, though the pace of decline is highly variable and the course may be interrupted by periods of functional stability. The prognosis is generally poor, with a 40% mortality rate within 2 years of onset.[135] Recipients who develop BOS early after transplantation and those with abrupt onset generally experience more rapid decline in lung function and higher mortality.[134,136,137]

A myriad of immunosuppressive strategies have been employed in the treatment of BOS, including use of conventional agents (e.g., pulse corticosteroids), inhaled cyclosporine, antilymphocyte antibodies, photopheresis, and total lymphoid irradiation, but consensus is lacking on the optimal approach.[135,138,139] At best, immunosuppressive measures appear to slow the rate of decline rather than to fully arrest or reverse the process. A potential role for macrolide therapy is suggested by several retrospective studies documenting short-term

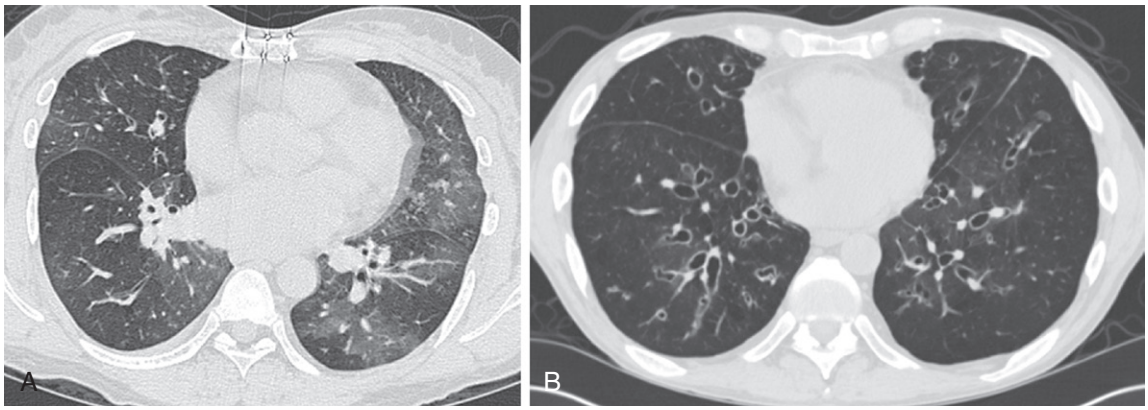

FIGURE 95-4 ■ Radiographic features of bronchiolitis obliterans syndrome (BOS). **A,** High-resolution computed tomography (CT) image obtained during expiration demonstrates a mosaic attenuation pattern consistent with air trapping. **B,** Image obtained from another patient with BOS demonstrates extensive bronchiectasis.

improvement in the FEV_1 in approximately 30% to 45% of patients with BOS treated with azithromycin.[140-143] In contrast to nonresponders, responders demonstrate higher pretreatment levels of BAL neutrophilia and a marked reduction in neutrophilia following initiation of therapy. This lends credence to the notion that the beneficial effects of macrolides relate in large part to their ability to suppress airway IL-8 production and neutrophil recruitment.[141,142] Although still controversial, performance of surgical fundoplication to control gastroesophageal reflux has been associated with improvement in lung function in some patients with BOS.[144] Adjuvant measures to mobilize respiratory secretions and control bacterial infection of the airways—including chest percussion, flutter or acapella valve, and inhaled and systemic antibiotics—may be of benefit in patients with accompanying bronchiectasis. The only definitive treatment for advanced BOS is retransplantation, but this strategy remains problematic in the context of a scarce donor organ pool.

The development of strategies to prevent BOS is an area of intense interest but, to date, little substantive progress. In recognition of the established link between acute rejection and BOS, most transplant centers routinely perform surveillance lung biopsies to detect and treat clinically silent acute rejection, but the impact of this strategy on risk of BOS remains uncertain.[145,146] Preliminary observations from the Duke transplant group suggest that early identification of recipients with gastroesophageal reflux and aggressive correction with fundoplication may delay or prevent onset of BOS.[147] Perhaps most promising is the demonstration in a recent randomized, placebo-controlled trial that the addition of inhaled cyclosporine to a conventional immunosuppressive regimen was associated with a dramatic reduction in the incidence of BOS.[148]

Posttransplantation Lymphoproliferative Disorder

Posttransplant lymphoproliferative disorder (PTLD) describes a spectrum of abnormal proliferative responses involving B cells in the majority of cases and ranging from benign polyclonal hyperplasia to malignant lymphomas. In approximately 90% of cases, Epstein-Barr virus (EBV) can be identified as the stimulus for B-cell proliferation, which proceeds in an unchecked fashion due to the muted cytotoxic T-cell response in the immunosuppressed host. EBV-naive recipients who acquire primary infection at the time of organ transplantation are at greatest risk of developing PTLD.[149] A higher intensity of immunosuppression and, in particular, the use of antilymphocyte antibody preparations have also been implicated as risk factors.

Among the myriad neoplasms that arise following lung transplantation, PTLD is second in frequency only to nonmelanoma skin cancers, with an incidence of approximately 5%.[150] The risk of developing PTLD is greatest within the first posttransplantation year, though up to half of all cases occur beyond this point. The majority of early-onset cases involve the allograft, typically presenting as one or more pulmonary nodules that may be accompanied by mediastinal adenopathy (Fig. 95-5). In contrast, intra-abdominal and disseminated forms of disease predominate in cases presenting beyond the first year.[150]

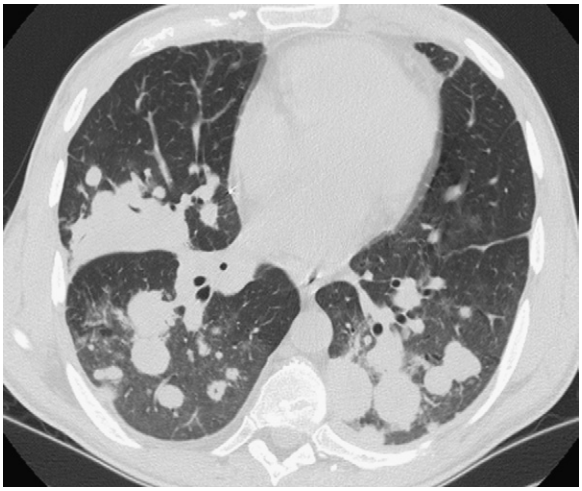

FIGURE 95-5 ■ Posttransplantation lymphoproliferative disorder. CT image demonstrates multiple nodules and masses, proven on biopsy to represent a high-grade B-cell lymphoma. In situ hybridization studies revealed the presence of Epstein-Barr virus RNA.

The diagnosis of PTLD is most firmly established by tissue biopsy, though fine-needle aspiration may occasionally yield sufficient material to make a cytologic diagnosis. Care must be exercised in interpreting transbronchial lung biopsies, because the aggregates of lymphocytes associated with acute cellular rejection can appear similar to foci of PTLD on these small tissue specimens. Demonstration of the presence of EBV-infected cells by in situ hybridization or immunohistochemical staining can help to confirm a diagnosis in difficult cases. Determination of EBV viral load in the peripheral blood using DNA amplification techniques has been touted as an ancillary diagnostic tool. Preliminary studies involving adult lung transplant recipients suggest that an elevated viral load correlates with the presence of PTLD with a high degree of specificity (i.e., low false-positive rate), but the sensitivity is as low as 39%.[151,152] Additional studies employing uniform assay techniques and threshold values for positive results are required before conclusions can be drawn about the clinical utility of this test.

Initial treatment of PTLD involves reduction in the magnitude of immunosuppression to permit partial restoration of host cellular immunity against EBV. Regression of tumor is seen in up to two thirds of cases, but there is an attendant risk of precipitating acute or chronic rejection and patients must be monitored closely.[153] For patients who fail to achieve a complete remission, cannot tolerate reduced immunosuppression, or have rapidly progressive disease, immunotherapy with anti-CD20 monoclonal antibodies (rituximab) has emerged as the preferred option. Use of this agent in the solid organ

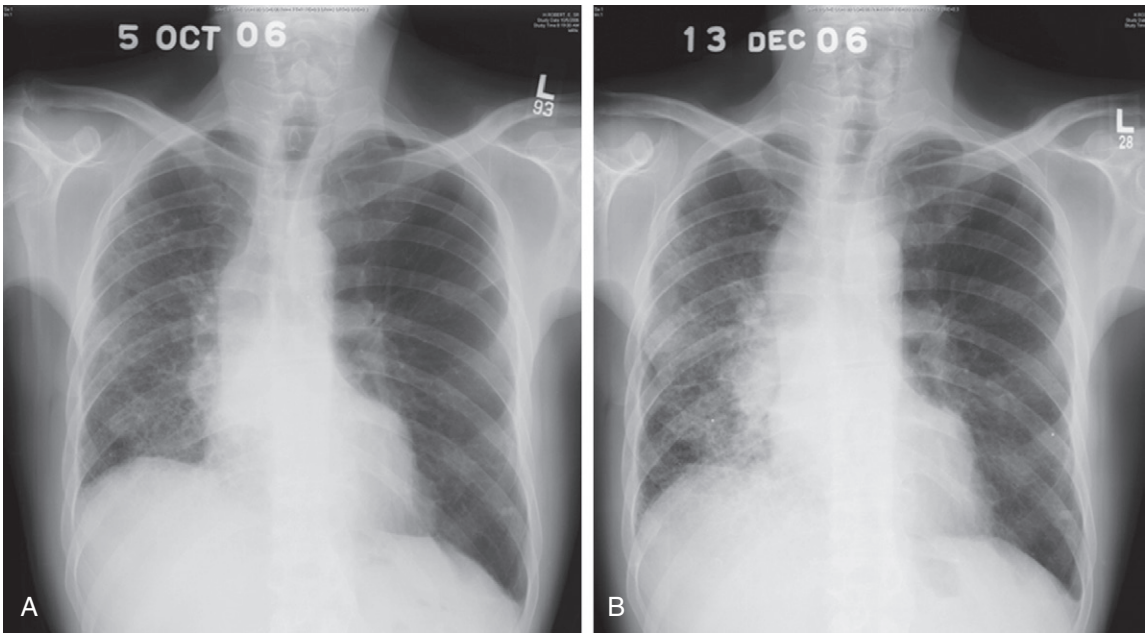

FIGURE 95-6 ■ Bronchogenic carcinoma arising in the native lung. The patient had undergone a left single lung transplant for idiopathic pulmonary fibrosis (IPF). **A,** Chest radiograph demonstrates slight fullness in the infrahilar region of the native right lung. **B,** Repeat chest radiograph only 2 months later demonstrates marked enlargement of the right infrahilar mass as well as an increase in adjacent interstitial opacities. This proved to be a right lower lobe squamous cell lung cancer with associated lymphangitic spread.

transplant population is generally well tolerated and associated with a complete response rate of 60%.[154] In contrast, experience with standard chemotherapy has been poor, with up to one quarter of patients succumbing to treatment-related complications.[154] There is no proven role for antiviral therapy in the setting of established PTLD, though there is suggestive evidence that the prophylactic use of antiviral agents may reduce the subsequent risk of developing PTLD.[155]

Lung Cancer

The development of lung cancer following lung transplantation has been reported almost exclusively in patients with underlying COPD or pulmonary fibrosis, the majority of whom have had significant prior smoking histories. The reported incidence of lung cancer following transplantation is 2% to 6% in patients with COPD and 3% to 4% for the pulmonary fibrosis population.[156,157,157a,157b] Data are conflicting on whether transplantation confers an increased likelihood of developing this form of cancer or whether the incidence is comparable with that of the general population with similar risk factors. Lung cancer most commonly arises in the native lung of single-lung transplant recipients. Less commonly, a previously unsuspected cancer may be incidentally detected in the explanted lung at the time of transplantation and may then recur in the allograft or distant sites. A high rate of recurrence has also been documented in instances when lung transplantation has been performed as definitive treatment for underlying bronchioalveolar carcinoma.[3] Finally, there are rare reports of lung cancer of donor origin transmitted to the recipient.[158]

Lung cancer in the transplant recipient often progresses at a rapid pace, potentially leading to initial confusion with an infectious process (Fig. 95-6).[156] This aggressive behavior may reflect loss of antitumor immune surveillance in the immunosuppressed host or may be due to a more specific effect of cyclosporine in promoting tumor growth.[159] Overall prognosis is poor but should not preclude attempts at curative resection in the rare instances in which early-stage disease is encountered.

Recurrence of Primary Disease

A number of primary disorders have now been documented to recur in the allograft following transplantation.[160] Although accurate figures are not available, sarcoidosis appears to have the greatest propensity to do so. Recurrence of sarcoidosis is typically asymptomatic and marked by incidental recovery of noncaseating granulomas on bronchoscopy and occasionally by the presence of micronodular opacities in the upper lobes on CT scan. Cases of recurrent lymphangioleiomyomatosis have also been reported. The abnormal smooth muscle cells found in the allograft are of recipient origin, suggesting that the mechanism of recurrence involves migration or metastasis from an extrapulmonary site.[161] Other diseases for which recurrence has been reported include Langerhans cell histiocytosis, desquamative interstitial pneumonia, and diffuse panbronchiolitis.

Recurrence of emphysema in the allograft was documented in a recipient 11 years after transplantation for alpha$_1$-antitrypsin deficiency.[162] The patient had resumed smoking and this was presumed to play a central role in accelerating the recurrence of disease. BAL fluid obtained after disease recurrence demonstrated free elastase activ-

ity, suggesting that the endogenous antiprotease defenses had been overwhelmed. These observations highlight the need for alpha$_1$-antitrypsin–deficient transplant recipients to abstain from smoking but do not provide justification for the routine use of enzyme replacement therapy following transplantation.

As previously mentioned, attempts to utilize lung transplantation as a definitive treatment for bronchioalveolar carcinoma resulted in recurrence rates of approximately 50%, leading the vast majority of centers to abandon this approach.[3]

RETRANSPLANTATION

Retransplantation has been utilized as a salvage technique for refractory graft failure. Outcomes following early, emergent retransplantation for primary graft dysfunction are poor, and consequently, use of this intervention in this setting is discouraged.[74,163] In contrast, retransplantation of carefully selected patients with chronic graft failure due to BOS results in survival rates that approach that of initial transplantation. The new allocation system introduced in the United States assigns a high priority to candidates with BOS, on par with that afforded to patients with IPF. This has led to shortened waiting times and to a doubling in number of retransplant procedures performed annually.[74] Although the feasibility and reasonable success of retransplantation for BOS have been established, the issue of its appropriateness in the setting of severe organ shortages remains a vexing ethical dilemma.

FUTURE DIRECTIONS

Since its introduction in 1963, lung transplantation has evolved from a medical curiosity to a standard option for select patients with advanced lung disease. Two major hurdles must yet be overcome in order to facilitate wider applicability of lung transplantation and more enduring results: the donor organ supply must be expanded to meet demand, and more effective and less toxic immunosuppressive strategies must be developed to prevent graft loss from chronic rejection. Increased utilization of "donation after cardiac death" donors may offer a partial solution to the former problem but the ultimate solution will likely come with advances in stem cell, tissue engineering, and xenotransplantation research. Similarly, a definitive solution to the issue of chronic rejection resides in research efforts to promote immune tolerance, a state of permanent graft acceptance in the absence of chronically administered immunosuppressive agents. It is only through these basic research initiatives that lung transplantation will truly fulfill its potential as a safe, effective, and durable treatment option.

KEY POINTS

- Lung transplantation is a therapeutic option for a broad spectrum of advanced nonmalignant disorders of the airways, lung parenchyma, and pulmonary vasculature. The most common indications are COPD, IPF, and CF.
- The lung allocation system now utilized in the United States grants priority to patients with the greatest predicted "net transplant benefit"—the difference between predicted 1-year survival with versus without transplantation.
- One-, 5-, and 10-year survival rates following transplantation are 79%, 52%, and 29%, respectively.
- Common early complications include primary graft dysfunction due to ischemia-reperfusion injury, bronchial anastomotic stenosis, and bacterial pneumonias.
- Acute cellular rejection, characterized by perivascular lymphocytic infiltration, occurs in the majority of recipients in the first year. It usually responds to high-dose corticosteroid therapy but is a major risk factor for subsequent development of chronic rejection (bronchiolitis obliterans).
- The major limitation to long-term allograft function and patient survival is bronchiolitis obliterans, characterized histologically by fibroproliferative obliteration of the small airways and physiologically by progressive airflow obstruction.

APPENDIX

GLOSSARY OF TERMS AND STANDARD SYMBOLS

I. PRIMARY AND QUALIFYING SYMBOLS

General

P	Pressure (Includes also *partial* pressure of a gas in a mixture of gases or in blood.)
L	Lung
W	Chest wall
RS	Respiratory system
Pl	Pleura

Ventilation

V	Volume of gas
$\dot{V}$	Flow of gas
I	Inspired
E	Expired
A	Alveolar
T	Tidal
ET	End-tidal
D	Dead space
STPD	*Standard Conditions: s*tandard *t*emperature (0° C), barometric *p*ressure (760 mm Hg), and *d*ry.
BTPS	*Body Conditions: b*ody *t*emperature and ambient *p*ressure, *s*aturated with water vapor at these conditions.
ATPS	*Ambient Conditions: a*mbient *t*emperature and *p*ressure, *s*aturated with water vapor at these conditions.

Gas Exchange–Blood Flow

Q	Volume of blood
$\dot{Q}$	Flow of blood
F	Fractional concentration of gas
C	Concentration in blood
S	Saturation in blood
b	Blood, in general
a	Arterial blood
v	Venous blood
$\bar{v}$	Mixed venous blood
c	Capillary blood
c′	Pulmonary end-capillary blood

II. VENTILATION AND LUNG MECHANICS

Static Lung Volumes

VC	*Vital Capacity:* The maximum volume of gas that can be exhaled after fully inflating the lungs.
FRC	*Functional Residual Capacity:* The volume of gas remaining in the lungs at the end of quiet expiration.
TLC	*Total Lung Capacity:* The volume of gas in the lungs after a maximum inspiration.
RV	*Residual Volume:* The volume of gas remaining in the lungs after a maximum exhalation.
IC	*Inspiratory Capacity:* The volume of gas that can be inhaled from resting end-expiration (FRC) to full inflation (TLC).
ERV	*Expiratory Reserve Volume:* The volume of gas that can be exhaled from resting end-expiration (FRC) to full exhalation (RV).
IRV	*Inspiratory Reserve Volume:* The volume of gas that can be inhaled from resting end-inspiration to full inflation (TLC).

Descriptors of Forced Breathing Maneuvers

FVC	*Forced Vital Capacity:* The volume of gas that can be forcibly exhaled after fully inflating the lungs.
FEV_t	*Timed Forced Expiratory Volume:* The volume of gas exhaled at a specified time after beginning the forced vital capacity maneuver. For example, FEV_1 = forced expiratory volume in 1 second.

FEV_t/FVC *Ratio of Timed Expiratory Volume to Forced Vital Capacity:* For example, FEV_1/FVC, usually expressed as a percentage.

FEF_x *Specified Forced Expiratory Flow:* The forced expiratory flow rate during a specified portion of the forced vital capacity. For example, $FEF_{200-1200\,mL}$ = forced expiratory flow rate between 200 and 1200 mL of the forced vital capacity; $FEF_{25-75\%}$ = forced expiratory flow rate between 25% and 75% of the forced vital capacity.

$\dot{V}max_{x\%}$ *Specified Maximum Expiratory Flow:* The instantaneous expiratory flow rate when *x* percent of the forced vital capacity has been exhaled. For example, $\dot{V}max_{50\%}$ = maximum expiratory flow rate at 50% of the forced vital capacity.

MVV *Maximum Voluntary Ventilation:* Volume of gas exhaled while making maximum breathing efforts during a certain time interval (often 12 seconds).

VR *Ventilatory Reserve:* The difference between ventilatory capacity during maximum exercise (estimated as MVV or calculated from FEV_1) and minute ventilation at peak exercise; VR, which is also known as *breathing reserve,* represents the potential for further increase in ventilation during maximum (or peak) exercise.

PImax *Maximum Inspiratory Pressure:* The maximum pressure generated by the respiratory muscles during an attempted inspiration.

PEmax *Maximum Expiratory Pressure:* The maximum pressure generated by the respiratory muscles during an attempted exhalation.

Descriptors of Ventilation

f *Respiratory Frequency:* The number of breaths during 1 minute.

VT *Tidal Volume:* The volume of gas inspired or expired during each breath.

$\dot{V}_E$ *Expired Ventilation:* The volume of gas (BTPS), usually measured at the mouth, exhaled during 1 minute.

$\dot{V}_I$ *Inspired Ventilation:* The volume of gas (BTPS), measured or calculated, inhaled during 1 minute.

$\dot{V}_A$ *Alveolar Ventilation:* The volume of gas (BTPS), exhaled from the lungs during 1 minute, that contributed to gas exchange; calculated as expired volume minus dead space ventilation.

$\dot{V}_D$ *Dead Space Ventilation:* The volume of gas (BTPS), exhaled from the lungs during 1 minute, that did not contribute to gas exchange; also known as *wasted ventilation.* Calculated from the equation

$$\dot{V}_D = \dot{V}_E \frac{Pa_{CO_2} - PE_{CO_2}}{Pa_{CO_2} - PI_{CO_2}}$$

where Pa_{CO2}, PE_{CO2}, and PI_{CO2} are the partial pressures of CO_2 in arterial blood, mixed expired gas, and inspired gas, respectively.

VD *Dead Space Volume:* The volume of the physiologic dead space; calculated as $\dot{V}_D/f$.

VD/VT *Ratio of Dead Space to Tidal Volume:* The proportion, usually expressed as a percentage, of each breath that does not contribute to CO_2 removal (i.e., the proportion of each breath that is wasted).

VE *Ventilatory Equivalent:* The minute ventilation required for each liter of gas exchanged, either O_2 or CO_2; used as a measure of the efficiency of the lungs as a gas exchanger. For O_2:

$$VE_{O_2} = \frac{\dot{V}_E(BTPS)}{\dot{V}_{O_2}(STPD)}$$

Volume-Pressure Relationships

C *Compliance:* General symbol for compliance, or the ratio of volume change of the structure per unit change in applied pressure across the structure.

CL *Lung Compliance:* The volume change divided by the difference between alveolar pressure (Palv) and pleural pressure (Ppl), which is also known as the transpulmonary pressure (PL).

CW *Chest Wall Compliance:* The volume change divided by the difference between pleural pressure (Ppl) and body surface pressure (Pbs), which is also known as the transthoracic pressure (PW).

CRS *Respiratory System Compliance:* The volume change divided by the difference between alveolar pressure (Palv) and body surface pressure (Pbs), or transpulmonary pressure (PL) plus transthoracic pressure (PW).

Cdyn *Dynamic Compliance:* Value for compliance based on measurements made during uninterrupted breathing.

Cst *Static Compliance:* Value for compliance based on measurements made during periods of no airflow.

C/V_L *Specific Compliance:* Value for compliance divided by the lung volume at which it was measured, usually functional residual capacity.

Flow-Pressure Relationships

R *Resistance:* General symbol for frictional resistance, or the pressure difference divided by flow.

R_{AW} *Airway Resistance:* Resistance calculated from pressure difference between airway opening (Pao) and alveoli (Palv) divided by the airflow.

RL *Total Pulmonary Resistance:* Resistance calculated by dividing flow-dependent transpulmonary pressure by airflow at the mouth.

G_{AW} *Airway Conductance:* The reciprocal of R_{AW}.

G_{AW}/V_L *Specific Conductance:* Value for airway conductance divided by the lung volume at which it was measured.

III. GAS EXCHANGE

Blood

Examples shown are for O_2; other gases (e.g., CO_2, N_2, CO) or other sites (e.g., $\bar{v}$, c') can be substituted when appropriate.

P_{O_2} *Partial Pressure of O_2:* General designation (expressed in mm Hg); source usually specified (e.g., arterial P_{O_2} or Pa_{O2}).

S_{O_2} *Blood Saturation:* General designation (expressed as a percentage); source usually specified (e.g., arterial S_{O_2} or Sa_{O2}).

C_{O_2} *Oxygen Content:* General designation (expressed in mL/dL); source usually specified (e.g., arterial C_{O_2}).

$\dot{V}_{O_2}$ *Oxygen Consumption:* The volume of O_2 (STPD) utilized by the body during 1 minute; usually calculated as the amount of O_2 extracted from inspired gas.

$\dot{V}_{O_2}$ max *Maximum Oxygen Consumption:* The maximal volume of O_2 (STPD) that can be utilized by the body during 1 minute of maximally attainable exercise.

$\dot{V}_{CO_2}$ *Carbon Dioxide Output:* The volume of CO_2 (STPD) produced by the body during 1 minute; usually calculated as the amount of CO_2 added to exhaled gas.

RQ *Respiratory Quotient:* The ratio of $\dot{V}_{CO_2}$ to $\dot{V}_{O_2}$ during steady-state metabolic activity.

RER *Respiratory Exchange Ratio:* The ratio of $\dot{V}_{CO_2}$ to $\dot{V}_{O_2}$, as in RQ, but also including the influence of transient changes in body stores of respiratory gases.

Gas to Blood

$(A–a)P_{O_2}$ *Alveolar-Arterial PO_2 Difference:* The difference in PO_2 between mean alveolar gas and arterial blood (expressed in mm Hg).

Alveolar Gas Equation: Often used to calculate mean alveolar P_{O_2} (P_{AO_2}):

$$P_{A_{O_2}} = P_{I_{O_2}} - P_{A_{CO_2}}\left[F_{I_{O_2}} + \frac{1 - F_{I_{O_2}}}{R}\right]$$

where $P_{I_{O2}}$ is the P_{O_2} of inspired gas; $P_{A_{CO2}}$ is the alveolar P_{CO_2} (usually assumed to equal arterial P_{CO_2}); $F_{I_{O_2}}$ is the fractional concentration of O_2 in inspired gas; and R is the respiratory exchange ratio.

DL *Diffusing Capacity of the Lung:* Expressed as the volume of gas transferred per minute per unit of alveolar-capillary pressure difference for the gas used, which is usually specified (e.g., $D_{L_{CO}}$ or $D_{L_{O_2}}$).

DM *Diffusing Capacity of the Alveolocapillary Membrane*.

$1/D_L$ *Total Resistance to Diffusion:* The sum of the resistance to diffusion of the test gas across the alveolocapillary membrane ($1/D_M$) and the resistance to diffusion within the red blood cells attributable to the chemical reaction between the test gas and hemoglobin ($1/\theta V_C$). These relationships are expressed by the Roughton-Forster equation:

$$\frac{1}{D_L} = \frac{1}{D_M} + \frac{1}{\theta V_C}$$

D_L/V_A *Diffusion per Unit of Alveolar Volume:* The value of D_L (STPD) divided by V_A (BTPS), both measured in the same breathing maneuver.

IV. HEMODYNAMIC DESCRIPTORS

$\dot{Q}_T$ *Cardiac Output:* The total output of the left ventricle during one minute.

$\dot{Q}_S$ *Pulmonary Shunt Flow:* The total amount of blood per minute perfusing completely nonventilated gas-exchange units; hence, blood that does not come in contact with inspired gas and contribute to oxygen uptake. Often called the *right-to-left shunt,* but this term also includes intracardiac shunts.

$\dot{Q}S/\dot{Q}T$ *Pulmonary Shunt Fraction:* The total pulmonary shunt ($\dot{Q}S$), or venous admixture, expressed as a percentage of total cardiac output ($\dot{Q}T$) according to the equation:

$$\frac{\dot{Q}S}{\dot{Q}T} = \frac{Cc'_{O_2} - Ca_{O_2}}{Cc'_{O_2} - C\bar{v}_{O_2}} \times 100$$

where Cc'_{O_2} is the O_2 content of end-capillary blood; Ca_{O_2} is the O_2 content of arterial blood; and $C\bar{v}_{O_2}$ is the O_2 content of mixed venous blood. When determined from specimens obtained while breathing 100% O_2, $\dot{Q}S/\dot{Q}T$ is a measure of right-to-left shunting of blood.

PPA *Pulmonary Artery Pressure:* The pressure—systolic, diastolic, or mean—measured in the pulmonary artery.

PLA *Left Atrial Pressure:* The pressure, usually mean, measured in the left atrium.

Pcap *Pulmonary Capillary Pressure:* The mean pressure in the pulmonary capillaries, sometimes abbreviated Pc, which cannot be measured directly in humans but is frequently estimated by the equation:

$$Pcap = PLA + 0.4(PPA - PLA)$$

PPW *Pulmonary Wedge Pressure:* The mean pressure measured by the pulmonary artery occlusion technique, which provides an estimate of the postcapillary, or pulmonary venous, pressure.

PVR *Pulmonary Vascular Resistance:* The resistance to blood flow through the lungs; a calculated value from the equation:

$$PVR = \frac{PPA - PLA}{\dot{Q}T}$$

in which PPW is often used to approximate PLA.

V. OTHER USEFUL TERMS AND EQUATIONS

PEEP *Positive End-Expiratory Pressure:* The condition in which the pressure in the lungs at the end of expiration is positive (i.e., higher than atmospheric). Usually applied externally by ventilator adjustments; when PEEP results from failure to exhale fully at the end of expiration, it is called *intrinsic* in origin (PEEPi).

$P_{0.1}$ *Mouth Occlusion Pressure:* The pressure measured in the mouth during the first 0.1 second of attempted inspiration after the airway is temporarily occluded while the subject is breathing. An estimate of the central drive to breathe.

TI/TTOT *Duty Cycle:* The ratio of the duration of inspiration (TI) to the duration of inspiration and expiration (TTOT), a reflection of respiratory timing.

Henderson-Hasselbalch Equation: Useful for calculating any one of three variables, pH, HCO_3^-, or H_2CO_3, when two of them are known:

$$pH = pK + \log\frac{[HCO_3^-]}{[H_2CO_3]}$$

where pK, the dissociation constant, is 6.10 for plasma at 37° C; $[HCO_3^-]$ is the concentration of bicarbonate in plasma; and $[H_2CO_3]$ is the concentration of carbonic acid in plasma (both in mol/L). The equation can be rearranged by using P_{CO_2} (in mm Hg) and its solubility in plasma so that

$$pH = pK + \log\frac{[HCO_3^-]}{[P_{CO_2} \times 0.0301]}$$

Starling Equation: Net fluid exchange (Jv) across the microvascular barrier in the lungs:

$$Jv = LpS[(Pc - Pi) - \sigma d(\pi c - \pi i)]$$

where Lp is the hydraulic conductivity ("permeability"); S is the surface area; Pc is the microvascular hydrostatic pressure; Pi is the perimicrovascular hydrostatic pressure; σd is the osmotic reflection coefficient; πc is the microvascular colloid osmotic pressure; and πi is the perimicrovascular colloid osmotic pressure.
